Failure during cycling.—Zinc electrode failure occurring after many cycles can be referred to as a phenomenon called "redistribution of solid zinc species (Zn and ZnO)." Inability of reforming the solid zinc species in their original position during cycling causes zinc dendrite penetration and shape change. High solubility of ZnO in KOH solution accentuates the redistribution of zinc species from one part of the electrode to the other.

Figure 5 shows that for the cell having no membrane only 55% of the discharge product (zincate ions) precipitates as ZnO and the remaining half diffuses into the counterelectrode compartment before precipitation occurs. On charge, once the zincate source in the zinc electrode compartment is depleted, zinc deposits will grow towards additional zincate which is transferring from the counterelectrode compartment. This type of mass transport leads to zinc dendrite formation which eventually causes short circuits to the counterelectrode. On the other hand, if a membrane is used as a separator, 95% of the discharge product precipitates as ZnO as shown in Fig. 4. Use of a membrane restricts zincate movement away from the test electrode. Charge of this electrode is less likely to cause dendrite growth through the separator because the source of zincate ions remains in the zinc test electrode. Comparison of these two examples shows the main reason why industrial cells having appropriate membranes successfully reduce dendrite formation and short circuits. These membranes could also prevent zinc metal dendrite nucleation within themselves.

Redistribution of solid zinc and zinc oxide from one part of the electrode to the other can occur through the movement of zincate ions. The process involving zincate movement, *e.g.*, on discharging, include the charge transfer reaction which produces zincate ions, mass transfer of zincate, and chemical precipitation of ZnO which consumes zincate. Therefore, current distribution which characterizes the charge transfer reaction, degree of super- (or un-) saturation which determines precipitation or dissolution of ZnO, and mass transfer modes (diffusion, migration, and convection) will govern the redistribution of solid zinc species.

Shape change is the redistribution process of the solid zinc species in the direction parallel to the electrode surface (y-direction). Choi *et al.* (12) have proposed that the shape change was caused by convective flows driven primarily by membrane electro-osmotic effects, while McBreen (7) has emphasized the effect of the difference in the y-direction current distribution during charge and discharge. Choi *et al.* (13) confirmed experimentally that sealing or tight packing of the cell, which was designed to prevent convective flow, successfully reduced the shape change. This observation favors the convection model over McBreen's model.

Discharge of a zinc electrode induces convective flow toward the counterelectrode, resulting in a decrease of the total volume of electrolytic solution in the zinc electrode compartment. If the electrode is vented, the solution in the top reservoir will flow downward. The solution picks up zincate ions along the flow path causing greater precipitation rates in the direction of flow. On the other hand, on charge the increase of total volume of electrolytic solution caused by electro-osmotic flow will push the unsaturated solution toward the reservoir. The reservoir solution now becomes unsaturated and greater dissolution is expected near the vent or reservoir. Repeated cycling causes movement of solid zinc species from near the reservoir portion of the electrode to positions remote from the reservoir. If the electrode is sealed, convective flow, and thus shape change, will be limited.

Similar treatment can be applied to the redistribution of solid zinc in the x-direction perpendicular to the electrode surface. The present work deals with a sealed electrode to minimize the convective flow driven by a membrane. Under this condition, the convective flow arising from the volume changes due to the overall electrode reaction is on the order of 10^{-7} cm/sec and is considered negligible.

The reaction or current distribution in the x-direction during discharge is highly nonuniform as shown in Fig. 3. On the other hand, current distribution on charging is more uniform compared to that on discharging, since precipitated ZnO reduces the effective zinc surface area near the electrode face and shifts the reaction toward the backing plate (see Fig. 6). On repeated cycling, this difference of anodic and cathodic current distributions together with differences in the degree of super- (or un-) saturation causes the redistribution of solid zinc species and thus significant distortion of the electrode structure. The distorted structure is shown in Fig. 7. This mechanism is similar to that described by McBreen. Similar structure was also observed experimentally by Sunu and Bennion (54). If convective flow due to membrane pumping is allowed, more serious redistribution is expected. Similarly, allowing free movement of zincate ion into the counterelectrode, by eliminating the membrane, showed a greater degree of redistribution (49). This movement of solid zinc species in the x-direction could contribute to the loss in the cell capacity on cycling service.

Other factors such as effects of gas generation and changes in morphologies and the active surface area with cycling were excluded from this work. The results of this work can be applied to the design of zinc electrodes to improve their utilization and cycle life. The results also point out areas where further research should be emphasized in order to gain further performance improvement.

σ_{Zn} = 2×10^5 mho/cm
σ_{ZnO} = 0.01 mho/cm
σ_I = 100.0 mho/cm

APPENDIX B

Mass Transfer Coefficients (k_A, k_B, k_{s*}) and Active Surface Areas (a, a_m, a_s)

The mass transfer coefficients k_A, k_B, and k_{s*} defined in Eq. [8], [9], and [11] are approximated by the following equations [see Ref. (49) for derivation]

$$a k_i = \frac{D_{ii}}{\delta} \frac{a - a_m}{\ln\left(\frac{a}{a_m}\right)}; \quad i = A, B$$

$$\frac{1}{a k_{s*}} = \frac{1}{\left(\frac{D_{AA}}{\delta}\right) \frac{(a - a_s)}{\ln\left(\frac{a}{a_s}\right)}} + \frac{1}{a_s k_{XTL}}$$

where δ is the characteristic diffusion length between the active metal surface and the bulk within the pores, k_{XTL} is the chemical rate constant for precipitation or dissolution of ZnO, and D_{AA} and D_{BB} are the diffusion coefficients of KOH and $K_2Zn(OH)_4$, respectively.

The area a_m and a_s represent the interfacial areas which are active for electrochemical reaction [A] and for chemical reaction [B], respectively. They were approximated as follows. It is assumed that the macroscopic averaged particles with uniform radius are arranged in face centered cubic closed packed positions. For a given reference porosity ϵ_o and radius R_o, the solid-solution interface area a_o per unit volume of the electrode can be estimated from the relation of $a_o = 3(1 - \epsilon_o)/R_o$. The specific surface area of the electrode at any state having porosity of ϵ can be related to the reference area a_o as $a/a_o = (1 - \epsilon)R_o/[1 - \epsilon_o)R]$. Since the ratio R/R_o is equal to $(a/a_o)^{0.5}$, the specific area a can be represented as

$$a = a_o \left(\frac{1 - \epsilon}{1 - \epsilon_o}\right)^{2/3}$$

In the absence of the inert conducting material, the area a_m and a_s become a_{Zn} (zinc area) and a_{ZnO} (ZnO area), respectively. They are approximated by the following equation

$$a_{Zn}(\text{or } a_m) = a - a_{ZnO}(\text{or } a_s) = a \frac{(\epsilon_{Zn} - \epsilon_{Zn*})^p}{(\epsilon_{Zn} - \epsilon_{Zn*})^p + (\epsilon_{ZnO})^q}$$

where p and q are the constants relating volume to surface area (p = q = 2/3 was assumed for cubical or spherical crystals), and ϵ_{Zn*} represents the volume fractions of nonactive zinc which can be caused by pore plugging (blockage of the first kind) and by complete coverage on zinc surface by ZnO (usually called passivation or blockage of the second kind). The ϵ_{Zn*} is approximated by

$$\epsilon_{Zn*} = \epsilon_{Zn,plug} + \lambda(\epsilon_{Zn,max} - \epsilon_{Zn,plug})$$

The meaning of the various volume fractions is explained by using the following example.

Let us consider a local section of the electrode having porosity of 0.3, 60% Zn, and 10% ZnO by volume. The partial molar volumes of zinc and zinc oxide are 9.15 and 14.51 cm³/mole, respectively. Due to the difference in the partial molar volume, 85.3% conversion of Zn into ZnO results in pore plugging, *i.e.*, $\epsilon = 0$, $\epsilon_{Zn} = 0.088$, and $\epsilon_{ZnO} = 0.912$. The remaining Zn cannot be converted into ZnO and is denoted by $\epsilon_{Zn,plug}$ (=0.088). On the other hand, if all ZnO is converted into Zn during a local deep charge, an electrode having $\epsilon_{Zn} = 0.663$, $\epsilon_{ZnO} = 0$, and $\epsilon = 0.337$ will result. This zinc content is the maximal amount of zinc available in the fully charged state and denoted by $\epsilon_{Zn,max}$ (=0.663). Then the quantity, $\epsilon_{Zn,max} - \epsilon_{Zn,plug} = 0.575$, can be interpreted by the maximal amount of active zinc which can be utilized. The fractional constant λ is defined based on this quantity to describe the nonactive zinc caused by passivation.

LIST OF SYMBOLS

- a — specific surface area per unit volume of the electrode, cm²/cm³
- a_m, a_s — specific active surface area for charge transfer reaction [A] and that for precipitation or dissolution of ZnO, cm²/cm³
- c_i — concentration of species i, mole/cm³
- c_{io} — initial concentration of species i, mole/cm³
- c_{is} — concentration of species i at the active metal surface, mole/cm³
- D_{ii} — diffusion coefficients with respect to volume average velocity, cm²/sec
- $(D_{ii})_o$ — diffusion coefficients with respect to solvent velocity, cm²/sec
- **F** — Faraday's constant, 96,487 C/equiv.
- I — superficial applied current density, A/cm²
- i_1 — superficial current density in the matrix phase, A/cm²
- i_2 — superficial current density in the solution phase, A/cm²
- $i_o{}^o$ — exchange current density, A/cm²
- j — local transfer current density per unit area of active zinc surface, A/cm²
- k_i — mass transfer coefficient of species i from active sites to bulk in the pores or vice versa, cm/sec

[3] The conductivity of electrolytic solution, k, (55), solubility of ZnO in KOH solution (56), activity coefficients of KOH and potassium zincate (57, 58), and diffusion coefficients of potassium hydroxide, D_{BB}, (59) were expressed as a function of concentration based on the various reported data [see Ref. (49) for those equations and references].

$k_{s^\bullet}$ rate constant combining mass transfer of zincate, k_A, with the rate constant for precipitation or dissolution of ZnO, cm/sec
L electrode thickness, cm
N_i flux of species i in the x-direction, mole/cm^2-sec
RT gas constant multiplied by absolute temperature, J/mole
R_i production or consumption of species i in Eq. [11], mole/cm^3-sec
$\mathbf{R}_e$ defined in Eq. [21] as $a_m i_o^o (\alpha_a + \alpha_c)\mathbf{F}/RT$
$s_i, s_{i^\bullet}$ stoichiometric numbers of species i defined by Eq. [6]
t, t^* tortuosity factor
$t_i, (t_i)_o$ transference number of species i with respect to volume average velocity and that with respect to solvent velocity
$\overline{V}_i$ partial molar volume of species i, cm^3/mole
v superficial volume average velocity, cm/sec
x distance from the backing plate, cm
z_i charge number of species i

Greek Symbols
α_a an anodic kinetic parameter
α_c a cathodic kinetic parameter
γ exponent in zincate concentration dependence of the exchange current density
ϵ porosity of the electrode
ϵ_i volume fraction of solid species i
ζ exponent in OH^- concentration dependence of the exchange current density
κ conductivity of solution, mho/cm
ν_{ik} number of ionic species i per molecule of electrolyte "k"
μ_i chemical potential of ionic species i, J/mole
σ_i conductivity of solid species i, mho/cm
ϕ_1 potential in the matrix phase, V
ϕ_2 potential in the solution phase, V

Subscripts
i any arbitrary species i; 1 for potassium ion, 2 for zincate ion, 3 for hydroxide ion, A for potassium zincate, and B for potassium hydroxide
o solvent or initial values or values referred to the solvent velocity

Transient and Failure Analyses of the Porous Zinc Electrode

II. Experimental

W. G. Sunu*[,1] and D. N. Bennion*[,2]

School of Engineering and Applied Sciences, University of California, Los Angeles, California 90024

ABSTRACT

Experiments were conducted to characterize behavior and failure mechanisms of porous zinc electrodes, prepared by pressing amalgamated zinc powder of particle size ranging from 250 to 325 mesh. The zinc test electrodes were disks with a cross-sectional area of 1 cm^2 and a thickness of 0.1 cm. Distribution of zinc and ZnO, and electrode overpotentials were measured during galvanostatic discharge in 40 w/o KOH solution saturated with ZnO. The observed reaction profiles were highly nonuniform and the reaction zone, located near the electrode surface, was very thin, typically 0.2 mm. The utilization of the present electrodes was very sensitive to the applied current density, initial porosity, amount of electrolyte, and the type of membrane. The measured reaction profiles and overpotentials were compared with the theoretical predictions of a recently developed mathmatical model. The agreement between observations and predictions provides a good interpretation of the discharge failure modes of negative zinc electrodes.

A number of workers have extensively investigated the anodic zinc behavior in alkaline solution with the major efforts being concentrated on the studies of anodic passivation of the planar zinc electrode. It has been generally accepted that the applied current density can be fitted to a linear relationship with the inverse square root of the passivation time (1-4). The linear relationship which was derived from the Sand equation (5) implies that the diffusion of the zincate ion away from the electrode is the controlling process for passivation. Therefore, passivation is expected to occur when the layer of electrolytic solution adjacent to the zinc surface reaches a critical concentration of zincate (3, 4).

Porous electrodes involve much more complicated and interrelated phenomena than the planar electrodes. In addition to passivation, conversion of zinc into ZnO during discharge decreases the pore size and thus limits the transport of electrolyte into the interior of the porous electrode. Some workers (6, 7) have observed that the utilization of zinc depends strongly on the initial porosity of the zinc electrode. Membranes, which have been used to prevent zinc dendrite penetration, also limit the transport of electrolyte species to and from the counterelectrode as was discussed by Shaw and Remanick (8). Furthermore, porous electrodes have highly nonuniform current distribution, resulting in a thin reaction zone. The remaining part of the electrode acts as an inert matrix which does not contribute to the cell capacity. Highly localized current density can cause passivation under certain circumstances, *e.g.*, under high current load. Nonuniform current distribution can also accelerate the decrease in pore size in the reaction zone.

Such processes and further failure mechanisms of porous zinc electrodes have been described in a mathematical model developed by Sunu and Bennion (9). The results of the mathematical predictions suggested that the zinc electrode could fail by one or any combination of the following mechanisms:

Failure during discharge—(*i*) blockage of the first kind (pore plugging), (*ii*) blockage of the second kind (passivation or surface coverage on zinc surface by precipitated ZnO), and (*iii*) depletion of KOH electrolyte.

Failure during charge—(*i*) depletion of zincate, and (*ii*) zinc dendrite formation.

Failure after many cycles—(*i*) zinc dendrite formation and short circuit, (*ii*) shape change in the y-direction, parallel to the electrode surface, (*iii*) redistribution of zinc species in the x-direction, perpendicular to the electrode surface, and (*iv*) accumulated gas evolution.

The objective of this paper is to observe and verify experimentally the proposed failure mechanisms, particularly during discharge. To fulfill this, zinc electrode overpotentials and current distributions across the electrode thickness were measured during the galvanostatic discharge and the results were compared with mathematical predictions.

There are several procedures for fabricating zinc electrodes: pressing of ZnO powder mix (ZnO, HgO, and additives), which gives the zinc electrode in the discharged state (10); pressing of amalgamated zinc powder (7); metal spraying process, and electrodeposition process which results in the zinc electrode in the charged state. To observe and identify various discharge failure modes, initial porosities and the volume of electrolyte reservoir should be well controlled during preparation procedures. The pressing technique developed by Morrel and Smith (7) which satisfies most of our requirements was employed in the present study. Electrodes having two different porosities, 33 and 60%, were prepared in the charged state and used as zinc test electrodes.

Three approaches have been suggested for the experimental determination of current distribution. The first approach is the direct measurement of potential distribution by using numerous reference electrodes along the electrode thickness (11). The second approach is the direct measurement of the current distribution by using a sectioned electrode and measuring the current in each section (12, 13). The third approach is to measure the reaction distribution of the discharged electrode by electrode sectioning followed by the analysis of each section. The charge state of each section can be analyzed using chemical analysis as shown by Nagy and Bockris (14) for the zinc electrode, Bro and Kang (15) for the cadmium

[2] Present address: Chemical Engineering Department, Brigham Young University, Provo, Utah 84602.

Key words: porous zinc electrodes, failure mechanism, electrode overpotentials, current distribution.

electrode, and Alkire (16) for the copper electrode. The sectioning approach could be extended to determine the concentration distribution of electrolyte species as illustrated by Brenner (17) and Flatt *et al.* (18). By freezing the electrolytic solution followed by sectioning and chemical analysis, they have determined the concentration profiles of ionic species at dissolving anode surfaces and at a depositing cathode surface. In the present study, zinc and ZnO profiles were measured using the sectioning method with EDTA titration. Freezing was not tried.

Experiments

Preparation of the pressed zinc electrode.—The zinc powder with particle sizes between 250 and 325 mesh (60-44 microns) was amalgamated with mercury in a mercuric acetate solution containing an amount of mercury equivalent to 2.5 weight percent (w/o) of the zinc weight. The test zinc electrodes were prepared by pressing amalgamated zinc powder onto a backing plate. The backing plate consisted of a titanium foil (0.001 in. thick) upon which a silver screen (0.004 in. thick) had been spot welded.

Electrodes with two different porosities were tested. The low porosity electrodes were obtained by pressing the Zn(Hg) powder in a stainless steel mold using 13,000 psi. The resultant electrode contained about 0.5g of zinc amalgam and had a porosity of 0.33. The high porosity electrodes were prepared by the procedure given by Morrel and Smith (7). A mixture of NaCl powder and Zn(Hg) powder having the weight ratio of 40 NaCl-60 Zn(Hg) was pressed onto a backing plate using 20,000 psi. The NaCl powder used as a filler had a particle size of 250-325 mesh. The resultant electrode was soaked in distilled water for 24 hr. Complete dissolution of NaCl was confirmed during this period. This gave a highly porous structure having a porosity of 0.6. Each electrode contained about 0.3g of zinc.

The electrodes made by the above procedure were disks which had a cross-sectional area of 1 cm^2 and thickness of 0.1 ± 0.01 cm. A small cross-sectional area, 1 cm^2, was chosen to minimize the extent of nonuniform current distribution in the direction parallel to the electrode surface.

Potential measurements.—A schematic drawing of the test cell is shown in Fig. 1. The main body of the cell was made of Plexiglas. The zinc test electrode was completely sealed by two O-rings when the cell was assembled by tightening screws. A silver screen having a zinc deposit was used as a counterelectrode. Two layers of RAI P2291 (40/20) cation exchange membrane (0.001 in. thick) and one layer of dynel, used as separators, were placed on top of the test electrode. The RAI membrane is a beta radiation, cross-linked, low density polyethylene film which has been gamma-radiation grafted with methacrylic acid. The dynel is a porous, nonwoven acrylonitrile which is resistant to oxidation in the cell environment. The sealed test zinc electrode contained a limited amount of electrolytic solution (0.03-0.11 cm^3), while the counter zinc electrode compartment contained a large amount of solution of 1.5 cm^3.

After evacuation, filling the cell with solution, and assembling the cell, the test electrodes were discharged galvanostatically in a 40 w/o KOH solution saturated with ZnO. The potentials of the test zinc electrode were measured with respect to Hg/HgO reference electrodes at three different positions; one above the membrane, one on the electrode surface, and one on the backing plate. The Hg/HgO reference electrodes were made by the procedure given by Falk and Salkind (19). An external zinc-mercury cell was connected in series in the electrometer circuit to cancel out the equilibrium potential of the zinc electrode. This arrangement allowed zero potential at the open

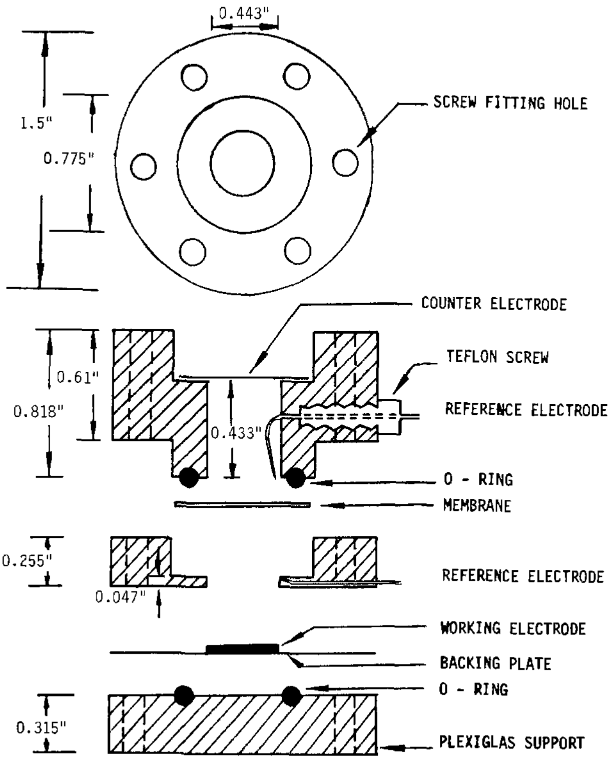

Fig. 1. Test cell assembly

circuit and the sensitivity of the potential data was improved. In retrospect, the net effect is using a Zn/ZnO (sat'd) reference electrode. Zinc electrode potentials at three locations and the potential difference between the zinc test and the zinc counter electrodes were recorded continuously using a Varian Associate 2000 recorder. The integrated current passed was counted by a coulometer, Model 541, Koslow Company.

Determination of reaction profiles.—Some electrodes were sectioned using the technique described by Bro and Kang (15). The discharged electrode was fitted into a fixture having a microadvancing screw which allowed the electrode to be advanced 0.025 in. per revolution. The electrodes having thickness of 0.1 ± 0.01 cm were then machined off by use of a milling machine in the direction parallel to the electrode surface. This sectioning operation usually resulted in 5-10 sections. The machined chips per each section were collected and analyzed to determine the amount of zinc and zinc oxide.

The standard technique for analyzing zinc and zinc oxide with EDTA titration has been described in detail by Welcher (20). The sectioned chips were dissolved in 1M NH_4Cl-NH_4OH buffer solution for 5 min. Previous studies (14, 21) have shown that this solution dissolves ZnO completely but attacks zinc negligibly during this period. The solution was vacuum filtered, adjusted to $pH = 10$ with 1M NH_4Cl-NH_4OH, and titrated with 0.1M (or 0.01M) disodium EDTA to determine the amount of ZnO. The weight of ZnO equivalent to 1 ml of 0.1M disodium EDTA was 8.14 mg. Following the analysis of the ZnO content, the filtered zinc powder was dissolved in a 10M HCl solution for several hours. The solution was adjusted to $pH = 10$ and then titrated with 0.1M (and 0.01M) disodium EDTA. The amount of zinc equivalent to 1 ml of 0.1M disodium EDTA was 6.538 mg.

In order to quantify the error caused by the dissolution of zinc, samples of amalgamated zinc powder were vigorously stirred in 1M NH_4Cl-NH_4OH solution for 5 min and vacuum filtered for 1 or 2 min. It was observed that the filtered solution contained

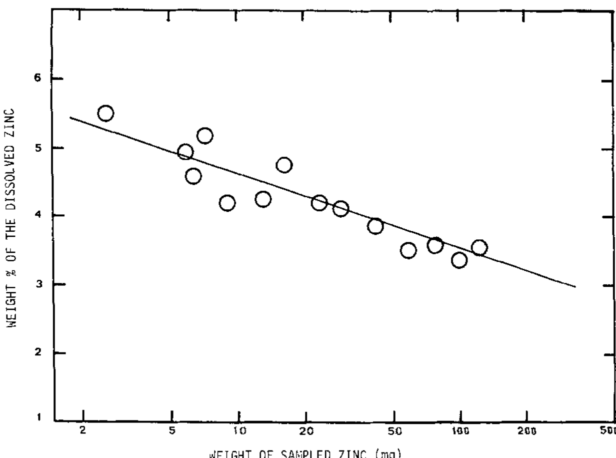

Fig. 2. Weight percent of the dissolved zinc in 1M NH_4Cl-NH_4OH within 6 or 7 min contact time.

approximately 4 w/o of the initial zinc as shown in Fig. 2. When corrections for the amount of dissolved zinc during selective dissolution of ZnO from a Zn-ZnO mixture were accounted for, titration errors remained within 1%.

Result

The reaction distributions, observed with two different current densities of 50 and 20 mA/cm^2 and two different porosities of 0.33 and 0.6, are shown in Fig. 3 to 7 in terms of the volume fractions of zinc and ZnO. In these experiments, a dynel cloth was placed between the test electrode surface and the membrane. This arrangement is designated by "ZDM configuration." The total capacity of the low porosity electrode is 23.6 A-min corresponding to a discharge for 471 min with 50 mA/cm^2 and that of the high porosity electrode is 14.05 A-min. These capacities are referred to as "100% depth of discharge" or as "100% utilization" throughout this paper.

Some of the measured profiles were compared with the profiles predicted from the mathematical model of Sunu and Bennion (9). The data used for numerical calculations were as follows: the initial specific surface area, $a_o = 300$ cm^2/cm^3; initial KOH concentration, $c_{3o} = 10M$; initial porosity, $\epsilon_o = 0.33$ for the low porosity electrode and $\epsilon_o = 0.6$ for the high porosity electrode; initial volume fractions of ZnO and inert conducting materials, $(\epsilon_{ZnO})_o = 0$ and $(\epsilon_I)_o = 0$; exchange current density, $i_o^o = 0.1$ A/cm^2 [taken from Ref. (22)]; tortuosity factor, $t = 0.5$; the transference number and the mass transfer coefficient of hydroxide ion across two layers of RAI P2291 membrane, $(t_3)_m = 0.5$ and $(L_{BB})_m = 1.5 \times 10^{-5}$ cm/sec [from Ref. (23)]. See Ref. (9) for other parameters.

All the parameters used were taken either from the literature data or from theoretical considerations. One exception is the effective conductivity of the pore solution which was taken as 12-27% of the conductivity of the free electrolytic solution. This choice may not be unreasonable considering the observations of Simonsson (24) and Romanova and Selitsky (25). They observed an effective conductivity which was one-tenth of the conductivity of the free solution. They attributed this large reduction in conductivity to the gas contained in the pores.

Figure 3 shows the volume fractions of zinc and ZnO of a low porosity electrode (ZDM configuration) which has been discharged to 8% depth at 50 mA/cm^2. The predicted profiles are shown as the smooth curves. The reaction profiles are highly nonuniform resulting in a very thin reaction zone. Discharge failure occurred at 8% depth in this experiment as well as in the theoretical calculation. The reaction profiles ob-

tained with a low current density of 20 mA/cm^2 are shown in Fig. 4. Even for the 20 mA/cm^2 discharge, a thin reaction zone is still observed and only one-fifth of the electrode is effectively utilized prior to discharge failure. After 23% depth of discharge (271 min), all the zinc at the electrode face is used up and reaches the condition for pore plugging. Discharge failure occurred at 22% depth in the theoretical calculation but near 32% depth in our experiments. This deviation was due to the cracking or swelling of the real electrode which opened the pore structure and allowed further discharge to 32% depth of discharge. The original theoretical model did not allow for swelling and cracking. This effect will be described in detail with the discussion of Fig. 9.

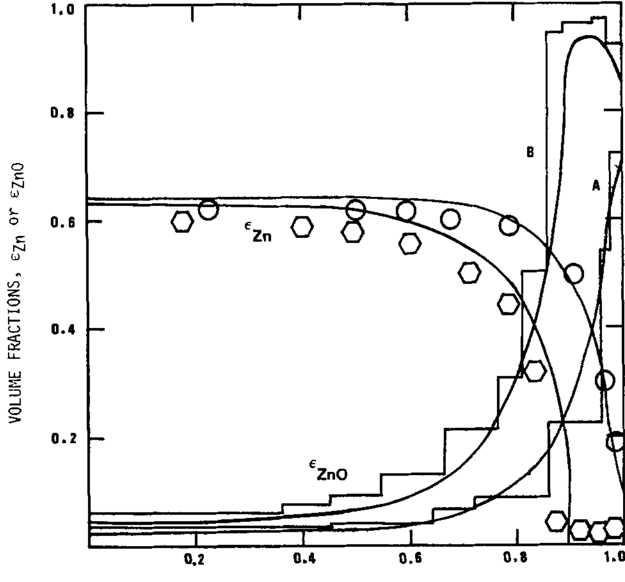

Fig. 4. Profiles of Zn (circles and hexagons) and ZnO (histograms) for the low porosity electrode discharged at 20 mA/cm^2. ○ and histogram A, measured profiles after 10% depth; ⬡ and histogram B, measured profiles after 23% depth; smooth curves, predicted profiles after 10% and 23% depths of discharge.

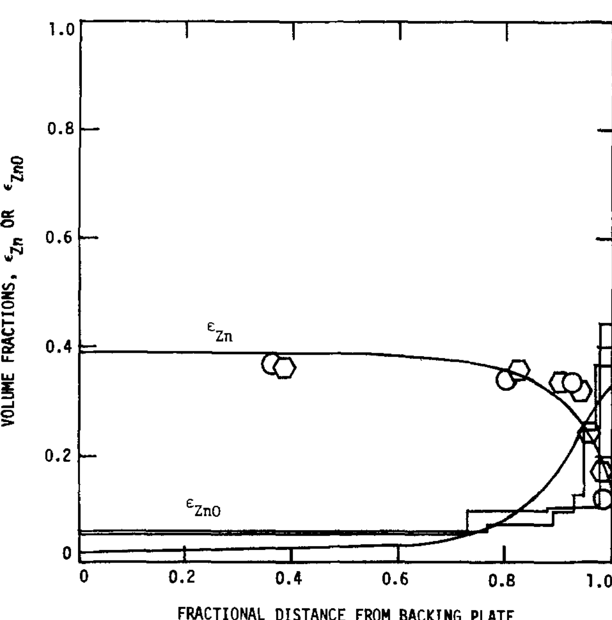

Fig. 5. Profiles of Zn and ZnO for the high porosity electrode discharged to 10% depth at 50 mA/cm². ○ and ⬡, measured profiles for Zn; histograms, measured profiles for ZnO; smooth curves, predicted profiles for Zn and ZnO.

The zinc and ZnO profiles for the high porosity electrode discharged to 10% depth at 50 mA/cm² are shown in Fig. 5. Further discharge to 21% depth (1 hr discharge) resulted in the profiles of Fig. 6. Two sets of data as well as the predictions are presented. Generally, the observed profiles, in particular, of the zinc showed good agreement with the predictions. For the high porosity electrode, ohmic loss as well as concentration overpotentials through the solution are smaller than those for the low porosity electrode. This small solution resistance shifts the reaction profile toward the backing plate to produce a more uniform profile. Evidently the porosity of this electrode is large enough to eliminate the discharge failure due to pore plugging, at least in the short cycle range.

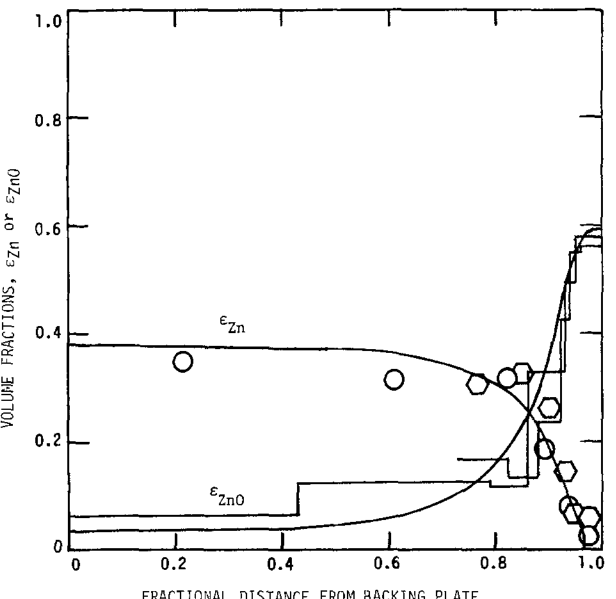

Fig. 6. Profiles of Zn and ZnO for high porosity electrode discharged to 21% depth at 50 mA/cm². ○ and ⬡, measured profiles for Zn; histograms, measured profiles for ZnO; smooth curves, predicted profiles for Zn and ZnO.

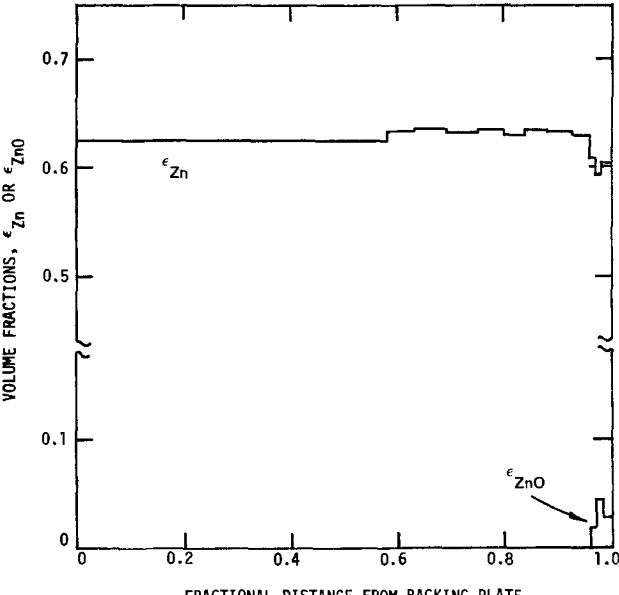

Fig. 7. Profiles of Zn (top line) and ZnO (bottom line) measured for the low porosity electrode after one cycle. At each half-cycle, 50 mA/cm² and 10% depth of initial zinc were applied.

Profiles shown in Fig. 7 were measured after one cycle of a low porosity electrode with an applied current density of 50 mA/cm². The total charge passed at each half cycle was equivalent to 10% conversion of initial zinc. Some of the ZnO precipitated on discharging was not dissolved completely on charging but remained near the face of the electrode. This type of Zn movement on cycling could cause electrode failure after many cycles.

The potential data taken during the preliminary test period were not reproducible. It was found that the reproducibility of the data was successfully improved when the amount of electrolytic solution accessible to the electrode was carefully controlled. Consequently, four different cell configurations having different amounts of electrolytic solution were used in the potential measurements. They include a low porosity electrode having dynel on top of the membrane (designated by L50-ZMD where numeric number represents the applied current density in mA/cm²), a low porosity electrode having dynel beneath the membrane (L50-ZDM), a high porosity electrode having dynel beneath the membrane (H50-ZDM), and a low porosity electrode having dynel but without a membrane (L50-ZD). For all the cases, dynel and membrane refer to the use of one layer of dynel cloth and two layers of RAI P2291 membrane, respectively. Placing dynel cloth below the membrane in ZDM configuration provides an additional solution reservoir of 0.03-0.04 cm³, but the dynel cloth used in the ZMD configuration simply serves as a supporting material to minimize the electrode swelling.

Figure 8 illustrates anodic overpotentials observed during discharge of low porosity electrodes at 50 mA/cm². The total capacity corresponding to a complete conversion of Zn into ZnO is 23.6 A-min (471 min at 50 mA/cm²) for the low porosity electrode and 14.05 A-min (281 min at 50 mA/cm²) for a high porosity electrode. The observed capacities were 1.65 A-min for L50-ZMD, 3.1 A-min for L50-ZDM, and 3.5 A-min for H50-ZDM. This observation indicates that the discharge failure is caused by KOH depletion since the capacity is approximately proportional to the electrolyte volume contained in the zinc electrode compartment. The theoretical result shown in Fig. 2 (curve c) of Ref. (9) is approximately comparable to this experimental result, the theory showing depletion of KOH concentration from an initial 8M to

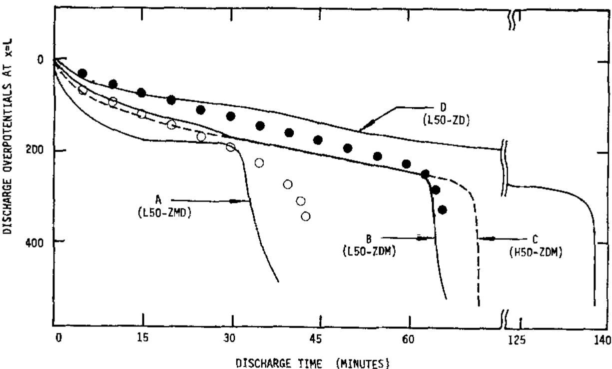

Fig. 8. Overpotentials at the face of the zinc electrode ($x = L$) on discharge at 50 mA/cm². ——— and - - -, measured overpotentials; ○, predicted overpotentials for L50-ZMD; ●, predicted overpotentials for L50-ZDM. L and H represent low porosity and high porosity electrodes, respectively, and Z, M, and D represent zinc electrode, membrane, and dynel, respectively (figure notation L50-ZDM represents a low porosity zinc electrode having a dynel beneath the membrane discharged at 50 mA/cm²).

2M after 10% depth of discharge. The theoretical calculation was based on one layer of RAI/P2291 membrane while the experiment was with two layers of membrane. Thus, the experimental depletion of KOH was greater due to higher OH^- ion transport resistance and failure due to KOH depletion actually occurred in the experiment but failure did not quite occur in the theoretical calculation reported in Ref. (9). Although not specifically reported, theoretical calculations predict KOH depletion and failure for two layers of membrane under these operating conditions. Discharge of the L50-ZD cell which has no membrane continued to 6.85 A-min or 29% utilization of the initial zinc. Eliminating the membrane increases the supply of hydroxide ions from the counterelectrode compartment and thus the utilization. However, further discharge is expected to be limited due to pore plugging since discharge to 29% depth could lead to the reaction profile which is very similar to curve B of Fig. 4. The predicted overpotentials were plotted as white circles for L50-ZMD configuration and as black circles for L50-ZDM configuration. The predicted overpotentials agreed reasonably well with observations except for those near discharge cutoff.

Figure 9 shows the anodic overpotentials measured at the face of the zinc test electrode during discharge with 20 mA/cm² current density. Those for 50 mA/cm² discharge are shown for comparison. Curve C L20-ZDM) and curves A and B (two sets of data for L20-ZMD) correspond to 7.2-8.4 A-min or 31-36% utilization. Discharge of the high porosity electrode (H20-ZDM) could continue further, beyond 9.6 A-min or 68% utilization. The addition of a dynel cloth as a solution reservoir of 0.03-0.04 cm³ (curve C) does not significantly increase the cell capacity compared to L20-ZMD cell (curves A and B). On the other hand, the use of a high porosity electrode which provides additional solution of 0.03 cm³ and additional space for ZnO precipitation substantially increases the capacity. Irregular overpotential drops were frequently observed instead of continuous increase, as shown in curve A at 1.25 hr discharge and also in other curves as smooth humps. The swelling or cracking of the electrode is responsible for this irregular potential behavior. All these observations favor the pore plugging model, attributing the failure during a 20 mA/cm² in low porosity electrodes to pore plugging.

It was mentioned that the numerical discharge calculations used in Fig. 4 show failure at 22% of the total cell capacity. The predicted overpotentials are plotted as white circles. The predicted discharge failure occurs earlier than the observation. When numerical calculations were modified to include the effect of electrode swelling, the resulting overpotentials resemble the observed overpotentials as shown by black circles. The modified numerical procedure can be described as follows. The reaction zone of the low porosity electrode (initial porosity of 0.33) is assumed to retain a constant porosity of 0.3 due to swelling. The increase of solid volume during discharge is then regarded as the expansion of electrode thickness toward the reservoir of 0.01 cm³ between the electrode surface and the dynel. When the porosity of this reservoir reaches 0.3, the porosity of the reaction zone is allowed to decrease further by the precipitation of ZnO. The result obtained with this numerical procedure agreed well with the observed overpotentials.

Figure 10 shows the overpotentials measured at three different positions and the potential difference between the zinc test (L50-ZDM) and the zinc counterelectrode. The potential difference of 80 mV between curves B and C, which is the potential drop across two layers of RAI P2291 membrane, is comparable to the ohmic loss of 90 mV calculated from the measured conductivities (23). The first discharge failed after 67.0 min. When the cell was allowed to rest for 8 min, it accepted an additional discharge for 12 min. Increase in the rest period leads to a longer time to failure for the second discharge. This result is further evidence that KOH depletion is the failure mechanism under this condition.

Figure 11 is the corresponding potential-time curves during continued charge with a current density of 50 mA/cm². During continued charge, 3.9 A-min was

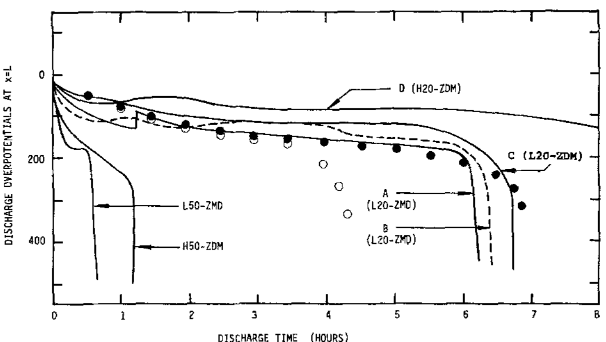

Fig. 9. Overpotentials at the face of the zinc electrode ($x = L$) on discharge at 20 mA/cm². ——— and - - -, measured overpotentials; ○ and ●, predicted overpotentials for L20-ZDM without and with correction for swelling, respectively. Explanation of figure notation is given in Fig. 8 caption.

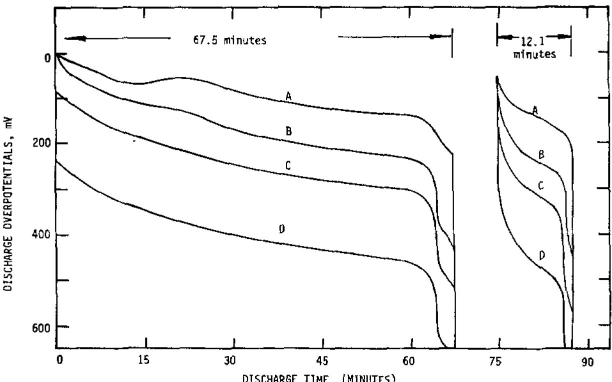

Fig. 10. Overpotentials measured at four different positions on discharge of L50-ZDM electrode at 50 mA/cm². Curves A, B, and C represent the overpotentials measured at the backing plate, at the face of the test electrode, and above the membrane, respectively. Curve D is the potential difference between the zinc test and the zinc counterelectrodes.

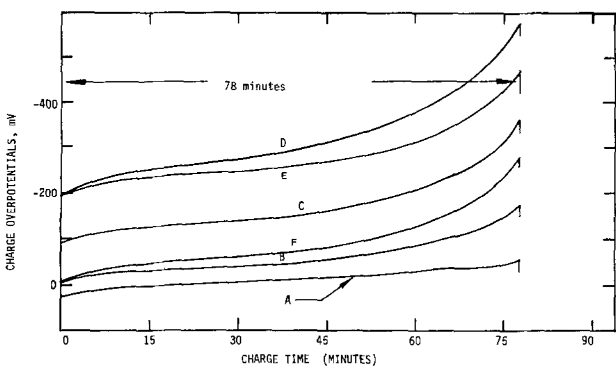

Fig. 11. Overpotentials measured at four different positions on charge of L50-ZDM electrode at 50 mA/cm². Explanation of curves A, B, C, and D is given in Fig. 10 caption. The gaps F-C and C-E are the overpotentials across the membrane and across the solution in the counterelectrode compartment, respectively.

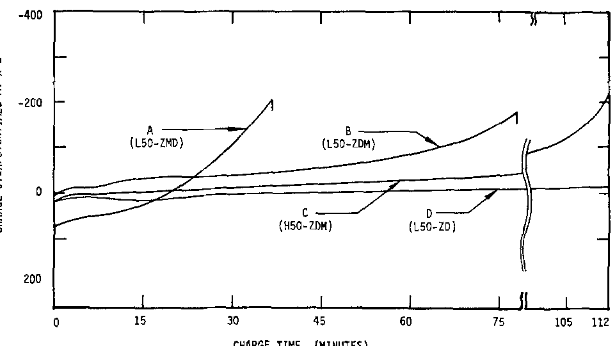

Fig. 12. Overpotentials measured at the face of the electrode (L50-ZDM) on charge at 50 mA/cm². Explanation of figure notation is given in Fig. 8 caption. The previous discharge time prior to onset of charge is 39.4 min for L50-ZMD, 69.6 min for L50-ZDM, 84.5 min for H50-ZDM, and 138.5 min for L50-ZD.

recovered, prior to significant overpotential rise, out of 3.98 A-min applied during discharge. Curves A, B, and C are the overpotentials measured at the backing plate, at the electrode surface, and top of the membrane. Curve D is the potential difference between the zinc test and the zinc counterelectrodes. Curve E was drawn based on the solution ohmic loss in the counterelectrode compartment. The distance from the membrane to the counterelectrode surface (1.1 cm) and the conductivity of 10M KOH solution (0.51 mho/cm) (26) results in the ohmic loss of about 110 mV which is the gap C-E. The gap D-E represents anodic overpotentials of the counter zinc electrode.

Comparison of Fig. 10 with Fig. 11 provides useful information on the potential behavior. The test zinc electrode has 0.07 cm³ of electrolytic solution and porosity of 0.33, while the electrodeposited counter zinc electrode contains 1.5 cm³ of solution with porosity of 0.6-0.8. The anodic overpotential of the zinc test electrode (curve B of Fig. 10) is much larger than that of the zinc counterelectrode (gap D-E of Fig. 11). This indicates that the high anodic overpotential of the test zinc electrode is due to the use of a low porosity and a limited amount of electrolytic solution.

Another interesting point to note is the potential difference between the electrode surface and the top of the membrane, namely, line spacings B-C of Fig. 10 and 11. The gap B-C is the sum of the potential drops across the solution reservoir located between the electrode surface and the dynel, across the dynel, and across the membrane. The gap B-C of Fig. 11 rises with time and is much larger compared to the gap B-C of Fig. 10 which is nearly constant throughout the operation. The potential drop across the membrane of 80 mV, *i.e.*, the gap B-C of Fig. 10 is used to produce the gap C-F of Fig. 11. The significant increase of the potential gap B-F, potential drops across the dynel and the solution reservoir, with time indicates that zinc deposition reaction takes place above the electrode surface and grows through the dynel toward the additional source for zincate ions.

The overpotentials during charge of zinc test electrodes following discharge of the electrodes shown in Fig. 8 are plotted in Fig. 12. The overpotentials were measured with an Hg/HgO reference electrode connected to the working zinc electrode surface by a capillary filled with 40% KOH in water. Observed failure times were 37, 78, and 112 min for the L50-ZMD, L50-ZDM, and H50-ZDM electrodes, respectively. Most of the charge withdrawn during discharging is replaced during charging prior to significant overpotential rise. For the cell without a membrane (curve D), very small cathodic overpotentials were observed. This result is further evidence that real cell overpotential losses can, to a considerable extent, be traced to mass transfer limiting processes across the membrane. Without the semipermeable membrane, zinc deposits penetrated the dynel cloth and continued to grow toward the counterelectrode. Because of the large electrode separation in the test cell, no failure was observed. However, dendritic growth of the type observed would have caused a short circuit in a practical battery cell. For test cells with a semipermeable membrane in the ZDM configuration, postoperation examination showed dendrite growth into the dynel stopping at the membrane surface.

Discussion

The present experimental data disclose three discharge failure modes: depletion of electrolyte, pore plugging, and passivation. The limiting process occurring during discharge, *i.e.*, the depletion of OH^- ion at the dissolving zinc surfaces, is referred to as electrolyte depletion if it is caused by the insufficient electrolyte content provided from the zinc electrode compartment, or as pore plugging if diffusion across the outer layer of the electrode is the governing process, or as passivation if diffusion across the layer of the ZnO film precipitated over individual zinc crystals limits the discharge.

Depletion of electrolytes.—During discharge the zinc electrode consumes hydroxide ions and produces water. Depletion of hydroxide ions becomes serious for sealed or tight packed cells having membranes, which are designed to minimize failure due to zinc dendrite penetration and shape change. Tight packing decreases the volume of electrolytic solution reservoir and generally membranes used to prevent zinc dendrite formation also limit the mass transfer of hydroxide ions between two electrode compartments. A restricted amount of electrolytic solution and/or limited flux of hydroxide ions across the membrane can lead to a situation in which the zinc electrode fails on discharge earlier than if a large amount of electrolyte is available.

Failure observed during discharge of the zinc electrode having two layers of RAI P2291 membrane with a current density of 50 mA/cm² was attributed to the depletion of hydroxide ions (see curves A, B, and C in Fig. 8). Depletion of electrolyte strongly depends on the type of the membrane, volume of a solution reservoir, and the porosity of the electrode. If it is assumed that all the zincate ions produced by zinc dissolution are converted into ZnO and that OH^- concentration inside the electrode is completely mixed, then the variation of KOH concentration with time can be approximated by the following equation

$$\frac{V}{A}\frac{\partial \epsilon c_3}{\partial t} = -\left[-(L_{BB})_m (c_3^o - c_3) - \frac{t_{3m}}{\mathbf{F}} I \right] - \frac{I}{\mathbf{F}}$$

The solution is

$$\frac{c_3}{c_3^o} = 1 - \frac{I(1-(t_3)_m)}{\mathbf{F}(L_{BB})_m c_3^o}\left[1 - e^{-\frac{(L_{BB})_m At}{V}}\right]$$
$$= 1 - \frac{1-(t_3)_m}{M}\left[1 - e^{-\frac{Mt}{\tau}}\right]$$

where V is the volume of the electrolytic solution contained in the zinc electrode compartment, A is the cross-sectional area of the electrode, I is the superficial current density, c_3 is the average (mixed) concentration of the hydroxide ion, c_3^o is the initial hydroxide concentration, and $(L_{BB})_m$ and $(t_3)_m$ are the mass transfer coefficient of KOH and transference number of OH^- ions across the membrane, respectively. The characteristic time $\tau(=c_3^o\mathbf{F}V/I/A)$ is defined by the period required for complete consumption of hydroxide ions when the boundary is insulated with respect to OH^- flux. For the cell configuration L50-ZMD ($V = 0.033$ cm^3, $c_3^o = 0.01$ mole/cm^3, and $I = 0.05$ A/cm^2), the characteristic time τ is 637 sec and is equivalent to only 2.3% conversion of the initial zinc into ZnO. This number is surprisingly small. The dimensionless parameter $M(c_3^o\mathbf{F}(L_{BB})_m/I)$ corrects for the flux of hydroxide ions across the membrane.

If the above equation is applied to the present test cells using the transport parameters reported by Sinha and Bennion (23), *i.e.*, $(L_{BB})_m = 1.5 \times 10^{-5}$ cm/sec and $(t_3)_m = 0.5$, the ratio c_3/c_3^o becomes zero after 31.7 min for the L50-ZMD electrode ($V = 0.033$ cm^3) and after 65.4 min for the L50-ZDM electrode ($V = 0.068$ cm^3), which are comparable to the experimental observations shown in Fig. 8 (curves A and B). The twofold increase in the amount of KOH contained in the zinc electrode doubles the electrolyte-limited discharge capacity. On the other hand, with 20 mA/cm^2, the calculated KOH concentration inside the low porosity electrode remains 3.1M at infinite time of operation. Discharge could continue until the decreased pore size near the electrode surface limit the diffusion of OH^- ions into the interior of the porous electrode. Consequently, the observed results of Fig. 8 and 9 lead to a conclusion that at high rate (50 mA/cm^2), depletion of hydroxide ions causes the zinc electrode to fail prior to pore plugging, while discharge at a low rate of 20 mA/cm^2 continues until pore plugging causes a discharge failure.

Pore plugging.—Discharge of most battery plates is accompanied by changes in the pore size because of the difference in the molar volumes of solid reactants and solid products. Since the molar volume of ZnO (14.51 cm^3/mole) is larger than that of zinc (9.15 cm^3/mole), the conversion of zinc into ZnO on discharge decreases the pore size near either side of the electrode surfaces. A nonuniform current distribution will accentuate this problem at the pore mouth. This phenomenon has been given some attention by Gidaspow and Baker (27) who emphasized porosity changes and pore plugging as a mechanism of discharge failure.

If all the zincate ions resulting from zinc dissolution precipitate as ZnO, the zinc electrode having a relatively low porosity of less than 0.4 can be easily blocked by the precipitation of ZnO. Failure due to pore plugging is expected to occur after 20% depth of discharge if penetration depth is assumed to be one-fifth of the electrode thickness. The pore plugging was confirmed both by experimental and theoretical reaction profiles shown in Fig. 4. The discrepancy between the observed and calculated overpotentials was interpreted by the effect of the electrode swelling or cracking. The test electrode used in our study was supported by Plexiglas except for the front surface, which had dynel cloth as a supporting material. Therefore, the stress arising either from the increase in solid volume or from the gas evolution caused swelling and cracking of the frontal surface which could increase the time required for pore plugging. With a correction for the electrode swelling, numerical overpotentials agreed very well with the experimental overpotentials.

Complete pore plugging leading to zero porosity is not necessary to cause failure. The electrode face having pore size smaller than a certain critical value can limit significantly the supply of hydroxide ions into the interior of the porous electrode, resulting in depletion of hydroxide ions and then passivation. Simonsson (24, 28) has proposed this process, namely, blocking of the outer layer of the electrode by a discharge product followed by acid depletion in the inner part of the electrode, as a failure mechanism during high rate discharge of the porous PbO_2 positive electrode in a lead-acid battery.

Passivation.—A number of workers (1-4, 29-35) have studied passivation behavior of the planar zinc electrode in alkaline solution. It is generally agreed that two mechanisms exist for the formation of the passive film; (a) direct formation on the electrode surface through a solid state reaction, and (b) indirect formation from a supersaturated zincate solution through a precipitation reaction. The two reaction mechanisms can be written as [*e.g.*, (35)]

$$Zn(OH)_2 \rightarrow ZnO + H_2O \quad [a]$$

$$Zn(OH)_4^{=} \rightarrow ZnO + H_2O + 2\,OH^- \quad [b]$$

Powers *et al.* (30, 33) and Hull *et al.* (34) have shown that a white porous film of ZnO (type I) forms by precipitation from a supersaturated solution before passivation occurs, while a coherent compact film of ZnO (type II) with color varying from light gray to black, which is responsible for passivation, appears directly on the surface beneath the type I film.

The passivation effect included in our mathematical model was the surface coverage of zinc surface by the precipitation of ZnO (blockage of the second kind) which corresponds to type I film. Our model did not include the passivation caused by type II film. Therefore, predicted overpotentials increased gradually until KOH solution in the pores decreased to zero (see circles in Fig. 8 and 9). These potential-time curves are similar in shape to those discussed by Elsdale *et al.* (36) and Coates *et al.* (37) who observed a gradual decrease in potentials in the vicinity of passivation. On the other hand, an abrupt increase in overpotentials was observed near the cutoff of discharge of the present cells which had limited amount of electrolytes (see Fig. 8 and 9). This is believed due to the formation of a type II passivating film which was confirmed visually by the gray color of the fully discharged, wet electrodes. The type II film of ZnO is expected to form if the zinc surface is severely depleted of hydroxide ion or if the ratio of zincate to OH^- ion concentration exceeds a certain critical value. Depletion of hydroxide ions at the active zinc surface would result in a decrease in solubility of ZnO, a rapid increase in the rate of ZnO precipitation or solid-state reaction, and eventually a rapid rise in overpotentials.

The exact details of how and when the dense, blocking type II film forms seem unknown. However, the following hypothesis is proposed to explain presently known behavior. Whenever the OH^- ion surface concentration drops below some critical value, $Zn(OH)_2$ precipitates and then converts to ZnO forming the dense type II deposit via mechanism [a]. Such an event would occur at high local transfer current rates or whenever OH^- ion depletion occurs generally in the electrode pores. When OH^- concentration is high, a light, porous ZnO precipitate forms from supersaturated zincate solutions via mechanism [b]. When the

porous type I film formed by mechanism [b] gets thick enough and/or local transfer current high enough, the OH^- ion surface concentrations at the bottom of the ZnO pores drops and type II film will form stopping further reaction. This type II film apparently redissolves much slower than type I films and can possibly be a cause of permanent failure of an electrode. It may be important to develop ways of preventing type II ZnO films.

Charge failure.—During charge, zincate becomes unsaturated and the limiting species is the zincate ion. Depletion of zincate ions could occur in two ways; slow dissolution of ZnO and the restricted diffusion of zincate. These two limiting factors were not observed in our experiments. Most of the coulombic charge applied during discharge was effectively recovered on charge without causing significant overpotential rise. This suggests that discharge products in any form of zincate, ZnO, or $Zn(OH)_2$ can be converted into zinc without difficulty. The ZnO mentioned here does not include the reagent ZnO powder which has been used in the fabrication of commercial zinc electrodes. Previous studies (38, 39) have shown that the dissolution of ZnO is a slow process. Slow dissolution of ZnO and the depletion of zincate ions could play an important role in limiting the initial low charge acceptance during formation of the zinc electrodes made of ZnO powder.

During charge of the L50-ZD electrode which had no membrane separator, very small cathodic overpotentials were observed until no zincate ions were available from the counterelectrode compartment. Zinc deposits penetrated the dynel cloth and continued to grow toward the counterelectrode compartment at a fairly constant overpotential. In one experiment, charge was allowed to proceed until failure, but addition of drops of fresh electrolytic solution to the counterelectrode compartment restored the original performance. Dendrite growth of this type will short out an actual cell whenever the membrane is bridged during cycling.

Summary

Distribution of zinc and ZnO and electrode overpotentials were measured during galvanostatic discharge in a 40 w/o KOH solution saturated with ZnO and compared with the theoretical predictions. The zinc electrode behaviors observed on discharge were interpreted using proposed discharge failure modes: depletion of electrolyte, pore plugging, and passivation. Results with two current densities of 20 and 50 mA/cm^2 and two porosities of 0.33 and 0.60 were discussed.

Both observed and predicted reaction profiles were highly nonuniform, resulting in a very thin reaction zone located near the face of the electrode. The reaction zone which effectively participates in the discharge reaction prior to failure was equivalent to about 20% of the 1.0 mm electrode thickness. The remaining zinc metal served simply as an inert matrix and did not contribute to the cell capacity.

During discharge at 50 mA/cm^2 for both low porosity and high porosity electrodes, the utilization of zinc was severely limited by the depletion of electrolytes within the zinc electrode compartment. The utilization depends strongly on the applied current density, initial porosity, the amount of electrolytic solution, and the type of membrane. At a low current density of 20 mA/cm^2, the utilization of zinc was much higher than that observed with 50 mA/cm^2 and the discharge continued until the decrease in pore size in the reaction zone played an important role in limiting further discharge capacity. The highly nonuniform reaction distribution accentuates the phenomenon of pore plugging at the pore mouth. Low current discharge of the high porosity electrode, in which the possibility of pore plugging was eliminated, continued to more than 50% utilization. Blockage of the zinc surface by the precipitated ZnO (or passivation) also could occur beyond this region.

The present cell showed much lower overpotentials during charge compared to those on discharge. Most of the coulombic charge applied during discharge was effectively recovered on charging. The reaction profile measured after one cycle shows that some of the zinc oxide which precipitated on discharge did not dissolve completely on charging but remained near the electrode surface. This accumulation after many cycles could decrease the pore size, at least locally, and deplete electrolytes in the interior of the electrode. It also could reduce the active zinc surface area, promoting high activation overpotential and the chance for an earlier passivation. Similar adverse effects are expected with the gas trapped in the pores. Further work is necessary to confirm this type of redistribution of zinc species on cycling.

The result of this work can be applied to the design of industrial zinc electrodes to improve their performance and cycle life. It also points out areas where further research should be emphasized to gain cycle life improvements.

Technical Note

Hazard Investigations of $LiClO_4$/Dioxolane Electrolyte

G. H. Newman,* R. W. Francis, L. H. Gaines,* and B. M. L. Rao*

Exxon Research and Engineering Company, Linden, New Jersey 07036

During extensive multicycle testing of the rechargeable Li/TiS_2 system (1-3), using a $LiClO_4$/dioxolane electrolyte, a hazard problem was encountered. A cell which had been cycling overnight on automatic equipment, at constant current, between preset voltage limits, was found destroyed. The cell had been charred and the glass container was shattered. An explosion was presumed to have occurred. This event resulted in the immediate initiation of an investigation of the possibility of the existence of an inherent explosion hazard in the use of the $LiClO_4$/dioxolane electrolyte. This paper reports the results of the investigation.

Experimental

The electrolyte safety investigation was carried out in two parts: (*i*) an "in-house" electrochemical cell abuse test program, and (*ii*) a hazard evaluation program carried out, under contract, by Hazards Research Corporation, of Denville, New Jersey

Electrochemical cell-abuse tests.—The "in-house" program was restricted to cell-abuse tests. The abuse tolerance of cells during overcharge and overdischarge (cell reversal) conditions of the Li/TiS_2 cells containing 2.5M $LiClO_4$/dioxolane electrolyte were studied. A control test was also run with an electrolyte consisting of $LiPF_6$ dissolved in dioxolane.

The test cells were constructed with 1×1 in. lithium and TiS_2 electrodes in a parallel plate configuration (Li $\approx$ 600 mA-hr, TiS_2 $\approx$ 200 mA-hr, Celgard®, and 304 stainless steel grids), and placed in a polyethylene bag. The cell assembly was mounted in a hermetically sealable glass container with glass to metal electrical through-puts. All cells contained 2-3 ml of electrolyte and were assembled in a dry room with ~1.5% RH.

Hazards Research Corporation tests.—Two types of tests were performed on solutions of $LiClO_4$/dioxolane and $LiPF_6$/dioxolane supplied by us and identical to the solutions tested by us in electrochemical cell-abuse tests. The tests were:

Impact tests.—A standard JANAF test was performed, wherein a known weight (2 kg) is dropped from various preset heights onto a carefully designed cup containing the electrolyte. A loud report (puncture of a retaining steel diaphragm), flame, or other evidence of

Table I.

Cell No.	Salt	Mode	Current (mA/cm^2)	Time	Final voltage	Remarks
8	$LiClO_4$	O.D.	150	~10 min	−9	Detonated
7	$LiPF_6$	O.D.	150	~5 min	−40	No fire, peak temp. 135°C, electrolyte gelled
11	$LiClO_4$	O.D.	150	~5 min	−4	Detonated
10	$LiPF_6$	O.C.	150	15 min	+40	No fire
12	$LiClO_4$	O.C.	150	10 min	+40	No fire
9	$LiClO_4$	O.C.	150	30 min	+40	No fire
43	$LiPF_6$	O.C.	150	30 min	+40	No fire, peak temp. 120°C
44	$LiPF_6$	O.D.	150	—	≈0	Cell shorted; no fire
46	$LiClO_4$	O.D.	15	6 hr	−24V	Detonated, overnight stand at 5¾ hr
48	$LiClO_4$	O.D.	15	5½ hr	−1.5V	Detonated
32	$LiClO_4$	O.D.	7.5	5½ hr	−9V	Detonated, triggered by 75 mA/cm^2 pulse
33	$LiClO_4$	O.D.	15	5 hr	−7V	Detonated
35	$LiClO_4$	O.D.	7.5	9 hr	−35V	Detonated

combustion, are considered a positive test. Tests are performed up to 36 in., at which point hydrodynamic shock is sufficient to yield a positive test with water.

Isothermal decomposition temperature.—The constant temperature stability of a sample is determined in a stainless steel reactor vessel equipped with thermocouples and rapid response pressure transducers. The equipment is shown schematically in Fig. 1.

Results and Discussion

The Li/TiS_2 cell abuse tolerance test results during overcharge and overdischarge (cell reversal) for the 2.5m $LiClO_4$/dioxolane are shown in Table I.

Overcharging (O.C.) of the cells containing $LiClO_4$ and $LiPF_6$ solutes (cells 10, 12, and 43) showed an increase in *IR* (polarized to 40V) due to the polymerization of dioxolane. The resistive heating resulted in a cell temperature rise to 120°C. Independent experiments have shown that the anodic polarization of $LiClO_4$/dioxolane solutions on a platinum electrode resulted in the initiation of polymerization of dioxolane at 3.25V *vs.* a lithium reference electrode. No explosive hazard was noted for any cell with either solution under overcharge conditions.

Overdischarge or cell reversal resulted in a detonation and fire in the case of all $LiClO_4$/dioxolane electrolyte cells tested. Cells 8 and 9 containing this electrolyte, when discharged at high current density, 1A (~150 mA/cm^2) detonated in 5-10 min. The onset of detonation was delayed up to 5 hr at lower current rates of 0.1A (15 mA/cm^2), as seen in cells 33, 46, and 48. Further reduction in current to 0.05A (7.5 mA/cm^2) extended the initiation time to ~9 hr. Although the measured overdischarge at all voltages varied in these experiments, the lowest voltage at detonation was noted to be −1.5V in cell 48.

Neither combustion nor detonation resulted under comparable conditions of discharge for cells with $LiPF_6$/dioxolane electrolyte, although peak temperatures of 130°C were measured (cells 7 and 44).

The results strongly suggested that the detonations on overdischarge are directly associated with the participation of the $LiClO_4$/dioxolane electrolyte.

Results of the impact testing are shown in Table II, along with the values for two known materials, NH_4ClO_4 and nitroglycerine. The expert opinion of Hazards Research Corporation is that the value of 25.5 in. obtained for the perchlorate solution is well within the range of "explosive materials." The value of 32.5 in. for the $LiPF_6$ solution signifies a solution which is "not very sensitive."

The isothermal decomposition test results are summarized in Table III. The conclusions of HRC were that "$LiClO_4$ solution is noticeably sensitive to impact, and detonates at elevated temperatures," and "$LiClO_4$ electrolyte and cell are obviously explosive materials and appropriate care should be observed in their handling and use."

Table II. Impact test results (2 kg JANAF drop weight test)

Sample	Height, inches for 50% probability of "explosion"
Water	36.0
2.5M $LiPF_6$-dioxolane*	32.5
2.5M $LiClO_4$-dioxolane	25.5
NH_4ClO_4 (dry solid)	18.9
Nitroglycerine	1.0

* No evidence of solvent polymerization at time of test.

Supplementary Data

1. We have found subsequent to the tests already described, that a cycled cell which "dead-shorted" internally from dendritic growth would also detonate.
2. During the course of our normal cell program, independent of the cell abuse tests described in this paper, several hundred cells were extensively cycled. Only six of these detonated. However, these detonations were quite violent, even though the cells contained only 3.5 ml of the solution.

Conclusions

Based on the results of the hazard investigation, it was concluded that $LiClO_4$/dioxolane electrolytes were unsafe for use in lithium secondary cells. All further development of secondary cells based on this electrolyte were terminated.

Table III. Isothermal decomposition results (340 cm^3 reactor)

Sample	Programmed temperature, etc.	T_{Max}, °C on exotherm	Pressure, PSIG after exotherm
50 cm^3 2.5M $LiPF_6$ in dioxolane	70 / 143 / 185 } Screen 1°C/min rise	135 / 163 / 360	8 / 43 / 500
	60 / 50 } Isothermal	72—4 hr (polymerization) / 50—8 hr (stable)	
50 cm^3 2.5M $LiClO_4$ in dioxolane	130 / 253 } Screening	(no exotherm data) 490	650 → >>6000

Method of Selecting Expanded Metal Grids for Battery Electrodes

Richard M. Meighan*

Eltra Corporation, C&D Batteries Division, Plymouth Meeting, Pennsylvania 19462

Expanded metal grids, although in use today in battery electrodes of several types, are still being explored for new applications in batteries. Even in that oldest of the rechargeable systems, the lead-acid battery, its application to industrial and electric vehicle battery grids has only recently begun to be explored. Within the last five years, however, expanded grids have been making an impact in the maintenance-free SLI (starting, lighting, and ignition) type lead-acid battery (1, 2). This technical note provides a method for selecting the expanded metal grid pattern most effective for direct substitution for an existing cast (lead) grid in a pasted battery electrode. This analysis applies to expanded grids made by the progressive die expansion process and similar types. The principal basis for comparison is the relative paste (active material) volumes of the two types of electrode plates. It is assumed that the electrochemical capacity is directly proportional to paste volume. Thus, the relative paste volume (expanded to cast), P_R, should be equal to or greater than unity to achieve an advantageous substitution with regards to capacity. Structural, *i.e.*, stiffness, and other factors may impact on this goal.

It should be emphasized that the prime usefulness of this method is to analyze the feasibility of substituting one or more expanded grid patterns for a particular cast grid prior to a costly expenditure in equipment or contracted trials. Once samples are in hand, more direct experimental methods may be applied to determine relative paste volume.

Method

For the purpose of this analysis it is convenient to compare only the part of both grids (cast and expanded) that is below the top horizontal grid bar and lug. (If, as in the example at the end of this note, the bottom horizontal bars are nearly the same dimension, those bars can be excluded also.) Thus, we define the same rectangular volume for both types of plates having equal dimensions of height, H, width, W, and thickness, T, whose volume is

$$V = HWT \quad [1]$$

This plate volume can be divided into two components, the grid volume, G, and the active material volume, P, thus

$$V = P + G \quad [2]$$

P is composed of solids and voids and is characterized by its wet and dry densities. (It is assumed that the densities of both grid and paste are respectively the same in both types of plates.)

The expanded grid (see Fig. 1) is considered here as a matrix of diamond-shaped holes each characterized by a long-way dimension, L, and a short-way dimension, S. S is measured parallel to the plane of the plate and from node corner to node corner whereas S' is measured parallel to the plane of expansion from node edge to node edge. (The nodes may have a length, n, but this does not enter into the following derivations.) The actual geometry of the holes is not important for the calculation of the grid metal volume as this quantity can be determined by considering the geometry of the metal prior to being expanded. (Some inaccuracy on the order of 1-6% will be incurred, *e.g.*, see later example.) The diamonds of length, L, are cut from sheet metal having a thickness, t_m, in strips w wide, the cutwidth. Therefore, the volume, v, of one strand of grid is

$$v = wt_mL \quad [3]$$

The total number of strands, N, in plate volume, V, is given by

$$N = 2N_sN_L \quad [4]$$

where N_s and N_L represent the number of diamonds in the short (S) and long (L) dimensional directions of the plate. The dimensions of the plate may be temporarily specified as D_s and D_L, which will be equal to either H and W or to W and H depending on the direction of expansion relative to the situation of the plate in the battery. Thus, N_s and N_L are defined by

$$N_s = D_s/S \quad \text{and} \quad N_L = D_L/L \quad [5]$$

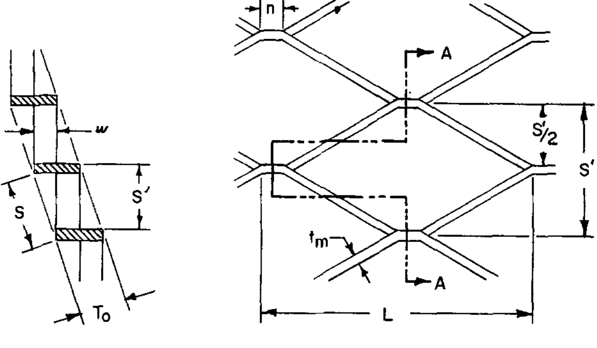

Fig. 1. Vertical and horizontal sectional views of a typical expanded metal grid showing various dimensions.

* Electrochemical Society Active Member.

Key words: batteries, capacities, expanded metal, grids, pasted plates.

The volume, G, of the grid metal in the plate is given by

$$G = Nv \qquad [6]$$

If Eq. [3], [4], and [5] are substituted into [6] then

$$G = 2wt_mHW/S \qquad [7]$$

Since the paste volumes of the expanded and cast grid plates are P_E and P_c and the relative paste volume, a figure of merit, is $P_R = P_E/P_c$ then by combining Eq. [1] and [7] into [2] and dividing by P_c one obtains

$$P_R = (HW/P_c)\,[T - 2wt_m/S] \qquad [8]$$

P_c can be determined (for the cast grid) in a similar manner, but since the cast grid is usually complicated in shape it is often easier to determine the paste and grid volume experimentally. All of the variables in Eq. [8] except t_m, w, and S will be specified at the outset. Both w and S are principal characteristics of the expansion process, whereas t_m is usually selected in conjunction with w for optimal structural and corrosion characteristics. Usually, but not necessarily, w and t_m will be nearly equal, thereby providing nearly square strands. It is useful to derive an expression for the cutwidth, w, so as to be able to estimate the value of this dimension that is necessary to obtain a given pasted plate thickness (by the progressive die expansion process).

Referring to Fig. 2b, it can be seen that the thickness, T_o, of the expanded grid can be set equal to the sum of two dimensions normal to the plane of the grid

$$T_o = T' + t' \qquad [9]$$

It is also apparent that

$$\cos\theta = T'/2w \quad \text{and} \quad \sin\theta = t'/t_m$$

and therefore

$$T_o = 2w\cos\theta + t_m\sin\theta \qquad [10]$$

Since the expanded grid will usually undergo a rolling operation to flatten it, to round off sharp node edges, and to perhaps size it, then a certain amount of reduction in grid thickness, expressed as a fraction, f_R, must be introduced. Also on pasting the grid a certain amount of overpasting, again expressed as a fraction, f_B, may occur, often intentionally. Both of these fractions are defined as follows

$$f_R = R/T_o \quad \text{and} \quad f_B = B/T$$

where R and B are the linear dimensions of the grid reduction and overpasting (see Fig. 2a). The thickness, T_R, of the reduced (rolled) grid is therefore

$$T_R = T_o - R = T_o(1 - f_R)$$

The thickness of the pasted plate will then be

$$T = T_R + B = T_o(1 - f_R) + f_BT \qquad [11]$$

Rearranging and combining [10] with [11] gives

$$T = F\,(2w\cos\theta + t_m\sin\theta) \qquad [12]$$

where

$$F = (1 - f_R)/(1 - f_B) \qquad [13]$$

As a first approximation we can assume $\theta \leq 10°$ and then solve for w to obtain

$$w \cong 0.51[(T/F) - 0.174\,t_m] \qquad [14]$$

With this expression one can estimate w in terms of actual or expected values of f_R, f_B, and t_m.

In comparing the expanded grid to the cast grid one should also give consideration to the relative grid conductances. This factor will be most significant at the top of the plate in the set of strands leading into the top horizontal grid bar since all of the current derived from the rest of the plate must pass through this top set of strands to reach the plate lug for flow from the plate. As a minimal consideration the sum of the cross-sectional areas of the expanded grid strands ($2N_wwt_m$) should be comparable to a similar sum for the cast grid. Often, cast grids, especially industrial sizes, may be a bit oversized so that the expanded grid may not need to provide as much cross-sectional grid area to effectively carry the same current. A more detailed analysis is required to factor in the effect of grid path length from bottom to top in combination with strand area.

Example

As an example of the application of this method of analysis the cast and expanded grids and plates described in Tables I and II are compared. The relative paste volume, P_R, from Eq. [8] is plotted in Fig. 3 against the short diamond dimension, S, for four values of F, *i.e.*, four combinations of f_R, f_B, and w. It can be seen that the expanded grid becomes more rapidly unfavorable ($P_R < 1$) to the left of $S = 1.0$ cm and that it becomes more favorable ($P_R > 1$) to the right. The point corresponding to the conditions stated in

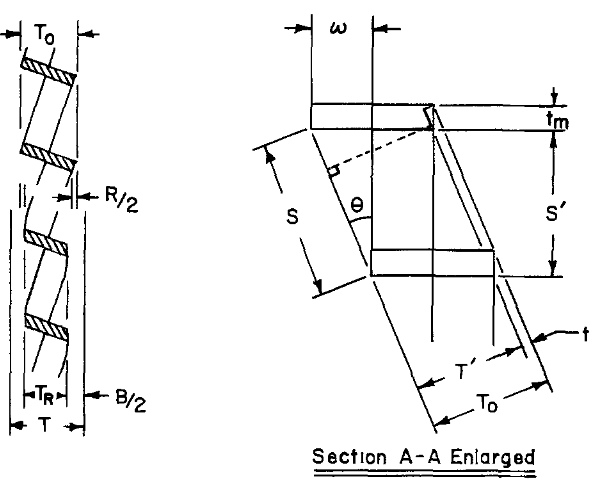

Fig. 2. More detailed views of Section A-A of Fig. 1

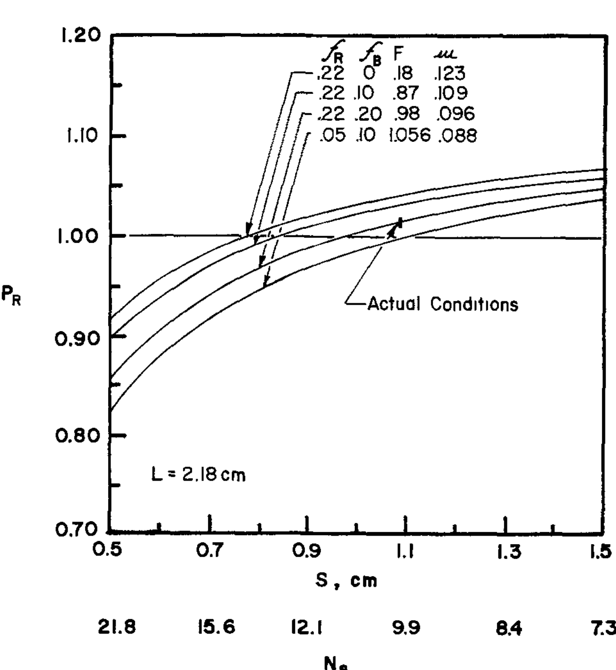

Fig. 3. Graph of P_R against S (and N_s) as it pertains to the example.

Table I. Comparison of plate specifications for cast and expanded SLI grids (dimensions in cm)

Grid	Height (no lug)	H	W	T	B	G (cm^3)	V (cm^3)	P (cm^3) Est.	P (cm^3) Meas.
Cast	11.43	10.99	15.24	0.2032	0.025	4.45	34.03	29.58	28.52*
Expanded	11.43	10.92	15.24	0.2032	—	3.79	33.82	30.03	28.29*

* Dry paste density (g/cm^3): cast, 4.12; expanded, 4.04.

Table II. Expanded grid parameters

t_m (cm)	w (cm)	S (cm)	L (cm)	N_s	N_L	f_B (assumed)	f_R (resulting)
0.114	0.109	1.09	2.18	10	7	0.1	0.22

Tables I and II is shown at $P_R = 1.016$ and $S = 1.09$ cm as a vertical bar. It is apparent that other combinations of w, S, f_R, and f_B will provide many values of $P_R \geqq 1.0$. The actual measured results, shown in Table III, indicate an initial advantage for the expanded plate relative to the cast grid plate in terms of discharge capacity (A-hr) per unit weight (kg) of plate. These values were observed after several initial conditioning cycles. It should be noted that although the cast grid volume (G) shown in Table I is 1.17 times that of the expanded grid volume, it is based only on the grid found between the top and bottom horizontal grid bars.[1] The actual grid weight ratio is 1.33 whereas the actual plate weight ratio is 1.12. Not unexpectedly the ratio of "A-hr per kg plate" values shown in Table III is also 1.12. This illustrates the heavy contribution that grid weight makes to energy density. Whereas the estimated paste volumes are in the ratio of 1.015 (expanded to cast), the ratio of the measured values is 0.99. This agrees well (to 2.5%) with the ratio of estimated values. Thus, if one had undertaken the goal of matching the capacity of the cast grid plate with the plate using the expanded grid of the configuration specified here, the goal would have been attained with the added advantage of increased energy density.

In conclusion, it can be seen that this analysis is useful for indicating the direction the grid designer should take when considering replacing a cast grid with an expanded grid in the same plate volume.

Acknowledgments

The author wishes to acknowledge the contributions of a refinement by R. Buchop, formerly of the Prestolite Division, and the experimental results by W. J. Schlotter of the C&D Batteries Division. Appreciation is also extended to C&D Batteries Division for the full support of this work.

[1] Note, that the G value of 3.79 cm^3 for the expanded grid is a calculated value, whereas the measured value is 3.70 cm^3, a difference of 2.4%.

LIST OF SYMBOLS

- B overpasting thickness
- D_L plate dimension parallel to L, equal to H or W
- D_s plate dimension parallel to S, equal to W or H
- F $= (1 - f_R)/(1 - f_B)$
- f_B fraction of plate thickness that is overpasted
- f_R fraction of initial expanded grid thickness reduced by rolling
- G volume of grid metal
- H grid height, appropriate for comparison to cast grid
- L long-way diamond length (expanded metal)
- N total number of grid strands
- N_L number of diamonds in L direction
- N_s number of diamonds in S direction
- N_w number of diamonds across plate width
- n node length
- P volume of active material in a plate
- P_c volume of active material in cast grid plate
- P_E volume of active material in expanded grid plate
- P_R relative paste volume, $= P_E/P_C$
- R reduction in initial grid thickness due to rolling
- S short-way diamond length parallel to plane of plate
- S' short-way diamond length parallel to plane of expansion
- T thickness of pasted plate
- T_o original thickness of expanded grid
- T_R thickness of expanded grid after rolling reduction
- t_m unexpanded sheet metal thickness
- T' partial grid thickness (used for derivation, see Fig. 2b)
- t' partial grid thickness (used for derivation, see Fig. 2b)
- V defined plate volume of interest
- v volume of one grid strand of length L
- W plate width
- w cutwidth defined by expanding process
- θ acute angle defined by S and S'

Corrosion Behavior of Glassy Chromium-Containing Alloys Prepared by Sputtering

Ronald B. Diegle

Battelle, Columbus Laboratories, Columbus, Ohio 43201

and M. D. Merz

Battelle, Pacific Northwest Laboratories, Richland, Washington 99352

Glassy alloys containing Cr, P, and various other elements have been shown to possess excellent corrosion resistance by a number of workers (1-8), and were the subject of a recent review by Masumoto and Hashimoto (9). These alloys resist localized as well as general corrosion in electrolytes such as $FeCl_3$ and acidified NaCl. Furthermore, as little as 2 or 3 a/o of alloyed chromium are sufficient to confer this resistance (7). The interest in these alloys presently is of a rather fundamental nature, such as learning more about the influence of structure on corrosion and passivity. However, it is clear that glassy alloys have practical value as corrosion resistant coatings provided that a means can be developed for applying them as such.

An inherent feature of the fabrication of many corrosion resistant glassy alloys is the high quench rate, about 10^5 C/sec, necessary to attain the glassy structure upon solidification from the melt. Elaborate techniques, such as melt spinning (10) and melt extraction (11), typically are used to attain these high quench rates. A limitation of all liquid quenching techniques is that the dimension of the specimen is necessarily thin in the direction of heat extraction; typically, this dimension is about 50-75 μm, with about 125 μm a reasonable upper limit for this class of alloys. Although the filaments and narrow strips that result from liquid quenching are suitable for laboratory research studies, they cannot be utilized as coatings. Sputtering, on the other hand, is a vapor deposition technique used for coating large areas and complex geometries with thick deposits. Therefore, sputtering was investigated as a possible means for depositing extremely corrosion resistant Cr-containing alloys in the glassy state.

Experimental

The sputtering targets used during this research had the compositions $Fe_{45}Ni_{30}Cr_2V_2P_{15}B_6$ and $Fe_{31}Ni_{30}Cr_{16}V_2P_{15}B_6$. Vanadium was an impurity unintentionally added through use of a ferrophosphorus alloy. The primary variable was chromium, which was either 2 or 16 atomic percent (a/o). The alloys were prepared by melting together appropriate quantities of components in an induction furnace under an argon atmosphere, homogenizing for ½ hr, and then pouring into cyclindrical molds 13 cm in diam. Sputtering was performed at Battelle's Northwest Laboratories with triode sputtering equipment. It was performed in krypton at rates between 25 and 40 μm/hr. The substrate was copper, chilled either to −196°C or water cooled to about 15°C.[1] Three types of deposits were prepared, namely, 16 Cr sputtered onto copper at either 15° or −196°C, and 2 Cr sputtered onto copper at −196°C. The deposits were about 75 μm thick, nonporous, and extremely adherent to the substrates. For the purpose of comparison, liquid quenched specimens were prepared by melt spinning as previously described (7).

Key words: pitting, passivity, amorphous, melt-spinning.

[1] For convenience the copper substrate temperatures are referred to either as −196° or 15°C. In actual fact the temperatures may have been somewhat higher because of the heat dissipated during the sputtering process.

The state of crystallinity of the deposits was examined by thin foil transmission electron microscopy (TEM), selected area electron diffraction (SAD), and differential scanning calorimetry (DSC). Surface topography was characterized by scanning electron microscopy (SEM), and composition by x-ray fluorescence (EDAX). Results were compared to those obtained from glassy alloys of nearly identical composition but prepared by melt spinning. Prior to structural characterization the deposits were removed from the copper substrates by dissolving the copper in concentrated nitric acid. The deposits were not noticeably affected by this treatment.

Corrosion was measured gravimetrically with coupons exposed in 10% $FeCl_3$ solution at ambient temperature, and by potentiodynamic anodic polarization in neutral and acidified 1M NaCl solutions. Sputtered deposits were subjected to gravimetric measurements after first removing them from the copper substrates as described above. For anodic polarization the specimens were left intact on the copper, which was masked with an acid resistant stop-off lacquer.

Results and Discussion

Structure.—Examination of the three sputtered deposits by TEM indicated the absence of resolvable structure, in particular, microcrystalline regions and associated grain boundaries. SAD verified the absence of detectable crystallinity, as denoted by broad diffuse ring patterns. Thus, the structures of the deposits were completely glassy within the limits of resolution of these two techniques.

DSC results from sputtered and melt spun alloys are summarized in Table I. The crystallization temperatures, T_c, of sputtered *vs.* melt spun alloys differed by 11°C for the 2 Cr alloys and by 4°C for the 16 Cr alloys. The heats of crystallization, ΔQ_c, varied by about 15% for the 2 Cr alloys and by about 12% for the 16 Cr specimens. There were no obvious trends in T_c and ΔQ_c relative to the method of specimen preparation, *i.e.*, sputtering or melt spinning. Furthermore, the effect of substrate temperature on these parameters for the 16 Cr material does not appear to be significant. It is apparent from Table I that the crystallization behavior of the sputtered 2 Cr and 16 Cr deposits approximated that of melt spun alloys of the same compositions.

Compositions of the sputtering targets and corresponding deposits were compared to determine whether

Table I. Temperatures and heats of crystallization of sputtered and melt spun glassy alloys

Chromium content, a/o	Preparation technique	Substrate temperature, °C	T_c, °C	ΔQ_c, cal/g-atom
2	Sputtering	−196	428	1275
2	Melt spinning	~15	439	1095, 1115
16	Sputtering	−196	460	1070, 1110
16	Sputtering	~15	464	1230
16	Melt spinning	~15	461	1095, 1115

enrichment or depletion of any elements had occurred during sputtering. Variations in concentration between target and deposit were generally 1 a/o or less. An exception was the chromium content of the nominal 16 Cr alloy, which was 2.3 a/o higher in the deposit. An important observation is that phosphorus was not depleted in the deposit. Since phosphorus is needed to achieve the glassy state and to enhance corrosion resistance, it is significant that it can be sputtered at a concentration that is close to that in the target. No information could be obtained about the initial and final concentrations of boron, since quantification of boron by EDAX was not possible.

Surface topography.—The surfaces of sputtered specimens contained numerous hillock-shaped mounds. Figure 1 shows SEM photographs of the as-sputtered surfaces of several deposits. Figure 1(a) shows these hillocks, which were present to a greater or lesser degree on all sputtered specimens. Figure 1(b) is a higher magnification view of these features. Although still present, the hillocks were smaller and fewer on the 16 Cr specimen sputtered onto a water-cooled substrate, Fig. 1(c). This behavior agrees with prior sputtering experience with other alloys, *i.e.*, that warmer substrate temperatures favor less pronounced growth features. Chromium content in the alloy did not strongly affect their formation for, as shown in Fig. 1(d), they were also present on the deposit containing 2 Cr. (Several of the larger hillocks had been broken off during handling, hence their truncated appearance.) Hillocks such as those shown in Fig. 1 were not present on melt spun filaments, although shallower, less cone-shaped mounds could be found on the shiny surfaces of the filaments.

The source of the hillocks shown in Fig. 1 is not known, although they sometimes appear on other types of sputtered alloys including crystalline alloys of considerably different compositions than those reported in the present investigation. They are thought to result from growth instabilities that occur during deposition of atoms onto a substrate. Their significance to alloy properties is not known; however, it is shown in a later section that they were not preferred sites for localized corrosion, neither did they compromise the corrosion resistance of the deposits.

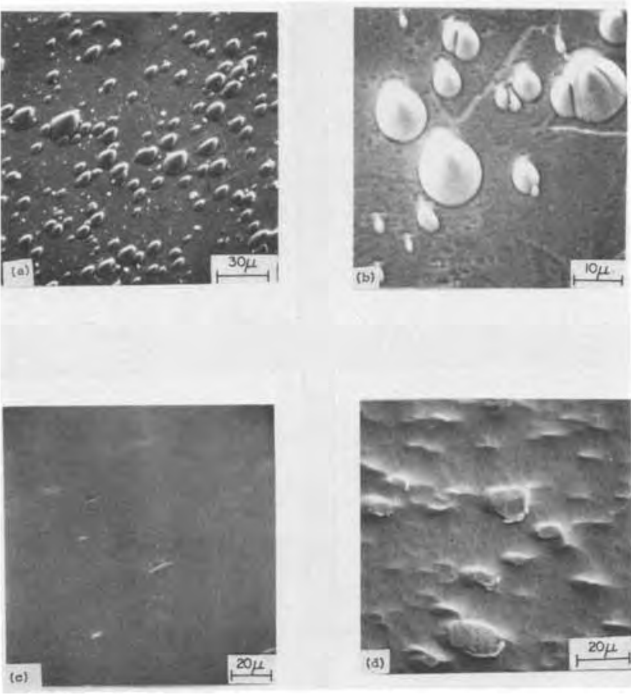

Fig. 1. SEM photographs of surfaces of sputtered deposits (a), (b) 16 Cr (LN_2 substrate); (c) 16 Cr (water-cooled substrate); (d) 2 Cr (LN_2 substrate).

Corrosion behavior.—The corrosion behavior of sputtered and melt spun specimens under freely corroding conditions was compared in 10% $FeCl_3$ solution. Data were obtained on duplicate specimens after 167 hr of exposure, and the corrosion rates were extrapolated to a μm/year basis. The corrosion rates of the 2 Cr deposits averaged 1114 μm/year, whereas those of the 2 Cr melt spun alloy averaged 427 μm/year or 38% of the former value. Analogously, the corrosion rates of the 16 Cr deposit averaged 1.8 μm/year and those of the 16 Cr melt spun alloy averaged 3.5 μm/year, or 43% of the former value. Three features are particularly noteworthy regarding these data, as follows:

(*i*) The effect of increasing the chromium concentration in the sputtered deposits was to reduce greatly the corrosion rates, in parallel with the influence of chromium in melt spun specimens.

(*ii*) Corrosion rates of the 2 Cr deposits were about two to three times greater than those of the corresponding melt spun specimens.

(*iii*) Corrosion rates of both the melt spun specimens and the sputtered deposits containing 16 Cr were relatively low, indicating that the alloys were spontaneously passive in the $FeCl_3$ solution.

Anodic polarization was used to obtain more detailed information about corrosion behavior, as shown in Fig. 2 and 3. Figure 2 shows that the 2 Cr sputtered deposit underwent an active-passive transition in 1M NaCl, pH 3, whereas the 2 Cr melt spun filament was spontaneously passive. A reaction of unknown origin gave rise to a slight active-passive transition at about −0.45 to −0.50V (SCE). The critical current density for passivation for the sputtered alloys was about 10^{-3} A/cm², and the minimum passive current density for all three specimens was about $9 \cdot 10^{-5}$ to 10^{-4} A/cm².

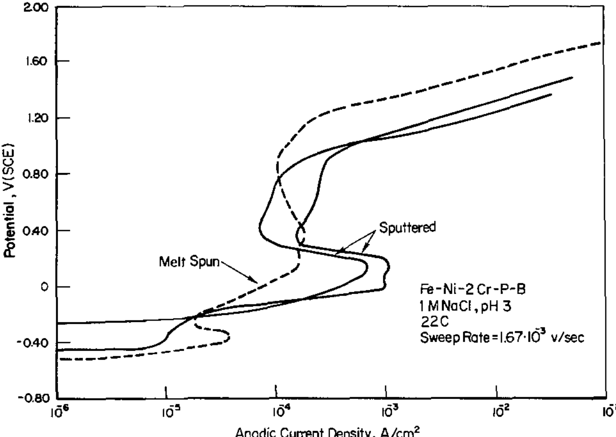

Fig. 2. Anodic potentiodynamic polarization curves of sputtered and melt spun 2 Cr alloys in 1M NaCl, pH 3, deaerated.

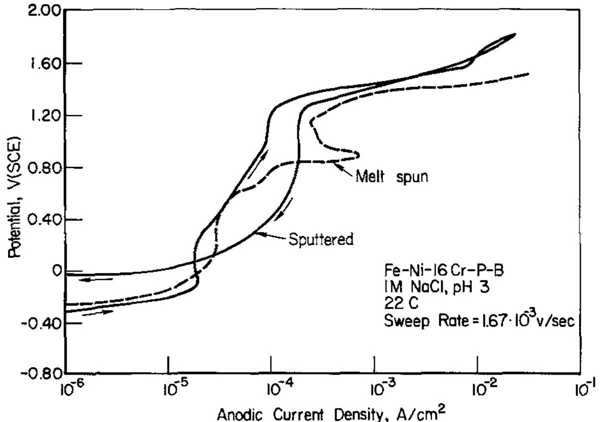

Fig. 3. Anodic potentiodynamic polarization curves of sputtered and melt spun 16 Cr alloys in 1M NaCl, pH 3, deaerated.

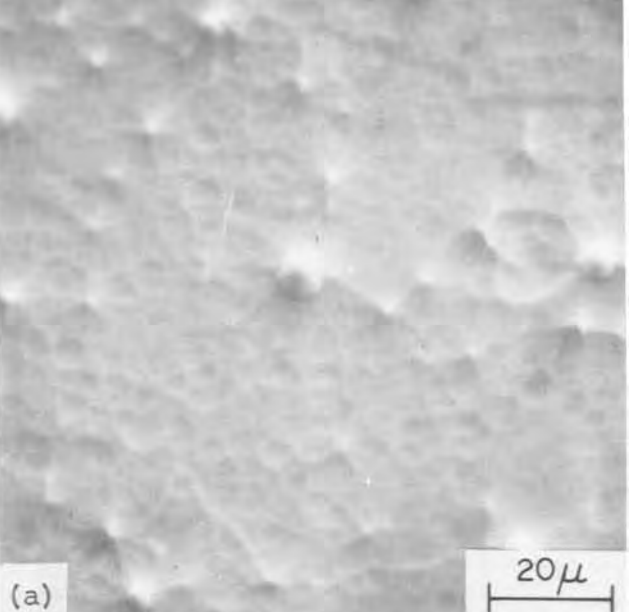
The steep increase in current at potentials above about 0.8V (SCE) was due to the selective oxidation of chromium as the hexavalent ion, Cr^{+6}.

As indicated in Fig. 3, the 16 Cr specimens were spontaneously passive in pH 3, 1M NaCl, with passive current densities in the approximate range of $2 \cdot 10^{-5}$ to $2 \cdot 10^{-4}$ A/cm^2. This spontaneous passivity extended even to pH 1 solutions (data not shown). The deposits exhibited passivity that was as complete, or nearly so, as that of corresponding melt spun alloys. Very significantly, the sputtered alloys resisted pitting corrosion to the same degree as those prepared by melt spinning. The positive hysteresis during the return sweep for the sputtered alloy was typical of polarization for all sputtered and melt spun specimens that were polarized to transpassive potentials. It may have been caused by temporary active dissolution in microscopic pits that formed at transpassive potentials, and then rapidly passivated at potentials in the passive region of polarization behavior.

Pitting could not be produced by polarization in the passive range of potentials, even for extended times. For example, the surface of a sputtered 2 Cr alloy that was potentiostatically polarized for 1 hr in 1M NaCl, pH 3, is shown in Fig. 4. The corrosion produced a scalloped appearance on the flat regions and no preferential attack of the hillock-shaped mounds. [The truncated tops evident in Fig. 4(b) were the result of surface damage prior to exposure to the electrolyte.] The corrosion that occurred in the passive potential range of behavior produced a sort of general attack, a surface roughening reminiscent of pits that were not able to propagate after initiating. Shallow pits were observed after potentiostatic polarization at potentials that were well into the oxygen evolution range, above about 1.3V (SCE). However, even at these very oxidizing potentials the pits that developed tended to propagate to depths of only several μm, after which they apparently passivated and new pits formed nearby. Shallow pit depths and high pit densities were a characteristic common to sputtered deposits polarized at transpassive potentials. Conversely, transpassive corrosion of melt spun filaments generally produced more through-pits and lower pit densities.

There was no substantial effect of substrate temperature on anodic polarization behavior. The polarization curves for the 16 Cr deposits sputtered at $-196°$ and 15°C were similar. Both types of deposits were spontaneously passive in 1M NaCl at pH 7 and 3, with the passive current densities of the water-cooled deposits ranging to about twice those of the liquid nitrogen-cooled specimens. However, pitting susceptibilities were unaffected, with pitting occurring only at transpassive potentials (*i.e.*, above about 1.20V (SCE) for the 16 Cr alloys). Examination of the specimens after polarization indicated that pits were shallower on the alloy sputtered at -196°C. The effect of substrate temperature on pitting and overall corrosion behavior needs further study to better define the role of this variable on corrosion.



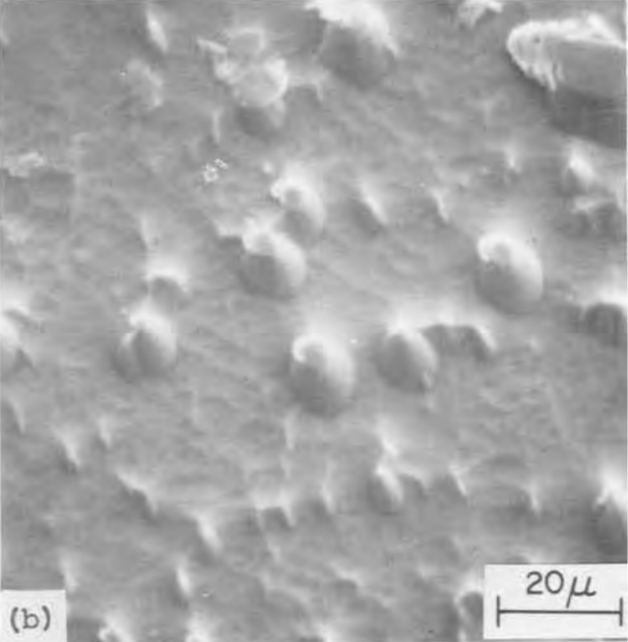


Fig. 4. SEM photographs of 2 Cr sputtered deposits polarized for 1 hr in 1M NaCl, pH 3, at the following potentials: (a) 0.60V (SCE); (b) 1.10V (SCE).

Conclusions

Sputtering can be used to prepare alloys of the Fe-Ni-Cr-P-B variety with a completely glassy structure. Thermal characteristics, such as temperatures and heats of crystallization, of sputtered alloys are similar to those of alloys of the same nominal compositions but prepared by melt spinning. Because of these similarities it is inferred that the structures of the two classes of alloys are also similar. The corrosion and electrochemical behavior of the sputtered deposits resembled, but was not identical to that of melt spun alloys of the same composition. Specifically, open-circuit corrosion rates and oxidation rates during anodic polarization of the sputtered deposits exceeded those of melt spun specimens, sometimes by about an order of magnitude. However, the sputtered deposits exhibited the same resistance to pitting corrosion as their melt spun counterparts, with pitting occurring to a large degree only at transpassive potentials in acidified chloride solutions. There is some evidence that a colder substrate temperature may favor improved corrosion resistance, but this tentative conclusion needs verification. Sputtering is a viable alternate technique for depositing extremely corrosion resistant glassy Fe-Ni-Cr-P-B alloys.

Electrochemical Studies on Amorphous Thin Film and on Sintered Polycrystalline CdS Electrodes

A. M. Redon* and J. Vigneron

Lab. Electrochimie Interfaciale, 1, Place A. Briand, 92190 Meudon, France

and R. Heindl*

Lab. de la Physico-Chimie des Matériaux par Techniques Avancées, 1, Place A. Briand, 92190 Meudon, France

The stability of semiconducting electrodes in photoelectrochemical cells is still the key problem to be resolved before these devices can be employed for solar energy conversion. Until now, only electrodes made of $SrTiO_3$ or TiO_2 or SnO_2 and similar materials have been found to be stable (1), but their bandgap ($\geq$3 eV) is too high to utilize the solar spectrum efficiently. More recently, Tributsch (2) has demonstrated that electrodes made of single crystals of MoS_2 and TiS_2 are stable over a period of 9 months WSe_2 has also been used as a semiconductor electrode in photochemical cells (3).

For practical application, single crystals are too expensive, so we have investigated the stability of thin film amorphous CdS electrodes which can be obtained by a simple spray technique and of electrodes made of sintered polycrystalline CdS.

Recently, the thermodynamic stability of CdS electrodes in solutions of various pH (4), and on the charge transfer with Na_2S in the electrolyte have been investigated (5).

It has been also stated that electrodes made from crystalline CdS can be stabilized with the help of redox systems, such as $Fe(CN_6)^{3-/4-}$ and $S^{-/2-}$ (6, 7). The use of thin film electrodes is especially interesting as cadmium is a metal which is found only in limited amounts on the earth. Thin film and polycrystalline CdS have the same bandgap (8).

Electrode Preparation

Amorphous thin film of CdS.—A spray of an aqueous solution of $CdCl_2$ and $SC(NH_2)_2$ is projected on a gold layer heated to 300°C. The gold, which has been previously deposited on a glass plate, provides the ohmic contact.

Polycrystalline sintered electrodes.—High purity CdS powder has been pressed practically at 50 kg bars and then sintered at 900°C under Ar for 4 hr. The light source is a 150W xenon lamp. Monochromatic illumination is performed with the help of a Jobin-Yvon monochromator (HRS_2). The dark current can be eliminated with the help of a chopper and a lock-in amplifier.

* Electrochemical Society Active Member.

The stability of the electrodes has been investigated by the measurement of the photocurrents *vs.* the time in 0.1M solution, in the absence of any redox system, and then in the presence of 10^{-3}M $Fe(CN)_6{}^{3-/4-}$ and

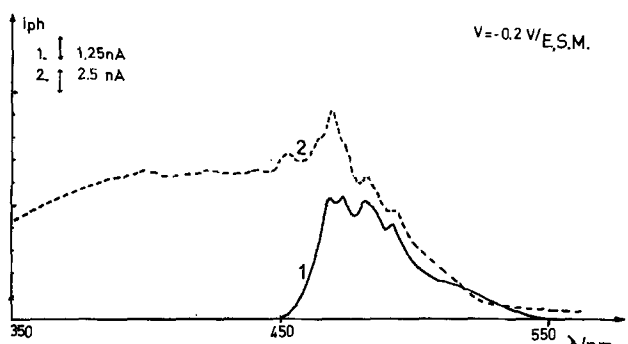

Fig. 1. Photocurrent vs. the wavelength of incident light (- - -) in 0.1M KOH electrolyte; (———) in 0.1M KOH + 1.5 × 10^{-3}M $K_4Fe(CN)_6$ + 1.5 × 10^{-3}M $K_3Fe(CN)_6$ in the dark.

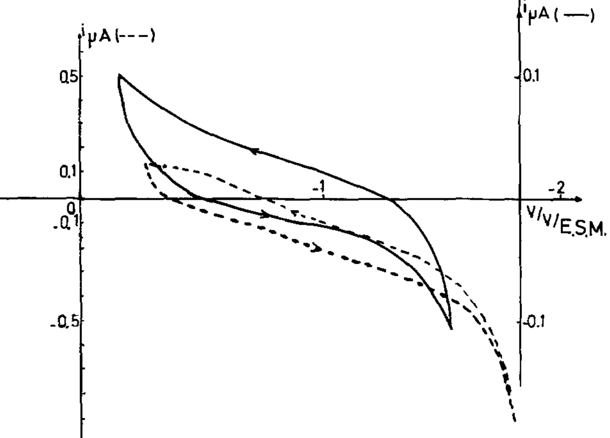

Fig. 2. Intensity potential curves in: (———) 0.1M KOH electrolyte; (- - - -) in 0.1M KOH + 1.5 × 10^{-3}M $K_4Fe(CN)_6$ + 1.5 × 10^{-3}M $K_3Fe(CN)_6$ in the dark.

10^{-3}M sodium polysulfide. The photocurrents decrease *vs.* the time, and the electrode is sensibly damaged after the experiment with the first redox couple, but stabilization is completely achieved with the second.

The bandgap can be obtained on Fig. 1. The differences in the curves at high energy are due to the absorption of the redox solution.

The intensity-potential curves in the dark are also recorded with and without the $Fe(CN)_6^{3-/4-}$ (Fig. 2). The same kind of results has been obtained with electrodes made of polycrystalline CdS.

Conclusion

Electrodes made of amorphous film of CdS made by spray technique are not very expensive and so are very interesting. Appreciable photocurrents can be obtained with them. The stabilization is observed only with the sodium polysulfide and not with the $Fe(CN)_6^{3-/4-}$ redox couple.

The Interaction of Stress and Mechanical Property Effects during Oxidation of Tantalum Base Alloys

R. E. Pawel* and J. J. Campbell

Oak Ridge National Laboratory, Metals and Ceramics Division, Oak Ridge, Tennessee 37830

ABSTRACT

Specimens of the tantalum base alloys Ta-10 W and Ta-10 W-2.5 Hf (T-222) were observed to ignite after prolonged oxidation at elevated temperatures. The characteristics of this behavior were examined, and the time-temperature regime in which one might expect this catastrophic response to oxidation of thin specimens was defined. Ignition of specimens was found to be the final step in a sequence that involved oxygen penetration into the alloy in advance of the oxide-metal interface, a resulting embrittlement and stress buildup, and finally a relaxation of the strain energy of the system through a sudden disintegration of the specimen along grain boundaries that, if confined, led to a violent ignition.

The effects and interactions of stress generation and mechanical properties during the oxidation of metals and alloys have been the subject of numerous investigations (1). The existence of large mechanical stresses arising during isothermal oxidation as a result of the oxidation process itself has been demonstrated for many systems, and several mechanisms of stress generation have been examined. The response of the system to these stresses depends in large measure on mechanical behavior in both the substrate material and in the products of oxidation. Both dramatic and subtle responses have been observed.

The details of the kinetics of oxidation and stress generation in tantalum base alloys containing tungsten and hafnium have been discussed previously (2). Basically, over the temperature range 500°-850°C, in pure oxygen at atmospheric pressure, the alloys Ta-10 W and Ta-10 W-2.5 Hf (T-222) oxidize in the initial stages at a decreasing, approximately parabolic, rate, during which time a protective oxide scale (β-tantalum pentoxide) grows and oxygen is absorbed into the metal. These kinetics exhibit a classical temperature dependence, and the activation energy, about 234 kJ/mole, suggests that the rate is controlled by diffusion of oxygen in the growing oxide film. Conversely, the flexure characteristics of these alloys during oxidation on one side suggested that the stresses in the specimens were primarily a result of oxygen solution effects in the metal beneath the oxide film. The flexure behavior was qualitatively consistent with that observed for oxidation of pure tantalum (3).

Continued oxidation at temperatures in the lower end of the above range results eventually in a typical breakaway behavior in which a change from a decreasing oxidation rate to an increasing rate is observed. This process is generally sluggish, starting with localized breakdown of the protective film, followed by the formation and propagation of regions of porous, nonprotective oxide, leading to high oxidation rates.

* Electrochemical Society Active Member.

Key words: alloy oxidation, kinetics, stress, embrittlement.

For each alloy the time at which breakaway oxidation started decreased with increasing temperature up to some maximum temperature. Above this temperature, (about 650°C for the Ta-10 W alloy, and 700°C for the T-222 alloy), the breakaway was postponed, and compact and protective films grew for comparatively long periods of time. This behavior resulted in unusual comparisons of the extent of oxidation in different experiments. For example, after 2 hr in oxygen at 650°C, the average thickness of the oxide on a Ta-10 W specimen is many times greater than that for a 700°C exposure.

While the persistence of the parabolic kinetics, as opposed to breakaway kinetics, at high temperatures suggests a degree of improvement in the resistance to oxidation for these alloys, an unexpected complication may arise. In this paper, we shall present the details of a rather spectacular manifestation of stress and mechanical property effects during oxidation that may have a general applicability. This behavior involved a change in the mechanical properties of the specimens and the development of a tensile stress in the samples, both brought about by oxygen solution effects during the oxidation reaction.

Experimental Procedure

The materials investigated in this work were the refractory metal alloys Ta-10 W and Ta-10 W-2.5 Hf (T-222).[1] Specimens were prepared from 1 × 2 cm coupons cut from 0.05 and 0.13 cm thick sheet obtained from Teledyne-Wah Chang. The coupons were hand-ground on metallurgical papers to the desired thickness in the range 0.02-0.12 cm. They were then annealed in vacuum for 1 hr at 1650°C (except as noted), mechanically polished through 0.3 μm alumina on a vibratory polisher, and then electropolished in a 90% H_2SO_4-10% HF solution.

The kinetic measurements were carried out in a quartz manometric oxidation rate apparatus in which

[1] Nominal analyses of these alloys were (*i*) Ta—10 W: 9.8 and 10.8 w/o W, <30 ppm C and N, <50 ppm O; and (*ii*) T-222: 10.5 w/o W, 2.5 w/o Hf, 140 ppm C, 22 ppm N, and 85 ppm O.

the pressure change between a reaction volume and a reference volume was measured by either a capacitance or an oil manometer. Prior to oxidation, the specimens were heated to the reaction temperature in vacuum. The measurements of the ignition or disintegration times were made by allowing the oxidation to proceed in small quartz tubes designed either to confine the residue (ignition) or to allow the residue to fall into a cold region. In the former case the temperature recorder provided an accurate indicator for specimen ignition. All experiments were carried out in dry oxygen at atmospheric pressure.

Results and Discussion

The oxide formed on Ta-10 W and Ta-10 W-2.5 Hf alloys at temperatures above the transition from normal breakaway kinetics remained uniform, adherent, and protective for surprisingly long periods, although spallation and an increase in the oxidation rate eventually occurred in the later stages (2). However, for specimens in this regime of protective oxidation, many experiments came to a sudden and violent end, often signaled by the ignition of the specimen. This behavior is illustrated in Fig. 1, which shows oxidation rate curves for Ta-10 W specimens at 600°, 650°, and 700°C obtained in the manometric rate apparatus. At 600°C the kinetics are independent of specimen thickness and exhibit typical breakaway behavior beginning at about 120 min. At 650°C, breakaway begins at about 15 min and the rate increases sharply. At 700°C, the parabolic kinetics persist for longer times with a small amount of localized cracking and spalling moderately affecting the oxidation rate (for the thicker specimen) at about 200 min. However, the thinner specimen at this temperature showed an abrupt and calamitous increase in the rate at 198 min as the specimen ignited in the rate apparatus. It is of interest to note here that the recorder and controller thermocouples, located on the outside of the quartz reaction tube, signaled this event with a temperature spike of 500°C or more. Similar kinetic behavior was observed for the T-222 alloy; however, the onset of the regime of continued protective film formation is shifted upwards in temperature, from about 700°C to about 750°C.

The inconvenience occasioned by the first several observations of this phenomenon (ignition of a specimen in an apparatus employing an oil manometer becomes a doubly spectacular event, when the oil is sucked into the hot reaction zone), as well as the scientific aspects, prompted additional experiments to classify the behavior. We soon found that for oxidation in this range of temperatures, pure tantalum did not exhibit ignition, but that the alloys Ta-10 W and T-222 (as well as T-111, Ta-8 W-2 Hf) responded violently for certain time-temperature exposures. On occasion, instead of ignition of the specimen at the appropriate time, the rate of oxygen consumption suddenly ceased. In these instances, it was observed that the residue of the specimen, essentially a collection of lightly oxidized grains, had managed to fall into a cold zone at the bottom of the apparatus rather than continuing to oxidize. Clearly, a disintegration of the specimen had taken place at the reaction temperature and this observation was a significant clue to the mechanism.

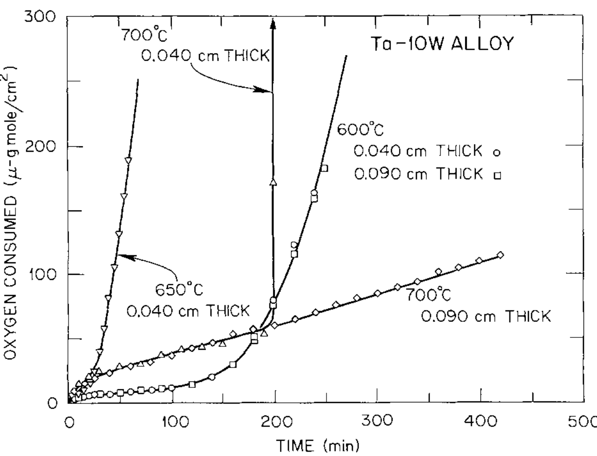

Fig. 1. Oxidation rate curves for Ta-10 W alloy in dry oxygen at atmospheric pressure. Specimens approximately 0.040 and 0.090 cm thick.

Such events are reminiscent of certain of the observations of Dooley and Stringer (4, 5) who studied the oxidation characteristics of Ta-4 weight percent (w/o) W and Ta-4 w/o Hf alloys. Although working predominantly at higher temperatures where linear oxidation kinetics dominated, these investigators reported grain boundary cracking and specimen fragmentation mainly during and after cooling for annealed specimens of Ta-4 w/o W oxidized at 950° and 1000°C. At 1050°C, these specimens ignited on admission of oxygen, as did similar specimens of Ta-4 w/o Hf. Ignition was not observed after extended periods of isothermal oxidation, although there were suggestions that some separation of the metal grains had taken place at temperature. It was postulated that the boundaries were "weakened by rapid oxygen diffusion along them" and that "stresses were increased by enhanced oxide strength and increased adherence between individual grains and the oxide." The "energetic event" that they report for oxidized specimens cooling from the reaction temperature appears to be comparable in kind to our observations of sudden and energetic fragmentation at the reaction temperature.

Several types of experiments were performed to describe this disintegration/ignition effect in a more quantitative fashion. First, we simply measured the time-to-ignition for specimens of these alloys by heating a specimen in vacuum in the bottom of a small quartz tube, admitting oxygen, and then noting the ignition time by the temperature spike on the temperature recorder. The ignition times proved to be different for the different alloys, and were a sensitive function of the specimen thickness as well as the temperature. Pure tantalum did not exhibit this behavior.

We also examined the microstructure of specimens oxidized very close to the point of disintegration or ignition. These specimens were obtained both by stopping the oxidation at an appropriate time, or by allowing the process to proceed so that the residue could quench itself by falling out of the hot zone of the furnace. It appeared that a fine grain size and at least some degree of confinement to the hot zone was necessary for complete ignition.

Finally, we did several experiments with a fine wire thermocouple attached directly to the specimen in order to see if any appreciable self-heating occurred prior to disintegration. We could detect no such temperature rise, thus indicating that the ignition is a result of—and not the cause of—the disintegration.

Plots of the ignition times as a function of specimen thickness at several temperatures are shown in Fig 2 for the Ta-10 W alloy. The open and filled symbols for data at each temperature represent results from two alloy heats containing nominally 9.8 and 10.8 w/o tungsten, respectively; the "#" points represent specimens of the indicated thickness that did not ignite, but rather oxidized to completion without a pyrotechnic response. Despite the scatter in the data, a series of straight lines on this log-log plot, constructed with a slope of 2, does describe the behavior with reasonable accuracy, and suggests that diffusion from the free surface, rather than wholly internal effects, is responsible for the events leading to ignition. Consistent with the fact that the specimen is clearly embrittled at the time of disintegration, oxygen is

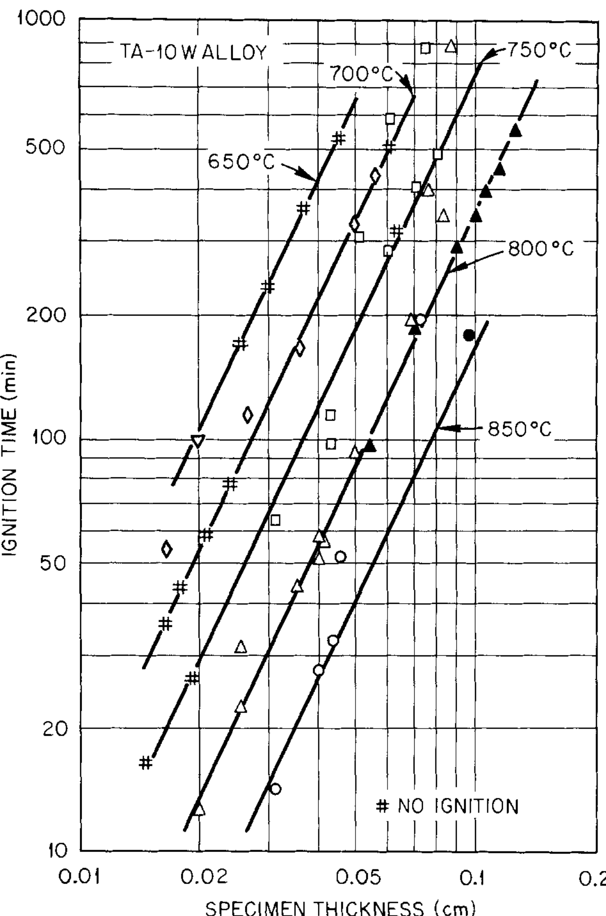

Fig. 2. Ignition times for the Ta-10 W alloy as a function of specimen thickness. ▽: 650°C; ◇: 700°C; □: 750°C; △: 800°C; ○: 850°C. Open data points are for Ta-9.8 W specimens; filled data points are for Ta-10.8 W. "#" represents experiments for which ignition did not occur. Ignition is observed in this thickness range for $T \geqq 700$°C.

the logical agent and, if we use these data to determine an "activation energy for ignition" (from the slope of the log reciprocal ignition time *vs.* reciprocal temperature plot), the value of 125 ± 17 kJ/mole (30 ± 4 kcal/mole) is in qualitative agreement with that for interstitial oxygen diffusion in these materials. This is in accord with the concept that both the stress in the specimen and the extent of embrittlement are related to oxygen diffusion in the metal in advance of the oxide-metal interface.

It is also significant to point out that ignition was observed in this alloy only at temperatures where breakaway oxidation is not a predominant feature. While a line signifying ignition was placed on Fig. 2 for Ta-10 W at 650°C, it is based on a single observation out of twelve attempts and probably should not be included in the set. Similar behavior was observed for ignition of T-222 alloy specimens as indicated in Fig. 3. Breakaway behavior persists to a higher temperature in this alloy (2), and ignition was not observed here for oxidation temperatures lower than about 750°C. There was also a difference in the ignition time for a T-222 specimen of a given thickness, about twice the time being required compared to that for the Ta-10 W alloy. This figure again emphasizes the time perspective of the phenomenon: thicker specimens of this set oxidized in a protective mode for 10 hr or longer, then over a period of perhaps a few seconds they disintegrated completely.

Metallographic examinations of specimens oxidized for times close to the ignition point directed attention to the severity of the embrittlement. Extreme intergranular effects were generally observed, as shown

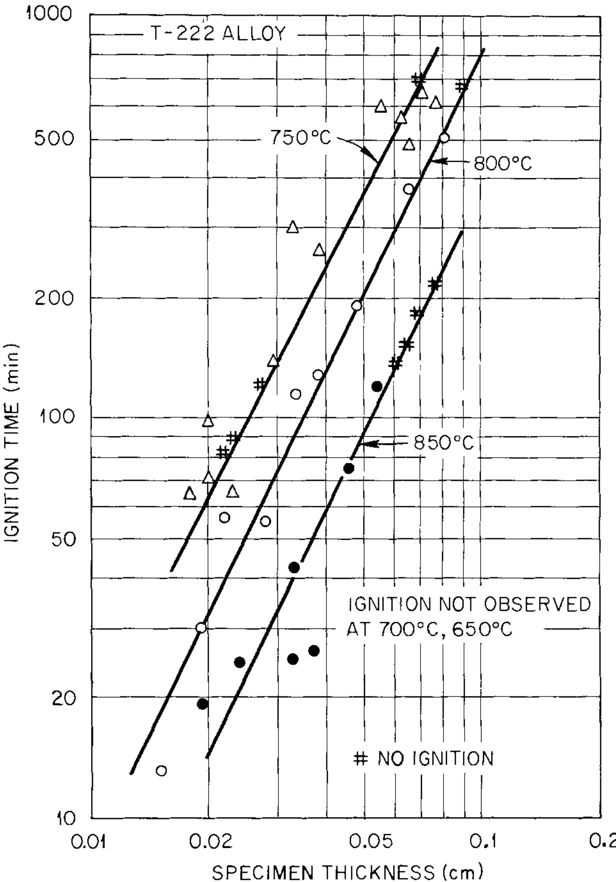

Fig. 3. Ignition times for the Ta-10 W-2.5 Hf (T-222) alloy as a function of specimen thickness. △: 750°C; ○: 800°C; ●: 850°C. "#" represents experiments for which ignition did not occur. Ignition was observed in this thickness range for $T \geqq 750$°C.

in Fig. 4, to the extent that the individual grains had a tendency to pop out during specimen preparation. Note that the thickness of the oxide film on this specimen is minimal compared to the oxygen embrittled zone suggested by the cracks. SEM examinations showed that the fracture surfaces of these specimens were essentially featureless at a resolution of a few tens of nm. A similar characterization of the structure and embrittlement in an oxygen-containing tantalum alloy (T-111) has been made by Liu, Inouye, and Carpenter (6), who suggested that the grain boundary cleavage was due to the formation of a thin, soft, precipitate-free-zone (PFZ) adjacent to the boundary.

A few specimens were prepared by vacuum annealing at 1800° and 2200°C to produce very large grains (up to about 1 mm diam) prior to oxidation. Appropriate isothermal exposures of these specimens led to disintegration at temperature but usually not to

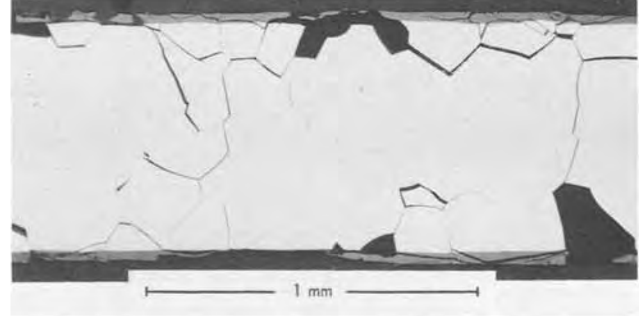

Fig. 4. T-222 specimen oxidized 120 min at 800°C. Note indication of extreme intergranular embrittlement. Specimen annealed in vacuum for 2 hr at 1800°C prior to oxidation.

ignition. The specimens came apart, with apparent force, at the grain boundaries but, as we shall propose in the next section, the surface-to-volume ratio in this case was insufficient to promote the catastrophic temperature increases from the rapid oxidation of fresh surfaces. The effect of grain size on the time required to disintegrate specimens was not large, but the few data available had a tendency to lie slightly above the standard time-to-ignition curve.

Conclusions

The phenomenon of embrittlement and ignition of these alloys undoubtedly arises as a consequence of oxygen solution into the alloy during the period of protective film growth. Speculation regarding the precise mode of the embrittlement is beyond the scope of this paper. However, it was affirmed here that comparable intergranular weaknesses were generated in both the hafnium-free and hafnium-containing alloys, and intergranular failure predominated in both without the observation of significant grain boundary precipitates in the SEM. Given this propensity for embrittlement, the period of protective oxidation is recognized to be of particular interest because, unlike breakaway oxidation where the oxide-metal interface moves more rapidly, the slower oxide growth results in a relatively high concentration of dissolved oxygen in the metal in advance of the interface.

We believe that the sudden and energetic disintegration of the embrittled specimen is brought about by the stress system built up by the oxidation process itself. During oxidation of these alloy specimens on one side, large mechanical bending strains have been observed (2). These strains were proposed to arise predominantly from oxygen solution effects, although the stress level in the oxide layers was also high. In any event, for a two-sided oxidation experiment, the gradient of compressive stress that exists concomitant with the oxygen concentration gradient requires that the central portion of the specimen cross section come under increasing tensile loads as oxidation proceeds. The strain energy is accumulated and then suddenly relieved by the mechanical failure of the specimen. Thus, the occurrence of this effect involves a critical interaction between stress generation, mechanical properties, and the relative rates of oxide formation and oxygen diffusion in the specimens. For example, a self-consistent explanation of the difference between the behavior of the Ta-10 W alloy and the T-222 alloy presented here involves the fact that hafnium either decreases the effective oxygen diffusivity in the alloy or serves as an efficient saturable trap for diffusing oxygen atoms.

In summary, the catastrophic disintegration or ignition of thin tantalum alloy specimens is envisioned as being the final step in the following sequence: (*i*) oxygen penetration into the alloy in advance of the oxide-metal interface, resulting in (*ii*) grain boundary embrittlement and (*iii*) a stress gradient. The stress levels and extent of embrittlement increase with time leading to (*iv*) a sudden disintegration. If the grain size is sufficiently small and the residue is confined; (*v*) a violent ignition of the specimen may result.

Surface Irregularities Induced by Anodic Oxidation of n-Type GaAs

Tsutomu Tsuji

Nippon Electric Company, Limited, Central Research Laboratories, Takatsu-ku, Kawasaki 213, Japan

ABSTRACT

GaAs surface irregularities caused by anodic oxidation in the dark were studied by changing materials and oxidation conditions. Three different texture irregularities, pebbled appearance, lines, and a mottled color splotch, were found on the oxidized surface or the surface free of the oxide layer. For the vapor epitaxial GaAs with a $0.6 \sim 3.0 \times 10^{17}$ cm^{-3} carrier concentration range, only the first irregularity was observed. None of these irregularities were observed on heavily doped epitaxial or bulk GaAs, whereas all of them were observed on n-type CZ material that had not been doped. Correlation to crystal defects is also discussed. It was found that pebbled texture and striations could be suppressed when anodization voltage was kept small or when electrolyte temperature was kept low.

GaAs microwave devices, such as GaAs FET's and optical devices, require very fine etching as well as occasionally passivation by an oxidized layer. Recently, it has been realized that anodic oxidation is a useful tool for very fine etching. For example, Rode *et al.* (1) demonstrated that anodic oxidation in the dark can be used for a self-controlled etching to get a uniform active layer for GaAs FET's. Müller *et al.* (2) used anodic oxidation for uniform and controlled fine etching of an ion-implanted GaAs layer. For these applications, surface smoothness of the oxidized layer and/or of the GaAs surface from which the oxide layer was removed is very important. Especially for the application to GaAs FET materials, a mirror-like smooth surface without any texture is needed to get a narrow gate (~0.5 μm) which is essential for obtaining a higher power gain and lower noise figure for a GaAs FET.

After the anodic oxidation of GaAs, a gray or granular texture has been observed by Logan *et al.* (3) and Spitzer *et al.* (4) on n-type bulk GaAs, whose carrier concentration was $0.5 \sim 5 \times 10^{17}$ cm^{-3}, and on p-type bulk GaAs, whose hole concentration was $1 \sim 5 \times 10^{18}$ cm^{-3}, when they were oxidized in H_2O_2. Hasegawa *et al.* (5) reported pits which spread from the fringe of the sample toward the inner area. There is no report of a systematic analysis of the surface after anodic oxidation. The purposes of this work are to study properties of irregularities, and to obtain a good smooth GaAs surface by anodic oxidation in the dark, which can be applied to the fabrication of GaAs FET's. Systematic study on the surface morphology for an oxidized surface has been accomplished by changing materials and conditions, such as anodization voltage or temperature.

This report lists three kinds of surface irregularities: pebbled appearance, lines, and a mottled color splotch on the oxide layer. All of these three irregularities were observed on undoped bulk GaAs, but none were observed on heavily doped vapor grown epitaxial or bulk GaAs. Only the first irregularity was observed on the vapor grown epitaxial GaAs with a low carrier concentration. Pebbled texture and striations (lines) were suppressed at a small oxidation voltage or at a low electrolyte temperature. The striations and the mottled color splotch were easily recognized by the naked eye. The lines and the pebbled texture had the same dependence on anodization conditions.

Experimental Procedure

The anodic oxidation studies were performed on Czochralski (CZ)-grown nondoped (not intentionally doped) n-type ($n \sim 4 \times 10^{16}$ cm^{-3}) boat-grown (BG) nondoped n-type ($n \sim 1.4 \times 10^{16}$ cm^{-3}), CZ-grown tin-doped ($n \sim 2 \times 10^{18}$ cm^{-3}), BG silicon-doped ($n \sim 2 \times 10^{18}$ cm^{-3}), and vapor-grown sulfur-doped ($n = 6 \times 10^{16} \sim 1 \times 10^{18}$ cm^{-3}) materials. The GaAs wafers were all (100) oriented. The bulk samples were chemomechanically polished with $0.1 \sim 0.3$ μm ZrO_2 in an aqueous solution of NaOCl, then were cleaned in boiling trichloroethylene and acetone, followed by a rinse in water, and 11 μm was etched from the surface in a solution of 3 H_2SO_4: 1 H_2O_2: 1 H_2O to remove the damaged layer.

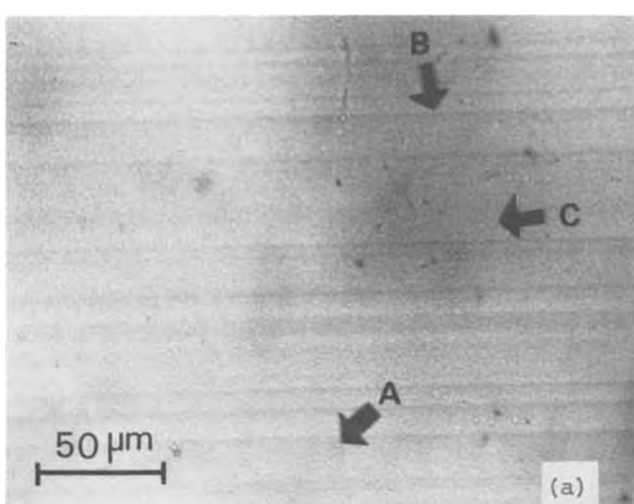
Anodization was carried out in the so-called AGW electrolyte (5), which was a mixture of a 3% aqueous solution of tartaric acid and ethylene glycol in 1:2 proportions. The pH for the electrolyte was 2.60 and the temperature was held at 25° ~ 27°C. In some cases, the electrolyte was heated with a water bath or was cooled down with ice or Dry Ice. The anodic oxidation was carried out with a constant voltage source which was connected to the cell in series with a current limiting resistor (5). The source voltage was set at 250V. Initial current densities were 1 mA·cm^{-2}, controlled by the current limiting resistor. Oxide thickness was monitored by the rise in cell voltage, ΔV, during the oxidation. A conventional microscope lamp with a tungsten bulb was employed for the oxidation under illumination. Light intensity was 77,000 lx. The oxide and GaAs surfaces were observed by an optical or an interference color microscope. The oxide layer was removed in HCl solution when the GaAs surface was to be observed.

Results

Three surface irregularities.—A photograph of a typical oxide film surface after anodic oxidation in the dark is shown in Fig. 1(a). A sketch of Fig. 1(a) is shown in Fig. 1(b). The crystal is CZ-grown nondoped bulk with a carrier concentration of 4×10^{16} cm^{-3}. Three surface irregularities are recognized as color differences on the oxide film: the first one is a pebbled texture observed all over the film. A specific sample of this irregularity is indicated by A in Fig. 1(a). The pebbled texture pits are roughly rounded in shape and about 0.5 μm in diam. The oxide inside of the pits is thinner than outside the pits. The second one, indicated by B, is striation with a line width of about 5 μm. The last irregularity, indicated by C, is an example of a mottled color splotch on the oxide film, which can be recognized by the naked eye.

Irregularities A and B are also observed on the GaAs surface after the removal of the oxide. It is interesting that the pebbled appearance becomes faint around any pits on the surface and is diminished on one side

Key words: defects, epitaxy, semiconductor, topography.



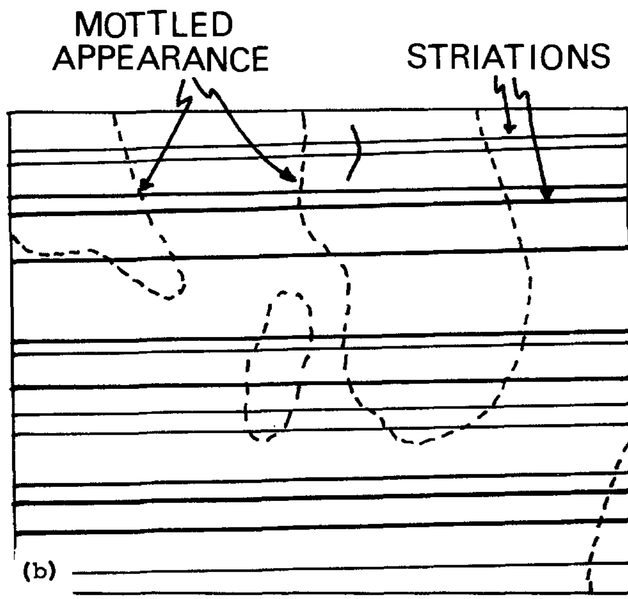


Fig. 1. Oxide surface irregularities produced by anodization in the dark. $\Delta V = 220V$. A: pebbled, B: lines, C: mottled color splotch

of the striations. Color differences for C irregularities correspond to 200 ~ 500Å in oxide thickness. These three irregularities seem to not depend on current density.

Dependence on oxide voltage drop.—Interference colors appear locally on the GaAs surface just after starting the oxidation in the dark. Nonuniformity in color is shown in Fig. 2(a). When the voltage drop across the oxide, ΔV, becomes about 40V, color differences are recognized all over the wafer. At the same time, a stripe pattern is observed as represented by the arrow in Fig. 2(a) and striations start to appear on both edges of the stripe pattern. The striations are indicated by arrows in Fig. 2(b). In this photograph, a mottled color splotch with indeterminate form can be seen. The nonuniformity in the color is not changed during further oxidation. Striations are observed distinctly with an increase in ΔV, as shown in Fig. 2(b).

An interference color micrograph on oxide and GaAs surfaces after a 2° angle-lapping is shown in Fig. 3. The striations consist of ridged and recessed lines. The ridged (or recessed) line on the oxide is the ridged (or recessed) line on the GaAs surface. This correspondence between the oxide and the GaAs surface is possibly due to local (selective) dissolution of oxide at the lines.

The pebbled surface texture appears at high oxide voltage drop, or with large oxide thickness, in contrast with the mottled color splotch and striations which can be visible at low oxide voltage drop. No pebbled texture surface can be recognized on the oxide surface when the voltage drop is below 70V. When the voltage drop is increased to 110V, the pebbled texture surface starts to appear on a thicker oxide at the mottled color splotch, and then expands all over the wafer. The pebbled texture surface becomes more distinct with an increase in the oxide thickness, similarly to lines.

Standard deviations in oxide irregularities (both pebbled texture and striations), which were measured by a Talystep, were 32Å at 140V and 89Å at 260V. The degree of surface irregularities after anodization in the dark increased at a high rate with an increase in ΔV. It should be noted that threshold voltages exist in appearance of surface irregularities: about 70 ~ 100V to the pebbled appearance and about 40V to the striations.

Almost the same surface irregularities are left on the GaAs surface after removal of the oxide film. In order to see if these surface irregularities depend on the oxide thickness or amount of GaAs consumed during the anodic oxidation, two kinds of oxidations were performed: (*i*) GaAs surface was oxidized until ΔV was 50 ~ 70V, and then the oxide film was etched off. By repeating this procedure four times, a 3400Å GaAs layer was etched off. (*ii*) GaAs was oxidized until ΔV was 177V, followed by removal of the oxide. In this way, a 2700Å GaAs surface layer was etched off.

From a comparison of these two surfaces, it is found that the GaAs surface etched by the four oxidation-cycles, was almost completely flat and smooth, but the GaAs surface etched less deeply in a single oxidation exhibited a very irregular texture surface. This result means that the striations and the pebbled texture surface do not depend on the amount of GaAs consumed, but are affected by the voltage drop of the oxide, or oxide thickness.

Dependence on crystal and carrier concentration.—The surface irregularities appearance depends on the growth method of GaAs and on the carrier concentration. Striations were revealed on only nondoped CZ material. Mottled color splotch was observed on nondoped bulk (both CZ and BG) materials. The pebbled texture was observed on all the materials except heavily doped ones.

No surface irregularities have been observed on heavily doped CZ, BG, and epitaxial GaAs with a net donor concentration of $1 \sim 2 \times 10^{18}$ cm^{-3}, even if the anodization is carried out until ΔV increases up to 220V.

Dependence on temperature and pH of electrolyte.—Electrolyte temperature effects on surface irregularities are shown in Fig. 4. The electrolyte temperature was changed from −30° to 45°C, while the initial current density and voltage applied to the cell were kept the same at each temperature. The pebbled texture becomes fainter by lowering the temperature and almost disappears at −30°C. The striations also become fainter with decreasing temperature, but have not disappeared even at −70°C.

The appearance of surface irregularities did not depend on the *p*H of the tartaric acid solution, which was varied from 1.85 to 6.30.

Light illumination effect.—No irregularities were observed on surfaces anodized under a strong illumination, even on the surface of nondoped bulk GaAs oxidized with an applied voltage on the film or more than 200V.

A mottled color splotch, which had been revealed by the first anodization in the dark, disappeared upon successive oxidation under a strong illumination, but lines and pebbled irregularities were enhanced. In the case of the first anodization to $\Delta V = 140V$ in the dark,

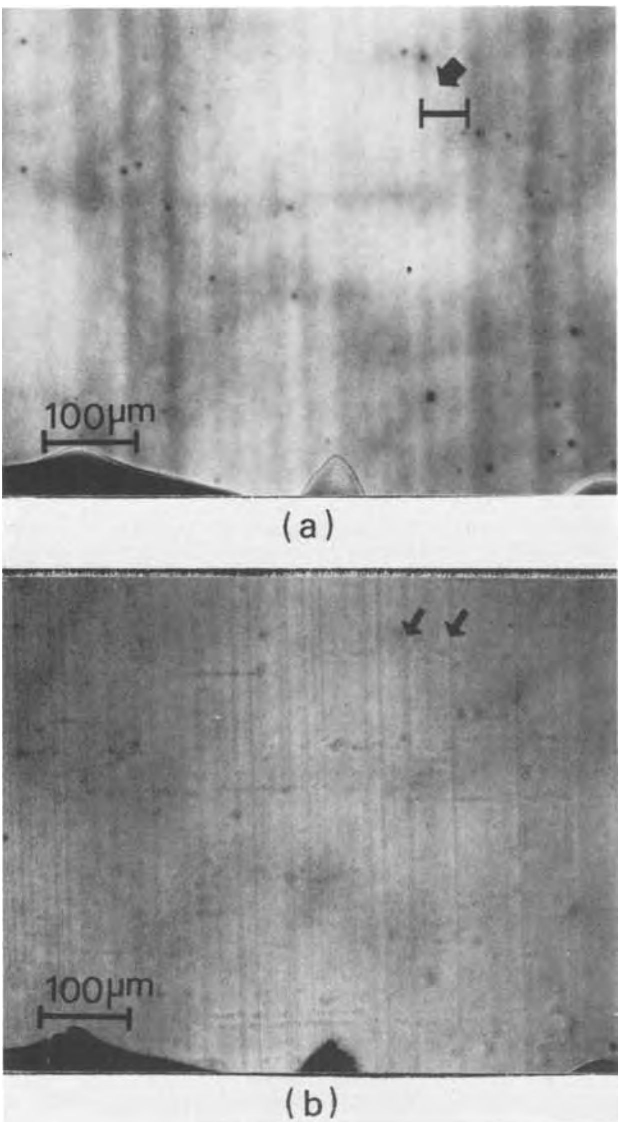

Fig. 2. Striations on the oxide surface with (a) voltage drop of the $\Delta V = 30V$, (b) $\Delta V = 200V$.

followed by the second anodization to $\Delta V = 140V$ under illumination, 280V total, the standard deviation of the surface irregularities after the additional oxidation under illumination was about 1.7 times larger than that after the first anodization in the dark. The three irregularities also appeared under the reverse sequence, namely when the first anodization was carried out under illumination and the successive anodization was in the dark. This fact means that, even when the GaAs surface is coated by a uniform smooth oxide film, surface irregularities will appear if oxidation is carried out in the dark. From these results, it can be said that appearance of the surface irregularity is a specific phenomenon of an anodic oxidation in the dark.

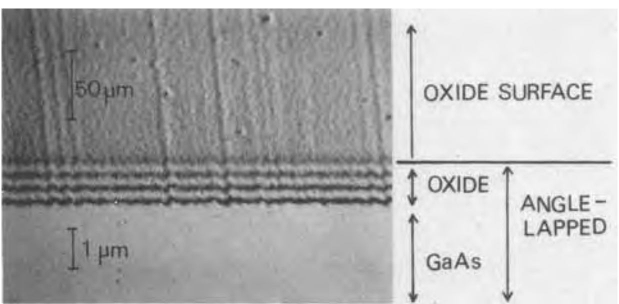

Fig. 3. Interference color micrograph showing 2° angle-lapped section.

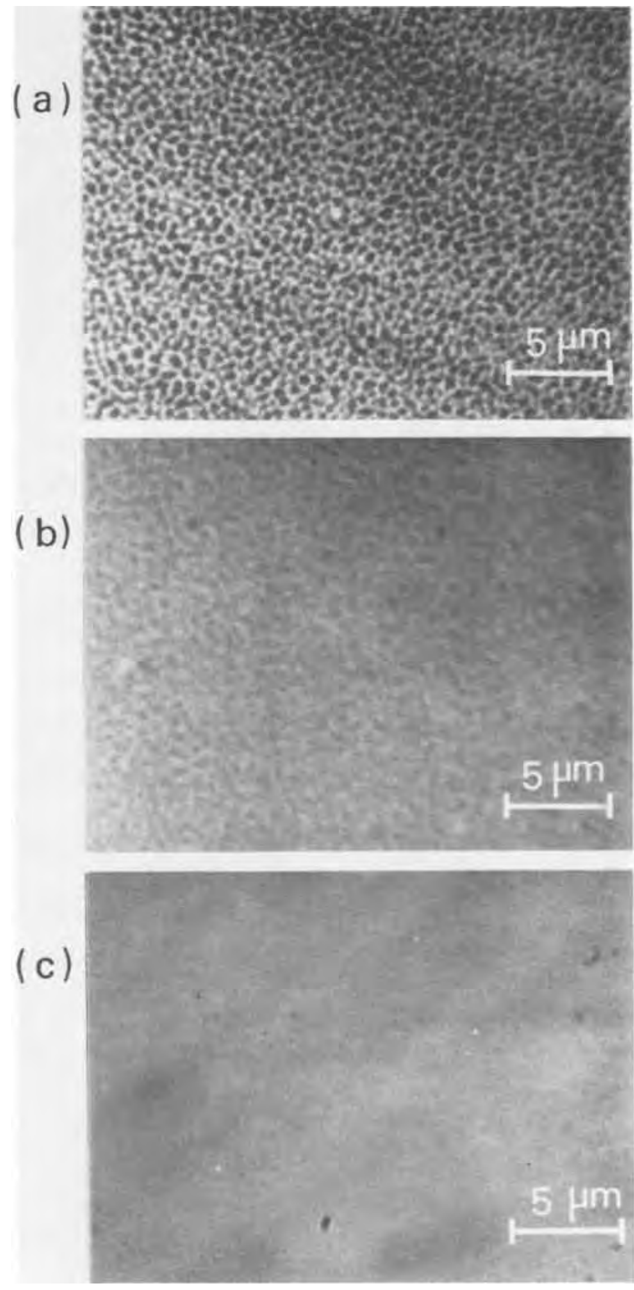

Fig. 4. Oxide surfaces after anodization at (a) 45°C, (b) 2°C, (c) −30°C.

Correlation to the striations revealed by the chemical etching.—It has been reported that an etchant consisting of HF, $AgNO_3$, CrO_3, and H_2O reveals the GaAs crystal defects (6). Recessed patterns are obtained on crystal defects by etching in the dark.

One part of a GaAs wafer was etched in the dark using the etchant and the other part was anodized in the dark. The sample was CZ-grown nondoped bulk GaAs. The anodization was carried out in the dark until the cell voltage was 140V. Figure 5 shows the GaAs surface obtained by the chemical etching in the dark (bottom), and the anodic oxide surface (top). Many striations are observed on the chemically etched surface. There is a perfect correlation between the striations appearing on the anodic oxide layer and the striations revealed by the chemical etching. It was found by a Talystep that the striations revealed by

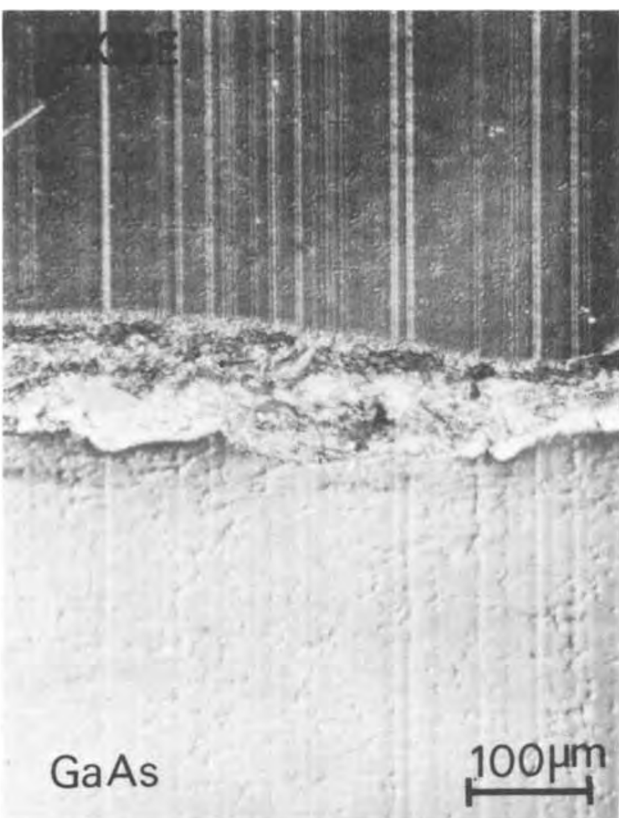

Fig. 5. Interference color micrograph of GaAs surface after chemical etching in the dark (bottom), and oxide surface produced by anodization in the dark at $\Delta V = 140V$ (top). The chemical etching depth is about 3.2 µm.

this preferential etching in the dark were recessed, which means that the striation position is at the array of crystal defects.

The striations revealed by the chemical etching have been well known to be due to the periodic fluctuation of the impurity concentration along the pulling direction, which is caused by the thermal asymmetry in the crucible of the pulling instalation. In the case of nondoped materials, silicon is the residual impurity.

Discussion

Cause of the surface irregularities.—Since mottled color splotch was eliminated by additional anodization under illumination, the mottled color splotch appearance can be explained very well as due to a doping inhomogeneity, as described by Colquhoun *et al.* (7). The doping inhomogeneity effect is eliminated by free carriers which are generated in a GaAs surface by illumination.

In aluminum anodization process, solvent action locally causes a pore on a point of the inhomogeneous oxide film, and a higher electrolyte temperature or a thicker film (*i.e.*, a longer pore) inclines to enhance the solvent action (8). For GaAs anodization, causes of striations and pebbled texture are possibly attributed to the solvent action, similarly to the aluminum anodization. From the present experiment, however, it should be difficult to discuss the detail of the generation mechanism of the striations and the pebbled texture.

Effect of depletion layer width on surface irregularities.—Striations due to the fluctuation of the impurity concentration exist in CZ crystals regardless of doped or nondoped materials. However, striations induced by the anodic oxidation process appeared on nondoped CZ materials, but did not appear on heavily doped CZ crystals. This is explained by differences of width of the depletion layer which is formed on the n-type GaAs surface in contact with the electrolyte. Crystal imperfections within a depletion layer affect the anodization process and a smaller width of the depletion layer results in a weaker effect of crystal defects or doping inhomogeneity. The depletion layer width at the avalanche breakdown voltage becomes smaller with increasing carrier concentration, for example, 9000Å for a carrier concentration of 4×10^{16} cm^{-3} and 650Å for 1×10^{18} cm^{-3}. Therefore, effect of crystal imperfections on the anodization process is weaker for heavily doped crystals as compared with nondoped ones.

Since no pebbled texture surface appeared on heavily doped (epitaxial or bulk) GaAs, the pebbled texture appearance is also affected by the depletion width. However, pebbled texture surface cannot be due to doping inhomogeneity because this irregularity cannot be eliminated out by illumination. Further detailed analysis will be needed.

Conditions for obtaining smooth surface.—A strong illumination is the most effective way to obtain a smooth surface in the anodization of any GaAs materials. However, for a self-controlled etching in a GaAs FET process, anodic oxidation must be carried out in the dark. Therefore, for this application of the anodization, a lower temperature and/or a smaller voltage drop across the oxide are useful conditions for suppressing the irregularities, such as pebbled texture and lines.

Conclusion

Surface irregularities induced by anodic oxidation in the dark for n-type GaAs were studied by changing materials and oxidation conditions. The results are as follows.

1. Three different surface irregularities were observed: pebbled texture, lines, and a mottled color splotch. All the irregularities are observed on undoped CZ material but none are observed on heavily doped (CZ, BG, and epitaxial) materials. In the case of vapor-grown epitaxial GaAs with a carrier concentration ranging from 0.6 to 3.0×10^{17} cm^{-3}, only the pebbled appearance is observed.
2. The lines correspond to the striations caused by the nonuniform distribution of the impurity in the CZ crystals. The mottled color splotch may be the result of doping inhomogeneity.
3. The pebbled texture and lines can be suppressed using a small oxidation voltage or a low electrolyte temperature.

Surface Segregation and Precipitation Phenomena in Ag-Al Alloys

A. G. Dirks and H. H. Brongersma

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

A series of Ag-Al bulk alloys was made by argon arc melting, while thin films of these alloys were prepared by ultrahigh vacuum vapor deposition. By means of light microscopy, x-ray diffraction, transmission electron microscopy and low energy ion scattering under ultrahigh vacuum conditions, the precipitation events during low temperature annealing were investigated.

The Ag-Al system has been the subject of recent interest (1, 2); particularly much attention has been paid to the growth kinetics of the compound Ag_2Al. In this paper we report on our studies of Ag-rich Ag-Al alloys either in the bulk or as a thin film. With a variety of experimental techniques we have compared the precipitation phenomena in both types of Ag-Al alloys. In order to assess the role played by the surface of the samples, we studied the outermost atomic layers by low energy ion scattering (LEIS) in detail. Precipitation effects have been found to occur first at interfaces, such as grain boundaries or surfaces, as these generally are the most likely sites for segregation and precipitation events [see, for instance, Ref. (3)].

Experimental

$Ag_{1-x}Al_x$ alloys with $0 \leq x \leq 0.21$ were made by argon arc melting of the pure elements (Ag 99.9% and Al 99.99%) and homogenized in argon-filled sealed silica capsules for 160 hr at 600°C. Thin specimens of these alloys needed for the transmission electron microscope (TEM) investigations were obtained by means of ion milling.

Thin films up to 1 μm in thickness were made within the same composition range by ultrahigh vacuum vapor deposition ($\leq 10^{-10}$ Torr). In the vacuum chamber the alloys were prepared by simultaneous electron beam evaporation of the pure elements onto substrates at room temperature.

The compositions of the samples have been analyzed by LEIS. The diameter of the scattering ion beam was 1 mm, the ion current ~100 nA, and the scattering angle 142°. A detailed description of the ion-scattering equipment has been given elsewhere (4). Quantitative data for Ag and Al were obtained by calibration against the pure elements. The sensitivity of O relative to Al was determined by studying the oxidation of an Al surface. It was found that the atomic sensitivities are not influenced by chemical effects in the present case. This finding is similar to that for earlier LEIS measurements on other targets, such as Cu-Ni alloys (5).

Experimental Results

X-ray diffraction experiments with as-deposited $Ag_{1-x}Al_x$ films showed that the diffraction lines which are indicative of the presence of the μ-Ag_3Al equilibrium compound are visible for $x \geq 0.09$. With higher x values the intensity and the number of these diffraction lines increased. The microstructure of all films, as studied by TEM, revealed crystallites having dimensions smaller than 0.1 μm.

Key words: surface segregation, precipitation, silver-aluminum alloys, low energy ion scattering, thin films.

Rutherford backscattering experiments with 2.7 meV He^+ ions were performed with films in the composition range $0 < x \leq 0.45$. Measurements of the as-deposited layers on SiO_2 substrates resulted in depth profiles having constant Al/Ag ratios.

As distinct from the thin films the x-ray diagrams for the bulk samples with $x \leq 0.15$ showed the Ag matrix reflections only. Neither x-ray analysis, nor TEM studies (at 100 keV and 1 meV electrons) could reveal the presence of the second phase, even after annealing the alloy for 550 hr at 210°C. With light microscopy only a fine grain boundary precipitate was found, the grains having dimensions of about 0.1 mm. Figure 1 is a bright field image of part of a monocrystalline region in a thinned $Ag_{0.85}Al_{0.15}$ sample. The corresponding matrix diffraction spots are shown in the inset. The sharp diffraction ring reflects the presence of a circa 100Å periodicity, which suggests the formation of a second phase (μ-phase?).

In Fig. 2 the data for a bulk $Ag_{0.90}Al_{0.10}$ alloy analyzed by 2 keV He^+ ions are shown. The sample had first been sputter cleaned by prolonged He^+ and Ne^+ ion bombardment. Next, the target was heated for 15 hr to 500°C. Upon cooling to 270°C the surface concentrations remain close to that of the bulk. However, the surface concentrations change markedly

when cooling further to 160°C. This effect is much more pronounced than expected from conventional surface segregation theories (see Discussion). When cooling the target to room temperature, the Al concentration in the surface decreases again since diffusion processes become slow as compared to the sputtering action of the analyzing beam. These results have prompted a detailed investigation of the surface composition as a function of temperature in other bulk Ag-Al alloys. Homogenized $Ag_{0.92}Al_{0.08}$ and $Ag_{0.89}Al_{0.11}$ were first sputter-cleaned by bombardment with 2 keV Ne^+ ions for 12 hr. During subsequent LEIS measurements in a vacuum in the 10^{-10} Torr range using 2 keV He^+ ions, we observed energy spectra showing three distinct peaks for O, Al, and Ag. Characteristic spectra for an $Ag_{0.92}Al_{0.08}$ alloy at 190°C are given in Fig. 3. Only after prolonged Ne^+ bombardment was it possible to reduce the oxygen coverage below 1 atomic percent (a/o). A summary of the LEIS measurements on a sample with $x = 0.11$ is shown in Table I. For the different temperatures of the alloy we calculated the net area of the three peaks within an energy range of about 100 eV, which is centered on the peak. The relative sensitivities are obtained as described above. This calibration resulted in the following relation O:Al:Ag = 1:15:76. Using

Table I. LEIS results for 2 keV He^+ ions scattered from an $Ag_{0.89}Al_{0.11}$ alloy obtained on four successive runs on the same sample. The values are a measure for the net area of the O, Al, and Ag peaks at the temperatures indicated. This net area has been calculated from the energy spectra, within an energy range centered on the respective peak maxima. Calibration against the pure elements *cf.* oxidized Al yielded the following atomic sensitivities O:Al:Ag = 1:15:76. The atomic concentrations are shown in parentheses.

these relative sensitivities we calculated the atomic percentages present at the surface of the alloy: see Table I. The possible error in concentration is highest for oxygen. With the data in Fig. 3 we calculated an O concentration of 12 ± 8 a/o. This concentration is about the same as that found for Al, probably implying that Al_2O_3 is formed. Other results are presented in Table I. Here the calculated oxygen values at the surface of the $Ag_{0.89}Al_{0.11}$ alloy are rather low. In Fig. 4 the Al-surface concentrations have been given as a function of temperature. Upon cooling from ~600°C the Al content increases markedly between 300° and 200°C. At lower temperatures this effect disappears due to the sputtering action of the ion beam.

Instead of measuring the whole energy spectrum at distinct temperatures, an impression of surface effects also can be obtained by continuous measurement of the peak height as a function of temperature. In Fig. 5 we have plotted the Al surface concentrations as calculated from the Al peak heights. Similarly as in the discontinuous heating experiments a rather sudden increase of the Al-surface content is found starting around 250°C.

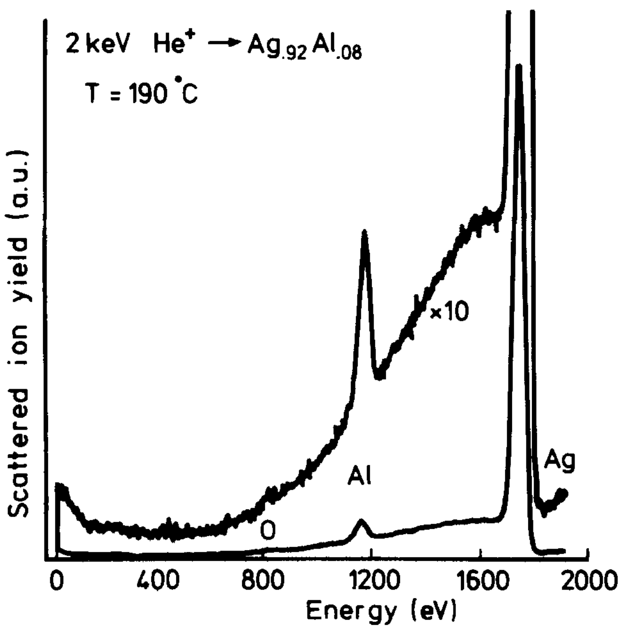

Fig. 3. Energy spectra for He^+ scattered from an $Ag_{0.92}Al_{0.08}$ alloy at 190°C.

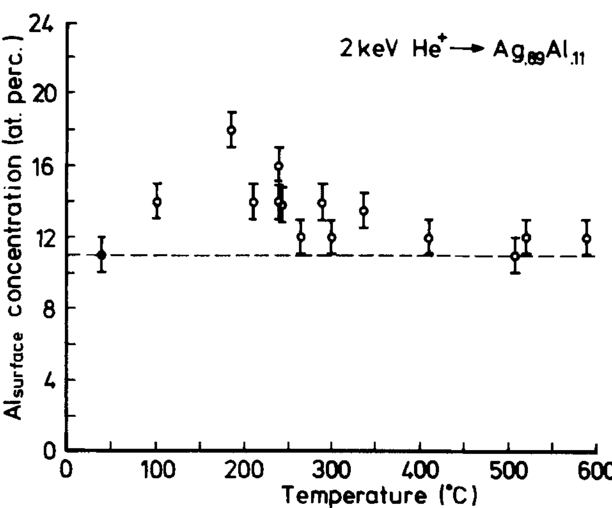

Fig. 4. Al surface concentration of an $Ag_{0.89}Al_{0.11}$ alloy as a function of temperature; data obtained by calculation of the peak area of energy spectra. The measurement at 40°C is less reliable, since the surface contained 4 a/o O.

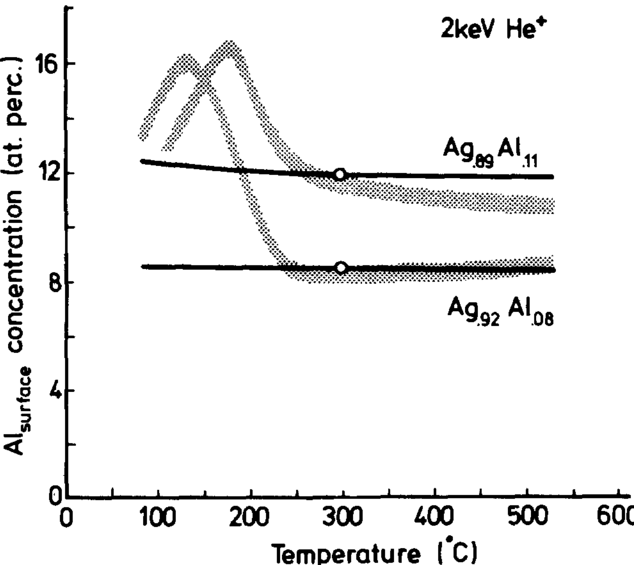

Fig. 5. Al surface concentration of $Ag_{0.89}Al_{0.11}$ and $Ag_{0.92}Al_{0.08}$ alloys as a function of temperature; data obtained by monitoring the Al-peak height (dotted regions) while cooling to 50°C in about 50 min. The drawn lines are calculated curves, normalized to the experimental curves at 300°C.

Discussion

When an Ag-rich Al alloy is cooled down from the α_{Ag} region of the Ag-Al phase diagram, the first precipitation phenomena, in equilibrium conditions, are observed at $T \sim 260$°C when $x = 0.11$ or $T \sim 185$°C when $x = 0.08$ (6). The LEiS data representing the surface concentrations (Fig. 4 and 5) revealed an increase of the Al content close to these temperatures.

From current surface segregation theories it is not immediately clear whether segregation will occur and if so, which element will be enriched at the surface. According to bondbreaking models (7) the element with the lowest heat of vaporization should segregate. This would be Ag($\Delta H_{vap.} = 67.9$ kcal/mole at 298°K) and not Al($\Delta H_{vap.} = 78.5$ kcal/mole at 298°K). However, heats of vaporization are not always a good measure of the strength of the cohesive bonds in a solid that are broken at a metal-vacuum interface (8). Therefore, a better approach is to consider the differences in surface energies rather than in heats of vaporization. The surface energies for Ag and Al at 0°K are 1250 and 1200 mJ/m^2, respectively (9). This more accurate approach would thus predict hardly any segregation. Moreover, if segregation occurs, it would rather be Al than Ag segregation. When Al segregation occurs, the concentration of the Al and the Ag at the surface (y_{Al} resp. y_{Ag}) with respect to the concentrations in the bulk (x_{Al} resp. x_{Ag}) will be given by

$$\frac{y_{Al}}{y_{Ag}} = \frac{x_{Al}}{x_{Ag}} \cdot \exp\left(-\frac{\Delta E}{kT}\right)$$

where ΔE is an energy difference between atoms at the surface and in the bulk. Independent of the precise value of ΔE, which can be calculated using various surface segregation models, the $\ln(y_{Al}/y_{Ag})$ should always be directly proportional to $1/T$.

The results at higher temperatures are in agreement with these expectations, but significant differences are observed around 250°C. The Al surface concentration rises suddenly much faster with decreasing temperature. At still lower temperatures the Al concentration drops again. At these temperatures the diffusion processes are too slow to compete with the sputtering action of the scattering ion beam; the equilibrium surface precipitate will therefore be removed from the outermost atomic layers. This explains the drop in Al at lower temperatures (Fig. 5).

In order to illustrate the differences with the experiment theoretical curves for $x = 0.08$ and 0.11 are also shown in Fig. 5. These curves have been normalized to the experimental curves at 300°C. It is clear that such a theoretical curve, which is in agreement with experiment at higher temperatures, cannot explain the results at lower temperatures. Since the deviations start close to temperatures, where it is known that phase separation (into Ag and an Ag_3Al μ-phase) occurs in the bulk (6), it is tempting to correlate the sudden increase of the Al surface concentration with this phase transition.

However, a phase transition in itself is only a reordering of atoms and does not affect the average surface composition. Apparently the phase transition is accompanied by another process that leads to an increase in the surface concentration of the Al. The origin for the Al-enrichment at the surface may be of a kinetic or a thermodynamic nature. Since a free surface is a well-known nucleation site it is quite possible that the growth of the Al-rich μ-phase will start preferentially at such an interface. One would expect, however, that the concentration of the μ-phase at the surface (and thus the concentration of the Al) would depend strongly on the details of the heat-treatment. This is not the case. Moreover, in-depth analysis of the samples show that the enriched layer has only a thickness of the order of a monoatomic layer.

A thermodynamic explanation seems, therefore, more likely. It could be that the surface energy of the μ-phase is lower than that of Ag, thus leading to segregation of the μ-phase to the surface. If the μ-phase would completely cover the surface this will lead to an Al-surface concentration of 25%. In view of the small differences between the surface energies and Ag and Al, it is doubtful that the differences between the μ-phase and Ag are large enough to explain the present results. Moreover, it would not explain that the enrichment is confined to the outermost atomic layer.

Another explanation is, that while the relative amounts of Ag and the μ-phase in bulk and surface are about the same, the Al is strongly enriched in the outermost layer of the μ-phase at the surface. Studies of van Santen and Sachtler (10) on Pt_3Sn alloys support this latter possibility. LEIS studies to try and further identify the origin of the strong low temperature segregation in Ag-Al alloys are underway.

Avalanche-Induced Hot Electron Injection and Trapping in Gate Oxides on p-Si

A. K. Sinha,* W. S. Lindenberger, W. D. Powell, and E. I. Povilonis

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Hot electron trapping in gate oxides can lead to threshold drifts in short channel MOSFET's. Therefore, factors affecting the efficiency of hot electron trapping have been investigated by rf-bias aging of MOS capacitors followed by flatband voltage measurements. It was found that avalanche-injection electron current levels of >5 μA cm^{-2} produce excessive amounts of hot electron trapping; currents of <4 μA cm^{-2} were preferred for oxide characterization. A relatively small amount of hot electron trapping produced an enormous density of fast surface states. The observed flatband shifts would, therefore, contain significant contributions from surface states. The total flatband shift due to hot electron injection and trapping increased with higher p-Si substrate doping levels ($10^{16} \rightarrow 10^{17}$ cm^{-3}) and with increasing oxide thickness (200 → 1000Å). Eectron beam irradiation (5-30 μC cm^{-2}) followed by a 450°C, H_2 anneal did not significantly change the hot electron trapping behavior of the gate oxide. Possible implications of these results on the generic reliability of VLSI devices are discussed.

An important generic reliability concern with NMOS-VLSI (n-channel metal oxide silicon—very large-scale integration) is possible threshold drifts due to hot electron trapping in the gate oxide (1). The use of saturating logic circuits with bootstrapping and shallow junctions creates large fields and avalanche multiplication near the drain edge, which increases the probability of hot electron injection and hence, of trapping. The extent of trapping is obviously dependent on device geometry and aging conditions. It is also a function of the oxide quality and its processing history. Thus, a wide range of trapping efficiencies for as-grown oxides has been reported in the literature (2). It has been also reported that exposure to E-beams can increase the tendency of gate oxides to trap electrons (3).

However, a quantitative comparison of various data is hampered by the fact, not generally appreciated in the literature, that the apparent trapping efficiency is a complicated function of the avalanche injection level, oxide thickness, and the substrate doping concentration. This paper documents such effects; it also presents independent data on the effect of E-beam irradiation on the neutral trap density of gate oxides.

Experimental

Measurements of the hot electron trapping efficiency were made by rf-bias aging of MOS capacitors, where, in each half-cycle, the p-Si goes into deep depletion and avalanche, hot electrons are accelerated across the potential barrier at the Si/SiO_2 interface, and a d-c electron current flows through the oxide to the gate (4). Any trapped electrons are manifested by a positive shift in the flatband voltage.

The apparatus for rf-bias aging followed that described by Nicollian and Berglund (5), and it is shown in Fig. 1. The rf-frequency was tuned in the range 400-600 kHz to obtain a series resonant circuit and maximize the displacement current through R_1 (10Ω) as displayed on the oscilloscope. The rf-generator voltage was increased until the desired level of d-c current flowed through the electrometer. The latter was operated in the 30 mV (0.03X) full-scale range in order to avoid any appreciable d-c biasing of the MOS capacitor.

SCHEMATIC FOR HOT ELECTRON TRAPPING APPARATUS

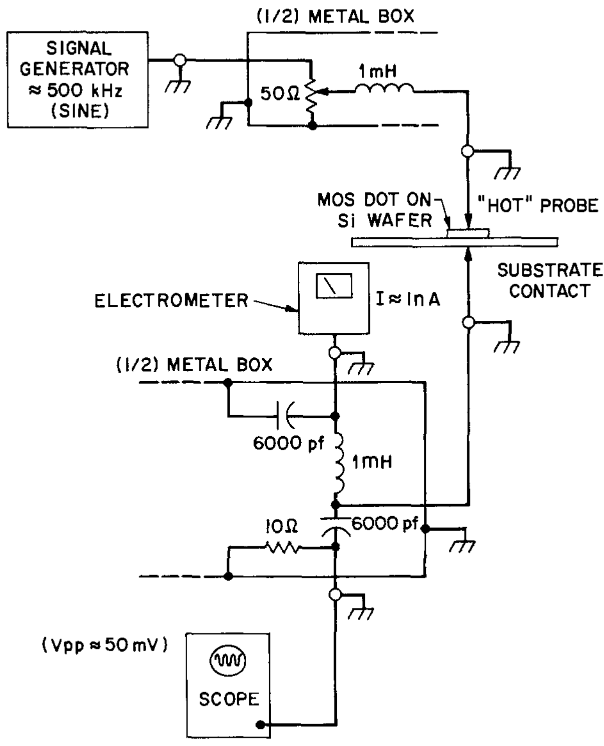

Fig. 1. Apparatus for rf-bias aging of MOS capacitors. [After Nicollian and Berglund, Ref. (5)].

* Electrochemical Society Active Member.

Key words: dielectrics, insulator, interfaces, reliability.

The samples were prepared by oxidizing p(100)Si wafers in dry O_2 + 3% HCl at 1000°C followed by an *in situ* Ar anneal for 30 min. An Al 0.5% Cu alloy film 1 μm thick was (In-Source®) evaporated on the gate oxide using an inductively heated source, and then patterned into 10- or 20-mil diam dots using photolithography and wet chemical etching. The back side was stripped of any SiO_2 and a 1 μm thick film of Al back contact was deposited. The wafers were then given a 450°C, H_2, ½ hr anneal to anneal out the surface states.

Prior to rf-bias aging, all wafers were subjected to capacitance-voltage (C-V) measurements at 1 MHz with ± bias-temperature aging (250°C, 2×10^6 V/cm, 15 min) to ensure that they were free of Na^+ and excessive slow-trapping instability of the flatband voltage, V_{FB} ($\Delta V_{FB} \lesssim 0.2V$) (6). After rf-bias aging for specified periods of time with constant current through the electrometer, C-V measurements were made to determine the flatband voltage shift due to hot electron trapping. For a given sample, a period of 24 hr was usually sufficient to obtain adequate data.

Results

The above procedure gave the apparent density of neutral traps, N_{eff}, as a function of the total number Q_{in}, of injected electrons (3). The quantities N_{eff} and Q_{in} are defined as

$$N_{eff} = \frac{\Delta V_{FB}}{q} \frac{\epsilon_{ox}}{t_{ox}}$$

$$Q_{in} = \frac{1}{qA} \int I dt$$

where, ΔV_{FB} is the positive shift in the flatband voltage as a result of hot electron trapping, q is the electronic charge, ϵ_{ox} is the dielectric constant of SiO_2, t_{ox} is the oxide thickness, A is the area of the capacitor, I is the average d-c component of the injected electron current, and t is the time. The hot electron trapping efficiency may be defined by dN_{eff}/dQ_{in} and it is generally a function of Q_{in}. The flatband voltage was read off the high frequency C-V curves using the depletion layer approximation; no corrections were made for surface states.

Effect of avalanche injection current level.—One of the unexpected results of this investigation was the observation that the density, N_{eff}, of electrons trapped at a given value of Q_{in} depends upon the magnitude of the average d-c component of the avalanche injection current. In order to eliminate any edge leakage effects due to fringing fields, these experiments were carried out on samples where the thin oxide area (450Å, 10 mil diam) was surrounded by a thick oxide (5000Å) guard ring, and the p-Si doping level was kept relatively high at $\sim 1 \times 10^{17}$ cm^{-3}. As shown in Fig. 2, the measured values of N_{eff} were found to be apparently independent of the current between 1 and 2 nA (2-4 μA cm^{-2}) and between 40 and 80 nA (0.08-0.16 mA cm^{-2}). However, there was a factor of 10 increase in the N_{eff} on going from 2 nA (4×10^{-6} A cm^{-2}) to 40 nA (7.9×10^{-5} A cm^{-2}). Moreover, at the higher currents (>10 nA) the observed trapping efficiencies were so dominated by the effect of injected current levels that it was difficult to evaluate other effects such as those due to substrate doping and thickness. Therefore, it was found practical to use an electron current of 1 nA for all the subsequent aging experiments; this level of current could be safely sustained by even the thinnest oxides (200Å) on lighter doped material (10^{16} cm^{-3}) without catastrophic breakdown.

Effect of p-Si substrate doping.—MOS capacitors with N_A of 2×10^{16} cm^{-3} showed a negligible degree of hot electron trapping for $Q_{in} \leqq 10^{17}$ cm^{-2}. This doping level is near the lower limit of that required for bulk avalanche and it may be associated with some field fringing in the Si-space charge region (4, 5).

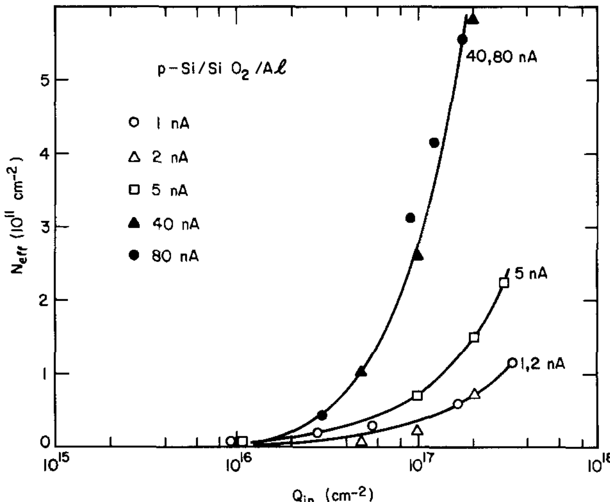

Fig. 2. Effective density of neutral traps vs. the total number per unit area of injected electrons for various levels of d-c electron currents.

Therefore, this observation of low trapping efficiency was reconfirmed by utilizing an MOS structure with a thick oxide guard ring. Upon going from an N_A of $2 \times 10^{16} \rightarrow 2.5 \times 10^{17} \rightarrow 6.8 \times 10^{17}$, the N_{eff} shows a rapid increase for $Q_{in} \sim 10^{17}$ (Fig. 3). The effect shown in Fig. 3 would become even greater if allowance is made for the fact that the 6.8×10^{17} Si had a thinner oxide and the 2×10^{16} Si had a thicker oxide than the 1.5×10^{17} material (see the next section). The observed increase in the hot electron trapping efficiency for higher substrate doping levels (N_A) appears to be over and above that simply attributable to edge effects, which dominate only at lower doping concentrations. Thus, the increase in the trapping efficiency with N_A continues to occur over the doping range ($10^{17} < N_A < 10^{18}$ cm^{-3}) where edge effects would be absent.

Effect of the oxide thickness.—As shown in Fig. 4, for a given doping level ($N_A \sim 2 \times 10^{17}$ cm^{-3}), the efficiency of hot electron trapping decreases on going from a gate oxide thickness of 970 → 600 → 150Å. This thickness effect can be reinforced by the doping effect, so that an MOS structure with 260Å thick oxide on 3×10^{16} p-Si showed no measurable hot electron

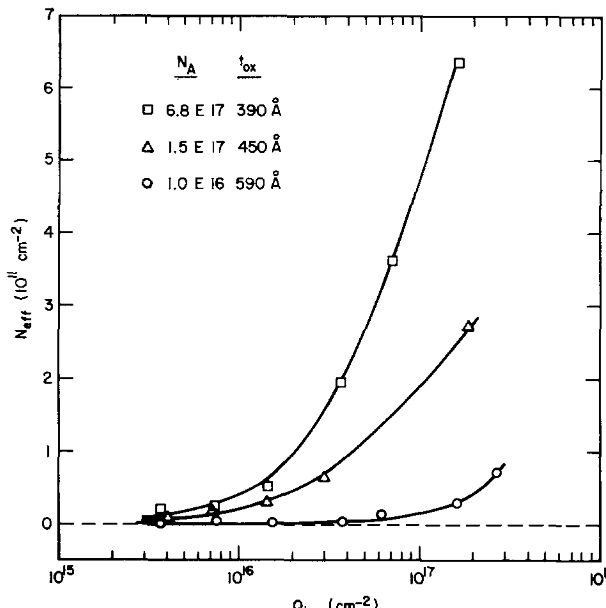

Fig. 3. The effect of p-Si substrate doping level on the hot electron trapping behavior of MOS capacitors on p-Si.

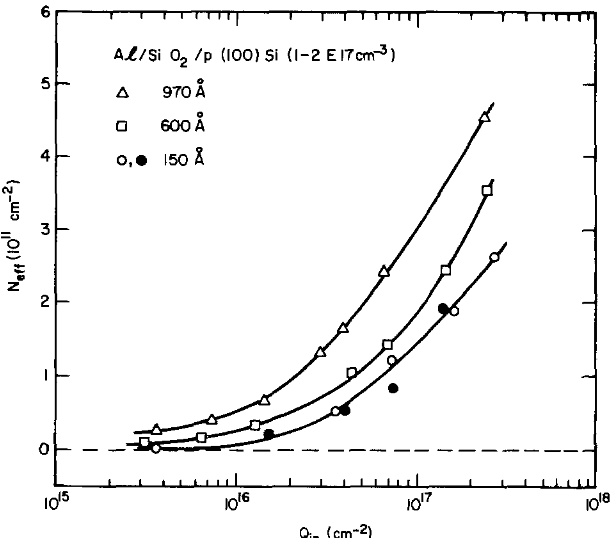

Fig. 4. The effect of gate oxide thickness on the hot electron trapping behavior of MOS capacitors on p-Si.

trapping induced flatband shift for Q_{in} as high as 2 × 10^{17} cm^{-2}.

Effect of E-beam irradiation.—Aluminum-metalized MOS capacitors containing 810Å SiO_2 on p(100)Si (N_A = 2.7 × 10^{16} cm^{-3}) were E-beam irradiated with doses of 10, 20, and 30 $\mu C\ cm^{-2}$ in three quadrants of a wafer whereas the fourth quadrant was left as a control. The irradiation produced a large number of surface states which were annealed out at 450°C, ½ hr, H_2. As shown in Fig. 5, no difference could be found in the hot electron trapping behavior of the nonirradiated control and the irradiated capacitors. In another experiment, various gate oxide areas were E-beam irradiated with 5, 15, and 20 $\mu C\ cm^{-2}$ and then metalized with Al dots and annealed at 450°C, H_2, ½ hr. Again, no difference could be observed between the hot electron trapping behavior of irradiated and nonirradiated areas. These results indicate that for the presently used combination of Si-doping level, oxide thickness, and E-beam doses, hot electron trapping instability should not be abnormally high.

The present results cannot be directly compared with those of Aitken *et al.* (3) who observed a factor of 2 increase in the hot electron trapping on going from nonirradiated controls to samples irradiated with a high E-beam flux of 100 $\mu C\ cm^{-2}$. Their samples had a higher doping level of 2 × 10^{17} cm^{-3}, a smaller oxide thickness of 440Å, and were annealed at 400°C, 30 min in forming gas following E-beam exposure.

Generation of surface states due to hot-electron injection.—Through quasi-static measurements in conjunction with high-frequency (1 MHz) *C-V* measurements (7), the density of surface states at midgap, N_{SS}, was determined for a limited number of samples subjected to avalanche injection and trapping. Figure 6 shows the results obtained for an MOS structure with a 0.5 μm thick oxide guard ring, 550Å gate oxide on p-Si with an acceptor concentration of 1.0 × 10^{17} cm^{-3}. The electron injection current density was 6 $\mu A\ cm^{-2}$ which is somewhat higher than the preferred levels. As may be seen from the right-hand ordinate of Fig. 6, an enormous density of surface states (> 10^{12} $cm^{-2}\ eV^{-1}$) is generated as a result of rf-aging. These surface states could not have been produced by any preferential conduction at the edges, since the acceptor concentration was relatively high and the edges were sealed with a thick oxide guard ring. The surface states also cause a stretchout of the high frequency *C-V* curves near the inversion point after extended aging, and this was found to be the case for all the samples studied. A detailed analysis of the surface states effect is being carried out and it will be published elsewhere.

Discussion

The present results on oxide thickness and Si-doping effects show that, through measurements of hot electron trapping efficiency, it is possible to distinguish between gate oxides which otherwise show the same (interface-dependent) MOS characteristics, *e.g.*, Q_{ss} and the slowtrapping instability. For this purpose, the choice of a low injection current at ~1 nA level (~2 $\mu A\ cm^{-2}$) is important, because it enables one to best resolve the effect of materials and process parameters on the hot electron trapping efficiency. On the basis of the observed thickness dependence of hot electron trapping efficiency, it may be concluded that the neutral traps are distributed throughout the oxide as opposed to, *e.g.*, the slow traps or the fast states which predominantly reside at or near the interface.

This point is further illustrated by Fig. 7 where the hot electron trapping efficiency at a Q_{in} of 10^{17} cm^{-2} is plotted against the oxide thickness. A linear dependence through origin would indicate a t_{ox}^2 dependence of ΔV_{FB}, and hence, a uniform distribution of traps throughout the oxide thickness. This seems to be the case with the present samples except for the thinnest oxide (150Å), where there is a positive deviation from the line drawn through origin. It is probable that for the latter situation, additional traps related to the interface are present. Our conclusion on the overall thickness dependence of hot electron trapping at room temperature is very similar to that published recently

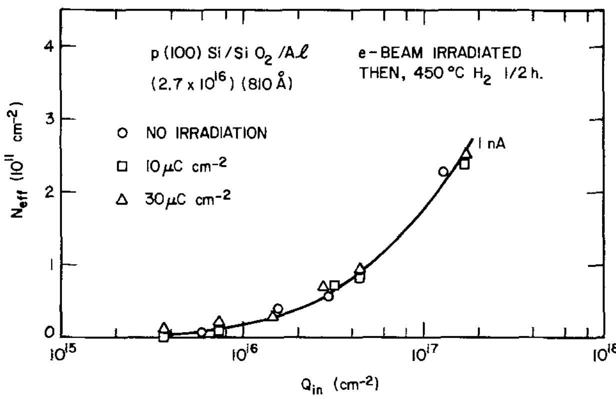

Fig. 5. Effect of E-beam irradiation of aluminized MOS capacitors followed by 450°C H_2 anneal on the hot electron trapping behavior of the gate oxide.

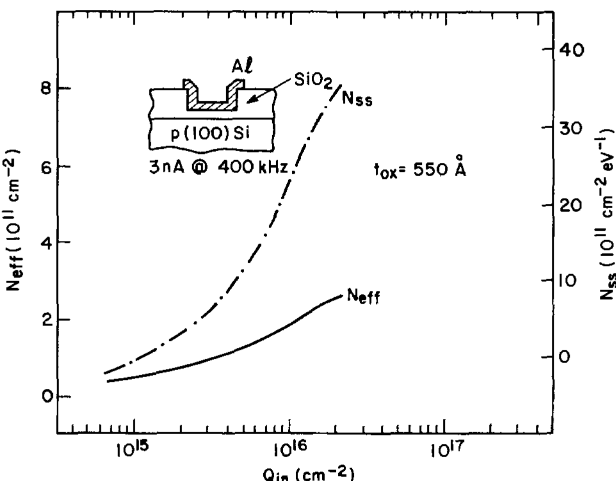

Fig. 6. The effect of gate oxide thickness on the hot electron trapping efficiency at Q_{in} of 10^{17} cm^{-2}.

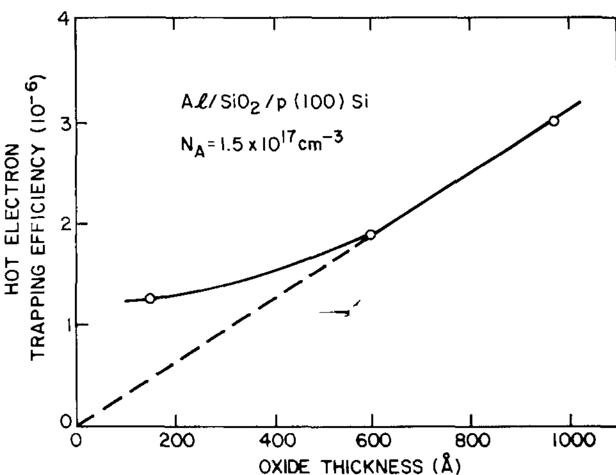

Fig. 7. Effective density of neutral traps and the density of surface states after rf-bias aging of an MOS capacitor with thick oxide guard ring.

(and after the present work was completed) by Young *et al.* (8).

In relating the present results to VLSI device technology, it may be concluded that the trend towards thinner gate oxides should be beneficial with regard to hot electron trapping instability. It should be emphasized, however, that even a small amount of hot electron trapping is always associated with an enormous increase in the surface states density. This factor alone may affect device performance, and also the estimate of the flatband voltage from C-V measurements after extended aging.

Conclusions

R-F-bias aging of MOS capacitors on p-Si was utilized to evaluate avalanche-induced hot electron trapping phenomena in gate oxides.

1. The hot electron trapping efficiency is a function of the avalanche injection current level: 1-2 nA (<4 μA cm^{-2}) are preferred values for controlled experiments, whereas with >10 nA (>5 μA cm^{-2}), an excessive degree of trapping is observed.

2. The flatband shift upon rf aging of capacitors increases with higher doping levels (10^{16}-10^{17} cm^{-3}) in the p-Si substrate and with increased gate oxide thickness (200-1000Å).

3. Electron beam irradiation with a dose of 5-30 μC cm^{-2} followed by a 450°C H_2 anneal did not appreciably degrade the hot electron trapping behavior of SiO_2 on p-Si ($N_A \approx 10^{16}$ cm^{-3}).

Optical Properties of $Na_3La_{1-x}Nd_x(PO_4)_2$ and $Na_3La_{1-x}Nd_x(VO_4)_2$

ABSTRACT

Diffuse reflectance and fluorescence spectra as well as lifetimes have been determined as a function of Nd^{3+} concentration in $Na_3La_{1-x}Nd_x(PO_4)_2$ ($0 < x \leq 1$) and $Na_3La_{1-x}Nd_x(VO_4)_2$ ($0 < x \leq 0.70$) phases. Due to the dissymetry of the anionic environment and the higher covalency of the Nd-O bond, the vanadate has a strong luminescence intensity at low concentrations. Important self-quenching is likely due to electric dipole interactions between Nd^{3+} ions leading to cross-relaxation via the $^4I_{15/2}$ manifold.

The development of fiber optical communications is at the origin of many studies concerning neodymium microlasers. Due to their high neodymium content, these materials can be pumped by light emitting diodes (LED) and consequently constitute a potential light source for optical integrated systems.

The first neodymium lasers such as Nd:YAG (1) showed a very important concentration-quenching. The study of the optical properties of the neodymium ultraphosphate NdP_5O_{14} (NdUP) gave rise to a second generation of materials with a high concentration in active ions, but reduced self-quenching. Most of them are borates and phosphates with a strongly covalent framework along two or three space directions isolating each rare-earth ion from one another. All these structures involve a large distance—about 5Å—between nearest neighbor Nd^{3+} ions.

An alternative way of obtaining large distances between active ions in crystals is to create cationic ordering within a given structure. This is the case for instance in the $Na_3Ln(XO_4)_2$ phases (Ln = rare-

Key words: inorganic, luminescence, lasers.

earth; X = P, V, As) for which the Na-Ln ordering leads to large Ln-Ln distances (2-4).

Therefore, it was attractive to study the optical properties of the $Na_3La_{1-x}Nd_x(PO_4)_2$ and $Na_3La_{1-x}Nd_x(VO_4)_2$ phases, in order to estimate their possibilities as coherent light sources.

Experimental Procedure

Samples of the $Na_3La_{1-x}Nd_x(PO_4)_2$ and $Na_3La_{1-x}Nd_x(VO_4)_2$ phases have been prepared from stoichiometric mixtures of Na_2CO_3 (Merck 99.9%), $(NH_4)_2HPO_4$ (Merck min. 99%), V_2O_5 (99%), and Ln_2O_3 (Rhone-Poulenc 99.99%) (5).

The diffuse reflectance spectra have been recorded at 300°K with a Cary 17 spectrometer.

For the fluorescence study the excitation of Nd^{3+} ions has been carried out by the radiation of a xenon-lamp over the range 500-600 nm.

Measurements of fluorescence lifetimes have been made on samples excited by pulses of 500-600 nm wavelength radiation from a flash-tube, with a pulse duration of approximately 1 μsec. The decay curves were recorded on the screen of an oscilloscope.

Structures of the $Na_3La_{1-x}Nd_x(PO_4)_2$ and $Na_3La_{1-x}Nd_x(VO_4)_2$ Phases

The $Na_3La_{1-x}Nd_x(PO_4)_2$ and $Na_3La_{1-x}Nd_x(VO_4)_2$ solid solutions exist with different allotropic varieties. The stable room temperature forms investigated here derive from a glaserite surstructure with a sodium-rare-earth ordering. This type of ordering, which is the same over the whole composition range ($0 \leq x \leq 1$ for the phosphate and $0 \leq x \leq 0.70$ for the vanadate) induces a minimum Nd-Nd distance of 4.65Å in $Na_3Nd(PO_4)_2$ (2) and a minimum La-La distance of 4.91Å in $Na_3La(VO_4)_2$ (3).

The rare-earth ions are located, respectively, in six and two different crystallographic sites in the phosphates and in the vanadates. Their oxygen coordination is 8 or 9 in the phosphate and 8 in the vanadate, if we take only into account the Ln-O distances below or equal to 3Å. Each LnO_y polyhedron (y = 8 or 9) is isolated from each other and its anionic configuration deviates notably from inversion symmetry.

Optical Properties

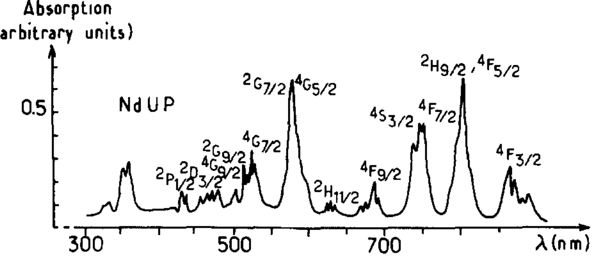
Diffuse reflectance.—The diffuse reflectance spectra of NdP_5O_{14}, $Na_3La_{0.80}Nd_{0.20}(PO_4)_2$, and $Na_3La_{1-x}Nd_x(VO_4)_2$ (x = 0.05, 0.20, 0.65) are shown in Fig. 1.

In the u.v. range the spectra of the vanadates consist of a charge transfer band typical of $(VO_4)^{3-}$ ions.

Although the optical densities can be affected by slight differences in the granulometry of the samples, we may conclude from the comparison of the spectra that the oscillator strengths in the vanadates are higher than in the phosphates.

A detailed investigation of the diffuse reflectance spectra of $Na_3Nd(PO_4)_2$ and $Na_3La_{0.35}Nd_{0.65}(VO_4)_2$ in the range of the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition has been made for determining the splitting of the $^4I_{9/2}$ level. In both structures, the rare-earth ions occupy several types of sites, so that an assignment of the various observed lines is impossible. The width of the group of lines gives an overestimation of the maximum splitting of the $^4I_{9/2}$ level and consequently of the local crystal-field around the Nd^{3+}: these values are 611 cm^{-1} for the phosphate and 977 cm^{-1} for the vanadate.

The most intense $^4I_{9/2} \rightarrow {}^2P_{1/2}$ lines which correspond to the lowest Stark level are located at 23,255 cm^{-1} for $Na_3Nd(PO_4)_2$ and 23,097 cm^{-1} for $Na_3La_{0.35}Nd_{0.65}(VO_4)_2$. These values are close to those observed for $NdVO_4$ (23,080 cm^{-1}) and $Y_3Al_5O_{12}$:Nd (23,139 cm^{-1}) (6, 7), in which neodymium is in similar eightfold coordinated sites. Their difference may be explained by the nephelauxetic effect which is more pronounced in the vanadate: in so far as the P-O bonds are more covalent than V-O bonds, the competitive Ln-O bonds are more covalent in the case of the vanadate.



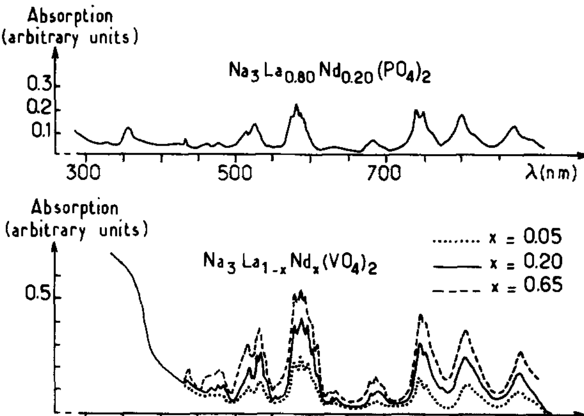


Fig. 1. Diffuse reflectance spectra of the NdP_5O_{14}, $Na_3La_{0.80}Nd_{0.20}(PO_4)_2$ and $Na_3La_{1-x}Nd_x(VO_4)_2$ phases (T = 300°K).

Study of the neodymium emission.—The $^4F_{3/2} \rightarrow {}^4I_{11/2}$ emission spectra ($\lambda \simeq$ 1060 nm) recorded at 300°K are compared in Fig. 2 with the NdP_5O_{14} spectrum obtained under similar conditions. The contribution to the emission of ions located in various different sites does not allow to distinguish the transitions between the various Stark levels, as previously for the diffuse reflectance spectra.

The neodymium concentration dependence of the fluorescence intensity is shown in Fig. 3: the emitted intensity of the vanadate is always higher than that of the homologous phosphate.

The variations of the Nd^{3+} $^4F_{3/2}$ lifetime as a function of the neodymium content are plotted in Fig. 4. Over the whole composition range the lifetimes in the phosphate are longer, but the concentration dependence in both cases is very similar.

If we call τ_0 the observed decay constant at high dilution (which is assumed to represent the radiative lifetime) and $\tau_{(m)}$ the observed decay constant at a Nd^{3+} concentration $N = 4.10^{21}$ ions $Nd^{3+} \cdot cm^{3-}$, the quenching ratio $\tau_0/\tau_{(m)}$ for both materials is about 10.

For $K_3La_{1-x}Nd_x(PO_4)_2$, which has a related structure, Hong and Chinn had obtained $\tau_0/\tau_{(m)} = 16$ (8).

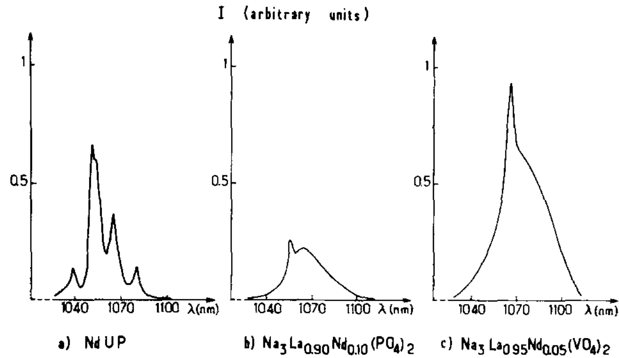

Fig. 2. $^4F_{3/2} \rightarrow {}^4I_{11/2}$ emission in (a) NdP_5O_{14} (b) $Na_3La_{0.90}Nd_{0.10}(PO_4)_2$, and (c) $Na_3La_{0.95}Nd_{0.05}(VO_4)_2$ (T = 300°K).

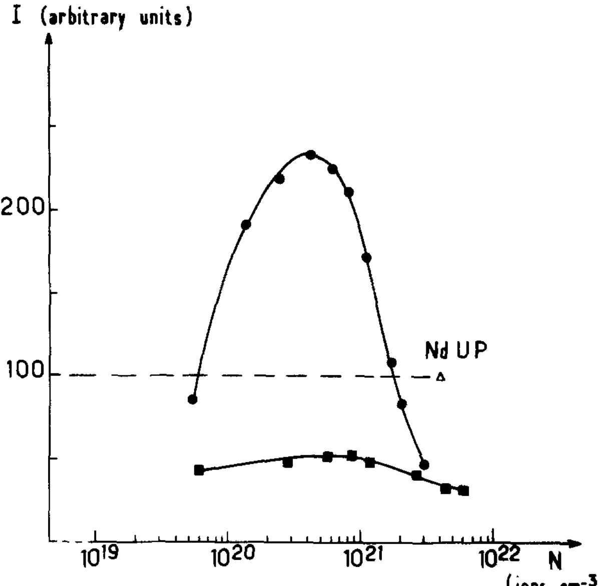

Fig. 3. Fluorescence intensity ($^4F_{3/2} \rightarrow {}^4I_{11/2}$) as a function of Nd^{3+} concentration for: ■ $Na_3La_{1-x}Nd_x(PO_4)_2$, ● $Na_3La_{1-x}Nd_x(VO_4)_2$.

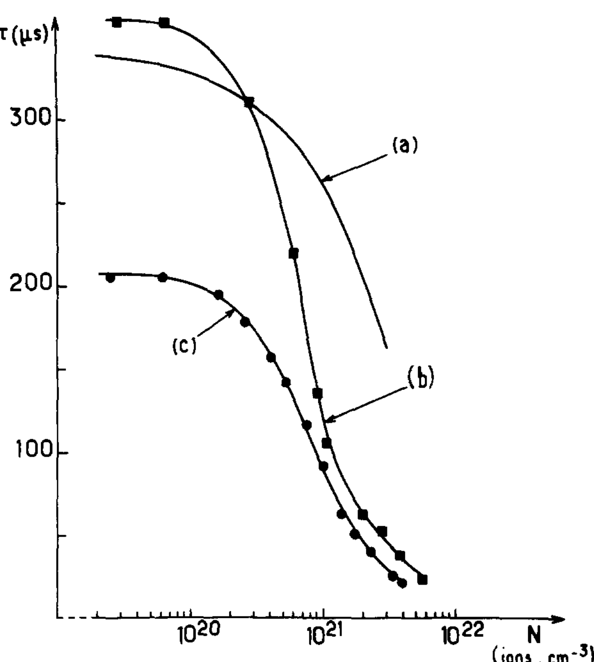

Fig. 4. $^4F_{3/2}$ lifetime as a function of Nd^{3+} concentration for: curve a, $La_{1-x}Nd_xP_5O_{14}$ [after (11)], curve b, $Na_3La_{1-x}Nd_x(PO_4)_2$, and curve c, $Na_3La_{1-x}Nd_x(VO_4)_2$.

Within the $4f^3$ configuration, the electric-dipole transitions are forbidden. However the lack of symmetry center at the Nd^{3+} sites creates an odd parity admixture of the $4f^3$ and $4f^25d^1$ configurations, allowing the transitions. With increasing deviation from inversion symmetry, the probability of electric-dipole radiative transitions increases and as a consequence the radiative lifetime shortens (9).

Whereas in $K_3La_{1-x}Nd_x(PO_4)_2$ ($\tau_o = 460$ μsec) six among the seven oxygen atoms forming the neodymium site are close to inversion positions, in $Na_3La_{1-x}Nd_x(PO_4)_2$ ($\tau_o = 360$ μsec), the six nearest neighbor oxygens around each neodymium atom form largely distorted octahedra: this less centrosymmetrical anionic configuration explains the shorter lifetime in our phosphate.

In the vanadate, as shown by the diffuse reflectance spectra, the Nd-O bonds are more covalent than in the phosphate: the probability of the radiative transitions increases and the lifetime of the $^4F_{3/2}$ level decreases.

Self-quenching analysis.—In strong self-quenching materials, deactivation is the result of electric-dipole interactions between Nd^{3+} ions and cross relaxation via the $^4I_{15/2}$ manifold (Fig. 5).

As showed previously by Auzel, such an energy transfer occurs only if the effect of the crystal field splitting compensates the energy difference between the transitions $^4F_{3/2} \rightarrow {}^4I_{15/2}$ and $^4I_{9/2} \rightarrow {}^4I_{15/2}$ of the free Nd^{3+} ion (10).

Figure 6, which gives schematically the energy levels of free Nd^{3+} ion and of Nd^{3+} in a crystal shows that self-quenching arises if E_{2m}-$E_{1m} > 0$. Following Auzel, this condition can be reduced to a single inequality (10)

$$\Delta E_1 \geqq 470 \text{ cm}^{-1}$$

In the $Na_3La_{1-x}Nd_x(XO_4)_2$ (X = P, V) phases, the presence of Nd^{3+} ions in slightly different crystal field sites gives rise to an additional broadening of ΔE_1. Thus the values obtained for our phosphate (611 cm^{-1}) and our vanadate (977 cm^{-1}) exceed largely 470 cm^{-1} and explain the observed strong self-quenching.

The self-quenching probability can be defined by $q_n = \tau_o - \tau/\tau$ (where τ is the lifetime for a given neodymium concentration).

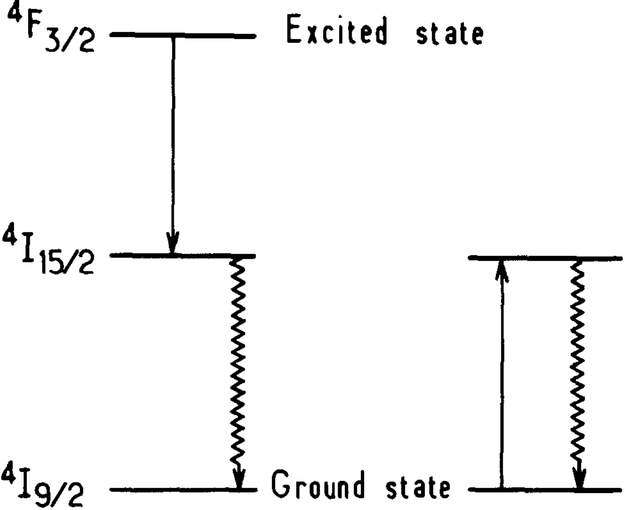

Fig. 5. Energy transfer and dissipation by cross-relaxation

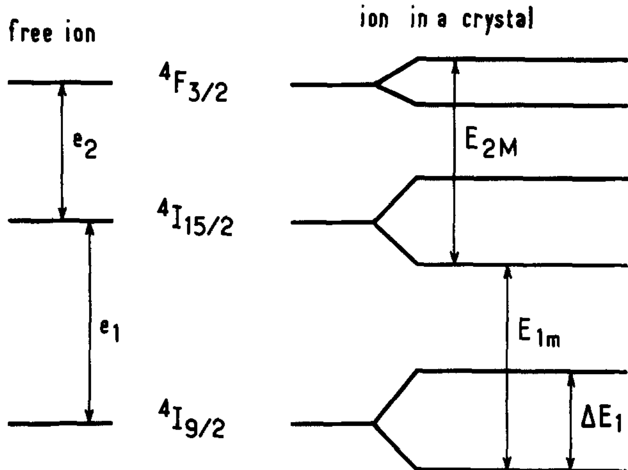

Fig. 6. Energy levels $^4F_{3/2}$, $^4I_{15/2}$, and $^4I_{9/2}$ of Nd^{3+} [following Auzel (10)].

Table I. Magnitude of the $^4I_{9/2}$ splitting and functional dependence of normalized concentration-quenching rate q_n on neodymium concentration N for several materials

Materials	ΔE_1 (cm^{-1})	Functional dependence of $q_n = \frac{\tau_0 - \tau}{\tau}$ on concentration N
$La_{1-x}Nd_xP_5O_{14}$	320 (10)	$\sim N$ (13)
$LiLa_{1-x}Nd_xP_4O_{12}$	375 (10)	$\sim N$ (13)
$KLa_{1-x}Nd_xP_4O_{12}$	320 (10)	$\sim N$ (13)
$Na_5La_{1-x}Nd_x(WO_4)_4$	370 (10)	$\sim N$ (13)
$La_{1-x}Nd_xAl_3(BO_3)_4$	410 (10)	$\sim N$ (13)
$K_3La_{1-x}Nd_x(PO_4)_2$	465 (15)	$\sim N^{1.8}$ for $N \leq 0.4 \times 10^{21}$ (8); $\sim N^{1.8}$ for $N \geq 0.4 \times 10^{21}$ (8)
$La_{1-x}Nd_xF_3$	500 (10)	$\sim N^2$ for $N \leq 2 \times 10^{21}$ (11); $\sim N$ for $N \geq 2 \times 10^{21}$ (11)
$Na_3La_{1-x}Nd_x(PO_4)_2$	611 (this work)	$\sim N^{1.8}$ for $N \leq 1 \times 10^{21}$ (This work); $\sim N$ for $N \geq 1 \times 10^{21}$ (This work)
$Na_3La_{1-x}Nd_x(VO_4)_2$	977 (this work)	
$(La_{1-x}Nd_x)_2O_2S$	410 (10)	$\sim N^2$ (16)

Figure 7 shows the variation of q_n as a function of the neodymium concentration N for $Na_3La_{1-x}Nd_x(PO_4)_2$ and $Na_3La_{1-x}Nd_x(VO_4)_2$. In both cases the evolution is described in the logarithmic diagram by two intersecting straight lines with a slope of about 2 at low concentrations and 1 at high concentrations.

Similar behavior has been previously reported for $La_{1-x}Nd_xF_3$ (11) and $K_3La_{1-x}Nd_x(PO_4)_2$ (8).

Table I gives the magnitude ΔE_1 of the $^4I_{9/2}$ splitting and the functional dependence of q_n on neodymium concentration for several materials.

Self-quenching due to cross-relaxation is theoretically expected to occur with square dependence of q_n on N (1, 11-13). Such a variation is more or less observed in materials involving high values of ΔE_1 and for relatively low activator concentrations.

On the other hand, in weak self-quenching materials, q_n is found to increase linearly with N. Among the various processes assumed to be responsible for such a variation, it was stated recently that the most probable one is migration of energy between Nd^{3+} ions up to annihilation by defects (11-14).

In $Na_3La_{1-x}Nd_x(PO_4)_2$ and $Na_3La_{1-x}Nd_x(VO_4)_2$, the values of the splitting ΔE_1 are much larger than 470 cm^{-1} and consequently lead to a great cross-relaxation probability.

In any way at low x values migration probability is likely weak and the observed fluorescence decay has to be ruled by cross-relaxation probability.

As x rises, energy migration probability increases strongly. The final exponential stage of the decay curve, which becomes the only one appearing, is ruled by self-quenching processes involving energy migration (11).

Finally, the particular behavior of the last material in Table I, $(La_{1-x}Nd_x)_2O_2S$, can be pointed out. In spite of a low ΔE_1 value, q_n increases as the square of Nd^{3+} concentration: strong self-quenching seems to be due to short Ln-Ln distances (4.19Å).

In conclusion, two important criteria are simultaneously required for the development of efficient microlasers: a weak crystal field at the neodymium sites and a large distance between Nd-Nd nearest neighbors.

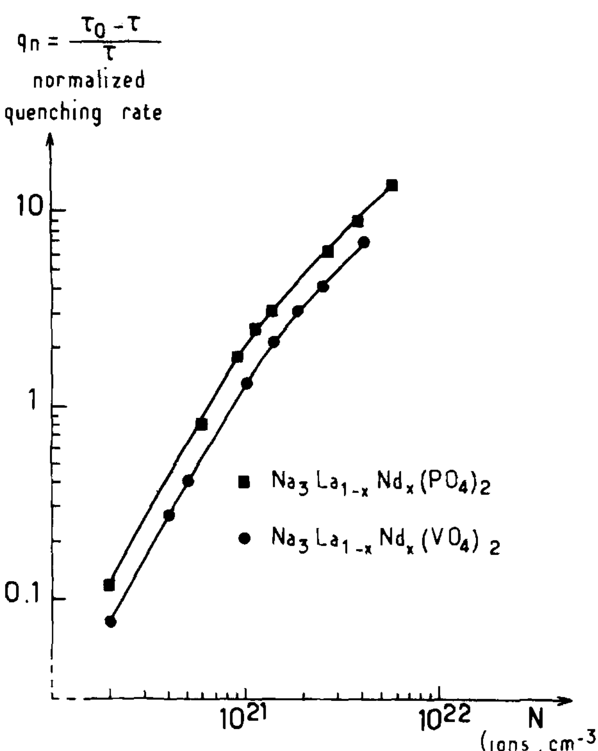

Fig. 7. Normalized concentration-quenching rate q_n as a function of neodymium concentration.

Direct Thermal Nitridation of Silicon Dioxide Films in Anhydrous Ammonia Gas

Takashi Ito,* Takao Nozaki, and Hajime Ishikawa*

Fujitsu Laboratories Limited, Semiconductor Devices Laboratory, 1015 Kamikodanaka, Nakahara, Kawasaki, Japan

ABSTRACT

It has been found that SiO_2 can be converted directly to silicon nitride or oxynitride at the surface of SiO_2 films by heating oxidized silicon wafers in anhydrous ammonia gas. At temperatures above 900°C, nitrided SiO_2 films have graded composites with respect to their nitrogen fraction. This analysis was performed by AES, infrared transmittance spectroscopy, and etch-rate profiles. Nitrided surface regions on SiO_2 films, in which the nitride fraction ranged from 10% to 50%, showed remarkable masking effects against subsequent oxidation at high temperatures.

Silicon nitride is a technologically important material in the production of high performance integrated circuits because of its strong oxidation resistance, barrier against diffusion of impurities, and chemical stability (1-4). Nitride films deposited by chemical vapor are used as gate insulators for nonvolatile memory cells in the form of dual dielectrics (5-8). These metal-nitride-oxide-semiconductor structures were also examined for their properties as stable gate insulators for scaled short-channel devices where film thicknesses of less than 250Å are required (9). Thin Si_3N_4 and SiO_2 composites resulted in unsatisfactory threshold voltage stability which was due to the high trapping efficiency of the nitride and the nitride-oxide interface (10, 11).

During CVD processing of Si_3N_4, nitrogen atoms diffuse into SiO_2-Si interfaces (12, 13). Nitride which formed at SiO_2-Si interfaces in the local oxidation process was found to cause gate oxide thinning near the LOCOS edges and to result in low gate-breakdown voltages (14). Kooi *et al* (14) showed that exposure of oxidized silicon wafers in 3% ammonia gas lead to the formation of oxidation resistant layers. Annealing in nitrogen gas is frequently used to remove the oxide charge from thermally grown silicon dioxide films. Nitrogen atoms easily diffuse through SiO_2 and rarely react with the silicon at high temperatures (15, 16). This process was reported to degrade the electrical properties of MOS structures (17, 18). All these experiments showed only the reaction between nitrogen atoms and silicon substrates and never clearly mentioned any conversion of SiO_2 films.

This paper describes the direct conversion of SiO_2 to nitride or oxynitride. In anhydrous ammonia gas at high temperatures, thermal nitridation of SiO_2 on silicon substrates has been found to occur more predominantly than thermal nitridation of the silicon substrates, even if the SiO_2 film is less than 100Å thick. This fact was discovered in the course of the research on the direct thermal nitridation of silicon (19-21). The nitridation procedure and analysis of thermally nitrided SiO_2 films on silicon substrates are reported here. The electrical properties of the films and MOS structures will be reported soon in another article (22).

Key words: thin film, direct conversion, composite, silicon nitride, oxynitride.

Experimental Procedure

Sample preparation.—Silicon, p-type, (100) oriented, CZ wafers with resistivities ranging from 1 to 5 Ωcm were degreased, chemically cleaned in a hot aqueous solution of $NH_4OH + H_2O_2$, and rinsed in deionized water. Wafers were then oxidized at 1000°C in wet oxygen gas flowing through a water bubbler. The film thicknesses of the SiO_2 films ranged from 100 to 1600Å. The oxidized wafers were loaded on a quartz susceptor and inserted into a quartz tube which was heated to a temperature range of 900°-1200°C. Pure nitrogen gas was flowing through the tube when the wafers were set. No nitridation was observed on SiO_2 surfaces heated under these conditions. Just after the temperature of the oxidized wafers reached a specified point, highly purified anhydrous ammonia gas was substituted for the nitrogen gas. Heating in the ammonia gas ambient was for 1-5 hr or for 17 hr.

Measurement.—The film thicknesses and refractive indexes of films on silicon were measured by ellipsometry with a wavelength of 5461Å. To assign consistency to these values, it was assumed that nitrided films have uniform structures with respect to the depth and that optical constants of the silicon substrate did not change through the nitridation process. The etching rates of films in a solution of $NH_4F:HF = 10:1$ were also examined by step-by-step etching.

Auger electron spectroscopy (AES) with a cylindrical mirror analyzer and infrared transmittance spectroscopy were used for structural analyses. Dielectric constants were calculated from accumulation capacitances of MOS structures and ellipsometric film thicknesses. Aluminum films were evaporated on nitrided SiO_2 surfaces to a thickness of 5000Å. Further, the effects of nitrided SiO_2 films against oxidation in various conditions were examined.

Results

Process conditions.—The surfaces of the nitrided SiO_2 films were as smooth as those of clean SiO_2 films grown thermally on silicon. No morphologies were observed on any experimental wafers. Figure 1 shows changes in film thickness with respect to nitridation

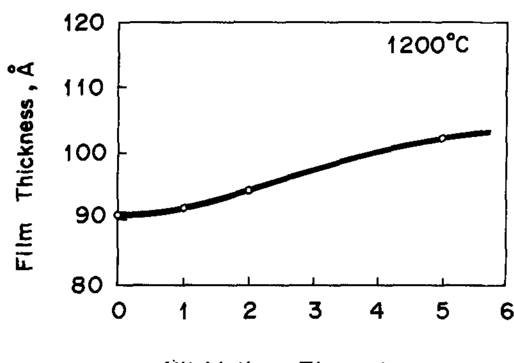

Fig. 1. Change in film thickness with respect to nitridation time at 1200°C.

time. The initial film thickness of 90Å increased slightly and then relatively rapidly in relation to nitridation time at a temperature of 1200°C. After 5 hr, the change in film thickness was about 10Å. Refractive indexes of the respective films are shown in Fig. 2. The initial value was 1.45, which is that of thermal SiO_2. The index rapidly increased to 1.65 after 1 hr of nitridation and little change was observed for films nitrided for longer periods. The rapid increase in refractive index was associated with the slight change in the film thickness shown in Fig. 1. Because nitrided SiO_2 films had nonuniform composites with respect to the depth, the refractive indexes depended on film thicknesses as shown in Fig. 2. Further data are shown in Table I.

Etching characteristics.—Etching rates in a solution of $NH_4F:HF = 10:1$ were measured for three samples. SiO_2 films were grown on all wafers to a thickness of 1600Å. Two wafers were heated in anhydrous ammonia gas at a temperature of 1200°C for 5 and 17 hr, respectively. One was used as a reference for SiO_2. Figure 3 shows change in film thickness with respect to etching time. The linear decrease in film thickness in the reference shows a general tendency of thermally grown SiO_2 films. On the other hand, the nitrided samples showed some retarding in changes of the film thickness. After 100 to 200 sec, both the films started to change in thickness at an etching rate of about one-third that of the reference. No significant difference was observed in the slope of the etching characteristics between the sample nitrided for 5 hr and that nitrided for 17 hr. This indicates that chemically passive layers, which have a very small etching rate in the solution, were formed on the surfaces.

Infrared transmittance spectroscopy.—Figure 4 shows the infrared absorption spectrum of a nitrided SiO_2 film with a thickness of about 100Å which was treated in anhydrous ammonia gas at 1200°C for 5 hr. A relatively thin film was chosen for the measurement

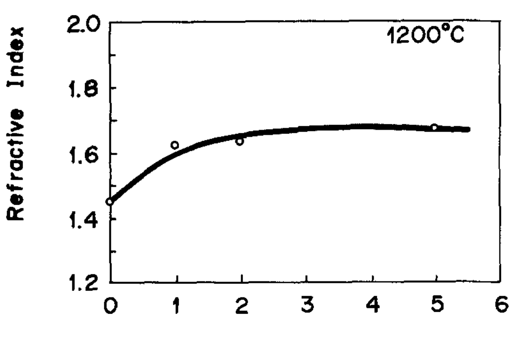

Fig. 2. Change in refractive index with respect to nitridation time at 1200°C. The saturated value shows a nitride fraction of about 50% in SiO_2 films.

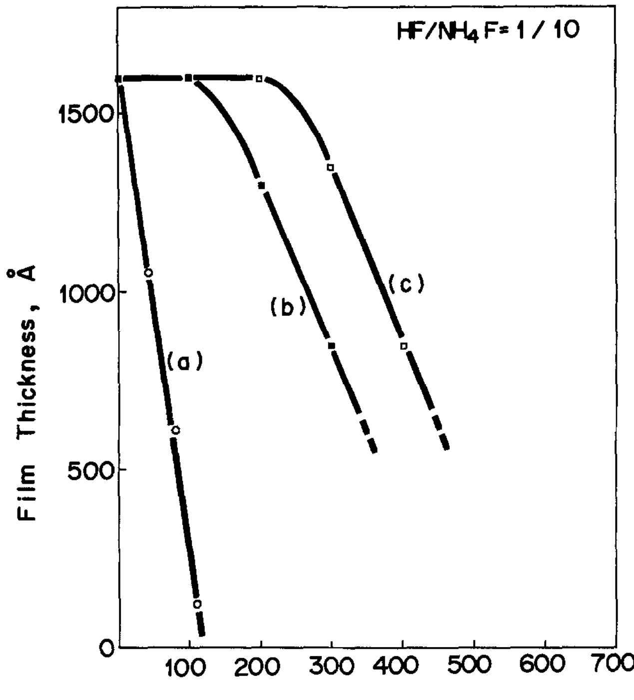

Fig. 3. Etching characteristics of films in a solution of $NH_4F:HF = 10:1$. SiO_2 film (a) is the reference. Films (b) and (c) were thermally nitrided at 1200°C for 5 and 17 hr, respectively.

because a large ratio of nitrided region to the remaining SiO_2 was expected if nitridation was limited to a region near the surface. Spectra (a) and (b) are for the wafers with no nitrided SiO_2 film and that with a nitrided SiO_2 film, respectively. Both were measured using a reference of an SiO_2 film which was grown under the same conditions as that in samples (a) and (b). The peak at 16.4 μm observed in (a) can be attributed to difference in thicknesses of the silicon wafers used for sample (a) and the reference. Due to the evenness in thicknesses of the SiO_2 films, the spectrum is almost flat over the range of 9-15 μm, all peaks being completely canceled.

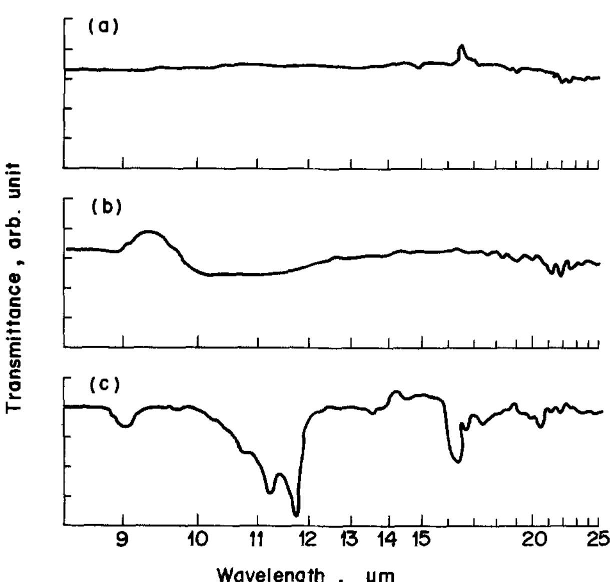

Fig. 4. Infrared transmittance spectra of a 100Å thick SiO_2 film (a), and of a film nitrided at 1200°C for 5 hr (b), where a 100Å thick SiO_2 film was used as a reference. (c) is for a thermally nitrided silicon flim (19).

With the samples nitrided at 1200°C for 5 hr, transmittance increased at 9.4 μm and broad absorption appeared at wavelengths from 10 to 11.5 μm. The increase noted seems to be caused by dissociation of Si-O bonds. The phenomenon is believed to be associated with the subsequent formation of a nitrided layer on the SiO_2 films, which gives rise to the appearance of absorption peaks caused by stretching vibration of Si-N bonds. Absorption peaks of a direct thermal nitrided silicon film with a reference of air is shown in Fig. 4(c) (19). The 10.7 11.2, and 11.8 μm peaks are most likely a result of Si-N bonds. The broad absorption peaks in Fig. 4(b) indicate that composition of the nitrided SiO_2 film was not uniform in depth, but rather changed gradually from SiO_2 to some nitride.

Auger electron spectroscopy.—A typical AES spectrum is shown in Fig. 5. The sample had a 500Å thick SiO_2 film nitrided at 1200°C for 1 hr. The sample surface was not bombarded with ions, and contamination by adsorptive carbon atoms were detected. Oxygen atoms were also adsorptive but identified with SiO_2 composites. Chemically shifted silicon peaks appeared mainly at 78 eV, indicating SiO_2 composites. Further, the very slight shoulder peak recognized at 87 eV is believed to indicate a chemically shifted silicon peak caused by the formation of silicon nitride (23). The intense peak at 375 eV is due to KLL transition in nitrogen atoms, something which was never observed with either as-grown SiO_2 films or nitrogen-annealed SiO_2 films.

Peak-to-peak depth profiles in AES spectra are shown in Fig. 6 and 7. In its initial state, the sample in Fig. 6 had the same structure as that shown in Fig. 5, but was bombarded step-by-step by argon ions with 2 keV of energy. The ion milling rate of both SiO_2 and Si_3N_4 was about 30 Å/min. The film surface was deficient in oxygen atoms. As measured by AES, the height of the oxygen peak rises with sputtering the nitrided SiO_2 film from the surface to the silicon interface. The nitrogen peak is the maximum at the film surface and gradually reduces with sputtering. Nitrogen atoms are localized mostly within a range of 30Å from the film surface. No pile-up was observed at the silicon interface. At the surface the nitrogen fraction was almost a third, demonstrating that escape probabilities of Auger electrons from nitrogen and oxygen are the same. Changes in the profiles of the chemically shifted silicon peaks appearing at 78-83 eV (a) and 62 eV (b), and the pure silicon peak at 92 eV (c) are associating with the observed nitrogen profile. Figure 7 shows a sample with a film thickness of 90Å. The

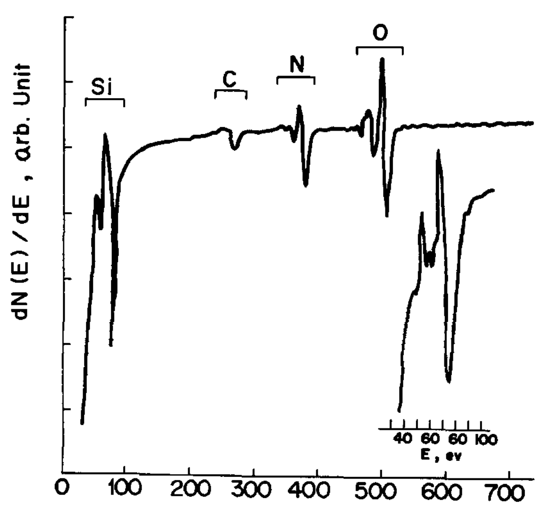

Fig. 5. AES spectrum of a nitrided SiO_2 film. A 500Å thick film was nitrided in anhydrous ammonia gas at 1200°C for 1 hr.

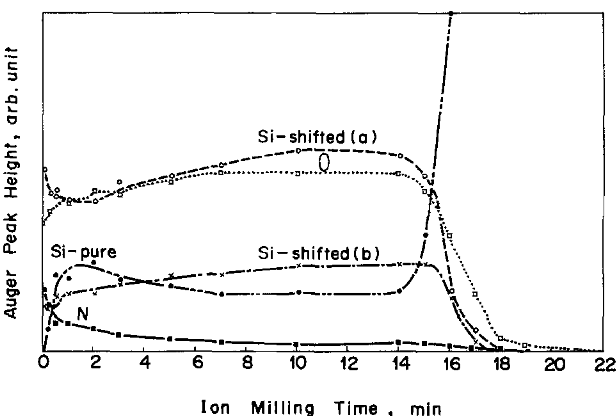

Fig. 6. Peak-to-peak depth profiles of various atoms in AES spectra of a 500Å thick SiO_2 film nitrided at 1200°C for 1 hr. Si-shifted (a) and (b) appeared at 78-83 and 62 eV, respectively.

conditions for nitridation were the same as those for the sample in Fig. 6. Gradual decrease of the nitrogen AES peaks shows that direct nitridation occurred predominantly on the SiO_2 surface rather than on the silicon interface, even when the SiO_2 film was thinner than 100Å. One consideration here is that silicon atoms may be provided through the SiO_2 film from the silicon interface. This, however, is excluded because the nitridation process does not depend on SiO_2 film thickness on silicon.

Dielectric constant.—Figures 8 and 9 show the dependence of relative dielectric constants on nitridation time. Film thicknesses of SiO_2 before nitridation were 100 and 500Å, respectively. Dielectric constants in both figures, measured at a frequency of 1 MHz using aluminum gate MOS structures, increased along with the nitridation time. After 5 hr, the value was 30% larger than that of the SiO_2 shown in Fig. 8. Referring to a relative dielectric constant of CVD Si_3N_4 films (24) (5.8 ± 0.1 at 1 MHz), the nitrided SiO_2 film seems to have dielectric properties similar to those of Si_3N_4. In

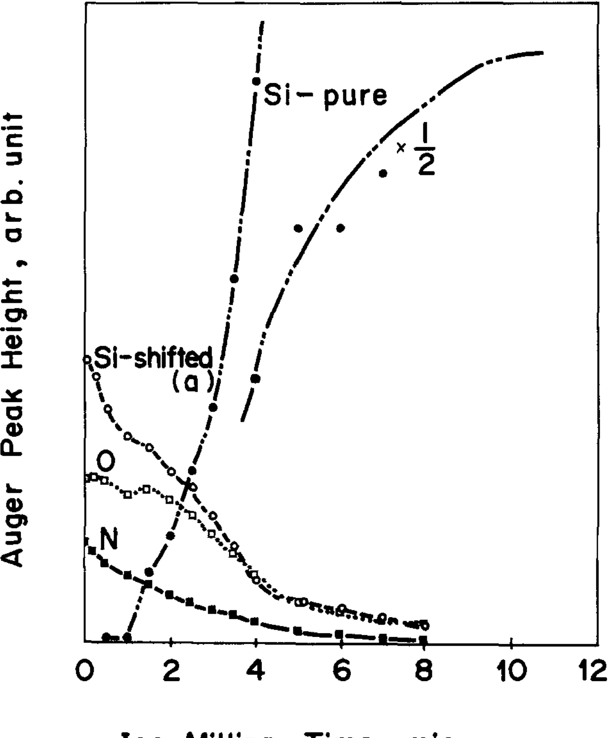

Fig. 7. Depth profiles of a 100Å thick SiO_2 film nitrided at 1200°C for 1 hr. Si-shifted (a) appeared at 78-83 eV.

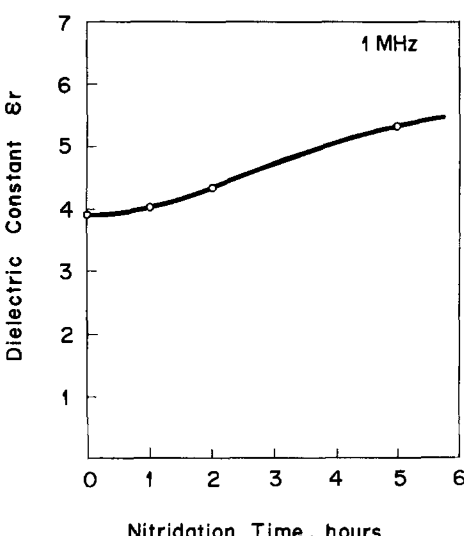

Fig. 8. Change in relative dielectric constant of a 100Å thick SiO_2 film nitrided at 1200°C, measured at a frequency of 1 MHz.

the case of the 500Å thick film shown in Fig. 9, the value was saturated after 1 hr of nitridation at both 1200°C (a) and 1000°C (b). This saturated value of 4.5, however, is 15% larger than that for the SiO_2 value. The difference between Fig. 8 and Fig. 9 is a result of the nitride fraction in SiO_2 films changing under those same nitridation conditions. The dependence on nitridation temperature is shown in Fig. 10, where 500Å thick SiO_2 films were employed. Nitridation of SiO_2 films apparently occurred at the relatively low temperature of 900°C which resulted in the 10% larger dielectric constant than for SiO_2.

Anti-oxidation masking.—Film thicknesses and refractive indexes of the samples after oxidation under various conditions are shown in Table I. All wafers were initially oxidized to produce an SiO_2 film thickness of 400Å having a refractive index of 1.45, sample A. Samples B and C were subjected to further oxidation in dry oxygen at 1150°C for 90 min and at 1200°C for 8 min, respectively. They yielded SiO_2 films which were 2200 and 850Å thick, respectively. When the wafer which was oxidized initially, sample D, was heated in anhydrous ammonia gas at 1200°C for 1 hr, the film thickness decreased by 10Å from the initial

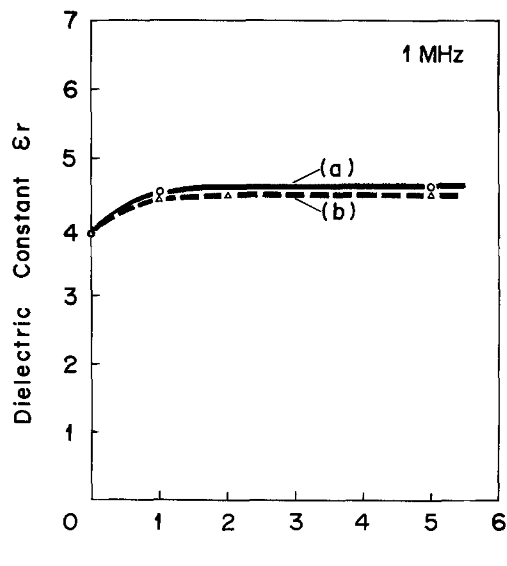

Fig. 9. Change in relative dielectric constant of 500Å thick SiO_2 films nitrided at 1200°C (a), and at 1000°C (b).

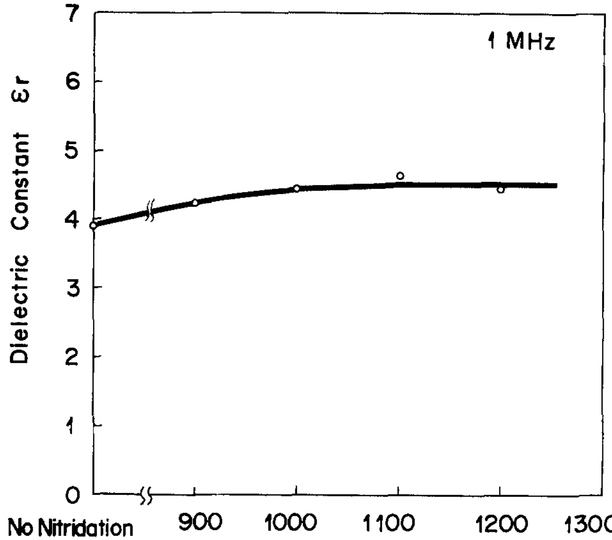

Fig. 10. Change in relative dielectric constant with respect to nitridation temperature of a 500Å thick SiO_2 film nitrided for 1 hr.

value and the refractive index increased to 1.57. This was due to direct conversion of SiO_2 to nitride which changed the film density. One nitrided SiO_2 film, sample E, was subjected to oxidation at 1150°C for 90 min, but the change was negligible. The composite of the nitrided surface region seems to approach that of SiO_2 in relation to the decrease in the refractive index. Further oxidation was performed on sample F at 1200°C for 8 min. The final thickness was not significantly changed from the initial value, and the film showed a masking effect against oxidation.

Discussion

The direct conversion of SiO_2 to nitride seems to obey the following reaction

$$3SiO_2 + 4NH_3 \rightarrow Si_3N_4 + 6H_2O$$

Although the change in standard free energy is positive, it is small enough to allow the reaction to take place. It requires, for example, 54 kcal/mole at 1200°C. Direct reaction between SiO_2 and nitrogen is not practical because it requires a change in standard free energy of more than 400 kcal/mole even at 1200°C. Active hydrogen atoms generated at high temperatures from dissociative ammonia gas may play an important role in the above reaction; it is well known that hydrogen gas dissolves the Si-O bonds in SiO_2 at high temperatures. The active nitrogen atoms provided by ammonia gas surely react with free or unbonded silicon atoms while the dissociated oxygen atoms are eliminated from the surface as a volatile species. Anhydrous ammonia gas hardly provides any oxidant species to silicon substrates. Heating oxidized silicon wafers in ammonia gas, which generally contain some amount of water, is a wide-spread process in CVD of Si_3N_4 films. Some researchers have tried to heat

F	Yes	Yes	Yes	Yes	439	1.49

oxidized silicon wafers in ammonia gas for other purposes (14, 25), but the direct conversion of SiO_2 to nitride was never pointed out in their reports. The chief reason for this difference would seem to be that the greater purity of ambient ammonia gas used here, anhydrous ammonia gas which was fully purified in a catalyzer, contributes to the conversion.

Silicon atoms are clearly provided by the dissociation of SiO_2 in relatively thick SiO_2 films. In SiO_2 films with a thickness of 100Å, for example, this is not the case. The lack of any decrease in oxygen atoms at a nitrided SiO_2 surface was shown in the AES profile in Fig. 7. Silicon atoms may be provided through the SiO_2 film from the silicon substrate. With SiO_2 films of any thickness of less than 100Å, it might become difficult to differentiate the direct thermal nitridation of SiO_2 films from that of silicon wafers. In any case, nitrided regions are formed predominantly at the surfaces of SiO_2 films. This process differs from nitride formation (15, 16) at Si-SiO_2 interfaces. As calculated with the refractive index of the nitrided sample shown in Fig. 2, the nitrogen fraction in a nitrided SiO_2 film with a thickness of about 100Å is about 50% on the average. The ratio was also deduced from the infrared spectrum shown in Fig. 4(b) and calibration data taken from CVD oxynitride films (26, 27). Reporting with ESCA data, Raider *et al.* asserted that homogeneous oxynitride films are composed of a range of species blended on a molecular scale and that they are not a mixture of silicon dioxide and silicon nitride (28). The composition of thermally nitrided regions on SiO_2 films is substantially oxynitride which surely cannot be a mixture.

Directly nitrided SiO_2 films exhibited strong masking effects against oxidation even at very high temperatures. They may be useful as diffusion masks against impurities, oxidation masks, and reaction barrier layers against unwanted material. A further advantage is that with nitrided SiO_2 films there is no interface region between the oxynitride and SiO_2 and there is a good interface with the silicon. This is because the films are chiefly thermally grown silicon dioxide. Although the microstructure of the films is not clear, stable thin insulator films with a higher density than SiO_2 might be formable. Nitrided surface regions might act as protective layers against contamination in device processes. Electrical characteristics of MOS structures with the nitrided SiO_2 films will be reported in the near future.

Conclusions

The direct thermal nitridation of SiO_2 films through heating oxidized silicon wafers in anhydrous ammonia gas has been found to be possible. The reaction is a direct conversion of SiO_2 to silicon nitride or oxynitride. At temperatures above 900°C, nitrided SiO_2 films have graded compositions with respect to their nitrogen fraction. A nitride fraction of about 50% was obtained at the SiO_2 surfaces. These surfaces exhibited remarkable masking effects against further oxidation at high temperatures. These films show great promise as thin protective layers against contamination and diffusion.

The Effects of Abrasion Gettering on Silicon Material with Swirl Defects

C. L. Reed and K. M. Mar*

Motorola Incorporated, Semiconductor Research and Development Laboratories, Phoenix, Arizona 85008

ABSTRACT

The effects of back abrasion gettering on Si material with swirl defects were studied by the techniques of preferential etching and electrical characterization of p^+n diodes. The damage layers were applied via lapping with particle slurries. Optical microscopy revealed the 0.5 μm lapping produces a polishing rather than an abrading effect. The etching results indicate that gettering with 2 and 15 μm abrasion reduces the etch pit density from 5×10^5 to $<5 \times 10^2/cm^2$. The electrical data shows a corresponding improvement: the I_R histograms of the gettered samples approach that of swirl-free material, and the wafer mapping of the diode reverse current I_R on the wafers indicates a definite positive effect of the gettering. Both the electrical and the etching results are interpreted with the current understanding of swirl defects, mass transport phenomena, and gettering action.

The first thermal process in the fabrication of Si devices is the growth of a masking oxide. With steam oxidation, swirl defects in the Si material can act as nucleation sites for the formation of oxidation-induced stacking faults, OISF (1, 2). It has been reported that these faults can cause a p-n junction's electrical characteristics to deviate considerably from the current-voltage curves of a defect-free diode (3). It is common practice to minimize a crystal defect's effect on device yield and performance by impurity gettering which aims to eliminate the species that act as nucleation centers for other defects, increase defect growth, and decorate existing defects. The trend of current thinking on gettering appears to emphasize the suppression of further nucleation rather than defect growth and/or decoration. Following this line of reasoning, an optimum time for a gettering step is before growth of the masking oxide, and this opinion is shared by the recent publications on the different preoxidation gettering techniques (4-10).

Pugh and Samuels (11) have studied in detail the defects that were produced by mechanical abrasion. During thermal annealing, dislocations will be generated in and propagated from the damage layer (12). These crystal defects are known to interact with impurities through the mechanisms of strain field interaction (13). Specific works on applying abrasion damage for impurity gettering to improve Si material quality have been reported (14-16). Mets (14) has observed that the combination of abrasion and thermal anneal can decrease the reverse current I_R of a p-n junction and that the generated dislocations were not annihilated after repetitive temperature cycles up to 1250°C. Pomerantz (15) and Rozgonyi *et al.* (16) have reported that preoxidation abrasion of the back-surface eliminated the epi faults that were nucleated by a defect in the substrate. This defect can be minimized by preoxidation gettering or abrasion of the back-surface of the wafer. In addition, Pomerantz indicated that effectiveness in reducing fault density depends somewhat on technique of damage layer application, viz., sandblasting, scribing, or lapping with Al_2O_3 grits of 1-50 μm particle size. However, the effect of abrasion gettering as indicated by the electrical characteristics of a p-n junction and preferential etching on material containing swirl type microdefects has not been reported.

For a gettering process in which the sinks, *i.e.*, damage layer, is applied at room temperature, one expects an optimized process to include the following three steps: (*i*) applying the damage layer to the back of the wafer; (*ii*) annealing to generate and propagate dislocations which attract point defects through strain field interaction, then slow cool to allow precipitation at preferred sites in the damage layer; and (*iii*) removing the decorated damage layer to obviate the redistribution of the gettered species back into the active regions of the wafer. In this work, however, no specific anneal and damage layer removal steps were designed in the process because it was intended to serve as a base line. The results of this base line process as applied to material with a high density of swirl type microdefects are presented in this report.

Experimental

Starting material and damage application.—Small single ingots of silicon were chosen for this study to control the variation due to starting material. The selected crystals were grown from <111> oriented seeds and were phosphorus-doped to a nominal resistivity of 1-3 Ω-cm. The growth technique for the swirled crystal was floated zone and that for the swirl-free material was Czochralski. Their crystal qualities were characterized by oxidizing polished wafers at 1150°C to activate the defects, subsequently Wright (17) etching to reveal the defects, and examining with an optical microscope to determine the defect density using the ASTM method (18).

Wafers were sliced from these ingots and shaped by the conventional processes to give specular, damage-free front surface and a chemically etched, strain-free back surface. The thickness of the wafers at this point was 305 ± 13 μm. Different degrees of back damage were applied by mechanically lapping the wafers with slurries that contained diamond particles with a mean size of 0.5 and 2.0 μm, and alumina particles of 15 μm. This lapping operation followed the established practice used in the wafer shaping operation. The topography of the damage layers were examined by optical microscopy.

Fabrication of test structure.—A square array of gated p^+n diodes were fabricated by the ordinary processes for patterning and dopant deposition. A 4850 ± 50Å masking oxide was grown with pure steam at 1100°C. The wafers were pushed and pulled from the furnace at the rate of 12 in./min under O_2. Boron diffusion was accomplished through a common two-step process using spin-on source containing B_2O_3 in a 2-methoxy-ethanol solution. The dopant deposition and redistribution temperatures were 960° and 1000°C, respectively. The resulting diffusion parameters in a

* Electrochemical Society Active Member.
Key words: back abrasion gettering, swirl defects, damage gettering, preoxidation gettering.

1-2 Ω-cm test wafer were 160 Ω/square and 0.4 μm. During this diffusion the back was also doped to a comparable sheet resistance. The ohmic contact pads consisted of 10 kÅ thick Al evaporated on unheated substrate.

Electrical testing data reduction.—All wafers were subjected to the same electrical testing procedures to obtain reverse bias characteristics of the diodes. In all measurements the gate was shunted to the base as shown in Fig. 1. To determine a suitable test voltage for measuring the reverse current, the mean avalanche voltage, $\overline{BV}_R$, was first established using the root mean square of the voltage readings at 10 mA. Then the diode distribution as a function of reverse current was determined for three test voltages of 0.1 $\overline{BV}_R$, 0.2 $\overline{BV}_R$, and 0.5 $\overline{BV}_R$. Initially these measurements were obtained manually on a 9 × 9 matrix (every ninth column and row of devices) which represents about a 1% sampling. This data served to delineate the boundary conditions for automated testing and to provide a base for correlation with the values obtained from testing with a Fairchild Sentry VII. A graphic program was used to map the I_R data according to the device's position on the wafer and to group the I_R data into histograms.

Davies (19) test reveals the logarithmic nature of the I_R distribution; therefore, a geometric mean (20) of the reverse current for each group of wafers was calculated using the expression of

$$\bar{I}_R = \text{antilog} \sum_{i=1}^{C} \frac{n_i \log I_{Ri}}{N}$$

where n_i is the number of devices in leakage category i with leakage I_{Ri}, N is the total number of devices, and C is the number of categories in the histogram. This weighted mean was used as a figure of merit for each group, and detailed *I-V* curves were generated from devices whose I_R at 0.5 $\overline{BV}_R$ were equal to the geometric mean.

Results and Discussion

Etch analyses of the substrate.—Figure 2 shows etched wafers with "swirl" that were nonabraded and with 2 and 15 μm abrasion. The nonabraded sample gave the characteristic milky appearance to the naked eye. The milky appearance is the result of light scattering by the many tiny etch figures. The wafer periphery displays the lowest density of etch figures and the core displays the highest density. This core pattern of swirl has a nearly uniform pit density. The pit sizes and the intensity of this milky appearance in the abraded samples are much smaller. The pit densities by the ASTM method are 5 × 10^5/cm^2 for the nonabraded wafers, 2 × 10^2/cm^2 for the 2 μm abraded, and 4 × 10^2/cm^2 for the 15 μm abraded sample. In comparison, the swirl-free ingot yields a pit density of <50/cm^2.

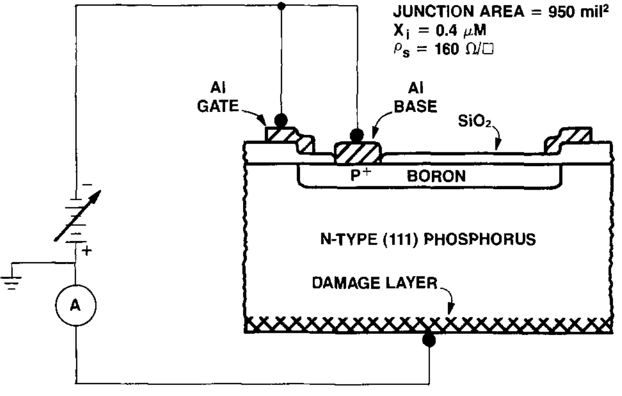

Fig. 1. Schematics of the measuring circuit and test structure

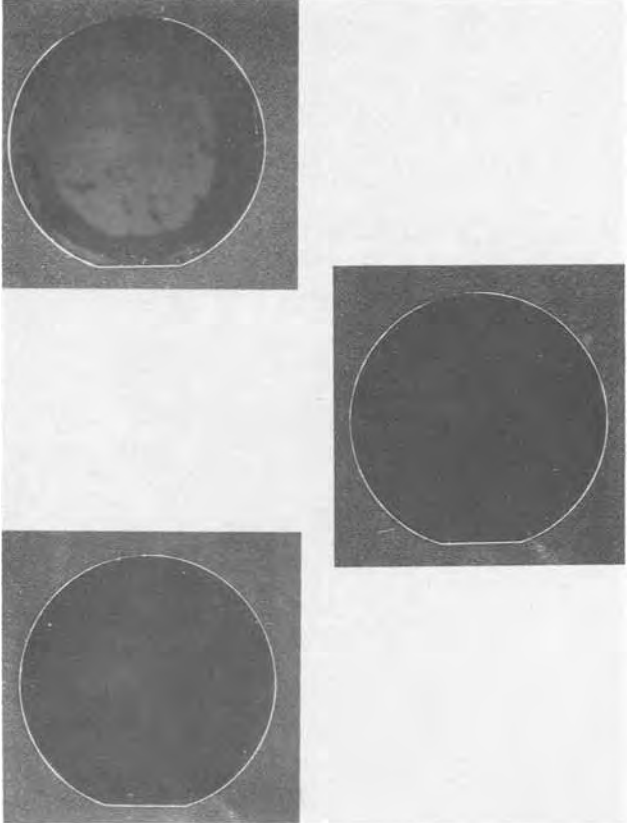

Fig. 2. Preferential etch decorated wafers that were gettered and ungettered. (a, top) is unabraded, (b, right) is 2 μm abraded, and (c, bottom) is 15 μm abraded.

A photomicrograph of the etch pits is shown in Fig. 3. This shallow etch pit morphology is the established characteristic for swirl defects (21). No characteristic etch figures for oxidation-induced stacking faults were observed after initial oxidation, or after diffusion in the region corresponding to the field oxide and the diffused regions of the device.

Damage layer characterization.—The topographies of the damage layers were examined optically before and after the growth of the masking oxide. The differences between the four groups are quite apparent to the naked eye and under a microscope. They are compared at 400× in Fig. 4. The nonabraded wafer shows an "orange peel" texture under Nomarski microscopy. In comparison, the 0.5 μm abraded wafer looks smoother to the naked eye and at 400×. This suggests that the 0.5 μm slurry served more to polish than to abrade the wafer. After the initial oxidation, optical microscopy revealed only slight remnants of the abrasion damage. Apparently, the growth of the masking oxide consumed most of the damage layer. Based on these observations and the preliminary electrical results showing marginal gettering effectiveness, this degree of abrasion damage was dropped from further consideration early in the study.

The topography of a 2 μm abrasion consists of scratches which are barely visible to the eye with oblique illumination, and the 15 μm abraded wafer exhibits a roughness which appears lusterless. Optical micrographs at 400× for the 2 μm scratches and the 15 μm roughness are shown in Fig. 4. The growth of 5 kÅ oxide produces no discernable difference in these topographies.

I_R histogram comparisons.—Figure 5 presents a comparison of the I_R histograms at ½ $\overline{BV}_R$ for the four groups of wafers. The vertical axis is the percent distribution of diodes in each I_R category and the horizontal axis represents the I_R categories in A/mil^2.

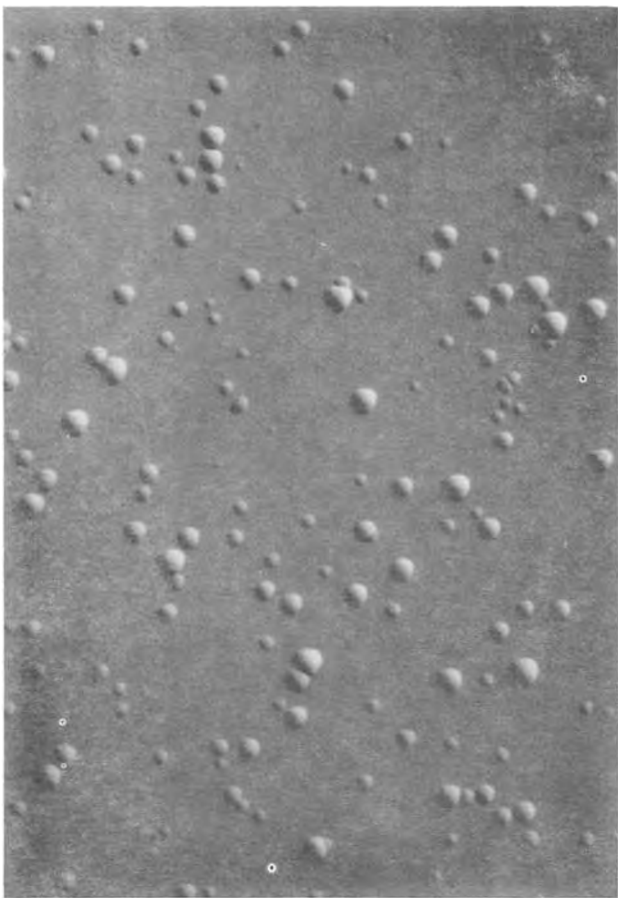

Fig. 3. Photomicrograph of the etch decorated surface of the ungettered wafer at 400×.

Each category is an order of magnitude wide except at the ends which include, respectively, all the diodes with $I_R \leq 10$ pA/mil^2 and > 10 μA/mil^2.

The top two patterns in Fig. 5 are typical cases for nonabraded swirl and swirl-free materials. This histogram for swirl-free material shows a strong skewing of the data into the lower I_R categories. In contrast, the pattern for swirl bearing material shows a broad or bimodal distribution. The bottom two histograms are for composite results of all wafers within each abraded group. They also show skewing of the data into the lower I_R categories, and are comparable to the swirl-free case.

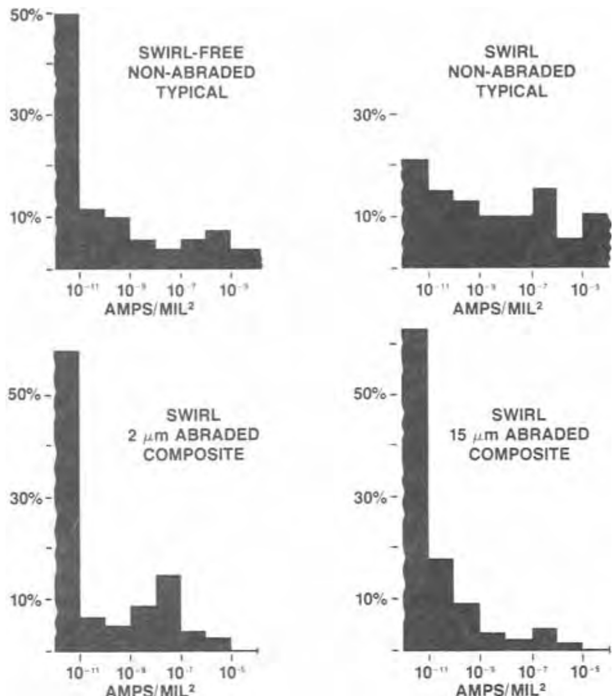

Fig. 5. I_R histograms at $V_R = 0.5\ \overline{BV}_R$

I_R mapping comparisons.—The mapping of I_R's on their respective locations in a wafer provides a positional correlation between material and device qualities. Such a correlation is shown in Fig. 6 for the nonabraded and the abraded swirl groups. In each group the median quality wafer is presented. The cross hatched and the clear areas represent, respectively, the devices whose I_R's are ≤ 10 pA/mil^2 and > 10 pA/mil^2 at ½ $\overline{BV}_R$. The top left photograph shows the core pattern of swirl which represents $> 2/3$ of the wafer map diameter. The central region of the two abraded wafers show a higher density of low leakage devices than that of the nonabraded wafer. The densities of the two abraded wafers are too close to differentiate. These comparisons demonstrate the positive effect of abrasion gettering on the swirl defects.

I_R-V_R characterizations.—I_R histograms and wafer maps reflect the mean quality of the material, but

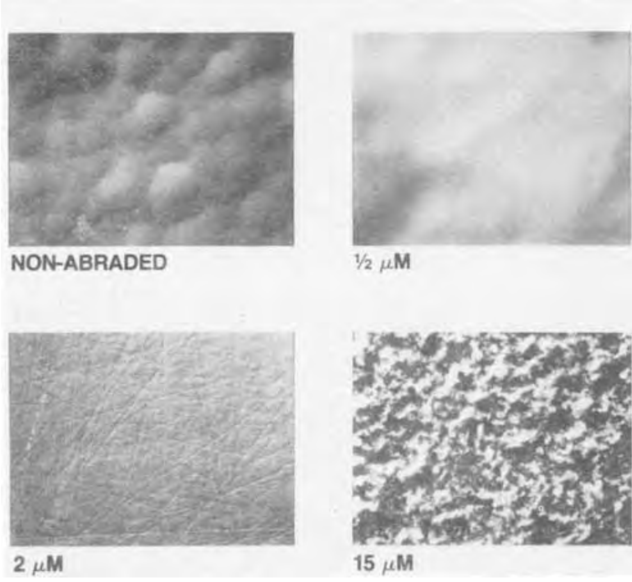

Fig. 4. Topographies of the nonabraded and abraded back surfaces at 400×.

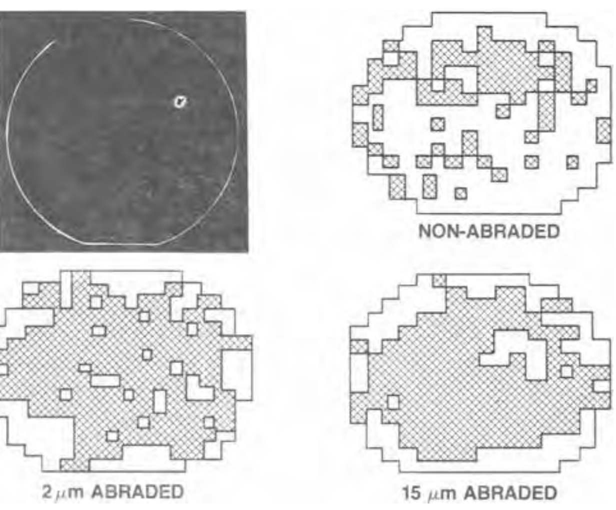

Fig. 6. I_R mappings of the gettered and ungettered swirl samples in comparison with the swirl pattern. The cross-hatched area contains devices whose I_R's ≤ 10 pA/mil^2.

they do not offer information on how the gettering benefit was derived. A substantial portion of this information can be obtained from the analyses of I_R-V_R curves. In Fig. 7, schematic I_R-V_R curves of an ideal, defect-free, and a single dominating defect affected diode (3, 22-24) are compared. These curves are drawn to reflect only the general shape but not the actual magnitude of the current. A total of four linear regions between these curves are distinguishable through their associated slopes. The truly interesting differences between these curves lie in the voltage range of $> kt/q$ and $< BV_R$, where k is the Boltzmann's constant, T is temperature in degrees Kelvin, and q is the electronic charge. In this voltage range, the curve for ideal diode has a zero slope, for defect-free diode has a slope <1 (0.33-0.5), and for defect affected diode has two linear regions whose slopes are <1 (region II) and >1 (region III).

Since the material and the fabrication processes of this work were controlled, I_R in region II can be assumed to reflect the concentration of the deep level traps in the depletion region of the junction (23). The possible candidates for these traps include point defects such as metallic impurities. The excess I_R in region III is caused by the precipitation of metallic impurities around a defect in the crystal lattice (3, 22-24).

The I_R-V_R curves of "typical" diodes for the four groups are given in Fig. 8, and a "typical" diode for this work is defined as the device whose I_R at ½ $\overline{BV}$ is equal to the geometric mean of the I_R distribution. The actual measurements covered the voltage range from 10 mV to avalanche; however, only the regions of particular interest are shown in Fig. 8. The dashed line on the far right marks the avalanche voltage, and the other dashed line approximately designates the ½ $\overline{BV}_R$ value.

Even though the curves in Fig. 8 are not clearly segmented, the drastic increase in slopes is apparent. It is reasonable to assume that 0.1V, which is $> kT/q$ (0.026V for 300°C), and 20V, which is $< BV_R$, are well into regions II and III, respectively. The corresponding differences in I_R's for the gettered and ungettered swirl material are approximately one and two orders of magnitude for the two respective voltages. The differences between the two abraded groups and the nonabraded swirl-free group is too small to be definite. These trends are further confirmed by the $\bar{I}_R$-$\bar{V}_R$ curves in Fig. 9. As previously discussed, the I_R's in

regions II and III are related to the metallic impurities. Therefore, a logical implication of these results is that a substantial portion of the gettering benefit was derived from the reduction of metallic impurities in the depletion region of the device.

Defect model interpretation of results.—The experimental data points toward two prominent results: the reduction of etch pit density and the decreasing magnitude of I_R which is interpreted as a reduction in metallic impurities. Preferential etching, as applied here, delineates strain field differential in the Si lattice, and its sensitivity is limited by the etchant's reactivity. The reduction of density and size of the etch pits is commonly interpreted as a reduction in density and size of the corresponding defects in Si.

The reported physical models of swirl defects are complexes of impurities (carbon and oxygen) and intrinsic point defects (25, 26) (Si interstitial and vacancy). Since Si is the host lattice, it is logical to assume that the size of the swirl defects is dominated by the component of the intrinsic point defect. The associated strain field of the defects would attract metallic impurities (extrinsic point defect), and consequently the swirl defects become impurity decorated.

In light of these defect models, the experimental results suggest that the damage layer and its thermally generated defects act as diffusion sinks for the fast diffusing point defects (27, 28). These enhanced solubilities (29) for the point defects in the damage region create concentration gradients in the nondamage region of the Si wafer. In turn, the concentration gradients act as the driving forces for the redistribution of these point defects.

After these gettering actions, the original defect nuclei of C-, O- intrinsic defect associates probably remain because, for the thermal temperature and time of this work, the diffusion lengths of C and O are insignificant in comparison to the fast diffusing species (30). However, the defect can become smaller in size and less decorated with impurities. This decrease in size explains the observed reductions of etch pit density and size in the preferential etching study.

Summary and Conclusions

The effects of back abrasion damage gettering on Si material with heavy swirl defect concentration were studied by the techniques of preferential etching and electrical characterization of p^+n diodes. The damage layers were applied via lapping the conventionally shaped wafer with slurries whose mean particle sizes were 0.5, 2, and 15 μm. Optical microscopy of the damage layers indicated that the 0.5 μm lapping produced a polishing rather than an abrasion effect. In addition, preliminary electrical results indicated that it produces no definite improvement in the diode distribution as a function of I_R.

The etching studies revealed that gettering with the 2 and 15 μm abrasion can reduce the etch pit density by 3 orders of magnitude from 5×10^5 to $<5 \times 10^2/cm^2$. This observation resulted more from a defect size than an actual defect density reduction. OISF's were not detected in any experimental or test wafers.

A corresponding improvement was observed in the statistical data of I_R histograms and maps of the p^+n diodes. This improvement, as inferred from I_R-V_R analysis of the "typical" devices, likely resulted from the reduction of metallic impurities within the active region of the device. Both of the electrical and etch results can be explained by the current understanding of swirl defects, mass transport phenomena, and gettering action.

In conclusion, this "base line" oriented back abrasion gettering process was able to improve the quality of material with a high swirl density to approach that of swirl-free.

Acknowledgments

The authors wish to express appreciation to Lee Campbell for application of different degrees of back damage to the wafers, Vaughn Akins for use of his electrical test facility, Charles Varker for many helpful discussions, and Beth Gersitz for careful typing of the manuscript.

The Photocorrosion of N-Cadmium Telluride and Its Suppression

J. S. Curran[1]

Commission of the European Communities, Joint Research Centre, Ispra Establishment, 21020 Ispra (Varese), Italy

ABSTRACT

The photoelectrochemical properties of n-type cadmium telluride were studied in water and five other organic solvents, with a view to suppression of the photocorrosion reaction which prevents this and other n-type small bandgap semiconductors from being used in a practical semiconductor-electrolyte junction solar cell. Only the low donicity organic solvents propylene carbonate and methyl nitrate reduce the corrosion rate significantly. A stable photocurrent can be obtained using a solution of ferrocene in these two solvents but analysis of photoelectrolyzed solutions revealed a slow photocorrosion. The dependence of the flatband potential and of the photocorrosion kinetics on the solvent is discussed, and the practical significance with respect to solar cell applications considered.

The current upsurge of interest in the behavior of the semiconductor-electrolyte interface reflects its possible application in the field of solar energy conversion, as recent review papers have stressed (1, 2). A major technical difficulty which must be overcome before any such application can be considered realistic is the persistent tendency for the small bandgap semiconductors (*i.e.*, those of interest for solar energy conversion) to undergo photocorrosion reactions, leading to the destruction of the electrode. This remains a fundamental obstacle whether the cell is regenerative or is designed to produce a fuel, and is exacerbated if the photoelectrode takes the form of a thin film. Any photocorrosion current flowing simultaneously with the current supporting the cell process must be extremely small if the cell is to operate over a period of years.

N-cadmium telluride typifies this problem; the only electrolyte which has so far been shown to stabilize this material contains toxic, colored, and air-sensitive polytelluride and telluride ions (3). Hence n-cadmium telluride was chosen as a basis for discussion of the general problem and as a model material to investigate experimentally the stabilizing ability of various organic solutions.

For n-type compound semiconductors the basic photocorrosion process in indifferent electrolyte is the dissolution of the more electropositive component; for n-cadmium telluride

$$CdTe + 2h^{\oplus} \rightarrow Cd^{2\oplus}(solution) + Te(solid) \quad [1]$$

If species are present in solution which are active towards cadmium (or tellurium) the reaction may be modified, *e.g.*,

$$CdTe + 2h^{\oplus} + 4I^{\ominus} \rightarrow CdI_4^{2\ominus} + Te \quad [2]$$

$$CdTe + 2h^{\oplus} + 2\,OH^{\ominus} \rightarrow Cd(OH)_2 + Te \quad [3]$$

The overall free energy change is more negative in reactions [2] and [3]. Furthermore, if the active species participates in the rate-determining step of the electrode kinetics then the corrosion will be accelerated.

For a stable regenerative cell there must be a successful competition with such corrosion reactions by a reversible redox reaction

$$Red + h^{\oplus} \rightarrow Ox \quad [4]$$

Clearly reactions of type [2] and [3] should be avoided, but an anion which can promote reaction [2] may instead perform a redox reaction, as is reported to be the case for iodide ion in acetonitrile at illuminated cadmium sulfide (4).

Since the intermediates and the final product of the corrosion process are stabilized by partial or complete solvation, the solvent itself can influence the rate of this process. The influence of a change of solvent on the overall free energy change for process [1] is calculable from the free energy of transfer of the single metal ion. This, in turn, is calculable from electrochemical potential measurements under an extrathermodynamic assumption such as the TATB assumption (5).

Using such data it is not difficult to find a solvent which makes the overall thermodynamics of reaction [1] less favorable by up to 100 kJ/g ion (1 eV). There are, however, additional factors to consider, the first being that the solvent must dissolve sufficient inert salt to furnish a high conductivity. This requirement excludes very poor solvents of metal ions, restricting the choice to a very few organic solvents which have been used in electrochemical studies. Even a conductivity of $5 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$, regarded as "high" for an organic electrolyte, would lead to a substantial ohmic loss within a solar cell unless the electrolyte layer were very thin.

In this work the Gutmann Donicity Number was used as a guide to the choice of solvent. This empirical parameter correlates well with both thermodynamic and kinetic constants for solvent-related processes (6). A low donicity number indicates poor cation solvation. The five solvents used in this work were chosen to see if there is a correlation between corrosion rate and donicity number.

The redox system must be very soluble, stable chemically in both oxidation states, absorb little visible light, and possess a redox potential between the bandedges of the small bandgap semiconductors (1, 2), *i.e.*, not far from the potential of the standard calomel electrode. This makes for an extremely restricted choice once more. The only class of compounds which may be able to meet all these demands is that of the substituted ferrocenes, which have already been used successfully to prevent corrosion (7, 8).

In this investigation ferrocene ($E_0 = 0.37$(SCE), $k_0 = 0.7$ cm sec^{-1}) (9) and iodide ion were used, the latter because of its reported ability to stabilize cadmium sulfide in acetonitrile (4).

[1] Present address: Laboratoire de Chimie, 69130 Ecully, France.

Key words: organic, electrolyte, semiconductor, stabilization, photoelectrochemistry.

Experimental

Single crystal slices of n-doped (1.2×10^{17} cm^{-3}) CdTe, already ohmically contacted on the back surface were obtained from Battelle Laboratory, Frankfurt. An additional thick gold layer was sputtered over the contacting film and a wire attached by silver epoxy. The whole was then sealed in a robust plexiglass or glass support with epoxy resin. This assembly was incorporated in a one-compartment sandwich cell, volume 2 ml, with a platinum grid counterelectrode behind a window.

Silicon rubber sealing rings were used. The reference electrode was always Ag/0.01M $Ag^{\oplus}$ and took the form of a Luggin capillary close to the photoelectrode. The reference electrode solution was normally made by *in situ* electrolysis of the silver wire in backing electrolyte.

Photoelectrochemical experiments with organic electrolytes were performed entirely inside a glove box flushed with dry nitrogen. Illumination was provided by a 500W high pressure xenon lamp in conjunction with filter solutions and a Spex monochromator.

Standard electrochemical apparatus supplied by Hi-Tek was employed in conjunction with a Hewlett-Packard 7045 A X-Y recorder. Because of the difficulty of making differential capacity measurements at high enough frequency to avoid the surface state capacity (10 kHz) in relatively poorly conducting organic electrolytes, Mott-Schottky plots were not used to measure the flatband potential (V_{FB}). Instead the method suggested by Butler was employed (10) which although it rests on some approximations is at least as reliable as the above alternative in this context.

The semiconductor electrode was polished with alumina down to 0.05 μm and then etched with a recommended solution (11) before each measurement. Chemicals used were all from commercial sources and were of reagent grade or better. Organic solvents and backing electrolytes were purified and dried according to procedures described in a comprehensive review (12).

For each solvent-solute combination the same procedure was followed. First an anodic potentiostatic scan was made, low intensity monochromatic light pulses being applied to obtain data for V_{FB} estimation. Thereby even in the presence of photocorrosion the total charge passed was low enough ($<10^{-3}$C) to obtain reproducible data. Then a higher photocurrent (≈ 1 m_{Acm}^{-2}) was passed under potentiostatic conditions and its decay with time (if any) followed. Finally, the CdTe electrode was removed and examined microscopically.

A more sensitive technique was used to detect small amounts of photocorrosion, atomic absorption analysis of resulting solutions for cadmium (13). Having passed some coulombs of photocurrent under potentiostatic control the resulting solution was wet-ashed and analyzed by standard techniques using a Perkin Elmer 5000 atomic absorption spectrophotometer.

Results

A survey of solvent-redox combinations to determine V_{FB} and stability under illumination is summarized in Table I. Figure 1 illustrates a typical i-V plot, and a corresponding i_p^2-V plot is given in Fig. 2. The intercept of this plot on the voltage axis gives an estimate of V_{FB} (10). Figure 3 illustrates the photocurrent-voltage behavior in the absence of any redox system, when only the pure photocorrosion process is occurring.

Ferrocene was found to have a strong stabilizing effect in both propylene carbonate (PC) and methyl nitrate (MN). This finding was further investigated in an experiment similar to Wrighton's (14). The solution undergoing controlled potential electrolysis was pumped through an optical cell and the absorption spectrum monitored. The optical density at 615 nm, a peak diagnostic of ferricinum ion (15) increased linearly with charge passed, confirming that the major product of photoelectrolysis was this ion.

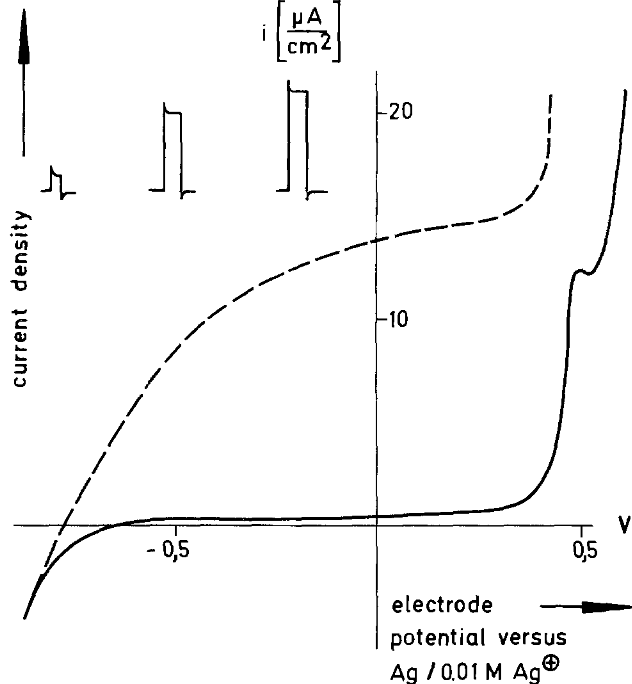

Fig. 1. Potentiostatic current-voltage plot for n-cadmium telluride in contact with methyl nitrate/0.1M $Mg(ClO_4)_2$/0.1M ferrocene solution. Voltage scan rate 10 mV sec^{-1}. Solid curve in darkness, dashed curve under weak monochromatic illumination, 650-750 nm. Reference electrode Ag/0.01M $AgClO_4$. Insets illustrate transient behavior.

The atomic absorption analysis technique was used to determine quantitatively the extent of corrosion suppression in MN and PC. The results are displayed in Table II. In these experiments the counterelectrode is able to remove some dissolved cadmium ion (it is very difficult to design a cell which avoids this) but a simple calculation shows the resulting underestimation of the photocorrosion is small. These measurements revealed that the qualitatively encouraging results of the earlier experiments in Table I were misleading and that considerable photocorrosion occurs. The corrosion rate appears to depend on the exact condition of the electrode surface, and is not reproducible.

The results for PC, in which ferrocene (saturated) has a low diffusion limited current (measured at a platinum electrode) show that as could be expected, the corrosion rate increases as the photocurrent approaches this value.

Some experiments were made with "as received" MN and PC/ferrocene solutions containing undried magnesium perchlorate, and also with electrolytes deliberately contaminated with a few percent water. Photocorrosion was increased in these solutions, but only slightly in the case of propylene carbonate.

In both MN and PC/ferrocene solutions with 1M tertiary butyl ammonium iodide as backing electrolyte photocorrosion occurs, though in PC the principal product of photoelectrolysis is evidently ferricinium ion, whose presence is easily observed because of its greenish color.

Discussion

An account of the photocorrosion process would be oversimplified if some attention were not paid to the kinetic complexity necessarily implied in a multi-electron process (16). Since a simultaneous two-electron process is unlikely because of the low density

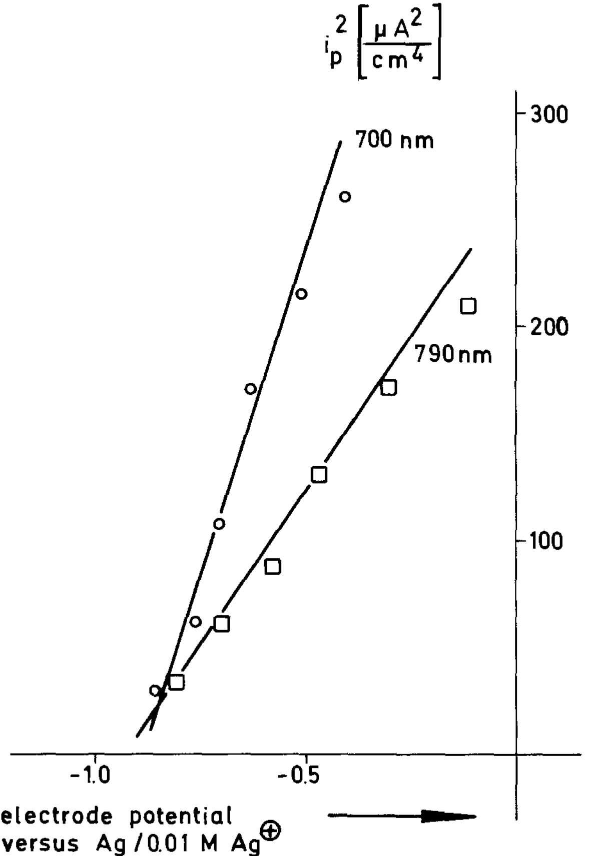

Fig. 2. Plot of photocurrent squared vs. voltage under potentiostatic conditions for n-cadmium telluride in contact with propylene carbonate/0.5M $Mg(ClO_4)_2$/0.05M ferrocene solution. Illumination 696-710 nm (○) and 780-800 nm (□). Reference electrode Ag/0.01M $AgClO_4$.

of states of holes at the surface under normal illumination at least one reaction intermediate is implied. The simplest representation is as follows

$$CdTe \underset{k_1}{\overset{h^{\oplus}}{\rightarrow}} CdTe^{\oplus} \underset{k_2}{\overset{h^{\oplus}}{\rightarrow}} CdTe^{2\oplus} \underset{k_3}{\rightarrow} Cd^{2\oplus} + Te$$

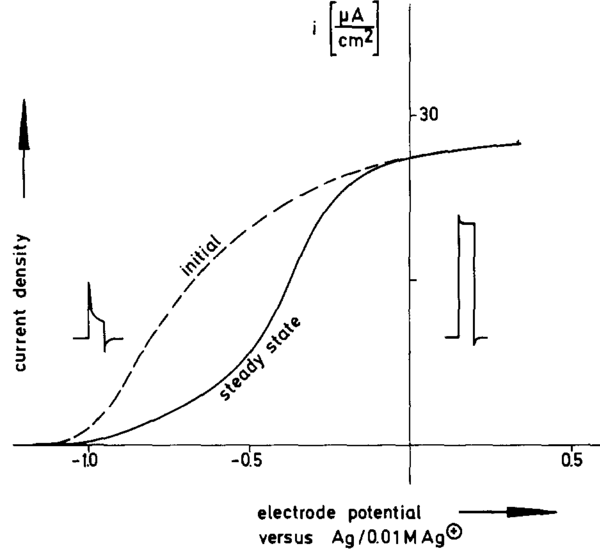

Fig. 3. Potentiostatic current-voltage plot for n-cadmium telluride in contact with propylene carbonate/0.1M $Mg(ClO_4)_2$ under weak pulsed illumination. Voltage scan rate 10 mV sec^{-1}, reference electrode Ag/0.01M $AgClO_4$.

The final step k_3 is only a rapid diffusional process if the bonding arrangement of the overall reaction is already complete; here it is assumed it may be a slow step.

If at potentials close to the flatband potential conduction band electrons can reach the surface and reduce the intermediates, then they act as recombination centers. Similarly at positive potentials it is possible for k_2 to be a conduction band (current doubling) process.

In the presence of a redox system the reduced species may be oxidized in principle by a hole at the valence bandedge or by any of the successive intermediates (17)

$$Red \xrightarrow[\text{or } CdTe^{n\oplus}]{h^{\oplus}} Ox$$

Table I. Flatband potentials and stabilities under illumination of n-cadmium telluride in various solutions

Solvent	PY	MeOH	H_2O	AN	PC	MN
Donicity No.	33	30	33	14.1	15.1	2.7

Diffusion-limited current			Approx. 1 mA cm^{-2}			Approx. 10 mA cm^{-2}	

Then the species Ox may be capable of the overall chemical interfacial reaction

$$CdTe + 2\,Ox \rightarrow Cd^{2\oplus} + Te + 2\,Red$$

or only of performing one of the oxidation steps. Ferricium ion (made by electrolysis of ferrocene solution) and iodine solutions in PC and MN left in contact with CdTe do not discernibly chemically oxidize it on the time scale of these experiments. Thus the corrosion processes observed at the illuminated electrode are due to holes in the first instance; the possibility that Ox performs only one of the oxidation steps is not ruled out.

Noticeably different forms of photocurrent-voltage plots are obtained in blank PC and MN electrolytes (Fig. 3) and when either iodide ion or ferrocene are present (Fig. 1). In the latter case, despite the fact that iodide ion does not strongly stabilize the photoelectrode while ferrocene does, the plot takes the form indicated for a system in which minority carrier generation is the rate-determining step (10) and good i_p^2-V plots can be obtained. In the former the steady-state quantum efficiency is decreased in the negative potential range, and a complex transient behavior appears. Nevertheless, the initial photocurrent (the peak of the photocurrent when a light pulse is applied) depends on the voltage in the same general way as above; i_p^2(peak)-V plots are good.

These facts are consistent with the explanation that the complex photocorrosion process leads to relatively slow charge transfer kinetics. The addition of iodide ion, which is probably adsorbed at the interface (see below) and which may form complexes with cadmium (18) accelerates the kinetics. The addition of ferrocene also accelerates the charge transfer kinetics, but this time by providing a rapid alternative route to the photocorrosion, hence suppressing the corrosion, but not completely. Recent calculations (19) show that slow charge transfer kinetics do indeed lead to the kind of curves illustrated in Fig. 3 under steady-state illumination. This analysis can in principle be extended to cases where some transient behavior is observed, as in Fig. 3, if it is assumed that the experimental system is able to accurately represent the initial photocurrent. When interfacial kinetic complications or recombination (or both) are important this initial current is partly nonfaradaic, but its value in the instant following the application of the light beam is nevertheless that of the hole flux initially reaching the surface. This in turn, under the appropriate conditions obeys the i_p^2-V relation (10). The results for n-CdTe in the low donicity electrolytes MN and PC typified by Fig. 3 can be interpreted in this way.

The flatband potentials listed in Table I do not depend on such an extended argument, since the very marked transient behavior of Fig. 3 was not observed with the solutions used. However a conservative assessment of the errors implicit in such measurements should recognize that the values may be too positive, to a small and varying extent.

If a probable error of ± 0.15V is attributed to the estimated V_{FB}'s in Table I, the figures are consistent with the hypothesis that relatively small variations in V_{FB} occur upon changing the solvent, as would be expected if solvent dipole orientation is the only source of surface charging (20, 21).

The simplest explanation of the negative shifts in V_{FB} in the presence of iodide ion is the specific adsorption of the ion occurs. Once again, since the V_{FB} values are based on i_p^2-V plots it is necessary to accept that this shift in principle may be due to more rapid charge-transfer kinetics at the interface, but it is unlikely that this effect can explain such large and consistent changes.

If it is accepted that the variations in both V_{FB} and the redox potential of ferrocene (22) upon a change of solvent are small and unimportant, it is difficult to reconcile the sensitivity of the ferrocene stabilization effect upon solvent change with a mechanism involving a hole at the valence bandedge. If ferrocene reduces one of the oxidized intermediates $CdTe^{\oplus}$ or $CdTe^{2\oplus}$, which possess partial solvation shells then the solvent influence is easier to explain, especially if $CdTe^{2\oplus}$ is the intermediate involved.

In both PC and MN it is apparent by the yellow color of the solution after photoelectrolysis that tertiary butyl ammonium iodide has a small stabilizing effect (electrolysis at platinum electrodes gives a yellow solution at the anode and no color at the cathode at the same current density). Sodium iodide in PC has no such effect. This must be attributed to a subtle difference in the composition of the Helmholz layer. Hence, once again, the direct oxidation of iodide ion by a hole at the valence bandedge seems unlikely to display such sensitivity to the Helmholz layer structure.

In terms of the kinetic scheme above and the subsequent assumptions the maximum possible corrosion suppression effect of low donicity solvent occurs when k_1 and $k_2 > k_3$ and the redox reaction is with $CdTe^{2\oplus}$. ΔG (transfer) for the $Cd^{2\oplus}$ ion from H_2O to a low donicity solvent can be estimated as 50 kJ/g ion (23). Since solvation can be partly developed for the $CdTe^{2\oplus}$ intermediate, the effect on the overall thermodynamics of the k_3 step will be somewhat less and that on the free energy of activation smaller still. This ultimately leads, in theory, to changes in the rate constant k_3 in the range of a factor of 10^{-3}, similar to those actually observed in electrochemical metal dissolution reactions (24). This figure is consistent with the extent of corrosion suppression effects found in this work and is of some practical significance for solar cells of this type. In order to function for some years at realistic current densities (10 mA cm^{-2}) the upper limit on i (corrosion)/i (redox) is in the region of 10^{-8}. Should the photoelectrode material photocorrode in aqueous electrolytes then this limit will not be reached by changing the solvent.

Conclusions

The failure of the various attempts recounted above to stabilize n-cadmium telluride to the degree necessary for use in a solar cell (in the absence of telluride ion) reveals the dangers of assuming that any given semiconductor which shows some degree of photocorrosion in aqueous redox systems can be satisfactorily stabilized by a pure organic electrolyte system. Although the data relates only to cadmium telluride the conclusion can be extended to other n-type semiconductors by virtue of the large difference between attained and required corrosion rates.

Though low donicity solvents like MN and PC disfavor corrosion processes, even lower donicity solvents cannot be used because of their inability to give sufficiently conducting solutions. Thus, there is a distinct limit to the potential stabilizing ability of organic solvents. The theory and experiments herein point to a very approximate factor of 10^{-3} as the best available suppression. This figure makes sense when it is compared with the influence of the solvent on the thermodynamics of the overall process.

This conclusion is complemented by considering the associated difficulty of electrical conductivity. Taking 0.005 Ω^{-1} cm^{-1} as an average value for the conductivity of a low donicity electrolyte means the electrolyte layer must be only 0.1 mm thick to reduce internal series resistance to an acceptable 2 Ω cm^{-2}. This in turn necessitates the use of a semitransparent counterelectrode acting also as a window, introducing further losses due to reflection, light absorption, sheet resistance, etc. Thin films of metal or metal oxide which can perform this latter function are not noted for their stability (25) and inevitably the cost and complexity of the cell is raised by their use.

There is some indication by analogy with the electrochemical dissolution of metals that mixed aqueous/organic electrolytes (26) and aqueous electrolytes containing surfactants (27) could suppress corrosion. Initial experiments in this laboratory were discouraging. In any case, the level of stabilization conceivable in such a system cannot again be expected to render an unstable photoelectrode useful in a solar cell.

Acknowledgments

The valuable contribution of Dr. W. Gissler towards this work is gratefully acknowledged, as is the technical assistance of Mr. A. Hoffmann and Mr. R. Schubert. The atomic absorption analysis was performed by Mr. P. Cavalli of the Joint Research Centre, Ispra. Dr. R. Memming gave some very constructive comments on the conduct of this work. The work described herein was entirely supported by a study contract with the Joint Research Centre. Ispra Establishment.

Anomalous Behavior on I-V Characteristic Curves of n-TiO_2 and n-$SrTiO_3$ Electrodes in Aqueous Solution

J. F. Julião,*[,1] Franco Decker,* R. Brenzikofer, and M. Abramovich**

UNICAMP, Instituto de Física, Campinas-SP, Brazil

ABSTRACT

Measurements of the *I-V* characteristics of n-TiO_2 and n-$SrTiO_3$ electrodes in aqueous KOH electrolyte in the dark show a deviation from the general behavior found in other semiconductor-electrolyte junctions, in the cathodic polarization region. The illumination of the semiconducting electrode with both u.v. and visible subbandgap light modifies these characteristics. We show that the observed phenomena are related to the reduction of oxygen dissolved in the electrolyte.

An interesting property of semiconductor-electrolyte (SE) junction devices is their ability to convert solar energy into either chemical (photoelectrolytic cell) or electrical energy (wet photovoltaic cell). This fact has drawn the attention of several researchers in the last few years (1-11). In particular, an understanding of the current flow mechanism should lend insight into chemical reactions occurring at the SE interface. In the present work we concentrate our study especially on the operation of these devices in the polarization region where electrons are transferred from the n-type semiconductor to the electrolyte (cathodic current).

In previous studies of SE cells (12, 13) it has been found that for an external applied voltage, V_{bias}, greater than several kT ($T \simeq 300°K$), the cathodic current, i, is given by

$$i = i_o \exp (bv_{bias}/kT) \quad [1]$$

where i_o and b are empirically determined constants. This behavior is illustrated by the dashed curve of Fig. 1. Equation [1] shows that the current in SE junctions has a behavior similar to that of Schottky-barrier semiconductor-metal junctions (14), but with different values of the parameter b.

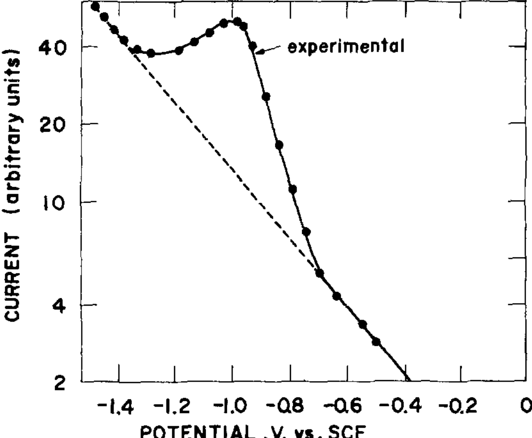

Fig. 1. Semilogarithmic plot of the current-modulus voltage characteristic of an n-TiO_2/1M KOH_2/Pt cell. The solid curve shows the experimental results taken in the dark and the dashed curve represents the Schottky barrier behavior according to Eq. [1] in the text. The scan rate was 4 mV/sec.

Morisaki *et al.* (15) and Mavroides (16), working respectively with TiO_2 and $SrTiO_3$ electrodes, found *I-V* characteristics which deviate from the behavior suggested by Eq. [1]. Here we reexamine this anomalous behavior, previously reported. Our experiments, performed with n-TiO_2/1M KOH/Pt and n-$SrTiO_3$/1M KOH/Pt open to air-type cells, also showed for both materials, in the dark and under illumination, the anomalous *I-V* characteristics, namely, a cathodic current peak (Fig. 1). This peak occurs around -1.0V *vs.* SCE for TiO_2 and around -1.2V *vs.* SCE for $SrTiO_3$; its magnitude and position, in the dark and under illumination, are slightly different. Hardee and Bard (17) also have previously observed an increase in the cathodic current, comparing TiO_2 electrodes under illumination and in the dark. They suggested that the increase may be due to reduction of dissolved oxygen generated when a reverse scan into the negative potential region was made.

In order to investigate the origin of the observed peak we have performed further experiments varying the O_2 concentration in the electrolyte and the illumination condition of the semiconducting electrode.

In both materials we observed a sensitivity to subbandgap light when polarized in a potential region between ~ -1.2 and ~ -1.4V *vs.* SCE, which is dependent on the potential and O_2 concentration. From these observations and the results obtained with chronoamperometry we suggest a new explanation different from that given previously by Morisaki and Mavroides.

Experimental

The TiO_2 and $SrTiO_3$ monocrystals supplied by Materials Research Company and N. L. Industries Incorporated, respectively, were cut perpendicular to the (001) axis. The surface to be illuminated was polished with 0.2μ diamond powder. The samples were reduced in an H_2 atmosphere at temperatures near 1000°C, for periods varying from 30 to 60 min for TiO_2 and from 1 to 3 hr for $SrTiO_3$, in order to produce n-type semiconductors. Subsequently, an ohmic contact was made at one sample surface by evaporation of a Cr and Au double layer, and a copper wire was attached to the contact by means of Ag paste. The samples were then encapsulated in polyester, leaving only the front surface free for contact with the electrolyte. We used a single compartment Teflon cell, open to air, containing an aqueous solution (1M KOH), a TiO_2 or $SrTiO_3$ working electrode, a Pt counterelectrode (about 10 cm^2 area), and an SCE reference electrode. As a light source, we used a 1000W ultrahigh pressure xenon lamp (infrared filtered by 10 cm of distilled water) focused on the entrance slit of a monochromator (Spex 14300). The visible light was obtained with the same lamp, crossing an Oriel LP-47 filter. Current-potential curves were obtained using a potentiostat circuit (18) with a sensitive current-to-voltage converter (10 nA) and a low phase shift for frequencies up to 100 kHz coupled to a triangular wave generator. The *I-V* curves were recorded on a Hewlett Packard Model 7004B X-Y recorder at a scan rate of 4 mV/sec in the sense of anodic to cathodic polarization. Figure 2 shows the scheme of this arrangement. The 1M KOH solutions were prepared from commercially available reagents, P.A. grade.

The *I-V* curves for each sample were recorded with the semiconducting electrode in the three following illumination conditions: in the dark, under visible radiation ($\lambda > 4700$Å), and under u.v. radiation ($\lambda = 3250$Å).

A first set of measurements was made with an electrolyte under standard conditions in contact with room atmosphere. Two other sets of measurements were performed by passing either N_2 or O_2 bubbles for several minutes before starting each voltage scan, in order to study the dependence on the degree of oxygenation. Before each experiment, the electrolyte was carefully stirred. We emphasize that in cells which remain open to air, such as the one described, it is not possible to obtain complete deoxygenation of the solution.

Experimental Results

Figures 3a and 3b show the *I-V* characteristics for typical samples of $SrTiO_3$ and of TiO_2, respectively, under three different irradiation conditions: in the dark, visible ($\lambda > 4700$Å), and u.v. ($\lambda = 3250$Å) light, with the electrolyte in contact with air. In the interval of cathodic polarization on the current voltage curves shown in Fig. 3a and 3b, we distinguish three regions: (*i*) the low polarization region, when $V_{on} < V < 0$, V_{on} being the voltage in which the anodic photocurrent starts to increase ($V_{on} \simeq -0.75$V for TiO_2 and $\simeq -0.90$V for $SrTiO_3$); (*ii*) the middle polarization region, where $V_H < V < V_{on}$ ($V_H \simeq -1.5$V is the voltage at which significant H_2 evolution at the SE junction occurs and depends on the amount of O_2 dissolved in the solution; (*iii*) the high polarization region, when $V < V_H$. A common characteristics of the curves in these figures is that for $V < V_{on}$ the cathodic current presents a peak and a valley structure. The peak values are around -1.0V in TiO_2 and -1.2V in $SrTiO_3$. This phenomenon is unexpected in the rectification characteristics of semiconductor-liquid junction cells described by Eq. [1], unless some electroactive species dissolved in the electrolyte or sticking to the electrode surface is being reduced at these potentials.

In addition, for $V_H < V < V_{on}$, Fig. 3a and 3b show that when the cell is under u.v. radiation the current peak is enhanced and slightly shifted in the direction

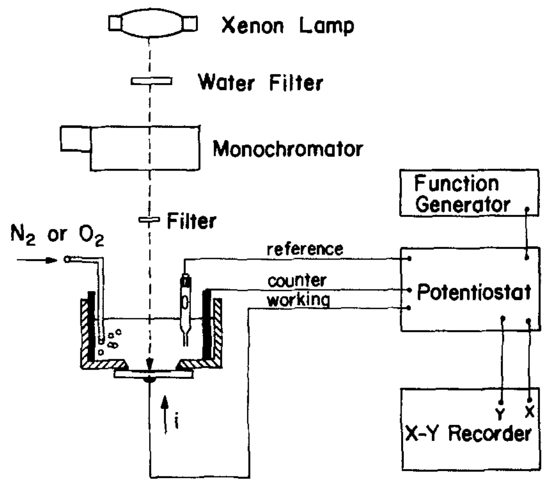

Fig. 2. Experimental setup for electrochemical measurements

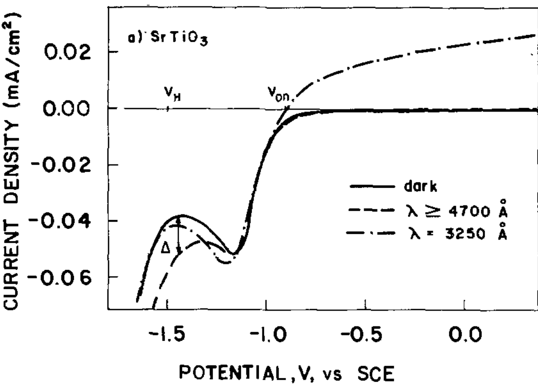

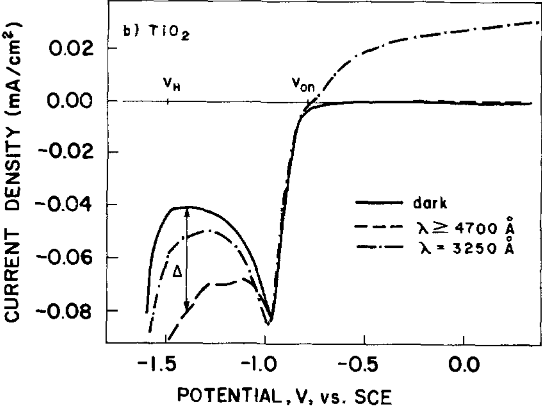

Fig. 3. Current-voltage characteristics of semiconductor-electrolyte junction under three different irradiation conditions. (a) $SrTiO_3$ electrode, (b) TiO_2 electrode. Δ is defined in the text. The scan rate was 4 mV/sec. Radiation intensity was 500 $\mu W/cm^2$ for $\lambda = 3250Å$ and 50 mW/cm^2 for $\lambda \geq 4700Å$.

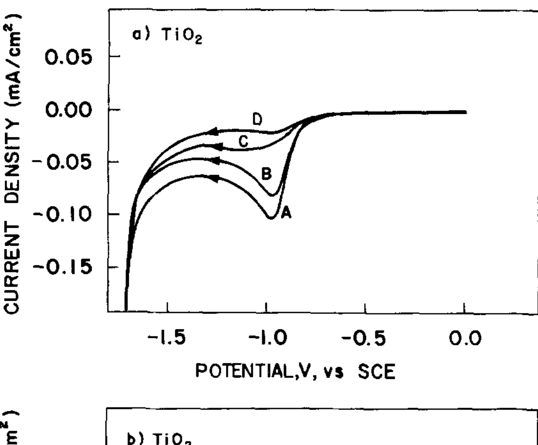

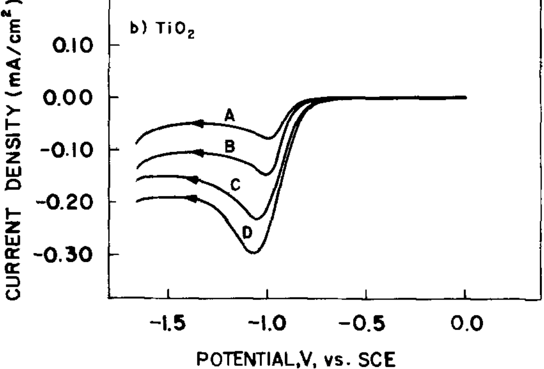

Fig. 4. Dark I-V characteristics of an n-TiO_2/1M KOH/Pt cell. The scan rate was 4 mV/sec. (a) Effect of bubbling through the electrolyte: (A) first scan, no gas bubbling; (B) after N_2 bubbling for 2 min; (C) after N_2 bubbling for 7 min; (D) after N_2 bubbling for 12 min. (b) Effect of O_2 bubbling through the electrolyte: (A) first scan, no gas bubbing; (B) after O_2 bubbling for 2 min; (C) after O_2 bubbling for 4 min; (D) after O_2 bubbling for 6 min.

of more negative potentials and that an additional current stimulated by visible light appears. In these figures, the quantity Δ describes the variation I (dark) $-$ I (visible) for $V = -1.4V$. Morisaki *et al.* (15), working with TiO_2 cells, have called a similar behavior, observed with visible light, "anomalous photoresponse," since it was produced with photons of lower energy than that of the semiconductor bandgap. The same phenomenon has been previously observed by Mavroides (16) with $SrTiO_3$ electrodes.

In order to understand how O_2 dissolved in the electrolyte affects the above results we have repeated the experiments with different O_2 concentrations in the solution. We have reduced the O_2 concentration by bubbling N_2 through the electrolyte and increased the O_2 concentration by either bubbling O_2 or by adding a small quantity of hydrogen peroxide, which becomes oxidized in basic solution (19). Our results show (Fig. 4) that the I-V characteristics are affected only for $V_H < V < V_{on}$. When the solution is submitted to a gradual deoxygenation, we observe a decrease in the absolute value of the cathodic current peak amplitude for the nonirradiated semiconductor electrodes, as shown in Fig. 4a. When increasing the concentration of O_2 in the electrolyte, the current peak increases and shifts in the direction of more negative potentials for the nonirradiated electrode as shown in Fig. 4b. At the same time the position of V_H also changes in the same direction. We have also examined the effect of several successive voltage scans in this region at a rate of 4 mV/sec, with the solution in air equilibrium or after bubbling N_2 for 30 min. In the first condition the peak amplitude diminished and reached a limit value of $\sim$40 $\mu A/cm^2$. In the second condition the peak disappeared and the I-V curve reached a plateau with the current at a value of $\sim$10 $\mu A/cm^2$.

We have also observed a correlation between Δ and the O_2 concentration in the solution. After bubbling N_2 through the cell for enough time, in order to minimize the quantity of dissolved O_2, Δ reaches a small limit value (Fig. 5, curve B). When the O_2 concentration in the solution is increased, Δ also increases (Fig. 5, curve A).

In order to investigate further the influence of visible irradiation on the O_2 reduction process, we have performed an experiment recording the current *vs.* time response of the cell when submitted to a $-1.2V$ potential step (chronoamperometry). The results were recorded with the semiconductor in the dark and under visible light; in both cases the electrolyte was air saturated.

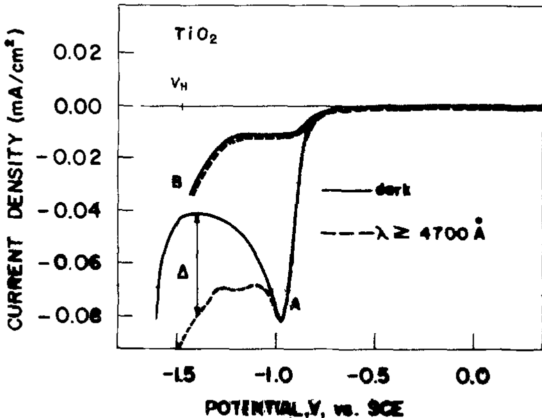

Fig. 5. Current-voltage characteristics of an n-TiO_2/1M KOH/Pt cell: (A) with electrolyte in equilibrium with air; (B) after bubbling N_2 for 40 min. The solid curves were taken in the dark and the dashed curves with subbandgap radiation.

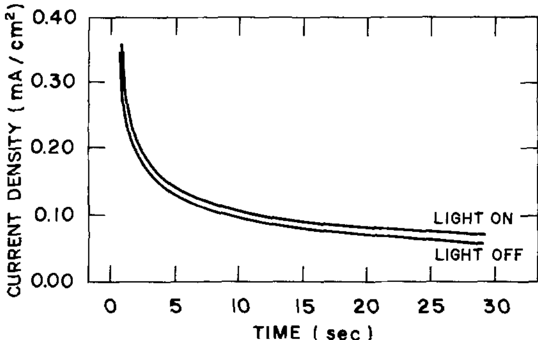

Fig. 6. Current vs. time response of the cell, submitted to a potential steps of −1.2V vs. SCE.

In the last experiment the cell was allowed to reach thermal equilibrium with light on, before applying the potential step. The results are shown in Fig. 6.

Discussion

It is generally known that in the semiconductor, near the interface with the electrolyte, a potential barrier or band bending, V_B, appears as a consequence of the electric field which is intrinsic to the space charge region. This band bending prevents the conduction band electrons from reaching the semiconductor surface, and it can be reduced to zero when an adequate cathodic polarization of value equal to the flatband potential, V_{FB}, is applied to the semiconducting electrode. The flatband potential, V_{FB}, for TiO_2 and $SrTiO_3$, according to most authors (8, 20, 21) is approximately −1.0 and −1.2V, respectively, in a 1M KOH electrolyte. A simple energy diagram (Fig. 7) shows the behavior of the TiO_2-electrolyte junction, taken as an example, for three different values of the applied voltage. For an unbiased cell, no net charge transfer occurs through the junction except in the presence of light with energy greater than the semiconductor bandgap. For bias close to the flatband potential, V_{FB}, (Fig. 7B) the conduction electrons

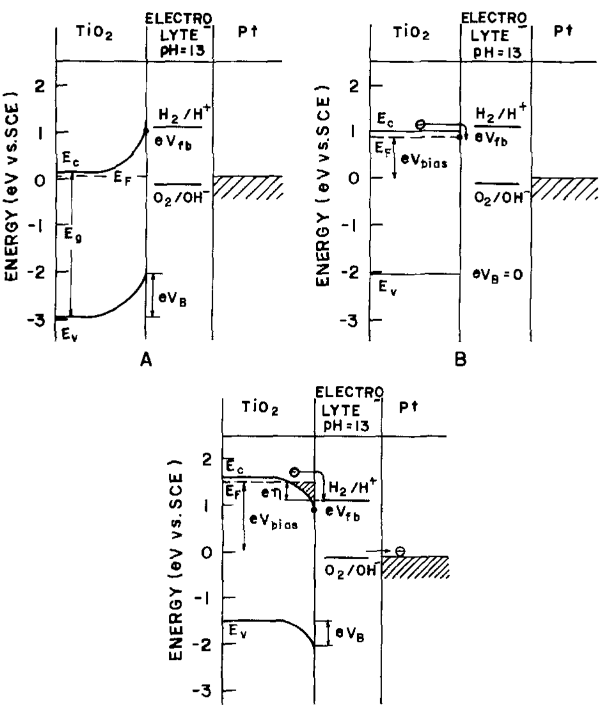

Fig. 7. Combined energy diagram for a TiO_2/1M KOH/Pt cell: (A) without external bias, TiO_2 and Pt short circuited; (B) under cathodic polarization of TiO_2, $V_{bias} = V_{FB}$; (C) under cathodic polarization of TiO_2, $V_{bias} \geqq -1.5V$.

reach the semiconductor surface and can react with the electroactive species possibly present at the interface. As shown in Fig. 3a and 3b, the cathodic current reaches a peak at potentials near V_{FB} for TiO_2 as well as for $SrTiO_3$. This peak shows a strong dependence on O_2 concentration (Fig. 4a and 4b), which suggests that it is associated with the reduction of dissolved O_2. The results obtained when the electrolyte was submitted to several successive scans confirms this hypothesis. For an alkaline solution the reduction at the semiconductor cathode might be a four-electron reaction as given by Eq. [2] (16)

$$4e^- + 2H_2O + O_2 \rightarrow 4\,OH^- \quad [2]$$

The energy level of the O_2/OH^- redox couple is about 1.2 eV below the conduction bandedge (22). It would appear, therefore, that if we assume that the electron transfer from the TiO_2 to the O_2/OH^- couple has to be iso-energetic (23, 24), a surface state located at the same energy as the O_2/OH^- couple should exist to mediate it.

Wilson (25) also observed a peak in the *I*-V characteristics of TiO_2 in the same polarization region but he interpreted it as an evidence of a bound charge-transfer state which acts as an intermediate in the oxidation of the solvent.

For $V_{bias} < V_H$ (Fig. 7c) there is a current step which is due to the water reduction through the reaction

$$4H_2O + 4e^- \rightarrow 2H_2 + 4\,OH^- \quad [3]$$

while at the Pt anode the reaction would be described by

$$4\,OH^- \rightarrow 2H_2O + O_2 + 4e^- \quad [4]$$

accomplishing, therefore, the electrolysis of water.

The enhancement and the shift of the cathodic current peak, when the cell is under u.v. illumination (Fig. 3a and 3b) can be explained as an additional reduction of the oxygen produced at the semiconductor surface in the anodic region current. This agrees with the detected behavior of the cathodic current peak when the O_2 concentration in the electrolyte is increased (Fig. 4, curve A).

The correlation observed between Δ (additional current stimulated by subbandgap radiation) and the oxygen reduction reaction could be attributed to one of the following alternatives: (*i*) excitation of electrons from the valence band directly to surface states, possibly associated with adsorbed species, and then transferred to redox couples O_2/OH^- in the electrolyte. The time constant for this overall process was observed to be of the order of 1 min in Ref. (15, 16); (*ii*) additional reduction (by conduction band electrons) of the dissolved O_2, because of the continuous renewal of the electrolyte near the interface by a convection process due to heating of the semiconductor surface under illumination.

The results of chronoamperometry were used to solve the ambiguity between the alternatives mentioned in the previous paragraph and to get more precise information about the O_2 reduction at the semiconductor interface. This experimental technique was applied to semiconductor electrodes on the basis of the following considerations. In most n-type semiconductors a potential barrier at a nonbiased SE interface prevents the bulk electrons from reaching the surface and reacting with electrochemical species at the expected potential. In our case, this implies that the O_2 reduction will occur at a potential slightly more negative than V_{FB} (Fig. 5 and 7A). Below this potential value, the electrode behavior becomes metal-like in respect to charge transfer to the electrolyte. In usual chronoamperometry, the potential of a metallic electrode is stepped to a region that is far removed from the equilibrium value. Therefore, this technique is particularly suitable for a semiconducting electrode if a potential step overcoming V_{FB} is applied.

The theoretical prediction for the decay current density, when the reaction is purely diffusion controlled, is described by the equation

$$I = n\mathbf{F}AD^{1/2}Co\pi^{-1/2}t^{-1/2} \quad [5]$$

where **F** is Faraday's constant, D is the diffusion coefficient, Co is the concentration, and n is the number of electrons that are transferred at the electrode in the diffusion reaction.

In Fig. 8 we show the plot I *vs.* $t^{-1/2}$ for a potential step of -1.2V *vs.* SCE, both in dark and with illumination. It can be seen that the experimental points in both cases are colinear as expected for diffusion-controlled processes (see Eq. [5]). Using the values of *Co*, *D*, and **F** given in Ref. (26), we have obtained 3.8 ± 0.3 for the slopes of the straight lines, which confirms the mechanism proposed for the O_2 reduction in Eq. [2] with the transfer of 4 electrons from the semiconductor to the solution.

The experimental points in Fig. 8 indicate that the diffusion-controlled mechanism for the decay current is valid for $t > 1$ sec. This is only compatible with the second alternative, mentioned before, that points out that the reduction rate is increased due to a convective flow stimulated by light heating. An electron transfer with time constant of the order of 1 min, associated with subbandgap light absorption, would not cause the straight line behavior observed in Fig. 8. We suggest that chronoamperometry could be used to study similar processes in semiconductor-electrolyte junctions.

In a separate publication (27) we show that the photocurrent Δ in Fig. 3 is a purely thermal effect and cannot be attributed to a subbandgap transition even if the photocurrent time constant is less than 1 sec.

Summary and Conclusions

The I-V characteristics of n-TiO_2/1M KOH/Pt and n-$SrTiO_3$/1M KOH/Pt cells were obtained in the cathodic polarization region in normal air equilibrium conditions or after N_2 or O_2 bubbling the electrolyte and under different illumination conditions. A deviation from the general behavior in SE junctions was observed and it is ascribed to a reduction at the semiconductor surface of the oxygen dissolved in the electrolyte.

The observed deviation in the *I-V* characteristics is sensitive to semiconducting electrode irradiation both with u.v. and with visible subbandgap light. Furthermore, we show that these photoeffects are entirely related to the electrolyte conduction rather than to a sensitivity of the semiconductor electrode when it is biased within the polarization region considered.

On the Oxidation Kinetics of Silicon: The Role of Water

D. R. Wolters

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

The theory of the kinetics of the thermal oxidation of silicon is extended after critical examination of the solubility and transport behavior of water in silica. From the solubility data for water in silica reported in the literature, the dissolution appears to be a two-stage process at temperatures up to 1200°C. In the first stage silanol groups are formed at a relatively slow rate. In the second stage these silanol groups react with water forming hydronium ions (H_3O^+) and silicate ions ($\equiv SiO^-$) fixed to the silica network. The second stage is relatively fast compared to the first stage. Consistent with this the transport of water appears to occur by the ambipolar diffusion of hydronium (H_3O^+) and hydroxyl ions (OH^-). The dissolution and transport of water predict a linear-parabolic rate law, which differs slightly from the one obtained by Deal and Grove. The catalytic role of water in mixed ambients is explained by a simple interaction between O_2 and H_2 formed by the oxidation of Si by H_2O. An expression for oxide growth accounting for this interaction is derived and properly fits the experimental data reported in the literature. It predicts correctly the linear dependence of the parabolic rate constant and the square root dependence of the linear rate constant on water partial pressure. It predicts also the initial growth regime.

The well-known linear-parabolic law for growth of oxide layers on silicon from Deal and Grove (1) is expressed by the equation

$$x_o^2 + Ax_o = B(t + t_{in})$$

Sometimes it is formulated with inverse constants (2)

$$k_{par}^{-1}x_o^2 + k_{lin}^{-1}x_o = t + t_{in}$$

In these equations x_o is the oxide thickness, t is the oxidation time, t_{in} is a correction term for so-called initial growth, $k_{par} = B$ is the parabolic rate constant, $k_{lin} = B/A$ is the linear rate constant. The relationship is derived by equating the flux of diffusing species through the layer to the fluxes at the two interfaces of the silica layer under the condition of a steady-state growth. Hence

$$h(c^* - c_{out}) = D\frac{\partial c}{\partial x} = kc_{in}$$

where c^*, c_{out}, c, and c_{in} are the concentrations of the oxidant in the ambient, outer surface, in the silica layer, and at the Si/SiO_2 interface, respectively, h and k are reaction rate constants, and D is the diffusion coefficient. By solving the differential equation subject to the boundary conditions it follows that $k_{par}(\text{or } B) = Dc$ and $k_{lin} = c(1/k + 1/h)^{-1}$.

The experimentally found parabolic rate constant k_{par} is proportional to the partial pressure of the oxidant. This proportionality would follow when $c \propto p(\text{oxidant})$ which suggests that Henry's law is obeyed. The solubility of oxygen in silica has not been measured directly in terms of concentrations and pressures. From diffusion or permeation data it might be concluded that the solubility is proportional to oxygen pressure. As we shall see such a conclusion is possibly unjustified as long as the precise mechanism of transport is unknown.

The solubility of water in silica varies with the square root of water pressure (3) and this is contradictory to the assumption, made in the Deal-Grove theory, that Henry's law is obeyed. This was already noted by Revesz (4). Because the reaction at the Si/SiO_2 interface is supposed to be of first order the linear rate constant $k_{lin} = B/A$ is assumed to vary proportionally with water pressure. For the oxidation of Si in pure water vapor this linear variation has indeed been reported (5). In mixed ambients, however, k_{lin} varies obviously with the square root of water partial pressure as will be demonstrated below. This cannot be accounted for by the theory of Deal and Grove. The anomalous variation of k_{par} and k_{lin} with water pressure demands a critical reexamination of the physicochemical model for dissolution and transport of oxidant in silica layers on silicon.

In the present paper a model for water incorporation is presented. The transport mechanism is derived from reported hydrogen profiles (6). An alternative linear-parabolic rate law is obtained by considering the diffusion process as time dependent. The interaction of water and oxygen flow through silica is deduced by considering the reaction of hydrogen, generated by the reaction of Si and water, and oxygen. The criteria to discriminate between the time-dependent diffusion and interface reaction-limited transport are given. The experimental evidence for the models are presented.

The Incorporation of Water in Silica

When water is incorporated in silica at very high temperatures (>1500°C) an Si-O-Si bond is broken to form two adjacent silanol groups (7). When water is incorporated at a lower temperature (*e.g.*, 1000°C) by diffusion into the silica it is generally accepted that water dissolves by the formation of silanol groups in the same way (3, 8, 9). An indication of this would be the square root relationship of solubility[1] and water pressure. It is known from the extensive literature on water in silica (3) that the water content of a silica sample is not unambiguously determined by temperature and water partial pressure when the silica is treated in water containing ambients at temperatures below 1200°C. The thermal history of a sample is an important variable determining the water solubility (3). However, the thermal history or as it is called "the fictive temperature" is itself determined by water uptake as has been concluded by Brückner (10) and confirmed experimentally by Shackelford (11, 12).

Key words: silicon dioxide, oxidation kinetics, water transport, time-dependent diffusion, initial growth mechanism.

[1] Solubility is used in the sense of equilibrium concentration of species resulting from a particular reaction of silica with water.

This dilemma is solved when two dissolution reactions are introduced with different reaction rates. One mechanism is assumed to dominate at high temperature; the other determines the dissolution at lower temperatures. At intermediate temperatures both reactions may proceed but in general with different reaction rates.

The two incorporation mechanisms which are proposed (13) are:

I. High-temperature incorporation

$$H_2O + \equiv Si-O-Si\equiv \rightleftharpoons 2 \equiv SiOH \quad [1]$$

in which two adjacent silanol groups are formed (7).

II. Low-temperature incorporation

$$H_2O + \equiv SiOH \rightleftharpoons \equiv SiO^- + H_3O^+ \quad]2]$$

here the silanol groups resulting from reaction [1] are hydrolyzed.

The hydrolization can proceed only when silanol groups are present, hence, when they are being formed by reaction [1] (or have been formed by [1] in a preceding high temperature treatment). In this section only the case in which mechanism I is frozen in will be considered. When the silanol concentration is constant the solubility can be approximated by the concentration of H_3O^+ ions resulting from reaction [2].

Since the electroneutrality condition demands that $[H_3O^+] = [\equiv SiO^-]$ one obtains

$$[H_3O^+] = ([H_3O^+]\cdot[\equiv SiO^-])^{1/2} \propto [\equiv SiOH]^{1/2}\cdot p_{H_2O}{}^{1/2} \quad [3]$$

As long as the silanol concentration is constant the solubility of water in silica is proportional to the square root of water pressure. When the silanol concentration is changed (*e.g.*, by thermal pretreatment) the low temperature solubility also changes.

This explains the variation of the solubility (3) at 750°C when samples were given thermal pretreatments at temperatures from 1000°-1300°C. Also the very slow changes of solubility when samples are kept at 1100°C for very long periods (3) can be explained by assuming two incorporation mechanisms of which one has a very slow reaction rate.

Transport of Water Through Silica

The nature of the diffusing species is investigated by inspection of the (H) profiles in oxide layers grown under steady-state conditions. In the first part the diffusion of single H_2O molecules is considered and the shape of the (H) profile is deduced. In the second part the diffusion of ionized water molecules (*e.g.*, $H_3O^+ + OH^-$) is considered. Comparison of the theoretical and experimental profiles makes clear which species must be taken into account.

Diffusion of single water molecules.—Breed and Doremus (14) analyzed hydrogen profiles of Burkhardt (6) and explained the minima found in the profiles by taking into account the reactions of water and hydrogen with silica. Their method is adopted here in a slightly different version. When water diffuses in steady-state conditions through silica it reacts with the network to form $\equiv$SiOH groups (or it reacts with a $\equiv$SiOH group to form $\equiv SiO^- + H_3O^+$, as discussed above). The $\equiv$SiOH groups are not mobile and the diffusion can proceed only when the reaction is reversed and water is formed from silanol groups. In such a situation the majority of water molecules can be present in the reacted form ($\equiv$SiOH) and only a minority in the mobile form (H_2O). Finally the water molecules react at the Si interface where they are converted into oxide and hydrogen. The reaction equation is

$$H_2O + 2Si \rightarrow \equiv Si-O-Si \equiv + H_2 \quad [4]$$

The hydrogen formed at the interface diffuses back through the silica. Just as water the hydrogen reacts with the network to form $\equiv$SiOH and $\equiv$SiH groups. The reaction is given by

$$H_2 + \equiv Si-O-Si \equiv \rightarrow \equiv SiH + \equiv SiOH \quad [5]$$

As has been shown by Van der Steen (9) reaction [5] proceeds rapidly at 1000°C.

Under steady-state conditions (15) the flux of oxidant J is constant or

$$J = -D\frac{\partial c}{\partial x} = \text{constant} \quad [6]$$

where $\partial c/\partial x$ is the concentration gradient of the diffusing oxidant.

By integration of Eq. [6] it follows that

$$c \propto \frac{x}{x_o} \quad [7]$$

where x_o is the oxide layer thickness. When H_2O molecules constitute the diffusant a linear water profile is expected. Since the majority of water molecules is incorporated as $\equiv$SiOH groups and two silanol groups are formed from one water molecule one finds

$$[H_2O] \propto [\equiv SiOH]^2 \propto \frac{x}{x_o} \quad [8]$$

Now, the contribution of $\equiv$SiH groups to the H-profile will be derived. The H_2 flux is directed from the Si interface to the ambient. Because the net incorporated amount of hydrogen is small compared with the total amount to be transported it follows that under steady-state conditions

$$J_{H_2} = -J_{H_2O} = \text{constant} \quad [9]$$

The diffusant concentration varies proportionally with the distance from the Si interface

$$[H_2] \propto \frac{x_o - x}{x} \quad [10]$$

From reaction [5] we see that at equilibrium

$$[H_2] \propto [\equiv SiOH]\cdot[\equiv SiH] \quad [11]$$

Substituting Eq. [8] and [10] in [11] the profile of the $[\equiv SiH]$ can be found, one obtains

$$[\equiv SiH] \propto \left(\frac{x_o - x}{x_o}\right)\left(\frac{x}{x_o}\right)^{-1/2} \quad [12]$$

At the ambient side $x = x_o$ the expression in Eq. [12] equals zero and hence ($\equiv$SiH) is very small. The major part of the experimentally found hydrogen will consist of $\equiv$SiOH groups and the profile will follow the expression of Eq. [8], *i.e.*, $[H] \propto (x/x_o)^{1/2}$. At the Si interface $x = 0$ and the expression of Eq. [8] equals zero. The hydrogen profile will follow the expression in Eq. [12]. Because the first term on the right-hand side approaches unity we find that $[H] \propto (x/x_o)^{-1/2}$. The expressions of Eq. [8] and [12] are depicted schematically in Fig. 1 on a log-log plot. The slopes of the lines correspond to the powers ½ and −½.

Diffusion of $H_3O^+ + OH^-$.—In this case the same method is used as above, but we must realize that from one diffusing particle ($H_3O^+ + OH^-$) four $\equiv$SiOH groups can be formed. Instead of Eq. [8]

$$[H_3O^+ + OH^-] \propto [\equiv SiOH]^4 \propto \frac{x}{x_o} \quad [13]$$

is obtained. The [H] profile varies proportionally with the fourth root of x/x_o, *i.e.*, $[H] \propto (x/x_o)^{1/4}$.

The hydrogen flux is equal but in the opposite direction to the water flux. The hypothetical water concentration varies linearly with the square root of

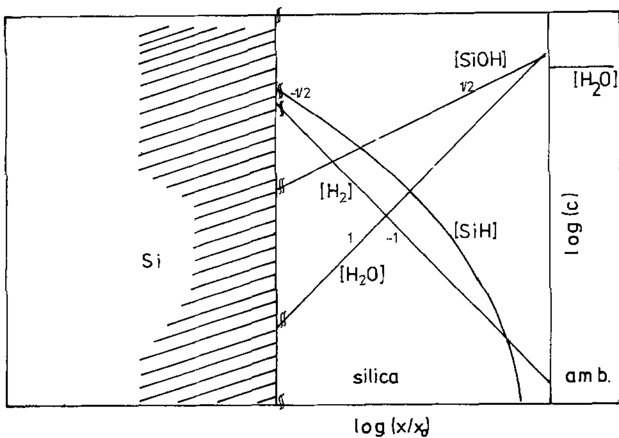

Fig. 1. Schematic representation of the expected concentration profiles of water, hydrogen, silane, and silanol groups when water molecules are the diffusing species in an oxide layer on oxidizing silicon. The concentrations of silane and silane groups are assumed to exceed the concentrations of water and hydrogen.

$H_3O^+ + OH^-$ concentration, *i.e.*, $[H_2O] \propto x/x_o)^{1/2}$. It is obvious that the $[H_2]$ profile is given by

$$[H_2] \propto \left(\frac{x_o - x}{x}\right)^{1/2} \quad [14]$$

Substituting Eq. [11] and [13] in [14] the [$\equiv$SiH] profile is obtained

$$[\equiv SiH] \propto \left(\frac{x_o - x}{x}\right)^{1/2}\left(\frac{x}{x_o}\right)^{-1/4} \quad [15]$$

Contrary to the first case we obtain profiles with powers of ¼ and −¼ (see Fig. 2).

The method outlined above can be generalized to all possible combinations of water-related species (see Table I). They all have their own characteristic number of H-atoms transported in one diffusional movement. The slopes on a log-log plot are equal to the reciprocal value of the number of H-atoms. Table I indicates that the slope of the H-profile on a log-log plot corresponds to the reciprocal of value of the number of H-atoms in the transported species.

The experimentally found profiles replotted from the data of Burkhardt (6) are given in Fig. 3, 4, and 5. The slopes at the ambient side are obviously ¼ for Fig. 3 and 4. The slopes at the Si-interface cannot be determined well for Fig. 3 and 4, but for the thinnest oxide layer in Fig. 5 there is a reasonable correspondence for calculated and measured profiles using the expression of Eq. [15]. It can be concluded that the probable mechanism is the simultaneous (or ambipolar) diffusion of H_3O^+ and OH^-, which

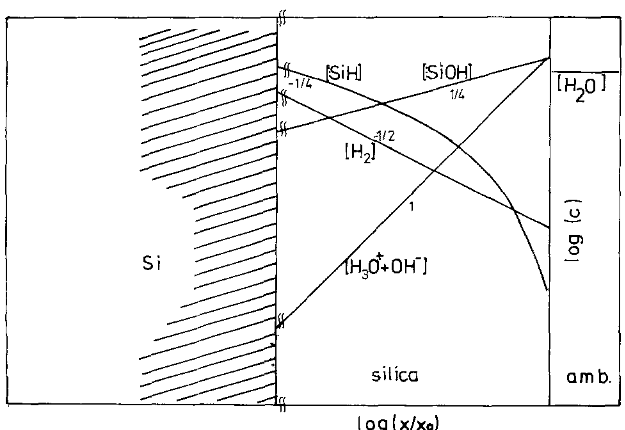

Fig. 2. The same as in Fig. 1 but here the diffusing species consist of $H_3O^+ + OH^- = (2H_2O)$.

Table I.

Species	Number of H-atoms	Slope
OH^- + hole	1	1
H_2O, H_2O^- + hole	2	1/2
H_3O^+ + electron	3	1/3
$H_3O + OH^-$	4	1/4

is in accordance with the slopes of ¼. Now the question arises where is the hydroxyl ion (OH^-) generated? In the scheme below it is proposed that the two H_3O^+ ions bound electrostatically to the two $\equiv SiO^-$ groups at the left (see "prior to jump") can be liberated forming an $H_3O^+ + OH^-$ pair. They leave two silanol groups behind and jump simultaneously (see "during jump") to react with two adjacent silanol groups (see "after jump") forming two H_3O^+ ions and $\equiv SiO^-$ groups at the right. The mechanism is based on the consideration that the silanol groups are incorporated as adjacent pairs (7).

—SiO^- H_3O^+		HOSi—	prior to jump
—SiO^- H_3O^+		HOSi—	
—SiOH	H_3O^+	HOSi—	during jump [16]
—SiOH	OH^-	HOSi—	
—SiOH	H_3O^+	$^-$OSi—	after jump
—SiOH	H_3O^+	$^-$OSi—	

The Parabolic Oxidation

When the rate of growth is determined predominantly by the transport of diffusant through the layer it is given by

$$\frac{dx_o}{dt} = M_o^{-1}\left(D\frac{\partial c}{\partial x}\right)_{x=0} \quad [17]$$

where M_o is the amount of diffusant needed to form a unity thickness of oxide. Under steady-state condition c varies linearly with x and hence we may replace $\partial c/\partial x$ by $(c_s - c_{in})/x_o$ where c_s is the surface concentration at the ambient side and c_{in} the interface concentration at the Si side (see Fig. 6).

After substitution of $\partial c/\partial x$ and subsequent integration Eq. [17] becomes

$$x_o^2 = 2M_o^{-1}D(c_s - c_{in})t \equiv k_{par}t \quad [18]$$

where $k_{par} = 2M_o^{-1}D(c_s - c_{in})$ is called the parabolic rate constant. At normal oxidant pressures $c_s >> c_{in}$

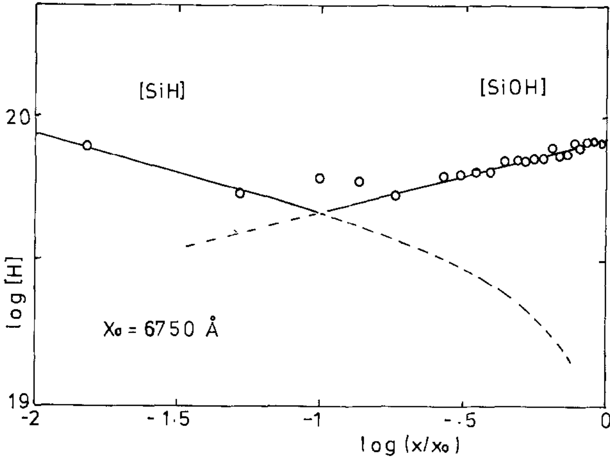

Fig. 3. Profiles measured by Burkhardt (6) in an oxide layer of 6750Å replotted on logarithmic scales showing the slope of 1/4. From this it may be concluded that two water molecules are transported simultaneously ($H_3O^+ + OH^-$). Drawn curves are calculated.

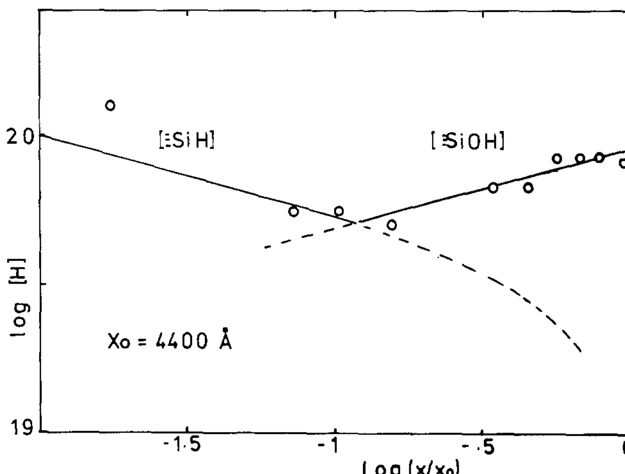

Fig. 4. The same as for Fig. 3 for an oxide-layer of 4400Å

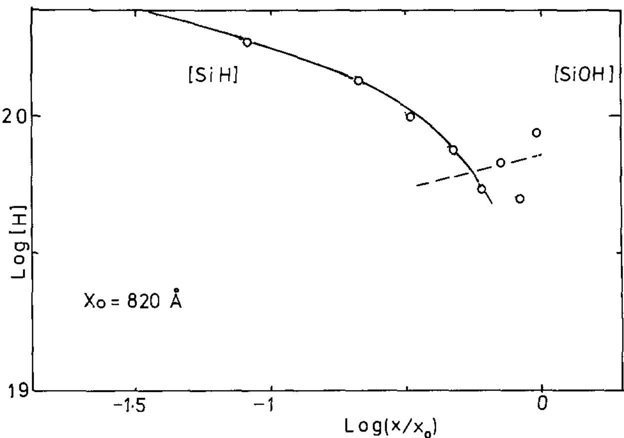

Fig. 5. The same as for Fig. 3 for an oxide-layer of 820Å

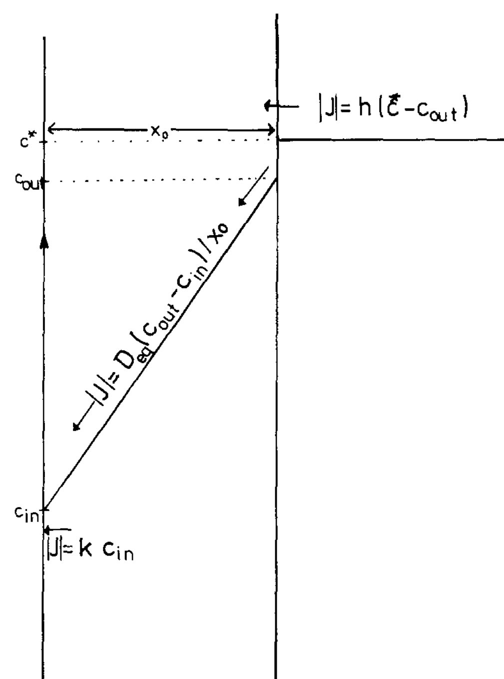

Fig. 6. Schematic profile of oxidant under steady-state condition

and hence

$$k_{par} \propto c_s \quad [19]$$

In the case that water vapor is used as oxidation agent c_s is equal to $[H_3O^+ + OH^-]$. It is convenient to relate c_s to the ambient pressure and for this purpose the exchange reaction or dissolution reaction of water in silica is needed. Earlier it was derived that

$$[H_3O^+] \propto p_{H_2O}{}^{1/2} \cdot [\equiv SiOH]^{1/2} \quad [3]$$

To generate an $H_3O^+ + OH^-$ couple it takes, however, two H_3O^+ ions as was depicted schematically above. Hence

$$2 \equiv SiO^- + 2H_3O^+ \rightleftharpoons H_3O^+ + OH^- + 2 \equiv SiOH \quad [20]$$

or

$$[H_3O^+ + OH^-] \propto [H_3O^+]^2 \quad [21]$$

Substitution of Eq. [3] in Eq. [21] gives

$$[H_3O^+ + OH^-] \propto p_{H_2O} \cdot [\equiv SiOH] \quad [22]$$

From Eq. [22] and Eq. [19] it follows that

$$k_{par} \propto p_{H_2O} \cdot [\equiv SiOH] \quad [23]$$

It is evident that the linear relationship between k_{par} and p_{H_2O} results from the fact that two water molecules have to dissolve before diffusion is possible. The square root of the solubility relation is canceled by the power of two appearing in Eq. [21]. In other words, a linear absorption isotherm is found for the real diffusant $(H_3O^+ + OH^-)$ and not for water which dissolves proportionally with the square root of water pressure.

The Linear Oxidation Regime

When, as is shown in the previous section in Eq. [23], the parabolic rate constant is dependent on the silanol concentration, it must also be dependent on thermal history and is expected to change slowly with time as discussed above. Thermal history-dependent changes of many physicochemical properties were reported by Brückner (10) and related to the silanol concentration.

In this section the time dependence of the diffusion coefficient is investigated and especially the influence of this time dependence on the growth curves of oxide layers on silicon. The approach is essentially based on the work of Crank (16) on slowly changing diffusion processes in history dependent systems [see Ref. (16), chap. 11.3.1]. Also the method of manipulation with the time dependence of the diffusion coefficient is taken from Crank [see Ref. (16) chap. 7].

The change of the diffusion coefficient is assumed to be a first-order change given by

$$\frac{\partial D}{\partial t} = (D_{eq} - D)\tau^{-1} \quad [24]$$

where D is assumed to increase with time until a final equilibrium value D_{eq} is obtained. τ is in general a concentration-dependent relaxation time. Crank introduces an instantaneous diffusion process which accounts for the flux immediatly after increase of penetrant concentration and derives an overall expression for the rate of change of the diffusion coefficient on location x

$$\left(\frac{\partial D}{\partial t}\right)_x = \left(\frac{\partial D_i}{\partial c}\right)\left(\frac{\partial c}{\partial t}\right)_x + (D_{eq} - D)\tau^{-1} \quad [25]$$

where D_i is the instantaneous diffusion coefficient. The number of adjustable parameters is so large, however, that comparison of theory and the experimental data cannot be very conclusive (16). In the following we shall make some assumptions which considerably restrict the number of parameters: (*i*) τ and D are assumed to be concentration independent, (*ii*) τ and D are assumed to be independent of x, and (*iii*) D_i and $\partial D_i/\partial c$ are assumed to be negligibly small.

Now Eq. [25] reduces to Eq. [24] and after integration the diffusion coefficient is given by

$$D = D_{eq}\left[1 - \exp\left(-\frac{t}{\tau}\right)\right] \quad [26]$$

D is now only dependent on t and we shall use this property in the following derivation (16).[2] When D is only dependent on t, Ficks second law

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}\left[D(t)\frac{\partial c}{\partial x}\right] \quad [27]$$

may be rewritten as

$$\frac{\partial c}{\partial t} = D(t)\frac{\partial^2 c}{\partial x^2} \quad [28]$$

Now a new time variable T defined by

$$T \equiv D_{eq}^{-1}\int_0^t D(t)dt \quad \text{or} \quad dT = \frac{D(t)}{D_{eq}}dt \quad [29]$$

is introduced. With Eq. [29] we may convert Eq. [28] into

$$\frac{\partial c}{\partial T} = D_{eq}\frac{\partial^2 c}{\partial x^2} \quad [30]$$

By this manipulation the right-hand side of Eq. [30] has become time independent. In the steady state $\partial c/\partial t = 0$ and when t is a function $f(T)$ of T only then also

$$\frac{\partial c}{\partial T}\frac{\partial f(T)}{\partial t} = 0$$

which implies that $\partial c/\partial T = 0$ when

$$\frac{\partial f(T)}{\partial t} \neq 0$$

and then the right-hand side of Eq. [30] is equal to zero too.

We have defined now a steady-state situation but it must be kept in mind that we use another time variable T. In the steady-state condition $J(T) = D_{eq}\partial c/\partial x$ = constant. This enables us to rewrite the growth rate, defined by Eq. [17]

$$\frac{dx_o}{dt} = M_o^{-1}\left[D(t)\frac{\partial c}{\partial x}\right]_{x=0} \quad [17]$$

into a form where the growth rate is (quasi) steady state

$$\frac{dx_o}{dT} = M_o^{-1}D_{eq}\left(\frac{\partial c}{\partial x}\right) \quad [31]$$

or

$$\frac{dx_o}{dT} = M_o^{-1}D_{eq}\frac{\Delta c}{x_o} \quad [32]$$

The concentration difference Δc has to be related to the ambient pressure p. Because D and Δc are effective quantities rather than a physically defined diffusion coefficient and concentration it is useful to express Eq. [32] in terms of permeation constant P and pressure difference Δp. In the case that D is constant and the absorption isotherm is linear (see preceding section) we may write

$$P_{eq}\frac{\Delta p}{x_o} = D_{eq}\frac{\Delta c}{x_o} \quad [33]$$

and substitute the corresponding terms in Eq. [32] to obtain

$$\frac{dx_o}{dT} = M_o^{-1}P_{eq}\frac{\Delta p}{x_o} \quad [34]$$

Integration of Eq. [34] gives

$$x_o^2 = 2M_o^{-1} \cdot P_{eq} \cdot \Delta p \cdot T \quad [35]$$

An expression for T can be found by substitution of $D(t)$ in Eq. [29] by the expression given in Eq. [26] and subsequent integration. By taking $T = 0$ when $t = 0$ one obtains

$$T = t + \tau\exp\left(-\frac{t}{\tau}\right) - \tau \quad [36]$$

Substitution of T in Eq. [35] gives the rate law for oxide growth as function of real time

$$x_o = \sqrt{B} \cdot \sqrt{t + \tau\exp\left(-\frac{t}{\tau}\right) - \tau} \quad [37]$$

where

$$B = 2M_o^{-1}P_{eq}\Delta p \equiv k_{par}$$

This is a linear-parabolic oxidation law which may be compared with the expression given by Deal and Grove (1)

$$x_o = \sqrt{B}\sqrt{t + \frac{A^2}{4B}} - \frac{A}{2} \quad [38]$$

where $A^2/4B$ is a characteristic time (to be compared with τ) and $A/2$ is the ratio of the effective diffusion coefficient D_{eff} and the reaction rates k and h for the exchange reactions at the interfaces given by

$$\frac{A}{2} = D_{eff}\left(\frac{1}{k} + \frac{1}{h}\right) \quad [39]$$

Equations [37] and [38] converge to the same parabolic rate law for relatively large times, *i.e.*, $t >> \tau$ and $t >> A^2/4B$

$$x_o \cong \sqrt{B} \cdot \sqrt{t} \quad [40]$$

For relatively small oxidation times, *i.e.*, $t << \tau$ Eq. [37] becomes linear

$$x_o \cong \sqrt{\frac{B}{2\tau}} \cdot t \quad [41]$$

and in the comparable situation, where $t << A^2/4B$, Eq. [38] reduces to the linear form

$$x_o \cong \frac{B}{A} \cdot t \quad [42]$$

When the two linear-parabolic expressions are plotted, as may be seen in Fig. 7, the resemblance is considerable. The maximum difference between the oxide thicknesses at comparable t is only 22%. However, the experimental error is mostly small enough to enable the discrimination between the two growth curves.[3] In order to discriminate between the two

[2] In the case of reaction of the diffusant with the lattice the loss of diffusant by immobilization must be taken into account [see Crank (16), chap. 14]. The continuity equation becomes, when $D \neq D(c,x)$

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2} - \frac{\partial s}{\partial t}$$

where the term $\partial s/\partial t$ accounts for the rate of change of absorbed or immobilized substance. In the case of a linear absorption isotherm (cf. Eq. [22]) the concentration of immobilized substances is given by

$$s = k \cdot c$$

where k is the absorption coefficient, $\partial s/\partial t$ can be substituted directly by $k\partial c/\partial t$, which gives

$$\frac{\partial c}{\partial t} = \frac{D}{k+1}\frac{\partial^2 c}{\partial x^2}$$

The continuity equation is reduced to the usual form without immobilization when an effective diffusion coefficient $D_{eff} = D/k + 1$ is introduced [see also Ref. (17)].

[3] Theoretically, it is possible that the exchange reaction at one of the interfaces and the time-dependent diffusion are equally rate determining, *i.e.*, $\tau \cong A^2/4B$. In this case one may proceed with the derivation of the growth rate using the expression of Eq. [34] and equating the diffusion-controlled fluxes passing through the interfaces. The derivation is the same as that used by Deal and Grove substituting t with T. The full expression is a combination of Eq. [37] and Eq. [38] and is given by (13)

$$x_o = \sqrt{B} \cdot \sqrt{t + \tau\exp\left(-\frac{t}{\tau}\right) - \tau + \frac{A^2}{4B}} - \frac{A}{2}$$

In the case that $\tau = A^2/4B$ and $t << \tau$ a square root law (*i.e.*, $\sqrt{x_o} \propto t$) is obtained. The experimental evidence for the square root law was not found.

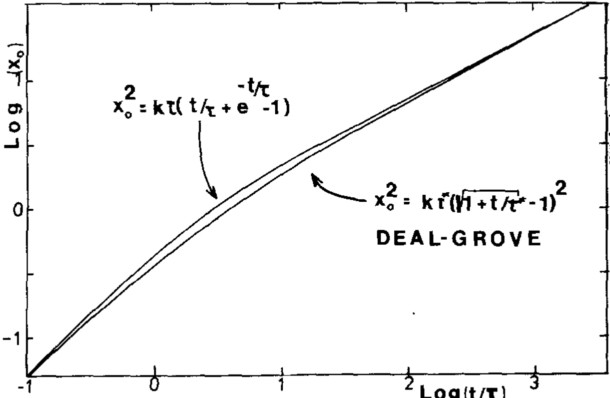

Fig. 7. Comparison of relationship given by Eq. [37] and [38]. $\tau^* \equiv A^2/4B$. The maximum difference between the two curves is only 22%.

linear-parabolic rates laws a curve-fitting procedure can be used. It is then advisable to take the derivative of the logarithmic form of the growth curves. This reduces the power n in the rate law $x_o \propto t^n$ to a value, *i.e.*, $d \log x_o/d \log t = n$. The curves are now completely determined by x_o, t, τ, and n (see Fig. 8). (For the experimental data see Discussion section.) A more sophisticated method is to investigate the dependence of the linear rate constants or the characteristic times on water partial pressure. In Table II the expected dependence for k_{lin} and k_{par} and $t_{char} = A^2/4B$ is given for the two alternative models.

Oxidation in O_2-H_2O Ambients

When silicon is oxidized in oxygen, trace amounts of water influence the oxidation rate. The parabolic rate constant increases significantly when, instead of ultra dry oxygen, normally dried oxygen with 25 ppm H_2O is used (19). Irene and Ghez (19) question the parallel and independent transport of water and oxygen. The influence of water is explained qualitatively by the assumption that traces of water loosen the silica network allowing the oxygen to move faster. There is one obvious argument which supports the assumption that the oxygen and water species do not move independently. Water reacts with silicon to form hydrogen (Eq. [4]). This hydrogen can diffuse back into an ambient of oxygen; it will then certainly react forming water again. It may also react with silica to form reduced species. These are reoxidized in a later step by diffusing oxygen.

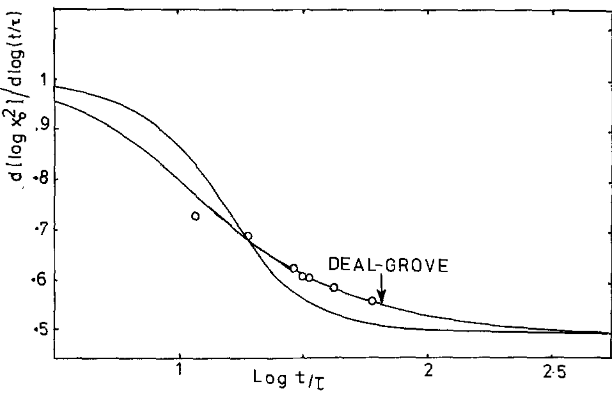

Fig. 8. The derivatives of the expressions in Eq. [37] and [38] in logarithmic form are plotted against the normalized time. The linear part of the growth curve corresponds to the value 1 on the vertical axis, the parabolic part corresponds to the value 1/2. The growth curves are totally defined by B, t, and τ (or $A^2/4B$). Drawn circles are representing the data of Pliskin (5) (see Discussion section).

It is assumed here that every hydrogen will encounter an oxygen, *i.e.*, will be oxidized. It can only leave the silica in the oxidized state. The situation can be easily understood by inspection of a schematical plot of the concentration against distance in the oxide layer. In Fig. 9 the situation is drawn where the partial pressure of water is much smaller than the pressure of oxygen. Because the reaction rate is larger at high concentrations and smaller at low concentrations the silicon is oxidized by an excess of oxygen and water is hardly consumed. The concentration gradient for oxygen will be constant in a steady-state process. There is no concentration gradient for water.

When the water concentration is increased the horizontal waterline rises and will somewhere cross the oxygen gradient. Now water takes part in the oxidation of the silicon, hydrogen will be formed, diffuse back in the direction of the ambient, and will ultimately react forming water. When the reaction rate is fast enough the excess water will be formed left of the cross-over point and will diffuse back to the silicon again. In this region the hydrogen will consume part of the oxygen. The concentration of oxygen will be lowered. Relatively more water takes the place of oxygen in the reaction at the silicon interface. It is easily understood that the situation will end up as depicted in Fig. 10. Water will be the only diffusant, left of the point x_i of equal concentration, and oxygen will be the only diffusant at the right-hand side. This means that the fluxes of diffusants must be equal in the two layers with thickness $o - x_i$ and $x_i - x_o$, hence

$$J_{(H_3O^+ + OH^-)} = J_{O_2} = J \quad [48]$$

From this flux J a fraction $(x_i/x_o)J$ increases the thickness of layer x_i and a fraction $[(x_o - x_i)/x_o]J$ is converted to increase the layer thickness $x_o - x_i$.[4] The increase of layer thickness dx_i in the time dt is given by

$$dx_i = \frac{x_i}{x_o} \cdot M_o^{-1} \cdot |J| \cdot dt \quad [49]$$

and for layer thickness $x_o - x_i$

$$d(x_o - x_i) = \frac{x_o - x_i}{x_o} M_o^{-1} \cdot |J| \cdot dt \quad [50]$$

From Eq. [48] it is clear that

$$|J| = D_{(H_3O^+ + OH^-)}(t) \frac{c_i}{x_i} = D_{O_2}(t) \cdot \frac{c_o' - c_i'}{x_o - x_i} \quad [51]$$

where c_i is the water species concentration at x_i and

[4] It is a formal way of stating; in fact the layer thickness x_o increases, and the layer thickness x_i increases with a rate which is x_i/x_o times the rate of the layer x_o.

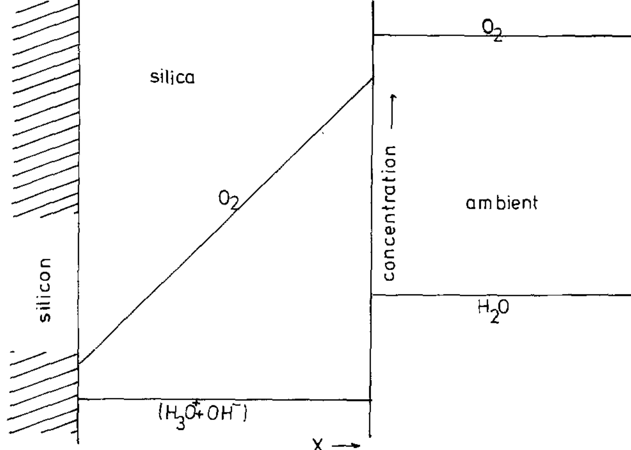

Fig. 9. Permeation of oxygen under steady-state conditions, when the pressure of water is extremely low. (The diffusion coefficient is assumed concentration independent.)

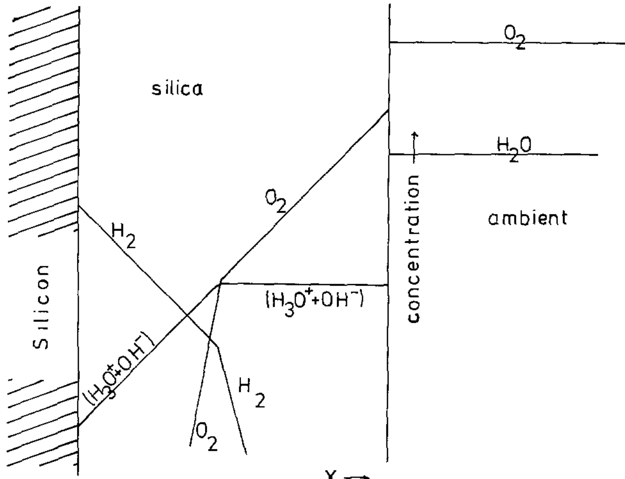

Fig. 10. The same as for Fig. 9 with a higher value for the partial pressure of water.

c_o' and c_i' the oxygen concentration at x_o and x_i, respectively. By substituting [31] and following the same method as in the previous section for Eq. [31]

$$\frac{dx_o}{dt} = M_o^{-1} \cdot |J| = \frac{k_{H_2O}\dot{T}_{H_2O}}{2x_i} = \frac{k_{O_2}\dot{T}_{O_2}}{2(x_o - x_i)} = \frac{k_t\dot{T}}{2x_o} \quad [52]$$

where $k_{H_2O}/2$, $k_{O_2}/2$, and $k_t/2$ are the parabolic rate constants for the water layer ($o < x < x_i$), the "oxygen" layer ($x_i < x < x_o$), and the total oxide layer ($o < x < x_o$), respectively, $\dot{T}_{H_2O}$, $\dot{T}_{O_2}$, and $\dot{T}$ are the various time functions dT/dt which are equal to the ratio of momentary and equilibrium diffusion coefficients, D/D_{eq} for the various layers. By substituting the corresponding expressions for $M_o^{-1}J$ in Eq. [49] and [50] the increase of the layer thickness becomes

$$dx_i = \frac{k_{H_2O}}{2x_o} T_{H_2O}\, dt \quad [53]$$

and

$$d(x_o - x_i) = \frac{k_{O_2}}{2x_o} T_{O_2}\, dt \quad [54]$$

By addition of Eq. [53] and [54] and subsequent integration, a general relationship for steady-state growth of a sandwich layer with two time-dependent diffusion coefficients is found

$$x_o^2 = k_{H_2O}T_{H_2O} + k_{O_2}T_{O_2} \quad [55]$$

in which the initial condition is used that $T_{H_2O} = T_{O_2} = 0$ when $x_o = 0$.

When we adopt the expression of Eq. [36] for T_{H_2O} and assume that oxygen diffusion is not retarded by absorption then $T_{O_2} = t$ and we can convert Eq. [55] to

$$x_o^2 = k_{O_2}t + k_{H_2O}\left[t + \tau \exp\left(-\frac{t}{\tau}\right) - \tau \right] \quad [56]$$

Equation [56] shows a three parameter expression and this may be compared to the expression used by Deal (18) which has three adjustable parameters too. One of the parameters in Deal's expression is an initial thickness x_{in} or initial time t_{in} correction term. This has to be introduced to correct for the so called "rapid initial oxidation phase." In the next section it will be shown that Eq. [56] predicts this nonlinear initial growth.

The "Initial Oxidation" Regime

The use of the Deal-Grove expression to describe the growth curves is consistent with the data only when a correction term is introduced to account for what is called "the rapid initial oxidation phase." This superlinear initial growth is found only for mixed O_2-H_2O ambients and for pure O_2 oxidation (1, 19). Deal and Grove (1) indicated that a field-assisted oxygen transport might be the explanation. The difference between oxygen and water vapor was explained from the difference in Debye length calculated from the number of charge carriers in the different oxides.

It was shown by Horiuchi *et al.* (20) that for extremely dry oxygen ambients an inverse logarithmic growth regime is found which is characteristic for the field-assisted growth (also called Mott-Cabrera mechanism). There is, however, a maximum thickness at which the Mott-Cabrera mechanism stops being effective. Horiuchi (20) shows that this thickness is about 60-70Å which is much less than the 200-800Å oxide thickness where the rapid initial growth is found (19).

After inspection of Eq. [56] it becomes clear that when

$$k_{O_2} \cdot t > k_{H_2O}\left[t + \tau \exp\left(-\frac{t}{\tau}\right) - \tau \right]$$

or

$$t < 2\frac{k_{O_2}}{k_{H_2O}} \tau \ (\equiv t_{in}) \quad [57]$$

there must be a parabolic regime preceding the linear part of the growth curve. The physical meaning of this parabolic mechanism is the direct oxidation of Si by oxygen without the intervention of reacting hydrogen, at least the latter is not rate determining. t_{in} is defined as the time when the initial growth stops being effective.

Discussion

To check whether the time-dependent diffusional transport (model presented here) or the constant diffusional transport with limiting interface reactions (model of Deal and Grove) applies to the oxidation mechanism, the experimental data may be analyzed on three characteristics (cf. Table II): (*i*) dependence of characteristic time ($A^2/4B$) on water partial pressure, (*ii*) dependence of k_{lin} ($= B/A$) on water partial pressure, and (*iii*) fitting of Eq. [37] or [38] (or Eq. [56]) to experimental data.

In the case that there is a rapid initial growth we may also check if the relationship given in Eq. [57] is obeyed.

Oxidation in pure water vapor.—From the small number of pure water vapor oxidation data those of Pliskin (5) have been selected for analysis. The values of the characteristic time $k_{par}/4k_{lin}^2$ or $A^2/4B$ have been plotted against water partial pressure in Fig. 11. From this it can be concluded that there exists an inverse relationship indicating that we are dealing with an interface reaction-limited growth (Deal and Grove mechanism).

In Fig. 8 the data of Pliskin (5) have been replotted in a special way. The slope of the logarithmic growth curve is determined on each experimental point using the two adjacent points. The values of the slopes may be compared with the derivatives of Eq. [37] and [38]. From Fig. 8 it follows that the points coincide with the Deal and Grove curve which is consistent with the conclusion above. Finally also the values of B/A plotted against water partial pressure suggest a reciprocal relationship. This is obvious when $A^2/4B \propto p_{H_2O}^{-1}$ (and $B \propto p_{H_2O}$), but the power is not exact unity as can be seen in Fig. 11. The conclusion may be that the oxidation mechanism is probably of the Deal-Grove type. Whether the limiting reaction is at the inner or at the outer surface of the silica layer is not yet clear.

Mixed O_2 and H_2O ambients.—The analysis of mixed ambient oxidation was restricted to the data presented by Deal *et al.* (1, 18, 21) and Irene *et al.* (2, 19,

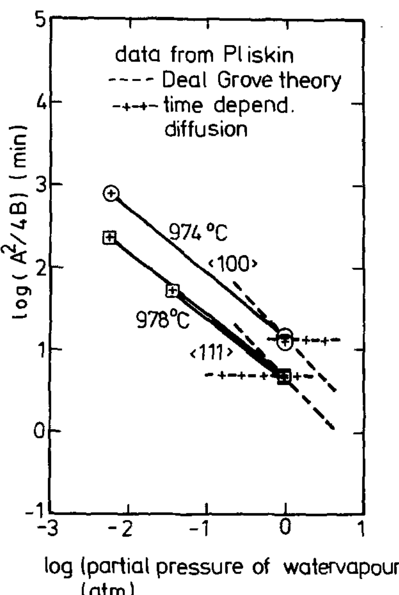

Fig. 11. Dependence of the characteristic time $A^2/4B$ on the water partial pressure in the ambient. Data taken from Pliskin (5).

22). The dependence of characteristic time $A^2/4B$ on water partial pressure can be seen in Fig. 12. The slightly inclined curves show that there is a very small variation of the characteristic time over several decades of water pressure. The slopes correspond to powers of less than 0.1. This suggests that the model of time-dependent diffusional transport may be applied.

The second criterion is to plot k_{lin} against water partial pressures. Deal (21) noticed a strong deviation of the experimental and theoretical dependence of k_{lin} on p_{H_2O}. As can be seen in Table II a linear dependence is expected in the Deal and Grove theory. It is shown in Fig. 13 that Deal's data for k_{lin} are consistent with the model presented here. Replotting k_{lin} against $p_{H_2O}{}^{1/2}$ a straight line is obtained with a remarkably small deviation. The difference between the <111> and <100> orientation is discussed later.

The third criterion is fitting the experimental data to Eq. [56]. This implies the sequential transport of oxygen by oxygen molecules and water species and excludes rate-determining exchange reactions. In addition, it assumes that the oxygen molecule diffusion coefficient is not time dependent. This assumption is based on results on tracer investigations by Rosencher *et al.* (23) which were reviewed by Mott (24). The experiments of Rosencher clearly prove that no oxygen is exchanged with the network oxygen during growth.

Deal's (21) and Irene's (22) data have been replotted in Fig. 14 and 15 together with the curves calculated by the expression given in Eq. [56]. The three parameters k_{O_2}, k_{H_2O}, and τ have been evaluated using a least squares technique. The deviation of the experimental data is almost everywhere within 3%, which is about the estimated error in the layer thickness determination Deal (21) and Irene (19) report a much larger

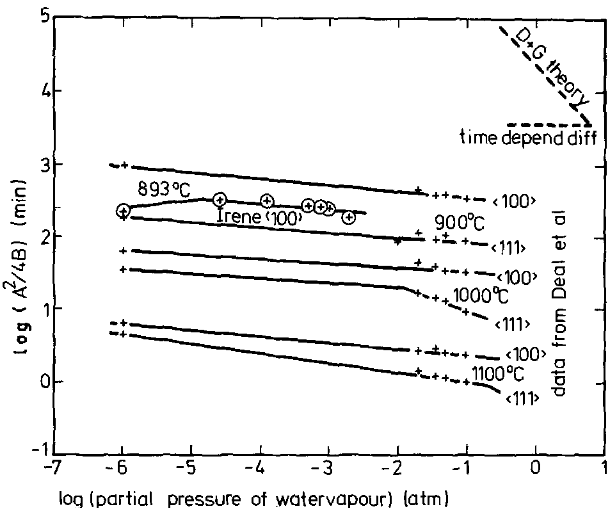

Fig. 12. The same as for Fig. 11 but now for mixed $O_2 + H_2O$ ambients. Data taken from Deal *et al.* (21) and Irene *et al.* (19).

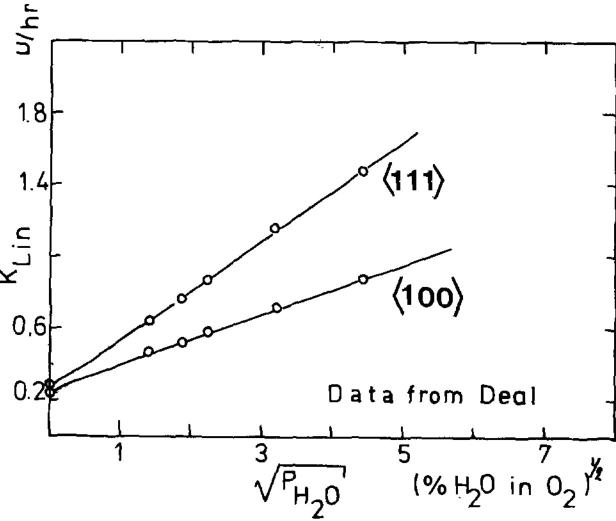

Fig. 13. The linear rate constant varies with the square root of water pressure as follows from Eq. [43] rather than being proportional to water pressure as would follow the Deal-Grove theory. Data taken from Deal *et al* (21).

deviation of experimental and theoretical data when using independent O_2 and H_2O transport.

It follows from the model of sequential transport of O_2 and H_2O that, even at very small water concentrations in the ambient, water may play a role in the oxidation rate (2, 19). Because the effective diffusion coefficient of water is two orders of magnitude larger than that of oxygen (1), water plays an equal role in the oxidation process when the partial pressure is only 1% (*i.e.*, $x_i = 1/2x_o$ when $p_{H_2O} = 0.01p_{O_2}$). In not thoroughly dehydrogenerated oxygen the partial pressure of water is expected to exceed 25 ppm (2). In a growing layer of about 1000Å, the region x_i, where

Table II. Dependence on water partial pressure of k_{lin}, k_{par}, and t_{char} for the two models

Model	Expression	k_{lin}	k_{par}	t_{char}
Totally diffusion determined $D = D(t)$	Eq. [37] $x_o = \sqrt{B}\cdot\sqrt{t + \tau\exp\left(-\frac{t}{\tau}\right)} - \tau$	Eq. [43] $\sqrt{\frac{B}{2\tau}} \propto \sqrt{p_{H_2O}}$	Eq. [45] $B \propto p_{H_2O}$	$\tau \neq f(p_{H_2O})$
Diffusion- and/or reaction rate at interface-determined. D = const. (Deal + Grove model)	Eq. [38] $x_o = \sqrt{B}\cdot\sqrt{t + \frac{A^2}{4B}} - \frac{A}{2}$	Eq. [44] $\frac{B}{A} \propto p_{H_2O}$	Eq. [46] $B \propto p_{H_2O}$	Eq. [47] $\frac{A^2}{4B} \propto p_{H_2O}{}^{-1}$

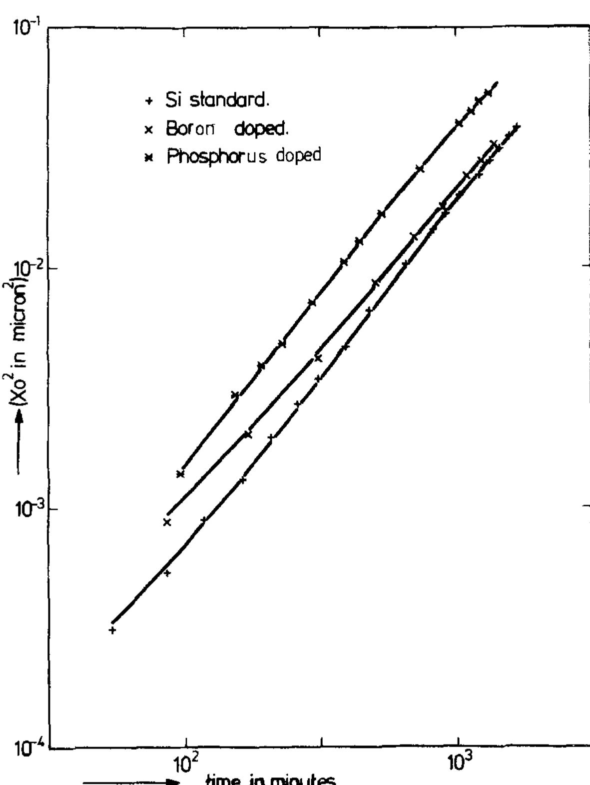

Fig. 14. Equation [56] fitted by a regression technique on the data of Irene *et al.* (22). The maximum deviation is within experimental error. It shows that the initial growth process is an implication of the model used here. P, B, and STD denote phosphorus, borium doped, and standard quality silicon, respectively.

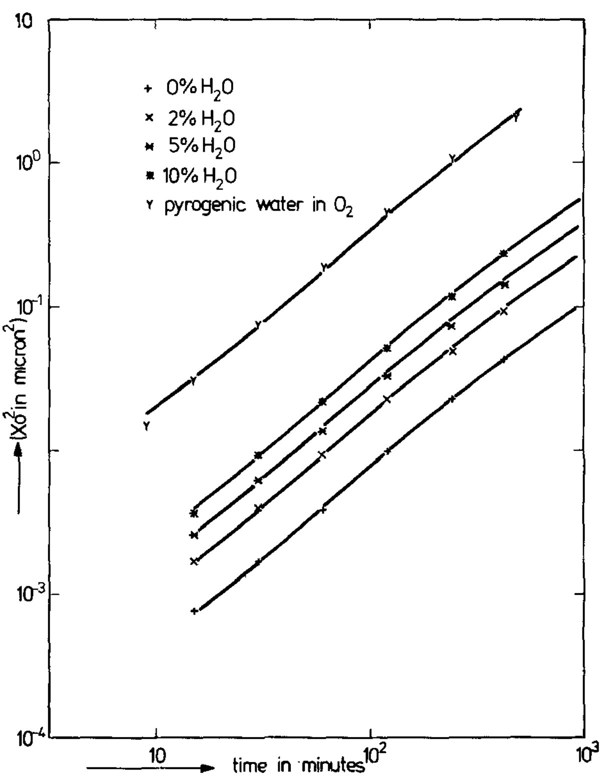

Fig. 15. The same as Fig. 14 fitted on the data of Deal *et al.* (21). Figures denote the volume percentage of H_2O in O_2. Pyr. denotes the use of $H_2 + O_2$ in a ratio corresponding to an H_2O/O_2 gas mixture from an oxygen gas stream bubbled through a water bath of 96°C. Using a model with independent fluxes of O_2 and H_2O through silica would give much larger deviations of experimental and theoretical curves (21).

water transport dominates, will extend to 25Å from the Si-interface.

The reversible increase and decrease of the oxidation rate by the variation of the water partial pressure from <1 ppm to 2000 ppm and back (19) can be explained in terms of the thickness variation of the region controlled by diffusion of $H_3O^+ + OH^-$.

Activation energies.—When for $H_2O + O_2$ ambients and for relatively dry O_2 ambients the values of τ are plotted against $1/T$, we expect to find a single activation energy for a model with a time-dependent diffusion. The values of τ [calculated from the data reported by Deal (5) and Irene *et al.* (19)] are plotted in such a manner for <100> and <111> Si orientation in Fig. 16 and 17, respectively. Below a certain value of $1/T$ an activation energy of 3.1-3.6 eV is found for all ambients and orientations. This indicates that it may be indeed a single activation energy which is thought to correspond to the incorporation reaction of water in the silica network. The strength of a Si-O-Si bond is expected to be in the order of 4 eV (8). This value is found for growth in pure water vapor (5). In mixed $O_2 + H_2O$ ambients there is an effect of the two layer mechanism which can cause a lowering of the effective activation energy. In fact, the value x_l/x_o in Eq. [49] and [50] is temperature dependent. In general, when we deal with a series-transport through two layers in steady-state conditions, then the layer with the highest resistance for transport will decrease in thickness and that with the lowest resistance will increase in thickness until the fluxes through the layers match. These layer thicknesses may be different for the same ratio of k_{H_2O} and k_{O_2} at different temperatures and therefore influence the apparent activation energies.

Above a certain value of $1/T$, *i.e.*, below 950°-1000°C, the activation energies scatter. These values of $1/T$, which are not easily determined from Fig. 16 and 17, correspond to the range of temperatures where the glass transition is expected. The glass transition range is characterized by the time needed for a glass to accommodate to a strain by reorganizing the network (16). In this region we expect anomalous diffusion effects to occur (16). The question arises whether the simple transport models we have used in the previous sections are then allowed. In fact stress-induced transport is known to give moving boundary (*i.e.*, growth) curves which mostly follow linear-parabolic rate laws too (16). There is no doubt that these effects play a role in the oxidation of silicon. In fact Eernisse (25, 26) has shown that silica growing in wet ambients is subjected to compression. Pliskin (5) reported mea-

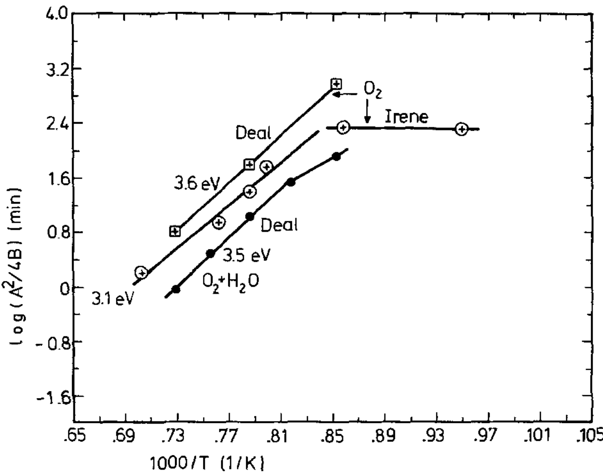

Fig. 16. Variation of the characteristic time $A^2/4B$ with reciprocal absolute temperature, typical is the sharp bending between 900° and 1000°C. Data for <100> Si. Data taken from Deal *et al.* (21) and Irene *et al.* (22).

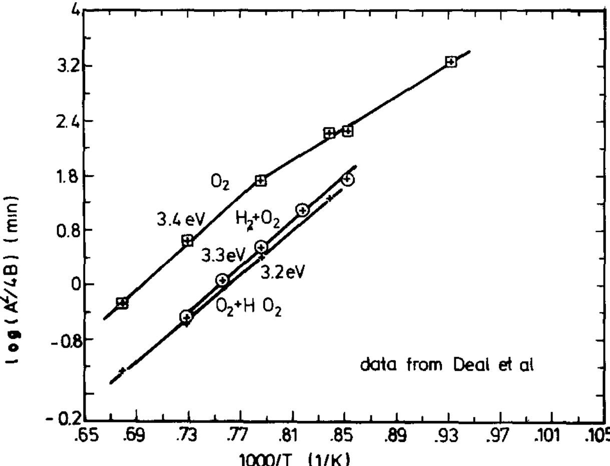

Fig. 17. The same as Fig. 16 but for <111> Si. Data from Deal *et al.* (1, 18, 21).

surable effects on the growth curves induced by stresses originating from locally stripped oxide films. There is one effect which may be explained qualitatively by the effect of the compression of silica during the growth. The compressive stress originates from the elastic deformation of the silicon substrate. It is expected to act especially on the first layers of silica adjacent to the Si/SiO_2 interface. In $H_2O + O_2$ ambients this is part of the layer where water transport is the prior mechanism. Because, as was stated above, the layer is thin when the resistance is large we expect especially a large effect of the compression in the region where the resistance to transport is large, *i.e.*, the linear region of the growth curves. As was stated above, the compression originates from the elastic deformation and an effect is expected from the orientation of the Si-substrate.

Young's molulus for <111> oriented Si is about 1.5 times that for <100> oriented Si so it might have an appreciable effect. Indeed the k_{lin} for <111> oriented Si is found to be larger than k_{lin} for <100> oriented Si (see Fig. 13), in the same order of magnitude. The dependence of k_{lin} on Si-orientation was explained in terms of the Si-Si-bond breaking and the number of dangling bonds by Ligenza (27). In that case it ought to show up in an activation energy difference for <111> and <100> oriented Si. We can see from Fig. 16 and 17 that there is no significant difference in the activation energy for the characteristic time $k_{par}/4k_{lin}^2$. The parabolic rate constant is found to be independent of orientation and as a consequence k_{lin} must have the same activation energy for both orientations.

There is only a difference in the magnitude of k_{lin} which increases with water pressure. This increase is proportional to the square root of water pressure and originates probably from the total amount of water dissolved in the compressed layer.[5] The swelling (11) of silica in water vapor is perhaps also the reason that the diffusion of water in silica is a process with a relatively small activation energy of about 0.7 eV (29). The activation energy was expected to correspond to the Si-O-Si bond breaking energy of about 4 eV [see Doremus (8)]. The swelling of silica may cause the bonds to break under mechanical strain.

The activation energy of 0.7 eV might equally well correspond to the activation energy for the formation of hydroxyl groups (OH^-) (see the scheme in the section on Transport of Water Through Silica). The large effect of contamination on growth rate of oxide layers might be because of the generation of (OH^-) groups by reaction with water [*e.g.*, Na^+ accelerates the growth rate of oxide layers enormously (4)]. The experiments of Jorgensen and Norton (30) where the growth of oxide layers could be inhibited or accelerated by positive or negative fields can be explained also by assuming that the negative minority charge carriers OH^- are stopped or accelerated, respectively.

[5] The fact that Si oxidizes at low temperatures (28) of 400°C and even at room temperatures is difficult to explain when a surface reaction with a high activation energy of 1.9 eV controls the oxidation rate at 1000°C. The absence of the Arrhenius equation for k_{lin} and the change of the activation energy in the glass transition range indicate that another effect (*e.g.*, stress effect) is involved.

Conclusions

1. The solubility of water is proposed to proceed in two steps: (*i*) the formation of $\equiv SiOH$ groups. A relative slow process at temperatures up to 1100°C; and (*ii*) hydrolyzation of $\equiv SiOH$ under formation of $H_3O^+ + \equiv SiOH^-$. The process is relatively fast at temperatures even below 900°C.
2. It has been shown that water migrates through silica by species containing 4 H-atoms. The ambipolar diffusion of $H_3O^+ + OH^-$ has been proposed.
3. The linear variation of k_{par} or B with water pressure in growing silica layers follows directly from the proposed mechanisms in 1 and 2 above.
4. By adopting a time-dependent diffusion coefficient an expression can be obtained describing the oxide growth in terms of a parabolic rate constant and a relaxation time.
5. A model for the sequential diffusion of water and oxygen is proposed. An expression for the time dependence of x_o (without surface reactions) has been obtained which includes the initial growth process also. Experimental growth curves can be represented accurately by the proposed expression.
6. The activation energy of the characteristic time $k_{par}/4k_{lin}^2$ has a value of 3.1-3.6 eV for dry and wet oxidations. The value is near to the Si-O-Si bond breaking energy.
7. It is argued that the difference in k_{lin} for various orientations may originate from stresses induced by the swelling of silica in water vapor.

Acknowledgments

The author wishes to thank Messrs. P. Hart, L. Heijne, J. Snel, J. Verwey, and H. Verwey for valuable discussions. He is indebted to Mr. C. van Opdorp for the suggestion of the use of the time-dependent diffusion coefficient which played an essential role in the achievement of the concept of the section on The Linear Oxidation Regime.

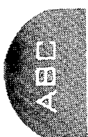
Reaction of Copper Oxide with H_2S

J. L. Sansregret

Exxon Research and Engineering Company, Advanced Energy Systems Laboratory, Linden, New Jersey 07036



The corrosion of copper by atmospheric pollutants is a problem of continuing interest to the electronics industry. A pollutant of particular concern is H_2S and its attack on copper has been a topic of some discussion in the literature. It has been shown that a thin oxide film on Cu protects the underlying metal from attack by H_2S in air at room temperature (1). It has also been reported that copper oxides grown in air (several hundred angstroms thick) provide good protection against H_2S at low relative humidities but little protection against H_2S at high relative humidities and that oxides grown in pure oxygen provide more protection than air grown oxides (2). Thus, it is speculated that in the attack of Cu_2O by H_2S an intermediate reaction path involving H_2O is required. We report here on conditions under which copper oxide films will suffer direct attack by H_2S and convert to Cu_2S without an intermediate reaction path involving H_2O. We propose that the crystallinity and porosity of a Cu_2O film are important parameters in determining its reactivity towards H_2S and comment briefly on the thermodynamics of this reaction.

The attack of copper oxide by H_2S constitutes a gas-solid phase ion exchange reaction wherein the oxide ions in the anion sublattice are replaced by sulfide ions. We have recently developed a thin film ion exchange-chemical spray deposition (CSD) process (3) for the growth of thin sulfide films that, in effect, models the attack of a copper oxide film by H_2S. In our process, thin sulfide films are grown through ion exchange of an oxide film to the sulfide by annealing in H_2S. We present here results relating to the problem of copper corrosion by H_2S and of protection by an overlaying copper oxide film.

Thin films of copper sulfide were grown by chemically spray depositing a copper oxide film and then annealing this film in H_2S to convert it to the sulfide. The copper oxide films were grown by spraying a water-methanol solution (25% H_2O by volume) of copper nitrate (0.01 M) onto a substrate to form the oxide. The films were then converted to the sulfide by annealing in flowing H_2S (5% in N_2) at 325°C for 30-45 minutes. Final film thicknesses were about 1.0 u.

The resultant films were characterized by x-ray diffraction, ESCA and optical absorption measurements. The oxide films were found to consist of a bulk film of amorphous Cu_2O with crystalline particulates of CuO embedded in it. The sulfided films were found to contain three phases: $Cu_{1.96}S$, $Cu_{1.8}S$, and $Cu_{1.75}S$. There was no evidence of an oxide phase in the sulfided films.

The conversion of the oxide to the sulfide,

$$Cu_2O + H_2S \rightarrow Cu_2S + H_2O \quad (1)$$

does occur despite the fact that the oxide is thermodynamically more stable than the sulfide (standard free energies of formation at 298°K for Cu_2O,

CuO, Cu_2S and CuS are, respectively, -34.98, -30.4, -20.6 and -11.7 kcal/mole (4). The driving force for the reaction of Equation 1 is the greater disparity in free energies of formation between H_2S and H_2O ($\Delta G°_{298}$ = -46.74 kcal/mole) than between Cu_2O and Cu_2S (ΔG_{298} = -14.38 kcal/mole); the overall change in free energy for the reaction of Equation 1 is $\Delta G°_{298}$ = -32.37 kcal/mole, indicating spontaneity to the right as observed.

We propose that, in the direct conversion of copper oxide to copper sulfide by exposure to H_2S without an intermediate reaction path involving H_2O, the porosity and crystallinity of the oxide are controlling factors. Oxides that are amorphous and relatively porous will readily convert to the sulfide whereas those that are crystalline and structurally less porous (i.e., oxides grown by oxidation of Cu metal) will not. The fact that oxides grown in oxygen are structurally less porous and offer slightly greater protection against attack by H_2S (2) would appear to confirm this trend.

Detection of Mobile Ion during the Anodic Oxidation of Silicon

G. Mende

Zentralinstitut für Kernforschung der Akademie der Wissenschaften der DDR, Rossendorf, Bereich 2, DDR—8051 Dresden, Germany

INTRODUCTION

During anodic oxidation of silicon either the cation or the anion or both must move across the thickening oxide film(1). The mobile ion can be determined by labeling a thin surface layer with a completely immobile marker atom and detecting its position after anodizing the specimen (1).

Schmidt and Owen (2) labeled an oxide film on silicon by anodizing in tetrahydrofurfuryl alcohol containing ^{32}P as phosphate. When this film was anodized in the same electrolyte which contains nonradioactive phosphate, the radioactive ^{32}P was found in the inner layers. The authors concluded that the cation was the species that migrated.

However, by implanting a thin anodic oxide film on silicon with Kr and Xe and determining its position after anodizing by means of Rutherford backscattering analysis, Mackintosh and Plattner (1) found that the anion was responsible for anodic oxide growth in four different electrolytes. From their experiments the authors draw the conclusion that P moves inward during anodic oxidation.

Commenting on the paper of Mackintosh and Plattner (1), Schmidt (3) suggested identifying unambigously the mobility of cations or anions by monitoring the sequence of cations before and after anodization with the help of epitaxial depositon of a very thin silicon layer isotopically enriched before anodizing in ^{30}Si on top of a norma silicon substrate.

In the present work an attempt is made to clarify this problem by comparing the depth distribution of ^{30}Si implanted into silicon with the depth distribution of ^{30}Si in anodic SiO_2 after anodization of silicon implanted with ^{30}Si. The amount of ^{30}Si can be identified as the radioactive isotope ^{31}Si after irradiation with thermal neutrons.

EXPERIMENTAL

Cleaned and polished ⟨111⟩ oriented samples of p-type silicon (10 ohm cm) were implanted nonaligned with ^{30}Si (dose= $3\cdot10^{16}$ atoms/cm^2, energy = 29 keV) and irradiated for $3.6\cdot10^3$ sec in the Rossendorf Research Reactor with a neutron flux of about $4\cdot10^{13}$ $cm^{-2}sec^{-1}$. After annealing treatment in a nitrogen atmosphere at 700°C for $1.8\cdot10^3$ sec the samples were anodized in a special galvanic cell (4). A 0.04N solution of KNO_3 ("purissimum per analysi") in ethylene glycol ("per synth.") served as an electrolyte. The current density was 7 mA/cm^2.

For determining the ^{30}Si implantation profile in silicon the implanted region (about 100 nm Si) was successively removed by anodizing of thin sheets (about 8 nm Si) under constant current and etching with HF (4). The radioactivity of the solution was detected with a Geiger-Muller-counter. The content of implanted ^{30}Si was calculated by means of a neutron-irradiated p-type silicon standard and by subtracting the natural content of ^{30}Si in silicon. The thickness of the removed layers was calibrated by anodic oxidation of neutron irradiated and annealed silicon which was implanted with ^{29}Si (dose=$3\cdot10^{16}$ atoms/cm^2, energy = 29 keV) to produce residual lattice damage similar to that in ^{30}Si implanted silicon after annealing treatment, and hence equal thickness/voltage increments during anodization.

For determining the ^{30}Si implantation profile in SiO_2 the implanted region (about 100 nm Si) was anodized in two steps (per step about 45 nm Si) under constant current density (7 mA/cm^2) followed by a constant voltage period for $1.8\cdot10^3$sec. The two films of anodized silicon were each successively removed (about 5 to 9 nm Si at a time) by etching for 60 sec with 1 ml of a 1:50 diluted solution containing 169g NH_4F, 67.5 ml HF and 259 ml H_2O (5). The etch process was stopped by removing the buffered HF solution and by adding 1 ml of saturated boric acid solution in water. The radioactivity of the dissolved layers was determined in the above-mentioned way. The thickness (5-9 nm Si) of each removed layer (related to the Si content of SiO_2) was calibrated by anodic oxidation and by selective etching of neutron irradiated and annealed Si which was implanted with ^{29}Si (dose= $3\cdot10^{16}$ atoms/cm^2, energy = 29 keV).

Key words: silicon, anodic oxidation, mechanism of growing oxide film.

RESULTS AND DISCUSSIONS

The results of the experiments are summarized in Fig. 1. The theoretical depth distribution of ^{30}Si implanted into silicon was calculated with the help of the tables by Smith (6) according to the LSS-theory(7). The ^{30}Si profile in anodic SiO_2 (thickness related to the Si content of SiO_2) agrees well with the ^{30}Si profile in Si and with the theoretical profile. If the silicon ions are mobile during anodization and their order changes, a significant difference between the ^{30}Si profile in SiO_2 and the ^{30}Si profile in Si must be measured. But the results prove that the sequence of silicon ions does not change during anodization. This may be supportive evidence for the mobility of oxygen ions, but could equally be caused by silicon ions being mobile but maintaining their sequence during anodic oxide growth. It needs further investigations in order to identify the mobile species during anodic oxidation of silicon.

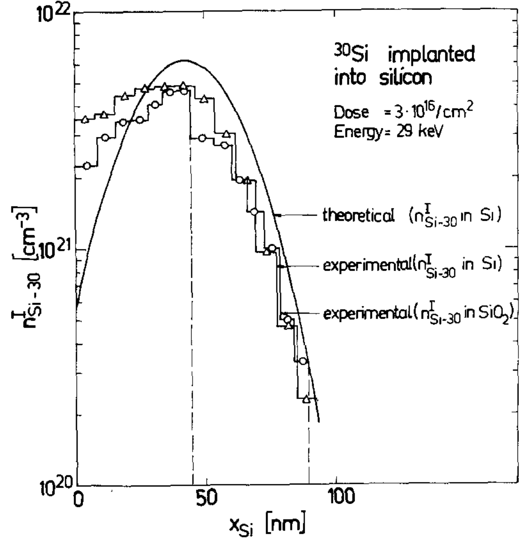

Fig. 1. The depth distribution of implanted ^{30}Si in silicon and in anodic SiO_2 (thickness related to the Si content of SiO_2). The standard deviation of thickness determination in SiO_2 is 15.5% and in Si is 9.5%. The standard deviation of determination of the implanted ^{30}Si content in SiO_2 is 15.7% and in Si is 10.7%.

A Chemical Method for Deposition of Thin Film of Bi_2S_3

P. Pramanik and R. N. Bhattacharya

Department of Chemistry, Indian Institute of Technology, Kharagpur 721302, India

Thin film formation of chalcogenides of Pb^{2+} by chemical deposition is a very well known process (1,2,3). But similar methods of deposition of thin films of Bismuth chalcogenides have not yet been reported. This brief communication describes a chemical method for the deposition of Bi_2S_3 thin films.

Thio-urea is used for slow release of S^{2-} ion and pH is maintained at 8. To keep Bi^{3+} ion in solution at pH 8, triethanolamine complex of Bi^{3+} is used.

One gm of bismuth nitrate $(Bi(NO_3)_3,5H_2O)$ is triturated with 10 ml triathanolamine and then 50 ml water is added to it. The resulting solution is continuously stirred till a nearly clear solution is obtained, which is then filtered.

A 20 ml of the Bi^{3+} solution is taken in a glass beaker. 30 ml of 1(M) thiourea solution and 1 ml of 17 (N) NH_4OH are added to it and the volume is made upto 100 ml with water. The substrate (glass or ceramic) is thoroughly cleaned and immersed in the solution. The container is placed into an oil bath at 100 - 110°C temperature for 40 minutes and then it is kept at room temperature for about 4 hours. Uniform films of Bi_2S_3 are obtained on the glass substrates. They are then taken out, washed with water and dried in air. The Bi_2S_3 films are about 0.05 - 0.1 microns thick.

NH_4OH is added to slow down the formation of Bi_2S_3 and to increase its adherence on the glass substrate.

X-ray diffraction data shows that films are amorphous in nature. Scanning electron micrograph shows that films contain random distribution of small crystallites, which is shown in figure (1). The films have high electrical resistance in comparison to single crystal. The resistivity lies in the range of 10-30 x 10^6 ohm-cm. The temperature variation of resistivity shows that activation energy of electrical conduction is 1.3 eV. The material has n-type conduction. The optical band gap of the film is found to be 1.47 eV shown in the figure (2) and it has feeble photo conductivity.

Desalination by Photoelectrodialysis

George W. Murphy*

Solar Energy Research Institute, Golden, Colorado 80401

We report the experimental demonstration of photoelectrochemically powered electrodialysis--photoelectrodialysis--as a desalination process. The concept and nomenclature have been recorded previously (1). A photoelectrochemical cell n-GaAs/ 0.16 M Na_2Se-0.02 M Na_2Se_2-C-0.16 M Na_2Se-0.02 M Na_2Se_2/Pt (2,3) and the "driven" component of an electrodialysis cell -C-0.06 M NaCl-A-0.06 M NaCl-C- (4) are collapsed into a unit, the principle of which is illustrated in Fig. 1. Here C is a cation- and A an anion-selective membrane. P is an n-type semiconductor (n-GaAs) short circuited to electrode E (Pt), which is inert except for its electron-exchanging capability with solution redox species. The selenide-polyselenide couple (represented here as Na_2Se-Na_2Se_2) is known to stabilize the n-GaAs electrode against photocorrosion. Compartments I and II contain this couple, and Compartments III and IV contain NaCl solution initially of the same concentration. Irradiation of the n-GaAs surface photooxidizes the selenide ion, thereby initiating the coupled chain of events illustrated: the reverse reaction occurs at the dark electrode, and the ion movements across the membranes result in demineralization of Compartment III and salt enrichment in IV.

This process will also be recognized as an application of a photochemical diode (5).

The experimental cell (not shown) was assembled from five machined ring discs of clear acrylic 2¼ in. O.D. and 1 in. I.D. and two 2¼ in. diameter end discs. An acrylic light tube was cemented to one end disc which served as a window. The light tube reduced the solution light path to approximately 3 mm. The cell thus exposes 1-in. diameter circles of the electrode and three membranes, forming three internal compartments 1/4 in. thick. The 1-3/16 in. diameter disc electrode was sealed by O-rings in channels machined in two of the discs. Membranes were cut to the full O.D. disc diameter and served as their own gaskets. After the electrode, membranes, and end discs were in place, they were compressed between two stainless steel end plates with six screws running the cell length. In addition to screw holes, six additional holes had been cut in the acrylic rims and membranes so as to provide channels for the "external" compartment, i. e., Compartment I of Fig. 1. The cation-selective membranes were Nafion 427 (du Pont) and the anion-selective membrane Raipore 5025, both kindly furnished by the companies. A 1.5-mm thick silicon-doped 100-face gallium arsenide wafer, one side polished, was purchased from Laser Diode Laboratories, Inc. Carrier concentration (company-furnished) was 1.1×10^{18} cm^{-3}. After making an ohmic contact to the unpolished side, a 1-mil platinum

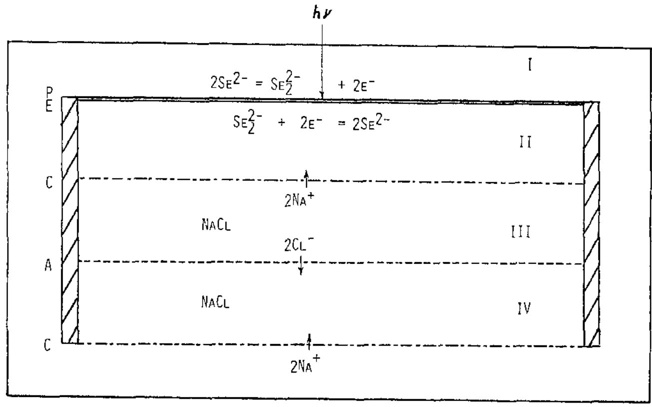

Fig. 1. Schematic Cross Section of Photoelectrodialysis Cell.

disc of the same diameter was cemented to it with silver epoxy. The gallium arsenide was etched and dipped in 0.01 M $RuCl_3$, after the procedure of Parkinson et al (3). With the electrode vs platinum in 0.8 M Na_2Se-0.1 M Na_2Se_2-1 M NaOH, a voltammogram yielded 0.8 volt on open circuit and 7.25 mA cm^{-2} at short circuit under 1000 watt xenon lamp irradiation, intensity 1.5 W cm^{-2}.

Sodium selenide was 99.9% packed under argon obtained from Cerac Chemical Co. Selenium powder used to make polyselenide was obtained from Alfa Ventron. All operations with Na_2Se and solutions made therefrom were carried out in a nitrogen atmosphere glove box. A stock solution of 0.8 M Na_2Se-0.1 M Na_2Se_2 was prepared and diluted fivefold before use in the photoelectrodialysis cell. NaCl concentration was 0.06 M, which is typical for a brackish water. The Na_2Se-Na_2Se_2 solution was circulated through Compartments I and II at a rate of about 0.1 ml/min by gravity from a reservoir. NaCl was circulated similarly through Compartment IV. The electrode was illuminated by collimated light from a 300-watt quartz halogen projector lamp, intensity 0.33 W cm^{-2}. At intervals samples were withdrawn briefly by syringe from the demineralization compartment into a micro conductivity cell and the conductivity determined.

The progress of demineralization is indicated by the conductivity plot in Fig. 2. A steady state of approximately 79% demineralization was reached in about seven hours. The desalted solution contained a suspended solid, probably selenium, indicating that some leakage of anions had occurred across the cation-selective membrane. Since the photovoltage characteristic of the electrode itself is capable of carrying the demineralization substantially to completion with ideal membranes, the 21% of starting conductivity in the steady state is a measure of the membrane imperfection.

In summary, the technical feasibility of photoelectrodialysis has been demonstrated. Economic

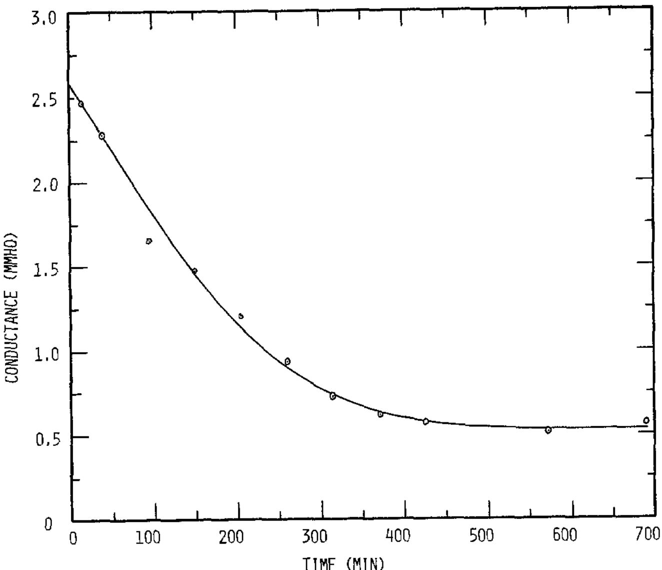

Fig. 2. Conductance of Compartment III vs Time During Desalination Experiment.

feasibility will depend in part on the development of inexpensive electrode and coupled redox materials, the same as for photoelectrochemical solar cells. Several research groups throughout the world have this as a primary objective. In addition, conditions must be found that result in negligible counterion leakage across the membrane. This might be accomplished with redox systems yielding good results at such low concentrations that the selectivity of available membranes is high, or improved membrane selectivity at the redox concentrations employed here.

Acknowledgment. I thank John Turner for the electrode voltammogram, Eric Mott for cell fabrication, and Arthur Nozik for helpful discussions.

Some Chemistry in the Li/SOCl₂ Cell

K. M. Abraham* and R. M. Mank

EIC Corporation, Newton, Massachusetts 02158

ABSTRACT

Cyclic voltammetry and constant current electrolysis studies of $SOCl_2$/$LiAlCl_4$ solutions showed that SO_2Cl_2, $SOCl^+AlCl_4^-$, SCl_2, $AlCl_3$, and Cl_2 are produced as oxidation products. Mechanisms of oxidation reactions are proposed to explain the formation of these products. Forced overdischarge of cathode limited cells produces Li_2S which reacts with $LiAlCl_4$ present in the cell to form $LiAlSCl_2$. Materials formed in anode limited cells during forced overdischarge include SO_2Cl_2, SCl_2, Cl_2, $SOCl^+AlCl_4^-$, $AlCl_3$, and a substance with infrared absorption at 1070 cm^{-1}. "Charging" of Li/$SOCl_2$ cells involves regenerative processes so that only small amounts of products accumulate in the cell.

The Li/$SOCl_2$ primary cell has received considerable research and development interest (1-20) ever since the initial reports on its discovery appeared (1, 2). The cell consists of a Li anode, an inert carbon cathode comprising porous carbon with binder on an Ni screen, and $SOCl_2$/$LiAlCl_4$ solution serving both as the solvent and depolarizer. Cell discharge reactions which satisfactorily explain previous analytical data from this laboratory (14), the studies of Dey and co-workers (7), and the recent results of Schlaikjer and co-workers (13) are

$$2SOCl_2 + 4Li \rightarrow 4LiCl + 2SO \quad [1]$$

$$2SO \rightarrow SO_2 + S \quad [2]$$

Major areas of research during the past few years have included: design and optimization of cells for various applications (3-13), studies of the cell chemistry to fully characterize discharge reactions (13-16), investigations of the voltage delay problem (17, 18), and studies of safety aspects (7, 19, 20). While considerable progress has been made in most of these areas, the explosion hazard associated with several operational modes of the cell has served as a major deterrent to its widespread practical use.

Our recent studies (19, 20) on the behavior of Li/$SOCl_2$ cells during forced overdischarge indicated that anode limited cells are potentially hazardous. During such forced overdischarge, several anode limited cells showed burning type explosions. Individual electrode potential measurements revealed that explosions in all the cells occurred after the anode potential had risen to values greater than 4V for considerable length of time prior to the explosion. It appeared that the explosions were caused by sensitive chemicals, produced by oxidation of materials present in the cell.

On the other hand, cathode limited cells appeared to be safe during forced overdischarge. Forced overdischarge of cathode limited cells typically proceeded with small reverse cell voltages, remaining steady at about −100 mV. These cells could be overdischarged for long periods of time during which the charge input considerably exceeded the amounts of both $SOCl_2$ and Li originally present in the cell. None of the cathode limited cells exploded during forced overdischarge. It appears that during forced overdischarge of cathode limited cells, Li dendrites form on the carbon electrode and lead to internal short circuits which readily accommodate the major part of the current. These short circuits provide the mechanism for the system to pass charges well in excess of stoichiometry. This situation has not appeared to constitute a specific hazard.

We have also found (21) that "charging"[1] of Li/$SOCl_2$ cells leads to regenerative cell processes so that there is no appreciable depletion of cell capacity even after an input of positive charge exceeding the amounts of $SOCl_2$ and Li originally present in the cell.

In this paper we present the results of analytical studies aimed at characterizing chemical and electrochemical reactions in Li/$SOCl_2$ cells during overdischarge and "charge." The various studies have been: (*i*) constant current electrolysis of $SOCl_2$/$LiAlCl_4$ solutions and analysis of products by infrared spectrometry; (*ii*) cyclic voltammetry of $SOCl_2$/$LiAlCl_4$ solutions; (*iii*) product analysis from Li/$SOCl_2$ cells after overdischarge and constant current "charge" using *in situ* cyclic voltammetry and infrared spectrometry.

Experimental

All experiments involving reagent handling and cell construction were carried out in the absence of air and moisture in the argon atmosphere of a dry box (Vacuum Atmospheres Corporation).

Electrolyte preparation.—The salt, $LiAlCl_4$, was prepared by melting at 190°C stoichiometric amounts of LiCl (Fisher Scientific Company, L-121, predried *in vacuo*, 10^{-3} Torr, at 400°C for 4 hr) and $AlCl_3$ (Fluka, puriss). The melt was purified by electrolysis between Al electrodes. The salt was dissolved in $SOCl_2$ (Eastman Kodak, Cat. No. 246) at room temperature. The solutions usually were 1.8M in $LiAlCl_4$.

* Electrochemical Society Active Member.

Key words: Li/$SOCl_2$ cell, cyclic voltammetry, infrared spectrometry, overdischarge, charge.

[1] The term charging implies a positive current applied to the carbon electrode.

Constant current electrolysis.—Constant current electrolysis of $SOCl_2/LiAlCl_4$ solutions was carried out in a two-compartment Pyrex glass cell having a 15 μm glass-frit separator. The cathode was a Teflon-bonded carbon electrode of known area and the anode was an expanded nickel (5Ni5-5/o, Exmet Corporation) screen. The individual electrode potentials were measured *vs.* an Li reference electrode. The electrolysis products were analyzed by infrared spectrometry.

Infrared spectral measurements.—The infrared spectra were recorded on a Beckman Acculab-5 dual beam spectrometer covering the range from 4000 cm^{-1} to 375 cm^{-1}. All spectra of liquid samples were obtained with Beckman TAC cells. These have AgCl windows and can be sealed permanently. The cells were of 0.025 or 0.1 mm path lengths. Spectra of gases were obtained with a Beckman Universal Gas Cell (10 cm path length) fitted with KBr or NaCl windows.

Cyclic voltammetry studies.—Cyclic voltammetry studies of $SOCl_2/LiAlCl_4$ (1.8M) solutions were carried out on both Ni and vitreous C electrodes. A three-electrode system with Li reference and counterelectrodes was used. The voltammetric scans were performed with an Amel Model 551 potentiostat in conjunction with their Model 566 function generator. The *i-E* curves were generally recorded using a Bascom-Turner Series 8000 Recorder equipped with microprocessor accessories.

Cyclic voltammetric studies of electrolyte from $Li/SOCl_2$ cells after various tests were performed *in situ.* Small prismatic cells comprising multiple carbon cathode and Li anode plates were used. Each electrode plate measured 3 $\times$ 2 cm per side. The cells were designed and tested in both anode and cathode limited configurations. In cathode limited cells, the electrode arrangement was Li/C/Li/C/Li/C/Li and the cell contained 2 A-hr Li, ~400 mg carbon, and 4 ml of $SOCl_2$/1.8M $LiAlCl_4$ electrolyte. The electrode package in anode limited cells was in the sequence, C/Li/C/Li/C with the cells containing 0.70 A-hr Li, ~400 mg carbon, and 4 ml of $SOCl_2$/1.8M $LiAlCl_4$. The cells were slightly flooded with electrolyte, since the small excess of electrolyte was necessary for analytical studies. In order to make *in situ* cyclic voltammetry measurements, a vitreous carbon microelectrode of 0.07 cm^2 area was introduced into the cell through a side arm of the glass envelope as shown in Fig. 1. During galvanostatic test, the microcarbon electrode was pulled away from electrolyte contact to avoid possible surface passivation. Prior to recording the voltammogram after various stages of discharge, overdischarge, or "charge," the electrode was pushed down and contact with the electrolyte was established by tilting the cell. The cell electrodes served also as the reference and counterelectrodes for cyclic voltammetry. Subsequently, electrolytes from these cells were analyzed by infrared spectrometry.

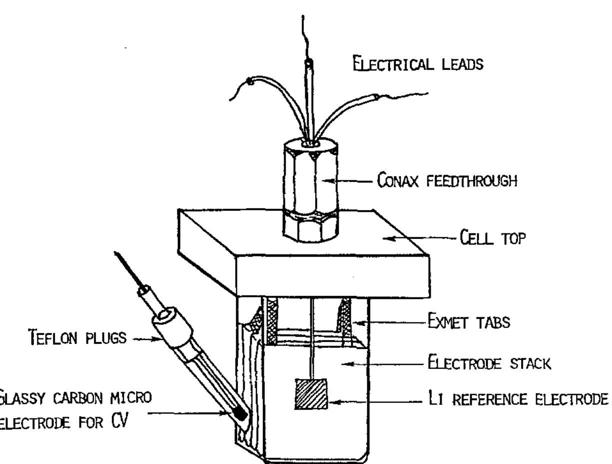

Fig. 1. Schematic view of the prismatic laboratory cell for *in situ* cyclic voltammetry.

Results and Discussion

Electrolysis of $SOCl_2/LiAlCl_4$ Solutions

Constant current electrolysis and product analysis.—Constant current electrolysis of $SOCl_2$/1.8M $LiAlCl_4$ solution on an Ni anode and carbon cathode proceeds with a constant anode potential of ~4.6V *vs.* Li^+/Li. The cell potential remains steady at ~ −0.9V. Infrared spectra of the catholyte and anolyte were recorded after electrolysis corresponding to ~0.1$e^-/SOCl_2$ and are shown in Fig. 2 and 3, respectively.

The only infrared identifiable product in the catholyte is SO_2, with absorptions at 1335 and 1150 cm^{-1} (22). The formation of SO_2 is consistent with the discharge reactions shown in Eq. [1] and [2]. The spectrum of the anolyte shows two new peaks at 1415 cm^{-1} and at 1110 cm^{-1}. The peak at 1415 cm^{-1} is due to SO_2Cl_2. This was established by infrared spectral measurements after adding SO_2Cl_2 to the anolyte. Neat SO_2Cl_2 exhibits two strong absorptions at 1205 and 1420 cm^{-1} (22). In the anolyte, the 1205 cm^{-1} absorption is hidden inside the strongly absorbing $SOCl_2$ peak at 1230 cm^{-1}. The absorption at 1110 cm^{-1} in the anolyte is most probably due to the S-O stretching vibration of the complex, $SOCl^+AlCl_4^-$ since a similar absorption was found in the infrared spectra of $AlCl_3$ solutions of $SOCl_2$ or $SOCl_2/LiAlCl_4$ electrolyte. The existence of the complex, $SOCl^+AlCl_4^-$,[2] in $AlCl_3$

[2] The ionic structure for the $AlCl_3$ complex of $SOCl_2$ is also consistent with the increasing conductivity of $SOCl_2$ with added $AlCl_3$ (24).

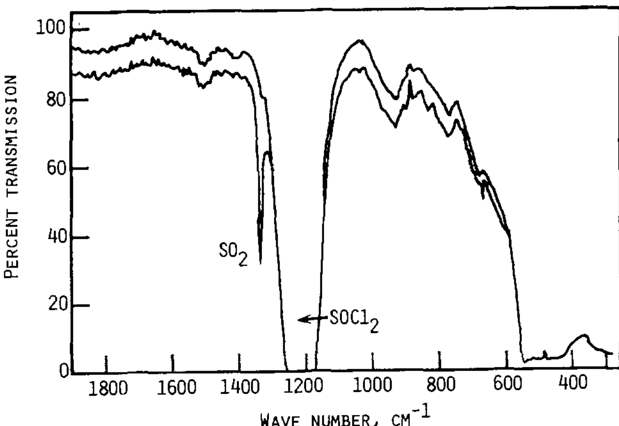

Fig. 2. Infrared spectrum of the catholyte (lower trace) after electrolysis of $SOCl_2/LiAlCl_4$ (1.8M) solution. The upper trace is the spectrum of the solution prior to electrolysis.

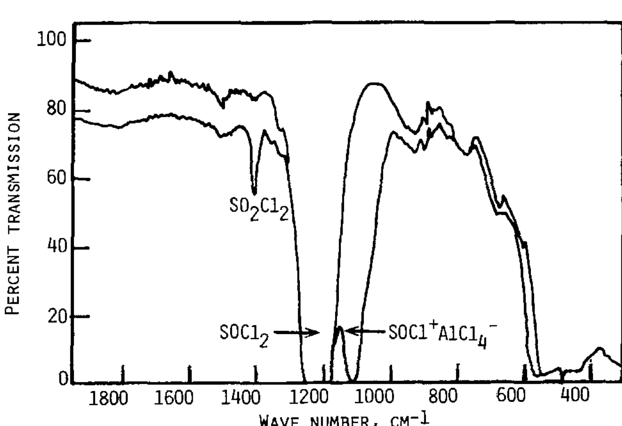

Fig. 3. Infrared spectrum of the anolyte (lower trace) after electrolysis of $SOCl_2/LiAlCl_4$ (1.8M) solution. The upper trace is the spectrum of the solution prior to electrolysis.

solutions of $SOCl_2$ has been previously established (23). The present work confirms its existence. The occurrence of the S-O symmetric stretching absorption in $SOCl^+AlCl_4^-$ at a lower frequency than in $SOCl_2$ is consistent with the ionic structure. Vapor phase infrared spectrometry showed SO_2Cl_2 also in the gas phase of the anode compartment. No other gaseous product could be identified by vapor phase infrared spectrometry. Reactions which would account for the oxidation products, SO_2Cl_2 and $SOCl^+AlCl_4^-$, are discussed in the next section.

Cyclic voltammetry studies and reaction mechanisms.—Prior cyclic voltammetry studies of $SOCl_2$/$LiAlCl_4$ solutions were primarily aimed at characterizing reduction reactions (15, 16). In the studies reported in this paper emphasis is on oxidation reactions in the $SOCl_2$/$LiAlCl_4$ solution.

A typical cyclic voltammogram on a glassy carbon electrode between 1.0 and 5.0V *vs.* Li^+/Li in $SOCl_2$/1.8M $LiAlCl_4$ solution is shown in Fig. 4. A similar voltammogram was obtained also on a Ni disk electrode. Although the overall features of the voltammogram were identical on both of the electrodes, the peaks appeared sharper on the carbon electrode. Also the cathodic peaks on Ni were slightly shifted to lower potentials.

On scanning the electrode cathodically first from open circuit, only the high current peak, I, at 2.65V and the weak current peak, II, at 1.80V are found. These peaks may be assigned, respectively, to reductions of $SOCl_2$ and SO_2, in accordance with previous observations by others (15, 16). The assignments are in agreement with reactions [1] and [2].

In the anodic region between 4.0 and 5.0V, the voltammogram shows two broad peaks, IV and V at 4.55V and 4.65V and a sharp, high current peak, VI, at 5.0V. In poorly resolved voltammograms, the two peaks IV and V merge together and appear as one peak. It was found that if the electrode was cycled several times between 4.0 and 1.0V, the height of the current peak around 4.6V became very large in a subsequent anodic sweep to 5.0V In these cases current peaks IV and V generally appeared together as a single peak.

When the electrode is scanned cathodically below 4.0V after the anodic sweep to 5.0V, three reduction peaks, VII at 3.6V, VIII at 3.25V, and IX at 2.8V, appear in the voltammogram. These are evidently due to reductions of solution anodization products. The appearance of these peaks and their relative peak heights

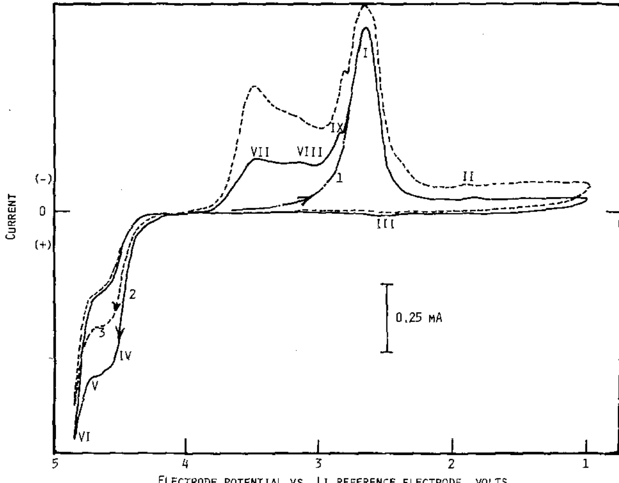

Fig. 4. Cyclic voltammograms of $SOCl_2$/1.8M $LiAlCl_4$ on a glassy carbon electrode. Scan rate = 100 mV/sec. Curve 1 was obtained by scanning the electrode cathodically first from OCV, 3.65V. Curve 2 was obtained by scanning the electrode anodically first from OCV. Curve 3 was obtained after twice cycling the electrode between 4.0 and 5.0V.

were found to depend on the potential of scan reversal. None of these three peaks appear when the scan is reversed at potentials below 4.0V. When the scan is reversed at ~4.6V, the peak at 3.25V appears as the major one. On increasing the reversal potential to values greater than 4.6V, the height of the peak at 3.6V also increases along with the appearance of the shoulder at 2.8V. If the electrode is cycled several times between 4 and 5V before sweeping cathodically, all three peaks show increased peak heights.

In a voltammogram obtained after addition of SCl_2 to $SOCl_2$/1.8M $LiAlCl_4$ solution and scanning the electrode cathodically first from open circuit, the onset of the cathodic current begins at ~3.8V with a peak at 3.65V. Similarly, the voltammogram obtained after adding Cl_2 to $SOCl_2$/1.8M $LiAlCl_4$ solution shows a reduction peak at 3.25V. When SO_2Cl_2 is added to $SOCl_2$/1.8M $LiAlCl_4$, a reduction peak is observed at ~2.9V as a shoulder to the $SOCl_2$ peak. It appears from these data that Cl_2, SCl_2, and SO_2Cl_2 are formed during the oxidation of $SOCl_2$/$LiAlCl_4$ solutions. We note that the reduction potentials of SCl_2, Cl_2, and SO_2Cl_2 observed here are in agreement with previous reports (15, 16).

Electrochemical oxidation of $SOCl_2$ was first studied by Spandau *et al.* (25). It was reported by these authors that electrolysis of 0.14M $(C_2H_5)_3NHCl/SOCl_2$ solution gave Cl_2 as the oxidation product. The primary cathodic product, according to the authors, was $SOCl^+$, which decomposed subsequently to various substances, the nature of which depended on the temperature of the experiment. Using cyclic voltammetry Behl (14) also identified Cl_2 as an oxidation product of $SOCl_2$/$LiAlCl_4$ solutions. He suggested an oxidation reaction as shown in Eq. [3]

$$2SOCl_2 + 2AlCl_4^- \rightarrow 2SOCl^+AlCl_4^- + Cl_2 + 2e^- \quad [3]$$

Our data, however, suggest more complex reactions.

The most probable reactions which correspond to current peaks, IV at 4.55V and V at 4.65V in the voltammogram would be oxidation of $SOCl_2$ as shown in Eq. [3] and oxidation of $AlCl_4^-$ as depicted in Eq. [4]

$$AlCl_4^- \rightarrow AlCl_3 + \tfrac{1}{2} Cl_2 + e^- \quad [4]$$

The $AlCl_3$ will immediately react with $SOCl_2$ to produce $SOCl^+AlCl_4^-$ (Eq. [5])

$$SOCl_2 + AlCl_3 \rightarrow SOCl^+AlCl_4^- \quad [5]$$

Because of the close proximity of the current peaks IV and V, it is difficult to assign them individually to the reactions [4] and [5]. However, we found the current peaks near 4.6V increased as a function of [$LiAlCl_4$] from 0.25M to 1.8M. This suggests that oxidation of $AlCl_4^-$ occur in this region.

The following evidences suggest that oxidation of LiCl according to Eq. [6] also occurs at ~4.6V

$$LiCl \rightarrow \tfrac{1}{2} Cl_2 + Li^+ + e^- \quad [6]$$

Electrodes which become passivated with LiCl in an initial cathode sweep can be regenerated by anodizing at ~4.6V. A considerably enhanced current peak is observed at ~4.6V after a cathodic sweep to 1.0V such that LiCl has plated onto the electrode surface.

Between ~4.6 and ~5.0V oxidation of $SOCl^+AlCl_4^-$ may occur to produce SO_2Cl_2 and SCl_2. The assignment is based on the fact that the amounts of these materials increase with scan reversal potentials above 4.6V. It is possible to conceive of several reaction schemes by which these materials are produced. We may speculate on the scheme shown below in Eq. [7]-[10]

$$SOCl_2 + SOCl^+AlCl_4^- \rightarrow [SCl(AlCl_4)]^{+2} + SO_2Cl_2 + 2e^- \quad [7]$$

$$[SCl(AlCl_4)]^{+2} + 2AlCl_4^- \rightarrow SCl(AlCl_4)_3 \quad [8]$$

$$SCl(AlCl_4)_3 \rightarrow SCl(AlCl_4) + Cl_2 + 2AlCl_3 \quad [9]$$

The overall reaction from Eq. [7]-[9] is

$$SOCl_2 + SOCl^+AlCl_4^- + 2AlCl_4^- \rightarrow SCl(AlCl_4) + SO_2Cl_2 + Cl_2 + 2AlCl_3 + 2e^- \quad [10]$$

In reaction [7], the oxidation of the oxide moiety in $SOCl^+AlCl_4^-$ is considered in a manner similar to the oxidation of Cl^-, considered in the primary oxidation shown in Eq. [3]. The oxygen presumably oxidizes $SOCl_2$ to SO_2Cl_2. The compounds $SCl(AlCl_4)_3$ and $SCl(AlCl_4)$ are $AlCl_3$ complexes, respectively, of SCl_4 and SCl_2. The complex $SCl(AlCl_4)$ has been identified in the reaction of SCl_2 and $AlCl_3$ (26). The disproportionation reaction shown in Eq. [9] is justifiable on the ground that SCl_4 is unstable at room temperature and disproportionates to SCl_2 and Cl_2 (27).

Product Analysis from Li/$SOCl_2$ Cells

Cathode limited cells.—The typical behavior of a cathode limited cell during forced overdischarge is shown in Fig. 5. The potential profiles suggest that the major anodic process would be the electrostripping of Li. The stripped Li would be plated onto the cathode where it could remain in the elemental form, or could be intercalated into the carbon to form C_xLi_y. Intercalation of Li onto carbon has been shown to begin at potentials as high as 1.5V *vs.* Li^+/Li (28). The long periods of forced overdischarge possible in cathode limited cells, probably due to short circuit (19, 20) suggests the formation of Li dendrites on the cathode.

The infrared spectrum of the electrolyte from the cathode limited cell shown in Fig. 5 after the forced overdischarge is depicted in Fig. 6. The main features of the spectrum are the absorptions at 1340 and 1150 cm^{-1} due to SO_2, the strong absorption centered at 1200 cm^{-1} due to $SOCl_2$, and the absorptions of medium intensities at 790 and 660 cm^{-1}. We have found that it is possible to chemically produce species with infrared absorptions at 790 and 660 cm^{-1} by treating Li_2S with $SOCl_2/LiAlCl_4$ solutions. When Li_2S is added to $SOCl_2$, no apparent reaction takes place, nor is there any apparent solubility of Li_2S. However, a reaction does take place when Li_2S is added to $SOCl_2$ containing $LiAlCl_4$. The absorptions at 790 and 660 cm^{-1} are present in the infrared spectrum of the solution product of the reaction involving equimolar amounts of Li_2S and $LiAlCl_4$ in $SOCl_2$. The reaction may be represented by Eq. [11]

$$Li_2S + LiAlCl_4 \rightarrow LiAlSCl_2 + 2LiCl \quad [11]$$

The existence of $AlSCl_2^-$ species has previously been identified (29) in solutions of Li_2S or Na_2S in NaCl/$AlCl_3$ molten salt electrolytes. The formation at room temperature of $LiAlSCl_2$[3] according to reaction [11] in a solvent such as $SOCl_2$ is not unreasonable. The infrared absorptions at 790 and 660 cm^{-1} may be associated with Al-S and Al-Cl bond vibrations, respectively, of $LiAlSCl_2$. These may be compared to the infrared spectra of Al_2S_3 which shows a band near 800 cm^{-1}, and to that of Al_2Cl_6, in which the terminal Al-Cl bond absorption is found at 630 cm^{-1}.

The above results suggest that during forced overdischarge of cathode limited cells, Li_2S is produced in the cell, Eq. [12], which reacts immediately with $LiAlCl_4$ to form $LiAlSCl_2$

$$2Li^+ + S + 2e^- \rightarrow Li_2S \quad [12]$$

It is probable that some $LiAlS_2$ is also present in these solutions.

Infrared spectral data showed the presence of $LiAlSCl_2$ also in the electrolyte from cathode limited cells which had been overdischarged on resistive load. It seems that in overdischarged cathode limited cells, which invariably contain S, the formation of Li_2S is a spontaneous process.

Anode limited cells.—Electrolytes from two types of anode limited cells were analyzed: (*i*) discharged cells in which the anode consisted of only an Ni grid with no Li on it. This type of cell represents an extreme case of anode limitation, (*ii*) complete cells which had been forced overdischarged.

The potential profile during discharge of a typical cell without Li on the anode is shown in Fig. 7. When discharged at a current density of 1 mA/cm^2, the anode polarized immediately to ~4.7V and remained steady at this value during the passage of 3.6 A-hr of charge. The cell potential remained steady at ~ −1.0V. It has been found that these types of cells could be forced overdischarged almost indefinitely without any significant change in cell polarization from the above values. The data suggest that the reactions in these cells involve regenerative processes so that very little net chemical change takes place.

The infrared spectrum of the electrolyte from the cell shown in Fig. 7 exhibited absorptions due to SO_2Cl_2 (1420 cm^{-1}), SO_2 (1340 cm^{-1}), and $SOCl^+AlCl_4^-$ (1110 cm^{-1}). There was also an absorption band at 1070 cm^{-1}. The material exhibiting the latter band has not yet been identified, but it may be a sulfur-oxy compound since S-O stretching vibrations are often found as strong bands in this region of the spectrum. Since this material was absent either

[3] We have synthesized $LiAlSCl_2$ from the reaction of LiCl and AlSCl in $SOCl_2$ and its infrared spectrum in $SOCl_2$ has been verified. This will be the subject of a future paper.

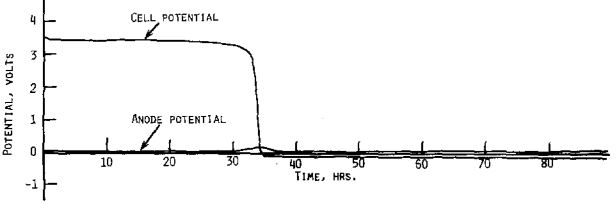

Fig. 5. Discharge and overdischarge of a cathode limited prismatic Li/$SOCl_2$ cell. Current = 36 mA; current density = 1 mA/cm^2.

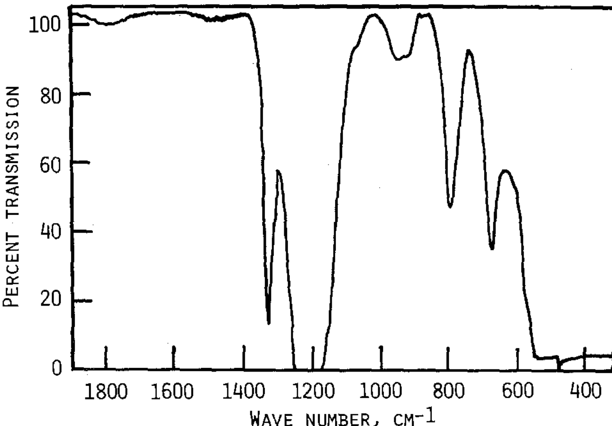

Fig. 6. Infrared spectrum of the electrolyte from cathode limited Li/$SOCl_2$ cell after forced overdischarge.

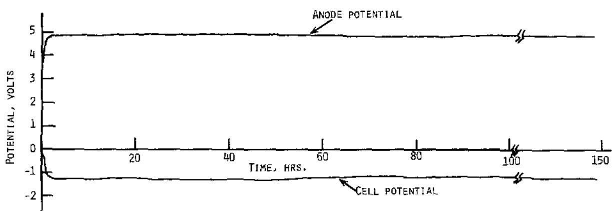

Fig. 7. Discharge curve for a prismatic Li/$SOCl_2$ cell without Li on the anode. Current = 24 mA.

in the catholyte or in the anolyte from the electrolysis cell, it must have been produced by chemical or electrochemical reaction(s) involving primary electrolysis products of $SOCl_2/LiAlCl_4$ solutions. Figure 8 shows the cyclic voltammograms at two different stages of discharge of the cell in Fig. 7. They show that SCl_2 ($\sim$3.6V) and Cl_2 ($\sim$3.2V) are also present in the cell.

Based on the analytical data as well as the oxidation reactions discussed in the previous section, the major regenerative processes in these cells may be explained by the following scheme

$$AlCl_4^- \rightarrow AlCl_3 + \tfrac{1}{2} Cl_2 + e^- \quad [13]$$

$$SOCl_2 \rightarrow SOCl^+ + \tfrac{1}{2} Cl_2 + e^- \quad [14]$$

$$SOCl^+ + AlCl_4^- \rightarrow SOCl^+AlCl_4^- \quad [15]$$

$$SOCl_2 + AlCl_3 \rightarrow SOCl^+AlCl_4^- \quad [16]$$

$$\tfrac{1}{2} Cl_2 + Li \rightarrow LiCl \quad [17]$$

$$\tfrac{1}{2} Cl_2 + Li^+ + e^- \rightarrow LiCl \quad [18]$$

$$LiCl + SOCl^+AlCl_4^- \rightarrow LiAlCl_4 + SOCl_2 \quad [19]$$

Note that the reaction shown in Eq. [19] regenerates the cell materials. As noted SO_2Cl_2 and SCl_2 are also produced in these cells and they would be formed according to reactions depicted in Eq. [7]-[9]. However, regenerative processes involving these materials may also occur so that they accumulate only in small amounts.

The potential profiles during forced overdischarge of an anode limited $Li/SOCl_2$ cell is shown in Fig. 9. The anode potentials exhibit considerable fluctuations, but they eventually arise to and stay at values considerably higher than 4.0V. Several C-size anode limited cells showing this type of behavior exploded (19, 20). The anode potential profiles suggest that oxidation of $SOCl_2$ or other materials present in the cell can occur during forced overdischarge. It is probable that explosions are caused by materials produced by the oxidation reactions.

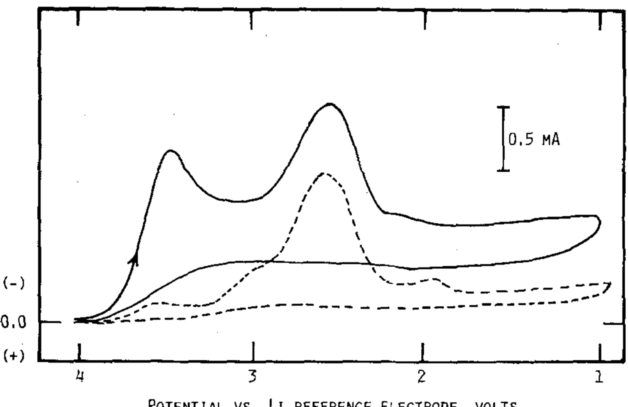

Fig. 8. Cyclic voltammograms of electrolyte from the cell in Fig. 7 on glassy carbon electrode. The solid curve represents the voltammogram obtained at the end of the test shown in Fig. 7. The voltammogram represented by broken lines was obtained after 0.10 A-hr discharge. The electrode was first scanned cathodically. Scan rate = 100 mV/sec.

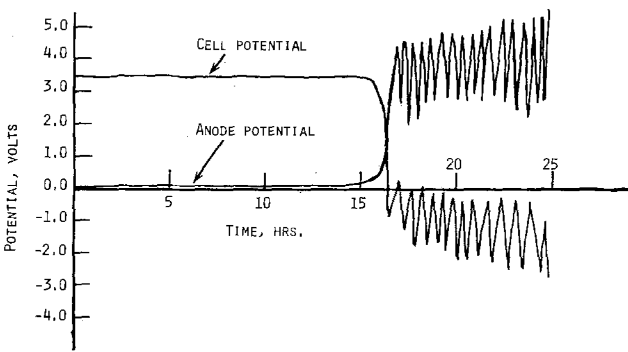

Fig. 9. Galvanostatic discharge and overdischarge of anode limited prismatic Li/SOCl₂ cell. Current = 24 mA; current density = 1.0 mA/cm².

The major feature of the infrared spectrum of the electrolyte from the cell shown in Fig. 9, which is typical of the many anode limited cells tested, was the absorption band at 1070 cm^{-1} along with peaks due to $SOCl_2$ and SO_2. The cyclic voltammogram of the electrolyte was similar to that shown in Fig. 8 indicating the presence of SCl_2 and Cl_2.

The known chemical properties of SCl_2 and Cl_2 suggest that these materials may not cause the kind of explosions we have observed in anode limited cells. The material with the infrared absorption at 1070 cm^{-1} could be a candidate, although no problems were encountered in the handling of the electrolyte containing the material. It is possible that other sensitive materials are produced in the cell which may have only transitory existence as intermediates but which may accumulate under special circumstances in the cell. As noted, the nature of the products or their eventual accumulation would depend on whether or not Li is present in the cell at the time it goes into the overdischarge mode, and on the degree of the regenerative processes in the cell. We have found (19, 20) that an $Li/SOCl_2$ cell may well be anode limited, even though it is not Li limited. The latter can result from poor electrical contact between Li and the anode current collector. These effects depend to a great extent on cell construction parameters and the amount of such products which accumulate during forced overdischarge would vary considerably from one cell to the other.

"Charged" Li/SOCl₂ cells.—The potential profiles during "charging" of a fresh $Li/SOCl_2$ cell is shown in Fig. 10. Upon applying a charging current of 1 mA/cm², the cell immediately polarized to 4.1V and showed no further change in polarization with continued "charging." The anode potential remained steady at $-$0.1V. In general, it was possible to subject the cells to "charging" currents utilizing charges considerably in excess of the amounts of $SOCl_2$ or Li originally present in the cell. Moreover, the cells could be discharged after the extended "charging" to yield capacities equivalent to those obtainable from fresh cells (21). The data suggest that the reactions associated with the charging of $Li/SOCl_2$ cells involve a sequence of regenerative cell processes. The behavior is similar to that found in the discharge of cells without Li on the anode.

The predominant reactions on a carbon electrode at potentials between 4.1 and 4.6V are the ones shown in Eq. [3] and [4]. The regenerative processes may then involve the same set of reactions shown in Eq. [13]-[18]. In this case the oxidation reactions take place on the C electrode and the reduction reactions take place on the Li electrode.

Cyclic voltammetry and infrared spectral data on electrolyte from cells after "charging" showed the net accumulation of several reaction products. The products identifiable from the infrared spectrum were

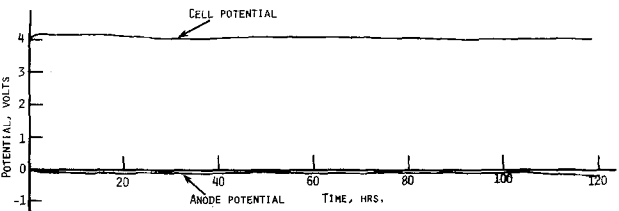

Fig. 10. Galvanostatic "charging" of prismatic Li/SOCl₂ cell. Current = 36 mA; current density = 1 mA/cm².

SO_2Cl_2 (1415 cm^{-1}) SO_2 (1335 cm^{-1} and 1150 cm^{-1}) and the material absorbing at 1070 cm^{-1}. The cyclic voltammogram is shown in Fig. 11. The compounds identifiable from the cyclic voltammogram are SCl_2 (reduction peak at ~3.6V) and Cl_2 (reduction peak at ~3.2V). All the materials except SO_2 are oxidation products of $SOCl_2/LiAlCl_4$ electrolyte. SO_2 is a reduction product of $SOCl_2$.

There is a close similarity between the products accumulated in anode limited cells during forced overdischarge and those in cells during "charging." Thus, although none of the cells (both C-size and small prismatic cells) we have tested (21) exploded during "charging," it is advisable to employ caution when $Li/SOCl_2$ cells are subjected to a "charging" current. We note that explosions in anode limited cells during forced overdischarge occurred only under very special conditions (19, 20).

Conclusions

Oxidation processes in $SOCl_2/LiAlCl_4$ solutions have been shown to involve reactions more complex than previously suggested (15). The materials, SO_2Cl_2, $SOCl^+AlCl_4^-$, $AlCl_3$, SCl_2, and Cl_2 have been identified as oxidation products. Reaction mechanisms have been proposed to account for the formation of these products.

Forced overdischarge of cathode limited $Li/SOCl_2$ cells leads to the formation of Li_2S. This reacts with $LiAlCl_4$ to form $LiAlSCl_2$ and probably $LiAlS_2$.

Among the materials formed in anode limited cells during forced overdischarge are SCl_2, Cl_2, and a material with infrared absorption at 1070 cm^{-1}. The latter is probably a sulfur-oxy compound. Analytical data suggest that other materials such as SO_2Cl_2 and $SOCl^+AlCl_4^-$ may also form in these cells during overdischarge. The formation and/or accumulation of these and other materials may depend to a great extent on whether or not Li is present in the cell during forced overdischarge.

The "charging" of $Li/SOCl_2$ cells leads to regenerative cell processes so that after a long "charge" only small amounts of products accumulate in the cell. Similar products were identified from "charged" cells and from forced overdischarged anode limited cells. This suggests that "charging" of $Li/SOCl_2$ cells may be hazardous, although none of the cells we have "charged" exploded.

Acknowledgment

The experimental assistance of Mr. P. G. Gudrais during the early phases of the work is gratefully acknowledged. We also acknowledge fruitful discussions with Dr. G. L. Holleck and Dr. S. B. Brummer. Ambient Temperature Cycling of an Na-TiS_2 Cell

Gerald H. Newman* and Lawrence P. Klemann*

Exxon Research and Engineering Company, Corporate Research Laboratories, Linden, New Jersey 07036

ABSTRACT

Sodium-titanium disulfide cells have been cycled at ambient temperature in sodium triethyl(N-pyrrolyl)borate-dioxolane electrolyte. During primary discharge at 2.5 mA/cm^2 two voltage plateaus or steps are seen in plots of cell emf *vs.* sodium stoichiometry in Na_xTiS_2 and a limiting cathode composition is reached when x is 0.8. During repeated discharge and recharge cycling the capacity of the higher voltage step is lost while the capacity of the lower voltage step remains essentially constant. A simple prismatic design for sodium organic electrolyte cells is described and characteristic properties of the electrolyte are discussed.

Considerable recent attention has been focused on lithium intercalation into the layered dichalcogenide, titanium disulfide. Detailed investigations into the structure (1-4) and physical properties (5) of lithium intercalates, and electrochemical intercalation studies (6-7) have contributed to the fundamental understanding of the chemical physics of the Li-TiS_2 system. Also, the results of early efforts to exploit the inherent reversibility of lithium intercalation for rechargeable batteries have been reported (6).

Pioneering investigations have extended the scope of intercalation reactions to include sodium as a guest element in the TiS_2 host lattice. Sodium intercalates of TiS_2 were prepared and characterized by Rouxel and co-workers (8) and by Silbernagel and Whittingham (9). Winn *et al.* (10) determined an equilibrium emf curve for Na_xTiS_2 as a function of sodium content. Their experimental procedure employed a sodium amalgam anode and a sodium vanadium bronze reference electrode in an electrolyte of NaI dissolved in propylene carbonate. More recently, Brummer *et al.* (11) cycled an Na-TiS_2 cell at 130°C. They used a cell configuration consisting of a molten sodium anode, a β-alumina separator, a TiS_2 cathode, and a 1,2-bis(methoxyethoxy)ethane solution of NaI as the electrolyte. The relatively elaborate experimental procedures employed in these previous electrochemical investigations of the Na-TiS_2 system were developed largely to circumvent the problem of sodium's reactivity toward organic electrolytes.

In our laboratories, investigations directed toward the systematic design of organic electrolytes for alkali metal batteries have led to the identification of a broad class of organoborate salts which are stable toward alkali metals. One of these electrolytes, a solution of sodium triethyl(N-pyrrolyl)borate in 1.3-dioxolane (12), has been used to cycle a simple prismatic Na-TiS_2 cell at ambient temperature as well as other solid-state cathodes (13).

Experimental

The steps involved in the preparation of $Na[(C_2H_5)_3B(NC_4H_4)]$ in dioxolane are shown in Eq. [1]. The

$$B(C_2H_5)_3 + NaH \rightarrow Na^+[B(C_2H_5)_3H]^-$$
$$\xrightarrow{\text{pyrrole}} H_2 + Na^+[B(C_2H_5)_3(NC_4H_4)]^- \quad [1]$$

intermediate, sodium triethylborohydride, was not isolated but was allowed to react with one equivalent of pyrrole to give a dioxolane solution of sodium triethyl(N-pyrrolyl)borate. The proton NMR spectrum of this solution showed peaks at 0.33 and 0.65δ (centers of multiplets, 15H, $-C_2H_5$ protons), 5.95 and 6.82δ (apparent triplets, 4H, $-NC_4H_4$ protons), and singlets for the dioxolane protons at 3.81 and 4.84δ ($-CH_2CH_2-$ and $O-CH_2-O$, respectively).

Specific resistivities of electrolyte solutions were determined at room temperature with a Yellow Springs Instrument Company dip-type conductivity cell (cell constant 1/cm) and a Wayne Kerr conductivity bridge. Prismatic Na-TiS_2 electrochemical cells were constructed as shown schematically in Fig. 1. The electrode supports were tantalum Distex® screens, 6.5 cm^2 in area with about 8 cm long tabs. Thin slices of sodium metal from the center of an ingot of J. T. Baker reagent grade sodium were pressed into the Ta grid and served as the anode (and reference) electrodes. A dry mix of TiS_2 and 10% Teflon powder was pressed into a Ta grid and hot bonded at 300°C under He. Polypropylene mat and microporous polypropylene separators were placed between the layers of the anode-cathode-anode sandwich. The cells were inserted into polyethylene bags and electrode alignment was maintained by means of small clamps. The electrolyte (about 5 ml of ~1.5m solution) was added to the bag and the cell assembly was mounted upright in a glass test vessel which had a ground glass joint (for airtight sealing) and sealed glass to metal through-puts, terminated on the inside with alligator clips (for electrical contact with the cell electrodes). The assembly of the Na-TiS_2 cell was done under

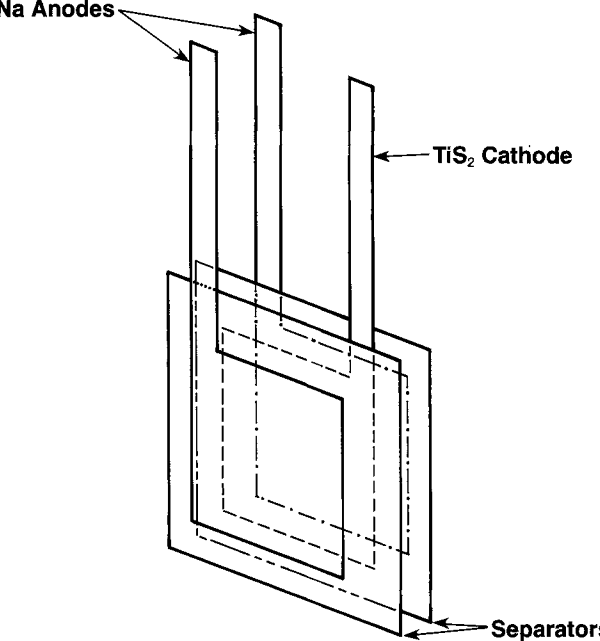

Fig. 1. Schematic construction design of prismatic Na-TiS_2 cells

* Electrochemical Society Active Member.
Key words: organic, battery, current density, diffusion.

an He atmosphere. The completed test units were removed from the dry box and clamped upright for cell testing which was accomplished using Propel automatic battery cycling equipment. Cycling was done at constant current to pre-set voltage limits.

Results and Discussion

The solubility of sodium triethyl(N-pyrrolyl)borate in 1,3-dioxolane is greater than 2.7m and its specific resistivity is concentration dependent. A minimum of 270 Ω-cm occurs at about 1.5m. The effect of solute concentration on specific resistivity is shown in Fig. 2, which also contains data for the analogous lithium and potassium boron complex anion salts for comparison. Proton NMR analysis of these salt adducts in dioxolane reveals significant changes in the chemical shifts of the aliphatic proton resonances associated with the $-C_2H_5$ groups bonded to boron, compared with their respective resonance positions seen in dioxolane solutions of free triethylboron. The changes seen in the NMR and the high conductivities observed for the final solutions are positive evidence for the formation of boron complex anion salts. We found no evidence to suggest that these anions undergo dissociation to free alkali metal pyrrole and triethylboron. Neither did we find evidence for rapid exchange between the $B(C_2H_5)_3$ complexed in the salt adduct and free triethylboron when both materials were intentionally mixed and examined by proton NMR. In this experiment resonances for both complexed and free $B(C_2H_5)_3$ were clearly distinguishable.

The alkali metal stability of the electrolyte coupled with its relatively low resistivity and high solubility enables the construction and ambient temperature high rate cycling of cells containing solid sodium anodes. We selected the Na-TiS_2 system for these investigations in order to compare our results with work previously reported and to study further the effects of multiple cycling.

The initial open-circuit voltages of the Na-TiS_2 cells were about 2.3V. Discharge of the cells was carried out at 2.5 mA/cm^2 resulting in a primary capacity equal to 80% of that theoretically possible for the amount of active TiS_2 present. Figure 3 contains the result of the primary discharge of one Na-TiS_2 cell and shows the dynamic cell emf (in volts)

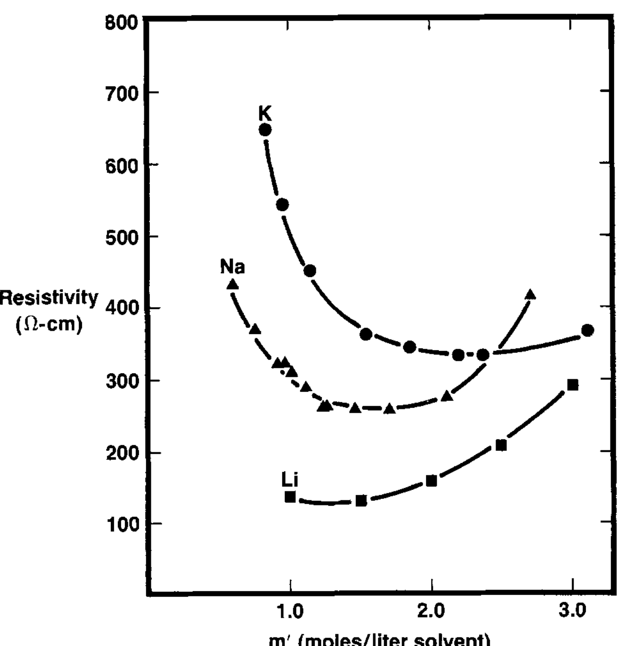

Fig. 2. Concentration dependence of $M^+[B(C_2H_5)_3(NC_4H_4)]^-$ solution resistivity in 1,3-dioxolane.

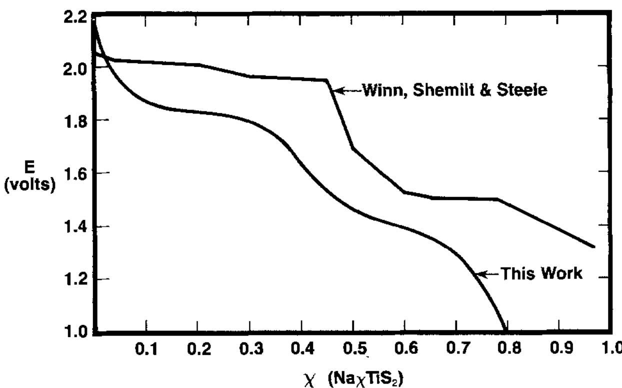

Fig. 3. Voltage vs. Na_xTiS_2 for the primary discharge of sodium-titanium disulfide cells.

as a function of the sodium stoichiometry, x, in, Na_xTiS_2. Two plateau regions or steps are clearly evident in Fig. 3. One step extends from TiS_2 to about $Na_{0.4}TiS_2$ and the second encompasses the composition range between $Na_{0.4}TiS_2$ and $Na_{0.8}TiS_2$, in qualitative agreement with previous reports (8-10).

Rouxel and co-workers (8) reported that ordering of the guest element during sodium intercalation produces three structurally distinct phases. These were described by Rouxel as being the 1st and 2nd stage triganol prismatic coordination sites and the third phase being the triganol antiprismatic coordination site. The data of Winn (10), included in Fig. 3 for comparison, was obtained at a maximum current rate of 40 $\mu A/cm^2$ and shows a third step (third phase) which contains additional sodium intercalation capacity for titanium disulfide above the $Na_{0.8}TiS_2$ composition. Silbernagel and Whittingham (9) did not obtain sodium contents above 0.8 using sodium naphthalenide as the sodium intercalation reagent for TiS_2. They concluded that the small diffusion coefficient for Na^+ in the host's antiprismatic coordination sites probably limited the rate of sodium intercalation above $Na_{0.8}TiS_2$. Clearly then our 2.5 mA/cm^2 discharge rate is too high to allow significant sodium intercalation in the region above $Na_{0.8}TiS_2$.

After their primary discharge, the cells were cycled at constant current. The first recharge at 0.6 mA/cm^2 showed two voltage plateaus (analogous to those observed during primary discharge) as a function of sodium content in the TiS_2 lattice (Fig. 4). Cycling was continued for 16 complete cycles. The results are summarized in Table I. Worth noting in Table I is the fact that the discharge rate was reduced to 1.25 mA/cm^2 during cycles 3 through 7 and then to 0.3 mA/cm^2 during cycles 8 through 16. In order to return the cell to a "full" state of charge, the system was potentiostated prior to the final discharge.

[A] M.U. = (actual discharge capacity/cathode capacity) × 100.
[B] Potentiostatically charged before this discharge.

Examination of the data contained in Table I shows that the capacity in the higher voltage plateau region (step 1 between TiS_2 and $Na_{0.4}TiS_2$) steadily and irreversibly decreases. Even when the discharge rate was lowered (between cycle No. 2 and 3 for example) there is no evidence for the recovery of lost capacity in this region.

On the other hand the cell cycling data demonstrates that very little capacity is lost in the lower voltage plateau (step 2 between $Na_{0.4}TiS_2$ and $Na_{0.8}TiS_2$) over 16 cycles. Even the minor loss in capacity that might be suggested by the data is essentially recovered completely when the rate of discharge is reduced (between cycle No. 2 and 3, and cycle No. 7 and 8). In fact, after the potentiostatic charge that followed cycle No. 15, the discharge capacity found (for step 2) in cycle No. 16 was 42% at 0.3 mA/cm^2. Comparison of this result with the 38% found in step 2 for the first discharge at 2.5 mA/cm^2 shows that there is no permanent loss of capacity in the lower voltage plateau ($0.4 < x < 0.8$ in Na_xTiS_2).

A composite of the voltage *vs.* composition curves for the 1st, 3rd, and 16th discharges is shown in Fig. 5. Here the loss of cycling capacity in the higher voltage plateau ($0 < x < 0.4$ in Na_xTiS_2) appears in sharp contrast to the essentially constant capacity observed in the lower voltage plateau ($0.4 < x < 0.8$ in Na_xTiS_2). These results strongly suggest that structural changes in the TiS_2 host lattice occur during sodium intercalation and deintercalation. Furthermore these structural changes appear to permanently affect the host's capacity to reversibly intercalate sodium ions. A more detailed interpretation of structural changes which are indicated must await the results of x-ray investigations of the sodium intercalates.

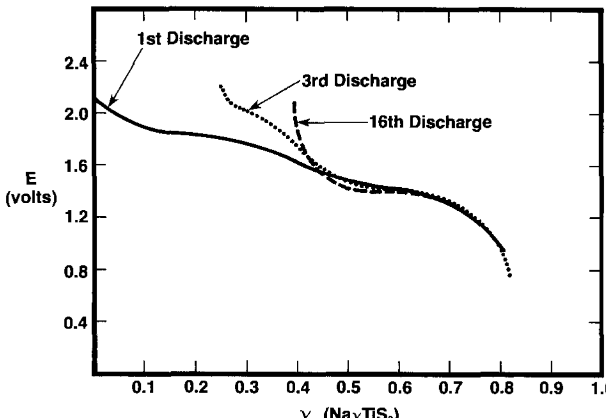

Fig. 5. Effect of cell cycling on voltage-Na_xTiS_2 curves

While we have demonstrated in this work the possibility of the reversible operation of an ambient temperature sodium anode cell we agree with an analysis (14) which shows the Na-TiS_2 system to be an impractical energy storage device. In fact, if the Na-TiS_2 couple were limited to the compositional range between $Na_{0.4}TiS_2$ and $Na_{0.8}TiS_2$, then the theoretical energy density would be only 144 W-hr/kg. This contrasts to the 480 W-hr/kg reported as the theoretical energy density for Li-TiS_2 (6).

Groupe de Recherche No. 4 du CNRS, Physique des Liquides et Electrochimie, Associé à l'Université Pierre et Marie Curie, 75230 Paris Cedex 05, France

ABSTRACT

The improvement of the lithium cycling efficiency obtained by substituting an aluminum substrate for a lithium substrate is explained by means of morphological and kinetic studies of the electrodes in the molar solution $LiClO_4$-propylene carbonate. SEM observations show that the insertion rate of the lithium deposit into aluminum can be sufficiently high so as to avoid dendritic growth; ESCA analysis reveals that propylene carbonate leads to a chemical formation of a polymeric membrane on the electrodes, which is less important on the aluminum than on the lithium substrate. Electrochemical impedance measurements associated with polarization curve data point out that most of the surface is active, giving rise to an exchange current density of about 17 mA/cm²; these studies also demonstrate that diffusion processes in the passivating layer and in the bulk of the electrode are responsible for the limited lithium cycling performances with the aluminum substrate.

The difficulties encountered in the development of high energy density lithium secondary batteries are mainly linked to the reactivity of lithium which leads to the formation of passivating layers on cathodically deposited lithium during both charge and storage periods. These layers are responsible for the failures observed during the experiments carried out to obtain a dissolution efficiency of the lithium deposit very close to 1, a condition required to make batteries which will work adequately for a great number of cycles.

Various attempts have been made to reduce the adverse effects of the chemical passivation either by a thorough purification of the electrolyte, or by introducing additives, or further, by altering the solvent reactivity by structural modifications (1-3). Nevertheless the improvements obtained by these different methods although appreciable are still limited.

Further attempts have been made using the property of lithium incorporation in metallic lattices, which is likely to lead to a reduction in the chemical activity of the electrode (4-6). As promising results have been obtained with an aluminum substrate (7), we have performed a systematic comparison of the electrochemical behavior of lithium deposited on this type of substrate and on a lithium substrate. In this study, we have used both electrochemical methods (polarization curves, electrode impedances), and surface study techniques: [scanning and transmission electron microscopy (SEM-TEM), x-ray photoelectron spectroscopy (ESCA XPS)].

Experimental

The experiments have been carried out with a molar lithium perchlorate ($LiClO_4$) solution in propylene carbonate (PC). $LiClO_4$ (Smith Chem. Company pure product) was dehydrated by heating under vacuum at a temperature close to its melting point. P.C. (Merck for synthesis) was dried over 3A activated molecular sieves (Merck). The residual water content in the solution thus obtained was below 10 ppm as determined by a coulometric titration based on the Karl-Fischer method (Aquavit Tacussel).

All experiments were conducted at 25° ± 1°C in a dry box (Jaram). The argon atmosphere was continuously recirculated through a column containing molecular sieves and active carbon. The humidity was monitored by a hygrometer (Shaw) and reduced to about 5 ppm water vapor.

The surfaces of the working electrodes are disks ($A = 0.2$ cm²) formed by the cross sections of cylinders 5 mm high; they were fitted into glass tubes for the lithium (Alfa Ventron 99.9%) and into Teflon tubes for the aluminum (Johnson Matthey 99.99%).

The electrodes, washed successively in pure propylene carbonate and in anhydrous hexane were observed by scanning electron microscopy (Cambridge Stereoscan). The layers were analyzed by transmission electron microscopy (Jeol 100 B) and x-ray photon electron spectroscopy (AEI ES 200 B). Special apparatus were designed for the transfer of the lithium samples to the SEM (8) and ESCA (9) observation chambers to avoid any atmosphere contamination.

The cell polarization was controlled by a fast response potentiostat-galvanostat (10). The potential measured between the working electrode and the lithium reference electrode was determined after correction of the ohmic drop by an interrupted current technique. By using a rotating disk electrode, the measured potential is free of any term due to concentration gradients in the electrolyte. The impedance of the electrode was measured in the frequency range from 10^{+5} to 10^{-3} Hz using a function transfer analyzer (Schlumberger Solartron 1174) with an ohmic drop compensator device (11).

Results and Discussion

Cycling Operations

Lithium substrate.—We have shown elsewhere, with a motionless electrode preliminarily submitted to an anodic polarization (50 mV of overpotential and 10 C/cm² of charge density), that a quite reversible behavior of the lithium electrode was only obtained with limited overpotentials, current, and charge densities (12). Accordingly, more than 500 galvanostatic cycles have been performed with a current density of 1 mA/cm² and a charge density of 1 C/cm², with a very low evolution of the involved overpotentials ($15 < |\eta| < 25$ mV).

Aluminum substrate.—The use of an aluminum substrate allowed a significant improvement in the cycling properties of lithium. With a motionless electrode submitted to an initial lithium incorporation ($Q = 50$ C/cm² and $i = 5$ mA/cm²), we have obtained more than 1500 cycles with a current density of 2 mA/cm²

* Electrochemical Society Active Member.

Key words: Li cathodic insertion, kinetics of insertion, impedance measurements, cycling efficiency, film analysis, electrodeposition.

and a charge density of 1 C/cm², corresponding to an average coulombic efficiency higher than 97%. It was still possible to obtain nearly 220 cycles (Fig. 1) with a current density of 2 mA/cm² and a cycling charge density of 2.5 C/cm², with 94% coulombic efficiency. The above numbers of cycles have been determined by stopping cycling when the discharge potential of the electrode was increased to 100 mV with respect to its initial value.

Electrode Morphology

Lithium substrate.—The first morphological studies performed with a lithium substrate have shown that an anodic prepolarization was able to clean the electrode surface; the polycrystalline structure of the substrate was clearly revealed after a cleaning of the electrode surface by an anodic polarization of 50 mV overpotential and 10 C/cm² charge density (12). Alternatively, using larger overpotentials led to surface damaging.

During the cathodic step, the lithium began to grow, on a clean surface, mainly on the crystallographic defects of the metal, such as the grain boundaries. This deposit could be wholly dissolved during a subsequent anodic polarization at 50 mV overpotential, insofar as the cathodic and anodic charge densities remained lower than 1 C/cm². With higher charge densities, or higher overpotentials, the electrode surface was spread with small islets of lithium deposit which could not later be dissolved under anodic polarization. With charge densities higher than 5 C/cm², the lithium deposit underwent a dendritic growth.

Aluminum substrate.—The cathodic reduction of Li^+ ions in galvanostatic conditions, on an aluminum substrate, did not lead to a dendritic formation as long as the charge density was smaller than a threshold value Q_d. The value of Q_d depended on the current density used, *e.g.*, $Q_d \sim 50$ C/cm² for $i = 10$ mA/cm², $Q_d \sim 100$ C/cm² for $i = 1$ mA/cm². The improvement corresponding to this slower formation of dendrites is linked to the formation of the intermetallic compound LiAl which was identified by x-ray diffraction analysis.

The way lithium was incorporated into aluminum depended on the type of preliminary treatment undergone by the aluminum substrate. For instance, the electropolishing of this metal in an anhydrous ethanol solution of lithium perchlorate induced the formation of a thick alumina layer leading to the dendritic growth of lithium for the lowest charge densities. The electrode surfaces used in this work had thus been prepared under strictly identical conditions consisting of a mechanical polishing inside the glove box.

The dissolution of the lithium incorporated in the aluminum could not be performed without a visible alteration of the substrate, unless this dissolution was limited to 30% of the initial lithium deposit. For higher percentages, the surface exhibited cracks which separated domains whose dimensions were similar to

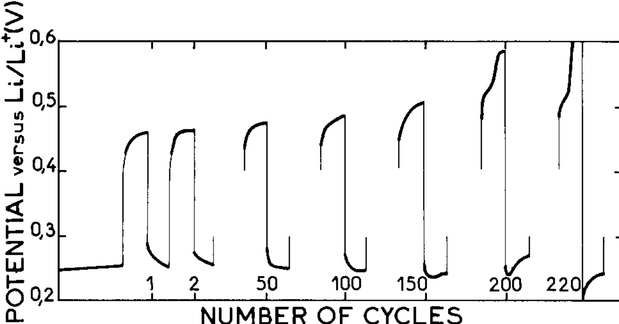

Fig. 1. Galvanostatic cycling with a motionless aluminum electrode. Initial lithium charge density of 30 C/cm². Current density $i = 2$ mA/cm². Charge density $Q = 2.5$ C/cm².

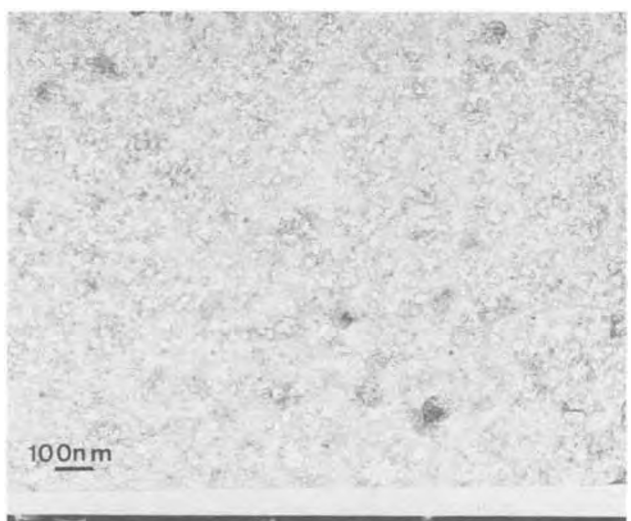
those of the grain boundaries. This behavior might be due to an intergranular penetration of lithium into aluminum.

Analysis of the Passivating Layers

Thin films, stripped from surfaces of both lithium and aluminum substrates by means of copper grids, have been observed by TEM: the electrodes were covered with a layer always plastic and porous in appearance. Figure 2 shows a layer obtained from a lithium-aluminum electrode submitted to a cathodic charge density $Q_c = 30$ C/cm² and a current density $i = 2$ mA/cm². The microdiffraction patterns, corresponding to the area observed on Fig. 2, showed the existence, inside the pores, of tiny Li_2CO_3 and LiCl crystallites (Fig. 3). Let us recall that, in the case of the lithium substrate, the presence of $LiClO_4$ crystallites had also been detected (13). The analysis of the electrode surface by x-ray photoelectron spectroscopy (ESCA XPS) confirmed the presence of $CO_3^=$, ClO_4^-, and Cl^- ions. The presence of lithium carbonate agreed with the decomposition of propylene carbonate, accompanied by formation of propylene, as proposed by Dey (14). However, in our opinion, the passivating properties of the layer were not due to a compact Li_2CO_3 layer, but rather to the plastic layer in which the crystallites have been observed, and which would be formed by polymerization of propylene as suggested by Bro in a discussion of Broadhead's paper (15). In the case of relatively thick layers formed on lithium substrate, it was possible to verify that the plastic part of the layer was



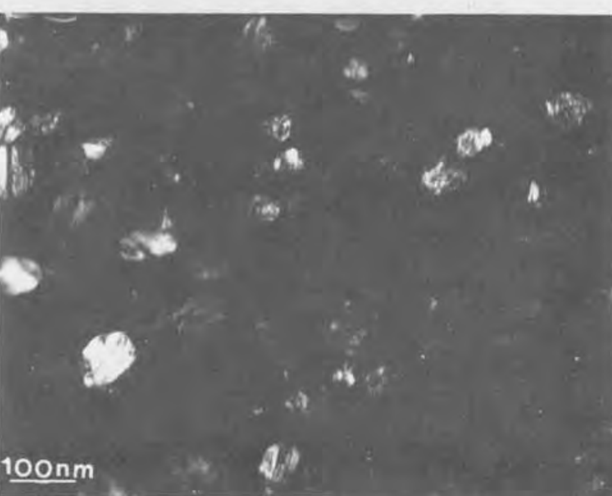


Fig. 2. Layer stripped from an aluminum-lithium electrode and observed in transmission electron microscopy: (a, top) bright field, (b, bottom) dark field.

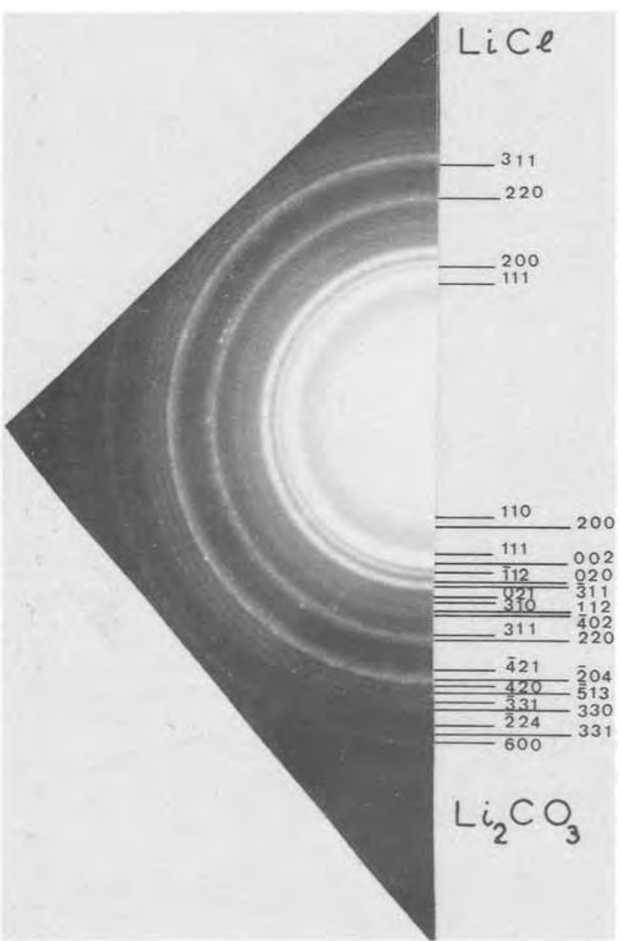

Fig. 3. Microdiffraction diagram of the area corresponding to the Fig. 2; electron beam 100 kV.

not soluble in any acid solution. Besides, mass spectroscopy analysis revealed the presence of organic compounds of molecular mass higher than the molecular mass of propylene, inside the layer submitted to a temperature of 150°C.

The decomposition of propylene carbonate has been observed whatever the treatment applied to the electrode: anodic dissolution, cathodic deposition, and standing time in the electrolyte. Therefore, the origin of these layers is certainly due to a chemical process of decomposition of propylene carbonate in the presence of lithium. On the other hand, the behavior of lithium during the aging of the solution (long periods of charge and discharge) remained the same so that completely removing the impurities did not avoid any formation of a passivating layer. This conclusion agreed with that of Koch about the electrolytes with tetrahydrofuran as the solvent (16). Thus, the formation of the plastic layer may be considered as unavoidable, and the more developed the more dendritic was the state of lithium deposit. The ionic erosion technique used during the ESCA study of the electrodes, allowed us to show, however, that the layer formed on aluminum was always thinner than the layer formed on massive lithium under similar conditions.

Electrode Kinetics

Polarization curves.—Lithium substrate.—We have shown elsewhere (12) that, for the clean electrode, the overpotential-current density curves $\eta = f(i)$ were symmetric and reversible when overpotentials were lower than 50 mV and when the cathodic polarizations were carried out fast enough to avoid any evolution of the area due to a dendritic growth. The analysis of these curves led to an exchange current density $i_o = 3.3$ mA/cm² and a transfer coefficient $\alpha = 0.5$ for the charge transfer reaction $Li \rightleftarrows Li^+ + e^-$, with a molar $LiClO_4$ solution in propylene carbonate and a residual water content lower than 10 ppm.

Aluminum substrate.—The curves (a) and (c) of Fig. 4 show the evolution of the current density *vs.* the potential of the aluminum electrode with respect to the lithium reference electrode, respectively, after and before correction for the ohmic drop. The analysis of these stationary curves obtained after a charge density of 20 C/cm² had shown, first, that the aluminum-lithium electrode tended to two different values of the open-circuit rest potential (OCP). Starting from a stationary polarization state obtained after a period of cathodic deposition, the electrodes reached an OCP $V_c \sim 335$ mV. After an anodic dissolution amounting to about 1/10 of the initial charge, the electrode reached another OCP $V_a \sim 385$ mV. This last value was corresponding to the free enthalpy for the formation of the intermetallic compound LiAl [$\Delta G \sim 8.9$ kcal/mole (5)]. The difference between V_a and V_c seemed thus to be attributed to the fact that there existed two equilibrium compositions of the aluminum-lithium electrode for anodic and cathodic polarizations.

The evolution of the free ohmic drop potential in the time $V = V(t)$ during a current interruption showed two distinct parts separated by a sharp discontinuity. The first part corresponds to the rapid discharge of the electrochemical double layer with a relaxation time τ of about 20 μsec. The second part occurred with a relaxation time τ' between 10 and 100 sec. The relatively long times τ' could not be attributed to the vanishing of a gradient in the electrolyte since the polarization curve did not depend on the rotation speed of the electrode, at the high rotation speeds used in the experiments ($\Omega \geqq 1000$ rpm). They were due to a relatively slow solid-state diffusion process which modified the composition of the electrode, after the current interruption. The instantaneous OCP values V^* of the curve b (Fig. 4) correspond to the potentials of the discontinuities of the curve $V = V(t)$. As $\tau << \tau'$ these values V^* corresponded to OCP of electrodes whose superficial compositions did not appreciably differ from the solid-state compositions existing just before the current interruption.

The conventional treatment of the polarization curve $\eta = f(i)$ with $\eta = V - V^*$ led to an exchange current density i_o higher than 15 mA/cm² with a transfer coefficient $\alpha = 0.5$. These values agreed with the variations of i_o when using different values of concentration of Li^+ ions in the electrolyte.

Electrode impedances.—The previous approximate estimation of i_o, for the aluminum substrate, has

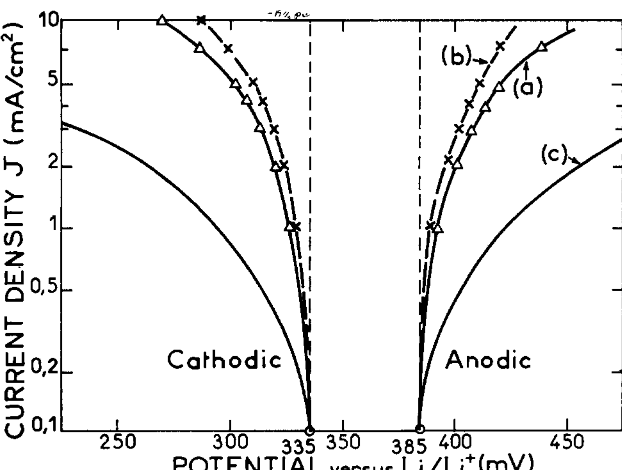

Fig. 4. Polarization curves with a disk aluminum electrode rotating at 2000 rpm. Curve (a) free ohmic drop potential, curve (b) instantaneous open-circuit potential, curve (c) potential vs. Li/Li⁺.

been made more precise with measurements of the electrode impedance (17). This technique allowed to get free from the difficulties linked to the variations in the composition of the electrode with the conditions of the electrolysis. Furthermore, it has been possible to confirm the phenomenon of solid-state diffusion mentioned above.

All the impedance diagrams obtained with a rotating disk electrode, under various stationary anodic and cathodic current densities between 0 and 10 mA/cm², comprised two distinct loops (Fig. 5), both independent from the rotation speed of the electrode ($\Omega \geqq$ 1000 rpm). The high frequency loop (between 10^{+5} and 2.5 Hz) was independent of the current density used. In contrast, the low frequency loops (between 2.5 to 10^{-3} Hz) had all the same shape with an initial straight line of slope 45°, but a size which was larger as the current density was lower.

These results can be explained if the previous results about the polarization curves are taken into account. In the case of the aluminum-lithium electrode, several kinds of electroactive lithium species are involved in the electrochemical reaction. The current density i is a function not only of the potential V and of the active part θ_a of the electrode area, but also of the concentrations c_i of the Li species on the surface of the metal, according to the relation

$$i = i(V, \theta_a, c_j) \qquad [a]$$

The electrode impedance Z is then related to the derivative of Eq. [a] with respect to the voltage (18)

$$\frac{di}{dV} = \left(\frac{\partial i}{\partial V}\right)_{c_j,\theta_a} + \sum_j \left[\left(\frac{\partial i}{\partial c_j}\right)_{\theta_a} \times \frac{dc_j}{dV} + \left(\frac{\partial i}{\partial \theta_a}\right)_{c_j} \times \frac{d\theta_a}{dV}\right] \qquad [b]$$

For a relatively high frequency, only the charge transfer process can follow the variations of the voltage imposed by the potentiostat (*e.g.*, for frequencies such that $1/N << \tau$) the $(\partial i/\partial c_j)$ terms of Eq. [b] can be neglected. Under these conditions, the right side of Eq. [b] reduces to

$$\left(\frac{\partial i}{\partial V}\right)_{c_j,\theta_a} = \frac{1}{R_t} \qquad [c]$$

where R_t is the transfer resistance corresponding to the charge transfer reaction $Li \rightleftarrows Li^+ + e^-$. This transfer resistance equal to 1.5 $\Omega \cdot$ cm, practically independent of the current density range of 0-10 mA/cm², showed that the electrode was in the micropolarization domain. From the conventional relation at zero current between the exchange current density and the transfer resistance ($i_o = RT/R_t\mathbf{F}$ where R, T, and $\mathbf{F}$ had their usual meaning), an exchange current density of nearly 17 mA/cm² was calculated, corroborating the results deduced from the polarization curves. On the other hand, the high value of the double layer capacity ($C_d \sim 40\ \mu F/cm^2$) measured with the aluminum-lithium electrode demonstrated that the active surface was larger then than in the case of the lithium electrode ($C_d \sim 5\ \mu F/cm^2$) (19).

Alternatively, for a relatively low frequency, the mass transfer processes can follow the variations of the voltage imposed by the potentiostat. Thus, the right hand of Eq. [b] tends to $di/dV = 1/R_p$ where R_p is the polarization resistance. In addition to R_t, this term R_p contains a contribution of a diffusion resistance R_d. The low frequency loops, with their initial straight line of slope 45°, confirmed that diffusion phenomena occurred in the bulk of the electrode. These phenomena might simultaneously occur in the porous layer covering the electrode and in the aluminum substrate. The diffusion of lithium could happen according to several processes, as those suggested by Nicholson (5) for a magnesium substrate: transport of lithium along the grain boundaries and penetration inside the grains.

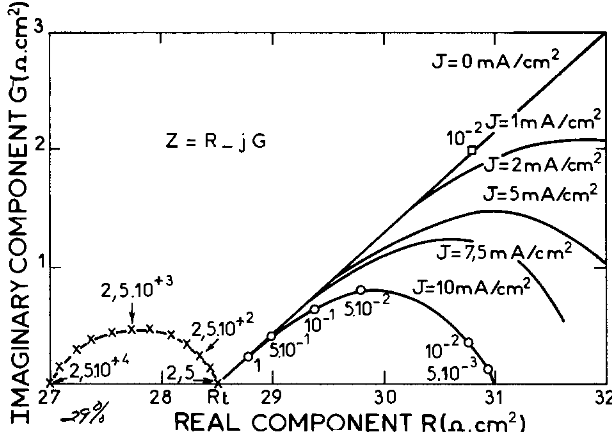

Fig. 5. Electrochemical impedance of the aluminum lithium electrode for various cathodic current densities. Experimental points correspond to frequencies in Hz.

Conclusion

Two essential facts have been demonstrated by comparison of the two kinds of electrodes made with a lithium and an aluminum substrate. First, the same chemical decomposition of propylene carbonate intervenes with both kinds of electrodes, yielding a plastic and porous layer. The lithium incorporation rate, though not fast enough to avoid the formation of a passivating layer onto aluminum, is however sufficiently high for cathodic charge densities 10-20 times larger than for a lithium substrate to be used without formation of dendrites; the development of a thick passivative layer, as in the case of lithium, is thus reduced. On the other hand, the incorporation of lithium into the aluminum substrate does not involve a prohibitive penalty voltage ($\Delta V < 0.4V$), and is homogeneous enough for obtaining a very large increase of the active part of the electrode surface intervening in the charge transfer process.

The results obtained with the aluminum substrate during the cycling operations, though more satisfactory than with lithium, are mainly limited by diffusion phenomena in the bulk of the electrode. The improvement of the performances of this kind of electrodes thus necessarily depends on an increase in the rate of these diffusion processes of lithium, through an adequate change of the structure of the substrate.

Zone Processes at the Formation of the Lead Acid Battery Positive Plate

D. Pavlov* and G. Papazov

Central Laboratory of Electrochemical Power Sources, Bulgarian Academy of Sciences, Sofia 1040, Bulgaria

ABSTRACT

The processes during formation at different current densities of the positive lead acid battery plates prepared with different phase compositions of the paste were studied. At the formation a PbO_2 zone is formed. The direction of its growth in the plate depends on the phase composition of the paste, the current density, the pH of the solution, the paste density, etc. It was found that at formation with a high current density of the plates with high sulfation pastes, the PbO_2 zone grows in the interior of the plate first and then to its surfaces. At formation with a low current density of the plates with low sulfation pastes this process is inverse. A diagram of chemical and electrochemical reactions which take place in a reaction layer is presented. The direction of the PbO_2 zone growth depends on the direction of H^+ and SO_4^{2-} ion flows which keep electroneutrality of the solution in the reaction layer. When the H^+ and SO_4^{2-} ion flows enter the reaction layer the PbO_2 zone grows in the surface layers of the plate and vice versa, when they go out of the reaction layer the PbO_2 zone grows first in the interior of the plate.

Formation is an essential process in the technology of the lead acid battery positive plate production. During formation lead oxide and basic lead sulfates of the cured paste turn into a lead dioxide active mass. Formation depends on the following conditions: (*i*) concentration of the formation H_2SO_4 electrolyte, (*ii*) phase composition of the cured paste, (*iii*) formation current density, (*iv*) paste density, and (*v*) temperature.

The overwhelming majority of previous studies were aimed at determining the influence of the abovementioned conditions on the active mass performance (1-22). In a paper of ours (23) we elucidated the chemical and electrochemical reactions by establishing the change of the plate phase composition during formation in electrolytes with various H_2SO_4 concentrations. In another paper (24) we determined the influence of current density on formation. The present paper aims to define the influence of phase composition of the cured paste and formation current density on the rates of chemical and electrochemical reactions at the various regions of the cross section of the plate.

Experimental Methods

Formation was carried out on 14 A-hr plates of automotive batteries. The pastes were prepared at 30°C. The amount of H_2SO_4 with specific gravity of 1.4 g/cm^2 was 0, 2, 4, 6, 8, 10, and 12% with respect to the 65% oxidized lead powder. Further in this paper we shall signify this amount by percent H_2SO_4 only. Through the variation of the quantity of added water all kind of pastes have been adjusted at a density of 4.2 g/cm^3. Pb-6% Sb grids were pasted and the plates were cured for 72 hr at 35°C and 100% humidity. The experimental cells consisted of a tested positive plate combined with two negative plates. The formation electrolyte was H_2SO_4 with sp gr 1.05. Formation was carried out at 2 and 10 mA/cm^2 of the plate apparent area. During formation the potential of the positive plate under polarization was measured. Every hour the circuit was opened and the potential was measured for 5 min *vs.* the $Hg/Hg_2SO_4/H_2SO_4$ electrode. Periodically samples were cut out from the tested plate. After rinsing and drying part of the active mass was subjected to x-ray diffraction analysis and porosity measurements. To determine the distribution of the formed PbO_2 zones and unformed paste, a cross section of the other part of the sample was observed and photographed.

Experimental Results

Influence of the paste phase composition on the direction of growth of the PbO_2 zone during the first formation stage.—Lead oxide and basic lead sulfates are yellow to white in color. Lead dioxide is dark brown to black. Thus the formed and unformed zones in the plate can be clearly distinguished. By the change of the color in the plate cross section the formation process may be easily followed.

Figure 1 presents photographs of the cross section of partially formed plates with pastes of 0, 2%, 4%, 6%, 8%, 10%, and 12% H_2SO_4. The dark zones correspond to PbO_2 and the light ones to unformed paste. Formation was carried out at a current of 10 mA/cm^2.

Key words: formation of PbO_2 battery plate, lead acid battery technology, processes in porous electrodes, movements of the electrochemical processes in space.

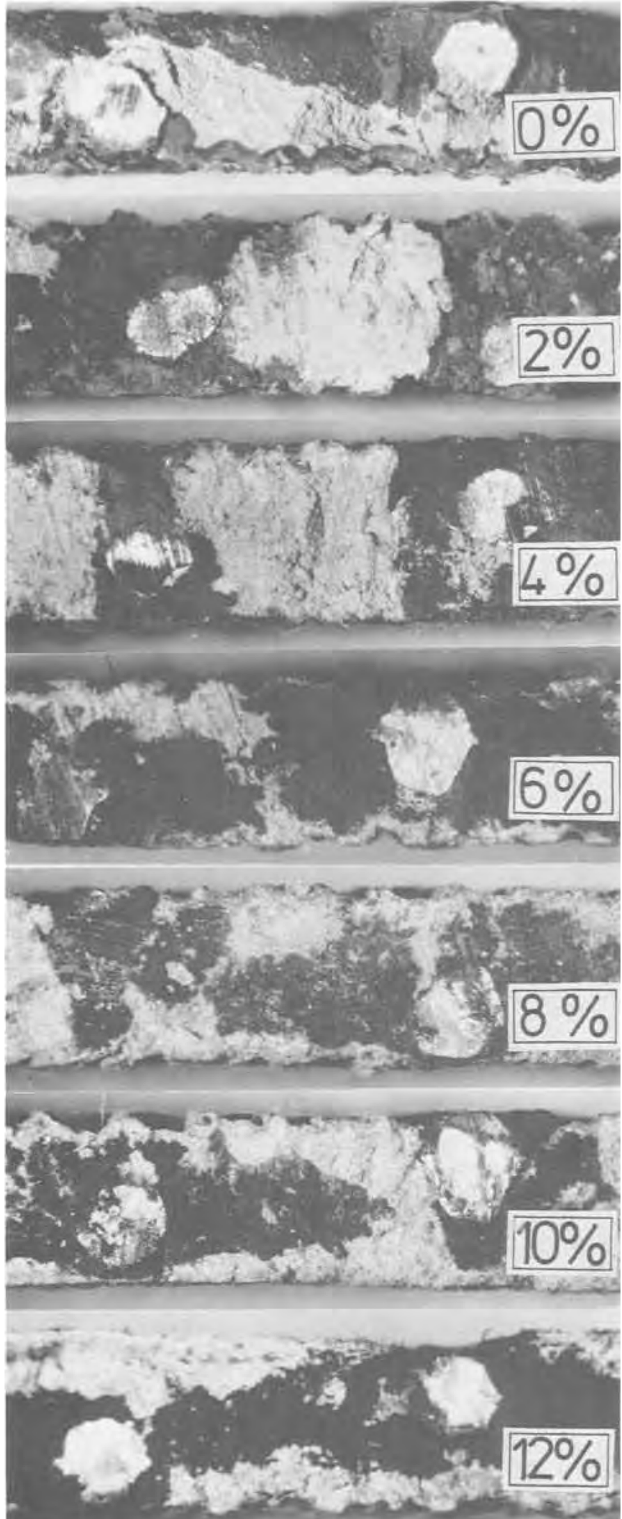

Fig. 1. Microphotograph of the cross section of segments between two grid bars of partially formed plates prepared with 0, 2%, 4%, 6%, 8%, 10%, and 12% H_2O_4 pastes. The dark portions of the plates are PbO_2 zones while the light ones consist of unformed divalent lead compounds.

The photographs were made when 10 to 14 A-hr had passed through the plate.

Formation begins always from the grid bars but the direction of the PbO_2 zone growth depends on the percent H_2SO_4 used for paste preparation.

When 0% H_2SO_4 paste is under formation the PbO_2 zone grows initially in the surface layers of the plate. After covering the surfaces the PbO_2 zones advance into the interior of the plate. At paste with 2% H_2SO_4, the rate of the PbO_2 zone growth in the surface layers slightly exceeds that into the interior. In the case of 6% and 8% H_2SO_4 pastes the direction of the PbO_2 zone growth is reversed in comparison with the low sulfation pastes. At 10% and 12% H_2SO_4 pastes the rate of growth of the PbO_2 zone into the interior exceeds many times the one in the surface layers.

Change of the plate phase composition during formation.—The relative intensity of the x-ray characteristic diffraction lines was adopted as a measure of the phase changes in the plate during formation (25). It is defined as a ratio of the "i" phase characteristic reflection intensity and the sum of the intensities of the characteristic diffraction lines of all phases. The reflections listed in Table I were adopted as characteristic. The values in brackets show intensities of the powder diffractograms. Since not all of them are equal to 10, the relative intensity values do not correspond to the absolute amounts of the phases in the plate. They can be used only as a measure for phase relative changes during formation.

The plates were prepared at 30°C using 0%, 4%, 8%, and 12% H_2SO_4. Up to 8% H_2SO_4 the paste consists of tet-PbO and $3PbO \cdot PbSO_4 \cdot H_2O$ (26). The 12% H_2SO_4 paste contains $PbO \cdot PbSO_4$, $3PbO \cdot PbSO_4 \cdot H_2O$, and small amount of tet-PbO (26).

Figure 2 presents the changes of the relative intensity of the phases in the plate during formation with 10 mA/cm^2. It is seen that initially $PbO \cdot PbSO_4$, $3PbO \cdot PbSO_4 \cdot H_2O$, and tet-PbO react whereby α-PbO_2, β-PbO_2, and $PbSO_4$ are formed. This period determines the first stage of formation (23). The first stage is completed by the flow of less than 30 A-hr which is approximately equal to the theoretical capacity of the plate. At the end of this stage the plate consists of α-PbO_2, β-PbO_2, and $PbSO_4$ crystals which can be seen all over the cross section of the plate. During a second formation stage $PbSO_4$ is oxidized to β-PbO_2.

The diffraction lines 0.312 and 0.350 nm chosen as characteristic of α- and β-PbO_2 are common with those of tet-PbO and $PbSO_4$. However, at the end of the formation only negligible amounts of PbO and $PbSO_4$ remain in the plates. The above diffraction lines present the β/α PbO_2 ratio of the phases. Figure 3 shows the dependence of this ratio on the percent H_2SO_4 in the paste. At pastes prepared with less than 4% H_2SO_4 the amount of α-PbO_2 in the active mass exceeds that of β-PbO_2. At more than 6% H_2SO_4, β-PbO_2 predominates in the active mass. Practice has affirmed the use of 4-5% H_2SO_4, which corresponds to a slightly larger amount of α-PbO_2 compared with that of β-PbO_2.

Change of the electrode potential during formation.—Figure 4 presents the dependences of the potentials under polarization and at open circuit on the quantity of electricity passed during formation of the plates with 2%, 6%, and 12% H_2SO_4 pastes. The potentials were measured *vs.* $Hg/Hg_2SO_4/H_2SO_4$ electrode.

At the very beginning of formation only the plate grid is electroconductive. That is why the current density is high and the polarization is great. As PbO_2 zones are formed and begin to grow the current density decreases and the polarization decreases too.

During the first stage both potentials remain low. When the oxidation of $PbSO_4$ to PbO_2 begins potential under current increases and attains a constant value in

Table I.

Diffraction line (d/nm)	Phase
0.350	PbO_2 [9.1] + $PbSO_4$ [0.8]
0.333	$PbO \cdot PbSO_4$ [10] + $PbSO_4$ [10]
0.326	$3PbO \cdot PbSO_4 \cdot H_2O$ [10]
0.312	tet-PbO [10] + α-PbO_2 [10]
0.300	$PbSO_4$ [10]
0.279	tet-PbO [6.2] + β-PbO_2 [10]

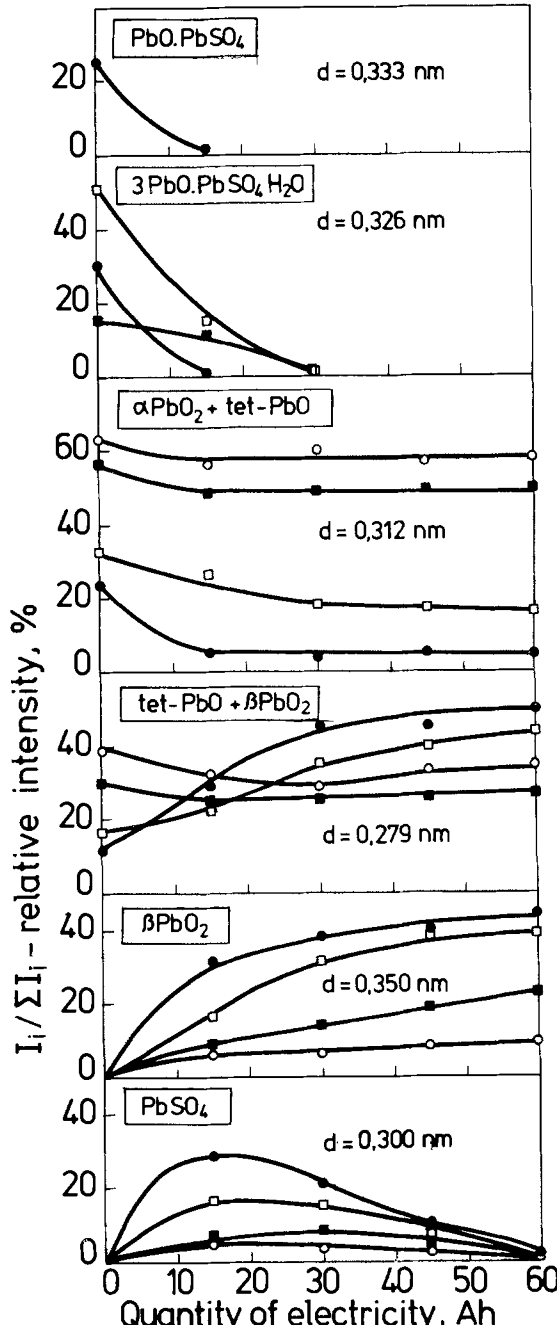

Fig. 2. Relative intensity changes of the phase characteristic diffraction lines during formation of plates with pastes prepared with: (○) 0% H_2SO_4; (■) 4% H_2SO_4; (□) 8% H_2SO_4, and (●) 12% H_2SO_4.

the second formation stage. In the first stage the potential under polarization is 150-200 mV more negative than that in the second one.

From Figure 4 it is also seen that plates with greater paste sulfation have higher electrode potentials under current and at open circuit than those plates the pastes of which are prepared with small amounts of H_2SO_4. In the second formation stage the plates consist only of α-PbO_2, β-PbO_2, and $PbSO_4$, the open-circuit potential reaches a constant value which does not depend on the initial paste composition.

Table II presents the equilibrium potentials of $5PbO \cdot 2H_2O/PbO_2$, $PbSO_4/PbO_2$, and basic lead sulfates/PbO_2 electrodes against the Hg/Hg_2SO_4 electrode. It can be supposed that the great difference between equilibrium potentials is the reason why formation takes place in two stages. The table shows also that the equilibrium potentials depend strongly on pH and less on the SO_4^{2-} ion activity. When pH increases the potentials become more negative. If it is assumed that the open-circuit potential is determined by the equilibrium $PbO_2/PbSO_4$ electrode system, we can calculate pH of the solution in the plate using the equi-

Table II.

$$5PbO_2 + 10\ H^+ + 10e^- = 5PbO \cdot 2H_2O + 3H_2O$$
$$E_1 = 0.500 - 0.059\ pH$$
$$4PbO_2 + 10\ H^+ + SO_4^{2-} + 8e^- = 3PbO \cdot PbSO_4 \cdot H_2O + 4H_2O$$
$$E_2 = 0.715 - 0.074\ pH + 0.007 \log a_{SO_4^{2-}}$$
$$2PbO_2 + 6H^+ + SO_4^{2-} + 4e^- = PbO \cdot PbSO_4 + 3H_2O$$
$$E_3 = 0.852 + 0.089\ pH + 0.015 \log a_{SO_4^{2-}}$$
$$PbO_2 + SO_4^{2-} + 4H^+ + 2e^- = PbSO_4 + 2H_2O$$
$$E_4 = 1.128 - 0.113\ pH + 0.029 \log a_{SO_4^{2-}}$$

librium potential equation for this system. At $a_{SO_4^{2-}} = 10^{-2}$, from the open-circuit potential curve we obtain the pH values which are plotted on the right-hand ordinate in Fig. 4. It can be seen that the higher the paste sulfation is, the lower is the pH of the pore solution of the plate. Figure 4 also shows that during formation pH of the pore solution decreases.

Influence of the current density on the PbO_2 zone direction of growth during formation.—Investigation was carried out on paste, prepared with 6% H_2SO_4. This paste corresponds to the region in Fig. 1 where the growth rate of the PbO_2 zone in the plate interior slightly exceeds that in the surface layers.

Figure 5 presents the PbO_2 zone advance during formation with a current of 10 mA/cm^2. First, the PbO_2 zones grow in the plate interior (Fig. 5b, c, d) and then toward the surfaces. Sometimes a white layer is observed at the boundary between the PbO_2 zones and the unformed paste.

When the formation processes follow this way the unformed paste surface layers stay for a long time in contact with the H_2SO_4 solution. Chemical reactions of sulfation take place between the paste and the sulfuric acid. White $PbSO_4$ layers are formed on both surfaces. They are the last to be oxidized to PbO_2.

Figure 6 presents formation with a current density of 2 mA/cm^2. The PbO_2 zone rate of growth is a little higher in the surface layers than that into the interior of the plate. Therefore at lower current density the PbO_2 zone rate of growth in the plate interior decreases and formation processes in the surface layers are accelerated.

Influence of the current density on the change of the plate phase composition during formation.—Figure 7 shows the dependence of the diffraction line relative intensity of PbO and basic lead sulfates as well as that of α-PbO_2, β-PbO_2, and $PbSO_4$ on the quantity of electricity passed. The intensity curves are indicative

Fig. 5. Photomicrographs of the cross section of the plate prepared with 6% H_2SO_4 paste during formation with a current of 10 mA/cm^2. (a) Unformed plate, (b-d) during formation (the dark portions are PbO_2 zones), (e) completely formed plate.

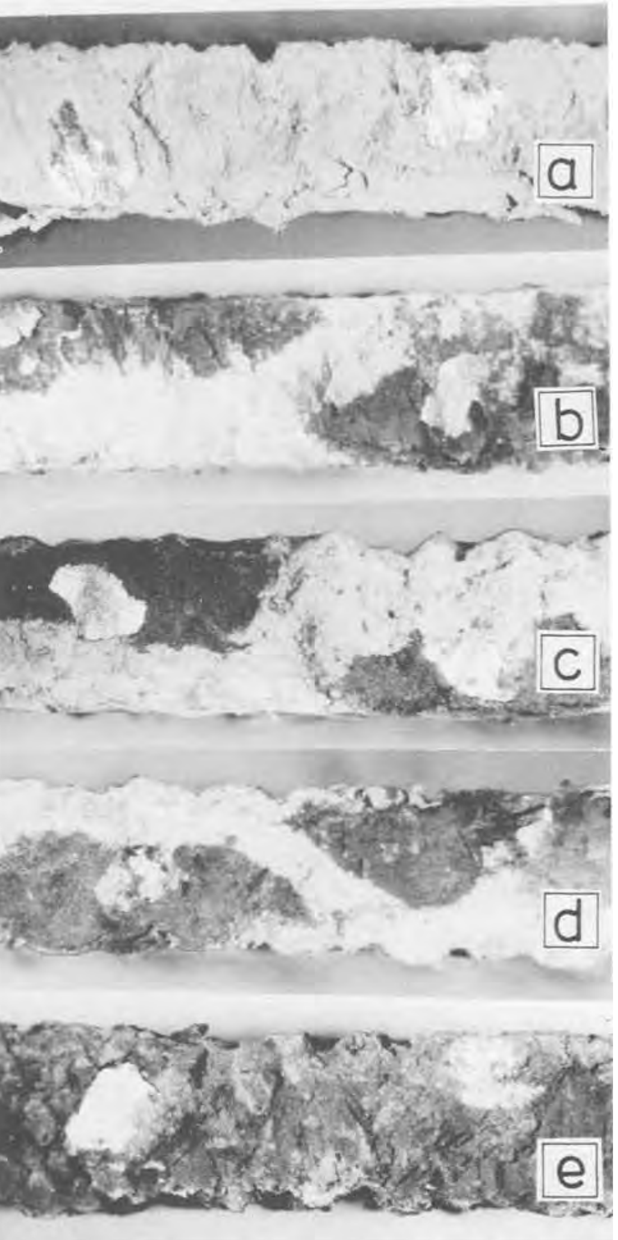

Fig. 6. Photomicrographs of the cross section of the plate prepared with 6% H_2SO_4 paste during formation with a current of 2 mA/cm^2. (a) Unformed plate, (b-d) plate during formation, (e) completely formed plate.

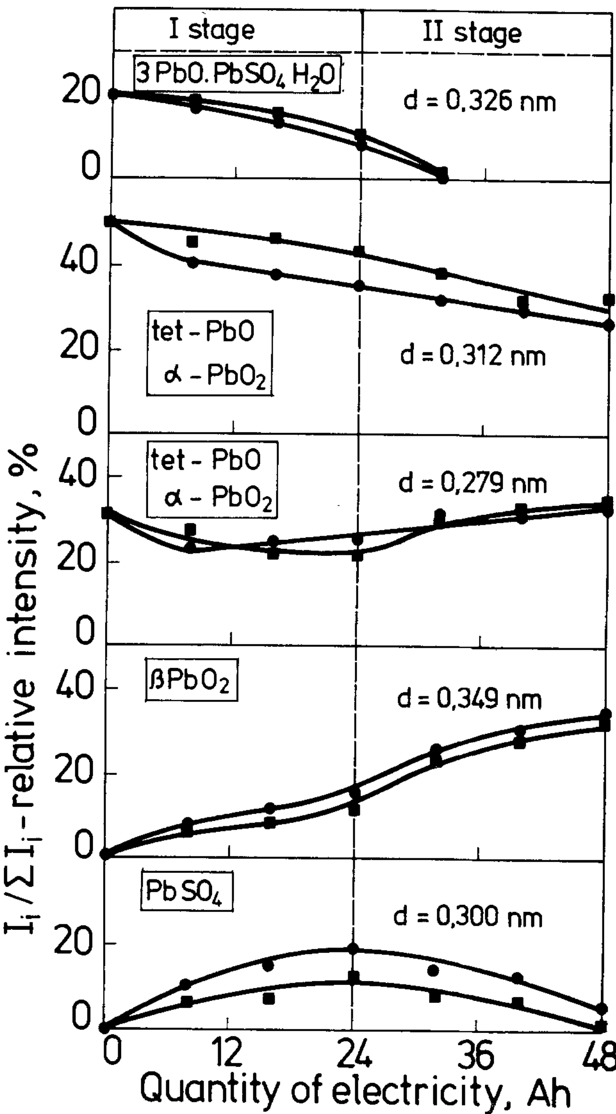

Fig. 7. Change of the phase composition of the plate during formation with a current of 10 mA/cm². (●) At the surfaces of the plate; (■) in the interior of the plate.

of the phase composition changes in the surface layers and in the plate interior. Formation was performed at 10 mA/cm². The plate was prepared with 6% H_2SO_4 paste. The amount of $PbSO_4$ in the plate reaches its maximum after passage of about 24 A-hr whereby the first stage is over.

Figure 8 presents formation of the above type of plates with current 2 mA/cm². After the passage of about 20 A-hr, PbO and $3PbO{\cdot}PbSO_4{\cdot}H_2O$ in the surface layers react completely. In the plate interior this process is over after about 28 A-hr. By this time the amount of $PbSO_4$ in the plate reaches its maximum and the first formation stage is over.

A comparison of Fig. 7 and Fig. 8 shows that in the first stage of formation at low current density the reactions are more advanced in the surface layers than in the plate interior. This coincides with the optical observations (Fig. 5 and 6).

Influence of the current density on the plate porosity during formation.—Table III presents the molar volume changes in the course of the chemical and electrochemical reactions. The table is based on data given by Burbank (8). The molar volume increases at the sulfation and oxidation of Pb and PbO to PbO_2. At the oxidation of $3PbO{\cdot}PbSO_4{\cdot}H_2O$ and $PbSO_4$ to PbO_2 it decreases.

The active mass porosity is characterized by two parameters: porosity and pore size distribution.

Table III.

Initial product	Final product	Change of volume with respect to the initial product for 1 g-atom Pb, % $\Delta V/Vmi$
tet-PbO	$PbSO_4$	+100
	β-PbO_2	+4.2
$3PbO \cdot PbSO_4 \cdot H_2O$	$PbSO_4$	+26.2
	PbO_2	−34.6
$PbSO_4$	PbO_2	−48.2
Pb	$PbSO_4$	+60.0
	PbO_2	+35.8

Figure 9 presents porograms of formation at 10 mA/cm². The porograms of the surface layers and the interior of the plate are plotted and compared with those of an unformed plate. The average pore radius does not change practically during the first formation stage. Neither does the plate total porosity (Fig. 9a, b). Only the pore size distribution changes. The pore number with a radius from 0.01 to 0.2 μm increases whereas the number of pores with a radius from 0.3 to 1 μm slightly decreases. During this period the increase of the solid phase volume (caused by sulfation processes) is compensated by the decrease of volume (caused by oxidation of $3PbO{\cdot}PbSO_4{\cdot}H_2O$ to PbO_2). During the second formation stage, due to oxidation of $PbSO_4$ to PbO_2 the porosity rises and the average pore radius increases from 2 to about 4 μm.

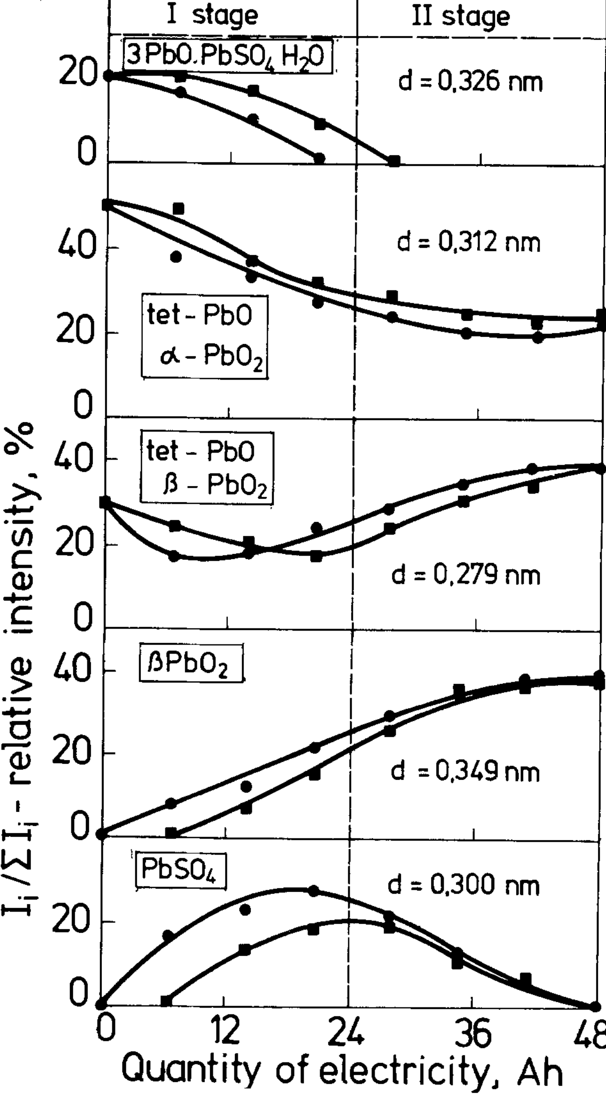

Fig. 8. Change of the phase composition of the plate during formation with 2 mA/cm². (●) At the plate surface; (■) in the interior of the plate.

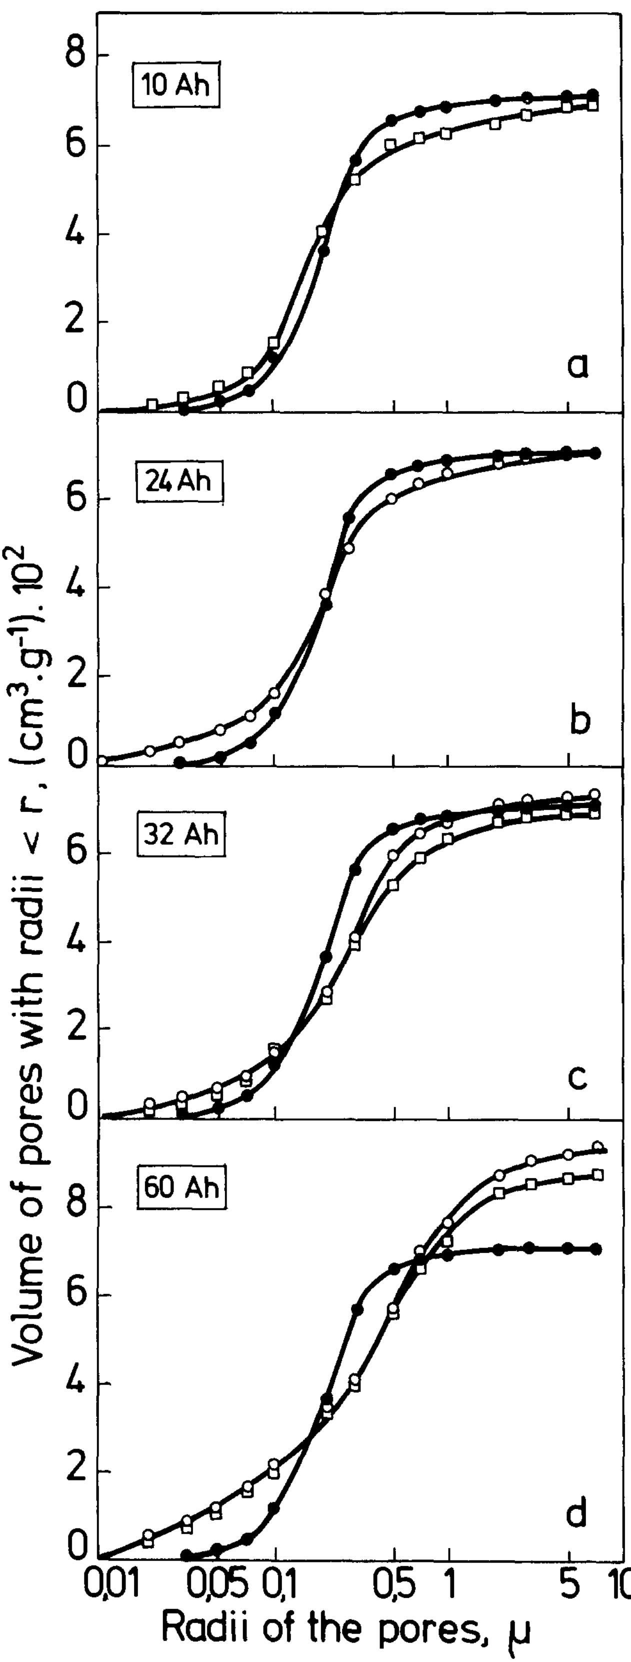

Fig. 9. Change in pore size distribution and volume porosity during formation with current 10 mA/cm. (●) Unformed plate, (○) at the surfaces of the plate, (■) in the plate interior.

Figure 10 presents porograms of formation at 2 mA/cm^2. The average pore radius remains almost unchanged after the passage of 12-17 A-hr (Fig. 10a, b). The number of the small pores increases and that of the large ones decreases. Total porosity decreases, which indicates that the processes of sulfation predominate over those of oxidation. In the second formation stage due to oxidation of $PbSO_4$ to PbO_2 the average pore radius rises from 2-2.5 to 7-9 μm and the active mass total porosity increases.

A comparison of the porograms of Fig. 9d and 10d shows that current density influences the average pore

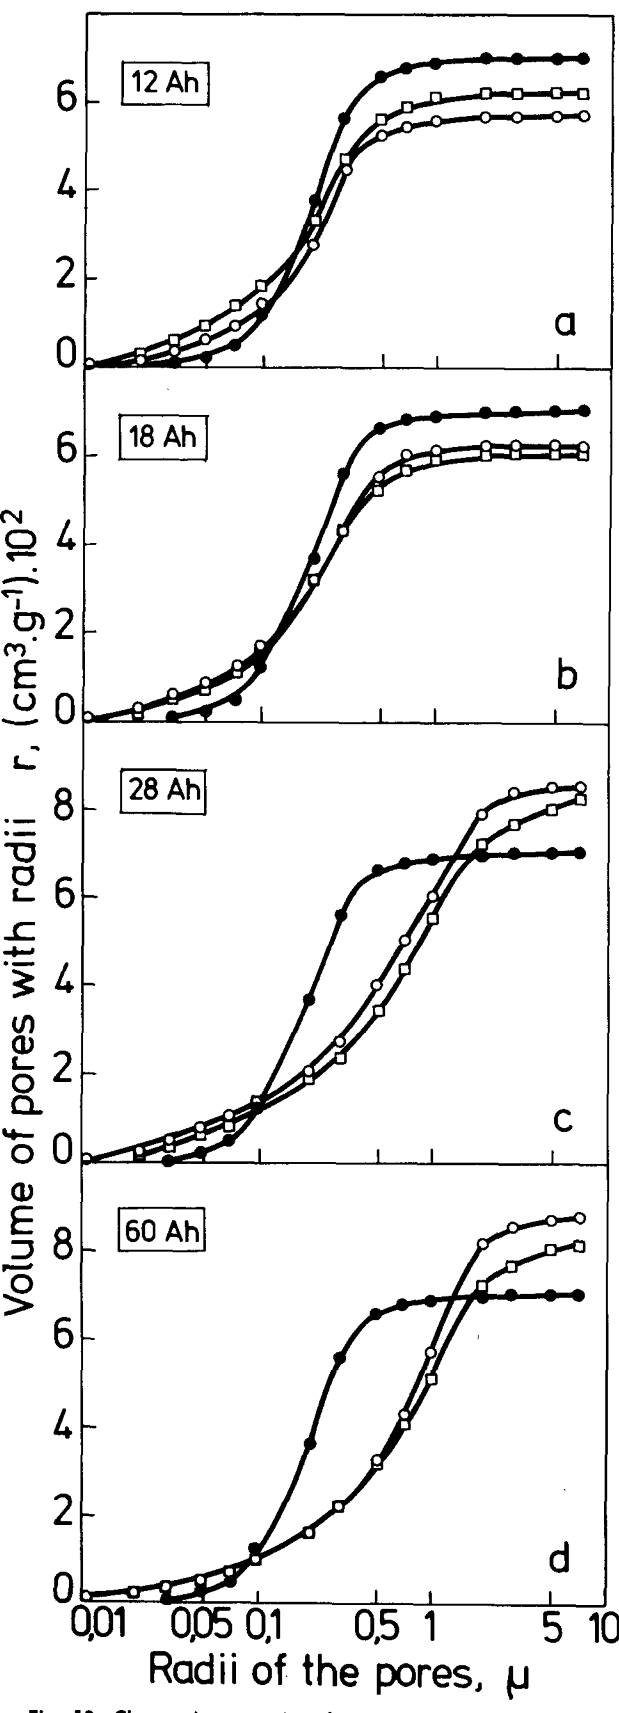

Fig. 10. Change in pore size distribution and volume porosity during formation with current 2 mA/cm^2. (●) Unformed plate, (○) at the surfaces of the plate, (■) in the plate interior.

size. When a larger amount of $PbSO_4$ crystals is formed in the first formation stage, the pores of the formed plate have a greater average radius. It is well known that porosity influences both the capacity and cycle life of the positive plate. Therefore, the formation current density determines to some extent the positive plate energy performances.

Discussion of the Results

The processes of formation should be studied in two scales (Fig. 11):

Elementary processes.—These are the physicochemical and electrochemical processes which take place at the crystal/solution interface and within the solid phases.

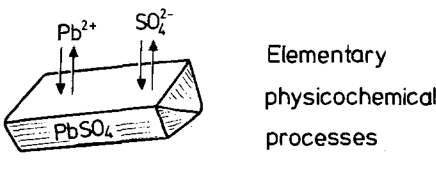
Zone processes.—They take place when the initial and the final products are solid porous phases which form zones permeable for the solution ions. Electrochemical reactions proceed in a reaction layer (Fig. 12). It is situated between the initial and final phases of the reactions (27). During the current flow the volume of the PbO_2 zone increases whereas the one of the reactant zone decreases. As a result of this process the reaction layer moves in space. This advance of the reaction layer in space represents the zone processes.

The zone processes during formation of lead acid battery plates pose to the theoretical electrochemistry an interesting problem for studying. It is necessary to establish the parameters which determine the growth direction of the product zone and the processes which control the reaction layer advance in space.

In this paper it was established that zone processes depend on the paste phase composition. When the paste sulfation is low, the PbO_2 zone grows at higher rate in the plate surface layers than in its interior. In paste with a high degree of sulfation the movement of the reaction layer in the plate is the reverse (Fig. 1).

The second parameter that zone processes depend on is current density. When pastes containing between 4% and 6% H_2SO_4 are subjected to formation at high current densities, the PbO_2 zone grows into the plate interior. The direction of the zone process is reverse that at formation with low current density.

In a previous paper (23) we established that the zone processes depend on the pH of the formation electrolyte. Thus in a strongly acidic electrolyte (H_2SO_4 with sp gr 1.15) the PbO_2 zone initially grows into the plate interior and then advances toward the surfaces. When the same plates are formed in an Na_2SO_4 solution the zone process direction is reversed.



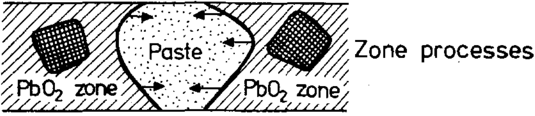


Fig. 11. Scheme of the elementary and zone processes

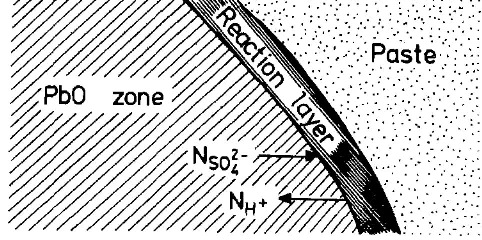

Fig. 12. Scheme of the reaction layer

In order to establish which processes control the direction of the reaction layer movement in the plate it is necessary: (*i*) to establish the chemical and electrochemical reactions which take place in the reaction layer, (*ii*) to determine the conditions under which these reactions proceed at a maximum rate, and (*iii*) to define in which parts of the plate the conditions for maximum electrochemical reaction rate are present so that the product zone can grow in this direction.

The chemical and electrochemical reactions were established by x-ray diffraction analysis determinations of the phase composition changes in the plate during formation. In papers (23, 28) we presented a scheme of the stoichiometric reactions when the paste consists solely of $3PbO \cdot PbSO_4 \cdot H_2O$. This scheme may be elaborated to become universal and to comprise all possible phases in the paste. By introduction of the necessary stoichiometric coefficients, this universal scheme may become a quantitative descrpition of the system of reactions which proceed in the reaction layer during formation. This system is presented in Fig. 13. It gives the stoichiometry of the reactions only, and not the elementary processes.

The coefficient m takes an account of PbO "molecules" in the basic lead sulfate. When the paste consists solely of PbO, $m = \infty$. The corresponding values of the coefficients before PbO and $PbSO_4$ are 1 and 0. When the paste consists solely of $PbSO_4$, $m = 0$ and the corresponding coefficients have values of 0 and 1. At $3PO \cdot PbSO_4 \cdot H_2O$, $m = 3$.

Figure 13 shows that the system of reactions requires an exchange of flows of H^+ and SO_4^{2-} ions and H_2O (signified by N_{H^+}, $N_{SO_4^{2-}}$, and N_{H_2O}) between the reaction layer and the bulk of the electrolyte. Let us assume that the exchange of H_2O is very rapid and does not control the processes in the reaction layer. The flows of H^+ and SO_4^{2-} ions may enter or leave the reaction layer depending on the paste phase composition, the current density, the electrolyte pH, etc. The scheme on Fig. 13 enables us to determine the direction of these flows. Let us express in terms of flow all ions which participate in the chemical and electrochemical reactions. This is possible if we consider the occurring processes in unit volume of the reaction layer per unit time.

We can determine the flow of H^+ ions, N_{H^+}, which enters or leaves the reaction layer, from the chemical reaction [5]. The OH^- and H^+ ions, formed as a result of reactions [1] and [3] should be expressed in terms of corresponding flows

$$N_{H^+} = n_{OH^-[1]} - n_{H^+[3]} \quad [6]$$

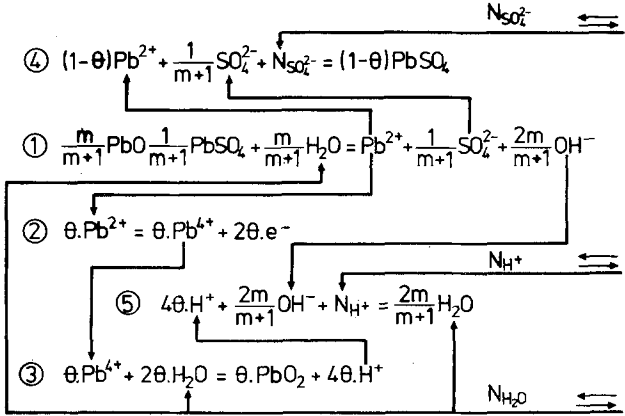

Fig. 13. Diagram of the chemical and electrochemical reactions occurring in the reaction layer during formation of the lead acid battery positive plate.

where $n_{OH^-[1]}$ signifies the OH^- ions formed per unit time in reaction [1] and $n_{H^+[3]}$ signifies the H^+ ions formed per unit time at reaction [3].

In the system of chemical and electrochemical equations in Fig. 13 the different "ion flows" are interconnected by their corresponding stoichiometric coefficients. Thus it becomes possible quantitatively to compare the "ion flows" with respect to one of them, for example that of the Pb^{2+} ions, formed in reaction [1]. The ratio of the flows is determined by the ratio of their stoichiometric coefficients in the corresponding chemical and electrochemical equations. For the OH^-[1] and Pb^{2+}[1] ions participating in reaction [1] (Fig. 13) this ratio is given by

$$\frac{n_{OH^-[1]}}{n_{Pb^{2+}[1]}} = \frac{2m}{m+1} \quad [7]$$

The ratio of the H^+ [3] and Pb^{2+} [1] ions stoichiometric coefficients is

$$\frac{n_{H^+[3]}}{n_{Pb^{2+}[1]}} = 4\theta \quad [8]$$

θ indicates what part of the Pb^{2+}[1] ion flow participates in the electrochemical reaction [2]

$$\theta = \frac{n_{Pb^{2+}[2]}}{n_{Pb^{2+}[2]} + n_{Pb^{2+}[4]}} = \frac{ki}{ki + v} \quad [9]$$

where $n_{Pb^{2+}[2]}$ is the part of Pb^{2+} ion flow which participates in the electrochemical reaction [2]. It is proportional to the current density i, and k is a coefficient of proportionality. $n_{Pb^{2+}[4]}$ is the part of Pb^{2+} ion flow which participates in the chemical reaction [4]. It is equal to the rate of the chemical reaction, yielding $PbSO_4$, which is expressed by V.

Combining Eq. [6], [7], [8], and [9] and transforming the expression one obtains for the N_{H^+} flow

$$N_{H^+} = \frac{2mV - 2(m+2)ki}{m+1} \quad [10]$$

In a similar way from chemical reaction [4] (Fig. 13) we can express the flow of SO_4^{2-} ions $N_{SO_4^{2-}}$, which the reaction layer exchanges with its surroundings

$$N_{SO_4^{2-}} = n_{Pb^{2+}[4]} - n_{SO_4^{2-}[1]} \quad [11]$$

where $n_{SO_4^{2-}[1]}$ is the SO_4^{2-} ion flow formed at reaction [1]. According to the scheme of Fig. 13, $n_{Pb^{2+}[4]}$ and $n_{SO_4^{2-}[1]}$ are correspondingly equal to

$$n_{Pb^{2+}[4]} = (1-\theta)\, n_{Pb^{2+}[1]} \quad [12]$$

$$n_{SO_4^{2-}[1]} = \frac{1}{m+1} n_{Pb^{2+}[1]} \quad [13]$$

Combining Eq. [11], [12], [13], and [9] we arrive at the following expression for the $N_{SO_4^{2-}}$ flow

$$N_{SO_4^{2-}} = \frac{mV - ki}{m+1} \quad [14]$$

Equations [10] and [14] show that the sign before N_{H^+} and $N_{SO_4^{2-}}$ depends on the paste phase composition through the coefficient m and depends on the current density through the value of i. When the term, comprising the rate of the chemical reaction in Eq. [10] and [14] is greater than the term comprising the rate the electrochemical reaction, the flows $N_{H^+} > 0$ and $N_{SO_4^{2-}} > 0$ so they will enter the reaction layer and vice versa. Table IV presents the coefficient values at the chemical and electrochemical reaction rates for several phases of the paste.

It is seen from the table that the H^+ and SO_4^{2-} ion flows mainly enter the reaction layer when the paste has a low degree of sulfation and the rate of chemical reaction [4] is high. On the contrary, when the paste has a high degree of sulfation and the formation is carried out at high current density, H_2SO_4 is formed in the reaction layer and flows of H^+ and SO_4^{2-} ions come out of it.

Table IV.

Phase	m	N_H	N_{SO_4}
PbO	∞	$2V$-$2ki$	V
$3PbO \cdot PbSO_4 \cdot H_2O$	3	$1.5V$-$2.5ki$	$0.75V$-$0.25ki$
$PbO \cdot PbSO_4$	1	V-$3ki$	$0.50V$-$0.50ki$
$PbSO_4$	0	$-4ki$	$-ki$

The rate of the electrochemical reaction [2] (ki) determines the growth of the PbO_2 zone in the cross section of the plate. Positive charges are evolved in the electrochemical reaction [2] (Fig. 13). To preserve the electroneutrality of the reaction layer solution these charges must be transported into the bulk of the electrolyte. This occurs through exchange of N_{H^+} and $N_{SO_4^{2-}}$ flows between every unit volume of the reaction layer and the electrolyte. If in some part of the reaction layer this process is low, the solution in the pores there becomes positively charged. This decreases the electrochemical reaction rate and the growth of the PbO_2 zone in this direction is stopped or slowed down.

The velocity of N_{H^+} and $N_{SO_4^{2-}}$ flows is determined by the electric field intensity and by the H^+ and SO_4^{2-} ion diffusion gradients which in the case of an equal pore width depend on the distance between the considered unit volume of the reaction layer and the surface of the plate. The width of the pores is determined by the paste density.

The reaction layer electroneutrality is most easily maintained at the surface layers of the plate. The distance which the H^+ and SO_4^{2-} ions must overcome is the shortest there. It is to be expected that during the first formation stage the PbO_2 zone should grow in the plate surface layers only. However, optical observations of the formation process (Fig. 1 and 6) show that this is true on plates with low sulfation pastes (Fig. 1) and when formation is carried out at low current density (Fig. 6). Under the above conditions, according to Table IV the N_{H^+} and $N_{SO_4^{2-}}$ flows enter the reaction layer.

Figures 1 and 5 show, however, that this condition alone is not sufficient to determine the direction of the PbO_2-zone growth. A second parameter controlling the advance of the product zone might be the potentials at which the electrochemical reactions take place in the reaction layer. The paste is built up by crystals of several phases (PbO, $3PbO \cdot PbSO_4 \cdot H_2O$, $PbO \cdot PbSO_4$, $PbSO_4$). Combined with PbO_2 phase each of them constitutes an electrode system. The potential of plate under current is defined by the equation

$$E = E^o + \eta \quad [15]$$

where E^o is the electrode system equilibrium potential and η is the electrode reaction overvoltage.

The reaction with the most negative equilibrium potential which has the lowest overvoltage will proceed at highest rate. According to Table II the equilibrium electrode potentials depend on the solution pH and in a lesser degree on the SO_4^{-2} ion activity in the reaction layer. pH of the reaction layer pore solution depends on reactions [1] and [3] (Fig. 13). The concentration of H^+ and SO_4^{2-} ions in the reaction layer increases when the formation is carried out with high current density on a paste with high degree of sufation (Fig. 4). Since the reaction layer is surrounded by two different zones (PbO_2 zone and paste) the diffusion gradients of H^+ and SO_4^{2-} ions should be different at both boundaries of the layer. As H_2SO_4 reacts with PbO and basic lead sulfates, H^+ and SO_4^{2-} flows should be directed toward the paste. Hence, the highest pH would be maintained at those regions of the reaction layer where the paste has not yet reacted. Such is the interior of the plate.

Table IV shows that at high paste sulfation and high current density the N_{H^+} and $N_{SO_4^{2-}}$ flows leave the reaction layer. It can be seen in Fig. 1 and 6 that under these conditions the PbO_2 zone grows first into the interior of the plate.

As formation advances, the N_{H^+} and $N_{SO_4^{2-}}$ flows become hindered and the potential of the plate rises. It reaches values at which the oxidation of $PbSO_4$ crystals to PbO_2 becomes possible. This marks the transition from the first to the second formation stage.

The Corrosion of a Strontium-Lead Alloy in Sulfuric Acid

K. R. Bullock* and W. H. Tiedemann*

Johnson Controls, Incorporated, Corporate Applied Research Group, Milwaukee, Wisconsin 53201

ABSTRACT

A patented proprietary strontium-tin-aluminum-lead alloy, developed for use in lead-acid batteries, has electrochemical characteristics similar to cast calcium-lead alloys but casting characteristics similar to antimony-lead alloys. Corrosion tests on this strontium alloy are reported at constant potentials from 0.600 to 1.290V (*vs.* Hg/Hg_2SO_4/5.6 molal H_2SO_4), H_2SO_4 concentrations from 0.8 to 5.1 molal and temperatures from 27° to 82°C. The corrosion properties of the strontium-lead alloy are compared with those of pure lead and of antimony- and calcium-lead alloys.

The most widely used materials for lead-acid battery grids are antimony-lead and calcium-lead alloys. Pure lead is too soft to be easily handled in most manufacturing operations and is therefore used only in special battery designs (1).

Although alloys containing 3-12% antimony have good mechanical properties, antimony has several undesirable effects on the electrochemistry of the lead-acid battery. Antimonial alloys corrode faster than pure lead at potentials above open circuit. When the antimony in the positive grid oxidizes, it can dissolve in the electrolyte and deposit on the negative electrode, lowering the otherwise high overvoltage for hydrogen evolution on lead (2). This increases both the amount of gassing on overcharge and the rate of self-discharge. The deposition of antimony on the lead electrode can also give rise to the evolution of toxic stibine gas on overcharge. (3).

Calcium-lead alloys were introduced (4) to overcome these problems and are now widely used to improve shelf life and to reduce the need for adding water to batteries. However, the calcium content of these alloys must be carefully controlled (5) to avoid formation of dross during casting and to minimize subsequent severe grid corrosion.

Recent development of lead-acid batteries for use in electric vehicles and load leveling has put even more stringent requirements on grid materials. The need to reduce the amount of lead in the grid requires the good casting characteristics of antimony-lead alloys while the need to improve efficiency and minimize maintenance requires the good electrochemical characteristics of calcium-lead alloys.

* Electrochemical Society Active Member.
[1] Globe-Union is now a division of Johnson Controls.
Key words: battery, cathode, potential, passivity.

A newly developed and patented strontium-tin-aluminum-lead alloy meets both these needs (6). It has electrochemical characteristics similar to those of calcium alloys but is easier to cast. Production costs are reduced because the strontium concentration is less critical than the calcium concentration and because the strontium alloy can be produced on equipment designed for manufacturing antimony alloys, eliminating the capital equipment expenditure required to cast calcium alloys. Production time is reduced because the strontium alloy age hardens faster than calcium alloys.

Since positive grid corrosion is a significant problem in lead-acid batteries, the corrosion behavior of lead and the common lead alloys has been studied in detail (7). If a new alloy is to find its proper place in the present multitude of lead-acid battery designs and applications, its corrosion behavior must be defined over a wide range of temperatures, potentials, and acid concentrations.

Two recently published papers contain some data on strontium-lead alloys. Bagshaw (8) studied the corrosion of strontium-lead alloys with additions of aluminum, cerium, and silver in H_2SO_4 (1.250 sp gr) by applying a 155 mA/cm^2 constant current for 1 day and by applying 8.5 mA/cm^2 under a 1.4 kg/mm^2 load. These conditions are much more severe than could be expected in typical battery operation. In addition, constant current corrosion does not allow separation of the possible corrosion mechanisms by their potential dependence. Weinlein, Pierson, and Marshall (7) studied the corrosion of a strontium-tin-aluminum alloy in 1.270 sp gr H_2SO_4 at constant potentials above the open-circuit voltage of the positive plate. They compared the corrosion behavior of typical antimony- and calcium-lead alloys oxidized under the same conditions.

In this paper, a more extensive series of constant potential corrosion tests on the strontium alloy is reported for potentials from 0.600 to 1.290V, acid concentrations from 0.8 to 5.1 molal (M) and temperatures from 27° to 82°C in order to provide working curves from which the corrosion behavior of the new alloy can be predicted for a specific application. The effects of acid concentration and temperature are carefully examined in regions where high corrosion rates can occur. Finally, the corrosion properties of the strontium alloy, of pure lead, and of typical antimony and calcium alloys are compared over a wide potential range.

Experimental Methods

Cast grids were corroded in electrolyte made from reagent grade sulfuric acid and distilled, deionized water. The temperature was controlled to ±1°C by a water bath and the potential was held constant to ±1 mV with a three-electrode potentiostat. Two lead grids, placed on either side of the working electrode, were the counterelectrodes and Hg/Hg_2SO_4/5.6M H_2SO_4 was the reference electrode. During the corrosion test, the current was repeatedly monitored.

After the grid had corroded for 4 days, the portion around the tab was cut out and allowed to self-discharge in the same solution at the same temperature. The open-circuit voltage of this grid sample was monitored as a function of time by a high impedance voltmeter.

The remaining portion of the grid was prepared for further analysis by rinsing it in distilled water and drying it at room temperature. The corrosion film of a 12g sample of the grid was stripped off with a solution containing sodium hydroxide, mannitol, and hydrazine dihydrochloride and the dissolved lead was analyzed by atomic absorption spectroscopy. Other portions of the grid were mounted in epoxy, cross sectioned, polished, and observed under cross-polarized light using a metallograph (American Optical Company Model 2400) with a 450W xenon lamp at 1000× magnification.

The strontium-lead alloy used to obtain the data shown in Fig. 2-6 and Fig. 9 contained 0.13% Sr, 0.04% Al, and 1.0% Sn. The strontium-lead alloy used in the temperature study shown in Fig. 7 and 8 contained 0.15% Sr, 0.02% Al, and 0.9% Sn. Average grid weights were 52.62g ($1\sigma = 1.06$) for the 0.13% Sr alloy and 53.61g ($1\sigma = 0.88$) for the 0.15% Sr alloy.

The pure lead grids (Fig. 2) were cast from corroding grade lead. Casting temperatures were 213°C for the upper mold, 227°C for the lower mold, and 460°C for the melt. The average grid weight was 72.4g ($1\sigma = 2.35$).

All grids used in this study were cast in the grid design shown in Fig. 1. They had a surface area of

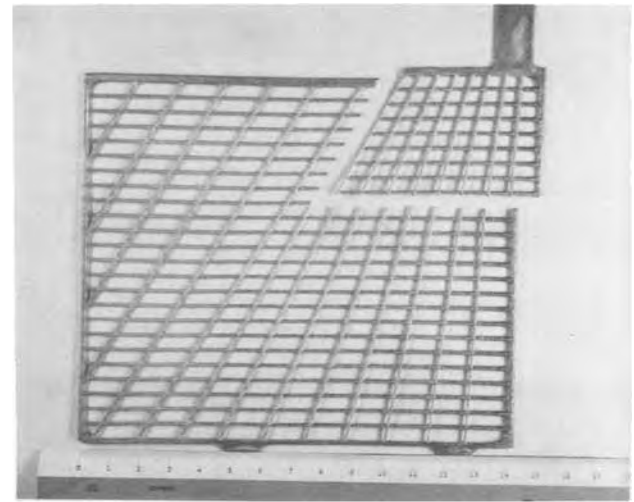

Fig. 1. Grid design used in all corrosion studies showing width in centimeters. Geometric surface area is approximately 170 cm^2.

approximately 170 cm^2 and a thickness of approximately 1 mm. The tab portion of the grid used in the open-circuit voltage decay studies is shown in the figure slightly offset from the portion used for analysis.

Results and Discussion

Lander (9, 10) studied the constant potential corrosion of pure lead as a function of acid concentration, potential, and time. He observed a peak in the corrosion rate at 1.0V (*vs.* $Hg/Hg_2SO_4/40.8\%$ H_2SO_4) with a minimum from about 1.2 to 1.5V. According to Lander and to numerous authors of subsequent studies (6), this minimum corresponds to the passivation of lead by PbO_2 formation. At the corrosion peak, PbO_2, $PbSO_4$, and PbO all form simultaneously. At voltages below the peak, PbO forms in the interior of the corrosion film and $PbSO_4$ at the solution/film interface.

Our corrosion studies agree qualitatively with Lander's results, as Fig. 2 shows. The mg of lead in the corrosion film/g grid sample/day corroded is plotted as a function of the corrosion potential (*vs.* Hg/ $Hg_2SO_4/5.6M$ H_2SO_4). The corrosion peak occurs at 1.0V and the minimum begins at about 1.15V. (Our reference potential is within 20 mV of Lander's.) The results of electrochemical, metallographic, and analytical studies indicate that the corrosion products follow the potential dependence outlined by Lander (10).

The strontium alloy curve in Fig. 2 is similar, with a minimum beginning at about 1.2V and a maximum at about 1.0V. Micrographs of strontium alloy corrosion films under cross-polarized light show brown PbO_2 in the minimum region, an outer white $PbSO_4$ film and inner red PbO film at potentials below the peak, and a heterogeneous layer at the peak which includes PbO, $PbSO_4$, and α- and β-PbO_2. The voltage plateaus in open-circuit voltage-time curves of these films agree with this visual interpretation. The main difference between the corrosion of pure lead and the strontium alloy is that the peak of the strontium curve is somewhat higher and broader.

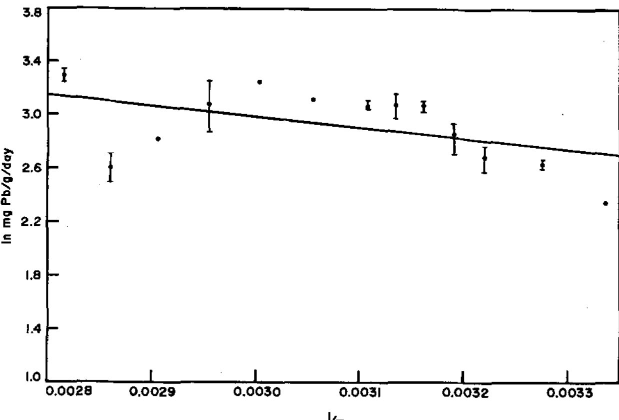

Fig. 8. The effect of temperature on the corrosion rates of strontium-lead alloy grids at 0.900V in 0.8M H_2SO_4.

The effect of the acid concentration on the corrosion of the strontium-lead alloy is shown in the three curves in Fig. 3 for 5.1, 2.7, and 0.8*M* H_2SO_4. In making a comparison of this type, the reference electrode must be considered. If a reference electrode with a fixed acid concentration is chosen, the junction potential between the acid in the corrosion cell and the acid in the reference electrode will vary, whereas if a reference electrode with the same acid concentration as the corrosion cell is chosen, the junction potential will be eliminated but the reference electrode potential will vary. We used an Hg/Hg_2SO_4/5.6*M* H_2SO_4 reference electrode in our experiments and measured the potential difference between this electrode and Hg/Hg_2SO_4 electrodes containing 5.1, 2.7, and 0.8*M* H_2SO_4 to obtain the data shown in Table I. The curves in Fig. 3 may be shifted in the negative direction by these values to reference each curve to the $Hg/Hg_2SO_4/H_2SO_4$ electrode with the same acid concentration.

While measurement of the weight of lead in the corrosion layer for a fixed corrosion time (4 days) and a fixed grid weight (12g) gives an overall corrosion rate, measurement of the 4 day corrosion current gives a steady-state, instantaneous corrosion rate. Figure 4 shows the 4 day currents as a function of potential for the three acid concentrations: 5.1, 2.7, and 0.8*M*. Oxygen evolution may contribute to the current, especially at the higher potentials. However, both methods of measuring corrosion rate show a shift in the corrosion peak to lower potentials as the acid concentration decreases. The peak corrosion rate is lower in 2.7*M* than in 5.1 or 0.8*M* H_2SO_4. These trends apparently result from a change in the relative rates of the competing corrosion reactions as the acid concentration varies. Low concentrations favor formation of α-PbO_2 and tetragonal PbO, whereas higher concentrations favor formation of β-PbO_2 and $PbSO_4$ (11, 12).

Micrographs of cross sections of the corrosion films formed at the peaks in 0.8 and 5.1*M* H_2SO_4 show substantial differences. The corrosion film formed at 1.100V in 5.1*M* H_2SO_4, shown in Fig. 5, is quite heterogeneous. Under cross-polarized light, this film appears to have brown PbO_2 and white $PbSO_4$ crystals scattered throughout. A continuous black layer which is probably α-PbO_2 covers the grid at the base of the corrosion film and black boulders of α-PbO_2 grow out from this layer. Isolated areas of red underneath the PbO_2 and $PbSO_4$ particles suggest the presence of tetragonal PbO. The corrosion film formed at 1.000V in 5.1*M* H_2SO_4 looks nearly the same. On the other hand, in the film formed at 0.900V in 0.8*M* H_2SO_4, shown in Fig. 6, three separate layers appear. The outer surface is composed of white $PbSO_4$ crystals. Underneath this is a dense black layer of α-PbO_2 and next to the grid is a red layer of tetragonal PbO. X-ray diffraction powder patterns of particles picked from these films by the McCrone method (13) show predominantly $PbSO_4$ at 1.100V in 5.1*M* H_2SO_4 and tetragonal PbO at 0.900V in 0.8*M* H_2SO_4.

The effect of changing acid concentration at the two peak potentials is also different, as the data in

Table III. Results of corrosion temperature studies

	Corrosion conditions			
	1.100V/5.1*M* H_2SO_4		0.900V/0.8*M* H_2SO_4	
	Corrosion rate			
	mg Pb/g/day	4 day i	mg Pb/g/day	4 day i
Slope [(°K)$^{-1}$]	−3319	−5386	−798	−1727
Index of determination	0.757	0.873	0.209	0.715
Activation energy [kcal/mole]	6.6	10.7	1.6	3.4

Fig. 3 and 4 show. At 0.900V, the corrosion rate decreases with increasing acid concentration, whereas at 1.100V, the corrosion rate increases with increasing acid concentration. These trends are consistent with the hypothesis that PbO formation is favored at the lower potential and $PbSO_4$ and β-PbO_2 formation at the higher potential (9, 10).

The effect of temperature on the peak corrosion rates of the strontium alloy in 5.1 and 0.8*M* H_2SO_4 is shown in the Arrhenius-type plots in Fig. 7 and 8, respectively. The number of experiments run at each temperature is shown in Table II. At the temperatures where the experiment was replicated, the error bars show the total spread in the data and the dot shows the ln of the average corrosion rate. Reproducibility is poor because several corrosion reactions are occurring simultaneously.

The straight lines shown in Fig. 7 and 8 were determined by linear regression analysis. Plots of the ln of the 4 day corrosion currents as a function of $1/T$ gave similar results. By using the equation

$$\ln \text{corrosion rate} = -Ea/(RT)$$

where Ea is the activation energy of the corrosion process and R is the gas constant, approximate activation energies were calculated. Table III shows the slopes, indexes of determination, and activation energies for the two sets of corrosion conditions calculated using both measurements of corrosion rate.

The line shown in Fig. 8 has an index of determination of only 0.209. This shows that the uncertainty in the data is large compared to the effect of temperature, if the assumptions of the Arrhenius equation are upheld. Nevertheless, a Student's t test allows us to reject at a 99% confidence level the hypothesis that temperature has no effect. When the 4 day current is used as a measure of corrosion rate, the index of determination is 0.715. These data show that temperature has very little effect on the corrosion rate at 0.900V in 0.8*M* H_2SO_4. At 1.100V in 5.1*M* H_2SO_4, the correlation is stronger and the activation energy is higher.

Since the corrosion experiments represented in Fig. 7 and 8 were replicated over a period of about 9 months on grids from the same production lot, the results could also be used to determine the effect of aging on corrosion rate. No correlation between grid age and corrosion rate was observed. This conclusion was further substantiated by corrosion tests at 1.100V in 4.4*M* H_2SO_4 on strontium-lead alloy grids aged at 100°C for 8.75-52.5 hr.

In Fig. 9, the total weights of oxidized tin and strontium in the 12g grid samples are compared with the total weight of oxidized lead as a function of the corrosion potential. The relative proportions of the oxidized components are about the same as in the metal throughout the active corrosion region.

In Fig. 10, the current-potential curve for a strontium-lead alloy at 82°C in 5.1*M* H_2SO_4 is compared with the curves for three lead alloys commonly used in lead-acid batteries: a 5.12% antimony-lead alloy, a 1.0% antimony-lead alloy, and a calcium-tin-lead alloy. The strontium and calcium alloys have lower corrosion rates at the peaks than the antimony alloys. The strontium peak occurs at a lower voltage than the peaks for the other alloys, giving it a broader passivation region. The poor reproducibility in the peak current measurements (due to the dramatic increase in corrosion rate) makes the exact peak location questionable, but these data as well as the data shown in Fig. 7 for 82°C indicate that the strontium alloy has at least as broad a passivation region as the calcium alloy and broader than the antimony alloys.

The antimony alloys have higher currents than the non-antimonial alloys at the higher potentials, both

Fig. 9. Corrosion of alloying components as a function of potential. - - - mg Pb, ··· mg Sn, —— mg Sr.

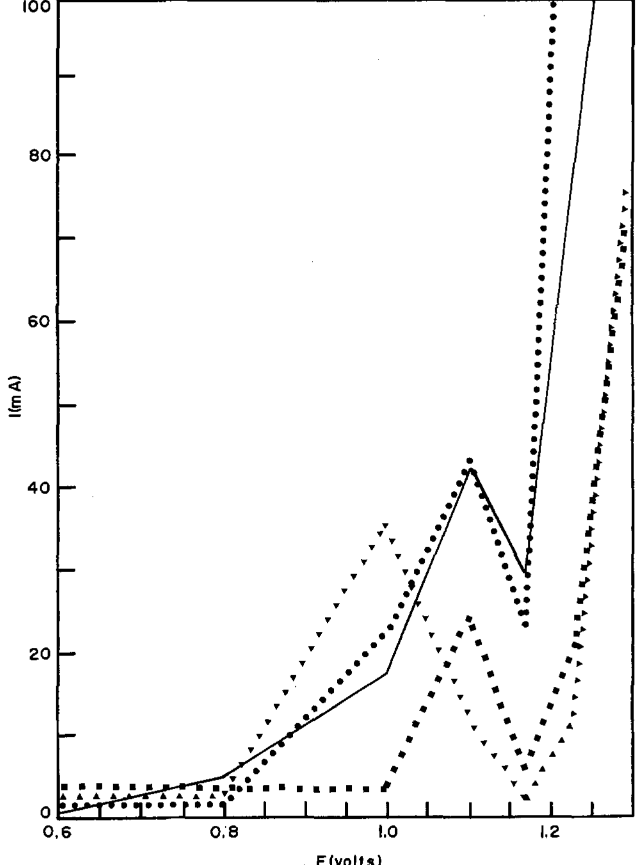

Fig. 10. Comparison of corrosion rates of typical lead alloys at 82°C in 5.1*M* H_2SO_4 as a function of potential. ▼▼▼ 0.13% Sr, 1.0% Sn, 0.02% Al; ■■■ 0.09% Ca, 0.5% Sn; —— 5.12% Sb, 0.5% As, 0.23% Sn, 0.062% Cu, 0.002% S; ●●●●● 1.0% Sb, 0..34% As, 0.15% Sn.

because the corrosion rates are higher and because the oxygen evolution rates are higher. Figure 11 shows cross sections of the corrosion films at 1.290V and Fig. 12 shows the microstructures of the 4 alloys. (The pictures in Fig. 12 were taken several years after the corrosion experiments were run.) The corrosion layers of the antimony alloys are much thicker and interdendritic corrosion is more significant, particularly for the 5.12% Sb alloy. The strontium alloy corrosion film is thin and looks very similar to the calcium alloy. Corrosion of the strontium alloy is apparently not influenced by the dendrite arm spacing, which is similar to that of the antimony alloys. There was no evidence of interdendritic penetration of the strontium alloy at any potential. The strontium alloy would be expected to withstand overcharge in a manner similar to the calcium alloy and better than the antimony alloys.

Conclusions

The corrosion behavior of the cast strontium-lead alloy is similar to cast pure lead and lead-calcium alloys. Two regions of high corrosion occur: (*i*) in high concentration acid (5.1*M*) near the open-circuit potential (1.0-1.1V *vs.* $Hg/Hg_2SO_4/5.6M\ H_2SO_4$) and (*ii*) in low concentration acid (0.8*M*) at low potentials (0.8-0.9V). Temperature greatly enhances the corrosion rate under the first set of conditions but not under the second. The strontium alloy corrodes less than antimony alloys at potentials above open circuit and has a broader passive region. These characteristics would be beneficial in float and cycling applications.

The corrosion behavior of the strontium-tin-aluminum-lead alloy thus appears to be acceptable for use in lead-acid batteries. This, coupled with its good electrochemical and metallurgical properties, makes it a possible alloy candidate for use in many lead-acid battery applications.

Side Reactions of Pyridine-Halogen Complexes

Arthur J. Coury* and Patrick T. Cahalan

Energy Technology, a Division of Medtronic, Incorporated, Minneapolis, Minnesota 55418

ABSTRACT

Halogen-pyridine charge transfer complexes have conductivities which make them useful as depolarizers in power cell cathodes. Pyridines and halogens undergo additional reactions of consequence to cell performance. Such side reactions include: alkyl group substitution, ring coupling, polymer molecular weight degradation, olefin addition, and ring substitution. Instrumental analysis of model systems and the commercial poly(2-vinyl-pyridine)/iodine ($P2VP/I_2$) system provided strong evidence for alkyl group substitution, coupling, and molecular weight degradation. The addition reaction was inferred from the presence of the needed reactants and their facile reactivity, but not confirmed analytically. Halogenation of the pyridine ring was not found, and, from literature sources, was assumed to be unlikely under conditions of cell use. The side reactions cited cause reduced cathode capacity. Hydrogen halides generated by such side reactions may cause corrosion, but may enhance conductivity properties. Deleterious pressure buildup or dimensional changes may result from side reactions occurring within sealed battery cans.

The combination of halogens (acceptors) with pyridine derivatives (donors) produces, initially, charge transfer complexes with conductivities useful as depolarizers in lithium-halogen power cell cathodes. The complex most often employed in pacemaker batteries is $P2VP/I_2$ (1).

Subsequently, several other reactions can occur depending on time, temperature, and stoichiometric ratio. The nature of these side reactions has recently been addressed by us as well as by other workers (2). Known reactions of pyridines which may be relevant to cell performance include: alkyl group substitution, ring coupling, polymer molecular weight degradation, olefin addition, and ring substitution. Insights into the reactions of halogens with pyridine and substituted pyridines were derived from literature sources and experimental studies of model complexes as well as from the commercial $P2VP/I_2$ system. The nature and magnitude of such reactions and some suggestions as to how they may affect the performance of power cells are discussed in this paper.

Experimental

Materials.—Pyridine (Aldrich, >99%, Gold Label), and ethylpyridine (Aldrich, 97%) were distilled before use. P2VP (Ionac Chemical Company, intrinsic viscosity range 0.8-1.0, 30C in pyridine) was oven dried before use. Iodine (Mallinckrodt, resublimed) and bromine (Mallinckrodt, purified grade) were used as received.

Apparatus and procedures.—Reactions studied at ambient or slightly elevated temperatures were performed by weighing the halogen and pyridine derivatives into glass containers sealed with glass or Teflon. For moderate heating <60°C, the glass containers were placed in forced-air ovens. High temperature studies (>100°C) were conducted in sealed glass ampules or Hastelloy C autoclaves, jacketed with heating mantles. Reagents were protected from moisture during weighing.

Analyses.—Infrared spectra were run on a Perkin-Elmer 457A grating infrared spectrophotometer (range 200-4000 cm^{-1}). Specimens were generally prepared as smears or solvent-cast films on potassium chloride plates. Nuclear magnetic resonance spectra were run on a Varian Anaspect EM360, using acetone D_6 as solvent. Mass spectra were determined using a du Pont Model 21-492 instrument interfaced with a Honeywell 716 computer.

Results and Discussion

Complex formation.—From vapor pressure measurements, the $P2VP{:}I_2$ ratio in the charge transfer complex is 1:1 (3) when excess iodine is present. With equimolar ratios of halogen to pyridine or substituted pyridines, there is evidence for a mixture of 1:1 molecular complex and a 2:1 ionic structure, *e.g.*, $(C_6H_5N)_2I^+I^-$ (4). Halogen molecules associate with pyridines at different strengths (Fig. 1) (5). Model reaction studies were performed on systems containing the halogens I_2 and Br_2, along with various monomeric and polymeric pyridines. Pyridine was chosen as one of the model compounds to eliminate alkyl group reactions.

Halogen-pyridine reactions.—Ambient mixing of equivalent amounts of Br_2 and pyridine resulted in an immediate exotherm and an orange solid followed by a slower reaction with transformation of the material to a tarry, black mass. The transformations assigned were complex formation followed by ring coupling to polypyridylene hydrobromide (Fig. 2). The reaction mechanism proposed by McElvain *et al.* (6) involves coupling of pyridines at activated ortho or

Key words: iodine cathode, organic reactions, halogenation.

para positions (Fig. 3). Crosslinking, hence the observed intractability, occurs when the pyridine coupling occurs at three ring sites. With Br_2 in excess pyridine, similar transformations were observed with a tarry precipitate forming which exhibited polypyridylene characteristics. These results are consistent with the equations in Fig. 3 which show that a stoichiometric excess of pyridine over Br_2 is necessary for polypyridylene formation to occur.

With pyridine in excess Br_2, charge transfer complex formation was instantaneous and exothermic. The resulting liquid appeared to be stable indefinitely (Fig. 4). In agreement with literature sources (7, 8), no ambient temperature ring bromination was found at any Br_2 ratio. High temperatures are required for ring bromination (Fig. 5) (7). With unsubstituted pyridine in excess Br_2, therefore, side reactions are suppressed at ambient conditions.

Halogen-alkyl pyridine reactions.—With alkyl-substituted pyridines, excess halogen induced another side reaction, halogenation at the carbon attached to the pyridine ring. It was slower than complex formation or ring coupling (when the latter occurred). For example, when 2-ethylpyridine was combined with excess Br_2, conversion to α-bromo-2-ethylpyridinium bromide perbromide occurred, as determined by nuclear magnetic resonance spectroscopy (α-protons) and infrared spectroscopy (Table I) to the extent of 27 mole percent (m/o) in 4.5 months (Fig. 6), under ambient conditions of storage. Pyridine hydrohalide salts, it is noted, form stable complexes with Br_2 (8). Less alkyl bromination occurred with equivalent amounts of the reactants, but alkyl polypyridylene formation was suggested by the intractable nature and black color of the product.

Infrared results.—Qualitative indications of the chemical species previously described were observed in infrared spectra. Pyridine C=N stretch frequencies, normally between 1585-1615 cm^{-1}, shifted upward

~10 cm^{-1} for charge transfer complexes and ~15-40 cm^{-1} for hydrohalide salts. A broad amine salt $(N\text{-}H)^+$ absorption developed at 2700-2900 cm^{-1} as pyridine hydrohalides formed. A peak assigned to C-Br stretching at 540-595 cm^{-1} appeared to be proportional to alkyl bromination. Examples of infrared group frequencies for model pyridine/Br_2 systems are given in Table I.

Iodine acceptor systems.—When I_2 was substituted for Br_2, complex formation was spontaneous but slower by virtue of being limited by diffusion of I_2 into the pyridine phase or dissolution of the I_2 by the pyridine phase. Side reactions were of the same chemical type, but considerably slower. For example, with equivalent amounts of 2-ethylpyridine/I_2, a dark liquid complex formed at room temperature which changed little by infrared analysis over seven days. Over 5.5 months, however, a massive amine salt vibration (centered at 2900 cm^{-1}) developed, possibly due to formation of the polypyridylene-type structure (Fig. 7). The analogous reactions occurred within hours with the use of Br_2 as acceptor.

P2VP-halogen systems.—With P2VP, reactions analogous to the model pyridine compounds were observed. Variations in the molecular weight and chemical structure of the P2VP were additional factors of concern for power cells.

Analytical results.—Infrared spectroscopy was used qualitatively to show development of side products in P2VP-halogen systems. Absorbances were analogous to those developed in the model reactions (Table II).

Nuclear magnetic resonance spectroscopy was valuable for quantitative estimates of alkyl chain halo-

genation by determining the ratio of integrated aliphatic (1.0-4.5 ppm, δ) to aromatic (7.0-10.0 ppm, δ) absorbances. Qualitative indications of pyridine salts (exchangeable protons) were detected near 15δ and in an absorbance which varied between 6-12δ dependent on temperature and concentration.

P2VP reactions in excess halogen.—In excess Br_2, at ambient temperatures, P2VP developed infrared absorbances indicative of alkyl chain halogenation within hours which increased over the length (seven days) of the study (Fig. 8).

At 120°/1.7 hr, a hard, insoluble product developed, indicating the possibility of polypyridylene formation. Any intermolecular coupling of P2VP would cause cross-linking and consequent intractability. The necessary free pyridine base is believed to be generated by thermal reversal of the charge transfer complex (Fig. 9).

With excess I_2, P2VP entered into side reactions more sluggishly. However, at 130°C/24 hr, significant salt and alkyl chain halogenation were detected. At 170°C/72 hr, nuclear magnetic resonance spectroscopy indicated the ratio of aliphatic to aromatic protons to be 2.4:4.0, *i.e.*, ~60% of the tertiary hydrogens were substituted by iodine (Fig. 10).

Fig. 8. Alkyl bromination of poly-2-vinylpyridine

Fig. 9. Polypyridylene formation in poly-2-vinylpyridine

Fig. 10. Alkyl iodination of poly-2-vinylpyridine

Higher temperatures effected the conversion of $P2VP/I_2$ mixtures from paste to fluid form and caused the release of volatile fragments. Mass spectrometry of the volatile reaction gases indicated short-chain alkyl iodides (CH_3I, $C_2H_4I_2$), I_2, HI, pyridine, and vinylpyridine.

Data from the analyses employed did not give a definitive picture of the nature of the polymer backbone degradation resulting from treatment with halogens. The side products previously described were indicated to a large extent, however, in the degraded residues from the high temperature treated systems.

Unconfirmed reactions.—Other chemical transformations which may occur but are not yet confirmed analytically involve olefinic functionality in 2-vinylpyridine (2VP) monomer and P2VP backbone chain. The 2VP is inevitably present in P2VP starting material, and may form during thermal degradation of the polymer.

A facile combination of 2VP with pyridine hydrohalide groups has been reported (Fig. 11) (9). The pyridine hydrohalides are available as products of most of the side reactions already described.

Formation of halogenated alkyl products by the addition of halogens or hydrogen halides to olefinic moieties (in 2VP or the P2VP alkyl chain) are considered possible transformations (Fig. 12). This addition mechanism is difficult to isolate, however, because of the similarity of the products to those formed from substitution reactions.

Summary and Conclusions

Most of the side reactions cited cause reduced cell capacity by prematurely depleting halogen. The hydrogen halides generated may cause corrosion problems, but may enhance conductivity characteristics. Undesirable pressure buildup or dimensional changes may result from side reactions occurring within the sealed battery can. While useful indications of the nature and extent of side reactions were derived from these studies, our understanding of reaction mechanisms and products is still incomplete. Work continues on elucidating chemical transformations and relating them to cell performance.

A New Membrane-Type *p*H Sensor for Use in High Temperature-High Pressure Water

Leonard W. Niedrach*

General Electric Company, Research and Development Center, Schenectady, New York 12301

ABSTRACT

The new sensor provides for the direct measurement of the *p*H of geothermal brines, water in nuclear reactors, and other high temperature solutions. The heart of the unit is an oxygen ion conducting ceramic that serves as the membrane in a structure somewhat akin to that of the conventional glass electrode. Yttria stabilized zirconias with both aqueous internal junctions and dry, metal-metal oxide internal junctions were employed in the present work. Test units were run continuously without failure for periods as long as 13 days at temperatures of 285°C and at pressures of 1200 psi. Under these conditions the response over the *p*H range 3-8 (at 285°) was linear with a slope up to 97% of theoretical. Unlike sensors involving electron transfer couples (*e.g.*, the hydrogen electrode, the palladium hydride electrode, metal-metal oxide couples) the membrane is insensitive to changes in the redox environment. In turn, the relatively inert membrane exerts no influence on the environment; this behavior contrasts markedly with that of the hydrogen electrode and many other candidates for use at high temperatures. Although primary emphasis was placed on high temperature performance, the ceramic membranes were also shown to function as *p*H sensors over the temperature range from 25° to 285°C. The conductivities of the yttria stabilized membranes, as measured in sensors, were found to be comparable in magnitude and activation energy with literature values for related materials measured at elevated temperatures in connection with their application in high temperature fuel cells and oxygen sensors.

Work leading to the concept of the new sensor was inspired by the recognized need for devices for the direct measurement of the *p*H at elevated temperatures of geothermal brines, of water in nuclear reactors, and in other high temperature applications including basic thermodynamic studies of aqueous systems. For such applications, membrane sensors are superior to those based on electron transfer couples (*e.g.*, the hydrogen electrode, the palladium hydride electrode, and metal-metal oxide couples) because unlike the latter, membrane electrodes are normally insensitive to changes in the redox environment and are resistant to poisoning by impurities such as sulfides. In turn, membrane materials can often be found that exert no significant influence on the environment. These considerations are paramount, of course, in accounting for the universal acceptance of the glass electrode for *p*H measurements at ambient temperature. In view of the difficulties that have been encountered in attempts to modify the classical glass electrode for high temperature-high pressure applications (1-3), alternative membranes were sought for the purpose.

In this connection the well-known lanthanum fluoride electrode for the determination of fluoride ion concentrations was selected as a useful model to establish criteria for the desired membrane material. This electrode functions because fluoride ions in the crystal and in the solution serve as the potential-determining species at the interface. At equilibrium the electrochemical potential of the fluoride ion, is defined in general form by

$$\bar{\mu}_{X^{-n}} = \mu^\circ_{X^{-n}} + RT \ln a_{X^{-n}} + n\mathbf{F}\phi \quad [1]$$

where $\bar{\mu}_{X^{-n}}$ is the electrochemical potential, $\mu^\circ_{X^{-n}}$ is the standard chemical potential, $a_{X^{-n}}$ is the activity of the fluoride ion, ϕ is the inner or galvani potential, n is the charge on the ion of interest, and the other terms have their usual meanings, is equal in both phases. The potential drop at the interface is therefore given by

$$\Delta\phi = \phi_m - \phi_a = \frac{1}{n\mathbf{F}} ({}_a\mu^\circ_{X^{-n}} - {}_m\mu^\circ_{X^{-n}} - RT \ln {}_m a_{X^{-n}} + RT \ln {}_a a_{X^{-n}}) \quad [2]$$

* Electrochemical Society Active Member.

Key words: oxygen ion conducting ceramics, stabilized zirconia, yttria stabilized zirconia, oxygen electrode.

where the subscripts a and m identify the aqueous and membrane phases, respectively. Since fluoride ion is the sole anion in the crystal, its activity in the solid phase remains constant and the only variable term involved in establishing the total potential drop across the interface is the fluoride ion activity in the aqueous phase.

It was reasoned that a parallel relation might exist between an oxygen ion conducting ceramic and the oxygen ion concentration (and hence indirectly the *p*H) in an adjacent aqueous phase. If so an oxygen ion conducting ceramic should function as a membrane-type *p*H sensor. This report shows that this sensitivity to *p*H is realized experimentally.

Stabilized zirconia tubes of the type employed in high temperature fuel cells and oxygen sensors were chosen as representative oxygen ion conducting membranes for initial tests. Zirconia is markedly less soluble than glass in water at elevated temperatures. Much work has also been done to characterize these ceramics and to develop fabrication techniques in connection with their earlier applications. Zirconia stabilized with yttria, calcia, and magnesia has been examined in the work to date, but the performance of the yttria containing materials has been far superior to the others, possibly because of their generally higher specific conductivities (4). The work to be reported will therefore be limited to yttria stabilized zirconia at two levels, 8.0 and 16.9 weight percent (w/o).

A variety of alternative oxygen ion conductors should be applicable as long as the transference number for the oxygen ion is close to 1.0 and that for electron and/or hole conduction is at least an order of magnitude, and preferably several orders of magnitude, less. An important criterion is the specific conductivity. While that of the yttria stabilized zirconia is adequate for practical applications at temperature above 95°C, it would be desirable to be able to cover the full temperature range from ambient upwards. Among the zirconias those stabilized with scandia have the highest reported conductivities (4, 5) and they may be adequate. Certain doped cerias also look promising from this point of view (5-7).

The purpose of this work was to demonstrate the performance of the new sensor in a preliminary way, establish some of its important operating characteristics, and obtain some indication of stability. Before it can become a practical device, an adequate system including reference electrode and calibration procedures will have to be developed, to which little attention was devoted. It will become clear, however, that the reference electrode may prove less stable and reproducible than the membrane sensor itself.

Most of the data were obtained at 285°C, but data obtained at lower temperatures indicate that with lower resistance ceramics the full range from ambient temperature to 285°C or higher can be encompassed with a practical device.

Experimental

Structure of the sensors.—Most of the sensors used in this work were somewhat akin to the conventional glass electrode in that a buffered saline solution in contact with a chlorided silver wire served as the internal element within the membrane sheath. For work in the temperature range 25°-95°C stabilized zirconia tubes closed at one end were employed. Initially a 0.1m NaCl or KCl solution containing one pH 7 pHydrion® buffer tablet per 100 ml was employed as the inner electrolyte, and contact was made by a chlorided silver wire immersed in this solution. In some cases the solution (including the buffer) was diluted by a factor of ten. For longer term experiments, particularly at 95°C, the open end of the tube was covered with a Teflon cap.

A few sensors for use at 25°-95°C were also prepared with "direct junction" internal connections. One such type was prepared by inserting a 30 mil, coiled copper lead wire into the tube and packing it in place with a 50:50 mixture by weight of finely divided copper and cuprous oxide (Fisher Copper Metal-Electrolytic Dust, purified; Baker Cuprous Oxide Powder, Analyzed Reagent) to a depth of 3 in. This type of junction has been used in the past in the fabrication of the well-known stabilized zirconia high temperature oxygen sensors (8-10), and alternative metal-metal oxide or mixed oxide couples could also be used. A second direct junction contact was prepared by filling the tube with mercury to a depth of three inches and inserting a platinum lead wire. It was presumed that enough mercuric oxide was present as a contaminant that this too served as a metal-metal oxide type contact. Sensors of this type were also closed with Teflon caps.

To extend the work to higher temperatures, the sealed structure shown in Fig. 1 and 2 was employed. An important element is the compressible Teflon seal in the Conax pressure fitting. This maintains the pres-

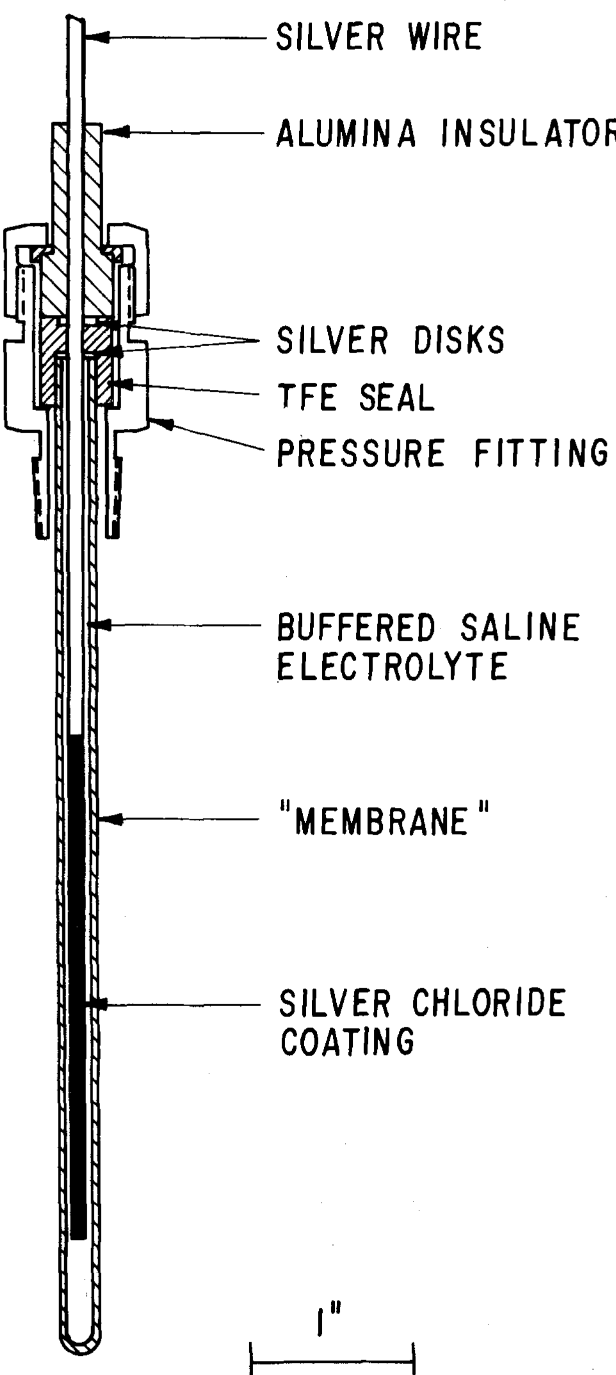

Fig. 1. Schematic diagram of sensor for use at elevated temperatures and pressures.

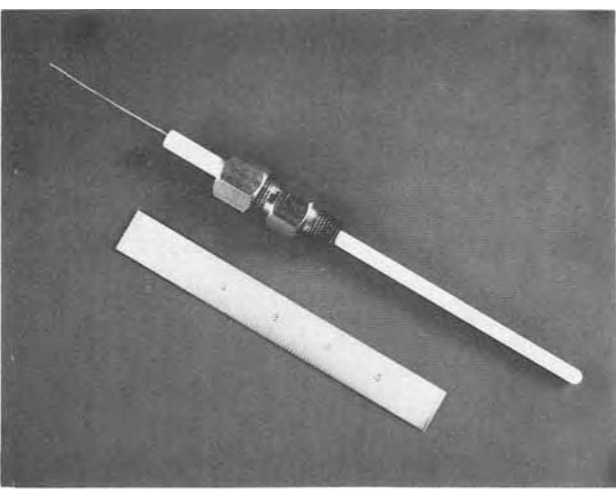

Fig. 2. Photograph of an assembled sensor

sure that builds up within the tube—the order of 1000 psi at 285°C—and serves to insulate the lead wire from the metallic parts of the fitting. The same internal electrolytes were employed as at lower temperatures, and in one case a solution containing 0.001m HCl and 0.009m KCl was used. Because of thermal expansion of such solutions, care was taken to allow sufficient free volume within the tube; normally they were filled to only 70% of capacity.

Some work was also done at the elevated temperature with the copper/cuprous oxide direct junction structure. This was sealed into the Conax fitting as above.

Test system and protocols.—Initial tests at ambient temperature were performed by immersing the sensor into appropriate solutions in an open beaker. An Ingold® combination electrode was used as a comparison standard, and its reference electrode also served the zirconia sensor. Because of the very high impedance of the ceramics at ambient temperature ($\sim 10^{11}\Omega$), it was necessary to make measurements in a faraday cage and to use a high input impedance electrometer (Keithley Model 602).

All other measurements were made with the test system shown schematically in Fig. 3. Here provision was made for pumping water, acid, or base into the heated and pressurized (if necessary) autoclave, which had a capacity of 1 liter. In this way the solution in the autoclave could be slowly "titrated" with acid or base, or aliquots of more concentrated reagent could be

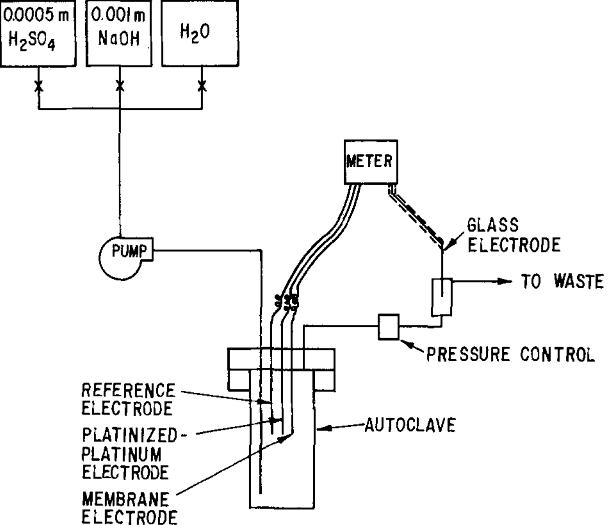

Fig. 3. System for evaluating sensors

introduced to cause more rapid changes in pH. Both 316 stainless steel and titanium autoclaves have been used.

The Conax fitting on the sensor permits direct mounting in the lid of the autoclave. Frequently two were tested concurrently. Also mounted to the lid through Conax fittings were an insulated platinized platinum wire and a reference electrode which consisted of a chlorided silver rod immersed in a 0.01m KCl solution contained within an insulating tube (11); the latter communicated with the water in the autoclave through a porous asbestos or zirconia junction. For some of the measurements at 95°C an Ingold Series 514 Hi Temperature combination pH electrode was mounted through the lid in place of the special reference electrode. In such cases the system was not pressurized, but otherwise procedures were standard.

During a run the potentials of all electrodes as well as the autoclave were monitored against the reference. In addition the ambient temperature pH could be measured downstream of the pressure control with an Ingold combination pH electrode. Keithley electrometers (initially Model 602 and later Model 616) were used for all the potential measurements. Automatic switching among the electrodes was accomplished with an Orion Model 855 Automatic Electrode Switch. Output was recorded continuously on a Hewlett Packard Model 7100B Strip Chart Recorder.

The reagents were normally pumped through the system at a constant rate of 3 ml/min with a Lapp Pulsafeeder Pump Model LS-20 while the pressure was maintained at 1200 psi, a pressure of about 200 psi over the vapor pressure of water when the system is at the highest operating temperature of 285°C. When more rapid transients were under study, water was pumped at the same rate through the system and suitable aliquots of 0.1m NaOH or 0.05m H_2SO_4 were introduced into the stream. Thermal convection produced essentially ideal mixing within the autoclave particularly at the higher temperatures.

Temperatures were controlled with a Leeds and Northrup Electromax III controller. They were monitored continuously with a Chromel-Alumel thermocouple.

Resistance measurements.—Occasionally resistance measurements were desired on the sensors. These were accomplished with the electrometer by connecting the built-in shunts across the inputs from the sensor and the reference electrode. Under these conditions the resistance is given by

$$R = R_{sh}(E_{oc} - E_{sh})/E_{sh}$$

where R is the series resistance of the membrane, the solution in the autoclave, and the reference electrode, R_{sh} is the resistance of the shunt, E_{oc} is the voltage measured without the shunt, and E_{sh} is that with the shunt. At the lower temperatures, R approximates that of the membrane itself. At higher temperatures a correction was derived by measuring the resistance between the platinum electrode and the reference and/or between the autoclave and the reference. These measurements provided an estimate for the series resistance of the solution in the autoclave and the reference electrode. The resistance measurements were subsequently converted to specific conductivity on the basis of the physical dimensions of the tubes. In the calculations allowance was made for the expansion of the water within the tubes with increasing temperature. Measurements were made with the sensor immersed in acidic and basic solutions with no difference in results.

Comparison standards for pH sensors.—Ideally one would like to establish the performance of a new sensor on the basis of comparisons of experimental observations with values predicted from accepted thermodynamic data. Unfortunately, at the outset of this work it was not clear that the experimental system was

clearly enough defined for this purpose. Thus uncertain liquid junction potentials were anticipated at the reference electrode-solution interface, some consumption of acid through corrosion of the autoclave and connecting tubing as well as some ceramic parts could occur, and rigorous steps were not taken to exclude carbon dioxide from the basic solutions.

It was therefore elected to judge the performance of the sensors on the basis of comparisons with other acceptable standards. For measurements at ambient temperature and 95° this presented no problem because commercially available glass electrodes could be used unambiguously for the purpose. At higher temperatures, however, this is not the case, and an alternative comparison was sought. Although a hydrogen electrode would seem a natural choice, our system and experience had been geared for work with aerated solutions. We therefore elected to use the "oxygen electrode" formed at the platinized platinum wire in the autoclave as the comparison standard at 285°. This, in contact with the aqueous solutions, all of which were equilibrated with air at ambient temperature before entering the autoclave,[1] can, in principle, serve as a *p*H sensor because of the hydrogen ions involved in the potential determining reaction

$$O_2 + 4H^+ + 4e^- = 2H_2O$$

Although not rigorously established as a *p*H sensor, the response of the oxygen electrode to *p*H has been demonstrated at ambient temperature (12), and during the course of the present work additional support was generated, particularly from direct comparisons with the glass electrode at 95°C. Comparison of its behavior at 285° with thermal data also proved reassuring, particularly during later experiments after the equipment had had time to age and passivate, *cf.* below.

Results and Discussion

*p*H Response

Performance at 25°.—Performance was first demonstrated in brief experiments at ambient temperature with yttria stabilized tubes. Data comparing the response of two membranes stabilized with 16.9 w/o yttria at 25° with that of a commercial glass electrode upon immersion in 0.1m sodium hydroxide, 2m hydrochloric acid, and a phosphate buffer (pHydrion at *p*H 7.0) are shown in Fig. 4. As can be seen the slopes of the two curves are very close to the ideal value of 1.000. While these results establish the response to *p*H, the high impedance of the yttria stabilized zirconia tubes at ambient temperature ($\sim 10^{11}\Omega$) makes them unacceptable for general application at this temperature. It is likely, however, that suitable membranes can be fabricated from alternative oxygen ion conducting ceramics, *e.g.*, doped cerias, that will have lower resistivities and thereby permit practical measurements at ambient temperature. This is desirable, not with the aim of replacing the glass electrode, but in the interest of having a single sensor responsive to *p*H from ambient temperature to higher levels so that *p*H can be followed continuously over an entire heating or cooling transient. Low temperature capability would also permit ready calibration and testing with the minimal complications associated with ambient conditions.

Performance at 95°.—Data comparing the response of a membrane stabilized with 8.0 w/o yttria with that of the high temperature Ingold electrode at 95° are shown in Fig. 5. Also included in the figure are corresponding data for the oxygen electrode formed at the platinized platinum wire. Although the response of this membrane electrode is only 92% of the glass, it is still in an acceptable range. The response of the oxygen electrode at this temperature is 88% of the glass. Using the ratio of the two, it is found that in this case the membrane response is 104% of that of the platinum electrode. In two other runs the same membrane electrode (with fresh internal solution) was tested at 95° without the glass electrode in the system. In these cases comparison only with the oxygen electrode was possible and values of 106 and 107% were obtained for the sensor, in reasonable agreement with the above

[1] Since the test system was operated about 200 psi above the saturation pressure of water at 285°C no gas phase was present in the autoclave and the concentration of dissolved oxygen in the water remained at the value established during the equilibration with air at ambient conditions.

				3	2nd day	93.3
				5	12th day	98.2

Mean response for 8.0% stabilizer = 95.0; σ = 4.6.
Mean response for 16.9% stabilizer = 93.8; σ = 4.3.
Grand mean = 94.7; σ = 4.4.

value. (As will be discussed below, two additional sensors with direct junction internals were also examined at 95° and gave linear responses that were 101 and 103% of that of the Ingold glass electrode.) It is thus clear that quite reasonable, and close to theoretical responses can be obtained from the new electrodes at 95°.

Behavior at 285°.—Because primary interest in the new sensors is in their application at higher temperatures, most of the emphasis has been placed on tests at 285°. Data in Fig. 6 show that there is again an excellent linear correlation between the response of the membrane sensor and that of the oxygen electrode over a range of pH established at the extremes by 0.0005m H_2SO_4 and 0.001m NaOH. In this case 16.9 w/o yttria served as the stabilizer and the data in the figure were accumulated over a period of 5.7 days. The response is 96% of that of the oxygen electrode, which at this temperature probably performs close to theoretical; *cf.* below. For comparison purposes, similar data for eight independent sensors tested at 285° are summarized in Table I. Included is information about the stabilizing agent and internal filling solution as well as the number of data points used in making the comparison and the period over which the data were taken. The overall average response was 94.7% of that of the oxygen electrode with a standard deviation of 4.4%. No significant difference is seen between the sensors stabilized with 8.0 w/o yttria and those with 16.9 w/o.

Additional data showing the parallel dynamic responses of the new membrane type sensor and the oxygen electrode to pH changes are shown in Fig. 7. The first transition was accomplished by introducing a 15 ml aliquot of 0.1m NaOH when the solution in the autoclave was 0.0005m H_2SO_4. The second transition was brought about by back-titrating the base with 0.0005m H_2SO_4.

As further support for the performance of the new sensors, an attempt was made to compare their responses with that predicted from available thermodynamic data. For this purpose, the data of Marshall and Jones (13) for the second dissociation constant of sulfuric acid at elevated temperatures were employed along with those of Sweeton, Mesmer, and Baes (14) for the dissociation constant of water. Activity coefficients for the dilute solutions were estimated from the theoretical predictions of Helgeson and Kirkham (15).

Calculated values for the pH of the 0.0005m H_2SO_4 and 0.001m NaOH solutions at 285°C as well as the theoretical response from interchanging the two are summarized in Table II. It is to be noted that the relatively high pH for the acid (relative to 3.02 at 25°) results from the marked decrease in the second ionization constant of sulfuric acid with increasing temperature—3.3×10^{-6} at 285° *vs.* 1.2×10^{-2} at 25°. For the 0.001m NaOH the pH is lower at 285° than at 25° because of the increased dissociation constant of water at the elevated temperature. Compared with these two effects, the influence of activity coefficient corrections on the calculated pH values of these dilute solutions is minor—of the order of 0.03-0.05 units.

Table II. Theoretical potential change for 0.0005m $H_2SO_4 \rightleftarrows$ 0.001m NaOH at 285°C

pH of 0.0005m H_2SO_4	3.32
pH of 0.001m NaOH	8.22
ΔpH	4.90
mV/pH unit	110.8
ΔmV	543

Response data for a number of sensors and the oxygen electrode based only on the full transition from acid to base or reverse are summarized in Table III. A definite trend is evident among the data in that the agreement with theory improves in the successive tests which are arranged in chronological order. This suggests in part, at least, that the discrepancies in the earlier runs reflect real variations in the pH of the solutions as a result of corrosion of the test system, most likely by the acidic solutions. During successive runs it would appear that a protective film developed on the walls and the rate of corrosion diminished,

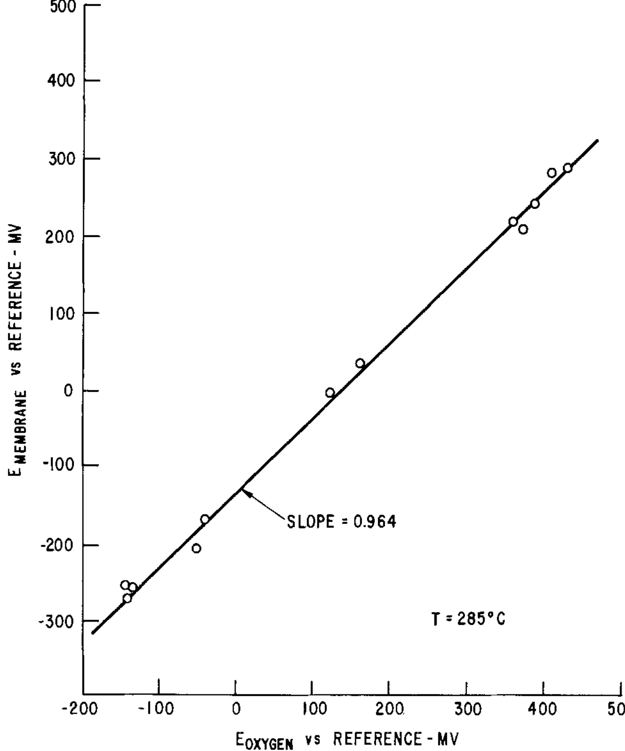

Fig. 6. Response of a sensor relative to that of the oxygen electrode at 285°C.

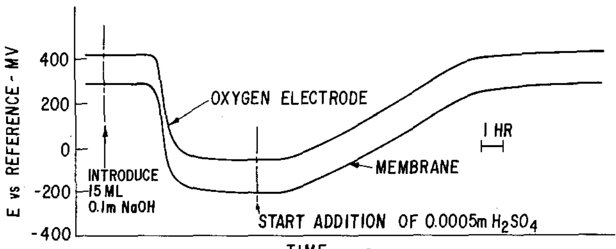

Fig. 7. Response of a sensor and the oxygen electrode to rapid and slow changes in pH at 285°C.

Fig. 8. Behavior of a sensor, the oxygen electrode, and the autoclave as the redox potential of the environment is changed at 285°C.

thereby introducing smaller discrepancies which by the time of run ZR02-17 were insignificant. The value for the oxygen electrode in Run ZR02-17 strongly supports the original assumption that the oxygen electrode at elevated temperatures functions well as a pH sensor and was a valid choice as a comparison standard. In comparing the sensors with the oxygen electrode in these tests a mean value of 95.3% was obtained, in good agreement with the data in Table I. The individual differences result from the fact that more data points were averaged for each run of Table I; only data obtained from the full transition between the acid and base were used for Table III.

Sensitivity to Redox Potential of the Environment

Because membrane-type sensors normally have the desirable feature of being insensitive to the redox potential of the solution being monitored, the behavior of the stabilized zirconia sensors was examined as the redox potential of the solution in the autoclave was changed. This was accomplished by changing from an air to a nitrogen purge of the 0.0005m H_2SO_4 solution being fed to the autoclave. The effect is illustrated by the data in Fig. 8 which includes plots of the potentials of the sensor, the oxygen electrode, and the autoclave against the reference electrode.

It is seen that after changing from an air to a nitrogen purge of the incoming 0.0005m H_2SO_4 a slow downward drift in potential was evident for the oxygen electrode and the autoclave. After several hours a more rapid drop occurred for both of these potentials. This is attributed to loss of the passive film on the autoclave with an associated increase in corrosion rate and liberation of hydrogen. The oxygen electrode then clearly showed its sensitivity to this change in the redox environment. The oxygen ion conducting ceramic membrane, however, retained an essentially constant potential throughout the transients. The small increase in potential at the time of the depassivation is believed to have been a response to a real transient change in pH.

It is useful to consider whether this behavior is consistent with the known properties of stabilized zirconia and whether it is likely to be a universal property of oxygen ion conducting ceramic membranes. A key factor to consider in this connection is the domain over which the ceramic functions "solely" as an oxygen ion conductor, *i.e.*, $t_{O^=} \gtrsim 0.99$, where $t_{O^=}$ is the transference number for the oxygen ion. If electronic or positive hole conduction becomes significant, deleterious shunting can occur and the full signal cannot be developed across the membrane.

Since the same principle applies in the older applications of these ceramics in fuel cells and oxygen sensors, attention has been addressed to the influence of environmental redox conditions on the oxygen ion conductance, particularly by Patterson (16, 17), whose data for calcia stabilized zirconia (CSZ) and yttria-doped thoria (YDT) have been adapted to Fig. 9. In this figure the shaded areas to the right of the boundaries identify the oxygen ion conducting domains for the two ceramics as defined by $t_{O^=} \gtrsim 0.99$. At any given temperature, environments having oxygen partial pressures (or equivalent redox potentials) in excess of that of the upper boundary cause excessive positive hole conductivity while partial pressures below the lower boundary result in excessive electronic conductivity. Although less data are available for yttria stabilized zirconia, there is some indication (18) that the oxygen ion conducting domain is somewhat wider than that for CSZ.

Also shown on the figure is the domain of oxygen partial pressures and temperatures that is encompassed by the equilibrium established in an aqueous system in the presence of from 1 atm of oxygen to 1 atm of hydrogen. This was calculated from available thermal

data (19). It is evident that over this entire range of conditions CSZ is a satisfactory oxygen ion conductor. The data for YDT serve as an example of what can occur in other cases. Here it is seen that at oxygen levels greater than 10^{-6} atmosphere the positive hole conductivity exceeds 1% and less satisfactory performance than for CSZ is to be expected under such conditions. On the other hand, in reducing environments the YDT has a considerably larger margin of safety than the CSZ for the operating range postulated. [It has been reported, however, that under some situations YDT suffers further complications in that hydrogen can enter the lattice and introduce proton conduction (20) which would also influence performance.] Limited data for doped cerias (7) suggest that at 1 atm of hydrogen, their oxygen ion conductivity might be somewhat compromised, but that they should function satisfactorily at higher oxygen partial pressures.

The behavior of the cerias is of particular interest in that the oxygen ion conductivity is considerably higher than those of the zirconia or thoria systems and they should be attractive for use at temperatures closer to ambient. This factor has promoted interest in their use in fuel cells (6, 7) and recently their virtue in oxygen sensors operational at lower than usual temperatures has been demonstrated (21).

Drift

Drift arises from two principal sources: (*i*) changes in the electrolyte concentration within the reference electrodes, and (*ii*) changes in the internal electrolyte in the sensor especially when the poorly buffered 0.001m HCl-0.009m KCl electrolyte was used.

That a significant drift has been associated with the reference electrodes is illustrated by the data, all obtained with 0.0005*M* H_2SO_4 in the autoclave, in Fig. 10 from runs ZRO2-5, 7, and 18. The data from runs ZRO2-5 and 7 show the drifts of the oxygen electrode and the sensor to be essentially parallel. In both cases the more concentrated buffered electrolytes, which should have good stability, were used as the internals of the sensors. It is therefore felt that in these cases the drift was largely associated with the reference electrode. In run ZRO2-18 mixed results were obtained. The drift of the oxygen electrode over the first few days was similar to that from the other two runs, and it eventually reached a plateau. This is again believed to be associated with the reference electrode. The much larger drift of the sensor is clearly a result of changes in the very poorly buffered internal electrolyte, 0.001m HCl-0.009m KCl, most probably as a result of reaction of the small amount of acid with the zirconia or, more likely, with impurities in the zirconia. If so, pretreatments of the ceramic with acid or the use of a more concentrated acid as the filling solution, *e.g.*, 0.01m HCl, should reduce the problem.

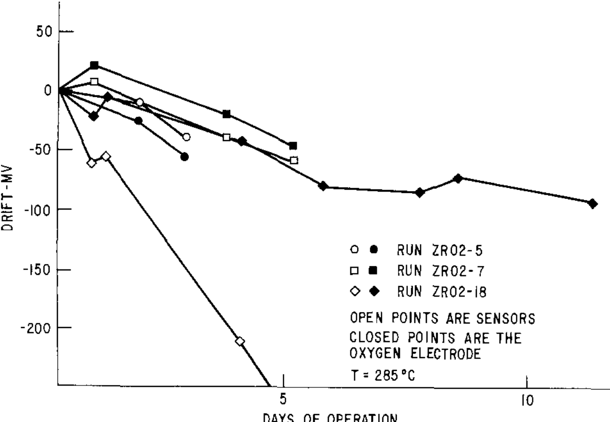

Fig. 10 Drift in potential of sensors and the oxygen electrode relative to 0.01*M* KCl/AgCl/Ag reference electrode at 285°C.

The drift in the reference electrode is larger than anticipated from previous experience (22). It may reflect differences in operating procedures. For example, we have normally been operating with solutions equilibrated with air (dissolved oxygen concentration about 8 ppm) while in earlier applications in simulated and actual nuclear reactor water (BWR type) the oxygen levels ran about 0.2 ppm. At the higher oxygen levels diffusion through the Teflon walls of the reference or through the diffusion junction itself could be higher and thereby promote chloride ion consumption from the solutions via the reaction

$$2Ag + 2Cl^- + H_2O \frac{1}{2} O_2 = 2AgCl + 2\,OH^-$$

As chloride is removed from solution via such a mechanism the potential of the reference couple would increase thereby causing a decline in the potential of other electrodes measured against it. This type of behavior has been observed with neutral saline solutions in contact with silver/silver chloride electrodes in confined spaces in the past (23). The fact that the potential eventually leveled off in run ZRO2-18 is consistent with such behavior. At 285°C the solubility of silver chloride is much higher than at room temperature (24) and could be instrumental in establishing the plateau at a potential not too far removed from the initial value. It is likely too that some KCl is lost from the reference electrode by diffusion through the porous asbestos or zirconia plug. Detailed analysis of the solutions after use should be helpful in diagnosing the problem, but this has not yet been done.

This drift has not interfered with the work so far because responses to *p*H can be determined over relatively short periods of time when the influence from drift is minimized. It is clear however, that for the successful exploitation of the new *p*H sensors a better understanding of drift is required.

Conductivity of Membranes

In order to establish more firmly that the sensors are indeed functioning as true membranes, it was felt necessary to demonstrate that their conductivities are comparable with those normally associated with such ceramics from earlier measurements at high temperatures. This is necessary because under certain limited conditions porous media can give responses resembling those from an intact membrane. [Lev has discussed this type of behavior as encountered with "incompletely sealed" cation sensitive glass microelectrodes (25).] With relatively large pores the behavior is like a liquid junction and only a diffusion potential is established. However, with pores of dimensions small with respect to the thickness of a double layer, exclusion of cations or anions can occur and the theoretical response of a membrane can be achieved. Under such conditions, transport of current through the pores is by ionic migration in an aqueous medium and relatively low activation energies of the order of 5 kcal/mole, should be encountered.

Measurements of cell resistance were made at various temperatures with both 8.0 and 16.9 w/o yttria stabilized tubes using the electrometer and the parallel shunt method outlined above. Plots of the data in terms of the logarithm of the specific conductivity *vs.* reciprocal temperature are shown in Fig. 11. From a least squares fit of the data, the activation energies and conductivities at 1000°C were calculated. These are listed in Table IV along with data from the literature for zirconia stabilized with 10 mole per cent (16.9 w/o) yttria obtained at higher temperatures in connection with the application of these ceramics in fuel cells and oxygen sensors. [Fewer data are available for comparison with the 8.0 w/o material, but the activation energy has been observed to decrease slightly with decreasing yttria content (26, 27).] Our results are comparable with the earlier data and, in addition, the activation energies are high for conductivities in an

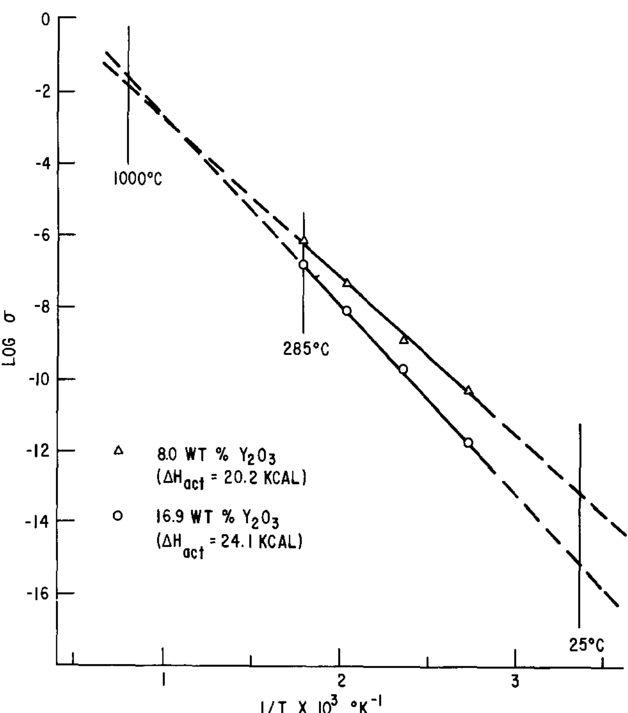

Fig. 11. Conductivities of yttria stabilized zirconias

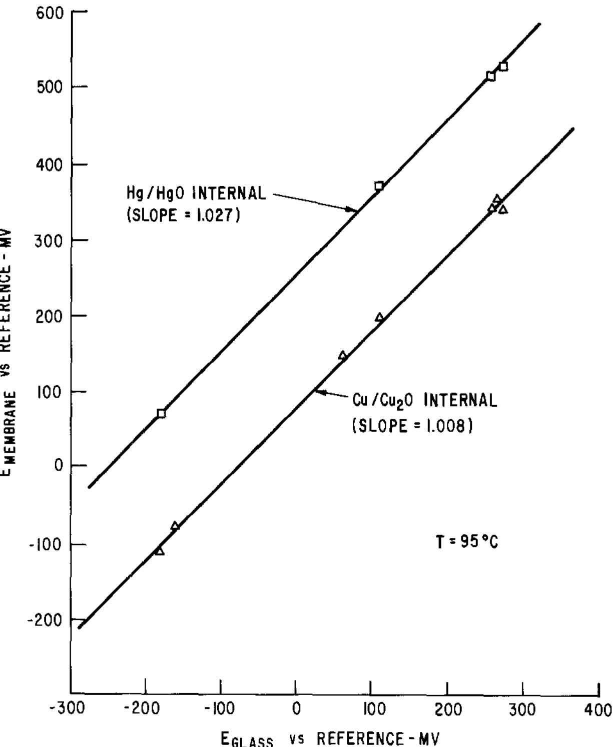

Fig. 12. Response of sensors with Cu/Cu_2O and Hg/HgO internal junctions relative to that of a glass electrode at 95°C.

aqueous phase. Both observations give assurance that the sensors are indeed functioning as true membranes. Helium leak tests also indicated that the sensors were impervious both before and after exposure in the autoclave, but it is difficult to translate this type of observation into behavior upon immersion in aqueous solutions.

One additional comment should be made about the behavior of porous media as sensors. It is improbable that they would show the pronounced specificity for hydrogen ion over the wide range actually observed. While it is possible that cation selectivity would prevail over the full range from 0.1m NaOH to 2m HCl at ambient temperature, it is likely that the response would shift from the hydrogen ion to the sodium ion as the solution became strongly basic. This would manifest itself by an inversion of the slope in the basic media when the sensor response is plotted against that of the glass electrode.

Alternative Internal Junctions

The behavior of the sensor was also examined briefly with dry internal junctions consisting of Cu/Cu_2O and Hg/HgO. The Cu/Cu_2O was employed in several sensors that were operated at both 95° and 285°C, while the single sensor prepared with the mercury couple was run only at 95°C.

Data obtained at 95°C with the Ingold glass electrode serving as the comparison standard are shown in Fig. 12. Both internal junctions resulted in sensors having linear responses that were close to those of the glass electrode. An equivalent sensor prepared with an aqueous internal junction and tested in the same group was somewhat lower in response; *c.f.*, Fig. 5.

At 285°C sensors with the Cu/Cu_2O internal junction again gave linear responses against the oxygen electrode as standard. In the two cases tested the responses were 89.8 and 96.1% of that of the oxygen electrode.

These results indicate that either the aqueous or nonaqueous type of internal should be satisfactory on the basis of pH response. A final choice may be dependent upon long term stability and/or the temperature coefficients of the two types of sensors.

Effect of Molybdenum on the Anodic Behavior of Amorphous Fe-Cr-Mo-B Alloys in Hydrochloric Acid

K. Asami, M. Naka, K. Hashimoto, and T. Masumoto

The Research Institute for Iron, Steel, and Other Metals, Tohoku University, Sendai 980, Japan

ABSTRACT

The addition of a small amount of molybdenum to amorphous Fe-Cr-B alloys improves the corrosion resistance in hydrochloric acid. In particular, amorphous Fe-25Cr-20B-xMo alloys containing 5 atomic percent or more molybdenum passivate spontaneously even in 6N HCl, showing no pitting by anodic polarization. However, an excess addition of molybdenum lowers the corrosion potential and raises the anodic current density in the passive region. This dual function of molybdenum was investigated with XPS and electrochemical methods. In the active region, an increase in the molybdenum content of the alloys decreases the anodic current density by the formation of a surface film containing large amounts of chromium and some molybdenum. The addition of molybdenum assists the formation of the passive hydrated chromium oxyhydroxide film. However, a passive film of molybdenum oxyhydroxide is unstable in comparison with the passive hydrated chromium oxyhydroxide film even at lower potentials in the passive region, and molybdenum suffers transpassive dissolution at higher potentials in the passive region. An excess of molybdenum results in a passive film whose content of molybdenum in an unstable valence state is high. Consequently, the addition of molybdenum is significantly effective in increasing the corrosion resistance, particularly in aggressive hydrochloric acid, but the lower the molybdenum content of the passive film the better is the protective quality of the film.

It is well known that addition of molybdenum to stainless steels increases their corrosion resistance toward pitting in chloride solutions, although the addition of molybdenum to iron or nickel is not effective in improving their corrosion resistance in hydrochloric acid (1). In particular, the combined addition of chromium and molybdenum to steels greatly improves their corrosion resistance in acidic chloride solutions, and hence molybdenum interacts synergistically with chromium (2).

It has been considered that molybdenum in the passive film reinforces its protective quality. Mahla and Nielsen (3) stripped a passive film from the surface of Type 317 stainless steel passivated in 5% HNO_3 + 0.5% $K_2Cr_2O_7$ at 60°C and found an enrichment of molybdenum in the passive film. Rhodin (4) confirmed the enrichment of both molybdenum and silicon in the passive film on molybdenum-bearing steels, which also contained a small amount of silicon.

Key words: corrosion resistance, passivity, passive film, XPS, surface analysis.

Nielsen and Rhodin (5) have assumed that the chemistry of a gel-like heteropoly acid complex controls both the mechanism of film formation and subsequent behavior of the steels on exposure to various corrosion environments.

Recent development of new techniques for surface analysis, such as AES and XPS, has enabled the determination of the constituents of a passive film without stripping it from the alloy substrate. Lumsden and Staehle (6), in reporting an AES study of a passive film formed on Type 316 stainless steel in a neutral chloride solution, stated that an enrichment of chromium occurs to some extent in the film, but that molybdenum and silicon are not concentrated in the film. Yaniv *et al.* (7) studied the composition of passive films formed on molybdenum-bearing ferritic stainless steels in acidic and alkaline solutions and found no enrichment of molybdenum.

XPS studies of passive films on ferritic stainless steels with and without molybdenum revealed that the passive films formed in 1N HCl consist mainly

of hydrated chromium oxyhydroxide $CrO_x(OH)_{3-2x} \cdot nH_2O$ (8, 9) similar to the passive films formed on crystalline binary Fe-Cr alloys (10) and ferritic stainless steels (11) in 1*N* H_2SO_4 and on Types 304 and 316 stainless steels in 30% HNO_3 (12). Molybdenum has been found in the passive films formed on both austenitic (12) and ferritic (8, 9, 11) stainless steels, but its content is very low, and pitting does not lead to any substantial change in the average composition of the films (9).

On the other hand, it is known that rapidly quenched amorphous alloys containing a certain amount of chromium have extremely high corrosion resistance (13-15). Addition of molybdenum also increases the corrosion resistance of these chromium-bearing amorphous alloys (16, 17). Furthermore, recent studies revealed that the addition of molybdenum to amorphous Fe-P-C (18) and Fe-C (19) alloys without chromium also increases their corrosion resistance and leads to anodic passivation in 1*N* HCl in contrast to crystalline binary Fe-Mo alloys.

The amorphous alloys usually contain a large amount of metalloid elements such as boron, carbon, silicon, and phosphorus. These elements play an important role in the corrosion resistance of amorphous alloys (20). One of the most important factors for the extremely high corrosion resistance of rapidly quenched amorphous alloys is their chemically homogeneous single phase, which is free of defects formed by solid-state diffusion and associated with the crystalline state.

Passive films formed on chromium-bearing amorphous alloys are composed mostly of hydrated chromium oxyhydroxide, which is the major constituent of stable passive films on ordinary stainless steels. On the other hand, amorphous Fe-Mo-metalloid alloys passivate by the formation of hydrated iron oxyhydroxide (23, 24). In the active region, the latter alloys, however, form surface films in which molybdenum is highly enriched (23, 24). The significant enrichment of molybdenum in a surface film formed in the active region has also been found for crystalline ferritic stainless steels containing molybdenum (8).

These results suggest that the role of chromium and molybdenum in increasing the corrosion resistance of amorphous iron-metalloid alloys is not essentially different from that in crystalline stainless steels. It is, therefore, convenient to use the amorphous alloys for the study of the effect of molybdenum on the corrosion resistance of a single-phase solid solution containing iron and chromium.

Recently we (17) investigated the effect of chromium and molybdenum additions on the corrosion behavior of amorphous Fe-20B, Co-20B, and Ni-20B alloys in 1*N* HCl and found the dual function of molybdenum: The addition of small amounts of molybdenum to Fe-20Cr-20B and Co-20Cr-20B alloys led to spontaneous passivation, but excess addition of molybdenum raised the passive current density and lowered the open-circuit potential for spontaneous passivation.

The work reported herein aims to clarify the origin of the dual function of molybdenum in the corrosion behavior of amorphous Fe-Cr-Mo-B alloys in 1*N* and 6*N* HCl. XPS was used to determine the composition and thickness of the surface film formed on the alloys as a function of their molybdenum content.

Experimental

Alloy ingots were prepared by melting commercial metals under an argon atmosphere. Amorphous Fe-Cr-B alloys with and without molybdenum were prepared as a shape 1-2 mm in width and 10-40 μm in thickness by the rotating wheel method, which consists of impinging a jet of molten alloy onto the outer surface of a rapidly rotating wheel. The nominal compositions of the alloys are shown in Table I. Prior to electrochemical measurements, the alloys were polished mechanically in cyclohexane with silicon carbide paper up to No. 1500. Electrolytes used were 1*N* and 6*N* HCl, which were prepared from reagent grade chemical and deionized water. They were exposed to air. Polarization curves of Fe-25Cr-20B-*x*Mo alloys ($x = 0$, 3, 5, and 10) were measured potentiodynamically with a potential sweep rate of 2.37×10^{-3} $V \cdot sec^{-1}$ in 6*N* HCl. Potentiostatic polarization curves were also measured for the same alloys in 6*N* HCl after polarization for 3600 sec at various constant potentials. A new specimen was used for each potentiostatic measurement.

Table I. Nominal compositions of amorphous alloys

Alloy	Composition (a/o)			
	Fe	Cr	B	Mo
Fe-20 Cr-20 B-*x*Mo	60	20	20	0
	57	20	20	3
	55	20	20	5
	50	20	20	10
Fe-25Cr-20 B-*x*Mo	55	25	20	0
	52	25	20	3
	50	25	20	5
	45	25	20	10

The stability of the surface film formed on the amorphous Fe-25Cr-20B-*x*Mo alloys was evaluated by the measurement of potentiostatic current density-time curves in 6*N* HCl. The passivation behavior of the amorphous Fe-20Cr-20B-*x*Mo alloys ($x = 0$, 3, 5, and 10) was also examined by the measurement of the change in current density immediately after mechanical abrasion of the specimen surface during anodic polarization at various constant potentials in the passive region in 1*N* HCl. The abrasion of the alloy surface was carried out at a constant force with a bench drilling machine in which was installed an abrasive rod made of resin solidified with No. 2000 silicon carbide powder.

After polarization at various constant potentials, x-ray photoelectron spectra from the alloy surface were measured by means of AEI ES200 electron spectrometer with Mg Kα excitation. Polarization was carried out for 3600 sec except for the Fe-25Cr-20B alloy in the active region. This alloy dissolved rapidly in the active region and hence this polarization was carried out for 1800 sec or less. The composition and thickness of the surface film were quantitatively determined from the integrated intensities of the spectral peaks. The detailed procedure of energy calibration and quantitative determination have been reported previously (25-27). The photoionization cross sections used have been summarized elsewhere (28). The measured spectrum of Mo 3d electrons was separated into spectra originating from Mo(VI), Mo(V), Mo(IV), and Mo(metallic) components in a manner similar to the separation method of the Fe $2p_{3/2}$ spectrum into Fe(III), Fe(II), and Fe(metallic) components (29). The binding energies of the Mo 3d electrons in various states were taken as 235.54, 234.40, 229.30, and 228.05 eV for Mo(VI) $3d_{3/2}$, Mo(V) $3d_{3/2}$, Mo(IV) $3d_{5/2}$, and Mo(metallic) $3d_{5/2}$ electrons, respectively.

Results

Polarization curves.—Potentiodynamic polarization curves of amorphous Fe-25Cr-20B-*x*Mo ($x = 0$, 3, 5, and 10) alloys measured in 6*N* HCl are shown in Fig. 1. The most striking characteristic is that these alloys do not suffer pitting corrosion by anodic polarization even in 6*N* HCl. Spontaneous passivation occurs even in this high concentration of hydrochloric acid when the molybdenum content of the alloy is 5 atomic percent (a/o) or more. An increase in the molybdenum content up to 5 a/o ennobles the corrosion potential, but further increase is not effective. A significant increase in the current density in the passive region is

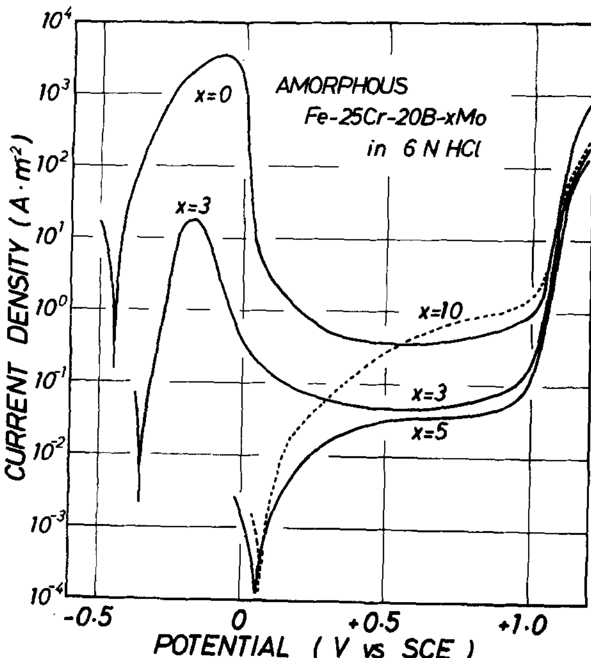

Fig. 1. Potentiodynamic polarization curves of amorphous Fe-25Cr-20B-xMo alloys in 6*N* HCl. The current density increase at negative potentials on each polarization curve corresponds to the cathodic current density.

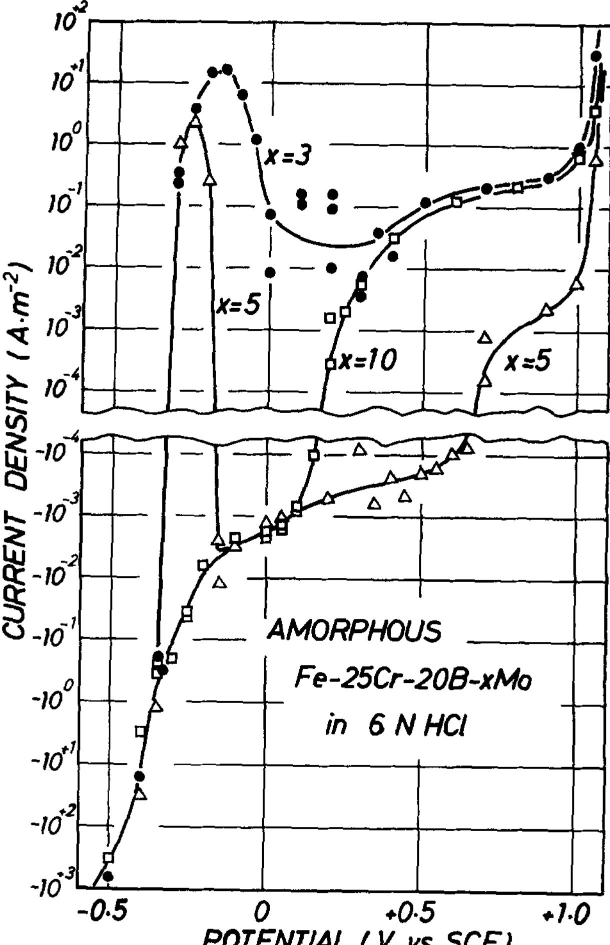

Fig. 2. Potentiostatic polarization curves of amorphous Fe-25Cr-20B-xMo alloys measured after polarization for 3600 sec at constant potentials in 6*N* HCl.

observed by the addition of 10 a/o molybdenum, suggesting a detrimental function due to excess molybdenum. All the alloys show a transpassive region above 1.0V.

Potentiostatic polarization curves of the same alloys measured in 6*N* HCl are shown in Fig. 2. The potentiostatic polarization curve of the amorphous Fe-25Cr-20 B alloy without molybdenum showed a high dissolution current similar to its potentiodynamic polarization curve and is not shown in the figure. The upper side of the figure corresponds to an anodic current and lower side to a cathodic current. Transpassive dissolution occurs above 1.0V for all the alloys.

The initial open-circuit potential of the 5Mo alloy in 6*N* HCl is between 0 and 0.5V. However, when the alloy is polarized at potentials lower than the initial open-circuit potential, an anodic current corresponding to the active state is observed as shown in Fig. 2. This is due to degradation of the air-formed film responsible for the initial spontaneous passivation. The current for this alloy is negative at potentials higher than about −0.2V and becomes positive at about 0.7V. In contrast, the 10 Mo alloy always shows a negative current by cathodic polarization, but a slight anodic polarization gives rise to a positive current at about 0.2V, which is quite low in the passive region, and further anodic polarization significantly raises the anodic current density.

The anodic current density in the passive region measured by potentiostatic polarization is generally lower than that obtained by potentiodynamic polarization. However, the potentiostatic anodic current density of the 3Mo alloy in the potential region between 0.5 and 1.0V is considerably higher than the potentiodynamic anodic current density. In addition, the current density of the 3Mo alloy measured at 0-0.5V was not reproducible. indicating a poor protective quality of the passive film on this alloy.

The stability of the surface film.—To compare the stability of the surface films on these amorphous alloys in 6*N* HCl, the change in current density with time was measured during potentiostatic polarization at various potentials. The results are shown in Fig. 3-5. Figure 3 shows the current density-time curves for the 3Mo alloy. In the active (−0.05, −0.15, and −0.30V) and transpassive (1.05V) regions, the current density is high and does not change appreciably with time. At a lower potential (0.3V) in the passive region, the current density decreases significantly and is often unstable, corresponding to the low reproducibility of the potentiostatic polarization curves for the 3Mo alloy in the vicinity of this potential as shown in Fig. 2.

The current density-time curves for the 5Mo alloy are shown in Fig. 4. The current density in the transpassive region (1.05V) does not decrease with time as in the case of the 3Mo alloy. In the passive region (0.4-0.9), prolonged polarization significantly lowers the current density. In particular, at lower potentials in the passive region (0.4, 0.55, and 0.65V) the current density sharply decreases with time and it finally becomes negative (cathodic).When the potential is lower in the passive region, the current turns negative in less time. The appearance of a negative current by potentiostatic polarization is attributable to the formation of a stable passive film. In contrast, the current in the potential region from −0.30 to −0.15V is initially negative but suddenly turns to a high positive value, suggesting breakdown of air-formed film in this potential region. This is responsible for the appearance of the active state in the potentiostatic polarization curve of the 5Mo alloy.

The change in the current density with time for the 10Mo alloy is shown in Fig. 5. The current density in the transpassive region (1.05V) is almost constant, similar to the 3Mo and 5Mo alloys. At lower potentials in the passive region, the current turns negative after a certain time. similar to the 5Mo alloy. At a higher potential in the passive region (0.8V), however, the initially high current density is maintained and is not

lowered by prolonged polarization, in contrast to the 5Mo alloy. Another difference between these two alloys is that the active current is not observed in the potential region in which the 3Mo and 5Mo alloys exhibit the active state, suggesting a high stability of the surface film on the 10Mo alloy in this potential region.

Passivation behavior.—To compare the passivation behavior, the current decay curves were measured immediately after mechanical abrasion during potentiostatic polarization in 1N HCl. It was difficult to maintain a constant surface area for the 0Mo and 3Mo alloy specimens in 6N HCl due to rapid dissolution immediately after mechanical abrasion. Also, all the amorphous Fe-25Cr-20B-xMo alloys passivate spontaneously in 1N HCl, and hence the difference in passivation behavior of some of the alloys was not clear in 1N HCl. Thus, current decay measurements were carried out in 1N HCl by using amorphous Fe-20Cr-20B-xMo alloy specimens.

The current decay curves measured at 0.1 and 0.5V are shown in Fig. 6 and 7, respectively. After mechanical abrasion during polarization at 0.1V the Fe-20Cr-20B alloy without molybdenum did not passivate, showing a constant high current density, and its current-time curve is not shown. From the beginning, the difference between the alloys with and without molybdenum is clear; the current density of the alloys with molybdenum drops rapidly, while the 0Mo alloy shows a slow decay and high steady current density. An increase in the molybdenum content facilitates the current decay at the low potential in the passive region (Fig. 6) and results in a low steady-state passive current density.

At the high potential in the passive region (Fig. 7), the decrease in current density is fastest for the 10Mo alloy in the early stage (<0.5 sec). However, the current decay slows down and the 10Mo alloy exhibits a

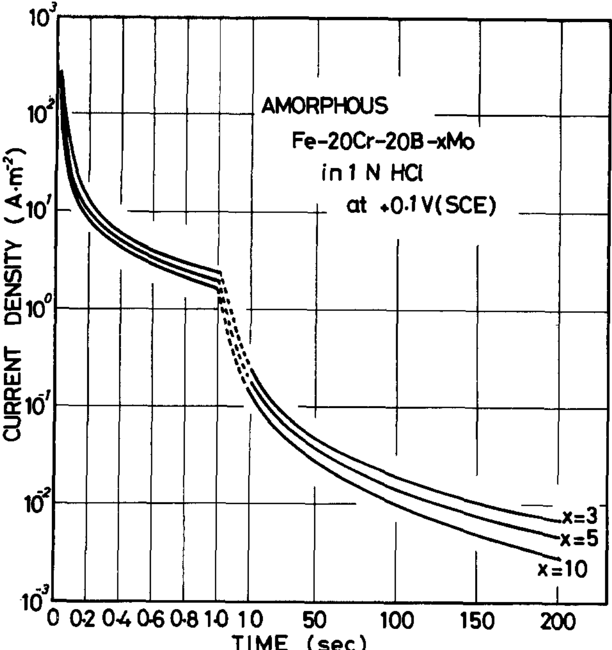

Fig. 6. Current decay curves of amorphous Fe-20Cr-20B-xMo alloys measured immediately after mechanical abrasion during potentiostatic polarization at 0.1V (SCE) in 1*N* HCl.

higher steady current density in comparison with the 3Mo and 5Mo alloys. This fact again indicates the dual function of molybdenum; the addition of molybdenum effectively suppresses active dissolution prior to passive film formation, but an excess of molybdenum decreases the protective quality of the passive film.

Analysis of film composition by XPS.—To determine a correlation between the surface film composition and the protective quality of the film, XPS analyses of the surface film were carried out for amorphous Fe-25Cr-20B-xMo alloys polarized at various constant potentials in 6*N* HCl. The Fe $2p_{3/2}$ and Cr $2p_{3/2}$ spectra consisted of two peaks corresponding to the oxidized state in the surface film and the metallic state in the underlying alloy. The Fe $2p_{3/2}$ spectrum for the oxidized state was further composed of spectra for ferrous and ferric states (10, 26, 29). Chromium in the surface film was in the trivalent state (26). The Mo 3d spectrum showed the peaks corresponding to hexavalent, tetravalent, and metallic molybdenum (30). Oxidized molybdenum further contained pentavalent molybdenum (30), although it did not give clear peaks in the measured Mo 3d spectra. The B 1s spectrum showed two peaks which were assigned to boron in borate in the surface film (about 192 eV) and in the underlying alloy (about 187.7 eV) (20). The O 1s spectrum exhibited a broad peak in which the spectra for oxygen in borate and in metal-O-metal, metal-OH and metal-OH_2 bonds were superimposed (10, 20, 26). Chloride ion, which gave the Cl 2p signal at about 198.9 eV, was also found in small amounts in the surface film.

The change in the cationic fraction of chromium in the surface film with polarization potential is shown in Fig. 8. A remarkable enrichment of chromium is found in the surface films formed on the 5Mo and 10Mo alloys even at lower potentials in the active and cathodic current regions. The difference in the cationic fraction of chromium between the surface films on these two alloys is almost insignificant, despite the fact that the signs of the current are different in the active region. The 0Mo and 3Mo alloys show some chromium enrichment especially in the passive region. The chromium content of the passive film increases with an increase in the molybdenum content of the alloy in this aggressive hydrochloric acid; it is lowest for the 0Mo alloy and highest for the 10Mo alloy, though the difference between the 10Mo and 5Mo alloys is negligibly small.

Figure 9, whose ordinate is expressed on a logarithmic scale, shows the change in the fraction of iron ions in the surface film with the polarization potential. It is clear that the iron content of the surface film is remarkably low on the 5Mo and 10Mo alloys and decreases in the passive region with an increase in the molybdenum content of the alloy.

The change in the molybdenum content of the surface film is shown in Fig. 10. The ordinate is again on a logarithmic scale. The molybdenum content of the surface film on all the alloys shows a maximum in the active region even for the 10Mo alloy which exhibits only a negative current at potentials lower than 0.2V. This maximum is in the reverse order of the molybdenum content of the alloy. The present authors (8, 23, 24) have previously reported that the active dissolution of molybdenum-bearing alloys gives rise to the formation of molybdenum-enriched corrosion product films on the alloys, and the faster the active dissolution the higher is the concentration of molybdenum in the film. It can, therefore, be said that all the alloys dissolve actively in the active region, and hence the negative current observed for the 10Mo alloy just indicates that the anodic current is less than the cathodic

current in this potential region. Similarly, a high molybdenum content in the surface film results from transpassive dissolution at 1.1V.

It can clearly be seen that molybdenum is deficient in the passive films formed on the 5Mo and 10Mo alloys. The molybdenum content shows a maximum at about 0.4V. Above this potential, the anodic current density of the molybdenum-bearing alloys tends to increase. The content and valence of chromium in the passive film are almost independent of the polarization potential showing no appreciable change in the vicinity of 0.4V. In contrast, the mean valence of molybdenum in the passive film clearly changes with the polarization potential as shown in Fig. 11, which gives the ratio of tetravalent or hexavalent molybdenum to total molybdenum in the film formed on the 3Mo alloy. Some pentavalent molybdenum species were also contained in the film but its ratio is not shown in the figure. The content of hexavalent molybdenum is higher than tetravalent molybdenum in the films formed in the active region and at potentials higher than 0.5V in the passive region. The formation of hexavalent molybdenum is thermodynamically impossible at potentials in the active region. Hence, the hexavalent molybdenum species found in the film formed in the active region appears to result from oxidation of tetravalent molybdenum during the transfer from the electrolyte to the XPS apparatus. This is a result of the poor protective quality of the film formed in the active region.

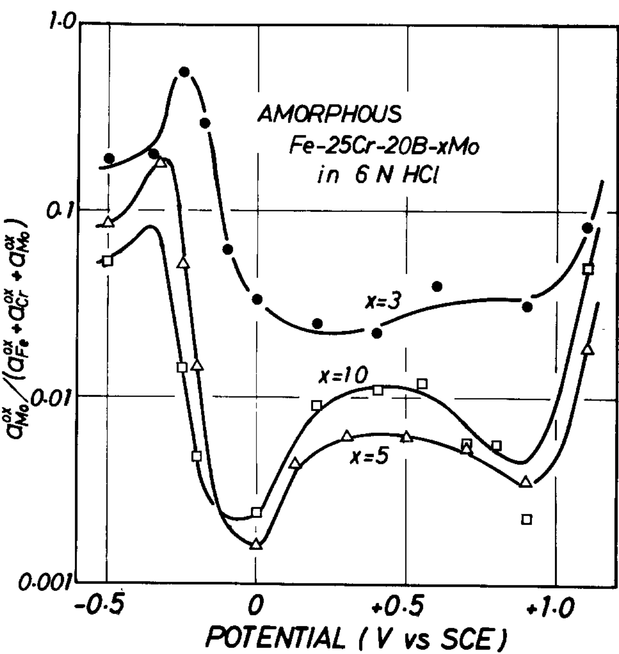

Fig. 10. Change in cationic fraction of molybdenum in the surface film formed on amorphous Fe-25Cr-20B-xMo alloys by potentiostatic polarization for 3600 sec in 6*N* HCl as a function of polarization potential.

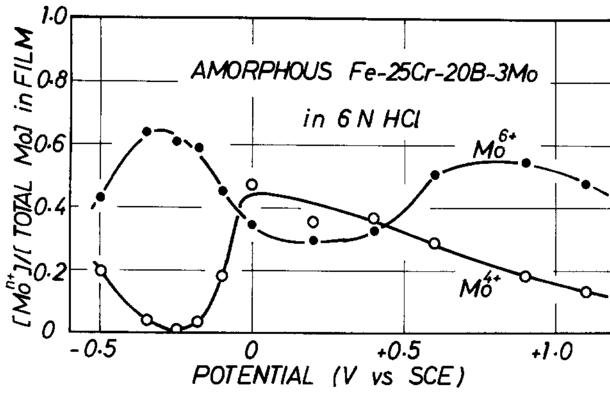

Fig. 11. Ratio of tetravalent or hexavalent molybdenum to total molybdenum in the surface film formed on amorphous Fe-25Cr-20B-3Mo alloy by potentiostatic polarization for 3600 sec in 6*N* HCl.

The change in the film thickness with polarization potential is shown in Fig. 12. All the molybdenum-bearing alloys form very thick surface films in the active region, including the 10Mo alloy which shows the negative current. In contrast, film thickening does not occur on the 0Mo alloy even at −0.1V where maximum anodic current density was observed. The passive film on the alloys with molybdenum tends to thicken with an increase in the molybdenum content. In particular, a thick passive film is formed on the 10Mo alloy at higher potentials in the passive region where hexavalent molybdenum species are accumulated in the surface film as shown in Fig. 11.

Discussion

It is most striking that, when amorphous Fe-25Cr-20B-xMo alloys contain 5 a/o or more molybdenum, spontaneous passivation occurs in 6*N* HCl with no pitting corrosion. This contrasts with the fact that any crystalline iron- or nickel-base alloy is not able to passivate spontaneously even in 1*N* HCl. The extremely high corrosion resistance of these amorphous

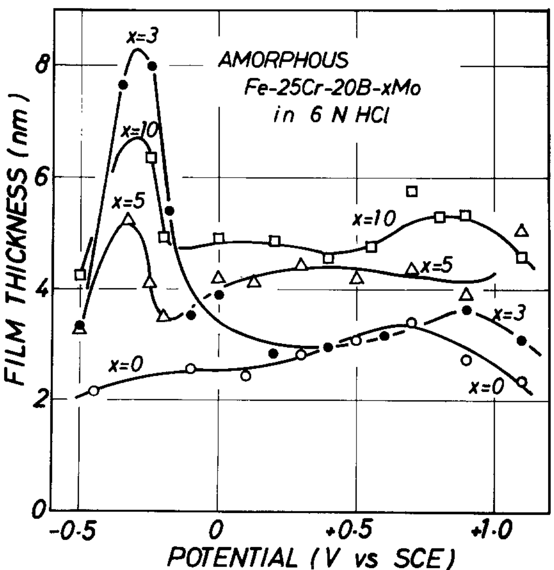

Fig. 12. Change in thickness of the surface film formed on amorphous Fe-25Cr-20B-xMo alloys by potentiostatic polarization for 3600 sec in 6*N* HCl as a function of polarization potential.

alloys is attributable to their chemically homogeneous defect-free, single-phase nature and the rapid passivation they exhibit (20, 31), as well as the beneficial effect of molybdenum. In this connection, these amorphous alloys contain boron but not phosphorus. The present authors (16, 20, 22, 32) have shown that phosphorus is the most effective metalloid in improving the corrosion resistance of amorphous alloys. Hence, it can be assumed that, if the boron in these amorphous alloys is substituted with phosphorus, spontaneous passivation in concentrated hydrochloric acid may occur at lower chromium and molybdenum contents.

Beneficial effect of molybdenum.—The anodic current density in the active region decreases with an increase in the alloy molybdenum content. In addition, a thick corrosion product film containing molybdenum ions is formed by polarization in the active region. The present authors (8, 23, 24) have reported that active dissolution of both amorphous and crystalline alloys containing molybdenum in 1*N* HCl gives rise to the formation of a molybdenum-enriched film, which suppresses active dissolution. Because molybdenum is passive in the active region of iron-base alloys, the faster the active dissolution the higher is the concentration of molybdenum in the film. This is reconfirmed in the present work.

In addition, it has been shown that a decrease in anodic current density in the active region in an aggressive concentrated hydrochloric acid is caused by the formation of surface films containing large amounts of chromium and some molybdenum. In the absence of molybdenum in the alloy, the maximum current density in the active region is of the order of 3000 $A \cdot m^{-2}$, even when some chromium enrichment occurs in the thin surface film. When the alloy contains 3 a/o molybdenum, a thick surface film whose molybdenum content is 60% of cations can grow; hence the maximum current density for active dissolution decreases to 15 $A \cdot m^{-2}$, although this current density is still high because the chromium content of the surface film is very low. When the molybdenum content of the alloy is raised to 5 a/o, the surface film, consisting of 80% chromium and 20% molybdenum as cations, suppresses the maximum current density for active dissolution to 2.5 $A \cdot m^{-2}$.

We have interpreted (8, 23, 24, 33) the role of molybdenum in the passivation of amorphous and crystalline iron-base alloys as follows: Active dissolution of alloy, which is necessary to accumulate beneficial metallic ions and/or OH^- ions at the alloy-solution interface prior to passive film formation in aggressive solutions, leads to the formation of a molybdenum-enriched corrosion product film which slows down the dissolution rate of passivating species through the film. This fact accelerates the accumulation of the passivating species under the film and hence facilitates the formation of a passive hydrated chromium or iron oxyhydroxide film between the corrosion product film and the underlying alloy. The corrosion product film is formed as a result of active dissolution and is not stable at high potentials in the passive region. Accordingly, when the condition for the rapid supply of molybdenum to form the corrosion product film fails by lowering of the dissolution rate through passive film formation, the corrosion product film dissolves in the solution. Therefore, the passive film does not contain an appreciable amount of molybdenum. When a part of the passive film is chemically or mechanically broken, molybdenum in the alloy similarly assists repassivation.

It can be clearly seen from Fig. 6 and 7 that active dissolution of molybdenum-bearing alloys rapidly slows down. This fact results in the formation of a passive film with a higher protective quality. For instance, the 3Mo alloy shows a high passive current density, indicating a low protective quality of the passive film. The enrichment of beneficial chromium in the passive film is not high, but the content of unstable molybdenum in the film is not low in comparison with the 5Mo and 10Mo alloys. When the molybdenum content of the alloy is low, it is not sufficient to suppress the dissolution of passivating species by the formation of molybdenum-enriched corrosion product film prior to the passive film formation in aggressive concentrated hydrochloric acids. As seen in the active region, the rapid dissolution of the alloy in the passive region appears to result in the formation of a passive film in which the iron and molybdenum contents are relatively high and chromium is relatively low. It can, therefore, be said that the addition of an insufficient amount of molybdenum to the alloy leads to insufficient suppression of active dissolution prior to the passive film formation and simultaneously to the formation of the passive film without a high protective quality due to insufficient chromium enrichment.

Detrimental effect of molybdenum.—It has been stated by many investigators (1-3, 34, 35) that incorporation of molybdenum into the passive film improves the protective quality of the film. When the dissolution rate of iron-base alloys is very high as in the active region, molybdenum selectively remains because the dissolution rate of molybdenum is slower than that of other constituents. Molybdenum, however, is not able to form its own passive film in the passive region of the alloys and dissolves even at the lower potentials in the passive region of the alloys, indicating a lower stability of the passive film of molybdenum in comparison with a passive hydrated chromium or iron oxyhydroxide film (8, 24).

The 5Mo and 10Mo alloys exhibit a negative current at lower potentials in the passive region, indicating the highly protective quality of the passive film. The passive film formed on those alloys at lower potentials in the passive region consists exclusively of chromium oxyhydroxide and chromium borate; the molybdenum content of the film is extremely low. In this connection, it has been known (20) that the formation of chromium borate is not effective in improving the protective quality of the passive hydrated chromium oxyhydroxide film. It can, therefore, be said that the protective quality of the film is provided by the formation of the hydrated chromium oxyhydroxide film without molybdenum. In particular, the passive film formed on the 10Mo alloy at the open-circuit potential has an especially high protective quality and can withstand polarization in the active region. Accordingly, the alloy shows a negative current in the active region, although the average composition of the passive film changes to some extent by polarization in the active region. When the molybdenum content of the alloy is low, for example 3 a/o, the chromium content of the passive film is not extremely high and the film contains a certain amount of molybdenum. Consequently, a high protective quality cannot be expected for a molybdenum-containing passive film.

On the other hand, polarization of the alloy containing an excess molybdenum, such as 10 a/o, at higher potentials in the passive region increases the content of unstable molybdenum in the passive film and hence results in an increase in the passive current density. In other words, molybdenum assists passive film formation and greatly improves the corrosion resistance, but the lower the molybdenum content of the passive film the higher is the protective quality of the film.

Relation between active dissolution and passivation.—The present authors (16), in reporting the effect of metalloid elements on the corrosion resistance of amorphous chromium-bearing alloys, have stated that phosphorus accelerates initial active dissolution of the alloys with a consequent enrichment of the beneficial chromic ions at the alloy-solution interface prior to passive film formation, which facilitates the rapid formation of the passive film in which these ions are highly concentrated. The beneficial effect of the high

anodic activity has also been found by comparison of amorphous iron- and nickel-base alloys (17). Amorphous Fe-Cr-20B alloys containing 30 a/o or more chromium passivate spontaneously in 1*N* HCl, while the amorphous Ni-30Cr-20B alloy shows a high active current density. Similarly, the amorphous Fe-20Cr-3Mo-20B alloy passivates spontaneously in 1*N* HCl, showing the corrosion potential at about 0.4 V(SCE). In contrast, even if the molybdenum content of amorphous Ni-20Cr-Mo-20B alloys is increased to 10 a/o, the active current is still clearly observed. In this manner, the higher anodic activity of iron-base alloys in comparison with nickel-base alloys is effective in accumulating the beneficial species at the alloy-solution interface and in facilitating spontaneous passivation.

Interesting results have been obtained by comparison of the passivation behavior of amorphous Fe-Mo-P-C alloys (24) and Fe-Mo-C alloys (23): the phosphorus-bearing alloys show a higher molybdenum content in the surface film formed in the active region and a lower active current density. The passive film formed on the alloys consists exclusively of hydrated iron oxyhydroxide, whereas the film formed on the Fe-Mo-C alloys contains a large amount of unstable molybdenum species. The passive current density of the phosphorus-bearing alloys is about one-tenth as high as that of the Fe-Mo-C alloys.

On the other hand, Fig. 7 and the investigation of ferritic stainless steels (8) clearly show that active dissolution of molybdenum-bearing alloys immediately after mechanical abrasion rapidly slows down in comparison with alloys without molybdenum, although molybdenum does not appreciably change the anodic activity of alloys.

These results lead to the following assumption: in the absence of phosphorus in the alloys, initial active dissolution is not sufficiently rapid to concentrate molybdenum in the corrosion product film prior to the passive film formation. This fact results in a corrosion product film which insufficiently suppresses dissolution of the passivating metallic ions through the film, and hence the relatively high dissolution rate leads to the formation of a passive film with a poor protective quality based on a high content of unstable molybdenum.

In this connection, the high anodic activity of the alloy is essentially different from the high aggressiveness of the solution with respect to passivation. Passivation is difficult in aggressive solutions (*e.g.*, amorphous Fe-Cr-Mo-B in 6*N* HCl, Fe-Mo-metalloid in 1*N* HCl). The formation of the molybdenum-enriched corrosion product film is necessary to concentrate the passivating species under the film. Hence, the passivating species become concentrated in the passive film formed on the molybdenum-bearing alloys. In contrast, if the solution is not highly aggressive [*e.g.*, ferritic 30Cr steels in 1*N* HCl (8)], passivation occurs even if molybdenum is not added. The addition of molybdenum assists passivation due to suppression of dissolution of the passivating species by the formation of the molybdenum-enriched corrosion product film prior to passive film formation. Therefore, the composition of the passive film is not appreciably different for the alloys with and without molybdenum. On the other hand, the high anodic activity of alloy leads to the formation of a corrosion product film in which molybdenum ions are highly concentrated. The effective suppression of dissolution of passivating species through the corrosion product film as well as the high anodic activity, facilitates the enrichment of the passivating species under the film and hence accelerates passive film formation.

We have proposed (8) that a passive film generally contains micropores which are repeatedly formed and repassivated. If the thickness and composition of the passive films formed on two alloys are apparently the same [*e.g.*, the films formed on ferritic 30Cr steels with and without molybdenum in 1*N* HCl (8)], the difference in the activity of micropores in these films is mainly responsible for the large difference in the passive current density. In other words, the repassivation process of micropores is the same as the passivation process mentioned above, and hence molybdenum assists the repassivation of micropores with a consequent decrease in the steady-state passive current density.

Film thickness.—Bond and Lizlovs (36) have pointed out the importance of film thickening in connection with an increase in the stability of the passive film with increasing time. Sugimoto and Sawada (1) have stated that the thickness of the passive film on 20Cr-25Ni-Mo stainless steels increases with molybdenum content of the steels in both sulfuric and hydrochloric acids. In the present work, among the molybdenum-bearing alloys, the thickness of the passive film increases with an increase in the molybdenum content of the alloy, but the change in the molybdenum content of the alloy is accompanied by a change in the composition of the passive film. In addition, the thickness of the passive film on the 3Mo alloy is almost the same as that of the film on the 0Mo alloy. Furthermore, we have shown that the addition of molybdenum to 19Cr (9) and 30Cr (8, 11) ferritic stainless steels does not lead to an appreciable change in both the thickness and composition of the passive film formed in 1*N* HCl and 1*N* H_2SO_4, despite the fact that the passive current density is greatly decreased by the addition of molybdenum. It is, therefore, difficult to correlate the high protective quality of the passive film with the film thickening that accompanies a change in the film composition.

Conclusions

1. Amorphous Fe-25Cr-20B-xMo alloys ($x = 0, 3, 5,$ and 10) do not suffer pitting corrosion even by anodic polarization in 6*N* HCl, and the alloys containing 5 a/o or more molybdenum passivate spontaneously in the solution.

2. The anodic current density in the active region decreases with an increase in the molybdenum content of the alloy due to the formation of a thick surface film containing large amounts of chromium and small amounts of molybdenum.

3. Molybdenum does not form its own passive film and is unstable even at lower potentials in the passive region of the alloys, at which transpassive dissolution of molybdenum does not occur. Molybdenum assists the formation of a passive hydrated chromium oxyhydroxide film. At lower potentials in the passive region, spontaneous passivation for the 5Mo and 10Mo alloys occurs by the formation of highly protective passive film consisting exclusively of chromium as cations; the molybdenum content of the film is extremely low.

4. A low molybdenum alloy, such as the 3Mo alloy, shows a high passive current density in 6*N* HCl, indicating a low protective quality of the passive film. A decrease in the molybdenum content of the alloy leads to a decrease in the content of beneficial chromium in the passive film and to an increase in the content of unstable molybdenum in the film.

5. At higher potentials from 0.5 to 1.0V(SCE) in the passive region, molybdenum also suppresses active dissolution prior to passive film formation and hence assists the film formation. However, an excess of molybdenum deteriorates the protective quality of the passive film due to the formation of unstable molybdenum species which dissolve by a transpassive reaction.

The Dealloying of Copper-Manganese Alloys

D. S. Keir and M. J. Pryor*

Olin Corporation, Metals Research Laboratories, New Haven, Connecticut 06504

ABSTRACT

Binary copper alloys containing 25 and 50% manganese were corroded in sodium chloride solution at various fixed potentials spanning their corrosion potential. Both Cu-Mn alloys exhibited dealloying at a high rate. The Cu-25%Mn alloy exhibited dealloying behavior similar to that observed in the Cu-Zn and Cu-Ni systems. Selective loss of manganese was maximized at the most active potential at which the alloy was held. When the potential was raised some 0.25V above the corrosion potential, dealloying was largely prevented. The Cu-50%Mn alloy exhibited different behavior with very pronounced dealloying occurring over the whole potential range studied. The morphology and composition of the dealloyed residues was also investigated in detail. The mechanism of dealloying in the Cu-Mn system is discussed.

The dealloying of copper base alloys has been quite extensively studied over the years with the primary attention being directed to Cu-Zn alloys. In the early work of Bengough and May (1) later supported by Kenworthy (2), it was suggested that both copper and zinc dissolve anodically from brass but that the copper is subsequently redeposited on cathodic sites after reaching an appropriate concentration in solution. More recent work of Pickering (3) has offered an alternate explanation, *i.e.*, that of the selective removal of zinc atoms from the alloy. Accordingly, in the dealloying of γ and ϵ brasses, Pickering was able to detect intermediate and more copper-rich phases in the alloy substrates after corrosion at controlled active potentials. Pickering and Byrne (4) also showed that the selective removal of zinc atoms predominated at potentials between the reversible potential for the anodic dissolution of zinc and that for copper; further as the latter potential was significantly exceeded proportionate alloy dissolution took place.

Studies similar to those of Pickering and Byrne were carried out by one of the authors on a range of copper-nickel alloys (5). Results essentially similar to those found by Pickering and Byrne on brasses were ob-

Key words: aqueous corrosion, dealloying, copper, manganese.

tained. Dealloying was promoted by application of potentials more active than the corrosion potential of a Cu-Ni alloy and was inhibited by raising the potential to some 250 mV above the corrosion potential. Here, however, the extent of dealloying was very minor compared with that observed on the copper-zinc alloys. The cupro-nickels also grew quite protective thick films during the initial dealloying with the result that some 20% of the total cations leaving the alloy were found in the corrosion product film.

The present study was designed to clarify the dealloying behavior of binary Cu-Mn alloys. Manganese shows substantial solid solubility in copper and is an effective solid solution strengthening agent. Cu-Mn binary alloys have been reported to be relatively susceptible to stress corrosion cracking in ammonia (6,7). What little information exists on their general corrosion behavior (8) indicates that manganese decreases salt spray resistance with the weight loss increasing with manganese content up to 40 weight percent (w/o). However, no information was provided on whether dealloying occurred in the salt spray testing or in the stress corrosion process.

It would be expected that copper-manganese binary alloys should be quite susceptible to dealloying. The reversible potential (E_o) for the reaction

$$Mn = Mn^{++} + 2e \qquad [1]$$

is $-1.16V$ compared with only $-0.763V$ for the half-cell reaction

$$Zn = Zn^{++} + 2e \qquad [2]$$

Accordingly, on the basis of thermodynamic considerations alone, the Cu-Mn alloys could well be more susceptible to dealloying than the brasses.

In order to throw light on this point, the investigation described in this paper was conducted. Copper-manganese alloys nominally containing 25 and 50 w/o manganese were exposed to sodium chloride solution over a wide potential range which was designed to bracket the corrosion potential of each alloy. The copper to manganese ratios found both in the films formed during the corrosion process and also in the solution were analyzed. In addition, the morphology and composition of the dealloyed residues were studied.

Experimental and Results

Materials and procedure.—Cu-25%Mn (actual 25.30% Mn) and Cu-50%Mn (actual 49.55% Mn) alloys were chill cast as 2.5 × 10 × 20 cm sections. Cu-25%Mn is a single phase (γ) alloy (10). It was hot-rolled at 800°C to a thickness of 0.63 cm, annealed at 700°C for 1 hr, milled, cold-rolled to 0.10 cm, annealed at 725°C for 1 hr, and water quenched. The Cu-50%Mn alloy may be single phase (γ) if quenched from above 650°C or two-phase (γ + α-Mn) if heat-treated below 650°C. The Cu-50%Mn casting was homogenized at 750°C for 16 hr, hot-rolled at that temperature to a thickness of 0.63 cm, annealed at 750°C for 2 hr, water quenched, and milled. The alloy was then cold-rolled to 0.10 cm thickness. The alloy was then again annealed at 750°C for 2 hr followed by water quenching to yield the single phase (γ) condition. The two phase (γ + α-Mn) condition was produced by further annealing selected specimens for 4 hr at 450°C.

Corrosion specimens measuring 1.5 × 5 cm were cut from the 0.10 cm thick sheet of the two above alloys. The surfaces were prepared by abrading on 400 and 600 grit fine metallurgical paper with a final polish. The specimens were degreased in benzene and methanol, dried in air, and then masked with electroplaters tape leaving an exposed circle with the total area of 1 cm^2.

The sodium chloride used in this investigation had a concentration of 0.5M and was made up from reagent grade sodium chloride dissolved in distilled deionized water. All experiments were conducted with the sodium chloride solution freely exposed to air.

All corrosion experiments were carried out in duplicate at a temperature of 25° ± 0.05°C with 150 ml of solution per specimen. The potential of the individual specimens was controlled by a Wenking Model 68-TS-3 potentiostat. A saturated calomel electrode was used as a reference electrode. It was contained in the same electrolyte in a separate vessel connected to the reaction vessel with a solution bridge. The Cu-25%Mn alloy was polarized at potentials varying from −0.25 to +0.50V on the standard hydrogen scale.[1] The Cu-50%Mn alloy was polarized in both metallurgical conditions (γ or γ + α-Mn) at potentials ranging from −0.60 to +0.25V.

After completion of an experiment, the solution was acidified and the copper and manganese determinations made by atomic absorption using a Techtron Model AA4 Spectrophotometer. The reaction product films were dissolved separately in dearated 12% H_2SO_4 at 60°C with copper and manganese again being determined by atomic absorption. The blank correction described earlier (5) was used to correct for very minor acid attack on the unfilmed alloys. A third specimen was always polarized in an identical fashion, carefully washed, and subjected to reflection electron diffraction at 100 kV. All specimens irrespective of alloy content or potential maintained showed surface films of Cu_2O only with the film being insufficiently thick to mask reflections from the underlying substrate.

The morphology and composition of the dealloyed residues were studied by SEM/microprobe analysis using an AMR Model 900 SEM with a PGT energy dispersive analyzer.

Results.—Table I shows the corrosion potential of copper and the two Cu-Mn alloys. Alloying with 25% Mn had only a minor effect on depressing the corrosion potential in the active direction. However, when copper was alloyed with 50% manganese irrespective of whether the alloy was single or two-phase, the corrosion potential dropped to close to −0.5V. In this respect, Mn at high concentration has an unusually strong influence in shifting the corrosion potential of the alloy in the active direction.

Analyses of the total reaction products (solid oxide film on the metal and copper and manganese ions in solution) were conducted as a function of time of polarization at +0.25V for the Cu-25%Mn alloy. The reaction product composition became essentially constant with time after around 20 hr. Accordingly, this time was used as a standard for the remainder of the investigation.

Anodic polarization curves were determined for the Cu-25%Mn alloy at three different sweep rates (0.9, 1.5, and 3.0 V/hr) in the sodium chloride solution. The anodic polarization curves were only slightly sweep rate dependent and exhibited the same features as the anodic polarization curves of copper-nickel alloys in sodium chloride solution (9).

Figure 1 shows the weights of Cu + Mn in solution for the Cu-25%Mn alloy after 20 hr holding at various fixed potentials between −0.25 and +0.50V. Because the separately analyzed Cu + Mn in the surface oxide film was only around 1% of that found in solution, it is insignificant to mass balance considerations and so is not included in Fig. 1. The amount

[1] All potentials in this paper are expressed on the standard hydrogen scale.

Table I. Steady corrosion potentials of Cu, Cu-25%Mn, and Cu-50%Mn alloy in 0.5M NaCl at 25°C

Alloy	Steady corrosion potential (/V)
Cu	0.00
Cu-25% Mn	−0.053
Cu-50% Mn	−0.470

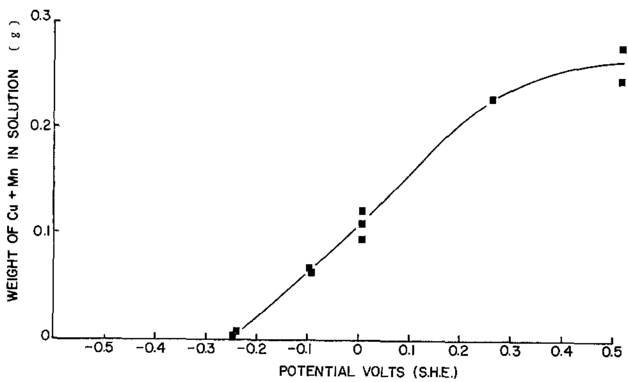

Fig. 1. Relationship between Cu plus Mn in solution from a Cu-25%Mn alloy held at five different potentials in 0.5M NaCl for 20 hr.

of copper and manganese dissolved from the alloy increased approximately linearly with increasing potential in the noble direction up to around +0.25V.

Figure 2 shows the effect of potential upon the percentage of manganese in solution. At −0.25V, the soluble corrosion product was almost 100% manganese. Between +0.25 and +0.50V, manganese left the alloy in a modestly greater weight percent than it was originally present. At the corrosion potential of the Cu-25%Mn alloy (−0.053V), the soluble corrosion product contained over 40% Mn. The form of the manganese content *vs.* potential curve is quite similar to that found earlier by Pickering and Byrne (4) for brasses and by one of the authors for copper-nickel alloys (5).

Figure 3 shows the weight of Cu + Mn in solution for the Cu-50%Mn alloy after 20 hr in 0.5M NaCl as a function of potential between −0.60 and +0.25V. Within the limits of experimental error, there was no difference in the results irrespective of whether the

alloy was in the single phase (γ) or the two-phase ($\gamma + \alpha$-Mn) condition. Figure 3 shows results for the single phase condition only. This curve is quite similar to that for the Cu-25%Mn alloy. Due to the much more active corrosion potential of the Cu-50%Mn alloy (Table I), most of Fig. 3 was determined under conditions of anodic polarization.

Figure 4 shows the percent of manganese in the soluble corrosion product for this alloy as a function of potential. Figure 4 illustrates dealloying behavior very different from that of the Cu-25%Mn alloy in Fig. 2. Even at potentials as high as +0.25V, the corrosion reaction still yielded in excess of 90 w/o Mn. This is a potential that is in excess of 0.7V more noble than the corrosion potential of this alloy. At the corrosion potential of the alloy, the manganese content of the soluble reaction product was around 99%. Further at 0.0V and above, the specimens were dealloyed throughout the whole cross section of the specimens. The Cu-50%Mn alloy exhibited extremely severe and rapid dealloying and it was not possible within the potential range studied to force the manganese to leave the alloy in the same proportion as it was present originally.

Figure 5 shows an SEM plan view of the dealloyed surface of a Cu-25%Mn alloy held at a potential of −0.10V for 20 hr. Magnification is ×1000 and it is evident that the residue was very porous. The mass balance studies in Fig. 2 showed that Mn comprised some 70% of the Cu + Mn content of the solution. Energy dispersive x-ray spectra were then made of the

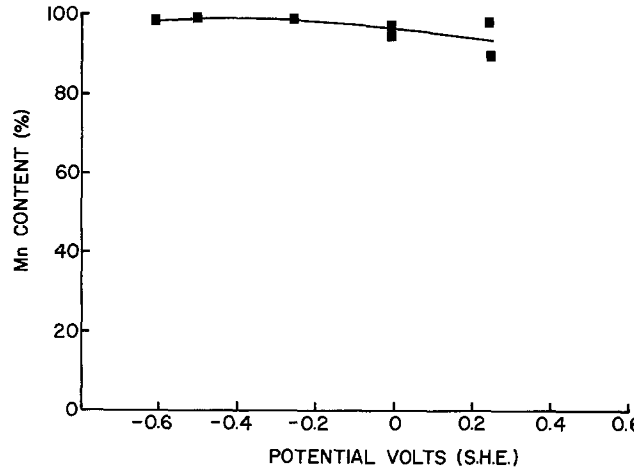

Fig. 4. Relationship between weight percent of Mn in solution from a Cu-50%Mn alloy held at five different potentials in 0.5M NaCl for 20 hr.

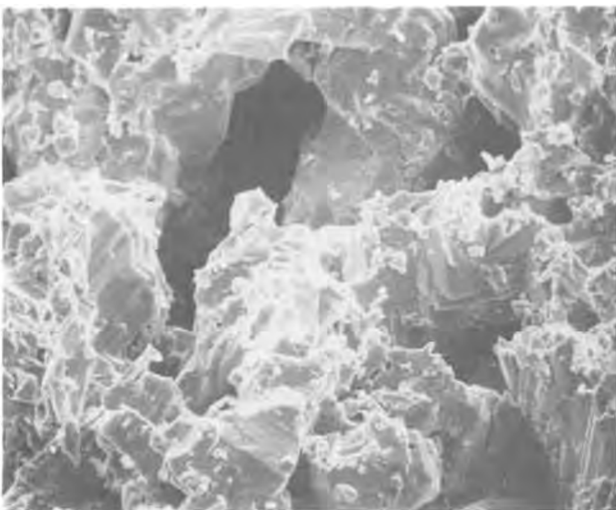

Fig. 5. Dealloyed surface of Cu-25%Mn alloy held at −0.10V in 0.5M NaCl for 20 hr (×1000).

original alloy surface and of the dealloyed surface layer. The spectra for the original Cu-25%Mn alloy (upper spectrum) and for the dealloyed surface layer (lower spectrum) are shown in Fig. 6. The Mn peaks were completely absent after holding at −0.1V for 20 hr thereby indicating that the dealloyed layer was substantially pure copper.

Figure 7 shows an SEM plan view (×1000) of the Cu-25%Mn alloy polarized for 20 hr at +0.25V. The dealloyed surface was much less porous as might be anticipated from Fig. 2 which shows that Mn comprised only slightly more than 30% of the Cu + Mn content of the solution. Energy dispersive x-ray spectra of the original alloy and of the dealloyed surface are shown in Fig. 8. From Fig. 8, it is evident that much manganese is lost from the surface layer[2] but that a small and infinite amount of the order of 2 w/o remains.

Figure 9 shows an SEM plan view (×1000) of the surface of the Cu-50%Mn alloy polarized for 20 hr at 0.00V. This dealloyed surface was much more porous than that of the Cu-25%Mn alloy polarized for 20 hr at +0.25V (Fig. 7). The dealloyed residue shown in Fig. 9 penetrated completely through the original alloy sheet. By careful manipulation, it was possible to fracture the quite brittle dealloyed residue and reveal two planes as shown in Fig. 10. The lower plane in Fig. 10 is the dealloyed surface shown in Fig. 9 but at a lower magnification (×200). The similarly appearing surface in the upper part of Fig. 10 is a parallel fracture plane located approximately midway through the thickness of the dealloyed residue. The intervening porous polyhedra in Fig. 10 are a transition zone between the two planes. Figure 11 contains a series of energy dispersive x-ray spectra of the dealloyed deposit shown in Fig. 10. The upper spectrum is that of

[2] The effective analytical depth of penetration of the electron beam is around 0.8μ on a compact surface and as much as 4μ on very porous surfaces.

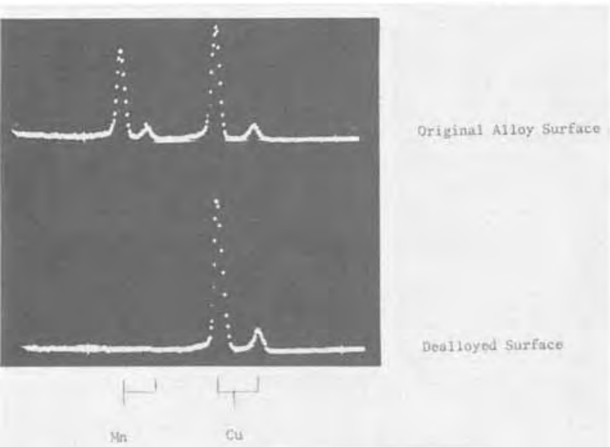

Fig. 6. Energy dispersive x-ray spectra from the surface of a Cu-25%Mn alloy. Upper, original alloy surface; lower, after holding at −0.10V in 0.5M NaCl for 20 hr.

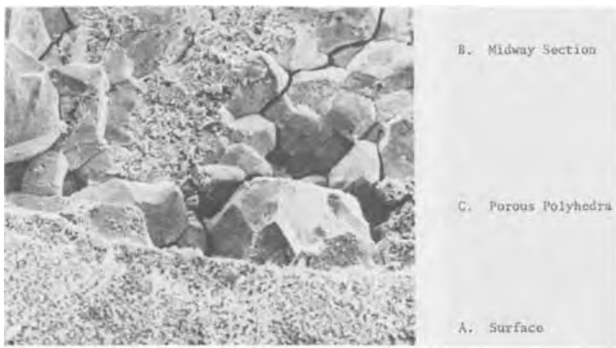

Fig. 10. Fractured sample of a dealloyed residue from Cu-50%Mn held at 0.00V in 0.5M NaCl for 20 hr—shows dealloyed surface (A), dealloyed plane midway through the section (B), porous polyhedra (C) (×200).

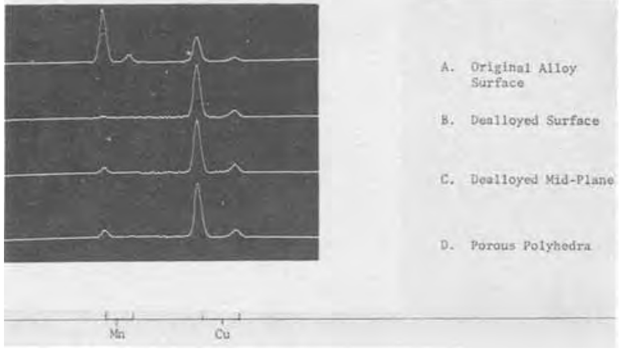

Fig. 11. Energy dispersive x-ray spectra from various features in Fig. 10. (A) original alloy surface; (B) dealloyed surface; (C) dealloyed mid-plane of residue; (D) porous polyhedra.

the original Cu-50%Mn alloy. The second (from the top) spectrum is from the dealloyed surface, Fig. 9. The manganese content is around 1.5 w/o. The third spectrum is from the fracture plane approximately midway through the dealloyed residue. This contains around 3.5 w/o Mn. The bottom spectrum is from the porous polyhedra in the transition zone between the two planes. These contain around 4.5 w/o Mn. Figure 12 shows the microstructure of the original Cu-50%Mn alloy at a magnification of 200 diam (similar to Fig. 10). There is no doubt that the porous polyhedra are original grains from the Cu-50%Mn alloy which have been almost completely dealloyed without changing size or contour. From Fig. 10, the individual dealloyed grains in the transition zone are also largely separate physically.

Fig. 12. Microstructure of Cu-50%Mn alloy ×200 etched in HCl-picric acid in isopropanol.

Discussion

For the Cu-25%Mn alloy (Fig. 2), the percentage of Mn found in solution (relative to the total Cu + Mn solution content) is influenced by potential in a similar manner to that found in α brass (4) and the cupronickels (5). At the corrosion potential of around -0.05V for the Cu-25%Mn alloy, the solution contains around 40% Mn and the specimen exhibits moderate dealloying; as the potential is shifted to around -0.25V, *i.e.,* closer to the manganese potential and much further below the copper potential, the manganese content of the solution rises to around 95% and copper dissolution is almost completely prevented. When the potential is raised to $+0.25$ or to $+0.50$V, *i.e.,* some 300 mV or more above the corrosion potential, manganese is around 30% of the Cu + Mn passing into solution, *i.e.,* only a modestly greater concentration than was present in the alloy. The resulting dealloying is relatively modest compared with that experienced at more active potentials. This potential dependent dealloying behavior is very similar to that reported previously for α brass (4) and for cupro-nickels (5).

The Cu-50%Mn alloy shows different behavior and much more extreme dealloying. From -0.60 to -0.25V, only manganese is found in solution with any copper being below the limits of the chemical analyses (<0.1 ppm). The only copper leaving the alloy is found in minute amounts in the thin surface oxide film. Copper is found in solution in small quantities only at 0.0 and $+0.25$V (Fig. 4). The corrosion potential of this alloy is -0.47V and at this potential, 99.9% of the metal ions leaving the alloy are manganese. Even at the highest potential studied ($+0.25$V), 92% of the cations leaving the alloy are manganese. Furthermore, the rate of dealloying at 0.0V and above was so high that the whole 0.1 cm cross section of the Cu-Mn alloy was penetrated from one side. It is evident that with the very highly alloyed Cu-50%Mn alloy, potential exhibits much less positive control over the dealloying phenomenon than at lower manganese contents of around 25%. Furthermore, even when the potential was raised some 0.7V above the corrosion potential, proportional alloy dissolution was not restored.

Based on past work and on the work reported in this paper, Cu-Ni alloys show the slowest kinetics of dealloying (5), α brass intermediate kinetics (4) and the Cu-Mn alloys by far the fastest kinetics, particularly the Cu-50%Mn alloy. If dealloying is regarded as being due to the selective removal of atoms of a more electrochemically active solute element, then some mechanism must be provided to explain the rapid propagation of dealloying into the alloy in real depth. Pickering (3) proposed a solid-state diffusion mechanism in Cu-Zn alloys with the diffusion rate being materially enhanced by the very large vacancy concentration occasioned by selective removal of the more electrochemically active zinc atoms. Diffusion data at room temperature and for this very selective metallurgical condition are not available in the literature. High temperature diffusion data for the three alloy systems within the temperature range of 750°-800°C suggests that at around 30 w/o solute, the diffusion coefficients are around 3×10^{-12} cm^2/sec for Ni in Cu-Ni (11), around 3×10^{-8} cm^2/sec for Zn in Cu-Zn (12), and around 7×10^{-10} cm^2/sec for Mn in Cu-Mn (13). Further, as the Mn content of Cu-Mn alloys is increased to around 50 w/o, D drops by around an order of magnitude. These high temperature diffusion data do not fit even qualitatively with dealloying kinetics falling in the order of

$$\text{Cu-Mn} > \text{Cu-Zn} > \text{Cu-Ni} \quad [3]$$

nor with the fact that Cu-50%Mn dealloys much more rapidly than Cu-25%Mn. Instead, dealloying kinetics seem to relate better to the difference between the po-

tential at which the alloy is maintained in solution and the half-cell potential of the solute element. If for instance the alloy potential is held at 0.00V, then the potential difference between the potential maintained in solution and the reversible potential of solute elements falls in the order of

$$\text{Cu-Mn (1.18V)} > \text{Cu-Zn (0.763V)} > \text{Cu-Ni (0.25V)} \quad [4]$$

which is in qualitative accord with the relative order of the kinetics of dealloying depicted in Eq. [3]. Such an analysis does not explain why dealloying kinetics increase with increasing solute content. This question will be addressed later in the Discussion.

The morphologies and compositions of the dealloyed structures provide convincing evidence favoring Pickering's view (3) that dealloying is the result of selective removal of solute atoms from the alloy as opposed to proportionate dissolution of the alloy followed by redeposition of copper (1, 2). Figures 5 and 7 show the surfaces of the Cu-25%Mn alloy at the same magnification (X1000) after dealloying for 20 hr at −0.10 and +0.25V, respectively. Normally, it would be expected that if redeposition was involved, the crystal size of an electrodeposit would decrease as the deposition potential is moved progressively in the more active direction (14). However, the crystal size of the dealloyed residue at −0.10V (Fig. 5) is much larger than that seen at +0.25V (Fig. 7). Furthermore, the dealloyed surface residue shown in Fig. 7 contains around 2% Mn in the dealloyed matrix (Fig. 8). The manganese does not exist as a separate phase detectable in the electron diffraction study and must therefore be assumed to be in solid solution in the matrix. At a potential of +0.25V, any redeposition of manganese from solution is quite impossible.

Even more convincing evidence supporting selective removal of manganese atoms from the lattice by application of appropriate electrochemical conditions is provided in Fig. 10 which shows a fractured sample of the residue from a Cu-50%Mn alloy dealloyed at 0.0V. Here, the original grain structure of the alloy may be clearly seen and the grain size is in the same 0.030-0.120 mm range as the original alloy (Fig. 12). There is further clear evidence of intergranular separation of many of the original alloy grains, presumably due to preferential attack of manganese-rich original grain boundaries. It is not believed that this intergranular separation is important in controlling the kinetics of the dealloying phenomenon. The original alloy grains, though maintaining their original size and morphology after dealloying, are in fact reduced to a porous network of dilute Cu-Mn solid solution. The morphology of the grain interiors may be seen from the dealloyed surface (Fig. 10) and from the similar center plane morphology in Fig. 10 which represents an area where one or more dealloyed grains were fractured during the specimen preparation. The surface plane, the center plane, and the unfractured dealloyed grains in Fig. 10 all contained a small amount of Mn presumed to be in solid solution at approximate levels of 1.5, 3.5, and 4.5 w/o, respectively (Fig. 11). The surface of the dealloyed grains is less porous than the grain interiors from Fig. 10. Assuming that the intergranular separation is due to a higher grain boundary manganese content, then the surface of the dealloyed grains should be more dense than their interior due to a manganese denuded layer being adjacent to the enriched grain boundaries.

The foregoing structural and compositional evidence clearly shows that the dealloying process in Cu-Mn alloys is the result of preferential electrochemical removal of Mn atoms from the alloys rather than a dissolution/redeposition mechanism. It is also more significant that dealloying only yields a pure copper residue only at the more electrochemically active potentials studied. At other more noble potentials, the dealloying residue is a dilute Cu-Mn solid solution.

The final aspects requiring discussion are the mechanisms of propagation of dealloying through the specimens and the morphology of the dealloyed layers. One mechanism for propagation could involve the selective removal of Mn atoms from the surface and subsurface layers together with the resulting creation of a very high vacancy concentration. This high vacancy concentration might permit renewal of Mn diffusing from the alloy substrate into the surface and subsurface dealloyed zones so as to sustain the dealloying process. A relatively long-range thermally activated process of this nature hardly appears feasible at room temperature particularly at the high rate necessary to sustain the dealloying process. A diffusion mechanism based on extrapolation from available high temperature data does not fit qualitatively with the dealloying kinetics observed in the α solid solutions within the Cu-Mn, Cu-Zn, and Cu-Ni systems (Eq. [3]). Furthermore the high temperature diffusion coefficient for Mn in copper is substantially higher at 25 w/o Mn than at 50 w/o Mn (13) yet dealloying kinetics are much faster at 50% Mn than at 25% Mn (Fig. 1 and 3).

An alternate explanation, more nearly consistent with the overall dealloying characteristics of copper base alloys may be found by considering the short range reorientation of the dealloyed surface layers in Cu-Mn alloys. Assuming that Mn is substantially removed by electrochemical polarization from the alloy surface, then the remaining Cu atoms will find themselves at large and unacceptable interatomic distances. The copper atoms will rapidly seek their characteristic distance of closest approach leaving voids in the surface whose volume will increase with increasing atom percent of Mn removed, *i.e.*, Fig. 10 for Cu-50%Mn *vs.* Fig. 7 for Cu-25%Mn. The atom rearrangement required to produce these skeletal Cu or Cu-rich structures is of an essentially much shorter range nature and does not require the diffusion of Mn over long distances. The rearrangement clearly results in the generation of new internal surfaces which should act as effective sinks for vacancies moving in the opposite direction to that in which the copper atoms collapse. The skeletal surface structure produced by the atomic contraction and vacancy annihilation permits access of the solution to the underlying alloy substrate and so the process may repeat itself without the necessity for anything other than short-range collapse of the copper atoms into an equilibrium crystal structure together with the attendant generation of new internal surfaces and vacancy annihilation. This model also explains why the dealloying kinetics of Cu-50%Mn are the same irrespective of whether the alloy was in the γ or in the $\gamma + \alpha$-Mn conditions. In the latter condition, the α-Mn will be removed preferentially and will be followed by the Mn in the remaining γ solid solution. The void volume within the skeletal residue will be identical to that obtained from dealloying of the γ Cu-50%Mn solid solution when they are dealloyed to the same final composition. Only the morphology of the skeletal deposit will vary slightly with its internal volume and therefore solution access to the substrate being the same. This mechanism provides for the atomic rearrangement of the Cu atoms, together with vacancy annihilation at the new internal surfaces to occur on a short-range basis within the surface layers only. It does not require long-range manganese diffusion from the unattacked substrate. It permits propagation of dealloying by providing solution access to the unattacked substrate through the porous skeletal structures generated by the creation of new internal surfaces.

Using the foregoing model, dealloying kinetics should be hastened when the skeletal structure is most porous and permits easiest access of the solution, *i.e.*, Cu-50%Mn at 0.00V (Fig. 10) and retarded when

the skeletal structure is denser and solution access is less favored, *i.e.*, Cu-25%Mn at 0.25V in Fig. 7. An explanation of this nature can also account for the formation of intermediate more copper-rich phases during dealloying of applicable higher alloy phases as found by Pickering (3). Selective electrochemical conditions involving application of the more active potentials were required to dealloy to a pure Cu residue in this study. All other experiments at somewhat more noble potentials yielded dilute Cu-Mn solid solutions as the terminal residue. Throughout the course of the experiments, a complete range of α solid solutions must have existed transiently during the dealloying process. If the system was such that intermediate more copper-rich phases could exist, as for instance in the dealloying of ϵ or γ brasses (3), then the formation of the lower phases would clearly result at some point in time during dealloying.

In summary, the model proposed in this paper suggested that dealloying kinetics in solid solutions of Cu with Mn, Zn, and Ni are primarily controlled by the difference in potential between that at which the alloy is maintained in solution and the reversible potential of the solute element. Within the Cu-Mn system those electrochemical conditions which lead to the most open skeletal structures of Cu or dilute Cu-Mn γ solid solution correlate with the greatest rates of dealloying or the greatest selectivity of Mn removal.

Anodic Behavior of Cemented WC-6% Co Alloy in Phosphoric Acid Solutions

M. H. Ghandehari*,[1]

Fansteel Metals, Muskogee, Oklahoma 74401

ABSTRACT

The anodic behavior of WC-6% Co alloy in nitrogen saturated phosphoric acid solution was studied by means of potentiostatic dissolution, polarization curves, and micrographic studies. At anodic potentials between open circuit ($E = -300$ mV) and -100 mV (*vs.* SCE) the binder phase alloy (Co-W) dissolves actively to yield dissolved Co and W while the WC phase remains unattacked. At approximately -0.1V the WC-Co alloy passivates resulting in an 80% decrease in current. Further anodic polarization causes the current to increase as active dissolution of the WC phase comes into play. Application of these results to Co/WC separation in alloy scrap recycling is discussed.

Cemented WC-Co alloys are dispersions of micron-size WC particles in a binder phase. These alloys are prepared by a liquid phase sintering process, during which some WC grains dissolve in Co producing a Co-W-C ternary binder alloy (1). The solubility of WC in Co is a function of physical and chemical properties of the constituents as well as the conditions of the sintering process (1). At room temperature, however, the amount of carbon remaining in the binder phase is small and hence difficult to measure. The thickness of the binder phase has been reported to range from 20 to 100Å for cemented alloys containing less than 12% by weight cobalt (2).

Extensive use of these alloys under a variety of corrosive environments suggests the need for kinetic studies of the basic corrosion processes. Examples of some of these environments are geothermal brines in drilling applications, acid extracts from wood (3, 4) in cutting of lumber, and lubricants in metal finishing industries. While it is desirable to inhibit corrosion in the above circumstances, a totally opposite need arises in metal recycling industries in which corrosion and total disintegration of used and rejected alloys are desirable (5, 6). Published literature on corrosion of

Key words: cemented carbides, binder phase, Co-W, corrosion, mixed potential.

cemented carbides is sparse and deals mostly with weight loss measurements (7, 9) as a means to compare corrosion resistances of these alloys under various conditions.

Because cemented carbide alloys are nonhomogeneous, the different components would be expected to dissolve at different rates and have different overvoltages for depolarizer reactions. Electrochemical measurements combined with mixed potential considerations (10) may provide a significant tool for investigating the corrosion behavior of these industrially important alloys.

In this study anodic polarization curves for WC-6% Co alloy have been determined in phosphoric acid solutions using the potentiostatic technique. Also, current *vs.* time behavior and current yields at several potentials have been measured. Finally, microstructural changes occurring during the corrosion have been examined. From these results a qualitative model is given describing the dissolution of WC-Co cemented alloys in dilute phosphoric acid solutions.

Experimental

A three electrode system was used to study anodic dissolution of WC-Co, WC, and Co electrodes. The cell consisted of a 600 ml Pyrex beaker which was filled approximately one-third with 1.2M H_3PO_4. The test and counterelectrodes were suspended from the gas-tight lid and were separated by approximately 5 cm. Test electrodes were prepared as follows.

Sintered pieces of WC-6% Co were made according to standard powder metallurgical techniques (1). WC electrodes were prepared by hot-pressing powders of the elements in a graphite die at about 2200°C and 5000 psi of pressure for about 10 min. The cobalt electrode was prepared from a piece of high purity cobalt foil. The electrode surfaces of the WC-6% Co and Co were 1 × 1 cm and that of the WC electrode was 2 × 2 cm. The back sides of the test electrodes were coated with silicone rubber. Prior to each test, the surface of the carbide electrode was ground and polished to produce a new surface using a standard procedure (ASTM B276-54, 1954). The polished surface was rinsed with ethanol and distilled water prior to each test. Examination of the carbide electrode surfaces with a metallograph revealed that they were free from pores. The surface of the cobalt electrode was pretreated with a few drops of HF-HNO_3 solution followed by rinsing with deionized water.

A piece of Pt wire, 0.1 × 5 cm, was used as the counterelectrode. Electrode potentials were measured by means of a Keithley electrometer and with respect to a saturated calomel electrode (SCE) which was positioned outside the cell, contacting the test electrode through a salt bridge full of cell electrolyte and a Luggin capillary. The cell was equipped with a Teflon-coated magnetic stirring bar for agitation. Solutions were stirred at a moderate rate which was kept constant throughout the experiments. All tests were run at ambient temperature of 25° ± 1°C. Reagent grade chemicals and deionized water were used to prepare the solutions. Nitrogen of 99.99+% purity, as specified by the manufacturer, was flushed through the solutions. Steady-state potentiostatic curves were obtained with either a Wenking or an Anotrol potentiostat by stepping the potential about 20 mV once each minute and recording the resultant pseudo steady-state current. The corresponding anodic and cathodic curves were constructed accordingly. For current-time measurement at a given electrode potential, the same potentiostat was used in conjunction with a Bristol X-Y recorder. Metallographic examinations were made using a Leitz Metallograph. Cobalt and tungsten dissolution was measured by analyzing the solutions for these elements using atomic absorption spectrometry (11). Relative standard deviations of 9% and 2.5% were found for the W and Co analyses, respectively. Standards were prepared in the same matrix to prevent determinant errors. The current yields for tungsten and Co dissolution were obtained by comparing the recorded current to those obtained from solution analyses.

Four to five kg quantities of WC-6% Co were electrolyzed simultaneously in a particulate bed electrode system at constant potential. This system was essentially a barrel-tank electroplating unit, strengthened to meet the mechanical requirement and modified to facilitate monitoring of the average potential of the pieces during the electrolysis (5).

Results

Steady-state polarization curves.—Typical potentiostatic, steady-state polarization curves for anodic dissolution of WC-6% Co and WC and for H^+-ion reduction on WC are shown in Fig. 1. The curve for Co dissolution is shown in Fig. 2. These polarization curves were repeatable upon successive cycling of the potential and gave essentially the same shape on the decreasing and increasing potential cycles except for some hysteresis. Changes in stirring did not influence the shapes of the curves. The open-circuit potential for WC-6% Co was typically about −300 mV which is between the open-circuit potential for Co (−500 mV) and WC (0-200 mV). The WC + 6% Co electrode shows three distinctive regions which are labeled A, B, and C in Fig. 1 for future reference. In region A the logarithm of the current density increases approximately linearly with the potential. At −0.1V the current drops abruptly by 70-80% and remains roughly constant while the potential increases some 0.7V. This

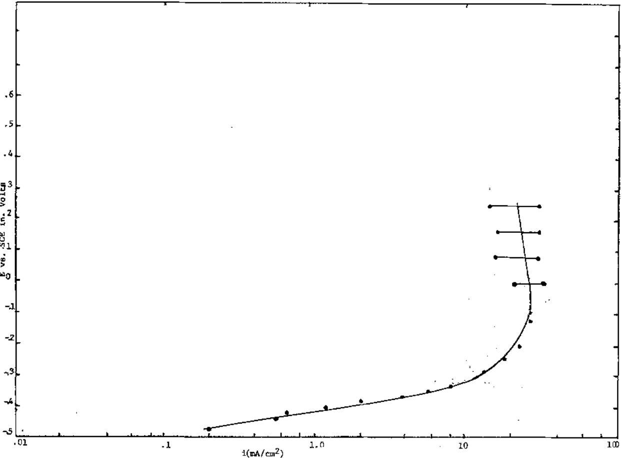

Fig. 2. Steady-state polarization curve for the oxidation at Co electrode in N_2 saturated solution of 1.2M H_3PO_4. Stirred solution, $T = 25°C$.

transition region is labeled "B." At $E \simeq 0.6V$ the current again increases exponentially with an increase in potential.

Current-time behavior.—Pieces of WC-6% Co electrodes were potentiostated between —250 and —100 mV, *i.e.*, potential region A of Fig. 1. At these potentials the current slowly decreased with time finally approaching a plateau in more than 10 hr. Figure 3 shows an *i-t* curve at −200 mV which is typical of all plots obtained.

Metallographic examination.—Figure 4 shows a micrograph of a cross-sectional area of a piece of WC-6% Co which was anodized in 1.2M H_3PO_4 for 24 hr. A definite boundary is observed between the binder-free WC skeleton (Fig. 4I) and the WC-6% Co phase (Fig. 4-II). The anodization took place in the dynamic particulate bed system, potentiostated at −60 mV. Further metallographic examinations of selected pieces of anodized WC-6% Co revealed a uniform coating of porous WC phase which covered the entire surface of the cemented carbides.

Reaction products.—WC-6% Co electrodes were potentiostated for several hours at various potentials in regions A and C of the polarization curve of Fig. 1. The solutions were analyzed for Co and W after each

dissolution experiment, the results being shown in Table I. At potentials positive of +600 mV gas was observed evolving from the anode surface. A previous investigator (12) has identified the gaseous products as CO_2 which results from dissolution of WC in aqueous solution.

The weight fractions of W in the dissolved alloy were calculated from the experimental values and are shown in the right-hand column of Table I.

Discussion and Conclusions

Anodic Dissolution of WC-6% Co

Region A.—The solution analyses and micrographs (see Fig. 4) lead to the conclusion that the Co-W binder phase selectively dissolves in region A, leaving behind the WC grains. Binder dissolution thus may be represented by Eq. [1] and [2]. Although tungsten oxidation may be questioned

$$Co \rightarrow Co^{+2} + 2e^- \quad [1]$$

$$(E^\circ \simeq -0.52V \text{ vs. SCE})$$

$$W + 4H_2O \rightarrow WO_4^= + 8H^+ + 6e^- \quad [2]$$

$$(E^\circ \simeq -0.2V \text{ vs. SCE}) \ (13)$$

at the negative end of region A, because $E < E^\circ$, the binder phase appears to dissolve in its entirety at the positive end of A. The tungsten in solution accounts for ~11-14% of the metal dissolved at −0.2 to −0.1V (see Table I), which is in the same range as the fraction of tungsten expected in the binder phase based on the solubility of W in Co (14, 15). A charge balance based on Eq. [1] and [2] was tested by comparing the dissolution currents of Table I to the measured anodic current, i_a. Results are shown in Table II. The measured currents are explained within analytical precision. Inasmuch as insoluble tungsten oxides could not be detected, they were presumed to be insignificant compared to soluble tungsten, thus justifying Eq. [2].

Because most of the current is carried by cobalt dissolution, it is not surprising that the composite

* Below detection limit (see Table I).
** Calculated (see the text).

polarization curve (Fig. 1) is similar to the cobalt polarization curve (Fig. 2), both in position and shape.

Region B.—Binder dissolution is accelerated with increasing potential but then undergoes an abrupt decrease by 80% at ~0.05V. This behavior is characteristic of an active-passive transition. (Figure 3 clearly shows that it is not caused by cobalt depletion.) The composition of the passive film was not identified from the present work, but could conceivably be caused by formation of either tungsten oxide or cobalt phosphate (Fig. 2 shows a somewhat similar curve for cobalt at −0.1V as observed for WC-6% Co at the same potential). The current appears to be limited by dissolution of a film of one of these substances at the passivation points.

Region C.—As the potential is increased, after passivity occurs at B, the current increases slowly at first and then rapidly as E increases beyond 0.6V. This is because reaction [3] becomes significant at potentials positive of its reversible potential. This reaction is characterized by electrode gassing and by complete consumption of the WC-Co alloy to

$$WC + 6H_2O \rightarrow WO_4^{=} + CO_2 + 12H^+ + 10e^- \quad [3]$$

$$(E° \simeq 0V \ vs. \ SCE) \ (13)$$

yield soluble products in the corresponding amounts. Also approximate charge balance is attained by considering Eq. [3] to produce all the soluble W except for a small amount produced by Eq. [2], this latter amount being calculated from the cobalt dissolution. The last entry of Table II shows the result of this comparison.

Application of Results to Corrosion of WC-Co Alloy

When an oxidant is present in solution, its rate of reduction coupled with alloy dissolution will define a corrosion potential and, from Fig. 1 a corrosion current (provided products of the reduction do not precipitate or otherwise complicate reactions [1] and [2]). In the absence of oxygen or other strong oxidants the reduction current will be H^+-ion reduction, for which the polarization curve is shown in Fig. 1. Extrapolation of this curve to the corrosion potential, E_{Corr}, in Fig. 1 yields currents of the same order as those measured from cobalt dissolution at open circuit (see Table II). Thus binder phase dissolution proceeds selectively under these corrosion conditions. The corrosion rate of the binder phase in cemented carbides is also expected to depend on its thickness, which is determined by the amount of cobalt, grain size, and grain size distribution of the WC phase. Low cobalt concentration and small particle size WC decrease the thickness of the Co-W layer on WC. This is exemplified by tests in which decrease in dissolution rate of the binder phase was observed when pieces of 0.5-1μ WC-5.5% Co were substituted for 1-2μ WC-6% Co (16).

Selective dissolution of the binder phase can be and has been (5) used to advantage in the recycling industry. In this case it is desirable to separate the cobalt from the tungsten carbide with as little energy expenditure as possible. Rather than dissolve the entire alloy with a strong oxidizing environment, it is possible to apply mild oxidizing conditions coupled with erosion to effect the separation with little expenditure of electrical energy. Thus particulate WC-6% Co was anodized in a rotating barrel-tank which contained the electrolyte. Anodic current dissolved the Co-containing binder phase, after which the WC phase (see Fig. 4-I) eroded by milling the partially anodized WC-6% Co to WC powder and fresh WC-Co surfaces.

Visible Light Response of Polycrystalline TiO_2 Electrodes

Y. Matsumoto, J. Kurimoto, Y. Amagasaki, and E. Sato

Department of Industrial Chemistry, Faculty of Engineering,

Utsunomiya University, Ishi-icho 2753, Utsunomiya, Japan

ABSTRACT

The photoelectrochemical properties of Co-doped polycrystalline TiO_2 electrodes (Ti/CoO_x) and undoped TiO_2 electrodes have been investigated. The undoped polycrystalline TiO_2 electrodes heated at temperatures over 700°C give the visible light response in addition to the original bandgap photoresponse. The Ti/CoO_x electrodes prepared at 400° ~ 550°C also give the apparent visible light response (550 ~ 420 nm), when the Co was highly doped in the TiO_2 layer from the TiO_2 surface to the interface of the Ti substrate/TiO_2 layer. The visible light response will be based on the newly formed d-band by the interaction of the interstitial Ti or Co ion in the TiO_2 lattice, which is below the π^* conduction band of the TiO_2 in energy position.

Many studies of TiO_2 electrodes which are used for the photoanode in the photoelectrolysis of water have been conducted (1-25). TiO_2 is suitable for the photoanode material in point of view of the stability in aqueous solution, but its large bandgap (3.0 eV) brings about only small efficiency in using the solar spectra: photons with shorter wavelengths than 400 nm responsible for hole production in TiO_2 is only about 3% in all solar photons (26). Therefore, some modifications of TiO_2 are necessary in using it as the photoanode material in order to increase the efficiency of solar energy conversion.

Recently, a few favorable results of the modified TiO_2 electrodes are reported. Maruska and Ghosh report that Al-doped and Cr-doped TiO_2 single crystals bring about the increases of the ultraviolet light (wavelengths shorter than about 420 nm) response and visible light (wavelengths longer than about 420 nm) response, respectively (16, 17). Augustynski *et al.* use polycrystalline TiO_2 electrodes doped with various elements, Al, Sr, Ga, Eu, B, and Be, as the photoanode (18, 19). Al and Be-doped TiO_2 electrodes show the interesting result that the quantum efficiencies to the ultraviolet light increase like Al-doped TiO_2 single crystal electrodes as stated above.

Polycrystalline TiO_2 electrode is more suitable for the photoanode than single crystal TiO_2 in preparation cost. Therefore, we use the polycrystalline TiO_2 electrodes doped with Co as the photoanode material in this paper, which is prepared with the thermal decomposition of aqueous solution of the Co salts. This electrode has also been investigated as the anode material in the chlorine and oxygen evolution reactions, and the high catalytic activity of Co_3O_4 formed on the electrode is demonstrated (27, 28). In this paper, as a result, Co_3O_4 layer does not influence the spectral dependence of the photocurrent but only the Co-doped TiO_2 layer shows interesting visible light response. Although the photocurrent of the polycrystalline TiO_2 due to the lights of the 500W xenon lamp fairly decreases by the Co coating, the extension of the spectral response by the Co-doping demonstrated in this paper suggests the possibility of raising the efficiency of solar energy conversion in spectra.

Experimental

The titanium plate (99.6%, 1.5 × 5 × 0.1 cm, Kobe Steel, Limited) was polished with emery papers and then washed with a cleanser (Marufuku, Limited). The sample was cleaned with the hypersonic technique, followed by washing with acetone. Coatings were applied by painting the $Co(NO_3)_2$ solution with a few drops of 30% H_2O_2 and then heating it in air at 400°C for 10 min. Five separate coatings were applied. After the final coating, the specimen was finally heated in air at various temperatures over 400°C for 1 hr, unless otherwise stated. The geometric area exposed to the electrolyte was reduced to 1 cm^2 on one side by epoxy resin to mask off the remainder of the electrode. The above Co coating electrode is represented as Ti/CoO_x electrode for convenience in this paper.

Co_3O_4, rutile, and anatase were observed for the samples finally heated at the temperatures from 550° to 700°C by x-ray analysis. Similar oxides will exist on the samples finally heated at 400°C, although the clear diffraction peak was not observed.

The solution was pre-electrolyzed 0.5M H_2SO_4. Hg/Hg_2SO_4 electrode was used as the reference electrode and electrode potentials cited in this paper are referred to this electrode. The counterelectrode was a platinum plate. A quartz H-type cell was used as an electrolytic cell. The polarization curves were measured by using a potentiostat (Nichia Keiki Limited, NP-G1050) and a function generator (Nichia Keiki Limited), and recorded by an X-Y recorder (Yokogawa Electric Works Limited, Type-3036). The monochromatic light of various wavelengths was obtained by a prism monochromator. A 500W xenon lamp (1.1 W/cm^2) was used as a light source. A sequence of measurements was done with the same experimental setup, so that the irradiation intensity is believed to have been kept constant during measurements. All measurements were done at room temperature.

Results

Figure 1 shows the current-potential curves under illumination with a 500W xenon lamp for the undoped TiO_2 and the Ti/CoO_x electrodes. For the Ti/CoO_x electrodes, two types are given in this figure. One is the nontreated Ti/CoO_x electrode and the other is the pre-electrolyzed Ti/CoO_x electrode at 2.5V for 2.5 hr under dark, at which oxygen evolution occurs. The potential for the onset of the photocurrent shifts to more positive potentials by the Co coating. This positive shift is undesirable for the photoelectrolysis with and without external voltage in a point of view of the energy conversion efficiency. However, the Ti/CoO_x electrodes were improved so that their photocurrent onset potentials come close to those of the TiO_2 electrodes by the pre-electrolyzed treatment, as the figure shows.

The Co_3O_4 layer on the Ti/CoO_x electrode probably causes positive shift in the flatband potential. This will be the main reason for the positive shift of the photocurrent onset potential by the Co coating. Oxygen evolution will strip off the Co_3O_4 layer from the

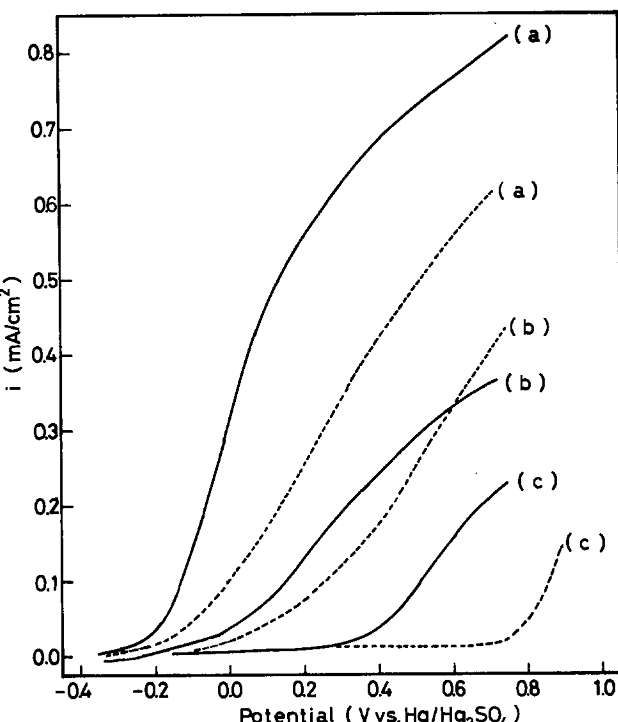

Fig. 1. Current-potential curves for TiO_2 and Ti/CoO_x electrodes heated for 1 hr under illumination with a 500W xenon lamp. (———) heated at 550°C, (- - - -) heated at 400°C, curve (a) TiO_2, curve (b) pre-electrolyzed Ti/CoO_x (2.4×10^{-7} mole Co/cm²), curve (c) Ti/CoO_x (2.4×10^{-7} mole Co/ Co/cm²).

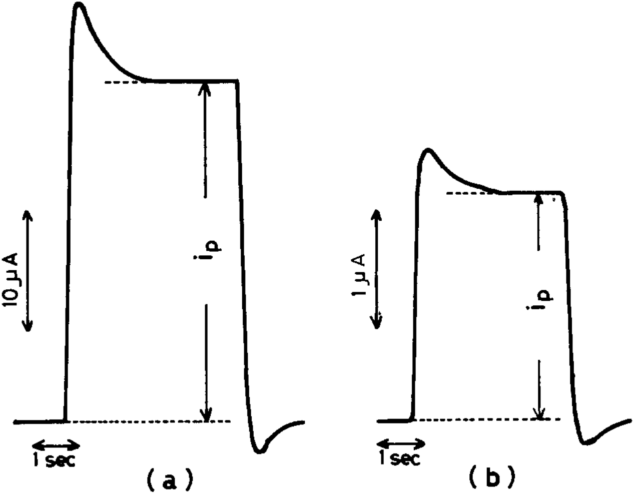

Fig. 2. Photoresponses of a pre-electrolyzed Ti/CoO_x (2.4×10^{-7} mole Co/cm²) electrode. (a) for $\lambda = 320$ nm, (b) for $\lambda = 450$ nm.

electrode surface of the Ti/CoO_x electrode by its gas pressure, leading to the direct exposure of the TiO_2 layer of the electrode to the electrolyte. Therefore, the flatband potential of the pre-electrolyzed Ti/CoO_x electrode becomes to be near that of the TiO_2 electrode, so the photocurrent onset potential of the Ti/CoO_x electrode shifts to negative by the pre-electrolyzed treatment. In any case, the good characteristic of the visible light response of the Ti/CoO_x electrode is almost the same as that of the pre-electrolyzed Ti/CoO_x electrode as described in a later section, although the photocurrents of the Ti/CoO_x electrodes are smaller than that of the TiO_2 electrode under illumination of ultraviolet lights.

The typical photoresponses of the pre-electrolyzed Ti/CoO_x electrode, which was prepared at 550°C for 1 hr, to the monochromatic lights of 320 and 450 nm at a constant potential of 0.6V are shown in (a) and (b) of Fig. 2, respectively. Both of the photoresponses are fast, as the figure shows. Similar photoresponses are also observed to the other monochromatic lights. The real photocurrent is the difference between the dark current and the illumination current, and is determined by the difference between the constant dark current and the constant illumination current in this paper (represented as i_p in this figure).

The spectral dependences of the real photocurrents obtained by the above method are shown in Fig. 3, 4, 5, and 6. It should be noticed in Fig. 3 that the apparent photocurrents due to the lights with the longer wavelength than about 410 ~ 420 nm (LW lights) appear for the Ti/CoO_x electrodes in addition to the original bandgap photocurrent of TiO_2 due to the lights with the shorter wavelength than about 410 nm (SW lights). The quite similar spectral dependence to Fig. 3 for the Ti/CoO_x electrode is also observed in 1M NaOH. Therefore, the above photocurrents due to the LW lights are mainly based on the oxidation reaction of H_2O or OH^- due to the produced hole. Moreover, no difference between the Ti/CoO_x electrode prepared by using $CoCl_2$ solution and the above Ti/CoO_x electrodes which are prepared by using $Co(NO_3)_2$ solution as described in the Experimental section, was observed in the spectral dependence of the photocurrent. This result confirms that the photocurrents due to the LW lights are assigned to Co. The low photocurrents of the Ti/CoO_x electrodes due to the SW lights are mainly based on disturbing to light passing to the TiO_2 layer by Co_3O_4 layer formed on the surface, because the photocurrents due to the SW lights increase by the pre-electrolyzed treatment as the figure shows. The photoresponses of

(c) Ti/CoO_x (2.4×10^{-7} mole Co/cm²) heated at 550°C, (d) pre-electrolyzed Ti/CoO_x (2.4×10^{-7} mole Co/cm²) heated at 400°C.

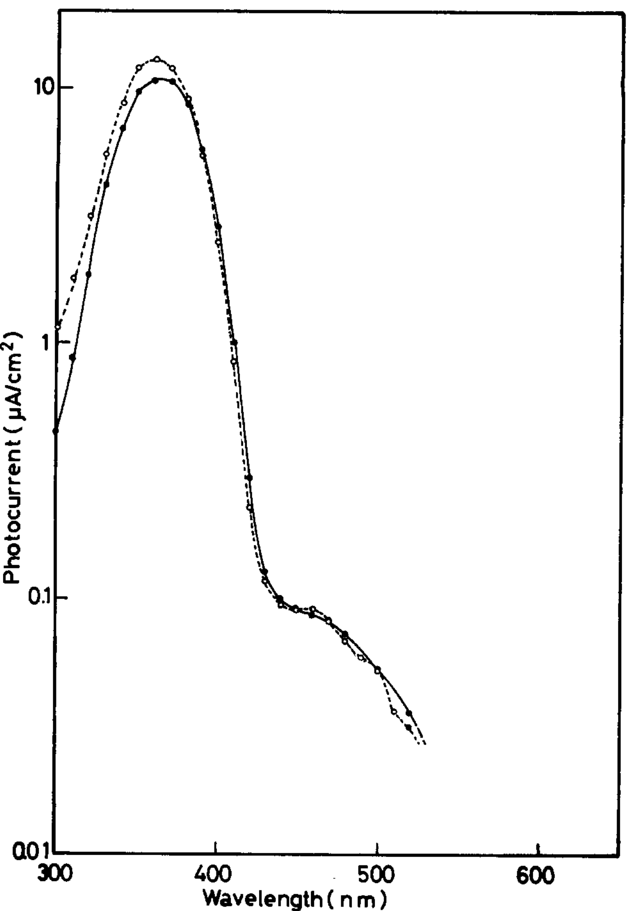

Fig. 4. Spectral dependences of the photocurrent (i_p) for TiO_2 and Ti/CoO_x (2.4×10^{-7} mole Co/cm^2) electrodes heated at 700°C for 1 hr (- -○- -) TiO_2, (—●—) Ti/CoO_x.

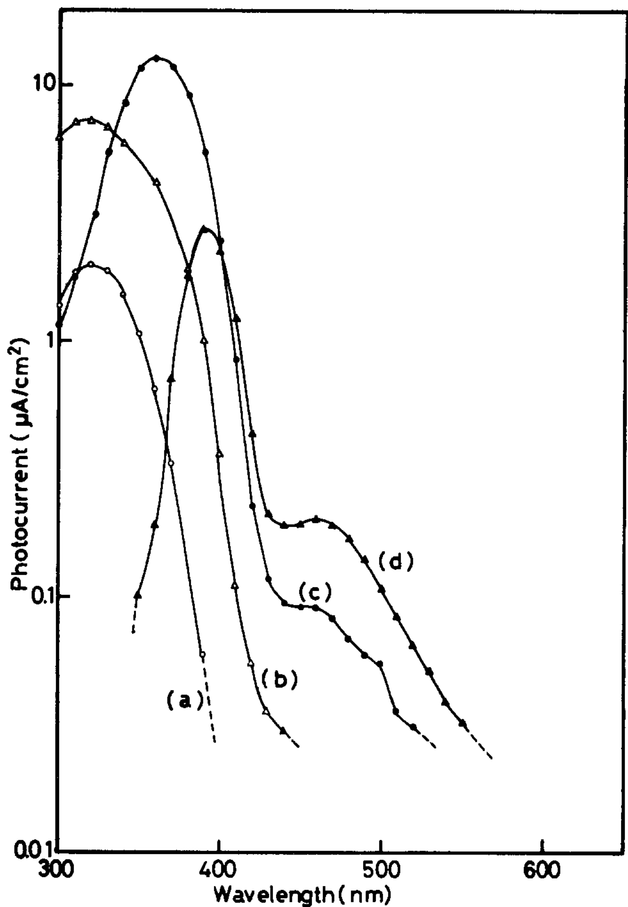

Fig. 5. Spectral dependences of the photocurrent (i_p) for TiO_2 electrodes heated for 1 hr. Curve (a) heated at 400°C, curve (b) at 550°C, curve (c) at 700°C, curve (d) at 800°C.

the Ti/CoO_x electrodes to the LW lights are associated with the highly doped Co in the TiO_2 lattice as stated in a later section.

In the cases of the electrodes heated at 700°C, almost the same spectral dependences were obtained for both the TiO_2 and the Ti/CoO_x electrodes as shown in Fig. 4. As shown in Fig. 5, in which the spectral dependences of the photocurrents for the TiO_2 electrodes heated at various temperatures are shown, the photocurrents due to the LW lights were observed for the electrodes heated at temperatures over 700°C. The same spectral dependences as Fig. 5 are also obtained for the TiO_2 electrodes heated in gas mixture of 0.2 atm O_2 and 0.8 atm He. Therefore, the photocurrents due to the LW lights shown in Fig. 4 are not assigned to Co, but simply to the heat-treatment at high temperature. In other words, the effect of Co on the LW lights response disappears by the heat-treatment at temperature over 700°C.

Two remarkable features of the spectral dependences of the photocurrents for the TiO_2 electrodes are brought about by the heat-treatment at temperatures over 700°C as shown in Fig. 5. One is the appearance of the photoresponse to the LW lights at the TiO_2 electrode as described previously. This will be based on the newly formed narrow band in the bandgap of the TiO_2. The other is of the photocurrents due to the SW lights. The peak of the photocurrent due to the SW lights becomes sharp and shifts to the long wavelength, showing that the conduction band and the valence band in the TiO_2 varied in energy. The TiO_2 electrodes which are prepared by using 99.9% Ti plate (High purity, Limited) also give quite similar spectral dependences to Fig. 5. Therefore, the above phenomena eventually will be given by some morphologic variations in the TiO_2 lattice due to the heat-treatment at high temperature.

Figure 6 shows the variation of the spectral dependences of the photocurrents of the Ti/CoO_x electrodes with the time of the final heat-treatment of 550°C. Although the appropriate time for the thermal diffusion of Co into the TiO_2 bulk will be desired, the photocurrents due to the LW lights decrease with the heat-treatment time. In this figure, the photoresponse of the $Ti/TiO_2/CoO_x$ electrode which is prepared as follows, is also shown. After the Ti plate coated by $TiCl_4$ solution (8.7×10^{-8} mole/cm^2) was heated in air at 550°C for 1 hr, the $Co(NO_3)_2$ solution was coated on the surface so that the amount of Co is 2.4×10^{-7} mole/cm^2, and then decomposed at 400°C five times. Finally, the sample was heated at 550°C for 20 min. Therefore, the TiO_2 layer of the $Ti/TiO_2/CoO_x$ electrode is the thickest in the electrodes in Fig. 6, while the photocurrent due to the LW lights at this electrode is the smallest as the figure shows.

From the above results, it is concluded that the thick TiO_2 layer in the side of the Ti substrate of the Ti/CoO_x electrode is undesirable for the photoresponse to the LW lights. This is in line with the result that the photocurrents due to the LW lights decrease with the heat-treatment time, because the thickness of the TiO_2 layer increases with the heat-treatment time. Moreover, the above conclusion is confirmed by the result that no photoresponse to the LW lights is observed for the TiO_2 (single crystal)/CoO_x electrodes which are prepared by coating the various amounts of Co on the single crystal TiO_2 and then heating at 550°C for 1 hr. Thus, it is required that the highly Co doped TiO_2 layer reaches to the Ti substrate interface for the purpose of obtaining the high LW lights photoresponse for the Ti/CoO_x electrode.

Discussion

Spectral dependence of the thermally oxidized TiO_2 electrode.—The band structure of the TiO_2 rutile proposed by Goodenough (29) is shown in (a) of Fig. 7 (in other figures of band structures, $t_{\parallel}$-band is omitted). The valence band is the Ti-O π band and the conduction band is the Ti-O π^* band. The Ti cation is octahedrally surrounded by the oxygen ion in the lattice, therefore, the π and π^* bands are formed by the interaction between the t_{2g} orbital of the Ti cation and the p_π orbital of the oxygen ion (29). The anatase structure also has the same octahedral unit, but is different only in the arrangement of this unit. This arrangement affects the π and π^* bonds little, leading to the similar band structure to Fig. 8 for the anatase. Since the hole is formed in the π band by the π band → the π^* band transition, the photocurrent appears only when the lights with the wavelengths corresponding to the energies from E_g (bandgap) to E are illuminated, as shown in Fig. 7. Therefore, the broadness and the position of the peak of the photocurrent due to the SW lights (see Fig. 5) will be mainly determined by the degree of the interaction between the t_{2g} orbital of Ti cation and the p_π orbital of the oxygen ion, which will depend on the distance between both ions. If the interaction becomes weak, the peak of the photocurrent becomes sharp and shifts to the long wavelength, *i.e.*, the low energy transition. As shown in Fig. 5, the same variation of the photocurrent as stated above for the TiO_2 electrode heated at temperatures over 700°C, therefore, is based on the decrease of the degree of the Ti-O π interaction. The interstitial Ti ions exist in the TiO_2 layer prepared by the thermal oxidation (29-32), especially in the Magnéli phase (33, 34). This is represented as Ti-$(Ti)_i$-Ti in the lattice, and affects the Ti-O bond in the octahedral unit (29). The decrease of the degree of the Ti-O π interaction for the electrode heated at high temperature will be brought about by a number of the interstitial Ti ions produced by the heat-treatment at high temperature. In addition, a number of the interstitial Ti ions will bring about the new band in the TiO_2. This new band will be the d-band formed by the interaction between the d-orbitals of the Ti ion, Ti-$(Ti)_i$-Ti in the lattice. Since the d-orbital of the Ti ion in the lattice is near or below the π^* band in energy position (29), the newly formed d-band will also be a little below the π^* band, and overlap the bottom of the π^* band. As a result, the photocurrent due to the LW lights, the low energy transition of the π band → the d-band [E' in (b) of Fig. 7], appears for the electrode prepared at the heat-treatment at temperatures over 700°C. The band structure of this TiO_2 electrode is shown in (b) of Fig. 7, which also shows the energy variations of the π and π^* bands.

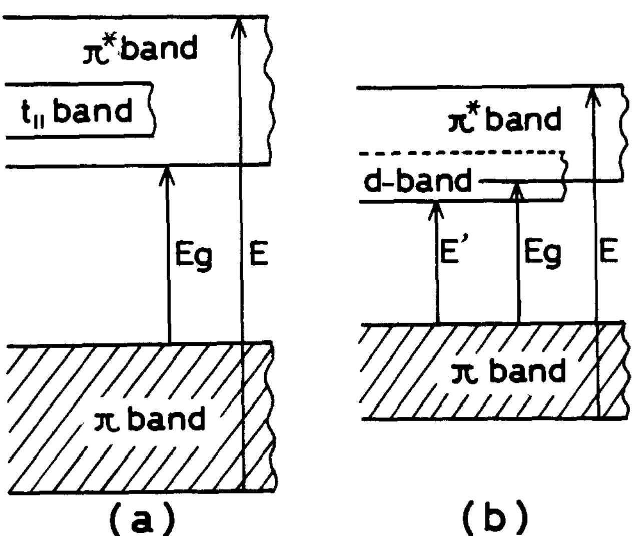

Fig. 7. Band structures of TiO_2. (a) for TiO_2 rutile, (b) for TiO_2 heated at high temperature.

Spectral dependence of the Ti/CoO_x electrode.—The photoresponse to the LW lights does not appear on the Ti/CoO_x electrode when Co was highly doped only on the surface of the TiO_2 layer. If the Co impurity band or the surface state due to the Co is formed a little above the π valence band in energy position, the photoresponse to the LW lights should be observed at this type electrode because the hole is always produced in the Co impurity band or the surface state by the transition from this band or state to the π^* conduction band due to the LW lights. Therefore, this is not proper in energy position. The Co impurity band exists below the π^* conduction band in the Ti/CoO_x electrode. Figure 8 shows the two types

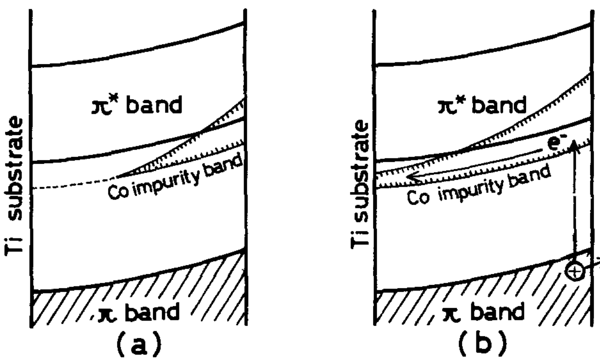

Fig. 8. Band structures of Co-doped TiO_2 layers of Ti/CoO_x electrodes. (a) Co impurity band is formed only in the surface region of the TiO_2 layer. (b) Co impurity band is formed throughout the TiO_2 layer.

of the band structures in this case. Figure 8(a) shows the case of the electrode doped only on the surface. As shown in (a) of this figure, the excited electron in the Co impurity band due to the LW lights cannot move to the bulk, leading to no photoresponse. On the other hand, in the case of the electrode in which Co was highly doped through the TiO_2 layer, from the surface to the interface of the TiO_2 and the Ti substrate, the excited electron in the Co impurity band can move into the Ti substrate through this band in the TiO_2 layer. This case leads to the appearance of the LW lights photoresponse, which is shown in (b) of Fig. 8.

The Co impurity band is formed only by the heat-treatment at the appropriate temperature (400° ~ 550°C). This implies that the Co is situated in the appropriate position in the TiO_2 lattice by the above temperature range so that the Co impurity band is formed. There will be two appropriate positions in the lattice. One is the Ti ion site in the TiO_2 lattice: the Ti ion is substituted by the Co ion. The other case is the interstitial site which is represented by Ti-$(Co)_I$-Ti as described in the previous section. In any case, the Co impurity band will be formed by the interaction between the d orbitals of the Co ions in the lattice.

In conclusion, the Ti/CoO_x electrode with small amounts of Co prepared at 550°C heat-treatment is superior in the visible light photoresponse. Therefore, this type of electrode is suitable for the photoanode for the photoelectrolysis of water with solar energy, but some improvements are further necessary in order to obtain the large photocurrent.

The Application of Linear Sweep Voltammetry to a Rotating Disk Electrode for the Reversible Deposition of an Insoluble Species

P. C. Andricacos* and H. Y. Cheh**

Department of Chemical Engineering and Applied Chemistry, Columbia University, New York, New York 10027

ABSTRACT

A Nernst diffusion model was employed to obtain an analytical expression for the transient current response of a reversible deposition reaction with insoluble product occurring on a rotating disk electrode under linear potential sweep conditions. The results indicated that for low sweep rates the current increases monotonically with time. However, at high sweep rates a maximum value for the current density at finite values of time is predicted. The peak current density normalized with respect to the diffusion limiting current density was found to be a linear function of the square root of a dimensionless sweep rate. Furthermore, in this region the response of a rotating disk electrode is the same as that in a stagnant system. An experimental investigation based on the reversible deposition of silver showed good agreement with the theoretical predictions.

Linear sweep voltammetry (LSV) in stagnant systems has developed into a useful analytical technique for the investigation of complex electrochemical mechanisms (1, 2). In a typical LSV experiment, the potential of a plane, cylindrical, or spherical electrode is increased linearly with time at a fixed rate and the current is measured. The electrolyte is stagnant and, therefore, the mathematical analysis is based on a semi-infinite diffusion model.

A complication often encountered in the application of LSV is the presence of natural convection. To reduce this effect, most investigations have been based on short time responses. An alternate approach would be to introduce well-defined forced convection. The rotating disk electrode (RDE) is a natural choice since the forced convection regime that it establishes has been described quantitatively in the literature (3). One can anticipate that the application of LSV to an RDE will lead to a powerful analytical tool.

An exact mathematical analysis of convective transport to an RDE with time-dependent electrode potential or current density is extremely complicated. Approximate methods have usually been employed in practice to perform this analysis. Let us describe two of these methods since both of them have been applied previously to the problem of LSV on the RDE.

Filinovskii and co-workers (4, 5) developed an analytical approximation in which the highest order term in the space coordinate was dropped from a transformed convective diffusion equation, using the argument that its effect would be small since the main region of concentration variation lies very near the electrode surface. The physical meaning of this approximation is dubious because the neglected term includes contributions from both convective and diffusive transport. For the problem of applying a step potential or current, Krylov and Babak (6) showed that the validity of this approximation deteriorates as time increases up to a maximum of approximately 7%. Similar conclusions were reached by Viswanathan and Cheh (7).

The other approximate method is based on the Nernst diffusion model. Convection is neglected in the governing diffusion equation. It is, however, included in the evaluation of the thickness of the diffusion layer. The Nernst diffusion model was first applied to the RDE by Siver (8, 9) for the application of galvanostatic and potentiostatic steps. Siver's results were compared by Hale (10) to numerical results which included convective effects. The maximum error by using the simple model was reported to be 4% for the case of the galvanostatic step. Other problems which have been based on the Nernst model include the investigations of Cheh (11, 12) on pulsed and periodically reversed currents, those of Buck and Keller (13) on step currents, and those of Tokuda and Matsuda (14-16) for a-c voltammetry. For the case of pulsed currents, Viswanathan *et al.* (17) have shown that the results based on the Nernst diffusion model agreed well with those based on a numerical calculation including convection for an RDE system.

Both Filinovskii's analytical approximation and the Nernst diffusion model have been applied to the problem of LSV on the RDE, the former by Girina *et al.* (18), the latter by Fried *et al.* (19-21). Both groups dealt with the problem of a reversible reaction with a soluble product. In the work by Fried and co-workers (19), the time dependence of the current density is given in terms of an integral which has to be evaluated numerically. As has been the case with LSV in stagnant systems, the quantities of interest are the dependence of the peak current density on the sweep rate and the value of the overpotential at which the current peak occurs. The current transient is of secondary importance. In this respect, the work of Fried and co-workers (19) fails to provide clear diagnostic criteria.

On the other hand, Girina *et al.* (18) reported that if the peak current density is normalized with respect to the diffusion limiting current density, and if the sweep rate is normalized with respect to the characteristic time of the RDE, then the resulting dimensionless current is a linear function of the square root of the dimensionless sweep rate, provided that diffusion is the rate-controlling process. Furthermore, these authors concluded that for short times, the response of the RDE is the same as that of a stagnant system. In other words, for short times the RDE is described by the classical Sevcik-Randles relation (22, 23). The same conclusion was reached by Fried *et al.* (21).

It is the purpose of the present paper to apply the Nernst diffusion model to the problem of LSV on an RDE for the simple case of a reversible reaction with an insoluble product. The theoretical results are then compared with experimental findings.

Theoretical

Consider the reversible reaction

$$O + ne^- \rightarrow R \qquad [1]$$

where O and R represent the chemical formula for the oxidized and reduced species, respectively, and n is the number of electrons transferred during the reaction. R is an insoluble species. The electrode potential, $E(t)$, is swept linearly with time at a rate v, *i.e.*

$$E(t) = E_i - vt \qquad [2]$$

where E_i is the equilibrium potential based on the bulk concentration of O, c^b, and t is time. Since E_i is the equilibrium potential, no current flows initially through the system. Thus, the concentration of O on the electrode surface is initially equal to c^b. Let the RDE be situated at $x = 0$, and the edge of the Nernst diffusion layer at $x = \delta$. In terms of the following dimensionless variables

$$C(\xi,\tau) = 1 - c(\xi,\tau)/c^b \qquad [3]$$

$$\xi = x/\delta \qquad [4]$$

$$\tau = Dt/\delta^2 \qquad [5]$$

the diffusion equation and the boundary conditions are

$$\frac{\partial C}{\partial \tau} = \frac{\partial^2 C}{\partial \xi^2} \qquad [6]$$

$$C(\xi,0) = 0 \qquad [7]$$

$$C(1,\tau) = 0 \qquad [8]$$

$$\frac{\partial C}{\delta \xi}(0,\tau) = -\frac{i(\tau)}{i_l} \qquad [9]$$

where $C(\xi,\tau)$ is the dimensionless concentration defined by Eq. [3], ξ and τ are the dimensionless distance and time defined by Eq. [4] and [5], respectively, D is the diffusion coefficient of O, $i(\tau)$ is the current density passing through the system at time τ, and i_l is the diffusion limiting current density defined by

$$i_l = n\mathbf{F}Dc^b/\delta \qquad [10]$$

Equation [6] subject to boundary conditions, Eq. [7]-[9], can be solved by the method of Laplace transform. Let $\overline{C}(\xi,p)$ be the Laplace transform of $C(\xi,\tau)$

$$\overline{C}(\xi,p) = L\{C(\xi,\tau)\} = \int_0^\infty e^{-p\tau} C(\xi,\tau)\,d\tau \qquad [11]$$

where p is the Laplace parameter. The solution is straightforward, and we obtain the following equation for the transformed current

$$\frac{\overline{i}(p)}{i_l} = p\overline{C}(0,p) \times p^{-1/2}\coth(p^{1/2}) \qquad [12]$$

$$= L\left\{\frac{\partial C}{\partial \tau}(0,\tau)\right\} \times L\{\theta_3(0,\pi i\tau)\} \qquad [13]$$

where

$$\overline{i}(p) = L\{i(\tau)\} \qquad [14]$$

and $\theta_3(0,\pi i\tau)$ is one of the theta functions (24) defined by

$$\theta_3(0,\pi i\tau) = 1 + 2\sum_{j=1}^{j=\infty} \exp(-j^2\pi^2\tau) \qquad [15]$$

By applying the convolution operation to Eq. [13], we obtain

$$\frac{i(\tau)}{i_l} = \int_0^\tau \frac{\partial C}{\partial \tau}(0,\tau-\lambda) \times \theta_3(0,\pi i\lambda)\,d\lambda \qquad [16]$$

where λ is a dummy variable.

A comparison between Eq. [16] and the solution of the corresponding problem in a stagnant system reveals that the only difference between the response of the RDE and that of the stagnant system (25) is the kernel of the integral. Whereas the kernel in Eq. [16] is the function $\theta_3(0,\pi i\lambda)$, that of the stagnant system is $(\pi\lambda)^{-1/2}$. By using an alternate expression (24) for $\theta_3(0,\pi i\lambda)$

$$\theta_3(0,\pi i\lambda) = (\pi\lambda)^{-1/2}\left[1 + 2\sum_{j=1}^{j=\infty}\exp(-j^2\lambda^{-1})\right] \qquad [17]$$

one sees that either as $\delta \rightarrow \infty$ or as $t \rightarrow 0$, the two systems become identical.

An explicit expression for the current density can be obtained from Eq. [16], once the dependence of $C(0,\tau)$ on τ is known. By introducing the dimensionless sweep rate, σ

$$\sigma = n\mathbf{F}v\delta^2/RTD \qquad [18]$$

such a dependence can be obtained from the Nernst equation for the electrode potential and Eq. [2]. Assuming that reaction [1] proceeds under equilibrium conditions in an ideal solution

$$C(0,\tau) = 1 - \exp(-\sigma\tau) \qquad [19]$$

from which

$$\frac{\partial C}{\partial \tau}(0,\tau-\lambda) = \sigma\exp(-\sigma\tau)\exp(\sigma\lambda) \qquad [20]$$

By combining Eq. [20] and Eq. [16] an explicit expression can be obtained for the normalized current density as a function of dimensionless time

$$\frac{i(\tau)}{i_l} = 1 - \sigma^{1/2}\cot(\sigma^{1/2})\exp(-\sigma\tau) + \sum_{j=1}^{j=\infty}\frac{2\sigma}{\sigma - j^2\pi^2}\exp(-j^2\pi^2\tau) \qquad [21][1]$$

Equation [21] indicates that as $\tau \rightarrow \infty$, $i(\tau)/i_l \rightarrow 1$. On the other hand, for $\tau = 0$, $i(\tau)/i_l = 0$.[1] For intermediate times, the normalized current density is a continuous function of dimensionless time. Numerical illustration of Eq. [21] is presented in Fig. 1. It is seen that for small values of σ, $i(\tau)/i_l$ increases monotonically from 0 to 1 as τ increases from 0 to ∞. For larger values of σ, a maximum value of the normalized

[1] The identity

$$\cot(c\pi) = (\pi c)^{-1} - \pi^{-1}\sum_{j=1}^{j=\infty}\frac{2c}{j^2 - c^2}$$

has been used in this derivation (26).

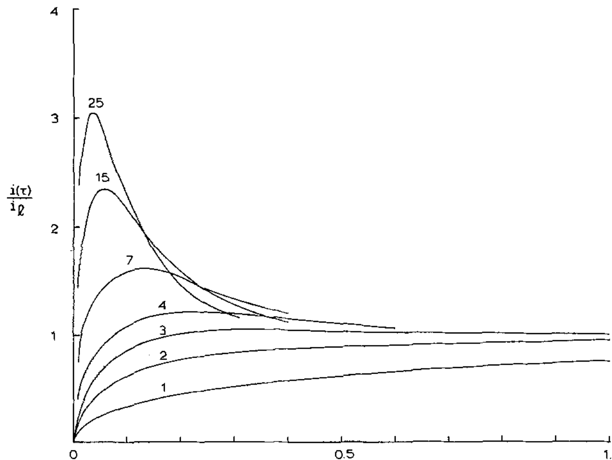

Fig. 1. Graphical representation of Eq. [21]. Numbers on curves indicate values of the dimensionless sweep rate.

current density occurs at finite values of τ. The condition at the maximum is

$$\frac{d}{d\tau}\left\{\frac{i(\tau)}{i_l}\right\}_{\tau=\tau_m} = 0 \qquad [22]$$

or

$$\sigma^{1/2}\cot(\sigma^{1/2})\exp(-\sigma\tau_m) = \sum_{j=1}^{j=\infty}\frac{2j^2\pi^2}{\sigma - j^2\pi^2}\exp(-j^2\pi^2\tau_m) \qquad [23]$$

A numerical analysis of Eq. [23] showed that τ_m is inversely proportional to σ for

$$\sigma > 4, \quad \sigma\tau_m = 0.854 \qquad [24]$$

The maximum or peak current density, i_p, can be calculated by combining Eq. [23] and [21]

$$\frac{i_p}{i_l} = (\pi\tau_m)^{-1/2}\left[1 + 2\sum_{j=1}^{j=\infty}\exp(-j^2\tau_m^{-1})\right] \qquad [25]$$

For $\sigma > 4$, the contribution of the series in Eq. [25] is negligible for all practical purposes. By neglecting the series and combining Eq. [25] and [24], one finds that

$$\frac{i_p}{i_l} = 0.611\sigma^{1/2} \qquad [26]$$

This equation shows that the peak current density, i_p, normalized with respect to the limiting current density is a linear function of $\sigma^{1/2}$. The slope is a constant independent of any physical property of the system. Also, by substituting into Eq. [26] the value for δ as derived by Levich (3)

$$\delta = 1.61 D^{1/3}\nu^{1/6}\omega^{-1/2} \qquad [27]$$

we obtain

$$\frac{i_p}{i_l} = 0.98(n\mathbf{F}v/RT\omega)^{1/2}(\nu/D)^{1/6} \qquad [28]$$

where ν is the kinematic viscosity of the electrolyte and ω is the rotation speed of the RDE. Equation [28] indicates that i_p/i_l has a weak dependence on the physical properties of the electrolyte.

Since for cases where there is no maximum for $i(\tau)/i_l$ its limiting value is 1, the minimum value of σ for which i_p/i_l can occur at finite values of τ_m is governed by

$$0.611\sigma^{1/2} > 1 \qquad [29]$$

or

$$\sigma > 2.68 \qquad [30]$$

An important quantity associated with i_p is its corresponding electrode potential. By combining Eq. [2], [5], [18], and [24], we obtain

$$\eta_p = E_p - E_i = -0.854RT/n\mathbf{F} \qquad [31]$$

$$= -22/n \text{ mV at } 25°\text{C} \qquad [32]$$

where η_p and E_p are the peak overpotential and the peak electrode potential, respectively. η_p is independent of the sweep rate, rotation speed, and physical properties of the system. Furthermore, in terms of dimensional quantities

$$i_p = 0.611 n^{3/2}\mathbf{F}^{3/2}R^{-1/2}T^{-1/2}D^{1/2}v^{1/2}c^b \qquad [33]$$

$$= 367 n^{3/2}D^{1/2}v^{1/2}c^b \text{ at } 25°\text{C} \qquad [34]$$

where i_p is in A/cm^2 and c^b is in moles/liter. Equation [33] implies that for $\sigma > 4$, i_p is independent of the rotation speed. Equations [31] and [33] are identical to the ones describing the LSV response of a reversible reaction with insoluble product in a stagnant system (27, 28). This result should not be surprising since the effects of convection are small at short times with high sweep rates.

Experimental

To experimentally verify the theory of LSV on an RDE for a reversible reaction with insoluble product, the deposition of Ag from $AgNO_3$ was chosen for the present study. This reaction has a very high exchange current density, which has been reported to be more than 1 A/cm^2 (29).

The experimental procedure involved two steps: (*i*) the determination of the limiting current density, and (*ii*) the determination of the peak current density upon linear sweeping of the potential. The cell employed had three compartments each for the reference, counter, and working electrodes. A Pt spiral and a saturated calomel electrode were used as counter and reference electrodes, respectively. The working electrode was a Pt rotating disk (Pine Instruments, DT6) mechanically polished to a mirror-like surface. It was rotated by a Pine Instruments Analytical Rotator modified by the addition of a low speed motor for use at low rotation speeds. A potentiostat/sweep generator (Pine Instruments, RDE3) and an X-Y recorder (Hewlett-Packard, 7044A) completed the electronic circuitry. The solution contained 2.057 mmoles $AgNO_3$, 1M KNO_3, and 0.01 g/liter gelatin. The latter was added to prevent the deposit from flaking off during the course of the experiment. The electrolyte was continuously deaerated with N_2. Prior to a run, Ag was deposited on the Pt RDE for 1/2 hr at approximately 50 $\mu A/cm^2$. In this fashion, deposition during the runs occurred on Ag rather than on Pt. This procedure approximated the theoretical assumption that the deposit had unit activity. At rotation speeds higher than 200 rpm, it was found that limiting currents were irreproducible, probably due to a nonuniform deposition which increased the surface area. Hence, lower rotation speeds were used.

The Levich equation for the limiting current density (3) was obeyed well for all rotation speeds used in this study. This indicated that the effect of natural convection is negligible even at $\omega = 37$ rpm, corresponding to a Reynolds number of approximately 60. The effect of natural convection on limiting current densities at low values of the Reynolds number has been found negligible in several investigations (30-34). Regarding the peak current density, one should note that natural convection has even smaller effects, since the concentration gradient at the peak current is less pronounced than at the limiting current. This can be easily seen with the aid of Eq. [19] and [24] indicating that the surface concentration at the peak current is 43% of the bulk value, as opposed to 0 in the limiting current region.

Experimentally obtained currents transients for $\omega = 37$ rpm are shown in Fig. 2. The corresponding i_p/i_l *vs.* $\sigma^{1/2}$ correlation is shown in Fig. 3. The value of 0.9 $\times 10^{-2}$ cm^2/sec was used for the kinematic viscosity of the electrolyte (35). The corresponding value for the diffusion coefficient of Ag^+ obtained from i_l *vs.* $\omega^{1/2}$ lines was 1.2×10^{-5} cm^2/sec. Peak overpotentials appeared at 30-55 mV to be compared with the theoretical value of 22 mV. Since peak overpotentials shift to more cathodic values as the sweep rate or peak current increases, their deviation from the theoretical value may be due to the uncompensated ohmic drop. Good agreement has been obtained between the theoretical predictions regarding the dependence of i_p/i_l on $\sigma^{1/2}$ and the experimental findings.

It should be mentioned here that additional experiments were carried out for two other systems. These were the deposition of Cu from $CuSO_4$ and the evolution of H_2 on Pt from an HCl solution (36). Linear dependence of i_p/i_l on $\sigma^{1/2}$ was observed in both cases. However, the slope of the lines and the peak overpotentials deviated considerably from the theoretical calculations. It is our postulate that the deviations from the theory are due primarily to the irreversibility of these reactions. Current work is being continued

to extend our theoretical investigation to include irreversible effects.

Conclusions

The problem of LSV on an RDE on which a reversible deposition reaction occurs was treated analytically by the use of a Nernst diffusion model. An explicit expression for the current transient was obtained. In terms of a dimensionless sweep rate and the peak current density normalized with respect to the limiting current density, the following conclusions were reached. For slow sweeps, no current maxima occur. For faster sweeps, the normalized peak current density is a linear function of the square root of the dimensionless sweep rate. The slope is a constant independent of any physical property of the system. In addition, the normalized peak current density shows a weak dependence on the physical properties of the electrolyte. The overpotential at which the current peaks occur depends only on temperature and on the number of electrons transferred during the reaction. Furthermore, the RDE response is the same as that in a stagnant system.

Good agreement was observed between the theoretical predictions and experimental results obtained for the reversible deposition of Ag. Deviations from the theory occurred in reactions with irreversible kinetics, such as the deposition of Cu and the evolution of H_2 on Pt.

Chemistry Department, Willamette University, Salem, Oregon 97301

ABSTRACT

The initial thermoelectric power (*TEP*) for hydrogen electrode thermocells has been determined for aqueous solutions of a weak acid, sulfamic acid at 29°C from 0.001 to 0.01 molal, and for aqueous solutions of a strong acid, perchloric acid at 25°C from 0.004 to 0.1 molal. For each acid the data have been fitted to a linear equation by least squares analysis and the linear coefficient for the *TEP vs.* a molality function has been compared with theoretical values. These values are calculated from a heat-of-transport theory, in which each theoretical linear coefficient consists of five terms. The theoretical and experimental values for each linear coefficient are in agreement to within 20% for NH_2SO_3H and 2.4% for $HClO_4$.

Investigation of the concentration dependence of initial thermoelectric powers (*TEP*) of hydrogen-electrode thermocells in this laboratory (1-3) led to application of our theory (2) to a weak electrolyte: aqueous sulfamic acid. This theory is an extension of other theories (4-7).

One difficulty in the analysis of experimental data for the *TEP vs.* κ (Debye-Hückel reciprocal length) in a weak electrolyte stems from the different equilibrium hydrogen-ion molalities in the hot and cold compartments of the thermocell due to the variation of the acid dissociation constant with temperature. In order to minimize this difficulty we chose to study the *TEP* as a function of concentration of aqueous sulfamic acid using a 10°C temperature difference centered at 29°C. At this temperature the acid dissociation constant has a maximum value of *ca.* 0.104 (8, 9). The equilibrium hydrogen-ion molalities at 24° and 34°C differ by less than 0.02% even at the highest acid molality studied (*ca.* 0.01 mole kg^{-1}). We also present results for aqueous perchloric acid for a 20°/30° temperature difference in order to show that the strong acid case is more easily analyzed.

The result for sulfamic acid at 29°C and the result for perchloric acid at 25°C are compared with each theoretical slope, which is calculated from the five terms that contribute to each slope (2).

These terms are: $(\hat{Q}'_{HA})^d$, $(\hat{Q}'_{HA^-})^e$, $(\bar{\bar{S}}'_{H^+})^d$, $(\bar{\bar{S}}'_{H^+})^e$, and (t'_{A^-}). The first and second terms are from the concentration dependence of $\hat{Q}_{HA}$, the heat of transport of the acid. The third and fourth terms are from the concentration dependence of $\bar{\bar{S}}_{H^+}$, the transported entropy of the hydrogen ion. The final term is from the concentration dependence of t_{A^-}, the transport number of the anion. In addition, the first and third terms arise from the "direct" effect (5-7, 10). The second and fourth terms arise from the "electrophoretic" effect. It was stated in an earlier paper (3) that the limiting value $\hat{Q}^o_{A^-}$ and $\hat{Q}^o_{H^+}$ are

needed to calculate the $(\hat{Q}'_{HA})^e$ and $(\bar{\bar{S}}'_{H^+})^e$ terms. The limiting value $\hat{Q}^o_{HA}$ is also needed to calculate (t'_{A^-}).

Theoretical Calculations

In order to calculate values for the five contributing terms to the slope of the *TEP vs.* κ plot for perchloric and for sulfamic acids, we first consider the *TEP* of a hydrogen electrode thermocell containing an aqueous acid HA as given by Eq. [1] (4)

$$\mathbf{F}(TEP) = (1/2)S^o_{H_2} - \bar{\bar{S}}_e + t_{A^-}(\hat{Q}_{HA}/T) - \bar{\bar{S}}_{H^+} \quad [1]$$

In Eq. [1] $S^o_{H_2} = 130.587$ or 130.974 J K^{-1} mole^{-1} (the standard entropy of hydrogen gas at 25° or 29°C (11, 3) and $\bar{\bar{S}}_e = 0.430$ or 0.447 J K^{-1} mole^{-1} (the transported entropy of the electron in the nonisothermal part of the platinum at 25° or 29°) (12a). The transport number of the perchlorate or sulfamate ion is t_{A^-} and $\hat{Q}_{HA}$ is the heat of transport of perchloric or sulfamic acid. It is convenient to define the function

$$Y = TEP - (R/\mathbf{F}) \ln m \quad [2]$$

in which the *TEP* has been corrected by the mass-action term occurring in $\bar{\bar{S}}_{H^+}$ of Eq. [1]. As shown in Ref. (2), Eq. [4b]-[4d] express t_{A^-}, $\hat{Q}_{HA}$, and $\bar{\bar{S}}_{H^+}$ as an intercept plus a slope term. When these expressions of $\sqrt{c}$ dependence are substituted into Eq. [1], the five contributing terms to the slope of the thermoelectric power (actually, *Y*) *vs.* $c^{1/2}$ are obtained, viz.

$$Y = Y^o + (1/\mathbf{F})[(t^o_{A^-}/T)(\hat{Q}'_{HA})^d + (t^o_{A^-}/T)(\hat{Q}'_{HA})^e - (\bar{\bar{S}}'_{H^+})^d - (\bar{\bar{S}}'_{H^+})^e + (\hat{Q}^o_{HA}/T)(t'_{A^-})]\sqrt{c} \quad [3]$$

in which terms of higher order than $c^{1/2}$ have been neglected. In Eq. [3] the superscript zero denotes infinite-dilution limiting values of each function and the primes stand for the nonideal slope of each function *vs.* $\sqrt{c}$. The coefficients of the $\sqrt{c}$ direct terms (5) (first and third terms of Eq. [3]) are given in Eq. [4] and [5]

$$\frac{t^o_{A^-}}{T}(\hat{Q}'_{HA})^d\sqrt{c} = \frac{t^o_{A^-}}{T}4RT\mathfrak{S}\left(\frac{1}{12} + \frac{3}{4}\frac{\partial \ln \epsilon_r}{\partial \ln T} + \frac{1}{4}\alpha T\right)\sqrt{c} \quad [4]$$

$$(\bar{\bar{S}}'_{H^+})^d\sqrt{c} = -\frac{1}{3}R\mathfrak{S}\sqrt{c} \quad [5]$$

where the term in parentheses will be denoted by $\mathfrak{S}'$ and the Debye-Hückel constant $\mathfrak{S} = N^2e^3[\pi/(500\epsilon_r^3R^3T^3)]^{1/2}$. In Eq. [4] ϵ_r is the relative permittivity of the solvent, α is the isobaric expansivity of the solvent, *e* is the protonic charge in esu, *T* is the Kelvin temperature, *N* is the Avogadro number, and *R* is the universal gas constant.

The coefficients of the $\sqrt{c}$ electrophoretic terms (2) (second and fourth of Eq. [3]) are given by Eq. [6] and [7]

$$(t^o_{A^-}/T)(\hat{Q}'_{HA})^e\sqrt{c} = (t^o_{A^-}/2T)(r_{H^+} - r_{A^-})(\hat{Q}^o_{H^+} - \hat{Q}^o_{A^-})B'\sqrt{c} \quad [6]$$

$$(\bar{\bar{S}}'_{H^+})^e\sqrt{c} = (r_{H^+}/2T)(\hat{Q}^o_{H^+} - \hat{Q}^o_{A^-})B'\sqrt{c} \quad [7]$$

in which r_i is the Stokes' radius of ionic species *i*. $\hat{Q}^o_i$ is the limiting value at infinite dilution of the individual ionic heats of transport, and the Debye-Hückel constant $B' = eN[\pi/(125\epsilon_rRT)]^{1/2}$.

Although the factor $(\hat{Q}^o_{H^+} - \hat{Q}^o_{A^-})$ cannot be determined experimentally, we evaluated it using the method previously described (3). In this method $\hat{Q}^o_{HA}$ is first determined using Eq. [8]

$$\mathbf{F}Y^o = (1/2)S^o_{H_2} - \bar{\bar{S}}_e + t^o_{A^-}(\hat{Q}^o_{HA}/T) - \bar{\bar{S}}^o_{H^+} \quad [8]$$

in which the superscript zero denotes the limiting or standard value of each quantity. In order to obtain Eq. [8], we subtract the mass-action term $R \ln m$ from both sides of Eq. [1] and use standard-state values for the molality-dependent variables (*TEP*, t_{A^-}, $\hat{Q}_{HA}$, and $\bar{\bar{S}}_{H^+}$). The values obtained were $\hat{Q}^o_{HClO_4} = 12.57 \pm 0.18$ kJ mole^{-1} and $\hat{Q}^o_{NH_2SO_3H} = 14.17 \pm 0.24$ kJ mole^{-1} using values at 25°C previously described (3) for $S^o_{H_2}$, $t^o_{A^-}$, $\bar{\bar{S}}^o_{H^+}$, and $Y^o/\mu V$ K^{-1} $= 507.60 \pm 0.54$ and 497.07 ± 0.83 for $HClO_4$ and NH_2SO_3H, respectively. We next calculated $\hat{Q}^o_{H^+} = 12.60 \pm 0.04$ kJ mole^{-1} on the absolute basis according to a suggestion of Ikeda (12b). Following Ikeda's interpretation of Wirtz's "Platzwechsel" theory (13a) for ion transport, we may write Eq. [9a] for the hydrogen ion

$$\hat{Q}^o_{H^+} = RT(1 + \partial \ln \lambda^o_{H^+}/\partial \ln T) \quad [9a]$$

where $\lambda^o_{H^+}$ is the infinite-dilution limiting value of the ionic mobility of the hydrogen ion. In Eq. [9a] we have equated the individual ionic heat of transport of the hydrogen ion $\hat{Q}_{H^+}$ to the "Hemmungsenergie" (molar activation energy for detachment of a proton from its neighbors) only, since for a proton it is reasonable to neglect the "Lochbildungsenergie" (molar activation energy for creation of a hole into which the proton will enter).

The value for $\hat{Q}^o_{H^+}$ determined from Eq. [9a] using $\partial \ln \lambda^o_{H^+}/\partial T = 0.0137$ K^{-1} from Owen and Sweeton (13b) differs from our earlier value of 13.127 kJ mole^{-1} (3), which was determined from Eq. [9b] (5)

$$\bar{\bar{S}}^o_{H^+} = S^o_{H^+} + (\hat{Q}^o_{H^+}/T) \quad [9b]$$

with Ikeda's value (12b) ($S^o_{H^+} = -5.1$ cal K^{-1} mole^{-1}) for the absolute value of the partial molar standard entropy of the hydrogen ion in aqueous solution and with our value (1, 3) $\bar{\bar{S}}^o_{H^+} = 22.69 \pm 0.08$ J K^{-1} mole^{-1}. For the hydrogen ion Eq. [9b] expresses the transported entropy (a measureable property of an individual ion that is not based on an arbitrary convention) in terms of $S^o_{H^+}$ and $\hat{Q}^o_{H^+}$, neither of which is experimentally accessible (5). References for ten values of $S^o_{H^+}$ ranging between -1 and -7 cal K^{-1} mole^{-1} are given by Ikeda (12b). Furthermore, our value (3) for $\bar{\bar{S}}^o_{H^+}$ and the value for $\hat{Q}^o_{H^+}$ calculated from Eq. [9a] may be combined according to Eq. [9b] in order to yield the absolute value $S^o_{H^+} = -4.7 \pm 0.1$ cal K^{-1} mole^{-1}.

We then determined $\hat{Q}^o_{A^-}$ at 25°C for each acid by subtracting $\hat{Q}^o_{H^+} = 12.60$ kJ mole^{-1} from the values for $\hat{Q}^o_{HA}$. This procedure yielded

$$(\hat{Q}^o_{H^+} - \hat{Q}^o_{ClO_4^-}) = 12.64 \pm 0.19 \text{ kJ mole}^{-1}$$

and

$$(\hat{Q}^o_{H^+} - \hat{Q}^o_{NH_2SO_3^-}) = 11.03 \pm 0.25 \text{ kJ mole}^{-1}$$

Finally, we made the assumption that the temperature coefficients of $\hat{Q}^o_i$ for all ions are the same.

The fifth term of Eq. [3] (2) is

$$\frac{\hat{Q}^{\circ}_{HA}}{T}(t'_{A^-}) = \frac{\hat{Q}^{\circ}_{HA}}{T}\frac{B_2(t^{\circ}_{A^-} - 1/2)}{(\lambda^{\circ}_{H^+} + \lambda^{\circ}_{A^-})} \quad [10]$$

where $B_2 = \mathbf{F}e^2N/3$ (299.79) $(125\ R\epsilon_r T)^{1/2}\eta_o$ with η_o the viscosity of the solvent. The expression for (t'_{A^-}) appearing in Eq. [10] was derived by taking the infinite-dilution limit of the expression for the concentration variation of the transport number due to first-order electrophoretic terms according to Robinson and Stokes (9). Also appearing in Eq. [10] is the heat of transport of the acid at infinite dilution. At 25°C for perchloric acid $\hat{Q}^{\circ}_{HA} = 12.57 \pm 0.18$ kJ mole^{-1} and at 29°C for sulfamic acid $\hat{Q}^{\circ}_{HA} = 15.11 \pm 0.27$ kJ mole^{-1}.

Shown in Eq. [11] are the five terms from Eq. [4], [5], [6], [7], and [10] respectively

$$Y = Y^{\circ} + Y'\sqrt{c}$$

where

$$Y' = (1/\mathbf{F})[4t^{\circ}_{A^-}R\mathfrak{S}\mathfrak{S}' - (-1/3R\mathfrak{S})$$
$$+ (B't^{\circ}_{A^-}/2T)(r_{H^+} - r_{A^-})(\hat{Q}^{\circ}_{H^+} - \hat{Q}^{\circ}_{A^-})$$
$$- (B'r_{H^+}/2T)(\hat{Q}^{\circ}_{H^+} - \hat{Q}^{\circ}_{A^-})$$
$$+ \hat{Q}^{\circ}_{HA}B_2(t^{\circ}_{A^-} - 1/2)/T(\lambda^{\circ}_{H^+} + \lambda^{\circ}_{A^-})] \quad [11]$$

Displayed in Table I are the five contributions to the $\sqrt{c}$ dependence of Y for sulfamic acid at 29°C and for perchloric acid at 25°C. Shown in Table II are the values of constants used in the calculation of these terms.

Experimental

The thermoelectric powers were measured using the method, electrodes, cell, and bubblers previously described (1), except for the following changes in experimental details. The previously used, W-shaped cell, which had been placed directly in the two thermostats, was replaced by a U-shaped external Pyrex cell with water jackets through which thermostated water circulated. The previously used electrode assemblies were replaced by electrodes in which each assembly consisted of a bubbler tube, two electrode tubes, and a thermocouple. A 3 mm OD, soft-glass tube, into which was sealed a No. 27 platinum wire, was inserted into each Pyrex electrode tube and sealed with Apiezon W. Platinum black was deposited on the electrodes after every 15 runs by reducing a 2% platinic chloride solution that contained 0.02% lead acetate. The electrolysis was carried out for 15-30 sec at a current density of 100 mA cm^{-2} until the deposit appeared uniformly black. No presoaking of the electrodes was necessary before a run.

Prepurified (99.995% pure, Airco) hydrogen was further purified by a "deoxo" cartridge (J. T. Baker Company) attached directly to the regulator. The hydrogen was then bubbled through deionized water to saturate it with water vapor before it entered the solution in the cell. Reagent grade sulfamic and perchloric acids were used to make stock solutions which were titrated with standardized NaOH solutions. The solutions for the *TEP* measurements were then prepared by dilution.

We determined the temperature difference with a one-junction iron-constantan thermocouple using values of 517 μV for 20°-30°C and 519 μV for 24°-34°C. These values were obtained by least squaring tabulated values (18) to a quadratic temperature equation. The temperature difference was known to within 0.01K, although the mean temperature varied up to 0.1K from the stated values. The thermocouples were immersed in paraffin oil and enclosed in a U-shaped, 3 mm OD, soft-glass tube and were suspended from each electrode assembly before being placed in each compartment of the thermocell.

After the solution had been deoxygenated by bubbling prepurified nitrogen through the saturators and the cell solution for 15 min, we switched to hydrogen and usually began taking readings after 20-30 min. The hydrogen bubbled at a rate of 10-20 sec^{-1}. Two readings were taken with each pair of electrodes, first with the current in the forward direction and then in the reverse direction. Any asymmetry in the electrodes was eliminated by interchanging the flow of the hot and cold water to the water jackets. Four more readings were again taken, making a total of eight in all. For all readings the thermocell was slightly tilted so that the hot compartment was elevated with respect to the cold, thus preventing the denser solution in the cold compartment from flowing into the hot compartment.

As in our work on HCl (1), all *TEP*'s have been corrected so that the hydrogen pressure in both the

hot and cold compartments was 760 Torr (=101.325 kPa). Because of the extremely dilute solutions no correction was made for the lowering of the vapor pressure due to the presence of solute. Use of Antoine's equation (19) for the vapor pressure of water made it unneceessary to use four different sets of constants for linear interpolation within 0.1°C of the four thermostat temperatures.

Results

In all runs the polarity of the thermocell was such that the hot electrode was positive except for the 14 most dilute runs of sulfamic acid. Details of the calculation of Y as a function of $\sqrt{m}/(1 + 1.5\sqrt{m})$ are shown in Table III for sulfamic acid at a 24°/34° temperature difference. For convenience we used this function of the equilibrium hydrogen ion molality at 29°C rather than a function of c because densities are not required and equilibrium molalities can be readily calculated (Eq. [13] and [15]). Furthermore, this function was chosen because it is proportional to $\kappa/(1 + \kappa a)$ which occurs in the Debye-Hückel theory. By plotting Y against $\sqrt{m}/(1 + 1.5\sqrt{m})$ rather than $\sqrt{c}$ or $\sqrt{m}$ only, we extended the apparent range where a single linear term suffices to represent the concentration variation of the data (4).

For sulfamic acid, a weak acid, in which *m* (equilibrium hydrogen ion molality) is a function of temperature, the ordinate is given by Eq. [12]

$$Y = TEP - (R/F) \ln \sqrt{m_{34}m_{24}} - (R/F)(T/\Delta T) \ln (m_{34}/m_{24}) \quad [12]$$

This expression can be developed in analogous manner to the barometric pressure-correction factor (1, 20). We neglected the third term on the right-hand side of Eq. [12] because the maximum value at the highest molality is only 0.016 μV K^{-1}.

The equilibrium molalities at 24°, 29°, and 34°C were calculated from Eq. [13] for each of the nine runs of Table III

$$m = 1/2[-K_a + (K_a^2 + 4\gamma^2 K_a M)^{1/2}] \quad [13]$$

in which *M* is the total molality of sulfamic acid. The acid dissociation constant K_a was determined from Eq. [14] of King and King (8, 9)

$$-\log K_a = 3792.8/T - 24.122 + 0.04155T \quad [14]$$

and the activity coefficient from Eq. [15]

$$\ln \gamma = -S\sqrt{m}/[1 + (3.85 \times 10^{-8})B'\sqrt{m}] \quad [15]$$

The values used for the Debye-Hückel constants in Eq. [15] are shown in Table II. To calculate *m* in Eq. [13] we used an iterative technique in which γ was first set equal to unity. The value obtained for *m* was then used in Eq. [15] to obtain an improved value for γ, which was then used to obtain an improved value *m*. This iterative technique was continued until successive values of *m* agreed to within 1×10^{-11} mole kg^{-1}.

In the case of perchloric acid, a strong acid, the ordinate is $Y = TEP - (R/F) \ln m$ as in Eq. [2]. The abscissa is $\sqrt{m}/(1 + 1.5\sqrt{m})$ in which *m* is the molality of perchloric acid. Details of this calculation are shown in Table IV.

For each acid the data were fitted to a straight line by linear least squares by minimizing the squares of the vertical distances from the points to the line. In order to determine the limiting slopes, we used the points at concentrations shown in Tables III and IV. At concentrations greater than 0.01 mole kg^{-1} for sulfamic acid and 0.1 mole kg^{-1} for perchloric acid, the curve was apparently no longer linear and became concave upward.

Displayed in Table V are the limiting values for the slope and intercept of Y *vs.* $\sqrt{m}/(1 + 1.5\sqrt{m})$ for sulfamic acid and perchloric acid.

Discussion

A comparison may be made between our TEP with the work of Goyan (22). He measured the initial emf of a hydrogen-electrode thermocell containing 0.01M $HClO_4$ and obtained 1.25 ± 0.05 mV for $\Delta T = 9.9K$. For this result the mean temperature was 25°C and the hot electrode was positive. We corrected his value so that the hydrogen pressure in both hot and cold compartments was 760 Torr and obtained $TEP = 99.9 \pm 4$ μV K^{-1} for Goyan's result. This value compares satisfactorily with our value of $104.2_4 \pm 0.6_3$ μV K^{-1} at the same concentration of 0.01M. Our value of $\hat{Q}^o_{HClO_4} = 12.57 \pm 0.18$ kJ $mole^{-1}$ compares favorably with Haase's result (23) of 12.22 kJ $mole^{-1}$.

By multiplying the theoretical slopes of Table I by the square root of the density of water at 25° or 29° we were able to compare these values with the experimental slopes of Table V. This agreement is 19.9% and 2.4% for sulfamic acid and perchloric acid, respectively.

Table V. Values determined for intercept and slope of linear equation fitted to data of Tables III and IV

Acid	Mean temperature (°C)	Range of molality (m/mole kg^{-1})	n (No. of runs)	Standard error of estimate[a] ($\mu V\ K^{-1}$)	Y^o ($\mu V\ K^{-1}$)	Y' ($\mu V\ K^{-1}$ $dm^{3/2}$ $mole^{-1/2}$)
NH_2SO_3H	29	0.001-0.008	9[b]	1.19	$504.0_1 \pm 0.8_3$[c]	$-90.0_3 \pm 15$
$HClO_4$	25	0.004-0.1	10	0.64	507.62 ± 0.54	-78.10 ± 3.76

[a] (Standard error of estimate)^2 = $[Y(\text{obs}) - Y(\text{calc})]^2/[n - 2]$, summed over the n data points.
[b] The nine values reported in Table III are weighted averages of 25 experimental runs.
[c] The errors indicated for each of the four constants are termed standard errors and were calculated by the method of Deming (21).

Use of a modified Walden rule ($\lambda\eta T$ = constant) (24) led to no significant change in the theoretical value of Y' ($<0.05\%$). Use of conductivity data for sulfamic acid interpolated from the data of Mazzi and Alberti-Oggioni (25) at 25° and 50°C changed the theoretical Y' by less than 0.2%.

The comparison of values for perchloric acid is excellent although the comparison of values for sulfamic acid is not quite within the acceptable range of standard error (last column of Table V). Nevertheless, we are encouraged by our results and hope that improvements can be made in the theory for the electrophoretic terms for the heats of transport and the transported entropies in electrolytes.

Sinusoidal A-C Modulation of a Rotating Hemispherical Electrode

Der-Tau Chin*

Department of Chemical Engineering, Clarkson College of Technology, Potsdam, New York 13676

ABSTRACT

An analysis has been made for the concentration polarization and the Warburg impedance of a rotating hemispherical electrode when the electrode is superimposed with a sinusoidal alternating current (a.c.). Numerical results are presented for the changes in the concentration of the diffusing species and for the calculation of the concentration overpotential at the electrode. It is shown that for the values of a dimensionless a-c frequency greater than 10, the behavior of the hemispherical electrode becomes the same as that of a rotating disk electrode, and the location of the reference electrode in an experimental setup has no significant effect on the potential measurements.

Alternating current (a.c.) has an interesting effect on the electrode processes. It can reduce the electrode polarization, shift the rest potential, destroy the electrochemical passivity (1-3), and produce periodical changes in the concentration of the reacting species at the electrode surface (4). This paper is concerned with the a-c modulation of a rotating hemispherical electrode.

The rotating hemispherical electrode is a supplementary tool to the rotating disk electrode. It has the advantages that (*i*) its current distribution is uniform below the limiting current potentials (5), and (*ii*) it is more suitable for the study of corrosion and dissolution reactions because its geometry remains relatively unchanged during the experimental runs (6). In this work, an attempt has been made to provide a theoretical background for the use of the rotating hemispherical electrode in the study of a-c corrosions. The present paper discusses the concentration overpotentials when the electrode is modulated with a sinusoidal a.c.

Analysis

Consider the following redox reaction taking place at the surface of a rotating hemispherical electrode

$$\mathrm{Ox} + ne^- = \mathrm{Red} \qquad [1]$$

The hemispherical electrode is mounted on a supporting rod of an equal radius r_0, as shown in Fig. 1, and is rotating with an angular velocity Ω in a stationary, infinitely large, incompressible solution of constant properties. It is assumed that sufficient supporting electrolyte is present in the solution and the bulk concentration of Red species is much higher than Ox species such that the migration effect is negligible and the concentration polarization may be described by the convective diffusion of Ox species. When the electrode surface is subjected to the passage of a direct current (d.c.) superimposed with a sinusoidal alternating current density

$$\tilde{i} = i_p e^{j\omega t} \qquad [2]$$

the concentration of Ox species may be expressed as a sum of a steady-state component $\bar{c}$ and a fluctuating component $\tilde{c}$

$$c = \bar{c} + \tilde{c} \qquad [3]$$

The problem for the steady-state component has been treated by Chin (6), and Nisancioglu and Newman (5). For the fluctuating component, the time-dependent convective diffusion equation in laminar flow may be given in the spherical polar coordinates (Fig. 1) as

$$\frac{\partial \tilde{c}}{\partial t} + v_r \frac{\partial \tilde{c}}{\partial r} + \frac{v_\theta}{r_0} \frac{\partial \tilde{c}}{\partial \theta} = D \frac{\partial^2 \tilde{c}}{\partial r^2} \qquad [4]$$

with the boundary conditions

$$\left.\begin{aligned} &\text{at} \quad \theta = 0, \ \frac{\partial \tilde{c}}{\partial \theta} = 0 \\ &r = \infty, \ \tilde{c} = 0 \\ &r = r_0, \ \frac{\partial \tilde{c}}{\partial r} = -\frac{i_p}{nFD} e^{j\omega t} \end{aligned}\right\} \qquad [5]$$

Here D represents the diffusivity of Ox species; v_r and v_θ are the radial and the meridional velocity components, respectively; i_p is the peak a-c density; ω is the a-c frequency; t is the time; and j is equal to $\sqrt{-1}$. One may normalize the above equations with the following dimensionless parameters and variables

$$\text{Schmidt number}, \quad \mathrm{Sc} = \nu/D \qquad [6]$$

$$\text{Dimensionless a-c frequency}, \quad K = \frac{\omega}{\Omega} \mathrm{Sc}^{1/3} \qquad [7]$$

$$\text{Dimensionless radial coordinate}, \quad \eta = (r - r_0) \left(\frac{\Omega}{\nu}\right)^{1/2} \qquad [8]$$

$$\text{Dimensionless time}, \quad \tau = \Omega t \qquad [9]$$

Dimensionless radial velocity,

$$H = \frac{v_r}{(\nu\Omega)^{1/2}} = H_1(\eta) + \theta^2 H_3(\eta) + \dots \qquad [10]$$

* Electrochemical Society Active Member.

Key words: concentration overpotential, Warburg impedance, convection, diffusion.

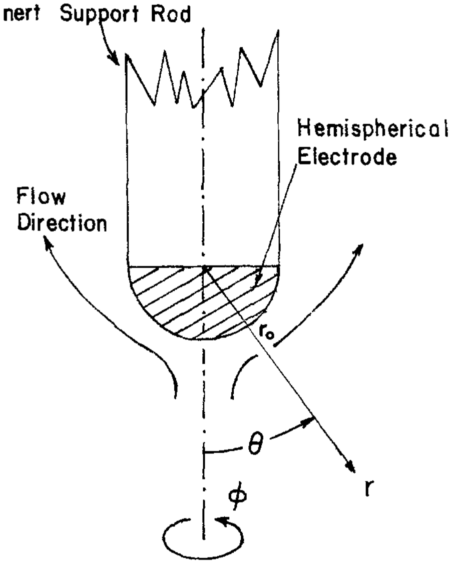

Fig. 1. Rotating hemispherical electrode and the spatial coordinates.

Dimensionless meridional velocity,

$$F = \frac{v_\theta}{r_0\Omega} = \theta F_1(\eta) + \theta^3 F_3(\eta) + \ldots \quad [11]$$

Dimensionless concentration,

$$M = \frac{n\mathbf{F}D}{i_p}\left(\frac{\Omega}{\nu}\right)^{1/2}\tilde{c} = [M_1(\eta) + \theta^2 M_3(\eta) + \ldots]e^{jK\mathrm{Sc}^{-1/3}\tau} \quad [12]$$

Substituting Eq. [6]-[12] into Eq. [4]-[5] and equating the terms having the like power of θ on both sides of the resulting equations, one has

$$\frac{1}{\mathrm{Sc}}\frac{d^2M_1}{d\eta^2} - H_1\frac{dM_1}{d\eta} - j\frac{K}{\mathrm{Sc}^{1/3}}M_1 = 0 \quad [13]$$

$$\frac{1}{\mathrm{Sc}}\frac{d^2M_3}{d\eta^2} - H_1\frac{dM_3}{d\eta} - \left(2F_1 + j\frac{K}{\mathrm{Sc}^{1/3}}\right)M_3 = H_3\frac{dM_1}{d\eta} \quad [14]$$

Boundary conditions

$$\left.\begin{array}{l} \text{at } \eta = 0, \quad \dfrac{dM_1}{d\eta} = -1; \quad \dfrac{dM_3}{d\eta} = 0 \\ \eta = \infty, \quad M_1 = M_3 = 0 \end{array}\right\} \quad [15]$$

The dimensionless velocity components F_1, H_1, and H_3 can be expressed in terms of a power series of η; they have been calculated by Cochran (7) and Banks (8). At high Schmidt numbers, the thickness of the concentration boundary layer is much smaller than the hydrodynamic boundary layer, and the first term in the power series can be used as a good approximation for the velocity components

$$F_1 = 0.51023\eta \quad [16]$$

$$H_1 = -0.51023\eta^2 \quad [17]$$

$$H_3 = 0.52762\eta^2 \quad [18]$$

Furthermore, for the analysis of concentration fluctuations at high Schmidt numbers, one may introduce a set of stretched variables and express the dimensionless concentrations in a complex form

$$z = \eta\mathrm{Sc}^{1/3} \quad [19]$$

$$M_1\mathrm{Sc}^{1/3} = X(\eta) + jY(\eta) \quad [20]$$

$$M_3\mathrm{Sc}^{1/3} = U(\eta) + jV(\eta) \quad [21]$$

Substituting Eq. [16]-[21] into Eq. [13]-[15], and separating the real and the imaginary parts on both sides of the resulting equations, one has

$$\frac{d^2X}{dz^2} + 0.51023z^2\frac{dX}{dz} + KY = 0 \quad [22]$$

$$\frac{d^2Y}{dz^2} + 0.51023z^2\frac{dY}{dz} - KX = 0 \quad [23]$$

$$\frac{d^2U}{dz^2} + 0.51023z^2\frac{dU}{dz} - 1.02046zU + KV = 0.52762z^2\frac{dX}{dz} \quad [24]$$

$$\frac{d^2V}{dz^2} + 0.51023z^2\frac{dV}{dz} - 1.02046zV - KU = 0.52762z^2\frac{dY}{dz} \quad [25]$$

Boundary conditions

$$\left.\begin{array}{l} \text{at } z = 0, \quad \dfrac{dX}{dz} = -1; \quad \dfrac{dY}{dz} = \dfrac{dU}{dz} = \dfrac{dV}{dz} = 0 \\ z = \infty, \quad X = Y = U = V = 0 \end{array}\right\} \quad [26]$$

Numerical Results and Discussion

Equations [22]-[26] have been solved numerically on a digital computer with a finite difference method (9). Results for the dimensionless concentration components, X, Y, U, and V are plotted in Fig. 2-5 as a function of z for various values of the dimensionless a-c frequency, K. It is seen that the profile of the concentration fluctuations is a strong function of the a-c frequency, K. The thickness of the concentration boundary layer does not appear to change with super-

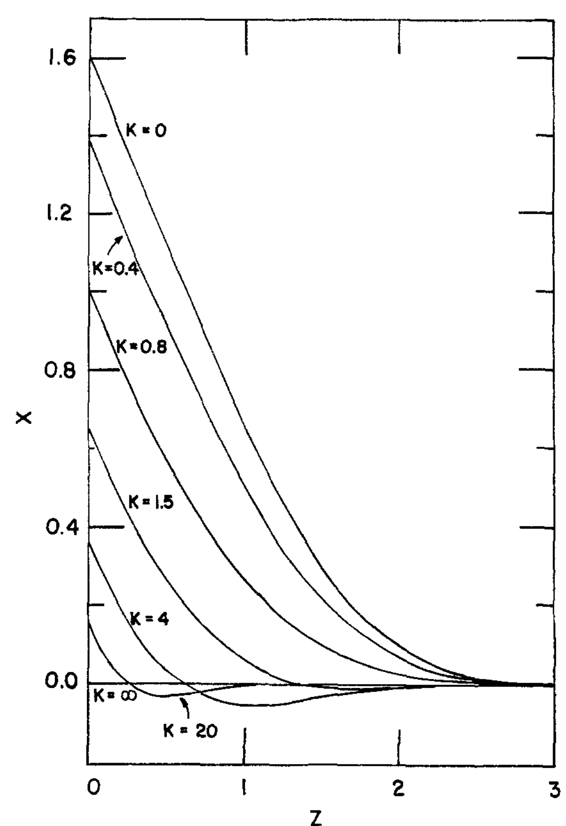

Fig. 2. Dimensionless concentration: X vs. z

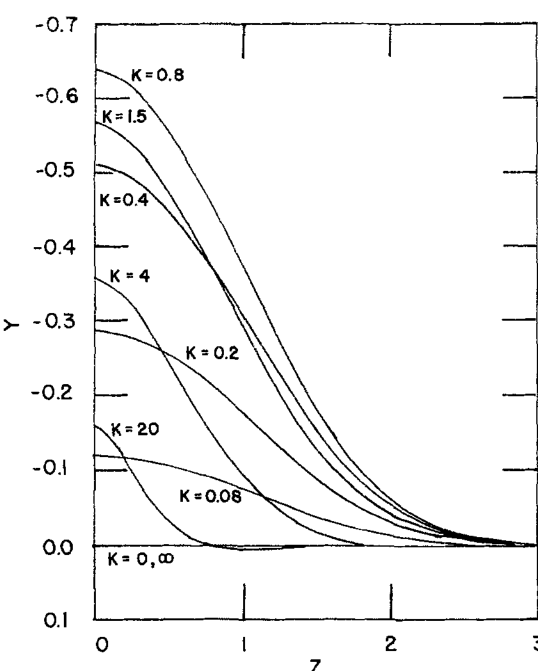

Fig. 3. Dimensionless concentration: Y vs. z

imposed a.c. for small values of K. The concentration changes occur within a region of $0 \leq z < 3.3$. However, at high a-c frequencies, the region diminishes rapidly with increasing values of K, and becomes zero at $K = \infty$.

The concentration overpotential caused by the convective diffusion of Ox species may be given as

$$\eta_{conc} = \frac{RT}{n\mathbf{F}} \ln \frac{c_s}{c_\infty} \quad [27]$$

where c_s is the concentration of Ox species at the surface of the electrode. In the absence of a d-c component, the concentration at the surface may be expressed as $c_s = c_\infty + \tilde{c}_s$, and the concentration overpotential becomes

$$\eta_{conc} = \frac{RT}{n\mathbf{F}} \ln \left(1 + \frac{\tilde{c}_s}{c_\infty}\right) \quad [28]$$

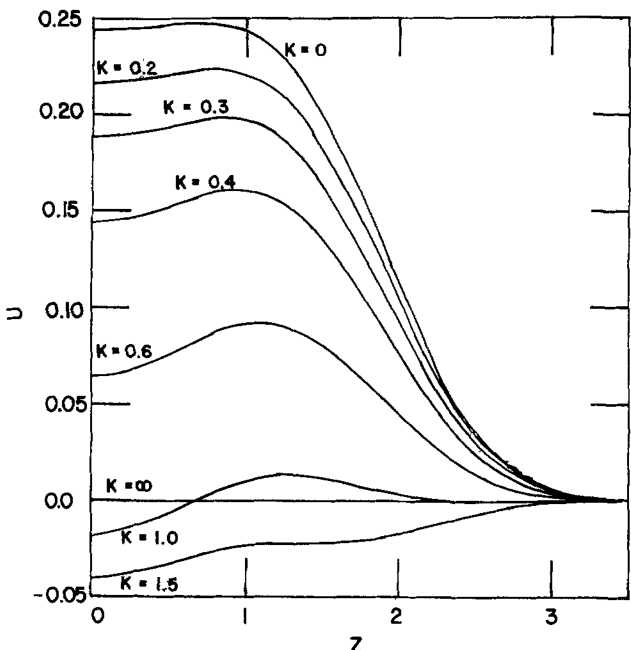

Fig. 4. Dimensionless concentration: U vs. z

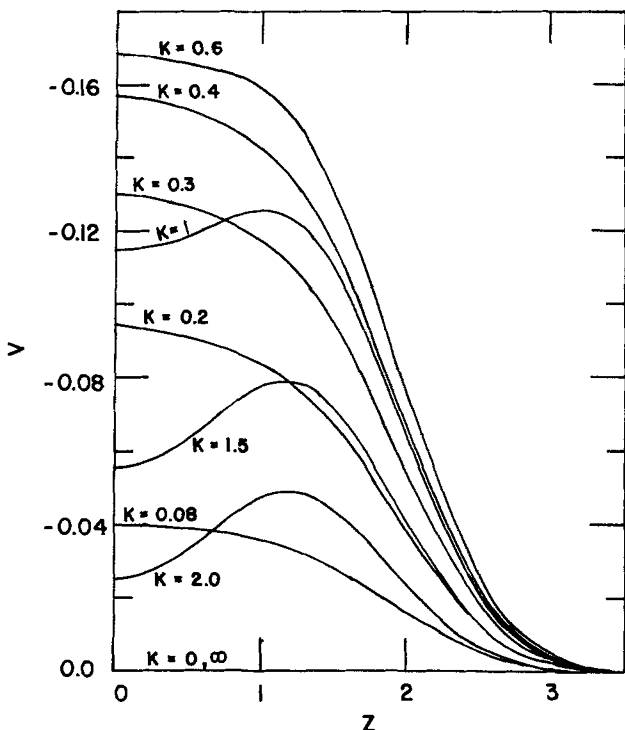

Fig. 5. Dimensionless concentration: V vs. z

where $\tilde{c}_s$ is the concentration fluctuations at the electrode surface. Equation [28] may be rearranged to the following expression by making use of the dimensionless concentrations

$$\eta_{conc} = \frac{RT}{n\mathbf{F}} \ln \{1 + N[(X_0 + \theta^2 U_0) + j(Y_0 + \theta^2 V_0)]e^{jKSc^{-1/3}\tau}\} \quad [29]$$

Here N is defined as

$$N = \frac{i_p}{n\mathbf{F}c_\infty D^{2/3}\nu^{-1/6}\Omega^{1/2}} \quad [30]$$

and may be regarded as a dimensionless peak a-c density. The quantities X_0, Y_0, U_0, and V_0, are the values of the dimensionless concentration components, X, Y, U, and V, respectively, at z equal to zero; they are plotted in Fig. 6-7, and are tabulated in Table I for a range of K from 0 to 150. The corresponding plots for Y_0 vs. X_0 and V_0 vs. U_0 on the complex planes are given in Fig. 8 and 9 where the values of K are indicated on each curve as the parameters.

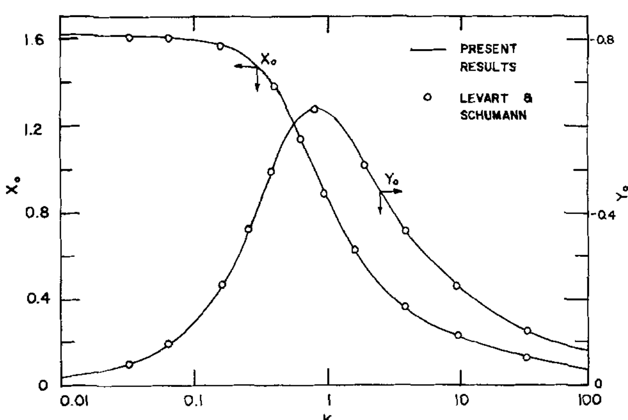

Fig. 6. Values of X and Y at $z = 0$ vs. the dimensionless a-c frequency, K. The present results are given as the solid lines. Levart and Schumann's results (10) for a rotating disk electrode are plotted as the open circles.

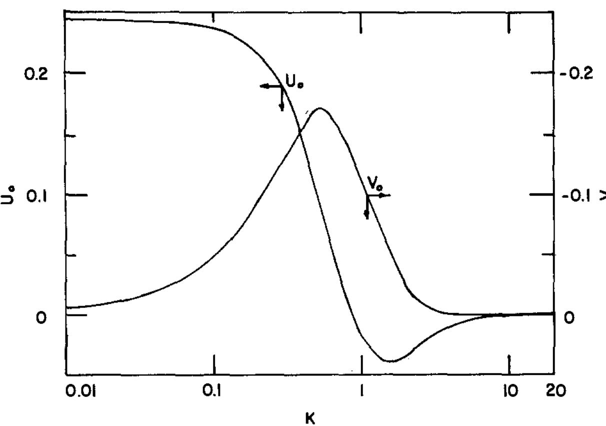

Fig. 7. Values of U and V at $z = 0$ vs. the dimensionless a-c frequency K.

For small dimensionless peak a-c densities, Eq. [29] may be simplified to

$$\eta_{\text{conc}} = \frac{RT}{n\mathbf{F}} N[(X_0 + \theta^2 U_0)^2 + (Y_0 + \theta^2 V_0)^2]^{1/2} e^{j(K Sc^{-1/3}\tau + \Psi)} \quad (\text{for } N << 1) \qquad [31]$$

where

$$\Psi = -\cos^{-1} \frac{X_0 + \theta^2 U_0}{[(X_0 + \theta^2 U_0)^2 + (Y_0 + \theta^2 V_0)^2]^{1/2}} \qquad [32]$$

The Warburg impedance is related to the concentration overpotential by

$$Z_w = \frac{\eta_{\text{conc}}}{\tilde{i}} \qquad [33]$$

Substituting Eq. [2] and [31] into Eq. [33], one has

$$Z_w = \frac{RT}{n^2 \mathbf{F}^2 c_\infty D^{2/3} \nu^{-1/6} \Omega^{1/2}} [(X_0 + \theta^2 U_0)^2 + (Y_0 + \theta^2 V_0)^2]^{1/2} e^{j\Psi}, \quad (\text{for N} << 1) \qquad [34]$$

Equations [31] and [34] indicate that with a small superimposed sinusoidal a.c., the response in the concentration overpotential will also be a sinusoidal wave of the same frequency. However, the potential fluctuations will have a phase shift of Ψ whose magnitude depends upon the a-c frequency and the location

of the reference electrode relative to the axis of rotation of the hemispherical electrode. Figure 10 shows the phase shift as a function of the dimensionless a-c frequency, K, for two different values of θ. The lower curve ($\theta = 0$) corresponds to a reference electrode located near the pole of the hemispherical electrode. In this case, the phase shift of the concentration overpotential waves increases with a-c frequency, and becomes approximately equal to $-45°$ at high frequencies. The upper curve ($\theta = \pi/2$) corresponds to a reference electrode located near the equator. In this case, the phase shift reaches a maximum of $-52°$ at K equal to 1.6. Beyond this value, the phase shift decreases with increasing K and approaches to that of $\theta = 0$ at high a-c frequencies. This behavior could be explained by the fact that at large a-c frequencies the values of U_0 and V_0 become negligibly small as compared to the values of X_0 and Y_0. At $K = 10$, for example, the neglect of the θ^2 terms in Eq. [29], [31], [32], and [34] would yield an error of less than

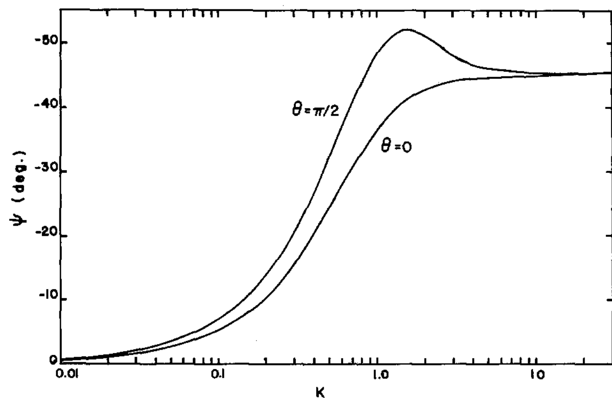

Fig. 10. Phase shift of the concentration overpotential, Ψ, vs. dimensionless a-c frequency, K, for the reference electrode located near the pole ($\theta = 0$) and the equator ($\theta = \pi/2$) of the hemispherical electrode.

1.5%. Thus, for K greater than 10, the position of the reference electrode in an experimental setup will have no significant effect on the potential measurements.

It should be noted that the present analysis is based on a series expansion for the concentration distribution at small values of θ. The rotating disk electrode can be treated as a special case by letting $\theta = 0$, and X_0 and Y_0 can be used to calculate the concentration overpotential and the Warburg impedance of the rotating disk electrode. For comparison, the values of X_0 and Y_0 calculated by Levart and Schumann (10) for a-c modulation at the rotating disk electrode are plotted in Fig. 6 as the open circles, ○. The present results agree with their calculations to within 0.1%. This implies that the fluctuations in the concentration overpotential and the resulting Warburg impedance of the hemispherical electrode will be the same as those of the rotating disk electrode if the dimensionless frequency of superimposed a.c. is greater than 10.

Conclusions

A study has been made of the concentration overpotential and the Warburg impedance of a rotating hemispherical electrode when a sinusoidal a.c. is superimposed onto the electrode. It is shown that a.c. does not change the thickness of the concentration boundary layer, and the effect of a.c. decreases with increasing a-c frequency. For small superimposed a.c., the response in the concentration overpotential is also a sinusoidal wave of the same frequency with a phase shift depending on the magnitude of a-c frequency and the location of the reference electrode. At high a-c frequencies of $K \geqq 10$, the behavior of the hemispherical electrode becomes the same as that of a rotating disk electrode, and the position of the reference electrode has no significant effect on the potential measurements.

Electrochemical Reduction of Pyridinium Ions in Ionic Aluminum Chloride: Alkylpyridinium Halide Ambient Temperature Liquids

R. J. Gale[1] and R. A. Osteryoung*,[2]

Department of Chemistry, Colorado State University Fort Collins, Colorado 80523

ABSTRACT

Reduction of 1-alkylpyridinium cation in 0.8:1 molar ratio $AlCl_3$:1-butylpyridinium chloride liquids at 40°C has been investigated by cyclic voltammetry and electrochemical pulse methods. A dimeric product of the primary pyridinyl radical coupling, 4,4'-tetrahydrobipyridine, forms in about 45% yield and undergoes fairly rapid chemical dissociation to the stable, electroactive, 1,1'-dibutyl-4,4'-bipyridinium monocation radical. This product may be reduced further by other dissociation fragments. The corresponding biquaternary bipyridyl base reduces in two steps, each with one-electron reversible behavior, at half-wave potentials of −0.56 and −0.96V *vs.* Al(O) in 2:1 solvent reference electrode. Tetrahydrobipyridine species with 1,2,4,6-substituted methyl groups were stable to dissociation under similar conditions. Molecular structural parameters that affect the reduction potentials of pyridinium ions and the stability of tetrahydrobipyridines are discussed briefly.

Mixtures of $AlCl_3$:1-butylpyridinium chloride (1-BPC) form aprotic melts of variable Lewis acidity which are liquids at room temperature. In the course of investigating their acid-base properties, it was observed that the chloride ion-rich mixtures (*i.e.*, <1:1 molar ratio, respectively) reacted spontaneously with an aluminum wire electrode. This reaction arises from the reduction of the 1-alkylpyridinium cation and consequently this electrode process, rather than the reduction of an aluminum ion species to elemental aluminum, determines the negative potential limit of the electrochemical stability of the basic solvent. The present work has attempted to establish the mechanism of alkylpyridium cation reduction in these solvents because a better understanding of how the pyridinium ion molecular structure relates to its reduction-oxidation might enable improvements to be made in the selection of discrete electrolyte properties.

A comprehensive review of dihydropyridine chemistry has been published encompassing reduction of pyridines and alkylpyridinium ions with specific metals and metallic ions (*e.g.*, Na, Zn, Mg, active Al, Cr^{2+}, V^{2+}), chemical reducing agents (*e.g.*, $LiAlH_4$, $Na_2S_2O_4$, $NaBH_4$, $NaCNBH_3$) and electrochemical methods (2). Also, the electrode reactions of diverse heterocyclic compounds have been reviewed by Lund (3). Many of these earlier reduction studies, particularly those of ring substituted 1-alkylpyridinium ions (4-7), resulted from attempts to understand the behavior of two key coenzymes, nicotinamide adenine dinucleotide (NAD^+) and nicotinamide adenine dinucleotide phosphate ($NADP^+$). Unsaturated double bonds contiguous to the hetero atom in heterocyclic compounds are more reactive than those in the benzene ring and they are usually the easiest to reduce, attack taking place at positions of low electron density, *i.e.*, the 2- or 4- positions in 6-membered rings. Pyridinyl radical production may occur by transferring one electron, from the appropriate metal for example, to the lowest unoccupied molecular orbital of the pyridinium ion species. Subsequent reactions of the radical intermediate, such as formation of a hydrogenated monomer, dimerization, dissociation, or further reduction, depend both on the reductant and the solvent conditions, especially the availability of proton. Extensive ring cleavage has been proposed to occur in certain cases, for example through C = N bond rupture of $AlCl_3$:pyridine Lewis acid-base adducts when pyridine solutions containing aluminum chloride are electrolyzed at mercury (8). Volke and Naarova (9, 10) have studied the electrochemical reduction of a series of 1-alkylpyridinium ions at a mercury electrode, in both aqueous and, because of adsorption complications, mixed aqueous/nonaqueous electrolytes. The half-wave potentials were found to vary only slightly (∼−50 mV maximum shift) with the 1-alkyl substituent (CH_3 to C_5H_{11}) but coulometric electrolysis values differed appreciably in the presence of a radical scavenger and it was suggested that the initial radical dimerization rates decreased as the 1-alkyl groups became increasingly bulky. Though not chemically identified, the main one-electron reduction products were postulated to be dihydropyridines. Nevertheless, a secondary dimeric alkyl viologen radical product was detected (<10% yield) and this could be easily characterized by electron paramagnetic resonance, ultraviolet spectroscopy, and its electrochemical behavior. More recently, Raghavan and Iwamoto (11, 12) have investigated the reduction of 1-alkylpyridinium ions in acetonitrile at platinum and mercury electrodes. As 1,1'-dialkyl-4,4'-bipyridinium monocation radical species were obtained by treatment of electrolyzed solutions with 1,4-benzoquinone, it was concluded that in this aprotic solvent the prime reduction product was a stable 1,1'-dialkyl-4,4'-tetrahydrobipyridine (alkyl = methyl, ethyl, or benzyl). In general, however, unequivocal characterization of the reduction product distribution has seldom been achieved and the experimental conditions and factors that can influence and determine mechanistic pathways are not fully understood. Further, scant electrochemical information is available for dihydropyridine and tetrahydrobipyridine compounds.

Results

The electron transfer characteristics of the alkylpyridinium ion reduction in melt may be readily studied by a Tafel plot of solvent electrolysis. Data illustrated in Fig. 1 were obtained from 10 msec potentiostatic pulses into the reduction background of

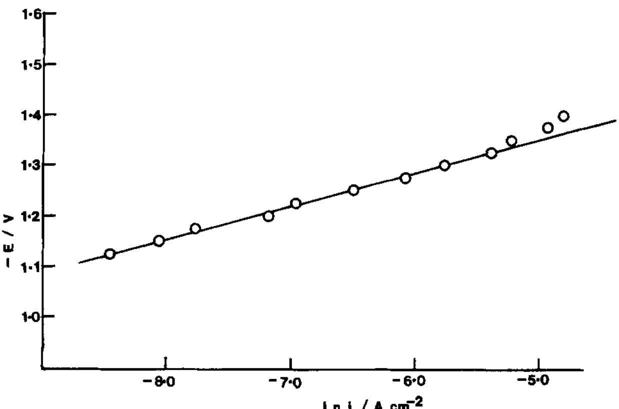

Fig. 1. Tafel plot of 0.8:1 melt reduction at a vitreous C electrode, 40°C.

the 0.8:1 molar ratio $AlCl_3$:1-BPC fused salt at 40°C, respectively. The short pulses were applied to minimize any complications from product formation and a Luggin probe reference electrode was used to minimize the *IR* drop. At constant values of the outer Helmholtz layer potential, the cathodic transfer coefficient α may be derived from the relation

$$\alpha = \frac{\alpha_c}{\nu} = -\left(\frac{RT}{nF}\right)\left(\frac{\partial \ln |I_c|}{\partial E}\right)_{T,P,c_i\ldots}$$

where R is the gas constant, T the thermodynamic temperature, ν is the stoichiometric number, and I_c is the cathodic kinetic current. The value of the cathodic transfer coefficient, $\alpha = 0.408$, is consistent with the kinetic parameters for simple, rate-determining, one-electron processes and this may be taken as evidence that the primary reduction reaction is the formation of a pyridinyl radical species

R–N⁺(pyridinium) + e⁻ → R–N(pyridinyl radical) [1]

followed by a rapid dimerization

2 R–N(pyridinyl radical) → R–N(tetrahydrobipyridine)N–R [2]

DBTBP.—At potentials more negative than ~−1.40V *vs.* Al(O) reference, the overpotential $\eta/\ln i$ gradient increases, which may be an indication of either (*i*) commencement of product reduction or filming complications, (*ii*) a second electron charge transfer to the pyridinium ion [*cf.* electronic absorption behavior (13)], or (*iii*) coreduction from pyridinium ion and the tetrachloroaluminate ion species.

Figure 2 illustrates cyclic voltammograms obtained by scanning into the solvent background to −1.40V *vs.* Al(O) reference. Onset of 1-butyl-pyridinium ion reduction with vitreous carbon electrodes occurs at ~−1.1V *vs.* Al(O) reference. No reverse anodic currents could be detected at the negative background limit at scan rates as fast as 200 $Vsec^{-1}$, or by scanning to −1.80V *vs.* Al(O) reference, which would be the case if the primary product from reduction undergoes an extremely rapid chemical reaction. At scan rates $dE/dt \lesssim 200$ $mVsec^{-1}$, a predominant anodic current peak A appears at −0.40 ± 0.04V (C electrode). Because the peak potential of wave A coincides approximately to that assigned to the oxidation of dimeric 4,4'-tetrahydrobipyridine species in acetonitrile (11), it also can be assigned to the coupled product 1,1'-dibutyl-4,4'-tetrahydrobipyridine (DBTBP) in the melt. Unlike the behavior of 1,1'-dimethyl-4,4'-tetrahydrobipyridine in acetonitrile, at scan rates $dE/dt \lesssim 200$ $mVsec^{-1}$, the peak current of A decreased markedly with decreasing scan rate and the wave is not defined at 50 $mVsec^{-1}$ (Fig. 2), indicating that DBTBP may be chemically unstable. In order to further characterize its electrochemistry in the basic melt, a sample of DBTBP was prepared by the reduction of 1-butylpyridinium chloride with sodium amalgam (14) (q.v. Experimental section). When 6.8×10^{-5} moles of DBTBP were micropipetted into ~10 ml of 0.8:1 melt at 40°C, the solution immediately became deep blue, the rest potential became −0.94V *vs.* Al(O) reference and approximately equal quantities of 1,1'-dibutyl-4,4'-bipyridinium monocation radical and the corresponding dihydrobipyridine were detected by cyclic voltammetry (Fig. 3) *vide infra.* After ~30 min and based on a diffusion coefficient of 7×10^{-7} cm^2sec^{-1}, the conversion yields were estimated to be about 25% for each product. Small anodic current peaks also were observed at +0.18 and +0.55V; however, the alkyl viologen radical and dihydrobipyridine comprised the major electroactive products. If a smaller quantity of DBTBP was added (<2 × 10^{-5} moles), the rest potential was less negative at ~−0.60V and 1,1'-dibutyl-4,4'-bipyridinium monocation radical was the only major electroactive product detected. Although these experiments confirm the unstable nature of the 4,4'-tetrahydrobipyridine in the melt and support the premise that its decomposition produces 1,1'-dialkyl-4,4'-bipyridinium monocation radical, unfortunately they do not provide any insight to the mode of hydrogen loss or to the dissociation mechanism

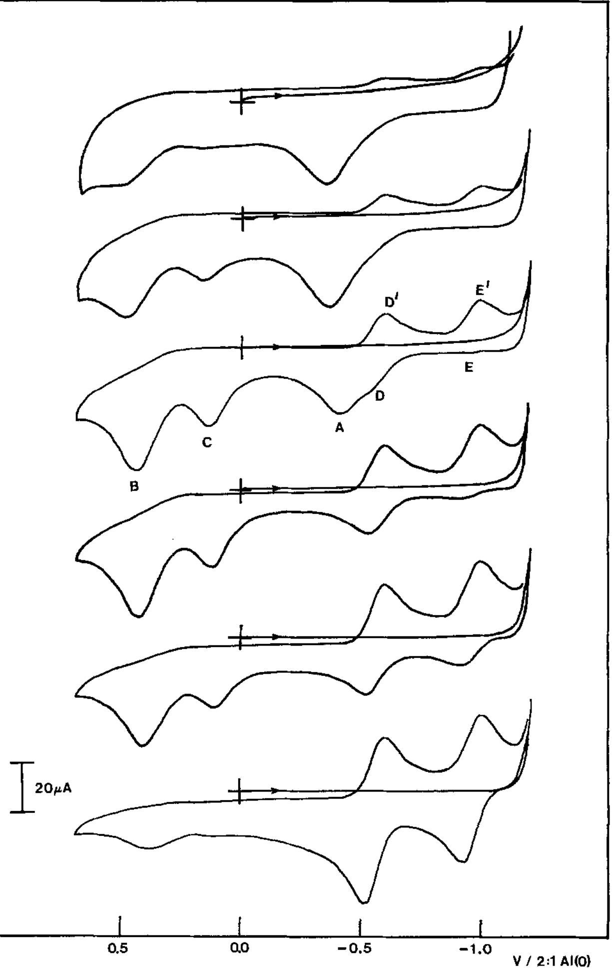

Fig. 2. Cyclic voltammetry of 0.8:1 melt reduction at 40°C, vitreous C electrode, 1 $Vsec^{-1}$ (top), 500 $mVsec^{-1}$, 200 $mVsec^{-1}$, 100 $mVsec^{-1}$, 50 $mVsec^{-1}$, 20 $mVsec^{-1}$ (bottom).

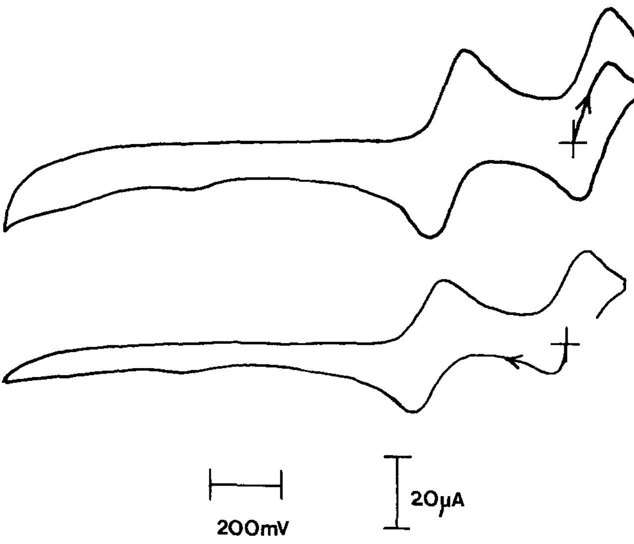

Fig. 3. Cyclic voltammograms after additions of 1,1′-dibutyl-4,4′-tetrahydrobipyridine to 0.8:1 $AlCl_3$:1-BPC melts; upper 16 μl/~10 ml melt, rest potential −0.909V; lower 20 μl/~10 ml melt, rest potential −0.940V; ν = 200 mVsec^{-1}.

- OmM → + unidentified products [3]

Coulometric experiments gave the ratio of the anodic charge (q_a) to cathodic charge (q_c) at a C electrode, q_a/q_c = 45% (50 msec double pulse, negative step 0.0 to −1.40V, positive −1.40 to 0.0V). These charge values were corrected for appropriate background double-layer charges to −1.00V negative limit. Raghavan has reported a corresponding figure of 70-95% coulometric ratio for 1-methylpyridinium ion in acetonitrile (11). In Fig. 2, the anodic current waves B and C exhibit time-dependent behavior at scan rates $dE/dt \lesssim 200$ mVsec^{-1}, similar to wave A. They may be attributed to other chemically unstable byproducts of pyridinyl radical dimerization or hydrogen exchange products, such as the 2,4′ or 2,2′ coupled dimers, *e.g.*

[4]

[5]

Additionally, there is a possibility of electroactive products that arise from tetrahydrobipyridine decomposition or even cleavage of the pyridinyl ring. Some attempts were made to isolate the products obtained from melt electrolyses at −1.25V in a vitreous C crucible, but proved inconclusive. After the passage of ~150C, for example, the melt was poured into degassed water, neutralized, and extracted with cyclohexane. Evaporation of the cyclohexane left a viscous, brown, tar-like material which gave infrared absorption bands at 1672, 1259, 1195, 803, and 722 cm^{-1}. Amides absorb strongly in the 1600-1700 cm^{-1} region of the spectrum and the residue could contain amide fragments, similar to those believed to be found after alkaline hydrolyses of $AlCl_3$:pyridine reduction products (8). In view of the likely air sensitivity and highly reactive nature of the primary products, this product analysis approach was considered to be unsatisfactory.

Figure 4 illustrates cyclic voltammograms of the background reduction of 0.8:1 molar ratio $AlCl_3$:1-methyl-2,4,6-trimethylpyridinium iodide. An oxidation peak at ~−0.50V *vs.* Al(O) 2:1 $AlCl_3$:1-BPC reference can be assigned to dimer product oxidation, *e.g.*

$- 2e^- \longrightarrow 2$ [6]

The primary radical could not be detected in cyclic voltammograms ν <200 Vsec^{-1} but the broad anodic wave is present at scan rates as low as 20 mVsec^{-1} and there is no evidence that this dimer can decompose to other electroactive products. The coulometric efficiency (q_a/q_c) was determined to be 67 ± 11%. An anodic wave [−0.78V *vs.* Al(O) 2:1 $AlCl_3$:1-BPC] is also obtained from reduction of 0.8:1 molar ratio $AlCl_3$:1-butyl-4,tert.butylpyridinium chloride melt (60°C) and following the suggestion made by Raghavan (11), it is probable that 2,2′ coupling ensues.

Melt electrochemistry of the biquaternary bipyridyl bases.—The two reversible couples D/D′ and E/E′ in Fig. 1 are indicative of the presence of the monocation radical and the dihydrobipyridine of 1,1′-dibutyl-4,4′-bipyridinium dication

$+ e^- \rightleftharpoons$ [7]

$+ e^- \rightleftharpoons$ [8]

The positive potential sweep reveals that at dE/dt

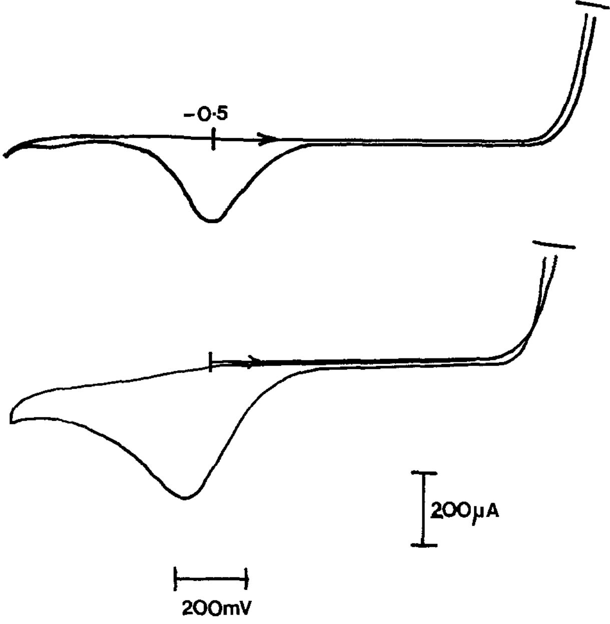

Fig. 4. Cyclic voltammetry of $AlCl_3$:1,2,4,6-tetramethylpyridinium iodide reduction at vitreous carbon. Background sweep to −1.70V vs. Al(O) in 2L1 $AlCl_3$:1-BPC reference, 60°. Upper ν = 20 mVsec^{-1}; lower ν = 1 Vsec^{-1}.

$\gtrsim$ 100 $mVsec^{-1}$, the transient concentration of the dihydrobipyridine in the surface reaction zone is less than that of the monocation radical, suggesting that the latter is the initial decomposition product of 4,4'-tetrahydrobipyridine dimer. The iR uncompensated peak separations for both of the couples are $(E_p{}^c - E_p{}^a) \approx 70$ mV, compared to the theoretical value of 62 mV for a one-electron process at 40°C. If a small quantity of aluminum metal is permitted to react with basic melt, the solution becomes deep blue and the u.v./visible spectrum of a diluted portion confirms that it contains the dialkyl viologen monocation radical [Fig. 5, *cf.* Fig. 2 (15)]. Acidification of the melt (>1:1) caused the disappearance of the blue radical in a chemically reversible manner because re-addition of 1-BPC restored the blue coloration. Presumably, the $Al_2Cl_7^-$ anion is reduced by the mono-radical to elemental aluminum in a finely divided state, to a subvalent aluminum species, or to a charge-transfer complex. Normal pulse voltammetric analyses of the viologen reduction waves (Fig. 6), which occur with half-wave potentials of −0.56 and −0.96V *vs.* Al(O) reference, for reactions [7] and [8], respectively, have $\log(i_d - i)/i$ slopes of 67 mV in close agreement to the theoretical 62 mV slope for one-electron reversible behavior. Assuming that 2 electrons are required to form each molecule of the monocation radical through dissociation of a 4,4'-tetrahydrobipyridine intermediate, the yield from the normal pulse voltammetric limiting current based on aluminum oxidation ($3e^-$) is estimated to be ~30%. The half-wave potentials for these two waves and their separation are reasonably consistent with values for dialkyl viologen reductions in nonaqueous solvents (*e.g.*, Table I). The maximum on the second reduction wave is indicative of adsorption complications, which are well known to occur under aqueous conditions [*e.g.*, (21-23)].

Discussion

From a comparison of the electrochemical potentials for the ferrocene/ferrocinium couple and the oxidation of 12 aromatic hydrocarbons in acetonitrile to those in the $AlCl_3$:1-BPC molten salt (24), the Al(O) reference in the 2:1 melt lies approximately at +0.15V *vs.* SCE and at −0.26V *vs.* Ag/Ag^+ (0.1M). As Raghavan (11) has reported that the cyclic voltammetric peak potential for the reduction of 1-methylpyridinium ion occurs at −1.28V *vs.* SCE in acetonitrile (*ca.* 5×10^{-4}M; Hg electrode), it would seem that the electrode reduction potential for 1-butylpyridinium ion in melt (~4.4M) is essentially unaffected by these changes in the solvent nature and electrode material. These studies

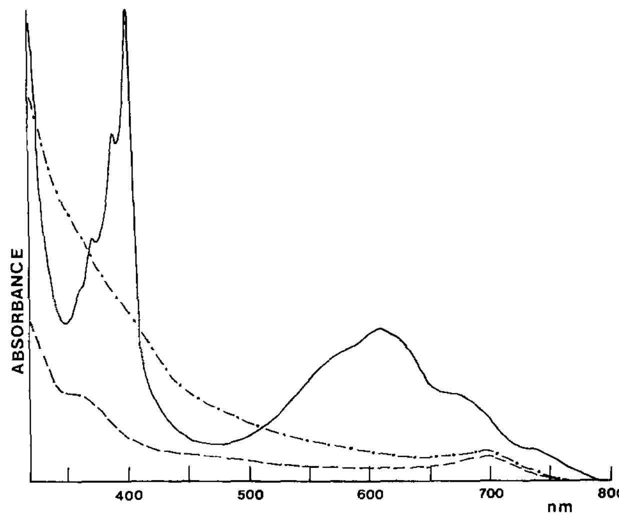

Fig. 5. U.V./visible spectrum of 0.8:1 melt reacted with aluminum (solid line), after $AlCl_3$ addition (>1:1) (dot-dash line), and background of 0.8:1 melt (dashed line).

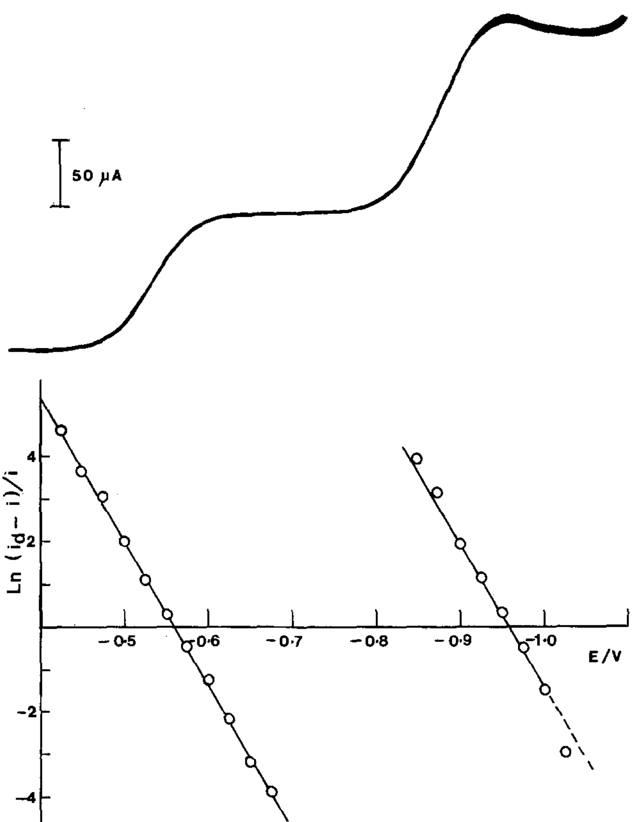

Fig. 6. Normal pulse voltammetry of 2.08×10^{-4} moles Al reacted with 8.7 ml 0.8:1 melt, 40°C, sweep rate 5 $mVsec^{-1}$, 100 mV pulse, C electrode.

affirm that the alkylpyridinium cation standard reduction potential in the basic $AlCl_3$:1-BPC melt approximates to that found in aqueous or certain nonaqueous solvents. This is consistent with a simple ionic model for the solvent structure and seemingly no modification of the electron transfer reduction reaction by alkylpyridinium cation/aluminum species interactions. Electrophilic pyridinium ions generally are reduced at less negative potential than pyridines, although Lewis acid complexation may alter drastically the ease of electron transfer and ligand reduction of unquaternized heterocycles. For example, the $AlCl_3$:pyridine adduct has an $E_{1/2}$ value of −1.00V in distinction to the value of −2.20V (*vs.* Hg pool reference) for the uncomplexed pyridine (8, 9).

There are two intrinsic factors that may be important to consider in the choice of an alkylpyridinium ion species for a particular molten solvent of this type, namely (*i*) the pyridinium ion reduction potential, and (*ii*) the relative stability of the primary pyridinyl radical. Each may be modified by the substituent groups that are present on the pyridinium ring and, as mentioned above, N-alkylation greatly facilitates reduction but changes in the chain length of N-alkyl

Table I. Comparison of literature data of dialkyl viologen half-wave potentials

Viologen salt	$E_{1/2}'/V$	$E_{1/2}''/V$	Solvent	Reference electrode	Ref.
Di-1-butyl	−0.56	−0.96	$AlCl_3$: 1-BPC	Al(O)	This work

substituents have minimal effect on the reduction potential (10). C-alkylation modifies the reactivities of compounds by raising or lowering the reduction potential due to the electron-donating power of the alkyl groups (3). Despite the paucity of electrochemical data concerning substituted alkylpyridinium ion species, there has been a reasonably successful attempt to correlate the energies of the longest wavelength charge-transfer band of alkylpyridinium iodides and the appropriate half-wave reduction potentials (13, 7). A second (shorter wavelength) charge-transfer band, not unexpectedly, could not be related to the half-wave potentials, although Tafel slope analyses might be able to detect the occurrence of a closely spaced, second electronic transition (*e.g.*, $\Delta E < 10$ kcal mole^{-1}). Kosower and Skorcz (25) have carefully measured the low energy, charge transfer bands of 20 different alkylpyridinium iodides and established that the transition energy is raised by either increasing the number of methyl groups attached to the ring or by changing the position of a single methyl group, 3-<2-<4-. Replacing a methyl by a t-butyl group in the 4-position had little net effect on the electron supply, suggesting that hyperconjugation does not contribute to the molecular ground state stabilization, unlike the effect found with the corresponding 2-constituents. Alkyl substitution is thought to afford greater stabilization to the ground state of the cation than to that of the radical (25). The commencement of reduction shifts negative, approximately −1.1, −1.3, and −1.4V for the cations 1-butylpyridinium, 1-butyl-4, tert. butyl-pyridinium and 1-methyl-2,4,6-trimethylpyridinium, respectively, thereby providing some increased accessibility to reduction processes. N-alkyl-pyridinium ions having electron withdrawing substituents, such as 2-, 3-, or 4-substituted cyano groups, reduce more readily than the unsubstituted compound. The effects of alkyl substitution on the chemical stability or the physical properties of the $AlCl_3$ melt mixtures, such as their liquidus characteristics, have not yet been investigated.

A second factor of interest is the stability of the primary pyridinyl radicals, whose reactivity is such that they cannot usually be detected by slow transient techniques. The product distribution arising from their subsequent reaction in $AlCl_3$:1-BPC solvents is more complex than that found from pyridinium ion reduction in acetonitrile (11) and it is complicated by the chemical instability of at least one of the dimers formed. The causes for this enhancement in the rate of the 4,4′-tetrahydrobipyridine dissociation are not understood but it could be related to the overall basicity of the media, *i.e.*, the chloride ion nucleophile concentration, or to increased rates of electron transfer. Loss of the 4-hydrogen is evidently facile whereas the 4-methyl group forms a stable C-C bond. Apparently, little systematic work has been carried out on the ability of constituents to stabilize dihydropyridines, but polycyclic or highly substituted molecules seem to be less reactive, possibly because of steric effects (2). Effects due to other N- or ring substituents (*e.g.*, OH^-, -CN, -halides, etc.) have not been investigated to date, either from the standpoint of the reduction potentials of compounds, the reactivities of reduction products, or the fundamental physical characteristics of the chloroaluminate melts.

Experimental

Handling methods and preparation of melts have been described in previous publications from this laboratory. All electrochemical experiments were made in a Vacuum Atmospheres Company dry box under purified argon. The cyclic voltammetry and programmed pulse measurements were made with PAR Models 175 Universal Programmer and 173 Potentiostat/Galvanostat coupled to a Houston Instruments 2000 Omnigraphic X-Y recorder. Normal pulse voltammograms were made using the PAR Model 174 Polarographic Analyzer. The reference electrode comprised coiled Al wire immersed in 2:1 molar ratio $AlCl_3$:1-BPC melt, respectively, isolated in a glass fritted tube. Working electrodes were either vitreous carbon of geometrical area 0.0855 cm^2 sealed in Pyrex glass (G.C.20 grade, Tokai Electrode Manufacturing Company, Limited) or tungsten wire button electrodes sealed in uranium glass. U.V./visible spectra were recorded, using cells filled and sealed in the dry box, on a Cary 17 Spectrophotometer. Mass spectroscopy data were obtained with an A.E.I. MS 12 instrument with the source ~150°C and probe ~80°C. N.M.R. measurements were made with either the JEOLCO MH100 100MHZ Spectrometer, the Varian EM360A 60MHZ Spectrometer or the JEOLCO FX100 Fourier Transform Spectrometers, in 5 mm tubes.

Syntheses and characterization of 1,1′-dibutyl-4,4′-tetrahydrobipyridine.—Preparation.—0.0583 moles of 1-butylpyridinium chloride in 50 ml water was stirred for 20 min with 100 ml diethyl ether and 250g Hg (Na 0.6% wt.) in an argon atmosphere. The yellow ether layer was separated and the ether removed by vacuum, to leave a yellow/brown oily residue, which was used without further purification. Despite storage in a sealed glass container in the dry box the color deepened and the product slowly decomposed. C, H, N microanalyses were made by Galbraith Laboratories, Incorporated, Knoxville, Tennessee 37921, theory for $C_{18}H_{28}N_2$ C 79.37, H 10.36, N 10.28; found C 79.16, H 10.19, N 10.14; yield 90.5%; measured density, ρ = 0.932(25°), M.wt. 272.4.

U.V. bands.—226 nm, 300 nm(sh)/solvent diethyl ether.

Mass spectrum.—Parent peak 272(1.3%), loss of single N alkyl group 215(1.4%), monomer radical formation 136(100%) (bracketted figures are approx. relative intensities).

C.m.r. data.—131.6(d), 99.5(d), 53.2(t), 42.8(d), 32.9(t), 20.4(t), 14.1(q)ppm. The gated-mode off-resonance technique confirms the 4,4′-bridging between the two pyridine rings.

P.m.r. data.—5.87-5.80 (d, 4, J = 8 Hz, C-2, −2′, −6, −6′ vinyl), 4.29-4.17 (m, 4, C-3, −3, −3′, −5, −5′ vinyl), 3.00-2.84 (m, 2, C-4, −4′ methine), 1.47-1.09 (m, butyl), 0.95-0.82 (t, CH_3)/solvent CD_3CN references to internal TMS.

Syntheses of 1-methyl-2,4,6-trimethylpyridinium iodide and 1-butyl-4, tert.butyl-pyridinium chloride.—Preparation.—Quaternizations are conveniently carried out in heavy-walled glass tubes (10 × 2 1/2 in. OD). ~100g of the pyridine was added to an equivalent molar quantity of the alkyl halide, the mixture frozen, the tube evacuated, sealed, and heated in an oven at 80°-100° for several days. Crude products were purified by 3 recrystallizations from acetonitrile/ethyl acetate mixtures.

Analyses.—$C_9H_{14}NI$, M.wt 263.1; theory C 41.08, H 5.36, N 5.32, I 48.23, found C 41.51, H 5.62, N 5.59, I 46.58 $C_{13}H_{22}NCl$, M.wt 227.8; theory C 68.55, H 9.74, N 6.15, Cl 15.56, found C 67.49, H 9.98, N 6.84, Cl 15.73.

Technical Notes

Development of a 7 kW H_2/O_2-Fuel Cell Assembly with Circulating Electrolyte in a Compact Modular Design

Karl Strasser

Siemens AG, Research Laboratories, D-8520 Erlangen, Germany

As a consequence of the energy crisis in the year 1973, the intensive discussion which followed, on the possibilities of a new orientation in the energy sector, has revived interest in fuel cells. The limited reserves of primary energy sources such as the fossile fuels and the resulting environmental strains due to their combustion have intensified the considerations of new energy systems in which hydrogen, among others, has received special importance.

In such energy converting systems, the application of the fuel cell is advantageous especially because of its favorable efficiency, noiseless conversion, low maintenance, and also due to the absence of polluting gases in the case of H_2.

In spite of these advantages the fuel cell could not find wide spread applications until now. The reasons lie not only in the relatively high costs of the fuel cell itself but also in the costs of reactants and their storage. The development of Siemens alkaline H_2/O_2-fuel cells was aimed at increasing the power density with simultaneous improvement in the reproducibility and in the engineering features of the unit (2).

Basic Principles

In an alkaline H_2/O_2-fuel cell system hydrogen is oxidized at the anode while oxygen is reduced at the cathode. A 30% potassium hydroxide solution is used as the electrolyte. Water and heat are the reaction products which dilute and heat up the electrolyte.

Figure 1 shows the schematic construction of the cell (3, 4). The free electrolyte between the gas-stop layers is typical of Siemens fuel cells. The electrodes consisting of Raney nickel (5-7) and doped silver (8) are gas diffusion electrodes which are compressed iso-

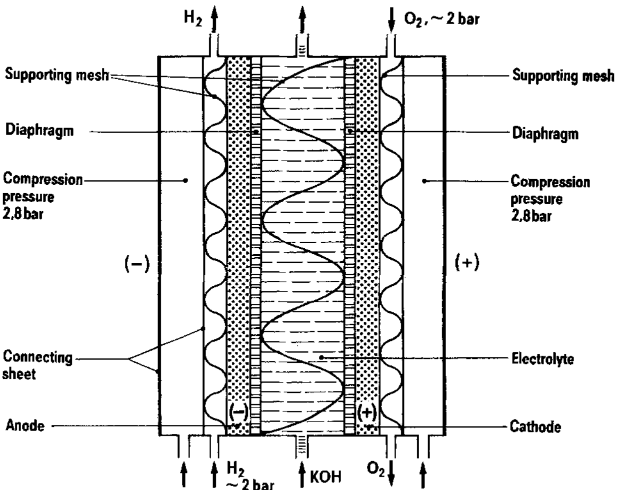

Fig. 1. Fuel cell with free electrolyte and supported gas diffusion electrodes.

statically over relatively flexible metallic contact sheets to improve the electrode contact on the electrolyte and current collecting sides (9). Due to the bipolar arrangement of electrodes, the cells of a stack are generally connected electrically in series. But it is also possible to connect groups of cells electrically in parallel.

The cells are operated with a hydrogen pressure of 2 bar, an oxygen pressure of 1.95 bar, and a compression pressure of 2.8 bar at 80°C approximately. Owing to the greater thickness of electrolyte layer through the "free electrolyte" the cell internal resistance and thus the voltage loss is larger than in comparable matrix systems.

Various auxiliaries are required in operating a fuel cell stack. They are shown in the functional schematic Fig. 2. Hydrogen and oxygen are supplied to the fuel cell stack via separate gas pressure regulators and gate valves which can be manipulated either by hand or over a potential-disconnected current circuit. The inert gas proportions are concentrated in the last step of a cascading system (10) and are removed by electrically regulated valves. Along with the in-streaming of the reacting gases inside the stack, the electrodes are simultaneously compressed isostatically over "pressure cushions" and pressure intensifiers or already "inflated" previously. During this course, a check valve prevents the "pressure gas" from escaping. Hydrogen also streams into the diffusion spaces of the evaporator through a pressure reducing valve. The resulting water and waste heat of reaction are initially removed from the fuel cell stack through the circulating electrolyte by means of a pump (11) and are again withdrawn from the electrolyte in the electrolyte regenerator. The waste heat is extracted from the electrolyte regenerator by a cooling water circulation in which the cooling water inflow is regulated by a valve depending on the temperature. According to the electrolyte level inside the tank the condensate emerging from the electrolyte regenerator is either led out or fed back to the electrolyte circulation.

The principle of electrolyte regeneration (12) through an evaporator is shown in Fig. 3. Due to the partial pressure gradients of vapor between the evaporating and condensing areas, water vapor is transported by diffusion from the electrolyte to the cooling water side where it condenses. In this manner, water and heat are simultaneously removed from the electrolyte.

Design of the 7 kW-Fuel Cell Unit

The construction assembly of the unit is represented in Fig. 4. The compact unit block having the dimensions of 245 × 240 × 1025 mm and the weight of 85 kg is composed of the functional groups of the fuel cell stack, the electrolyte regenerator, the electromechanical controlling unit, the supply system, and the electronic control device. It possesses electrical plugs on

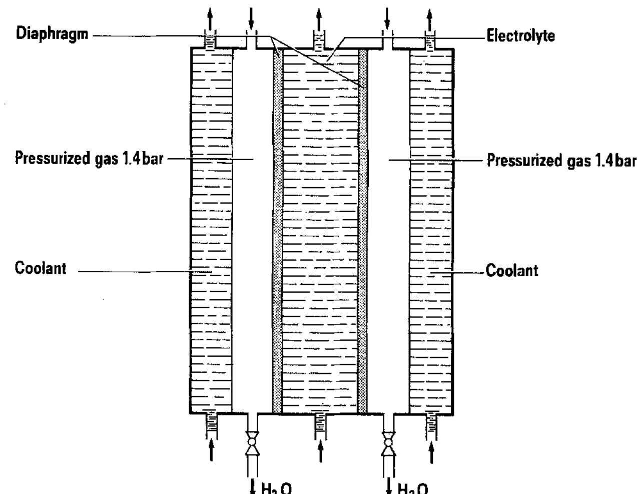

Fig. 3. Fuel cell unit: electrolyte evaporator cell

the fuel cell stack side for the consumer, and connections on the opposite side for hydrogen, oxygen, cooling water, condensate, and scavenging or leakage gas. All control elements are flange connected to a wall of the electrolyte tank that is created by the distribution block. The electronic control unit is bolted to the fuel cell stack on the service side and is joined to the control elements on the supply side through pilot connections.

The unit is designed as a module whose rated voltage can be varied by switching the cell groups in series and in parallel in four different steps (6-9; 12-18; 24.5-35 and 49-70V) and whose power can be set by altering the number of cells also in four steps. In a plant consisting of several modules, each unit is connected over a detachable plug-linkage with the supply system which forms a part of the module casing.

The most important functional group of the assembly is the fuel cell stack which, in general, consists of 70 cells switched electrically in series. Characteristic for the cells are the free electrolyte space, which is filled with textured plates for the reason of electrode supporting, the bonded gas diffusion electrodes, and the "pressure cushions" (Fig. 1). Due to the special structure of the textured plate the transport of gas bubbles is facilitated and, at the same time, a low flow resistance is ensured. By virtue of preparation, catalyst and binder are firmly bonded to a supporting texture which conducts the current further to a contacting sheet. This contacting sheet possesses imprinted flow channels for the reactants, and on its reverse side, pressure gas is admitted with the purpose of compressing the electrode isostatically.

Figure 5 shows an exploded view of the cell. The asbestos diaphragms (13) which prevent the mixing of

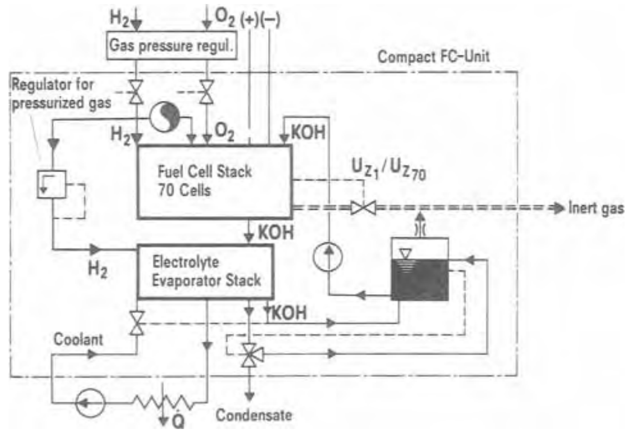

Fig. 2. Functional schematic of the fuel cell unit

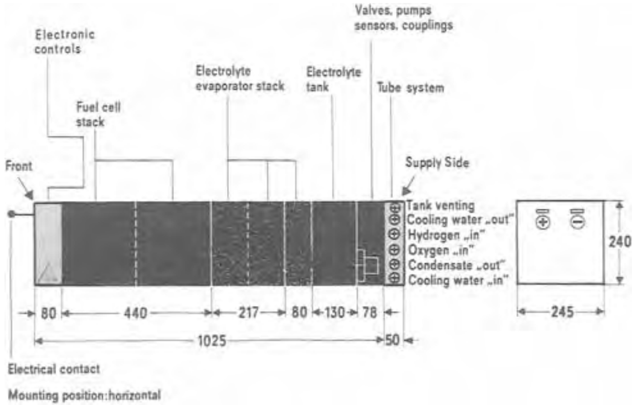

Fig. 4. Design and dimensions of the 7 kW compact fuel cell unit.

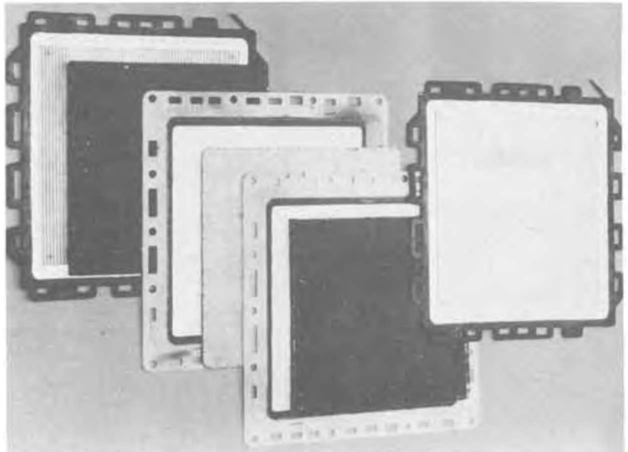

Fig. 5. Exploded view of the cell

gases and electrolyte are sealed tightly with polysulfone frames by means of an epoxy resin, and the contacting sheets of pure nickel are pressed around tightly with an elastomer frame. Owing to the grooves provided in the frames, the network of axial and radial channels for electrolyte, reactants, cooling water, and condensate is created while building the assembly. In preparing the electrodes a sedimentation process has proved useful. Raney nickel is used as catalyst for the anode. It is doped with small quantities of titanium for a better stability at 80°C and for a higher performance at lower temperatures. A silver catalyst precipitated from aqueous solution and containing stabilizing additives of the oxides of nickel, bismuth, and titanium is used for the cathode. The catalysts are powdery. The electrodes are obtained by whirling a mixture of catalyst powder, Teflon suspension, and a small amount of asbestos fibers in water and sedimenting it on a pure nickel texture. The electrodes thus obtained are mechanically stable, easy to handle, and their loading differences lie in the range of $\pm 5\%$. The catalyst loading density of anode is approximately 120 mg/cm² and that of cathode approximately 60 mg/cm². The electrode area is approximately 340 cm².

The assembly of the evaporator components is very similar to that of the fuel cell.

Developmental Problems

After initial difficulties concerning the reproducible properties of the anode catalyst, satisfactory results were achieved by using a titanium-doped catalyst.

The current-voltage characteristics which were measured with single cells could also be reproduced with fuel cell stacks by applying the isostatic compression method utilizing the so called "pressure cushions" in the fuel cell stacks.

Different potentials at the individual cells of a stack cause parasitic currents to flow through the electrolyte channel network, diminishing the efficiency. Moreover, an important requirement for a uniform removal of water and heat from the fuel cells is that the electrolyte volume is uniformly distributed over the cells which are streamed through in parallel. By dimensioning the electrolyte channels appropriately and by elaborate flow tests a deviation of less than $\pm 5\%$ was attained in the relative temperature distribution. In the permissible voltage range of 42-70V of the assembly, the parasitic losses amount to 15-35W, *i.e.*, approximately 2% at the point of rated load and are thus negligible.

The diaphragms have caused considerable difficulties by gas leakages, owing to inhomogeneities of materials and the relatively low mechanical strength. Satisfactory results were achieved after improving the preparative method and altering constructive details.

Special conditions are not imposed on the insulation resistance because of the low voltage of the unit. However, it was found that even low currents can lead to operational inefficiency of the unit by electrochemical corrosion of the materials. This problem was solved by using materials having an electrical insulation resistance of more than 10^6 Ωcm.

Results of Measurements with 7 kW Types

After the successful test of trial stacks containing a small number of cells, the projected power was demonstrated with the first 7 kW assembly in June 1977. A 3.5 kW compact unit was put into operation in February 1978 after undergoing different improvments. The assembly differs from the standard model in its fuel cell stack which contains only half the number of cells (35 cells) and in its evaporator which is only half the standard size. The second 7 kW assembly was built in May 1978 and tested subsequently. The third 7 kW compact unit is under test successfully since February 1979. Figure 6 shows this unit mounted in a rack in order to investigate its performance under inclined positions.

The current-voltage characteristic of the unit is illustrated in Fig. 7. The curve is slightly bent due to the elevation of the mean electrolyte temperature from approximately 72°C at idling state to approximately 80°C at rated current. At a rated current density of 420 mA/cm², corresponding to a current of 142A, the mean cell voltage amounts to approximately 0.768V and the assembly voltage to 53.8V. The characteristic

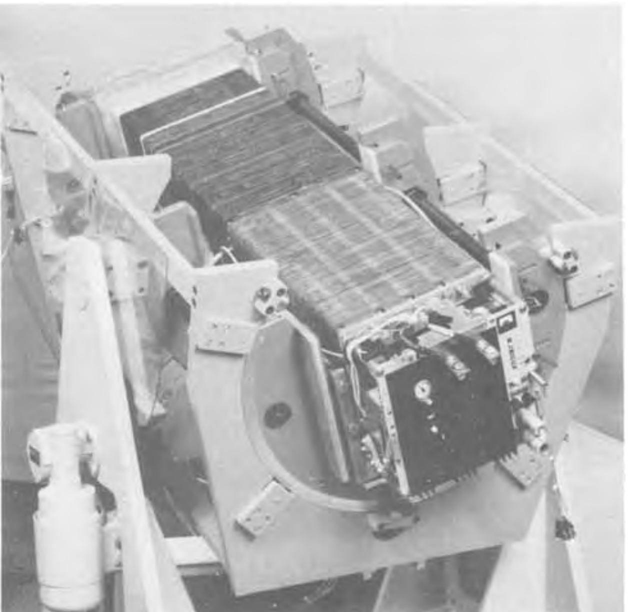

Fig. 6. 7 kW compact fuel cell unit

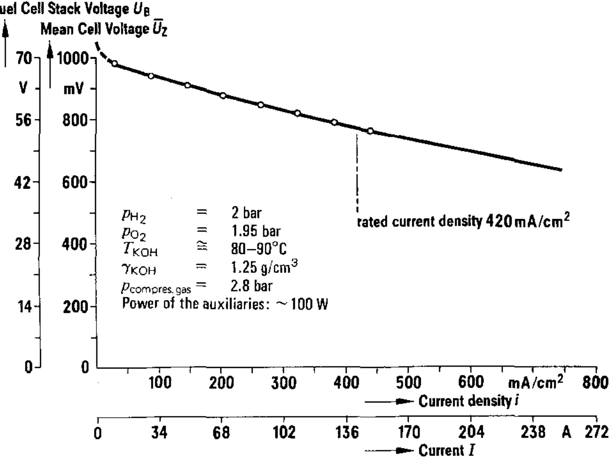

Fig. 7. Current-voltage characteristic of the 7 kW fuel cell unit

was measured at an H_2 pressure of 2 bar, at an O_2 pressure of 1.95 bar, and at a KOH concentration of 6-7M. The pressure of the enclosed compression gas system varies in a range of 2.4-3 bar along with the temperature.

Figure 8 shows the voltage of individual cells of the stack at the point of rated current. In spite of certain process-relevant deviations in the working conditions of individual cells of the stack, for example, the temperature, the inert gas concentration, the reactant pressures, or the loading due to parasitic currents, the scattering of the cell voltages in the stack is smaller than ±10 mV. The voltage of the cells 12, 13, 20, and 21 could not be measured due to difficulties in the electrical contacts. But a small deviation can be assumed even in these cells since the mean cell voltage value calculated from the total voltage is 0.768V. The voltage of cell 70, that of the reference cell which scavenges inert gas from O_2 side, is a function of the inert gas concentration. The cell voltage at rated current drops to about 200 mV between two cleanings in a period of about 30 sec.

The rated power of the assembly amounts to 7.55 kW; the internal consumption of 100W by the controls is already included. Figure 9 shows the power of the fuel cell stack as dependent on the current density. The point of rated load lies on the still ascending part of the curve. The permissible power is limited by the heat removal from the electrolyte circulation. However, 1.4 times the rated load is permissible for a short time. A further limitation in power is given by the anodic oxidation potential. The assembly is switched off by a voltage control at a mean cell voltage of 0.6V, before the anodic oxidation potential is reached.

However, owing to the deterioration in efficiency, these voltage ranges are generally not of importance. The efficiency at the point of rated load is about 51%. As shown in Fig. 10, it increases in the partial load

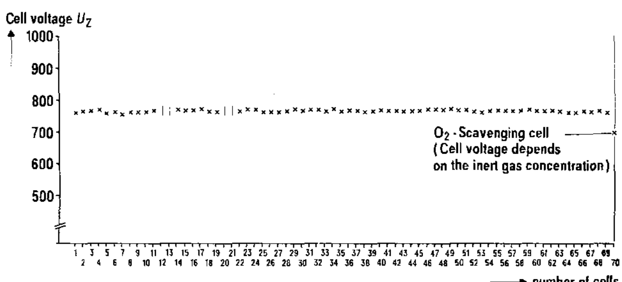

Fig. 8. Voltage of each cell in the fuel cell stack at rated load

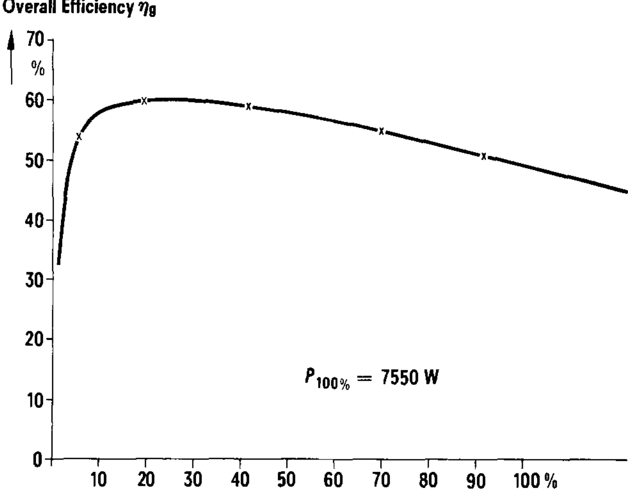

Fig. 10. Overall efficiency of the 7 kW fuel cell unit as a function of the load factor.

range and attains a maximum of over 60% at a load factor of 10-30%. In this particular behavior, the fuel cell is distinguished from all other known systems of energy conversion.

Under the switched off state, hydrogen is admitted to the fuel cells on anode and cathode sides. Upon reswitching, the assembly voltage increases slowly due to gas exchange on the O_2 side, and independent of loading, it attains after 4-5 sec, the final value corresponding to the current and the working conditions. Figure 11 shows the voltage rise in five different cases of loading on switching at normal operating conditions. Switching times of less than 1 sec were attained in tests with trial stacks. Switching times under 3 sec are attainable by dimensioning the gas channels appropriately, especially the channels of scavenging gas in the assembly.

Figure 12 shows the course of the stack voltage at changing the current from 0 to 140A. The voltage follows the current change with a time delay of roughly 200 msec. The voltage value is finally established after about 3 sec during loading as well as during idling. In this test only an ohmic resistance was connected and disconnected.

If the assembly is switched off the oxygen supply is cut out and oxygen present in the stack is let out at least partly by opening the O_2 scavenging valve. Gas exchange during switching is associated with a certain time lag. Since, it is also the case during switching off and moreover, since reacting gas is stored in the elec-

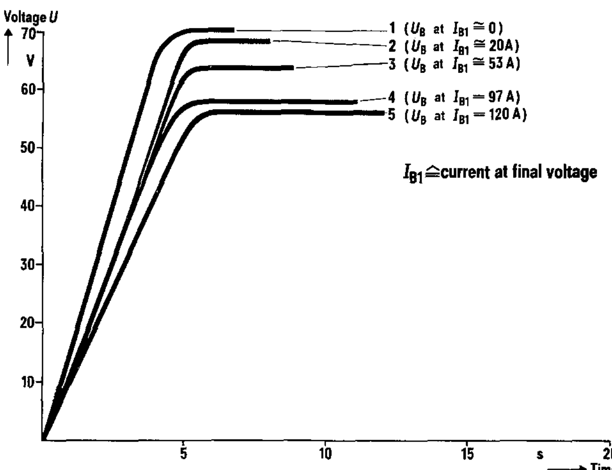

Fig. 11. Voltage of the fuel cell unit during switching on under normal operating conditions.

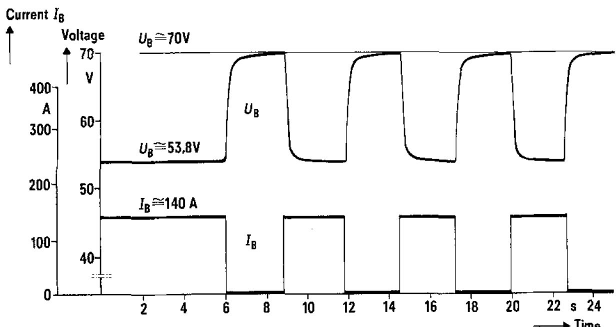

Fig. 12. Voltage of the fuel cell unit at changing load under normal operating conditions.

trodes, a longer period will be required for the voltage drop during switching off than required during switching on, as shown in Fig. 13. The figure shows the voltage behavior of the unit at four stages of switching off with different ohmic resistances as load. The wave-like shape of the curve is determined by the process and mode of control. The voltage drops to 20% of the rated value within 5 sec on switching off under rated power. According to investigations carried out with trial stacks, these times can still be reduced.

If the assembly is switched on at room temperature a certain time will be required until the working temperature is attained. The derivable power from the unit at room temperature at 49V is nearly 40% (Fig. 14). The rated power will be attained in 7-8 min if this voltage is kept constant by regulating the load during the warm-up phase. The assembly gets heated up by its own losses without additional internal heating. The lower the load the longer will be the start-up time.

Progress by Developmental Work

Figure 15 summarizes the progress made in the developmental work by comparing the current-voltage characteristics. The cells compared have almost the same dimensions. Section 1 represents the technical state available before beginning the project, a 2 kW unit with 33-celled stack, built 1970 and a 5 kW unit with 100-celled stack, built in 1973. Section 2 represents the technical stage reached by the first 7 kW unit, built in 1977. Section 3 represents the technical state of art, achieved with succeeding assemblies and other trial stacks.

Compared with the past technique which has been replaced now, the following progress could be made: an increase in current density by 100%, an increase in cell power by 300% at room temperature, an increase in cell power by 140% at working temperature, a reduction in start-up time by ~60%, and a reduction of power/weight ratio by ~70%.

A further increase of the power density of Siemens alkaline H_2/O_2 fuel cells containing free electrolyte and using non-noble metal catalysts is probable. The

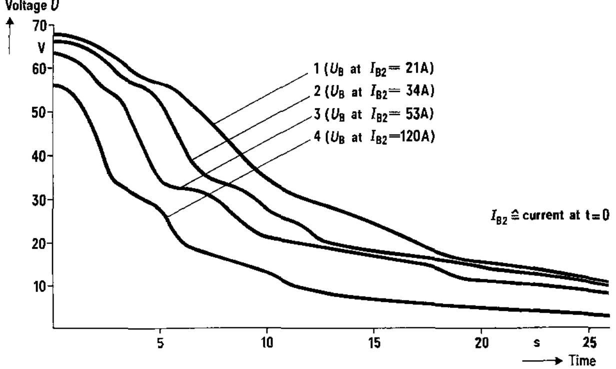

Fig. 13. Voltage of the fuel cell unit after switching off under normal operating conditions.

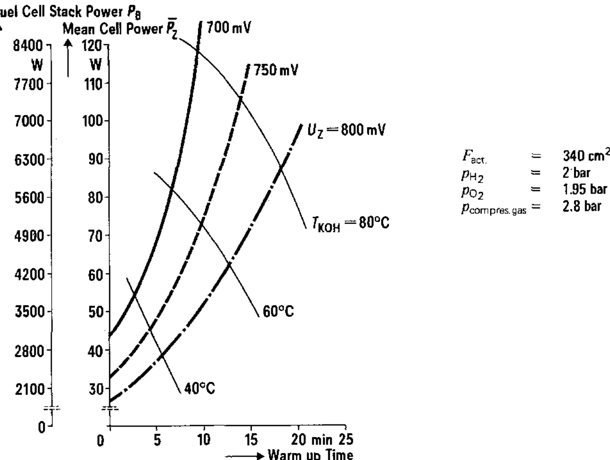

Fig. 14. Warm up behavior

practical use of such fuel cells, however, depends not only on technical characteristics such as the power density of the fuel cell unit, but just as much on the production costs of the units, the availability of storage capacity, and the costs of the reactants and the costs of the auxiliaries (H_2 tank, O_2 tank, cooling water condenser, etc.). The present overall situation limits the use of fuel cell units to special applications. However, if the importance of hydrogen as a fuel increases, and advances are made in its production, storage, and distribution, there would arise a number of possible applications including use in conjunction with a modified alkaline H_2/air fuel cell. The favorable part-load behavior of the fuel cell and its environmental acceptability, as well as the storage of energy in chemical form combined with the possibility of simple tanking, make it suitable for mobile and stationary power supplies (including standby power supplies) in that it will replace at least a proportion of conventional accumulators. In comparison with accumulators, the favorable weight of the entire system (power density inclusive of gas cylinders and cooling system is higher by a factor of 4) together with the aforementioned advantages, the possibility of rapid tanking, environmental acceptability, and favorable efficiency characteristic in the part-load range open up further application possibilities with respect to the electric propulsion of land and waterborne vehicles. The power density and the fact that operation is independent of the atmospheric air make fuel cells suitable for applications involving the propulsion of submarines, *e.g.*, for research purposes or for the maintenance of technical equipment (submarine cables, drilling rigs, etc.). It is also quite conceivable that they could be used for producing electric energy locally with simul-

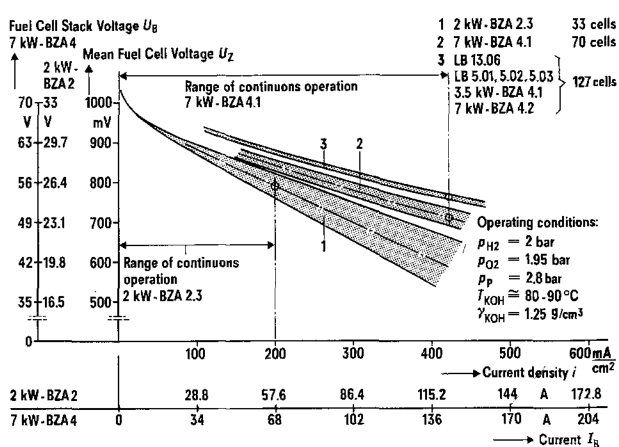

Fig. 15. Fuel cell units; comparison of the current voltage characteristics.

taneous utilization of the thermal losses for space heating. But we will first endeavor to collect experience with the operation of fuel cell pilot plants of small and medium ratings. Economic use of fuel cell units in the future will entail considerable effort to reduce costs and improve reactant production methods.

A dispersion of insoluble particles in certain solid ionic conductors is known to increase their total electrical conductivity (1-3). This note reports data on the electrical conductivity of intermediate compositions within the $LiI-H_2O-Al_2O_3$ system.

Experimental

In view of the complex equilibria among various hydrates of LiI and anhydrous LiI (4), the following drying procedure was adopted. A commercially obtained anhydrous LiI (Foote Mineral Company) was heated under vacuum ($<1 \times 10^{-3}$ Torr) at 60°C for 5 hr followed by 100°C heating for another 5 hr. Finally, it was dried at 140°C under vacuum overnight. The kinetics of the drying process is not known but the x-ray powder diffraction of the samples prepared as above showed only the diffraction lines due to anhydrous LiI. Alumina powders (Adolf Meller Company) of 0.3 μm nominal diameter[1] were dried under vacuum at ~750°C for 17 hr. Both dried materials were manipulated in a glove box in which air was dried by circulation through a column packed with P_2O_5 [0.04 ppm V H_2O (5)] to ensure that the water vapor pressure inside was less than that required for the formation of the LiI monohydrate (0.5 ppm V at 25°C) (6, 7). Anhydrous LiI was observed to be stable even after extended exposure in the above-mentioned glove box. All salts (including the hydrates) were blended with the alumina in an agate mortar and pestle inside the glove box. A portion was loaded into a stainless steel die and pelletized at 120,000 psi at room temperature. At the same time another portion of the sample was sealed into a capillary for the x-ray diffraction measurements. The water content of the samples was qualitatively monitored by the x-ray powder diffraction method. Unusually long x-ray exposure times were required to record the weak diffractions of the minor component. The hydrates were prepared by exposing powdered anhydrous LiI to various humid environments. In the absence of any elaborate control of water vapor pressure, it was not possible to obtain pure mono-, di-, and tri-hydrates. Hence, for a given hydrate, a trace of a second equilibrium phase was always present. The sample pellets were sandwiched and spring loaded between various combinations of electrodes of stainless steel and/or Li metal. Generally, the measured values did not depend on the electrodes used. However, Li electrodes tended to deteriorate at elevated temperatures (> ~50°C) when the H_2O content approached monohydrate level. The conductivity measurements (1.6 kHz a-c or d-c measurements at voltages below 0.5V) were carried out under a flow of dried argon using a Wayne-Kerr B221 Bridge, Keithley 616 Electrometer, and Keithley 260 Nanovolt source. No thermal pretreatment was carried out prior to the

Key words: conductance, x-ray powder diffraction, hydrates.

[1] The reported size of Al_2O_3 is determined by two different methods. Using BET, Adolf Meller reports 30 m^2/g while an independent laboratory reports to us ~23 m^2/g. Using these numbers and assuming spherical particles one calculates ~0.05 μm diam particle size. SEM observations show the particles to be platelet-like with the smallest dimension 0.2 μm (undried) to 0.08 μm (dried). There is a size distribution (unknown to us) and there is some agglomeration: 0.5-2 μm (undried) and 1.5-4 μm (dried).

measurements. Measurements were started at about 25°C and the temperature was monotonically increased.

Results and Discussion

The logarithm of a-c conductivity *vs.* $1/T$ for the LiI-H_2O system is shown in Fig. 1. The conductivity of anhydrous LiI is in good agreement with previously reported values (1, 8, 9) between 25° and 190°C. Because the di- and tri-hydrate are not stable above about 70°C, measurements were limited to lower temperatures. The x-ray powder pattern of the dihydrate is given in Table I. This pattern was identified as LiI · $2H_2O$ by interpolation of 100 plane d-spacings of LiI, LiI · H_2O, and LiI · $3H_2O$.

When a trace amount of LiI · H_2O was present in LiI (denoted by △ in Fig. 1), the Arrhenius plot was not linear and the conductivity increased sharply with temperature to ~130°C above which the conductivity values become erratic giving high values. Below ~130°C the curve was reproducible with respect to temperature cycles. Results using d.c. (Li electrodes) and a.c. (Li electrodes) on this sample were identical.

We cannot explain the curvature of this Arrhenius plot, however the maximum change in conductivity occurs at 130°C which corresponds to the reported eutectic of LiI · H_2O and LiI · $1/2H_2O$. This result suggests that a highly conducting solid LiI · $1/2H_2O$ phase is formed or a fusion process occurs. Further study of the phase diagram is needed.

Below ~70°C the conductivity of the monohydrate containing a trace amount of dihydrate depended on the annealing temperature of the conductivity pellet (~2 hr) as indicated by closed circles in Fig. 1. As the temperature of the sample was initially raised the conductivity followed the curve a. When it was annealed at 70°C and was cycled in temperature between 70°C and room temperature, curve b was followed. Heating the sample above ~100°C and temperature-cycling produced curve c. Heating between 100° and 130°C yielded curve d which on cooling followed curve c. The kink at ~78°C is believed to be due to the eutectic of LiI · H_2O and LiI · $2H_2O$. The magnitude of the kink tends to become smaller with repeated temperature cycling and with higher annealing temperature (~120°C). The samples of lesser LiI · $2H_2O$ content behaved similar to curve c without complications shown in curves a and b. Above 130°C the system become unstable with slow sample deterioration. These data suggest that the conductivity of pure LiI · H_2O would extend below ~78°C (as an extension of curve d or parallel to d, because no eutectic would form), yielding a value of $\sim 2 \times 10^{-5}$ Ω^{-1} cm^{-1} at 25°C, and would exhibit the same activation energy as LiI. It has been pointed out that this two orders of magnitude increase in conductivity, relative to that of pure LiI, is consistent with the reported structures (16).

The addition of 24 mole percent (m/o) dried Al_2O_3 to anhydrous LiI did not result in a conductivity enhancement (open circles in Fig. 2). However, the presence of Al_2O_3 extended the extrinsic region giving the knee temperature about 300°C compared with 250°C reported for pure LiI by Jackson and Young (8). There was no difference in conductivity between samples prepared by ground-mixing of LiI and Al_2O_3 and by ground-mixing followed by fusion. In the later case, the ground-mixed sample of dried LiI and Al_2O_3 was placed in a quartz boat inside a quartz reaction tube and the reaction tube was stopcock-sealed inside the dry box described earlier. The reaction tube, situated in a furnace, was evacuated and heated to 300°C while pumping. Finally the sample was fused in vacuum at 500°C for an hour. In contrast, when water was present along with Al_2O_3 there was an increased conductivity. This observed increase with the presence of water and Al_2O_3 is in accord with other observations (10, 2). The conductivity enhancing role of H_2O is also found in a similar electrolyte system, namely LiI · $xAl_2(SO_4)_2$ · nH_2O (11).

For two samples of LiI with a trace of LiI · H_2O denoted by △ (case I) and by × and □ (case II) in Fig. 2, the H_2O was introduced into the system of LiI Al_2O_3 through different paths. In case I, H_2O was carried in by undried Al_2O_3 while LiI carried water in the form of LiI · H_2O in case II. Invariably LiI · H_2O was indicated in both cases by x-ray diffraction. In case II, the magnitude of the conductivity varied qualitatively with H_2O content and the activation energy was 0.5-0.8 eV. The activation energy for case I was 0.76 eV and tended to decrease with Al_2O_3 and H_2O content. From the relative intensities of the powder diffraction lines, it was estimated that about 5 m/o of lithium iodide was present as the monohydrate phase with the balance being anhydrous lithium iodide for case II denoted by □ in Fig. 2. According to weight loss measurements on drying Al_2O_3 powder, the sample case I would contain 2 m/o LiI · H_2O. These

Fig. 2. (1)]; ——— 50-60 m/o Al_2O_3 + LiI [Ref. (13)].

results suggest that the presence of a few mole percent of the hydrate phase in the LiI-Al_2O_3 material increases the conductivity by one to two orders of magnitude.

X-ray powder diffraction showed both the dried and undried Al_2O_3 to be α-form.[2] Therefore one must infer the difference is due to the change in surface of Al_2O_3 resulting in the alteration of H_2O distribution. It is reasonable to assume that the undried Al_2O_3 localizes H_2O such that LiI · H_2O is under the influence of the surface since the dehydration efficiency of LiI · H_2O and Al_2O_3 are comparable being 0.5 ppm V and 1 ppm V (12) at room temperature, respectively. Either the increase in H_2O content or the deactivation of the Al_2O_3 surface by heating would result in more free LiI · H_2O and yield a lower activation energy approaching that of LiI · H_2O in case I.

It is noted that the conductivity of LiI · H_2O-Al_2O_3 with a trace of LiI is comparable to that of LiI · H_2O without Al_2O_3. For comparison. the conductivity data of LiI-Al_2O_3 in the literature (1, 13) are included in Fig. 2 (denoted by — and -•-•-•-•-•-). The authors did not specify the H_2O content in their samples. It is possible that some moisture in the samples (handled under <15 ppm V H_2O environment) affected their results. More recent reports (14) show that the degree of predrying of the Al_2O_3 varied the resultant 25°C conductivity by one order of magnitude. Von Alpen and Bell (15) recently reported the conductivity of LiI and LiI(Al_2O_3). Their conductivity data for anhydrous LiI agrees with previous values. Dried γ-Al_2O_3 (50 m/o) caused about an order of magnitude increase in σ but less than the two plus orders reported by Liang *et al.*, for ~40-60 m/o Al_2O_3 of unspecified particle size.

[2] Meller Company reports 0.3 μm Al_2O_3 to consist of 70% α- and 30% γ-Al_2O_3.

Summary

The conductivity of LiI prepared under low pH_2O (<0.05 ppm V) has been measured and results agree with earlier investigations. Additions of 24 m/o predried Al_2O_3 particles, 0.3 μm nominal size mixed and pressed dry into pellets, did not enhance the conductivity. The conductivity of hydrates of LiI with and without Al_2O_3 particles has been measured and the enhanced conductivity was attributed to the presence of H_2O. The conductivity increase when Al_2O_3 particles were added is primarily due to the presence of H_2O.

The activation energy of the mixture depends on the thermal treatment of Al_2O_3 when the H_2O content is low. An understanding of the existence of the LiI · 1/2H_2O and the entire LiI · H_2O system requires further study.

Pyrolytic Deposition of MnO_2 Layers in Saturated Water Vapor Atmospheres

J. M. Albella, L. Fernández-Navarrete, and J. M. Martínez-Duart

Departamento de Física Aplicada and Inst. Física Estado Sólido, C.S.I.C. Universidad Autónoma, Cantoblanco, Madrid, Spain

The pyrolytic decomposition of manganese nitrate to produce the MnO_2 layer in solid electrolyte tantalum capacitors results in a degradation of the electrical characteristics of the dielectric Ta_2O_5 and the contact resistance (1-4). The resulting harmful effects can be partially avoided by introducing moist air in the oven while performing the pyrolysis (5). In this case the resulting layers of MnO_2 present a higher degree of compaction and better contact with the rest of the cathode layers (6). In spite of its technical significance there is a lack of results in the literature on the characteristics of the MnO_2 pyrolytic deposition in saturated water vapor atmospheres and the influence of the MnO_2 layers in the electrical characteristics of capacitor structures using MnO_2 as electrolyte.

In this paper the pyrolysis of the manganese nitrate $Mn(NO_3)_2 \cdot 6H_2O$ was performed at 250°C in an oven saturated with water vapor. The pyrolytic decomposition of the nitrate usually took a minimum of 2 hr. The oven was provided with a small orifice to let the reaction gases escape and at the same time insure a relative humidity of practically 100% and a slight overpressure relative to atmospheric.

It has been found convenient in this work to follow the changes, during the decomposition of the manganese nitrate, of the products of the reaction. This provided a means of controlling step by step the pyrolytic reaction and gave direct information of the properties of the end product. For this purpose, the resistivity was measured by means of a cell provided with platinum electrodes and using a Hewlett Packard 4261-A LCR bridge at a frequency of 1 kHz. The platinum electrodes (size 5×5 mm^2, separated 2 mm) were fixed within the reaction cell and the temperature was measured with a sheathed thermocouple located close to the electrodes.

The cell in which the decomposition of the manganese nitrate was performed was generally introduced in the oven when the temperature was 100°C and subsequently the temperature of the oven was raised to 250°C. Figure 1 shows the variation of the resistivity and the temperature during the reaction in the saturated water vapor atmosphere. Three stages, indicated by the letters A, B, and C can be distinguished in the curve for resistivity. It is interesting to point out that these stages can be correlated to those found by Gallagher *et al.* using thermogravimetry and differential thermal analysis techniques (7-9).

The first stage in Fig. 1 of the pyrolytic decomposition is dominated by the loss of the water of crystallization and consequently the temperature increases very slowly. Similarly the resistivity rises slowly during this stage, probably as a consequence of a growing viscosity, but its variation with time becomes much steeper as the transformation of the nitrate in oxynitrate ($MnONO_3$) proceeds (stage AB). Next, the formation of the MnO_2 begins by the decomposition of the unstable $MnONO_3$ which cannot be isolated. Therefore, the section BC of the curve in Fig. 1 is characterized by a strong decrease in the resistivity due to the large electrical conductivity of the MnO_2 which behaves as a nearly degenerate semiconductor.

Key words: solid electrolyte, semiconducting oxide, electrolytic capacitor.

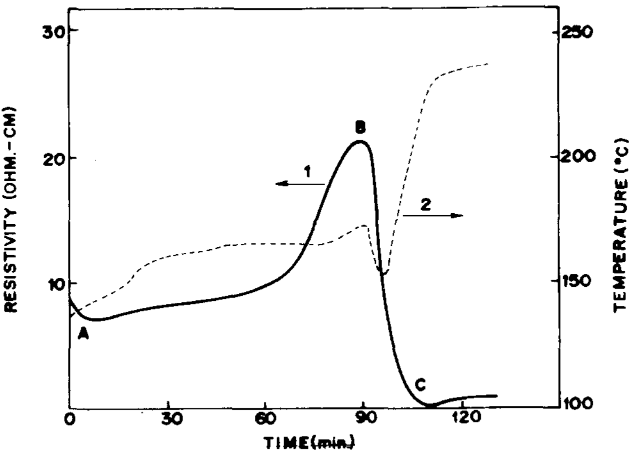

Fig. 1. Variation of the resistivity (solid line) and the temperature (broken line) during the manganese nitrate pyrolytic decomposition in a wet atmosphere.

Comparing the results of the pyrolytic decomposition in a saturated water vapor atmosphere with decomposition in a regular dry ambient, the former presents several technical advantages. The rate for the $MnONO_3 \rightarrow MnO_2 + NO_2$ reaction is much faster in the moist atmosphere, as a consequence of the smaller activation energy for the reaction in this ambient (9). Also, the resistivity of the resulting MnO_2 is substantially lower when the pyrolysis is performed in the water vapor atmosphere, as will be seen below in more detail. Other differences are related to the porosity, density, and structure of the resulting MnO_2 product. Figure 2 shows a scanning electron micrograph of the MnO_2 layers deposited in the water vapor atmosphere. In this case, the layers present a higher degree of compaction, a better uniformity, and a smaller grain size (12 μm *vs.* 100 μm

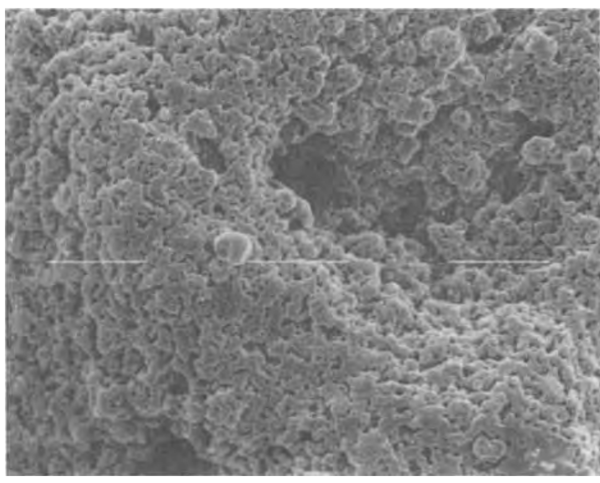

Fig. 2. SEM micrograph of the surface of the MnO_2 samples obtained in a wet atmosphere (reticule 100 μm).

for the dry atmosphere case). Furthermore, the apparent density[1] was 3.74 ± 0.10 g/cm^3 for the samples formed in the wet atmosphere and 3.33 ± 0.10 g/cm^3 for those obtained in dry air. X-ray determinations of structure were also performed showing that the interior of the MnO_2 layers essentially consisted of the β-MnO_2 phase. However, the surface region presented a high proportion of γ-MnO_2 (10) which could amount up to 52% of the total for the samples deposited in a dry atmosphere.

The resistivity of the MnO_2 samples was measured in d.c., under a polarization of 0.25V, and in low frequency a.c., yielding essentially the same results. The value of the resistivity and the slope of the log ρ *vs.* $1/T$ curve at 20°C is given in Table I. It can be observed from it that the samples pyrolyzed in the moist atmosphere show an electrical conductivity more than one order of magnitude higher than those pyrolyzed in the regular atmosphere. The electrical conduction in MnO_2 is supposed to be due to oxygen vacancies producing donor levels (n-type conduction). According to this, a value of 0.015 eV is obtained for the donor level in the MnO_2 samples deposited in the water vapor saturated atmosphere, value which is substantially lower than the corresponding value of the sample deposited in a dry atmosphere (Table I), and other values reported in the literature for samples pyrolyzed under this condition (10, 11).

Since an important technical application of the MnO_2 is as a solid electrolyte in the capacitor industry, the behavior of the MnO_2 layers pyrolyzed under different ambients were tested in capacitive structures of the TMM type (Ta-Ta_2O_5-MnO_2-metal) prepared on tantalum foil previously subjected to standard cleaning and chemical polishing procedures (12). For this purpose, the tantalum was anodized in a 0.01% H_3PO_4 aqueous solution at a constant current density of 1 mA · cm^{-2} until a formation voltage of 100V was reached. After the pyrolytic deposition of the MnO_2 layer during a minimum of 2 hr the foil was reanodized at 55V in an HNO_3 electrolyte (ρ = 800 Ω-cm). The dielectric properties of the TMM structures were measured with a General Radio 1620 capacitance bridge in the 10^2-10^5 Hz frequency range and the contact resistance R_c was obtained from the dissipation factor (tan δ) following the series-circuit analysis of McLean (13). The values of R_c are also shown in Table I. The much better value of R_c obtained for the capacitive structures with the MnO_2 deposited in the saturated water vapor atmosphere might be attributed to the higher electrical conductivity and the smaller porosity of the corresponding MnO_2 layers.

The scintillation voltage V_s during the reanodization of the Ta-Ta_2O_5-MnO_2 structures was measured on samples formed at voltages V_f between 40 and 200V and reoxidized at a current density of 1 mA · cm^{-2} until the scintillation or breakdown phenomenon first appeared. The results obtained for V_s as a function of V_f are shown in Table II, each value representing the average for three similar capacitive structures.

[1] In order to determine the density, the volume considered is limited by the geometrical external surface of a given portion of mass in a container and therefore does incorporate the empty spaces due to the inherent porosity.

Table I. Electrical characteristics of the MnO_2 layers

Sample	Resistivity (Ω · cm)	Slope (eV)	Contact resistance (capacitive struct.) (Ω)
Wet pyrol.	0.42 + 0.01	0.015	0.50
Dry pyrol.	7.5 + 0.10	0.070	17.8

Table II. Scintillation voltage of the MnO_2 layers (V)

V_f	V_s (wet pyrol.)	V_s (dry pyrol.)
40	40	45
80	65	60
120	90	80
160	110	75
200	130	75

The largest uncertainty in the measurements of V_s was found in the higher formation voltage ranges (V_f between 160 and 200V) and was always less than 10%. It can be deduced from Table II that for low formation voltages ($V_f < 120$V) V_s shows a close to linear variation for the capacitor structures with the MnO_2 deposited in both wet and dry atmospheres. However, when $V_f > 120$V the former atmosphere causes a scintillation voltage approximately equal to 0.75 V_f, whereas the latter shows a value of V_s always below 80V. This fact might be due to both a greater damage in the Ta_2O_5 dielectric caused by the pyrolytic deposition or a lesser degree of oxidation (14) of the MnO_2 layers deposited in the regular atmosphere as compared to the saturated water vapor one. In this respect, it can also be remarked that the leakage current density through these structures, measured after polarizing during 5 min at one-fourth the formation voltage (V_f = 100V in this case), showed a value of about 10^{-7} A · cm^{-2} for the structures in which the MnO_2 layers were deposited in the wet atmosphere, being approximately one order of magnitude larger for the case of the MnO_2 layers pyrolyzed in the standard ambient.

Concentration Dependence of the Gibbs Energy of Transfer of NaCl from D_2O to H_2O

Mahmood Toofan and Peter A. Rock*

Department of Chemistry, University of California, Davis, California 95616

The thermodynamic properties of transfer of electrolytes from heavy to light water can provide useful data for the interpretation of the effect of electrolytes on the structure of water (1, 2). The most direct method for the determination of the molar Gibbs energy of transfer, $\Delta\overline{G}_{tr}$, of an electrolyte from one solvent to another solvent involves the use of electrochemical double cells without transference (3). An appropriate cell for the determination of $\Delta\overline{G}_{tr}$ of NaCl from heavy to light water is

$$Ag(s)|AgCl(s)|NaCl(D_2O)|Na(Hg)|NaCl(H_2O)|AgCl(s)|Ag(s) \quad [1]$$

where Na(Hg) represents a flowing sodium amalgam junction. The net cell reaction of cell [1], operating under reversible conditions, is

$$NaCl(D_2O) = NaCl(H_2O) \quad [2]$$

Voice (4) has used cells of type [1], and appropriate analogues, to determine $\Delta\overline{G}^\circ_{tr}$ from D_2O to H_2O for a variety of electrolytes; he has also summarized and critically evaluated the results of previous workers. All of the electrochemical investigations prior to the work reported herein were confined to concentrations below about 0.3*M*, and only a very slight effect, if any, of concentration on the $\Delta\overline{G}_{tr}$ values was observed.

The detailed structures of D_2O and H_2O are different owing to the greater strength of deuterium bonds relative to hydrogen bonds. Consequently, electrolytes that are water structure breakers (5) or water structure makers might be expected to exhibit concentration-dependent $\Delta\overline{G}_{tr}$ values. For this reason we decided to determine $\Delta\overline{G}_{tr}$ for reaction [2] over the range 0.3-4*M* in order to ascertain if the Gibbs energy of transfer of NaCl from heavy to light water exhibits a concentration dependence. We have found that $\Delta\overline{G}_{tr}$ for NaCl is concentration dependent and we have offered a qualitative explanation for this effect. The effect of different concentration scales on the values of $\Delta\overline{G}_{tr}$ is also discussed.

The Ag(s)|AgCl(s) electrodes were prepared by the thermal-electrolytic method (6); the bias potentials of the pairs of electrodes used were less than 0.03 mV. The mercury (Quicksilver Products, Incorporated, C.P. triple distilled) was covered with 0.001M HNO_3(aq) and agitated with a stream of air. The dried Hg was run out from the base of the cleaning vessel into a vessel containing a known quantity of clean Na(s) under an argon atmosphere. The Na(Hg) (*ca.* 0.003*M*) was agitated with a stream of argon gas for about 24 hr. The amalgam was stored under argon and agitated gently to allow any insoluble impurities to rise to the surface. A flowing amalgam junction was used in the cell. During measurements the amalgam was run continuously into the cell through capillaries at a flow rate of about 2-3 $cm^3 \cdot min^{-1}$. A doubling of the flow rate had no effect on the measured emf. The NaCl cell solutions were prepared from weighed quantities of dried primary standard NaCl(s) and oxygen-free H_2O(l) or D_2O(l) (99.7 atomic percent D). The cell contents were continuously purged with argon gas delivered to the cell through presaturators. Continuous emf measurements were made using a Keithley 602 Solid-State Electrometer the output of which was fed to Mosley-Autograf Model 7101B chart recorder. The system was calibrated by feeding in known voltages from an NBS-certified L and N K-3 potentiometer. After a cell was set up it was allowed to equilibrate for about 2 hr before the amalgam flow was started. The Ag(s)|AgCl(s) electrodes were equilibrated with separate samples of respective cell solutions before insertion in the cell. The measured emf values were stable within ±0.05 mV. All measurements were made at 24° ± 1°C.

Two separate sets of experiments were run. In the first set of experiments the molalities (moles of solute/kilogram solvent) of NaCl in H_2O and D_2O were made equal in each experiment. In the second set of experiments the aquamolality (moles of solute per 55.508 moles of water) of NaCl in H_2O and D_2O were made equal in each experiment. The results are given in Table I, and the data are displayed graphically in Fig. 1.

As is evident from Fig. 1 the results for the equimolal and equiaquamolal cases are quite different. Up to 1*M* most of the difference $\mathcal{E} - \mathcal{E}_a$ can be accounted for solely on the basis of the difference in the two concentration scales because $\mathcal{E}^\circ - \mathcal{E}^\circ_a = (2\,RT/\mathbf{F})\ln(M_{D_2O}/M_{H_2O}) = 5.42$ mV, where the M_i values are the molecular weights. For example, at 1*M*, $\mathcal{E} - \mathcal{E}_a = 5.65$ mV. However above 1*M* the difference in $\mathcal{E} - \mathcal{E}_a$ increases and at 4*M*, $\mathcal{E} - \mathcal{E}_a = 8.85$ mV. The equimolal data are difficult to interpret in terms of the influence of NaCl on the structure of water because, although the moles of NaCl per kilogram of water is the same in the two solutions, the ratio of the moles of water to moles of salt is 55.51/*M* for NaCl(H_2O) and 49.93/*M* for NaCl(D_2O). In addition differences in ion-ion interactions arising from "dilution" of the NaCl on being transferred from D_2O to H_2O are superimposed on the effect of salt on the water structure. Over the range 1-4*M*, $\gamma_\pm$ for NaCl increases with increasing *m* (7) and this effect will make $d\mathcal{E}/dm > 0$ $[-(2RT/\mathbf{F})\ln(\gamma_{\pm NaCl(H_2O)}/\gamma_{\pm NaCl(D_2O)}) > 0]$. These difficulties are essentially eliminated in the equiaquamolal case because the ratio of moles of isotopic water to moles of salt is the same in the two solutions, namely, 55.51/*M*.

Table I. Results of measurements on the cell (24° ± 1°C): Ag(s)|AgCl(s)|NaCl(m,D_2O)|Na(Hg)|NaCl(m,H_2O)|AgCl(s)|Ag(s)

m	$\mathcal{E}$	$\mathcal{E}_a$
0.300	—	5.75
0.500	12.25	—
0.600	—	6.25
1.000	12.45	6.80
1.500	—	6.85
2.000	12.85	6.65
3.000	13.50	6.20
4.00	14.25	5.40

$\mathcal{E}$ is the cell voltage for the equimolal solutions and $\mathcal{E}_a$ is the cell voltage for equiaquamolal solutions. All voltages are ±0.05 mV except for the 0.5*M* cell which is ±0.15 mV.

Key words: Gibbs energy, sodium chloride, heavy water, electrolyte transfer.

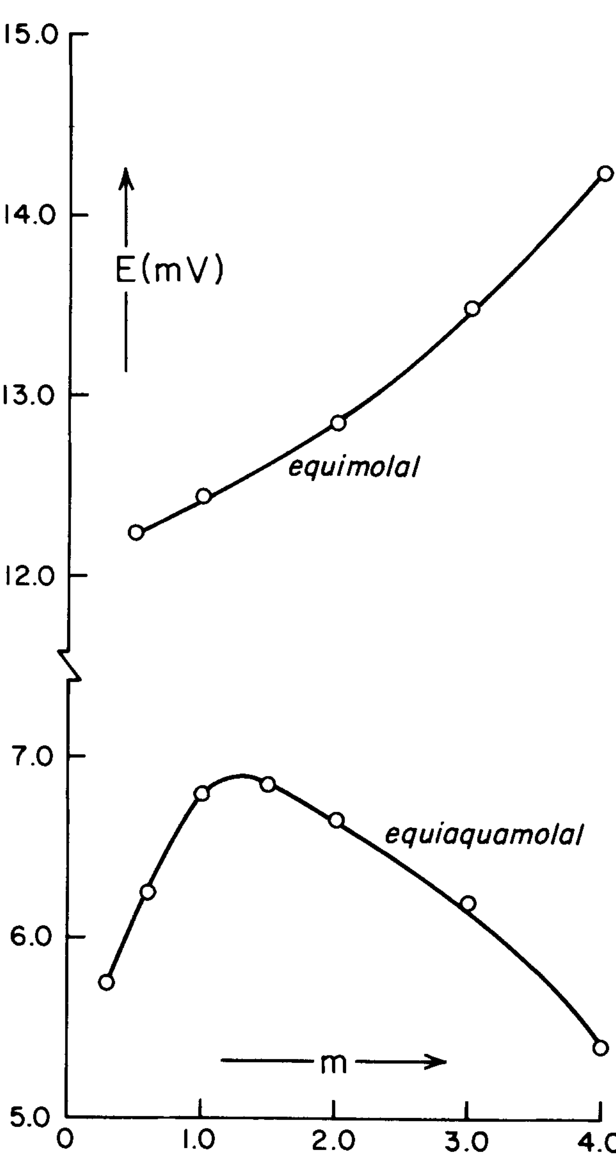

Fig. 1. Emf as a function of molality (24°C) of the cell: Ag(s)|AgCl(s)|NaCl(m,D_2O)|Na(Hg)|NaCl(m,H_2O)|AgCl(s)|Ag(s).

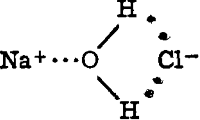
We interpret the $\mathcal{E}(m)$ data for the equiaquamolal transfer reaction as follows: because the O—D···O bonds (deuterium bonds) in D_2O are stronger (by about 0.5 kcal/mole) than the O—H···O bonds (hydrogen bonds) in H_2O, a water structure-breaking salt like NaCl (2, 1) will exhibit a negative $\Delta\bar{G}_{tr}$, and therefore a positive value of $\mathcal{E}_{tr}$ for the process

$$NaCl(D_2O) \rightarrow NaCl(H_2O)$$

In other words more Gibbs energy is released on reforming the deuterium bonds on desolvation of the ions than is consumed on breaking the hydrogen bonds in resolvating the ions. This effect will increase with increasing aquamolality until the water structure is effectively completely broken down, *i.e.*, when all of the water molecules are involved in either primary or secondary coordination of the ions. This apparently occurs for NaCl in water at a ratio of moles of water to moles of ions of about 18 to 19, *i.e.*, at the maximum in the $\mathcal{E}$ *vs.* m curve, *ca.* 1.5*M*; with further increase in aquamolality solvent-separated ion pairs of the type



begin to appear, and because such ion pairs do not involve O—H···O (or O—D···O) bonds, but rather the much weaker O—H···Cl^- (or O—D···Cl^-) bonds, the isotope effect on $\Delta\bar{G}_{tr}$ decreases.

The Multiplicity of Anodic Current Peaks Related to the Potentiodynamic Electro-oxidation of Carbon Monoxide on Polycrystalline Platinum

S. A. Bilmes, N. R. de Tacconi, and A. J. Arvía

Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas, División Electroquímica, Universidad Nacional de La Plata, 1900 La Plata, Argentina

The adsorption of CO on platinum electrodes from acid aqueous solutions has been the subject of numerous publications over the last decades as shown in the recent review on the subject presented in Ref. (1). The reported results and their interpretations are still only partially understood and the advanced explanations open to discussion. Nevertheless it should be noticed that the difficulty in correlating some of the electrochemical data on the electro-oxidation of CO on platinum may arise from the fact that the results obtained by different authors using transient techniques are not strictly comparable. There is evidence, however, that the electro-oxidation of CO on platinum occurs as though two distinct and separable entities were involved (2).

On the other hand, the adsorption of CO on platinum from the gas phase has also been investigated over a long period of time (3). The pertaining literature is reviewed in Ref. (4). More recently the gas phase CO adsorption was studied on single crystal platinum surfaces and the chemisorption of CO on the Pt(111) surface, as deduced from the results using LEED techniques, thermal desorption, and work function measurements were also explained in terms of the existence of two different adsorption sites on the metal. Therefore, despite the differences of the above-mentioned interfaces and the difficulty for the straightforward comparison of the corresponding results, it seems reasonable to expect that the Pt-CO adsorption interaction in the presence of the electrolyte solution may also involve a relatively complex adsorption process which is reflected in a composite anodic potentiodynamic display.

In order to explain the existence of multiple current peaks associated with the potentiodynamic oxidation of CO species on platinum, potentiodynamic runs were performed with a systematic and stepwise increase and decrease of the cathodic switching potential, within the potential range where the oxygen-containing species formed on platinum to the order of the monolayer thickness are electroformed and electroreduced (5). Within this potential range the adsorbed CO-species on platinum are also electro-oxidized. The potential/time program employed to perturb the electrochemical interface is chosen so that the maximal interaction between electrosorbed oxygen and CO is achieved.

The experiments were carried out at 25°C on a polycrystalline spectroscopically pure smooth platinum wire electrode (0.24 cm² apparent area). The electrode was immersed in a purified 1*N* $HClO_4$ solution to minimize anion adsorption and interaction effects (6). The counterelectrode was also made from Pt. The potential of the working electrode was referred to the normal hydrogen electrode. The electrolyte was saturated at 1 atm pressure with CO prepared from AR chemicals and purified to satisfy the highest purity standards (7). The electrochemical cell as well as the CO generator and ducts were made of Pyrex glass, the stopcocks were lubricated with concentrated AR sulfuric acid to avoid as far as possible the interference of any contaminants.

Figure 1 shows the conventional *E*/*I* profile recorded after holding the electrochemical interface at open circuit during 20 min in the CO saturated electrolyte at 1 atm pressure, and then running a symmetrical repetitive triangular potential sweep at 0.1 V/sec. For the sake of comparison the voltammogram obtained in the same conditions with the nitrogen saturated solution is also included in the figure. The *E*/*I* display exhibits the anodic and cathodic current peaks related to the hydrogen adatoms in the 0.04-0.35V range and the cathodic current peak related to the electroreduction of the oxygen-containing surface species on platinum in the 0.52-1.00V range. Within the 0.82-1.04V potential range, a large and relatively sharp anodic current peak is recorded. The latter is associated with the electro-oxidation of the CO species and it overlaps the first portion of the anodic current corresponding to the electrosorption of the oxygen-containing species which extends up to 1.46V. This *E*/*I* display agrees, in principle, with those earlier reported by other authors (8-10). The comparison with the blank shows that the presence of CO produces a sharp decrease of the charge pertaining to the hydrogen adatoms while there is no significant influence as far as the charge corresponding to the oxygen-containing species is concerned.

Figure 2 shows the *E*/*I* profile obtained with stepwise increase of the cathodic switching potential. In order to have a clean metal surface free of adsorbed CO, the potential of the electrochemical interface was cycled between $E_{\lambda,c}$ and $E_{\lambda,a}$, during 2 min at a fast potential sweep (100 V/sec) before recording

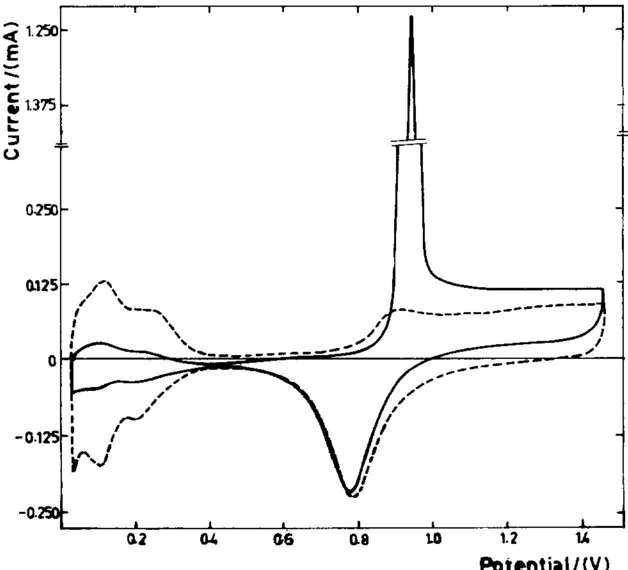

Fig. 1. Potentiodynamic *E*/*I* profiles of platinum in 1*N* $HClO_4$ run at 0.1 V/sec at 25°C. (———) CO (1 atm) saturated solution; (- --) N_2 saturated solution.

* Electrochemical Society Active Member.
Key words: gas, electrode, adsorption.

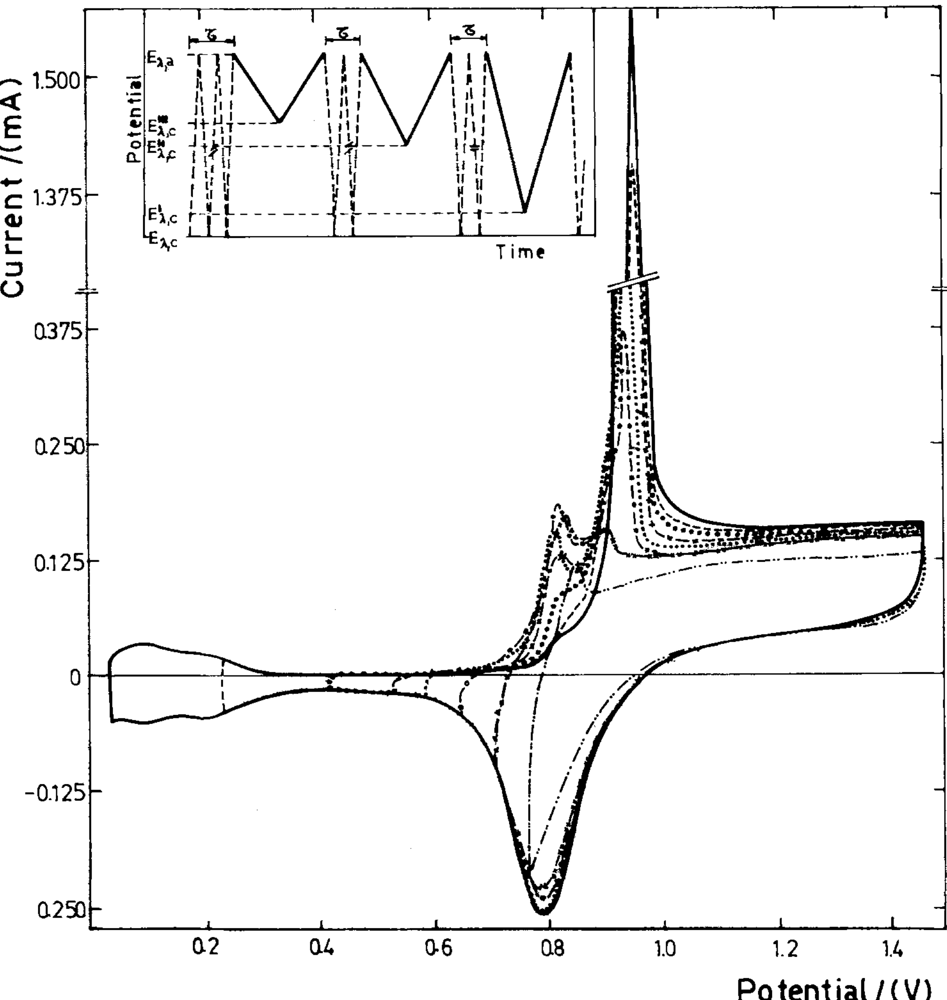

Fig. 2. Potentiodynamic E/I profiles in 1N $HClO_4$ run at 0.1 V/sec at 25°C. These profiles were obtained with different $E_{\lambda,c}'$ following the E-t program depicted into the figure. (Before each profile the interface was cycled between $E_{\lambda,a}$ and $E_{\lambda,c}$ at 100 V/sec during τ = 2 min). (—··—··) $E_{\lambda,c}'$ = 0.77V; (—XX—XX—) $E_{\lambda,c}'$ = 0.71V; (—°—°) $E_{\lambda,c}'$ = 0.65V; (······) $E_{\lambda,c}'$ = 0.59V; (—x—x—x—) $E_{\lambda,c}'$ = 0.53V, (°°°°) $E_{\lambda,c}'$ = 0.41V; (— — —) $E_{\lambda,c}'$ = 0.23V; (———) $E_{\lambda,c}'$ = 0.04V.

the E/I profile at 0.1 V/sec between $E_{\lambda,c}'$ and $E_{\lambda,a}$. Figure 3 shows the E/I displays obtained under the same conditions as in Fig. 2 but the potential range of the sweep covers only the oxygen monolayer electrodesorption. From the E/I displays in the CO saturated electrolyte (Fig. 2 and 3) one concludes that at least three anodic current peaks can be assigned to the electro-oxidation of CO on platinum. The first peak is seen at 0.8V and starts to contribute only when the amount of oxygen remaining on the surface during the electroreduction process is slightly lower than 50% of the total electroreduction charge. The second, at 0.91V, is better defined when the fraction of clean metal is *ca.* 70% and finally, the third, at 0.95V, which coincides with the one found under conventional potentiodynamic experiments, requires that the oxygen-containing species has been practically completely electroreduced. The latter remains as the only anodic current contribution related to CO when the cathodic switching potential value falls within the potential range of the hydrogen adatoms. Under these circumstances no current contribution of the former current peaks is noticed. A comparison with the blank sweep (Fig. 1) shows that these current peaks can only be due to the presence of CO. For each E/I display (Fig. 3) which shows the multiplicity of peaks, a further potential cycling within the same potential range at 0.1 V/sec produces the progressive increase of the current peak at 0.91V at the expense of those current peaks located at 0.8V and at 0.95V. Unfortunately, as the CO readsorption effect has not been quantitatively determined, reliable charge ratios from the already described E/I displays cannot be evaluated. The presence of CO in the electrolyte only influences to a minor extent the characteristics of the E/I profile in the oxygen electrodesorption potential range including the aging effects (11, 12).

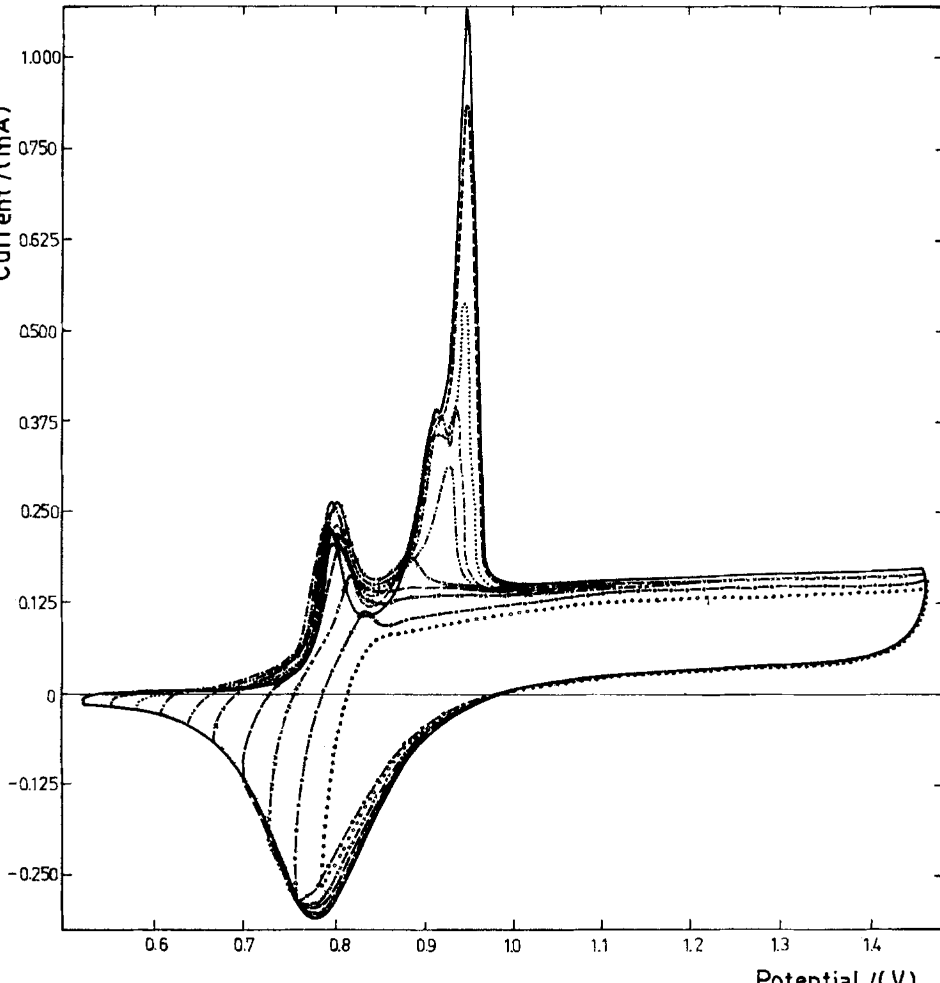
One is inclined to believe that the described effect on the anodic E/I display might be due to an impurity interference, but this apparently is not the case since the potential sweep comes from the positive potential side and it occurs when the fraction of free metal surface is still relatively small. Furthermore, the oxidation current peak indicates that the first adsorbed species is more easily electro-oxidized than that formed when CO adsorbs at more negative potentials. On the other hand, the multiplicity effect is more noticeable when the structure of the surface becomes more complex, *i.e.*, when free sites, PtOH, and various PtO species are simultaneously on the surface as one may conclude from the study of aging effects all along the potential range of the oxygen monolayer electroreduction on Pt (11, 12).

Therefore, the CO electro-oxidation reaction should comprise two different types of processes according to the adsorbed reactant entering the electrochemical oxidation. The two main type of adsorbed species are the $Pt(CO)_{ad}$ species which originate through the Pt-CO chemical interaction and the various $Pt(O)_{ad}$ species including Pt(OH) which result from the Pt-H_2O electrochemical interaction. The electro-oxidation of the different CO adsorbed species is represented by the overall reactions

$$Pt(CO)_{ad} + H_2O = Pt + CO_2 + 2H^+ + 2e \quad [1a]$$

$$Pt + H_2O = Pt(O)_{ad} + 2H^+ + 2e \quad [1b]$$

and the direct electro-oxidation of CO through the electrosorbed oxygen on platinum is given by the reactions



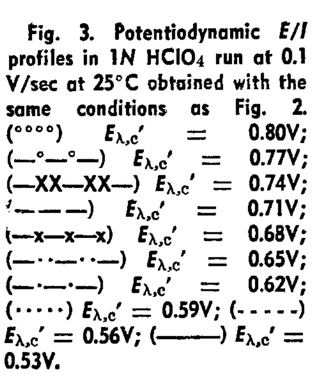


Fig. 3. Potentiodynamic E/I profiles in 1N $HClO_4$ run at 0.1 V/sec at 25°C obtained with the same conditions as Fig. 2. (°°°°) $E_{\lambda,c}' = 0.80V$; (—°—°—) $E_{\lambda,c}' = 0.77V$; (—XX—XX—) $E_{\lambda,c}' = 0.74V$; (— — —) $E_{\lambda,c}' = 0.71V$; (—x—x—x) $E_{\lambda,c}' = 0.68V$; (—··—··—) $E_{\lambda,c}' = 0.65V$; (—·—·—) $E_{\lambda,c}' = 0.62V$; (·····) $E_{\lambda,c}' = 0.59V$; (- - - -) $E_{\lambda,c}' = 0.56V$; (———) $E_{\lambda,c}' = 0.53V$.

$$Pt(O)_{ad} + CO = Pt + CO_2 \quad [2a]$$

$$Pt + H_2O = Pt(O)_{ad} + 2H^+ + 2e \quad [2b]$$

where the parenthesis denote any of the possible either CO or O sorbed species on platinum. Reactions [1a] and [1b], which occur at lower potentials, involve a competition for metal sites by the CO and O species. Contrarily, reactions [2a] and [2b] are only related to the electrosorbed oxygen species on platinum.

The existence of a relatively large anodic background current in the potential range where the electrosorption of oxygen takes place suggests that the electrooxidation of CO occurs also beyond the region of the corresponding main current peak. This effect could probably be associated with a chemical surface oxidation reaction involving CO according to reaction [2a] followed by the fast electrosorption of oxygen as indicated by reaction [2b].

On the other hand, a chemical surface reaction such as

$$Pt(O)_{ad} + Pt(CO)_{ad} = 2Pt + CO_2 \quad [3]$$

is to be expected in lower potential range where free Pt sites are available. This conclusion is not surprising in view of recent results on the interaction between oxidized Pt and CO in the gas phase (13, 14).

Therefore, the present experiments furnish a clear evidence that CO can be oxidized in aqueous acid electrolytes on polycrystalline platinum electrodes in different reactions which are associated with the multiplicity of the corresponding electrochemical anodic spectrum. They also suggest the possible existence of different CO adsorbed species on Pt. This has just a resemblance to the results reported for the Pt/CO (gas) interface although it should be kept in mind that at present a quantitative comparison between the behavior of the two interphases is impossible.

The present results are therefore, at least partially, relevant to the understanding of the contradictory interpretations of results presented in the literature on the electrochemistry of the Pt/aqueous acid solutions/CO (1 atm) interface.

The Observation of Effects of Finite Specimen Geometry on the Oxidation Kinetics of Zircaloy-4

R. E. Pawel and J. J. Campbell

Oak Ridge National Laboratory, Metals and Ceramics Division, Oak Ridge, Tennessee 37830

ABSTRACT

The oxidation of zirconium and zirconium-base alloys at temperatures above the alpha-beta transition involves the growth of layers of oxide and oxygen-stabilized alpha into the host beta phase. If the growth is governed by diffusion processes, the oxidation of thin specimens will exhibit significant variations in the kinetics of layer growth if the duration of the reaction is sufficient to promote large changes in the degree of saturation of the underlying metal with oxygen. We have examined this effect for the oxidation of Zircaloy-4 in steam by modeling analyses and by a series of extended-time oxidation experiments at 1300°C. These experiments confirmed the predicted increase in the kinetics of alpha layer growth as the beta phase becomes saturated. For example, at 1300°C, the rate constant increases by more than a factor of 2. While the appearance of "alpha incursions" leading to an irregular alpha-beta interface also seems to be initiated at this time, the experimental observations generally agreed well with those predicted on the basis of the modeling analysis. This behavior needs consideration in the interpretation and comparison of oxidation data, particularly where large differences in the specimen geometry or dimensions are involved.

The oxidation of Zircaloy-4 in steam at high temperatures has recently been examined from both kinetics (1) and diffusion modeling (2) standpoints. Despite the complex microstructure of the oxide phase, it has been shown that the isothermal growth of the product oxide and oxygen-stabilized alpha layers can be described accurately in the early stages by parabolic kinetics over the temperature range 1000°-1500°C. Furthermore, the modeling analysis produced sets of effective chemical diffusion coefficients for oxygen in both the oxide and alpha phases that compared favorably, where comparisons were possible, with data obtained by other means. The apparently ideal nature of the growth of the oxidation products, as well as the self-consistency of the treatments in terms of diffusion models, has increased our confidence in the applicability of a simplified modeling analysis to this system.

Previous modeling analyses for the oxidation of Zircaloy have been applied mainly to offer a foundation for the quantitative prediction of the extent of reaction during transient temperature exposures. While some of these treatments have been based simply on the parabolic rate constants for layer growth, at least two programs (3, 4) have been used that apply a more sophisticated finite-difference diffusion analysis to examine both layer growth and oxygen concentration gradient effects in all of the phases present. Programs of this sort, at least in principle, offer the ability to examine potential effects of a variety of boundary conditions on the oxidation characteristics, and they have provided a basis for comparison and evaluation for numerous oxidation experiments.

This paper presents calculations and experimental results describing the changes in layer growth kinetics that occur as a consequence of finite geometry influences during extended isothermal reaction of a thin specimen. For the case of Zircaloy-4 oxidizing in steam, substantial effects are observed particularly for the growth rate of the alpha layer. The modeling and experimental results are compared and discussed in terms of their relevance to the design of experiments and their interpretation.

Key words: zirconium, oxidation, diffusion, kinetics.

The Oxidation Model

In order to construct a useful mathematical model to describe the kinetic events during high temperature oxidation of Zircaloy, it is necessary to consider the reaction phenomenology with particular emphasis on the diffusion processes in the various phases. Numerous investigators have dealt with various aspects of this problem (5) and we will not detail them here. Our model has been discussed previously (2) and does not depart in substance from those of other workers. Basically, in the temperature range of interest to the present paper, we depict the oxidation of Zircaloy as the growth of uniform layers of oxide and oxygen-stabilized alpha into the host beta phase as shown in Fig. 1. We assume, with previous experimental justification, that the growth of these phases is diffusion controlled and that the diffusivity of the mobile reactant within each phase can be described by a single effective chemical diffusion coefficient. The rate of growth of the oxide layer is proportional to the velocity of the oxide-alpha boundary, which depends on diffusion and concentration parameters in the two product phases. Similarly, the rate of growth of the alpha layer is equal to the difference in the velocities of the alpha-beta and oxide-alpha boundaries.

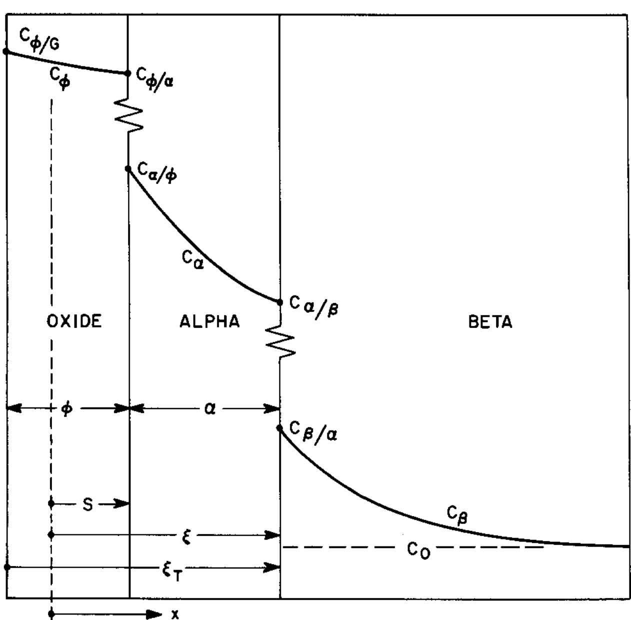

Fig. 1. Schematic diagram of the multiphase, moving boundary diffusion problem as beta Zircaloy reacts with oxygen to form layers of alpha and oxide. C_0 = initial oxygen concentration in Zircaloy; $C_{A/B}$ = concentration in the A phase at its interface with the B phase (G = gas; ϕ = oxide; α = alpha; β = beta); ϕ = oxide layer thickness; α = alpha layer thickness; S and ξ define the position of the oxide-alpha and alpha-beta boundaries with respect to the original specimen surface at $x = 0$.

In the oxide, growth is thought to take place by an anion diffusion mechanism, although for the temperature range under consideration here the particular modes of mass transport have not been clearly defined. Additionally, the oxide formed on Zircaloy-4, while uniform in thickness, has a complicated morphology (2, 6) that suggests the possibility of a similarly complicated influence on the diffusion behavior. However, no major influence or perturbation of the macroscopic growth characteristics has been observed, and we have considered the oxide to be structurally homogeneous for the purpose of our calculation. We view the value of D_ϕ (see Fig. 1) as an "average" or "effective" value of the chemical diffusion coefficient for oxygen in the oxide that, in conjunction with the concentration gradient, accurately describes the local mass transport.

The diffusion of oxygen in the metallic alpha and beta phases of Zircaloy-4 takes place by an interstitial mechanism, and again we have assumed concentration- (or position-) independent chemical diffusion coefficients for oxygen, D_α and D_β. To the extent that this assumption might not be valid, such an assignment implies that an "average" value is a useful entity in determining mass transport. Our earlier calculations of D_α from the kinetic data were made on this basis (2), and in support, arguments have been made that concentration effects are relatively small for oxygen diffusion in both alpha and beta Zircaloy at these temperatures (7, 8).

Thus, the model describes a classical multiphase, moving-boundary diffusion problem that, at least for the simpler boundary conditions, has analytical solutions relating layer growth to the concentration and diffusion parameters in each phase. A variety of approaches and solutions have been published, including several that have dealt specifically with the oxidation of zirconium and Zircaloy (2, 5a, 5d, 9-12). These treatments have been of value in interpreting and correlating oxidation results.

For the case of constant interface concentrations as indicated in Fig. 1, the ideal diffusion controlled growth of both oxide and alpha phases will remain parabolic (thickness squared proportional to time) so long as a semi-infinite geometry condition prevails for oxygen diffusion in the beta phase. Parabolic kinetics will also be observed for the case where the original oxygen concentration in the beta phase is equal to the saturation concentration, $C_{\beta/\alpha}$, and no oxygen flux into the beta from the alpha-beta boundary exists. In this latter case, the absence of the oxygen flux into the beta leads to a comparatively faster movement of the alpha-beta boundary that results in a higher growth rate for the alpha layer. The alpha growth will still be parabolic, but the corresponding parabolic rate constant will be larger. Thus, it follows that for "thin" specimens in which the beta phase tends to fill up with oxygen during the period of reaction, the parabolic constants governing the rates of growth for both oxide and alpha layers must increase from their initial values to some final values. The effect will obviously be larger for growth of the alpha phase, although the influence will be felt in the oxide also. As we will point out later, an interesting result from this model requires that, despite increases in the rate constants for growth of both the oxide and alpha layers during oxidation of saturated specimens, the rate constant for oxygen consumption is slightly decreased.

The influence of geometrical effects has thus been recognized, and analytical descriptions dealing specifically with the finite geometry aspects of the diffusion problem have been discussed (10, 12). While these analytical expressions may furnish insight that is often overlooked in numerical solutions, they are cumbersome and the numerical solutions, which can easily handle a variety of complicated boundary conditions, have become more popular. Such a computer code, MULTRAN, was constructed in our laboratory by Malang (13). This program models idealized diffusion-controlled layer growth processes by solving the diffusion equations for mass flow in a one-dimensional, multiphase, moving boundary system with finite geometry. The program uses finite-difference calculations and can be applied to reactions with up to five separate product phases. It was used to model the reaction sequences and experiments reported in this paper for the oxidation of Zircaloy-4. The appropriate input to this program (diffusion coefficients, equilibrium concentrations, and densities for all phases) were obtained in part from the analysis (2) of our previous work (1) in this area. It should be pointed out that these data were obtained from sets of experimental measurements utilizing short reaction times at each temperature so that the observed kinetics were not influenced by geometrical effects.

Experimental Procedure

Oxidation tests were conducted for Zircaloy-4[1] in flowing steam at atmospheric pressure in a low thermal inertia oxidation apparatus that employed radiant heating. In this apparatus, described previously (1), a 3 cm length of 1.1 cm diam tubing was exposed to steam on its outer surface while being heated according to a programmed temperature cycle. Three Pt *vs.* Pt-10% Rh thermocouples were attached to the inner surface of the specimen tube at its midpoint and, in order to minimize temperature measurement errors, the interior of the tube was protected from oxidation by a slow flow of helium maintained at a slightly positive pressure relative to the external steam pressure. One thermocouple furnished the programmer/recorder signals, while the other two (180° apart) were attached to a computer-operated data-acquisition system, CODAS. The detailed record of the temperature history at these two points on the specimen served as the basis for calculation of the effective isothermal reaction time at the nominal oxidation temperature.

After oxidation, each specimen was sectioned at the elevation containing the thermocouple beads and prepared for metallographic examination by conventional

techniques (1). The specimens were lightly etched, anodized, and measurements of the oxide and alpha layer thicknesses were made at the two monitor thermocouple positions with a digital micrometer eyepiece. These measurements were reasonably straightforward except when the alpha-beta interface was heavily populated with "alpha incursions," *i.e.*, irregular growths of alpha protruding into the beta region. In this latter case, two measurements of the alpha layer thickness were made: one measurement was that of the thickness of the "compact" (uniform thickness) portion only of the alpha layer; the other was of an "effective" alpha layer thickness that included a visual estimate of the average additional thickness attributable to the incursions. These "effective" thickness measurements were, of necessity, less accurate than the corresponding measurements of the compact layer thicknesses.

Results and Discussion

The experimental layer thickness measurements that define the growth of the oxide and alpha layers on Zircaloy-4 specimens in steam at 1300°C are presented in Table I. As noted above, we have also tabulated the "effective" alpha layer thickness that includes, where applicable, an estimate of the equivalent thickness due to the presence of the alpha incursions in the microstructure. In addition, based on the assumption of linear gradients in the oxide and alpha phases, a calculated value of the oxygen consumed for each specimen is included. The growth morphology is sampled in the progression of microstructures in Fig. 2 and 3. In order to assist the reader in visualizing the diffusion processes, included in each of these figures is a schematic drawing of the layer thicknesses and oxygen concentration gradients. The average oxygen concentration in the beta layer, expressed as a percentage of the saturation value, is also listed. These gradients and percentages were obtained from the modeling analysis using the MULTRAN program.

Morphology.—The series of micrographs confirms that the oxide and alpha layers grow uniformly in the early stages of the reaction. However, as the reaction proceeded, commensurate with the approach to oxygen saturation of the beta phase, the alpha beta boundary developed irregularities (Fig. 3) and, for longer times, extensive coarsening of the beta and incursions of the alpha in advance of the compact portion of the alpha layer were observed. In our isothermal experiments, the oxidation was terminated by switching off the power to the radiant heaters, allowing the specimen to cool mainly by radiation to the now-cold surroundings and by convection to the flowing steam. This resulted in initial cooling rates greater than 100°C/sec, and the temperature dropped below 1000°C within 5 sec, below 800°C in about 13 sec. Given this short cooling period, it is unlikely that the massive incursion structures form only on cooling as has been suggested (14), but they may form in large part during the isothermal oxidation, beginning at such a time as the oxygen concentration gradient in the beta phase in advance of the interface becomes relatively flat. The flat gradient implies a limited diffusion flux away from the alpha-beta interface as well as high oxygen concentrations all across the beta phase. These conditions favor departures from ideal, diffusion-controlled layer growth and tend to emphasize the influence of factors such as favored growth directions and other structural aspects of the process. In support of this argument, variations in the cooling rates after isothermal oxidation (see below) produced little change in the appearance of the interface. Thus, such departures from ideal layer growth imply that local growth rates become sensitive to some developing property or event in the system. While the identity of this event is not apparent, incursions have been observed only in the "late" stages of oxidation of a specimen of a given thickness, and they are observed much earlier for two-sided oxidation than for oxidation on one side only (11, 15, 16). Although the possibility of an altogether different correlation cannot be discarded, the consistent observa-

† Computed on basis of linear oxygen gradients in both oxide and (compensated) alpha thicknesses.

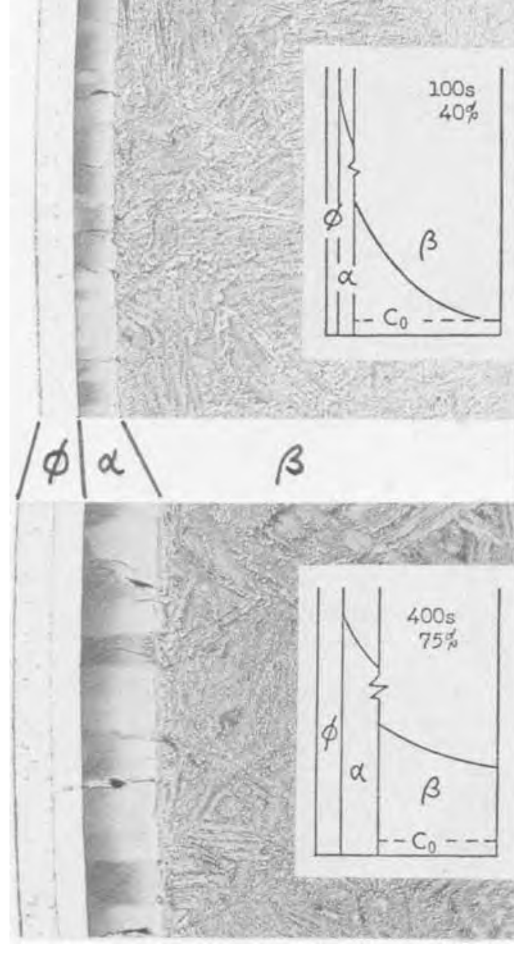

Fig. 2. Cross sections of Zircaloy-4 specimens oxidized in steam at 1300°C for 100 sec (above) and 380 sec (below). See Table I for details and experimental measurements. The inset schematics portray relative phase thicknesses and oxygen concentration gradients and indicate the average relative saturations of the (prior) beta phase. In both cases, the alpha/beta boundary has remained sharp with only a few minor asperities visible at higher magnification.

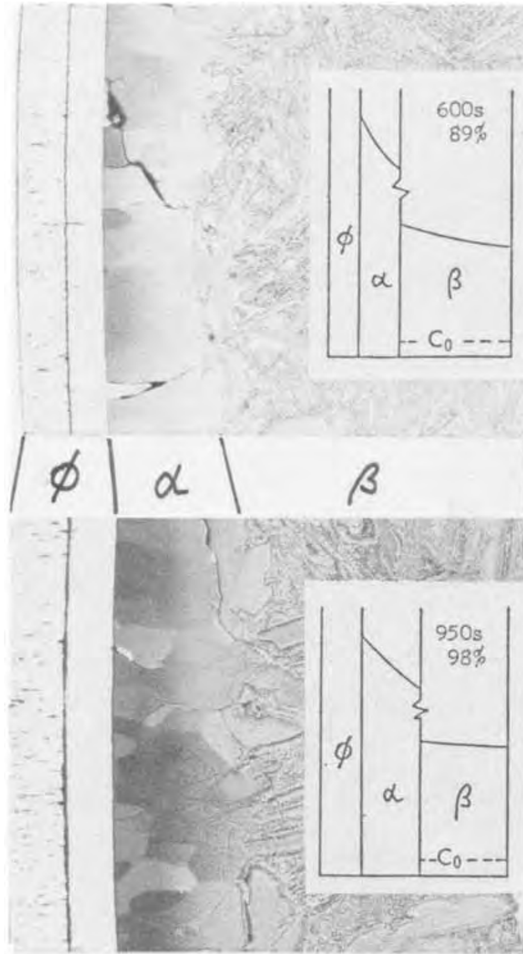

Fig. 3. Cross sections of Zircaloy-4 specimens after oxidation at 1300°C for 600 sec (above) and 950 sec (below). The alpha/beta interfaces now exhibit irregular growth shapes. While the thickness of the "compact" portion of the alpha layer is reasonably well defined in both instances, the observation of the alpha incursions signal the end of the period of ideal, diffusion-controlled growth.

tion of incursions at times that signal the filling-up of the beta phase with oxygen is potentially significant.

The present observations for oxidation at 1300°C suggest a correlation between the beginning of incursion formation and the attainment of oxygen concentration levels in the beta phase between 75% and 90% of the saturation value. In a similar sequence for oxidation at 1200°C (17), no incursions were found for a 600 sec exposure, although many incursions developed after 1200 sec, the two times corresponding to saturation values of about 70% and 90%. An earlier correlation (11, 15) indicated saturation levels of about 90-95% were required to produce alpha incursions during isothermal oxidation. However, this analysis was based on Mallett's (18) data for oxygen diffusion in beta Zircaloy rather than the recent measurements of Perkins (7). The latter diffusivity values are lower by almost a factor of 2, and a recalculation in terms of the newer data would suggest that the onset of incursions occurred at somewhat lower saturation values, *viz.*, between about 80% and 90%.

It is reasonable to expect that slow cooling after isothermal oxidation would promote alpha incursion formation as well as alpha precipitation in advance of the interface for specimens containing sufficient oxygen in the remaining beta phase (11, 14). However, we have observed that cooling rates in the range of 2°-5° C/sec for specimens having lower oxygen levels in the beta phase do not stimulate extensive incursion growth. For example, Fig. 4 illustrates the microstructures for specimens cooled at 2°C/sec from 1300°C after 120 and 300 sec oxidation periods. At the start of the cooling cycle, the beta phases were about 45% and 66% saturated, respectively. The "prior" beta regions of these specimens exhibited coarser structures than those found in quenched specimens with similar amounts of oxidation (see Fig. 2 and 3). However, few incursions of the type found after extended isothermal exposures were observed. Similarly oxidized specimens cooled at 5°C/sec displayed comparable features with finer structures in the prior beta phase. While Sawatzky *et al.* (14) observed large incursions and very coarse prior beta structures for a similar cooling rate, their isothermal oxidation periods (at 1200°C) were long enough to saturate completely the beta phase prior to the start of cooling. Thus, it appears that cooling rates affect the incursion growth and microstructure to a greater extent when the beta phase is in a near-saturated condition.

Kinetics.—The kinetics of layer growth in the early stages of the reaction of Zircaloy-4 in steam have been examined in detail (1). Both oxide and alpha layers grow parabolically, and in our previous work the maximum time was purposely limited so that any geometrical effects would be minimized. For example, for these experiments at 1304°C, the longest oxidation time was about 150 sec. In the present work, we have extended the maximum experiment time to insure, for our particular specimen dimensions, that the shrinking beta phase eventually saturates with oxygen. The consequences of this effect on the kinetics were examined experimentally and through computer modeling.

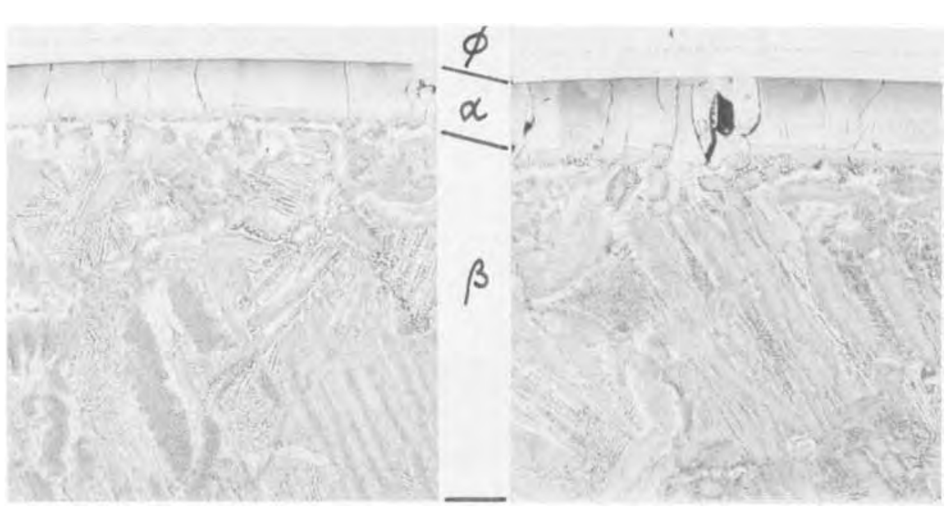

Fig. 4. Cross sections after oxidation for 120 sec (left) and 300 sec (right) at 1300°C followed by cooling at 2°C/sec to 800°C. At the start of cooling for these experiments, the beta phases were about 45% and 66% (average) oxygen saturated, respectively. While the structure in the (prior) beta phase of each specimen is coarse and shows evidence of precipitation in advance of the alpha-beta interface on cooling, few large alpha incursions are observed. Indeed, the decreased oxide/alpha thickness ratio for these specimens suggests that additional alpha growth during cooling was at least in part a uniform addition to the compact alpha layer.

The layer thickness data for oxidation at 1300°C listed in Table I are presented in the parabolic plot of Fig. 5. In this figure, we have also included curves based on (*i*) the rate constants for oxide and alpha growth for the short-time experiments (1), and (*ii*) those calculated by the MULTRAN computer program using the appropriate dimensions of our specimens (one-side reaction for 0.0635 cm wall thickness) and initial oxygen concentration [$C_o' = 0.12$ weight percent (w/o)].

Several significant points are immediately obvious from the figure. First of all, the short-time data are in excellent agreement with the previous parabolic growth correlations. However, for times greater than about 500 sec, the growth of both layers appears to deviate from the initial values. Finally, while the change in the kinetics of alpha growth is adequately predicted by the MULTRAN calculation, the smaller deviation exhibited by the oxide growth is not.

The good agreement of the two shortest experiments with the previous data for oxide growth supports the idea that this present data set should perhaps not be represented by a single parabolic growth constant but, rather, that after an initial period, the growth rate decreases at a slightly more rapid rate than would be expected for true parabolic behavior. As is evident from Fig. 5, the effect here is a small one, and the change in the apparent rate constant at longer times is only marginally different in the statistical sense. This is not an uncommon result when experimental data are examined in this sort of time regime. Structural effects in the oxide are usually involved (19).

On the other hand, longer oxidation times clearly promote positive deviations from the initial parabolic growth exhibited by the alpha layer. Such deviations are predicted by the modeling analysis based on our specimen geometry and ideal growth behavior. The fact that uniform alpha layer growth is not completely followed, because of the tendency toward incursion formation as growth proceeds or as the beta phase becomes saturated with oxygen, makes it difficult to assess completely the agreement between theory and experiment. The experimental data do show, however, increases in both the thickness of the compact portion of the alpha layer and, particularly, the incursion-compensated layer thickness that are consistent with the MULTRAN prediction of a factor of 2 increase in

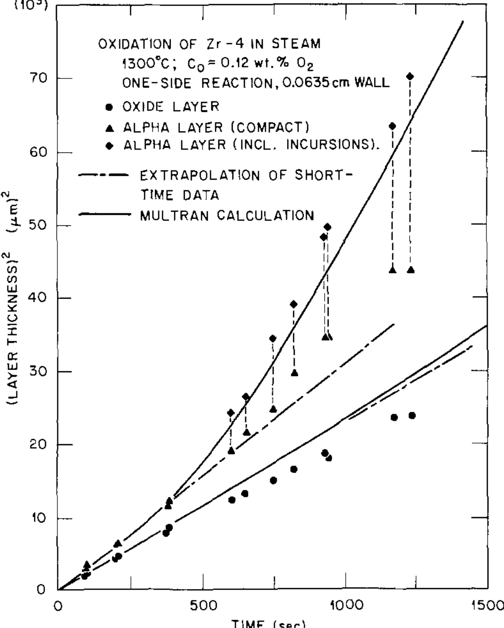

Fig. 5. Growth of oxide and alpha layers on Zircaloy-4 in steam at 1300°C. Data are compared with extrapolations of parabolic growth predicted from previous short-time experiments.

the effective parabolic rate constant for alpha growth at this temperature as oxidation proceeds.

These experiments and calculations point out the importance of specimen geometry and initial oxygen concentration to the layer growth kinetics and to the kinetics of oxygen consumption. The initial layer growth kinetics on specimens of Zircaloy-4 containing (originally) little or no oxygen, and specimens saturated with oxygen at the reaction temperature, would be parabolic but be described by different rate constants. Thus, a specimen of "finite geometry" would exhibit changes in layer growth behavior as the oxygen concentration gradient in the beta phase became influenced by the fact that the beta was filling up with oxygen. On saturation of the beta phase, the layers would grow at the "new" parabolic rate. In Table II, the parabolic rate constants for oxide growth, $\delta_\phi^2/2$, alpha growth, $\delta_\alpha^2/2$, and oxygen consumption, $\delta_\tau^2/2$, are presented for Zircaloy-4 with a typical initial oxygen concentration ($C_o = 0.12$ w/o) and for saturated samples at temperatures from 1000° to 1500°C. The two sets of rate constants were obtained from MULTRAN calculations using the inputs previously described (2). The table shows that for a saturated beta phase, the growth of both layers is faster while the rate of oxygen consumption is smaller (because no additional oxygen is being absorbed into the beta phase).

The effect of initial oxygen concentration on the rate of oxide growth should be comparatively small, the calculated ideal increase in the rate constants for saturated specimens ranging from about 3% to 17%, depending on the temperature, over that for a specimen containing little original oxygen. Very careful experiments would be required to detect differences of this magnitude. Our data actually show a small decrease in the rate constant for oxide growth at the longer times, as discussed above. On the other hand, the rate constants for alpha layer growth are increased from 45% to 135% for the same conditions, a change less apt to be overlooked in the spread of experimental data. Thus, the oxidation of a thin specimen should, and does, show geometrical effects on the alpha layer growth behavior. As noted above, despite the increased growth rates of the product layers for saturated specimens, the rate of oxygen consumption in this instance is actually reduced by a small amount. If the reaction is continued for a time sufficient to eliminate the beta phase from the system, then the alpha layer would itself become subject to saturation with oxygen. This occurrence would have more pronounced effects on the growth of the oxide phase and on the rate of oxygen uptake, calculated to be +74% and −41% changes, respectively, in the parabolic rate constants at 1300°C compared to that for an originally oxygen-free specimen. The experimental data of Pemsler (20) for pure zirconium reacting in oxygen exhibit at least qualitative agreement for the magnitude of these changes, showing about a factor of two increase at 1290°C for the rate constant for oxide growth.

The apparent sensitivity of the alpha growth to the degree of saturation of the underlying beta phase needs consideration when designing experiments and interpreting experimental results. For example, the experimental rate measurements from one-sided and from two-sided tests will be identical (other things being equal) so long as the conditions that define oxygen diffusion into the beta phase remain identical to the two cases. It is significant, however, to note that for a two-side test, the beta phase fills to a given degree of saturation in one-fourth the time required for the case of a one-side test. This situation is illustrated in Fig. 6 where computer-modeled alpha layer growth at 1300°C is plotted for saturated and unsaturated specimens and for one- and two-sided oxidation. The alpha growth for the two cases is identical only for about the first 100 sec, then the curves diverge, each

* $\delta_k^2/2 = k\, dk/dt$.

eventually acquiring a slope approximately equal to that for the originally saturated specimen. Clearly, such experimental data must be interpreted with geometrical effects in mind. Additionally, because incursion formation begins when the oxygen concentration gradient in the beta phase becomes small, incursion formation should occur much earlier for a two-sided oxidation test. The figure also includes the percentage relative saturation of the beta phase for the one- and two-sided reactions for these specimens. As noted previously, incursions and serious deviations from semi-infinite geometry behavior are observed at saturation levels between about 75% and 90%.

The data of Leistikow, Schanz, and Berg (16) may be interpreted in terms of, and offer at least qualitative verification for, the above model. For two-sided oxidation at 1300°C under equivalent conditions, they observed alpha incursions after only 120 sec (their shortest experimental time). In addition, their parabolic rate constant for alpha growth, calculated on the basis of the compact alpha layer thickness, was measurably higher than ours (1) despite the fact that the rate constants for oxide growth agreed closely. This behavior is consistent with the analysis presented in Fig. 6 both as to the time at which incursion growth was initiated and to the apparent difference in the parabolic constants for alpha layer growth determined from the slope of the thickness squared *vs.* time plot.

Conclusions

1. The set of oxidation experiments for Zircaloy-4 in steam at 1300°C exhibited departures at longer times from the simple early stage parabolic growth of the product layers, oxide and oxygen-stabilized alpha Zircaloy. These changes in the kinetics were examined by modeling the system as a multiphase, moving-boundary diffusion problem. Within the accuracy of the experimental measurements, a reasonable conformity of the observations and the model predictions was observed. It is thus important to consider the potential effects of specimen geometry when designing oxidation experiments or interpreting kinetic data.

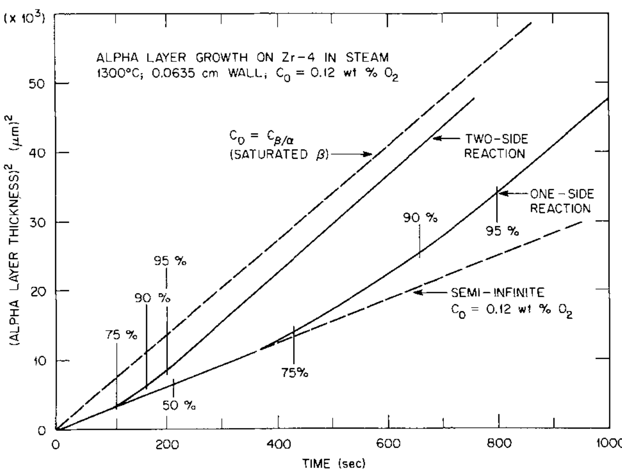

Fig. 6. Calculated alpha layer growth on 0.0635 cm thick Zircaloy-4 specimen in steam at 1300°C for one- and two-side reactions. Dashed curves depict semi-infinite geometry behavior for original oxygen concentrations in the beta phase of 0.12 and 1.00 w/o (saturation value at 1300°C). Tics on curves represent percentage relative saturation of oxygen in the beta phase.

2. Alpha incursions, irregular growths of alpha Zircaloy into the host beta phase, appeared to form during isothermal oxidation when the oxygen concentration gradient in the beta phase became small. Their presence was observed when the relative saturation in the beta phase was calculated to be between 75% and 90%. Slow cooling may promote incursion growth in specimens containing oxygen at or near this level.

3. Modeling the high temperature Zircaloy oxidation reaction in terms of an ideal diffusion-controlled layer growth process provided an explanation for certain of our observations of experimental behavior in terms of specimen geometry effects. Computer results yielding quantitative assessments of these effects for the Zircaloy-steam reaction as functions of temperature and specimen dimensions were presented.

The Solubilities of NiO, Co_3O_4, and Ternary Oxides in Fused Na_2SO_4 at 1200°K

Dilip K. Gupta* and Robert A. Rapp**

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

The solubilities of the oxides NiO and Co_3O_4 in molten Na_2SO_4 have been established as a function of Na_2O activity at 1200°K. A reference electrode of Ag/Na_2SO_4-10 m/o Ag_2SO_4 in a mullite tube was used as a sodium activity probe for the Na_2SO_4 melt. A second reference electrode of Pt, O_2 (air)/zirconia (3.5 w/o CaO) served as an oxygen activity probe for Na_2SO_4. The combination of measurements of the sodium probe and oxygen probe in the melt provided the Na_2O activity in Na_2SO_4 directly, and eliminated the necessity for any bare metal electrode. Saturated melts were analyzed by atomic absorption spectroscopy for the dissolved metal contents. The observed dependences of the solubilities of NiO and Co_3O_4 in Na_2SO_4 on the activities of sodium oxide are in agreement with those predicted from the Na-Ni-S-O and Na-Co-S-O phase stability diagrams, respectively. Activity coefficients were calculated for the solute species. Preliminary measurements were made of the aluminum contents in Na_2SO_4 melts saturated with NiO and Co_3O_4 in an alumina crucible. The unusual dependences of aluminum content on salt basicity suggested the existence of the ternary oxides $NiAl_2O_4$ and $CoAl_2O_4$. While the preliminary aluminum measurements were not considered reliable, a theoretical model was developed to predict the expected solubility behavior for a ternary oxide in Na_2SO_4.

Nickel- and cobalt-base alloys and coatings with excellent resistance to oxidation at high temperatures have been developed. These materials are designed to develop tightly adherent and slow growing Cr_2O_3 or Al_2O_3 scales when exposed to high temperature gases. But the oxidation of such alloys and coatings is sometimes accelerated considerably when an electrolytic deposit (a thin layer of fused salt) covers the surface of the metal at high temperatures. Although a number of fused salt films are known to cause serious hot corrosion attack of metals, sodium sulfate has received the greatest attention, and the phenomenology of the attack has been explored extensively.

A knowledge of the solubilities of pertinent oxides in the corrosion products as a function of the chemical state of Na_2SO_4 should assist in understanding the occurrence and importance of the fluxing (dissolution) of the protective oxides formed during hot corrosion.

Stroud and Rapp (1) reported the solubilities of α-Al_2O_3 and Cr_2O_3 in Na_2SO_4 at 1200°K as a function of P_{O_2} and a_{Na_2O} (or P_{SO_3}). Probably because of some reaction of Na_2SO_4 with the Pt wire electrode, some aspects of the Stroud and Rapp work are inconsistent with thermodynamic expectation. First, the minimum in the α-Al_2O_3 solubility dependence upon a_{Na_2O} did not occur near the center of the Al_2O_3 stability regime. Secondly, counter to expectation, the basic solubility of Cr_2O_3 as CrO_4^{2-} ions was found to be higher at $P_{O_2} = 10^{-4}$ atm than for $P_{O_2} = 1$ atm. A renewed study of Cr_2O_3 and Al_2O_3 solubilities using improved technique is underway. Liang and Elliott (2, 3) have also reported a few values for the equilibrium solubilities of Cr_2O_3, Al_2O_3, and NiO in Na_2SO_4 at 1200°K.

In the present work, the solubilities of the oxides NiO and Co_3O_4 have been established for P_{O_2} equal to 1 atm as a function of a_{Na_2O} at 1200°K. These solubilities have been related to the respective phase stability diagrams for NiO in Fig. 1 and for Co_3O_4 in Fig. 2. These phase stability diagrams are analogous to Pourbaix diagrams of E *vs* pH for aqueous solutions The redox potential is plotted against the negative of salt basicity (defined as log a_{Na_2O}). The thermodynamic data needed for establishing these Pourbaix diagrams at 1200°K are listed in Table I. Other authors (4-6) have previously presented similar diagrams. In Fig. 1 and 2 dashed lines have been provided to indicate constant activities (10^{-2}, 10^{-4}, 10^{-6}) for the acid and basic salts in equilibrium with the metal oxide and liquid Na_2SO_4. These diagrams could provide quantitative values for the solubilities of metal oxides in the fused salts if the identity and the activity coefficients of the solute ions in Na_2SO_4

Key words: oxide solubilities, fused salt, sodium sulfate, hot corrosion.

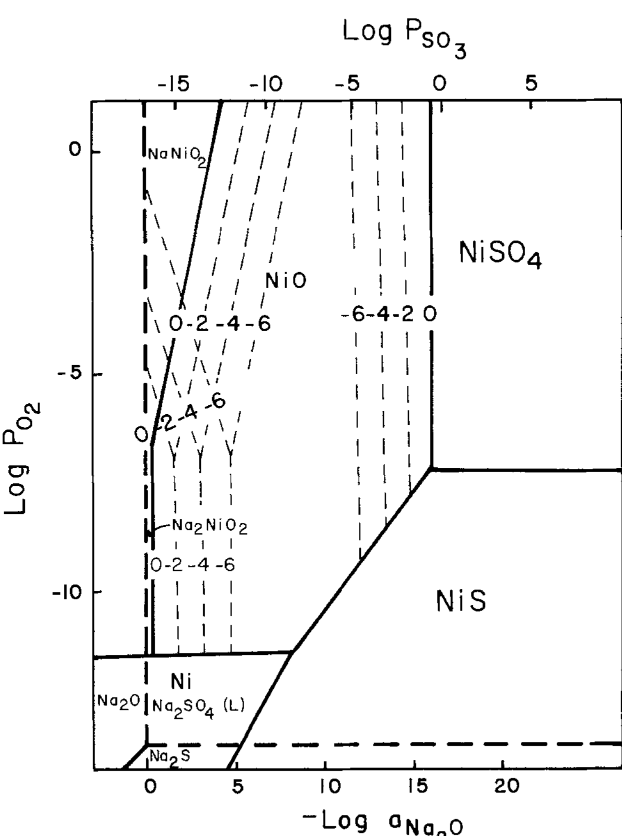

Fig. 1. Thermodynamic phase stability for Na-Ni-S-O system at 1200°K.

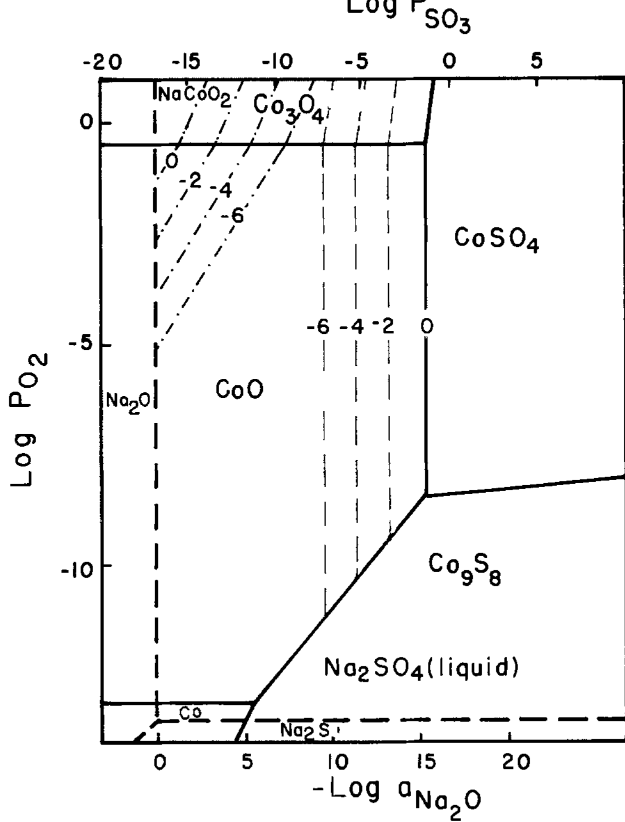

Fig. 2. Thermodynamic phase stability for Na-Co-S-O system at 1200°K.

are known. Alternatively, if the solubility of the oxide in the fused salt is established experimentally as a function of a_{Na_2O}, both the identity and the activity coefficient of the solutes in dilute solutions can be obtained.

The reliability of the values thus obtained for the activity coefficients depends on the accuracy of the Gibbs energy of formation data of the soluble metal salts, the metal oxides, Na_2SO_4, and the accuracy of the experimental results. Data are apparently not available for the Gibbs energy of formation of $NaCoO_2$. Hence the determination of the activity coefficient for the basic solute species of Co in sodium sulfate is not possible. However, for the sake of completeness of the Na-Co-S-O Pourbaix diagram, the Gibbs energy of formation of $NaCoO_2$ has been crudely estimated by assuming that the activity coefficient of $NaCoO_2$ in Na_2SO_4 is the same as that calculated for $NaNiO_2$ in Na_2SO_4 at 1200°K from this study.

Electrochemical Electrodes

Several studies (7-9) have demonstrated reversible electrochemical measurements of oxygen and SO_3 (or Na_2O) activities in liquid sulfates. Liang and Elliott (10) used a beta-Al_2O_3 electrolyte and a reversible W, WS_2, Na_2S reference electrode to determine the activity of sodium oxide (or P_{SO_3}) in sodium sulfate at 1200°K. The activity of sodium oxide in the Na_2SO_4 melt was fixed by an equilibrium with the prevailing pressures of SO_3, SO_2, and O_2. The limitation of this procedure is that the equilibration of the melt with P_{SO_3} of a gas phase limits the range of values of P_{SO_3} (or a_{Na_2O}) over which oxide solubilitites can be studied.

Flood and Boye (11) utilized an SO_2, O_2 electrode to obtain thermodynamic information on the systems K_2SO_4-$K_2S_2O_7$-SO_3 and ZnO-$ZnSO_4$-SO_3. More recently, Stroud and Rapp (1) used a modification of this cell.

In the current study, the cell

(−) Au, O_2, SO_3, Na_2SO_4	Mullite	Na_2SO_4-10 m/o Ag_2SO_3, Ag/Pt (+)	
Working electrode (WE)	(Na^+)	Reference electrode (RE)	[I]

was used to establish the activity of sodium oxide in the fused sodium sulfate melt at 1200°K. Because of its simplicity of construction and stability, many authors (12-17) have used the closed-end mullite ($3Al_2O_3 \cdot 2SiO_2$) tube with the 90 Na_2SO_4/10 Ag_2SO_4 melt contacting an Ag wire as a reversible sodium ion

probe. A glassy grain boundary phase in the mullite provides exclusive sodium ion conduction.

As demonstrated by Watt, Andersen, and Rapp (12), among others, the voltage of cell [I] can be given as

$$E_I = E^\circ{}_I{}' + \frac{2.3RT}{2F}\log\frac{a_{Na_2O}(WE)}{P_{O_2}{}^{1/2}(WE)} \quad [1]$$

where

$$E^\circ{}_I{}' = E^\circ{}_I - \frac{2.3RT}{2F}\log\frac{a_{Na_2SO_4}(RE)}{a_{Ag_2SO_4}(RE)} \quad [2]$$

and

$$E^\circ{}_I = -\frac{1}{2F}\{\Delta G^\circ{}_f(Na_2SO_4) - \Delta G^\circ{}_f(Na_2O) - \Delta G^\circ{}_f(Ag_2SO_4)\} \quad [3]$$

for the virtual cell reaction

$$Na_2O + Ag_2SO_4 \rightarrow Na_2SO_4 + 2Ag + 1/2\ O_2 \quad [4]$$

To determine the value of $E^{\circ\prime}$, the ratio of the activity coefficients of Na_2SO_4 to Ag_2SO_4 in the 90 Na_2SO_4:10 Ag_2SO_4 reference electrode was determined by Shores and John (18) at 900°C to equal 3.26. This corresponds to a value of 3.17 at 1200°K assuming regular solution behavior for the 90 Na_2SO_4:10 Ag_2SO_4 melt. From the thermodynamic data in Table I and use of the ratio 3.17 for $\gamma_{Na_2SO_4}/\gamma_{Ag_2SO_4}$, the voltage of cell [I] at 1200°K is

$$E_I(V) = 1.454 + 0.119\log\frac{a_{Na_2O}(WE)}{P_{O_2}{}^{1/2}(WE)} \quad [5]$$

The separate measurement of the oxygen activity in the Na_2SO_4 melt was established by the cell

(−) air, $P_{O_2} = 0.21$, Pt	ZrO_2(3.5 w/o CaO)	Na_2SO_4, O_2, SO_3, Au/Pt (+)
(RE)	(O^{2-})	(WE) [II]

where

$$E_{II} = \frac{RT}{4F}\ln\frac{P_{O_2}(WE)}{0.21} \quad [6]$$

or

$$E_{II}(V) = 0.0403 + 0.0595\log P_{O_2}\ (atm)\ (WE) \quad [7]$$

Upon measuring the voltage between the individual reference electrodes of cells [I] and [II], equal to the algebraic sum of E_I and E_{II}, a voltage E_{III} is obtained which provides the measure of a_{Na_2O} for the Na_2SO_4 melt without the influence of any corrosion reaction on the metallic wire contacting the melt

$$E_{III}(V) = 1.4943 + 0.119\log a_{Na_2O}(WE) \quad [8]$$

Experimental Apparatus and Procedures

The experimental apparatus for the solubility studies is illustrated in Fig. 3. About 5-10g of reagent-grade oxide powders were charged with about 25g of reagent-grade sulfate powder (J. T. Baker Chemical Company) in an alumina crucible placed inside the external mullite tube. The mullite and zirconia electrodes were inserted into the melt through stainless steel adapters (Cajon) with o-rings epoxied into the water-cooled stainless steel flange.

The reference electrode of Ag(s)/Na_2SO_4-10 m/o Ag_2SO_4 was contained in a 1 cm OD mullite (MV30, McDanel) tube to serve as the sodium probe. A Pt-wire, spot-welded to the small piece of Ag wire served as the electronic lead wire for the sodium probe. The mullite tube was sealed at the top with a piece of Tygon tubing and a pinch clamp to minimize any drift caused by loss of SO_3. However, some transport of Ag through the mullite tube occurred, as silver could be detected in the Na_2SO_4 in the crucible.

The 1 cm OD zirconia (3.5 w/o CaO) oxygen reference electrode was prepared by platinizing the inside bottom of the tube, and a stripe at 12 cm from the bottom. Two Pt-Pt/10% Rh thermocouples, each in alumina protection tubes, were placed inside the zirconia tube, such that one of the thermocouples touched the bottom while the other thermocouple touched the Pt stripe. The reference gas inside the zirconia tube was air. The zirconia tube was also platinized on its outside surface (contacting the chamber gas) at about 12 cm from the bottom. A Pt lead wire to this electrode served to measure the oxygen activity of the gas phase over the melt. A short gold electrode wire was immersed in the melt but was spot-welded to a Pt wire which served as the lead wire. Thus, no thermoelectric voltage contributions were introduced to cell readings. The temperature was controlled by a solid-state temperature controller (Barber-Colman) at 1200° ± 2°K.

All chemicals used were of reagent-grade quality without further purification. All gases were dried by passing them through silica gel. Gases were conducted to the surface of the melt through a quartz tube inserted through the stainless steel flange. Mixtures of SO_2 (Matheson) and O_2 (Liquid Carbonic) gases and Na_2O_2 additions were used to shift the melt basicity toward lower and higher activities of sodium oxide, respectively. Sodium peroxide was used rather than Na_2O because of the hygroscopic nature of Na_2O. The thermal decomposition of Na_2O_2 to Na_2O and O_2 was assumed to be rapid. The combination of the sodium and the oxygen probes enabled the monitoring of the a_{Na_2O} of the melt at all times. Cell emf values showed a slight shift with time, presumably resulting from slight attack of the mullite, zirconia and alumina refractories. Such buffering behavior has been reported elsewhere (3, 10).

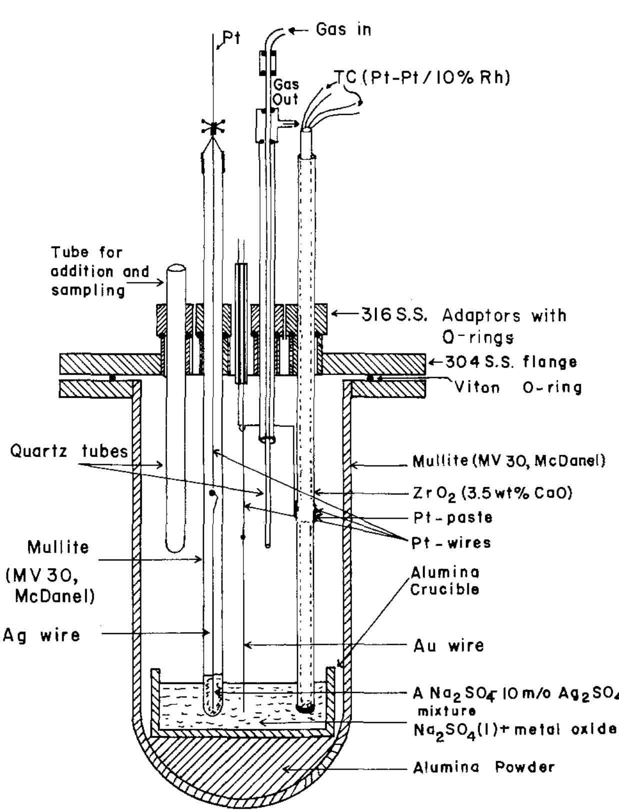

Fig. 3. Experimental setup for measuring the oxide solubility in fused sodium sulfate at 1200°K.

The a_{Na_2O} values calculated from the emf readings of the sodium probe and oxygen probes using both the P_{O_2} above the melt and in the melt, respectively, became approximately equal after 2-3 days, which was inferred to indicate the equilibration of the melt with the gas phase.

The solubilities of the oxides NiO and Co_3O_4 in the molten Na_2SO_4 were determined after freezing saturated samples of the melt onto an alumina rod. The samples were weighed and dissolved in dilute acid (0.03*N*) having the same anions as that of their respective standard solutions for atomic absorption analysis. The amount of dissolved metal was determined in an atomic absorption spectrophotometer (Perkin Elmer; Series 360) using a graphite furnace. The amount of the dissolved compound was then calculated using known stoichiometries.

Results and Discussion

NiO solubility.—The experimental solubility data are shown in Fig. 4. Other values, reported by Liang and Elliott (3) for the solubility of NiO in Na_2SO_4, after adjustment for the difference in their value for the Gibbs energy of formation of Na_2SO_4 to that in JANAF Tables (23), is also shown in this diagram.

After 24 hr from the attainment of the steady emf, the samples were taken at intervals of 12-24 hr. Under these conditions, no observable difference in the solubility as a function of time was noticed, implying that the measured solubilities are the saturation solubilities. In Fig. 4, the dependence of the acid solute concentration upon the basicity (log a_{Na_2O}) agrees well with a line of slope 1 for the following reaction

$$NiO + Na_2SO_4 = NiSO_4 + Na_2O \qquad [9]$$

and

$$\left\{ \frac{\partial (\log a_{NiSO_4})}{\partial (-\log a_{Na_2O})} \right\} = 1 \qquad [10]$$

No dependence upon P_{O_2} for the acidic dissolution of NiO as Ni^{2+} is expected because the nickel valence is not changed upon dissolution (vertical line on Fig. 1). Excellent agreement with Liang and Elliott (3) is found for the solubility of NiO at log $a_{Na_2O} = -11.79$ (corresponding to -12.69 of their study) of about 150 wt ppm. However, the solubility determined here for a very acid condition is about an order of magnitude higher than that reported by Liang and Elliott (3). The high solubility for NiO in acidic conditions is consistent with the observation of Wortman *et al.* (20), who have reported deposits of yellow $NiSO_4$ on blades from engines suffering hot corrosion at considerably lower temperatures.

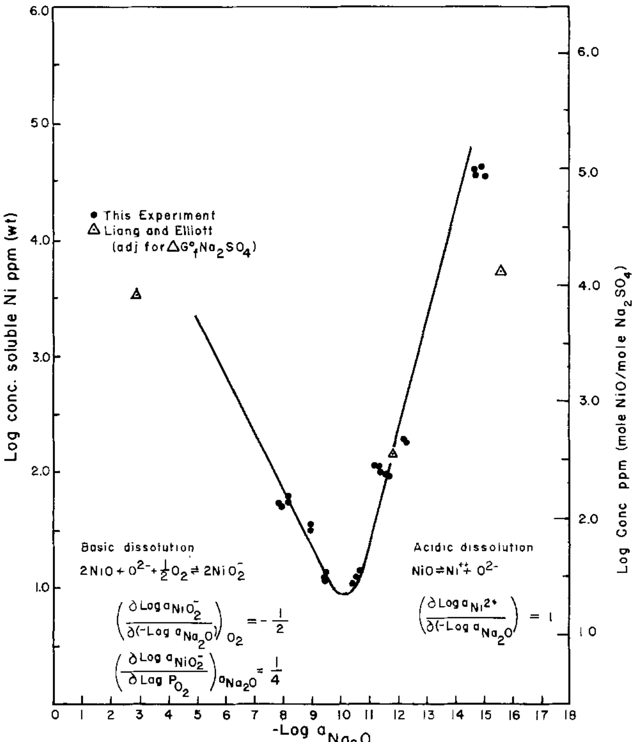

Fig. 4. Solubility of NiO in fused Na_2SO_4 at 1200°K

For the basic dissolution of NiO in Na_2SO_4, the measured solubility data of Fig. 4 agree well with the following reaction

$$2NiO + Na_2O + 1/2\, O_2 = 2NaNiO_2 \qquad [11]$$

where

$$\left\{ \frac{\partial (\log a_{NaNiO_2})}{\partial (-\log a_{Na_2O})} \right\}_{O_2} = -\frac{1}{2} \qquad [12]$$

and

$$\left\{ \frac{\partial (\log a_{NaNiO_2})}{\partial (\log P_{O_2})} \right\}_{a_{Na_2O}} = \frac{1}{4} \qquad [13]$$

Thus, in basic sodium sulfate melts at 1 atm oxygen, nickel oxide dissolves as nickelate ions, NiO_2^-, with trivalent nickel. Indeed, the correlation of Eq. [12] to Eq. [11] would also be valid for a multiple of NiO_2^-, such as $Ni_2O_4^{2-}$. Since the basic nickelate species has a valence (+3) different from that in its oxide (+2), an oxygen pressure dependence of Eq. [13] for $NaNiO_2$ solubility is expected. The data in Fig. 4 were corrected slightly from the measured P_{O_2} in the melt to 1 atm P_{O_2}, according to the theoretical oxygen dependence of Eq. [13]. Liang and Elliott (3) have reported the basic solubility of NiO as $NaNiO_2$ of 0.4 w/o at log $a_{Na_2O} = -2.67$ (corresponding to -3.57 of their study). In the present experimental setup attainment of such high basicity was practically limited because of attack on the ceramics and metals by the highly reactive oxide ions.

The presence of $NaNiO_2$ in the quenched basic salt samples was confirmed by x-ray analysis. Goebel and Pettit (21) consider that the oxide ions in sodium sulfate react with NiO in forming a basic solute species to account for the accelerated hot corrosion of pure NiO in Na_2SO_4 in an oxygen environment.

The thermodynamic phase stability diagram for the Na-Ni-S-O system in Fig. 1 indicates NiO stability for 1 atm of P_{O_2} for $3.7 < -\log a_{Na_2O} < 16.2$. The Gibbs energy of formation for $NiSO_4$ was taken from the tabulation by Kellogg (27); an uncertainty of ±2 kJ/mole is indicated. The Gibbs energy of formation of $NaNiO_2$ reported by Shaiu, Wu, and Chiotti (22) was used to establish the NiO/$NaNiO_2$ boundary of Fig. 1; this value for $\Delta G^\circ_{NaNiO_2}$ is uncertain by ±13 kJ/mole. The authors suggested that this value was not very reliable.

According to a Raoult's law choice of standard state, the activities of the condensed phases $NaNiO_2$ and $NiSO_4$ in equilibrium with molten Na_2SO_4 are considered to be unity at the NiO stability boundaries at $-\log a_{Na_2O}$ equal to 3.7 and 16.2, respectively.

The activity coefficients of the soluble $NiSO_4$ and $NaNiO_2$ species were calculated with respect to pure solid $NiSO_4$ and $NaNiO_2$ as the standard states

$$\{\gamma_{NiSO_4}{}^{Na_2SO_4}\}_{\text{dil. soln}} = \frac{a_{NiSO_4}}{N_{NiSO_4}};$$

$$\{\gamma_{NaNiO_2}{}^{Na_2SO_4}\}_{\text{dil. soln}} = \frac{a_{NaNiO_2}}{N_{NaNiO_2}} \qquad [14]$$

The activity coefficient $\gamma_{NiSO_4}{}^{Na_2SO_4}$ was calculated to equal 0.12. But because of the uncertainty in the value for $\Delta G^\circ_{NiSO_4}$, the true value may lie between 0.09 and 0.20. The activity coefficient for $NaNiO_2$ in Na_2SO_4, $\gamma_{NaNiO_2}{}^{Na_2SO_4}$, was calculated to equal 50. Again, because of uncertainties in the value for $\Delta G^\circ_{NaNiO_2}$, the true value may lie between 10 and 300.

The results in Fig. 4 show a minimum in the NiO solubility at $-\log a_{Na_2O} = 10.3$, which is consistent with that expected from the phase stability diagram for the Na-Ni-S-O system. The solubility minimum is expected to lie somewhere near the middle of the NiO stability range ($3.7 < -\log a_{Na_2O} < 16.2$), as decided by the actual values of Raoultian activity coefficients for the solutes.

Co_3O_4 solubility.—Experimental values for the solubility of the cobalt oxide Co_3O_4 in fused Na_2SO_4 at 1 atm O_2 are plotted in Fig. 5. Similar to nickel oxide, the saturated samples of Co_3O_4 dissolved in Na_2SO_4 were quenched for quantitative determination by atomic absorption spectrophotometry. No change in the solubility was observed after about 20 hr from the attainment of steady emf's for the melt probes.

Lines were drawn according to the theoretically predicted slope of 1 for acid dissolution according to the following equation

$$2Co_3O_4 + 6Na_2SO_4 = 6CoSO_4 + 6Na_2O + O_2 \quad [15]$$

where

$$\left\{ \frac{\partial(\log a_{CoSO_4})}{\partial(-\log a_{Na_2O})} \right\}_{O_2} = 1 \quad [16]$$

and

$$\left\{ \frac{\partial(\log a_{CoSO_4})}{\partial(\log P_{O_2})} \right\}_{a_{Na_2O}} = -\frac{1}{6} \quad [17]$$

Because of the oxygen dependence of the solubility of Co_3O_4, the data points were corrected from the P_{O_2} values indicated by the zirconia probe in the melt to a common P_{O_2} of 1 atm. The corrected data of Fig. 5 agree with the expected dependence of acid solute concentration upon a_{Na_2O} according to Eq. [16].

The thermodynamic phase stability diagram for the Na-Co-S-O system at 1200°K was shown in Fig. 2. The line for unit activity of $CoSO_4$ at $P_{O_2} = 1$ atm, assuming pure liquid $CoSO_4$ as the standard state, lies at the value of $-\log a_{Na_2O} = 15.2$.

The Raoultian activity coefficient $\gamma_{CoSO_4}{}^{Na_2SO_4}$ was calculated by the same method just explained for NiO measurements. The calculated activity coefficient $\gamma_{CoSO_4}{}^{Na_2SO_4}$ equals 2.5. No previous data have been reported in the literature for comparison. From the uncertainty in $\Delta G°_{CoSO_4}$, the true activity coefficient could have values between 1 and 5.

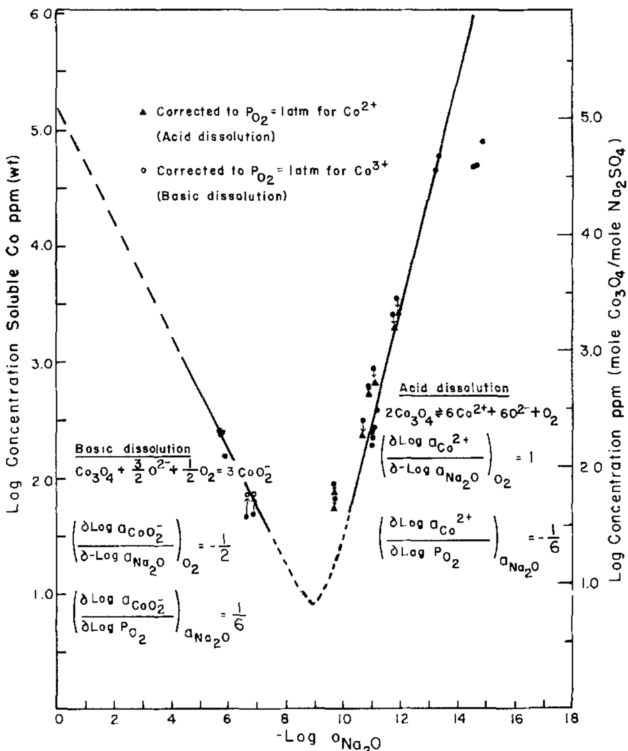

Fig. 5. Solubility of Co_3O_4 in fused Na_2SO_4 at 1200°K

For the basic dissolution of Co_3O_4 in Na_2SO_4, the P_{O_2}-corrected data fitted well to a line of slope $-\frac{1}{2}$, according to reaction [18]

$$Co_3O_4 + \frac{3}{2}Na_2O + \frac{1}{2}O_2 = 3NaCoO_2 \quad [18]$$

and

$$\left\{ \frac{\partial(\log a_{NaCoO_2})}{\partial(-\log a_{Na_2O})} \right\}_{O_2} = -\frac{1}{2} \quad [19]$$

also

$$\left\{ \frac{\partial(\log a_{NaCoO_2})}{\partial(\log P_{O_2})} \right\}_{a_{Na_2O}} = \frac{1}{6} \quad [20]$$

This implies that Co_3O_4 dissolves in Na_2SO_4 as a CoO_2^- solute species (or a multiple such as $Co_2O_4^{2-}$) in a basic environment ($-\log a_{Na_2O} < 9.2$). There is no datum reported in the literature for $\Delta G°_{NaCoO_2}$. Here, for the sake of completeness of the Na-Co-S-O phases stability diagram, a value for $\Delta G°_{NaCoO_2}$ was estimated upon making the tenuous assumption that the activity coefficient $\gamma_{NaCoO_2}{}^{Na_2SO_4}$ equals 50, the same as $\gamma_{NaNiO_2}{}^{Na_2SO_4}$. Both cobalt and nickel dissolve as MO_2^- species for basic Na_2SO_4 melts, where M has the +3 valence state. The calculated boundary between Co_3O_4 and $NaCoO_2$ thus lies at about $-\log a_{Na_2O} = 1.3$. The calculated value for the Gibbs energy of formation for $NaCoO_2$ at 1200°K is -291.3 kJ/mole $\pm$ 19 kJ. The measured Co_3O_4 solubility data exhibit a minimum at a value for $-\log a_{Na_2O} = 9.2$, which is consistent with that expected from the stability diagram.

The solubility of the higher oxide Co_3O_4 was determined in this study. However, the construction lines for constant solute activity of Fig. 2 point out the continuity in solute activity as cobaltous oxide CoO becomes stable at lower P_{O_2}. Thus the solubility curve for CoO at any lower P_{O_2} can be calculated upon using the same activity coefficients established in this study. Obviously, the acid solubility of CoO as $CoSO_4$ for a given value of log a_{N32O} will be slightly higher than that for Co_3O_4 at 1 atm. This acid solubility for CoO should not depend upon P_{O_2}. The basic solubility of CoO as $NaCoO_2$ for a given value of log a_{Na_2O} is significantly lower than that for Co_3O_4. According to the solubility equilibrium

$$2CoO + Na_2O + \frac{1}{2}O_2 = 2NaCoO_2 \quad [21]$$

$$\left\{ \frac{\partial(\log a_{NaCoO_2})}{\partial(-\log a_{Na_2O})} \right\}_{O_2} = -\frac{1}{2} \quad [22]$$

and

$$\left\{ \frac{\partial(\log a_{NaCoO_2})}{\partial(\log P_{O_2})} \right\}_{a_{Na_2O}} = \frac{1}{4} \quad [23]$$

The specific dependences of oxide solubility on a_{Na_2O} and P_{O_2} in the salt are important in testing certain proposed scale fluxing mechanisms and criteria for the hot corrosion of metals. For example, Rapp and Goto (28) have proposed that the existence of a negative solubility gradient for an oxide in the salt film would support a continuing scale dissolution and reprecipitation mechanism in hot corrosion.

Spinel solubility.—The same salt solutions saturated with NiO and Co_3O_4 were also analyzed by atomic absorption for soluble aluminum in Na_2SO_4 at 1200°K. The resulting data for an "apparent" solubility as a function of a_{Na_2O} are shown in Fig. 6. No solid alumina powder was charged into the Na_2SO_4 melts. Only the alumina crucible and the mulllite tube (MV30, McDanel) were considered to be the sources

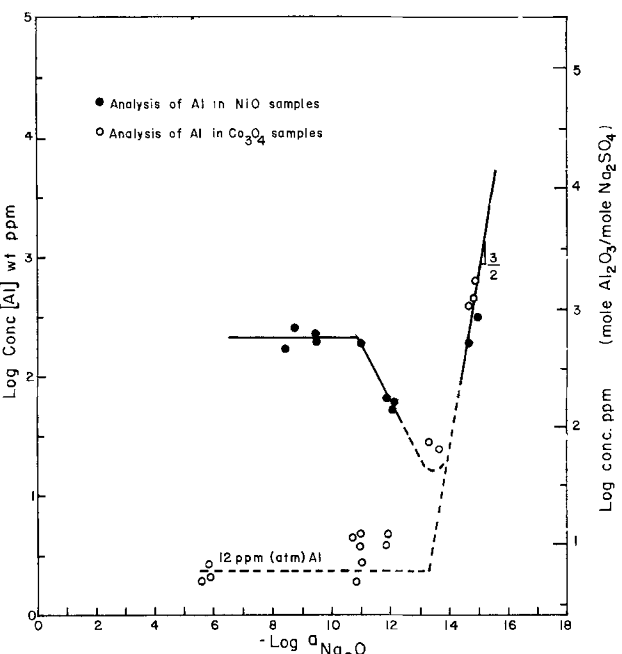

Fig. 6. Analysis for Al content in the quenched samples of NiO and Co_3O_4.

of alumina. Gibbs energy data in Table I predict that over a large range of a_{Na_2O}, alumina should react to form spinels, $NiAl_2O_4$ or $CoAl_2O_4$, in the presence of excess NiO and Co_3O_4, except for very acid ($-\log a_{Na_2O} > 15.2$) conditions where these oxides (NiO and Co_3O_4) dissolve as their respective sulfates. The thermodynamic stability of $NiAl_2O_4$ is indicated on superimposed Na-Ni-S-O with Na-Al-S-O diagrams in Fig. 7, and $CoAl_2O_4$ stability is shown on the Na-Co-S-O and Na-Al-S-O systems in Fig. 8. The $NiAl_2O_4$ stability extends from $4.7 < -\log a_{Na_2O} < 17.1$, and for $CoAl_2O_4$, the boundary extends from $2.8 < -\log a_{Na_2O} < 16.8$. Unlike the dissolution of binary oxides in Na_2SO_4 at 1200°K, the solubility of a ternary oxide as a function of a_{Na_2O} would be expected to exhibit a sequence of different regimes, depending on the predominant solute species present and the particular condensed phases which are stable and present. The following analysis is a novel treatment for the expected solubility for a ternary oxide:

Region I.—In a region of very basic melt, the stable condensed phase for aluminum is $NaAlO_2$, and for metal M (M will be used for Ni or Co hereafter) is $NaMO_2$. The solubilities of these condensed phases as AlO_2^- and MO_2^- solute species should not depend upon $\log a_{Na_2O}$ or P_{O_2}. Therefore, the dilute solution of the condensed phases $NaAlO_2$ and $NaMO_2$ in Na_2SO_4 should show no dependence of soluble Al on the Na_2O activity according to following reactions

$$NaAlO_2(s) = Na^+ + AlO_2^- \qquad [24]$$

where

$$\left\{\frac{\partial(\log a_{NaAlO_2})}{\partial(-\log a_{Na_2O})}\right\}_{O_2} = 0 \qquad [25]$$

Region II.—In a somewhat less basic melt, the binary oxide of metal M, MO (rather than $NaMO_2$), is the stable condensed phase, and is present in excess in Na_2SO_4 along with the stable $NaAlO_2$ phase. Again, the dissolution of Al as an AlO_2^- species (or multiple thereof) should exhibit no dependence of soluble Al concentration on a_{Na_2O} because the preceding Eq. [24] and [25] would again apply.

Region III. —In this region of basic melt, both the spinel MAl_2O_4 and M-oxide are stable and present as condensed phases. The basic solute species AlO_2^- and MO_2^- are stable. The dissolution of MAl_2O_4 as AlO_2^- ions and MO_2^- is described by Eq. [26], and the basicity ($\log a_{Na_2O}$) dependence of soluble aluminum

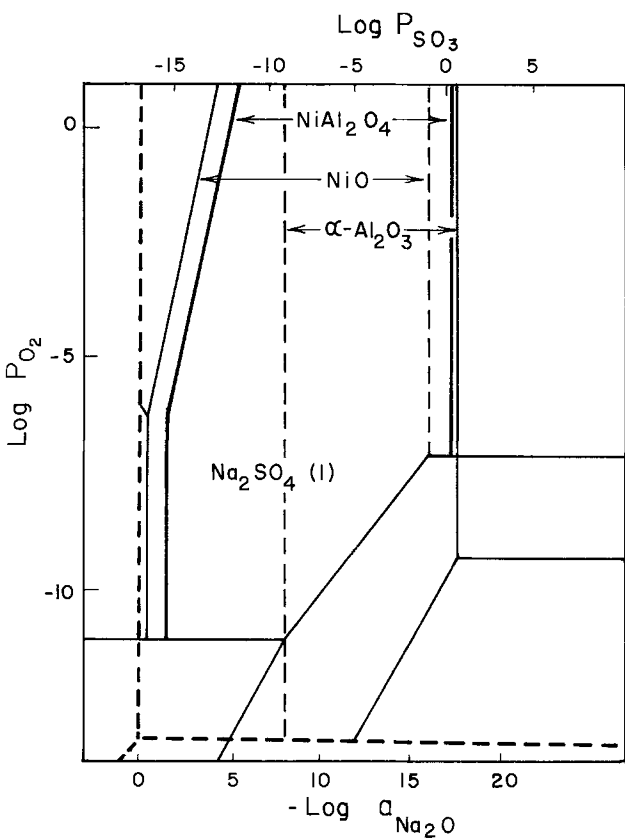

Fig. 7. Superimposed phase stability plots for the Na-Ni-S-O and Na-Al-S-O systems at 1200°K. The limits of stability for the phases $NiAl_2O_4$, NiO, and α-Al_2O_3 have been indicated.

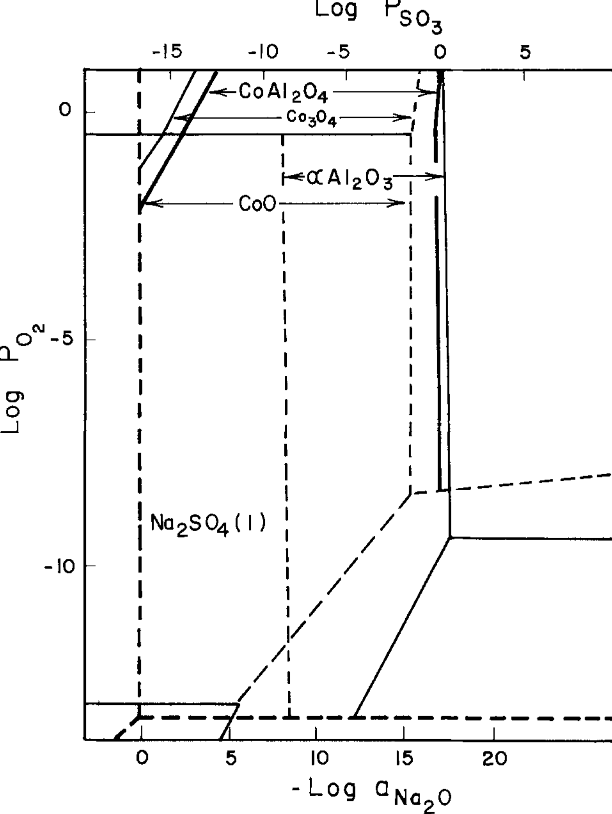

Fig. 8. Superimposed phase stability plots for the Na-Co-S-O and Na-Al-S-O systems at 1200°K. The limits of stability for the phases $CoAl_2O_4$, Co_3O_4, CoO, and α-Al_2O_3 have been indicated.

concentration by Eq. [27]

$$MAl_2O_4 + \frac{3}{2} Na_2O + \frac{1}{4} O_2 = 3Na^+ + MO_2^- + 2AlO_2^- \quad [26]$$

and

$$\left\{ \frac{\partial (\log [Al]_{sol.})}{\partial (-\log a_{Na_2O})} \right\}_{O_2} = \left\{ \frac{\partial (\log a_{NaAlO_2})}{\partial (-\log a_{Na_2O})} \right\}_{O_2} = -\frac{1}{2} \quad [27]$$

Region IV.—In this regime, the $MAlO_2$ spinel and MO are stable and present as the condensed phases and the soluble species are AlO_2^- and M^{2+}. Note that nickel oxide and cobalt oxide should dissolve as acid species (M^{2+} ions) at a basicity where aluminum dissolves as a basic species (AlO_2^- ions)

$$MAl_2O_4 = M^{2+} + 2AlO_2^- \quad [28]$$

There is no expected dependence of soluble aluminum upon a_{Na_2O}.

Region V.—In this acid regime, $MAlO_2$ spinel and excess MO are stable and present as condensed phases, and Al^{3+} and M^{2+} are the soluble acidic species

$$MAl_2O_4 + 8Na^+ = M^{2+} + 2Al^{3+} + 4Na_2O \quad [29]$$

Here, the dissolution of MAl_2O_4 as $Al_2(SO_4)_3$ depends also upon the dissolution behavior of NiO. Upon differentiation of the logarithm of the equilibrium constant for Eq. [29]

$$\left\{ \frac{\partial (\log [Al^{3+}]_{sol.})}{\partial (-\log a_{Na_2O})} \right\} = 2 - \frac{1}{2} \left\{ \frac{\partial (\log [M^{2+}]_{sol.})}{\partial (-\log a_{Na_2O})} \right\} \quad [30]$$

But according to the previous Eq. [9] and [10], the latter derivative equals unity, so that

$$\left\{ \frac{\partial (\log [Al^{3+}]_{sol.})}{\partial (-\log a_{Na_2O})} \right\}_{O_2} = \frac{1}{2} \left\{ \frac{\partial (\log a_{Al_2(SO_4)_3})}{\partial (-\log a_{Na_2O})} \right\}_{O_2} = \frac{3}{2} \quad [31]$$

Region VI.—In this very acid regime, the $MAlO_2$ spinel is stable and present as a condensed phase, but NiO or Co_3O_4 are no longer present at unit activity, because $NiSO_4$ or $CoSO_4$ are stable. Then the solubility of the Al^{3+} species is independent of the dissolution of NiO and Co_3O_4 as $NiSO_4$ and $CoSO_4$, respectively. The MAl_2O_4 dissolution is again described by reaction [29], but the dependence of soluble Al concentration upon a_{Na_2O} is given by the rollowing equation

$$\left\{ \frac{\partial (\log [Al^{3+}]_{sol.})}{\partial (-\log a_{Na_2O})} \right\}_{O_2} = \frac{1}{2} \left\{ \frac{\partial (\log a_{Al_2(SO_4)_3})}{\partial (-\log a_{Na_2O})} \right\}_{O_2} = 2 \quad [32]$$

Region VII.—In this extremely acid regime, the spinels are not stable but alumina is the stable condensed phase. Alumina dissolves as the acid species Al^{3+} in a melt consisting of Na_2SO_4 and MSO_4

$$Al_2O_3(s) + 6Na^+ = 2Al^{3+} + 3Na_2O \quad [33]$$

The dependence of the acid ion solubility on a_{Na_2O} is given by

$$\left\{ \frac{\partial (\log [Al^{3+}]_{sol.})}{\partial (-\log a_{Na_2O})} \right\}_{O_2} = \frac{1}{2} \left\{ \frac{\partial (\log a_{Al_2(SO_4)_3})}{\partial (-\log a_{Na_2O})} \right\}_{O_2} = \frac{3}{2} \quad [34]$$

Region VIII.—In this most acid regime, the stable condensed phases are the sulfates of Al and Ni or Co. In this regime of total liquid miscibility, no dependence of soluble aluminum concentration on the a_{Na_2O} would occur.

These different regimes are summarized for the Ni-Al-Na-S-O system in Fig. 9. The comparable boundaries for $NiAl_2O_4$ and $CoAl_2O_4$ differ only by about one order of magnitude ($CoAl_2O_4$ extending towards the more basic side). Obviously, a similar plot can be offered for the Co-Al-Na-S-O system. The theoretically predicted basicity dependences for the aluminum solute species are summarized in Fig. 10.

Because of practical experimental limitations (attack of the emf probes), the solubility measurements in very acid (right of region V) or very basic (left of

	Condensed Phases	Solute Species
I	$NaNiO_2$, $NaAlO_2$	NiO_2^-, AlO_2^-
II	NiO, $NaAlO_2$	NiO_2^-, AlO_2^-
III	NiO, $NiAl_2O_4$	NiO_2^-, AlO_2^-
IV	NiO, $NiAl_2O_4$	Ni^{2+}, AlO_2^-

region III) melts may not be possible. The steep rise in the experimentally measured aluminum contents in acid melts of Fig. 6 is not inconsistent with the slope of 3/2 expected for the regime V, but only little displacement is apparent in the data from the Co- and Ni-containing solutions. The existence of the broad plateau (Al solute concentration independent of a_{Na_2O}) in the Co_3O_4-saturated solutions of Fig. 6 seems to correlate with behavior expected for regime IV, except that the plateau extends too far in the basic direction. The data from NiO-saturated melts of Fig. 6 seem to lack the expected plateau for regime IV, and the existing plateau for $-\log a_{Na_2O} < 11$ occurs in a melt insufficiently basic to correspond to regime II. Further, the difference by two orders of magnitude in the plateaus of Fig. 6 for the NiO- and the Co_3O_4-saturated solutions is also not explainable. Then in general, the data of Fig. 6 do not fit the expected pattern of Fig. 10 for the solubility of aluminum in a system where ternary oxides are stable. But on the other hand, the observed pattern is also not consistent with that expected for a simple Al_2O_3 solubility, which should resemble Fig. 4 and 5 (but with different slopes) if only one acid and one basic species of aluminum were formed.

These seeming inconsistencies are explained by realizing that the experiments from which aluminum was analyzed were not designed or optimized to establish the spinel solubilities. Powdered Al_2O_3 or MAl_2O_4 were not available to the melt, and care was not taken to insure that equilibrium was reached with respect to saturation by the aluminum solute species. Then the data of Fig. 6 should not be considered as reliable equilibrium data, but rather they only suggest that inherently different results should be expected when a ternary oxide is present. The theory summarized in Fig. 9 and 10 is offered for comparison with future experiments which can be designed to establish the solubilities of ternary oxides.

Obviously, the theory should directly predict the solubilities of other ternary oxides in other oxyanion melts (nitrates, carbonates, borates, vanadates, silicates, etc.) The several assumptions made in this theory should be explained so that the theory can be extended or amended for other systems. The solute species for Ni, Co, and Al are assumed to be the same as those for the respective binary oxides. Thus, this treatment assumes that there are no Ni-Al-O or Co-Al-O soluble complex ions, *e.g.*, $NiAlO_4^{2-}$ or $NiAlO_2^+$. Clearly, interactive soluble species may be possible in some systems. In principle, complex ionic species could be identified by the basicity and oxygen activity dependences of the solubilities.

Summary and Conclusions

The solubilities of NiO and Co_3O_4 in Na_2SO_4 in 1 atm O_2 at 1200°K, have been experimentally determined as a function of salt basicity ($\log a_{Na_2O}$).

Nickel oxide, which dissolves as nickel sulfate in acidic salts and as sodium nickelate (NiO_2^-) in basic salts, shows a well-defined minimum in solubility at $-\log a_{Na_2O} = 10.3$. The identification of these species is inferred upon comparing the dependence of NiO solubility upon the basicity ($\log a_{Na_2O}$) of Na_2SO_4 melts with models derived from the thermodynamic stability plot. The activity coefficients for nickel sulfate and sodium nickelate dilute solutions were established as 0.12 and 50, respectively, but a large uncertainty is inherent in the calculations.

The solubility of cobalt oxide, Co_3O_4, is very similar in behavior to that of nickel oxide. Cobalt oxide is a slightly more basic oxide, and shows a minimum in the solubility plot at $-\log a_{Na_2O} = 9.2$. The Co_3O_4 dissolves as $CoSO_4$ (Co^{2+}) in acid dissolution and, as $NaCoO_2$ (CoO_2^-) in basic dissolution in Na_2SO_4 at 1200°K. The activity coefficient of 2.5 was established for a dilute solution of $CoSO_4$ in Na_2SO_4.

The knowledge of the solubilities of NiO and Co_3O_4 should assist in understanding the occurrence of fluxing of protective oxides encountered during the hot corrosion of metals.

The Na_2SO_4 melts saturated with NiO and Co_3O_4 were also analyzed for soluble aluminum content, although the studies were not designed to establish the alumina or spinel solubility. The resulting data for soluble aluminum concentrations deviated from that expected for a simple binary oxide, and an influence of $NiAl_2O_4$ or $CoAl_2O_4$ formation was suspected. A novel theory was developed to interpret (predict) the solubility of a ternary oxide in Na_2SO_4. The correlation of the theory to the measurement of soluble aluminum was not satisfactory, but an improved experiment would be expected to yield better results.

Mechanism of Na_2SO_4 Induced Corrosion at 600°-900°C

K. L. Luthra* and D. A. Shores*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The kinetics of Na_2SO_4-induced corrosion were measured by accelerated oxidation tests on Co-30Cr and Ni-30Cr as a function of temperature from 600°-900°C, SO_3 in the environment and deposit composition. The alloys were rapidly attacked at temperatures between 650° and 750°C when a liquid sulfate phase was obtained from an initially pure solid Na_2SO_4 deposit. The rapid rate of attack resulted from sulfation of the transient surface nickel or cobalt oxides and the dissolution of these transition metal sulfates into Na_2SO_4 to yield a liquid phase. This retarded the formation of a protective Cr_2O_3 scale. The exposure conditions under which liquids could form from Na_2SO_4-$CoSO_4$ mixtures were calculated from thermodynamic considerations.

Many fossil-fueled devices for energy conversion are susceptible to rapid degradation of high temperature alloy components when subjected to molten salt deposits. Because of the nearly universal presence of sulfur and alkali metals in fossil fuels, the corrosive deposits usually contain alkali sulfates (Na_2SO_4, K_2SO_4). The mechanism of Na_2SO_4-induced corrosion at high temperatures, where Na_2SO_4 (mp = 884°C) is liquid, has been extensively studied. This form of attack, commonly known as hot corrosion, results in typical sulfidation with an aluminum and/or chromium depletion zone in the alloy.

Recently, a different, but related, form of hot corrosion has been identified in marine propulsion gas turbines under service conditions where the surface temperatures of the first stage blades and vanes were in the range of about 650°-700°C (1). The attack on Co-base coatings resulted in an unusual morphology: pitting, little or no depletion of Al or Cr in the alloy, and corrosion products which contained water soluble Co and Ni. Burner rig tests and other studies have been able to reproduce these characteristic features of intermediate temperature attack only when Na_2SO_4-containing deposits are used in conjunction with sufficient SO_3 in an oxidizing environment (2, 3).

Only a few investigators have studied the mechanism of alkali sulfate induced corrosion at intermediate temperatures (600°-884°C) (4-6). Umland and Voigt (4) investigated the formation of soluble Ni, Co, and chromate ions in crucible-type corrosion tests. Several nickel-, cobalt-, and iron-base alloys were exposed to melts containing Na_2SO_4, K_2SO_4, or mixtures thereof in air or in air containing SO_3 over the temperature range 650°-900°C. They found a maximum in corrosion rate at 750°C which coincided with the highest recovery of Ni and Co sulfates from the melt. This study was subsequently extended by Balajka and Danek (5), who observed enhanced corrosion of Ni in alkali sulfate melts containing $CoSO_4$ at intermediate temperatures. They interpreted their results in terms of Umland and Voigt's suggestion that cobalt in the 2+ and 3+ valence states formed complex ions in sulfate melts. These ions were proposed as the basis of a redox system which enhanced the transport of oxidant through the melt. Recently, Jones and Gadomski (6) studied the behavior of four Co- or Ni-base alloys in corrosion tests at 538°-871°C with deposits of various eutectic composition sulfate mixtures. Those deposits which melted and liberated corrosive gas (probably SO_3), owing to the decomposition of the transition metal sulfate, produced rapid rates of attack. These included mixtures of Na_2SO_4 with the sulfates of Fe, Ni, Co, and Cu.

The present paper is concerned with the mechanism of Na_2SO_4-induced corrosion at intermediate temperatures. Corrosion studies have been conducted on the model alloys Co-30Cr and Ni-30Cr as a function of P_{SO_3} in oxidizing environments from 600°-900°C. The observed corrosion behavior has been correlated with the formation and stabilities of Na_2SO_4-$CoSO_4$ and Na_2SO_4-$NiSO_4$ liquids.

Experimental Procedure

The kinetics and mechanism of salt-induced attack at intermediate temperatures were studied by the accelerated oxidation test. In this test the alloy specimen was preliminarily coated with a thin film of salt and then exposed at the desired temperature in a slowly flowing, controlled gaseous environment. The kinetics of reaction were monitored by measuring weight changes as a function of time. The corrosion tests were carried out on two binary alloys, Ni-30Cr and Co-30Cr.[1] Specimens of Co-30Cr were machined from small, chill cast ingots, while those of Ni-30Cr were obtained from rolled sheets 1 mm thick. Materials used for the preparation of Ni-30Cr and Co-30Cr were 99.9% pure.

The alloy specimens (6.3 × 12.5 × 1 mm) were polished through 600 grit SiC abrasive paper and were degreased with alcohol and acetone. The salt deposit was applied to a warm (~150°C) specimen by spraying an aqueous solution of the desired salt with an

* Electrochemical Society Active Member.

Key words: kinetics, oxidation, corrosion, alloy, cobalt.

[1] Alloy compositions are listed as weight percent while the gas and salt compositions have been given as mole percent.

air brush. In most tests 2.5 ± 0.2 mg/cm^2 of salt was used. To start a test, specimens were brought to temperature in less than 10 min in the desired gas environment. Weight changes during the test were recorded with a Cahn microbalance with a precision of ±0.01 mg. This was done at an interval of about 1 min during the first 10-15 min of test. The interval between the observations was increased as the reaction progressed, and the weight was monitored every 15-30 min after 3-4 hr. At the end of the experiments, which continued for 24-72 hr, specimens were cooled to room temperature in less than 10 min in the same environment in which the experiments were conducted.

After the corrosion tests, selected samples were rinsed with hot water for subsequent analysis of water soluble elements (Na, Ni, Co, Cr) in the corrosion products. These elements were determined by atomic absorption with an uncertainty of ±5 μg. On some specimens metallography, x-ray diffraction and electron microprobe analysis were used to characterize the reaction products.

Various O_2-SO_2 gas mixtures containing from 30 ppm to 10% SO_2 have been employed. Gas mixtures (analyzed grade) were prepared by Union Carbide Corporation (Linde Division) from gases of the following purity: oxygen 99.6% and anhydrous sulfur dioxide 99.9%. Many of the experiments were carried out in O_2-0.15%(SO_2 + SO_3). This mixture simulates the partial pressure of (SO_2 + SO_3) in combustion gases at 10 atm, such as would be derived from a fuel ($CH_{1.7}$) containing 1 weight percent (w/o) sulfur using an air/fuel ratio (by weight) of 60. The gases were passed over a platinum catalyst at the test temperature to ensure that the equilibrium partial pressure of SO_3 was attained. At temperatures from 600° to about 750°C a platinized ceramic honeycomb catalyst was used, but this was replaced with several layers of platinum gauze for higher temperatures up to 900°C. In earlier experiments, the corrosion rates of IN-738 sprayed with Na_2SO_4 were observed to be erratic when the platinum catalyst was not used, and these rates were about 2-10 times lower than the rates obtained in equilibrated O_2-SO_2-SO_3 mixtures (7).

Results

A series of accelerated oxidation tests has been carried out on Co-30Cr and Ni-30Cr under a variety of exposure conditions in which the principal variables were temperature, concentration of SO_3 in the gas phase, and initial composition of the salt deposit. In many cases interactions involving the oxide scale, SO_3, and the salt led to substantial changes in the composition of the deposit. Because of the salt-gas-oxide interactions, the rate of attack under corrosive conditions was studied as a function of the amount of the salt deposit. Figure 1 shows for Co-30Cr that increasing the salt deposit from 2.5 to 5.7 mg/cm^2 of Na_2SO_4 yielded a substantially higher rate of attack after an initial period of 2-4 hr. Consequently, to establish a common basis for comparison, subsequent kinetic studies were carried out with 2.5 mg/cm^2 of Na_2SO_4 or in two special tests with mixtures of sulfates which contained 2.5 mg/cm^2 of Na_2SO_4.

The effect of temperature on the rate of attack of Co-30Cr coupons has been studied over the range of 600°-900°C in O_2-0.15%(SO_2 + SO_3) with an initial salt deposit of 2.5 mg/cm^2 of Na_2SO_4. Plots of weight gain as a function of time are shown in Fig. 2. The results were reproducible with an uncertainty of about ±15%. As may be seen, the rate of attack varied with temperature, with the fastest rate occurring at an intermediate temperature. Since the corrosion rate also changed with time, two different criteria were chosen as a basis for comparing the behavior as a function of temperature: (*i*) the initial corrosion rate averaged over the first 4 hr, and (*ii*) the corrosion rate averaged over 24 hr. The average

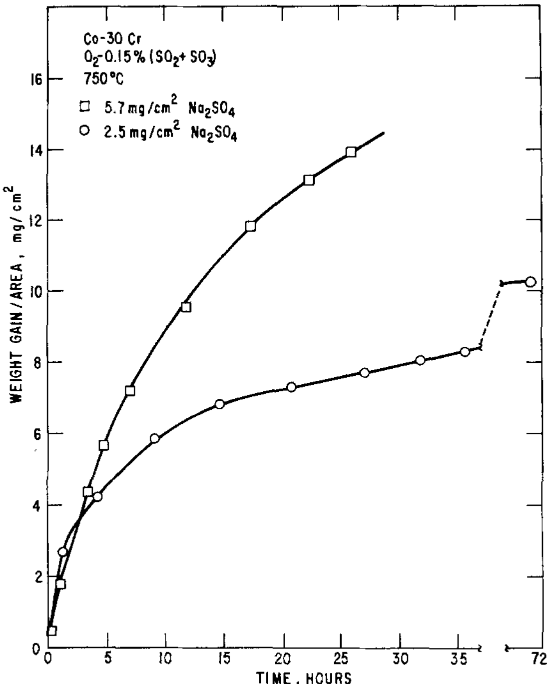

Fig. 1. Effect of the amount of salt on the Na_2SO_4 induced corrosion of Co-30Cr at 750°C in O_2-0.15% (SO_2 + SO_3).

corrosion rate was obtained by dividing weight gain/area over that period by time. By both criteria the corrosion rate is fastest at temperatures around 650°-700°C, as shown in Fig. 3. An identical series of tests was conducted with the Ni-30Cr specimens in O_2-1%(SO_2 + SO_3). The uncertainty in the initial corrosion rates averaged over the first 4 hr of reaction time was very high (up to about ±25%). Therefore, only the corrosion rates averaged over 24 hr are shown in Fig. 4, which is a plot of the rate of attack *vs.* temperature. The corrosion rate is highest at about 650°-750°C.

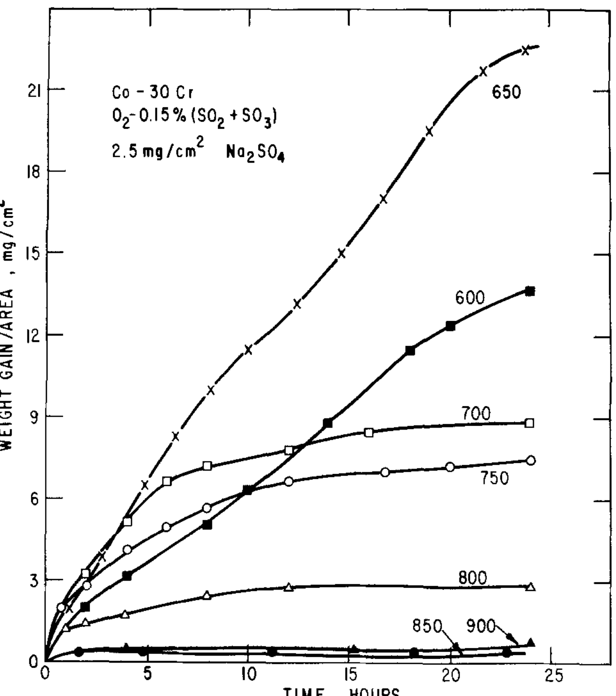

Fig. 2. Effect of temperature on the variation of weight gain/area with time for the corrosion of Co-30Cr, coated with 2.5 mg/cm^2 of Na_2SO_4, in O_2-0.15% (SO_2 + SO_3).

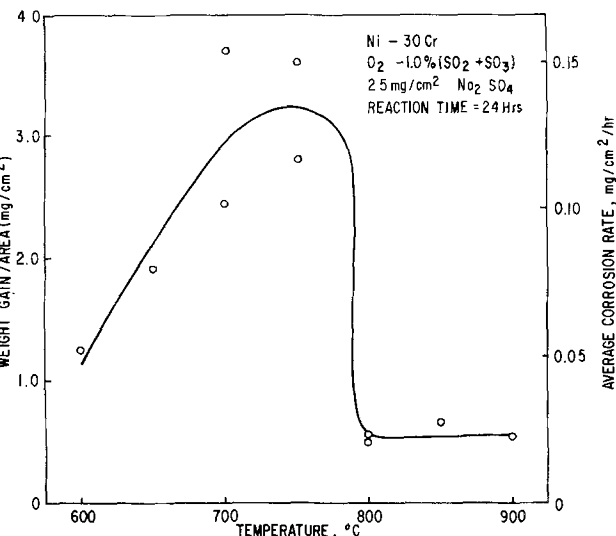

Fig. 4. Effect of temperature on the corrosion rate of Ni-30Cr, coated with 2.5 mg/cm^2 of Na_2SO_4, in O_2-1% (SO_2 + SO_3).

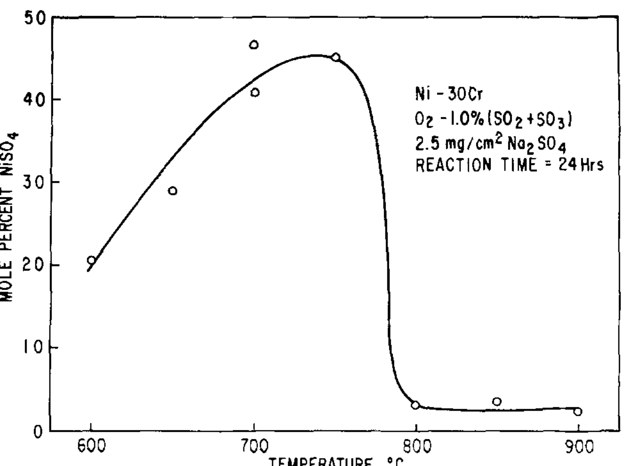

Fig. 6. Effect of temperature on the ratio of soluble corrosion products Ni/(Ni + Na_2) on Ni-30Cr samples, coated with 2.5 mg/cm^2 of Na_2SO_4, in O_2-1% (SO_2 + SO_3). (Reaction time = 24 hr.)

After the corrosion tests, selected specimens were rinsed in hot distilled water, and the solutions were analyzed for Na, Co, Ni, and Cr. The concentration of Cr was observed to be very small (<5 $\mu g/cm^2$ of sample surface). The water soluble nickel and cobalt were present as $NiSO_4$ and $CoSO_4$ in the corrosion products, as confirmed by x-ray diffraction. The results of the analysis for Co and Na in the salt deposits on the Co-30Cr specimens from the corrosion tests described in Fig. 2 are presented in Fig. 5. The ratio Co/(Co + Na_2) represents the degree to which the initially pure Na_2SO_4 deposit had become contaminated with $CoSO_4$. This ratio reaches a maximum at about 650°C. A similar analysis of the deposits on the Ni-30Cr specimens is summarized in Fig. 6. The cation ratio [Ni/(Ni + Na_2)] for these tests was highest at around 700°-750°C. In general, for both alloys rapid attack occurred in the temperature range where the deposit acquired substantial concentrations of transition metal sulfates.

The accelerated oxidation tests were also conducted as a function of gas and salt composition. In Fig. 7 is shown the effect of (P_{SO_2} + P_{SO_3}) for $P_{O_2} \cong 1$ atm on the kinetics of attack of Co-30Cr with an Na_2SO_4 deposit. A very low corrosion rate was obtained in O_2 containing 30 ppm (SO_2 + SO_3), and it was found after the test that the salt had not melted. Under all other conditions, the salt had melted. Also, the corrosion rates increased with P_{SO_3} except for the rate in O_2-10% (SO_2 + SO_3), which was lower than in gas mixtures containing 1% or 2% (SO_2 + SO_3). Since the formation of a liquid phase at 750°C resulted from the formation of $CoSO_4$ (as will be discussed later), experiments were carried out in which the initial deposit was a mixture of sodium and cobalt sulfates. The results of these experiments are shown in Fig. 8. Although the salt was liquid in the case of Na_2SO_4-50% $CoSO_4$ from the beginning of the experiment, the extent of corrosion was much lower than that with pure Na_2SO_4. As discussed before, the corrosion rate tends to increase with an increase in salt amount (Fig. 1). To ensure that the above decrease in corrosion rate was not due to a decrease in the amount of Na_2SO_4, experiments were also carried out using salts which contained 2.5 mg/cm^2 of Na_2SO_4 instead of 2.5 mg/cm^2 of the total salt. Even under these conditions, the extent of corrosion was observed to be low for Na_2SO_4-60% $CoSO_4$. It should be noted that after a few hours, the rate

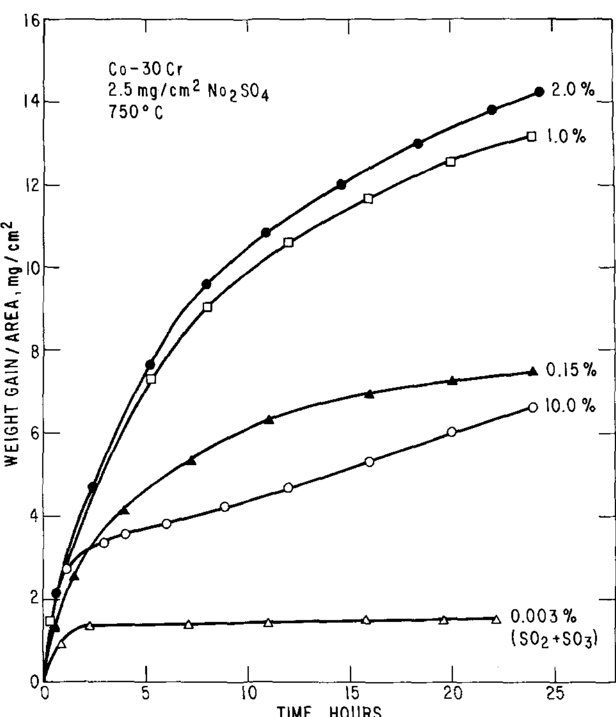

Fig. 7. Effect of (SO_2 + SO_3) on the corrosion of Co-30Cr at 750°C.

of attack with Na_2SO_4 was about the same as that with Na_2SO_4-$CoSO_4$ mixtures. The soluble salt analysis of the Co-30Cr sample reacted in Na_2SO_4 and Na_2SO_4-$CoSO_4$ mixtures showed that the melts reached a steady-state composition of Na_2SO_4-61 ± 8% $CoSO_4$.

A similar series of experiments was carried out with Ni-30Cr, and the results, shown in Fig. 9, were similar to those observed for Co-30Cr. The salt had melted on all the specimens except for the one exposed in

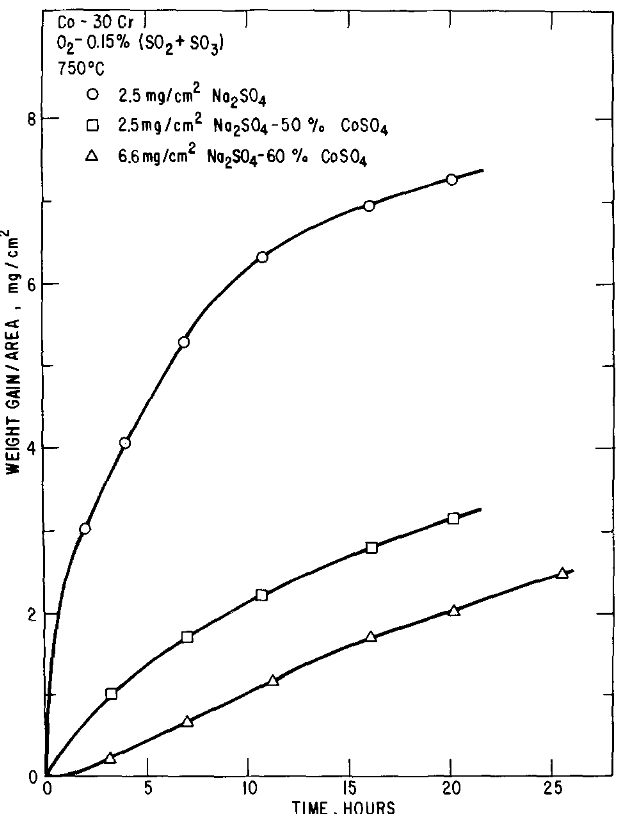

Fig. 8. Effect of salt composition on the corrosion of Co-30Cr at 750°C in O_2-0.15% (SO_2 + SO_3).

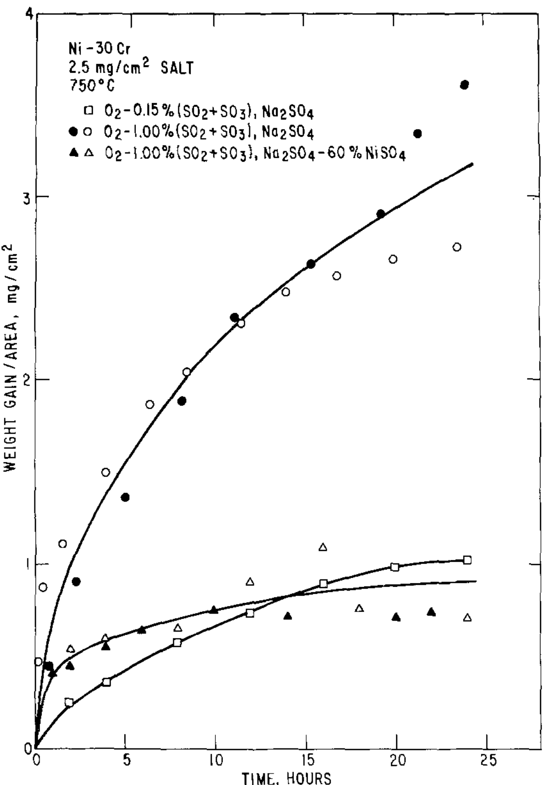

Fig. 9. Effect of salt composition and gas composition on the corrosion of Ni-30Cr at 750°C.

O_2-0.15% (SO_2 + SO_3). The reaction rates increased with the (SO_2 + SO_3) content of the gas. Also, the extent of corrosion as measured by weight change on specimens coated with Na_2SO_4-60% $NiSO_4$ was lower than that with pure Na_2SO_4.

Metallographic examination of the corroded specimens of Ni-30Cr and Co-30Cr showed sharp differences in the morphology of the reaction product. Corrosion occurred uniformly on the specimens of Ni-30Cr. However, the Co-30Cr specimens, exposed in an environment where a liquid phase could form on the surface, typically revealed pronounced nonuniform attack at intermediate temperatures. Usually, the attack was highly localized in the form of pits. To avoid dissolving and losing the water soluble sulfates of sodium and cobalt during metallographic preparation, the samples were polished using kerosene. The morphology of the pitting attack on a Co-30Cr sample in O_2-0.15% (SO_2 + SO_3) is shown in Fig. 10. X-ray images for chromium and cobalt obtained by an energy dispersive analyzer on an SEM showed that chromium was concentrated in the area below the initial interface while cobalt was concentrated in the external areas. The white phase visible near the gas surface was identified as Co_3O_4. At the higher levels of P_{SO_3} in the gas, where Co_3O_4 was unstable [for example, in O_2-2% (SO_2 + SO_3) at 750°C], pitting was still observed, but the outer section of the corrosion product consisted of $CoSO_4$ deposits instead of Co_3O_4.

Microprobe analysis of the internal regions of the pits (below the original salt/metal interface) showed the presence of sodium, chromium, cobalt, and sulfur, suggesting that the liquid Na_2SO_4-$CoSO_4$ had penetrated into the pit. Figure 11 shows a photomicrograph of the internal region of a pit on Co-30Cr under polarized light. Alternate bands, presumably of areas rich in Cr_2O_3 (bright) and the liquid $CoSO_4$-Na_2SO_4 (dark), can be clearly seen. That the liquid phase does indeed penetrate the pit was also confirmed by another test. One of the samples of Co-30Cr corroded in O_2-0.15% (SO_2 + SO_3) was water washed and

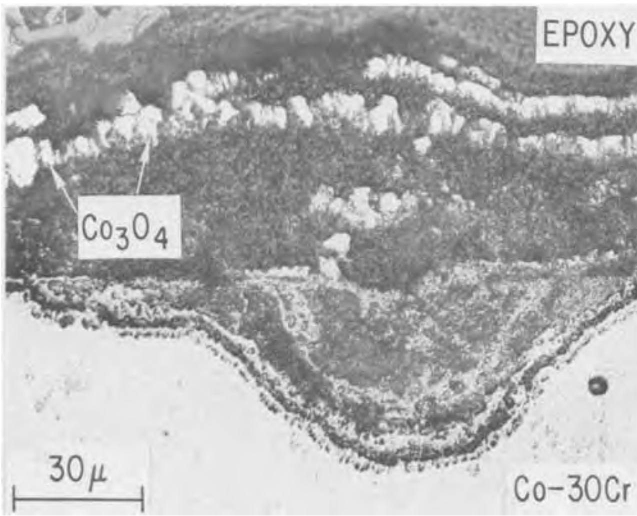

Fig. 10. Optical micrograph of a cross section of the corrosion product on Co-30Cr sprayed with 2.5 mg/cm^2 of Na_2SO_4 and reacted for 10.5 hr in O_2-0.15% (SO_2 + SO_3) at 750°C. The penetration of the alloy occurs irregularly, normally in the form of pits. The large white particles near the gas interface are Co_3O_4 in an Na_2SO_4-$CoSO_4$ liquid. 550×.

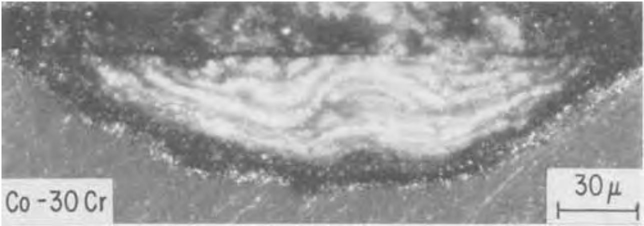

Fig. 11. Optical micrograph (under polarized reflected light) of a cross section of the internal region of a pit formed on Co-30Cr sprayed with 2.5 mg/cm^2 of Na_2SO_4 and reacted in O_2-0.15% (SO_2 + SO_3) at 750°C. The bands seen in the pit are presumably the areas rich in Cr_2O_3 (white bands) and Na_2SO_4-$CoSO_4$ liquid (dark bands). 350×.

a thick copper layer (~1 mm) was electroplated from a copper sulfate solution. Due to the high solubility of Na_2SO_4 and $CoSO_4$ in water, any salt present in the pits will be dissolved leaving pores to be filled with Cu. X-ray dispersive analysis of a cross-sectional area of a pit showed primarily Cu, Cr, and O; copper was observed to be rich in thin bands similar to the dark areas in Fig. 11.

Discussion

Thermodynamic considerations.—Pure sodium sulfate is not molten at the intermediate temperatures (650°-750°C) where high corrosion rates have been observed in our experiments. However, the phase diagrams for Na_2SO_4-$CoSO_4$ and Na_2SO_4-$NiSO_4$ show eutectics that melt at 565°C for Na_2SO_4-50% $CoSO_4$ and 671°C for Na_2SO_4-38% $NiSO_4$ (8). Since a liquid phase is regarded as necessary for high corrosion rates, it is of interest to determine the conditions under which these eutectics can form on the alloy specimens containing nickel and/or cobalt.

The formation of $NiSO_4$ or $CoSO_4$ from their respective oxides can be expressed by

$$NiO(s) + SO_3(g) = \underline{NiSO_4}(s, l) \quad [1]$$

$$CoO(s) + SO_3(g) = \underline{CoSO_4}(s, l) \quad [2]$$

$$1/3\ Co_3O_4(s) + SO_3(g) = \underline{CoSO_4}(s, l) + 1/6\ O_2(g) \quad [3]$$

where the underline implies that the sulfate is present in solution at an activity less than one.

Solid Na_2SO_4 can dissolve $NiSO_4$ and/or $CoSO_4$ to a considerable extent (8). Figure 12 shows the Na_2SO_4-$CoSO_4$ phase diagram with a schematic representation of the isoactivity lines for SO_3 in equilibrium with Co_3O_4 and the Na_2SO_4-$CoSO_4$ liquid and/or solid. Liquid formation from an initially solid Na_2SO_4 will occur when the activity of $CoSO_4$ in Na_2SO_4-$CoSO_4$ solid solution becomes equal to or greater than that corresponding to the liquidus line. The activity of $CoSO_4$ and the P_{SO_3} in equilibrium with oxide are constant across the two phase (solid and liquid) region. Similar considerations apply to the Na_2SO_4-$NiSO_4$ system.

The minimum P_{SO_3} required to form an Na_2SO_4-$CoSO_4$ liquid in equilibrium with Co_3O_4 has been estimated for temperatures between 650° and 900°C. The standard Gibbs energy data for $SO_2(g)$, $SO_3(g)$, $CoO(s)$, and $Co_3O_4(s)$ were obtained from the JANAF Tables and supplements (9). At P_{O_2} = 1 atm, Co_3O_4 is more stable than CoO at temperatures below 947°C. Thus, the P_{SO_3} required to form an Na_2SO_4-$CoSO_4$ liquid can be obtained from the free energy data for reaction [3], taking the activity of Co_3O_4 as unity. The results are presented in Fig. 13 as curve A, which shows the estimated values of P_{SO_3} as a function of temperature for $P_{O_2} \cong 1$ atm. The mole fraction of $CoSO_4(s)$ needed to form the liquid was obtained from the phase diagram shown in Fig. 12. The activity coefficient of $CoSO_4(s)$ in Na_2SO_4-$CoSO_4$ solid solution was estimated from the phase diagram and the available thermodynamic properties of Na_2SO_4. The procedure used for estimating $\gamma_{CoSO_4(s)}$ is given in the Appendix. Also included in the Appendix are the results of experiments used to confirm curve A.

At any temperature, an increase in P_{SO_3} above that given by curve A will increase the activity of $CoSO_4$ in Na_2SO_4-$CoSO_4$ liquid in contact with Co_3O_4. The composition of the stable liquid phase will change progressively from that corresponding to the liquidus line at the Na_2SO_4 end of the phase diagram to that at the $CoSO_4$ end. Figure 12 shows that solid $CoSO_4$ does not dissolve any appreciable amount of Na_2SO_4. The activity of $CoSO_4(s)$ at the liquidus line on the $CoSO_4$ end should therefore be one. Curve B in Fig. 13 shows as a function of temperature the P_{SO_3} needed to form solid $CoSO_4$. Thus, the equilibrium values of P_{SO_3} in contact with Co_3O_4 and Na_2SO_4-$CoSO_4$ liquids corresponding to the two liquidus lines in Fig. 12 can be obtained from curves A and B in Fig. 13. At P_{SO_3} values higher than curve B Co_3O_4 is unstable, and the deposit should consist of $CoSO_4(s)$ and a

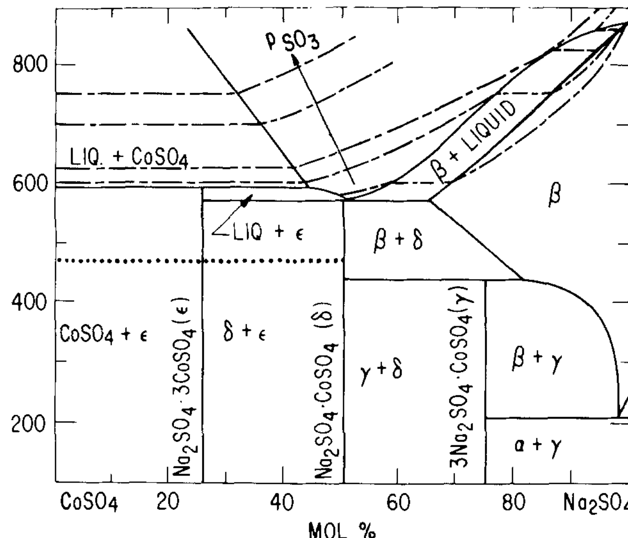

Fig. 12. Na_2SO_4-$CoSO_4$ phase diagram with a schematic representation of the isoactivity lines for SO_3 in equilibrium with Co_3O_4 (8).

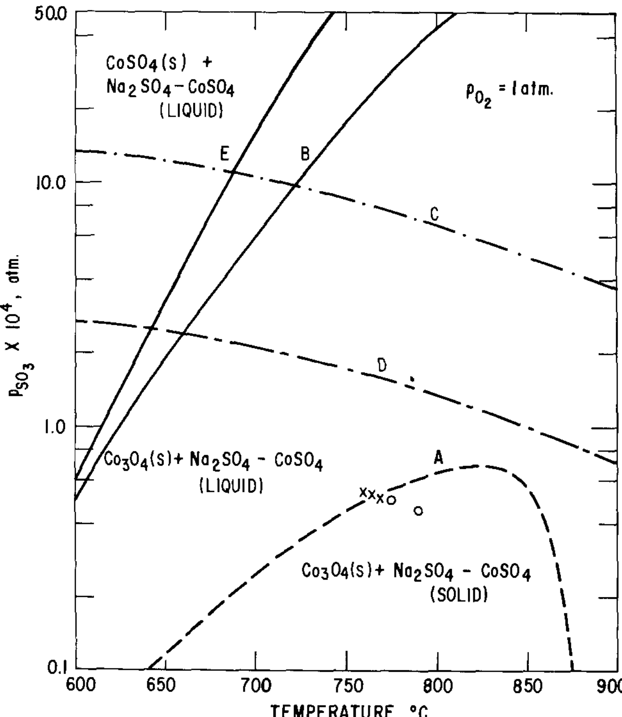

Fig. 13. Stability diagram for the Co_3O_4-$CoSO_4$-Na_2SO_4 system. A liquid phase is stable at P_{SO_3} values above curve A which shows the estimated values of P_{SO_3} in equilibrium with Co_3O_4 solid, an Na_2SO_4-$CoSO_4$ solid and an Na_2SO_4-$CoSO_4$ liquid. Curve B shows the P_{SO_3} in equilibrium with Co_3O_4, $CoSO_4$(s) and liquid Na_2SO_4-$CoSO_4$. Curves C and D show the SO_3 content of O_2-0.15% (SO_2 + SO_3) and O_2-0.03% (SO_2 + SO_3) gas mixtures. For comparison with curve B for the Co_3O_4-$CoSO_4$ system, curve E shows the P_{SO_3} above which $NiSO_4$(s) is more stable than NiO(s). The symbols × (for liquid formation) and ○ (for no liquid formation) refer to experiments on Co_3O_4 to verify curve A.

liquid whose composition corresponds to the liquidus line on the $CoSO_4$ end of the phase diagram. The relative proportions of solid and liquid phases will be determined by the concentrations of Na_2SO_4 in the deposit.

Curves C and D in Fig. 13 show the equilibrium P_{SO_3} as a function of temperature for O_2-0.15% (SO_2 + SO_3) and O_2-0.03% (SO_2 + SO_3) gas mixtures, respectively. It can be seen that a far higher P_{SO_3} is available in these mixtures than is needed to stabilize liquid $CoSO_4$-Na_2SO_4 mixtures over the temperature range 600°-850°C. Thus, on alloys and coatings whose oxidation products contain cobalt oxide, a liquid phase may be expected to form during the accelerated oxidation test at temperatures well below the melting point of Na_2SO_4.

Reaction [3] shows that the activity of $CoSO_4$ in equilibrium with Co_3O_4 is inversely proportional to $P_{O_2}{}^{1/6}$. Thus, the P_{SO_3} needed to stabilize an Na_2SO_4-$CoSO_4$ liquid should decrease with a decrease in P_{O_2}. At low P_{O_2} values, where CoO is more stable than Co_3O_4, P_{SO_3} values needed to stabilize Na_2SO_4-$CoSO_4$ liquids can be obtained from the free energy data for reaction [2]. For example, at 750°C, for $P_{O_2} \leq 5 \times 10^{-4}$ atm a liquid phase can form if $P_{SO_3} \geqq 1.5 \times 10^{-5}$ atm. These P_{SO_3} values will be independent of P_{O_2}. Similarly, the P_{SO_3} needed to form solid $CoSO_4$ (curve B in Fig. 13) will decrease with P_{O_2}.

Similar calculations can be carried out for the $NiSO_4$-Na_2SO_4 system using the free energy data for reaction [1] from Ingraham (10). Curve E in Fig. 13 shows the equilibrium P_{SO_3} in contact with NiO and $NiSO_4$ at unit activities. Clearly, the P_{SO_3} needed to form solid $NiSO_4$ from NiO is higher than that needed to form solid $CoSO_4$ from Co_3O_4. Similarly, higher SO_3 levels are needed to stabilize an Na_2SO_4-$NiSO_4$ liquid than that needed to stabilize an Na_2SO_4-$CoSO_4$ liquid (curve A). Experiments described in the Appendix showed that the SO_3 level needed to form an Na_2SO_4-$NiSO_4$ liquid on NiO was $\sim 5 \times 10^{-4}$ atm at 750°C, which is about 10 times higher than the SO_3 level needed to form an Na_2SO_4-$CoSO_4$ liquid on Co_3O_4 at 750°C.

It should be noted that $CoSO_4$ and $NiSO_4$ have appreciable solid solubility in Na_2SO_4 (8, 11). Therefore, water soluble cobalt and nickel may be detected in the Na_2SO_4 deposits even for P_{SO_3} levels where a liquid phase is not obtained.

Reaction mechanism.—According to the current concepts of high temperature oxidation, when a resistant alloy is heated in an oxidizing environment, the surface will be oxidized through a series of stages (referred to as transient oxidation) before achieving a final, steady-state scale composition (12-14). Consider the oxidation of a cobalt-base alloy containing Cr. The rapid uptake of oxygen at the beginning of oxidation will be accompanied by the formation of nuclei of cobalt oxide and Cr_2O_3 on the surface. It is well known that the diffusion of cobalt through cobalt oxide is much faster than that of Cr through Cr_2O_3. Therefore, cobalt oxide will soon cover the nuclei of Cr_2O_3. Since Cr_2O_3 is more stable than cobalt oxide, alloys containing a sufficiently high concentration of Cr will eventually develop a continuous film of Cr_2O_3 underneath the cobalt oxide at the alloy/scale interface, and the oxidation rate will be reduced. At low or intermediate temperatures, the diffusion rates of Co and Cr in the alloy and oxides will be low, and the transient oxidation processes may persist for long times before a steady-state continuous scale of Cr_2O_3 is achieved. Oxidation of a nickel-base alloy containing chromium will occur in a similar fashion.

The presence of a porous, solid Na_2SO_4 deposit at the exposure temperature is unlikely to affect oxidation processes. During transient oxidation NiO or Co_3O_4 will come in contact with the deposit. With SO_3 present in the gas phase $NiSO_4$ and $CoSO_4$ will form via reactions [1] and [3]. If the partial pressure of SO_3 in the gas is lower than that necessary to form a liquid phase, the corrosion reaction will slow down in a short time owing to the formation of a protective film of Cr_2O_3. At higher P_{SO_3}, however, a liquid phase may form. Under these conditions it is proposed that high corrosion rates are obtained as a result of the rapid dissolution of cobalt oxide or nickel oxide which prevents the formation of a protective Cr_2O_3 film. This may occur by undercutting and isolating particles of Cr_2O_3 before the film can become continuous, but the details of this process have not been established.

To help substantiate the role of transient oxidation processes three means of altering the initial kinetics were explored under conditions where liquid sulfate deposits were stable. The first test consisted of carrying out corrosion experiments with Na_2SO_4-$CoSO_4$ and Na_2SO_4-$NiSO_4$ mixtures to reduce or eliminate the driving force for sulfation of Co_3O_4 and NiO. This was expected to decrease the high initial rates of attack observed with Na_2SO_4. In Fig. 8 the kinetics of attack of Co-30Cr in O_2-0.15% (SO_2 + SO_3) with pure Na_2SO_4 are compared with those for Na_2SO_4 containing 50 and 60 mole percent (m/o) $CoSO_4$. Clearly, the initial rate of attack is reduced with the mixed sulfate deposits. Similarly, the Ni-30Cr alloy shows a lower rate of attack with an Na_2SO_4-60% $NiSO_4$ deposit than with an Na_2SO_4 deposit (Fig. 9).

As a second means of altering the corrosion rate, a Co-30Cr sample was oxidized at 925°C in an H_2/H_2O environment ($P_{O_2} \approx 10^{-19}$ atm) to establish a protective, steady-state scale of Cr_2O_3 with little or no cobalt and cobalt oxide on the surface. The sample was slowly cooled to room temperature in

1 hr and coated with Na_2SO_4. The results of the accelerated oxidation test at 750°C in O_2-0.15% (SO_2 + SO_3) are shown in Fig. 14. As expected, the initial rate of attack was reduced, but corrosion was not eliminated, presumably because of the presence of some cobalt on the surface, which allowed the formation of a liquid salt; indeed the reacted sample had an Na_2SO_4-$CoSO_4$ liquid on the surface.

Third, by operating the accelerated oxidation test at high temperature (900°C) the transient oxidation stage can be appreciably shortened, and hence the protective Cr_2O_3 film may be obtained. Although the formation of a liquid phase was not a factor since Na_2SO_4 itself was molten, the potential for the sulfation reaction to yield an activity of $CoSO_4$ as high as at 750°C with O_2-0.15% (SO_2 + SO_3) was ensured by raising the (SO_2 + SO_3) to 4%. As shown in Fig. 14, the initial corrosion rate at 900°C was lower than that at 750°C, and the rate decreased with time to very low values. Even with a somewhat higher potential for sulfation in O_2-10% (SO_2 + SO_3), Fig. 14, the initial rate of attack was still less than that at 750°C, and as with the previous case corrosion essentially stopped after a few hours.

The above tests show that the initial high corrosion rates at intermediate temperatures result from the rapid sulfation of cobalt oxide or nickel oxide. The resulting liquid salt deposit prevents the formation of a protective Cr_2O_3 film. Appreciable rates of attack can be obtained beyond the time when the salt is apparently saturated with transition metal sulfates. The corrosion reaction can proceed by oxidation and sulfation at the scale/salt interface and/or dissolution at the scale/salt interface followed by the formation of Co_3O_4 or $CoSO_4$(s) at the gas interface. The reactions involved in these processes and differences from reaction models proposed in the literature will be described in a subsequent publication.

The corrosion rates of Ni-30Cr in O_2-1% (SO_2 + SO_3) mixtures (Fig. 4) were observed to be much

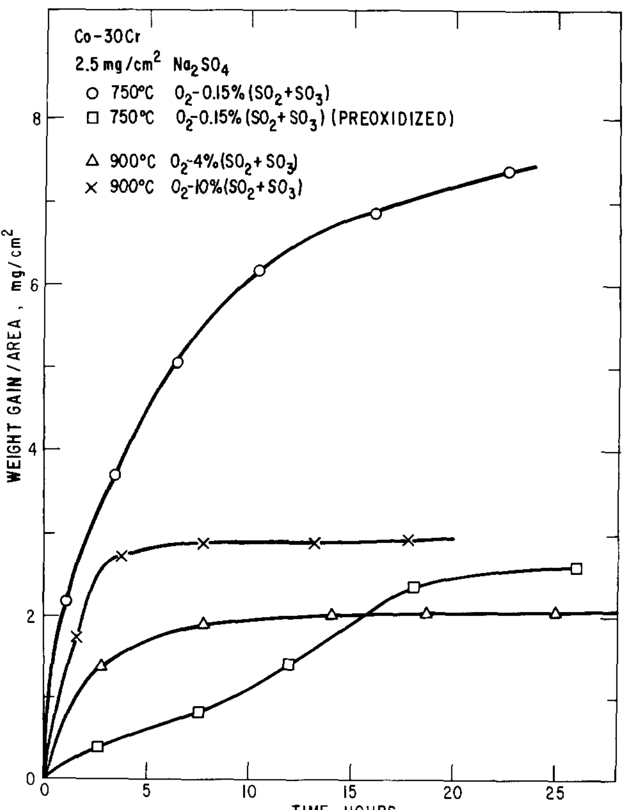

Fig. 14. Variation of weight gain/area with time for the corrosion of Co-30Cr samples, coated with 2.5 mg/cm² of Na_2SO_4, exposed to different O_2-SO_2-SO_3 environments at 750° and 900°C.

lower than those of Co-30Cr in O_2-0.15% (SO_2 + SO_3) (Fig. 3). This cannot be attributed to the lower stability of $NiSO_4$ in comparison to $CoSO_4$ because of the differences in P_{SO_3}. The higher P_{SO_3} level in the experiments with Ni-30Cr makes reaction [1] more favorable than reaction [3] in the experiments with Co-30Cr. For example, at 750°C, the activity of $NiSO_4$ in equilibrium with NiO(s) and O_2-1% (SO_2 + SO_3) is 0.91 while that of $CoSO_4$ in equilibrium with Co_3O_4 and O_2-0.15% (SO_2 + SO_3) is 0.50.

The higher corrosion rates for Co-30Cr can be correlated with the observed difference in the morphology of the corrosion product. It is observed that cobalt can dissolve at the bottom of the pit, migrate through the liquid salt, and form Co_3O_4 or $CoSO_4$(s) at the gas interface (see, for example, Fig. 11). Therefore, high corrosion rates can persist for long times on Co-30Cr. However, no such rapid migration of nickel was observed on Ni-30Cr. The transport processes involved in the migration of cobalt and oxidants (SO_3, O_2) will be described in detail in a subsequent publication.

Effect of temperature and P_{SO_3}.—The effects of temperature and P_{SO_3} on the corrosion rates are interconnected because these variables influence the formation of a liquid from an Na_2SO_4 deposit. Accelerated oxidation tests on Co-30Cr in O_2-0.15% (SO_2 + SO_3) and Ni-30Cr in O_2-1% (SO_2 + SO_3) at 600°-900°C yielded maxima in corrosion rate at 650°C for Co-30Cr and at 700°-750°C for Ni-30Cr. Also, at 750°C the reaction rates increased with increasing P_{SO_3} (Fig. 7 and 9). As described before, the rapid sulfation of cobalt oxide or nickel oxide prevents the formation of a protective chromium oxide film during the early part of the corrosion reaction. On Co-30Cr the reaction can proceed rapidly for longer times because cobalt dissolves at the scale/salt interface and redeposits as $CoSO_4$ or Co_3O_4 close to the gas interface. The following discussion of the effect of P_{SO_3} and temperature pertains specifically to the initial stage, although some aspects of the argument can also be applied to the later reaction processes.

It is proposed that the rate of sulfation of cobalt and nickel oxides is influenced by diffusion of SO_3 through the liquid salt. The transport rate of SO_3 should increase with (P_{SO_3} − $P_{SO_3}{}^i$), where $P_{SO_3}{}^i$ is the P_{SO_3} at the scale/salt interface. Thus, the reaction rate will tend to increase with P_{SO_3}. However, at very high P_{SO_3} the reaction rates may actually decrease, if the formation of solid sulfates impedes the transport of reactants in the reaction product layer. This is in agreement with our experimental results at 750°C on Co-30Cr which showed a higher corrosion rate in O_2-1% (SO_2 + SO_3) than in O_2-10% (SO_2 + SO_3).

The effect of temperature on the corrosion rate is influenced by many factors. Two important ones are: (*i*) the tendency to develop a protective oxide film, and (*ii*) the transport rate of SO_3 through the salt. Since the interdiffusion of Cr in the alloy and the diffusion of Cr through Cr_2O_3 will be faster at higher temperatures, the tendency to develop a protective Cr_2O_3 film will increase with temperature and will tend to decrease the corrosion rate. Also, as described before, the reaction rate is expected to increase with the transport rate of SO_3 through the liquid salt, which itself depends on two opposing factors: diffusion coefficient through the liquid salt and (P_{SO_3} − $P_{SO_3}{}^i$). With increasing temperature the diffusion coefficient will increase, but P_{SO_3} will decrease. In addition, at lower temperature the transport rate of SO_3 may be inhibited by the formation of solid sulfates. Under these competing effects, the corrosion rate should exhibit a maximum at some intermediate temperature.

The concentration of water soluble cobalt and nickel in the corrosion products was observed to be a maximum at about 650° and 750°C, respectively. The de-

crease in the concentration of nickel and cobalt at temperatures above 700°-750°C is due primarily to a decrease in the maximum activities of $CoSO_4$ and $NiSO_4$ in the melt. At lower temperatures, the salt chemistry may be modified by the formation of solid sulfates. For example, solid $CoSO_4$ is stable in O_2-0.15% (SO_2 + SO_3) at temperatures below about 725°C. That solid $CoSO_4$ does indeed form at lower temperatures was confirmed by comparing the mole fraction of Na_2SO_4 recovered from the salt deposits on corroded specimens of Co-30Cr (see Fig. 5) to the mole fraction of Na_2SO_4 in a liquid in equilibrium with solid $CoSO_4$ (Fig. 12). If solid $CoSO_4$ is present in the salt deposits, the experimental values of the mole fraction of Na_2SO_4 will be less than those obtained from the phase diagram. Table I shows that at temperatures below 725°C the salt deposits on corroded specimens of Co-30Cr consisted of solid $CoSO_4$ and an Na_2SO_4-$CoSO_4$ liquid.

Conclusions

High corrosion rates are obtained when Co-30Cr and Ni-30Cr alloys coated with Na_2SO_4 are exposed to O_2-SO_2-SO_3 environments containing sufficient SO_3 to form Na_2SO_4-$CoSO_4$ and Na_2SO_4-$NiSO_4$ liquids, respectively, on these alloys. Thermodynamic calculations show that these liquids can form at moderate SO_3 levels in the gas. For example, a liquid phase can be obtained on cobalt containing alloys at about 50 ppm SO_3 in the gas phase at 750°C and $P_{O_2} = 1$ atm. The rapid sulfation of cobalt and nickel oxides on the surface of the alloys prevents the formation of a protective Cr_2O_3 film, resulting in high corrosion rates. The corrosion rates on Co-30Cr were higher than on Ni-30Cr under equivalent sulfation conditions. On Co-30Cr the corrosion reactions can proceed rapidly for long times, because cobalt can dissolve at the scale/salt interface and precipitate as Co_3O_4 or $CoSO_4$ close to the gas interface. The combination of various factors involved in the sulfation reaction and the enhanced tendency to form a protective Cr_2O_3 film at high temperatures results in a maximum in the corrosion rates at about 650°-750°C.

APPENDIX

Estimation of the P_{SO_3} Required to Form Na_2SO_4-$CoSO_4$ Liquid

The equilibrium P_{SO_3} required to stabilize an Na_2SO_4-$CoSO_4$ liquid on cobalt oxide can be determined at any temperature from the standard Gibbs energy changes of reactions [2] and [3] and the Na_2SO_4-$CoSO_4$ phase diagram, provided the activity coefficient of $CoSO_4$ in the solid solution ($\gamma_{CoSO_4(s)}$) in equilibrium with the liquid phase is known. However, there are no measurements in the literature on the activity coefficient of $CoSO_4$ in liquid or solid solutions of Na_2SO_4 and $CoSO_4$. Therefore, values of the activity coefficient as a function of temperature were estimated from the phase diagram using the known thermodynamic properties of Na_2SO_4 and $CoSO_4$. The Gibbs energy data for $CoSO_4$(s), Na_2SO_4(s), and Na_2SO_4(l) were taken from the JANAF Tables and supplements (9), while that for $CoSO_4$(l) were obtained using the solid data, the melting point (15), and an estimated entropy of melting of 3.5 eu.

Because of the existence of compounds in the phase diagram of the $CoSO_4$-$NaSO_4$ system, liquid solutions are unlikely to be ideal. Activity coefficients calculated from the assumption of an ideal behavior of liquid Na_2SO_4-$CoSO_4$ resulted in activities of Na_2SO_4 greater than unity in Na_2SO_4-$CoSO_4$ solid solutions along the solidus line (for example, 1.25 at 650°C and 1.16 at 750°C). This is physically inconsistent and demonstrates that the Na_2SO_4-$CoSO_4$ liquid cannot be treated as an ideal solution.

As a first approximation, activity coefficients were obtained assuming both the solid and liquid solutions along the solidus and liquidus line to be regular. It should be noted that the models based on the regular solution approximation have been extensively used to calculate thermodynamic data in metal-slag systems, silicates and molten salts (16). Also, as shown below, these calculations yielded reasonable and consistent values of the activity coefficient over a small temperature range.

Let X_1 and X_2 be the mole fractions of $CoSO_4$ in solid and liquid solutions. Then

$$\frac{\ln \gamma_{CoSO_4(s)}}{(1-X_1)^2} = \alpha_s = \frac{\ln \gamma_{Na_2SO_4(s)}}{X_1^2} \quad [A-1]$$

and

$$\frac{\ln \gamma_{CoSO_4(l)}}{(1-X_2)^2} = \alpha_l = \frac{\ln \gamma_{Na_2SO_4(l)}}{X_2^2} \quad [A-2]$$

where γ denotes activity coefficients and α_s and α_l are the α-functions for the solid and liquid solutions, respectively.

For solid/liquid equilibrium

$$\underline{CoSO_4}(s) = \underline{CoSO_4}(l) \quad [A-3]$$

at temperature T

$$\Delta G°_{CoSO_4(l)} - \Delta G°_{CoSO_4(s)} = -RT \ln \frac{X_2 \gamma_{CoSO_4(l)}}{X_1 \gamma_{CoSO_4(s)}} \quad [A-4]$$

where $\Delta G°$ is the standard Gibbs energy of formation.

Combining Eq. [A-1], [A-2], and [A-4], one obtains

$$\frac{\Delta G°_{CoSO_4(l)} - \Delta G°_{CoSO_4(s)}}{RT} = -\ln \frac{X_2}{X_1} - (1-X_2)^2 \alpha_l + (1-X_1)^2 \alpha_s \quad [A-5]$$

The standard Gibbs energy of formation of $CoSO_4$ solid dissolved in Na_2SO_4 was approximated by the value for pure $CoSO_4$ solid owing to the lack of more relevant data. Similarly

$$\frac{\Delta G°_{Na_2SO_4(l)} - \Delta G°_{Na_2SO_4(s)}}{RT} = -\ln \frac{(1-X_2)}{(1-X_1)} - X_2^2 \alpha_l + X_1^2 \alpha_s \quad [A-6]$$

The simultaneous solution of Eq. [A-5] and [A-6] yields α_l and α_s, and hence the activity coefficients can be obtained from Eq. [A-1] and [A-2].

It was observed that in the range of 650°-750°C, the calculated values of α_s and α_l varied inversely with temperature. This suggests that in this temperature range the liquid and solidus composition *vs.* temperature data can be correlated with the assumption of a regular solution behavior. The resulting values of $\gamma_{CoSO_4(s)}$ varied from 0.24 at 650°C to 0.20 at 750°C.

For determining the SO_3 levels required to form the liquid phase at temperatures above 750°C (curve A in Fig. 12), a constant $\gamma_{CoSO_4(s)}$ value of 0.20 was used.

Owing to the high sensitivity of the calculated curve to small errors in the standard Gibbs energy values of reaction [3] and to the uncertainty associated with the calculated activity coefficient of $CoSO_4$, curve A was experimentally verified in the temperature range of 750°-800°C. Cobalt and CoO coupons were oxidized in air or oxygen at 750°C to produce a thin film of Co_3O_4 ($\approx$ a few microns) on the surface. These samples were sprayed with a thin film ($\approx$ 2.5 mg/cm^2) of Na_2SO_4 and exposed in O_2-SO_2-SO_3 environments for a few hours. The salt on the surface of the samples was then examined under a low power microscope at $\approx$20× magnification for signs of melting. The results of these experiments are shown in Fig. 12. The symbols x and o denote the conditions of salt melting and not melting, respectively. These results are clearly in good agreement with curve A.

Institute of Industrial Science, University of Tokyo, Tokyo, Japan

ABSTRACT

In order to elucidate the mechanism of self-protection of weathering steel, the action of atmospheric rust was studied through a discussion of physical, chemical, and electrochemical nature of rust, with special attention to the effect of copper addition. The aggregating state of rust layer is influenced by two factors: the time of exposure and beneficial elements added to steel. Copper addition inhibits the growth of primary colloidal particle. This action of copper has an effect on the properties of rust and serves to increase the protective ability of rust layer.

This paper is concerned with the self-protection mechanism of weathering steel.

The atmospheric rust on weathering steel protects the steel under it. The exposure time required to form a protective rust layer depends on atmospheric conditions (1-5). There is little difference between the corrosion rate of weathering steel and that of mild steel in the first months of exposure, but a difference in corrosion rates gradually becomes apparent after the first year of exposure. Even the corrosion rate of mild steel decreased with exposure time.

Such corrosion behavior of steel in the early stage of exposure means rust particles on steel form layers, the protectiveness of which is increased by aging process themselves and the alloy elements added to steel, such as copper, chromium, and phosphorous, etc.

The results of many exposure tests (2-5) comparing weathering steel and mild steel have repeatedly demonstrated the value of weathering steel for use in an industrial atmosphere. This fact indicates that weathering steel utilizes atmospheric pollutants, particularly SO_2 gas, to form protective layers.

Key words: weathering, self-protection, copper.

Interestingly, x-ray analysis has indicated that there is little difference in the crystalline substance between the rust on weathering steel and that found on mild steel. Therefore, it is suggested that the amorphous substances are very important.

On the other hand, many workers have indicated that the atmospheric corrosion of steel proceeds by an electrochemical mechanism. In 1965, Evans suggested that the atmospheric corrosion mechanism of rusted steel involved an electrochemical reduction of rusts formed on steel (6). Evans' mechanism has been supported experimentally, and the author supports this position, also. This mechanism suggests that some rusts accelerate the corrosion of steel.

These characteristics of atmospheric rust mean that the action of rust is quite complex. In this paper the action of atmospheric rust was studied through a discussion of physical, chemical, and electrochemical nature of iron rust, with special attention to the effect of copper addition.

Physical Properties of Rust

Appearance of rust.—The surface rusts of pure iron exposed for 4 months are yellow-orange and are apt

to flake off from the bulk rust. On the other hand, the surface rusts of iron copper alloy exposed for 4 months have red-brown color, which is converted to dark brown by further exposure. Small orange spots are observed on the surface rust after rain. The change of rusts on iron copper alloy in color is similar to that of rusts on weathering steel. The chemical compositions of pure iron and iron copper alloy are shown in Table I.

Figure 1 shows the scanning electron micrographs of the surface texture of pure iron and iron copper alloy exposed for 4 months.

The outer rust layer on pure iron is more loose and better crystallized than the inner layer. The rusts of iron copper alloy are quite different from those of pure iron. 0.2% copper addition improves the aggregating state of rust particles. The shape of an aggregate is like a mushroom, which is composed of many fine crystals.

Figure 2 shows the surface rust on weathering steel exposed for 4.5 years. The chemical composition of weathering steel is shown in Table I. These photographs explain the process of formation of outer layer very well.

A in Fig. 2 shows the area where the outer layer flaked off from the bulk rust, thus forming initial corrosion products. The shape of these corrosion products is similar to that of iron copper alloy as mentioned earlier. After an extended period of exposure, these corrosion products become interconnected (Fig. 2B) and are converted to a compact outer layer (Fig. 2C).

Artificial rust.—In order to make the effect of copper more clear, artificial rusts were studied.

Artificial rusts are prepared by an interfacial reaction between concentrated ferric-ferrous salt solution and sodium hyproxide solution. Figure 3 shows the process of producing artificial rust. Artificial rust is very useful because it is able to be produced in layers which are similar to atmospheric rust layers in their appearance and structure. In the case of artificial rust containing copper, the copper content is from 2 to 5 weight percent (w/o). Therefore, the effect of copper addition on artificial rust is magnified in comparison with that of atmospheric rusts.

In the research on artificial rust, two important effects of copper addition were found. One of them is the fact that copper addition increases the mechanical strength of rust layers. Namely, even if a shock were given to the test tube, the layers of artificial rust containing copper were not destroyed. It was concluded that copper addition improves the flocculent state of colloidal aggregate; that is, copper addition causes an increase in flocculent force of colloidal particles.

Another important effect of copper addition is to inhibit the formation of spinel-type oxide. Namely, β-FeOOH (Akaganeit) and Fe_3O_4 (Magnetite) are detected in the artificial rust without copper, while the artificial rust with copper does not contain magnetite. Therefore, copper addition inhibits the formation of spinel-type oxide and thus decreases the electric conductivity of the rust layer.

Physical quantities of rust.—Physical quantities of rust layer were calculated from nitrogen absorption isotherms measured in the relative pressure up to 0.93 by the method of Cranston and Inkley (7).

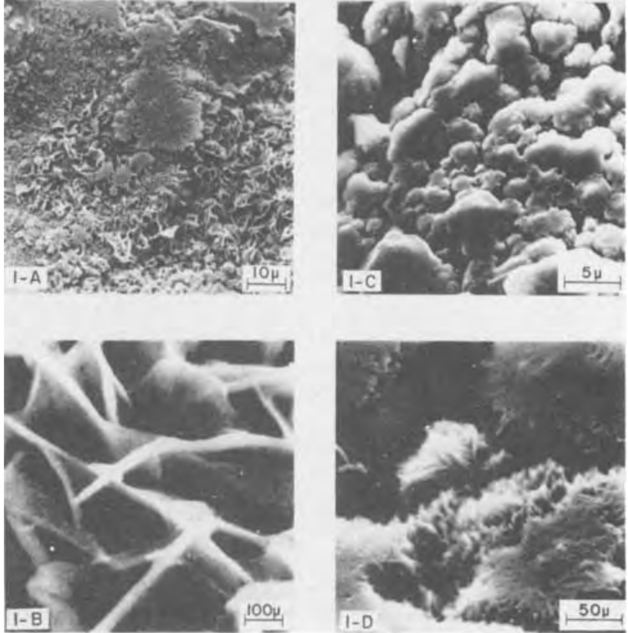

Fig. 1. Surface texture of rust layer on pure iron and iron copper alloy exposed for four months in urban atmosphere. (A,B) rust formed on pure iron, (C, D) rusts formed on Fe-0.2Cu alloy.

Figure 4 shows the pore-size distribution of the rust on pure iron exposed for 4 months and the rust on iron copper alloys exposed for one year. The pore sizes of atmospheric rusts are distributed in a range up to 15 nm, and the highest peak always appears in the diameter less than 5 nm.

Figure 5 shows the relationship between copper content and the total pore volume or the specific surface area of atmospheric rust. As the copper content increases, both factors tend to increase, but then decrease with extended exposure time.

These results show a same behavior of rust layer as shown in Fig. 1 and 2; that is, copper addition makes the rust layer more porous by inhibiting the growth of rust particles and, the longer the exposure time, the more compact is the layer formed by the aging process itself, in which the number of pores in the rust layer is decreased.

Chemical properties of rust.—Many results already reported show that the corrosion rate of steel depends on the nature of the atmospheric environment, in particular, there is a correlation between the corrosion rate, the concentration of SO_2 in the atmosphere, and that a weathering steel is less sensitive to SO_2 than a mild steel (2-5).

The relationship between the rust layer on steel and SO_2 in the atmosphere has been studied for about 20 years. The observation by Mayne (8) that iron sulfate in rust layers caused the breakdown of paint film led to the rusting mechanism of steel proposed by Schikorr (9) and Barton (10). The presence of SO_2 in the atmosphere results in the formation of H_2SO_4 in the rust layer, which attacks the steel under the rust layers. In regard to the relationship between SO_2 and the rusts on low alloy steel, Copson found that the greater the

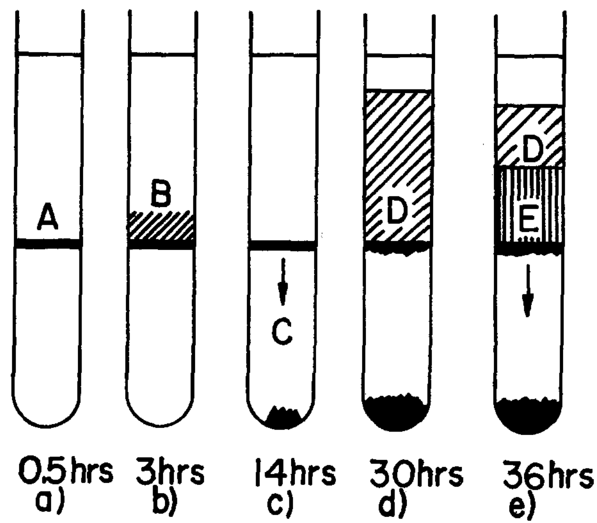

Fig. 3. Formation of artificial rust. (a) 5 ml of $FeCl_3$-$FeCl_2$ or $FeCl_3$-$FeCl_2$-$CuCl_2$ solution is gently added to 5 ml of 3M NaOH solution in a test tube with diameter 13 mm. A thin membrane is formed immediately at the interface (A). The total concentration of metallic salts is 0.75M. The notation of mixing ratio of them is indicated as (6-4-0), (6-3-1Cu) etc.; for example (6-3-1Cu) shows a solution of $FeCl_3$,$FeCl_2$, and $CuCl_2$ in the ratio of 0.6×0.75:0.3×0.75:0.1×0.75M. (b) After several hours it grows to a crust of hydrated oxide aggregate, over which yellow fine particles precipitate (B). (c) After 10 hr, some potions in contact with sodium hydroxide solution begin to fall down (C). (d) The floc of ferric hydroxide is formed over the crust facing metallic salt solution (D). (e) Black precipitated layer (E) by degrees is formed at the interface between a crust and D. After 24 hr, a crust is removed from the test tube and washed by deionized water. They are dried at room temperature after immersing in deionized water for 24 hr.

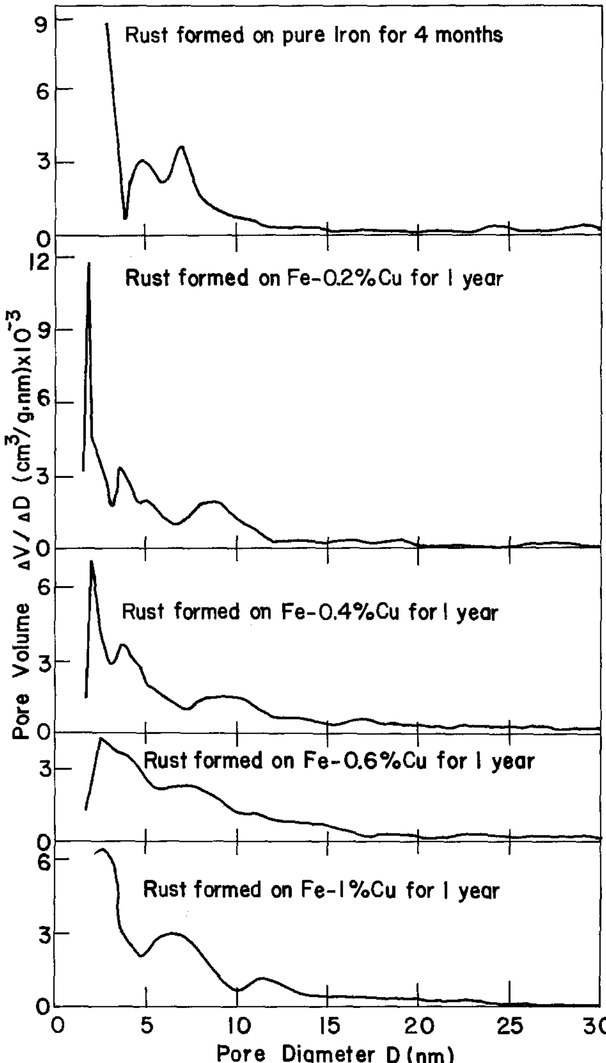

Fig. 4. Pore size distributions of rust layers on pure iron exposed for four months and iron copper alloys exposed for 1 year.

corrosion resistance of steel, the more sulfates existed in the loose layer (11). Copson (11) and Vernon (12) suggested that copper added to steel forms insoluble basic copper sulfate. However, basic copper sulfate has not been detected in the rust formed on copper-containing steel.

Since atmospheric rust layers have many pores as mentioned above, they are considered to have specific ability such as iron absorption.

In order to elucidate the chemical characteristics of the rust layer, the behavior of electrolytes in the rust layer, particularly the buffer ability of rust suggested by Barton (10), was investigated.

Buffer capacity of rust.—The buffer capacity, β, of a solution can be expressed in terms of the quantity of strong acid, C_A of the quantity of strong base, C_B, required to affect a unit change in pH of the solution, and may then be written

$$\beta = -\frac{dC_A}{dpH} = \frac{dC_B}{dpH}$$

It can be graphically represented by the slope of the titration curve. In this study the buffer capacity of rust, β, was determined from the titration curve of a suspension of 0.5g rust in 50 ml deionized water. The titration curve was obtained by using H_2SO_4.

Therefore, the buffer capacity of rust may be written as

$$\beta = -\Delta(H_2SO_4)/\Delta pH$$

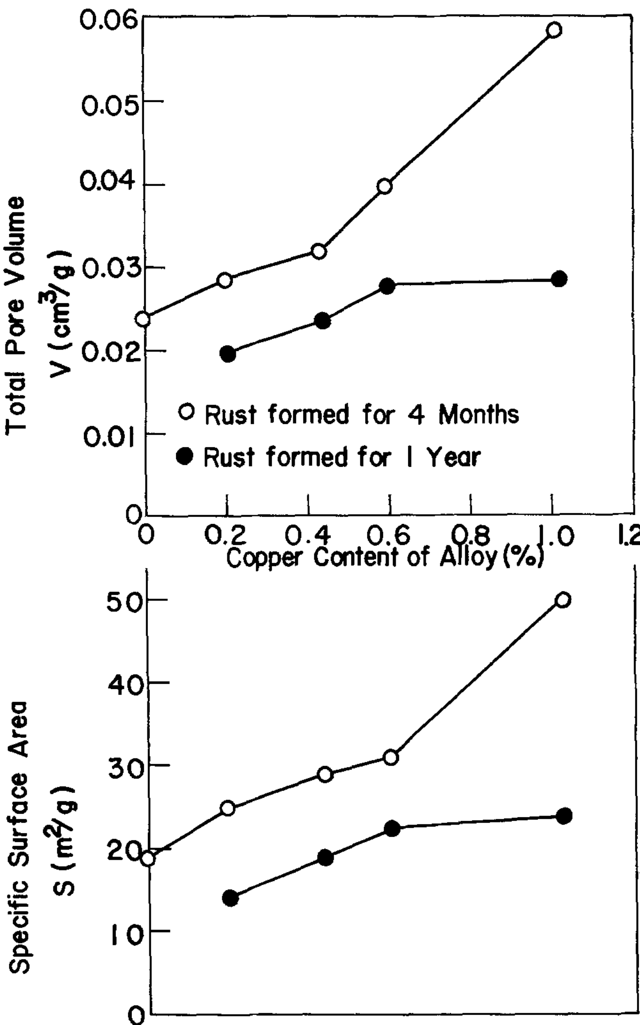

Fig. 5. Relationship between copper content of alloy and total pore volume or specific surface area of rust layer.

The dimension of buffer capacity of rust, β, is mole $\cdot$ liter^{-1} $\cdot$ g^{-1}.

Figure 6 shows the buffer capacity of artificial and atmospheric rust. Atmospheric rusts were obtained from Cu bearing steel (in Table I) exposed for one year in an urban district. In the case of artificial rust, copper addition increased the buffer capacity in the whole pH range, and especially caused great buffer ability in the pH range from 4 to 6. On the other hand, the buffer capacity of atmospheric rust in pH range from 4 to 6 was not able to be determined since the pH of the suspension of atmospheric rust was less than 4. However, it is suggested from the buffer ability of artificial rust that atmospheric rusts with copper in the early stage of exposure have higher buffer capacity than those without copper in pH 4-6. In pH $<$ 4, the same tendency was observed for atmospheric rust; that is, the rust on copper bearing steel had buffer capacity three times higher than that on pure iron. Therefore, copper added to steel increases the buffer capacity of the rust.

In the pH range from 3.5 to 7, the buffer ability results from the absorbing action of rust; in this instance, the rust layer keeps the concentrated H_2SO_4 in its pores (13). Consequently, the rust layers, in particular the outer layer, with great buffer capacity inhibit the attack of H_2SO_4 on steel. While in the rust layer, the H_2SO_4 which was absorbed accelerates the formation of a compact outer layer through the repeated dissolution and reprecipitation of rust particle in the presence of cupric ion. The formation of a compact outer layer promotes the growth of an inner layer.

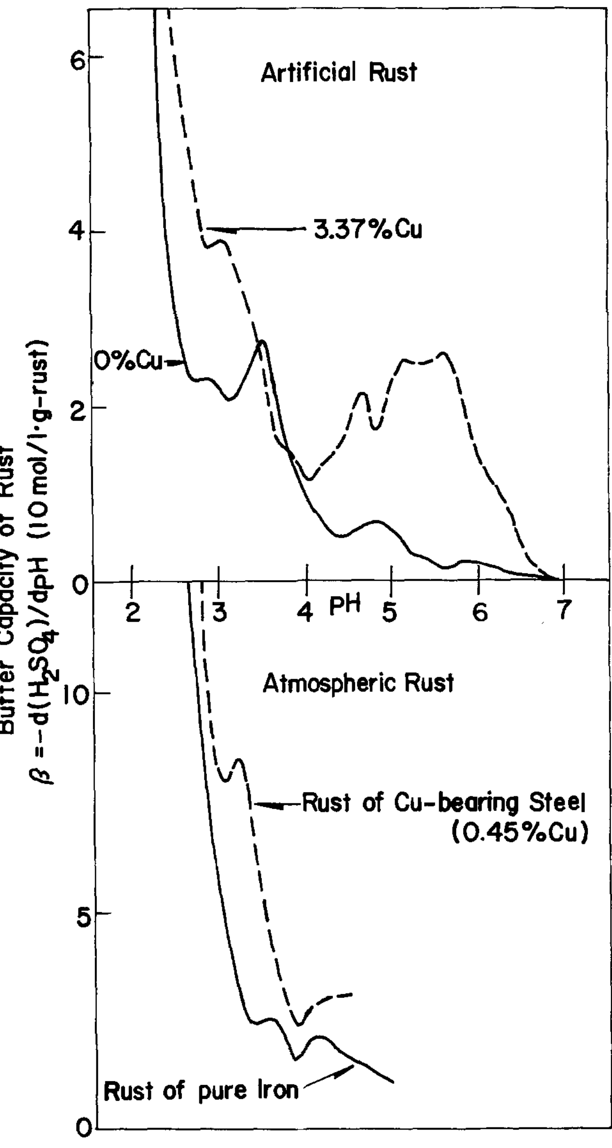

Fig. 6. Buffer capacity of artificial and atmospheric rust

Electrochemical properties of rust.—In order to elucidate the electrochemical properties of iron rust, the rust electrode was prepared from a rusty plate of pure iron. Pure iron specimens were exposed in an urban environment. The surface rust of pure iron exposed for 4 months was apt to flake off as a plate from the bulk rust. The thickness of rust plate was *ca.* 500 μm.

Figure 7 shows two kinds of rust electrodes. The rust plate was fixed on an acrylic plate with a conductive adhesive. The rust electrode with a capillary (a) was prepared for studying cathodic polarization behavior of rust layers. The rust electrode (b) was prepared for examining the change in crystalline material in the rust layer during electrochemical reduction.

Figure 8 shows the internal polarization curves of various galvanic couples in 0.1M Na_2SO_4. The internal polarization curve indicates the possibility that the rust layer acts as the cathode electrode in rusted iron. Internal polarization curves were determined in 0.1M Na_2SO_4 solution when exposed to air to be decreasing in steps the external resistance arranged in series in the short circuit of the galvanic couple of pure iron/electrode of rust [(a) in Fig. 7] or conductive adhesive. The apparent surface area of the electrode was 10 $\times$ 10 mm. The distance between the electrodes was 20 mm. The rest potential of the rust electrode was *Ca.* 0.2V (SCE). The galvanic

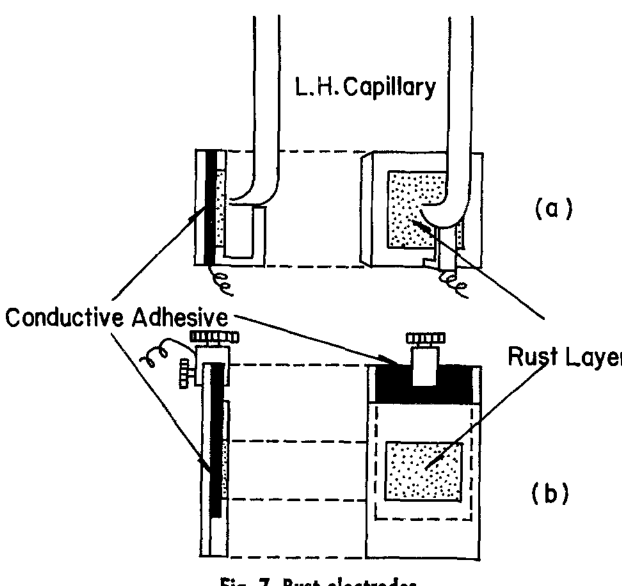

Fig. 7. Rust electrodes

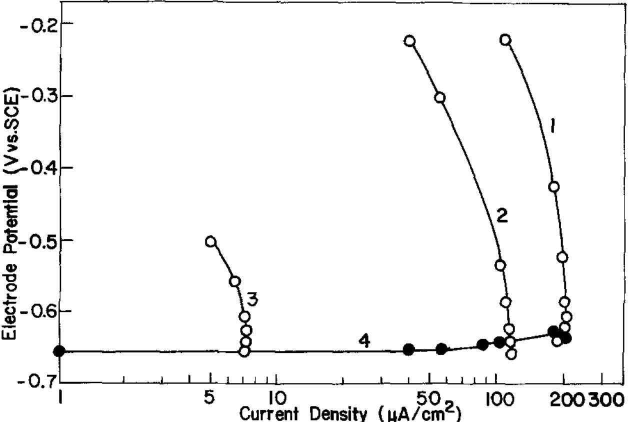

Fig. 8. Internal polarization curves of various couples. Curve 1: rust layer before reduction, curve 2: rust layer partially reduced, curve 3: conductive adhesive, curve 4: pure iron.

current of pure iron/electrode of conductive adhesive is 7 $\mu A/cm^2$, which is very small in comparison with 200 $\mu A/cm^2$ of pure iron/rust electrode and is the reduction current of dissolved oxygen on the surface of conductive adhesives. By comparison, the galvanic current density of pure iron, a partially reduced rust electrode is 100 $\mu A/cm^2$. These results indicated that a part of the cathodic reaction of rusted steel is the reduction of the rust layer and that some rusts accelerate the corrosion rate beyond that of dissolved oxygen as Evans suggested (6).

Figure 9 shows the change of crystalline substance in rust layers by cathodic reduction. The sample was the rust electrode (b) in Fig. 7. The crystalline parts of pure iron rust plate were composed of γ-FeOOH (Lepidocrocite), α-FeOOH (Geothite), and Fe_3O_4 (Magnetite). The crystalline materials in the surface layer were γ-FeOOH, α-FeOOH, and Fe_3O_4. The x-ray diffraction intensity of γ-FeOOH was the strongest while that of α-FeOOH was very weak. The interior of the rust plate consisted mainly of Fe_3O_4 and a little α-FeOOH. γ-FeOOH was not detected. In the separating face from the bulk rust, the growth of crystalline material was inhibited and the intensity of α-FeOOH was stronger; that of Fe_3O_4 was weaker than those of the interior. γ-FeOOH did not exist there. The reduction current density is 100 $\mu A/cm^2$. Electrolyte solution is 0.1M Na_2SO_4.

The x-ray identification of a crystalline substance was carried out by wetting the rust electrode with

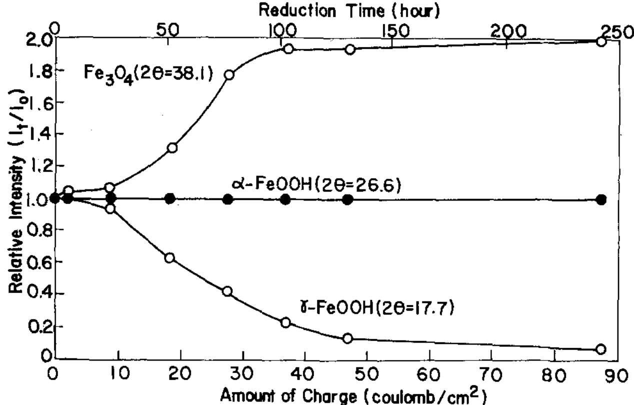

Fig. 9. Change in the intensity of crystalline substances in the rust layer with cathodic reduction. I_0: The intensity of various crystalline substances before cathodic reduction; I_t: the intensity of various crystalline substances after t hr reduction.

deionized water to avoid drying of the rust. The relative intensity (I_t/I_0) in Fig. 9 is the ratio of the intensity of various crystalline substances before cathodic reaction to the intensity of various crystalline substances after t hr reduction. The pure Fe_3O_4 powder (2θ = 38.1), which formed by a dry process, was used as a standard of crystalline substances. γ-FeOOH is apt to be reduced cathodically, and α-FeOOH is not reduced. The effect of reduction on the x-ray intensity of γ-FeOOH appears after 20 hr, 7 Ccm^{-2} being required.

From the fact that γ-FeOOH was not identified in the inner layer, which occupied the major portion of the rust plate, and that γ-FeOOH in the surface layer was not influenced in the initial reduction stage, it is concluded that the reduction of rust occurs in the inner layer and that the substance reduced electrochemically is not only γ-FeOOH; *i.e.*, there are reducible amorphous substances in addition to γ-FeOOH in the rust layer. γ-FeOOH appears to be converted directly to Fe_3O_4 by cathodic reduction in Fig. 9. However, there may not be a direct relationship between γ-FeOOH and Fe_3O_4. Figure 9 shows that γ-FeOOH changed into the other solid phase and that Fe_3O_4 was also formed from reducible amorphous substances. The reducible amorphous substances are hereafter referred to as intermediate substances.

Figure 10 shows the difference in electrochemical behavior between rusted plain steel and rusted weath-

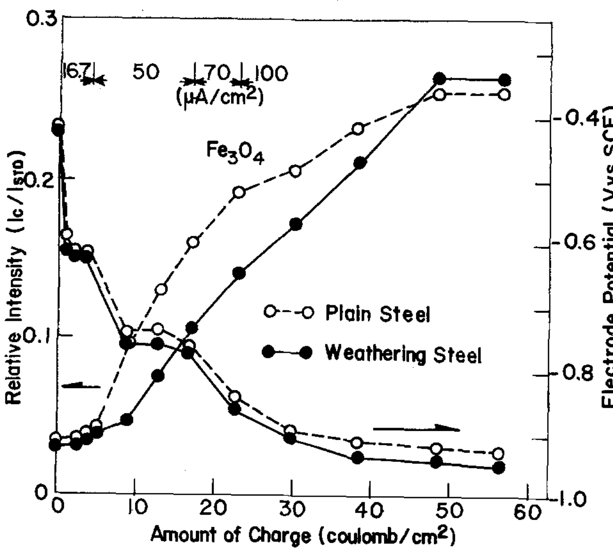

Fig. 10. Changes in the intensity of Fe_3O_4 and the potential of rusted steel with cathodic reduction.

ering steel. The chemical compositions of both steels are shown in Table I.

Specimens of both steels were exposed for three years in an urban atmosphere. The apparent surface area of the rusted steel electrode was 15 × 15 mm. The cathodic current density was increased from 16.7 to 100 $\mu A/cm^2$ in steps. The x-ray diffraction intensity of Fe_3O_4 was slightly stronger in the rust on plain steel than that on the weathering one before cathodic reduction. Relative intensity (I_c/I_{std}) in Fig. 10 is the intensity ratio of Fe_3O_4 in the rust layer for that of pure Fe_3O_4 powder formed by a dry process. There is no difference in potential, but a great difference in the increase of Fe_3O_4 between them by cathodic reduction. The potential behavior of both rusted steels shows that the reduction of rust occurred in the rust layer on weathering steel as much as in that on plain steel. Therefore, the rust layers on weathering steel contain less intermediate substances, which are apt to be converted to crystalline magnetite by cathodic reduction, than those on plain steel. The cathodic reduction of rust at the initial stage occurs in the inner layer, which had been most affected by beneficial elements added during the exposure period. Therefore, the difference in the formation of crystalline magnetite at this initial stage between both rusted steels emphasized the electrochemical characteristics of the rust layer on weathering steel.

Generally rusts on steel are reduced electrochemically for a short time just after the rust layer is wetted by rain, etc. Even if the rust layer was wetted for a long time, the reduction of rusts does not contribute to the corrosion rate, except the initial time of rain, and the main cathodic reaction is the reduction of dissolved oxygen on steel or magnetite in the rust layer since magnetite is a good electric conductor, as Evans pointed out (6), and γ-FeOOH and α-FeOOH are not electric conductors.

It is concluded that beneficial elements added to steel inhibit the formation of crystalline magnetite in the cathodic reaction process and thereby increase the electric resistance of the rust layer.

Conclusion

The atmospheric rust layers on steel are secondary aggregate of primary colloidal particles. The aggregating state of the rust layer is influenced by two factors: the time of exposure and beneficial elements added to steel. In particular, copper addition inhibits the growth of primary colloidal particles. This action of copper has an effect on the physical, chemical, and electrochemical properties of rust and serves to increase the protective ability of the rust layers.

The summary of results are shown as follows:

(*i*) Copper addition to iron inhibits the growth of iron oxide, in particular, spinel-type oxide in the rust layer and accelerates the formation of amorphous substances. This effect induces an increase in flocculent force of colloidal aggregate and thereby develops mechanical strength of the rust layer and decreases the electric conductivity of the rust layer.

(*ii*) The pore size of atmospheric rust distributed in the range up to 15 nm, and the highest peak always appears below 5 nm.

The total pore volume in the rust layer formed for 1 year is 1.94-2.84 × 10^{-2} (cm^3g^{-1}).

The specific surface area of rust formed for 1 year is 14.2-23.9 (m^2g^{-1}). Both factors increase with copper content and decrease with the time of exposure.

(*iii*) Atmospheric rusts on steel have buffer ability for H_2SO_4. Copper added to steel increases the buffer capacity three times as much as those without copper at pH 3.3. This action of atmospheric rust inhibits the attack of H_2SO_4 on steel and accelerates the formation of the compact outer layer to protect the inner layer.

(*iv*) Beneficial elements added to steel decrease the formation of intermediate substances, which are converted to crystalline magnetite by cathodic reaction and thereby increase the electric resistance of the rust layer.

Properties of Thin Polyimide Films

L. B. Rothman*

IBM Data Systems Division, East Fishkill, Hopewell Junction, New York 12533

ABSTRACT

Polyimide is receiving increasing interest as a possible insulator on semiconductor devices, replacing SiO_2. Several commercially available polyimides have been characterized by testing films of them for electric breakdown strength, conductivity, adhesion, and other properties. The results of these tests are summarized, and the polyimides are compared to sputtered SiO_2.

Polyimide has excellent thermal stability and chemical resistance, along with good dielectric properties. This combination of characteristics makes it promising as a replacement for SiO_2 for insulating semiconductor devices. Several multilevel metal structures using polyimide as the insulator have been described in the literature (1-4).

To develop a base of understanding in support of this use of polyimide, several commercially available materials have been tested for a variety of functional properties. Film thickness ranged from 1 to 3 μm. Electrical and physical measurements were compared with measurements for sputtered SiO_2 films.

Sample Preparation

A description of the polyimide materials as received from the vendor is shown in Table I. There are considerable differences in these materials, including solvent system, solids content, and viscosity. Two of the materials were received in powder form, which is an advantage in terms of shelf-life. The materials received in solution, such as polyamic acid, had a shelf-life of approximately one year when stored at 4°C.

In order to cast films of 1-3 μm thickness by spin coating, the materials were diluted with additional solvent to the solids content shown in Table I. It is interesting that there is also a difference in the solids content of the solutions for coating the same film thickness. As received, all the materials had a great deal of particulates and, therefore, all the solutions had to be filtered prior to use. Filtering was done using silver membrane filters with a pore size of 0.45 μm. Thin films of 1-3 μm were prepared by spin coating at spin speeds of 4-6 krpm. Curing was done on hot plates. All of the testing was done on blanket polyimide films.

Table I. Comparison of various polyimide resins as received and as used

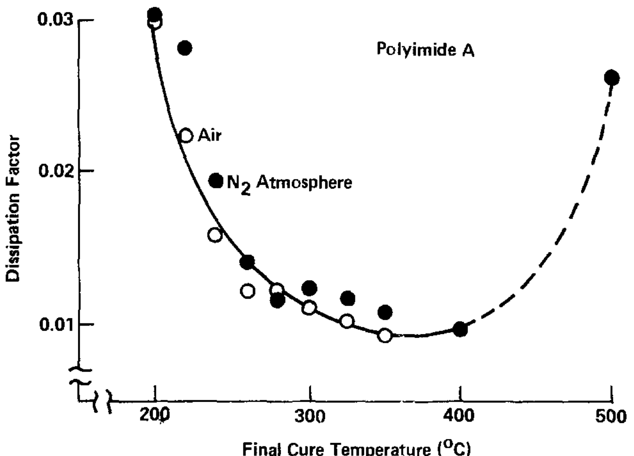
	As received			As used
Polyimide	Solids content (w/o)	Viscosity (cps)	Solvent	Solids content (w/o)
A	16	6000	NMP	13
B	27	5600	NMP/acetone 3:2	18
C	38-42	250-350	DMF	32
D	63-67	3000-7000	NMP	47
E	55	4000	NMP/methanol 4:1	36
F	Powder			60
G	Powder			15

NMF: methylpyrrolidinone.
DMF: dimethylformamide.

Dielectric Properties

In order to use polyimide as a replacement for SiO_2 for insulating semiconductor devices, it must have good dielectric properties. Measurements of breakdown strength, conductivity, dielectric constant, and the dissipation factor have been made on fully cured polyimide films with comparisons made to sputtered SiO_2.

The cure cycle was determined by dissipation factor measurement, as suggested by Gregoritsch (5). An Al-polyimide-Al dot structure was used and the dissipation factor was measured at a frequency of 1 MHz, as a function of the final cure temperature. Some results are shown in Fig. 1a and b. The dissipa-



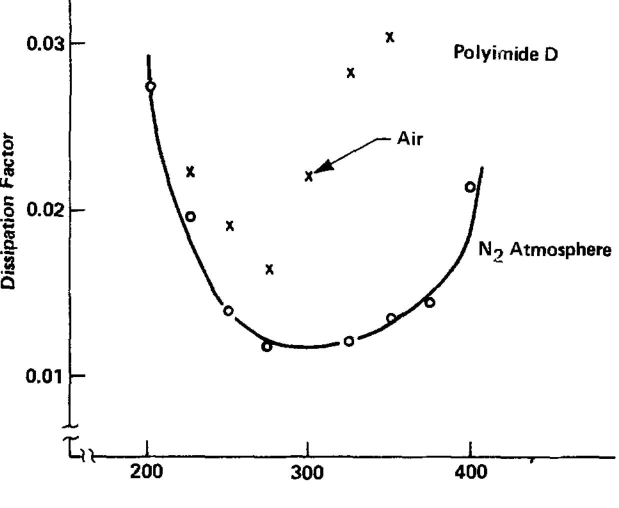


Fig. 1. Dissipation factor as a function of final cure temperature for (a) 1.5 μm film of Polyimide A, (b) 1.5 μm films of Polyimide D. Time at final cure temperature was 30 min.

tion factor decreases with increasing cure temperature until full cure is reached and then increases as decomposition starts to occur. Curing in nitrogen and air were investigated. Figure 1b shows that for Polyimide D there is a substantial difference in the dissipation factor between curing in air and nitrogen whereas Polyimide A does not exhibit this effect. For the data which follows, the curing of the polyimides was therefore done in a nitrogen atmosphere for the final cure. The dissipation factor of the fully cured 1.5 μm polyimide films was approximately 0.01 for all the materials tested.

The dielectric breakdown strength was measured using an Si-polyimide-Al dot structure. The polyimide film thickness used was 1.5 μm. Al dots of 1.5 mm diam were used. Fifty measurements were made on each wafer. The voltage was ramped at a rate of 1 V/sec until breakdown occurred. It can be seen in Table II that all of the polyimide films tested exhibited good dielectric breakdown strength, which is comparable to SiO_2. The data reported in Table II are for polyimide films cast from carefully filtered solutions as described previously. Without filtering the raw materials the dielectric breakdown strength was in the low 10^5 V/cm range.

For measurements of conductivity, an Al-polyimide-Al dot structure was tested in electric fields ranging from 5×10^4 to 5×10^5 V/cm and temperatures up to 250°C. Figure 2 shows that the log of the resultant current varies linearly with the square root of the electric field for all of the materials tested. This exponential dependence of the current on the square root of the applied voltage has been reported previously for Kapton polyimide films (6). It is observed in Fig. 2 that the conductivities of individual polyimides differ widely, and all of them are considerably higher than that of sputtered SiO_2. All of these materials, however, appear to be adequate insulators, since for typical semiconductor device use conditions (85°C, 10^5 V/cm) their resistivities are over 10^{12} Ω-cm.

Data is not presented for Polyimide F due to problems of instability in the film, probably due to water absorption. The films of Polyimide F would appear quite conductive ($J > 10^{-3}$ A/cm^2) as initially tested. After baking the test samples for an hour at 200°C and then immediately testing, the conductivity of the films was similar to the other polyimide films. If the test sample remained at ambient conditions for a few hours, it would become conductive once again. This phenomenon was not observed with any of the other materials.

The dielectric constant was measured at a frequency of 1 MHz and found to be approximately 3.5 for all of the polyimide films tested compared to 3.8 for sputtered SiO_2. This lower dielectric constant of polyimide is an advantage over SiO_2.

Planarization

For high density multilevel metal-insulator structures it is desirable to have a planar surface. It has been reported in the literature (1, 2) that polyimides can be used as the insulator to provide such a planar structure. During the cure cycle for the polyimide film there is a tendency for flow to occur. Also, during the cure cycle there is a great deal of shrinkage due to solvent loss. It was observed that some of the materials tested exhibited a combination of less shrinkage and more flow than others. It is the combination of shrinkage and flow during the three stages of the cure cycle which provides polyimide films with the ability to planarize or smooth out any topological structures on a substrate.

Table II. Dielectric breakdown strength of 1.5 μm polyimide films

Polymide	Average breakdown field ($\times 10^6$ V/cm)
B	4.74
D	5.62
A	5.94
G	6.28
E	6.63
C	7.06
F	7.50
SiO_2 (sputtered)	8.60

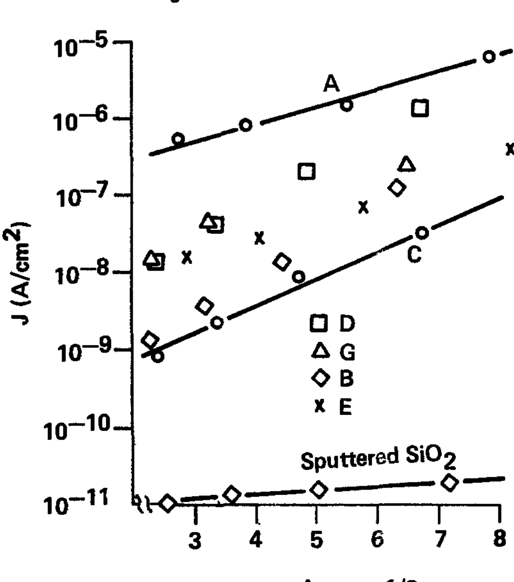

Fig. 2. Current density vs. applied field at 250°C for various polyimide films with a comparison to sputtered SiO_2.

The degree of planarization is determined by the ratio of the step height resulting with the polyimide film to the initial step height of the metal pattern as shown in Fig. 3. Another factor in the degree of planarization is the slope of the resulting step.

The planarity measurements were made with a Taylor-Hobson Talystep and also SEM examination. Some general observations for all the polyimide films are that the degree of planarization is directly dependent on the thickness of the polyimide films. The slope of the polyimide over the metal land decreases with increasing polyimide thickness. It was also observed that the degree of planarization is dependent on both the width and spacings of the metal lines which the polyimide is covering as shown in Fig. 4. Thin lines with narrow spaces result in better planarization. Unfortunately, this geometry dependence of planarization becomes quite complicated since a group of closely spaced lines, separated by a large distance ($\geq$12 μm) from other lines, act as one wide land. However, it seems that a group of narrow lines planarizes slightly better than a single line of the same overall width. The degree of planarization, therefore, is dependent on the geometry of the

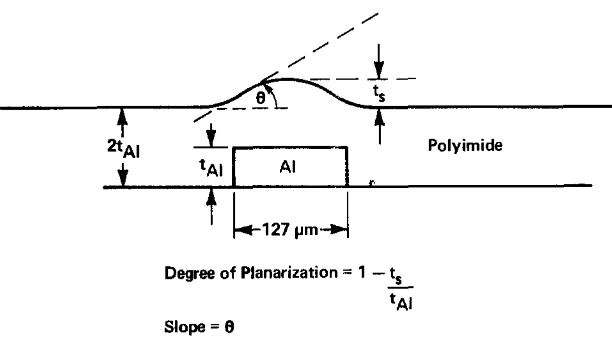

Fig. 3. Degree of planarization for polyimide over a metal step

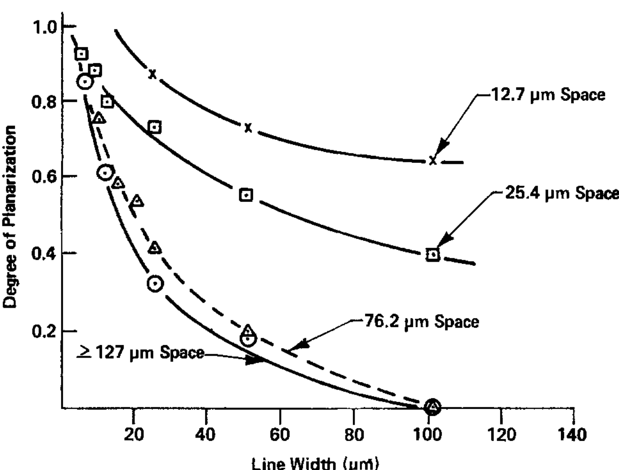

Fig. 4. Planarization as a function of line width and space for Polyimide C films.

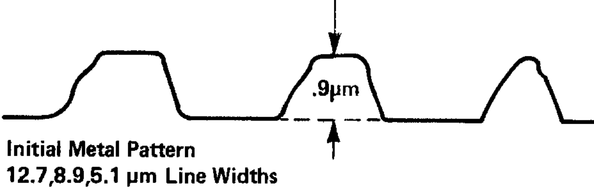
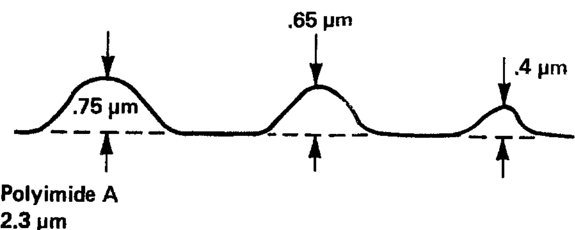
metallization pattern (*i.e.*, individual line widths, line spacings, and group dimensions).

A difference in the degree of planarization was observed for the various materials tested. Figure 5 shows Talystep measurements for two polyimides over a metal pattern of varying line widths. The trend toward more planarization as the line width decreases is seen for both materials; however, in general, Polyimide C planarizes more than Polyimide A. Figure 6 illustrates the difference in planarity of the two materials. In order to make an easy comparison of planarization, measurements were made over a single metal line of 12.7 μm in width. Table III shows the degree of planarization for the various polyimide films. Three of the materials seem to provide a conformal type coating, while the other four polyimides seem to planarize more. There appears to be a correlation between the solids content of the coating solution and the degree of planarization. Higher solids content material provides more planarization.





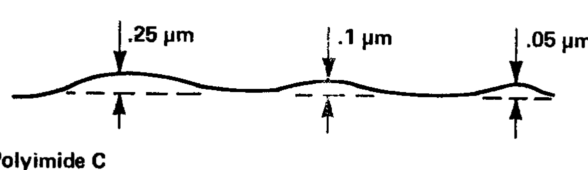


Fig. 5. Talystep measurements comparing degree of planarization achieved with Polyimide A and Polyimide C films.

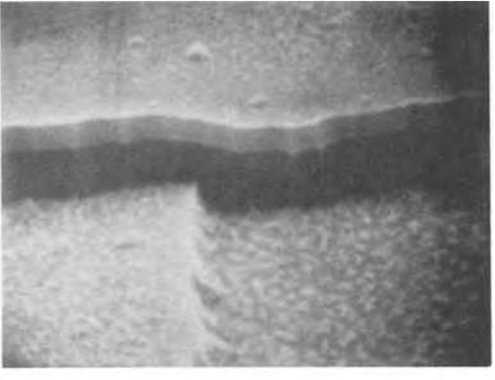

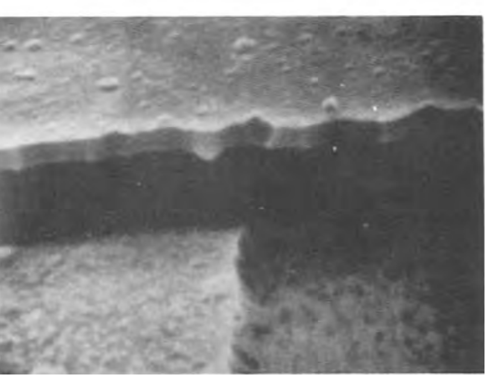

Fig. 6. SEM pictures compare the degree of planarization of Polyimides A (top) and C (bottom). Pictures show a cross section of a polyimide film (which is covered with Al) over a metal line. (The cross section was made by RIE and the Al over the polyimide was used as a mask). (6000×.)

Due to the many geometry effects, it does not seem possible to completely planarize a typical metal pattern with a polyimide film. Good edge coverage, however, is obtained with all of the various polyimide films even when planarization is not achieved. This good edge coverage of polyimide films is an advantage over standard sputtered SiO_2 films deposited with a re-emission coefficient of ~0.3 (7). Typically SiO_2 films are somewhat conformal but have a tendency to cusp at the edges of metal lines resulting in poor edge coverage.

Adhesion

One of the most important properties of a thin film, such as polyimide, is its adhesion to the semiconductor substrate and metallurgy, and the adhesion of other materials to the polyimide film. Of the numerous methods for the measurement of adhesion of thin films (8), the technique we found the most reliable was the peel force test.

A schematic of the peel force test apparatus is shown in Fig. 7. The force transducer is fixed on a sliding stage. It is connected by a long rod to the test sample. The test sample consists of a strip of wafer of known width attached by two sided tape to a glass slide. It is mounted such that approximately

Table III. Degree of planarization for 2 μm polyimide films over 1 μm Al lines

Polyimide	% of solids in solution used to coat 2 μm film	Degree of planarization (over 12.7 μm line)
A	13	0.17
B	18	0.30
G	15	0.32
C	32	0.72
D	47	0.78
E	36	0.78
F	60	0.82

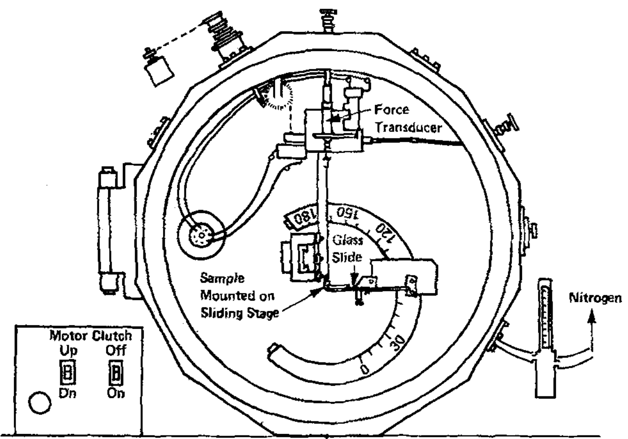

Fig. 7. Schematic of peel force test apparatus

a quarter inch of the wafer strip overhangs the edge of the glass slide. The wafer strip is carefully broken where it overhangs the glass slide, leaving the film intact. Then this part is bent up and attached to the flat end of the rod using glycophalate. The stage was adjusted for a peel angle of 90° for consistency and ease of peeling. The peel rate is 0.15 mm/sec. The stage holding the test sample slides at the same rate as the stage holding the force transducer providing a constant peel angle. The output of the force transducer is recorded on a strip chart recorder. The peel test is performed in an enclosed chamber which is purged with dry nitrogen.

Strips of wafers of various widths were used to obtain a relative measure of adhesion. A graph of peel force *vs.* width as shown in Fig. 8 is plotted and the slope of this line (K) is used as the relative measure of adhesion. It is also observed that the intercept of this line is not always zero due to edge effects: damage inflicted to the interface at the edges while the wafers were scribed into strips.

Adhesion measurements were made after processing and again after temperature-humidity stress cycles.

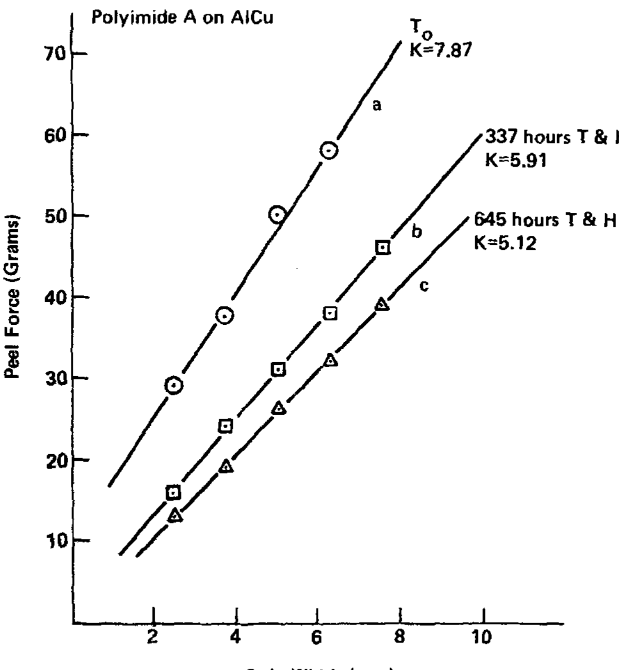

Fig. 8. Peel force *vs.* strip width for Polyimide A on AlCu, as a function of time in a temperature/humidity chamber. (a) initially $K = 7.87$ g/mm, (b) after 337 hr at 85°C, 80% relative humidity $K = 5.91$ g/mm, (c) after 645 hr $K = 5.12$ g/mm.

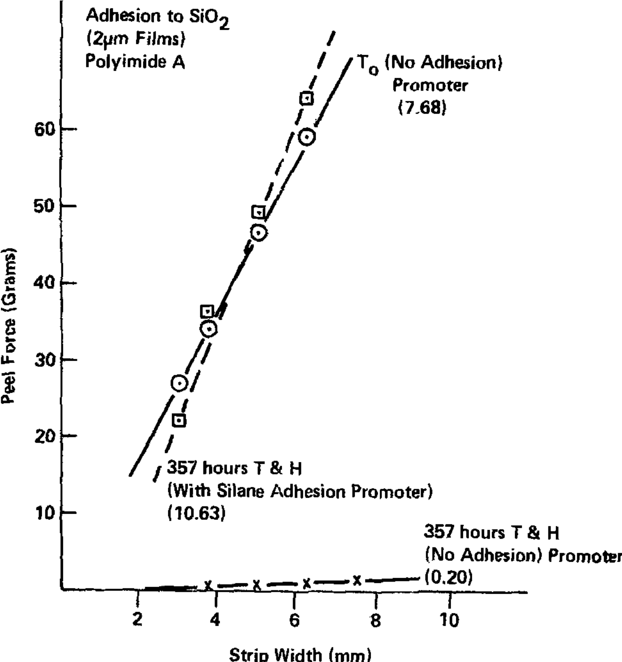

Fig. 9. Polyimide adhesion to SiO_2. Using silane adhesion promoter: No peel at T_0 and $K = 10.63$ g/mm after 357 hr at 85°C, 80% relative humidity. Without any adhesion promoter: $K = 7.68$ at T_0 and $K = 0.20$ g/mm after 357 hr of T&H.

Figure 8 shows that the adhesion tends to degrade after exposure to temperature-humidity stressing.

The initial adhesion of polyimide to Si and SiO_2 surfaces was good; long exposure to stressing, however, tended to degrade the interface. It was found that silane adhesion promoters (9) improved the long-term stability of the bond. Figure 9 shows a comparison for Polyimide A on SiO_2. Both at T_0 and after stressing the adhesion of the polyimide film to SiO_2 is improved when a silane-type adhesion promoter was used.

It is observed in Table IV and Fig. 8 that the major degradation in the adhesion appears after the initial exposure to T&H stressing.

The "no peel" condition shown in Table IV indicates excellent adhesion. It occurs when the peel starts and a full scale deflection is recorded on the chart recorder and the polyimide film tears, thereby implying a peel factor of 31.5 g/mm or greater. A partial peel condition is more difficult to interpret. This is when the polyimide film starts to tear unevenly as it is peeling, indicating that the adhesion of the film is not uniform across the surface, and that there are areas of very good adhesion where the polyimide film is not peeling.

For all the data presented a silane adhesion promoter was used on Si and SiO_2 surfaces. However, for Al surfaces no difference was found in the adhesion of polyimide with or without an adhesion promoter.

Table V illustrates that the adhesion at T_0 of polyimide to Si is good for all the materials tested. After T&H stressing, however, two of the materials show a degradation in their adhesion to Si surfaces.

Table IV. Polyimide adhesion to SiO_2 as a function of temperature and humidity stressing at 85°C, 80% relative humidity

	Adhesion to SiO_2: K (g/mm) hr T&H					
Polyimide	T_0	357	762	1122	1770	2495
A	PP	11.03	9.06	10.24	6.70	8.27
B	NP	NP	NP	NP	NP	NP

NP: no peel, excellent adhesion. T&H: 85°C, 80% relative humidity. 2 μm polyimide films.

Table V. Polyimide adhesion to Si

Polyimide	Adhesion to Si: K (g/mm)	
	T_0	After 563 hr T&H
F	NP	NP
D	NP	NP
C	NP	NP
G	PP	8.67
E	NP	NP
A	NP	18.52
B	NP	NP

3 μm polyimide films on Si wafers.
NP: no peel condition, excellent adhesion $\gtrsim$31.52 g/mm.
PP: partial peel, films start to peel unevenly then tear.
T&H: 85°C, 80% relative humidity.

The adhesion of polyimide films over Al and Al alloys was excellent for almost all the materials tested as shown in Table VI. The adhesion of Al over polyimide was satisfactory before the T&H stress cycle, but severely degraded after it for all materials tested. Typically, values of K greater than 18 g/mm were measured at T_0; however, after 200 hr at 85°C, 80% relative humidity, the value of K went down below 3 g/mm. Annealing the metal at 350°C in nitrogen before test improves the Al to polyimide adhesion,

Table VI. Polyimide adhesion to Al

Polyimide	Adhesion to Al: K (g/mm)	
	T_0	After 564 hr T&H
F	NP	NP
D	NP	NP
C	PP	PP
G	PP	PP
E	NP	NP
A	10.64	8.27
B	PP	PP

3 μm polyimide films of Al surface without using any adhesion promoter.
T&H: 85°C, 80% relative humidity.
NP: no peel condition, excellent adhesion $\gtrsim$31.52 g/mm.
PP: partial peel, film starts to peel unevenly then tears.

resulting in a peel factor of approximately 10 g/mm after the stress cycle.

Conclusion

In summary, the polyimide films of various vendors exhibited differences in functional properties. The dielectric properties of polyimide films are not quite as good as sputtered SiO_2 with regard to breakdown strength and resistivity. The adhesion of polyimide to various materials is also not always as good as SiO_2 depending on the polyimide. Polyimide does provide an advantage in good edge coverage and some planarization of topography. Considering all of these properties, polyimide films seem to be more than satisfactory for application to semiconductor devices.

The Dependence of the Memory Effect in ZnS:Mn A-C Thin Film Electroluminescence on Mn Distribution

V. Marrello and A. Onton

IBM Research Laboratory, San Jose, California 95193

ABSTRACT

It is known that the width of the memory loop of the brightness-voltage characteristic in ZnS:Mn a-c thin film electroluminescence devices depends on the Mn doping concentration and on the ZnS:Mn film thickness. In this study we have varied the ZnS thickness fraction doped with Mn and its location. The results of this study show that the memory loop widens incrementally with the ZnS thickness fraction doped with Mn. We infer that the Mn doping is affecting the high-field bulk conductivity of the ZnS.

The "memory effect" in ZnS a-c thin film electroluminescence (EL) is related to the Mn doping of the ZnS (1). In addition, studies have shown that the width of the "memory loop," *i.e.*, the width of the hysteresis in the brightness-voltage characteristic, is a function of the Mn doping concentration (2, 3) and the ZnS:Mn film thickness (3, 4). The Mn doping can influence the memory effect by affecting the bulk conductive properties of the ZnS and or by introducing electronic trapping states near the ZnS-dielectric interface. The purpose of this study was to determine the relative importance of these effects on the "memory effect."

Key words: electroluminescence, ZnS:Mn, thin film device.

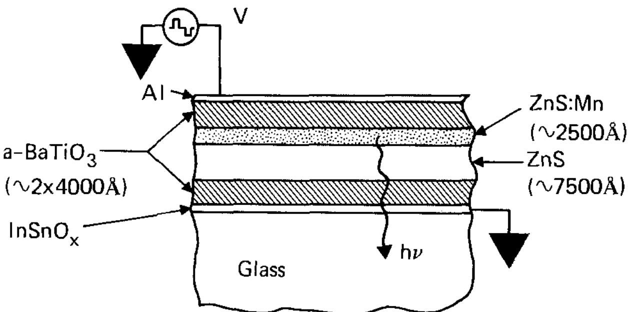

Fig. 1. A schematic cross section of a particular ZnS a-c thin film EL device used in this study having one-fourth of the ZnS film thickness doped with Mn and located at the "top" of the ZnS film.

This study was further stimulated by a recent result (5) that the Mn EL efficiency decreases strongly with distance from the cathodic to anodic region of the ZnS. In analogy with those measurements on EL efficiency (5), we measured the dependence of the "memory loop" width on the ZnS thickness fraction doped with Mn and its location.

For this purpose similar sets of three devices were fabricated by sequential depositions of sputtered a-$BaTiO_3$, evaporated ZnS, and sputtered a-$BaTiO_3$ without breaking vacuum. During the ZnS deposition, the substrate temperature was ~175°C, resulting in a sticking coefficient of ~2/3. Within a set, devices having 1/4, 1/2, and 3/4 of the ZnS thickness doped with Mn were made. The ZnS was doped by co-evaporation of Mn. The Mn concentration in the doped region amounted to ~0.7 atomic percent. The device structure is shown schematically in Fig. 1 for a particular device which had the "top" one-fourth of the ZnS doped with Mn. Four such sets of devices were prepared with the Mn doping distributed as shown in the inserts to Fig. 2.

The brightness-voltage amplitude characteristics of such unaged devices were measured using 20 μsec wide, alternating polarity, voltage pulses at 2 kHz. The results are shown in Fig. 2 where we have plotted the "memory loop" width as a function of the ZnS thickness fraction that is Mn doped. Similar devices, with entirely undoped ZnS or with uniformly Mn doped ZnS had "memory loop" widths of 0 and 10% V_{th}, respectively. The results shown in Fig. 2 indicate that memory loop width increases with an increase in the fraction of the ZnS thickness doped with Mn for each set of devices. Also, for a given ZnS thickness fraction doped with Mn, the "memory loop" width depends on the location of the Mn doping. To facilitate comprehension of the data, they have been separated into four groups in Fig. 2: curve (a) Mn doping proceeding from the "top" down, curve (b) Mn doping proceeding from the "bottom" up, curve (c) outside in, and curve (d) inside out. We observe that:

1. The Mn doping of the first 1/4 thickness of the ZnS to deposit has negligible effect on the "memory

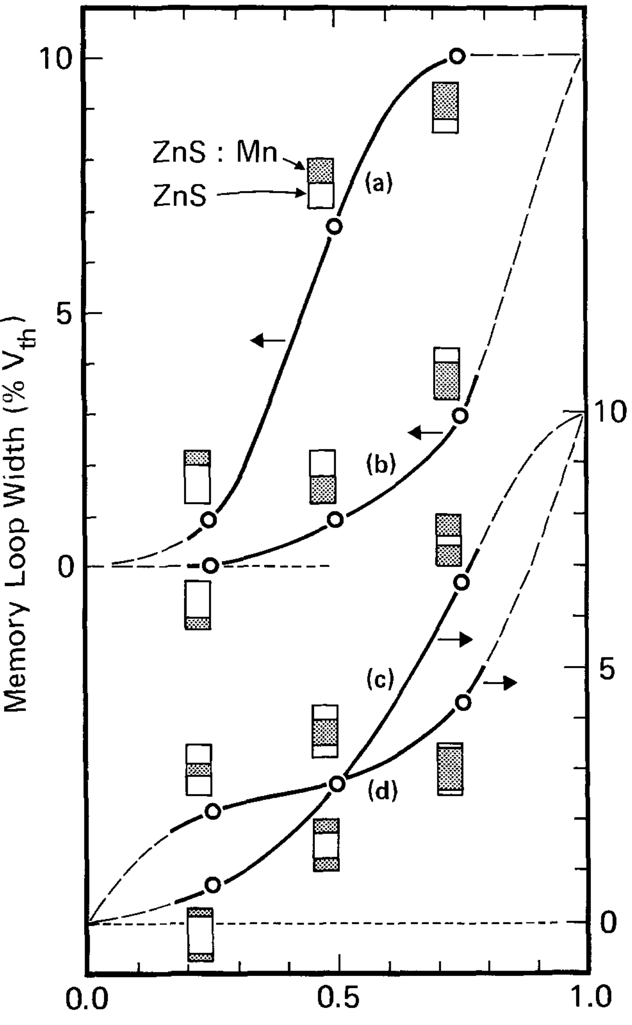

Fig. 2. The ZnS:Mn a-c thin film EL "memory loop" width in units of percent of the EL voltage threshold (~200V in these devices) as a function of the ZnS thickness fraction doped with Mn. The inserts show graphically the placement of the Mn doping in the ZnS layer. The bottom of the insert corresponds to the first to deposit ZnS.

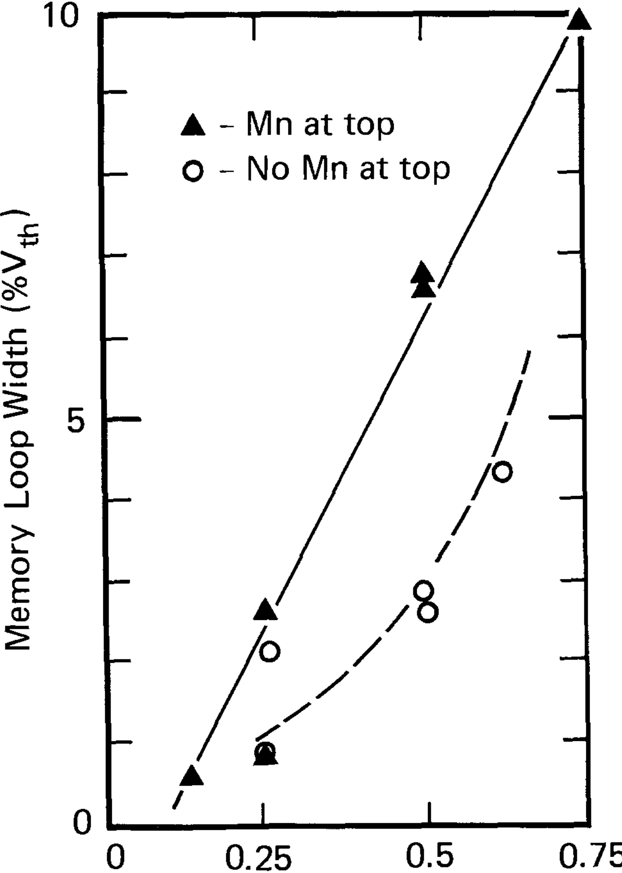

Fig. 3. The data on the "memory loop" width as a function of the ZnS thickness doped with Mn from Fig. 2 replotted omitting the effects of the "bottom" one-fourth of the ZnS and categorizing the data by whether the "top" layer was or was not doped with Mn.

loop" width when present, in curve (b), thickness fraction 1/4, (b, 1/4), or absent (a, 3/4). We speculate that this is related to poor morphology of the first to grow ZnS since it has been found that the EL efficiency in this region is also low (5).

2. Excluding the bottom 1/4 of the device from consideration, we find a satisfactory agreement of the "memory loop" width in devices (a, 1/4) = 0.9 and (c, 1/2) = 2.7, as well as in devices (b, 1/2) = 0.9 and (d, 1/4) = 2.2. These results are equivalent within the device fabrication reproducibility.

3. Although Mn doping near the top of the ZnS is not sufficient to produce a wide "memory loop" width alone, absence of Mn doping there has the most degrading effect on the "memory loop" width.

The last observation, 3 is illustrated in Fig. 3, where the "memory loop" width data presented in Fig. 2 has been replotted with the following modifications: (*i*) The bottom one-fourth of the device has been excluded, and (*ii*) the data have been categorized as to whether the Mn doped fraction did or did not include the top layer. The incremental "memory loop" width is related linearly to the ZnS film thickness fraction doped with Mn when the "top" interface is doped with Mn. Adding Mn to the "top" ZnS layer has a distinct (~ factor of 2) effect on the incremental "memory loop" width. Presumably the same phenomena would occur at the "bottom" interface if the ZnS morphology were comparable to that at the "top" interface. We conclude that the "memory effect" phenomenon is related strongly to bulk conductivity characteristics produced by the Mn doping. The general behavior is consistent with the presence of bulk differential negative resistance in ZnS:Mn, The detailed analytical dependence is undoubtedly complicated by the nonuniformity of the ZnS in the thickness direction, filament formation (6), as well as the internal field enhancing polarization phenomenon (4) which by themselves can lead to a hysteresis under suitable conditions such as have been studied for the case of the a-c plasma panel (7). This latter component, the internal field enhancement phenomenon, in the hysteresis is most likely what gives rise to the increase in the "memory loop" width as Mn doping is added to the "top" layer of the ZnS film. This is because the field enhancement phenomenon involves charge storage at the ZnS/dielectric interface which is also affected beneficially with respect to memory loop width by Mn doping of the ZnS.

Gas Phase Composition in the Low Pressure Chemical Vapor Deposition of Silicon Dioxide

P. J. Tobin,* J. B. Price,* and L. M. Campbell

Motorola Semiconductor Products Group, Integrated Circuits Division, Mesa, Arizona 85202

ABSTRACT

The gas phase composition during the low pressure chemical vapor deposition of silicon dioxide from silane and oxygen at 360°C has been studied as a function of oxygen to silane mole ratio. The total input flow was constant at 100 sccm. For each mole ratio, the system pressure, deposition rate, and exhaust gas composition were measured. Hydrogen was the major gaseous reaction product. A small amount of water was produced in a secondary reaction. Pressure variation with oxygen to silane ratio has been interpreted in terms of the variation of the exhaust gas viscosity with its composition. A theoretical calculation of the pressure in the system has shown good agreement with the experimental result. The dependence of total reaction efficiency and wafer reaction efficiency on O_2/SiH_4 was determined and used to deduce the efficiency of the reaction which occurs on other surfaces in the system or in the gas phase.

The chemical vapor deposition of thin films of SiO_2 using SiH_4 and O_2 at atmospheric pressure and low temperature (up to 450°C) is a process which has been well studied and widely used in the semiconductor industry (1).

Recently, the technology of low pressure chemical vapor deposition (LPCVD) has been extended to this reaction (2-4). The introduction of commercial LPCVD systems with arsenic and phosphorus doping capability (5), along with the acknowledged economic advantages of this technology (6), ensures wider application in the future (7).

In this work, an LPCVD system designed for the deposition of SiO_2, undoped or doped (8), was used to study some characteristics of the oxidation of silane to produce undoped SiO_2 on silicon wafers.[1] Specific-

[1] Work on doped films is in progress.

ally, the deposition rate and the composition of the effluent gas were measured as a function of the composition of the input gas. An important aspect of the results to be described is the relationship between the effluent gas composition and the system pressure. Since pressure is easily measured and often used as a process control parameter, application of these results can be useful for the establishment or affirmation of the desired operating conditions.

Previous studies of this reaction at 15°-100°C showed that the oxidation of silane is a typical chain reaction, exhibiting the characteristic phenomena of an upper and lower critical explosion limit (9). In that work, water was the only gaseous product detected suggesting the overall reaction

$$SiH_4 + 2\,O_2 \rightarrow SiO_2 + 2H_2O$$

More recently, the controlled oxidation of silane under conditions characteristic of 1 atm CVD has been reported (10, 11). In the work of Strater (10), nitrogen carrier gas with 0.4% SiH_4 and 0.8% O_2 flowed through a quartz chip filled gas reactor the temperature of which was varied from 240°-450°C. Use of a spectrophotometer to analyze the effluent gases led to the conclusion that H_2 rather than H_2O vapor is formed. A material balance of a partially complete SiH_4-O_2 reaction at 241°C suggested that any other gaseous reaction product, if present, would be below the 2% level for the conditions studied. These experiments therefore led to the conclusion that the best equation which would describe the SiH_4-O_2 reaction is the following one

$$SiH_4 + O_2 \rightarrow SiO_2 + 2H_2$$

It will be shown in this work that during low pressure CVD of SiO_2 on Si wafers at 360°C, the major gaseous product of SiH_4-O_2 reaction is H_2. A significant, but considerably smaller, amount of H_2O vapor is also produced.

These results are not necessarily inconsistent with the results of the work previously described. The absence of carrier gas and the low reaction pressure in the LPCVD case (~0.5 Torr) could significantly alter the kinetics of the oxidation, thereby affecting the effluent gas composition.

Experimental Techniques

The LPCVD system used for these experiments employs an enclosed, stainless steel, wafer boat (8). The enclosure was fabricated from perforated metal. Reactant gases are delivered to the center zone of a quartz diffusion tube using two metal tubes. A number of small holes in the wall of each tube distribute the gas along the length of the wafer boat. Oxygen is supplied by one manifold and SiH_4 by the other. A mechanical pump connected to the system through a tee evacuates the diffusion tube from both ends.

The pressure in the system was measured at the end cap (8) with a capacitance manometer.[2] The effluent gas was sampled at the same point for compositional analysis. This analysis was performed with a UTI Model SS-20 Gas Sampler in conjunction with a UTI Model 100C Precision Mass Analyzer.[3] In order to sample gases at pressures greater than 50 mTorr (the specified maximum inlet pressure for the SS-20 Gas Sampler) a variable leak valve[4] was installed between the LPCVD system and the sampler inlet. Use of this valve enabled the pressure in the mass analyzer to be maintained below 5×10^{-6} Torr, thus assuring linear detector response, even though the LPCVD system pressure was typically 0.3-0.5 Torr.

The possible influence of the sampling process on the measured composition must be considered. In general, such a technique may introduce some degree of mass selectivity. However, for a properly designed system such as the one employed in this work, the relative partial pressures in the mass analyzer are the same as in the system being sampled as long as the gases do not have greatly differing adsorption coefficients (12).

The potential magnitude of errors introduced by differential adsorption are difficult to evaluate. In the present work other data which corroborate the results of mass analysis support the view that any errors introduced in the sampling process are insignificant.

The experimental procedure consisted of establishing O_2 and SiH_4 input flows corresponding to O_2 to SiH_4 mole ratios in the range of 0.4-10 with the total flow, O_2 plus SiH_4, maintained constant at 100 sccm.[5] For each mole ratio, the deposition rate during a 1 hr run was measured using 10 test wafers which were distributed uniformly within a total boat load of 67 wafers (3 in.). Wafer spacing was 9.5 mm (3/8 in.). Film thickness was measured with a Nanometrics Film Thickness Analyzer.[6]

During the deposition, the effluent gas composition was measured by repeatedly scanning the mass range, 2-50 AMU and recording the output of the ion detector on a strip chart recorder. The pressure in the LPCVD system was simultaneously measured with a precision of approximately 0.3%.

Experimental Results and Discussion

Gas composition analysis.—A typical spectrum of the effluent gas is shown in Fig. 1. The current in the ion detector is shown plotted as a function of the mass to charge ratio (m/e) of the detected species. Due to cracking of the exhaust gas components in the quadrupole detector, each species is represented by a series of peaks. Occurrence of cracking fragments from two gas components of the same mass value[7] can complicate interpretation of the spectra. For example, measurement of a pure O_2 spectrum shows that most of the O_2 is detected as O_2^+ at 32 AMU. During deposition this ion detector current occurs at the same mass value as the current from SiH_4^+. To avoid this problem, cracking fragments having mass values at which there was no overlap were used to monitor the parent gas concentration. A cracking pattern measured for the parent

[5] Calibrated flow tubes were used for gas flow measurement.
[6] Nanometrics Incorporated, Sunnyvale, California 94086.
[7] Since all of the species detected were singly charged, identification can be made in terms of mass alone.

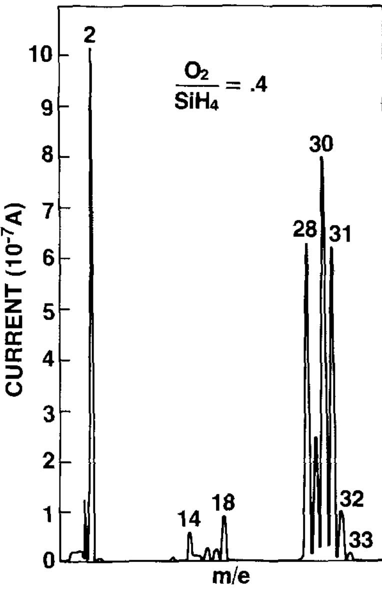

Fig. 1. Spectrum of the effluent gas for O_2/SiH_4 = 0.4. T = 360°C. Pressure = 380 mTorr. Total flow = 100 sccm.

gas alone was then used to infer the total detector current for the parent species.

The problem of overlap is shown in detail in Table I where the major cracking fragments of each effluent gas component are shown. Since SiH_2^+ has no interference and is a major component in the cracking pattern of SiH_4, this peak was used to monitor the SiH_4 concentration.

The peak at 16 AMU was used to monitor O_2 concentration since the O^+ signal from H_2O is very small (2%). The amount of water vapor was determined from the H_2O^+ detector current at 18 AMU.

In order to determine the concentration of H_2 in the effluent gas using the H_2^+ ion current, it was necessary to first subtract out that portion of this current which arose from cracking of SiH_4. This was accomplished by first measuring the ratio of the detector current at 2 AMU (H_2^+) to that at 30 AMU (SiH_2^+) for a pure SiH_4 spectrum. This ratio, together with the 30 AMU signal during the deposition run, was used to calculate that portion of the 2 AMU signal due to cracking of SiH_4. The remainder of the signal amplitude at 2 AMU was identified with H_2 reaction product.

Calculation of the mole percent of each gas, M_i, was accomplished using the following approximate equation (13)

$$M_i = 100 \times \frac{\sum_{j=1}^{N} I_j}{\sum_{j=1}^{M} I_j} \quad [1]$$

The sum in the numerator extends over the ion currents arising from cracking fragments of species i while the sum in the denominator represents the total detector current for all cracking fragments of all four effluent gas species. Since no corrections were applied for mass dependent electron multiplier gain and quadrupole transmission (13, 14), the data to be presented may be only semiquantitatively correct, so far as relative concentrations at a particular O_2/SiH_4 are concerned. However, measurements of deposition rate and system pressure given below support the validity of the conclusions drawn from these data. The variation of composition with O_2/SiH_4, on the other hand, is much less affected by the use of the approximate expression (Eq. [1]) since quadrupole transmission and multiplier gain are fixed instrumental constants.

The results of the compositional analysis are shown in Fig. 2. The silane concentration decreases and the O_2 concentration increases with increasing O_2/SiH_4. Hydrogen is a major oxidation product whose concentration passes through a maximum at $O_2/SiH_4 = 1$. Water is detected as a secondary product with a maximum concentration (10%) occurring at $O_2/SiH_4 = 2$.

The average deposition rate, like the hydrogen concentration, has a maximum value (175Å/min) at $O_2/SiH_4 = 1$ (Fig. 3). These results suggest that the following equation represents the primary reaction

$$SiH_4 + O_2 \rightarrow SiO_2 + 2H_2 \quad [2]$$

Table I.

m/e	Silane	Water	Oxygen	Hydrogen

while a secondary reaction represented by the following equation

$$SiH_4 + 2\,O_2 \rightarrow SiO_2 + 2H_2O \quad [3]$$

occurs simultaneously. The stoichiometric ratios of O_2/SiH_4 for maximum H_2 and H_2O production, 1 and 2, respectively, coincide with the maxima shown in Fig. 2.

System pressure.—In this section, it will be shown that analysis of the variation of system pressure with O_2/SiH_4 lends further support to the identification of the hydrogen producing reaction (Eq. [2]) as the major one. The uppermost curve in Fig. 4 gives the dependence of system pressure on O_2/SiH_4 (top scale). A weak minimum is observed at $O_2/SiH_4 = 1$. This is shown in the following to be due to a minimum in the viscosity of the effluent gas which occurs at $O_2/SiH_4 = 1$.

The lower two curves in Fig. 4 show the pressure in the system when O_2 or SiH_4 alone is introduced into the system at the same flow value which it had under reaction conditions. The magnitude of the two flows may be read at the bottom of the figure. Even though the primary reaction (Eq. [2]) conserves volume, the sum of the pressures of O_2 and SiH_4 alone does not equal the pressure when both gases flow simultaneously (Fig. 4). This is due to variation in the viscosity of the effluent as is demonstrated below.

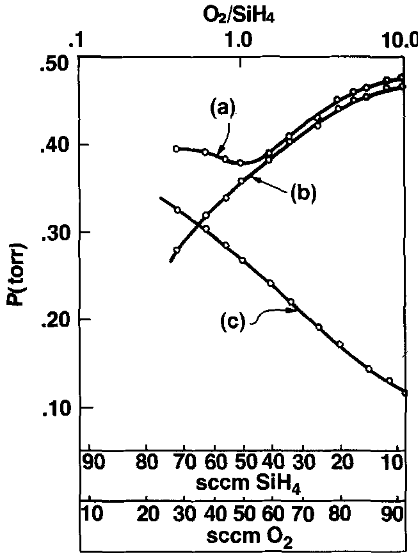

Fig. 4. (a). System pressure during reaction (O_2 and SiH_4) vs. O_2SiH_4 (upper scale). (b) System pressure with O_2 only flowing vs. input O_2 flow (lower scale). (c) System pressure with SiH_4 only flowing vs. input SiH_4 flow (lower scale).

An analysis of the fluid flow in the system may be based on the Poiseuille equation for viscous flow in a straight tube as follows (15)

$$Q = \frac{\pi a^4}{8L}\frac{1}{\eta}P_{avg}(P_i - P_o) \quad [4]$$

where Q = throughput (Torr-liter/min), a = tube radius (cm), L = tube length (cm), η = viscosity of the gas (centipoise), P_i = inlet pressure (Torr), P_o = outlet pressure (Torr), and $P_{avg} = \frac{1}{2}(P_i + P_o)$ (Torr). It is now assumed that the above equation can be applied to the more complicated tube configuration (Fig. 5) which is employed in the LPCVD system (8), the geometrical constants in Eq. [4] being replaced by an experimentally determined constant, K. The inlet pressure is identified with the pressure in the process tube and P_o with the pressure at the pump. By absorbing numerical factors into K, Eq. [5] can be applied to the present situation in the following form

$$Q = K\frac{1}{\eta}(P_i^2 - P_o^2) \quad [5]$$

The throughput, Q will therefore vary linearly with $P_i^2 - P_o^2$. The constant of proportionality, K/η along with a viscosity value for the gas may be used to deduce K. Pressure and flow data for SiH_4 and O_2 were analyzed in this manner using linear regression analysis. The coefficient of correlation in both cases was 0.999. The derived values for K/η and K are summarized in Table II. Viscosity values for SiH_4 and O_2 were taken from a tabulation by the flow tube manufacturer (15).[8] As required by Eq. [5], the value of K is independent of the gas species (within 3%).

Using the experimentally determined value of K, Eq. [5] should be valid as the composition and, therefore, the viscosity of the effluent varies with O_2/SiH_4 under reaction conditions.

[8] Room temperature viscosity values (23°C) were used since the effluent gases quickly cool to ambient temperature as they enter the vacuum pumping line.

Table II.

	K/η (liter/Torr-min)	η (cp)	$K\left(\frac{\text{cp-liter}}{\text{Torr-min}}\right)$
O_2	400	0.02045	8.18
SiH_4	671	0.0115	7.71
			Avg. 7.94 ± 0.23

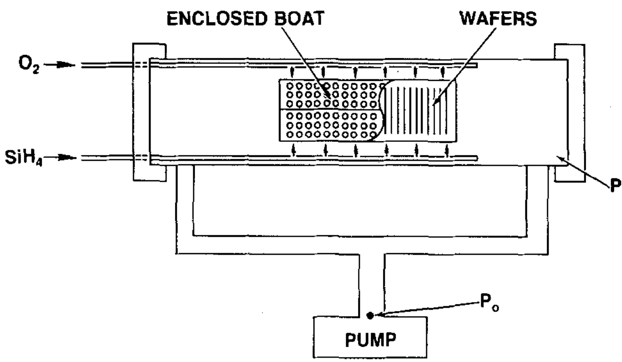

Fig. 5. Schematic of the LPCVD pumping system

To test the validity of this expression in that case the kinetic theory model of Chapman and Enskog (17), as refined by Wilke (17), was used to calculate the viscosity of the effluent gas mixture as a function of O_2/SiH_4. According to this theory, the viscosity of a mixture of O_2, SiH_4, H_2, and H_2O can be calculated by means of the following expression

$$\eta = \sum_{i=1}^{4} \frac{X_i\eta_i}{X_i + \sum_{\substack{j=1 \\ j\neq i}}^{4} \phi_{ij}X_j} \quad [6]$$

where η_i = viscosity of the ith component, X_i = mole fraction of the ith component, and ϕ_{ij} = interaction coefficient, i with j. Values of ϕ_{ij} were determined from the nomogram constructed by Brokaw (17). Viscosity values used for H_2 and H_2O are 0.0085 and 0.00926 cp, respectively (16). Viscosities for O_2 and SiH_4 are given in Table II. The results of the exhaust gas analysis shown in Fig. 2 were used for the mole fractions, X_i.

The results of the calculation were combined with Eq. [5] to derive a relation between the system pressure and the incoming O_2/SiH_4. The input value of 76 Torr-liter/min was used for Q since the major reaction (Eq. [1]) conserves gas volume. That is, the throughput at the entrance to the pump-out line is almost equal to the throughput at the inlet to the process tube before any reaction takes place.

The results of the calculation are compared with a replot of the experimental data in Fig. 6. Clearly the agreement is quite good. Closer inspection of the theoretical expression for viscosity (Eq. [6]) shows that the minimum at $O_2/SiH_4 = 1$ is due to the large H_2 concentration in the system (Fig. 2). Hydrogen, being the least viscous component in the effluent gas, lowers the viscosity of the mixture to a minimum value which in turn leads to the pressure minimum at $O_2/SiH_4 = 1$ shown in Fig. 6.

Reaction efficiency.—The data shown in Fig. 2 may be used to calculate the overall percent SiH_4 reacted, herein referred to as total reaction efficiency. For example, at $O_2/SiH_4 = 2$, approximately 2.4% of the effluent gas is SiH_4. From Fig. 4, the input SiH_4 concentration under these conditions is 33.3% (33.3 sccm out of a total of 100 sccm). Thus, the incoming SiH_4 is 93% reacted (30.9/33.3 × 100%). This figure for the efficiency of the reaction includes SiO_2 deposition on the walls of the diffusion tube and boat, gas phase reaction, and deposition on the wafer surfaces. The variation of total efficiency with O_2/SiH_4 is shown as curve (a) in Fig. 7. For $O_2/SiH_4 < 1$ the total efficiency is low simply because

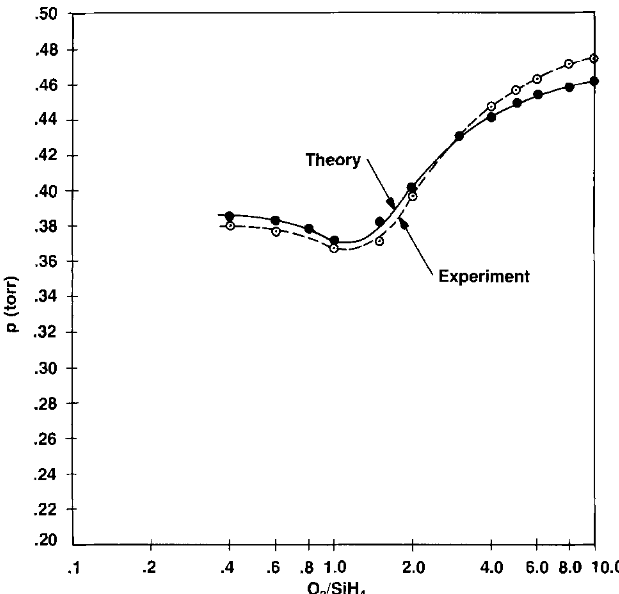

Fig. 6. System pressure vs. O_2/SiH_4. Theory, solid curve; experiment, dashed curve.

there is less than a stoichiometric amount of O_2 available. The total efficiency reaches a maximum of 93% at $O_2/SiH_4 \approx 2.0$ and then drops slightly as O_2/SiH_4 increases further. This decrease may be due to inhibition by excess oxygen. That is, stoichiometric units of SiO_2 take longer to form because excess oxygen retards the incorporation of the necessary Si.

The efficiency of deposition on the wafers alone can be calculated from the data in Fig. 3 and 4. Using the total wafer surface area, the density of LPCVD SiO_2 (2.25 g/cm³)[9] and the stoichiometric relation that 1.25g SiO_2 form per 1 liter SiH_4 reacted, the following numerical relationship was derived

$$\text{reaction efficiency on wafers} = \frac{\text{dep. rate (Å/min)}}{\text{input } SiH_4 \text{ (sccm)}} \times 5.18$$

The results of this calculation are plotted as curve (b) in Fig. 7.

Although the wafer reaction efficiency shows the same general trend as the total efficiency [curve (a)], the rise to a maximum of 27% at $O_2/SiH_4 \approx 3$ occurs more gradually. Further, the decrease in efficiency at higher O_2/SiH_4 is smaller for curve (b) than for curve (a).

[9] Determined gravimetrically.

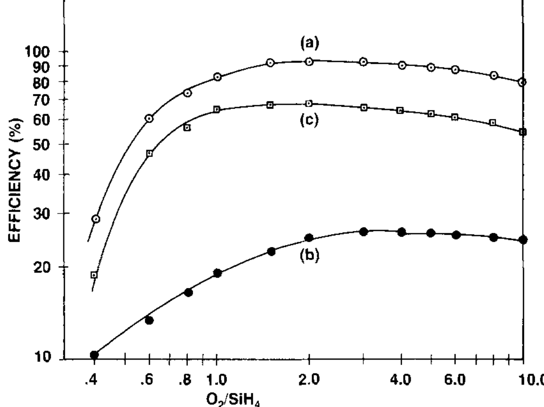

Fig. 7. Percent SiH_4 reacted vs. O_2/SiH_4. Curve (a), Total reaction; curve (b), wafers only; curve (c), other surfaces plus gas phase reaction.

Subtraction of the wafer efficiency from the total efficiency yields curve (c) which corresponds to the reaction on all surfaces except the wafers plus any gas phase reaction. Comparison of (b) and (c) leads to the conclusion that unwanted deposition, which often leads to particulate contamination, is minimized by operation at $O_2/SiH_4 > 3$. Other considerations, however, such as high deposition rate, may require compromise in the choice of O_2/SiH_4.

The exact relationship between the lower two curves in Fig. 7 may depend on system geometry, boat and tube design, as well as constructional material. The general trend, however, is probably characteristic of LPCVD SiO_2 systems.

Summary and Conclusions

The LPCVD of SiO_2 from SiH_4 and O_2 at 360°C was studied as a function of O_2/SiH_4 with the total flow fixed at 100 sccm. A residual gas analyzer was used to measure the gas phase composition for each O_2/SiH_4. Deposition rate and system pressure were also measured for each experimental run.

Analysis of the results of the gas phase composition measurements lead to the conclusion that the primary reaction produces H_2 as its gaseous by-product according to the following equation

$$SiH_4 + O_2 \rightarrow SiO_2 + 2H_2$$

A smaller amount of the SiH_4 (~10% max) oxidizes by the following reaction which has H_2O as a gaseous by-product

$$SiH_4 + 2\,O_2 \rightarrow SiO_2 + 2H_2O$$

The deposition rate showed a maximum at $O_2/SiH_4 = 1$ strongly supporting the identification of the hydrogen producing reaction as the primary one.

The pressure in the system passed through a weak minimum at $O_2/SiH_4 = 1$. Analysis showed that variation in the viscosity of the effluent gas with incoming O_2/SiH_4 produces the pressure minimum. A kinetic theory model for the viscosity of the four component gas effluent was used to derive a theoretical prediction for variation of pressure with O_2/SiH_4. The theoretical result agrees quite well with the data, reproducing the pressure minimum observed at $O_2/SiH_4 = 1$.

Data on input flows and effluent gas composition were used to calculate the percent of the incoming SiH_4 reacted in the process tube (*i.e.*, the total efficiency) as a function of O_2/SiH_4. This efficiency pertains to deposition on the wafers and all other surfaces (boat plus tube walls), as well as gas phase reaction. The efficiency has a maximum value of 93% at $O_2/SiH_4 = 2$ and drops slightly for higher O_2/SiH_4. The reaction efficiency on the wafers alone was calculated from the deposition rate and the input flows. These results showed that a maximum of 27% of the incoming SiH_4 produces SiO_2 on the wafers. Comparison of the two efficiency curves suggested that $O_2/SiH_4 > 3$ minimizes unwanted reaction.

Segregation of Arsenic to the Grain Boundaries in Polycrystalline Silicon

B. Swaminathan,* E. Demoulin,[1] T. W. Sigmon, R. W. Dutton, and R. Reif**,[2]**

Integrated Circuits Laboratory, Stanford University, Stanford, California 94305

ABSTRACT

The arsenic distribution in polycrystalline silicon films deposited on single crystal silicon and on oxide, was measured using 2.2 MeV, $^4He^+$ ion backscattering, after various high temperature annealing steps. Pile up of arsenic was observed at the interfaces of the deposited films. This can be interpreted in terms of a model based on segregation of arsenic to the grain boundaries in the films.

There has been some controversy in the attempts to explain the higher resistivity observed for polycrystalline silicon when compared to monocrystalline silicon for similar doping concentrations. One model (1) proposes that the dopant atoms are trapped at the grain boundaries in the polycrystalline silicon where they are electrically inactive. The other model suggests (2) that the dopant atoms are distributed evenly throughout the polycrystalline silicon with the carriers trapped at the grain boundaries. In this paper we present evidence that there is some segregation of arsenic to the grain boundaries in polycrystalline silicon, contrary to what is reported for boron and phosphorus in a recent paper (3).

Most of the experiments involved 5000Å layers of polycrystalline silicon deposited at 620°C in a low pressure chemical vapor deposition reactor. Silicon wafers of <100> orientation doped with 10^{15} cm^{-3} of boron, both with and without 1000Å of thermal oxide were used as substrates for the deposition.

For the first set of experiments two identical quarter wafers of the polysilicon on single crystal silicon were used. One of these quarter wafers was annealed at 1200°C for 1 hr in a nitrogen ambient. Both wafers were then implanted with 10^{16} cm^{-2} of arsenic at 40 keV. Following the implant 5000Å of oxide were deposited on both wafers which were then annealed at 1000°C for 5 hr in a nitrogen ambient. The oxide was then removed from the wafers with hydrofluoric acid. The backscattering spectra, taken with 2.2 MeV $^4He^+$, are shown in Fig. 1(a) and (b) for the two samples (4). The higher energy portion of the spectra (>1.5 MeV) represent ^4He backscattered from the arsenic in the samples. Using the near surface approximation and a system energy calibration of 3.58 keV/channel, the depth scales shown on the figures can be obtained. It is seen that the arsenic distributions in both wafers are quite similar, the arsenic concentration in the polysilicon being approximately 1.4×10^{20} cm^{-3} in both wafers. However, for the sample which did not receive the 1200°C preanneal there is a pile-up of arsenic at the polysilicon/single crystal silicon interface. The calculated number of arsenic atoms in the peak at the interface is 3×10^{14} cm^{-2}. By tilting the sample 60° with respect to the analyzing beam it was determined that this region is less than 100Å thick.

The observed pile-up can be explained in terms of segregation of arsenic to the grain boundaries. Consider the four sections shown in Figure 2. Sections 1 and 4 are planes which lie on an interface between the polysilicon grains and either oxide or single crystal silicon. The interface between the polysilicon grains and the single crystal substrate is analogous to the interface between grains in the polycrystalline material. Sections 2 and 3, through the middle of the deposited layer could pass through an occasional grain boundary, but are mainly through the bulk of the grains. The backscattering measurement averages over the 1 mm square area of the incident beam, and therefore if the arsenic segregates to the interfaces of the grains, a pile-up would be

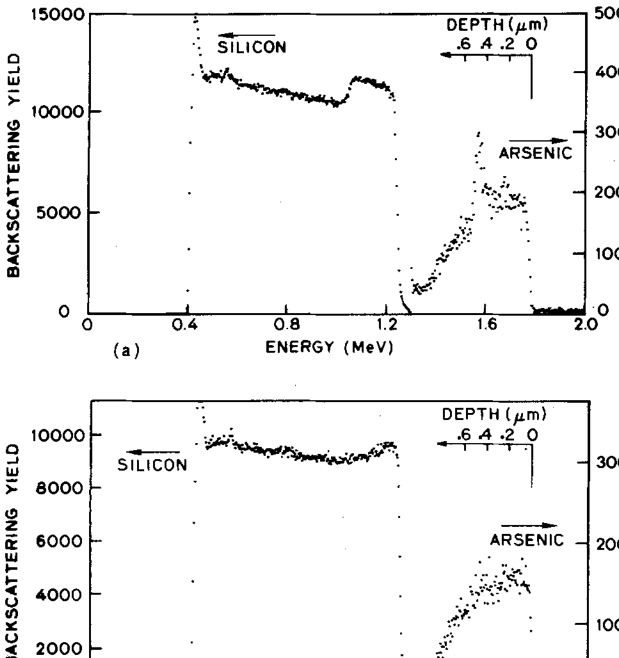

Fig. 1. (a) Energy spectrum of ^4He atoms backscattered from a 2.2 MeV $^4He^+$ beam incident on polycrystalline/single crystal silicon sample implanted with 10^{16} cm^{-2} of ^{75}As and annealed for 5 hr at 1000°C in nitrogen. (b) Backscattering spectrum from sample annealed at 1200°C for 1 hr before implantation and drive-in.

expected at both the top and bottom of the deposited layer.

There is no pile-up of arsenic for the sample pre-annealed at 1200°C, Fig. 1(b). This is because the 1200°C heat-treatment destroyed the grain structure of the deposited layer. Channeling measurements showed that the layer consists essentially of monocrystalline silicon oriented on the substrate, the residual defects being identified by TEM as a high density of twins and stacking faults.

The explanation of the arsenic pile-up in terms of segregation to the interfaces of the grains predicts a pile-up at both interfaces of the deposited layer. In Fig. 1(a), this pile-up is seen only at the bottom interface of the layer. This is believed to be caused by the removal of the arsenic at the polysilicon/oxide interface by the hydrofluoric acid used to etch away the oxide cap. To verify this an identical sample was measured with some of the oxide remaining. A pile-up was indeed observed at the polysilicon/oxide interface for this sample. Since the region in which the pile-up takes place is so easily removed by dilute hydrofluoric acid, further support is lended to the estimation of this region being less than 100Å thick. It is probably not more than a few monolayers thick.

The behavior of the polysilicon/oxide interface is somewhat different from that of polysilicon/single crystal silicon interface. To demonstrate this, a wafer with 5000Å of polysilicon deposited on oxide was implanted with 2×10^{15} cm^{-2} of arsenic at 100 keV. An oxide cap was deposited and the sample annealed at 1000°C in nitrogen for 1 hr. Another similar wafer was prepared with an implant dose of 10^{16} cm^{-2}. For the sample with the lower concentration of arsenic a pile-up was again observed at the polysilicon/oxide interfaces at the top and bottom of the deposited layer, see Fig. 3(a). For the sample with the higher concentration of arsenic no pile-up was evident, see Fig. 3(b). We believe that this is due to the saturation of sites at the interface to which the arsenic atoms tend to segregate. In the case of the polysilicon/oxide interface these sites appear to be saturated when the arsenic concentration in the polysilicon is approximately 2×10^{20} cm^{-3}. However for the polysilicon/single crystal silicon interface, pile-up was observed at arsenic concentration levels higher than 2×10^{20} cm^{-3}.

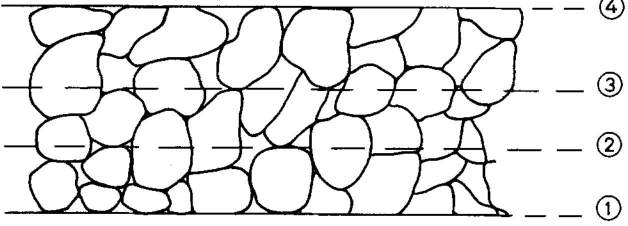

Fig. 2. Four sections through a polycrystalline layer

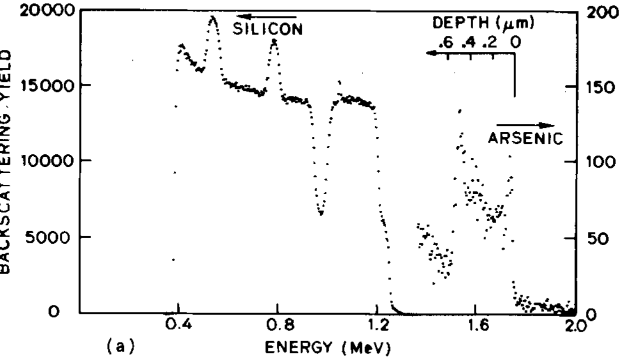
A possible objection to the explanation of the pile-up as a manifestation of segregation of arsenic to the grain boundaries, is that the pile-up could be caused by interfacial impurities. In fact there is probably a thin native oxide layer at the interface for the low pressure chemical vapor deposited polysilicon on single crystal silicon samples. The effect of interfacial impurities was tested by the following experiment. An epitaxial layer was grown on a <100> silicon wafer using silane in an atmospheric pressure epitaxial reactor. The temperature was reduced to 600°C in the same run, with the hydrogen flowing, and then 5000Å of amorphous silicon was deposited. The interface between the epitaxial layer and the amorphous layer can therefore be assumed to be free of impurities. Arsenic was implanted into the amorphous silicon at a dose of 10^{16} cm^{-2} and the sample annealed at 900°C for 3 hr in nitrogen. During the anneal the amorphous layer becomes polycrystalline. Backscattering analysis again showed that there was indeed an arsenic pile-up at the polysilicon/single crystal silicon interface.



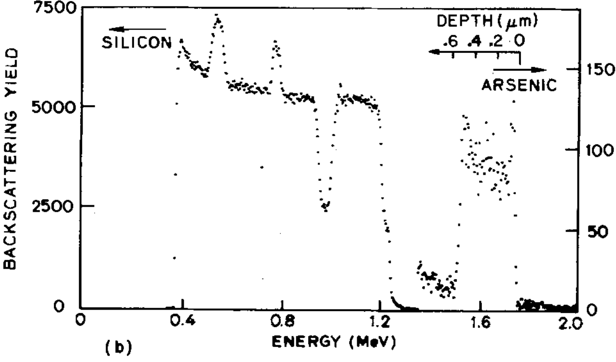


Fig. 3 (a) Backscattering spectrum using 2.2 MeV $^4He^+$ ions from sample of polysilicon deposited on oxide, implanted with 2×10^{15} cm^{-2} of ^{75}As and annealed at 1000°C in N_2 for 1 hr with a deposited oxide cap; spectrum taken with 1000Å of the oxide cap remaining. (b) Backscattering spectrum from similar sample with implantation dose of 10^{16} cm^{-2} ^{75}As.

Mandurah *et al.* (5) have recently made measurements of the resistivity of doped polycrystalline silicon films deposited on oxide, and from these measurements have deduced the existence of impurity trapping at grain boundaries. We measured the arsenic distribution in three of their samples. The samples were all 5000Å low pressure chemical vapor deposited polysilicon on oxide, and implanted with 2×10^{15} cm^{-2} of arsenic. One of the samples was annealed at 1000°C for 1 hr in nitrogen. The other two samples also received the 1000°C anneal and in addition were annealed in nitrogen at 900°C for 12 hr and at 850°C for 24 hr, respectively. The annealing times were chosen so that a steady-state value of resistivity was obtained for each annealing temperature. Pile-up of arsenic was observed in all three samples. Furthermore both the amount of the pile-up as well as the resistivity followed the same trend, being greatest for the sample annealed at 850°C and least for the sample annealed only at 1000°C.

Experiments were also performed in which polycrystalline silicon films deposited on single crystal silicon and implanted with arsenic, were oxidized in either dry or wet oxygen. The results for these samples were similar to those for the samples annealed in nitrogen. Pile-up of arsenic was again observed at the various interfaces.

Monkowski *et al.* (3) used a *C-V* technique to conclude that for boron and phosphorus, there is no segregation to the grain boundaries. The lowest temperatures at which their samples were annealed was 1225°C. Our experiments as well as those of Ref. (5) suggest that segregation to the grain boundaries is lower for polycrystalline samples annealed at higher temperatures. This could explain their negative results.

It is difficult to obtain quantitative information from the results presented here. However, an estimate of the percentage of arsenic present at the grains can be made for the sample annealed at 1000°C for 5 hr [Fig. 1(b)]. Let us assume that the grains are cubes 2500Å on side. The 5000Å polycrystalline film will consist of two layers of such cubes. Taking into account the shared faces of the cubes, there will be an equivalent of 7 cube faces to which the arsenic can segregate in the polycrystalline film. It was observed that 3×10^{14} cm^{-2} atoms are present at the polysilicon/single crystal silicon interface. This figure multiplied by 7 or 2×10^{15} cm^{-2} is the approximate number of arsenic atoms at the grain boundaries. Thus approximately one-third of the arsenic in the polycrystalline layer appears at the grain boundaries.

ABSTRACT

Electrolysis of the cell

$$(+)\ Pb/35\ m/o\ Na_2O\ \text{sodium borate glass}/Hg\ (-)$$

was investigated at 50°C, using a modified moving boundary method (in the anode region) based upon sodium and lead concentration profiles (obtained by ion beam ablation) and ultraviolet spectroscopy of the Pb^{2+} ion. It was found that Na^+ ions left the anode region for the cathode but, contrary to related experiments with silicate glasses, there was not an equivalent replacement by the Pb^{2+} ions generated at the anode. Instead, O^{2-} ions migrated to the anode and most of the Pb^{2+} ions formed PbO. It is suggested that a "structure-switching ion transport" mechanism operates, migration of the O^{2-} ions involving an interchange between threefold and fourfold coordination by the boron atoms as the oxygens are handed on from one borate group to the next. The ultraviolet spectrum of the small concentration of Pb^{2+} ions in the Na_2O-depleted anode region registered a lower basicity than the original glass (optical basicity values 0.49 and 0.60, respectively) but the sites were more basic than for a corresponding borate glass obtained from the melt.

Oxide glasses, such as silicate, borate, and phosphate glasses, usually are ionic conductors. Although most glasses are fairly good conductors when hot, at lower temperatures, *e.g.*, ambient temperature, the conductivity is very low, and for measuring any changes arising from the electrolysis (assuming a reasonable period of time) it is necessary to employ sensitive analytical techniques. For example, the combination of coulometry, subsurface cation concentration profiling [by the ion beam ablation method (1)] and absorption spectroscopy has recently been used for carrying out modified moving boundary experiments in alkali silicate glasses (2-4). The results of these experiments have shown that conductivity is due to the migration solely of metal ions. There appears to be no migration of O^{2-} ions, and presumably this is on account of the stability of the silicon-oxygen network.

The question arises as to what factors might allow O^{2-} ions to migrate when an oxide glass is electrolyzed. Perhaps the most obvious factor is the ability of the glass-forming cation to switch readily from one coordination number to another. In the case of silicate glasses, the silicon(IV) species is reluctant to be anything but four-coordinate. On the other hand, borate glasses are well known to contain boron in threefold and fourfold coordination, preference for one or the other depending directly on the proportion of O^{2-} ions originally used in making the glass (*i.e.*, the $NaO_2{:}B_2O_3$ ratio in the case of a sodium borate glass, for example). Thus, whereas electrolysis of a silicate glass results in the metal anode being converted to its cation with subsequent migration into the glass, it is possible, in the case of a borate glass, that the process of oxide ion migration to the anode will occur as an additional or even an alternative process.

If migration of both oxide ions and metal ions of the glass proceeds, this will result in a lowering of the basicity of the glass, since, for example in a sodium borate glass, there would be a loss of Na_2O. It would be useful therefore if the glass basicity could be monitored during the electrolysis. The basicity of glass has been probed very successfully by measuring the shifts in the ultraviolet spectra of s^2 metal ions such as Pb^{2+} (5, 6). The use of lead as anode material therefore suggests itself for experiments designed to invesigate ion migration in glasses. The intense and characteristic u.v. absorption of the Pb^{2+} ion should indicate whether the lead anode has formed Pb^{2+} ions which have entered the glass, and furthermore if this did occur, the position of the u.v. absorption maximum should reveal the basicity of the sites occupied by the Pb^{2+} ions.

These principles are exploited in the present study of ion migration in sodium borate glass.

Key words: migration, anode, spectroscopy.

Experimental

Thin plates ($20 \times 30 \times 0.5\ mm^3$) of a sodium borate glass containing 35 mole percent (m/o) Na_2O were vacuum-coated with a 50 nm thin layer of metallic lead covering an area of $10 \times 20\ mm^2$. The particular glass composition was chosen since it represented an optimum compromise of conductivity ($\sigma = 6 \times 10^{-10}\ \Omega^{-1}\ cm^{-1}$ at 50°C), ultraviolet transparency, and durability. The lead layer was contacted with a thin platinum wire and was made the anode of an electrolytic cell whose cathode was a pool of mercury on which the glass floated

$$(+)\ Pb/glass/Hg\ (-) \quad [1]$$

The cell was operated in argon atmosphere, and the total applied voltage of 800V generated a current density of 5-10 $\mu A\ cm^{-2}$ so that an electric charge of 0.01-0.05C was transported through the 0.5 mm thickness of glass during 15-90 min of electrolysis. Sparking between the edges of the lead layer and the mercury pool was eliminated by placing the glass plate in a PTFE box with open top and a $10 \times 20\ mm^2$ rectangular opening in the flat bottom through which the lower (uncoated) surface of the plate contacted the mercury cathode. This distorted the electric field through the gas space thus decreasing the field strength between the two metals.

After electrolysis the glass plate was removed from the mercury pool and the unreacted lead on the coated surface was dissolved in clean mercury. The resulting, optically transparent, glass was then subjected to a combined (ultraviolet) spectroscopic/ion ablation study in order to invesigate sodium and lead ion concentration profiles below the anodic surface.

The ion sputtering method for measuring concentration profiles (1), its application to moving boundary experiments in solids (2-4), and the principles of obtaining optical basicities from ultraviolet spectra (5, 6) have been detailed previously.

Contact between the lead layer and the platinum wire was made by a narrow stripe of platinum paint applied to the glass prior to vacuum deposition of the lead layer. It should be noted that such plates could be used only within a limited time (several weeks) after preparation. After longer periods, the electrical contact deteriorated and also the lead area covering the platinum became nonconducting. Presumably storage results in some of the lead being converted into PbO, the lead having behaved as the electrode of an electrically shorted cell involving the glass as electrolyte (with perhaps traces of water) and the platinum as the other electrode.

Results and Discussion

Figure 1a shows the sodium concentration profile from the surface inwards (to a depth of approximately 200 nm) for a sample of the 35 m/o Na_2O sodium borate glass. The concentration profile of another sample of the same glass, which had been coated with a thin film of metallic lead subsequently removed with mercury, was found to be identical to that in Fig. 1a, indicating that the lead coating treatment had no effect on the sodium ions in the glass. It is apparent from Fig. 1a that the sodium concentration of the bulk glass extends up to a few nm below the glass surface; the slight change within this region was caused by ion exchange involving adsorbed water molecules of the atmosphere during storage, which leads to the formation of protonated glass and of a layer consisting of sodium oxide, hydroxide, or carbonate, according to the conditions of storage, on the glass surface. This corrosion has been studied in detail previously (1, 7).

Figure 1b presents sodium and lead concentration profiles near the anodic glass surface after an electrolysis during which a charge of 0.049C was transported through the glass plate with subsequent removal of the metallic lead with mercury. It is apparent from the low sodium ion concentration in the anode region that there has been almost complete migration of the sodium ions towards the cathode. The ultraviolet absorption spectrum of the glass prior to subjecting the former anode surface to ion ablation (that is, just after dissolving away the unreacted lead with mercury) is shown in Fig. 2a. This is quite different from the spectrum of Pb^{2+} in sodium borate glass (which usually has a distinct peak in the range 42,000 cm^{-1} to 47,000 cm^{-1}) and strongly suggests that a process other than substitution of an equivalent quantity of Pb^{2+} ions for Na^{+} ions has occurred during electrolysis of the glass. The lead profile, obtained by ion ablation, (Fig. 1b) reveals a high lead concentration to a very short depth (about 20 nm) and then a very low concentration of lead to much greater depth. From previous experience of ion ablation experiments with PbO films on glass, carried out in these laboratories, it seems likely that the initially high lead concentration in Fig. 1b is due to the formation of PbO. Furthermore, the ultraviolet spectrum in Fig. 2a is very similar to that obtained for PbO vacuum deposited as a thin film, see Fig. 2b (the absorption of Pb^{2+} ions that have entered the glass does not significantly affect the spectral comparison). Thus, it appears that during the electrolysis, most of the lead which is anodically oxidized is converted into PbO.

In order to detect the remaining Pb^{2+} ions which had entered the glass, further samples of electrolyzed glass were subjected to sufficient ion ablation to remove the PbO and were scanned in the ultraviolet region. An example of the resulting spectra is shown in Fig. 3. It is typical of a solution of Pb^{2+} in sodium borate glass (5). Further experiments indicated that

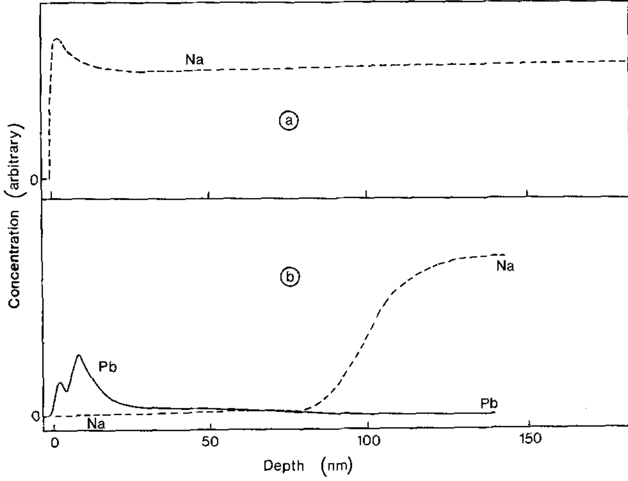

Fig. 1. (a) Sodium concentration profile below the surface of untreated sodium borate glass (35 m/o Na_2O). The same profile is obtained after vacuum deposition of thin lead layer (50 nm) and subsequent dissolution in mercury. (b) Sodium and lead concentration profiles near the anodic surface of a sodium borate glass covered with a 50 nm thick lead layer after electrolysis and subsequent removal of lead (see text for details). Total charge transported: 0.049C; current density: 8 μA cm^{-2}; 50°C.

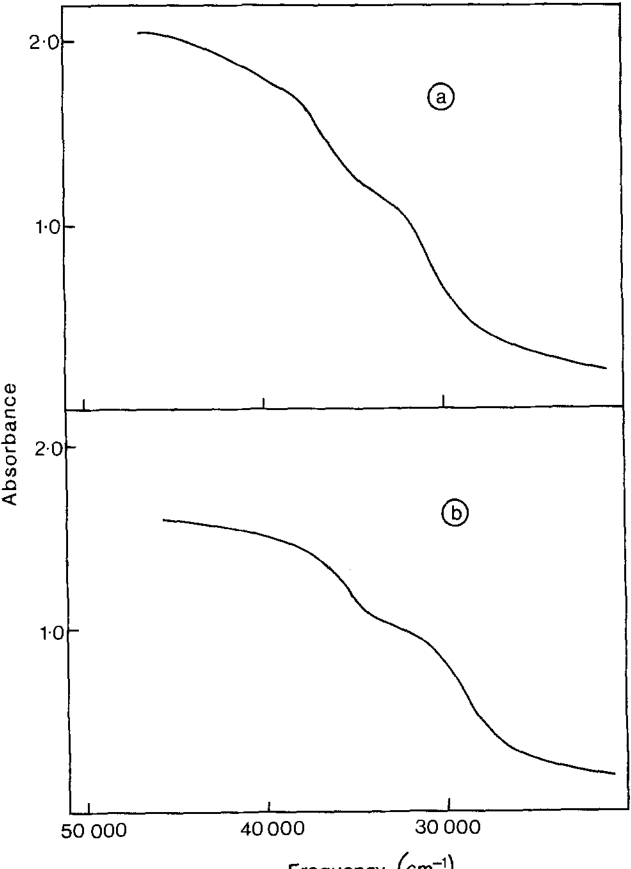

Fig. 2. (a) U.V. spectrum of a sodium borate glass after electrolysis and removal of lead anode [see Fig. 1(b) and text for details]. (b) U.V. spectrum of PbO film (40 nm) vacuum deposited onto vitreous silica substrate.

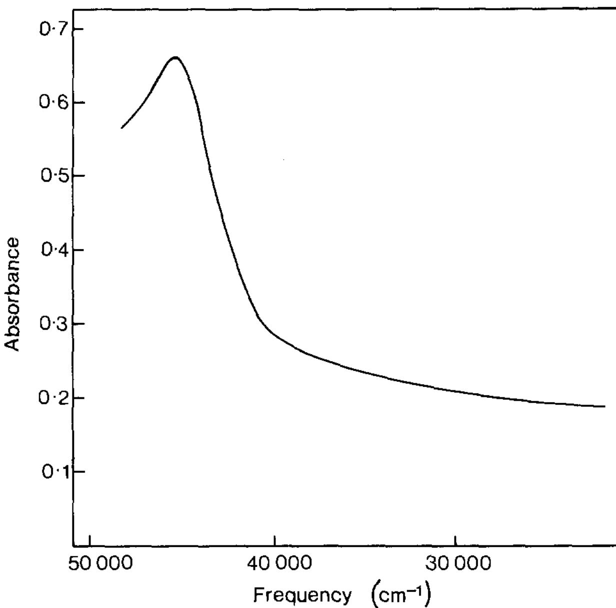

Fig. 3. U.V. spectrum of the sodium borate glass plate [of Fig. 2(a)], after removal of PbO layer.

at depths beyond the Na^+ concentration change, no Pb^{2+} was detectable.

Thus, the processes occurring in the anode region appear to be (*i*) migration of Na^+ ions towards the cathode, (*ii*) migration and formation of O^{2-} ions at the anode, (*iii*) oxidation of lead to Pb^{2+} ions, and (*iv*) combination of Pb^{2+} and O^{2-} ions to form PbO. This process is in contrast to those typically occurring in silicate glasses if truly nonblocking electrodes, *i.e.*, electrolyte solutions, are employed. For example, in the field-driven protonation of alkali silicate glass, all of the alkali ions are replaced by protons (2-4). It has been recently suggested, however, that small amounts of O^{2-} ions may be displaced towards the anode even in an $Li_2O\text{-}2SiO_2$ glass if completely blocking electrodes are applied (8).

Since the cell operates with only mercury as the cathode, it is reasonable to assume that the cathode reaction consists of Na^+ ion drift to the surface, their discharge, and dissolution of the sodium thus formed in mercury

$$Na^+ + e + (Hg) \rightarrow Na(Hg) \quad [2]$$

Combination of anode and cathode reactions yields the cell reaction

$$Pb + xNa_2O \cdot yB_2O_3 + (Hg) \rightarrow PbO + (x-1)Na_2O \cdot yB_2O_3 + 2Na(Hg) \quad [3]$$

In effect, this reaction is reversible, since after the electrolysis an emf of several hundred mV was observed which had the same sign as the electrolyzing voltage applied. Moreover, it was found that the electrolysis could be reversed to regenerate approximately the original glass composition, corresponding to Fig. 1a. Equation [3] therefore might represent a reversible battery process.

It was suggested earlier in this paper that the property of boron to switch its coordination between threefold and fourfold could assist the migration of O^{2-} ions. Since the results of the experiments indicate that O^{2-} ions have indeed arrived at the anode, it is worthwhile considering the possible transport mechanism. Of course, O^{2-} ions as such do not exist in the glass: the addition of ionic oxides, such as Na_2O, to a borate glass involves boron atoms increasing their coordination from three to four, rather than the introduction of O^{2-} ions. The stoichiometry of this process (but not the structural details since BO_4 units are seldom found linked directly to each other) may be represented by

$$Na_2O + \text{O-B(O)-O} + \text{B-O} \rightarrow 2Na^+ + [\text{O-B-O-B-O}]^{2-} \quad [4]$$

This is in contrast to the addition of a basic oxide to a silicate glass where instead bridging oxygens are converted to terminal. It is essentially the reverse of this reaction (Eq. [4]) which is invoked for the migration and formation of O^{2-} ions at the anode

$$[\ldots]^{2-} \rightarrow \ldots + O^{2-} \quad [5]$$

The above mechanism would represent the generation of O^{2-} at the anode, ready for combination with Pb^{2+} ions to form PbO. However, if the mechanism were extended so that instead of an O^{2-} ion being generated it was "handed over" by one of the four-coordinate boron atoms to a nearby three-coordinate boron atom (which then became four-coordinate), it can be appreciated how an apparent movement of oxide ions through the medium could be achieved. All that is required is a continuous interchange between threefold and fourfold coordination on the part of the boron atoms with an appropriate rotation or other slight oscillation of the borate groups. The conduction of the borate glass might therefore be described as a "structure-switching ionic transport."

Migration of O^{2-} ions rather than Pb^{2+} ions is obviously the favored process during the electrolysis (Fig. 1b). It is possible that Pb^{2+} migration is hindered owing to the larger size of Pb^{2+} compared with Na^+ (ionic radii are 1.20 and 0.96A, respectively). The primary reason, however, is perhaps the dipositive charge of the Pb^{2+} ion which would have to enter the glass where cationic sites were originally occupied by unipositive ions. The Pb^{2+} ion would occupy only one site (to which it would be relatively tightly bound) while, because of electroneutrality, one cationic site for each Pb^{2+} entered would have to remain without countercharge. This reasoning is supported by the observation (9) that silver ions do enter the borate glass when a silver rather than lead metal layer is made the anode in cell (Eq.

[1]), although the ionic radii of Ag^+ (1.26A) and Pb^{2+} (1.20A) are comparable. Silver oxide was not detected at the surface during these experiments. From the drastic increase observed for the resistance during the electrolysis of the silver-covered glass it must also be concluded that Ag^+ ions have a much lower mobility than Na^+ ions in the borate glass. Further, it appears that the presence of Ag^+ ions, once in the network (in the anode region), prevents the structure-switching mechanism of the borate groups, and thus it is possible that this mechanism only operates when a large proportion of metal ions (Na^+, Ag^+, etc.) have withdrawn from the network.

Because of the O^{2-} ion migration towards the anode during the electrolysis, a platinum anode is not expected to behave as a blocking electrode but to evolve oxygen. This expectation is supported experimentally by the observation that electrolysis with such an electrode results in only a minor increase in resistance, whereas for a silicate glass typical blocking behavior is observed. Furthermore, it is found that a proton-injecting electrode, consisting of a thin Pt layer on the glass in a dry hydrogen atmosphere, causes crystallization in the anode region (9). Obviously hydrogen ions produced at the Pt, H_2 anode combine with the O^{2-} ions to give water which reacts with the boric oxide glass to give boric acid, *i.e.*

$$6H^+ + 3\,O^{2-} + B_2O_3 \rightarrow 2H_3BO_3 \qquad [6]$$

This is not a good glass former and thus crystallizes.

With effective removal of Na_2O from the anode region, a marked decrease should be observed in the basicity compared with the original glass (see beginning of paper). Glass basicity is expressed conveniently on the optical basicity scale (5, 6) and most glasses have optical basicities, Λ, in the range 0.4-0.7. The 35 m/o Na_2O sodium borate glass has $\Lambda = 0.60$ (5, 6). It is possible to calculate the optical basicity registered by the Pb^{2+} ions that have entered the Na_2O-depleted anode region from the frequency maximum, 45,700 cm^{-1}, observed for the absorption band (Fig. 3) (5, 6)

$$\Lambda = \frac{61{,}000 - 45{,}700}{31{,}000} = 0.49$$

Thus, as anticipated, there is a decrease in optical basicity. This decrease, however, is less than expected, since the sodium on concentration profile (Fig. 1b) suggests that the Na_2O content of the anode region is no more than approximately 3%, corresponding to an optical basicity of around 0.44. The observed value corresponds to a sodium borate glass of 18 m/o Na_2O. The reason for this apparent discrepancy may be due to the sites available to the Pb^{2+} ions, that enter the glass, being markedly different from those adopted by Pb^{2+} when a glass is formed from the melt. This result is worth further study, especially using other anode materials which give rise to s^2 basicity probe ions, *e.g.*, thallium or bismuth.

New Complex Fluorides $EuMgF_4$, $SmMgF_4$, $SrMgF_4$, and Their Solid Solutions: Photoluminescence and Energy Transfer

E. Banks,* S. Nakajima, and M. Shone[1]

Department of Chemistry, Polytechnic Institute of New York, Brooklyn, New York 11201

ABSTRACT

Three previously unknown compounds, $EuMgF_4$, $SmMgF_4$, and $SrMgF_4$, and solid solutions, have been prepared by a method involving the use of Mg metal as a reducing agent for the Eu and Sm. Both $EuMgF_4$ and $SmMgF_4$ appear to be excited via a 4f → 5d transition (broad band). $EuMgF_4$ emits a bright blue under 356 nm peak excitation, the emission peak being at 437 nm. $SmMgF_4$ has sharp line emission assigned to $^5D_0 \rightarrow {}^7F_{0\text{-}6}$ transitions. In solid solutions $Sr_{1-x}Eu_xMgF_4$, maximum efficiency is found at $x = 0.75$ and the efficiency of $EuMgF_4$ is only about 5% less, adding $EuMgF_4$ to the small group of known "stoichiometric phosphors." This is correlated with magnetic measurements which show little or no exchange interaction between neighboring rare earth ions. The magnetic behavior of the Sm^{2+} ion in $SmMgF_4$ suggests the possibility of mixing of the $J = 0$ and $J = 1$ states of the ground state manifold, owing to strong acentric crystal fields. In solid solutions $Eu_{1-x}Sm_xMgF_4$, there is remarkable energy transfer from Eu^{2+} to Sm^{2+}, the Eu^{2+} emission being barely detected at $x = 0.01$ and completely absent at higher Sm concentrations. Evidence for both radiative and nonradiative transfer was found, but the nonradiative mechanism appears to predominate.

Compounds of the type $BaMF_4$ (M = Mg, Mn, Fe, Co, Ni, Cu, or Zn) crystallize in the orthorhombic space group $A2_1am$ (1-3). Over the past few years, several technologically useful properties have come to light. Among the most important properties are piezoelectric behavior in M = Mg, Co, Ni, Mn, and Zn (2), magnetoelectric effect in $BaCoF_4$ (4), greater piezoelectric coupling in $BaMnF_4$ than quartz, and excellent microwave ultrasonic transmission characteristics in this same compound (5).

Bergman *et al.* (6) reported $BaMnF_4$ and $BaMgF_4$ to be noncritically phase matchable at room temperature for a 1.06 μm pump laser and resistant to optical damage at powers of up to 10^9 W/cm^2.

All of the known materials of this class have magnetically inert Ba^{2+} in planes between puckered sheets of corner sharing MF_6 octahedra (7). It was the intention of this study to substitute magnetically and optically active Eu^{2+} and Sm^{2+} for Ba^{2+}. In addition we prepared what was hoped to be the Sr^{2+} analogue of $BaMgF_4$.

In the first parts of this paper a qualitative outline of the structure, preparative methods, and experimental findings concerning $EuMgF_4$, $SmMgF_4$, and $SrMgF_4$ is presented. The spectroscopic and magnetic properties are then discussed in detail.

Crystal Structure of (Eu,Sm,Sr)MgF_4

As yet, no definitive crystal structure has been determined for $SrMgF_4$, $EuMgF_4$, or $SmMgF_4$. Table I presents a summary of the lattice parameters taken from high angle x-ray diffraction patterns, along with x-ray and measured densities.

While the cell parameters show clearly that these compounds are orthorhombic, tests for second harmonic generation were negative. Therefore, it is tentatively concluded that none of the new compounds have the space group $A2_1am$. The space group Amam then suggests itself from preliminary examination of a Patterson function map (8).

Key words: complex fluorides, rare earth luminescence, energy transfer, stoichiometric phosphors.

Table I. Summary of lattice parameters and density

Compound and lattice parameters	Density (x-ray) (g/cm³)	Density ± 5% (measured) (g/cm³)
1. $EuMgF_4$		
a_o = 3.933 ± 0.003A	5.23	5.34
b_o = 14.43 ± 0.011		
c_o = 5.608 ± 0.004		
Cell vol. = 320.41A³		
2. $SmMgF_4$		
a_o = 3.915 ± 0.002A	5.13	4.91
b_o = 14.440 ± 0.009		
c_o = 5.661 ± 0.003		
Cell vol. = 324.41A³		
3. $SrMgF_4$		
a_o = 3.917 ± 0.004A	3.90	3.89
b_o = 14.459 ± 0.013		
c_o = 5.637 ± 0.005		
Cell vol. = 319.64A³		

Nevertheless, the point symmetry around Eu, Sm, and Sr should be almost equivalent to that of $BaMnF_4$, that is, an eight-fold coordination of F^- ions all of whose Ba-F bond lengths are unequal. The possibility of such low point symmetry is supported by the appearance of an intense $^5D_0$-$^7F_0$ optical transition seen in $SmMgF_4$. The point symmetry around (Eu, Sm, Sr) is now thought to be C_s similar to that of Ba in $BaMnF_4$.

Experimental

All preparations and purifications were carried out in graphite (Ultra Carbon, F purity) crucibles in an argon (Matheson, prepurified) flow system. A two-zone Cu work coil connected to an rf generator supplied heat to the sample while a Leeds and Northrup optical pyrometer was used to measure temperature.

Purification of the starting materials [EuF_3 (ROC/RIC, 99.9%), SmF_3 (Lindsay Division of American Potash, 99.9%), SrF_2 (ROC/RIC, 99.9%, optical grade), and MgF_2 (British Drug House, 99.9%)] was accomplished by drying to constant weight at 250°C and subjecting these materials to treatment with dried NH_4F (Fisher, 99%) in a flow system. Water was scrubbed from the argon by flowing the gas over Drierite and through an acetone-Dry Ice trap.

In some experiments EuF_2 and SmF_2 were used. These were prepared by hydrogen reduction (Mathe-

son Gas Products) of the trifluoride at 850°C for 4 hr, with regrinding and reheating. All purified materials were stored in a vacuum desiccator over $MgClO_4$.

$SrMgF_4$ was prepared by combining stoichiometric amounts of SrF_2 and MgF_2 in a capped graphite crucible and heating for three 5 hr runs at 875°C. After each run the product was checked for starting materials.

$EuMgF_4$ was most easily prepared by reduction of mixtures of EuF_3 and MgF_2 in the ratio of 2:1 within the graphite crucible. A five-fold excess over stoichiometry of fresh Mg turnings (Fisher Reagent Grade) was added above the mixture. The position of the crucible in the work coil is shown in Fig. 1. Heat was applied so that the temperature in the hot zone was 850°C while that of the cool zone was 750°C. The initial heating period of 2 hr was followed by three 3 hr heating cycles. After each heating period the sample was ground, checked by x-rays for excess EuF_2 or MgF_2, and returned for further heating after adjusting the composition.

The second method of $EuMgF_4$ production involved combination of EuF_2 and MgF_2 with only one piece of Mg added. The same procedure of extra heating, grinding, and adjusting of starting materials is performed as for the method above.

$SmMgF_4$ could only be prepared from SmF_3 and MgF_2 with an excess of Mg. The two heating zones were measured at 830° and 730°C, respectively, for successful preparation. No secondary heating periods were found to be helpful.

All excitation and emission spectra were recorded using an Hitachi-Perkin Elmer Model MPF2A spectrofluorimeter. Liquid nitrogen spectra were obtained with the aid of a cryostatic Dewar provided for this instrument.

Quantum efficiencies were measured against the fluorescent output of sodium salicylate which had been calibrated against a known halophosphate lamp phosphor. Fluorescence was recorded under 365 nm Hg excitation using a Jarrell-Ash spectrometer and the area under the emission curve was then integrated. Corrections were made for scattering from nonfluorescent MgO at 365 nm.

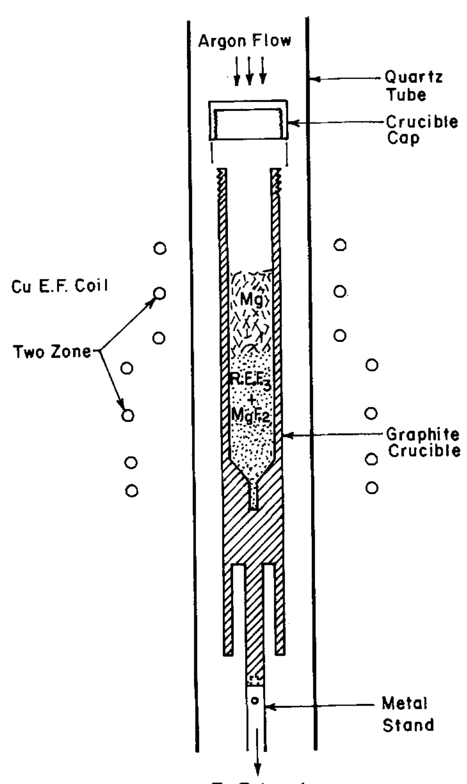

Fig. 1. Crucible and heater assembly

The lifetimes of the 437 nm emission of $EuMgF_4$, $Eu_{0.995}Sm_{0.005}MgF_4$ and $Eu_{0.99}Sm_{0.01}MgF_4$ were measured on an SLM series 4000 spectrofluorometer. A demodulation technique was used to record the lifetimes.

Magnetic measurements were made with a Princeton Applied Research vibrating sample magnetometer (VSM) to liquid helium temperature.

Densities of $EuMgF_4$, $SrMgF_4$, and $SmMgF_4$ were determined by the pycnometer method of Reilly and Rae (9). A 2 milliliter pycnometer bottle was used. Carbon tetrachloride was chosen as the pycnometric liquid because of its lack of reactivity and high density.

Results and Discussion

With the preparative methods that were used, it was found to be difficult to prepare $EuMgF_4$ directly from EuF_2 and MgF_2. Such experiments yielded only 20% conversion even after 3 days of heating. Longer experiments gave products which were already decomposed. This is thought to be due to small amounts of water vapor accumulating during grinding and, in general, during the long run periods.

Two possible equations for the formation of $EuMgF_4$ are then

$$EuF_3 + \tfrac{1}{2} MgF_2 + \tfrac{1}{2} Mg \rightarrow EuMgF_4 \quad [1]$$

and

$$EuF_2 + MgF_2 \xrightarrow[\text{catalyzed}]{Mg} EuMgF_4 \quad [2]$$

Mg, present as vapor at reaction temperature, is believed to have four functions. First, it acted as an oxygen and water scavenger. Second, it appeared to catalyze the reaction. Third, it acted as a strong reducing agent. Fourth, it was used to make up Mg deficiencies in the compounds. To test this, EuF_3 and Mg alone were reacted. The outcome was partial conversion to $EuMgF_4$. A possible course for the reaction is

$$EuF_3 + \tfrac{1}{2} Mg \rightarrow EuF_2 + \tfrac{1}{2} MgF_2 \xrightarrow[\text{catalyzed}]{Mg} EuMgF_4 \quad [3]$$

Indeed, the appropriate amount of EuF_2 is observed in the x-ray diffraction pattern. During the course of the preparations only one complex phase ($EuMgF_4$) was evident utilizing x-ray diffraction analysis.

$EuMgF_4$ was found to be a white powder, stable in moist air, when prepared in a pure state.

In distinction to $EuMgF_4$, $SrMgF_4$ was preparable by using the two binary fluorides directly. This leads one to believe that $SrMgF_4$ is somewhat more stable in the presence of hydroxyl than its lanthanide counterparts. $SrMgF_4$ was also found to be a white, air stable compound.

The reactive nature of Sm^{2+} precluded the use of multiple grinding and heating operations because of the deleterious effect of moisture. Formation of $SmMgF_4$ is thought to proceed by the pathway

$$SmF_3 + \tfrac{1}{2} MgF_2 + \tfrac{1}{2} Mg \xrightarrow[\text{catalyst}]{Mg} SmMgF_4 \quad [4]$$

$SmMgF_4$ is a red compound which appears to be stable in moist air even when exposed for periods in excess of one week.

All three new compounds appear to melt incongruently at about 900°C. Samples heated above that temperature were found to have melted. X-ray patterns showed only mixtures of the binary fluorides (*e.g.*, EuF_2 and MgF_2).

For $EuMgF_4$, both the excitation and emission spectra (Fig. 2 and 3) show the f-d band transition typical of Eu^{2+} compounds. The room temperature excitation spectrum shows a peak at 356 nm while

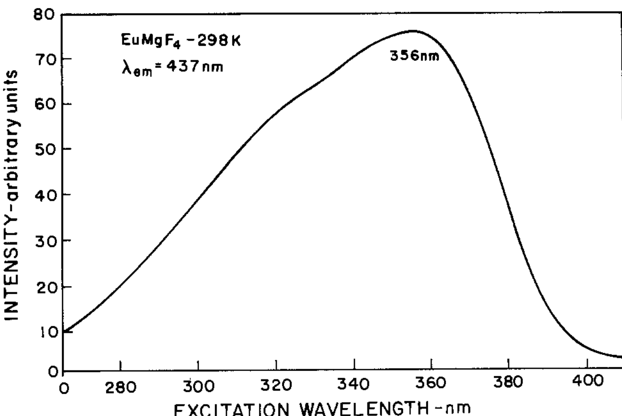

Fig. 2. Excitation spectrum of $EuMgF_4$, 298°K

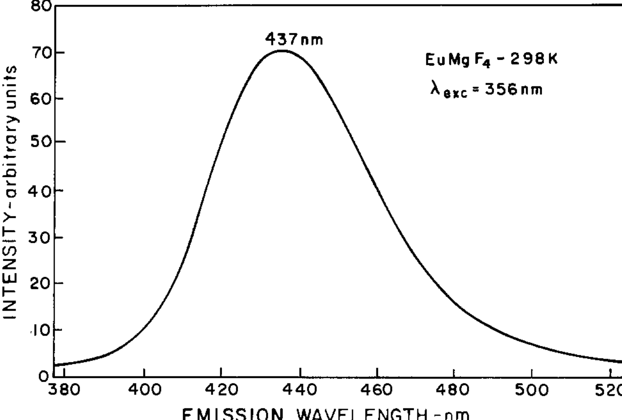

Fig. 3. Emission spectrum of $EuMgF_4$, 298°K

the emission spectrum shows a maximum at 437 nm. No f-f transitions were observed, in accord with the findings of Fouassier (10) for eight coordinate Eu^{2+}.

At room temperature, the emission and excitation bands have meaningful spectral overlap only in the region of 380-400 nm. The 33% quantum efficiency measured for $EuMgF_4$ is remarkable considering the rather poor quality of the product. This is only 5% less than the maximum found in $Eu_{0.75}Sr_{0.25}MgF_4$. At 77°K the bands narrow because of lower molecular vibrational amplitude and there is no overlap at all. This implies, by the theories of Forster (11) and Dexter (12), that there will be neither coulombic interactions between distant bivalent europium ions nor significant exchange interactions among neighboring Eu^{2+} ions. The lack of coulombic interaction is attributed to the symmetrical nature of the $^8S_{7/2}$ ground state (13).

Measurements of magnetic susceptibility were made on $EuMgF_4$ and $SmMgF_4$ to determine the magnitude of any exchange interactions that might be present which could mediate energy transfer and concentration quenching behavior. Paramagnetic susceptibilities were measured from 4.2°K to room temperature on $EuMgF_4$, $SmMgF_4$, and the solid solution $Eu_{0.5}Sm_{0.5}MgF_4$, which behaved as expected for a random distribution of Eu^{2+} and Sm^{2+} in the structure. $EuMgF_4$ was found to obey a Curie-Weiss law, remaining paramagnetic down to 4.2°K, with a Weiss constant, $\theta = -3$°K. This indicates very weak exchange coupling. The effective moment for Eu^{2+} calculated from the high temperature magnetic data was $\mu_{eff} = 7.8$ BM, which agrees well with the literature value of 7.9 BM (14), so there is little doubt that all the Eu is in the bivalent state. The magnetic data on $SmMgF_4$ are discussed below, after the discussion of its fluorescence.

A firm explanation of the exchange interactions in $EuMgF_4$ cannot be given at this time because the structure is not known with certainty. However, the followinig line of thought seems most sensible at this stage. By linearizing the ratio of unit cell volumes of $EuMgF_4$ to $BaMnF_4$ it is found that the average europium-europium distance would be approximately 4.4Å. In EuF_2, a cubic antiferromagnet, the europium-europium distance is 4.1Å and there are eight antiferromagnetic pathways through coordinate fluoride ions (15). However, assuming the $BaMnF_4$ structure, some of the europium-fluorine pathways may not lead to other europium atoms directly, therefore limiting the amount of antiferromagnetic interaction compared to EuF_2. McGuire and Shafer (15) also show that direct exchange falls off sharply at distances of 4.4Å or greater in europium chalcogenides while antiferromagnetic superexchange was weak in all cases regardless of distance. Fluorides would show weaker antiferromagnetic superexchange than chalcogenides because of the greater ionicity of fluorides.

The fluorescence of various solid solutions of $EuMgF_4$ in $SrMgF_4$ show that there is very little concentration quenching as the amount of europium is increased. (Fig. 4).

The wavelength required to promote the electron into the d band decreases from $\lambda_{ex} = 356$ nm in $EuMgF_4$ to $\lambda_{ex} = 316$ nm in $Sr_{0.99}Eu_{0.01}MgF_4$. In the latter compound, the lattice becomes more rigid and resistant to electron cloud expansion due to the higher charge to size ratio of strontium as compared with europium.

At 77°K the excitation and emission spectra of $Sr_{0.99}Eu_{0.01}MgF_4$ (Fig. 5) show considerable fine structure which is unresolved in the same spectra of $EuMgF_4$. This fine structure could possibly arise from excitations from the f level to various vibrational d band levels, although the possibility of f-f transitions cannot now be ruled out.

In Fig. 6, the excitation spectrum of $SmMgF_4$ at 298°K shows a broad band excitation extending from below 340 nm to above 620 nm. At 77°K the same spectrum extends from below 340 nm but shows a sharp drop-off above 560 nm. This is directly attributable to depopulation of the $J > 0$ levels in the $^7F_{0\text{-}6}$ ground state known to exist in bivalent samarium. All of the spurious weak lines on the excitation band are due to xenon lamp lines or diffraction effects.

The room temperature emission spectrum of $SmMgF_4$ (Fig. 7) consists of a number of lines superimposed on a broad band continuum. Transitions from the $^5D_0$ to the $^7F_{0\text{-}6}$ are responsible for the lines while transitions from the $4f^5$-5d band to the $^7F_0$ produce the continuum. At 77°K the continuum disappears and there is an increase in the number and intensity of the lines in the spectrum (Fig. 8).

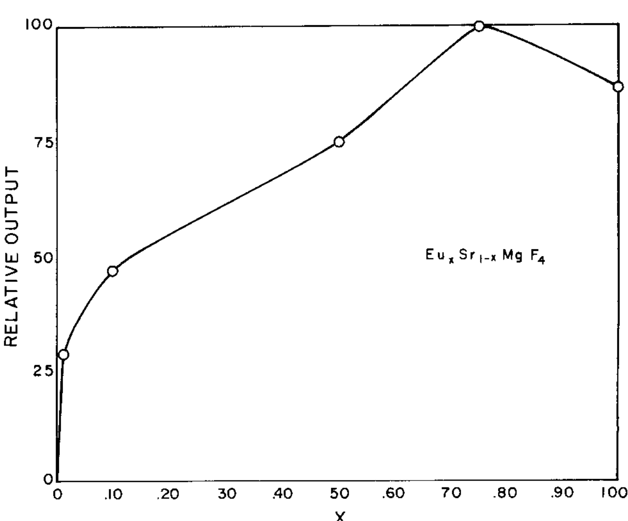

Fig. 4. Concentration dependence of Eu^{2+} emission peak intensity (298°K) in $Sr_{1-x}Eu_xMgF_4$.

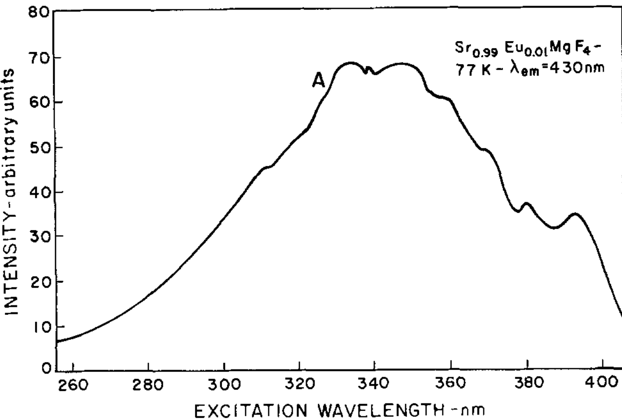

Fig. 5a. Excitation spectrum of $Sr_{0.99}Eu_{0.01}MgF_4$ at 77°K

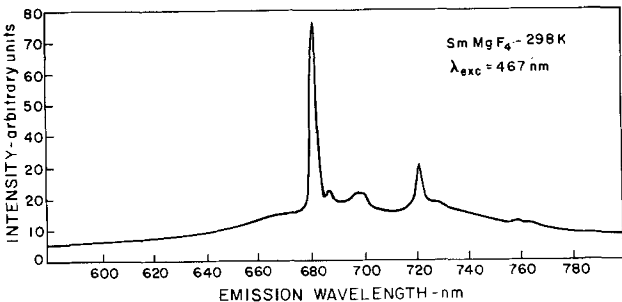

Fig. 7. $SmMgF_4$ emission spectrum, 298°K

Since temperature quenching of the $^5D_1$ and $^5D_0$ levels occurs through an intervening $4f^5$-5d band (16), the appearance of considerable sharp line emission at room temperature is an indication of substantial asymmetry at the samarium site. Such emission follows only from severe breakdown in the selection rules.

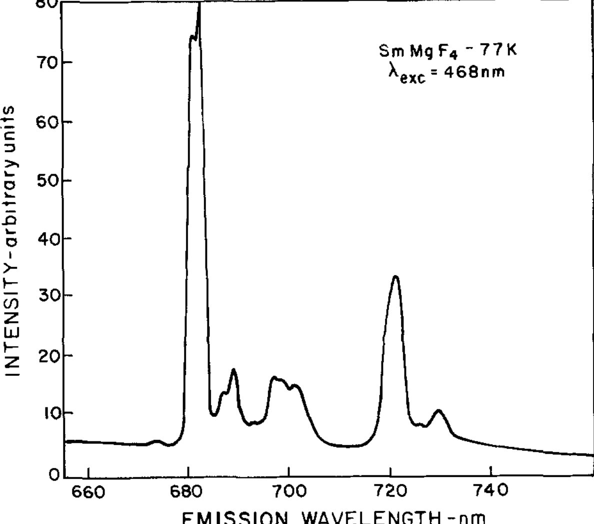

Fig. 8. $SmMgF_4$ emission spectrum, 77°K

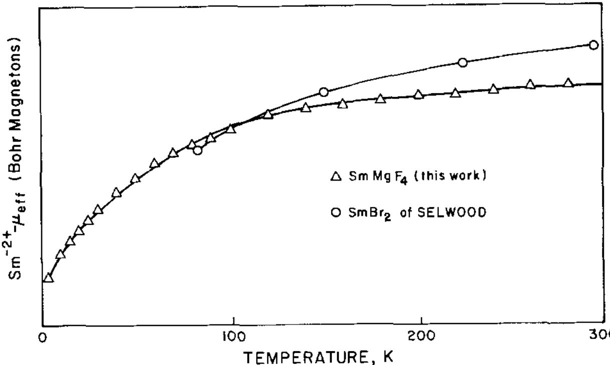

Fig. 9. Effective magnetic moment of Sm^{2+} in $SmMgF_4$ and $SmBr_2$, temperature dependence.

Assignments of the peaks were made on the basis of comparisons with the work of Dieke (17) on Sm^{2+} and Blasse (18) on Eu^{3+}. Room temperature peak assignments are listed in Table II. The designation of the first peak at 681 nm as $^5D_0$-$^7F_0$ is consistent with the postulated low symmetry around bivalent samarium, which is supported by the observation of an intense line spectrum at room temperature. The positions and sizes of the other peaks then fit easily into a general scheme when the first peak is assigned to $^5D_0$-$^7F_0$.

Bivalent samarium becomes nonmagnetic at 0°K because at that temperature only the J = 0 state of the $^7F_{0\text{-}6}$ ground manifold is populated. The result of depopulation of the upper states with decreasing temperature is a nonlinear decrease in the effective Bohr magneton number. This phenomenon was first observed by Selwood (19) for $SmBr_2$. $SmMgF_4$ follows approximately the same pattern. Susceptibility measurements were made down to 4.2°K where μ_{eff} = 0.62 BM (Fig. 9). No attempt is made to evaluate the Weiss con-

Table II. Positions and designations of transitions in $SmMgF_4$ at room temperature

Position (nm)	cm^{-1}	Designation	Intensity
681	14,684	$^5D_0$-$^7F_0$	vs
687	14,556	$^5D_1$-$^7F_3$	w
697	14,358	$^5D_0$-$^7F_1$	m
701	14,266	$^5D_0$-$^7F_2$	m
721	13,870	$^5D_1$-$^7F_4$	s
729	13,717	$^5D_1$-$^7F_4$	vw
762	13,123	$^5D_0$-$^7F_3$	vw

stant as the anomalous temperature coefficient renders this parameter meaningless. The magnetic data show that at 300°K $\mu_{eff} = 3.13$ BM while Selwood (19) gives 3.6 BM for $SmBr_2$. At 83°K Selwood measured $\mu_{eff} = 2.29$ BM while $SmMgF_4$ gave a value of 2.35 BM. Following a van Vleck theoretical curve down to about 12°K, the divergence between the curve and the measured value for $SmMgF_4$ becomes roughly 0.3 BM with the measured value being the greater. It should be remarked that Selwood's measurements closely follow van Vleck's theory for bivalent samarium (19).

These observations may be indicating a slight mixing of the $^7F_0$ and $^7F_1$ states. Although this type of mixing has not been seen in the past, it is possible if the crystal field strength is very high at the bivalent samarium site, with very low site symmetry. Such mixing is easier in bivalent samarium than in tervalent europium because the $^7F_{0\text{-}6}$ levels are considerably closer together in the former ion.

The series $Sr_{1-x}Sm_xMgF_4$ shows considerable concentration quenching at $x = 0.1$. Since temperature independent concentration quenching in bivalent samarium originates only from exchange interaction and not from a multipolar resonance mechanism (width of the $^7F_{0\text{-}6}$ manifold is much smaller than the distance from this manifold to the ^5D level), a moderately strong antiferromagnetic exchange interaction may be present. Direct exchange is precluded because of the estimated large Sm^{+2}-Sm^{+2} distances and the small μ_{eff}. The low symmetry of the F state would be especially effective in strengthening antiferromagnetic interactions.

All of the solid solutions in the series $Eu_xSm_{1-x}MgF_4$ show the excitation spectra for both bivalent europium and bivalent samarium (Fig. 10). However, the bivalent europium emission is not seen in any of the solid solutions except $Eu_{0.99}Sm_{0.01}MgF_4$ (Fig. 11).

Since the emission band of bivalent europium overlaps the absorption band of bivalent samarium, it was suspected that the observed energy transfer could well be the trivial case of radiative transfer, the Eu emission exciting the Sm ions. Comparison of mechanically mixed samples of $EuMgF_4$ and $SrMgF_4$ with $EuMgF_4$ and $SmMgF_4$ showed that the bivalent europium emission was attenuated to a greater extent by $SmMgF_4$ than in the $SrMgF_4$ mixture. This leads to the conclusion that there is emission and reabsorption. However, lifetime measurement of the 437 nm Eu^{2+} emission band ranged from 1.08×10^{-6} sec in $EuMgF_4$ to 9.73×10^{-8} sec in $Eu_{0.99}Sm_{0.01}MgF_4$, indicating the presence of nonradiative transfer. Both mechanisms may be operative in the solid solutions, but radiative transfer cannot be very significant, judging from the complete quenching of the Eu^{2+} emission.

The actual energy transfer may well take place by coulombic (dipole-induced dipole) interactions which should be greater between Eu^{2+} and Sm^{2+} than between Eu^{2+} and Eu^{2+}. This is because of the differences in the symmetry of the ground state ions.

Stoichiometry and Masking Ability of LPCVD Silicon Nitride Against Arsenic Diffusion

Anant Dixit,* C. S. Chen,[1] and C. E. Volk*

Burroughs Corporation, San Diego, California 92127

ABSTRACT

Masking failure of LPCVD silicon nitride films during high temperature arsenic diffusion is observed, when these films are deposited with ammonia to dichlorosilane ratio <7:1 at the deposition temperature of <760°C. This masking failure is noticed after diffusion when the silicon nitride film is stripped in HF: a number of unetchable areas are left on the silicon wafer. The unetchable areas are not visible on as-deposited films. Helium backscattering data indicate that this masking failure occurs in nonstoichiometric silicon-rich films.

Chemically vapor deposited silicon nitride films are widely used in semiconductor processing for masking against diffusion into silicon. Correct stoichiometry of the silicon nitride film plays an important role in this masking ability of the film.

Before the advent of low pressure CVD systems, silicon nitride was deposited at atmospheric pressures around 900°C, using a large ammonia to silicon compound ratio of approximately 1000:1 (1). The larger ratio was required to suppress the rate of silicon deposition in comparison to the silicon nitride deposition. In low pressure CVD systems it is desirable to keep the operating pressure during deposition below 1 Torr for better uniformity (2). For LPCVD silicon nitride systems where dichlorosilane is the preferred source for simpler and better reactor operation, the low pressure condition requires smaller ammonia to dichlorosilane ratio. At the lower pressures reactant gases mix more completely, allowing these much smaller ammonia to dichlorosilane ratios during deposition. However, as the smaller gas flow ratio approaches the theoretical limit of 1.33 (ratio of stoichiometric Si_3N_4), the resulting silicon nitride film may deviate from correct stoichiometry due to the silicon deposition process competing with the silicon nitride deposition process.

In this paper, we report the observation of localized fluctuations in the stoichiometry of the LPCVD silicon nitride films and consequent masking failure against arsenic diffusion, when these films are deposited under certain conditions.

Procedure

LPCVD silicon nitride films were prepared under different deposition conditions on thermally oxidized silicon substrates. The wafers were then processed through a standard arsenic buried layer diffusion process, after which the film was stripped in conc HF or hot phosphoric acid, and inspected for diffusion damage.

Results

Depending on the process condition, a number of unetchable or slowly etching nitride spots were visible on the wafer, often with an unaided eye. Two such illustrations are shown in Fig. 1. The size of these spots was in the range of a few microns to several centimeters, sometimes extending over large portions of the wafer.

The standard diffusion cycle consists of coating the wafers with spin-on arsenic glass followed by a drive-in cycle at 1200°C for several hours. A few wafers were processed through an arsenic implant/drive cycle. The implanted wafers also had unetchable spots, although at a much reduced scale as compared with the wafers processed through the standard diffusion cycle.

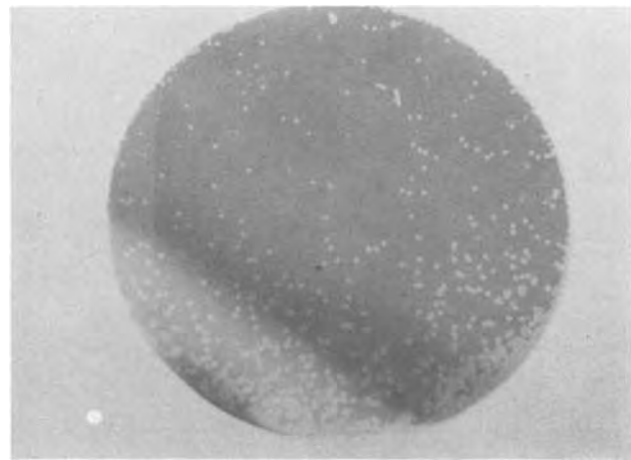

Fig. 1a. Nitride spots on 3 in. silicon wafer

* Electrochemical Society Active Member.
[1] Present address: Hughes Aircraft, Newport Beach, California 92663.

Key words: LPCVD silicon nitride, arsenic diffusion, stoichiometry.

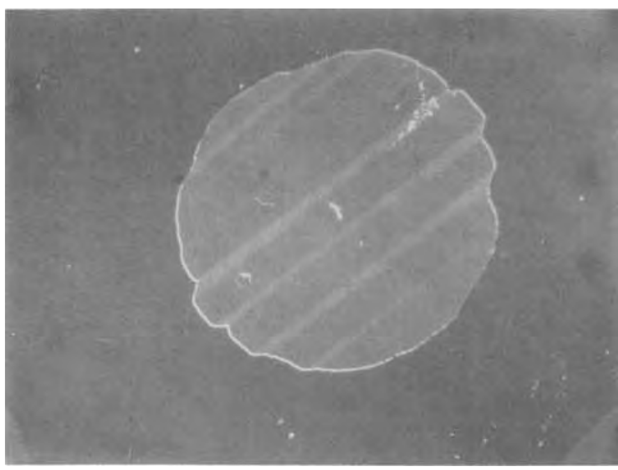

Fig. 1b. Microscopic picture of one of the nitride spots shown in Fig. 1a. (300×).

It must be noted that these defects are not visible on the as-deposited silicon nitride films or films heat-treated in a diffusion furnace without an arsenic source, and subsequent nitride etch did not reveal any unetchable nitride spots. The defects are revealed on the arsenic diffusion treated wafers only after the nitride etching step. The effect is more enhanced when etched in hot phosphoric acid. The nitride films were essentially free of cracks, and free of pinholes as evaluated by a Navonics bubble tester.

The final wafer quality depended on a number of process conditions: (*i*) oxide thickness under the nitride film, (*ii*) nitride deposition temperature, (*iii*) ammonia to dichlorosilane ratio during deposition, (*iv*) lower diffusion temperature, and (*v*) wafer handling.

Increasing the thickness of the oxide films, in general, reduced the density of unetchable spots, but did not eliminate them completely, as illustrated in Table I.

Reduced diffusion temperature reduced the density of spots significantly. An extensive study also revealed that poorly handled wafers enhanced the density of the unetchable nitride spots. However, an arsenic diffusion was essential to produce these unetchable nitride spots.

High deposition temperature and higher ammonia/dichlorosilane ratio during deposition eliminated the etchable nitride spots as can be seen from the data in Table II. Thus, at the deposition temperature of 760°C, a defect-free wafer could be obtained if the ammonia to dichlorosilane ratio during deposition was greater than 7:1. However, if the deposition temperature was raised to 790°C, a lower ammonia/dichlorosilane ratio of 4:1 could be used to obtain a defect free wafer.

In order to understand the effect of deposition conditions on the properties of silicon nitride films the refractive index and the etch rate of the films were monitored. The refractive index was measured by the Gaertner ellipsometer and calculated using the NBS ellipsometer program. The etch rate of the films in conc HF was measured at the constant room temperature of 22°C. Four wafers from each test condition were used to collect data on refractive index and etch rate. Measurement were made on the center of the wafer and the average values are recorded. The results are summarized below.

Table I. Effect of oxide thickness

Oxide thickness (A)	Defect count in 200 fields of view
10,000	1-3
5,000	3-7
3,000	10-15
1,000	Often all across the wafer

Silicon nitride—1500A, NH_3/DCS—4:1, Dep. temp—760°C.

Table II. Arsenic diffusion effect on silicon nitride, underlying oxide thickness 3000Å

Ammonia/ DCS	Dep. temp (°C)	Wafer condition after arsenic diffusion and nitride strip
2:1	760	Large nitride spots
4:1	760	Small nitride spots
7:1	760	Clean wafer
2:1	790	Small nitride spots
4:1	790	Clean wafer
7:1	790	Clean wafer

Refractive index.—At 790°C, an increase in dichlorosilane flow by more than 200% increased the refractive index by only 0.04 as can be seen in Fig. 2a. This suggests an increased silicon content or higher density of the films. However, it may be noted that no such trend is seen for films deposited at 760°C. No trends are noticed with respect to changes in ammonia flow and deposition temperature as can be seen from Fig. 3a and 4a.

Etch rate in conc HF.—Etch rate seemed to be invariant with respect to changes in dichlorosilane flow at either deposition temperature of 760° or 790°C as seen in Fig. 2b. However, etch rate increased significantly with increasing deposition temperature, as seen in Fig. 3b and 4b. This variation again suggests an increased silicon content or higher density of the films resulting in lower etch rates.

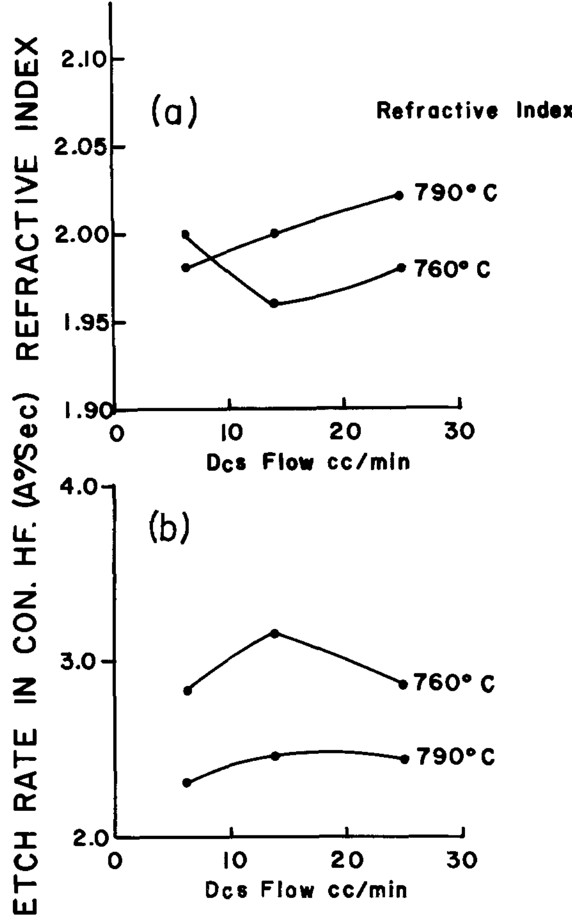

Fig. 2. Effect of dichlorosilane flow on nitride parameters. (a) Refractive index, (b) etch rate.

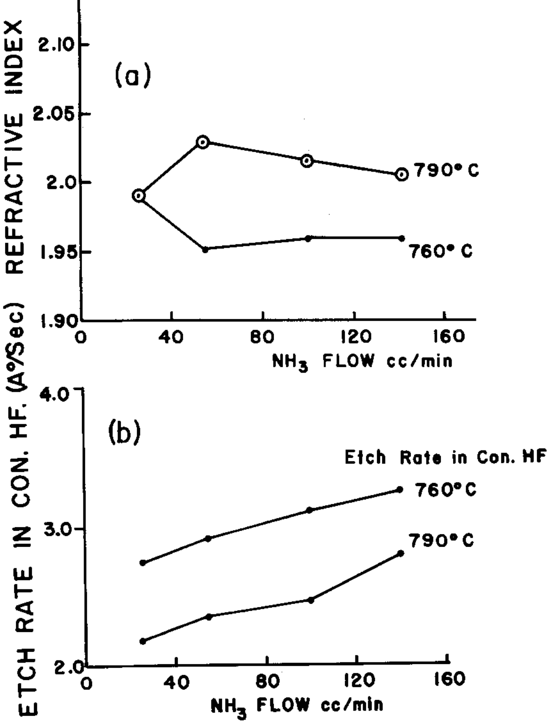

Fig. 3. Effect of ammonia flow on nitride parameters. (a) Refractive index, (b) etch rate.

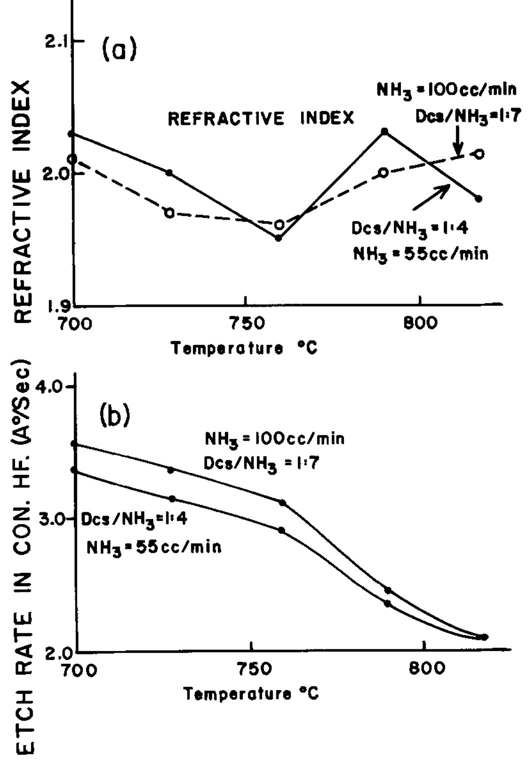

Fig. 4. Effect of temperature on nitride parameters. (a) Refractive index, (b) etch rate.

The study of refractive index and etch rate variation of the films, however, did not provide any indication about the origin of the unetchable nitride spots. To resolve this problem, a few samples of silicon nitride, deposited at 760°C on 1000Å thermally oxidized substrates were produced under various deposition conditions. Half of these wafers were processed through the arsenic diffusion cycle. The other half of these wafers were analyzed by helium backscattering to obtain film compositions (3).

In Fig. 5 a typical backscattering yield is plotted as a function of energy for an as-deposited silicon nitride film. The compositions are calculated from the areas under the peaks of nitrogen, oxygen, and silicon, and their corresponding energy losses and capture cross sections. The composition was averaged over four different areas of the samples. Chlorine as a trace impurity of 0.25% of the nitride is also seen.

A typical backscattering yield distribution for the unetchable nitride spots is shown in Fig. 6. It was not possible to calculate the composition of these films due to the nonuniformity of the interface. A clear arsenic peak is seen in this film.

The alternate method of Auger analysis to estimate the composition of the film was inconclusive. All films deposited appeared to have correct stoichiometry although some of the films exhibited a high density of unetchable nitride spots. This is possibly because the sputter etch, required during the Auger analysis, changes the composition of the atomic layers that are being analyzed (4).

The nitride/silicon ratio for the as-deposited films, from the backscattering analysis and the corresponding gas flow ratios are entered in Table III. Defect density on the corresponding wafers which were processed through the arsenic diffusion is also sum-

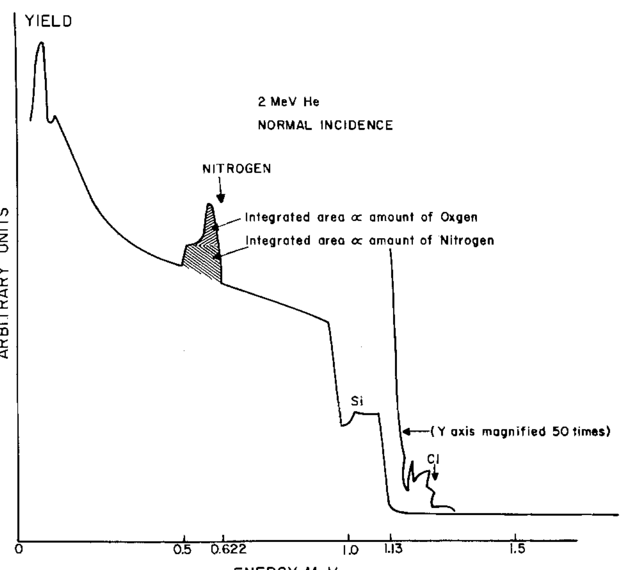

Fig. 5. He backscattering on as-deposited silicon nitride

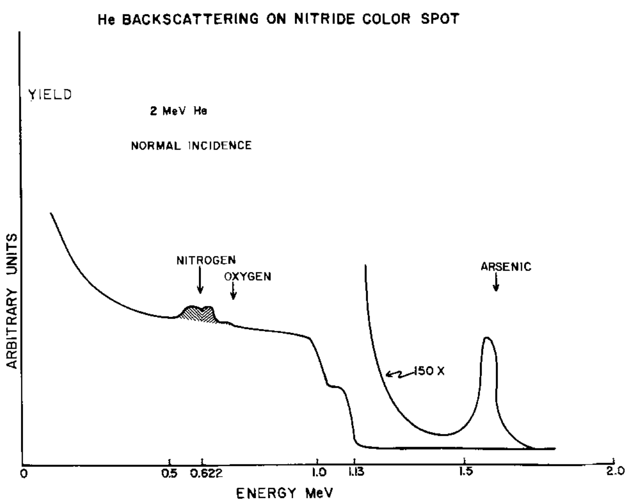

Fig. 6. He backscattering on unetchable silicon nitride spots

Table III. Dependence of unetchable nitride spots on process conditions. Deposition temp 760°C; arsenic diffn 1200°C

Defect count in 200 fields of view at 100×	Visible spots without optical aid	Ammonia/DCS ratio	Nitrogen/silicon ratio from He backscattering
2	Few spots on edges	4:1	1.31
89	All over the wafer	4:1	1.15
1.0	No	5:1	1.28
1.0	No	8:1	1.31
0	No	13:1	1.34
0	No	16:1	1.34

marized in Table III. It can be seen from these data that as the ammonia/dichlorosilane ratio increased the films had more correct stoichiometry. Films produced with smaller ammonia/dichlorosilane ratios have higher silicon content and correspond to those which failed during arsenic diffusion and therefore had a high density of unetchable nitride spots.

Conclusions

Unetchable nitride spots remain on silicon wafers when the wafers are processed through an arsenic diffusion cycle using LPCVD silicon nitride as a diffusion mask. The diffusion damage under these spots indicate failure of the impurity masking property of the nitride film in the region of the nitride spot. The random occurrence of these spots suggests that there are fluctuations in the masking property of the film. It is seen that the density of these spots is reduced significantly as the silicon nitride films become less silicon rich, approaching the proper stoichiometry, as evaluated by He backscattering. Since these spots occur randomly across the wafer, it indicates random fluctuations in the stoichiometry of the nitride film across the wafer. These spatial fluctuations could not be identified with the refractive index and etch rate measurements.

We believe that arsenic atoms diffuse through these silicon-rich regions forming a complex compound with the underlying silicon dioxide film and the silicon substrate; these silicon-rich regions etch very slowly in conc HF. Increased underlying oxide thickness reduces this occurrence, since oxide is a diffusion mask which reduces the total number of arsenic atoms reaching the silicon substrate, thereby diminishing the role of the silicon substrate in the formation of this complex compound. Similarly a reduced diffusion temperature decreases the defect density because of the reduced Dt product of arsenic in oxide. The exact mechanism of formation of these unetchable nitride spots as well as the structure of these spots could not be determined in the present work. The nitride spots occur when either arsenic spin on glass source or arsenic ion implant source is used during the arsenic diffusion cycle, indicating that the nitride spots occur primarily due to the failure in the masking ability of the nitride films and secondarily related to the type of arsenic source.

Proper stoichiometry and hence proper masking ability of the nitride films are obtained when higher ammonia/dichlorosilane ratio and higher temperature during deposition are selected in producing these films.

Oxidation Enhanced Diffusion of Boron and Phosphorus in (100) Silicon

K. Taniguchi,* K. Kurosawa, and M. Kashiwagi*

NEC-Toshiba Information Systems, Incorporated, Kawasaki City, Kanagawa 210, Japan

ABSTRACT

Diffusion of boron and phosphorus in dry O_2, wet Ar, and wet O_2 ambients was investigated to obtain a formula describing the oxidation enhanced diffusion. At low impurity concentration, the diffusion coefficient is expressed as a function of oxide growth rate, depth, and temperature

$$D = D_o \exp\left(-\frac{\Delta E_1}{kT}\right) + F \cdot \left(\frac{dX_o}{dt}\right)^{0.3} \exp\left(-\frac{X}{25}\right) \exp\left(-\frac{2.07}{kT}\right)$$

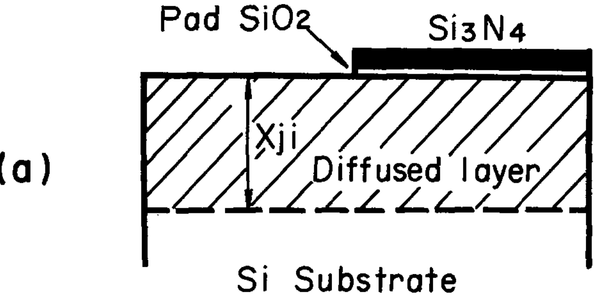
where dX_o/dt is in μm/hr and X is in μm. F value is 6.0×10^{-2} cm^2/hr for boron and 5.2×10^{-2} cm^2/hr for phosphorus. This equation can be explained by a dual mechanism involving both vacancy and interstitial silicon atoms. A depth dependence of the diffusion coefficient is explained by a model that excess interstitial silicon atoms are captured by vacancies migration into bulk silicon. At high impurity concentration, less enhanced diffusion was observed.

Since characteristics of semiconductor devices depend strongly on the final impurity profiles in the electrically active region, detailed understanding of impurity diffusion is generally required to reproducibly control the impurity profiles. The current state of the art for optimization of diffusion processes in the fabrication of integrated circuits, however, relies on an empirical approach based on the trial and error method. Recently, there has been an intensive effort in the industry in the development of the computer-aided process simulation for integrated circuits (1). Though a large number of reports (2-10) have been published on oxidation enhanced diffusion, any generally acceptable model has not been available yet. The simultaneous presence of both oxidation enhanced diffusion and anomalous diffusion due to high impurity concentration makes it difficult to interpret the experimental results precisely and accounts for the remarkable spread among the values of the diffusion coefficient found in the literature. The main purpose of this study is to distinguish the oxidation enhanced diffusion from the anomalies due to high impurity concentration and to present a useful model for process simulation at low impurity concentration.

Experimental

The starting material was p- and n-type, (100) oriented Czochralski silicon wafers with resistivity of 6-8 Ω-cm. All the wafers were chemically mirror finished on one side. Boron and phosphorus were deposited on the surfaces as diffusion sources, the concentration of which were in the range of 2×10^{14}-4×10^{16} atoms/cm^2 by using BN and $POCl_3$ sources, respectively. The wafers were then thermally oxidized at 900°C for 5 min in wet O_2. To avoid out-diffusion of deposited impurities and to protect the silicon surface from oxidation, the silicon surface was initially covered with a 0.1 micron thick Si_3N_4 layer.

The drive-in of impurities was carried out at 1100° and 1200°C in a nitrogen ambient to obtain a wide variety of junction depths ranging from 1-5 microns. The oxide and nitride were photolithographically engraved into parallel stripes to define oxidizing and nonoxidizing surfaces on the wafer. Then, oxidation was carried out at temperatures in the range of 950°-1150°C in dry oxygen, wet Ar (H_2O partial pressure in Ar gas varying from 0.05 to 1 atm), or wet oxygen. The sample structures before and after oxidation are illustrated in Fig. 1. X_{jf} and X_{jfo} show the junction depths under the masked and unmasked surface, respectively. Note that X_{jfo} is measured from the original silicon surface. The thicknesses of the oxide film grown on the silicon surface during oxidation have been determined by ellipsometry and interferometry. The sheet resistivity and the junction depth were also determined by four point probe and grooving staining, respectively. The junction depth was measured at four position on each piece, and the



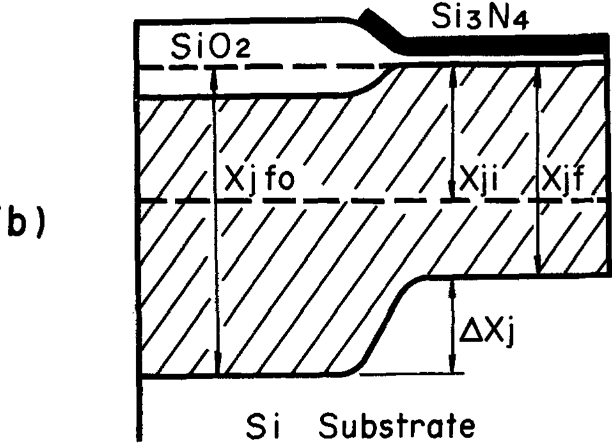


Fig. 1. Schematic diagram illustrating the sample structures, (a) before and (b) after oxidation.

* Electrochemical Society Active Member.
Key words: oxidation, diffusion, boron, phosphorus.

average and standard errors were estimated from these measurements. The standard errors for junction depth were about 0.02 micron in this study.

Analysis

In this study, diffusion length ($2\sqrt{Dt}$) for drive-in is much larger than that for predeposition. Thus, the extent of penetration in the predeposition profile can be regarded as negligibly small in comparison to that for the final profile resulting from the drive-in diffusion. Accordingly, the predeposition profile can be mathematically represented by a delta function. The impurities distribution after drive-in diffusion subjected to this approximation then will be given by the well-known Gaussian distribution

$$C_{(x)} = \frac{Q}{\sqrt{\pi B}} \exp(-X^2/4B) \quad [1]$$

where Q is the total number of impurity atoms in a 1 cm^2 section of silicon and $2\sqrt{B}$ is the effective diffusion length of impurity atoms.

The values of Q and B can be calculated from the initial junction depth, X_{ji}, and sheet resistivity, ρs, before oxidation using the following equations

$$\rho s^{-1} = q \int_0^{x_{ji}} \mu_{(c)} \cdot C_{(x)} d_x \quad [2]$$

$$X_{ji} = \sqrt{-4B \ln \frac{\sqrt{\pi B}\, N_B}{Q}} \quad [3]$$

According to Caughey and Thomas (11), the mobility, $\mu_{(c)}$ can be expressed by the following equation

$$\mu_{(c)} = \mu_{min} + \frac{(\mu_{max} - \mu_{min})}{1 + (C/C_{ref})^{\beta}} \quad [4]$$

where μ_{max} and μ_{min} are the minimum and maximum mobility values, C_{ref} a reference concentration value, and β an exponential factor that controls the slope around $C = C_{ref}$. From the work of Antoniadis (7), the following values are chosen for this work

Impurity	μ_{min}	μ_{max}	C_{ref}	β
Boron	49.70	467.7	1.6×10^{17}	0.70
Phosphorus	55.24	1388.2	1.1×10^{17}	0.73

when μ_{min} and μ_{max} are in cm^2/Vsec and C_{ref} is in atoms/cm^3. If the drive-in profile is given by Eq. [1], then the profile under the masked surface after oxidation can be represented by the equation

$$C_{(x)} = \frac{Q}{\sqrt{\pi(B + D_N t)}} \exp[-X^2/4(B + D_N t)] \quad [5]$$

Equation [5] can be applied directly to evaluate the diffusion coefficient, D_N, under the masked surface which was computed by matching the corresponding measured junction depth to the calculated one.

The diffusion coefficient, D, under the oxidized surface was also calculated by assuming Gaussian distribution for simplicity

$$C_{(x)} = \frac{Q}{\sqrt{\pi(B + Dt)}} \exp[-X^2/4(B + Dt)] \quad [6]$$

where X is measured from the original silicon surface. The coefficient, D, is separated into two terms; $D = D_N + \Delta D_o$. One is the diffusion coefficient in the nonoxidizing ambient, D_N. The other is the increment of diffusion coefficient due to oxidation, ΔD_o. This Gaussian assumption is somewhat questionable since it neglects the impurity redistribution at the moving oxide-silicon interface.

In the following, we will verify this assumption under the oxidized surface. Figure 2 shows impurity profiles for two typical segregation coefficients which were calculated by using the Kato and Nishi theoretical model (12). Though changes in the segregation coefficient alter the profile near the silicon surface, they influence sheet resistivity while producing little effect on junction depth. The two cases can be considered as follows: in one case $k = 0.1$, the oxide has a tendency to take up impurity, in the other case, $k = 10$, the oxide has a tendency to reject impurity. Therefore, the Gaussian profile which takes no account of the impurity redistribution is expected to be between the two curves as shown in Fig. 2. For convenience, the difference between these two junction depths of $k = 0.1$ and $k = 10$ is defined as δ_{X_j}. The theoretical calculation using the possible maximum diffusion coefficient of 1.5×10^{-9} cm^2/hr proves that the δ_{X_j} values fall inside the experimental error (0.02 micron) for large initial junction depths of more than 1.1 micron in this study. Since the diffusion coefficients obtained in this work are smaller than 1.5×10^{-9} cm^2/hr as shown in the later section, the diffusion coefficients calculated by this simple Gaussian model are proved to be accurate within experimental accuracy.

In this connection, we check the errors in diffusion coefficients ascribed to the experimental measurement error of junction depth. For example, in the case of $D = 10 \times 10^{-10}$ cm^2/hr and $Q = 10^{14}$ cm^{-2}, the errors in diffusion coefficient are evaluated as ± 3.5, ± 4.5, and $\pm 7.0 \times 10^{-11}$ cm^2/hr for 1.0, 2.5, and 4.5 microns of junction depth, respectively, by using the simple Gaussian model and the 0.02 micron of measurement error. The error-calculations for various Q values ($Q = 10^{13} \sim 10^{15}$ cm^{-2}) give nearly the same result. Therefore, the errors in diffusion coefficients are estimated as less than 7% in this work. It should be noted that the diffusion coefficient thus obtained

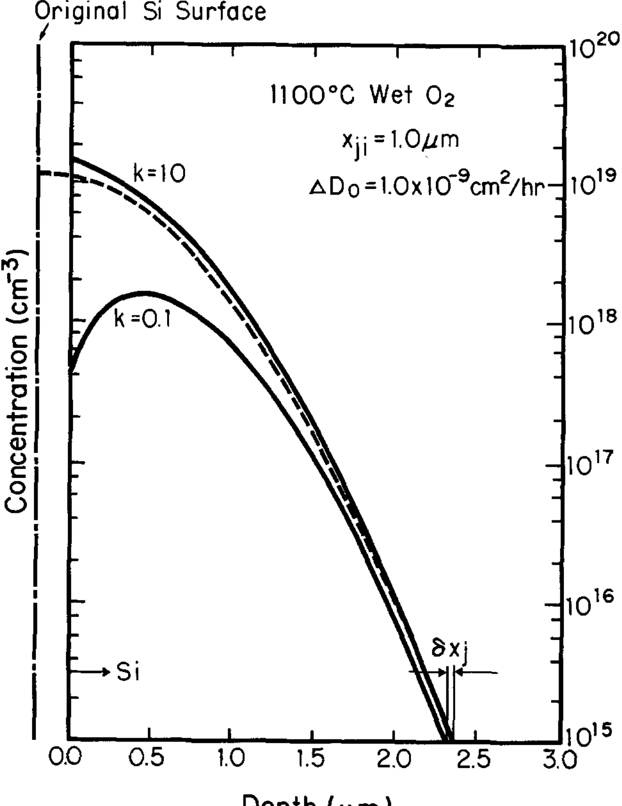

Fig. 2. Calculated impurity profile after oxidation for two typical segregation constants; $k = 10$ and 0.1. The dashed line shows the Gaussian profile which takes no account of impurity redistribution as Si/SiO_2 interface.

is an effective value near the junction depth because the changes in the segregation coefficient as well as diffusion coefficient near the silicon surface have little influence on the junction depth.

Dependence of impurity concentration.—Figure 3 shows the relationship between the diffusion coefficient and total amount of impurities. The initial junction depths for these samples are 3.2 microns and oxidation was carried out at 1100°C in the wet O_2 ambient. It can be seen from this figure that the diffusion coefficients do not show concentration dependence when the total amount of impurity is less than 3×10^{15} atoms/cm^2. A remarkable feature of the data presented here is that the diffusion coefficients of boron and phosphorus in a nonoxidizing ambient increase with impurity concentration while ΔD_0 decreases with impurity concentration. These results indicate that boron and phosphorus diffuse via a dual mechanism in oxidizing ambient.

Dependence on junction depth.—Figure 4 shows the relationship between ΔD_0 and initial junction depth

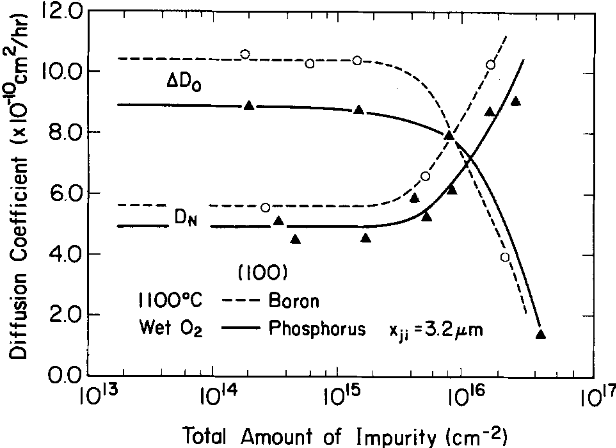

Fig. 3. Diffusion coefficient *vs.* total amount of impurity for boron and phosphorus diffusion at 1100°C in wet O_2 ambient.

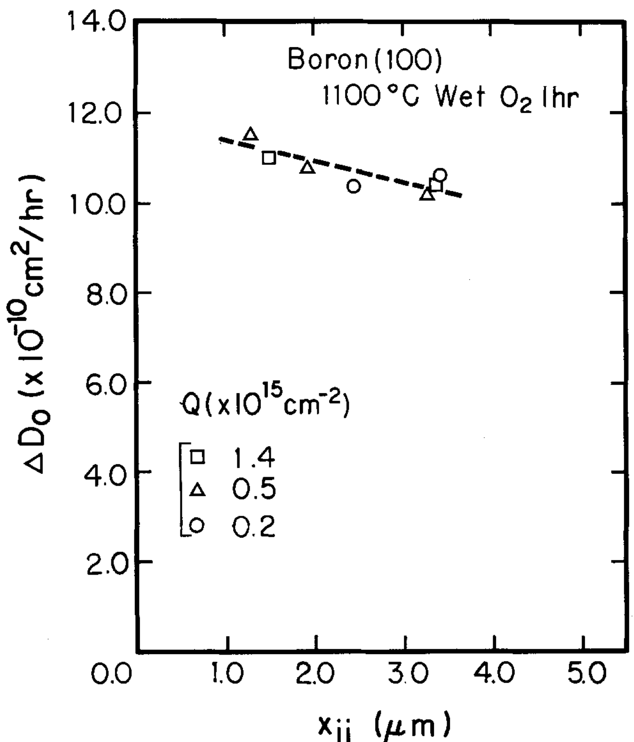

Fig. 4. Depth dependence of ΔD_0 for boron at 1100°C in wet O_2 ambient for (100) Si surface.

for various amounts of boron atoms. It is clear that ΔD_0 depends on the distance from the silicon surface. This approximately linear dependence suggests that some mobile species formed on the silicon surface during oxidation, which are responsible for the enhanced diffusion, must penetrate into the silicon bulk crystal and be captured during migration into bulk silicon. The diffusion length of the species is estimated at about 25 microns from the extrapolated line on the abscissa. If the amount of impurity is less than 3×10^{15} atoms/cm^2, this value is independent of kind of impurity. Figure 5 shows the ΔD_0 *vs.* initial junction depth for various amounts of phosphorus atoms. Depth dependence and diffusion length of mobile species are similar to those of boron.

Dependence on oxidation rate.—Figure 6(a) and (b) show log plots of ΔD_0 as a function of the time-averaged oxide growth rate for boron and phosphorus, respectively. Straight lines have been drawn through the experimental open circle points which are obtained in wet Ar ambient. Although the enhancement of the diffusion constant, ΔD_0, is believed to be proportional to the averaged oxide growth rate (6), Fig. 6(a) and (b) show $\Delta D_0 \propto (X_0/t)^{0.3}$. Note that ΔD_0 is the measured time-averaged diffusion coefficient. Masetti (6) reported that phosphorus diffusion coefficient is strongly influenced by the nature of the ambient and that there is different ambient dependence between dry O_2 and wet O_2. In the present study, however, there is no difference in ΔD_0 between dry O_2 and wet Ar at the same oxide growth rate, as shown in Fig. 6(a) and (b) by the solid circles. It was found that the diffusion coefficients obtained from the profiles under the masked surface were independent of the oxidation rate.

Dependence on oxidation temperature.—Figure 7 shows the relationship between the oxidation temperature and ΔD_0 for boron and phosphorus. In this experiment, the oxidation time when diffusion occurred simultaneously was chosen for each temperature to obtain the same oxide thickness, that is, 0.8 microns. The points in Fig. 7 follow quite accurately Arrhenius law with activation energy of 2.55 eV for both impurities. The same activation energy for boron and phosphorus diffusion suggests that these two impurities diffuse by the same mechanism. About the same activation energy is also obtained from the experiments (14) on stacking fault growth which could result from the flow of interstitial silicon atoms

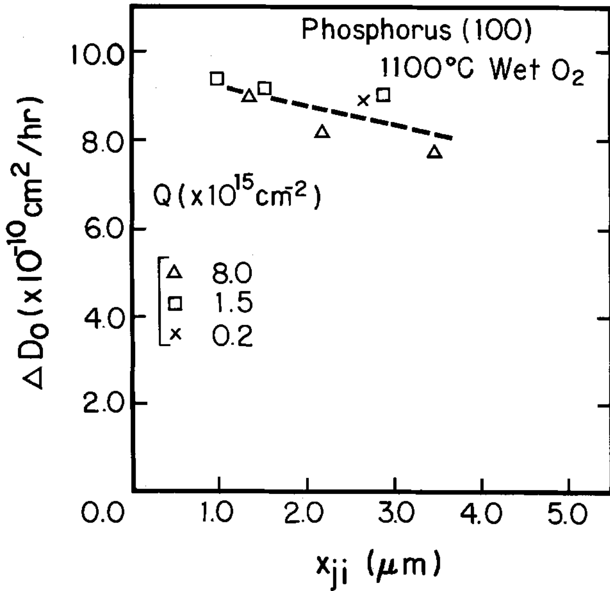

Fig. 5. Depth dependence of ΔD_0 for phosphorus at 1100°C in wet O_2 ambient for (100) Si surface.

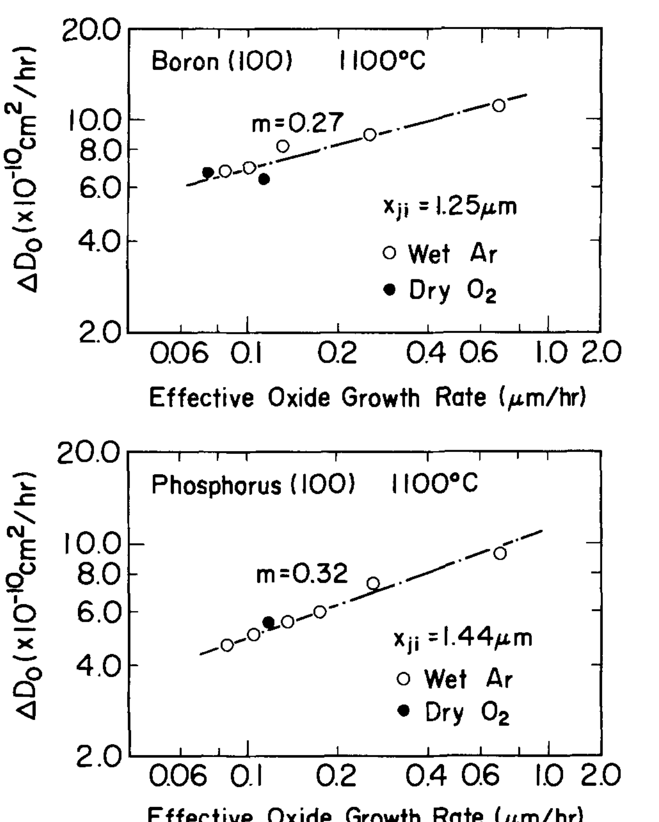

Fig. 6. Oxide growth rate dependence of ΔD_0 for (100) surface (a, top) boron and (b. bottom) phosphorus.

from the interface into the silicon bulk. For comparison with these experimental data, the diffusion coefficients obtained by Fair (15) and Antoniadis (7) under nonoxidized ambient are also plotted in Fig. 7 by dotted lines. A remarkable feature of the data presented here is the multifold increase in boron and phosphorus diffusion coefficient at lower temperature.

Discussion

Since the diffusion coefficient in the oxidizing ambient is shown by the sum of ΔD_0 and D_N which have different activation energies, and different concentration dependence, the oxidation associated diffusion is assumed to take place via a dual mechanism. One of them, D_N, the diffusion coefficient in an inert atmosphere, is described by the vacancy mechanism as widely accepted. On the other hand, the oxidation enhanced diffusion term, ΔD_0, can be considered to take place via an interstitialcy mechanism.

Oxidation induced stacking fault growth behaves almost the same as oxidation enhanced diffusion, as far as activation energy value (18) and orientation dependence (17) are concerned. These facts strongly support the idea that the two phenomena can be ascribed to a common origin. Moreover, the growth of stacking faults is due to an enhanced interstitial silicon concentration in the vicinity of the oxide-silicon interface relative to the thermal equilibrium value as pointed out by Sanders and Dobson (19).

Now, we propose a diffusion model to explain the depth dependence of the oxidation enhanced diffusion by analogy with the behavior of stacking fault growth, in which excess interstitial silicon atoms generated at the silicon surface will be captured by vacancies during migration into bulk silicon. Following Hu (13), motion of the interstitial silicon atoms will be described by the following equation

$$\frac{\partial c_i}{\partial t} = D_i \frac{\partial c_i}{\partial x^2} - kC_v(C_i - C_i^*) - R_{ppt} \qquad [7]$$

where D_i is the diffusion coefficient of interstitial silicon atoms and C_i^*, C_v, and R_{ppt} are the thermal equilibrium concentration of interstitial silicon, the concentration of vacancy, and the rate of precipitation, respectively. Hence, $kC_v(C_i - C_i^*)$ shows the recombination rate of vacancy and interstitial silicon. For an approximate solution, $\partial c_i/\partial t = 0$ is assumed because of the extremely fast diffusion of silicon self-interstitials.

Though excess interstitial silicon atoms reduce the concentration of vacancies near Si/SiO_2 interface by recombination, we make the assumption that the number of interstitial silicon atoms generated at the interface is very small compared to that of vacancy near surface. Therefore, C_v/C_v^* nearly equals unity regardless of the distance from the silicon surface. (C_v^* is the thermal equilibrium concentration of vacancy in bulk.)

For low impurity concentration, when R_{ppt} in Eq. [7] is negligible, the distribution of interstitial silicon is given by

$$C_{i(x)} = C_i^* + [C_{i(o)} - C_i^*] \exp(-X/L_D) \qquad [8]$$

where L_D is the effective diffusion length of interstitial silicon atoms. Since the enhanced diffusion coefficient of impurity is directly proportional to the concentration of the interstitial silicon, ΔD_0 also follows the exponential law

$$\Delta D_o = K[C_{i(o)} - C_i^*] \exp(-X/L_D) \qquad [9]$$

In the case of $X << L_D$, the oxidation enhanced diffusion coefficient can be expanded into a simple formula which shows linear depth dependence

$$\Delta D_o = K_o[1 - X/L_D] \qquad [10]$$

Thus, there is a good qualitative agreement between theory and experimental results shown in Fig. 4 and Fig. 5.

Since this equation does not have a concentration term, oxidation enhanced diffusion should be concentration independent in the case of low impurity concentration. This is justified in comparison with the results as shown in Fig. 3. On the other hand, for $Q > 3 \times 10^{15}$ cm^{-2}, the oxidation enhanced diffusion coefficients, ΔD_o, decrease drastically. This behavior is qualitatively explained as follows. The vacancy concentration in this case is proportional to the doped impurity concentration. If the vacancy concentration is high enough to reduce the concentration of the excess interstitial silicon to very low by recombination of vacancy and interstitial silicon atoms, there will be no oxidation enhanced diffusion, which coincides with the annihilation of oxidation induced stacking fault at high substrate impurity concentration (16).

To obtain the model utilized in process simulation, we will derive the relationship between an instantaneous diffusion coefficient ΔD_o^i and the measured time averaged diffusion coefficient ΔD_o, in the following way.

We suppose that ΔD_o^i is proportional to instantaneous oxidation rate, dX_o/dt, with an exponent, n, to be determined

$$\Delta D_o^i = K\left(\frac{dX_o}{dt}\right)^n \quad [11]$$

As expected, the oxide growth is observed to follow accurately the usual parabolic law

$$X_o^2 = Bt \quad [12]$$

where B is the parabolic rate constant. Therefore, the time averaged diffusion coefficient ΔD_o can be derived by using Eq. [11] and [12]

$$\Delta D_o = \frac{1}{t}\int_0^t \Delta D_o^i dt = \frac{KB}{X_o}\int_0^{X_o}\left(\frac{dX}{dt}\right)^n \frac{2X}{B}dX$$

$$= \frac{2K}{2-n}\left(\frac{1}{2}\right)^n\left(\frac{X_o}{t}\right)^n \quad [13]$$

To be consistent with the experimental data in Fig. 6(a) and (b), one can choose $n = 0.3$. Then, Eq. [13] becomes

$$\Delta D_o = 0.95K\left(\frac{X_o}{t}\right)^{0.3} \quad [14]$$

By comparison with Eq. [11], one sees that the prepower value, K, in Eq. [11] is enhanced by a factor of 1.05 compared with that of the time averaged diffusion coefficient, ΔD_o.

In the following, we discuss only ΔD_o^i instead of ΔD_o and neglect the subscript, i, for simplicity.

From the aforementioned results and Eq. [9], in the case of low impurity concentration, the following formula is obtained describing ΔD_o as a function of oxide growth rate ($= dX_o/dt$), depth, and temperature for wet oxidation

$$\Delta D_o(x) = F^\circ\left(\frac{dX_o}{dt}\right)^n \exp(-X/L_D)\exp(-\Delta E_2/kT) \quad [15]$$

where $F = 6.0 \pm 0.4 \times 10^{-2}$ cm^2/hr for boron, and $5.2 \pm 0.4 \times 10^{-2}$ cm^2/hr for phosphorus, and $\Delta E_2 = 2.07 \pm 0.04$ eV. The uncertainties which affect the activation energy and F values come primarily from the uncertainty associated with the junction depth measurements. It should be noted that activation energy in the last term is a converted value at 1 micron/hr oxidation rate. The exponent, n, and the diffusion length of interstitial silicon, L_D, decrease very slightly with temperature; $n = 0.33$ at 1000°C and $n = 0.30$ at 1100°C, $L_D = 30$ microns at 1000°C and $L_D = 25$ microns at 1100°C. Therefore, in case of relatively shallow diffusion, the temperature dependence of these values is neglected. Consequently, the diffusion coefficient in an oxidizing ambient can be described by the following formula at low impurity concentration

$$D = D_o \exp(-\Delta E_1/kT) + F\cdot\left(\frac{dX_o}{dt}\right)^n \exp(-X/L_D)\exp(-\Delta E_2/kT) \quad [16]$$

where $D_o \exp(-\Delta E_1/kT)$ is the diffusion coefficient in an inert atmosphere.

Finally, to check the accuracy of our oxidation enhanced diffusion model, comparisons between computed and measured ΔX_j and oxidation time have been made. Figure 8 shows the relationship between ΔX_j and oxidation time, together with the corresponding theoretical curves computed by using the Kato and Nishi model (12) and the diffusion coefficient values given in Eq. [15]. The dashed line calculated by using the linear oxidation rate dependence of diffusion coefficient, however, does not follow the experimental points. On the other hand, the solid lines calculated by using the present model is in very good agreement with experimental results.

Conclusions

The diffusion coefficient of chemically deposited boron and phosphorus in (100) silicon has been obtained experimentally under various oxidizing ambients. The diffusion coefficients were calculated from the values of X_j and ρs by using a simple Gaussian distribution after oxidation. From the experimental results, the following behavior of impurity diffusion can be observed.

1. The oxidation enhanced diffusion coefficient can be described by the following formula for low impurity concentration

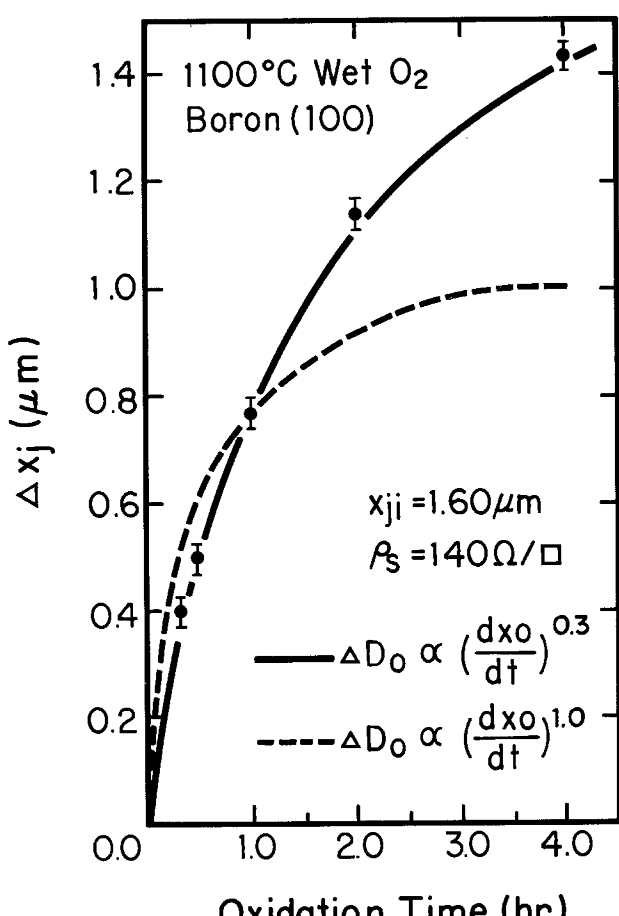

Fig. 8. Oxidation time vs. ΔX_j. The solid curve is calculated by using the present model.

$$D = D_0 \exp\left(-\frac{\Delta E_1}{kT}\right) + F \cdot \left(\frac{dX_0}{dt}\right)^n \exp\left(-\frac{X}{L_D}\right) \exp\left(-\frac{\Delta E_2}{kT}\right)$$

The depth dependence of ΔD_0 is explained by assuming that excess interstitial silicon atoms are captured by vacancies during migration into bulk silicon.

2. The oxidation enhanced diffusion expressed by the above formula can be explained by a dual mechanism, *i.e.*, the vacancy and interstitialcy mechanism.

Retardation of Destructive Breakdown of SiO_2 Films Annealed in Ammonia Gas

Takashi Ito, Hideki Arakawa, Takao Nozaki, and Hajime Ishikawa*

Fujitsu Laboratories Limited, Semiconductor Devices Laboratory, Nakahara, Kawasaki, Japan

ABSTRACT

It has been found that a remarkable improvement in dielectric breakdown characteristics of MOS structures can be achieved by annealing SiO_2 films in purified NH_3 gas at 900°-1200°C even if sodium-contaminated Al electrodes are used. This effect is due to the surface nitrided region of SiO_2 which acts as a barrier against ion migration.

A thinner reproducible and reliable gate insulator is needed for very large scale integration in metal-oxide-semiconductor structures (1). The practical problems faced in this are instability due to hot carrier trapping (2) and nonuniformity of breakdown characteristics of such insulators (3). Oxide films thinner than those now used widely are so fragile that they must be protected from destruction throughout their production and use. Si_3N_4 deposited on thermally grown SiO_2 (4) and phosphorus-doped oxide (5) were studied as methods of protection against contamination. Further, direct thermal nitridation of Si was proposed as a method for producing uniform and dense gate insulators (6).

The breakdown characteristics of thermally grown SiO_2 on Si were found to be markedly influenced by processing and materials (7). SiO_2 films grown under carefully controlled conditions, for which breakdown phenomenon relates to the nature of the material, are destroyed as current concentrates into the relatively low energy-barrier points on the film.

* Electrochemical Society Active Member.
Key words: MOS, silicon nitride, current distribution equilibrium, contamination barrier.

This paper demonstrates that the breakdown characteristics of thin SiO_2 films are greatly improved by annealing them in purified ammonia gas. Importantly, high field current instability does not occur until the current increases to about two orders greater than that allowed with conventional SiO_2 films. This effect is attributed to a surface region of nitrided SiO_2 (8).

Experimental MOS diodes were fabricated using boron-doped, p-type, 0.8-1.2 Ωcm, (100) oriented silicon wafers which were 2 in. in diameter.

After cleaning, SiO_2 films were thermally grown in wet oxygen ambient at a temperature of 1000°C. The film thickness was from 500 to 700Å. Relatively thick oxide films were chosen here because the onset of current instability comes sooner as the oxide becomes thicker (9). The wafers were then annealed in fully purified ammonia gas at temperatures ranging from 900° to 1200°C. The annealing time was from 1 to 5 hr. Aluminum electrodes with a thickness of 5000Å were evaporated from a tantalum boat. A tungsten boat was partly used in an experiment involving intentional sodium contamination. Al dot electrodes with diameters from 100 to 1200 μm were patterned photolithographically. The Al electrode was

thick enough to preclude so-called self-healing breakdown and to allow the lowest breakdown voltages to be measured. The back sides of the wafers were lapped and evaporated with 5000Å thick aluminum films. The diodes were sintered in pure nitrogen at 450°C for 15 min.

The typical breakdown characteristics of both unannealed and NH_3 annealed SiO_2 films are shown in Fig. 1. The polarity of the applied voltage was a negligible factor. The following experiments were done by applying negative voltage to Al dot electrodes; hole accumulation in p-type Si. A conventional MOS diode with an unannealed 700Å thick SiO_2 film and a dot electrode 400 μm in diameter showed fast transition from an initial high resistive state (a) to a conductive state (b) as soon as the maximum internal field exceeded the breakdown field. Current instability occurred at values below 50 μA. The breakdown was destructive. A 64 kΩ current-limiting resistor was used to take the photograph of the transition.

The maximum field strength was about 8.5 MV/cm. In the case of a diode with an SiO_2 film annealed in NH_3 at 1100°C for 2 hr this transition was not observed until the current increased to a few hundred microamperes. This equilibrium current shown in Fig. 1(c) did not lead to any destructive breakdown. This photograph was taken without using an external current-limiting resistor. Because of the film's nondestructive characteristics, its breakdown voltage increased a little.

The relation of breakdown current, *i.e.*, the maximum equilibrium current just prior to final breakdown, on NH_3 annealing conditions is shown in Fig. 2 and 3. Diodes measured were those with an SiO_2 thickness of 500Å and an Al dot diameter of 400 μm. All measurements of breakdown voltages were done on a curve tracer. Time-dependence of breakdown characteristics was not measured. As the series resistance was less than 10Ω and the ramp rate of the applied voltage was about 3 MV/cm · sec, the initial and final breakdown voltages were identical. The distribution of breakdown current through more than 50 diodes within a wafer is also indicated in both figures. The unannealed oxide film allowed an equilibrium current of only 20-30 μA. The breakdown current increased as the annealing temperature increased and saturated at about 10^3 μA. This was 2 times larger than that of the unannealed film. Because the breakdown current was found to be nearly proportional to the peripheral length of the electrode and not to its area, current density, which is derived from average current per unit area, was meaningless. Increases in the breakdown current appeared clearly at temperatures above about 900°C. The breakdown current gradually increased over time until 2 hr passed at 1000°C as shown in Fig. 3. Higher temperatures are expected to reduce the saturation time. It is projected to be only 1 hr at 1200°C. As shown in Fig. 1, breakdown voltage was also improved through NH_3 annealing. Figure 4 shows the increase of breakdown field along annealing time at 1200°C. The value of the NH_3 annealed oxide film was 10% higher than that of the unannealed film.

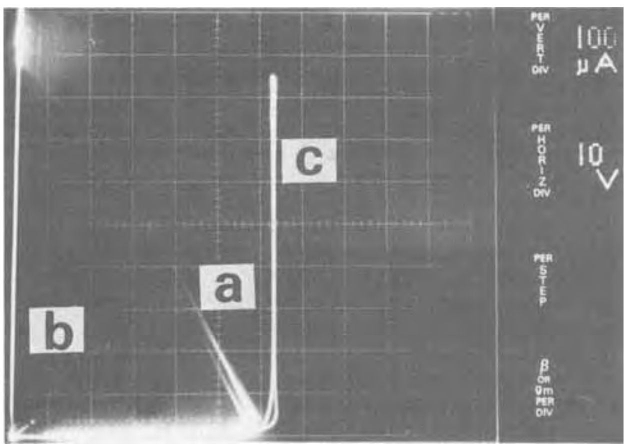

Fig. 1. Typical breakdown characteristics of a conventional 700Å thick SiO_2 film (a) and (b), and of an NH_3 annealed film (c). Negative voltages were applied to 400 μm diam Al dot electrodes.

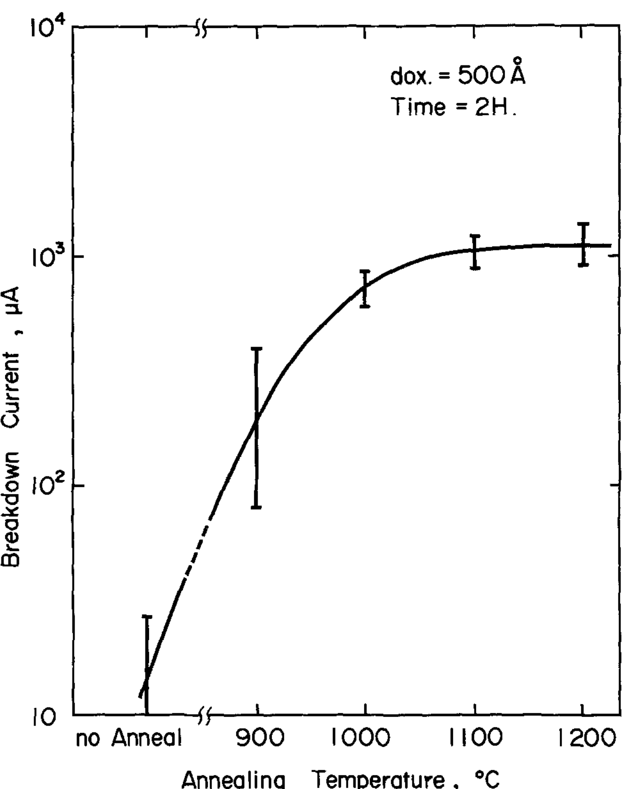

Fig. 2. Breakdown current, defined as the maximum equilibrium current just prior to breakdown, vs. NH_3 annealing temperature. Diameter of Al dots was 400 μm.

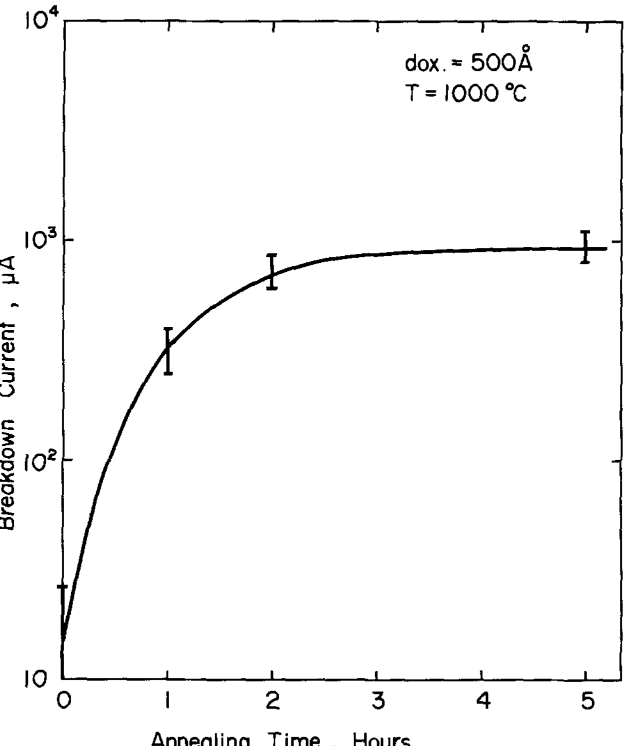

Fig. 3. Breakdown current vs. NH_3 annealing time

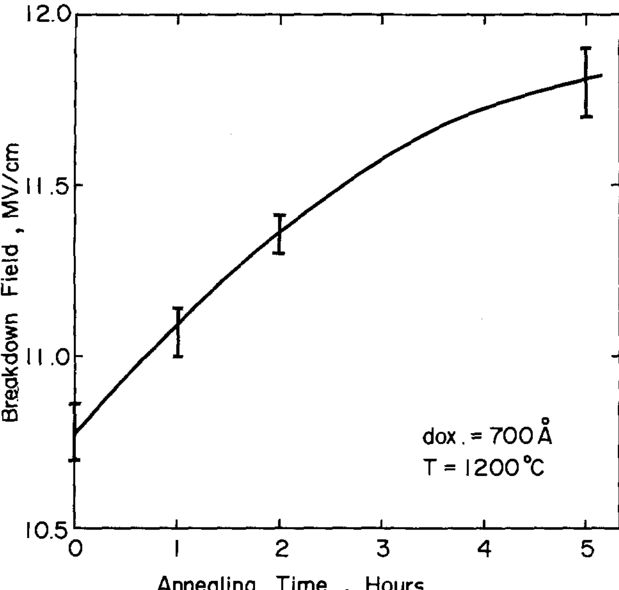

Fig. 4. Maximum field strength of NH_3 annealed SiO_2 films

Observation of the Al dot electrode surfaces after oxide breakdown revealed partly removed regions where material had evaporated. Figure 6(a) shows the surface of a diode with an NH_3 annealed SiO_2 film. Although there are some small pits evident on the plane surface, it is clear that the breakdown occurred mainly at the electrode's periphery. This phenomenon was identical with unannealed and NH_3 annealed SiO_2 films. This means that NH_3 annealing brings about no change in the breakdown energy of SiO_2 films because of almost the same areas of the removed regions.

The present experimental results may be explained by using the oxide breakdown mechanism model proposed by Ridley (10). This model is based on Fowler-Nordheim tunnel injection of carriers from a cathodic protuberance, filamentary joule heating, and activation of mobile ions which enhance the injection field. The current flow just prior to breakdown, which is increased about 2 times after NH_3 annealing, is distributed nearly uniformly on the dot electrodes. This may be a result of the uniform surface structure of NH_3 annealed SiO_2 films. Because localized heating is avoided, high current is allowable.

The current distribution just prior to breakdown shown schematically in Fig. 5(a) is for an MOS diode with conventional SiO_2. Current concentrations occur at low energy-barrier points as demonstrated by DiStefano (11) with internal photoemission scanning.

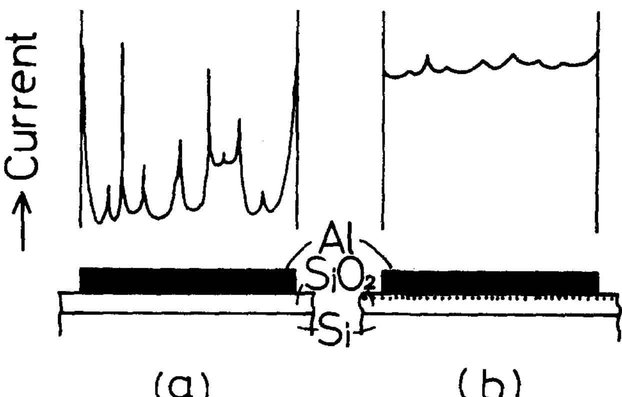

Fig. 5. Schematic diagrams of current distribution on Al dot electrodes of MOS diodes for conventional (a) and NH_3 annealed (b) SiO_2 films.

NH_3 annealed SiO_2 (b) allows far higher current flow as a result of greater uniformity of its surface.

To make this effect clear, Al electrodes which were evaporated from a sodium-contaminated W boat were used. The effect of NH_3 annealing was as remarkable as in the case of contamination-free samples. The surfaces of Al electrodes after breakdown are shown in Fig. 6(b) and (c). The results are far different from those shown in (a). The SiO_2 films in (b) and (c) are unannealed and NH_3 annealed, respectively. Many self-healing breakdown pits which will eventually lead to final breakdown, can be recognized in Fig. 6(b.) They are thought to be associated with the fluctuation of potential on the SiO_2 surface which is caused by sodium-ion contamination. After NH_3 annealing, these lower energy-barrier points were removed. Current flowed almost uniformly on the Al electrode until it led to final breakdown. In this case, final breakdown occurred at the weakest point, as shown in Fig. 6(c). The breakdown current was a little lower than that for sodium-free samples. This notable occurrence in the sodium-contaminated samples is believed to be caused by the formation of a protective surface layer on the SiO_2 film which acts as a barrier against sodium contamination or as a gettering region for mobile ions.

The NH_3 annealed SiO_2 was subjected to analysis by Auger electron spectroscopy. A nitrogen peak was detected in the AES spectra of all SiO_2 films annealed in NH_3 gas at temperature above 900°C. Further chemical etching in hydrofluoric acid showed a nitrided surface layer on the SiO_2 (8). Argon sputter etching revealed the thickness of the nitrided layer to be a few tens of angstroms.

Because of the existence of the nitrided layer, a nondestructive breakdown model might possibly be applied to the explanation of the breakdown data for deposited Si_3N_4 films (12). The current-voltage characteristics of the NH_3 annealed SiO_2 were, however, due to the Fowler-Nordheim tunnel model and not to the Poole-Frenkel model. Therefore, that model (12) cannot be used.

A distribution histogram breakdown of voltages of the NH_3 annealed SiO_2 film was exceptionally sharp. Vromen (13) reported degradation of the breakdown field for SiO_2 films annealed in nitrogen. This is caused by defects generated on the interface between SiO_2 and Si. Although some reaction between NH_3 and Si at the Si-SiO_2 interfaces may be possible, the total uniformity in the breakdown-voltage histogram indicates that none occurred. Nitrided surface layers should prevent nonuniform localized reaction.

In summary, it has been found that a remarkable improvement in the breakdown characteristics of MOS structures can be achieved by annealing SiO_2 films in fully purified NH_3 gas at 900°-1200°C, even if sodium-contaminated Al electrodes are used. This effect is due to the surface nitrided region of SiO_2 which acts as a barrier against contamination. Interfacial properties of MOS structures with surface nitrided SiO_2 films will be reported soon in other articles.

Painted, Polycrystalline Thin Film Photoelectrodes for Photoelectrochemical Solar Cells

Gary Hodes,* David Cahen, Joost Manassen, and Monica David

The Weizmann Institute of Science, Rehovot, Israel

ABSTRACT

A simple, versatile method for fabricating semiconductor layers for use as photoelectrodes in photoelectrochemical cells is described. This method, in which a slurry of the semiconductor is painted onto a substrate, is demonstrated particularly for Cd (and Zn) chalcogenides, but is shown to be applicable to other materials of photovoltaic interest, such as $CuInS_2$. Also, the method allows for simple fabrication of layers of solid solutions, such as cadmium mixed chalcogenides.

The future of photovoltaic devices for terrestrial use depends, to a large extent, on the ability to produce thin film semiconductor layers at a competitive price (1). Devices using a semiconductor/liquid junction (photoelectrochemical cell:. PEC) instead of a semiconductor/semiconductor or a semiconductor/metal one, are receiving a great deal of attention,

inter alia because here conversion efficiency suffers less when the semiconductor single crystal is replaced by a polycrystalline layer (2).

We report here on a new simple method for preparation of thin film, polycrystalline semiconductor layers on a conducting substrate. Such layers are suitable for use as photoelectrodes in a PEC. The method is related to silk screen printing but is considerably less complicated for laboratory use.

Many of the uses of thin film polycrystalline semiconductors in solid-state photovoltaics have been limited to the use of a single crystal substrate, onto which the polycrystalline layer is applied (often by vacuüm evaporation) to form the active junction (3). Some notable exceptions, using silk-screen printing, are the preparation of CdS-Cu_xS cells (4) and the fabrication of CdS/CdTe solar cells (5). In the latter case 8% conversion efficiency was achieved, while in the former case the cell had too high a series resistance to be able to compete with the various other methods of fabricating thin film CdS-Cu_xS cells [see (6) for a review of other methods].

Previously we reported on electroplating techniques for the preparation of thin film photoelectrodes, such as CdSe (2, 7). The present method yields photoelectrodes with similar conversion efficiencies, and has the advantage of greater versatility and can be adopted for, and applied to, preparation of layers of a wide range of materials.

Photoelectrodes with conversion efficiencies comparable to those of electroplated ones (in the case of CdSe) can be prepared in the following general way: a powder of the material of choice is used as such, or prepared by cosintering its components, in an inert atmosphere. This powder is mixed with a suitable fluxing material (*e.g.*, $ZnCl_2$), and dispersed in liquid to obtain a slurry. The slurry is painted on a conducting substrate and dried. Subsequently it is annealed at elevated temperature and, after cooling a well-adhering polycrystalline layer is obtained.

Table I gives some examples of binary and ternary chalcogenide photoelectrodes prepared in this manner. Preparative conditions have been optimized for Cd-chalcogenides only. It should be noted, however, that even without attempts to adjust conditions the method yields photoactive layers of such other materials as $CuInS_2$, GaAs, and MoS_2.

All electrodes are given a standard etch of 10 sec in 3% HNO_3 in HCl at room temperature. Some electrodes are given an additional "ion treatment" which results in an increase of open-circuit voltage of the electrodes. For the $ZnCl_2$ treatment, the electrode is immersed in a 1M aqueous solution of $ZnCl_2$ (or any soluble Zn salt) then rinsed very lightly with water, and dried. For the K_2CrO_4 treatment, a similar dipping in an aqueous K_2CrO_4 solution is carried out, but rinsing is not necessary.

An important advantage of this painting method is the case with which the composition of the semiconductor can be varied in a controlled way. An example of this versatility is the solid solution system, Cd(Se, Te), preparation of which is described later. This enabled us to study the effect of changes in alloy composition on conversion efficiency and output stability.

Figures 1 and 2 show SEM pictures of electrodes prepared using commercially available CdSe (Fig. 1) and using a cosintered mixture of CdSe and CdTe (65:35 atomic percent; Fig. 2). From these pictures we see that the average final particle size is larger in the mixture as a result of the annealing cosintering step.

Although all entries in Table I refer to layers on Ti substrates it is possible to use other substrate materials as well, notably Cr or Mo.

The fluxing agent has a dual role in formation of the layers. Primarily, by dissolving the outer layers of the semiconductor grains, and subsequently vaporizing off, it binds the grains together and thus imparts structural coherence to the layer. It also promotes re-

Table I.

All electrodes 1 cm². Starting powders Alfa 4N, ≤10 μm for CdTe, 5N, 3 μm for CdSe, analytical grade for others. Slurry prepared from 50 mg powder and 0.05 ml liquid or multiples thereof. Liquid composition: 5% nonionic detergent in water (v/v) or a 1:5 mixture of a saturated solution of ethylcellulose in toluene with ethylene glycol monobutyl ether (8).

crystallization and growth of larger grains. In addition, it can act as a dopant for the semiconductor. The halide component of most fluxes can act as an n-type dopant for most of the II-VI semiconductors. An even greater degree of n-type doping occurs if a group III halide is used instead of, or together with, another flux (see, *e.g.*, CdTe in Table I prepared with, and without, an $InCl_3$-containing flux).

For the preparation of the mixed semiconductor layers, the desired solid solution is prepared by heating the individual components in powder form together with a flux, which is usually $CdCl_2$. For example, to prepare $CdSe_{0.65}Te_{0.35}$, CdSe and CdTe (in a molar ratio of 6.5/3.5) are mixed with ~25% (w/w) $CdCl_2$, and sintered in argon at 650°-670°C for 40 min. X-ray diffraction shows the powders have the expected compositions (assuming the validity of Vegard's law for the lattice dimensions). The product is ground up, washed with water (to remove any excess $CdCl_2$), and used to prepare a layer as described above. In this case, the flux serves mainly to facilitate formation of a true solid solution, in this respect, it is not absolutely essential, because a solid solution could be prepared also by sintering a pressed pellet of the components without flux (9). The flux method, however, is generally the more convenient one.

The liquid to be used for preparing the slurry has to wet the powder thoroughly (thus, if water is used, some detergent is added), and enable the preparation of a smooth slurry for equal distribution of the powder over the substrate. Also its boiling point should not be so low that excessive evaporation occurs during drying. With these conditions in mind we do not find the nature of the liquid to be critical, and water suffices in most cases.

As in the case of electroplated layers, the annealing process determines the final (photo-) electrical properties of the layer, and the exact conditions for it, as well as the optimal fluxing agent will depend on the material used. As shown here, though, once such conditions are determined they can be applied, with minor changes only, to a series of similar materials.

Finally, we comment on the performance of painted photoelectrodes. Table I shows that their efficiencies are comparable to those of electroplated thin layer photoelectrodes (10). Output stability, too, is comparable, and >10,000 C/cm² at ~35 mA/cm² can be passed through CdSe or $CdSe_{0.65}Te_{0.35}$ electrodes with less than 10% decrease in output. CdSe electrodes of 4 cm² area with 3% conversion efficiency can be prepared routinely by this method.

A Model of SIPOS Deposition Based on Infrared Spectroscopic Analysis

W. R. Knolle* and H. R. Maxwell, Jr.*

Bell Laboratories, Reading, Pennsylvania 19604

ABSTRACT

SIPOS deposited rapidly at atmospheric pressure (AP) is different from SIPOS deposited more slowly at low pressure (LP). The transmission infrared spectra of the AP and LP SIPOS films can be different for the same oxygen content. We interpret our infrared data for AP SIPOS in terms of a statistical model for the bonding of silicon and oxygen that predicts less than 1% SiO_2 character [$Si(O_4)$ tetrahedra] for the AP SIPOS. The LP SIPOS films have more SiO_2 character than the AP SIPOS. We believe this arises from the slower deposition rate for LP SIPOS where oxygen can preferentially bond to an already oxygen-bonded Si. Stress measurements and reactivity to HF for LP SIPOS films correlate with the infrared data and are consistent with our interpretation of the infrared data.

SIPOS (semi-insulating polycrystalline silicon) is an oxygen-doped silicon film that can be used as part of a passivation scheme on high voltage semiconductor devices (1). The SIPOS is deposited by the reactive decomposition of silane (SiH_4) and nitrous oxide (N_2O) either at atmospheric pressure (AP) or at a lower pressure (LP). The oxygen content of the film can be controlled by the ratio of the N_2O to SiH_4 gas flows in the deposition reactor (1).

We have used transmission infrared spectroscopy to investigate the SIPOS films deposited at AP and LP. The differences between the infrared spectra

* Electrochemical Society Active Member.
Key words: semiconductor, passivation, thin films.

are explained in terms of silicon-oxygen bonding differences between the two films. A statistical model of film deposition we believe explains the AP deposition while the LP SIPOS has more SiO_2 character than would be predicted by this model. The physical properties of the SIPOS not only depend on oxygen content but rate of deposition as well.

We describe the deposition of the AP and LP SIPOS and present the infrared spectra and our analysis of these data. Stress measurements and reactivity of the SIPOS to conc HF corroborate our interpretation of the infrared data. The SIPOS films that we believe have some SiO_2 character are in compression (SiO_2 is in compression on Si) and react with conc HF (SiO_2 etches rapidly in HF). Finally we describe how this physical difference between the films might arise.

It should be noted that the results reported here apply to as-deposited SIPOS films that have received no postdeposition anneal. Annealed SIPOS films have quite different physical properties from the as-deposited films (2).

Experimental Details

SIPOS deposition.—AP SIPOS films were deposited on 2 in. diam Si wafers in a radiantly heated cold wall reactor at 650°C. The wafers were laid flat on a susceptor in the reactor and SIPOS was deposited on one side of the wafer. For oxygen determination by the gravimetric technique (3) SIPOS should be on both sides of the silicon-nitride-covered wafer. Therefore, two consecutive runs were made with the same N_2O to SiH_4 ratio. Five different ratios were used to obtain SIPOS films with oxygen contents between 18 and 37 atomic percent (a/o) oxygen. The data for these runs are presented in Table I. The thickness of the SIPOS film was determined by angle lapping the wafer and counting the interference fringes under sodium light (λ = 5890Å) (4). The average thickness and average deposition rate are presented for the two depositions at each oxygen content. As can be seen in Table I the deposition rate depends inversely on the oxygen content of the film (1).

The LP SIPOS films were deposited in a hot wall reactor at 644°C. The Si wafers were loaded on a boat and held vertically in the furnace, perpendicular to the gas stream so that deposition occurred on both sides of the wafer. The SIPOS was deposited over a range of conditions in order to vary the deposition rate and oxygen content of the LP SIPOS. Deposition rates ranged from 143 to 23 Å/min. For example, a 37 a/o O LP SIPOS film was deposited at 0.16 Torr at a deposition rate of 29 Å/min. Another LP SIPOS film with 22.7 a/o O was deposited at 0.35 Torr at a deposition rate of 63 Å/min. The N_2O/SiH_4 ratio was greater for the higher oxygen content LP SIPOS film. Detailed analysis of these LP SIPOS films deposited under various conditions will be presented in a forthcoming paper (5).

Infrared measurements.—The transmission infrared spectra were recorded on a Perkin-Elmer Model 621 Grating Infrared Spectrophotometer. An Si substrate without any SIPOS was placed in the reference beam to eliminate interference from the substrate in the sample beam. A wafer adjacent to the silicon-nitride-covered wafer was used for the infrared measurement. The absorbance, A, of an infrared peak was measured by the base line technique (6) and the area of an absorption was approximated by $A \cdot W$ where W is the full width at half of the maximum absorbance (7). The transmission infrared technique is not as sensitive to the condition of the SIPOS surface as are other techniques that have been used to investigate SIPOS (8, 9) and so the infrared spectra should be representative of the bulk of the as-deposited SIPOS films. There was no physical or chemical treatment of the SIPOS film prior to recording the infrared spectrum.

Stress and HF reactivity.—The stress of the SIPOS film was measured with an optically levered laser technique (10). The difference between the radius of curvature of the Si wafer measured before and after deposition can be related to the stress in the deposited SIPOS film. The precision of the stress measurement is $\pm 1 \times 10^9$ dynes/cm^2.

SIPOS films can be etched in a solution of buffered HF and hydrogen peroxide (1). The peroxide presumably oxidizes the SIPOS film and the buffered HF etches the newly formed oxide. HF is not believed to etch suboxides of Si, so as an indication of SiO_2 content, the reactivity of the SIPOS film to conc HF was measured by immersing the wafer in HF and noting the time when a reaction began. Times up to 15 min in HF were measured.

Results

Table II lists the infrared results for the AP SIPOS films. The oxygen content x of a SIPOS film SiO_x is listed in column 1. The average of the infrared data for the two runs at each N_2O to SiH_4 ratio is listed. Since the absorbance of a peak is proportional to the thickness and oxygen content of the SIPOS the infrared absorbances in Table II have been divided by the SIPOS thickness. Figure 1 shows the infrared spectra of the $x = 0.33$ (25 a/o O) and $x = 0.58$ (37 a/o O) AP SIPOS films. There are two infrared peaks in this range: a strong absorption at 1025 cm^{-1} believed due to an Si-O-Si stretching vibration and a weak absorption at 865 cm^{-1}. For the AP SIPOS films the strong and weak absorptions increase in intensity with increasing oxygen content. Furthermore, as is apparent from column 4 of Table II as well as Fig. 1, the width of the strong absorption increases with increasing oxygen content. Also, the strong absorption remains at 1025 cm^{-1} $\pm$ 5 cm^{-1} over the range of oxygen contents investigated.

Figure 2 shows the infrared spectra of AP and LP SIPOS with the same oxygen content. The LP SIPOS was deposited at 0.16 Torr with a deposition rate of 29 Å/min while the AP SIPOS was deposited at a rate of 370 Å/min. For the infrared spectrum of LP SIPOS the same two peaks appear, however, the strong absorption shifts to higher frequency with increasing oxygen content while the 865 cm^{-1} peak actually decreases in intensity. Plotted in Fig. 3 is the ratio of the 865 cm^{-1} peak intensity to the strong absorption intensity as a function of oxygen content for the AP and LP SIPOS films. For the AP SIPOS the ratio increases monotonically while for the LP SIPOS the ratio rises to a maximum at about 25 a/o O ($x = 0.33$) and then decreases.

Table I. AP SIPOS deposition data

Oxygen content a/o O	Oxygen content x	Deposition time (min)	N_2O/SiH_4	Thickness (μm)	Deposition rate (A/min)

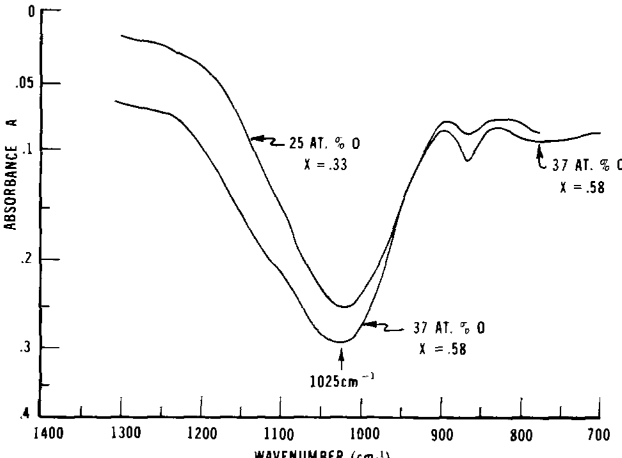

Fig. 1. Infrared spectra of AP SIPOS films, SiO_x, with oxygen content $x = 0.33$ and $x = 0.58$.

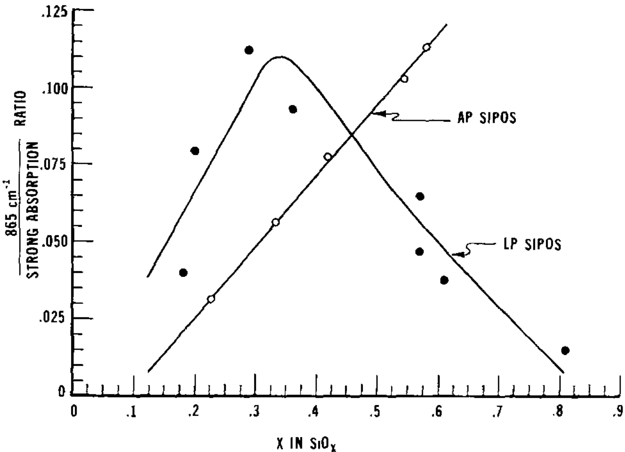

Fig. 3. Ratio of the 865 cm^{-1} peak to the strong absorption intensity as a function of oxygen content. The ratio increases for AP SIPOS while it increases and then decreases for LP SIPOS.

Figure 4 summarizes the infrared, stress, and HF reactivity data for various LP SIPOS films. In Fig. 4 a P beside a point means the SIPOS film lasted at least 15 min in HF without showing any physical reaction to the HF. An F means the film lifted off the substrate or that lifting of the film had begun within 15 min. The ordinate in Fig. 4 is the measured stress in units of 10^9 dynes/cm^2 with the convention that positive stress is tensile and negative stress is compressive. The abscissa is the infrared peak position in cm^{-1} for the strong absorption. Since the strong absorption remains at 1025 cm^{-1} for the AP SIPOS we did not plot the data for the AP SIPOS films. These films were all in tension and did not lift off in HF.

The data in the upper left-hand quadrant of Fig. 4 are either for low oxygen content (less than 30 a/o O) or rapidly deposited (greater than 45 Å/min) LP SIPOS or both. These films are all in tension and do not react to HF. The four data points in the lower right-hand quadrant are for higher oxygen content LP SIPOS or LP SIPOS films deposited at a slower rate or both. These films are in compression and react to HF in less than 15 min.

Discussion

Statistical model for AP SIPOS.—Philipp (11) concluded from an analysis of optical data that SiO_x films with $1 \leq x \leq 2$ have a structure made up of a statistical distribution of Si tetrahedra of the type $Si(Si_yO_{4-y})$. We have calculated these statistical distributions for the five different oxygen content AP SIPOS films that were deposited. The results are presented in Table III. Briefly, the table is generated in the following way. For a SIPOS film deposited with SiO stoichiometry, the probability of an O atom bonding to an Si atom in the film is 0.5. And so, for SiO_x stoichiometry, the probability of an O atom bonding to an Si atom is $0.5x$. When an O atom does not bond to an Si atom, it is assumed that an Si atom does. The probability of an Si atom bonding to an Si atom for SiO_x stoichiometry is just $1\text{-}0.5x$. The probability of obtaining an $Si(SiO_3)$ tetrahedron is $4(1\text{-}0.5x)\ (0.5x)\ (0.5x)\ (0.5x)$ for an SIPOS stoichiometry of SiO_x. The 4 arises because there are 4 possible ways of arranging the atoms about the central Si atom in

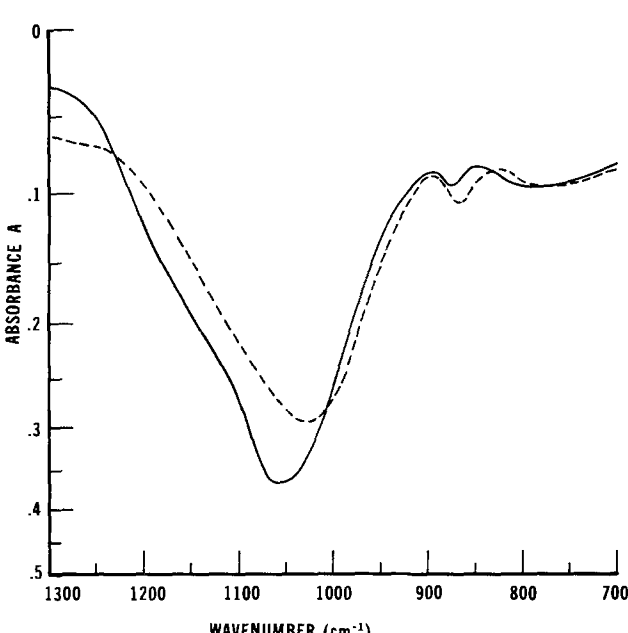

Fig. 2. Infrared spectra of AP and LP SIPOS films with identical oxygen content of 37 a/o O. The strong absorption is shifted to higher frequency and the intensity ratio of the 865 cm^{-1} peak to the strong absorption is less for the LP SIPOS. Solid line is LP SIPOS and dashed line is AP SIPOS.

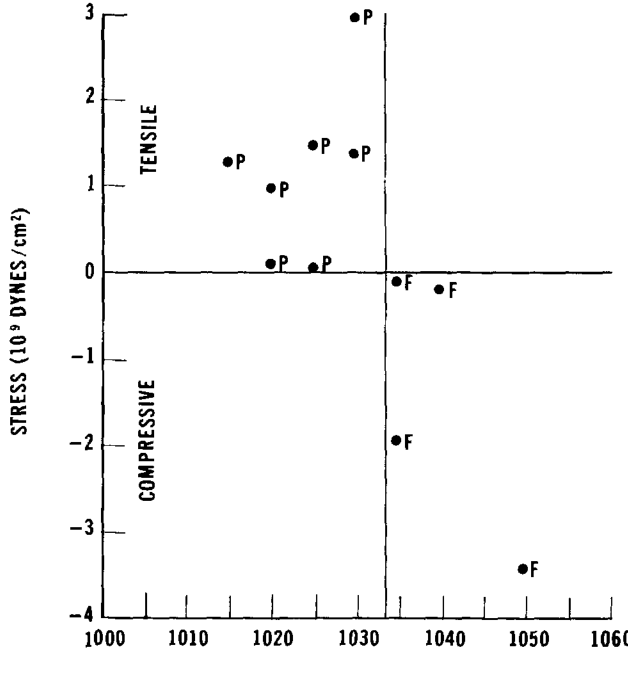

Fig. 4. Correlation of stress and HF reactivity with position of the strong infrared absorption for various LP SIPOS films. P means SIPOS did not react with HF in 15 min. F means film lifted or began to lift within 15 min.

The numbers in parentheses are the renormalized probabilities excluding the $Si(Si_4)$ tetrahedron.

the SIPOS film. The probabilities for the other tetrahedra are calculated in a similar way. The numbers in parentheses in Table III are the renormalized probabilities of the Si/O tetrahedra excluding $Si(Si_4)$ since it does not contribute to the infrared absorption. Note that the sum of each column in Table III is 1.0, that is, all of the Si atoms are bonded tetrahedrally to either Si or O.

To explain the infrared results for the AP SIPOS films we consider the probabilities of the various Si tetrahedra listed in Table III. At higher oxygen content there is less likelihood for $Si(Si_4)$ tetrahedra and there will be more of the four different Si/O tetrahedra. For example, $SiO_{0.23}$ should have a Si-O-Si stretching vibration primarily defined by the $Si(Si_3O)$ tetrahedra (82.5% of the possible Si/O tetrahedra). For $SiO_{0.58}$, the $Si(Si_3O)$ tetrahedra contribute only 55.7% of the possible Si/O tetrahedra while $Si(Si_2O_2)$ and $Si(SiO_3)$ now make substantial contributions. Therefore the Si-O-Si stretching vibration for $SiO_{0.58}$ arises from a less well-defined state and the infrared absorption at 1025 cm^{-1} should be broader. This broadening of the infrared absorption with increasing oxygen content is observed for the AP SIPOS.

The amount of $Si(O_4)$ tetrahedra, that is, SiO_2, calculated for any of the SIPOS films is small, being less than 1% for the highest oxygen content AP SIPOS film investigated. If we assume that only the SiO_2 component will shift the strong absorption to higher frequency then no shift for these films would be expected and in fact no shift for the AP SIPOS is observed.

Addition of SiO_2 to SIPOS.—We do not believe that the infrared results for the LP SIPOS films can be explained by the statistical model since the statistical model predicts very little SiO_2 component in the SIPOS films. With very little SiO_2 component (less than 1%) then no shift in the peak position of the strong infrared absorption would be expected. However, the shift to higher frequency with greater oxygen content of the strong absorption in the infrared spectrum of LP SIPOS can be simulated by adding the measured infrared spectrum of a 900°C thermally grown SiO_2 film to the infrared spectrum of an SIPOS film. Figure 5 shows the results for the addition of small amounts of the SiO_2 infrared spectrum to the measured infrared spectrum of a 22.7 a/o O (x = 0.294) LP SIPOS film. The SIPOS and SiO_2 spectra were digitized and added as $a SiO_2 + b SiO_{0.294}$ with $a + b = 1$. From Fig. 5 it can be seen that the infrared absorption occurs at 1025 cm^{-1} for this LP SIPOS film. Furthermore this film did not lift off in conc HF and therefore presumably this LP SIPOS film had very little SiO_2 character. Figure 6 is a plot of the calculated shift of the strong absorption as a function of percent SiO_2 added. The top abscissa of Fig. 6 shows the stoichiometry of the film resulting from the addition of SiO_2 and $SiO_{0.294}$. No difference in the position of the strong absorption could be measured for less than about 4% SiO_2 character. The shift to higher frequency of the Si-O-Si absorption with increasing oxygen content had been reported for films with stoichiometry between SiO and SiO_2 (12).

We believe it is the difference in the amount of SiO_2 that accounts for the difference in the measured infrared spectra of SIPOS films shown in Fig. 2. Two SIPOS films with the same oxygen content but different calculated infrared spectra can be generated by the addition of different amounts of SiO_2 to different initial SIPOS films. For example, if 6% of the SiO_2 strong absorption is added to 59.2% of the $SiO_{0.294}$ LP SIPOS (22.7 a/o O) strong absorption then an infrared spectrum is generated for an SIPOS film with a stoichiometry of $SiO_{0.45}$ (31 a/o O). This film has 9.2% SiO_2 character and a calculated strong absorption in the infrared at 1050 cm^{-1}. The same 31 a/o O film can be obtained by adding 2% of the SiO_2 absorption to 98% of the strong absorption of an AP SIPOS film with stoichiometry of $SiO_{0.414}$ (29.3 a/o O). For this AP SIPOS film the strong infrared absorption occurred at 1025 cm^{-1} and the film did not lift off in conc HF and so should have had little SiO_2 character. The resulting film is calculated to have a strong infrared peak at 1030 cm^{-1}. In Fig. 2 the measured strong absorption occurs at 1050 cm^{-1} for the LP SIPOS film which is a shift of 25 cm^{-1} in the position of the strong absorption. In Fig. 6 we would conclude from the infrared shift that the LP SIPOS film has about 10% SiO_2 character whereas the random bonding model (see Table III) predicts less than 1% SiO_2 character [Si (SiO_4) tetrahedra].

We believe the data summarized in Fig. 4 are consistent with more SiO_2 character in LP SIPOS films that have the strong infrared absorption shifted to higher frequency. In Fig. 4, the LP SIPOS films that reacted to HF and were in compression had the strong infrared absorption at higher frequency. If this shift is due to more SiO_2 then the reactivity of these films to conc HF is understandable since HF etches SiO_2 rapidly whereas it is believed not to attack suboxides rapidly. Furthermore SiO_2 on Si is in compression. The SIPOS films with the higher frequency infrared

absorption and presumably more SiO_2 character are in compression rather than tension.

Deposition rate.—During the deposition of SIPOS we would expect the Si-O bond in SIPOS to be polarized, that is, have some ionic character represented as $Si^{\delta+}$-$O^{\delta-}$, where $\delta+$ represents a small amount of positive charge on the Si atom due to the greater electronegativity of the oxygen atom. Another incoming oxygen atom would be attracted preferentially to the $Si^{\delta+}$ rather than to an Si atom that is not bonded to anything but other Si atoms. In the case of Si bonded to other Si atoms, there is no reason to suppose that the Si-Si bond is polarized and therefore the oxygen atom would not be preferentially attracted to it. For the low oxygen content AP SIPOS films, the growth rate is so rapid that there is evidently not enough time for the O atom from N_2O to seek out the $Si^{\delta+}$ atom that already is bonded to an O atom. And so, the random bonding model governs the deposition of rapidly deposited AP SIPOS. For example, a SIPOS deposition rate of 410 Å/min (typical for the AP SIPOS) corresponds to a deposition rate of 2.5 monolayers/sec taking the density of SIPOS to be the same as Si. In contrast, a deposition rate of 27 Å/min (typical for higher oxygen content LP SIPOS) corresponds to only one monolayer deposited every 6 sec. Therefore these films have more SiO_2 character than would be predicted by the statistical model. This SiO_2 character is evident in the infrared spectrum as well as the film stress and reactivity toward HF.

Model of SIPOS.—For the rapidly deposited AP SIPOS the statistical or random bonding model predicts a large fraction of $Si(Si_4)$ tetrahedra—0.613 for $SiO_{0.23}$ to 0.254 for $SiO_{0.58}$ (see Table III). Within this network of amorphous Si[13] are the remaining Si/O tetrahedra with less than 1% $Si(O_4)$, that is, SiO_2. For the more slowly deposited LP SIPOS we believe there is more SiO_2 character, that is, more $Si(O_4)$ tetrahedra, and so for the same oxygen content the LP SIPOS should have more $Si(Si_4)$ tetrahedra than the corresponding AP SIPOS film. The $Si(Si_4)$ tetrahedra are expected to form a connected network (14) and, therefore, the random bonding model would predict for SIPOS a phase of Si and a phase of Si/O tetrahedra. Our results support the model of SIPOS deduced from ESCA (8) and electron diffraction (9).

Conclusions

AP and LP SIPOS films are different. The differences between the films depend on the rate of deposition: rapid for the AP and slow for the LP SIPOS.

An analysis of the transmission infrared spectra of AP and LP SIPOS leads us to conclude that LP SIPOS has more SiO_2 character than an AP SIPOS film with the same oxygen content under the deposition conditions described herein. The infrared data for AP SIPOS films can be explained by a statistical model of Si-O bonding. For these SIPOS films the incoming O atom does not have time to find an Si atom already bonded to an O atom and so statistics govern the deposition and the distribution of Si—O bonds. For the slowly deposited SIPOS there is enough time for some of the incoming O atoms to find the already oxygen-bonded Si atom and so there is more SiO_2 character to the slowly deposited SIPOS than would be predicted by the statistical model.

Stress measurements and reactivity of SIPOS films to HF are consistent with the interpretation of the shift to higher frequency for the strong infrared absorption of LP SIPOS films.

Continuum Formulation of Spreading Resistance Correction Factors

John Albers

National Bureau of Standards, Electron Devices Division, Washington, DC 20234

ABSTRACT

A continuum formulation of spreading resistance correction factors is derived from the Choo *et al.* recursion relation for the kernel of the spreading resistance correction factor integral. Specifically, a differential equation for the kernel of the correction factor integral is derived in the limit as the layer thickness approaches zero. The resulting differential equation is nonlinear and inhomogeneous but can be transformed into a linear second order equation which can be solved analytically in several cases. The continuum form of the correction factor is compared with the correction factor generated from the finite-layer thickness version of the Laplace equation description for the case of an exponentially varying resistivity. Depending upon the number of layers used, the exponential constant, and the total thickness of the structure, the continuum and discrete forms of the correction factor differ by factors as large as 2.75 thus indicating a limitation in the accuracy of finite layer algorithms for spreading resistance data interpretation.

The multilayer Laplace equation description of spreading resistance described by Schumann and Gardner (1, 2) is based upon the assumption that the resistivity of each of the layers used in the model is constant over the entire thickness of the layer. The resistivity is then assumed to change abruptly at the interface between the layers. However, the probes of a spreading resistance apparatus view the material as a continuum. This distinction leads to a possibility of error in the analysis depending upon such variables as material thickness and the actual rate of change of the resistivity over distances comparable to the thickness of the layers used in the multilayer analyses. Both Schumann and Gardner and Choo *et al.* (3) observed that the calculated correction factor depends upon the number of layers used in the calculation. This observation is, of course, due to the failure of the basic assumption of constant resistivity over the thickness of the layer. Both sets of authors found that up to 50 layers are required to ensure convergence of the resulting calculated correction factor to within 5%. However, the dependence of the relation between the calculated correction factor and the number of layers upon such variables as the rate of change of the resistivity with depth, the substrate resistivity, and the total thickness of the structure is not evident.

The purpose of this paper is to present an exact solution to this problem by allowing the layer thickness to approach zero. The limiting process gives rise to a differential equation for the kernel of the correction factor integral in terms of the derivative of the natural logarithm of the resistivity. The differential equation so derived is nonlinear and inhomogeneous, but because it is of the Riccati type (4) it can be transformed into a linear second order differential equation which can be solved analytically for several forms of the resistivity. This analysis provides the basis for the investigation of the error incurred in the use of the finite-layer thickness algorithms in the analysis of spreading resistance data.

Key words: resistivity, interface, Laplace equation.

Derivation of the Continuum Differential Equation

The multilayer solution of Laplace's equation relates the spreading resistance of an n-layer structure to the resistivities of the n layers through the relation (1, 2)

$$R_n = \frac{\rho_n}{2a} CF_n \qquad [1]$$

where ρ_n is the resistivity of the layer contacted by the probes, a is the effective electrical contact radius of the probes, and CF_n is the n-layer correction factor which depends upon the resistivities of the n layers. Specifically, the correction factor for the two-probe configuration may be expressed as (1, 2)

$$CF_n = \frac{4}{\pi}\int_0^\infty A_n(\lambda) \left\{ \frac{J_1(\lambda a)}{\lambda a} - \frac{J_0(\lambda S)}{2} \right\} \sin(\lambda a) \frac{d\lambda}{\lambda} \qquad [2]$$

where S is the separation between the probes, $J_0(X)$ and $J_1(X)$ are Bessel functions of zero and first order, respectively, and λ is the integration variable. The explicit dependence of the kernel of the correction factor integral, $A_n(\lambda)$, on the resistivities of the n layers and the layer thickness, t, has been suppressed for simplicity. As noted by Choo *et al.* (3), the dependence of the kernel of the correction factor integral upon the resistivities of the n layers may be obtained from the original formulation of the problem by Schumann and Gardner; but it is more convenient to introduce the functions $T_m(\lambda)$, defined as

$$T_m(\lambda) = \rho_m A_m(\lambda) \qquad [3]$$

where $m = 1, \ldots, n$. The utility of these functions is that they are related to each other by means of the recursion relations

$$T_m(\lambda) = \frac{W(\lambda t)\rho_m + T_{m-1}(\lambda)}{1 + W(\lambda t) T_{m-1}(\lambda)/\rho_m} \quad (m = 2, \ldots, n) \qquad [4]$$

where all layers are chosen to have the same thickness, t

$$T_1(\lambda) = \rho_1 \quad [5]$$

and

$$W(\lambda t) = \frac{1 - \exp(-2\lambda t)}{1 + \exp(-2\lambda t)} \quad [6]$$

The layer indexes are chosen such that ρ_1 is the resistivity of the deepest layer and ρ_n is that of the surface layer.

Before considering the limit as t approaches zero, it is important to note from Eq. [4]-[6] that

$$T_m(0) = T_{m-1}(0) = \ldots\ldots = T_1(0) \quad [7]$$

and hence from Eq. [3]

$$A_m(0) = \rho_1/\rho_m \quad [8]$$

i.e., the value of the kernel of the correction factor at $\lambda = 0$ is uniquely determined by the ratio of the substrate resistivity and the resistivity of the layer being considered. Also, it can be shown from Eq. [3], [4], and [6] that

$$\lim_{\lambda \to \infty} A_m(\lambda) = 1 \quad [9]$$

Equations [8] and [9] in conjunction with the condition

$$A_1(\lambda) = 1 \quad [10]$$

which follows from Eq. [3] and [5], provide constraints and the initial condition for the solution of the continuum model differential equation.

The basis for calculating the continuum limit of the multilayer equations is founded in the observation that if the position of the first layer is chosen as the origin of a coordinate system and the positions of the mth and $(m - 1)$st layers are taken as x and $x - t$, respectively, then the recursion relation (Eq. [4]) takes on the form

$$T(x, \lambda) = \frac{W(\lambda t)\rho(x) + T(x - t, \lambda)}{1 + W(\lambda t)T(x - t, \lambda)/\rho(x)} \quad [11]$$

This recursion relation defines a function $[T(x,\lambda)]$ at the position x in terms of another function $[\rho(x)]$ evaluated at the same position and the function being defined $[T(x - t)]$, evaluated at the position $x - t$. It is important to emphasize that Eq. [11] is really Eq. [4] cast in a version suitable for calculating the continuum (zero layer thickness) limit. The values of x allowed in Eq. [11] are $x = nt$ where $n = 1, 2, \ldots$. The functions $\rho(x)$, $A(x,\lambda)$, and $T(x,\lambda)$ as used in the above are evaluated at a discrete set of points. Once the continuum limit has been taken, $\rho(x)$, $A(x,\lambda)$, and $T(x,\lambda)$ will be functions of the continuous variable x. After some rearrangement, Eq. [11] may be written in the form

$$\frac{T(x,\lambda) - T(x - t,\lambda)}{W(\lambda t)} = \rho(x) - \frac{T(x,\lambda)T(x - t,\lambda)}{\rho(x)} \quad [12]$$

From Eq. [6], it can be shown that $W(\lambda t)$ approaches zero as λt. Hence, for sufficiently small t, $W(\lambda t)$ may be replaced by λt. Further, the derivative $dT(x,\lambda)/dx$ is defined as $\lim_{t \to 0} \frac{T(x,\lambda) - T(x - t,\lambda)}{t}$. Then in the limit as t approaches zero, Eq. [12] becomes

$$\frac{dT(x, \lambda)}{dx} = \lambda \left\{ \rho(x) - \frac{T^2(x, \lambda)}{\rho(x)} \right\} \quad [13]$$

which is a differential equation for the function $T(x, \lambda)$ which is to be solved subject to the initial condition

$$T(0, \lambda) = \rho(0) \quad [14]$$

However, the principal concern of the present paper is in a differential equation for the kernel of the correction factor integral. Hence, making use of the continuum form of Eq. [3], *i.e.*

$$T(x, \lambda) = \rho(x)A(x, \lambda) \quad [15]$$

Eq. [13] may be written in the form

$$\frac{dA(x, \lambda)}{dx} + F(x)A(x, \lambda) + \lambda A^2(x, \lambda) - \lambda = 0 \quad [16]$$

where the function, $F(x)$, is defined as

$$F(x) = \frac{1}{\rho(x)} \frac{d\rho(x)}{dx} = \frac{d \ln \rho(x)}{dx} \quad [17]$$

Equation [16] is nonlinear and inhomogeneous, but is of the Riccati type (4). Hence, under the transformation

$$A(x, \lambda) = \frac{1}{\lambda U(x, \lambda)} \frac{dU(x, \lambda)}{dx} \quad [18]$$

Eq. [16] may be written in the form

$$\frac{d^2U(x, \lambda)}{dx^2} + F(x) \frac{dU(x, \lambda)}{dx} - \lambda^2 U(x, \lambda) = 0 \quad [19]$$

Equations [17]-[19] form the central result of the analysis.

The above formulation may be used to calculate the continuum form of the kernel of the correction factor integral and, by numerical integration of Eq. [2], the correction factor and, hence, spreading resistance. For a specific choice of the resistivity function, $\rho(x)$, the function $F(x)$ is calculated according to Eq. [17] and is used in Eq. [19] to obtain the function $U(x, \lambda)$. As Eq. [19] is a second order linear equation, two constants of integration appear in the solution. Calculation of $A(x, \lambda)$ from $U(x, \lambda)$ by means of Eq. [18] and imposing the initial condition on $A(x, \lambda)$, *i.e.*, $A(0, \lambda) = 1$, eliminates the need for an explicit form for the two constants of integration. The solution, $A(x, \lambda)$, is required to satisfy the constraints that: (*i*) $A(x, 0) = \rho(0)/\rho(x)$, and (*ii*) $\lim_{\lambda \to \infty} A(x, \lambda) = 1$ which have been previously discussed.

It is of interest to note that the resistivity enters Eq. [19] as $d \ln \rho(x)/dx$. Because the resistivity *vs.* depth for most semiconductor device applications is approximately of the form of an exponential or a Gaussian, the function, $F(x)$, in Eq. [19] has a simple form. It must be emphasized that the substrate point is used as the origin of the coordinate system in the above development and hence all functions and their derivatives are defined relative to that point.

Calculation of Kernel for Uniform Resistivity Material

As an example of the continuum form of the kernel of the correction factor integral as presented in Eq. [17]-[19], consider the case of a material of uniform resistivity $\rho(x) = $ const. In this case, $F(x) = 0$ and Eq. [19] takes on the form

$$\frac{d^2U(x, \lambda)}{dx^2} - \lambda^2 U(x, \lambda) = 0 \quad [20]$$

which has the general solution

$$U(x, \lambda) = C_1 \exp(-\lambda x) + C_2 \exp(\lambda x) \quad [21]$$

Using Eq. [18] and [21] to calculate $A(x, \lambda)$ and imposing the initial condition on $A(x, \lambda)$, *i.e.*, $A(0, \lambda) = 1$, leads to the conclusion that $C_1 = 0$. Hence, for a material of uniform resistivity, the kernel of the correction factor integral is unity for all x and λ. The same conclusion may be obtained from the finite layer thickness formulation (see Eq. [3]-[5]).

Calculation of the Kernel for a Material Having Exponential Resistivity

Consider a material having a resistivity defined relative to that of the substrate ($x = 0$) by

$$\rho(x) = \rho(0) \exp(Cx) \quad [22]$$

where the exponential constant, C, can have either positive or negative values. In this case, the function $F(x)$ takes on the form, $F(x) = C$ and equation for the continuum form of the kernel of the correction factor integral becomes

$$\frac{d^2U(x,\lambda)}{dx^2} + C\frac{dU(x,\lambda)}{dx} - \lambda^2 U(x,\lambda) = 0 \quad [23]$$

which, being a second order linear equation with constant coefficients, has the general solution

$$U(x,\lambda) = C_1 \exp(m^+x) + C_2 \exp(m^-x) \quad [24]$$

where

$$m^{\pm} = \frac{-C \pm (C^2 + 4\lambda^2)^{1/2}}{2} \quad [25]$$

Substituting Eq. [24] into Eq. [18] and imposing the boundary condition, $A(0, \lambda) = 1$, yields the following relation for the constants

$$C_1 = C_2\Gamma(\lambda) \quad [26]$$

where $\Gamma(\lambda)$ is defined as

$$\Gamma(\lambda) = \frac{(\lambda - m^-)}{(m^+ - \lambda)} \quad [27]$$

Hence, the kernel of the correction factor integral for an exponentially varying resistivity may be written in the form

$$A(x,\lambda) = \frac{\Gamma(\lambda)m^+ \exp(m^+x) + m^- \exp(m^-x)}{\Gamma(\lambda)\lambda \exp(m^+x) + \lambda \exp(m^-x)} \quad [28]$$

From Eq. [25] it is straightforward to obtain

$$m^+m^- = -\lambda^2 \quad [29]$$

Dividing the numerator and denominator of Eq. [28] by $\exp(m^+x)$ and making use of Eq. [29] yields the following equation for the kernel of the correction factor for an exponentially varying resistivity

$$A(x,\lambda) = \frac{(m^+ + \lambda) - (m^- + \lambda)\exp(-\gamma x)}{(\lambda - m^-) + (m^+ - \lambda)\exp(-\gamma x)} \quad [30]$$

where

$$\gamma = (C^2 + 4\lambda^2)^{1/2} \quad [31]$$

One of the important conclusions to be drawn from Eq. [30] is that the kernel depends only upon the variables C, x, and λ and does not depend upon the value of the resistivity *per se*. From Eq. [30], it is relatively straightforward to show that: (*i*) $A(0, \lambda) = 1$, (*ii*) $A(x, 0) = \exp(-Cx)$, and (*iii*) $\lim_{\lambda \to \infty} A(x, \lambda) = 1$. Further, in the limit as C approaches zero, the kernel of the correction factor for an exponentially varying resistivity as given by Eq. [30] reduces to the uniform layer result.

Comparison of Continuum and Discrete Correction Factors for an Exponentially Varying Resistivity

In order to gain insight into the difference between the correction factor as calculated from the continuum formulation and as calculated from the finite layer thickness formulation, several exponentially varying resistivities were used to calculate the correction factor according to the continuum form for the kernel, Eq. [30], and according to the finite-layer thickness form, for the kernel, Eq. [2]-[6]. In all cases, a probe radius of 2 μm and a probe separation of 50 μm were used in the calculations.

Specifically, a resistivity having a value of 10^{-3} $\Omega \cdot$ cm at the surface and a value of 10^8 $\Omega \cdot$ cm at the substrate was used to simulate a junction-like structure. For the simulations of a high resistivity layer over a low resistivity layer, two situations were used. The first has a surface resistivity of 10^8 $\Omega \cdot$ cm and a substrate resistivity of 10^{-3} $\Omega \cdot$ cm. The second was less strongly graded, having a surface resistivity of 10^1 $\Omega \cdot$ cm and a substrate resistivity of 10^{-3} $\Omega \cdot$ cm. In all of the above cases, calculations were performed for total layer thicknesses of 1, 5, 10, 50, and 100 μm. The continuum form of the correction factor was evaluated at 51 points, and the finite-layer thickness approximation to the correction factor was evaluated for the 51 layer case. In addition, the various 1 μm structures were investigated with varying number of layers in order to determine the effect of the number of layers used in the finite-layer thickness formulation.

In all cases considered, the calculated correction factor is found to be approximately constant over most of the structure. The results of the calculation and comparison of the continuum and finite-layer thickness form the correction factor for a resistivity which is meant to mimic junction structure are presented in Table I. The surface values of the continuum and finite-layer thickness correction factor are presented and the ratio is also given. It is important to notice that the ratio is approximately constant over the range of layer thicknesses considered.

The results of the equivalent calculation for the cases of a surface resistivity of 10^8 $\Omega \cdot$ cm and 10^1 $\Omega \cdot$ cm and a substrate resistivity of 10^{-3} $\Omega \cdot$ cm are presented in Tables II and III, respectively.

The results of the calculation of the dependence of the calculated correction factor upon the number of layers used in the calculation of the finite-layer

thickness description are presented in Fig. 1-3. Figure 1 depicts the results for the calculation of the correction factor for a surface resistivity of 10^{-3} $\Omega \cdot$ cm and a substrate resistivity of 10^{8} $\Omega \cdot$ cm. This, as mentioned previously, is meant to be an approximation to a junction isolated structure. Figure 2 presents the results for the case of a surface resistivity of 10^{8} $\Omega \cdot$ cm and a substrate resistivity of 10^{-3} $\Omega \cdot$ cm while the results of the calculation for a surface resistivity of 10^{1} $\Omega \cdot$ cm and a substrate resistivity of 10^{-3} $\Omega \cdot$ cm are presented in Fig. 3. Both are meant to represent a high resistivity layer over a low resistivity layer. It is seen that for each case significant errors arise in the finite layer approximation formulation and that the magnitude of the error is almost exactly equal to the normalized change of the resistivity over a distance of one-half the step size, *i.e.*, $(\rho(x) - \rho(x - t/2))/\rho(x) = 1 - \exp(-Ct/2)$. For strongly graded structures, at least 200 points are required to obtain a 6% accuracy level for the finite layer approximation. For less strongly graded structures, at least 50-100 points are needed to assure 6% accuracy.

It is possible that errors in the finite-layer approximation might be reconciled by shifting the x-axis one-half interval or by redefining the probe location (again by one-half interval).

Discussion

It is important to note one of the limitations of the Schumann and Gardner formulation of the Laplace equation description of spreading resistance. In the original formulation (1, 2), the coefficients of the expansion of the potential in each of the layers in terms of the solution of Laplace's equation for a uniform, laterally semi-infinite material are obtained by means of assumed continuity of the potential and the current density across the interface between the layers.

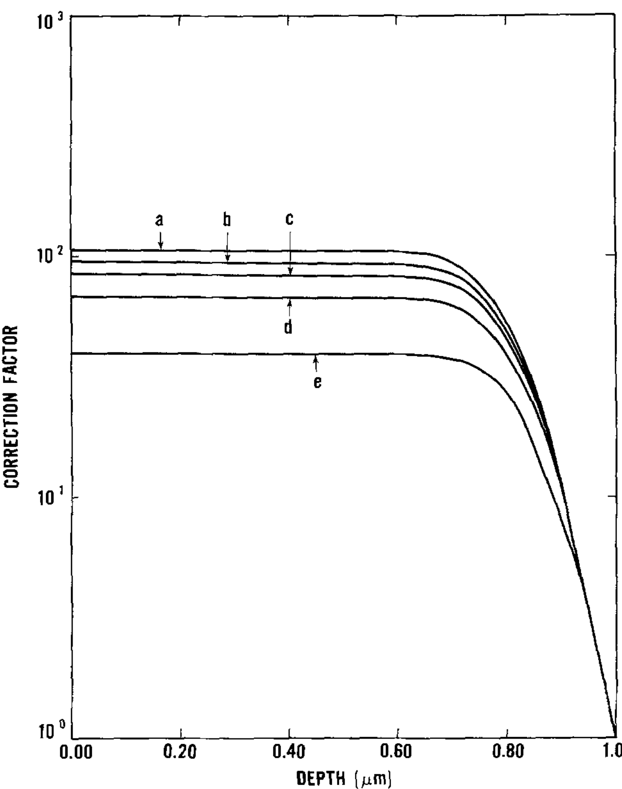

Fig. 1. Correction factor calculated from continuum formulation and correction factors calculated from finite-layer thickness model for variable number of layers for a 1 μm structure with a surface resistivity of 10^{-3} $\Omega \cdot$ cm and a substrate resistivity of 10^{8} $\Omega \cdot$ cm Continuum calculated correction factor (a), finite-layer thickness correction factors calculated with 101 layers (b), 51 layers (c), 26 layers (d), and 11 layers (e).

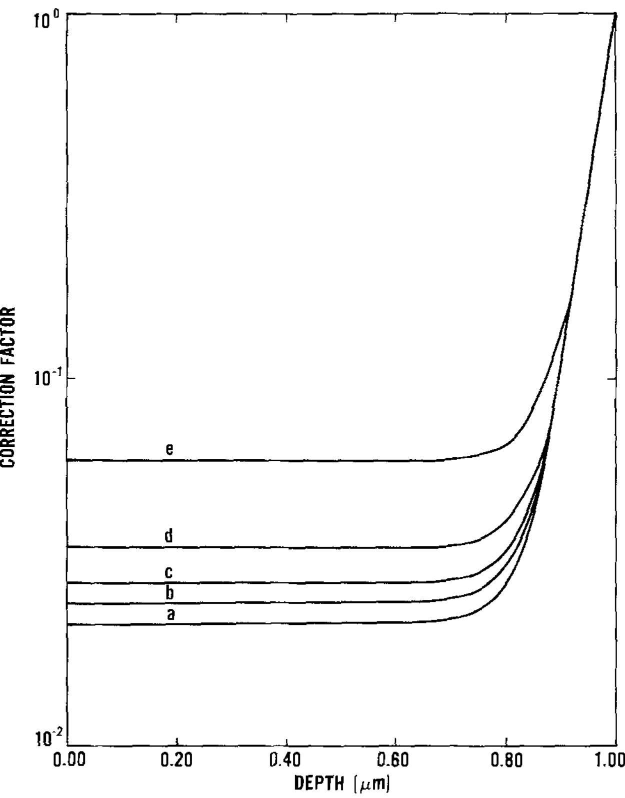

Fig. 2. Correction factor calculated from continuum formulation and correction factors calculated from finite-layer thickness model for variable number of layers for a 1 μm structure with a surface resistivity of 10^{8} $\Omega \cdot$ cm and a substrate resistivity of 10^{-3} $\Omega \cdot$ cm. Continuum calculated correction factor (a), finite-layer thickness correction factors calculated with 101 layers (b), 51 layers (c), 26 layers (d), and 11 layers (e).

For the case of an insulating but nonjunction type substrate, the correction factor for the substrate point is approximately unity, independent of the value of the substrate resistivity. This is inherent in the use of Eq. [5] for the finite-layer calculation or the use of Eq. [10] for the continuum calculation. For the case of an insulating junction structure, the same conclusion as above also holds. Again, this may be directly traced to the use of Eq. [5] or [10]. The resistivity in the region of the insulating interface may be made as large as possible; however, the correction factor as calculated by means of the Schumann and Gardner equations will always give a correction factor which is approximately unity. Spreading resistance measurements made on junction-isolated structures indicate that the correction factor becomes very large in the vicinity of the junction. This is, of course, due to the restriction of the current path between the probes owing to the presence of the junction. This current restriction is not contained in the Laplace equation description of Ref. (1) and (2).

There is another point which further hinders the use of the Laplace equation description both in the generation of model data and in the analysis of experimental data for junction structures. This point focuses upon the depletion region present in the region of the junction. The accompanying charge accumulation would indicate that the approximation of the Poisson equation by the Laplace equation, which is far easier to solve, is not justifiable. Away from the depletion region local charge neutrality is certainly maintained, thus, justifying the use of Laplace's equation. Consequently, the use of a very high resistivity to model a junction region is not correct in the junction region itself but is useful in the region

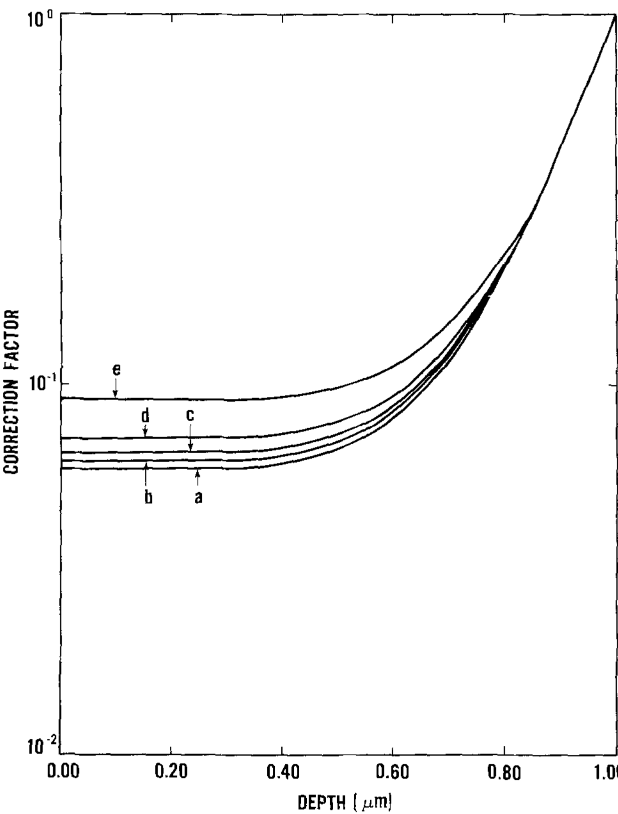

Fig. 3. Correction factor calculated from continuum formulation and correction factors calculated from finite-layer thickness model for variable number of layers for a 1 μm structure with a surface resistivity of 10^1 $\Omega \cdot$ cm and a substrate resistivity of 10^{-3} $\Omega \cdot$ cm. Continuum calculated correction factor (a), finite-layer thickness correction factors calculated with 101 layers (b), 51 layers (c), 26 layers (d), and 11 layers (e).

away from the junction. Consequently, the correction factor which is calculated from a resistivity which is meant to mimic an insulating junction structure will be greater than unity away from the high resistivity end point.

It should be noted that closed form analytic solutions of Eq. [17]-[19] can be obtained only for a constant resistivity or an exponentially varying resistivity. For resistivities of the Gaussian form, a power series solution can be obtained. These, however, cannot be summed to obtain a closed form solution.

Conclusions

A differential equation has been derived for the kernel of the correction factor integral in the limit of zero layer thickness. The equation has been solved analytically for the case of an exponentially varying resistivity and the corresponding calculated correction factors have been compared with the correction factors calculated from the finite-layer thickness formulation of the Laplace equation description of spreading resistance. For a 51 layer approximation, the differences fall in the range of approximately 6-27% for the cases considered. When fewer layers are used in the approximation, the differences are larger. This implies that the use of finite-layer thickness algorithms on a limited data base is subject to inherent errors. This is especially important in the analysis of spreading resistance data on very shallow implants (typically in the 0.1 μm range) where state-of-the-art bevelling techniques provide for 10-20 data points at most to be obtained in the shallow layer (5). The results of the calculations presented in Table I indicate that the finite-layer algorithms predict correction factors which are too small. This, in turn, would lead to dopant profiles which are lower in concentration relative to the actual profile. The same conclusion would be obtained for deep diffusions (50-100 μm) typical of power device structures where the total thickness of the structure and the need for a reasonable size data set would necessitate a depth spacing in the 1-2 μm range. For these deep structures, the above calculations indicate that increased accuracy of profile determination can be achieved by increasing the number of points in the data set.

The above conclusions would further lead to the prediction that the sheet resistance obtained from finite-layer thickness algorithm analysis of spreading resistance data on junction-type structures are large when compared with four-probe sheet resistance measurements. This follows from the observation that the continuum correction factor is typically larger than that obtained from the layered description.

For a buried layer structure, the results of the calculations presented in Tables II and III and Fig. 2 and 3 indicate that finite-layer algorithms predict correction factors which are too large. Hence, the dopant densities in profiles obtained from finite-layer algorithms are larger than those in the actual profile. Further, the sheet resistance obtained from finite-layer thickness algorithm analysis of structures of this type are small compared to four-probe sheet resistance measurements.

Photoelectrolysis of Water with Natural Mineral TiO_2 Rutile Electrodes

J. F. Julião,*,[1] Franco Decker,* and M. Abramovich**
UNICAMP, Instituto de Física, Campinas, S.P., Brazil

ABSTRACT

Natural mineral rutile (TiO_2) was studied as anode for photoelectrolysis of water. Both its photoelectrochemical behavior and semiconducting properties are examined in comparison with those of Fe-doped synthetic single crystal TiO_2, the latter independently studied to simulate the high impurity content existent in the mineral. The natural and synthetic Fe-doped TiO_2 electrodes showed a performance comparable to that of arc-plasma sprayed raw rutile, including a low breakdown potential. Flatband potentials and donor densities were determined from Mott-Schottky plots and evidence for deep and shallow donors is discussed. Photoresponse measurements allowed us to verify the influence of the iron impurities on the performance of such electrodes.

The photoelectrolysis of water has been investigated by several authors (1-7) in the last few years. Electrodes of polycrystalline TiO_2 made by hot-pressing powdered rutile (2), by oxidation of metal foils (2-4), and by chemical vapor deposition (CVD) (5, 6) show a behavior similar to that of single crystal TiO_2 (7) and have the advantage of being easier to prepare. Until now, little attention has been paid to the semiconductor properties of natural TiO_2 rutile crystals, perhaps because these minerals are usually impure (8). However, it has been recently shown that impure polycrystalline TiO_2 electrodes, prepared by arc-plasma sprayed raw rutile powder (9), behave similarly to other polycrystalline ones with respect to photoelectrolysis. In the present paper we report the photoelectrochemical behavior of electrodes made either of single crystal or polycrystalline natural TiO_2, obtained from mines located in different regions of Brazil. These electrodes showed a performance comparable to that of synthetic single crystal or other polycrystalline TiO_2 electrodes. The results demonstrate the possibility of using low cost raw materials in primitive form for photoelectrolysis of water.

Since large amounts of iron impurities were detected by x-ray analysis in the mineral samples, their effect on the performance of the photoelectrolytic cell is discussed by comparing the behavior of the natural rutile electrodes with that of two intentionally Fe-doped TiO_2 synthetic single crystal electrodes.

Experimental Procedure

Sample characterization and heat-treatments.—Samples of titanium oxide were obtained from three Brazilian states: Bahia, Ceará, and Minas Gerais. X-ray diffractometry and powder diffraction analysis showed that the samples from Ceará and Minas Gerais were TiO_2 with rutile structure, while the sample from Bahia was closer to $(Fe, Fe, Ti)_{1.71}\ O_3$ (crichtonite). Figure 1 shows the diffraction data for the sample from Ceará

The rutile sample from Ceará was a dark stone and contained impurities of Fe, Cu, Pb, Mn, Ni, Cr, and Nb, with high predominance of iron, according to x-ray spectroscopic analysis. It was shown to be polycrystalline, from Laue diffraction analysis and from now on it will be labeled NPC TiO_2 (natural polycrystalline TiO_2). The rutile sample from Minas Gerais was a small, slightly violet, semitransparent crystal and contained diverse impurities other than the Fe, which is, however, the predominant one. It was shown to be a single crystal, so that from now on it will be labeled NSC TiO_2 (natural single crystal TiO_2). Comparing the x-ray spectrograms we found that the NPC TiO_2 sample had a concentration of iron higher than the NSC TiO_2 sample.

Heat-treatment in a reducing atmosphere was used to obtain n-type semiconducting samples in the conditions described in the Table I. The high resistivity of the samples from Bahia did not decrease even after a prolonged treatment; therefore, its use as an electrode in the cell was not attempted. For the other natural rutile samples, the treatment decreased their resistivities and changed the relative intensity between the diffraction peaks, but not their relative positions. Therefore, we can conclude that the samples maintained their crystal structure, even though several defects were introduced in the lattice (8, 10, 11).

The synthetic TiO_2 single crystal was supplied by Materials Research Company and contained Si, Fe, Al, and Nb as its major impurities, according to data from the manufacturer.

To allow a comparison between natural and synthetic electrodes, and since Fe is the main impurity in natural rutile, we raised the Fe concentration in two synthetic single crystal samples by doping. Iron impurities were introduced by diffusing a thin film of Fe metal previously deposited on the sample surface by vacuum evaporation, following the method used by Andersson (12). The final iron concentrations were 290 and 410 ppm and these doped samples will be labeled, respectively, SSC-Fe(A) TiO_2 and SSC-Fe(B) TiO_2. Another synthetic single crystal TiO_2 sample

Table I. Reduction conditions used for the various samples studied. The reduction atmosphere was 90% N_2 + 10% H_2 at 1 atm. T_r is the reduction temperature and t_r the reduction time. The table also shows the Fe-impurity contents and the final resistivity, ρ, for each sample.

TiO_2 electrodes	Reduction T_r (°C)	Parameters t_r (min)	Resistivity (Ω-cm)	Fe-impurities (ppm)
NPC	800	60	3.8	Unknown
NSC	800	20	4.0×10^1	Unknown
SSC	700	20	1.1×10^2	60*
SSC-Fe(A)	700	20	1.0×10^3	290
SSC-Fe(B)	700	20	1.7×10^3	410

* Residual impurity, according to manufacturer analysis.

(SSC-TiO_2) was also used as a "standard" anode. In the Table I we give the reduction conditions, final resistivity, and Fe-impurities for each samples used here.

Electrode preparation.—The electrodes were prepared by cutting 1 mm thick slices from both the natural and the synthetic crystals with a diamond saw. The samples NSC, SSC, SSC-Fe(A), and SSC-Fe(B) samples had the (001) surface exposed. The NPC sample was cut so that its surface was visually free of cracks. The samples were then mechanically polished flat to optical grade, using diamond paste. Then, each crystal was washed with the following sequence: trichloroethylene, isopropanol, acetone, methanol, deionized water, concentrated HCl, and deionized water. After reduction treatments, ohmic contacts (checked with a curve tracer) were provided by rubbing In-Ga paste on the back crystal surface. A copper wire was then attached to the samples by means of Ag cement. Finally, the contact was coated with epoxy and the electrode was imbedded in a polyester capsule leaving an ~0.15 cm^2 active area exposed to the solution. Finally, each crystal was cleaned again following the procedure described above.

Electrochemical measurements.—The electrochemical measurements were performed in 1M NaOH electrolyte under potentiostatic conditions, using a three compartment cell, provided with a flat quartz window and a saturated calomel electrode (SCE) as the reference electrode. The counterelectrode was a Pt bright foil with 10 cm^2 area. The space charge capacitances were determined from measurements of impedance and phase angle between a-c current and a-c potential with a lock-in amplifier (PAR-124 A). For this purpose a small a-c voltage of 3 mV at 1 kHz was superimposed on the externally applied d-c voltage; other frequencies have also been used in the interval 10-10,000 Hz.

The photocurrent measurements with high intensity u.v. light (~80 mW/cm^2) were performed using a 100W high pressure mercury lamp with the beam focused on the semiconductor electrode through a bandpass filter (WBS-320: 4000Å ≥ λ ≥ 2000Å). For spectral photoresponse measurements the light source used was a xenon arc lamp run through a monochromator giving ~1 mW/cm^2 intensity over the spectral region of interest. The intensity of light was measured by an IL 700 Research Radiometer with an SE-400 W detector. A digital electrometer (Keithley 616) was used to measure the potential *vs.* SCE of the counterelectrode.

The electrolyte in the cathode compartment was purged with high purity nitrogen. The solutions were prepared with commercially available reagents without further purification. Before each experiment the samples were rinsed with methanol (CH_3OH) and deionized water.

Results and Discussion

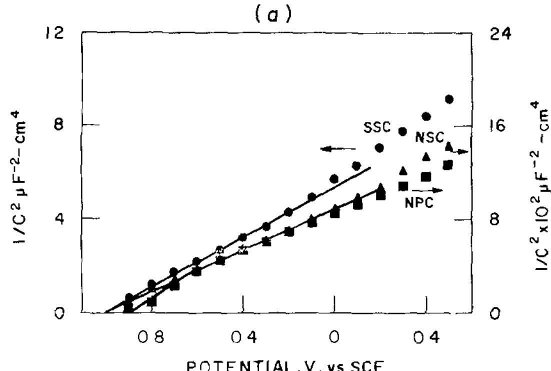
Flatband potential.—An easy method to obtain the flatband potential, V_{FB} (the particular value of the Fermi level for which the energy bands of the semiconductor are not bent), is to measure the space charge capacitance, C_{sc}, in function of the interface potential, V. In the case of highly doped semiconductors (16) the total capacitance C of the TiO_2/electrolyte interface is determined by C_{sc}, and described by the well-known Mott-Schottky equation

$$1/C_{sc}^2 = \frac{2}{q\epsilon\epsilon_0 N_D}\left(V - V_{FB} - \frac{kT}{q}\right) \approx \frac{1}{C^2} \quad [1]$$

where ϵ and ϵ_0 are the dielectric constants of TiO_2 and vacuum, respectively, N_D is the concentration of donors, $V - V_{FB}$ gives the potential drop across the space charge layer and q and kT have the usual value.

Figures 2a and b show the Mott-Schottky plots for all samples, constructed from capacitance *vs.* electrode potential measurements at 1 kHz. Flatband potentials were obtained from the intercepts of $1/C^2$ *vs.* V, and substracting $kT/q = 0.025$V. Donor densities, N_D, were calculated from the slope of these curves. For the corresponding calculation a dielectric constant $\epsilon = 173$ was used for single crystal (17), while for the polycrystalline sample we used an average value of $\bar{\epsilon} = 120$ (18). The slope and the intersection with the V axis depend on the frequency. Therefore, the values of V_{FB} and N_D, presented in Table II, are only approximate.

The $1/C^2$ *vs.* V curves for the NPC and SSC-Fe(B) show a striking feature. They are not single straight lines but bent curves. This result may be interpreted by assuming two linear slopes for each $1/C^2$ *vs.* V plot, with a steep slope at lower potentials and a much lower slope at higher anodic potentials. A break in the capacitance curve may occur if nonionized deep donor levels are present within the bulk (19). With increasing the band bending, however, the occupation of these levels may change within the space charge



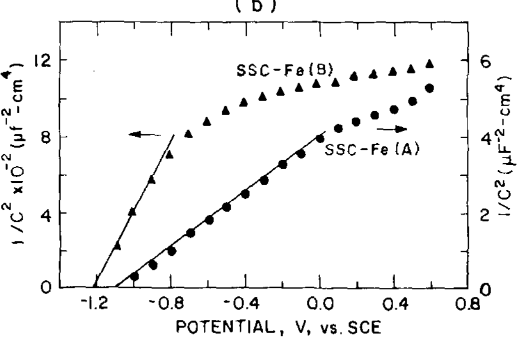


Fig. 2. Mott-Schottky plots for: (a) natural (NPC and NSC) and synthetic (SSC) TiO_2; (b) Fe-doped synthetic single crystal [SSC-Fe(A) and SSC-Fe(B)] TiO_2. The electrodes were in dark at T = 25°C in a solution 1M NaOH.

region. Assuming only one discrete energy level for such an additional donor of a density N, two Mott-Schottky slopes can be derived from Eq. [1], representing the existence of two kind of donor levels. The first slope, measured at small band bendings, is only determined by the ionized shallow donors with density N_1, and the second by the sum of both the shallow and the deep donor levels with density $N = N_1 + N_2$: here, N_2 is the density of the deep donor levels. The critical potentials (V_C), where the slope changes value, represent the ionization potential for the deep donor and are given in Table II.

From considerations about the Fermi-Dirac distribution function governing the number of ionized donors, Kennedy and Frese (20) studying the change in slope for polycrystalline α-Fe_2O_3 showed that the relation below is valid

$$q(V_C - V_{FB}) \cong E_F - E_{D_2} \quad [2]$$

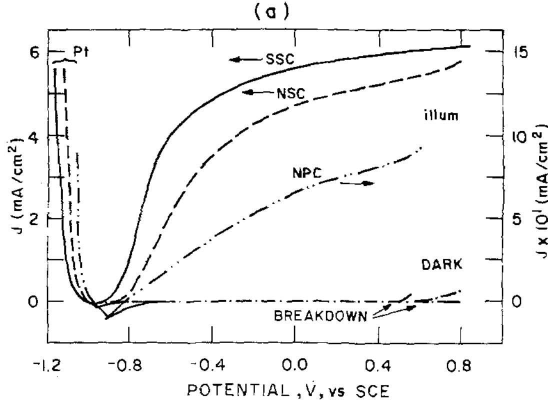
where E_F is the Fermi level and E_{D_2} is the deep donor level. Using this relation we can estimate from our data that the deep donor level is located in the energy gap ∼0.3 eV below the Fermi level. Although we have not measured the position of the Fermi level relative to the bottom of the conduction band, it is known (10) that for highly reduced TiO_2 with an oxygen vacancy density of the order of 10^{17} cm^{-3}, the Fermi level is located ∼0.2 eV below the conduction band. The position of the deep donor level is then ∼0.5 eV below the conduction band.

From EPR studies on Fe-doped single crystal TiO_2, Andersson (12) showed that strong reduction, made in vacuum, probably causes a transformation of Fe^{3+} into Fe^{2+} ions. These Fe^{2+} ions, will preferentially occupy the Fe^{2+} level near the conduction band that is vacant before the reduction treatment. This level is located ∼0.5 eV below the conduction band, according to Mizushima (21). The evidence presented supports our proposition that the deep donor level is Fe^{2+}, assuming that the reduction of the TiO_2 in an $H_2 + N_2$ atmosphere causes the same transformation between the Fe ions. It is interesting to note that a similar behavior for the Mott-Schottky plots was observed for polycrystalline α-Fe_2O_3 (20) in which the deep donor level is assigned also as being Fe^{2+}.

Current-potential characteristics.—Figures 3a and b show the current-potential (I-V) characteristics of the different electrodes in 1M NaOH with pH = 13. In the dark and beyond a certain potential, V_{BR}, a significant increase in the anodic current was observed for the natural TiO_2 as well as for the synthetic Fe-doped TiO_2 electrodes. These breakdown potentials, V_{BR}, are in the range of 0.5-0.7 vs. SCE, close, therefore, to the values observed for some polycrystalline TiO_2 electrodes, made by arc-plasma sprayed raw rutile (0.4V) and by CVD or oxidation of metal foils (0.6-2.0V). For the SSC TiO_2 electrodes, we did not observe appreciable anodic currents for potentials up to 10V.

For TiO_2 the high anodic currents in the dark have been attributed to tunneling of electrons from the solution through the narrow space charge region into the conduction band (6); this tunneling process could occur via grain boundaries containing impurity atoms in polycrystalline samples (9). In our samples, however, the thickness of the space charge region is not the most important factor for occurrence of this current. In fact, with synthetic crystals a breakdown was observed associated with Fe doping and independently on the donor density N_D. Therefore, we conclude that in our samples the iron impurities play the most important role in the breakdown phenomenon, facilitating the tunneling of electrons from solution through either a narrow or a thick space charge region and into the conduction band. This tunneling of electrons is likely to occur via iron precipitates that are known to form on lattice defects in TiO_2 (12, 13). In fact, in our Fe-doped single crystal samples, reddish-brown iron precipitates were visually observed. This fact and the estimated thickness of the space charge region, W_o, listed in Table II support our hypothesis. In the NPC sample W_o is narrow and the formation of precipitates may be more accentuated because of the grain boundaries. This might explain the lower breakdown potential (0.5V) observed for such electrodes.

Under u.v. illumination (∼80 mW/cm^2) the electrodes show different values for the onset of anodic photocurrent, V_o. The measurements of V_o were performed by using a chopped light beam. Values of V_o close to V_{FB} were observed for all samples (see Table



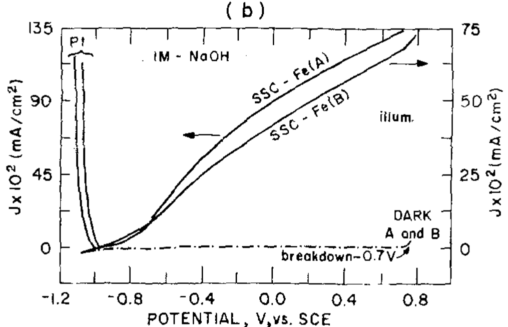


Fig. 3. Typical current-potential characteristics for n-TiO_2 electrodes in 1M NaOH, pH = 13, both in dark and under polychromatic u.v. illumination (∼80 mW/cm^2). (a) Synthetic single crystal (SSC), natural polycrystalline sample (NPC), and natural single crystal (NSC); (b) Fe-doped synthetic single crystal: SSC-Fe(A) and SSC-Fe(B). The electrolyte in the Pt compartment was deoxygenated with high purity nitrogen.

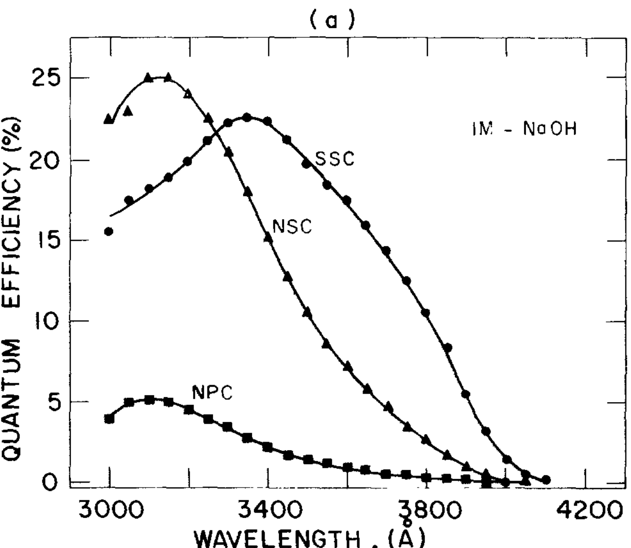
II). In electrolytes of lower pH, V_o is shifted by 58 mV/pH in the direction of more positive potentials. The shape of the photocurrents *vs.* potential curves are different too; at 0V *vs.* SCE, the photocurrent density, J_o, for the SSC and NSC electrodes is about four times larger than J_o for the NPC and SSC-Fe(A) and about ten times larger than J_o of the SSC-Fe(B) electrode. These results show that the photocurrent density is limited by the amount of Fe impurities in the material. A similar decrease in the value of the photocurrent density with the increase of Fe impurity contents in single crystals TiO_2 was also observed by Butler (14) and by Ghosh and Maruska (15). This behavior may be explained considering that the Fe ions act as traps for the photogenerated carriers, thus diminishing the current observed in the external circuit.

Quantum efficiency.—Figures 4a and b show the quantum efficiency η, (defined as the number of electrons flowing/incident photons), as a function of wavelength for the different electrodes used in this work. They were calculated from their spectral photoresponse, corrected for the spectral distribution of the light source and for the reflection at the quartz window. The electrodes were polarized at 0V *vs.* SCE in a solution of 1M NaOH (pH = 13), and scanning was toward longer wavelength.

The quantum efficiency drops to zero in all samples for λ ~4100Å. This indicates that the NPC TiO_2 electrode has a well-defined band structure in the same way as the natural and synthetic single crystal TiO_2 electrodes. The bandgap, E_g, for the NPC electrode obtained from the plot of $(\eta h\nu)^{1/2}$ *vs.* $h\nu$, as shown in Fig. 5a, was ~3.1 eV, typical for TiO_2. The plots in that figure are based on the relation

$$\eta h\nu = |L_p + W_o(V - V_{FB})^{1/2}|A(h\nu - E_g)^{n/2} \quad [3]$$

given by Butler (22), assuming the validity of the Schottky barrier theory for these semiconductor-electrolyte junctions, and that near the bandedge the optical absorption coefficient is proportional to $(h\nu - E_g)^{n/2}/h\nu$, with $n = 4$ or an indirect bandgap. The value of n was calculated from the slope of the straight line in the plot of ln $(\eta h\nu)$ *vs.* $(h\nu - E_g)$, as shown in Fig. 6. The bandgap for the other samples, SSC and NSC, had approximately the same value, but for the two Fe-doped TiO_2 E_g ~ 2.9 eV (Fig. 5b). This value shows that the iron impurities present in the synthetic single crystal TiO_2, even when their concentration exceeds the saturation limit (presence of precipitates), do not introduce an absorption band that significantly shifts the bandgap of these crystals toward longer wavelength.



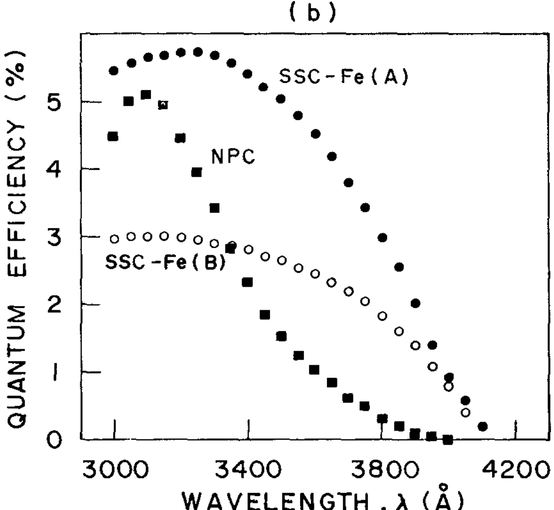


Fig. 4. Quantum efficiency in percent as a function of λ (Å): (a) natural (NPC and NSC) and synthetic (SSC) TiO_2; (b) Fe-doped synthetic single crystal [SSC-Fe(A) and SSC-Fe(B)] TiO_2 and NPC TiO_2. The electrodes were polarized at 0V vs. SCE. The solution was 1M NaOH and was deoxygenated in the Pt compartment. $T = 25°C$.

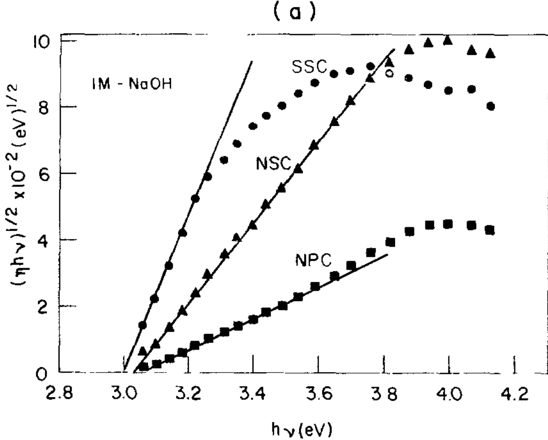

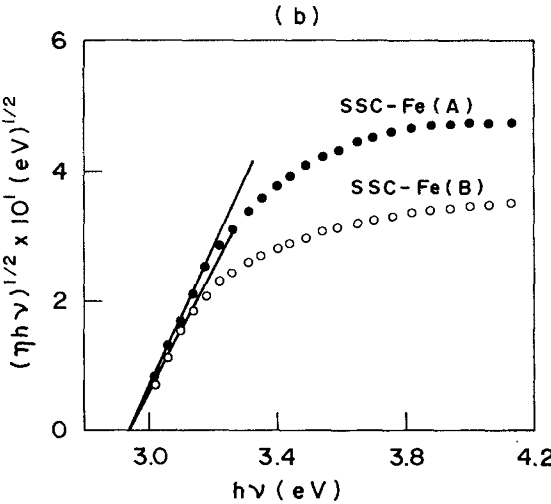

Fig. 5. The variation of quantum efficiency with photon energy for determination of the bandgap of the semiconductor electrodes, according to Eq. [3]. (a) Natural TiO_2 rutile (NPC and NSC) and synthetic single crystal TiO_2 (SSC); (b) Fe-doped samples of synthetic single crystal TiO_2. The corresponding bandgap are: ~3.1 eV for the NPC; ~3.0 eV for NSC and SSC; and ~2.9 eV for SSC-Fe(A) and SSC-Fe(B).

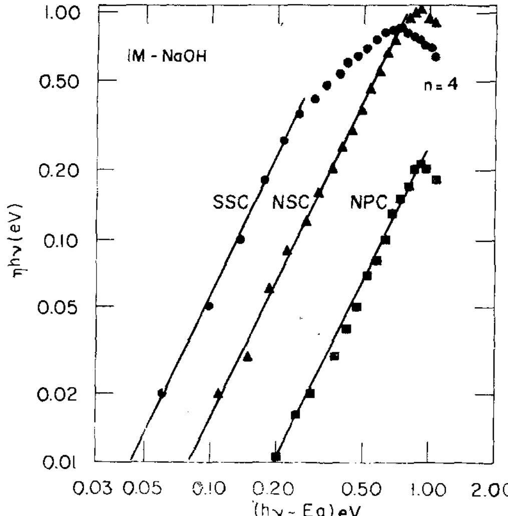

Fig. 6. The behavior of the quantum efficiency with photon energy for the NPC, NSC, and SSC TiO_2 electrodes as described by Eq. [3]. The solid lines present a slope indicating an indirect bandgap for the natural and synthetic TiO_2.

The overall quantum efficiency of the NPC electrode has a lower value than that of the NSC and SSC electrodes (Fig. 4a) and is comparable with the overall quantum efficiency of the SSC-Fe(A) and SSC-Fe(B) electrodes (Fig. 4b). This result agrees with that mentioned for the *I-V* characteristics of the electrodes, where it was seen that the presence of iron impurities reduces the photocurrent and where it shows that the impurity sensitization with Fe ions is a rather inefficient way of enhancing the solar energy conversion of the TiO_2 electrodes.

Conclusions

The photoelectrochemical behavior of natural TiO_2 rutile was shown to be similar to that of synthetic single crystal TiO_2, except for a lower breakdown potential, that is comparable with that reported for arc-plasma sprayed raw rutile. Flatband potentials and donor densities were determined from Mott-Schottky plots, and evidence for deep and shallow donors in the NPC TiO_2 is discussed. The deep donor level was proposed to be Fe^{2+}. By comparison with the behavior of synthetic Fe-doped TiO_2 we were able to show that the Fe impurities existent in the natural TiO_2 rutile are the most important factor in the occurrence of the low breakdown potential. We showed also that in TiO_2 the quantum efficiency diminishes with the concentration of Fe impurities. In addition to these general results we also found that for each sample the flatband potential calculated from the Mott-Schottky plots is in good agreement with the potential for onset of anodic photocurrent. From the wavelength dependence of photocurrent we were able to determine the nature of the gap as being indirect and to estimate the size of the gap, which was ~3.1 eV both for the poly and single crystalline natural TiO_2 samples.

Finally our results demonstrate the possibility of using natural TiO_2 rutile, a very abundant mineral in Brazil, as semiconducting anode for photoelectrolysis of water. The results show also that the impurity sensitization with Fe ions is a rather inefficient way of enhancing the solar energy conversion of the TiO_2 electrodes.

ABSTRACT

The presence and growth of elemental arsenic in as-grown and thermally annealed plasma oxidized films have been studied using Raman scattering and x-ray photoemission. The origin of arsenic growth observed in the annealed samples is fully consistent with the presence of a thermodynamically driven interfacial reaction involving As_2O_3 in the film and the substrate. The products of this reaction are Ga_2O_3 and As.

Current interests in native oxides on GaAs have tended to focus on determinations of the bulk and interfacial oxide compositions resulting from various growth procedures. The presence of elemental arsenic in the region of the oxide-substrate interface has been of particular interest due to its possible influence on electrical characteristics in device related applications. Two recent developments suggest that certain aspects of the current understanding of the interfacial composition problem may need to be re-examined when thermal processing or long-term compositional stability become important considerations.

The first development involves a recent estimate of the condensed phase portion of the Ga-As-O ternary diagram (1) which indicates that the interfacial phases which can exist in thermodynamic equilibrium with GaAs during its oxidation are Ga_2O_3 and As. The second development concerns the observation of thermally induced interfacial reactions between As_2O_3 and GaAs in electrochemically anodized films (2, 3). Similar reactions should occur in any type of native oxide film which contains As_2O_3 whenever there is sufficient energy available to overcome diffusion and reaction barriers.

The purpose of the present work was to examine the compositional properties of dc and rf plasma oxides with particular emphasis being placed on the detection of elemental arsenic in as-grown and thermally annealed films. Both x-ray photoelectron spectroscopy (XPS) and Raman scattering were employed for these purposes.

Experimental

n-Type Si-doped ($1.0\text{-}1.1 \times 10^{18}$ cm^{-3}) GaAs wafers were used in the preparation of the dc and rf plasma-grown native oxides. The samples were mechanically and chemically polished and then etched in $H_2SO_4:H_2O_2:H_2O$ (4:1:1) for 2 min at 50°C followed by a 2 min room temperature etch in $NH_4OH:H_2O_2:H_2O$ (1:1:40). Oxidation conditions for the rf and dc plasma samples are presented in Table I. The samples labeled RF5 through RF8 received a postoxidation anneal at 300°C for 1 hr under argon.

The bare substrate and electrochemically anodized reference wafers were Sn-doped ($\sim 2 \times 10^{18}$ cm^{-3}) samples which had been alumina-lapped (0.2 μm) and bromine-methanol polished. The electrochemical oxidation was carried to 75V (~1500Å) under constant current (0.2 mA/cm^2) conditions utilizing a 3% phosphoric acid/ethylene glycol electrolyte (1:2 by volume) adjusted to $pH = 6.2$ with NH_4OH.

The apparatus involved in the dc and rf plasma oxidations has been described in detail in Ref. (4) and (5). XPS and Raman spectra were acquired using a Physical Electronics Industries (Model 548) electron spectrometer and an Instruments SA (Model HG-2S) Raman spectrometer. For Raman spectra the impinging laser excitation (5145Å) was polarized in the plane of incidence (H) and the polarization of the light scattered normal to the incident beam was either unanalyzed (U) or analyzed perpendicular to the scattering plane (V). These two polarization configurations are denoted by HU and HV, respectively.

Results and Discussion

Bulk oxides.—The primary oxide species comprising the bulk films were examined using x-ray photoemission. Normal Raman cross sections associated with transparent materials are insufficient in the present case involving 1000-2000Å films to permit similar information to be obtained by that technique. The detection of arsenic by Raman scattering, however, is quite sensitive due to resonance enhancement of its scattering cross section which occurs in mate-

rials possessing electronic absorption bands that overlap the excitation frequency.

Photoemission spectra of the arsenic and gallium 3d core states in dc plasma films are presented in Fig. 1 for purposes of identifying the oxide species in the surface, bulk, and interfacial regions. No significant differences were observed between the XPS spectra of dc and rf plasma oxidized samples. The relevant 3d core level binding energy separations necessary for the chemical identification of the film components are provided in Table II.

The 3d core state intensities representative of an as-grown surface (sample DC-1) are shown in Fig. 1A. Ga_2O_3 and As_2O_3 are the anticipated products; one notes however, that the As 3d-Ga 3d binding energy difference (24.6 eV) on this surface is larger than expected (24.0 eV) for those species. In addition the As 3d linewidth is exceptionally large (3.1 eV) compared to spectra from pure As_2O_3 (6-8). The broad As 3d linewidth and its shift to higher binding energies indicate the presence of an admixture of +3 and +5 arsenic in the detected surface depth (40-60Å). Although it is not possible at present to identify the pentavalent species, $GaAsO_4$ and As_2O_5 would be the most likely candidates.

Evaluation of the surface As/Ga ratio observed on the dc and rf samples ranged from 0.7 to 0.8. These estimates were based on atomic cross sections derived from cleaved (110) GaAs, and are somewhat lower than the bulk value of 0.93 obtained by Kauffman *et al.* (9) using ion-induced x-ray analysis on rf plasma films.

Figure 1B shows the 3d photoemission intensities on an argon ion sputtered film (2 kV, 2×10^{-5} Torr Ar). The reduction in the As/Ga 3d area ratio and the growth of a low binding energy shoulder on the As 3d peak are indicative of selective sputtering and argon beam reduction artifacts. The observed binding energy shift between the main As 3d peak and its shoulder (2.7 eV) is consistent with the reduction of As_2O_3 down to elemental arsenic (8). To demonstrate that the shoulder on the main arsenic peak was a sputtering artifact rather than intrinsic deposits of unoxidized arsenic in the bulk film, we dissolved ~100Å of the argon-bombarded sample with a 1/5 (volume) mixture of H_3PO_4/methanol. This chemically etched sample (Fig. 1C) shows no evidence of the former shoulder, only Ga_2O_3 and As_2O_3 are evident. Resputtering the chemically etched sample regenerated the lower binding energy arsenic peak. The bulk As/Ga ratios in the films cannot be accurately determined unless a careful measurement of selective sputtering in As_2O_3 and Ga_2O_3 mixtures is performed. Similarly, chemical etching can also result in selective dissolution. We did not pursue this aspect of the compositional analysis.

Several of the samples were chemically stripped of their oxides using either H_3PO_4/methanol (1:5) or HCl/H_2O (1:2) etching solutions. Oxide removal by the H_3PO_4/methanol solution was relatively slow and proceeded somewhat nonuniformly as judged by the pattern of interference colors observed after etching.

Table II

Compounds	Components	Binding energy separation (eV)	Ref.
GaAs	Ga-As	22.0	(8)
		22.0	(6)
Ga_2O_3/GaAs	Ga-Ga	1.2-1.4	(8)
		1.4	(6)
As_2O_3/GaAs	As-As	3.4-3.6	(8)
		3.4	(6)
As_2O_3/Ga_2O_3	As-Ga	24.2	(8)
		24.0	(6)
As/GaAs	As-As	0.4-0.6	(8)
As_2O_5/GaAs	As-As	4.5-4.7	(8)
		4.7	(6)
$GaAsO_4$/GaAs	As-As	4.7	(6)

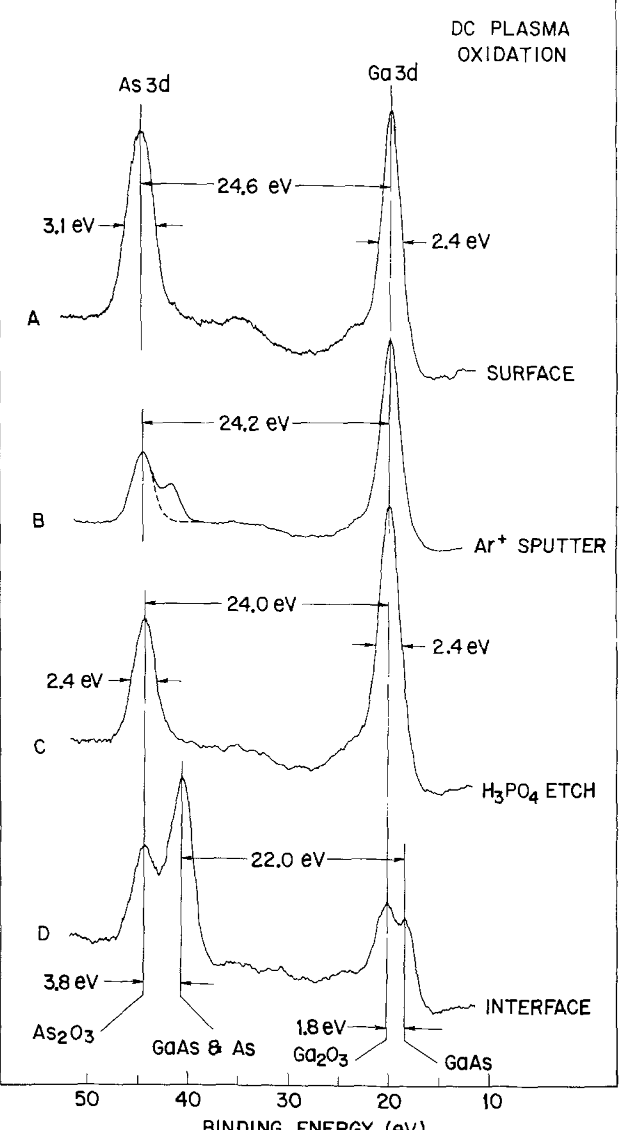

Fig. 1. As and Ga 3d core level photoemission stimulated by AlK_α radiation. The binding energy positions of oxide and substrate components are marked by vertical lines. The maximum Ga peak height corresponds to approximately 800 counts/sec.

The interfacial region on a chemically stripped (H_3PO_4/methanol) film is shown in Fig. 1D. Both substrate and residual oxide components are apparent in both sets of 3d core states. Even without a rigorous deconvolution of the As and Ga 3d peaks into separate oxide and substrate components, it is readily apparent that the As/Ga area ratio associated with the substrate signals at 40.8 and 18.8 eV exceeds the value of 1.31 observed on cleaved (110) GaAs. The presence of elemental arsenic in the interfacial region is consistent with this observation since the chemical shift between the arsenic 3d core levels in GaAs and As is sufficiently small [0.4 eV, Ref. (8)] relative to typical measured substrate linewidths (~1.9 eV) that these two signals would effectively add and thus increase the expected As/Ga area ratio. Raman scattering data in the following section further supports this assignment.

Binding energy reference levels were established in the following manner. The Ga 3d photopeak of Ga_2O_3 was used to establish the relative alignment of the spectra. The overall binding energy scale was then fixed by assigning the Ga 3d core level in GaAs to a value at 18.8 eV. Oxide charging due to secondary electron emission is apparent in Fig. 1D where one has the substrate signal with which to reference the

oxide binding energy positions. Both the Ga and As 3d signals associated with their oxides are shifted to 0.4 eV higher binding energy relative to the substrate than anticipated from Table II; this charging phenomena is commonly observed in photoemission on insulators.

Even though Raman scattering performed prior to any chemical etching indicated comparable amounts of elemental arsenic were present in these samples, no evidence for interfacial arsenic was obtained on samples chemically stripped in HCl/H_2O solutions. We surmise that the HCl solution dissolved whatever arsenic was originally present along with the oxide. Similar results were obtained on one sample using NH_4OH/H_2O (1:1) for an etchant.

Arsenic detection in as-grown and thermally annealed films.—The optical transparency of the oxide components of these films at the laser excitation wavelength (514.5 nm) allows *in situ* surface reflection Raman scattering to be performed. In general, only materials with Raman allowed, resonance enhanced cross sections will be detected. In the present case, both arsenic and GaAs will be detected with high sensitivity. The identification and structural form of the detected species are obtained by examination of the position of the Stokes shifted Raman peaks and their lineshape. The incident excitation impinges on the sample at Brewster's angle and the Raman scattered light is collected normal to the direction of the incident beam.

Raman scattering in the HU polarization configuration is shown in Fig. 2 for bare and oxidized GaAs. All wafers were (100) oriented with nominal 1000Å as-grown films on the oxidized samples. Scattering from the bare substrate in the region of primary interest (150-300 cm^{-1}) consists of the zone center longitudinal and transverse optic modes (LO, TO) at 291 and 268 cm^{-1}, respectively, along with two-phonon scattering of transverse acoustic modes between 150-240 cm^{-1} (10). Coupled LO-plasmon features (11) and additional two-phonon scattering are also present above 300 cm^{-1}.

Two primary features are apparent in Fig. 2 in the region between 150-300 cm^{-1}. The first is the variation in intensity nominally associated with the TO phonon of GaAs at 268 cm^{-1}. The second feature is the observation of a new peak around 205 cm^{-1} superimposed on the two-phonon scattering from the substrate. An accurate analysis of the intensity around 268 cm^{-1} is complicated because of the multiplicity of scattering processes which can contribute to the Raman intensity in this spectral region. There will be a contribution from allowed TO substrate scattering because the propagation of light into the substrate is not parallel to the (100) direction in a surface reflection configuration. In addition, there will be strain-induced (12) enhancement of this TO scattering due to roughening of the substrate during the oxidation process. This TO enhancement is particularly apparent from a comparison of the bare substrate and electrochemically anodized sample. For carrier concentrations around $10^{18}/cm^3$, the L_- mode of the coupled LO-plasmon interaction will occur in this vicinity (11). Any amorphous GaAs present in the interfacial region would also contribute a broad peak centered at roughly 260 cm^{-1} (13). Finally, both orthorhomic and rhombohedral structures of crystalline arsenic display sharp A_g type modes in the region between 265-257 cm^{-1} (14-16). We will not treat the scattering around 268 cm^{-1} in any further detail.

A variety of evidence suggests that the additional scattering observed around 205 cm^{-1} on the two-phonon background should be assigned to elemental arsenic. Raman spectra for amorphous arsenic (17, 18) typically display a broad band (180-160 cm^{-1}) in the HU configuration which contains a weak peak

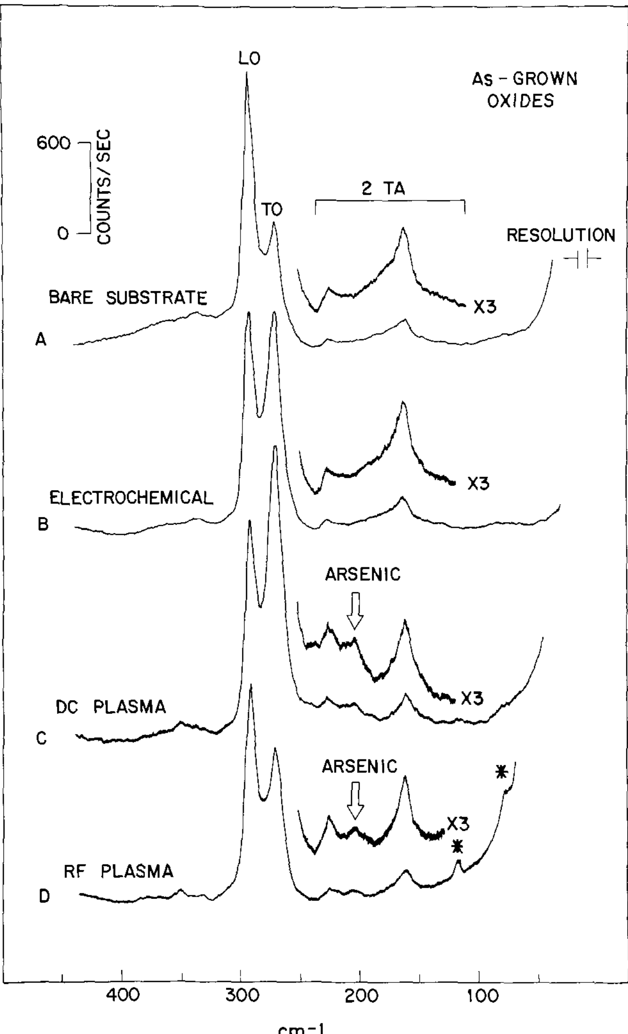

Fig. 2. Raman scattering (HU) from as-grown films of native oxides on GaAs. Asterisks denote the position of laser plasma lines.

at ~200 cm^{-1}. Crystalline arsenic modes of E_g character would also contribute between 195-200 cm^{-1} (14-16). Crossed polarization spectra (HV) effectively suppress the two-phonon contribution from the substrate. Such spectra showed a broad, structureless band of low intensity extending from 180-260 cm^{-1} consistent with reported crossed polarization spectra of amorphous arsenic (17, 18). The Raman data thus supplement and are fully consistent with the suggestion of elemental interfacial arsenic obtained from the photoemission spectrum of Fig. 1D. In addition, recent reports utilizing the nondestructive optical technique of spectroscopic ellipsometry have observed optically absorbing components in rf plasma oxidized (19) and electrochemically anodized (20) films. The identity of the absorbing species is somewhat difficult to assess in this technique however. Photoemission intensity from elemental Ga would be observed some 1.1 eV (8) to lower binding energies than the Ga 3d signal in GaAs. The lack of asymmetry on the low binding energy side of the Ga 3d in Fig. 1D in conjunction with the As/Ga ratio being greater than one rather than less than one suggests that elemental Ga is not present as the absorbing species. Small particles of GaAs embedded in the oxide during oxidation are also highly unlikely and would not explain the observed Raman scattering peak around 200 cm^{-1}. The bulk of the existing evidence favors elemental arsenic as the absorbing species in these films.

Comparison of Fig. 2B-D in the vicinity of 200 cm^{-1} demonstrates that the electrochemically anodized film contains less elemental arsenic than either the rf or dc oxides in the as-grown state. A qualitative estimate of the detection sensitivity of the Raman technique for crystalline arsenic (3) suggests that 10-20Å of As should be observable. A comparable figure for amorphous As may be 2-3 times larger. The recent ellipsometric studies support the observed differences between electrochemically anodized and plasma oxidized films. In those studies, electrochemically anodized films grown at 0.1 mA/cm^2 were observed to contain less than 6Å of total arsenic and to display interface widths less than 25Å (20). In addition, the interface widths were observed to be current density dependent. Our efforts to establish the arsenic detection sensitivity of Raman scattering (3) suggest that a total of 6Å would not be detected in our measurements. In the rf films analyzed, high current density growth resulted in the sharpest interface (~84Å) which contained ~20Å of arsenic (19). In addition, the bulk films contained between 1-2 volume percent of a-As (assumed), which would contribute another 9-18Å of As in 900Å of a bulk film. Detection of 30-40Å of a-As is consistent with the additional scattering intensity observed around 200 cm^{-1} in Fig. 2C and D. All of the rf samples including those annealed at 300°C for 1 hr (RF-5-8) showed comparable Raman intensity in this region. Somewhat more variation was exhibited by the dc plasma oxides. In particular, samples DC3 and DC5 showed weaker though discernible scattering peaks around 200 cm^{-1}.

The ternary Ga-As-O phase diagram (1) mentioned in the introduction specifies that Ga_2O_3 and As are the phases which can coexist in thermodynamic equilibrium with GaAs. Diffusion of As_2O_3 from any region of the film to the oxide-substrate interface should result in a reaction according to

$$As_2O_3 + 2GaAs \rightarrow Ga_2O_3 + 4As \quad [1]$$

whenever there is sufficient energy available to overcome the reaction barrier. The existence of this reaction has already been verified using Raman scattering in electrochemically anodized films which were thermally annealed (2, 3). TEM (21) and ellipsometric studies (22) of annealed rf plasma oxides have also observed the presence of crystalline arsenic deposits in the interfacial region. The connection between these observations and the reaction scheme presented in Eq. [1] was not made in Ref. (21) and (22) however.

The thermodynamic origin of Eq. [1] implies that interfacial reactions involving native oxides on GaAs should occur at sufficiently high temperatures independent of the growth technique provided that As_2O_3 is one of the film constituents. Rutherford backscattering and ion-induced x-ray data support the contention that the As_2O_3/Ga_2O_3 ratio of As/Ga is close to 1:1 in bulk films of both rf plasma oxidized (9) and electrochemically anodized (23) samples. In order to verify the reaction on plasma films and to compare the reaction rates, the three samples of Fig. 2B-D were encapsulated together in an evacuated quartz tube (5×10^{-7} Torr) and inserted in a tube furnace at 400° ± 10°C for 1 hr. Figure 3 shows the results of Raman scattering from these thermally annealed samples.

Intense crystalline modes of metallic arsenic are now observed around 200 and 260 cm^{-1}. The variation observed in the different lineshapes suggests that a mixture of crystalline and amorphous arsenic is present. The crystallization rate appears to differ among the samples and may be sensitive to certain details of the film composition such as water inclusion during electrochemical anodization. The spatial location of these deposits at the oxide-substrate interface has previously been demonstrated in annealed anodic (3) and rf plasma (21, 22) films.

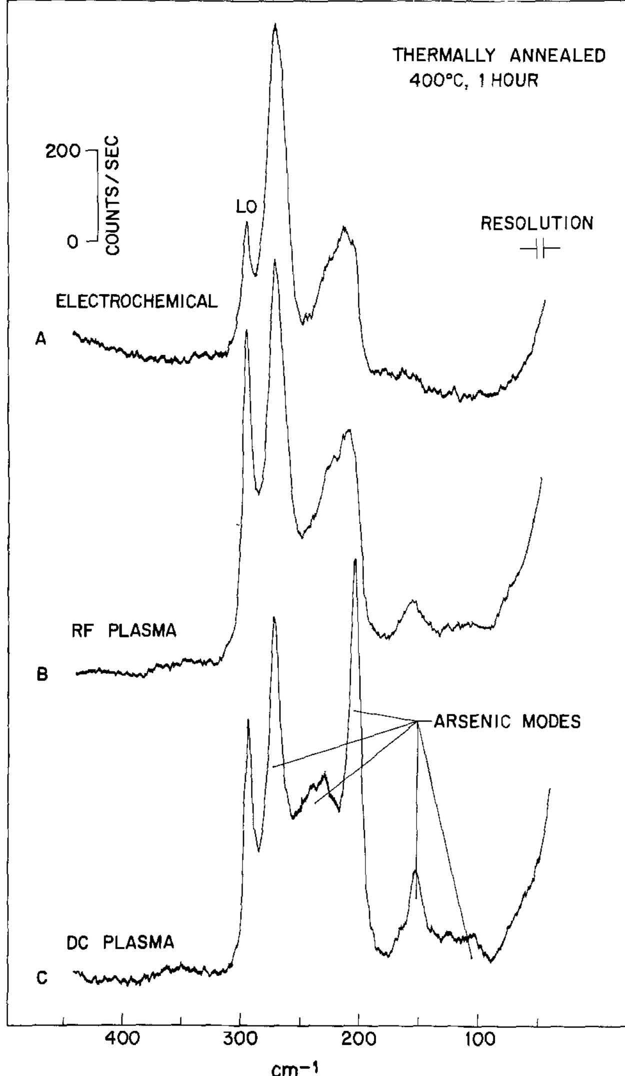

Fig. 3. Raman scattering (HU) from thermally annealed films. Crystalline and amorphous arsenic modes as well as the substrate LO are shown.

From a comparison of the Raman intensities observed in Fig. 2 and 3, it is readily apparent that the total As content of these films has increased substantially during the annealing. This feature is consistent with arsenic generation implicit in Eq. [1] but is inconsistent with a model of the plasma oxide-GaAs interface proposed by Chang (24). In that model, the primary effect of thermal annealing ($T < 450°C$) supposedly is to convert amorphous arsenic present in the as-grown state to one of its crystalline allotropes. Such a model clearly cannot account for the considerable increase in the arsenic intensity observed after annealing.

In summary, photoemission and Raman scattering have been employed to study the nature of plasma oxide films grown on GaAs. The bulk films consist of As_2O_3 and Ga_2O_3 with evidence for some form of pentavalent arsenic in the surface layers. As-grown electrochemically anodized films were observed to contain less elemental arsenic than their dc and rf plasma counterparts over the limited range of plasma oxidation conditions employed in this study. Thermal annealing results in an interfacial reaction between As_2O_3 and the substrate independent of the growth procedure for the oxide film. Substantial deposits of elemental arsenic are generated and subsequently incorporated in the oxide during this reaction.

Etching Characteristics of Defects in the InGaAsP-InP LPE Layers

Tsuyoshi Kotani, Satoshi Komiya, Saburo Nakai, and Yutaka Yamaoka

Fujitsu Laboratories Limited, Nakahara-ku, Kawasaki, Japan

ABSTRACT

Defects in the InGaAsP-InP multiepitaxial layers on the InP (111)P substrate were investigated using chemical etching techniques. Threading dislocations. stacking faults, dislocation rosettes, and dislocation crowds were revealed on InP epitaxial layers by the AB etch at 60°C. They were identified from their etch features and it was suggested that dislocation rosettes and crowds were caused by localized mismatch stress.

There is considerable interest in the quaternary InGaAsP for injection laser (1, 2), LED (3, 4), and photodiode (5, 6) applications in fiber optic communication systems (7, 8) developed for the 1.0-1.5 μm wavelength range, since in this quaternary alloy layers bandgap can be varied while maintaining lattice match to the InP substrate (9, 10). It is known that the first degradations of GaAlAs-GaAs DH lasers or LED's are caused by some defects in the active layer (11-13). Ettenberg and Nuese reported that the degradation rate depends on the energy gap of the active layer (14). Therefore, it is important to investigate defects in the InGaAsP-InP LPE multilayers matched to the InP substrate. This paper describes the etching characteristics of defects in the InGaAsP-InP LPE layers on the InP (111)B substrate.

Key words: etch pit, dislocation, liquid phase epitaxy, InGaAsP.

Experimental Procedure

The LPE growth method utilized in this work was the well-known slider boat technique. An InP (111)B substrate was chemically polished and its damage layer was removed. The solutions for LPE growth were saturated at 670°C for an hour and cooled at the rate of 0.5°C/min over a temperature interval of 40°C. After the InP buffer layer was grown, the growth of the quaternary layer was started from 648°C at the matching condition (15). A super cool of 2°C was employed for the growth of the 2nd and 4th InGaAsP layers. The energy gaps of the second active layer and the 4th layer for p-contact are 1.00 and 1.06 eV, respectively. The characteristics of wafer 1 with a typical double heterostructure are shown in Table I.

The lattice match between the epitaxial layers and substrate was evaluated using a double crystal x-ray

Table I. Characteristics of wafer 1

	Substrate and epitaxial layers	Dopant	Carrier conc. (cm^{-3})	Thickness (μm)
Sub.	InP (111)B	Sn	$n = 5 \times 10^{17}$	
1st	InP	Sn	$n = 5 \times 10^{17}$	5
2nd	$In_{0.75}Ga_{0.25}As_{0.52}P_{0.48}$	—	—	1.0
3rd	InP	Zn	$p = 1 \times 10^{18}$	1.0
4th	$In_{0.79}Ga_{0.21}As_{0.56}P_{0.44}$	Zn	$p = 5 \times 10^{18}$	0.8

diffractometer with parallel setting of the (333) plane. The half angles of rocking curves from the (333) reflection of the (111)B InP substrates were about 8-10 sec. Figure 1 shows the diffraction profile of wafer 1 shown in Table I. While the sharp main peak 1 is due to the InP layers and substrate, the much broader diffraction peak 2 is due to InGaAsP layers and may suggest large distribution of the lattice constants. The lattice mismatch between peaks 1 and 2 is $\Delta a/a = 9.1 \times 10^{-4}$. Other DH wafers have similar diffraction profiles, when the same compositions of melts are employed.

There are a few reports on the etchants revealing defects in the InP substrate (16, 17),[1] but they are inadequate to evaluate thin epitaxial layers as shown in Table I. It is well known that the AB etch, which consists of a mixture of 2 ml H_2O, 8 mg $AgNO_3$, 1g CrO_3, and 1 ml HF, reveals defects in the GaAs substrate (18). Stirland has also reappraised the etching properties of the AB etch for the GaAs substrate (19). InGaAsP-InP epitaxial wafers were also studied by the AB etch (20-22). The etch features of the InP (111)B and (100) substrates by the AB etch maintained at 60°C are shown in Fig. 2(a) and (b), respectively, and two specimens were etched simultaneously. These etch features are very similar to those observed on the Si-doped GaAs substrate (19), *i.e.*, most of dislocations are mainly delineated as the dot- and dash-like features in Fig. 2(a) and (b). These features represent a two-dimensional projection onto the surface produced by the etch of the dislocations contained within the volume of InP removed by the etch. However, some of dislocations are revealed as conical etch pits on the InP (111)B substrate. The straight lines or band-like features are associated with striations and were frequently observed on the InP substrates, but not observed on the epitaxial layers. Figures 2(c) and (d) show the etch pit patterns of the same areas on the two InP substrates with (111)B and (100), respectively, when subsequently etched by the dislocation etchant of (1HBr:5HF) (17). The etch features at emergent dislocations are different owing to the etchants, however, the etched pattern in Fig. 2(b) compares well with the etch pit pattern in Fig. 2(d).

[1] Since the etchant (1HBr:5HF) has no memory effect and revealed no striations on any substrates, these samples were etched by (1HBr:5HF) without being polished by any etchants after the AB etchant. Therefore, the striation image on Fig. 2(c) and (d) is the afterimage of that revealed by the AB etch, while deep etch pits correspond to dislocations through etched surfaces.

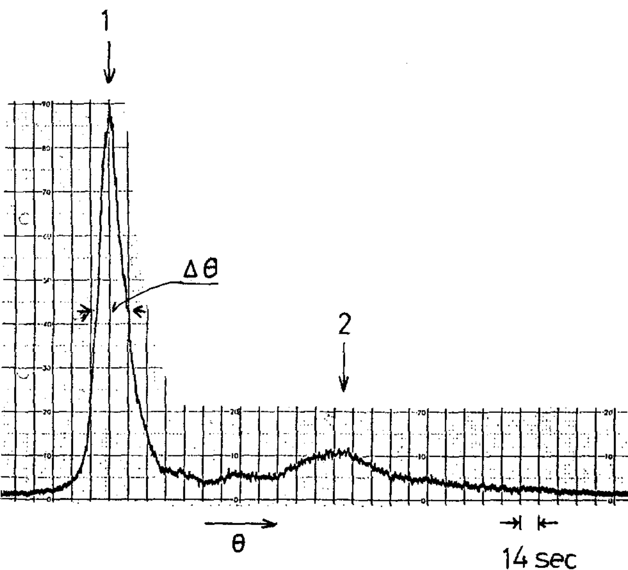

Fig. 1. Rocking curve of the (333) reflection of wafer 1 by using a double crystal x-ray diffractometer. The (333) reflection plane of the similar InP (111)B substrate was employed as an x-ray monochrometer and they were set in parallel. Cu-$K_{\alpha 1}$ radiation was employed and confined to 0.5 mm on the wafer surface by point slits. The half-angle of peak 1 is of $\Delta\theta = 24$ sec and the mismatch of the peak 2 is of $\Delta a/a = -9.1 \times 10^{-4}$.

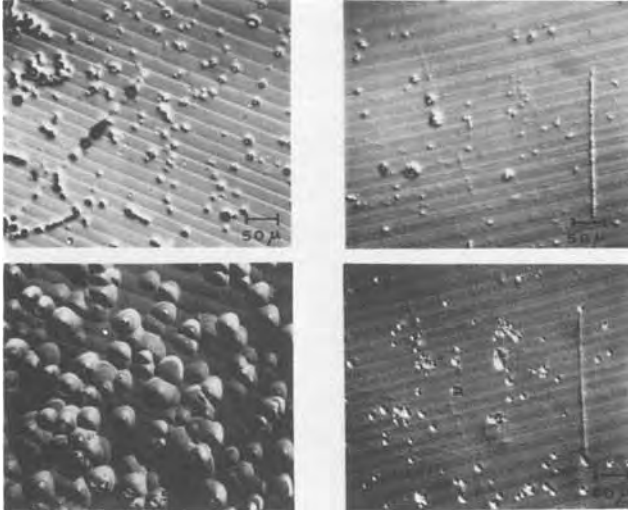

Fig. 2. The interference contrast micrographs of the etched surfaces of the InP (111)B and (100) substrates by the AB etch and (1HBr:5HF). Figures (a, top left) and (b, top right) show the (111)B and (100) surfaces of the InP substrates, respectively, after 15 min AB etch at 60°C. Figures (c, bottom left) and (d, bottom right) show the (111)B and (100) surfaces of the InP substrates after 2 min (1HBr:5HF) etch at room temperature, respectively.

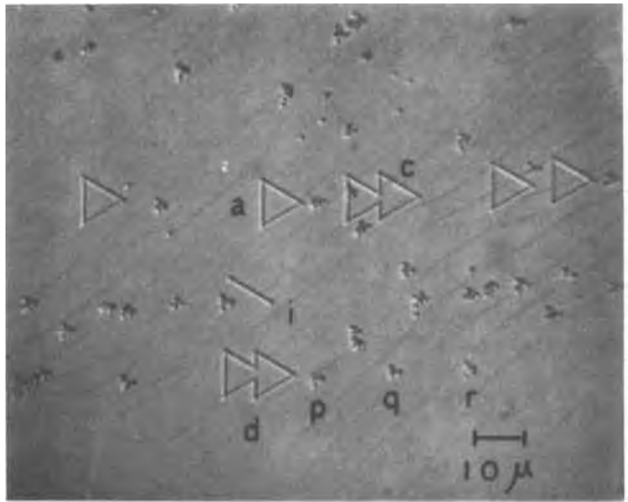
Wafer 1 has been examined using these etchants as follows. When the wafer was etched for 2.5 min by the AB etch, the 4th InGaAsP layer was preferentially etched off because of more rapid etch rate and then the etch feature of the third InP layer was examined by interference contrast. After the remaining third layer was selectively polished by the (1HBr:10HF) etchant (17), it was also etched by the AB etch and the etch features of the first InP layer were examined too.

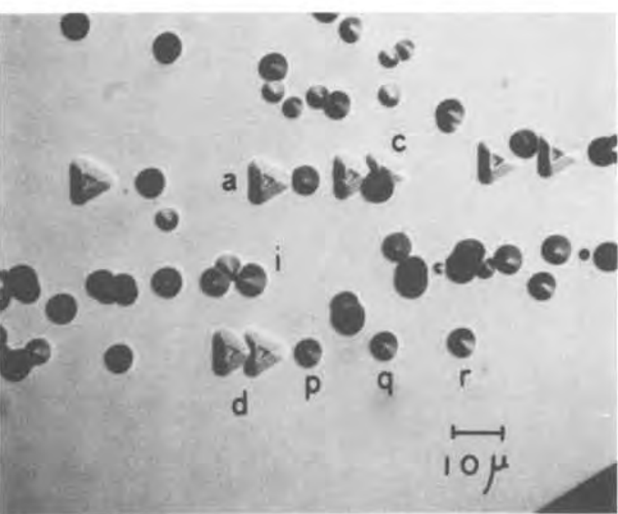
Results and Discussion

Dislocation etch pits.—Figures 3(a) and (b) show the etch features of the same area on the third and first InP layers of wafer 1 by the AB etch at 60°C, respectively. As shown in Fig. 3(a) and (b), conical etch pits were revealed on the epitaxial InP layers by the AB etch, although only part of the etch feature was observed as conical etch pits on the InP (111)B substrate. The multiplication of threading dislocation in the epitaxial layers was observed in Fig. 3(a) in comparison with that shown in Fig. 3(b). For example, each of the etch features "p," "q," and "r" consists of several etch pits on the third InP layer in Fig. 3(a) but is observed as only a single etch pit on the first InP layer in Fig. 3(b). Most of dislocation etch pits on the third InP layer of other DH wafers by the AB etch were observed as a cluster of several triangular etch pits, as shown in Fig. 3(a). This multiplication of threading dislocation is caused by the generation of dislocations due to plastic deformation and its details were discussed in another paper (23).[2]

[2] As shown in Fig. 4 of this reference (23) etch pits were revealed on as-grown homoepitaxial InP layer by the AB etch, so etch pits on the first InP layer in Fig. 3(c) are not due to the memory effect of the AB etch.

Stacking faults.— Stacking faults having three different configurations, *i.e.*, the single line "i," triangle "a,"





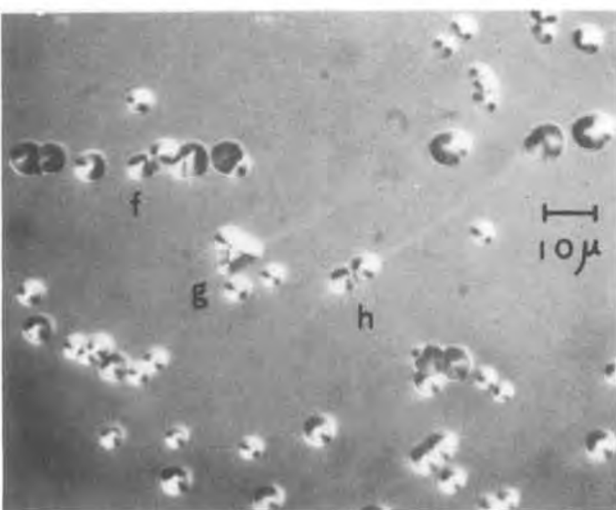


Fig. 3. The micrographs of the etched surface of the third and first InP layers of wafer 1 by the AB etch. Figure (a, top) is the etch pit pattern on the third InP surface after 2.5 min AB etch at 60°C. After the third InP layer of wafer 1 was preferentially removed by the etchant (1HBr:10HF), it was etched by the AB etch at 60°C for 3 min. Figures (b, middle) and (c, bottom) show the etch pit patterns on the first InP layer surface. An etch pit or triangle defects are denoted with the same letters in Fig (a) and (b).

and their combination "c" were observed in Fig. 3(a). Considering the etched shape of the triangle "a" in Fig. 3(b), these stacking faults have also a three-dimensional structure consisting of (111) surfaces for the (001) growth plane (24, 25). Their original position can be known from their size on the surface, though it is present clearly behind the second layer. It is evident that all the stacking faults in Fig. 3(a) occur at the interface between the first epitaxial layer and the substrate. Comparing Fig. 3(a) with 3(b), they pierce through the three epitaxial layers without any perturbation at two heterointerfaces between the InP and InGaAsP layers (26), and probably through the 4th InGaAsP layer, too. However, the stacking faults were not observed on the as-grown surface of the 4th InGaAsP epitaxial layer by optical microscope. They were frequently observed as surface-imperfections on the epitaxial surface of VPE Si (27) or GaAs (28). The structure of the surface imperfections, the so-called "shadow," are formed as a result of the blocking or perturbation of lateral growth. These surface imperfections were also observed on the surface of liquid phase epitaxial wafer with similar double heterostructure of GaAlAs-GaAs (29). In the case of LPE growth, it is probable that the surface imperfection due to stacking fault is also caused by the perturbation of dominant lateral growth such as terrace steps. However, such typical terrace steps were rarely observed on the InGaAsP LPE layer doped by various dopants, Sn, Te, Zn, and Cd, even when it had sufficiently the lattice constant matched to the InP substrate ($\Delta a/a \lesssim 1 \times 10^{-4}$). Furthermore, such surface imperfections with the regular square shape were sometimes observed on the lattice matched ternary InGaAs layer grown on the InP(001) substrate. This implies that two-dimensional epitaxial growth such as nucleation, step growth, and bunching mechanisms may be blurred, because this quaternary alloy consists of four elements with very different ionic radii as opposed to the ternary GaAlAs. Anyhow, it seems that some growth mechanism of the quaternary layer affects formation of the surface imperfections associated with stacking faults.

There were several reports on etching characteristics of stacking faults on VPE Si layer (24, 25). The partial dislocations terminating line defect with Burgers vector of $+a/6 <211>$ were revealed as deep etch pits at the ends of etched groove, whereas terminating triangle defect with Burgers vector of $+a/6 <110>$ were not revealed as etch pits at the corners of etched triangular grooves. As shown in Fig. 3(b) and (c), the conical deep etch pits are observed at both ends of line defects "h" and "i" but the etch pits at the apexes of triangle such as "a" are not so clear. This result suggests that the partial dislocations terminating this line defect have Burgers vector of $+a/6 <211>$, and agree with the results of Mahajan *et al.* (30) on stacking faults in the LPE homoepitaxial InP layer. The stacking fault combination "c" or "d" resulted from the interaction of two triangle defects and partially annihilated on the third InP etched surface. Therefore, it seems that the two triangles of the combining stacking fault are of similar types.

Dislocation rosette and crowd.—Figure 4 shows the etch pit pattern on the first InP layer of wafer 1. In addition to randomly distributed etch pits, two types of etch pit clusters "D" and "E" were observed in Fig. 4 and they were sometimes revealed on each epitaxial layer of the similar DH wafers by the AB etch. Figures 5 and 6 show the typical patterns of their etch pit clusters. The cluster in Fig. 5 is usually called the dislocation rosette though it is produced by intentional indentation experiment (31) or bonding process (32). The cluster in Fig. 6 consists of randomly distributed etch pits from its center region of high density and we call it the dislocation crowd in order to distinguish the dislocation rosette.

Fig. 4. Etch pit pattern on the first InP layer

Fig. 5. A typical dislocation rosette pattern revealed on the first InP epitaxial layer of wafer 1 by the AB etch.

The dislocation rosette consists of two etch pit arrays along only two <110> directions among the equivalent three in the (111) plane and each array consists of pairs of large and small etch pits. The one side of the double lines of etch pits in a <110> array consists of the small etch pits and the other consists of the large etch pits. Maeda *et al.* reported on the three slip modes of a dislocation rosette on the indented (111)B GaP surface (31). Considering the rosette pattern of Fig. 6, it seems that a pair of etch pits in a <110> array is associated with the dislocation half-loop along a prismatic glide cylinder and the Burgers vector is of equivalent six modes of $+a/2$ <110> in the (111) growth plane.

Figure 7 (a) shows many dislocation rosettes on the thicker InGaAsP layer of 4.3 μm with the close composition to one of the second quaternary layer of wafer 1, and the lattice mismatch is of $\Delta a/a = -10 \sim +6 \times 10^{-4}$ as a result of the compositional gradient along the growth direction (33, 34). Figure 7 (b) shows the growth pattern on the first InP layer after the quaternary layer was etched by the etchant (H_2SO_4:H_2O_2:H_2O = 90:5:5). The notable wavy patterns and many parallel lines to three <110> directions due to misfit dislocations are observed in Fig. 7(b). As shown by "A"-"F" in both figures, the dislocation rosettes correspond to the fronts of the wavy patterns, respectively. Furthermore, all of them consist of only two <110> arrays of etch pits. Generation of these dislocation rosettes is explained from the results as follows. There is the lattice mismatch of $\Delta a/a = -9 \times 10^{-4}$ between the parallel growth planes of the quaternary layer and InP layer in wafer 1. Assuming that the lattice planes of the quaternary layer perpendicular to the growth (001) plane are more closely matched

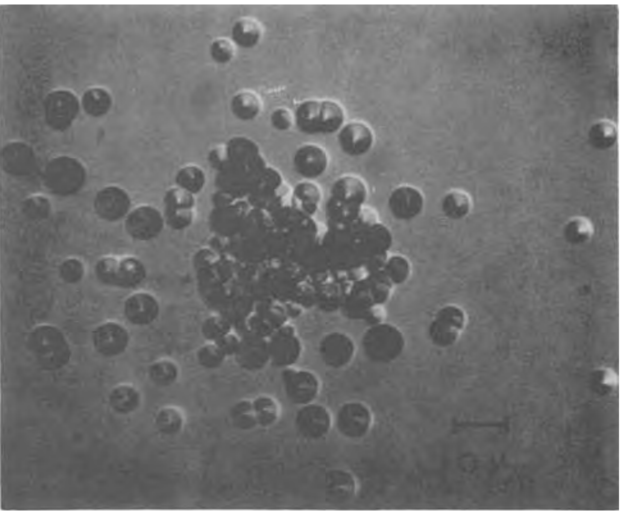

Fig. 6. A typical dislocation crowd pattern revealed on the first InP epitaxial layer of wafer 1 by the AB etch.

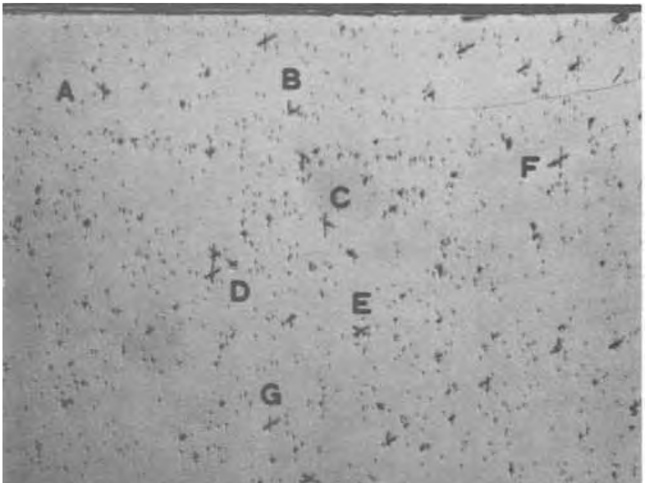

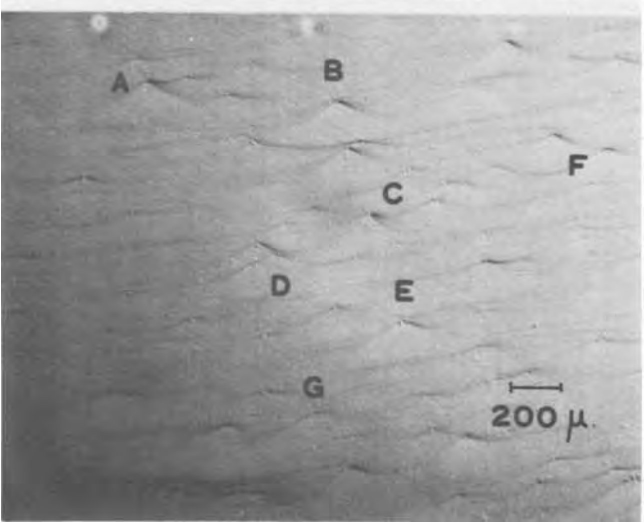

Fig. 7. (a, top) A distribution of the dislocation rosettes on the etched InGaAsP quaternary layer. (b, bottom) The wavy pattern on the first InP layer.

to that of the InP (35), the inner stress σ in the (001) plane due to the lattice mismatch is derived from a formula $\sigma = E/(1 - v)x\Delta a/a$ (34, 36). When the stress σ is approximately estimated from the values of $E/(1 - v) = 1.2 \times 10^{12}$ dyne/cm^2 for GaAs [37], the value σ equals to 1.1×10^9 dyne/cm^2 at room temperature. Though the lattice match at high temperatures is probably more important (38, 39), this mismatch stress had never induced in wafer 1 any misfit dislocations. Nevertheless, this misfit stress is not sufficiently small, and it may be sufficient to induce local plastic deformation when it was localized at the smaller area. Then, it is probable that this notable wavy pattern on the first InP layer has caused such localization. While the dislocation rosette with three or six etch pit arrays is usually induced by symmetric stress around a point in such a case of indentation experiment (31), this localized stress should be asymmetric because of geometry of the wavy pattern and it induced the dislocation rosette with only two etch pit arrays. Furthermore, dislocation crowd may also be caused by such localized stress at a similar wavy pattern, although it rarely was observed.

Mahajan *et al.* (40) has recently reported that dislocation clusters in optically degraded regions in InGaAsP layer were developed from threading and inclusion-generated dislocation by the glide process. Inclusion in the epitaxial layer can probably cause localization of the mismatch stress, but it is not apparent whether this rosette is the same defect.

In summary, the defects in the InGaAsP-InP DH wafer grown on the InP (111)B substrate were investigated by the observations of chemical etching features. The threading dislocations, stacking faults, dislocation rosettes, and dislocation crowds were observed and it was suggested that the dislocation rosettes and crowds were caused by localization of mismatch stress.

Control of Zn Doping for Growth of InP pn Junction by Liquid Phase Epitaxy

O. Wada,[1] A. Majerfeld,[2] and P. N. Robson

Department of Electronic and Electrical Engineering, University of Sheffield, Sheffield S1 3JD, England

ABSTRACT

The method of Zn doping for the liquid phase epitaxial growth of a high quality InP pn junction has been investigated. The evaporation of Zn from the growth melt was found appreciable at the growth temperature as low as 640°C and therefore causing the unwanted Zn diffusion into the substrate from the vapor. The diffusion of Zn from the growth melt was also observed and its effective diffusion coefficient in undoped InP was estimated to be $1.0 \pm 0.3 \times 10^{-10}$ cm^2 sec^{-1} at. 620°-640°C. The characterization of grown layers was carried out over a wide range of the Zn doping density. The distribution coefficient of Zn was determined from Hall measurement to be 0.84 below the Zn fraction in the melt of 10^{-2} atomic percent. Above this fraction, it was speculated that a strong carrier compensation limits the N_A-N_D value below $2\text{-}3 \times 10^{18}$ cm^{-3} and also results in the energy decrease and the half-width increase of the photoluminescence. In order to eliminate these disadvantages of Zn doping, an improved growth method was developed by an optimized use of *in situ* etch. The etching of the substrate by pure In solution was found to be characterized by the apparent diffusion coefficient of P in In, 6×10^{-4} cm^2 sec^{-1} at 640°C, and the structure grown by this method was found free from the misplacement of pn junction and also exhibiting the current-voltage characteristics of a nearly abrupt junction.

Recently InP has been receiving considerable interest because of its promising application to microwave devices as well as optical devices. One of the important technologies in processing InP devices is the formation of high quality pn junctions, which are widely required for various devices like InP IMPATT diodes and light emitting diodes. Several investigators have studied the liquid phase epitaxial (LPE) method to realize InP pn junctions consisting of Zn- or Cd-doped p^+-type layer and Sn-doped n-type layer (1, 2).

Since it has been shown that both Ge and Si, which behave as amphoteric dopants in GaAs, cannot produce a p-type conduction in InP grown by the LPE method (1, 3), Zn is considered to be one of the most convenient dopants to prepare p-type InP layers. When Zn is chosen as p-type dopant in the LPE growth, however, one should pay attention to its high vapor pressure as well as to the relatively high diffusion coefficient in the semiconductor bulk at the growth temperature. The evaporation of Zn in the Ga melt during GaP growth has resulted in the carrier density profile decreasing toward the epitaxial layer surface (4). The misplacement of the pn junction observed in the GaAs (5) and the InP (2) homojunctions and the InP-$In_{1-x}Ga_xAs_{1-y}P_y$ heterojunction (6) is considered to be attributable to either the Zn diffusion during the p^+-type layer deposition or to the cross-contamination of melts caused by the Zn evaporation. However, the understanding of this kind of problem in the LPE method has been left vague since no systematic studies have been carried out. Concerning the electrical characteristics of a Zn-doped layer, the net acceptor concentration has been reported to saturate at $3\text{-}4 \times 10^{18}$ cm^{-3} for higher Zn fractions in the growth melt (1). The effect of high doping has not been fully investigated so far, regardless of its importance in the p^+n junction structure.

The purpose of the present paper is to investigate the properties of Zn as a dopant for p-type InP layers, in order to develop the LPE growth technique to fabricate a high quality p^+n junction. In the course of our experiment, we have found that anomalous layers are formed in the n-type substrates during the growth of a Zn-doped p-type layer. The mechanism of this anomaly is analyzed in conjunction with the evaporation of Zn from the melt as well as the diffusion of Zn into the substrate. The effect of the Zn doping density is investigated in terms of the electrical property determined by the Hall measurement and the optical property obtained by the photoluminescence measurement. Finally, a growth method which can eliminate the formation of such anomalous layers is demonstrated and the suitable growth procedures for the fabrication of high quality pn junctions are discussed.

Growth Techniques

The growth system consisted of a horizontal furnace with a transparent gold-plated reflector and a sliding boat made of high purity graphite. The spacing of the Kanthal winding and the thickness of the gold film were optimized and a flat temperature profile within ±0.5°C deviation was obtained over the length of the boat. The furnace temperature was controlled by a Eurotherm Model 120 controller monitoring the temperature near the bottom of the graphite boat. The hydrogen was introduced into the reactor tube having the inner diameter of 43 mm through a Pd-diffused purifier at the rate of approximately 0.3 liter/min.

Two different sliding boats were used in our experiment. Boat 1 had a single 4 mm thick slider which had two melt bins with the cross section of 4×4 mm^2. An additional 8×8 mm^2 window was prepared in the slider. An InP plate set in this window protected the substrate during the pregrowth heating; this technique was useful to eliminate the thermal erosion of the substrate surface (7). Boat 2 had two sliders on the framework. Three 6×8 mm^2 melt bins as well as a 14×11 mm^2 window for the substrate cover were provided in the lower slider, the thickness of which was 3 mm. The top slider also had melt bins with same sizes as lower ones. A part of the melt stored together with the source InP in the upper bin can be introduced into the lower bin and made out of contact with the source InP by sliding the top slider on the lower one. The growth melt can be thus completely isolated in this system so that the losses of P and Zn are mini-

mized. The surfaces of the framework and the lower and the top sliders were finished to give intimate contacts, and the upper melts were protected by graphite covers over the bins.

The growth melt was saturated with InP mostly at 650°C for more than 30 min. It was once cooled down and then Zn of an appropriate amount was added to it and also the substrate was charged before the growth run. The substrate rested in the downstream of H_2 flow during the pregrowth period, and the minimum separation between the substrate and the growth melt was ~3 cm in both boat systems. The growth was carried out by contacting the melt, supercooled to 6°-13°C below the saturation temperature, to the substrate during either the isothermal growth or the ramp growth. The cooling rate used was 0.6°-2.6°C/min and the growth time was varied from 1 to 45 min.

Undoped bulk crystals with the carrier concentration around 4×10^{15} cm^{-3} and the mobility of about 5000 cm^2/V · sec were used as both phosphorus sources and growth substrates. Fe- and Cr-doped semi-insulating substrates with the resistivity ranging in 10^5-10^6 Ωcm were also used. The substrate and the source InP were etched in 0.5% Br · CH_4O solution and then stored in isopropylalcohol until they were charged into the furnace. High purity In (99.9999%, Johnson Matthey, Grade A1) and Zn (99.9998%, Metals Research) were weighed and etched by dilute HNO_3 just prior to the charging.

Results and Discussion

Junction cross section.—The cross section of the grown layer was stained with a solution of KOH + $K_3[Fe(CN)_6]$ (8) at room temperature: this etchant has been found more sensitive to the effect of our interest than the AB etchant (9). Most of the samples grown without any special precaution showed either two or three lines after staining regardless of a single deposition of the p$^+$-layer on the substrate. Figure 1 demonstrates an example of a microphotograph showing the formation of anomalous layers below the Zn-doped layer. In this case, a layer having two regions with different thicknesses has been grown by means of the shift of the melt bin using boat 1. The substrate with ~3.5° off <111> plane has been used and the growth times have been 15 and 30 min for the two regions, respectively. The straight line M shows the metallurgical interface. It is noticed that the additional lines, L and V, are deeper for longer growth duration. The depths of these two lines measured from the metallurgical interface are plotted *vs.* the growth time in Fig. 2. In this measurement, the growth has been carried out by boat 1 at ~640°C from a supercooled

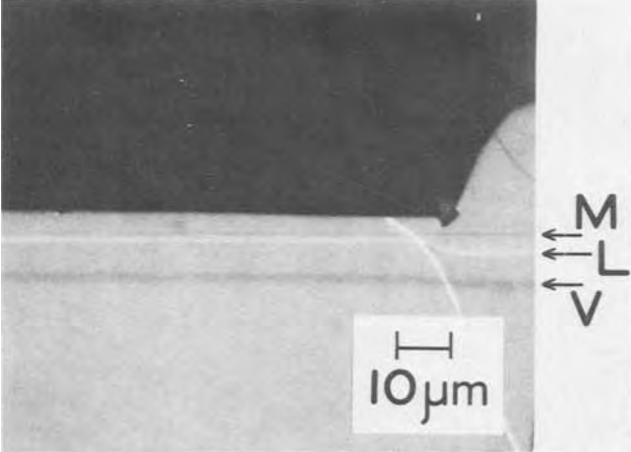

Fig. 1. Microphotograph showing the stained cross section of a p$^+$ layer grown on an undoped substrate. The growth time is 36 min on the right end and 16 min for the rest. The stained line M corresponds to the metallurgical interface, below which two extra lines L and V are revealed.

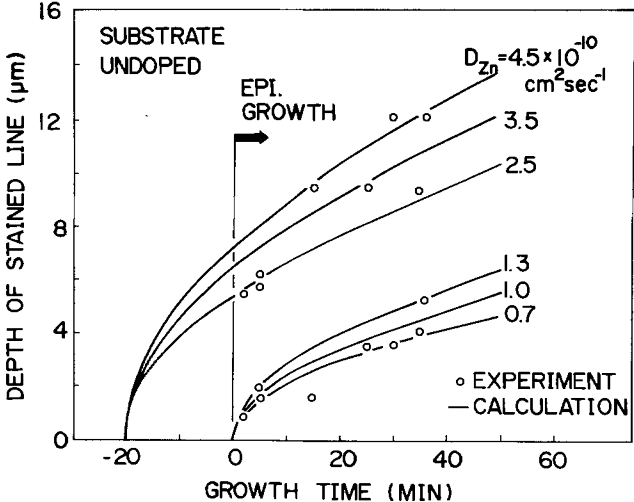

Fig. 2. Relationship of the depth of the stained line measured from the metallurgical interface vs. the growth time. The lines have been calculated with the assumption of a simple Zn diffusion for various values of the diffusion coefficient. The preheat duration of 20 min has been assumed.

melt with the Zn atomic fraction in the range of 0.06-0.02%. As seen in Fig. 2, line V is already several micrometers deep even on the early stage of the growth, whereas line L appears after the growth initiates.

The following possible origins can be considered to account for this anomaly: (*i*) the thermal conversion of the surface of the undoped substrate, (*ii*) the in- or out-diffusion of impurity, and (*iii*) the diffusion of Zn into the substrate. Our ancillary experiment showed that an anomalous layer is formed when the melt includes Zn even if it is located away from the substrate during heating. On the contrary, neither the growth of an undoped layer nor the heat-treatment of the substrate without Zn in the reactor exhibited any trace of anomaly. These facts suggest that possibility (*iii*) is working in our case, and the following mechanism is considered to operate. First, a fraction of Zn in the melt evaporates out and the Zn atoms in the vapor diffuse into the substrate even before actual contact of the melt with the substrate. After the contact the Zn atoms remaining in the melt diffuse into the substrate. These two processes are generating, primarily, the layer far below the interface and the one next to the interface, respectively. If the diffusion profile is assumed to obey a complementary error function, the diffusion depth d is expected to be given by

$$d \simeq (D_{Zn}t_d)^{1/2} \quad [1]$$

where D_{Zn} is the diffusion coefficient of Zn in InP and t_d stands for the diffusion time. The lines shown in Fig. 2 have been calculated by this equation with assumed values of D_{Zn}. Although the pregrowth duration in which ramp cooling took place ranged from 10 to 30 min, we have used 20 min as the median value in the calculation. The values of D_{Zn} are obtained to be $3.5 \pm 1.0 \times 10^{-10}$ cm^2 sec^{-1} for the diffusion from the vapor in the temperature range of 620°-650°C and $1.0 \pm 0.3 \times 10^{-10}$ cm^2 sec^{-1} for the diffusion from the liquid in the temperature range of 620°-640°C. Taking into account the Zn evaporation continuously occurring during the growth and also the appreciable variation of the initial Zn fraction in the melt, these values are considered to be in a reasonable agreement with earlier works (10, 11).

In order to know the loss of Zn in the melt during the growth, a sequence of weight measurement of the melt was carried out after each heat-treatment period. The melt consisted of 330 mg In with or without InP saturated at the heating temperature. First, the melt saturated with InP was heated at 650°C in boat 1 in

order to know the loss rate of P, and it was found very small, 9.5×10^{-3} hr^{-1}; this is in a good agreement with Hsieh's data (12). Next, the melts having different Zn weights were charged in boat 1 and were heated at 650°C. As for the set of melts unsaturated, the one with higher Zn fraction was located at the upperstream of the H_2 flow and the other one at 2.7 cm downstream from it. As shown in Fig. 3, the melt rapidly loses weight because of the Zn evaporation. The error bars indicated in the figure are for inaccuracies in determining small weight differences by a microbalance. A point worthwhile mentioning is that the melt with a lower Zn fraction initially gains its Zn weight until it reaches the same Zn weight fraction as the other one has. Essentially same effect is observed on InP-saturated melts. In this measurement, the melt with lower Zn weight was located 1.2 cm upstream with respect to the higher Zn melt. These features indicate that the Zn atoms in the higher Zn melt are transported to the lower Zn melt via the vapor phase. Judging from a relatively small Zn weight difference found between two InP-saturated melts after 30 min heating, the Zn transportation is considered to be nearly independent of the gas flow direction at least at the flow rate used (~0.3 liter/min). The slightly slow Zn loss in the InP-saturated melt may be attributable to the formation of solid phase Zn_3P_2 which is stable at this temperature (13). It is remarked that, when the melt is protected by the top slider in boat 2, the Zn loss is well prohibited. If the Zn loss is fully controlled by the evaporation into the free atmosphere, the time dependent weight of Zn ($W(t_e)$, W_0 at $t_e = 0$) at a fixed temperature is considered in an analogy of vacuum pumping (14) and is expressed in a form of

$$W(t_e) = W_0 \exp(-t_e/\tau) \quad [2]$$

where τ is the time constant being proportional to the reciprocal of the melt surface area. Our data are well approximated by this equation and τ is estimated to be 12 and 200 min for the unprotected and the protected melts, respectively, indicating that the effective surface area is decreased by 18 times by the protection regardless of the three times larger bin cross section of boat 2 than that of boat 1.

The effect of Zn evaporation from the melt has been reported in LPE growth of GaAs (5) and GaP (4), and Solomon and Defevere (15) proposed a technique of sealing the melt by means of a floating plug. The growth temperatures for those materials are much higher than ours. However, the present results indicate that even at 640°-650°C the Zn evaporation can affect the melt composition. The absorption of Zn observed here is supporting the possibility of the cross contamination of the multiple melt as has been suggested by Coleman (6). Moreover, as shown in the present case, the direct diffusion of Zn evaporated from the melt into the substrate prior to the actual growth can contribute to the misplacement of the pn junction, especially when the carrier concentration of the substrate is relatively low.

Electrical characteristics of p^+ layer.—Successive light etching followed by Van der Pauw Hall measurement was applied to determining the spatial distributions of the net carrier concentration N_A-N_D and the hole mobility μ_p in a p^+-type layer grown on a Cr-doped substrate. The data were analyzed by the method reported by Darwish (16) so that the values of N_A-N_D and μ_p, averaged over the thickness of the etched segment of epitaxial layer, were deduced. An example of the result measured on the layer grown by an unprotected melt with boat 1 is shown in Fig. 4. The etched thickness has been shown as error bar length in this figure. The arrows show the positions of the stained lines. The arrow at $X = 1.8$ μm shows the metallurgical interface and the one at $X = 5.1$ μm indicates the diffusion front of Zn in vapor, though the stained line corresponding to the diffusion front of Zn in liquid is missing in this example. N_A-N_D exhibits a long tail into the substrate, confirming the formation of a p-type layer due to the Zn diffusion. Although the width of this layer (3.3 μm) is much smaller than that estimated from Fig. 2 for the growth time of 20 min, this has been a common experience in our measurement on Cr- and Fe-doped substrates and the mechanism of the carrier generation due to the Zn diffused in a semi-insulating InP is suspected to be more complicated than in an undoped InP. A sharp peak of N_A-N_D observed at the interface is considered to be caused by a high surface concentration of Zn associated with the diffusion (17). N_A-N_D is found to

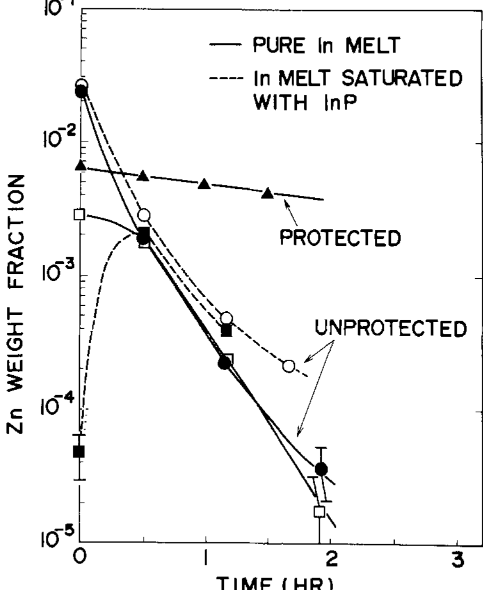

Fig. 3. Results of the weight measurement of the Zn included in the melt at 650°C for unprotected melt and at 640°C for protected melt. The unprotected melt shows rapid gain and loss of Zn weight, whereas the protected melt exhibits a slow weight loss.

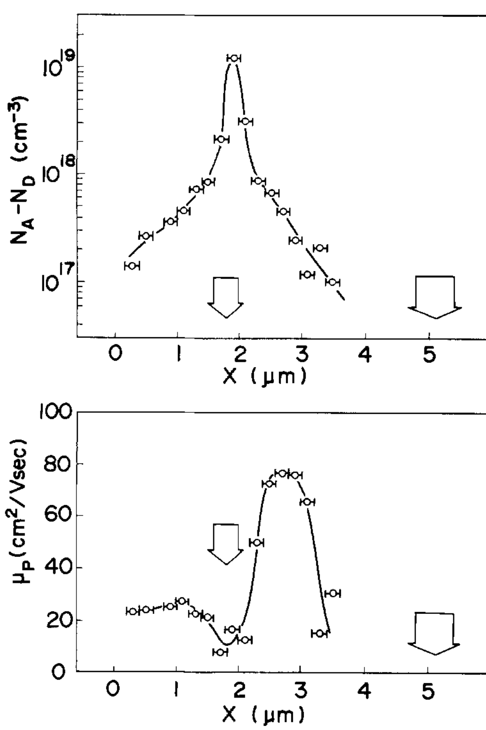

Fig. 4. Profiles of the net carrier concentration and the hole mobility in the depth direction of the layer. The epitaxial layer surface is at $X = 0$, and the arrows at 1.8 and 5.1 μm show the positions of the stained lines.

be much smaller inside the epitaxial layer than at the interface. The value of μ_p is also very small inside the epitaxial layer compared to that in the diffused layer. Since the value of μ_p in the diffused layer is in an agreement with the result of Hooper and Tuck (18), small N_A-N_D together with correspondingly small μ_p in the epitaxial layer is considered to imply that the net carrier concentration is less than the concentration of Zn atoms actually introduced in the crystal.

The net carrier concentrations were measured on samples with different Zn doping densities. The effect of Zn diffusion was minimized by adopting a quick growth procedure with a protected melt, and the Hall measurement data were analyzed in accordance with the thickness calibrated for the Zn diffusion depth. The plot of N_A-N_D *vs.* Zn atomic fraction in the melt is shown in Fig. 5 together with the data reported by Astles *et al.* (1). In the smaller range of Zn fraction, a linear relationship is obtained and the distribution coefficient of Zn, k_{Zn}, is estimated to be 0.84, which is smaller than $k_{Zn} = 1.4$ determined by Astles *et al.* (1). At the Zn fraction above 0.01 atom percent (a/o), N_A-N_D saturates at $2\text{-}3 \times 10^{18}$ cm^{-3} and even decreases as indicated by a single experimental data included in Fig. 5. Although the behavior of N_A-N_D above the Zn fraction of 0.1 a/o would need more work to be explained, the saturation effect observed here is considered to indicate that a high Zn doping causes a lowering of the ratio of the electrically active Zn atom concentration to the total concentration of Zn atoms introduced, being consistent to our hypothesis made in regard to Fig. 4. This is also consistent with the result of Kundukhov *et al.* (19). As for the result in Fig. 4, the fraction of Zn remaining in the melt during the growth has been estimated to be more than 0.01 a/o; this fraction is large enough for the lowering of the carrier to atom concentration ratio to occur. Mahajan *et al.* (20) recently found by the transmission electron microscopic analysis on the crystal with the carrier concentration of $2\text{-}5 \times 10^{18}$ cm^{-3} that some of Zn atoms introduced in the crystal can form precipitate. Such precipitate could contribute to reduce the numbers of free carriers. However, the observed decrease of the carrier concentration exceeds 1×10^{19} cm^{-3} at the Zn fraction of 0.1 a/o (see Fig. 5) and this is considered to be too high to be explained by the precipitate density, equivalently below 10^{13} cm^{-3} as determined by Mahajan *et al.* Instead, the most likely model to interpret the lowering of the carrier to atom concentration ratio would be the occurrence of the carrier compensation as suggested by Hooper and Tuck (18), in which the Zn atoms are incorporated in the interstitial sites to create donors due to the formation of some kind of complex.

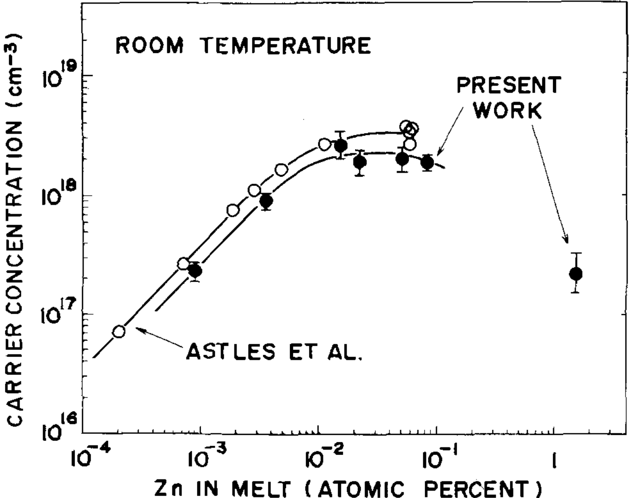

Fig. 5. A plot of the net carrier concentration vs. the Zn atomic fraction in the melt.

Photoluminescence properties of p^+ layers.—Photoluminescence (PL) measurement was carried out at RSRE, Malvern, England, on a number of Zn-doped layers at 6°K by a setup similar to that reported earlier (21), in which a high pressure mercury arc was used as the excitation source. A few samples were made of undoped substrates heat-treated in the furnace with the presence of a melt containing Zn, so that we could examine PL on Zn-diffused layers. Zn is a common residual impurity in In and has been found to exhibit a PL peak due to band-acceptor recombination at 1.37-1.38 eV (3, 22, 23). The PL peak of the Zn-diffused layer was found in our experiment at 1.374 eV, which exhibited the typical Zn peak, and this peak maintained its energy at low Zn fractions. However, above the Zn fraction of 0.003 a/o, the peak shifted to lower energy and simultaneously broadened. The changes of peak energy and the full half-width are plotted in Fig. 6 and 7, respectively, where the results reported by Williams *et al.* (22) and Röder *et al.* (23) are also plotted on the basis of the linear relationship shown by Astles *et al.* (1) between the net acceptor concentration and the Zn fraction in the melt. Although our data involve inaccuracies in estimating the Zn fraction, the peak shift and the increase of the half-width are obvious above the Zn fraction of 10^{-3}-10^{-2} a/o and their variations qualitatively agreed with the reported results shown. It is interesting to note a coincidence of the behavior between the carrier concentration and the PL data. As has been shown in Fig. 5, N_A-N_D begins to saturate at the Zn fraction of 10^{-2} a/o, above which the PL peak shifts and broadens. Such PL characteristics are considered

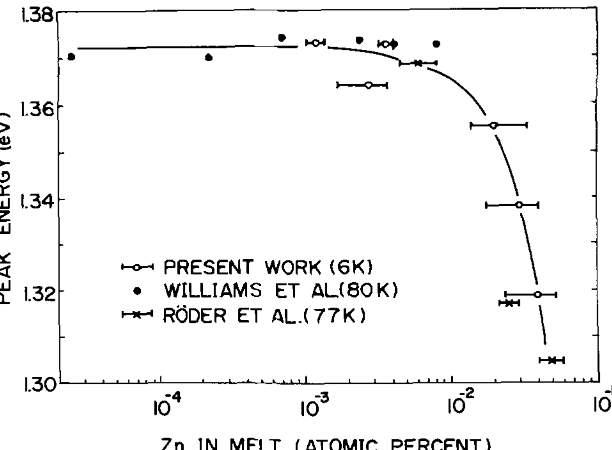

Fig. 6. Dependence of the photoluminescence peak energy on the Zn fraction in the melt.

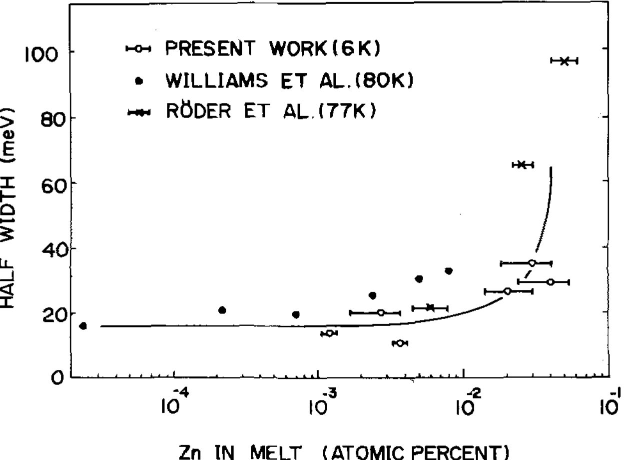

Fig. 7. Dependence of the half-width of the photoluminescence peak on the Zn fraction in the melt.

to be partly due to the development of the acceptor band in this range of Zn concentration. The acceptors are considered to form an impurity band above a net concentration of 1×10^{18} cm^{-3} and the PL transition is dominated by the band acceptor recombination near the top of the acceptor band. Since the top of the acceptor band moves deeper into the forbidden gap with the increase of the concentration, the PL peak energy is reduced; similar effect has been found in Zn-doped GaAs (24). However, more characteristically in higher doping range, the effect of carrier compensation, which has been pointed out previously, may also play an important role in the reduction of PL peak energy through the shift of the Fermi energy inside the impurity band, as has been reported on Zn-doped GaAs by Tuck (25). This model is likely able to explain the coincidence between the behavior of the carrier concentration and the PL in the high doping range, although a clear understanding of the compensation mechanism is subject to more detailed investigations.

Improved method of growing pn junctions.—As has been pointed out in previous sections, the evaporation of Zn from the melt before the growth, followed by its diffusion into the substrate during the growth is one of the unwanted effects associated with the Zn doping. The melt protection has been proposed for the minimization of this effect. The protection, however, may not be satisfactory to completely eliminate the unwanted Zn vapor around the substrate. Therefore, we examined a method to get rid of the Zn-diffused layer after its formation by extensively applying the *in situ* etch technique (26). When this technique is incorporated in our growth procedure, it is important to optimize the etching duration since the Zn diffusion is able to occur even from the Zn-contaminated etching solution if the etching velocity is not larger than the Zn diffusion velocity.

We measured, therefore, the etching characteristic using a pure In solution. In the measurement, the substrate was made in contact with the etching solution for a certain time at a constant temperature. The weight loss of the substrate was then measured and converted into the etched depth using the solution-substrate contact area. Boat 2 was most suitable for this experiment because a constant solution thickness could be realized all over the substrate surface. The etched depth of a substrate with 3.5° off (100) plane at 640°C is plotted *vs.* the etching time in Fig. 8. When the effect of solution convection can be neglected, the etching process is considered to be limited by the diffusion of P in In and the total weight $M(t)$ of the substrate etched in time t for unit substrate area is expressed (27) by

$$\frac{M(t)}{M(\infty)} = 1 - \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2\pi^2} \exp\left[-D_P(2n+1)^2\pi^2 t/4l^2\right] \qquad [3]$$

where D_P and l stand for the diffusion coefficient of P in In and the solution thickness measured perpendicular to the substrate surface. The data calculated from $l = 3$ mm (boat 2) for different values of D_P are also shown in Fig. 8. The saturation level of the etched thickness has been estimated to correspond to a weight fraction of InP in In solution of 8.5×10^{-3} which is in a good agreement with the solubility of P in In at this temperature (13). It is found in the figure that our experimental data are well explained when $D_P = 6.0 \times 10^{-4}$ cm^2 sec^{-1} is assumed. Hsieh (12) used a theory of the diffusion-limited LPE growth to derive a value of D_P of 6.1×10^{-5} cm^2 sec^{-1} at 640°C. Recently Srnanek and Hobovcik (28) carried out the desolution experiment similar to ours to obtain the D_P value close to Hsieh's. Although the origin of the discrepancy between our and other's D_P values is not known yet, it is particularly useful for the present purpose that

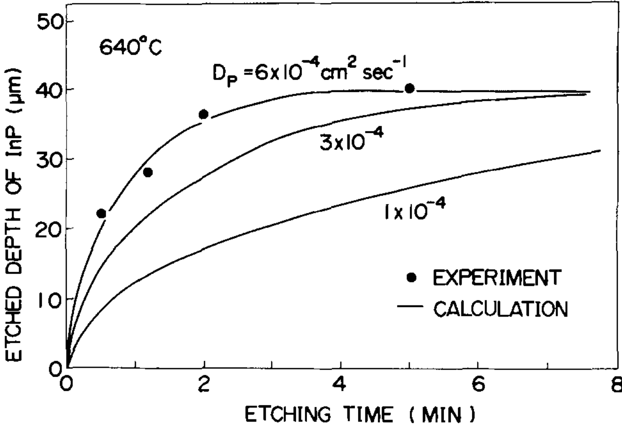

Fig. 8. A plot of the depth of InP substrate etched by a pure In solution with a fixed volume *vs.* the etching time. The calculations with three different values of the diffusion coefficient of P have been shown.

the etching is appreciably quick and also characterized by a single value of D_P equal to 6.0×10^{-4} cm^2 sec^{-1} at 640°C.

The layer Zn-contaminated prior to the etching, the thickness of which would be several microns, can be completely removed within the etching duration only less than 10 sec, as known from Fig. 8. The exact velocities of the InP etching and the Zn diffusion from the solution can be determined, respectively, from the derivatives of Eq. [3] and [2] together with the values of D_P and D_{Zn} determined in our experiment. From this consideration, it is shown that the etching velocity is ten times greater than the Zn diffusion velocity up to 2.7 min after the solution-substrate contact. On the basis of the present data, we grew a p^+-layer using the *in situ* etch technique. Typical examples of photomicrographs of stained cross sections are demonstrated in Fig. 9. The layer shown in Fig. 9(a) has been grown with the etching time of 10 min and the growth time of 2 min, and the appearance of line L indicates that the Zn diffusion occurred during the etching process because of a too long etching time. On the other hand, Fig. 9(b) shows a single layer without any effect of Zn diffusion both from the vapor and from the liquid. The times of the etching and the growth in this case were, respectively, 40 sec and 1 min, and the Zn fraction in the melt was restricted below 10^{-2} a/o. This result shows the effectiveness of the *in situ* etch with an optimized duration as well as the control of the Zn fraction in the melt.

As described so far, (*i*) the use of the *in situ* etch by a pure In melt in addition to the protection of the melts, (*ii*) the minimization of the growth period, and (*iii*) the control of the Zn fraction in the melt give a solution to diminish the major problems associated with the Zn doping. In order to confirm our findings, we measured the current-voltage (I-V) characteristics of pn junctions made by various methods in the course of the present study. Figure 10 shows the forward I-V characteristics of junctions prepared with and without the *in situ* etch. The diodes used in these measurements consisted of mesa etched junctions with the area of approximately 2×10^{-3} cm^2 having the p- and the n-contacts of alloyed Au-Zn and Au-Ge/Ni films, respectively. For both junctions, the forward current density, J, can be approximated by $J = J_s \exp(-V/nkT)$, where J_s, V, and n represent the saturation current density, the applied voltage, and the ideality factor. As seen in Fig. 10, the junction which is contaminated by Zn shows poor and unreproducible characteristics; the ideality factor is much larger than 2, and, in particular, a strong current saturation is observed at fairly low voltages, indicative of the existence of a high resistivity layer in the transition region between the Zn-diffused layer and the n-type bulk. The capaci-

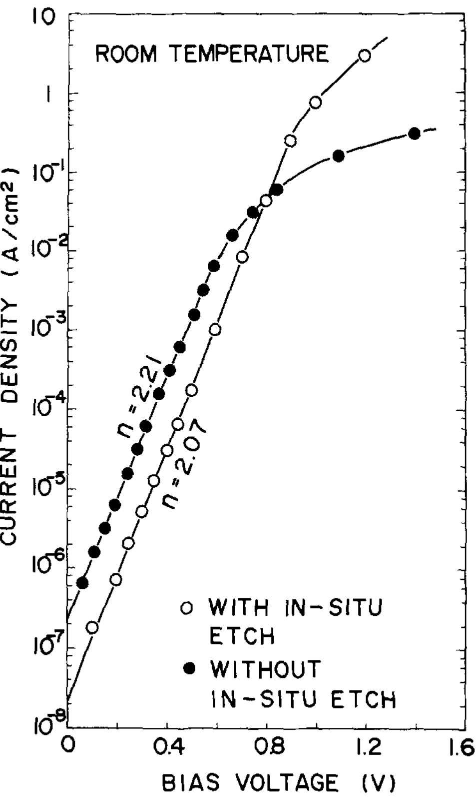

Fig. 10. Forward current-voltage characteristics of pn junctions fabricated by the growth methods with and without the *in situ* etch technique.

tance-voltage (C-V) measurement on the same junction has indicated the graded nature of the carrier concentration profile in the n-type substrate, and this is consistent with the high resistivity in the transition region. On the other hand, the junction fabricated by the improved method with the *in situ* etch exhibits a reasonable characteristic with the ideality factor as small as 2.0 and an excellent linearity of the ln I-V is found over a range of the current exceeding 10^6 times difference. The current saturation observed above 0.9V is caused by the series resistance of the n-type substrate. The C-V analysis carried out on the same junction has confirmed a fairly constant distribution of the carrier concentration and also has given the built-in potential of 1.14 eV which is close to the value, 1.21 eV, predicted for a p^+n abrupt junction.

Summary

The formation of anomalous layers below the metallurgical junction between the Zn-doped p^+-layer and the n-type substrate was interpreted in terms of the evaporation of Zn from the melt followed by its diffusion from the vapor phase into the substrate and also the diffusion of Zn remaining in the melt into the substrate. The evaporation of Zn was confirmed by the separate measurement of the weight loss of the melt, and the diffusion of Zn in InP was found to exhibit a value of diffusion coefficient, 1-4 $\times$ 10^{-10} cm^2 sec^{-1}, at a temperature around 630°C. The depth profiles of the net carrier concentration and the hole mobility were analyzed and found to agree with the above model. A low net carrier concentration found in the epitaxial layer was presumed to be caused by the effect of compensation of the carriers. The carrier reduction was revealed above the Zn fraction of 10^{-2} a/o in the melt by the Hall measurement. PL measurements showed the energy decrease and the broadening of PL peak in higher range of Zn doping. By considering these features, we developed an improved method to prepare a pn junction free from the Zn contamination. The application of *in situ* etch technique as well as the use of a melt protector were found effective to eliminate the Zn diffusion. The *in situ* etch was characterized by the apparent diffusion coefficient of P in In, 6 $\times$ 10^{-4} cm^2 sec^{-1} at 640°C. Also quick growth process with the Zn amount suppressed was found preferable. This knowledge enabled us to optimize the growth sequence and the resulted junction was free from anomaly. This method was confirmed, by the measurement of the I-V and C-V characteristics of p^+n junctions, to greatly improve the quality of the devices.

The Use of Electrical Test Structure Arrays for Integrated Circuit Process Evaluation

Martin G. Buehler*

National Bureau of Standards, Electron Devices Division, Washington, DC 20234

ABSTRACT

Four different classes of electrical test structure arrays for the analysis of integrated circuit manufacturing processes are described. They include test structures that evaluate the density of random faults, the variation of parameters within a chip, the alignment between photomasks, and the carrier generation lifetime of small diodes. All of the structures allow for the rapid collection of large amounts of data through the use of electrical test methods. Thus, a statistically significant amount of data can be collected that allows a detailed study of processing steps.

The successful fabrication of a large scale integrated circuit chip requires that process and device parameters be confined to tight design windows and that random fault densities be uniformly low (1). Because many of these parameters vary unpredictably across a wafer, they cannot be effectively evaluated by the measurement of a few elements on a wafer. Electrical test structure arrays fabricated across a wafer allow a detailed evaluation through the rapid acquisition of a statistically significant number of data points.

The variations in process and device parameters across a wafer may be divided into three categories. First, some parameter variations are identical from wafer to wafer but are unrelated to the periodicity of the chip dimension. These are introduced by such processing steps (2) as diffusion, ion implantation, epitaxial layer growth and plasma etching. Second, other parameter variations are repeated periodically across a wafer with a periodicity corresponding to the chip dimension. These variations are introduced by optical pattern generation and step and repeat processes. Finally parameter variations may be random in nature. These are caused by such effects as crystalline imperfections in the semiconductor material, faults in the patterning of the various layers, or distortions introduced by the many fabrication steps.

Spatial variations in parameters directly impact chip yield. In addition, they affect the circuit designer who uses the mean value of the parameters for his circuit model and assumes that the circuit has enough margin in performance to function in spite of parameter variations.

This paper describes four classes of test structure arrays used to diagnose integrated-circuit manufacturing processes. They include test structures that evaluate the density of random faults, the variation of parameters within a chip, the alignment between photomasks, and the carrier-generation lifetime of small diodes. It is hoped that this paper will encourage the use and further development of this class of characterization techniques.

Random Fault Density

In this paper, the term random fault refers to such faults as breaks in metal lines or metal-to-silicon-contacts. The density of random faults is determined from a random fault test structure which is a collection of elements such as metal-to-silicon contacts or metal crossovers that are tested for electrical continuity or isolation. The elements are usu-

* Electrochemical Society Active Member.
Key words: integrated circuit; linewidth; photomask alignment; process control; random faults, test patterns; test structures.

ally connected in series as is the case for the metal-to-silicon contact test structure. If enough elements are used, the structure is useful for process control, design rule optimization, and new process and equipment evaluation (3). In many test patterns observed by the author, the random fault test structures have an insufficient number of elements. Such structures are useful only for the identification of catastrophic fabrication problems.

A comprehensive metal-to-silicon contact test structure (3) is illustrated by the metal mask shown in Fig. 1. The test pattern is a square 200 mil (5.08 mm) on a side and contains a large number (38,400) of contacts subdivided into the eight arrays shown in the figure. The test pattern which is repeated periodically across the photomask is replicated across a wafer. The yield of a particular array with the same number of contacts is calculated from the fraction of good arrays found on the wafer. In the testing of an array, it is assumed that when a fault is encountered only one fault has occurred and that the fault is the intended fault (in this case a metal-to-silicon contact fault). The yield calculation assumes that faults occur randomly across the wafer. When such assumptions obtain, then the expected yield of an array containing N contacts follows the exponential relation (4)

$$Y = \exp(-DN) \qquad [1]$$

where D is the characteristic number of faults per contact.

The pattern shown in Fig. 1 was fabricated periodically across various silicon-on-sapphire wafers. Within each wafer, one of four possible contact dimensions was used. The result are indicated in Fig. 2. An analysis of the yield curves shown in Fig. 2 leads to a fault density, D, for each curve. These values are listed in Table I along with the reciprocal fault density, D^{-1}, which indicates the number of elements found in an array with a yield of 37%. For example, for the 3.6 μm contact, 37 out of 100 arrays, each composed of 4300 contacts, can be expected to be good. In the design of a circuit with a particular number of contacts, the appropriate contact dimension to be used for a high yield circuit can be estimated from the D^{-1} values listed in Table I. As seen in the table, a modest change in the contact dimension from 3.6 to 5.1 μm results in almost a tenfold change in D^{-1} from 4,300 to 38,000 contacts/fault.

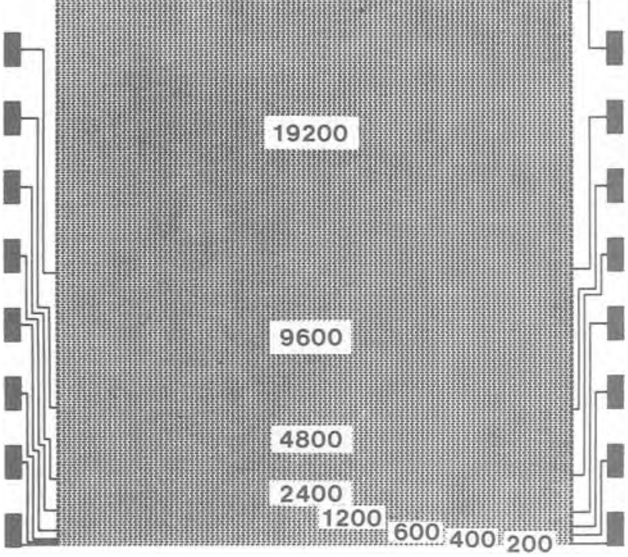

Fig. 1. Metal mask used in the fabrication of various metal-to-silicon contact arrays. The number of contacts in each array is indicated by the numerical value (3).

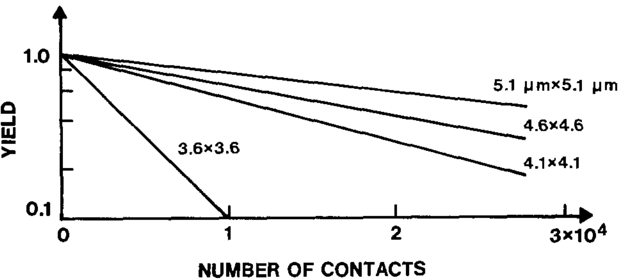

Fig. 2. The integrity of various metal-to-silicon contacts with different dimensions (3).

Table I. Fault densities for contacts shown in Fig. 2

Contact dimension (μm)	D (faults/ contact)	D^{-1} (contacts/ fault)
3.6	2.3×10^{-4}	4,300
4.1	6.0×10^{-5}	17,000
4.6	4.3×10^{-5}	23,000
5.1	2.6×10^{-5}	38,000

An effective yield analysis requires a well-designed random fault test chip that has a collection of arrays where the number of elements in each array progresses from a few to many contacts. Such a progression allows the construction of a yield curve and the evaluation of the fault density. For a successful analysis, the number of elements in each array must be chosen *a priori* when the photomask is designed so that the yield in some of the arrays lies between zero and 100%.

As explained earlier, the application of Eq. [1] to a yield analysis of random fault test structures assumes one fault per array, that the fault is the intended fault, and that the faults do not cluster. Faults can cluster in certain regions of a wafer due to the introduction of crystalline defects (4, 5), wafer handling, or poor mask alignment. For example, rotational misalignment between certain photomasks can appear as a spurious radial component in the fault density. A well-designed random fault test structure will have liberal design rules where possible so that the effect of photomask misalignment is minimized.

Random fault test structures tend to be complex structures so that the faults encountered may not be those which the structures are intended to detect (6). For example, in a contact array, a fault could occur at a step in the metallization, or an entire metal connection could be missing. Other unintended faults can occur due to mechanical probing problems. To avoid probing errors, structures were designed with extra large probe pads as shown in Fig. 3. The probes touch down at the X points and electrical continuity between probes on the same pad determines that both probes are down. Such an arrangement avoids unintended faults due to probing errors.

Once a fault has been identified electrically, the array must be examined optically to verify that the fault is the intended fault. This requires a careful microscopic inspection of the array which can be time consuming. In addition, some faults, like a poor metal-to-silicon contact, may not be amenable to visual inspection. Because of the complex nature of these arrays, some workers (6) recommend against using these structures for predicting circuit yield.

Despite the shortcomings mentioned above, the structures are useful when used with caution for process control, design rule optimization, and equipment evaluation (3). Because a comprehensive random fault test structure requires a large amount of area, it should be fabricated on a special test wafer, such as a process validation wafer (1), which is processed along with production wafers.

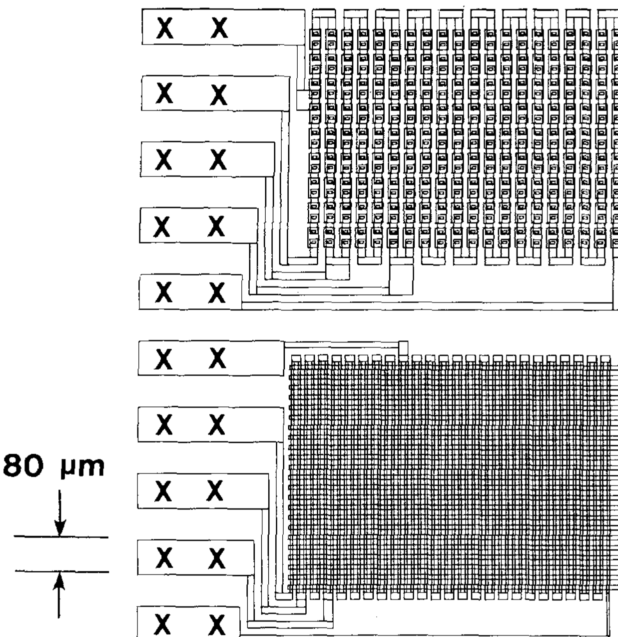

Fig. 3. Metal-to-silicon contact array (upper) and metal-step coverage array (lower) probeable with a 2 by 10 probe.

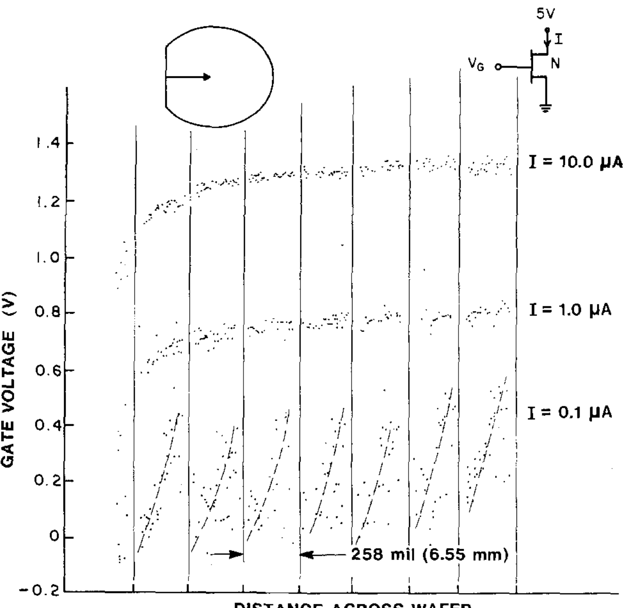

Fig. 4. The gate voltage at various source/drain current levels as a function of position across a wafer where a large intrachip variation is apparent at low currents (7).

Intrachip Parameter Variation

The importance of the variation in parameters within a test chip was stressed by Ham (7) in pointing out that the local variations within a chip can easily exceed the chip-to-chip variation across a wafer. Ham's observations of intrachip threshold variations and our observations of intrachip linewidth variations serve to illustrate the effect.

Intrachip MOSFET parameters were studied with the use of a comprehensive test pattern (or chip) (6) designed for silicon-on-sapphire. Each chip, which is 259 mil (6.55 mm) on a side, contains 43 individually probeable MOSFET's arranged across the pattern. The transistors are self-aligned silicon gate devices with a channel length of 0.3 mil (7.6 μm) and a channel width of 0.6 mil (15.2 μm). Each photomask level was prepared from a master reticle by a step and repeat procedure.

The gate voltage required to produce 0.1, 1.0, or 10 μA current through each channel transistor in the intrachip array is shown in Fig. 4. In this figure, data were purposely omitted near the chip boundaries for ease of viewing.

For the 0.1 μA current, the gate voltage varies periodically with the chip dimension. A possible explanation for this intrachip variation at low currents is that the device current is predominantly an edge current which is more sensitive to gate dimensions than the main channel current which dominates at higher current level (8). If this explanation is correct, the shape of the 0.1 μA curve in Fig. 4 indicates that the gate length is varying periodically with the chip dimension.

The second example of intrachip parameter variations concerns the variation in linewidth within a test pattern (9). This was studied by fabricating a test pattern consisting of 120 cross-bridge sheet resistors (10) arranged in 8 rows across a pattern (or chip) 200 mil (5.08 mm) on a side. The linewidth was determined by first evaluating the sheet resistance, R_s, at the intersection of the cross and then evaluating the bridge portion of the structure. The linewidth, W, was calculated from

$$W = LR_sI/V_{12} \quad [2]$$

where L is the distance between the voltage taps, I is the current through the current carrying channel, and V_{12} is the voltage difference between the voltage taps of the bridge.

As with the MOSFET example, the photomask was prepared from the same master reticle by a step and repeat procedure. The pattern was exposed with the use of a contact printing alignment system and etched in an 800 nm thick, 0.044 Ω/□ e-gun evaporated aluminum layer deposited on an oxide film thermally grown on a 2 in. (5.08 mm) diam silicon wafer.

The chip-to-chip linewidth variation for the cross bridge located in the lower left-hand corner of the chip is shown by the wafer map in Fig. 5 for each of the 53 chips tested. In the wafer map, every fourth symbol represents a measured value; all other points are interpolated. The photomask linewidth was 0.60 mil (15.2 μm) and, as seen from the key in the figure, the final average linewidth is about 11.4 μm. The key shows the number of values that lie in each linewidth increment. The variability in the linewidth across the wafer as shown in Fig. 5 is attributed to those factors which affect the contact between the photomask and the photoresist-covered wafer, such as the flatness of the silicon wafer, the flatness of the photomask, the pressure applied between the wafer

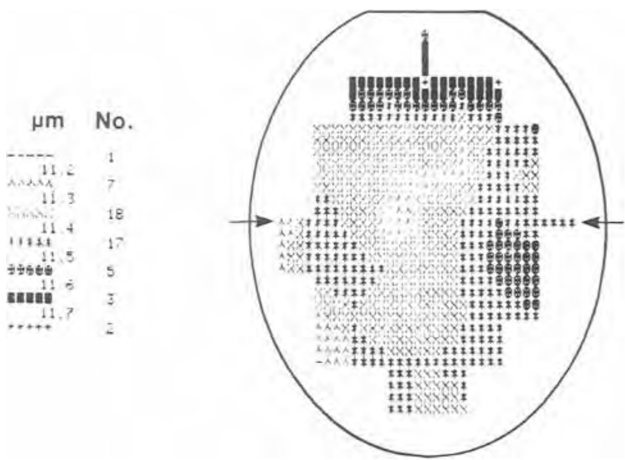

Fig. 5. Intrachip linewidth variations across a 2 in. (50.8 mm) diameter silicon wafer due primarily to the variability in the contact between the photomask and the photoresist-covered wafer.

and photomask, dust particles located between the wafer and photomask, and nonuniform etching across the wafer (11).

The intrachip linewidth variation is plotted in Fig. 6 as a function of position across the wafer. These data were taken from the bottom row of each chip. The row chosen for this plot is indicated by the arrows in Fig. 5. The plot, shown in Fig. 6, indicates that the linewidth varies periodically with the chip dimension across the wafer. This periodic variation is superimposed on the nonperiodic chip-to-chip linewidth variation. At this time, the periodic linewidth variation is assumed to be due to aberrations in the optics of the image repeater used to step and repeat the 10× reticle. The periodic linewidth variations observed in Fig. 6 are comparable with the linewidth distortion of 0.1 μm expected for the wafer imaging system used in this study.

Care must be exercised in interpreting linewidth data. In addition to the effects mentioned above, such as wafer flatness and optical aberrations, the sheet resistance variations must also be considered. As seen from Eq. [2], the sheet resistance directly influences the linewidth. For the linewidth data shown in Fig. 6, the sheet resistance varies very smoothly; it has a slope of 0.0005 Ω/□/cm in the middle of the wafer and a relative standard deviation less than 0.05%. The influence of the sheet resistance variation on the linewidth shown in Fig. 6 is less than the size of the symbols used to represent the data.

The periodic variations shown in Fig. 6 are relatively small, being about 1.5% of the mean linewidth of 11.4 μm, but it is expected that the variation of 0.17 μm will be independent of the linewidth. For example, for a linewidth of 1 μm, the variation is expected to be a significant 17%. Such variations can be a limitation in a manufacturing process and indicate that improved techniques, such as electron beam lithography, will be needed for the fabrication of submicrometer lines.

The linewidth information obtained from the cross-bridge array is potentially useful in developing control of the very small dimensions needed in future circuits. Studies of linewidth variations within a chip can assist in the evaluation of pattern generators, image repeater systems, and mask alignment machines. In addition, the linewidth array is useful in establishing design rules and margins for circuit design parameters.

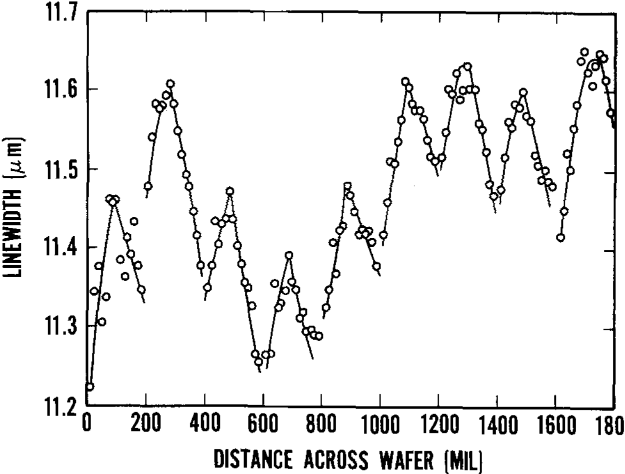

Fig. 6. Intrachip linewidth variations across the wafer shown in Fig. 5. The period of the linewidth variations corresponds to the width of the chip, 200 mil (5.08 mm). The periodic linewidth variation is assumed to be due to aberrations in the optics of the image repeater used to step and repeat the 10× reticle.

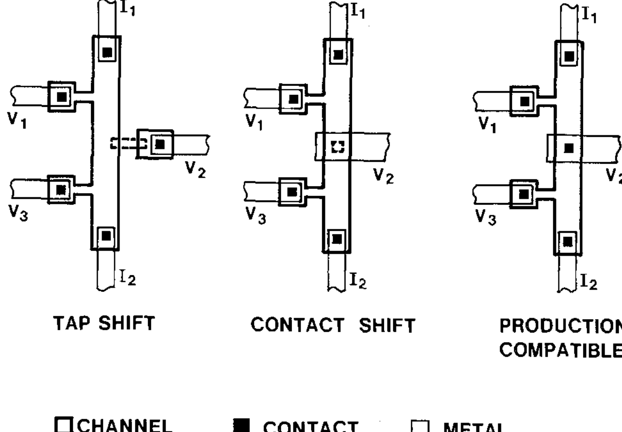

Fig. 7. Three different electrical alignment test structures

Photomask Alignment

Three test structures for measuring alignment electrically are shown schematically in Fig. 7 as the tap-shift (12), contact-shift (13), and production-compatible (14) test structures.[1] The structures described in Ref. (12-14) differ in design detail but not in principle from those shown in Fig. 7. As shown in the figure, current is forced along the channel from point I_1 to I_2. The voltage differences, V_{12} and V_{23}, are used to evaluate the alignment. If $V_{12} = V_{23}$, then the alignment is perfect.

The three structures, shown in Fig. 7, differ in the manner in which the channel is tapped at point V_2. In the tap-shift and contact-shift structures, the tap rectangle and contact square both appear on the photomask used to define the conducting channel. This photomask is used twice. The first time, it is used to define the conducting channel. The second time, it is shifted by an appropriate amount and used to form the shift feature. In the production-compatible test structure, the contact feature appears on a separate photomask.

In the shift-type structures, photomask step-and-repeat error and photomask runout are eliminated. In the tap-shift structure, the results are not complicated by irregularities introduced by the contacting step. Unfortunately, these structures are not production-compatible.

A complete production-compatible test structure (16) is shown in Fig. 8. The vertical or y-alignment is determined by forcing a current between points I_1 and I_2 and measuring the voltage differences, V_{12}, V_{23}, and V_{34}. The displacement of the contact window at point V_3 from the midpoint between taps V_2 and V_4 is given by

$$L_y = L_{12}(V_{34} - V_{23})/(2V_{12}) \quad [3]$$

where L_{12} is the distance between taps V_1 and V_2. The horizontal or x-alignment is determined in a similar manner by forcing the same current as used above between points I_2 and I_3 and measuring V_{56} and V_{67}. The x-alignment is given by

$$L_x = L_{12}(V_{67} - V_{56})/(2V_{12}) \quad [4]$$

The x- and y-alignments are then combined to form a vector representing the local displacement in the vicinity of the test structure.

The test structure shown in Fig. 8 was used to evaluate the alignment between the contact and channel photomask steps. This structure is part of the NBS-15 test pattern (17) which is a rectangle 1.7 × 2.4 mm. The pattern was repeated on 100 mil (2.54 mm) centers across a wafer 2 in. (50.8 mm) in

[1] Another structure was reported recently (15). With this structure, the alignment is determined from the width of a current-carrying channel formed by a shift-type sequence explained in the text.

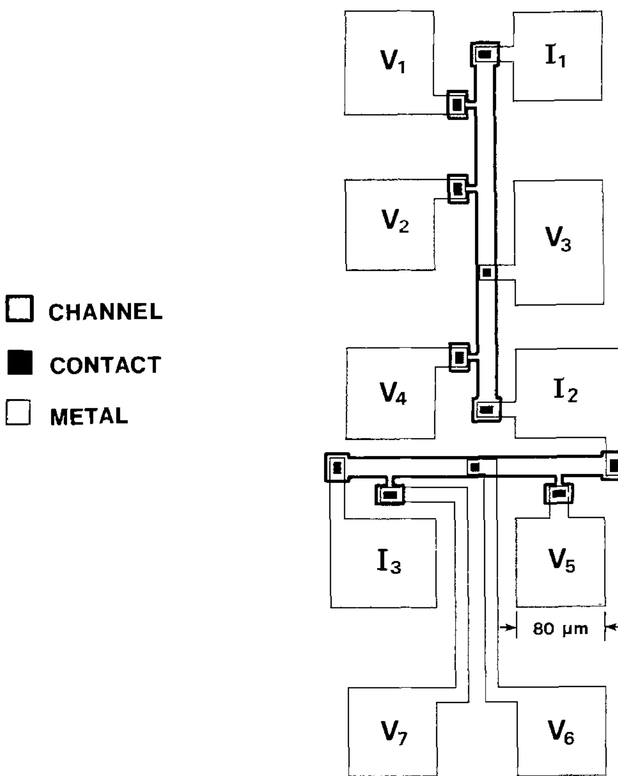

Fig. 8. Production-compatible electrical alignment test structure for evaluating the contact-to-channel alignment (16).

diameter. The conducting channel was formed by a high temperature diffusion step. An array of 62 test structures located on 200 mil (5.08 mm) centers was measured. The displacement vectors for each of the 62 test structures are shown in the wafer map displayed as the original data in Fig. 9.

The mean rotation and translation components, introduced by the operator in aligning the contact photomask relative to the channel photomask, were determined by performing a least squares fit to the vectors from the 62 test structures. These mean components were then removed from the original data, and the difference vectors were plotted in the other wafer map shown in Fig. 9. This wafer map is indicative of alignment distortions that occurred between the channel and contact photomask steps. Such distortions are introduced by a variety of factors, such as deformation of the wafer or photomasks due to small temperature gradients during mask alignment, wafer warpage due to the high temperature diffusion step used to form the conducting channel, photomask step-and-repeat errors, or photomask runout.

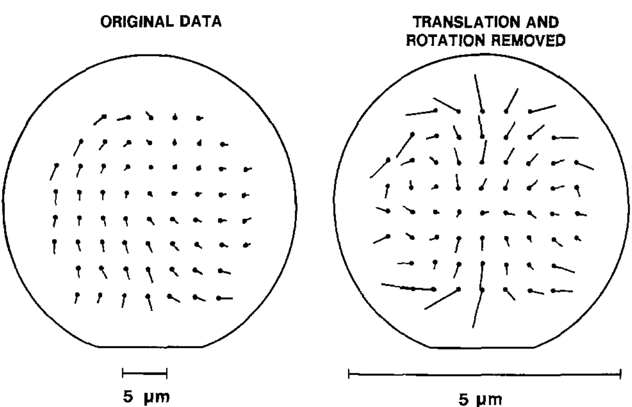

Fig. 9. Wafer maps of the contact-to-channel alignment as determined from the production-compatible test structure shown in Fig. 8.

Vector maps derived from a van der Pauw-type tap-shift test structure (12) are shown in Fig. 10. These data were obtained from an array of 118 test structures fabricated on a 3 in. (75 mm) diam silicon wafer and located on 222 mil (5.64 mm) centers. The mean rotation and translation components were again evaluated by a least squares fit technique. Removal of these components leads to the results shown in Fig. 10 which indicates a net expansion behavior. Because this is a tap-shift test structure, this behavior is not influenced by photomask step-and-repeat error or photomask runout. In addition, wafer warpage is not a factor because the conducting channel and tap features were defined at room temperature prior to the formation (ion implantation) of the channel. The expansion behavior might be explained by the wafer bowing that occurs in an oxidized silicon wafer when some of the oxide is removed, especially from the back side of the wafer. Alternatively, this behavior might be due to a net thermal expansion of the photomask between its first and second image.

The vector maps shown in Fig. 9 and 10 were both obtained using contact-printing mask alignment systems. The magnitude of the largest misalignment vectors, after removal of the operator-induced translation and rotation components, is about 1 μm. This residual misalignment is characteristic of the various processing steps used to fabricate the wafer. It represents the best alignment an operator can hope to achieve. In order to reduce the residual misalignment, more advanced processes must be used. Such misalignments are expected to be a limitation on the ability to fabricate integrated circuits with submicrometer dimensions. The alignment test structures have proved useful in evaluating the performance of mask aligners (12), alignment markers (13), and operators (13).

Carrier Lifetime

Gated diodes have been used for a number of years to evaluate the surface and bulk leakage currents of p-n junctions (18). Such measurements are slow, requiring many minutes, and they generally require test structures that are large compared to circuit elements. Because of the very small currents involved, these measurements are not compatible with production-oriented test equipment.

The integrated gated-diode electrometer is a production-compatible test structure (19) shown in Fig. 11 and consists of three on-chip circuit elements: a gated diode, MOSFET switch, and output MOSFET. The output MOSFET is connected in a source-follower configuration with its drain connected to the supply voltage, V_B, and its source connected to an external resistor, R_L, that is returned to the substrate potential, V_S. In operation, the MOSFET switch is closed momentarily by applying an appropriate switch bias, ϕ_R. This connects the reverse-bias voltage, V_R, to the gated diode. The voltage, V, of the gated diode is sensed through the output MOSFET at the

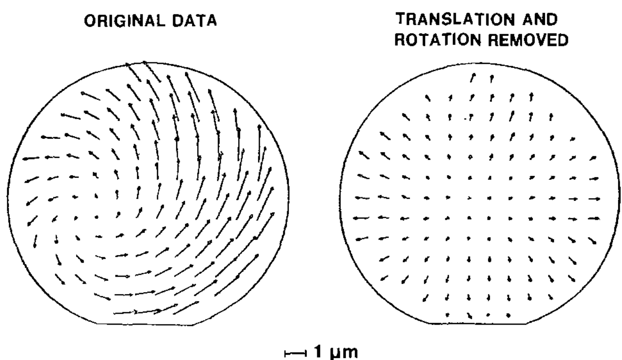

Fig. 10. Wafer maps of the tap-to-channel alignment as determined from a tap-shift test structure (10).

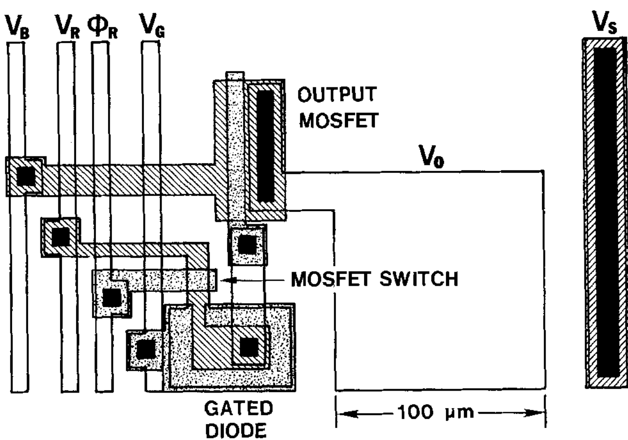

Fig. 11. Integrated gated-diode electrometer fabricated with a self-aligned polysilicon gate process (18).

point, V_O. The rate of decay of the voltage on the gated diode is indicative of the leakage currents in the diode. By measuring the voltage decay at various gate biases, V_G, the bulk lifetime and the surface recombination velocity can be determined.

The carrier-generation lifetime, τ, characteristic of the gated diode is given by the following expression

$$\tau = \beta(n_i/N)(V_R + V_b - \sqrt{V_b}\sqrt{V_R + V_b})/(dV_o/dt) \quad [5]$$

where β is the d-c voltage gain, V_b is the built-in voltage, n_i is the intrinsic carrier concentration, and N is the dopant density on the lightly doped side of the diode. The parameter V_b is determined from $V_b = (kT/q)\ln(N/n_i)$ where k is the Boltzmann constant, T is the temperature, and q is the electronic charge. The d-c voltage gain is given by $\beta = g_m/(g_m + R_L^{-1})$ where g_m is the MOSFET mutual transconductance; for the devices studied here $\beta \approx 0.8$.

The lifetime derived from the above expression is the bulk lifetime beneath the metallurgical junction when the gate of the diode accumulates the silicon beneath the gate. When the gate inverts the silicon beneath the gate, the lifetime derived from Eq. [5] is an effective lifetime composed of a weighted sum of the lifetimes beneath the junction and the gate. When the gate depletes the silicon beneath the gate, the V *vs.* time plot can be analyzed to reveal the surface recombination velocity.

The circuit shown in Fig. 11 was connected with other circuits to form the array seen in Fig. 12. This array is repeated in a test pattern that is 197 mil (5.00 mm) by 217 mil (5.51 mm). Such an array allows a detailed examination of the local variation in lifetime and surface recombination velocity using diodes that are the same size as circuit elements.

The use of the array shown in Fig. 12 is illustrated by the wafer map shown in Fig. 13. In the wafer map, every fourth symbol represents an average lifetime; all other points are interpolated. The average lifetimes were determined from the six integrated gated-diode electrometers labeled V_{01} to V_{06} in Fig. 12. A detailed profile across the wafer is included in Fig. 13 where the six lifetime values are shown individually. The total number of lifetime values represented by the wafer map is 324.

The lifetimes shown in Fig. 13 were obtained with the gate of the gated diode biased so as to invert the surface beneath the gate. Thus, an effective bulk

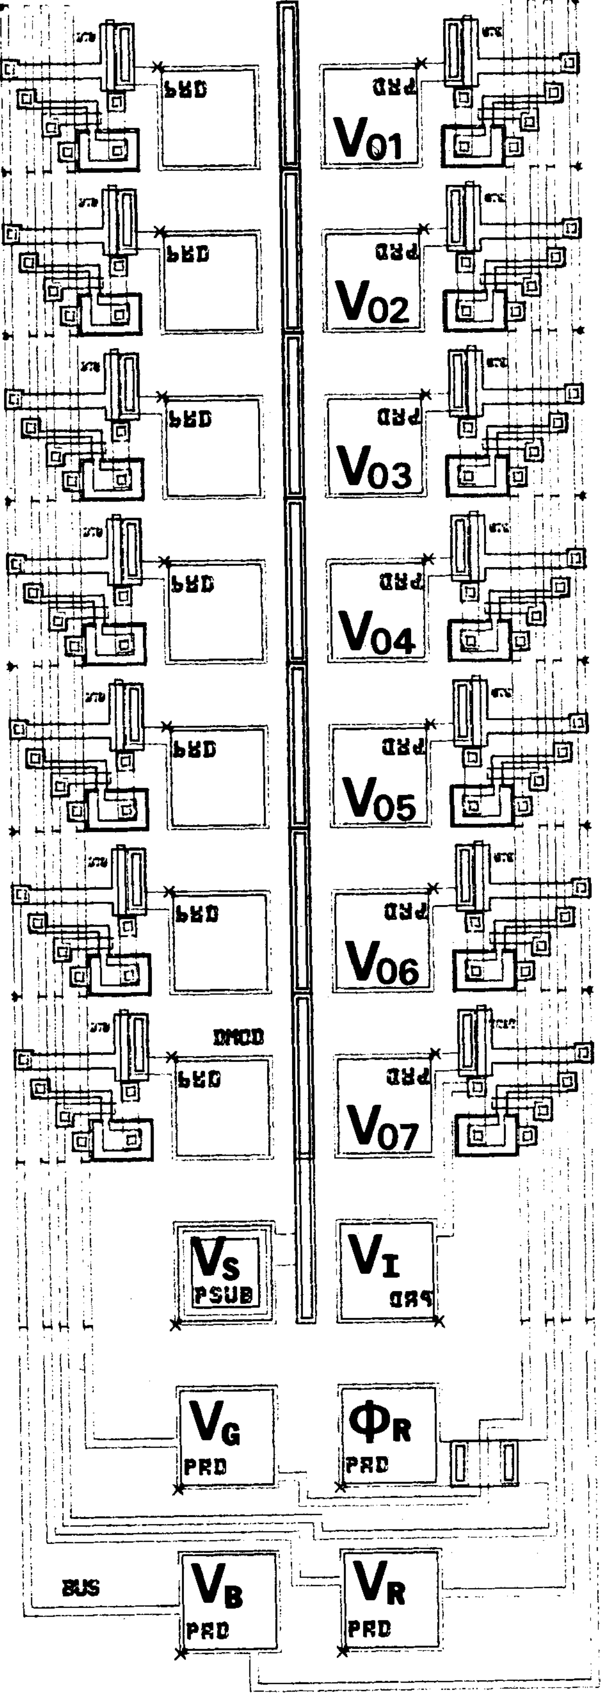

Fig. 12. Integrated gated-diode electrometer array composed of the circuit shown in Fig. 11 (18).

lifetime was determined. The lifetime values as seen in Fig. 13 were obtained on a wafer that was gettered by implanting phosphorus on the back surface of the wafer. This procedure improved the lifetime around the periphery of the wafer, but the values in the center remained close to the values observed on un-

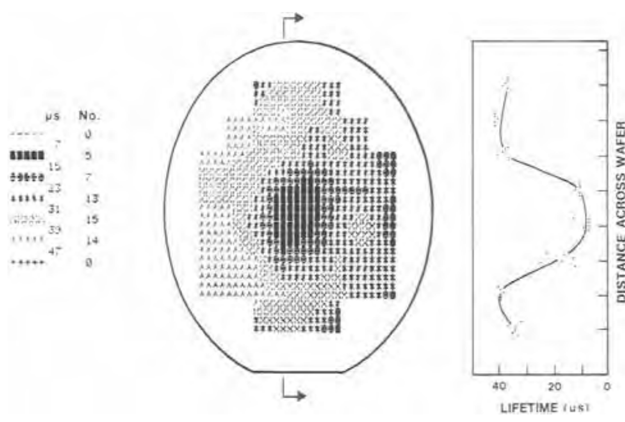

Fig. 13. Bulk lifetime wafer map and profile determined with the use of the integrated gated-diode electrometer array. The wafer map represents the average of six lifetime values measured in one array.

gettered wafers. Notice that the detailed lifetime profile shown in Fig. 13 does not show an intrachip dependence.

The importance of this test structure is found in the amount of detailed information that can be obtained concerning fundamental material parameters. As such, this array is useful in developing processes that produce long bulk lifetimes. In addition, this array is useful to the circuit designers who must allow for distributions in parameters such as memory retention time.

Conclusions

As presented here, the test structure arrays provided detailed information about integrated circuit manufacturing processes that cannot be obtained by conventional test pattern approaches. As the circuit elements become smaller and the wafers larger, the information derived from such arrays is needed to optimize processes and design rules, to evaluate machine and operator performance, and to provide circuit designers with proper design values and distributions.

The arrays discussed in this paper allow for the rapid collection of a statistically significant amount of data. Results from several test structures (MOSFET and cross bridge) illustrated that establishing the "average" value for a parameter from the measurement of only one structure in a test pattern is not sufficient when the parameter has a strong intrachip variation. Because some of the arrays (random fault) require a large amount of area for an effective analysis, they are best implemented on a separate process validation wafer.

Acknowledgment

The author wishes to thank L. W. Linholm and M. R. Doggett, NBS, for the data appearing in Fig. 5 and 6 and D. McCarthy and J. Acevedo, Westinghouse, for the data shown in Fig. 13. ABSTRACT

New data for the resistivity-dopant density relationship for boron-doped silicon have been obtained for boron densities between 10^{14} and 10^{20} cm^{-3} and temperatures of 296°K (23°C) and 300°K. For dopant densities less than 10^{18} cm^{-3}, results were calculated from resistivity and junction capacitance-voltage measurements on processed wafers. For more heavily doped material, boron densities were obtained from the nuclear track technique and from Hall effect measurements on specimens cut from bulk silicon slices. The Hall factor was assumed to be 0.8 in the calculation of hole density. The results differ significantly from the commonly used Irvin curve for boron densities greater than 10^{16} cm^{-3} with a maximum deviation of 45% at 5×10^{17} cm^{-3}. The data are in better agreement with the Wagner curve, but for boron densities less than 10^{17} cm^{-3}, the measured resistivities were always higher than those predicted by the Wagner expression. Least squares fits to analytical expressions were determined for the resistivity-dopant density product as a function of resistivity and of dopant density for temperatures of 23°C and 300°K. Similar fits were obtained for the calculated hole mobility as a function of resistivity and of hole density.

The conversion between resistivity and dopant density of silicon is widely used in the semiconductor industry. During the past decade, the most frequently used conversion curves for both n- and p-type silicon were those formulated by Caughey and Thomas (1) based on the curves of Irvin (2). Irvin's curve for p-type material included results of measurements on silicon doped with aluminum, gallium, and boron. More recently, Wagner (3) published a conversion for boron-doped silicon based on ion implantation results which differed from that of Irvin by up to 50% for boron densities in the range 10^{16}-10^{18} cm^{-3}. Because of the magnitude of this discrepancy, a comprehensive redetermination of the relationship was undertaken. This paper gives the results of measurements on boron-doped silicon with dopant densities in the range 10^{14}-10^{20} cm^{-3}.

Experimental

The test structures and experimental procedures for the electrical measurements were essentially the same as those used in a similar study on phosphorus-doped silicon (4). For dopant densities of 10^{18} cm^{-3} or less, data were obtained from test structures fabricated on silicon slices. The resistivity was measured directly on planar four-probe square array structures (5). The dopant density was determined from capacitance-voltage (*C-V*) measurements on n^+p junction diodes. These test structures and other diagnostic structures were assembled on microelectronic test patterns NBS-3 (6) and NBS-4 (7). The starting material, in both ingot and slice form, was obtained from several different suppliers and was selected for minimum resistivity gradients by mechanical four-probe measurements prior to fabrication of the test patterns by bipolar processing (8). Spreading resistance measurements were made on a number of the wafers and no fine structure was seen. The maximum resistivity gradient over the size of a test structure was judged to be less than 1% and the gradient over the distance separating resistivity and *C-V* structures was less than 2%. The resistivity data obtained from the square array structures after processing agreed to within a few percent with the mechanical four-probe measurements prior to fabrication. Various measurements were made on the wafers to verify the fabrication and to assure that leakage currents were low enough for proper operation of the test structures.

For dopant densities greater than about 10^{19} cm^{-3}, Hall effect and resistivity measurements were made on van der Pauw specimens ultrasonically cut from bulk silicon slices. The measurements were made at controlled temperatures of 296°K (23°C) and 300°K for a magnetic flux density of 0.6T (6 kG) following standard procedures (9). The hole density, p, was calculated from the expression $p = r/qR_H$ where q is the electronic charge, R_H is the Hall coefficient, and r is the Hall factor. The factor r was set equal to 0.8 as the majority of experimental results (10-13) and recent calculations (14) on moderately doped p-type material suggest a value in this range. No measurements of r for dopant densities greater than 2×10^{18} cm^{-3} appear to be available. The complex nature of the valence band in silicon is the reason why r is less than unity, even for degenerate material. In a preliminary account (15) of this work, r was taken as unity, but the probability of a different value was mentioned.

The nuclear track technique (NTT) was used to determine boron densities in the range 10^{15}-10^{20} cm^{-3}; the procedure and results have been published previously (16). The NTT determines the total boron density in contrast to the *C-V* and Hall effect techniques which measure the electrically active p-type dopant density less any compensation by n-type dopants. Considering the similar results from ingots and wafers from different suppliers covering a wide range of boron density, as well as the agreement between NTT and *C-V*/Hall effect measurements, compensation and electrically inactive boron do not appear to be significant in the material used for this work.

Results

Figure 1 is a graph of resistivity as a function of effective dopant density. Experimental points are from the junction *C-V*, Hall effect, and NTT measurements. The curves are those of Irvin (2) and Wagner (3). It is apparent even on the log-log scale that the data between 10^{16}-10^{19} cm^{-3} depart considerably from the Irvin curve.

Figure 2 is a graph of the product of resistivity and dopant density as a function of resistivity at 300°K. Since to the first approximation resistivity is inversely proportional to dopant density, a plot of the product allows deviations from this relationship to be seen, particularly for low resistivities where the product is large. To obtain the data points shown for the Hall effect, the factor r was taken as 0.8 in computing the hole density from the Hall measurements of Chapman *et al.* (17), Crowder (18), and this work as discussed in the previous section. The NTT results are seen to be in good agreement with both the Hall effect and the junction *C-V* data. The curves shown are the Irvin relationship for p-type silicon, the Wagner relationship for boron-implanted silicon, and an analytical fit to selected data. The fitting procedure is discussed in the next section.

Figure 3 is a plot of calculated hole mobility as a function of hole density at 300°K. The data from this work as well as the other plotted points were converted to hole density for calculations of the mobility using the results of Li (19) for percent ionization. The fairly recent data of Tsao and Sah (20) are significantly lower than the data of this work. This may result from the fact that back-surface contact resistance can strongly affect resistivity values obtained from the spreading resistance structure used by Tsao and Sah. The Caughey and Thomas (1) curve is a fit to the Irvin relationship with the assumption that the hole density equals the dopant density. The same assumption was used to obtain the Wagner curve; however, it was not a point-by-point determination but simply a change in one parameter of the Caughey and Thomas expression as required to fit data on boron-implanted silicon. Just as the Irvin curve is a poor fit to the resistivity-dopant density data of this work the Caughey and Thomas expression is a poor fit to the mobility data. The Wagner expression is considerably better, but there are still noticeable deviations with respect to the experimental data.

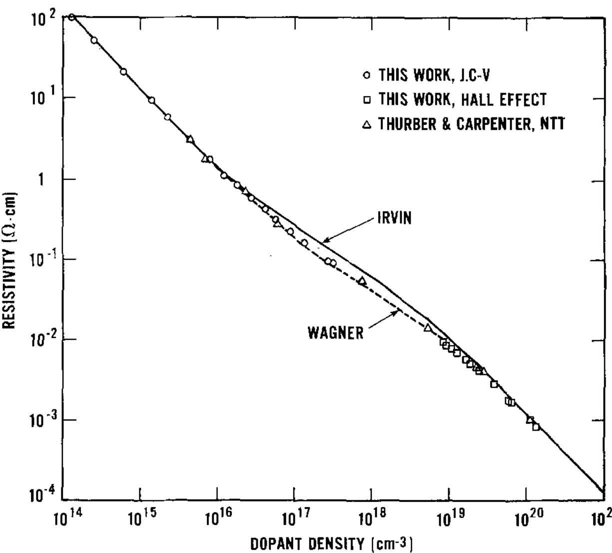

Fig. 1. Resistivity as a function of effective dopant density for p-type silicon at 300°K. Data points are from junction capacitance-voltage, Hall effect, and nuclear track technique measurements. Curves shown are the Irvin (2) relationship for p-type silicon and the Wagner (3) expression for boron-implanted silicon.

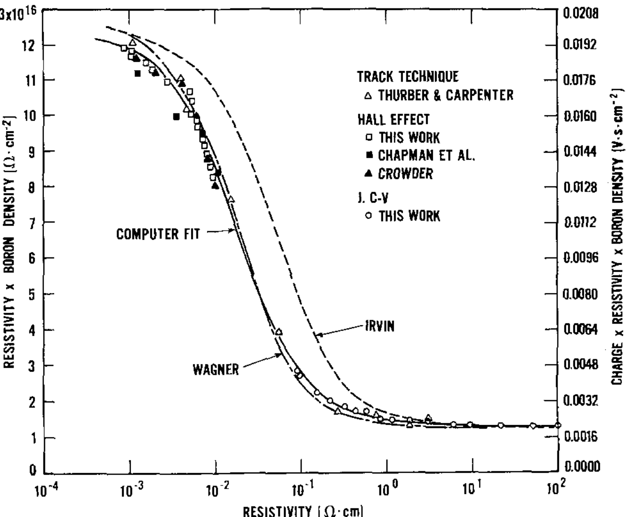

Fig. 2. Resistivity-dopant density product as a function of resistivity at 300°K for boron-doped silicon. The junction capacitance voltage and Hall effect measurements are compared with the published work of Thurber and Carpenter (16), Chapman *et al.* (17), Crowder (18), Irvin (2), and Wagner (3). The solid curve is an analytical fit to portions of this data as discussed in the text. Values of the product $q\rho N$ are on the right ordinate.

The theoretical calculation of Li (19) in Fig. 3, valid for densities less than 3×10^{18} cm^{-3}, is in excellent agreement with the *C-V* data of this work.

Computer Curve Fits

The curve fits of the data were done using the DATAPLOT language (21) for nonlinear least squares fitting. The expressions for the earlier fits to phosphorus-doped silicon (4) were in the form of quotients of two third-degree polynomials in order to fit the shape of the product and mobility curves at high phosphorus densities. However, for boron-doped silicon, the product is well behaved at very high densities such that "min-max" relationships similar to those proposed by Caughey and Thomas (1) give satisfactory fits. Modifications are necessary for the fits of mobility as will be discussed later. These relationships have the advantage that two of the parameters,

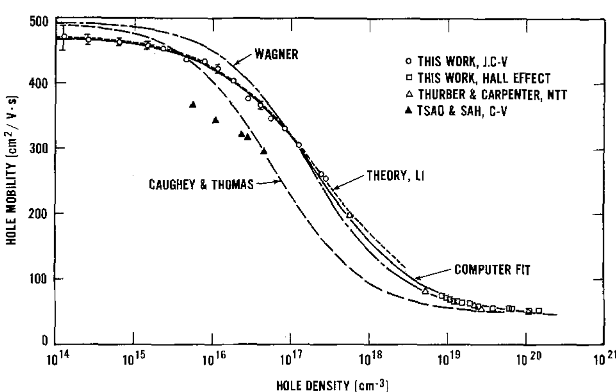

Fig. 3. Hole mobility as a function of calculated hole density for boron-doped silicon at 300°K. All data points, except those in the heavily doped range, have been corrected for incomplete ionization using the work of Li (19). The curves are from Caughey and Thomas (1), Wagner (3), Li (19), and an analytical fit to the data shown on the graph with the exception of the points of Tsao and Sah (20). The Caughey-Thomas and Wagner expressions were obtained without consideration of deionization and are plotted assuming equivalence of hole and dopant densities. This gives lower mobility in the range 10^{17}-10^{19} cm^{-3}. The error bars on the *C-V* data of this work show the standard deviation calculated from the individual mobility values for that wafer. When not shown, the error bars lie within the plotted symbol.

$(q\rho N)_{min}$ and $(q\rho N)_{max}$, have a readily identified physical significance in that they approximately equal the true value of these quantities.

The expression for the product $q\rho N$ as a function of ρ was taken as

$$q\rho N = (q\rho N)_{min} + \frac{(q\rho N)_{max} - (q\rho N)_{min}}{1 + \left(\frac{\rho}{\rho_{ref}}\right)^{\alpha}} \quad [1]$$

where q is the electronic charge, N is the boron density, ρ is the resistivity, $(q\rho N)_{min}$ and $(q\rho N)_{max}$ are the asymptotic minimum and maximum values of the product, ρ_{ref} is a reference value corresponding to the resistivity for which the derivative of the product is a maximum, and α is a measure of the slope of the curve near the reference value. The data used for the fit were the junction C-V and Hall effect results of this work, and the NTT results for boron densities greater than 5×10^{17} cm^{-3}. The NTT results are omitted for lower values of dopant density because the NTT data, while in general agreement with the C-V results, show somewhat more scatter. For high boron densities, the NTT results may be better than those from the Hall effect because of the need to assume a value for the Hall factor. This same set of 300°K data, and its counterpart at 23°C, was used for all of the curve fits. The resistivity values of the 39 fitted data points spanned the range 0.00085-100 Ω-cm with corresponding dopant densities between 1.4×10^{20} and 1.3×10^{14} cm^{-3}. The least squares curve at 300°K is shown in Fig. 2 for comparison with experimental data and other curves. All four parameters as determined by the fit are given in Table I for 23°C and 300°K. The approximate standard deviation is given for each parameter in its own units, and the residual standard deviation (RSD) for the fit is listed in units of $q\rho N$. The RSD is the square root of the quotient of the sum of the squared residuals divided by the number of degrees of freedom.

The expression for the product $q\rho N$ as a function of dopant density has the same form as Eq. [1] except for a negative value of the exponent because of the inverse relationship between ρ and N

$$q\rho N = (q\rho N)_{min} + \frac{(q\rho N)_{max} - (q\rho N)_{min}}{1 + \left(\frac{N}{N_{ref}}\right)^{\alpha}} \quad [2]$$

The fit was made to the same set of data. The four parameters are listed in Table II for 23°C and 300°K. The curve for 300°K and the experimental data used to obtain it are shown in Fig. 4.

Hole mobilities were calculated from resistivity and hole density values. Except in the heavily doped range,

where hole density is assumed to equal dopant density, hole densities were obtained from dopant densities using the percent ionization calculations of Li (19). A suitable expression for the hole mobility, μ_h, as a function of hole density, p, was found to be

$$\mu_h = A \exp(-p_c/p) + \frac{\mu_{max}}{1 + \left(\frac{p}{p_{ref}}\right)^{\alpha}} \quad [3]$$

This form gave a significantly better fit than the simpler form of the type used for fitting the product curves. The effect of the exponential factor in the first term is to increase the mobility in the region of the curve where the dopant and hole densities deviate significantly from each other. The hole mobility approaches the constant value A for very large hole densities. The five parameters, determined by the fit to the same 39 data points, are listed in Table III for 23°C and 300°K. The curve for 300°K is shown in Fig. 3 for comparison with experimental data and other curves.

The form for the hole mobility as a function of resistivity was taken as

$$\mu_h = A \exp(-\rho/\rho_c) + \frac{\mu_{max}}{1 + \left(\frac{\rho}{\rho_{ref}}\right)^{\alpha}} \quad [4]$$

It was also found that the simple "min-max" form did not fit the mobility *vs.* resistivity data well, particularly in the low resistivity range. The inclusion of the exponential in the first term improved the fit considerably and its effect is similar to that of the exponential in Eq. [3]. In this expression, the mobility is dominated by the first term at low resistivities and by the second term at high resistivities. Again, the fit was made to the same set of data, and the parameters are listed in Table IV for 23°C and 300°K. The curve for 300°K and the experimental data used for the fit are shown in Fig. 5. The curve fits the shape of the experimental data very well at low resistivities so that extrapolation of Eq. [4] at the low

p_{ref} (cm⁻³)	$2.11 \times 10^{17} \pm 0.09 \times 10^{17}$	$2.23 \times 10^{17} \pm 0.10 \times 10^{17}$
α	0.718 ± 0.013	0.719 ± 0.013
RSD (cm²/V sec)	3.18	3.07

Table IV. Parameters and residual standard deviation (RSD) for the fit of μ_h vs. ρ using Eq. [4]

Temperature	23°C	300°K
A (cm²/V sec)	52.4 ± 3.8	51.6 ± 3.7
ρ_c (Ω · cm)	0.00409 ± 0.00077	0.00406 ± 0.00077
μ_{max} (cm²/V sec)	482.8 ± 2.4	467.3 ± 2.4
ρ_{ref} (Ω · cm)	0.0825 ± 0.0020	0.0794 ± 0.0019
α	−0.811 ± 0.018	−0.808 ± 0.019
RSD (cm²/V sec)	4.89	4.78

resistivity end should give reasonable values. Thus, A can be considered to be approximately equal to the minimum value of the mobility. The mobility *vs.* hole density fit is not as good at the low mobility end, as it is slightly below the data at $p = 10^{20}$ cm^{-3} and goes to a lower asymptotic value than is the case for Eq. [4]. Consequently, an extrapolation of Eq. [3] at the low mobility end is less likely to be correct.

In comparing the product fits as a function of resistivity with those as a function of dopant density, it is evident that minimum and maximum values which should be correspondingly equal are somewhat different. This is, of course, a consequence of the independent fits where no parameters are fixed. The $(q\rho N)_{min}$ values differ by 2% and the fits differ by this same percentage at $N = 10^{14}$ cm^{-3}. The $(q\rho N)_{max}$ values differ by 4%; however, these are asymptotic values, and at the upper limit of the experimental data ($N \approx 10^{20}$ cm^{-3}) there is still considerable curvature. The difference between the fits in this region is less than 1%. The product fits are self-consistent within 3% for all dopant densities (and corresponding resistivities) in the range 10^{14}-10^{20} cm^{-3}. That is, when the product $q\rho N$ is calculated for a given dopant density with Eq. [2], a resistivity is derived which can be used in the $q\rho N$ *vs.* ρ expression (Eq. [1]) to again calculate the product. The latter product will be within 3% of the former.

The μ_{max} values for the mobility fits as a function of hole density differ by about 0.7% from the μ_{max} values for the fits as a function of resistivity. The mobility fits are self-consistent within 2% for all hole densities (and corresponding resistivities) in the range 10^{14}-5×10^{17} cm^{-3}. In the 10^{18} cm^{-3} range, there are differences of up to 8%. The self-consistency improves in the low 10^{19} cm^{-3} range but increases again to 6% at 10^{20} cm^{-3} as the fits depart for very heavy doping.

Conclusions

The resistivity-dopant density results obtained from this work differ significantly from the commonly used Irvin curve for boron densities greater than 10^{16} cm^{-3} with a maximum deviation of 45% at 5×10^{17} cm^{-3}. Hole mobility values, calculated from this work with

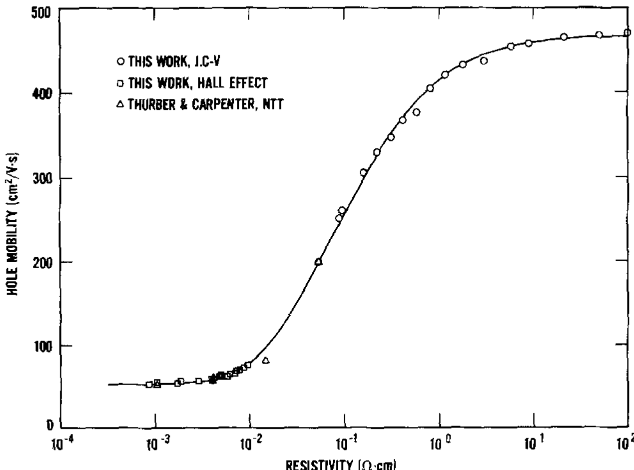

Fig. 5. Graph of hole mobility as a function of resistivity for 300°K. The curve is an analytical fit to the data points shown.

correction for percent ionization of the dopant atoms, are much larger than similar experimental data of Tsao and Sah, but are in good agreement with the theoretical calculations of Li. Analytical expressions, convenient for engineering calculations, were fitted to the resistivity-dopant density data as a function of resistivity and dopant density for temperatures of 23°C and 300°K. Similar analytical expressions were fitted to the calculated hole mobility as a function of resistivity and hole density. The expression for hole mobility *vs.* hole density is in reasonable agreement with Wagner's result. The maximum discrepancy occurs in the low 10^{18} cm^{-3} range where the Wagner mobility is 10% lower because deionization effects were not included. In the lightly doped range, the mobility from this work is 5% lower than that of Wagner.

Vapor Phase Epitaxial Growth of ZnSe Films Using Metallic Zn and Metallic Se

Tetsuo Muranoi and Mitsuo Furukoshi
Department of Electronics, Faculty of Engineering, Ibaraki University, Hitachi City, 316 Japan

ABSTRACT

Single crystal layers of ZnSe have been epitaxially grown on GaAs and sapphire substrates using metallic Zn and Se. A nozzle for the Se flow was placed at about 1 cm in front of the substrate, and this arrangement resulted in much less Se consumption than in the case when the nozzle was further separated from the substrate. The epitaxial conditions were investigated as a function of the source and substrate temperatures. When the substrate temperature and one of the source temperatures were fixed, the growth rate increased with the other source temperature and then saturated. Below the saturation point, the growth rate is proportional to the flow rate and the vapor pressure of each source material. Dependence on substrate temperature of growth rate is shown to be surface-controlled phenomenon below 770°C and is one of mass transfer controlled phenomena above 770°C. The epitaxial growth on GaAs substrates occurred in the substrate temperature range of 650°-880°C with a growth rate ranging from 1 to 30 μm/hr. The resistivity of the as-grown layer was too high (10^6 Ω · cm) to be useful for LED application.

ZnSe is a promising material for various optoelectronic devices, such as light emitting diodes in the blue region of the spectrum. Several methods for the vapor phase epitaxy of ZnSe film have been reported. As the source material in an open tube method, ZnSe powder (1-3), Zn-H_2Se (4), and organometallic zinc-H_2Se (5) have been used previously. When ZnSe powder is used, HCl is sometimes added to the reaction system in order to transport material (1, 2), but etching of the substrate can be a problem. Without the use of HCl (3), however, the growth rate is relatively low. Organometallic zinc-H_2Se system (5) requires only one hot temperature zone and allows a good controllability of the source material flow. But these materials are very toxic or are difficult to handle. Yim *et al.* (4) has reported on Zn-H_2Se that the single crystal epitaxy of ZnSe has been achieved with 10^{-5} mole/min Zn and 2×10^{-6} mole/min H_2Se.

This paper describes the vapor phase epitaxial condition of ZnSe film using metallic Zn and Se as the source materials. This method has an advantage that one could investigate the growth conditions of ZnSe epitaxial films by applying a simple reaction mechanism between elemental Zn and Se, without toxic and difficult materials to handle, under various ratios of the source materials by varying only the source temperature and carrier gas flow rates.

Experimental

Film deposition was investigated mainly by the growth rate with 5° angle lapping and the deposition time, which was 30 min in most cases. The film thickness was proportional to the time within the experimental error.

The nominal purity of Zn was six-nine (supplied by High Purity Chemical Laboratory) and that of Se was five-nine (supplied by Mitsui Mining and Smelting Company, Limited). (100)GaAs was mainly used as the substrates. (111)B-GaAs and $(1\bar{1}02)$-sapphire were also used. Mirror-smooth etched wafers of GaAs and sapphire were supplied by Hitachi Electric Cable Company, Limited and Kyoto Ceramic Company, Limited, respectively.

A reflection electron microscope was used to determine single crystallinity. Specimens were cleaved and chemically etched to investigate the interface between ZnSe and the substrate.

Key words: heteroepitaxy, open tube method, growth rate, nozzle for Se.

Figure 1 is a schematic diagram of the experimental apparatus and typical temperature profiles used. A quartz reaction tube, 150 cm long and 27 mm ID, was used. Several substrates were placed horizontally on a quartz boat in the reaction tube and the temperature was maintained by an electric furnace 72 cm long having five zones. The reaction was completed by pulling the furnace followed by air-cooling with a blower. Zn and Se were held in quartz vessels as shown in Fig. 1. The end of the Zn and Se vessels and the top of the substrate boat were set at the desired temperatures. A nozzle of 6 mm ID quartz tube for the Se flow was placed at about 1 cm in front of the substrates. With this arrangement, the Se vapor was kept from reacting with Zn until it reached the close proximity of the substrate, and therefore the amount of Se consumed for any given run was only one-tenth or one-twentieth of the amount required for the case of 10 cm separation between the nozzle and the substrate. Zn and Se flow rates were obtained from the source consumption, which was measured by weighing the source vessels before and after the deposition, and was determined with a cross-sectional area at the Se nozzle. The carrier gas over molten Zn was a mixture of Ar (300 cm^3/min) and H_2 (100 cm^3/min), and the carrier gas over molten Se was also Ar (100 cm^3/min) and H_2 (10 cm^3/min). It is important to mention that H_2 was used as a carrier gas since without H_2 a white deposit (presumably ZnO) formed near the Zn boat even though Ar used was a 6-nine purity and that it was passed over DEOXO and zeolite gas dryer.

Results and Discussion

Figure 2 shows some examples of the microstructure and the reflection electron diffraction patterns of the films. It can be seen from the net patterns that (100), (111), and (110) oriented ZnSe grew on (100) GaAs, (111) B-GaAs, and $(1\bar{1}02)$ sapphire, respectively.

Figure 3 shows the growth rate at $T_{sub} = 800°C$ as a function of Zn temperature, Zn flow rate, and published equilibrium vapor pressure (6). Figure 4 gives similar properties in the case of Se (7). Epitaxial growth was achieved below the deposition rate of 30 μm/hr. For any given T_{Se} in Fig. 3, the deposition

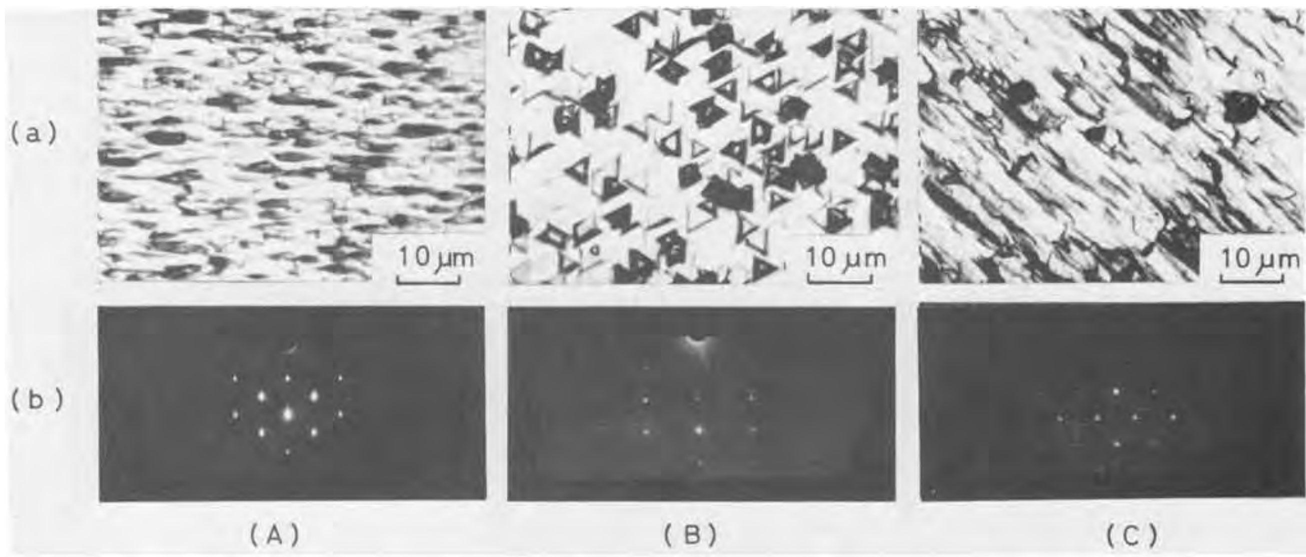

Fig. 2 (a) Photomicrographs and (b) reflection electron diffraction patterns of ZnSe layers on (A) (100) GaAs, (B) (111) B-GaAs, and (C) (1$\bar{1}$02) sapphire. (T_{sub}, T_{Zn}, T_{Se}) = (700°C, 558°C, 342°C) for (100) GaAs, (800°C, 593°C, 342°C) for (111) B-GaAs, and (800°C, 558°C, 380°C) for sapphire.

rate increased with T_{Zn} and then saturated. The saturation temperature became higher with higher T_{Se}. The film grew in an excess Zn in the saturation region and grew in an excess Se below the saturation point since the flow rates of both source materials were nearly the same at the saturation point. For a given T_{Zn}, T_{Zn} = 593°C shown in Fig. 4, the deposition rate showed a similar tendency to saturate. The equilibrium vapor pressure, the source material flow rate, and the deposition rate below saturation had the same temperature dependence. This showed that the deposition rate below saturation is proportional to the source material flow rate and the vapor pressure.

Epitaxial growth commenced within 5 cm of the Se nozzle. However, for properly adjusted flow rates, epitaxial growth could be achieved for substrates 10 cm from the nozzle. For the 10 cm separation, T_{Se} had to be increased to compensate for material deposited on the reaction tube prior to the substrate. For example, when a growth condition was set at (T_{sub}, T_{Se}) = (800°C, 416°C), the epitaxial growth was realized at T_{Zn} in the range 540°-630°C as shown in Fig. 3.

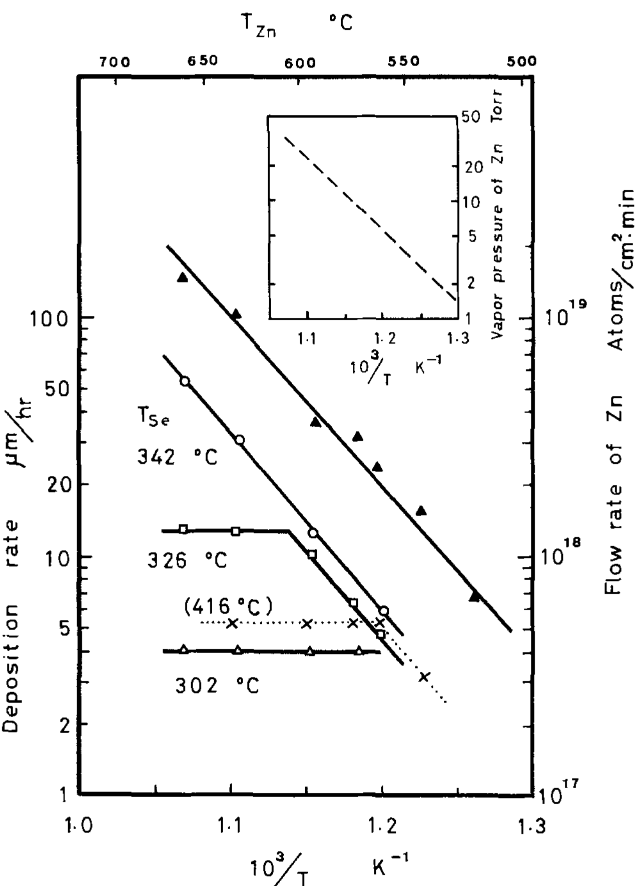

Fig. 3. Deposition rate at T_{sub} = 800°C (open symbols and crosses), flow rate of Zn (closed symbols), and equilibrium vapor pressure of Zn (broken line) as a function of Zn temperature. Cross symbols (×) denote deposition rates at T_{Se} = 416°C when the substrate and the nozzle were placed 10 cm apart.

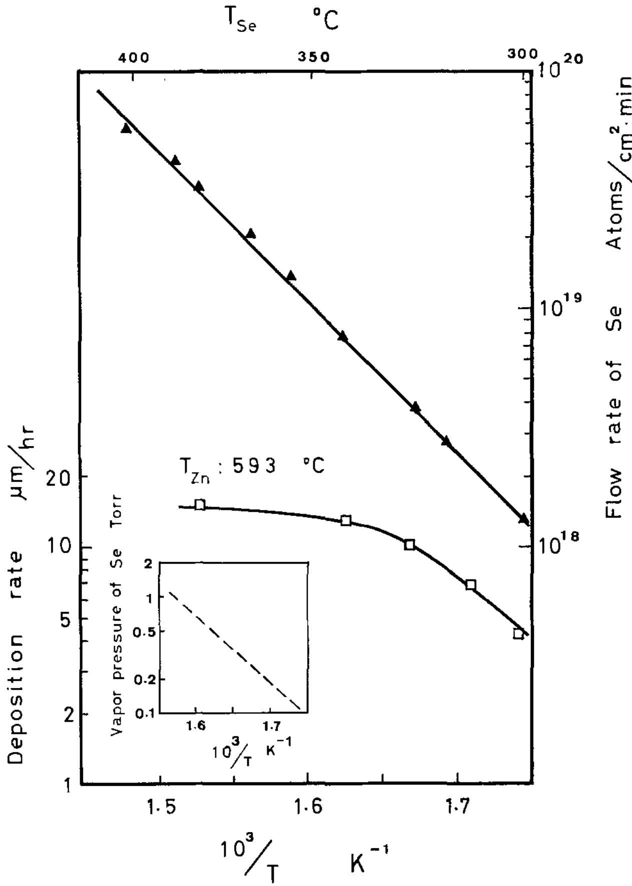

Fig. 4. Deposition rate at T_{sub} = 800°C (open symbols), flow rate of Se (closed symbols), and equilibrium vapor pressure of Se (broken line) as a function of Se temperature.

The epitaxy on GaAs took place in a relatively wide range of T_{sub}: 650°-880°C, T_{Zn}: 540°-660°C, and T_{Se}: 300°-380°C, while on sapphire it was only one case at (T_{sub}, T_{Zn}, T_{Se}) = (800°C, 558°C, 380°C) that epitaxy occurred over the entire substrate surface although the epitaxy itself was partly observed above T_{sub} = 650°C. This can be understood because of the difference in the crystal structure and the lattice parameter between ZnSe and sapphire.

Figure 5 shows the growth rate as a function of T_{sub} for (T_{Zn}, T_{Se}) = (558°C, 342°C) and (558°C, 300°C). For T_{sub} below 770°C, the growth rate increased with T_{sub} and was the same for T_{Se} = 342°C and 300°C. Above 770°C, the growth rate was constant for T_{Se} = 342°C but decreased for T_{Se} = 300°C due to reevaporation. For T_{sub} = 940°C, film growth was not observed for T_{Se} = 342°C. Such temperature dependences of deposition rates are observed for heterogeneous reactions (8). Such surface-controlled phenomena are expected to be temperature dependent and flow rate independent. The region below 770°C is seen to be temperature dependent but flow rate independent. Above 770°C, the growth rate is seen to be mass transfer controlled.

The data of Yim *et al.* (4) are plotted with the present results in Fig. 5. These slopes are almost the same although the experimental conditions were different. This indicates the same reaction mechanism in both cases. The roles of H_2Se and Se molecules in the reaction are unclear. H_2Se was produced by a reaction between Se molecules and H_2. This is shown in Fig. 6 which shows the Se consumption in 30 min at T_{Se} = 342°C *vs.* H_2 content when the total gas flow rate over the molten Se was fixed at 110 cm³/min. H_2Se was formed because the Se consumption increased with H_2 content.

Yim *et al.* reported (4) that Ga_2Se_3 resulted from excess H_2Se (10^{-5} mole/min) on GaAs and that the Zn vapor concentration had little effect on film formation for the Zn concentration studied (10^{-6}-10^{-5} mole/min). Here epitaxial growth of ZnSe could be obtained wtih excess Se even at 4 × 10^{-5} mole/min Se flow rate. The limitation here on epitaxial growth

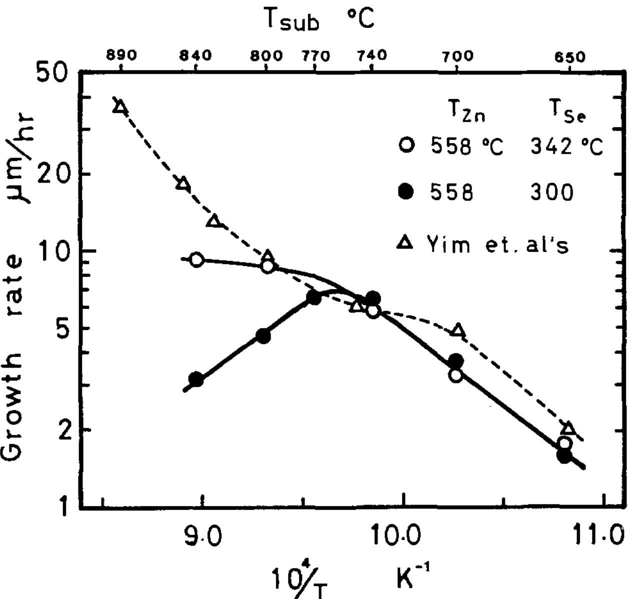

Fig. 5. Growth rate of ZnSe film on (100) GaAs vs. reciprocal of substrate temperature. Open circles (○) and closed circles (●) denote (T_{Zn}, T_{Se}) = (558°C, 342°C) and (558°C, 300°C), respectively. The data of Yim et al. on Zn-H_2Se (4) are plotted with triangles (△).

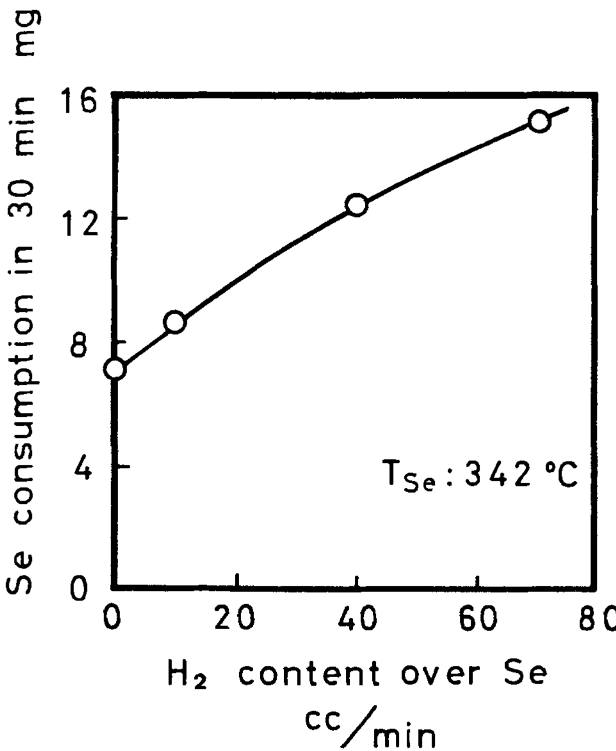

Fig. 6. Se consumption in 30 min for T_{Se} = 342°C vs. the H_2 content of the selenium Ar + H_2 carrier gas. The total Ar + H_2 flow was 110 cm^3/min.

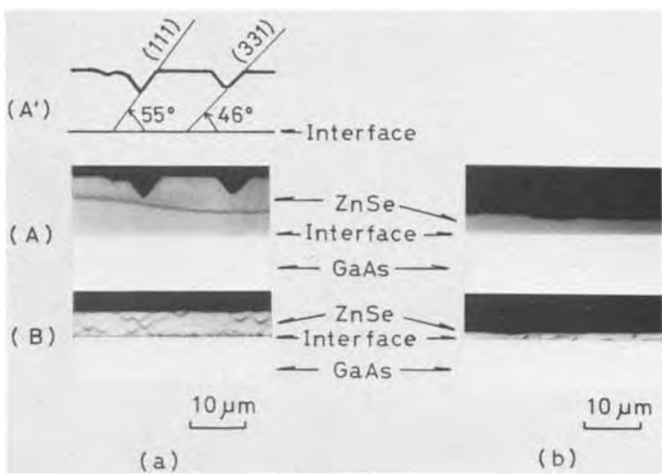

Fig. 7. Interface of ZnSe layer and GaAs substrate. (A) As-cleaved and (B) chemically etched surfaces; (a) (100) GaAs and (b) (111) B-GaAs.

was the deposition rate itself. It is difficult generally to grow epitaxially at high deposition rates.

Specimens grown on (100) GaAs and (111) B-GaAs were cleaved and chemically etched in 40% NaOH aqueous solution at 75°-80°C for a few minutes to investigate the ZnSe-GaAs interfaces. The dark gray part is ZnSe, the white GaAs. The as-cleaved surface shows a clear and smooth interface. The etched surface shows that the region within 1 or 2 µm of the interface was strongly etched. This indicates that stacking faults occurred. The epitaxy interface of either (100) GaAs or (111) B-GaAs showed much the same etched appearance. However, the as-deposited film surfaces were different. Films grown on (111) GaAs were almost flat. Films grown on (100) GaAs sometimes had a hill-and-valley structure, especially for film thickness greater than 10 µm; also, the (111) and (331) planes appeared on bevels judging from the angles (55° and 46°) between the bevel and the interface as shown in Fig. 7(a)-(A') since a cubic structure makes angles of 54.7° between (100)- and (111)-planes and 46.5° between (100)- and (331)-planes.

The film resistivity measured with a sandwich structure on p-type GaAs was about 10^6 Ω · cm, a value too high to be useful for a light emitting diode. Impurity doping must be investigated to lower the resistivity.

Conclusions

Single crystal layers of ZnSe have been epitaxially grown on GaAs and sapphire substrates using metallic Zn and metallic Se. The nozzle for the Se flow was about 1 cm from the substrate. The Se consumption was only one-tenth or one-twentieth of the case when the separation between the nozzle and the substrate was 10 cm. Epitaxial conditions were investigated as a function of the source and substrate temperatures. (100), (111), and (110) oriented ZnSe grew on (100) GaAs, (111) B-GaAs, and (1$\bar{1}$02) sapphire, respectively. When T_{sub} and one of the source temperatures were fixed, the growth rate increased with the other source temperature and then saturated. Below the saturation point, the growth rate is proportional to the flow rate and the vapor pressure of each source material. For GaAs, epitaxial growth occurred for T_{sub} in the range 650°-880°C (1-30 µm/hr in Fig. 3 and 5). Temperature dependence of the growth rate is a surface-controlled phenomenon below 770°C and is mass transfer controlled above 770°C. The interface region within 1 or 2 µm was strongly etched, indicating that stacking faults occurred at the interface. The resistivity was too high (10^6 Ω · cm) for LED application.

Acknowledgments

The authors are grateful to their former student Mr. H. Yoshida for assistance with the experimental work, and to Mr. M. Kobiyama for his kindness in teaching them how to operate the electron microscope.

Chemical Vapor Deposition of Tin on Iron or Carburized Iron

S. Audisio

Laboratoire de Physicochimie Industrielle,
Institut National des Sciences Appliquées de Lyon, 69621 Villeurbanne Cedex, France

ABSTRACT

An experimental investigation of the chemical vapor deposition of tin on iron and carburized iron substrates is presented, using stannous chloride vapor as the source of tin, in an inert or reducing atmosphere. At temperatures between 450° and 750°C, the mechanism of vapor coating is the displacement reaction in an inert or reducing atmosphere, but in a reducing atmosphere, reduction reactions also occur. The coating consists of iron-tin compounds or iron-tin carbides, the structure of which is obtained by diffusion and thus influenced by the time and temperature of deposition. The relations between nuclei formed at the beginning of the deposition and the substrate show that these nuclei may have an epitaxial growth. Epitaxial relationships between the FeSn nuclei and the iron substrate are given.

The surface of many materials must be protected from hostile environments of their applications. For many situations protective coatings are applied by hot dipping, electrodeposition, metal spraying, evaporation, sputtering or chemical vapor deposition (CVD) to minimize effects such as wear, erosion, corrosion, or high temperature oxidation. CVD coatings are widely used in the technologies of aeronautics, nuclear engineering, solid-state electronics, and refractory protective coatings.

Various aspects of CVD of tin (stannizing) have been clarified by previous investigators (1, 2) on copper, brass, and bronze, but a complete analysis has not yet been carried out for a study of tin deposits on iron and carburized iron.

The first purpose of this study is to develop a fuller understanding of the CVD of tin on such materials. This includes study of the chemical reactions which occur, and correlation of the rates of coating formation and the coating structures with the factors controlling the kinetics (temperature, duration). The second purpose is to establish the crystallographic relations between the tin-iron compounds and the substrates.

Chemical Reactions-Kinetics, Coating Composition, and Morphology

CVD apparatus and process.—The CVD of tin was obtained by the pack cementation method. Pack stannizing was carried out in cylindrical iron retorts closed with a slip-fitted iron cap and thus was not tightly sealed. The pack consisted of powder mixtures of 99.93% pure tin, various activators (NH_4Cl, $FeCl_2$, or $SnCl_2$), and MgO as inert filler. Prior to use, the filled retort was evacuated to less than 0.01 Torr (1.334 Pa). It was then backfilled by argon and placed quickly in the heated reactor chamber. During the coating operation a flow of hydrogen or argon was maintained. Coating temperatures ranged from 450°-750°C and duration from 1-10 hr. Substrates used in this study included pure iron (iron decarburized under moist hydrogen for 150 hr at 1050°C) or carburized iron (CH_4/H_2 gas mixture at 1050°C for 4 hr).

The iron or carburized iron samples were either small plates (20 × 10 × 2 mm) or wires (diameter 0.4 mm, length 30 mm). Surface preparation consisted of light abrasion followed by chemical polishing. Three or four specimens were placed in the center of the pack. After holding at the temperature for the desired time interval, the retort was swiftly removed from the furnace and allowed to cool to room temperature in a hydrogen atmosphere. After cooling, the weight gains (Δm) of the samples were measured. Some samples were prepared for metallographic examination, hardness test, chemical and x-ray analysis. The samples were covered by electrodeposited nickel and then were cross-sectioned and polished with diamond paste using standard metallographic techniques. When the thickness of the coating is very small, particularly on the carburized iron, a special microscope technique was used to facilitate the investigation. Every sample was ground at an angle of 5° to the surface. In this way the surface layer was effectively enlarged by a factor of about 10. Microhardness tests were conducted on the coating using a Vickers indenter with a 10g load. X-ray diffraction data were obtained from the wire samples (Debye-Scherrer method) or from the flat samples (diffractometer method) with x-ray apparatus using Fe-filtered CoK_α radiation.

Key words: mechanism, coating, epitaxial growth, intermetallic.

Results and discussion.—The chemical reactions were studied in argon-$SnCl_2$-$FeCl_2$ and hydrogen-$SnCl_2$-$FeCl_2$ systems. In both cases the same temperature (600°C) and the duration of treatment (4 hr) were chosen. The quantity of deposited tin (m_d) was chemically analyzed after the complete dissolution of the sample (iodometric method). From the weight increase, Δm, and the quantity m_d, it was possible to evaluate the ratio n_{Sn}/n_{Fe} where n_{Sn} and n_{Fe} are the number of atoms of deposited tin and the number of atoms of iron which left the sample

$m_d = n_{Sn} \cdot M_{Sn}$ M_{Sn} = relative atomic mass of tin
$\Delta m = m_d - n_{Fe} \cdot M_{Fe}$ M_{Fe} = relative atomic mass of iron

$$\frac{n_{Sn}}{n_{Fe}} = \frac{m_d}{m_d - \Delta m} \cdot \frac{M_{Fe}}{M_{Sn}} \quad [1]$$

The following reactions were believed to occur when $SnCl_2$ was used:

a. Thermal decomposition reaction

$$SnCl_{2(g)} \rightarrow Sn_{(s)} + Cl_{2(g)} \quad [2]$$

b. Displacement or exchange reaction

$$SnCl_{2(g)} + Fe_{(s)} \rightarrow Sn_{(s)} + FeCl_{2(g)} \quad [3]$$

c. Reduction reaction

$$SnCl_{2(g)} + H_{2(g)} \rightarrow Sn_{(s)} + 2HCl \quad [4]$$

In a reducing atmosphere, the following reaction can occur

$$FeCl_{2(g)} + H_{2(g)} \rightarrow Fe_{(s)} + 2HCl \quad [5]$$

In the temperature range 450°-750°C, reaction a is strongly endothermic, so it is not considered likely.

When the displacement reaction occurs, the weight increase of the sample should be somewhat less than the weight of the tin deposited and the n_{Sn}/n_{Fe} ratio ought to be equal to 1. Then, from Eq. [1] we can calculate Δm

$$\Delta m = m_d\left(1 - \frac{M_{Fe}}{M_{Sn}}\right) = 0.53 m_d$$

In the case of a reduction reaction, the weight increase of the sample should be equal to the weight of deposited tin. There is no departure of iron ($n_{Fe} = 0$)

$$\Delta m = m_d$$

Table I shows the weight increase of samples, the amount of tin deposited, and the n_{Sn}/n_{Fe} ratio, in inert (argon) and reducing (hydrogen) atmospheres. In argon-$SnCl_2$-$FeCl_2$ system the n_{Sn}/n_{Fe} ratio is equal to 1, and the chemical reaction is mainly the displacement reaction. In hydrogen-$SnCl_2$-$FeCl_2$, the n_{Sn}/n_{Fe} ratio is greater than 2. The displacement and the reduction reactions occur simultaneously.

Kinetics, coating composition, and morphology.—The kinetics and coating composition of stannized iron or stannized carburized iron were studied in a hydrogen-$SnCl_2$-$FeCl_2$ system. The high temperature treatment (>450°C) allows diffusion of the deposited atoms to take place. Consequently, the coating consists of different tin-iron compounds or tin-iron carbides depending on the operating parameters, *i.e.*, temperature duration.

Tables II and III list the compounds formed when stannizing temperature is in the range 450°-650°C. The metallographic cross sections of the coated iron are shown in Fig. 1 and 2. The coating appears to be uniform in thickness and free of cracks. Over this range of temperature, it consists of one layer, although the x-ray patterns show the presence of several compounds corresponding to the phase diagram of the tin-iron system, Fig. 3. In the accompanying micrographs of stannized iron coatings, electrolytic nickel deposited on the coating is shown at the top of each picture and the base metal is shown at the bottom.

Table I. Weight increase of samples, amount of tin deposited, and n_{Sn}/n_{Fe} ratio for inert or reducing atmospheres

Atmosphere	Δm (mg)	m_d (mg)	n_{Sn}/n_{Fe}
Reducing (H_2)	16.9	22.03	2.04
Inert (argon)	12.1	19.41	1.23

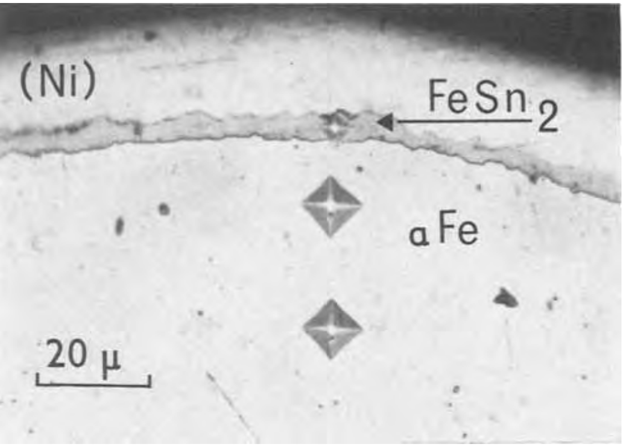

Fig. 1. Metallographic cross section of stannized iron. Treatment 6 hr at 495°C.

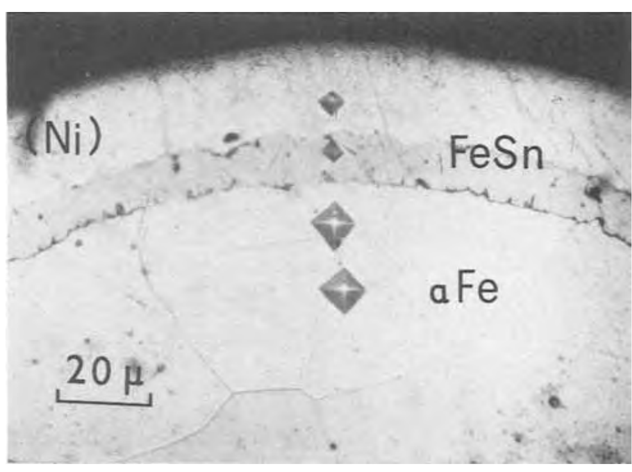

Fig. 2. Metallographic cross section of stannized iron. Treatment 8 hr at 580°C.

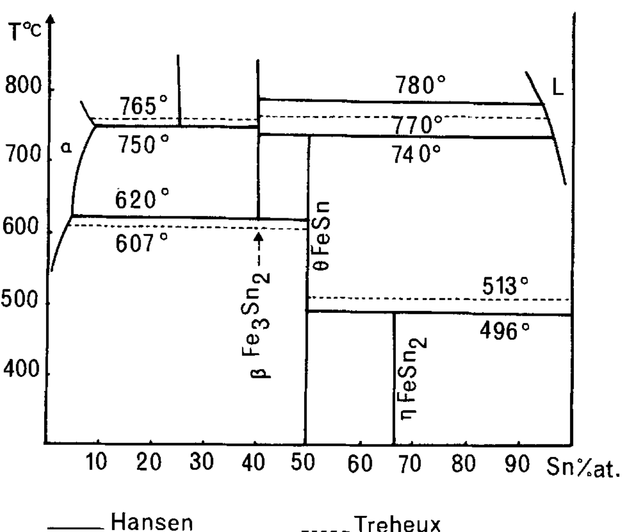

Fig. 3. Phase diagram of the iron-tin system

For carburized iron, the coating consisted mainly of two layers due to the tin-iron compounds and to the tin-iron carbides. These layers are shown in the metallographic section of Fig. 4. The coating formed at 580°C for 10 hr consists of the FeSn compound at the surface and the tin-iron carbide Fe_3SnC_x next to the carburized iron base.

Figure 5 shows the influence of temperature and duration of treatment on the thickness of tin-iron deposits. The thickness (e) of the $FeSn_2$ compound

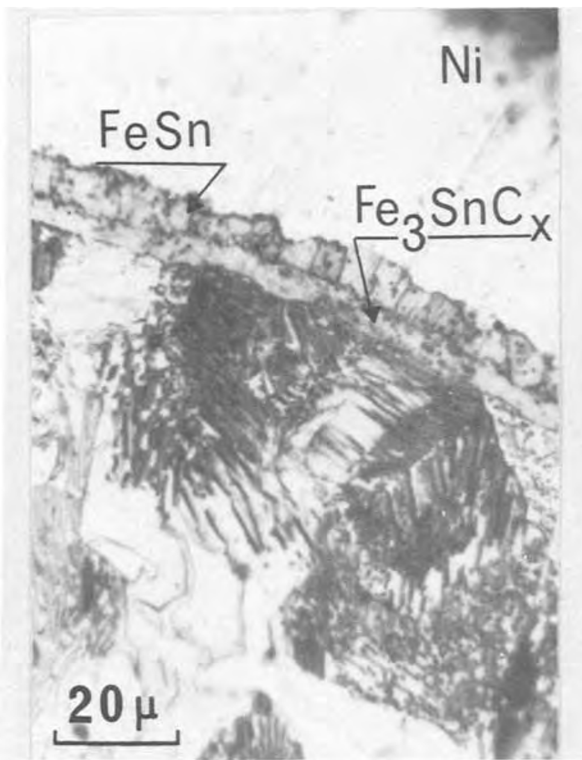

Fig. 4. Metallic cross section of stannized carburized iron. Treatment 10 hr at 580°C.

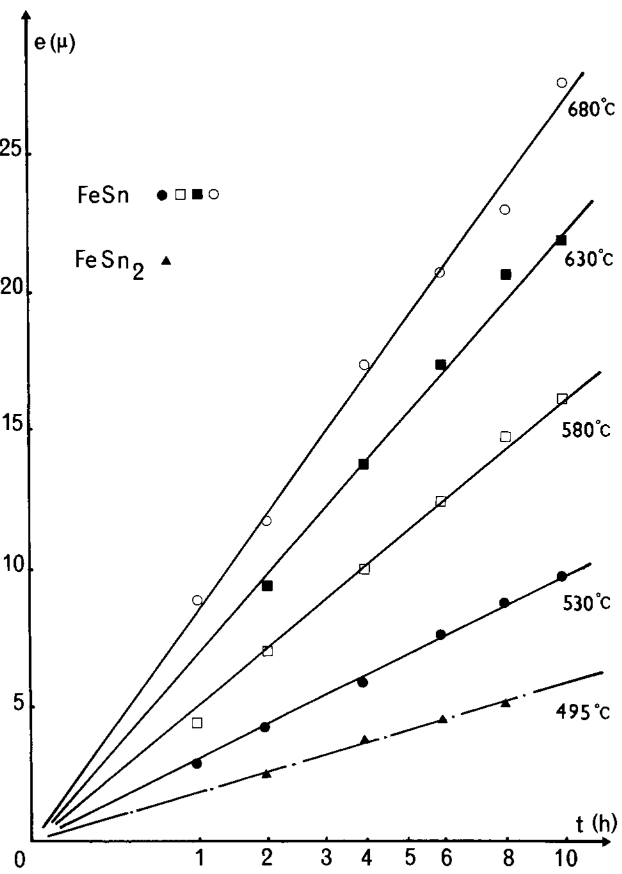

Fig. 5. Effect of temperature and duration of treatment on deposit thickness.

at 495°C and of the FeSn compound between 530° and 680°C *vs.* the coating time (t) follows the general law $e = A\sqrt{t}$. When varying only the temperature (treatment time 4 hr), the growth of the FeSn compound followed an Arrhenius low

$$e_{FeSn} = A'e - \frac{Q_{FeSn}}{RT}$$

The apparent activation energies determined from the slope of the FeSn line in Fig. 6 are about

$$Q_{FeSn}\text{: 14 kcal/mole for } \theta < 610°C$$

$$Q_{FeSn}\text{: 7 kcal/mole for } \theta > 610°C$$

The parabolic behavior of the $FeSn_2$ and FeSn compound growth indicates that the rate-limiting factor is the intermetallic diffusion. Thermodynamic equilibrium at the gas-metal interface is probably realized. The appearance of even a new submicroscopic phase must have an influence on the growth kinetic of the coating according to the Kidson theory (3). Thus, the slope discontinuity observed for 610°C on the curve $e = f(1/T)$ (Fig. 6) corresponds to the appearance of submicroscopic nuclei of the Fe_3Sn_2 compound as expected from the phase diagram (Fig. 3)

$$Fe_3Sn_2 \rightleftarrows Fe + 2FeSn$$

Treheux (4), during a study on the diffusion of tin in iron dipped in molten tin, also observed a slope discontinuity in a similar curve at $T = 607°C$. These submicroscopic nuclei are not visible by microscopy, though the x-ray data show their existence (cf. Table II).

On carburized iron, the coating thickness *vs.* temperature does not follow an Arrhenius law. Above 600°C, the thickness does not increase further, Fig. 6. The Fe_3SnC_x carbide formed impedes diffusion of the iron atoms at the surface and stops growth of the coating.

Epitaxial Growth of FeSn Compound on Iron Substrate

Samples coated by pack cementation showed a coating morphology which was relatively smooth and fine-grained in the range 450°-750°C. However, when the substrate had coarse grains, the deposit had a different aspect in relation with these grains. Several publications have dealt with crystallographic de-

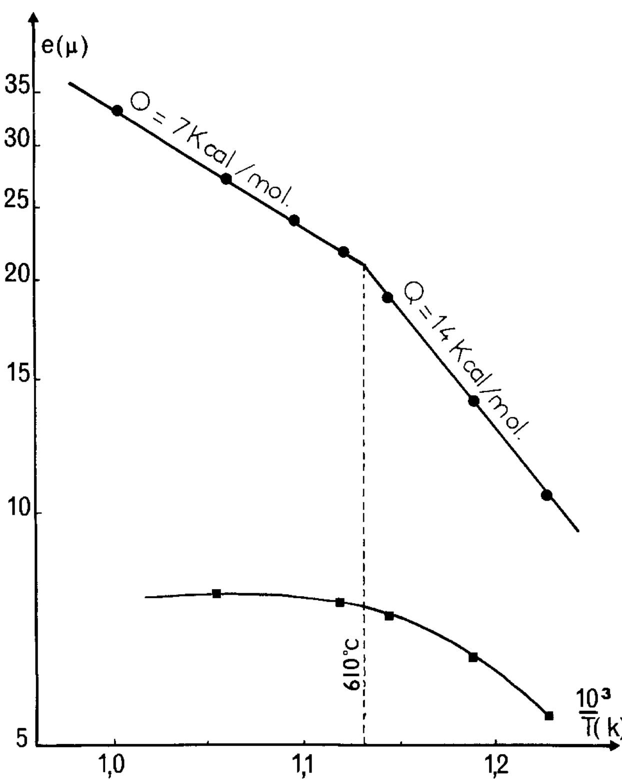

Fig. 6. Arrhenius plot of the FeSn compound (●) and of the tin-iron carbide (■) deposition.

pendence of the nuclei formed on the substrate during CVD process (5-8). The observations related above, and previous studies of epitaxial growth of the Fe_3Si compound during siliconizing and chromizing (9, 10, 11), suggest a relation between the tin-iron compound and the substrate if particular conditions of treatment are realized. Thus, we studied these relations for the FeSn compound at 600°C on iron substrate.

Experimental equipment and procedure.—For this study, we used a conventional CVD process with the silica coating tube extending through two sections of a furnace. The coating reagent (anhydrous stannous chloride) was placed in an alundum boat in the first heating zone of the furnace at 450°C. The sample to be coated [Armco iron plate, 60 × 10 × 0.5 mm, with fine grains or large grains (single crystals) obtained by the critical strain-hardening method (12)] was placed in the second zone at 600°C. The samples were chemically polished and cleaned of any residual contamination. They could be introduced or removed quickly from this zone. Hydrogen completely purged of oxygen was allowed to flow through the system. The coating mixture was 95% hydrogen, 5% $SnCl_2$. After holding at temperature for the desired time interval (5-40 min), the sample was quickly removed under a hydrogen flow to a cold zone. A combination of optical microscopy and x-ray diffraction techniques was used to study the sample surface.

Results and discussion.—Optical microscopy.—In short treatments of 5-10 min, the nucleation of the deposit appears in some particular points. Some grains have few or no nuclei (*e.g.*, grains A and B, Fig. 7). Others are almost completely covered (grains C and D, Fig. 7; A′ and B′, Fig. 8). In one grain, the size and the shape of the nuclei are generally the same. Surface defects such as polishing scratches (r), grain-boundaries, and impurities (p), affect the nucleation as shown in Fig. 7-10. At the boundary grains, the nuclei are larger and shaped differently from those in the adjacent grains.

Film growth proceeds by enlargement of islands around these nuclei, or by generation of fresh nuclei. At later stages (after 20 min of treatment) the remaining interstices in the layer are filled, and a completely continuous structure results without special orientation.

X-ray analysis.—X-ray diffraction patterns of the nuclei were not similar to those obtained with a powder of the FeSn compound. Some lines of the pattern are missing, others are stronger than those of the powder pattern, which suggests an orientation phenomena. On a stannized iron, single crystal which

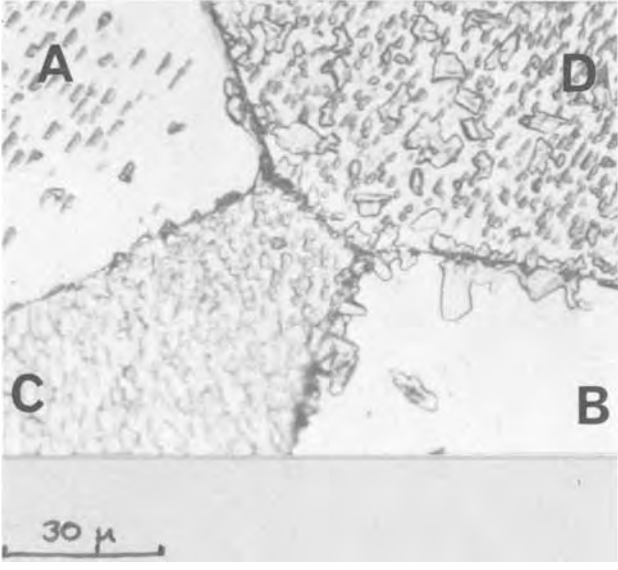

Fig. 7. Influence on the FeSn nucleation of the crystalline orientation of the iron substrate.

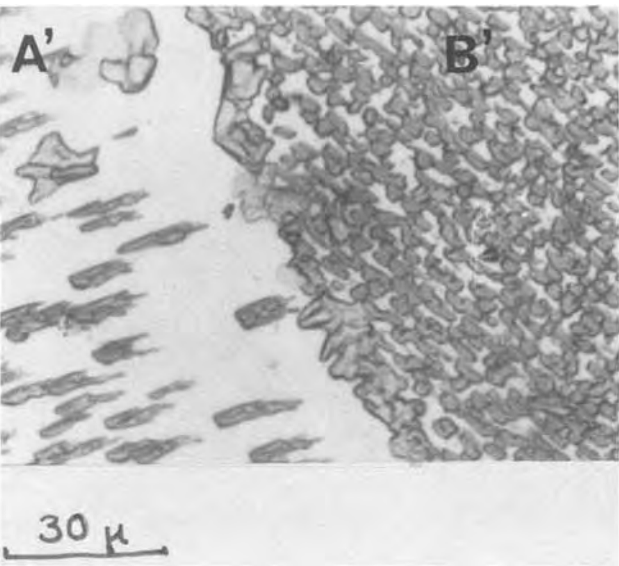

Fig. 8. Influence on the FeSn nucleation of the crystalline orientation of the iron substrate.

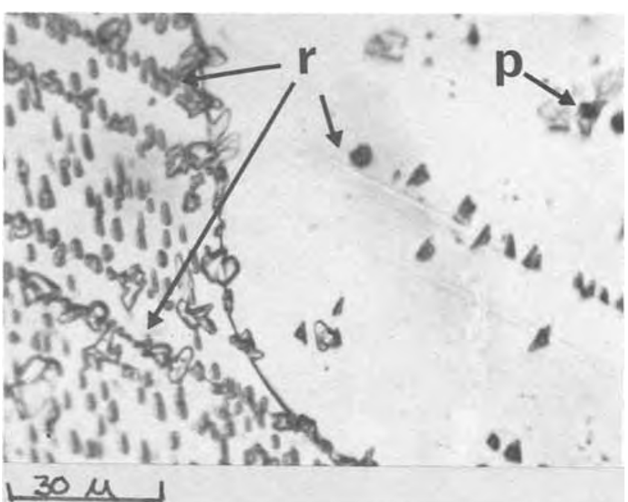

Fig. 9. Influence on the FeSn nucleation of the surface defects, (r) polishing scratches and (p) impurities.

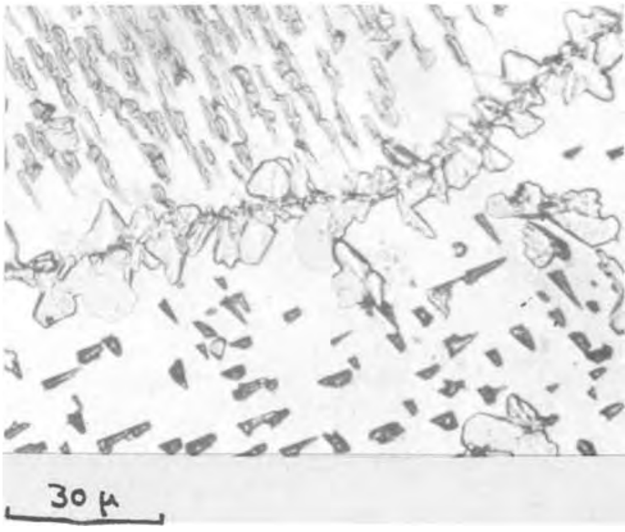

Fig. 10. Influence on the FeSn nucleation of the grain boundaries

has the (211) orientation, the diffraction curve shows only two peaks: those corresponding to the (211) iron planes and those corresponding to the $(20\bar{2}0)$ planes of the FeSn compound, Fig. 11. Laue back-diffraction patterns on iron single crystals before and after stannizing show diffraction rings instead of diffraction spots for treatment times longer than 20 min.

FeSn compound has a hexagonal structure, with P 6/mm as Hermann-Mauguin space group and a = 5.29Å, c = 4.44Å as parameters. There is a set of 6 atoms (3 Sn, 3 Fe) per lattice point. The coordinates of the tin atoms (000) (1/2 3/2 1/2) (2/3 1/3 1/2) and those of iron atoms are (1/2 00) (0 1/2 0) (1/2 1/2 0). The iron atoms are all in the (0001) planes, Fig. 12. The (0001) and $(20\bar{2}0)$ planes are those with highest planar density in iron atoms. In these planes, there are unit cells which have lattices almost similar to cells in the (110) and (211) iron planes, Fig. 13. The misfits in both cases are respectively 7.7% and 6.8% for a and a′, and 13.3% and 9.9% for b and b′. A relationship can exist between the closest packed directions of FeSn and iron. For instance, when the FeSn nuclei have their $(20\bar{2}0)$ planes parallel to the (211) iron planes, the $|\bar{1}2\bar{1}0|$ direction of the FeSn compound is parallel to the $|\bar{1}11|$ direction of iron. Therefore, conditions are favorable for epitaxial growth (13). We think that nuclei on the surface of an iron substrate are oriented by the underlying grains, followed by epitaxial growth. For polycrystalline substrates, the planes parallel to the surface are randomly orientated and the closest packed directions form various angles with these planes. Epitaxial growth is favored when these angles are smallest (13). When plane orientation is not favorable for epitaxial growths the FeSn nuclei appear preferentially as macrographic defects such as polishing scratches or grain boundaries. Later ($t > 10$ min) they appear inside the grains at crystallographic defects or areas of chemical contamination, cf. micrographs Fig. 7-9. As treatment time increases, nonoriented nuclei increase. The iron base eventually loses its influence on the epitaxial nuclei, and the deposit degenerates completely into a polycrystalline deposit. Some preferential orientations can still remain for a short time and then disappear.

A Flow Model for Autodoping in VLSI Substrates

G. R. Srinivasan*

IBM Data Systems Division, East Fishkill, Hopewell Junction, New York 12533

Substrates used in VLSI technology have a high density of buried layer device elements that cause enhanced autodoping during the epitaxial growth. Since autodoping affects many of the device characteristics, it is important to know the level of autodoping, and its variation between devices, in substrates with different device densities. A model was proposed recently that relates autodoping to the buried layer density (1). In this communication we provide experimental support for the model, based on the analysis of autodoping from VLSI substrates with varying areas of arsenic buried layers.

The model is based on the solution to the transport equation that describes the dopant redistribution in a flow system of uniform velocity. We can write for this case

$$D_g \nabla^2 C_g - V \frac{\partial C_g}{\partial x} = 0 \qquad [1]$$

where C_g and D_g are the concentration and diffusivity of the dopant in the carrier gas, and V is the flow velocity along X. If we assume that the autodoping concentration, C_a, (i.e., maximum concentration in the lateral auto-doping peak) is proportional to C_g, we can obtain an expression for autodoping due to a point source by solving Eq. [1]. This is given by (See Ref. 1 for details)

$$C_a = (A/r) \exp\{(-V/2D_g)(r - x)\} \qquad [2]$$

where A is the proportionality constant, r is the lateral distance from the point autodoping source, and x is the projection or r along the flow direction.

For autodoping contribution from a rectangular array of point sources that represent the buried layer pattern in a typical LSI wafer, we sum the contribution from each point source, and define an average autodoping concentration, $\bar{c}$, as (1)

$$\bar{c} = \langle \sum_i \sum_j C_a \rangle \qquad [3]$$

where i and j are the indices of the point in the rectangular array, and the angular brackets indicate a spatial average of C_a in the unit grid element in the array.

Figure 1 shows the result of this calculation using Eq. [3] where $\bar{c}$ is plotted as a function of n, the number of point sources in the array for several grid sizes. We see from this figure that $\bar{c} \overset{\propto}{\sim} n^{1/2}$ for grid size $\lesssim$100 μm, which is typical of the LSI substrates. We also calculate the autodoping uniformity by defining the maximum variation, Δc, in $\bar{c}$ within a unit grid element. Figure 2 shows the variation of Δc with n for 1 μm and 1000 μm grid spacings. We note that for both these cases Δc <5% for n>1000. By associating an infinitesimal area around each point we now define an areal fraction, f, occupied by the buried layers in the substrate as

$$f = \lim_{N \to \infty} n/N, \qquad [4]$$

where N is the total number of points in the wafer. Thus, we can write

$$\bar{c} \overset{\sim}{\sim} Kf^{1/2}. \qquad [5]$$

where K is a constant of proportionality.

Figure 3 shows the experimental data (2) for the variation of arsenic autodoping (reciprocal epitaxial sheet resistance, R_s) with

*Electrochemical Society Active Member.

Key words: epitaxy, impurity, integrated circuits, semiconductor.

the buried layer subcollector density in VLSI substrates that are used in bipolar circuitry. These data are obtained by measuring epitaxial sheet resistance, R_s on device wafers which had various buried layer densities. The epitaxial depositions were made in a Laminar flow reactor system with identical deposition conditions. $1/R_s$ is a measure of total autodoping in the epitaxial layer. We see that the data can be represented by the equation $10^4/R_s = 2.25 f^{1/2}$ in agreement with Eq. [5]. Thus, the theory is successful in predicting the autodoping enhancements in VLSI substrates.

The model is also capable of explaining the autodoping increases due to increases in the wafer load in the epitaxial reactor by summing up contributions from each wafer using a procedure similar to that indicated here. Finally, the model can also be extended to buried layers of finite size and special geometries, upon which we will report elsewhere (3) and discuss the flow effects in some detail.

α-Fe_2O_3 Photoanodes Doped with Silicon

John H. Kennedy,* Ruth Shinar, and John P. Ziegler

Department of Chemistry, University of California, Santa Barbara, California 93106

INTRODUCTION

Previous papers reported on the photoelectrochemical properties of α-Fe_2O_3 (1,2) in which undoped high purity and titanium-doped polycrystalline materials were used. Undoped material exhibited high photocurrents even at 0 V vs. SCE and, in general, were superior to Ti-doped α-Fe_2O_3. More recent purchases of high purity α-Fe_2O_3 (99.999%) showed that the sintered pellets were highly resistive and exhibited no photocurrent. Varying the sintering conditions had little effect although the sintering in the presence of a reducing atmosphere (90% N_2 - 10% H_2) yielded electrodes with some photoactivity. However, they also showed large dark currents.

Analysis of the original α-Fe_2O_3 by emission spectroscopy showed it to contain a silicon impurity of ca. 0.1 a/o whereas the later batches only contained several ppm Si. Experiments were conducted in which the new high purity α-Fe_2O_3 was doped with varying amounts of SiO_2 and the results are reported here.

EXPERIMENTAL

Si-doped electrodes were prepared from α-Fe_2O_3 (99.999%, Apache Chemical Co. and Alfa Products) by mixing with reagent grade SiO_2 powder, pressing and sintering. Sintering was carried out in air at 1250°-1350°C for from 4 to 24 hr followed by quenching to room temperature. The silicon doping level was varied from 0.001-2 a/o. Electrodes containing 1 a/o TiO_2 were also prepared for comparison. Old, nominally pure α-Fe_2O_3 (Apache Chemical Co.) which contained ca. 0.1 a/o Si by emission spectroscopy analysis was used without additional doping. Pressed pellets of this material were sintered in air at 1300°C for 14 hr. Densities were from 85 to 100% of the theoretical value.

Electrical connections were made using silver epoxy as previously described (1). Typical resistances measured at 1 KHz with a conductivity bridge were from 1 to 2 kΩ.

The cell arrangement consisted of the α-Fe_2O_3 working electrode, Pt counterelectrode and a SCE reference electrode. Current-potential curves were obtained with a PAR Model 174 polarographic analyzer at a scan rate of from 2 to 10 mV/sec. Electrodes were illuminated with a 150 W Xenon lamp. For spectral response a Bausch and Lomb visible grating monochromator was employed.

RESULTS

Photocurrent vs. applied potential for the nominally "pure", 0.1 a/o Si-doped, and 1 a/o Ti-doped α-Fe_2O_3 in 1M NaOH is shown in Fig. 1. The match in characteristics was quite close for the undoped old material and the new high purity material doped with 0.1 a/o Si. The match was even closer in an electrolyte containing 0.05M borax buffer at pH 9. As can be seen from Fig. 1 the Ti-doped material exhibited the same plateau value of photocurrent but only at considerably higher applied potentials. Only Si-doped materials gave high photocurrents at 0 V vs. SCE. Measurements shown in Fig. 1 were taken with polychromatic light with only an infra-red filter in the light path.

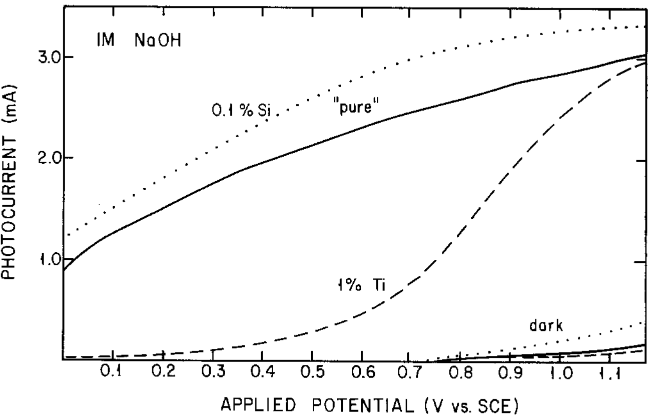

Fig. 1. Photocurrent vs. applied potential observed for undoped, 0.1 a/o Si-, and 1 a/o Ti-doped α-Fe_2O_3 electrodes in 1M NaOH. Polychromatic light from 150 W Xenon source.

Photocurrents were somewhat higher with 2 a/o Si doping and considerably less with

0.01 a/o Si as shown in Fig. 2. High doping levels (>1 a/o) have not been studied in depth yet because it was found that dark currents were significantly higher at applied potentials >0.4 V vs. SCE and frequently increased with age of the electrode.

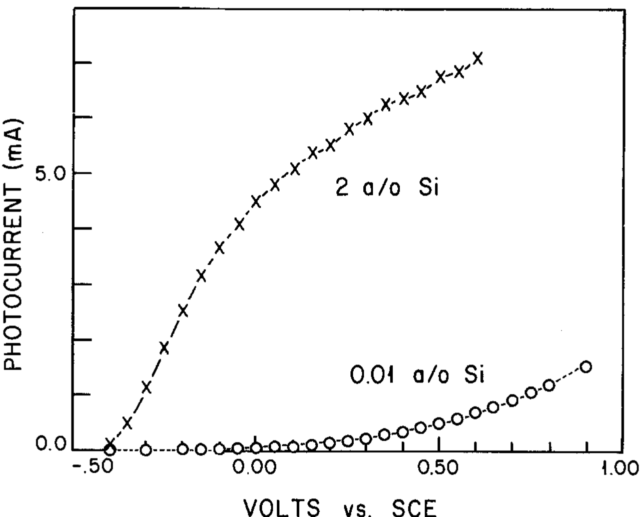

Fig. 2. Photocurrent vs. applied potential observed for 0.01 a/o and 2 a/o Si-doped α-Fe_2O_3 in 1M NaOH. Dark current started to rise above +0.6 V vs. SCE for 2 a/o Si-doped electrode. Polychromatic light from 150 W Xenon source.

Spectral response for the old "pure" material and Si-doped α-Fe_2O_3 was identical and, aside from the maximum photocurrents obtained, was the same as Ti-doped electrodes as shown in Fig. 3.

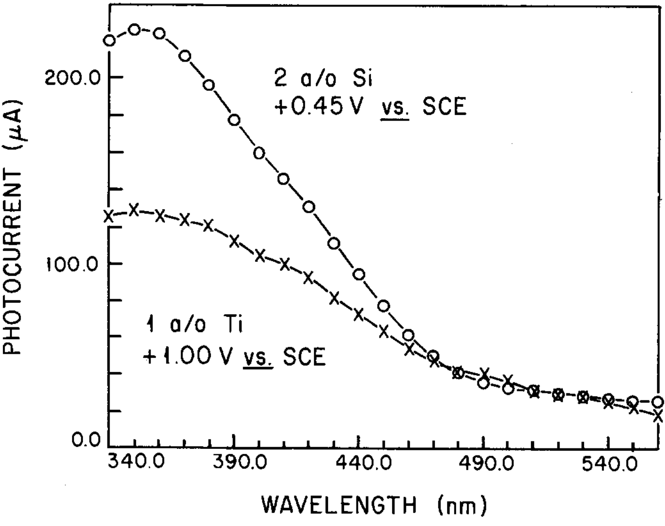

Fig. 3. Spectral response for 2 a/o Si-doped electrode compared to 1 a/o Ti-doped electrode.

Photocurrent vs. applied potential for electrodes illuminated at 400 nm is shown in Fig. 4. The characteristics are similar to those seen in Fig. 1. It should be noted that dark current for the 2 a/o Si-doped electrode started to rise when the applied potential was >0.4 V vs. SCE while dark currents for lower doping levels (<1 a/o) were quite low until the applied potential was >0.8 V vs. SCE.

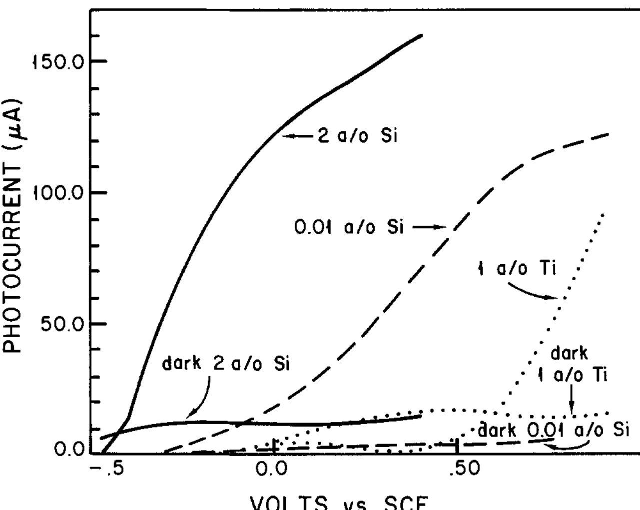

Fig. 4. Photocurrent vs. applied potential for Si and Ti-doped α-Fe_2O_3 illuminated with 400 nm light.

Surface effects for these electrodes were also found to play an important role in determining photoresponse. Dipping an electrode that showed a fairly low photocurrent in 1M KI solution at pH 9 improved the electrode's response to light when illuminated in 1M NaOH. Photocurrents were observed to increase by a factor of 3 after 3 weeks of soaking in 1M KI at pH 9. This is shown in Fig. 5 for a 0.1 a/o Si-doped electrode. The high photocurrent remained stable for more than two months and disappeared only after heating the electrode to 130°C. Electrodes which showed the highest photocurrents could be improved a small amount by the KI treatment but it was apparent that the treatment primarily improved the surface of poorer electrodes to the point where they would match the performance of the best electrodes. Treatment with iodide in 1M NaOH did not improve the electrodes. This was attributed to strong adsorption by OH^- in 1M NaOH preventing iodide from reacting with the surface.

CONCLUSIONS

The earlier results obtained with undoped α-Fe_2O_3 were actually a consequence of an incidental silicon impurity. Silicon, a group IV A element, is a better dopant for

α-Fe_2O_3 than titanium, a group IV B element. This conclusion is presently being pursued with other group IV elements as dopants.

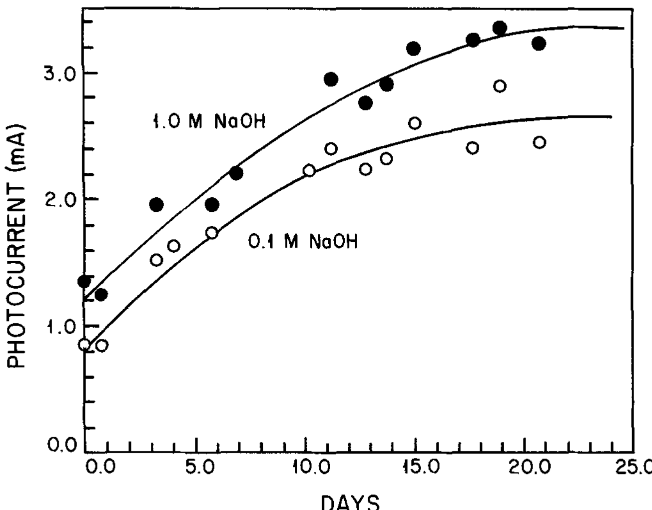

Fig. 5. Photocurrent observed at +0.9 V vs. SCE in 0.1 M and 1 M NaOH as a function of time immersed in 1 M KI at pH 9.

Photocurrent at 0 V vs. SCE increases with increasing silicon content but dark current also increases, especially above 1 a/o.

Surface effects caused by solutes in the electrolyte may play a significant role in modifying the photoresponse exhibited by the α-Fe_2O_3 electrodes. Competition reactions between OH^- and other solutes such as halide ions will be reported at a later date.

Protection of n-GaAs Photoanodes with Photoelectrochemically Generated Polypyrrole Films

Rommel Noufi,* Dennis Tench,* and Leslie F. Warren

Rockwell International Electronics Research Center, Thousand Oaks, California 91360

It is generally recognized that the key obstacle to the development of electrochemical solar cells is photodegradation of the semiconductor electrodes. In principle, this problem could be overcome by the use of an electrically conducting polymer film on the electrode. By acting as a barrier to ion/solvent transport, such an insoluble film would prevent photodegradation while permitting electron exchange with the electrolyte. Good adhesion, uniformity and interfacial charge transport properties are expected for electrochemically generated films since deposition is initiated at the interface by electrochemical oxidation/reduction. Electrodeposition of polypyrrole films, having conductivities in the 10 to 100 Ω^{-1} cm^{-1} range, on Au and Pt electrodes has recently been reported (1-3). In this communication, we describe the photoelectrochemical generation of polypyrrole films on n-GaAs and the characteristics of the resulting photoanodes.

Electrodeposition of polypyrrole on n-GaAs was performed with tungsten-halogen illumination (50 mW/cm^2) at a constant electrode potential of 0.45 V vs SCE (saturated calomel electrode) from mechanically stirred acetonitrile solution containing 0.1 M pyrrole and 0.1 M Et_4NBF_4 (supporting electrolyte). The semiconductor electrodes were single crystals (3 x 10^{16} $carriers/cm^3$) and were etched in 1:1 H_2SO_4/H_2O_2 solution before use. Deposition on illuminated n-GaAs begins at a less anodic potential (0.2 V) than on Pt (0.8 V), as might be expected for a photoassisted process. During deposition, the current remained practically constant at 100 $\mu A/cm^2$. Based on the charge passed, the film thickness was usually in the 100 monolayer range (assuming 50 $\mu C/cm^2$ per monolayer). Details of the electrode mounting and measurement techniques have been described previously (4). In all experiments reported here, electrode illumination was provided by a tungsten-halogen lamp. The counter electrode was generally Pt (~ 25 cm^2).

Figure 1 shows linear sweep cyclic voltammograms at various sweep rates for a polypyrrole-coated n-GaAs electrode under illumination in an acetonitrile solution containing only supporting electrolyte. As indicated by the corresponding anodic and cathodic current peaks, the film itself is reversibly oxidized and reduced. This film redox reaction is also observed with Pt substrates and apparently involves anion exchange with the solution (1). The onset of film oxidation corresponds with the flatband potential on n-GaAs (-1.0 V), although it occurs at more anodic potentials on Pt (-0.4 V). Likewise, the voltammetry peaks for the film-covered semiconductor occur at more cathodic potentials (about -0.5 V compared to -0.1 V vs SCE). As expected, the film redox reaction does not occur on n-GaAs in the dark. It is remarkable, however, that the cathodic peak still occurs when illumination is interrupted after the anodic portion of the cycle. This indicates that electron exchange between the film and the semiconductor valence band occurs in both the anodic and cathodic directions.

Cyclic voltammetric studies were also performed for film-covered and bare n-GaAs electrodes, with and without illumination, in aqueous solutions containing redox couples covering a range of redox potentials (V_R), i.e., $Fe^{3+/2+}$ (0.53 V vs SCE), $Fe(CN)_6^{3-/4-}$ (0.12 V) and Fe(III)EDTA/Fe(II)EDTA (-0.13 V). The pH was varied from 0 to 14 to vary the flatband potential (V_{fb}), measured by ac impedance, from -0.4 to -1.4 V. V_{fb} values were equivalent for the film-covered and bare electrodes and open circuit photovoltages were always close to the predicted values (V_R - V_{fb}). These results

*Electrochemical Society Active Member

Key Words: electrochemical solar cells, photoelectrode stabilization, polymer films

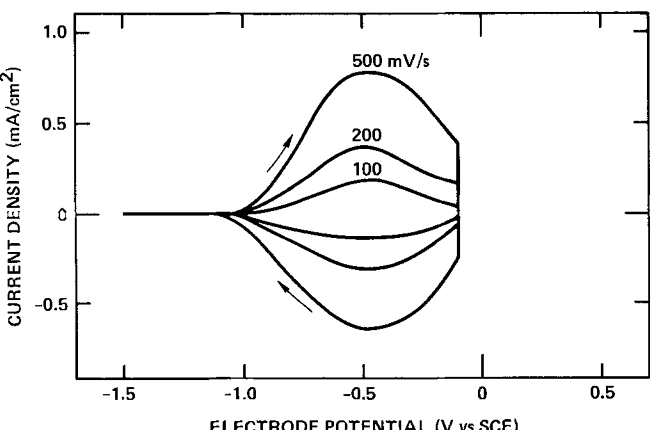

Fig. 1 Cyclic voltammograms for a polypyrrole-coated GaAs photoanode illuminated at 60 mW/cm^2 in acetonitrile solution containing 0.1 M Et_4NBF_4.

indicate that Fermi level pinning does not occur for n-GaAs in these aqueous systems.

Figure 2 shows a current-voltage curve for a polypyrrole-coated GaAs photoanode under illumination at 170 mW/cm^2 in an aqueous 0.2 M $Fe(CN)_6^{3-/4-}$/0.1 M NaCN/0.1 M NaOH solution. Although unprotected GaAs photodissolves in this system, the film-covered electrode is stable, i.e., the curve in Fig. 2 was not preceptively changed after 50 cycles at 100 mV/s. The output characteristics are comparable with the protective film compared to the bare electrode except that the short circuit photocurrent is reduced 39% (from 31 mA/cm^2 to about 19 mA/cm^2). This photocurrent reduction presumably results from suppression of the photodissolution process, light absorption in the relatively thick films used here, or both. The open circuit voltage (1.37 V) is noteworthy since it is practically equivalent to the bandgap of GaAs (1.4 eV). In aqueous systems, film peeling is presently a problem, usually occuring within 10 to 20 minutes under illumination and apparently originating at the edges of the film (which are exposed to the electrolyte). However, polypyrrole-coated GaAs photoanodes have operated at 5.5 mA/cm^2 (90 mW/cm^2) in methanol/0.2 M each tetraethylammonium $Fe(CN)_6^{3-/4-}$/0.1 M Et_4NBF_4 solutions for 100 h without detectable weight loss or deterioration of the electrode surface, whereas the photocurrent for unprotected GaAs decays to a negligible value in less than one minute in this system.

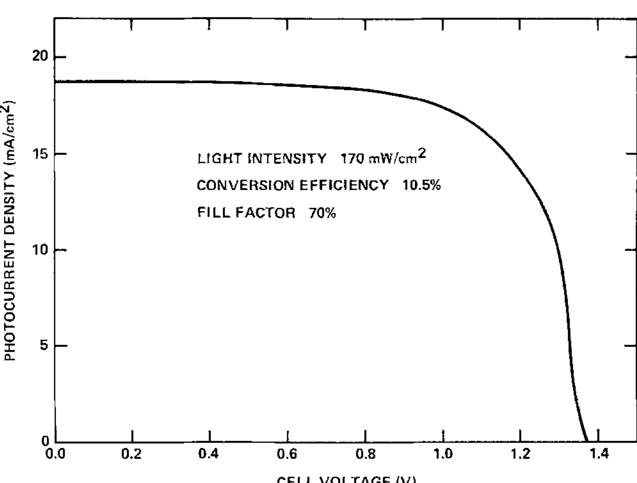

Fig. 2 Photocurrent-voltage curve for the cell polypyrrole-coated GaAs/aqueous 0.2 M $Fe(CN)_6^{3-/4-}$ + 0.1 M NaCN + 0.1 M NaOH/Pt under illumination at 170 mW/cm^2.

These results show that electrodeposited polypyrrole films protect n-GaAs photoanodes from dissolution while permitting electron exchange with the electrolyte. With further work, such films could provide the photoelectrode stability and performance characteristics required for a practical electrochemical solar cell.

Resistance Rise in Sodium-Sulphur Cells

D. S. Demott

British Rail, Research and Development Division, Derby, England

Resistance increases in sodium-sulphur cells during extended periods of cycling have been reported by various groups of workers (1-4). These increases have usually been ascribed to corrosion of metallic components in the sulphur electrode compartment or to impurities in either the sodium or sulphur electrodes. Recently, however, we have experienced very severe rates of resistance increase which, as we show here, are attributable to the sodium/β"-alumina interface.

The rate of resistance rise which we have observed in our cells has been very variable. Formerly the average rate of rise was 0.4 ohm cm^2 per 100 cycles but the problem has gradually become so severe that the resistance can now double within ten cycles (equivalent to a rate of rise of 20 ohm cm^2 per 100 cycles) or even less. This resistance rise has been most pronounced during cell discharge, the charge resistance usually remaining relatively constant. This type of asymmetric resistance behaviour of β"-alumina has been observed previously in both sodium-sulphur cells and sodium/β"-alumina/sodium tests (5-8). We have also frequently found two further effects to be associated with the rapid rise in discharge resistance. Firstly, an even higher transient resistance occurs at the start of discharge; this high transient discharge resistance also appears after the cell has been left on open circuit at any state of discharge, the effect even being detectable after a current interruption of only a few seconds. Secondly, the minimum discharge resistance decreases with increasing current.

All these effects are illustrated in Fig. 1 which shows discharge and charge curves for a typical high resistance cell. The time dependent and non-ohmic effects are also very apparent in polarisation curves which were plotted for the same cell (Fig. 2). These curves were obtained by allowing the cell to stand on open circuit until a steady voltage was obtained (approximately 5 minutes) before applying each constant discharge or charge current; the cell voltage was then measured after 1, 30 and 120 seconds.

No correlation could be found between the variation in magnitude of these effects and any known differences in cell construction (e.g. types of sulphur electrode, current collector and sodium electrode and minor variations in the β"-alumina tubes - nominal composition 8.9% Na_2O, 0.7% Li_2O, < 10% β-phase). This, and the observation that similar effects can occur in sodium/ β"-alumina/sodium tests, was strong evidence that the problem was associated with the sodium/β"-alumina interface. Consequently, it was decided to investigate whether renewal of the sodium led to any improvement in cell resistance.

With our central sulphur cell design (1) renewal of the sodium electrode is a straightforward matter. This is done by cooling the cell in the fully charged state and cutting away the mild steel cell case. Sodium is removed from the outside of the β"-alumina tube by scraping and by reaction with ethanol; the complete β"-alumina tube and sulphur electrode assembly can then be reassembled into a new cell case with fresh sodium. When applied to cells which have shown a rapid resistance increase this procedure invariably results in a reduced cell resistance; a typical example is shown in Fig 3. Not only is the subsequent discharge resistance usually lower than the previous minimum value but it normally remains constant over a large number of cycles and the time dependent and non-ohmic effects are eliminated. However, we have found that cells which are subjected to sodium renewal after only a few cycles can again rise in resistance; 20-30 cycles appear necessary before renewal in order to achieve a stable resistance. It has, furthermore, been found that cells which have shown a relatively modest rate of resistance rise (e.g. a 50% rise over 600 cycles), without showing the pronounced

Key Words: sodium-sulfur cells, beta alumina, resistance.

non-ohmic and time dependent effects described above, can also be restored to their original resistance by renewal of the sodium electrode.

Various experiments have been performed to elucidate the cause of these improvements following sodium electrode renewal. Briefly, these have shown that:-

i) the improvement is not simply due to the thermal cycle experienced by the cell.

ii) improvement cannot be achieved by washing of new β''-alumina tubes in the same solutions used for sodium removal.

iii) no correlation can be found between the resistance of cells and any impurities in the sodium removed from them; the fact that the resistance problems can be eliminated by sodium renewal further indicates that if impurities are responsible they do not arise from the sodium or any other components of the sodium electrode since these are invariant.

iv) heating of a high resistance cell to 500°C (with the sulphur electrode in the single phase region), with and without current flowing, in order to improve the wetting of the β''-alumina surface by the sodium (7), led to no improvement when the cell was returned to 350°C.

v) renewal of the bulk of the sodium in a cell without disturbing the sodium in contact with the β''-alumina surface does not have the observed beneficial effect. This was done by cutting off the bottom of the cell case, melting the sodium out of the pressure can, replacing it with fresh sodium and re-welding the bottom of the cell. Unlike cells in which the β''-alumina was cleaned free of sodium this cell continued to exhibit the high resistance effects.

Although, at present, we have not been able to establish the mechanism of resistance increase, it is evident that the cause of the observed effects is removed during the sodium renewal procedure. Clearly, for practical reasons, renewal of the sodium electrode cannot provide the ultimate solution to this problem and further experimentation is necessary in order to locate the source of the resistance rise and means of preventing it. However, since we have found the effect to occur to varying degrees over a range of β''-alumina compositions, it is possible that it is a contributory factor to the resistance increases frequently observed in sodium-sulphur cells of different design.

Molybdenum Oxide Cathodes in Secondary Lithium Cells

P. A. Christian,[1] J. N. Carides, F. J. DiSalvo, and J. V. Waszczak

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The electrochemical behavior of molybdenum oxide cathode materials with stoichiometries between MoO_2 and MoO_3 in nonaqueous lithium secondary cells are examined. Of the oxides Mo_4O_{11}, $Mo_{17}O_{47}$, $(Mo_{0.92}V_{0.08})_5O_{14}$, Mo_8O_{23}, and Mo_9O_{26} the greatest reversible capacity (>1 Li/Mo) after several deep discharge/charge cycles was exhibited by $Mo_{17}O_{47}$ in cells with a $LiClO_4$/propylene carbonate electrolyte. Excepting Mo_4O_{11}, which gives a reversible capacity of >0.75 Li/Mo after 20 deep discharge/charge cycles, the reversible capacities of the other molybdenum oxides are considerably less than that of $Mo_{17}O_{47}$. The limiting reversible lithium capacity of 1.5 Li/Mo for $Mo_{17}O_{47}$ was determined by treating $Mo_{17}O_{47}$ with an n-butyllithium solution and the lithium bronze formed with an I_2 solution. For an average cell voltage of 1.85V and a capacity of 1.5 Li/Mo, the theoretical energy density of $Mo_{17}O_{47}$ (~490 W-hr/kg) is comparable to that reported for TiS_2 and stoichiometric V_6O_{13}. The magnetic properties of both $Mo_{17}O_{47}$ ($MoO_{2.765}$) and the lithium bronze $Li_{1.41}MoO_{2.765}$ were also investigated and are discussed.

Various transition metal chalcogenides with two-dimensional layered or one-dimensional chain structures have been reported to topochemically incorporate lithium reversibly (1). However, there are relatively few reports of reversible lithium incorporation by compounds with three-dimensional framework structures (1-10). Recently, we reported that several vanadium oxides, VO_y ($2 < y < 2.5$), with structures shear-related to that of ReO_3 reversibly incorporate lithium at room temperature both in model chemical reactions and in electrochemical cells (11, 12). Of these vanadium oxides, V_6O_{13} ($VO_{2.167}$) affords cathodes with high capacity and excellent rechargeability in secondary (rechargeable) lithium cells (11). The empty perovskite-like cavities and interconnecting channels in the structures of these vanadium oxides can serve as sites and routes, respectively, for lithium incorporation as do the expandable van der Waal's gaps of chalcogenides with layered or chain structures. A variety of other transition metal oxides have structures which are shear-related to that of ReO_3, including the molybdenum oxides Mo_9O_{26}, Mo_8O_{23}, and Mo_4O_{11} (13). In a study of the electrochemistry of MoO_3 Besenhard and Schöllhorn also reported (3) that cathodes containing Mo_8O_{23} can be galvanostatically reduced resulting in the uptake of more than 1.0 Li per Mo. However, the reversibility of the reduction and lithium incorporation were not determined in that study. More recently, Pistoia and co-workers (7, 8) have examined the use of Mo_9O_{26},Mo_8O_{23}, and Mo_4O_{11} as cathodes in secondary lithium cells. They have reported that cathodes containing Mo_8O_{23} exhibited a capacity of up to 0.8 Li/Mo and maintained good recharge efficiencies for over 15 cycles (9). However, no detailed results were presented for cells with Mo_9O_{26} or Mo_4O_{11} cathodes.

In the present paper, reversible lithium incorporation by the known molybdenum oxides with stoichiometries between MoO_2 and MoO_3 is reported. In addition to those molybdenum oxides structurally related to ReO_3, we have evaluated $Mo_{17}O_{47}$ and Mo_5O_{14} for use as possible cathode materials. Both of these oxides have complex three-dimensional structures based on mixed networks of polyhedra and are permeated by large, open channels (13, 14) similar to those present in the tetragonal and hexagonal tungsten bronzes (15, 16). Although Mo_5O_{14} is apparently metastable (17), the structure can be stabilized by a partial substitution of vanadium for molybdenum (18). A ternary phase with the composition $(Mo_{0.92}V_{0.08})_5O_{14}$ was used in our study. This material was prepared from the appropriate amounts of V_2O_5, MoO_3, and MoO_2 as described by Ekström and Nygren (18). The other molybdenum oxides were prepared from mixtures of the appropriate amounts of MoO_3 and Mo powders pressed into pellets and heated in evacuated, sealed quartz tubes (13, 19). The identities of the phases formed were verified by x-ray powder diffraction using CuK_α radiation (17). All attempts to grow single crystals of $Mo_{17}O_{47}$ and $(Mo_{0.92}V_{0.08})_5O_{14}$ by vapor transport with I_2 or $TeCl_4$ afforded only mixtures of Mo_4O_{11} and MoO_3.

The results of our electrochemical cell studies of Mo_9O_{26}, Mo_8O_{23}, and Mo_4O_{11} cathode materials are essentially in agreement with those of Pistoia and co-workers (6-8) (Table I). However, they reported detailed cycling data only for the Mo_8O_{23} cathodes (6, 8). For the other two oxides, the capacities of the first cycle discharges were given. In our experience, the performance of a cell on the first cycle discharge is not a reliable indicator of subsequent cell performance. For example, cells containing $NbSe_3$ (20) or TiS_3 (21) cathodes exhibit dramatic differences between the shapes of the first and subsequent discharge curves.

[1] Present address: Western Electric Company, Engineering Research Center, Princeton, New Jersey 08540.

Key words: stoichiometry, discharge, electrolyte.

Table I. The extent of reaction of molybdenum oxides with n-butyllithium and the reversible cell capacities after one, five, and twenty cycles are shown. Ideally, for a given compound the lithium content would be independent of the method of determination or cycle number. The cell capacities are in Li/Mo, while the upper and lower voltage limits are 2.8 and 1.5V, respectively. See text for further discussion.

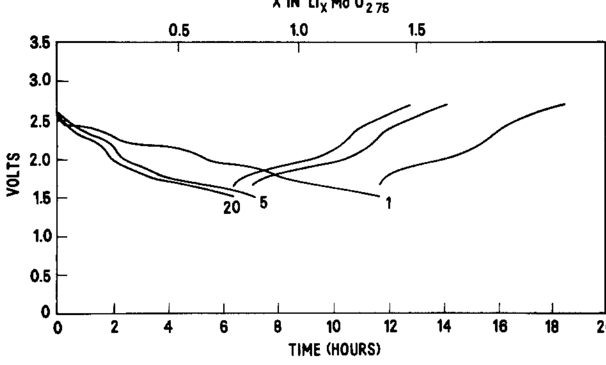
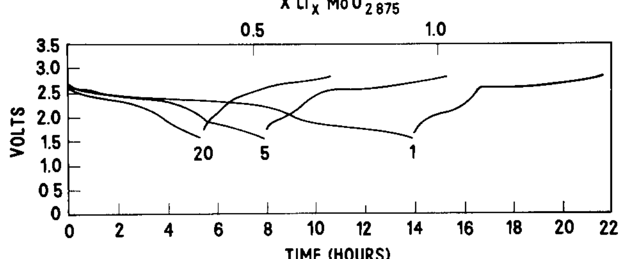
Furthermore, we typically find for the vanadium oxides (22), at least, that the decrease in capacity between the first cycle discharge and the second is greater than that between any two subsequent consecutive discharge cycles. The "extra" irreversible capacity of the first discharge may be attributed tentatively to reactions of lithium with trace impurities in the electrolyte, pacification of surfaces of the cathode particles, irreversible incorporation of lithium by some sites, and possibly other extrinsic causes such as loss of mechanical and electrical integrity of the cathode due to volume changes on charge and discharge.

The electrochemical test cells used in our studies have been described in detail elsewhere (23). The electrolyte used in these cells was 1.0M $LiClO_4$ in dried, vacuum distilled propylene carbonate. Approximately 10-20 mg of active cathode material were used in a 1 cm diam cathode. Discharge currrents were typically in the range 0.2-0.5 mA. Cells were cycled automatically between appropriate upper and lower voltage limits.

Pistoia and co-workers have estimated the maximum amount of lithium which can be incorporated by Mo_4O_{11}, Mo_8O_{23}, and Mo_9O_{26} as 2.1, 2.3, and 2.3 Li/Mo, respectively, by extrapolating to zero current a plot of cell capacity *vs.* discharge current (2). The values of cell capacity used were themselves based on an extrapolation of the voltage *vs.* capacity plots to 0.0V because of electrolyte decomposition below 0.8V. Consequently, the values calculated for the specific energies of these three oxides approach 1000 W-hr/kg! We have estimated the limiting values of lithium incorporation for Mo_4O_{11}, Mo_8O_{23}, and Mo_9O_{26} as 1.62, 1.26, and 1.08 Li/Mo (Table I), respectively, by treating them with excess n-butyllithium in hexane (24, 25). The reduction potential of n-butyllithium under these reaction conditions has been estimated as ~ 1.1V *vs.* Li/Li^+ (12). The theoretical energy densities calculated using our n-butyllithium values for these oxides are on the order of 400-500 W-hr/kg.

Cycling data for cells containing Mo_4O_{11}, Mo_8O_{23}, and Mo_9O_{26} cathode materials are shown in Fig. 1. The cell capacities observed for the first, fifth, and twentieth cycles are given in Table I. For Mo_8O_{23} our values closely correspond to those of Pistoia and co-workers





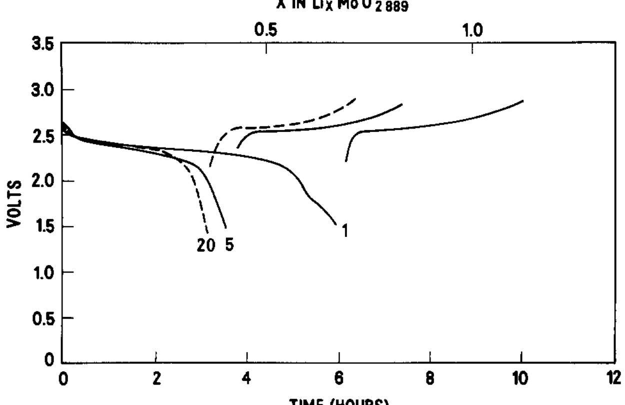


Fig. 1. Cycle data for cells containing (a, top left) Mo_4O_{11}, (b, top right) Mo_8O_{23}, and (c, bottom left) Mo_9O_{26} cathodes. Cycle numbers are indicated as are specific capacities.

(8). Although Mo_8O_{23} exhibits good rechargeability (9), $Mo_{17}O_{47}$ has greater reversible capacity after several cycles resulting in better overall cell performance.

Our previous studies of lithium incorporation by rutile-related metal dioxides (20) and ReO_3-related vanadium oxides (11, 22), as well as the present study of lithium incorporation by molybdenum oxides all support our earlier suggestion (26) that both channel/site size and electronic conductivity are the predominant factors influencing the extent of reversible lithium incorporation by metal oxides with framework structures. Kihlborg (17) has measured the specific electrical resistivities of compressed powder samples of Mo_9O_{26}, Mo_8O_{23}, Mo_4O_{11}, and $Mo_{17}O_{47}$. Like V_6O_{13}, $Mo_{17}O_{47}$ is also metallic at room temperature ($\rho < 0.05$ $\Omega\cdot$cm), whereas the other oxides are semiconductors with specific resistivities of about 1 $\Omega\cdot$cm or greater (17). The electrical resistivity of $(Mo_{0.92}V_{0.08})_5O_{14}$ has not been reported.

Treatment of samples of $Mo_{17}O_{47}$ and $(Mo_{0.92}V_{0.08})_5O_{14}$ with excess n-butyllithium in hexane at room temperature for several days, leads to apparent limiting compositions of 1.78 ± 0.05 Li/Mo and 1.71 ± 0.05 Li/Mo respectively. The x-ray powder diffraction patterns of these bronzes have been measured and are tabulated in Tables II and III. A preliminary indexing of the pattern of lithiated $Mo_{17}O_{47}$ ($Li_{1.78}MoO_{2.765}$) suggests that the unit cell expands in the b direction and contracts in both the a and c directions upon incorporation of lithium. The unit cell volume, however, increases by less than 4%. The corresponding values for $Li_6V_6O_{13}$ and $Li_8V_6O_{13.2}$ are 6% and 15%, respectively (22). The unit cell volume of $(Mo_{0.92}V_{0.08})_5O_{14}$ increases by about 10% upon lithium incorporation. In this case, the unit cell appears to expand in all three directions. Chemical oxidation of $Li_{1.73}MoO_{2.765}$ with a solution of I_2 in acetonitrile removed about 80% of the lithium from the bronze. This implies that either the potential of the bronze $Li_xMoO_{2.765}$ is greater than that of I_2 (~ 2.85V *vs.* Li/Li$^+$) at low lithium contents or that at high lithium contents some irreversible reduction occurs. Direct measurement of the potential of the bronze as a function of the lithium content in electrochemical cells revealed very little capacity above 2.85V. This suggests that some structural degradation occurs at high lithium contents, as has been observed for framework compounds such as $Li_xV_2O_5$ for $x > 1.0$ (27), and also for layered oxides such as Li_xMoO_3 for $x > 1.5$ (1). We have assumed that the products of any irreversible part of the reaction are poorly crystalline or amorphous, so that they do not contribute to the observed x-ray diffraction pattern. This is usually the case, for example, as observed for V_2O_5, MoO_3, and MoS_2 (1). Using the results of the butyllithium and I_2 reactions, we estimate the maximum reversible lithium incorporation to be 1.5 Li/Mo in $Mo_{17}O_{47}$. $Mo_{17}O_{47}$ can be assigned the following Mo valence distribution: $Mo_{13}{}^{6+}Mo_4{}^{4+}$. If reversible lithium incorporation produced all Mo^{4+}, the expected lithium uptake would be 26/17 (1.53) Li/Mo—a value close to that estimated from the butyllithium and I_2 reactions.

Electrochemical cells containing $Mo_{17}O_{47}$ and $(Mo_{0.92}V_{0.08})_5O_{14}$ cathode materials were tested for 30 or more charge/discharge cycles (Fig. 2). The capacity of the $(Mo_{0.92}V_{0.08})_5O_{14}$ cathode appear to decrease much more rapidly than that of $Mo_{17}O_{47}$ cathodes (Fig. 3). Voltage limits have been optimized to ensure good cyclability of the $Mo_{17}O_{47}$ cathodes. These empirically determined limits are 2.9V for the upper charging limit and 1.4V for the lower discharging limit. Increasing the upper voltage limit or decreasing the lower voltage limit leads to lower cell capacity after several cycles, suggesting that irreversible changes occur when the cathode potential is greater than 2.9V or less than 1.4V *vs.* Li. This in turn suggests that some irreversible reaction will always occur when using n-butyl lithium as a lithiating agent, since its equivalent potential is about 1.1V. Ideally the maximum lithium uptake of any material would be independent of its method of determination (*e.g.*, reaction with n-butyllithium or a particular cycle of an electrochemical cell). However, in reactions with n-butyllithium some irreversible changes may occur (such as producing Li_2O or other decomposition products) resulting in artificially high estimates of the maximum reversible lithium incorporation. In electrochemical cells not only can irreversible reactions occur but also poor mechanical and electrical integrity of the cathode can occur especially after cycling. In the latter case artificially low estimates of the maximum reversible lithium content are obtained. Based on the limiting capacity estimated from the n-butyllithium reaction, the subsequent reversible I_2 reduction (1.5 Li/Mo), and the

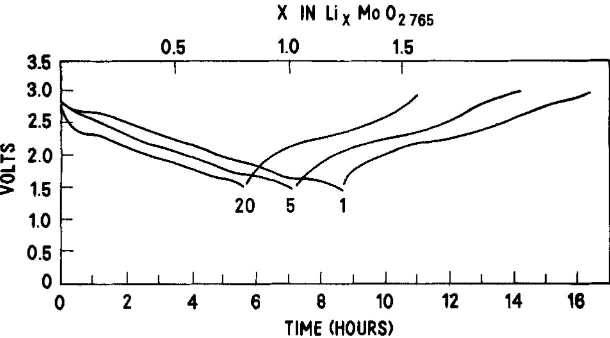

Fig. 2. Cycle data for a cell containing a $Mo_{17}O_{47}$ cathode. Beyond the 20th cycle the cell had a 98% recharge efficiency (to at least the 35th cycle, at which point data collection stopped).

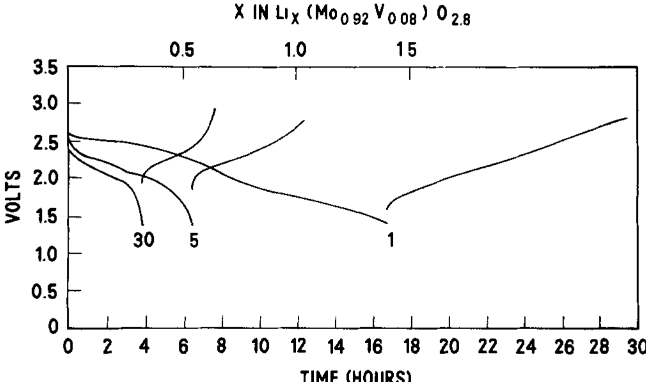

Fig. 3. Cycle data for a cell containing a $(Mo_{0.92}V_{0.08})_5O_{14}$ cathode. Cycle numbers and capacities are as indicated.

average cell potential of 1.85V (Fig. 2) a theoretical energy density of 490 W-hr/kg is calculated for $Mo_{17}O_{47}$. This is comparable to the 480 W-hr/kg reported (28) for TiS_2.

In addition to investigating the electrochemical properties of $Mo_{17}O_{47}$ we have also investigated the magnetic properties of both $Mo_{17}O_{47}$ and the bronze $Li_{1.41}MoO_{2.765}$. In order to determine if there is any change of the Pauli paramagnetism of $Mo_{17}O_{47}$ to local moment behavior at high lithium contents, the magnetic susceptibilities of both $Mo_{17}O_{47}$ and $Li_{1.41}MoO_{2.765}$ were measured from 4.2° to 300°K (Fig. 4). A weak local magnetic moment appears to be present when the sample is lithiated. This is in marked contrast to the magnetic susceptibility of V_6O_{13} which is effected at very low levels of lithium incorporation (22). The magnitude of the susceptibility of $Mo_{17}O_{47}$ at 300°K is $\chi_g = 3.08 \times 10^{-7}$ emu/g compared to the previously reported value of 0.85×10^{-6} emu/g (29). However, it might be expected that the magnetic susceptibility is anisotropic, and random orientation of the powder crystallites is not assured in this or the previous work. The susceptibility decreases slightly with decreasing temperature to $\chi_g = 2.60 \times 10^{-7}$ emu/g at 4.2°K. This weakly temperature dependent, positive value of the susceptibility is due to the Pauli paramagnetism of the conduction electrons in the metallic compound. The susceptibility of the bronze $Li_{1.41}MoO_{2.765}$ can be fit by a simple Curie-Weiss expression above 15°K: $\chi_g = 0.85 \times 10^{-6} + 72.2 \times 10^{-6}/(T + 7.0)$ (emu/g). The magnetic moment per molybdenum calculated from the Curie constant is only 0.29 Bohr magnetons. However, this temperature dependent term may arise from a small fraction of the sample irreversibly reduced by butyllithium. Consequently, it is not certain that this part of the susceptibility is intrinsic. The positive temperature independent contribution to the susceptibility suggests that the lithium bronze is also a metallic conductor.

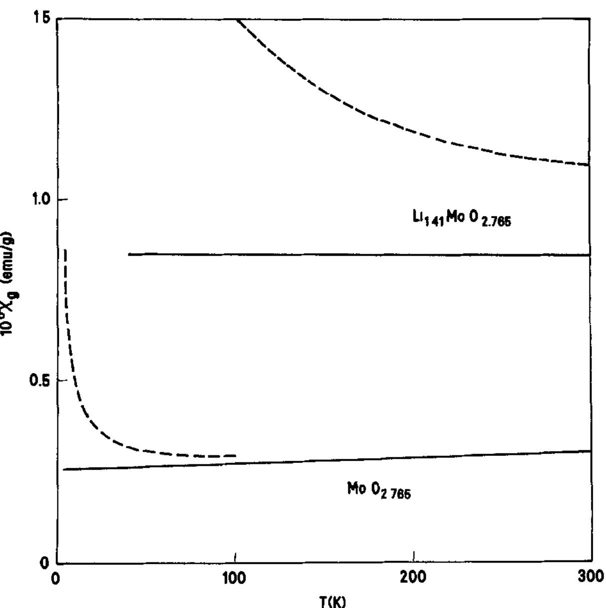

Fig. 4. Magnetic susceptibilities of $Mo_{17}O_{47}$ and $Li_{24}Mo_{17}O_{47}$ bronzes. The dashed lines show the Curie part of the susceptibility. In $Mo_{17}O_{47}$ the Curie part most likely arises from paramagnetic impurities, while in the lithiated product the much larger Curie contribution may arise from a small irreversibly lithiated fraction of the sample.

From this and previous work (26, 30) it is clear that all molybdenum oxides with compositions MoO_x for $2 \leq x \leq 3$ reversibly incorporate Li. In our cells $Mo_{17}O_{47}$ has the highest capacity after several cycles. However the voltage drop for $Mo_{17}O_{47}$ on full discharge (~ 1.9V) is greater than that for both TiS_2 (~ 0.6V) and off-stoichiometric $V_6O_{13.2}$ (~ 0.8V). Also, the average cell voltage of the $Mo_{17}O_{47}$ (1.85V) is somewhat below that of V_6O_{13} (2.2V). Thus, the theoretical energy density of $Mo_{17}O_{47}$ cathodes (490 W-hr/kg) is considerably less than that calculated for off-stoichiometric $V_6O_{13.2}$ (~ 800 W-hr/kg) cathodes (11). Consequently, $Mo_{17}O_{47}$ is not as promising a candidate for use as the active cathode in secondary lithium batteries as off-stoichiometric V_6O_{13}.

Manuscript submitted April 7, 1980; revised manuscript received June 10, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

ABSTRACT

A new rechargeable cell Na/Na^+ ion conductor/SCl_3^+ in molten $AlCl_3$-NaCl is described. This cell operates at temperatures in the range of 180°-250°C and has an open-circuit voltage of 4.2V. The discharge process involves the reduction of tetravalent sulfur to the elemental state; sulfur can be further reduced to sulfide. The preferred sodium ion conductor is β''-alumina. High energy density values, large percent utilization of the active material, and good energy efficiency have been demonstrated. The performance of cells prepared in the discharged and charged states were found to be the same. The number of deep charge/discharge cycles has exceeded 400.

High energy density batteries for load leveling and electric vehicle applications have received considerable attention in recent years. Aqueous, organic, molten salt, and solid electrolytes have been extensively studied; different systems have been tested as possible electrodes (1-6). During the last few years we have examined several possible positive electrodes for batteries using molten chloroaluminates (mainly $AlCl_3$-NaCl mixtures) as solvents and aluminum or sodium as anodes (7-12). Molten chloroaluminates offer many advantages, such as low liquidus temperatures and high conductivity (13, 14), for molten salt battery applications. The acid-base properties of $AlCl_3$-NaCl mixtures and the factors affecting the stability of different oxidation states as a function of both temperature and melt composition are well characterized (15-19). The use of aluminum as the negative electrode is potentially attractive since this metal is quite electropositive, relatively inexpensive, and has a low equivalent weight. In addition, with aluminum electrodes it is possible to obtain high currents without appreciable polarization (20-22). Potential problems caused by dendrite formation during charging and by passivation phenomena (formation of a poorly conducting Al_2Cl_6 layer at high current densities) during the dissolution of aluminum can be minimized by adding selected additives (23) and by using proper melt compositions (24). The compatibility of the sodium electrode separated by β- (or β''-) alumina with chloroaluminate melts has also been demonstrated (25-27).

Molten chloroaluminates have been used as solvents in the Al/Cl_2 (28, 29), Na/Cl_2 (25), Al/S (30, 31), Al/MCl_x (32), and Na/MCl_x (25-27, 33, 34) batteries. Al/Cl_2 batteries have an open-circuit voltage (OCV) of about 2.2V and a high theoretical energy density (~ 1400 W-hr/kg) (28); an OCV of ~ 3.5V has been reported for Na/Cl_2 batteries (25). The problems associated with the use of chlorine, normally adsorbed on carbon powder, make, however, the above batteries somewhat less desirable. Low OCV's (about 1.2V at 200°C) and a relatively poor performance or discharge are reported for Al/S batteries (30, 31). The most developed battery using chloroaluminates is based on the Na/$SbCl_3$ system for which an OCV of 2.83V and a theoretical energy density of 825 W-hr/kg have been reported (25, 34).

This paper describes investigations on the use of positive oxidation states of sulfur, mainly S(IV), as positive electrode materials in $AlCl_3$-NaCl melts in laboratory cells using either aluminum or sodium negative electrodes (7-12). The electrochemistry of sulfur in these melts has been the subject of several studies by our group (35-37) as well as by others (38, 39) and will be recalled here only to the extent which is necessary for a better understanding of the experimental results.

Experimental

Melt preparation and other experimental procedures have been reported elsewhere (40, 41). Sulfur was purified by repeated sublimations under vacuum. S(IV) was introduced into the melt either by electrochemical oxidation of elemental sulfur or as SCl_3AlCl_4. Sulfur tetrachloride could not be used because it is not stable at room temperature. On the other hand, SCl_3AlCl_4 may be prepared rather easily by reacting sulfur with the stoichiometric amount of $AlCl_3$ and a 10% excess chlorine in sealed Pyrex tubes. Details of the preparation and characterization of this salt are reported elsewhere (42). The adduct is stable if handled in a dry

atmosphere and may be dissolved in molten chloroaluminates [stable solutions up to ~ 1*M* in S(IV) have been prepared provided the mole fraction of $AlCl_3$ is greater than 0.5 (see below)].

Different types of cells and separators have been used for single cell experiments. A typical cell consisted of a Pyrex compartment filled with the positive mix which was separated from the negative electrode by means of a β″-alumina tube containing sodium. In some experiments the negative electrode was an aluminum coil immersed in the melt and separated from the positive electrode compartment by means of glass or ceramic frits or coarse α-alumina crucibles. Beta-alumina (or β″-alumina) tubes were obtained from Ceramatec, Incorporated, Ford Motor Company, or the General Electric Company. A typical cell arrangement for an Na/S(IV) cell is shown in Fig. 1. The cells were normally equipped with an Al(III)/Al reference electrode separated from the other compartments by a thin Pyrex membrane. Additional information on laboratory cells is given below.

Commercially available electrochemical instrumentation, such as a Wenking potentiostat Model 66TS3 and Princeton Applied Research potentiostats and digital coulometer Models 173/179, 371, and 379 were used.

Brief review of solvent properties and of sulfur electrochemistry in molten chloroaluminates.—The acid-base properties of molten chloroaluminates and sulfur electrochemistry in these melts are crucial to the understanding of the cells utilizing positive oxidation states of sulfur and are reviewed briefly below.

In the molten chloroaluminate systems the terms "acid" and "base" denote a chloride ion acceptor and a chloride ion donor, respectively (15-18, 43). The acidity of the medium is usually described in terms of *p*Cl ($\equiv -\log [Cl^-]$). For a given ratio of $AlCl_3$ to NaCl the *p*Cl is determined by several equilibria, the predominant equilibrium near the 1:1 $AlCl_3$/NaCl ratio being

$$2AlCl_4^- \rightleftharpoons Al_2Cl_7^- + Cl^- \quad [1]$$

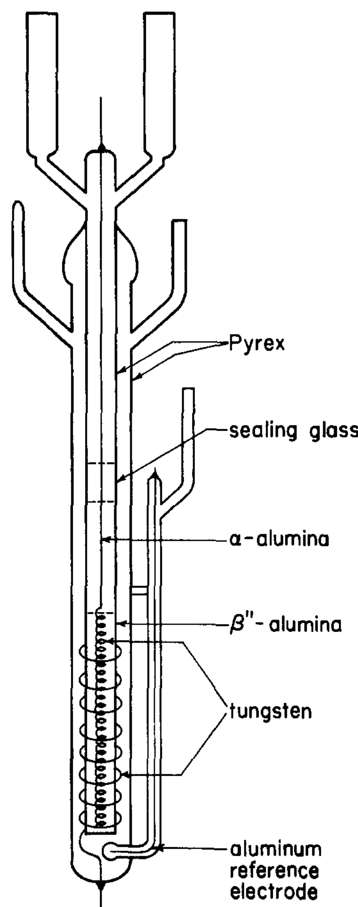

Fig. 1. Typical laboratory cell (not to scale)

The *p*Cl may be measured with either an aluminum or a chlorine electrode immersed in the melt. The lowest *p*Cl corresponds to a melt saturated with NaCl; at 175°C *p*Cl = 1.1 for an $AlCl_3$-$NaCl_{sat.}$ melt (43). The maximum variation in *p*Cl occurs near the 1:1 $AlCl_3$-NaCl ratio. As a result of this variation, concentration cells using aluminum electrodes in melts of different composition have been reported (32); voltages of ~0.6V may be obtained when one of the Al electrodes is in an $NaCl_{sat.}$ melt and the other electrode is in an $AlCl_3$-NaCl [63-37 mole percent (m/o)] melt (≡ 63/37 melt) (16).

Elemental sulfur, present in the melt predominantly as S_8 (44), can be either oxidized or reduced in both basic (excess of NaCl) and acidic (excess of $AlCl_3$) melts (35-38). The reduction of sulfur results in sulfide, probably present as either AlSCl or $AlSCl_2^-$ (39). The cyclic voltammograms at low temperatures (~ 175°C) indicate the presence of a large overpotential for the sulfur/sulfide couple; this couple becomes more reversible at higher temperatures (~ 250°C).

The oxidation of sulfur in basic melts leads to S(I) (36, 38); some evidence for the formation of S(II) at high temperatures (~ 270°C) has also been obtained (36).

In acidic melts (52-63 m/o $AlCl_3$) the electrochemical oxidation of sulfur is quite complex (37, 45). The final oxidation product is S(IV), present as SCl_3^+ as indicated by Raman and potentiometric measurements (46, 47). The intermediate electrochemical oxidation products include S_{16}^{2+} (or S_8^+), S_8^{2+}, and S_2^{2+}. Evidence for S_4^{2+} and S(II) in acidic melts, in addition to the species mentioned above, has been obtained by spectrophotometric measurements (46, 48).

Formal potentials estimated from voltammetric data for various sulfur redox couples in both acidic (63/37) and basic ($NaCl_{sat.}$) melts at 250°C *vs.* three reference electrodes are given in Table I. The potential values in Table I also represent approximate open-circuit voltages (OCV) for cells consisting of the respective sulfur redox couple as the positive electrode and either sodium or aluminum electrode as the negative electrode. Thus, the highest OCV should result for a cell consisting of tetravalent sulfur dissolved in an acidic melt and a sodium electrode. The need for an acidic melt throughout the discharge process, in which S(IV) is reduced to elemental sulfur, stems from the instability of S(IV) in basic melts (36, 47).

Sodium electrode.—Since sodium reacts with molten chloroaluminates to produce aluminum, the sodium electrode must be separated from the melt by means of an Na^+-ion conductor such as β- (or the better conducting β″-) alumina (49, 50). The use of the Na/β-alumina electrode with acidic chloroaluminate melts has been reported previously (26, 27, 34). We have

‡ Values obtained by adding 1.60V (see text) to the values in the third column.

measured the potential of the Na/β''-alumina electrode immersed in the 63/37 melt *vs.* the Al(III)/Al reference electrode in the NaCl saturated melt as -1.60 ± 0.02V at 250°C. The behavior of the Na/β''-alumina electrode under discharge (or charge) conditions is largely dependent on the pretreatment of the β''-alumina tube before and after the addition of sodium and on the temperature of the operation. Additional information is presented below.

Cell chemistry and capacity and energy densities.—Based on the above results several possible cells may be devised using either an aluminum or a sodium negative electrode separated from the positive electrode compartment by a suitable separator. The possible negative electrode reactions are

$$Al + 4Cl^- = AlCl_4^- + 3e \quad [2]$$

$$Na = Na^+ + e \quad [3]$$

In the case of the Al electrode the availability of Cl^- ions is ensured by saturating the melt in the negative electrode compartment with NaCl.

In discussing the chemistry of the positive electrode, the following assumptions are made: (*i*) S(IV) is assumed to be present as SCl_4 in order to simplify the pertinent stoichiometry. (*ii*) S^{2-} is assumed to be solvated by the solvent ions to give AlSCl and $AlSCl_2^-$ in acidic and basic melts, respectively. The reactions describing the discharge and charge of the positive electrode may be written as follows

First step

Electrochemical reaction:

$$SCl_4 + 4e \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} S + 4Cl^- \quad [4]$$

Transport:

$$4Na^+_{\text{(negative electrode)}} \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} 4Na^+_{\text{(positive electrode)}} \quad [5]$$

$$SCl_4 + 4e + 4Na^+ \rightleftharpoons S + 4NaCl \quad [6]$$

where reactions [4] and [6] occur only in acidic melts because of the stability of S(IV).

Second step

$$S + 2e + Al_2Cl_7^- \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} AlSCl + AlCl_4^- + 2Cl^- \quad [7]$$

$$2Na^+_{\text{(negative electrode)}} \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} 2Na^+_{\text{(positive electrode)}} \quad [8]$$

$$S + 2e + 2Na^+ + Al_2Cl_7^- \rightleftharpoons AlSCl + 2NaCl + AlCl_4^- \quad [9]$$

where reactions [7] and [9] occur in acidic melts. The Cl^- ions produced in [6] and [9] react with $Al_2Cl_7^-$ ions to produce $AlCl_4^-$ ions.

In basic melts the following reactions take place

$$S + 2e + AlCl_4^- \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} AlSCl_2^- + 2Cl^- \quad [10]$$

$$2Na^+_{\text{(negative electrode)}} \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} 2Na^+_{\text{(positive electrode)}} \quad [11]$$

$$S + 2e + AlCl_4^- + 2Na^+ \rightleftharpoons AlSCl_2^- + 2NaCl \quad [12]$$

By combining reactions [6], [9], and [12] one obtains

$$SCl_4 + 6e + 6Na^+ + Al_2Cl_7^- \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} AlSCl + 6NaCl + AlCl_4^- \quad [13]$$

$$SCl_4 + 6e + 6Na^+ + AlCl_4^- \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} AlSCl_2^- + 6NaCl \quad [14]$$

where reaction [13] represents the overall electrode reaction for a 6 electron process occurring in two steps in acidic melts, and reaction [14] represents the same 6 electron process in which the first step occurs in acidic and the second in basic melts. In both cases the net result of the electrochemical reaction is a gain of 6 moles of NaCl per mole of S(IV) reduced in the positive electrode compartment. Thus, the melt pCl^- continues to decrease during the discharge process until the melt becomes saturated with NaCl.

The maximum capacity and energy densities (ED) which may be obtained in the case of reactions [13] and [14], respectively, for two selected initial compositions of the solvent are shown in Table II. The energy densities have been computed on the basis of the reactions listed in the first column of Table II which are equivalent to reactions [13] and [14] if the solvation of S^{2-} by the solvent ions is not taken into account. This does not introduce errors because the aluminum content in the positive electrode compartment does not change during the charge or discharge; the weight of the solvent has been included in the energy calculations. The same OCV values have been used in the ED calculations for both initial solvent compositions although the measured OCV's in the 70/30 melt are slightly higher than those in the 63/37 melt. In the case of Al/S(IV) cells the ED's are not listed because their evaluation requires the weight of the solvent in the negative electrode compartment which would be required to keep the compartment basic. It is clear, however, that the additional weight of the solvent, together with the lower OCV's, decreases the specific energy of Al cells compared with Na cells.

Laboratory cells.—We have examined cells using both sodium and aluminum electrodes and S(IV) as the active positive electrode material. The results obtained confirm the feasibility of rechargeable cells of this type. With aluminum electrodes the main problem involves dendrite formation during the charging process. The dendrites can penetrate the separator (such as a coarse α-Al_2O_3 crucible) causing short circuit of the cell. Additional studies of aluminum deposition in the presence of additives to minimize dendrite formation (23) are required in order to demonstrate a practical rechargeable aluminum electrode in these melts. Another problem associated with Al/S(IV) cells is the considerable difference in vapor pressure between the positive and the negative electrode compartments which operate with acidic and basic melts,

respectively, in order to obtain the maximum operating voltage (Table II).

Na/S(IV) cells have given much more satisfactory results. The feasibility of this system has been demonstrated with 4.5 A-hr and smaller capacity cells. The cell size was determined by the dimensions of the ceramic tube. Size A cells used 10 cm long, 10 mm OD β''-alumina tubes which were sealed to an α-Al_2O_3 tube which in turn was sealed to glass; the coulombic capacity of these cells was in the range of 1.5 A-hr. The larger capacity ($\sim$ 4.5 A-hr) size B cells utilized $\sim$ 20 cm long, 15 mm OD β''-alumina tubes which were either sealed in the same manner as size A cells or to Corning 7052 glass (51). The cells were kept under vacuum at 300°-450°C for several days before adding sodium to the ceramic tube; the baking was continued for a few days to improve wetting of the β''-alumina by sodium before adding the positive mix to the external compartment. The performance of the cells depends greatly on the quality and pretreatment of β''- (or β-) alumina, since most of the polarization is related to the separator (see below). The positive mix was prepared by either mixing the acidic melt (typical composition 63/37) with an appropriate amount of SCl_3AlCl_4 in the dry box or by oxidizing elemental sulfur added to a neutral or slightly acidic melt (typical composition 50/50). In some experiments carbon (Shawinigan Black or vitreous carbon foam from Chemotronics International) was also added to the cathode compartment in an attempt to increase the effective surface area of the current collector. However, best results to date have been obtained in the absence of carbon using only a tungsten spiral as the current collector. Tungsten was also used as the current collector in the negative electrode compartment.

Typical galvanostatic charge-discharge curves for a size B cell and the potentials of each electrode *vs.* an

Current density 17.2 mA/cm² for discharge and 8.6 mA/cm² for charge. Discharge time 8.8 hr. Percent utilization is calculated for the 4e⁻ process.

aluminum reference electrode are shown in Fig. 2. The discharge corresponds to the formation of elemental sulfur; it was terminated at the beginning of a sharp drop in the potential of the positive electrode. In some cells the reduction of sulfur to sulfide was also investigated; such discharge curves exhibit a second plateau with a closed-circuit voltage (CCV) of $\sim$ 1V less than that of the first plateau. Only a cursory study of the second plateau has been performed to date. In one size A cell 20 charge/discharge (to sulfide) cycles were attained before failure occurred (see below).

Most of the studies have involved only the first plateau. It may be seen from Fig. 2 that the potential of the sodium electrode is quite constant for both charge and discharge. It is apparent that the processes responsible for the polarization of the Na electrode (more likely, polarization occurring at the β''-alumina interfaces) are the major causes of polarization for the whole cell. The increase in the potential of the S(IV) electrode at the end of the charge process is accompanied by some chlorine evolution. However, the chlorine reacts rapidly with any sulfur species that have not been electrochemically oxidized to the +4 state. This conclusion is supported by the results of vapor pressure measurements during charge and discharge processes (52). The pressures measured differed little from those obtained for pure chloroaluminate melts thus indicating that no significant amounts of gaseous products are formed during normal cell operation. No deleterious effects on the separator by chlorine produced by some overcharge have been observed.

A decrease in the utilization of the active positive electrode material and an increase in polarization were observed with increasing current density (Fig. 3). With the present configuration the maximum current densities applied were 70 mA/cm² for discharge and 35 mA/cm² for charge (current densities were based on the inner area of the β''-alumina). At high current densities the mass transfer of sulfur species probably could not keep up with the electrochemical steps. A different cell configuration will be required to solve this problem. The variation of CCV with current density at three different temperatures is shown in Fig. 4. Ohmic polarization is indicated by the linearity of the plots; approximately equal slopes are observed for both charge and discharge processes. The effective "resistance" of the β''-alumina separator that may be estimated from Fig. 4 ($\sim$ 80 Ω cm at 220°C) is considerably higher than the value reported for pure β''-alumina (6.5 Ω cm at 220°C) (53). Further studies of the causes of polarization at the separator interfaces are currently in progress (54).

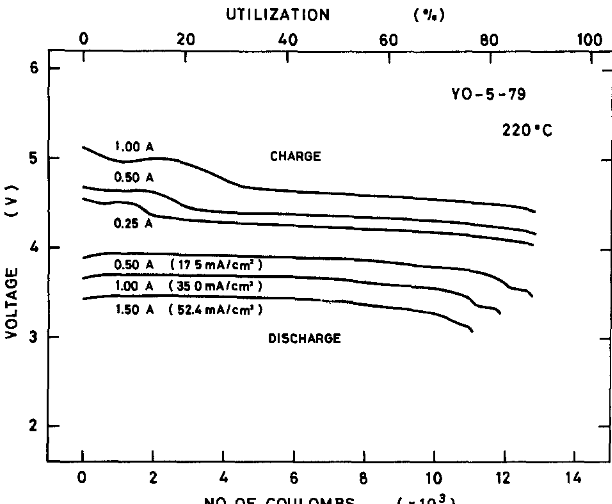

Fig. 3. Galvanostatic charge-discharge curves at several current densities at 220°C.

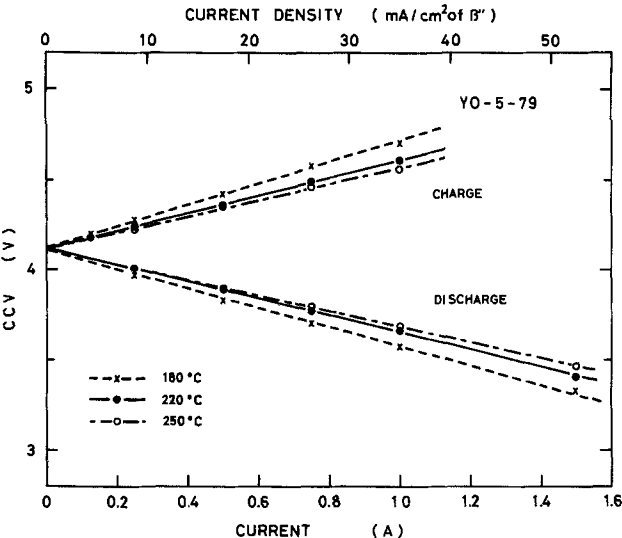

Fig. 4. Current dependence of the CCV measured at the midpoint of discharge at three temperatures.

The cell performance was studied in the temperature range 180°-255°C. As expected, the polarization decreased with increasing temperature (Fig. 4, 5). However, some loss in the percent utilization of S(IV) and in the energy density (this parameter does not include the weight of the separator or that of the cell) with temperature was observed (Fig. 6). Further studies in this area are in progress. Typical cell parameters are given in Table III.

The variation of the percent utilization of S(IV) and average discharge and charge voltage with the number of cycles is shown in Fig. 7. It may be seen that the voltages and percent utilization are reasonably constant. One cell has been in continuous operation for more than 9 months; the number of deep discharge/charge cycles has exceeded 400.

Most of the early cell failures were caused by the formation of cracks in the β"-alumina or in the β"-α alumina seal. These problems have been minimized by lengthening the pretreatment of the separator (currently 2 weeks at 350°C). The performance of the cells is independent of which species, elemental sulfur or SCl_3AlCl_4, is chosen as the starting material.

Only β"-alumina has been found satisfactory as the separator material. The cells prepared with β-alumina tubes exhibited excessive polarization. The NASICON is gradually attacked by the solvent.

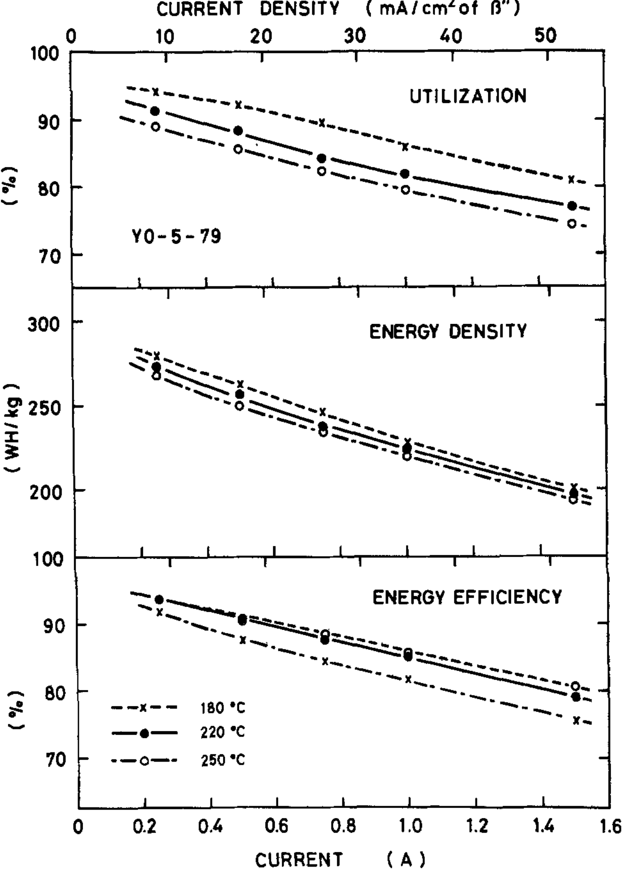

Fig. 6. The dependence of the percent utilization and energy efficiency and of the energy density on the current density at three temperatures.

In summary, our experimental results obtained with laboratory cells demonstrate the feasibility of the rechargeable Na/S(IV) chloroaluminate battery. Such a battery possesses several advantages, such as (*i*) very high voltage, (*ii*) high energy densities, (*iii*) low operating temperature compared to the lithium (aluminum)-iron sulfide and the sodium-sulfur batteries, (*iv*) effective utilization of sulfur (4 or 6 electrons exchanged per sulfur atom), and (*v*) inexpensive active electrode materials (sulfur and sodium).

Good energy efficiency values have been obtained with relatively simple cell designs.

Based on considerations presented above we believe that the development of the Na/S(IV) chloroaluminate

Defect Structure, Ionic Conductivity, and Diffusion in Calcia-Stabilized Zirconia

Akio Nakamura* and J. Bruce Wagner, Jr.*

Center for Solid State Science, Arizona State University, Tempe, Arizona 85281

ABSTRACT

A quantitative theoretical model which accounts for the variations of ionic conductivity of calcia-stabilized zirconia, $Ca_{2x}Zr_{1-2x}O_{2-2x}$, with oxygen vacancy concentration, x, and temperature, T, has been developed based on the consideration of effective anion-site coordination of effectively negatively charged calcium ion, $Ca^{2'}$. The theory extends the conventional concept of dopant-defect complexes (or associates) and demonstrates that ionic conduction in this system proceeds by a multimode mechanism through and between different degrees of dopant-defect associates. The primary mechanism is oxygen transport through the channel of onefold effectively $Ca^{2'}$ coordinated anion sublattice, that is, oxygen vacancy $V_O^{2\cdot}$ transport inside the onefold bonded ($Ca^{2'}$-$V_O^{2\cdot}$) defect complex. The theory subsequently predicts the occurrence of a rather sharp maximum of ionic conductivity at oxygen vacancy concentration $x = 0.0625$ and reproduces the experimental isothermal log σ *vs.* x curves reported by various investigators quite satisfactorily. Accordingly, numbers of parameters which characterize the defect structure, the ionic conduction, and the diffusion process in this system are derived from the curve-fitting procedure of the theoretical expression for ionic conductivity with experimental ones.

It is now well recognized that zirconia stabilized in the cubic fluorite structure by substitution of aliovalent oxides, such as CaO, Y_2O_3, and rare earth oxides, is essentially an oxide ion conductor with its high ionic conductivity due to high oxygen vacancy concentration introduced into the anion sublattice by these substitutions (1). Numerous experimental works on electrical conductivity on these systems have shown that ionic conductivity of these systems exhibits a maximum value around the minimum dopant level required to stabilize the cubic fluorite phase at constant temperature. For example, in CaO-stabilized zirconia, $Ca_{2x}Zr_{1-2x}O_{2-2x}$, the maximum occurs around 12-13 mole percent (m/o) CaO content (2-5) ($x = 0.060$-0.065) and in the Y_2O_3-stabilized zirconia, $Y_{4x}Zr_{1-4x}O_{2-2x}$, around 8-9 m/o Y_2O_3 content (2, 4, 6) ($x = 0.037$-0.041). At higher concentrations within the cubic fluorite phase regions, the ionic conductivity decreases with increasing dopant content. The activation energy for ionic conduction is also reported to increase with increasing dopant content (4, 5). Similar behavior is also reported in the other fluorite oxide systems, *i.e.*, ThO_2 (7) and CeO_2 (8) based solid electrolytes, where, since pure thoria and ceria have cubic fluorite structure, dopants such as CaO and Y_2O_3 are used only to introduce the extrinsic oxygen vacancies into the anion sublattice. This decrease in ionic conductivity with increasing vacancy concentration has been qualitatively regarded as the result of vacancy ordering (5) vacancy clustering (9), or dopant-vacancy association (10) in the higher oxygen vacancy concentration range.

Recently, several attempts to explain this behavior have been undertaken: O'Keeffe (11) and Barker and Knop (12) have shown that when vacancy-vacancy repulsive interaction is so strong that the numbers of the first and the second nearest neighbor vacancy-vacancy configurations are prohibited, the maximum in ionic conductivity shifts to the lower vacancy concentration ranges than that expected from the usual hopping model in which $\sigma \propto x(1 - x)$, so that σ_{max} is expected at $x = 0.5$. Casselton (6) for the Y_2O_3-ZrO_2 system and Hammou (13) for the Y_2O_3-ThO_2 system, respectively, proposed models to explain this behavior using the extended Lidiard model (14) which is based on the presence of dopant-vacancy complexes and Debye-Hückel type interactions. Hammou also tested Barker's model mentioned above. None of these models resulted in quantitative agreement with experimental data.

* Electrochemical Society Active Member.
Key words: electrolyte, conductance, transport.

Most recently, Schmalzried (15) interpreted these phenomena under the assumptions of (*i*) Debye-Hückel type electrostatic interaction for low defect concentration range and (*ii*) ordering of oppositely charged defects for high defect concentration range, neglecting the formation of defect associates. Schmalzried showed that these assumptions lead to a decrease of the correlation factor of defects with increasing defect concentration and also to an increase in the activation energy for defect motion in a qualitative manner. Judging from the preceding brief literature survey, there seems to exist no theoretical model which accounts for the phenomena in these systems in a quantitative manner. Accordingly, the aim of the present paper is to propose an alternative theoretical model to serve this purpose by choosing calcia-stabilized zirconia as a representative system.

In the next section, a brief survey of the ionic conductivity data of calcia-stabilized zirconia reported in literature is given, and in the subsequent section the theoretical model is described.

Ionic Conductivity Data of Calcia-Stabilized Zirconia, $Ca_{2x}Zr_{1-2x}O_{2-2x}$, System

Figure 1 shows the isothermal log σ *vs.* oxygen vacancy concentration x plots at T = 600°, 800°, 1000°, 1200°, and 1400°C reported in literature. Included are data only by the authors who studied σ as a function of dopant content in a systematic manner.

The data of Stricker and Carlson (2), Tien (3), Dixon *et al.* (4), and Tien and Subbarao (5) all agree that the stability region of the cubic fluorite phase extends from around 12-13 m/o CaO to around 20-22 m/o CaO at temperatures between approximately 600° and 1400°C. Furthermore, the conductivity maximum exists inside the cubic fluorite phase near the monoclinic-cubic solid solution phase boundary, *i.e.*, at 12-13 m/o CaO content (x = 0.060-0.065). In contrast, Carter and Roth (16) report that the stability region extends from about 10 to 19 m/o CaO at 1400°C and their data seem to show the tendency that the conductivity maximum shifts from around 13 m/o CaO at 1000°C to 15 m/o CaO at 1400°C.

As is apparent from Fig. 1, the ionic conductivity of calcia-stabilized zirconia initially increases with oxygen vacancy concentration x, and reaches a maximum around 12-13 m/o CaO content (x = 0.060-0.065). The conductivity then decreases, initially rather sharply and then more slowly, with oxygen vacancy concentration x within the cubic fluorite phase region. The rate of decrease of ionic conductivity with x increases with decreasing temperature and the conductivity decreases by a factor of ~1/20 at 600°C when x increases from 0.065 to 0.100. This means that the activation energy for ionic conduction increases with x. Typical values are 26.2 kcal/mole for 13 m/o CaO and 31.1 kcal/mole for 20 m/o CaO (5).

Another interesting feature is the order-disorder transition. Subbarao *et al.* (5, 17) observed this phenomenon below 1000°C in samples with higher CaO content (18 and 20 m/o CaO). Some of these data, designated as "ordered," are also included in Fig. 1. "Ordered" samples at these compositions have a lower but finite conductivity which is converted to that of the "disordered" phase after heat-treatments at 1400°C. Carter and Roth (16) also examined this order-disorder phenomenon rather extensively. Their data indicate that below 1100°C, even in samples with low CaO content (13.2 and 14.2 m/o CaO), in some cases the resistivity changes by a factor of over 10, showing no tendency to saturate with time. The reason for this discrepancy between Subbarao *et al.* (5, 17) and Carter and Roth (16) is not clear at present, although it seems reasonable to assume from these observations that in samples with higher CaO content and at lower temperatures calcium ions $Ca^{2\prime}$ and oxygen vacancies $V_O^{2\cdot}$ would order in some fashion which causes the

substantial decrease in ionic conductivity after prolonged heat-treatments.

Theoretical

The main aim of the theoretical model is to reproduce the experimental log σ *vs.* x curves shown in Fig. 1 over the entire temperature ranges in a quantitative manner consistent with the physical reality of the system. This includes the increase in activation energy for ionic conduction with x.

As far as the authors are aware, Kröger (10) was the first to suggest that ionic conduction and oxygen diffusion in calcia-stabilized zirconia (CSZ) probably occurs via migration of oxygen vacancies $V_O^{2\cdot}$ in $(Ca_{Zr}V_O)_m^x$. Kröger described this association process by a usual defect equilibrium equation

$$mCa_{Zr}^{2\prime} + mV_O^{2\cdot} \rightleftarrows (Ca_{Zr}V_O)_m^x \quad [1]$$

Applying the mass action law to the above equation and assuming electrostatic binding energy of the defect complex, Kröger concluded that most of the calcium (and therefore $V_O^{2\cdot}$) is present as neutral calcium ion-oxygen vacancy pairs or clusters. This description corresponds in general form with the theory of Lidiard

for aliovalent impurity diffusion in alkali-halide systems (14). But when the impurity (dopant) concentration and therefore also the defect concentration becomes as high as in CSZ, these treatments do not appear to be valid. First, let us assume that oxygen and therefore $V_O^{2\cdot}$ diffusion proceeds via defect complexes $(Ca_{Zr}V_O)^x$ ($m = 1$ in Eq. [1]). In the fluorite structure, since every cation has 8-first, 24-second, 24-third . . . nearest neighbor anion sites, all the anion sites will be just effectively onefold coordinated by dopant cations $Ca^{2'}$ when the dopant concentration reaches $2x = 2/Z'$ for $Ca_{2x}Zr_{1-2x}O_{2-2x}$, *i.e.*, in this case $Z' \cdot 2x = 2$, where Z' is the effective anion site coordination number of $Ca^{2'}$ in this system. This means that at the composition $x = 1/Z'$, every $V_O^{2\cdot}$ jump occurs inside $(Ca^{2'}\text{-}V_O^{2\cdot})$ onefold effectively associated defect complexes. Therefore, conductivity should be a maximum. Beyond this composition the average effective $Ca^{2'}$ coordination number to the anion sublattice becomes greater than 1, *i.e.*, the number of density of 2-fold $Ca^{2'}$ coordinated anion sites becomes an appreciable fraction of the total available jump sites; so the ionic conductivity should decrease, because the effective path for $V_O^{2\cdot}$ migration through $(Ca^{2'}\text{-}V_O^{2\cdot})$: 1-fold effectively $Ca^{2'}$ associated defect complexes decreases. This is indeed the case for CSZ if we assume an effective anion site coordination number of $Ca^{2'}$: $Z' = 16$: the experimental observed ionic conductivity maximum occurs around $x = 0.060\text{-}0.065$, whereas the theoretically derived conductivity maximum is expected at $x = 1/Z' = 1/16 = 0.0625$. If only the first nearest neighbor $Ca^{2'}\text{-}V_O^{2\cdot}$ configuration is taken into account, Z' becomes equal to 8, and the conductivity maximum is expected at $x = 1/8 = 0.125$, which is almost twice the observed oxygen vacancy concentration at the maximum. This means that the second and the higher order nearest neighbor $Ca^{2'}\text{-}V_O^{2\cdot}$ configurations also contribute to the effective anion site coordination number of $Ca^{2'}$, Z', with a contribution that is equal to that from the first nearest neighbor $Ca^{2'}\text{-}V_O^{2\cdot}$ configuration ($Z' = 8$). This fact seems to be quite reasonable in the light of the rather long-range character of electrostatic interaction between charged defects $Ca^{2'}\text{-}V_O^{2\cdot}$ (18). We might regard the first nearest neighbor $Ca^{2'}$ and $V_O^{2\cdot}$ configuration as the ground state of the $(Ca^{2'}\text{-}V_O^{2\cdot})$ defect complex, and the second (and the higher order) nearest neighbor $Ca^{2'}\text{-}V_O^{2\cdot}$ configuration as the first excited state (and the higher order excited states) of the $(Ca^{2'}\text{-}V_O^{2\cdot})$ defect complex.

But actually the greater the distance between $Ca^{2'}$ and $V_O^{2\cdot}$, the more the electrostatic interaction between them would be increasingly screened and weakened. Consequently we include here only the first nearest neighbor and the second nearest neighbor $Ca^{2'}\text{-}V_O^{2\cdot}$ configurations, assuming further that $Ca^{2'}$ coordination number to each 24-second nearest neighbor anion sites is $\sim 1/3$. At this level of approximation, the total effective coordination number of $Ca^{2'}$ to anion sites Z' becomes equal to $(8 \times 1) + (24 \times 1/3) = 16$, which yields the conductivity maximum at $x = 0.0625$ in accordance with experimental observations.

When the CaO content becomes 25 m/o, *i.e.*, $x = 0.125$, the effective anion site coordination number of $Ca^{2'}$ becomes 2, *i.e.*, $Z' \cdot 2x/2 = 2$. This situation is shown in Fig. 2a. Figure 2a shows the unit cell of $Ca_{0.25}Zr_{0.75}O_{1.75}V_{O0.25}$ ($x = 0.125$). The unit cell of the fluorite structure contains 4 cations and 8 anions. So at the composition $2x = 1/4$, one out of four cations is $Ca^{2'}$. In Fig. 3 these $Ca^{2'}$ are situated at the eight corner cation sites of the unit cell. The remaining three cations are Zr^x, which are situated at the face center position of six face planes. One out of 8 anions in the unit cell is $V_O^{2\cdot}$ ($x = 1/8$). As is apparent from this figure, 1/4 of the four (= 1) first nearest neighbor cations around $V_O^{2\cdot}$ is $Ca^{2'}$, which yields onefold $Ca^{2'}$ coordination to $V_O^{2\cdot}$, and 1/4 of the twelve (= 3) second nearest neighbor cations around $V_O^{2\cdot}$ are $Ca^{2'}$,

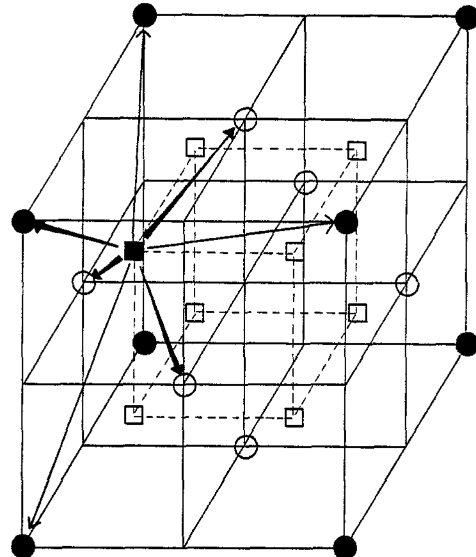

Fig. 2a. Unit cell of the fluorite lattice of $(CaO)_{0.25}(ZrO_2)_{0.75}$ ($2x = 1/4$, $x = 0.125$).

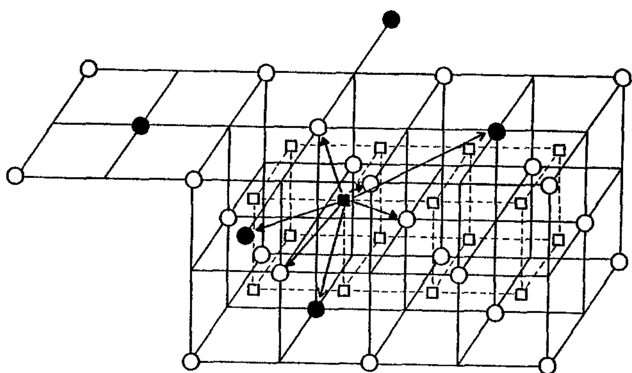

Fig. 2b. $Ca^{2'}\text{-}V_O^{2\cdot}$ configuration in $(CaO)_{0.125}(ZrO_2)_{0.875}$($2x = 1/8$, $x = 0.0625$). ● $Ca^{2'}$, ○ Zr^x, □ O^x, ■ $V_O^{2\cdot}$, → 4 first nearest neighbor cations around $V_O^{2\cdot}$, ⟶ 3 (out of 12) second nearest neighbor $Ca^{2'}$ around $V_O^{2\cdot}$.

which yields another onefold coordination to $V_O^{2\cdot}$. So, at this composition every $V_O^{2\cdot}$ (and anion site) is on an average twofold $Ca^{2'}$ coordinated and every $V_O^{2\cdot}$ jump occurs inside effectively twofold associated $(Ca^{2'}\text{-}V_O^{2\cdot}\text{-}Ca^{2'})$ defect complexes. Similarly, Fig. 2b shows the $Ca^{2'}\text{-}V_O^{2\cdot}$ configuration in $Ca_{0.125}Zr_{0.875}O_{1.875}V_{O0.125}^{2\cdot}$ ($x = 0.0625$) where every two unit cells contain one $Ca^{2'}$ ($2x = 1/8$) and one $V_O^{2\cdot}$ ($x = 1/16$). In Fig. 2b, $Ca^{2'}$ are situated at face centered positions of the top plane or bottom plane in an alternative array. Every $V_O^{2\cdot}$ (and anion site) is just onefold coordinated by $Ca^{2'}$, either by one first nearest neighbor $Ca^{2'}$ (= 1) or by three second nearest neighbor $Ca^{2'}$ ($1/3 \times 3 = 1$). So at this composition every $V_O^{2\cdot}$ jump occurs inside effectively onefold associated $(Ca^{2'}\text{-}V_O^{2\cdot})$ defect complexes.

Note that the stabilized cubic fluorite phase appears just when onefold associated $(Ca^{2'}\text{-}V_O^{2\cdot})$ defect complexes extend throughout the anion sublattice, giving rise to a conductivity maximum ($x = 0.0625$); and disappears with the disappearance of this defect complex ($x = 0.125$). In these defect concentration ranges, conventional defect equilibria treatments such as Eq. [1] are not applicable, for there exist no more free dissociated anion sites on which $V_O^{2\cdot}$ can reside.

Description of the Theoretical Model

Let us designate at a given composition x, the relatively free state, and the relatively bound state of the

anion sublattice for $V_O^{2\cdot}$ as F and B, respectively. In the case of CSZ within the vacancy concentration range $0.0625 \leq x \leq 0.125$ over which the cubic fluorite phase extends, we can assume that the F-state and the B-state correspond to the 1-fold $Ca^{2'}$ coordinated and 2-fold $Ca^{2'}$ coordinated anion sublattice, respectively. This follows because the $Ca^{2'}$-average coordination number to the anion sublattice is $1 \leq \frac{Z' \cdot 2x}{2} = 16x \leq 2$. For each concentration of F-state and B-state, the site fractions N_F and N_B will be given by the following equation

$$1 \times N_F + 2 \times N_B = Z' \cdot 2x/2 = 16x, \quad N_F + N_B = 1,$$
$$N_F = 2 - 16x, \quad N_B = 16x - 1$$
$$0.0625 \leq x \leq 0.125 \quad [2]$$

Equation [2] neglects the statistical fluctuations of the system. The distribution of oxygen vacancies $V_O^{2\cdot}$ and oxide ions O^x between these states is assumed to be given by the following quasi-chemical equilibria

$$V_O^{2\cdot}(B) + O^x(F) \rightleftarrows V_O^{2\cdot}(F) + O^x(B) \quad [3]$$

Applying the mass action law to Eq. [3] yields

$$K = \exp\left(-\frac{\Delta G^\circ}{RT}\right) = \exp\left(\frac{\Delta S^\circ}{R}\right) \cdot \exp\left(-\frac{\Delta H^\circ}{RT}\right) = \frac{[V_O^{2\cdot}(F)][O^x(B)]}{[V_O^{2\cdot}(B)][O^x(F)]} \quad [4]$$

where K, ΔG°, ΔH°, and ΔS° denote the equilibrium constant, standard Gibbs free energy change, standard enthalpy change, and standard entropy change for Eq. [3], respectively, and [ ] designates the concentration of each chemical species in site fractions.

From the site and mass conservation, the following equations hold

$$[V_O^{2\cdot}(\text{total})] = [V_O^{2\cdot}(F)] + [V_O^{2\cdot}(B)] = x$$
$$N_F + N_B = 1$$
$$[V_O^{2\cdot}(F)] + [O^x(F)] = N_F$$
$$[V_O^{2\cdot}(B)] + [O^x(B)] = N_B \quad [5]$$

Rearranging Eq. [5] yields

$$[V_O^{2\cdot}(B)] = x - [V_O^{2\cdot}(F)]$$
$$[O^x(F)] = N_F - [V_O^{2\cdot}(F)]$$
$$[O^x(B)] = 1 - N_F - x + [V_O(F)] \quad [6]$$

Inserting Eq. [6] into [4], the following quadratic equation for $[V_O^{2\cdot}(F)]$ is obtained

$$(1-K)[V_O^{2\cdot}(F)]^2 + \{K(x+N_F) + (1-N_F-x)\}[V_O^{2\cdot}(F)] - K \cdot N_F \cdot x = 0 \quad [7]$$

Solving Eq. [7] for $[V_O^{2\cdot}(F)]$ (> 0) yields

$$[V_O^{2\cdot}(F)] = \frac{-\{K(x+N_F) + (1-N_F-x)\} + \sqrt{\{K(x+N_F) + (1-N_F-x)\}^2 + 4xK(1-K)N_F}}{2(1-K)} \quad [8]$$

Then, from Eq. [8] and [6], all the concentrations of each chemical species can be obtained given K and x.

The total ionic conductivity of the system $\sigma_{(\text{total})}$ will be given by the sums of partial ionic conductivity $\sigma_{i\text{-}j}$ (i, j = F, B)

$$\sigma_{\text{total}} = \sum_{i\cdot j=F\cdot B} \sigma_{i\text{-}j} = \sum_{i\cdot j=1\cdot 2} \sigma_{i\text{-}j} \quad [9]$$

For simplicity, the indexes F and B were designated by 1 and 2 respectively, where $\sigma_{1\text{-}1}$ and $\sigma_{2\text{-}2}$ designate the partial ionic conductivity due to $V_O^{2\cdot}$ transport through

Fig. 3. Schematic variation of σ with oxygen vacancy concentration x when $V_O^{2\cdot}$ transport only through $Ca^{2'}$-1-fold coordinated anion sublattice is assumed. Numbers beside each curve at $0.0625 \leq x \leq 0.125$ designate K values of Eq. [16].

the channels of the 1-fold $Ca^{2'}$ coordinated and 2-fold $Ca^{2'}$ coordinated anion sublattice, respectively, and $\sigma_{1\to2}$ and $\sigma_{2\to1}$ designate those due to $V_O^{2\cdot}$ transport from 1- to 2-(or reverse)fold $Ca^{2'}$-coordinated anion sublattice.

Each partial ionic conductivity will be given by the following expression utilizing the usual form for hopping ionic conduction

$$\sigma'_{i\text{-}j} = \frac{\sigma_{i\text{-}j}}{N \cdot Z \cdot e} = [V_O^{2\cdot}(i)] \cdot \frac{N_j}{N_i + N_j} \cdot \left(1 - \frac{[V_O^{2\cdot}(j)]}{N_j}\right) \cdot \mu_{(i\text{-}j)} = \frac{[V_O^{2}(i)][O^x(j)]}{N_i + N_j} \cdot \mu_{(i\text{-}j)} \quad [10]$$

where $\mu_{(i\text{-}j)}$ denotes the mobility of $V_O^{2\cdot}$ for the i-j jump process. Each partial ionic conductivity $\sigma'_{i\text{-}j}$ is normalized by the numerical factor, $(N \cdot Z \cdot e)^{-1}$ from the actual ionic conductivity $\sigma_{i\text{-}j}$. In this expression N is numbers of anion sites per unit volume (cm^3), Z is valence number of $V_O^{2\cdot}$, and e is the electronic charge.

From dynamic equilibria between 1- and 2-states

$$\sigma'_{1\to2} = \sigma'_{2\to1} \quad [11]$$

Combination of Eq. [4], [10], and [11] yields

$$K = \frac{\mu_{(2\to1)}}{\mu_{(1\to2)}} = \exp\left(-\frac{\Delta G^\circ}{RT}\right) \quad [12]$$

Equation [12] is the well-known relationship for chemical equilibria resulting from opposing elementary reaction processes.

Inserting Eq. [10] into Eq. [9], the final expression for the normalized total ionic conductivity of the system is obtained

$$\sigma'_{\text{normalized}} = \frac{\sigma_{\text{total}}}{N \cdot Z \cdot e} = \sigma'_{1\text{-}1} + \sigma'_{2\text{-}2} + 2\sigma'_{2\to1}$$
$$= [V_O^{2\cdot}(1)][O^x(1)]\mu_{(1\text{-}1)} + [V_O^{2\cdot}(2)][O^x(2)]\mu_{(2\text{-}2)} + 2[V_O^{2\cdot}(2)][O^x(1)]\mu_{(2\to1)} \quad (N_1 + N_2 = 1) \quad [13]$$

where $[V_O^{2\cdot}(i)]$ and $[O^x(i)]$ (i = 1, 2) are given by Eq. [6] and [8] for a given K and x.

Basic Character of Theoretical Model

We will first examine the theoretical model in more qualitative but illustrative manner. For this purpose, for mathematical simplicity, we will adopt the following approximation in this section: $[V_O^{2\cdot}(i)] << [O^x(i)] \cong N_i$ (i = F, B), (which corresponds to neglecting the $(1 - x)$ term in the conventional $\sigma \propto x(1-x)$ form by assuming $(1 - x) \sim 1$). At this level of approximation, Eq. [3] can be easily solved to give

$$[V_O^{2\cdot}(F)] = \frac{x \cdot N_F \cdot \exp(-\Delta G^\circ/RT)}{N_B + N_F \cdot \exp(-\Delta G^\circ/RT)} = \frac{x \cdot N_F \cdot K}{N_B + N_F \cdot K}$$

$$[V_O^{2\cdot}(B)] = x - [V_O^{2\cdot}(F)] = \frac{x \cdot N_B}{N_B + N_F \cdot \exp(-\Delta G^\circ/RT)} = \frac{x \cdot N_B}{N_B + N_F \cdot K} \quad [8']$$

Using Eq. [2] for N_F and N_B, and also Eq. [13] for $\sigma'_{\text{normalized}}$ the following expression for $\sigma'_{\text{normalized}}$ is obtained, valid for $0.0625 \leq x \leq 0.125$

$$\sigma'_{\text{normalized}} = \frac{\sigma_{\text{total}}}{N \cdot Z \cdot e} = \frac{x}{(16x - 1) + (2 - 16x) \cdot K} \times \{(2 - 16x)^2 \cdot K \cdot \mu_{(1\text{-}1)} + 2(2 - 16x)(16x - 1) \cdot \mu_{(2\rightarrow1)} + (16x - 1)^2 \mu_{(2\text{-}2)}\} \quad [14]$$

Following the same procedure, for the composition range $0 \leq x \leq 0.0625$

$$N_F = N_0 = (1 - 16x): \text{ (Ca}^{2\prime}\text{-0-fold state)}$$

$$N_B = N_1 = 16x: \text{ (Ca}^{2\prime}\text{-1-fold state)}$$

and

$$\sigma'_{\text{normalized}} = \frac{x}{16x + (1 - 16x) \cdot K'} \times \{(1 - 16x)^2 \cdot K' \cdot \mu_{(0\text{-}0)} + 2 \cdot (1 - 16x) \cdot 16x \cdot \mu_{(1\rightarrow0)} + (16x)^2 \cdot \mu_{(1\text{-}1)}\} \quad [15]$$

where $K' = \exp(-\Delta G^{\circ\prime}/RT)$ and $\Delta G^{\circ\prime}$ designates the Gibbs free energy difference between $Ca^{2\prime}$-0-fold and 1-fold states.

When $\Delta G^{\circ\prime} = \Delta G^\circ = 0$ ($K' = K = 1$), all the sites become energetically equivalent, so all the $\mu_{(i\text{-}j)}$ become equal and $\sigma'_{\text{normalized}} \propto x$ from Eq. [14] and [15].

Another interesting limiting case is the one in which ionic conduction occurs exclusively inside the channel of the $Ca^{2\prime}$-1-fold coordinated anion sublattice, (*i.e.*, $K' << 1$, $\mu_{(1\text{-}1)} >> \mu_{(0\text{-}0)}, \mu_{(1\rightleftarrows0)}$, $K < 1$, $\mu_{(1\text{-}1)} >> \mu_{(2\text{-}2)}, \mu_{(2\rightleftarrows1)}$). In this case from Eq. [14] and [15]

$$\sigma'_{\text{normalized}} = x \cdot 16x \cdot \mu_{(1\text{-}1)}; \quad 0 \leq x \leq 0.0625$$

$$= \frac{x(2 - 16x)^2 \cdot \mu_{(1\text{-}1)} \cdot K}{(16x - 1) + (2 - 16x) \cdot K} \quad 0.0625 \leq x \leq 0.125 \quad [16]$$

Figure 3 shows $\sigma'_{\text{normalized}}/\mu_{(1\text{-}1)}$ *vs.* x curves using $K = \exp(-\Delta G^\circ/RT)$ as parameter. Included also is the usual curve, $\sigma \propto x$. It is apparent from this figure that if ionic conduction proceeds only via $Ca^{2\prime}$-1-fold associated ($Ca^{2\prime}$-$V_O^{2\cdot}$) defect complexes, there appears a rather sharp conductivity maximum at $x = 0.0625$, and then σ decreases more rapidly, the smaller the value of K.

These features are qualitatively in fair agreement with experimental observations as shown in Fig. 1.

From Eq. [16] the maximum conductivity σ'_{max} at $x = 0.0625$ is given by

$$\sigma'_{\text{normalized(max)}} = \sigma'_{1\text{-}1}(x = 0.0625) = 0.0625\mu_{(1\text{-}1)} \quad [17]$$

However, in this approximation, according to Eq. [16] ionic conductivity becomes equal to zero at $x = 0.125$ where the $Ca^{2\prime}$-1-fold coordinated anion sublattice disappears. At this composition, only the $Ca^{2\prime}$-2-fold coordinated anion sublattice exists (see Fig. 2a), so from Eq. [14] we obtain

$$\sigma'_{\text{normalized}}(x = 0.125) = \sigma'_{2\text{-}2}(x = 0.125) = 0.125 \cdot \mu_{(2\text{-}2)} \quad [18]$$

Equations [17] and [18] indicate that from the conductivity data at $x = 0.0625$ and 0.125, we can obtain the mobility $\mu_{(1\text{-}1)}$ and $\mu_{(2\text{-}2)}$ inside the separate channels. Using these values of $\mu_{(1\text{-}1)}$, $\mu_{(2\text{-}2)}$, we can draw the theoretical log σ *vs.* x curves over the whole range of $0.0625 \leq x \leq 0.125$, choosing appropriate values of K and $\mu_{(2\rightarrow1)}$.

Numerical Evaluation of the Theoretical Model

In order to obtain mobilities $\mu_{(1\text{-}1)}$ and $\mu_{(2\text{-}2)}$, approximate values of $\sigma_{\text{total(max)}} = \sigma_{1\text{-}1}(x = 0.0625)$, and $\sigma_{\text{total}}(x = 0.125) = \sigma_{2\text{-}2}(x = 0.125)$ were read from experimental log σ *vs.* x plots shown in Fig. 1. For $x = 0.125$ which is well beyond the cubic fluorite phase so that experimental points for σ_{total} are not available, extrapolations from the data points around $x \sim 0.100$ composition were made. Moreover, the values of σ_{max} at $x = 0.625$ and σ_{total} at $x = 0.125$, were also adjusted to get the best fit between theoretical and experimental curves in the subsequent calculations. At a given pair of such σ's, $\mu_{(1\text{-}1)}$ and $\mu_{(2\text{-}2)}$ were calculated from Eq. [17′] and [18′]

$$\sigma'_{\text{max}} = \sigma'_{1\text{-}1}(x = 0.0625) = x(1 - x) \cdot \mu_{(1\text{-}1)} = \frac{15}{16^2} \cdot \mu_{(1\text{-}1)} \quad [17']$$

$$\sigma'_{\text{total}}(x = 0.125) = \sigma'_{2\text{-}2}(x = 0.125) = x(1 - x) \cdot \mu_{(2\text{-}2)} = \frac{7}{8^2} \cdot \mu_{(2\text{-}2)} \quad [18']$$

Using these values of $\mu_{(1\text{-}1)}$ and $\mu_{(2\text{-}2)}$, and assuming approximate values of K and $\mu_{(2\text{-}1)}$, the theoretical log σ *vs.* x curves were constructed at each temperature in intervals of $\Delta x = 0.005$ for $0.0625 \leq x \leq 0.125$ until the best fit to the experimental curves was obtained.

At $T = 600°$ and 800°C, the best fits are already obtained without introducing $\sigma_{2\rightleftarrows1}$ terms, *i.e.*, assuming $\mu_{(2\rightleftarrows1)} \sim 0 \therefore \sigma_{2\rightleftarrows1} \sim 0$. At higher temperatures $T =$ 1000°, 1200°, and 1400°C, the relative contribution from the partial ionic conductivity $\sigma_{2\rightleftarrows1}$ becomes appreciable, and to obtain the best fit these contributions cannot be neglected.

Results and Discussion

The best fit theoretical curves obtained using the rigorous formula for σ_{total} (Eq. [13]) and for concentrations of the respective chemical species as given by Eq. [6] and [8] are shown in Fig. 1 as solid lines at each temperature within the composition range $0.0625 \leq x \leq 0.125$. Numbers of characteristic parameters used to construct these curves are tabulated in Tables I and II. Also included is the theoretical curve for σ_{total} for $0 \leq x \leq 0.0625$ at 1000°C when it is assumed that only $\sigma_{1\text{-}1}$ contributes to the ionic conductivity: *i.e.*

$$\sigma'_{\text{normalized}} = \frac{\sigma_{1\text{-}1}}{N \cdot Z \cdot e} = x(16x - x) \cdot \mu_{(1\text{-}1)} = x \cdot 15x \cdot \mu_{(1\text{-}1)}, \quad 0 \leq x \leq 0.0625 \quad [13']$$

Agreement between the theoretical curves and the experimental ones is quite satisfactory over the entire

Table I. K, σ_{max} ($x = 0.0625$), and σ ($x = 0.125$) used to construct the theoretical curves in Fig. 1

1200	2.428×10^{-4}	2.024×10^{-5}	1.500×10^{-5}	5.357×10^{-5}
1400	5.756×10^{-4}	9.640×10^{-5}	7.500×10^{-5}	2.027×10^{-4}

temperature range: $600°C \leq T \leq 1400°C$ and the stability range of the cubic fluorite phase: $0.0625 \leq x \leq 0.10$.

Figure 4 shows Arrhenius plots of $\sigma_{i\text{-}i}(x)$ (i = 1, 2; x = 0.0625, 0.125) and $\sigma_{i\text{-}i}(x) \cdot T$ (i = 1, 2; x = 0.0625, 0.125). From this figure, we can obtain the Arrhenius equations for $\sigma_{i\text{-}i}$ and $\sigma_{i\text{-}i} \cdot T$, respectively

$$\sigma_{1\text{-}1}(x = 0.0625) = \sigma_{max} = 1.138 \cdot 10^3 \exp\left(-\frac{25.022 \text{ kcal/mole}}{RT}\right) \quad (\Omega \cdot cm)^{-1}$$

$$\sigma_{2\text{-}2}(x = 0.125) = 2.317 \cdot 10^4 \cdot \exp\left(-\frac{38.835 \text{ kcal/mole}}{RT}\right) \quad (\Omega \cdot cm)^{-1} \quad [19]$$

and

$$\sigma_{1\text{-}1} \cdot (x = 0.0625) \cdot T = \sigma_{max} \cdot T = 4.57 \cdot 10^6 \cdot \exp\left(-\frac{27.474 \text{ kcal/mole}}{RT}\right) \quad (\Omega \cdot cm)^{-1} \cdot °K$$

$$\sigma_{2\text{-}2}(x = 0.125) \cdot T = 7.18 \cdot 10^7 \cdot \exp\left(-\frac{40.936 \text{ kcal/mole}}{RT}\right) \quad (\Omega \cdot cm)^{-1} \cdot °K \quad [20]$$

To obtain the actual value of ionic conductivity the number of charge carriers per cubic centimeter is necessary. To this end, the average lattice constant: a_0 = 5.131Å (1) for the nominal composition $Ca_{0.15}Zr_{0.85}O_{1.85}$ was adopted, neglecting the relatively small variation of a_0 with composition. Then

$$\sigma_{i\text{-}i}(x) \; (i = 1, 2; x = 0.0625, 0.125) = N \cdot Z \cdot e \cdot x(1 - x) \cdot \mu_{(i\text{-}i)} = N \cdot x(1 - x) \cdot \frac{Z^2 \cdot e^2 \cdot D_{(i\text{-}i)}}{kT} \quad [21]$$

where N is the number of anion sites per cm³ and given $N = 5.922 \times 10^{22}/cm^3$ using the above a_0 value. In the latter part of Eq. [21] the Nernst-Einstein relation was used

$$\mu_{(i\text{-}i)} = \frac{Z \cdot e \cdot D_{(i\text{-}i)}}{kT} \quad [22]$$

Combining Eq. [19], [20], and [21] leads to the Arrhenius equations for $\mu_{(i\text{-}i)}$ and $D_{(i\text{-}i)}$

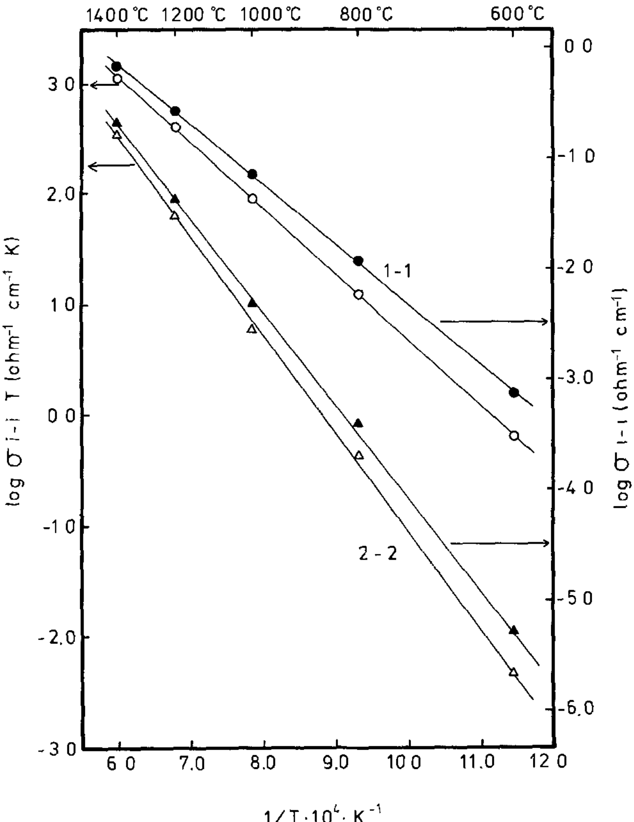

Fig. 4. log $\sigma_{i-i}(x)$ and log $\sigma_{i-i}(x) \cdot T$ (x = 0.0625, 0.125, i = 1.2) vs. $1/T$ plots.

$$\mu_{(1\text{-}1)} = 1.19 \cdot \exp\left(-\frac{25.022 \text{ kcal/mole}}{RT}\right) \quad cm^2 \cdot sec^{-1} \cdot V^{-1}$$

$$\mu_{(2\text{-}2)} = 1.16 \cdot 10^1 \cdot \exp\left(-\frac{38.835 \text{ kcal/mole}}{RT}\right) \quad cm^2 \cdot sec^{-1} \cdot V^{-1} \quad [23]$$

$$D_{(1\text{-}1)} = 1.77 \cdot 10^{-1} \cdot \exp\left(-\frac{27.474 \text{ kcal/mole}}{RT}\right) \quad cm^2 \cdot sec^{-1}$$

$$D_{(2\text{-}2)} = 1.49 \cdot 10^0 \cdot \exp\left(-\frac{40.936 \text{ kcal/mole}}{RT}\right) \quad cm^2 \cdot sec^{-1} \quad [24]$$

Values of $\mu_{(i\text{-}i)}$ and $D_{(i\text{-}i)}$ are tabulated in Tables II and III, respectively, together with $\mu_{(i\text{-}j)}$ ($i \neq j$ = 1, 2) and $D_{(i\text{-}j)}$, which were also used to derive the theoretical curves. To obtain $\mu_{(1\to2)}$ from $\mu_{(2\to1)}$ Eq. [12] and K values in Table I were used.

Figure 5 shows Arrhenius plots of the various diffusion coefficients of the oxygen vacancy $D_{(i\text{-}j)}$. From this figure it is apparent that $D_{(1\text{-}1)} >> D_{(2\text{-}2)} \sim D_{(1\to2)}$

Table III. Diffusion coefficients of oxygen vacancy $V_O^{2\cdot}$ $D_{(i-j)}$ through and between $Ca^{2\prime}$-1-fold and $Ca^{2\prime}$-2-fold coordinated anion sublattice

$> D_{(2\to1)}$ as expected. This means that diffusion of $V_O^{2\cdot}$ through the relatively free state (1-1) proceeds much more easily with a lower activation energy and with a higher absolute value than that through the relatively more bound state (2-2).

An interesting feature of $D_{(2\to1)}$ and $D_{(1\to2)}$ is the fact that there exists a rather sharp kink in the Arrhenius plots for $D_{(2\to1)}$ and $D_{(1\to2)}$ around and below 1000°C. Indeed, as was mentioned in the previous section, the theoretical curves at $T = 600°$ and 800°C were constructed without any contribution from $\sigma_{(2\rightleftharpoons1)}$, and yet shows good agreement with the experimental ones. At 1000°C, their contributions are still small but at higher temperatures $T = 1200°$ and 1400°C, they become considerable. It seems premature to draw any definite conclusion concerning the origin of this phenomenon. However, it is interesting to note that even in "disordered" samples, it is often reported that there seems to exist a slight hump in the Arrhenius plots of log σ *vs.* 1/T above 1000°C, which becomes more apparent in the samples with higher CaO content (1, 5). Figure 6 shows the log K *vs.* 1/T plot for the chemical equilibria given by Eq. [3] and tabulated in Table I. A good straight line relationship holds for $600°C \leq T \leq 1400°C$. From this figure we obtain for the equilibrium constant K

$$K = \exp\left(\frac{\Delta S°}{R}\right) \cdot \exp\left(-\frac{\Delta H°}{RT}\right) = \exp\left(-\frac{\Delta G°}{RT}\right)$$

$$= 2.7 \cdot \exp\left(-\frac{6.606 \text{ kcal/mole}}{RT}\right) \quad [4']$$

Accordingly

$$\Delta S° = 0.993 \text{ eu} = 1.974 \text{ cal/mole °K} \sim R$$

$$\Delta H° = 6.606 \text{ kcal/mole}$$

$$\Delta G° = \Delta H° - T\Delta S° = 6.606 \times 10^3 - 1.974 \cdot T \text{ cal/mole} \quad [25]$$

Figure 7 shows the variations of oxygen vacancy concentrations on the $Ca^{2\prime}$-1-fold coordinated and $Ca^{2\prime}$-2-fold coordinated anion sublattices; $V_O^{2\cdot}$ (1) and $V_O^{2\cdot}$ (2), with total oxygen vacancy concentration $[V_O^{2\cdot}]$ total = x at 600°, 1000°, and 1400°C calculated according to Eq. [6] and [8]. Also included in Fig. 7 are the site fractions of 1- and 2-state; N_1 and N_2. It is interesting to note that the variations of $[V_O^{2\cdot}\ 1]$ and $[V_O^{2\cdot}\ 2]$ with x is steepest at $x = 0.0625$ and become more gradual with increasing x. The equiconcentration point $[V_O^{2\cdot}\ 1] = [V_O^{2\cdot}\ 2]$ shifts to the higher x value position as temperature increases, but remains in the low x region in these temperature ranges.

Experiment shows that the activation energy for ionic conduction increases with increasing x and decreases with increasing temperature at constant x. Both features are accounted for by the present model. These follow because with increasing x, the relative contributions from $\sigma_{1\rightleftharpoons2}$ and $\sigma_{2\text{-}2}$ which have activation energies higher than $\sigma_{1\text{-}1}$ increase, and, as shown in Fig. 7 at constant x, the higher the temperature, the higher the relative contribution from $[V_O^{2\cdot}\ 1]$ and hence the contribution from $\sigma_{1\text{-}1}$, which has the lower activation energy, increases.

Oxygen diffusion measurements on this system reported so far are those by Kingery *et al.* (19), Simpson and Carter (20), and Hagel (21). References (19) and (20) report agreement of the measured oxygen diffusion coefficient $D_{O^{18*}}$ with that calculated from ionic conductivity assuming an oxygen transport number of 1 and the correlation factor of 0.65 for the fluorite structure. In contrast, Hagel (21) obtained an oxygen diffusion coefficient $D_{O^{18*}}$ appreciably lower than that calculated from his own conductivity data. If the ionic conduction and therefore the oxygen diffusion in this system are multimode processes as described by the present model, the penetration profile of O^{18*} from the gas phase would not yield a curve characterized by one error function complement. Such experiments are quite difficult to carry out and, depending on the relative contributions of each mode, the result may appear to fit a single error function complement as was shown for the diffusion of sulfur in NiO by Howng and Wagner (22).

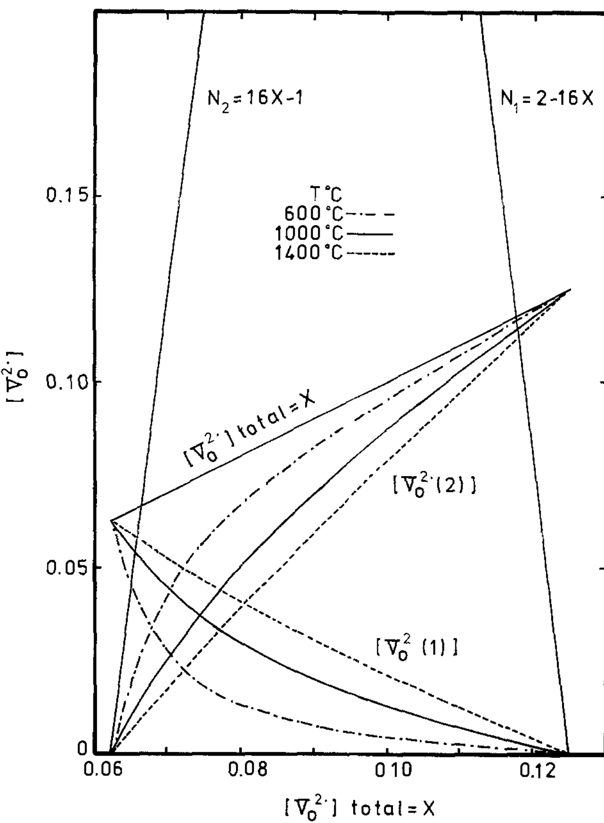

Fig. 7. Oxygen vacancy distribution between $Ca^{2\prime}$-1-fold and $Ca^{2\prime}$-2-fold coordinated anion sublattice as a function of total oxygen vacancy concentration $[V_O{}^{2\cdot}]$ total $= x$. $T = 600°$, 1000°, 1400°C. $[V_O{}^{2\cdot}\ 1]$: oxygen vacancy concentration on $Ca^{2\prime}$-1-fold coordinated anion sublattice. $[V_O{}^{2\cdot}\ 2]$: oxygen vacancy concentration of $Ca^{2\prime}$-2-fold coordinated anion sublattice. N_1: site fraction of $Ca^{2\prime}$-1-fold coordinated anion sublattice. N_2: site fraction of $Ca^{2\prime}$-2-fold coordinated anion sublattice.

Internal friction measurements on this system conducted by Wachtman and Corwin (23) seem to support the above speculation on the oxygen diffusion coefficient and partially substantiate our proposed theoretical model. Wachtman and Corwin observed the symmetrical peaks associated with $V_O{}^{2\cdot}$ motion in the cubic fluorite phase region, but the peaks were too broad to result from a relaxation process with a single relaxation time. They thought that the concentrations of $V_O{}^{2\cdot}$ and $Ca^{2\prime}$ are so high that many complex groupings and/or various arrangements of $Ca^{2\prime}$ and $V_O{}^{2\cdot}$ occur which cause the various types of local $V_O{}^{2\cdot}$ jumps and therefore a distribution of relaxation times. Their interpretation is similar to that of Kröger (10) mentioned previously.

As was shown in the foregoing, the proposed theoretical model seems to succeed to some extent in giving a quantitative character to these qualitative interpretations. The basic feature of the theoretical model is that it extends the conventional concept of dopant (impurity)-defect complex or associate for highly defective systems and shows in a straightforward way the occurrence of a maximum of the ionic conductivity and a multimode transport mechanism for these systems. However, in formulating the theoretical model, crude assumption for the effective anion site coordination number of $Ca^{2\prime}$ to the second nearest neighbor ($Ca^{2\prime}$-$V_O{}^{2\cdot}$) configuration was made. So far, our knowledge about defect interaction at the second (and the higher order) nearest neighbor configuration is quite lacking. Moreover, the statistical fluctuations of the system were also neglected. (See Eq. [2]. Even in the composition range $0.0625 \leq x \leq 0.125$, there exist also small numbers of $Ca^{2\prime}$-0-fold, 3-fold, 4-fold anion sites, which were all neglected. Also, the existence of nonintegrally $Ca^{2\prime}$ coordinated sites such as $Ca^{2\prime}$-1/3-fold, $Ca^{2\prime}$-5/3-fold anion sites were neglected.) These fluctuations would be dependent on the $Ca^{2\prime}$ distribution and should be important in dealing with the order-disorder transition in this system.

Summary

A quantitative theoretical model to explain the variations of ionic conductivity of calcia-stabilized zirconia with oxygen vacancy concentration and temperature has been presented. The theory extends the conventional concept of the impurity (dopant)-defect complex or associate for highly defective systems and shows that ionic conduction in this system proceeds by a multimode mechanism: Eq. [13]. The theory predicts the occurrence of a rather sharp maximum of ionic conductivity at oxygen vacancy concentration $x \sim 0.0625$ (12.5 m/o CaO), at which the entire anion sublattice is just covered by onefold associated ($Ca^{2\prime}$-$V_O{}^{2\cdot}$) complexes, in accordance with experimental observations.

Values of characteristic parameters such as the diffusion coefficients and mobilities of oxygen vacancies $V_O{}^{2\cdot}$ through and between 1-fold and 2-fold $Ca^{2\prime}$ coordinated anion sublattice; $D_{(i\text{-}j)}$, $\mu_{(i\text{-}j)}$, and the equilibrium constant K for the distribution of oxide ions and oxygen vacancies between 1-fold and 2-fold $Ca^{2\prime}$ coordinated anion sublattice were obtained by a curve-fitting procedure of the theoretical expression for ionic conductivity to experimental $\sigma(x, T)$ data reported in the literature. Resultant theoretical curves of isothermal log σ *vs.* oxygen vacancy concentration x, inside the stability region of the cubic fluorite phase $0.0625 \leq x \leq 0.10$ and $600°C \leq T°C \leq 1400°C$ were shown to reproduce satisfactorily the experimental curves reported by various investigators.

Thermal Decomposition of LiSCN-Containing Lithium Battery Electrolyte

B. M. L. Rao* and G. E. Milliman

Advanced Energy Systems Laboratory, Exxon Research and Engineering Company, Linden, New Jersey 07036

ABSTRACT

Thermal decomposition of LiSCN in 1:3-dioxolane was investigated to understand the safety aspects in its usage as an electrolyte for ambient temperature, high energy density organic electrolyte cells. TGA and direct combustion techniques were used in the studies. Attention was given to assess the volatile hydrogen cyanide content in the decomposition products, because of a possible toxic hazard. The results indicated that the thermal decomposition of LiSCN at 650°C in air formed 0.01 weight percent (w/o) volatile cyanide, presumably due to impurities. However, the presence of moisture and/or the solvent (1:3-dioxolane) enhanced the extent of cyanide generation to 0.5-1.5 w/o. Based on the results, caution is recommended in dealing with thermal runaway conditions.

In electrolyte development efforts for ambient temperature, high energy density lithium batteries, many lithium salts and organic solvents combinations have been explored. This area of electrochemical research has been recently reviewed by Basenhard and Eichinger (1). Compatibility of the electrolyte components with the electrode materials on stand and under operating conditions, electrolyte conductivity, and cost considerations have played an important role in this venture. Recently, increased attention is being given to safety and environmental impact aspects, as required. This paper deals with a safety-related investigation on the thermal decomposition of LiSCN·1.3-dioxolane electrolyte developed for use in ambient temperature rechargeable lithium cells (2, 3). It was carried out to assess the possible release of toxic cyanide fumes during thermal runaway conditions that may be encountered in the manufacture (*e.g.*, welding operations), in storage (cell shorting, warehouse fire, etc.), in service (*i.e.*, high current or high voltage conditions), and during disposal (*i.e.*, incineration) of the batteries.

LiSCN is a pseudohalide. It is reported (4) to undergo decomposition in a solid state near its melting point of 237°C. Lee (5) indicates <1 weight percent (w/o) decomposition in air at 400°C, from thermogravimetric analysis. Although decomposition products are not obvious from these experiments alkali thiocyanates are known to release cyanide and hydrogen cyanide, among other products, during reactions with hydrogen or metals in fused salt media.

Lithium thiocyanate is highly soluble (>4.5 moles/liter) in 1:3-dioxolane. An electrolyte composition with 2.0-3.0 moles/liter LiSCN in 1:3-dioxolane with $2\text{-}3 \times 10^{-3}$ $(\Omega\cdot cm)^{-1}$ specific conductivity (23°C) was investigated in Li/TiS_2 cells (3) and, as such, has been the subject of safety interest of this work. The present study was carried out because of the low flash point of the cyclic ether solvent (13°C) and the associated combustion possibilities.

Experimental and Results

Thermogravimetric analysis.—Anhydrous LiSCN forms a monosolvate upon recrystallization from 1:3-dioxolane. As solvent loss from leaky cells, or thermal conditions, prior to electrolyte combustion are likely to result in this compound, initial experiments were performed using thermogravimetric analysis (TGA) on monosolvate prior to detailed studies on thermal decomposition. TGA data for the anhydrous LiSCN 1:3-dioxolane monosolvate carried out in air and dry nitrogen are given in Fig. 1.

Procedures for the thermal decomposition.—Thermal decomposition experiments were performed in a tube furnace setup, shown in Fig. 2. Test samples were weighed into combustion boats, placed in the tube furnace (shown in Fig. 2), heated to 600°-650°C in the course of an hour, held at the maximum temperature for 2 hr, and then gradually cooled to room temperature in 3-5 hr. During this procedure, dry or moist air was passed to ensure combustion and to flush the gaseous effluents into absorber traps of 100 ml, 1M NaOH, provided for cyanide analysis.

Procedure for cyanide analysis.—The measurement of cyanide in aqueous sodium hydroxide solutions was accomplished in two ways. If the cyanide content of the absorber solutions was sufficiently high, >25 μg CN^-/ml, the solutions could be potentiometrically titrated with 0.005M Ag^+, using a Metrohm Model E-536 automatic recording titrator equipped with Metrohm EA-107 glass and EA-275 silver electrodes to the equivalence point corresponding to $Ag^+ + 2CN^- \rightarrow Ag(CN)_2^-$. If the cyanide content of the absorber solutions was <25 μg CN^-/ml, the cyanide was measured using an Orion Model 94-06 cyanide-ion selective

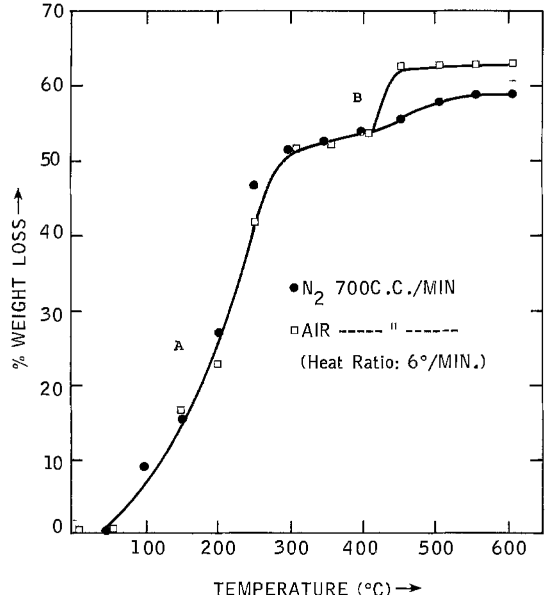

Fig. 1. Thermogravimetric analysis of LiSCN-dioxolane monosolvate.

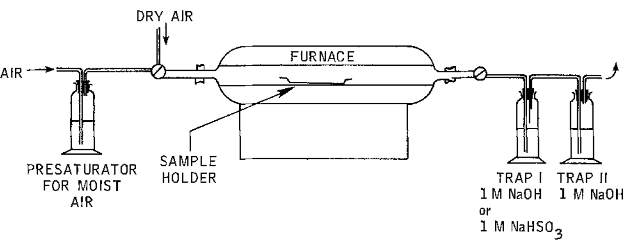

Fig. 2. Schematic of combustion arrangement

electrode, an Orion Model 90-01 single-junction reference electrode, and an Orion Model 801-A Digital Ionalyzer. The Ionalyzer was calibrated using solutions containing between 0.05 and 5 μg CN^-/ml, obtained by dilutions of a 1000 μg CN^-/ml solution, prepared from potassium cyanide in 0.5M NaOH, with 0.5M NaOH. The cyanide content of the absorber traps was adjusted to calibration range by dilution with water or NaOH solution, so that the solution which was used for measurement was 0.5M in NaOH. Since sulfide could possibly arise from the degradation of LiSCN and traces of sulfide interfere with the measurement of cyanide using the cyanide electrode, the absorber solutions were treated to ensure the absence of sulfide prior to cyanide measurements. This was accomplished by the addition of a small amount of cadmium carbonate to the solutions and the subsequent removal of cadmium sulfide and excess cadmium carbonate and/or cadmium hydroxide by filtration.

Thermal decomposition of anhydrous LiSCN.—Results of cyanide determination in the scrubbing solution obtained from thermal decomposition in anhydrous LiSCN, using the above procedure, is provided in Table I.

Thermal decomposition of 3M LiSCN in 1:3-dioxolane.—During potentiometric determination of cyanide in the scrubbing solutions from thermal decomposition of 3M LiSCN in 1:3-dioxolane, an erratic behavior of potential between the ion-selective electrode and the reference electrode was encountered. The establishment of steady rest potential took an inordinately long time, and there was a memory effect when electrodes were placed in subsequent solutions. This behavior had not previously been encountered during measurement of cyanide in NaOH solutions. It was hypothesized that this behavior was caused by formaldehyde, formed by the decomposition of dioxolane (6), reacting directly with the silver bromide sensing element of the cyanide electrode, or complicating the system via formation of a formaldehyde-cyanide complex. The removal of the formaldehyde was accomplished by the addition of an $NaHSO_3$ scrubber to the absorption train in front of the NaOH scrubber. Both the ion selective electrode and the potentiometric titration procedures were used for cyanide analysis in some of the NaOH absorption traps. The results obtained by the two independent procedures, given in Table I, are in excellent agreement.

Discussion

TGA data for LiSCN·1:3-dioxolane monosolvate, given in Fig. 1, indicate weight loss in regions A and B. These regions correspond to loss of solvent from the monosolvate and the thermal decomposition of LiSCN, respectively. This is based on the estimate which indicates a 53% weight loss due to solvent from LiSCN 1:3-dioxolane monosolvate, which appears to be complete in region A (Fig. 1) independent of carrier gas. Thermal decomposition of anhydrous LiSCN ensues in region B, with increased weight loss in air compared to nitrogen. Lee (5) indicates $<1\%$ decomposition for LiSCN below 400°C.

Data in Table I indicate that the quantity of volatile cyanide, *i.e.*, HCN, generated by the anhydrous LiSCN in dry air, is low (<0.01 w/o), as expected. However, the decomposition of anhydrous salt in moist air enhances the amount of volatile cyanide released to 0.4 w/o, a fortyfold increase over the amount of cyanide released in dry air. The electrolyte, *i.e.*, 3M LiSCN, 1:3-dioxolane solution, yields volatile cyanide, both in the absence and presence of moisture, with the latter yielding 1.5 w/o decomposition of LiSCN to cyanide.

It is seen, from the data in Table I, and the amount of cyanide in the solid residue, that the quantity of cyanide generated from 10 ml of 3M LiSCN 1:3-dioxolane solution, under the experimental conditions, is low ($<5 \times 10^{-3}$g). Although HCN is a combustible gas, its escape to the environment presents a potential hazard, because of its toxicity. It is to be noted that relatively large amounts of HCN may be produced by incomplete combustion of certain nitrogen-containing materials, such as wool, silk, urethane, polyamide, and acrylics. Established safety procedures, as in these cases, may be applicable to handling of combustion incidents involving the LiSCN-1:3-dioxolane electrolyte.

Table I. Thermal decomposition of LiSCN electrolyte and cyanide analysis

Test sample			CN^- determined (g) by		
Material	Quantity of LiSCN combusted (g)	Combustion condition	Sp. ion	Ag^+ titration	% LiSCN decomposition to CN^-
10 ml 3M LiSCN in dioxolane	1.95	Dry air 650°C, ~2 hr	3.7×10^{-3}	3.5×10^{-3}	0.45-0.47
		Moist air 650°C, ~2 hr	11.2×10^{-3}	11.1×10^{-3}	1.42-1.43
LiSCN anhydrous	1.95	Dry air 650°C, ~2 hr	2.4×10^{-6}	—	3×10^{-6}
		Moist air 650°C, ~2 hr	3.1×10^{-3}	—	0.4

The degree of sophistication of precautions would depend on the quantity of electrolyte involved. Appropriate safety experts need to be consulted in this regard.

Hydrogen Evolution and Zinc Nodular Growth in the Zinc Chloride Battery

Dennis Kralik*[,1] and Jacob Jorne*

Department of Chemical Engineering, Wayne State University, Detroit, Michigan 48202

ABSTRACT

The problem of hydrogen evolution in the zinc chloride battery is investigated experimentally with special respect to the magnitude of the phenomenon under various $ZnCl_2$ and supporting electrolyte concentrations, pH, current density, and electrolyte purity. Metallic impurities of low hydrogen overvoltage can be responsible for accelerated hydrogen evolution during charge and discharge. In addition, the morphology and porosity of the zinc deposit and the presence of dendrites affect the magnitude of hydrogen evolution. Low hydrogen evolution rates are observed on rough and dendritic deposits and vice versa. Two methods of decreasing hydrogen evolution are presented: (*i*) pretreatment of the $ZnCl_2$ electrolyte with zinc particles, and (*ii*) potentiostatic deposition of metallic impurities in flow-through porous-graphite electrode above the zinc deposition potential.

Hydrogen evolution in the zinc chloride battery results in two disadvantages: (*i*) the hydrogen formed may react explosively with chlorine (1), and (*ii*) hydrogen evolution represents a coulombic inefficiency during both the charge and discharge processes.

In our experiments a single zinc chloride cell was used. The cell, shown in Fig. 1, consists of a dense graphite electrode on which zinc is deposited, and a porous flow-through graphite electrode on which chlorine is evolved. In the actual battery, the chlorine is then stored as chlorine hydrate. The overall reactions of the battery are

$$ZnCl_2(aq) \rightleftharpoons Zn(s) + Cl_2(g)$$

$$Cl_2(g) + xH_2O \rightleftharpoons Cl_2 \cdot xH_2O$$

$$x \sim 5.9$$

Hydrogen evolution on electrodeposited zinc can be caused by two mechanisms: (*i*) corrosion of zinc, *i.e.*, anodic dissolution of zinc accompanied by simultaneous hydrogen evolution, the so-called local cell action, and (*ii*) cathodic hydrogen evolution (electrochemically) during zinc deposition. The net result of these two mechanisms is identical. Hydrogen evolution on pure zinc is very low (the exchange current density is in the range of 10^{-10} A/cm^2). However, the presence of metallic impurities such as iron, copper, chromium, vanadium, arsenic, and germanium, even at the ppm level, in the solution and consequently in the zinc deposit can cause a dramatic increase in hydrogen evolution by creating local cells (2). It is assumed in the present work that the increased hydrogen evolution is caused by the presence of impurity ions in the solution and, consequently, in the zinc deposit. Attempts to determine the origin of the impurities identify the degradation of the graphite chlorine electrode as the source of contamination leading to hydrogen evolution (3). Several metallic impurities are found capable of causing considerable hydrogen evolution. Antimony is probably the most determinal impurity tested. At the

Key words: zinc, chlorine, impurities, zinc chloride, dendrite, roughness.

1 mg/liter level, cobalt, germanium, nickel, and tin also cause considerable hydrogen evolution (3). Surprisingly, arsenic is not observed to be a catalyst for hydrogen evolution on zinc (3), as indicated by others (2).

Experimental

Hydrogen evolution was measured volumetrically in acidic zinc chloride solutions, as shown in Fig. 2. The evolved hydrogen was collected in inverted burettes which were placed above the zinc cathode, zinc anode, and reference zinc. All the zinc plates were obtained in the single cell by electrodeposition from various $ZnCl_2$ solutions which were prepared by direct reaction of chlorine gas and pure zinc in aqueous solution. The zinc deposits were peeled gently off the graphite substrate, washed thoroughly, dried, and weighed. The single cell was made of Kynar by Energy Development Associates, Madison Heights, Michigan.

The apparent active area of the electrode was 68 cm^2, the total current was 3A, and the charging process lasted for 1-2 hr. The experimental setup is shown in Fig. 3. A 2.5 liter $ZnCl_2$ (2m) solution was circulated through a flowmeter and the cell using a Kynar pump with a Teflon gear. The evolved chlorine was stripped during the charging by nitrogen bubbling throughout the experiment. Prior to each experiment, the pH was adjusted by adding HCl and nitrogen was bubbled to remove oxygen and remaining dissolved chlorine. The charging time was adjusted so that the amount of electricity was always the same: 0.080 Ahr/cm^2. No additives or leveling agents have been used.

Hydrogen evolution was investigated in acidified zinc chloride solutions, with and without sodium chloride or potassium chloride supporting electrolytes. The magnitude of the hydrogen evolution was measured under various conditions, such as zinc chloride concentration, electrolyte purity, supporting electrolyte, current density, and pH.

Two methods for the removal of metallic impurities were used: the first method consisted of suspension of zinc pieces in zinc chloride solution. Since impurities are ions of more noble metals than zinc, they should deposit on the zinc particles suspended in the electrolyte. This method is referred to as zinc pretreatment. The second method consisted of a potentiostatic removal of impurities in a flow-through porous graphite electrode held above the zinc deposition potential (−0.76V). The impurity ions were cathodically electrodeposited on the porous graphite cathode and removed from the solution. Because of the low concentration of impurities, it is believed that their removal was mass transfer limited. The counterelectrode consisted of zinc deposit on a nonporous graphite substrate and was prepared by charging the zinc chloride single cell. Under this arrangement chlorine was absent and could not react with the deposited impurities.

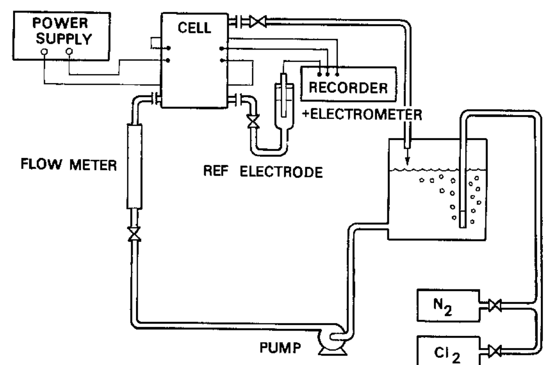

Fig. 3. The experimental apparatus of the zinc chloride single cell.

Results and Discussion

Hydrogen evolution from potentiostatically treated zinc chloride solution was much lower than from untreated solution as can be seen in Fig. 4. Figure 5 shows the rates of hydrogen evolution for zinc anode, zinc cathode, and reference zinc in zinc-treated and untreated 2m $ZnCl_2$ + 4m KCl solution. Pretreatment with zinc pieces resulted in a decrease of hydrogen evolution for all cases. The hydrogen evolution rate increased with time on the cathode as can be seen from the slope of the curve, while it decreased with time on the anode. This is due to the fact that the surface of the cathode became increasingly rougher due to zinc deposition, while the surface of the anode became smoother during the electrodissolution. The cathodic area increased with time, and consequently the rate of hydrogen evolution is increased on the zinc cathode while decreased on the zinc anode. The rate of hydrogen evolution on the reference zinc is lower than the rate on the zinc anode, although it is expected that the zinc anode is becoming progressively smoother through electrodissolution. This apparent contradiction probably is due to the fact that the deposition rate of the impurities is mass transfer limited and is enhanced by the natural convection at the anode.

The effects of the current density on the hydrogen evolution, on the apparent density of the deposit, and on the coulombic efficiency are shown in Fig. 6. The nodular growth increased as the current density was increased, in accord with the prediction that a higher

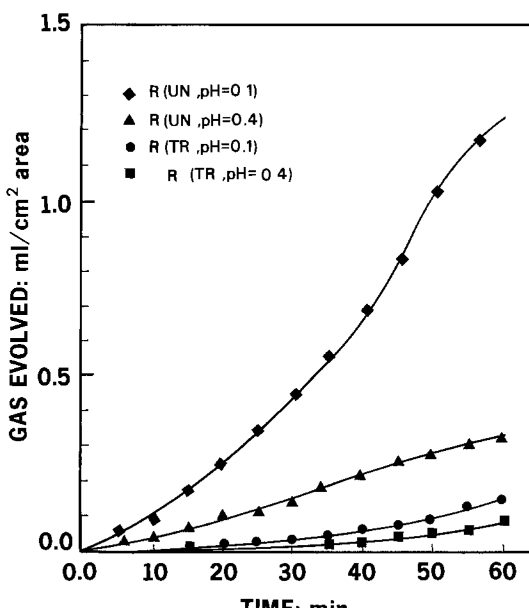

Fig. 4. Hydrogen evolution in potentiostatically treated solution containing 2m $ZnCl_2$. Only the reference zinc is presented. Current density i = 40 mA/cm^2. R = reference zinc, UN = untreated solution, TR = treated solution.

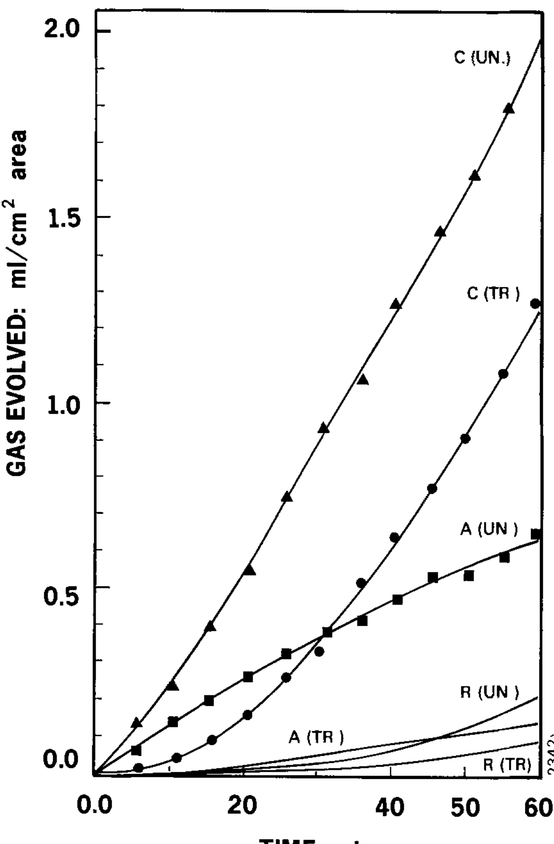

Fig. 5. Hydrogen evolution from zinc pretreated solution containing 2m $ZnCl_2$ + 4m KCl. pH = 0.4; current density: i = 40 mA/cm^2. C = cathode zinc, A = anode zinc, R = reference zinc, UN = untreated solution, TR = treated solution.

current density at the nodular tips promotes their growth. As a result, the apparent densities (weight per apparent unit volume) of the deposits decreased with increasing the current density.

On the other hand, the hydrogen evolution rate increased with increasing current density since the higher the current density, the larger the actual surface area of the deposit available for hydrogen evolution. By increasing the current density the deposition rate of the zinc ions increases, while the deposition rate of the impurities remains constant because it is mass transfer limited. Since the impurity ion concentration is several orders of magnitude smaller than the zinc ion concentration, it is very probable that the surface of the rapidly growing zinc nodules is kept clean because adsorbed impurity atoms are buried as fast as they reach the surface. So the only reason for increased hydrogen evolution rate is the increased surface area of the zinc deposit.

Figure 7 shows the dependence of hydrogen evolution on the pH of the solution. All the zinc deposits were prepared in untreated 2m $ZnCl_2$ solution, pH = 0.1. However, the hydrogen evolution tests were repeated in 2m $ZnCl_2$ solutions of pH = 0.1 and 0.4. Higher hydrogen evolution rates can be observed on the cathode, anode, and reference zinc at pH = 0.1, as expected. The rates of hydrogen evolution are lower on the reference zinc in comparison to the zinc anode. This behavior is probably due to the smoothing of the anode through electrodissolution. An opposite trend is shown in Fig. 5 and is believed to be due to natural convection at the anode. However, the data of Fig. 8 were obtained in treated solution and in the absence of impurities in the solution. In all the experiments the rate of hydrogen evolution decreased with time on the anode and increased with time on the cathode, again, probably due to the smoothing of the anode and the roughening of the cathode.

The presence of sodium chloride and potassium chloride as supporting electrolytes generally decreased the rate of hydrogen evolution as shown in Fig. 8. A qualitative correlation was found between the rate of hydrogen evolution and the morphology of the zinc deposit. Nodular zinc was obtained at high zinc chloride concentration. When the zinc chloride concentration was reduced from 2.0 to 0.2m, the nodular growth was eliminated and the rate of hydrogen evolution increased substantially.

Figure 9 summarizes the results on reference zinc and shows that as the zinc chloride concentration decreases, the apparent density of the deposit increases (nodules are eliminated), and hydrogen evolution is increased. In addition, the coulombic efficiency of zinc deposition starts to decrease as the zinc chloride con-

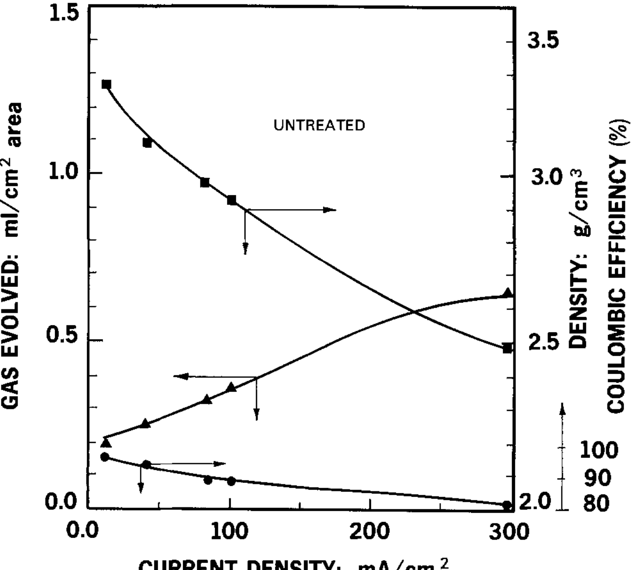

Fig. 6. Effect of current density on hydrogen evolution and on the apparent density of zinc deposits. Gas evolution is presented for the reference zinc after 40 min. Electrolyte: 0.6m $ZnCl_2$ + 2.0m NaCl + 2.0m KCl. pH = 0.1, untreated.

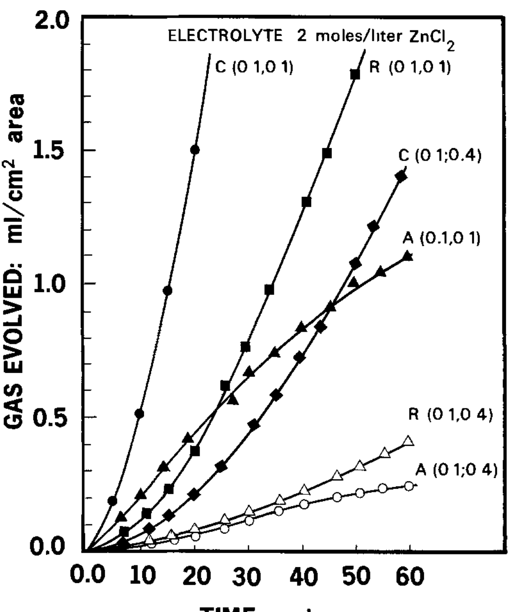

Fig. 7. Effect of pH on hydrogen evolution. First index refers to pH of deposition, second index to pH of hydrogen evolution test. Deposits were obtained from untreated 2m $ZnCl_2$ solution, and hydrogen evolution tests were performed in zinc-treated solution. Current density: i = 40 mA/cm^2. C = cathode zinc; A = anode zinc; R = reference zinc.

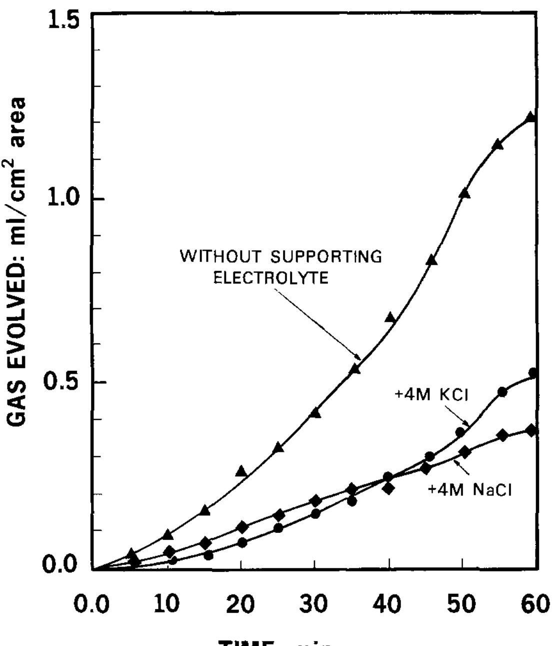

Fig. 8. Effect of supporting electrolytes on hydrogen evolution. Electrolyte: 2m $ZnCl_2$; pH = 0.1; current density: i = 40 mA/cm². Electrode: reference zinc prepared in untreated solution.

centration drops below 0.6m; the current density is 40 mA/cm² and zinc deposition becomes partially mass transfer limited. Since it is believed that the source of impurities is the slow degradation of the graphite chlorine electrode (3), the concentration of the impurities is not proportional to the zinc chloride concentration.

The critical current density (I_c) and the minimum concentration of zinc ions (C_m) required for nodular growth can be estimated according to the theory of Price, Vermilyea, and Webb (4). According to this

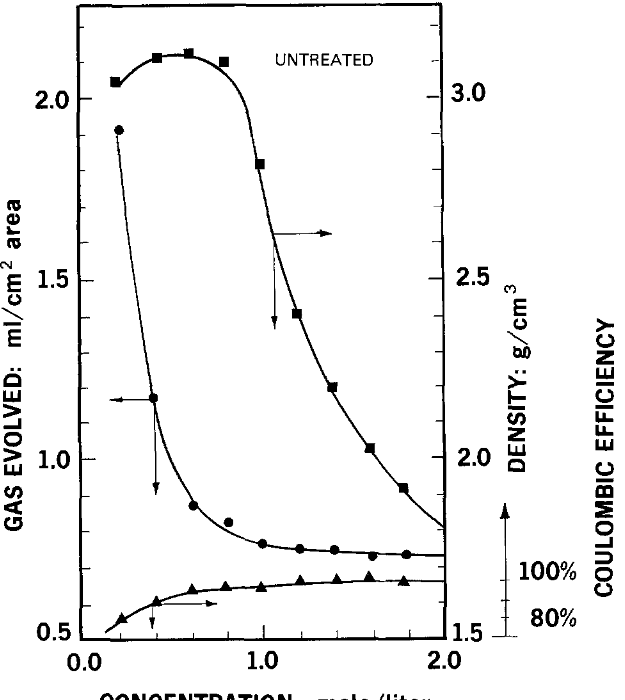

Fig. 9. Effect of zinc chloride concentration on hydrogen evolution and on the apparent density of the deposit. Zinc chloride solutions without supporting electrolyte. pH = 0.1; current density: i = 40 mA/cm². Hydrogen evolution is presented on reference zinc after 40 min.

theory impurity atoms adsorb on the surface of a growing crystal and interfere with the motion of lattice steps over the surface. When the concentration of impurity atoms adsorbed on the surface is above a critical value depending on the overvoltage, step motion is completely blocked and no further growth of the crystal occurs. A critical radius for the curvatures of the steps can be estimated, given by the following equation

$$\rho_c = \frac{\delta}{\Delta G_v} \quad [1]$$

where δ is the edge energy of the step per unit area and ΔG_v is the free energy decrease per unit volume (ΔG_v is proportional to the supersaturation or overvoltage). It is assumed that a strongly adsorbed particle can prevent the part of the step with which it is in contact from moving. When a section of a step encounters two adsorbed particles which are closer together than $2\rho_c$ it cannot advance past the particles because in so doing the radius of curvature of a portion of the step would become less than ρ_c. Hence, if the average distance between particles adsorbed on the surface is greater than $2\rho_c$ the steps will be able to advance freely, while at greater coverages the growth of the crystal may be entirely prevented (4). In other words, if the impurity ion concentration is high in the solution and consequently on the surface of the growing zinc crystals, two adsorbed neighboring impurity atoms will be closer to each other than $2\rho_c$, thus the zinc crystals will not be able to grow, and the nodular growth will be prevented. This case results in a smooth zinc deposit possessing a high surface concentration of impurity atoms, thus yielding a high hydrogen evolution rate.

On the other hand, when the impurity concentration is low, two adsorbed impurity atoms will be further apart on the zinc surface than $2\rho_c$, thus the steps of the nodular growth can advance freely. In this case the impurity atoms adsorbed on the rapidly growing surface will be incorporated into the crystal as lattice steps move around and past them. Finally, the result is a rough, nodular zinc deposit with a low surface concentration of impurity atoms yielding a low hydrogen evolution rate.

A significant prediction of the theory of Price, Vermilyea, and Webb (4) is that there is a critical current density for the continued growth of a metal crystal in a solution containing impurity ions. At the critical current density there is a balance between the rate of diffusion of impurity ions to the zinc surface and the rate of their incorporation into the crystal. The equation for the critical current density for a spherical crystal of a given metal and for a given metal ion concentration and temperature is (4)

$$I_c = \text{const.} \left(\frac{C_i}{r}\right)^{1/3} \quad [2]$$

where C_i is the concentration of impurity ions in the $ZnCl_2$ solution and r is the radius of the growing zinc crystal. The above equation is valid for crystals with radii less than about 10 μm.

The minimum concentration of zinc ions for nodular growth is given by (4)

$$C_m = \frac{I_c r}{ZFD_{Zn}} \quad [3]$$

where Z is the valency of zinc ion, and D_{Zn} is the diffusivity of zinc ion, $D_{Zn} \sim 10^{-5}$ cm²/sec.

According to these equations, a zinc ion concentration below approximately 0.06m $ZnCl_2$ and a current density below approximately 240 mA/cm² are needed to prevent nodular growth. Below this concentration the diffusion of zinc ions to the nodular tips is too slow, the nodular growth ceases, and a denser zinc deposit is obtained.

When the zinc chloride concentration was reduced from 2.0 to 0.2m the nodular growth became mass transfer limited. When zinc was deposited from 0.2m $ZnCl_2$ solution the impurities, in spite of their reduced concentration, reached the surface faster than they could be buried, thus the smooth surface possessed relatively high surface concentration of impurity atoms and yielded a high hydrogen evolution rate.

Figure 10 shows the zinc nodules developed during cathodic deposition from 1.85m zinc chloride $pH = 0.5$ untreated solution. The crystalline structure of the nodules and the layers formed by the steps during crystal growth are clearly visible. One can even roughly estimate the radii of the nodular tips at approximately 10 μm.

Figures 11 and 12 show zinc surfaces deposited from the same 1.23m zinc chloride $pH = 0.7$ untreated solution. The surface, exposed to anodic dissolution, reveals the fine structures of the nodules. At the greater enlargement, the sizes of the steps and the radius of the nodular tip can be estimated with acceptable accuracy. Figure 11 shows an almost perfect zinc crystal not yet destroyed by anodic dissolution. In Fig. 12, the single nodule and its crystals are partially exposed by anodic dissolution, thus revealing the steps, in reversed chronological succession, by which the impurity ions were embedded in the crystals of the nodules.

In conclusion, relatively low hydrogen evolution is observed on rough and nodular zinc deposits. Higher hydrogen evolution is observed on smooth and dense deposits which are obtained from $ZnCl_2$ solutions of low concentration. Both zinc pretreatment and potentiostatic removal of impurities are effective methods in reducing the rate of hydrogen evolution on zinc in acidic $ZnCl_2$ solutions. Both methods were successful in reducing the hydrogen evolution rate to a low level below 1 mA/cm^2 which corresponds to less than 2.5% current inefficiency.

The source of impurities is believed to be the graphite of the flow-through porous electrode (3). The nature of the impurities is not verified, however, traces of antimony, cobalt, germanium, nickel, and tin can cause considerable hydrogen evolution even at the ppm range. In order to achieve a smooth zinc deposit, free of dendrites, and low hydrogen evolution, a search should be made for a cationic leveling agent which exhibits high overvoltage for hydrogen evolution. In addition, the $ZnCl_2$ solutions should be purified by zinc pretreatment or potentiostatic pretreatment in order to remove metallic impurities.

Kinetics of Electroless Copper Plating

IV. Empirical Rate Law for H_2CO-EDTA Baths

Francis M. Donahue, K. L. M. Wong,[1] and R. Bhalla

Department of Chemical Engineering, The University of Michigan, Ann Arbor, Michigan 48109

ABSTRACT

Data for H_2CO-EDTA electroless copper plating baths were correlated by

$$r_p = 2.81 \frac{[Cu^{2+}]^{0.43}[HCHO]^{0.16}}{[OH^-]^{0.70}[EDTA]^{0.04}} \exp\left[11.5 \frac{(T-313)}{T}\right]$$

This rate law was compared with published data for EDTA and Rochelle salt baths. Mass transport effects and/or substrate catalytic activity were shown to explain some of the differences among the various authors.

In recent years the kinetics of electroless copper plating have been well studied. Shippey and Donahue (1) and El-Raghy and Abo-Salama (2), examining solutions with Rochelle salt as the ligand, and Molenaar, Holdrinet, and van Beek (3), with EDTA, determined complete rate laws for their plating baths. Dumesic, Koutsky, and Chapman (4) and Saranov, Bulatov, and Mokrushin (5) obtained reaction orders for some or all of the solution species, but did not determine the rate constant. Although Goldie (6) did not determine any of the components of the rate law, sufficient data were reported for the partial evaluation of a rate law. Schoenberg demonstrated the effects of pH (7) and organic additives (8), but determined no components of the rate law.

Dumesic and co-workers (4), using a rotating cylinder in order to achieve a well-defined forced convection condition, have shown that variations in the mass transfer coefficient affect the value of the apparent reaction order for cupric ion. Donahue (9), noting that most studies of electroless plating have been performed in the absence of traditional forced convection conditions, has shown that a well-defined (if nonuniform) mass transport condition exists due to the hydrogen gas evolved during the plating reaction. He ascribed differences in the apparent reaction orders for cupric ion in the literature to the effects of mass transport.

This paper will present data for EDTA baths and determine an empirical rate law from these data. Further, since this work represents the seventh published study leading to, at least, partial rate laws, it is now possible to compare the results obtained by the various authors and to evaluate the common and unique properties of the empirical rate laws which have been reported.

Experimental

The principal features of the experimental arrangement and procedure have been given elsewhere (1, 10). Ethylenedinitroloacetate anion (EDTA) was the ligand. The bath was not agitated and had a volume of 200 ml (this assured that less than 0.5% of the copper in solution would be consumed in the normal plating process). Plate thickness measurements were taken at 5 min intervals (the ½ in. plastic tubing was replaced by 6 mm glass tubing with a substantial decrease of the mass of the resistance probe; this permitted relatively fast thermal equilibrium of the reference leg with the solution).

Plating rates were determined from linear regressions of plate thickness-time data when the measured mixed potentials were essentially constant. Reaction orders were determined from linear regressions of the appropriate log plating rate-log concentration data (1). The specific rate constant was determined by solving

$$k = \frac{r_p}{[Cu^{2+}]^a[OH^-]^b[HCHO]^c[EDTA]^d} \quad [1]$$

for each of the data sets rather than the "intercept" method proposed previously (1).[2]

Results

The data for the plating baths are given in Table I. The rate law parameters computed from the data are summarized in Table II. The low correlation coefficients for the reaction orders of HCHO and EDTA reflect the uncertainties associated with the reported values.

The empirical rate law is

$$r_p = 2.81 \frac{[Cu^{2+}]^{0.43}[HCHO]^{0.16}}{[OH^-]^{0.70}[EDTA]^{0.04}} \exp\left(11.5 \frac{(T-313)}{T}\right) \quad [2]$$

Approximately 90% of the measured plating rates were within 20% of the predicted values.

[1] Present address: BASF Wyandotte Corporation, Pigments Division, Holland, Michigan 49423.

Key words: catalytic properties, electroless copper plating, kinetics, mass transport, rate laws.

[2] The method employed here gives equal weighting to all experiments while the intercept method can create a bias depending upon the number of experiments used to compute the respective reaction orders.

Discussion

It is evident that sufficient kinetics studies of electroless copper plating have been performed to permit some generalizations to be made concerning the empirical rate law. The reaction orders for bath components from published works are summarized in Table III. These data represent two different ligands, *i.e.*, Rochelle salt (1, 2, 5, 6) and EDTA (3, 4), with copper sulfate, formaldehyde, and sodium hydroxide as the other bath components.

The role of mass transport in the apparent reaction orders of cupric ion has been discussed elsewhere (9). It is sufficient to note that, if the computed interfacial concentrations are used to evaluate the reaction order, the differences among the various reactions for cupric ion are substantially diminished, and the reaction order has a value of approximately 0.3. Further, the higher the reaction order (based on bulk concentrations), the greater is the effect of mass transport. It has also been shown that the other bath components are generally insensitive to mass transport effects.

Table III. Summary of reaction orders for electroless copper plating

This work	0.43	−0.70	0.16	−0.04

* Partial analysis of "strong" solutions.
** "Final deposition rate" of 0 rpm.

Schoenberg (7) has shown that an optimum *p*H exists for electroless copper plating. This observation is supported if the summary for EDTA baths is taken as a unit. Dumesic and co-workers (4) obtained a positive reaction order for hydroxide while the results of this work showed a negative reaction order. Molenaar and co-workers (3), with the highest plating rates of the set, obtained a reaction order of approximately zero. Therefore, this summary reflects the transition from a rate increase with increasing hydroxide concentration through a maximum to a region where the rate decreases with increasing hydroxide concentration. However, since the *p*H's of these solutions were all similar, it is evident that the substrate plays some role in this "optimum *p*H" phenomenon. The data for Rochelle salt baths are also consistent with an optimum *p*H, but are less convincing since no negative reaction orders have been reported.

The reaction order of the ligand, where evaluated, is seen to be very small and more or less independent of its chemical nature. Similarly, the reaction order of formaldehyde is also low.

These generalizations concerning the reaction orders of the bath components, while demonstrating a degree of unity among published rate studies, have underlined essential differences among them which, in all likelihood, cannot be resolved. These points are (*i*) the catalytic properties of the surface on which the deposition occurs, and (*ii*) the effects of mass transport on the apparent specific rate constant and the apparent reaction order for cupric ion.

Because each of the authors used a particular method of measuring the plating rate (five different methods were used by the authors cited), the substrates on which plating was performed (two different classes of substrates were used, *i.e.*, metal and sensitized nonconductors) probably possessed different initial morphologies and, depending on the plating rates, which could have changed during the plating process [*e.g.*, note the "initial" and "final" rates of Dumesic and co-workers (4)]. Therefore, one intuits that all of the authors studied the plating rate of the electroless copper process on surfaces with different catalytic (or electrocatalytic) properties. This could explain the fact that large differences in plating rates have been reported for similar baths, *e.g.*, compare Shippey (1) with El-Raghy (2) and Goldie (6). Since no method of defining the catalytic properties of the surface is available and the suggestion that differences exist is *a posteriori*, the question cannot be resolved.

The effects of mass transport are also intimately associated with the previous question of catalytic properties of the surface. If an interfacial reaction is slow (*i.e.*, the surface has a low catalytic activity), mass transport effects are usually small.[3] The previous remarks about the apparent low reactivity of the surfaces in the studies of El-Raghy (2) and Goldie (6) and the comment of Donahue (9) that "... Goldie and El-Raghy evidently were operating in a region where mass transfer effects were minimal..." would tend to support this argument. Molenaar (3) and Dumesic (4), where mass transfer effects were large (9), were probably operating with highly catalytic surfaces. The role of mass transport of cupric ion and its effect on the apparent reaction order have been adequately treated elsewhere (9), but, from these comments, it is evident that these effects cannot be assayed adequately until the experiments have been completed. Simi-

[3] This assumes, of course, that the concentration of reactant is not particularly low.

larly, the apparent specific rate constant is strongly influenced (see Eq. [1]) by both the concentration (interfacial or bulk) and the apparent reaction order ("interfacial" or "bulk") of cupric ion used in the computation.

The remarks given to this point in this "Discussion" have been aimed at understanding the unity among published rate studies and attempting to resolve the differences which exist. In conclusion, it seems appropriate to focus on the reasons for the diverse results and on the nature and purpose of empirical rate laws. An empirical rate law is a mathematical description of data obtained for a collection of plating baths. To the extent that the rate computations and concentration measurements are correct and the procedure (1) is followed, the empirical rate law is a valuable descriptor of the process under consideration. Thus, if one wants to ascertain the optimum plating bath composition,[4] the rate law can be used (11) provided the mass transport conditions are not changed in the transition from laboratory to plant, the sample preparation procedure is not changed and concentrations of bath components are interpolated (not extrapolated) in the computations. Therefore, given our present knowledge of the nature of the electroless plating process and the uncertainties associated with the substrate-mass transport interactions, it is to be expected that different sample preparation procedures will lead to different rate laws.

Conclusions

Kinetics studies of Cu^{2+}-HCHO-EDTA baths have resulted in an empirical rate law. This rate law has been compared with those for other EDTA baths, and the resulting analysis has shown that mass transport of cupric ion plays some role in all baths, an apparent optimum hydroxide ion concentration exists (which, however, depends on the nature of the substrate) and formaldehyde and EDTA have low reaction orders. Similar conclusions were drawn for Rochelle salt baths.

The interaction between substrate catalytic activity and mass transport were discussed, but no resolution of these effects for published rate studies seems feasible at this time.

[4] This optimization is based on kinetic considerations only. A complete optimization would have to consider "extra-kinetic" properties of the deposit such as morphology, ductility, adhesion, etc.

The utility and limitations of empirical rate laws were discussed.

An Electron Diffraction Study on Mixed $PdCl_2/SnCl_2$ Catalysts for Electroless Plating

Tetsuya Osaka* and Hideaki Nagasaka

Department of Applied Chemistry, Waseda University, Okubo, Shinjuku-ku, Tokyo 160, Japan

and Fumio Goto

Nippon Electric Company, Limited, Memory Research Laboratory, Basic Technology Research Laboratories, Miyazaki, Takatsu-ku, Kawasaki 213, Japan

ABSTRACT

The activated or catalyzed surface conditions for initiating electroless metal deposition were studied by means of transmission electron microscopy and electron diffraction analysis. Four mixed $PdCl_2/SnCl_2$ catalysts, including two commercial samples, and five accelerators (NaOH, HCl, H_2SO_4, NH_4OH, and NH_4BF_4) were used in this study. The acceleration with NaOH gave the finest remaining particles which were almost bare active nuclei, while the acceleration with ammonate group (NH_4OH and NH_4BF_4) coagulated small particles to produce high density particles. The electron diffraction patterns after activation, for the catalysts prepared in our laboratory, showed amorphous broad diffraction rings which were explained as fcc structure, while for the commercial catalysts, they showed relatively sharp and netlike profiles which could be attributed to orthorhombic structure. The electron diffraction patterns after acceleration with NaOH became the sharper profiles of fcc structure, however in the case of ammonate group, they showed the complicated profiles of non-fcc structure. Finally the catalytically active sites or nuclei are discussed.

There have been two groups of investigations of the $PdCl_2/SnCl_2$ catalyst solution initiating electroless plating onto nonmetallic substrates, namely, to focus on whether the catalytic activity is due to Pd-Sn solute complexes or to the presence of colloidal particles in the catalyst solution. Matijević *et al.* (1) concluded that colloidal particles in solution exhibit catalytic activity on the basis of colloid science measurements. The present authors (2) also showed the colloidal states to be active by photospectroscopy (u.v. and vl) and electron microscopy. The final active sites initiating metal deposition have been discussed with some results of electron diffraction (3, 4), Mössbauer (5), and Rutherford scattering spectroscopies (6). By electron diffraction analysis Feldstein *et al.* (3) showed the fcc diffraction patterns which were due to Pd_3Sn. Cohen *et al.* (5) using Mössbauer spectroscopy constructed a model in which the colloidal particles consist of Pd-Sn alloy core with a stabilizing layer of adsorbed Sn(II) ions. Meek (6) indicated from Rutherford scattering measurement that the Pd/Sn ratio becomes $(\lesssim)$ 1 after activation and $\simeq 3$ after acceleration and finally $\simeq 6$ at the initial stage of copper plating. The present authors (2) derived the conclusion from x-ray photoelectron spectroscopy that the Pd/Sn ratio after acceleration depends on the catalyst activity and that it is less than unity. In this communication, we will discuss the surface conditions of Pd-Sn particles on the substrate revealed by electron diffraction study and also investigate the acceleration effect on surface conditions.

Experimental

Three samples of $PdCl_2/SnCl_2$ catalysts which were employed in the previous study (2) and the commercial sample "F" were used and the detailed preparations and compositions were previously shown in Ref. (2). The sample "A" (low catalytic activity) and "D" (high catalytic activity) were prepared in our laboratory with reference to some patents and Matijević's experiments (1). Sample "E" (Hitachi Kasei Company HS-101B) and "F" (Shipley Company Cataposit No. 44) were used as typical commercial samples (*cf.* Table I). Sample "F" is one of the salty catalysts using NaCl instead of HCl. Five accelerators (1M NaOH, 6M HCl, 1.12M H_2SO_4, 1M NH_4OH, and 1M NH_4BF_4) were used for the test of acceleration effect. The catalyst activity and the acceleration effect were tested with mixed potential measurements in an electroless nickel plating bath (composition and conditions: $NiCl_2 \cdot 6H_2O$ 29.4 g/l, malonic acid 20 g/liter, L-aspartic acid 21.0 g/liter, demethylamine borane 3.54 g/liter, pH 9.5 adjusted with NH_4OH, bath temperature 70°C). All solutions were prepared with reagent grade chemicals and doubly distilled water. The immersion time was 3 min for activation and acceleration processes, respectively. A water rinse step was added between each step of pretreatment for electroless plating. Copper wire and collodion film were adopted as substrates for mixed potential measurements and transmission electron microscopy. Electron microscopy measurements were made using a JEOL JEM-7A instrument with a 100 kV electron source. Electron diffraction patterns were analyzed with reference to the instrumental factor determined by a standard sample of evaporated gold.

Results and Discussion

Acceleration effect on catalyst functionality.—The mixed potential measurement in the plating bath was proposed to investigate the functionality of catalysts in the previous paper (2), and it was shown that the catalyst activity order corresponds to the reverse order of the induction time (*i.e.,* initiation time of electroless plating after immersion of copper wire). The induction time can be easily determined from the drastic change of the mixed potential of copper wire. Table II shows the induction time measured in the Ni-B electroless plating bath. The activity order of catalyst solutions, previously shown in Ref. (2), is A $<$ D $<$ E, and the salty catalyst "F" is situated in position between "A" and "D". The reason that the commercial sample "F" has lower activity can be attributed to the increase

F	2.0	1.9	3.7	2.2	3.6

of charged metal atoms which is caused by the usage of salt instead of HCl (*cf.* the later discussion). The accelerators NaOH and HCl are more active than the others. Although the differences are not so clear, the order of catalyst activitv after acceleration is NaOH $\simeq$ HCl $>$ NH_4BF_4 $>$ NH_4OH $>$ H_2SO_4. Rantell and Holtzman (4a) found a similar order of NaOH $>$ NH_4HF_4 $>$ H_2SO_4, while the deterioration of catalytic activity through prolonged treatment in the case of acid group accelerators, which was pointed out by Rantell and Holtzman, was not so clearly noticed in our experiments.

Transmission electron microscopy.—The activated surface conditions were investigated by transmission electron microscopy using collodion film. The colloidal particle sizes of catalysts "A", "D", and "E" adsorbed on collodion films, which were previously discussed in Ref. (2), were uneven particles of several tens Å or less, more uniformly patches of 400 $\sim$ 700Å particles, and uniformly high density particles 300 $\sim$ 600Å in diameter. The salty catalyst "F" gives uniform distribution with colloid sizes 300 $\sim$ 400Å in diameter similar to that of "E." Typical examples after the acceleration process using "D" with several accelerators are demonstrated in Fig. 1. The appearance after acceleration can be classified into three groups (NaOH, H_2SO_4; HCl; NH_4OH, NH_4BF_4). Sodium hydroxide strips the surface layers most effectively, and the finest remaining particles seem to be almost bare active nuclei after removing stannous and stannic oxides or hydroxides. Sulfuric acid also strips the surface particles but it is clear from the larger remaining particle sizes that the acceleration action of H_2SO_4 is lower than that of NaOH. With HCl accelerator the remaining particles become smaller and uniform particle contribution of several tens Å particles. In the case of NH_4OH or NH_4BF_4, it is shown that the acceleration process coagulates the small particles to produce high density particles. Since it is confirmed by the electrochemical potential sweep technique as shown in Ref. (2) that the acceleration with NH_4BF_4 clearly removes adsorbed Sn, leaving Pd nuclei on gold, it may be concluded that the coagulating particles whose diameters become larger than those after activation do not consist of Sn oxides or hydroxides but ammonate compounds such as Pd-ammonia complexes which are produced by chemical reactions. Rantell and Holtzman (4b) reported phenomena similar to those with ammonate accelerators, that the catalyst particle sizes become larger after acceleration with NH_4HF_4 on ABS surfaces, and they discussed the formation of $Pd(NH_3)_4^{2+}$ complex in the case of ammonium hydroxide. Thus, it is concluded from the electron microscopy observation that the catalyst activity after acceleration is affected not only by the catalytic grain density and size but also by

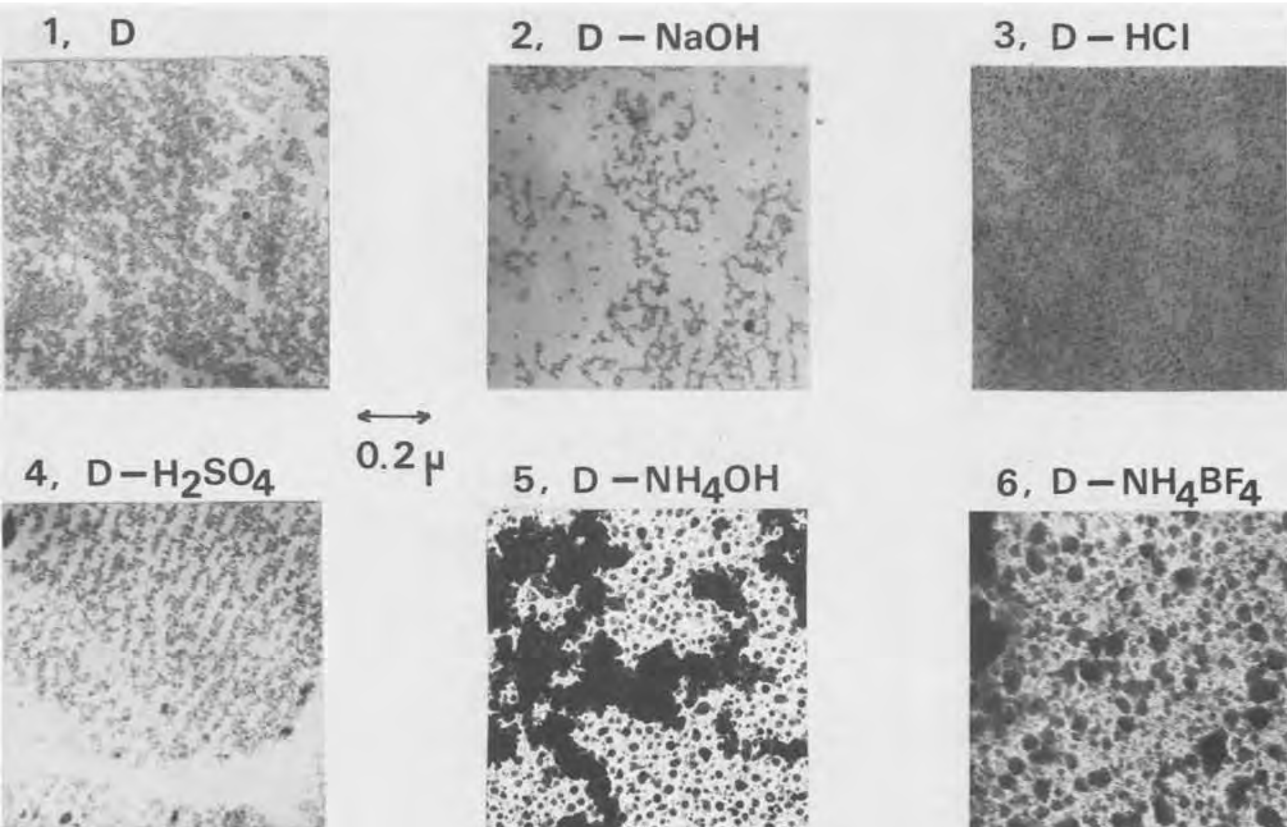

Fig. 1. Electron micrographs of various samples on collodion film after activation or acceleration. 1: after activation with catalyst "D," 2, 3, 4, 5, 6: after activation with catalyst "D" and acceleration with each solution.

the other factors as seen in the case of NH_4OH or NH_4BF_4 accelerators.

Electron diffraction patterns after activation process.—An electron diffraction analysis was applied to the activated surfaces in order to obtain further insight into the catalyst particle conditions after activation and/or acceleration. Figure 2 shows the electron diffraction patterns after activation with four catalyst samples. Both catalysts "A" and "D" which were prepared in our laboratory according to some patents give amorphous broad fcc (face-centered cubic) profiles with lattice parameters $a = 3.719$ and 3.986, respectively. Whereas, the commercial samples "E" and "F" do not show simple fcc profiles, but relatively highly crystallized and netlike patterns which can be attributed to orthorhombic structure. Feldstein *et al.* (3) and Rantell *et al.* (4b) reported from electron diffraction studies that the product after acceleration has fcc structure, though it is amorphous after activation only. The results of "A" and "D" in Fig. 2 are obviously amorphous conditions with broad diffraction rings, but they can be interpreted as fcc structure similar to those after acceleration with NaOH accelerator (*cf.* Table IV). The composition for Pd-Sn alloys was reported as follows (7, 8): the solid solubility of Sn in Pd is approximately 17 atomic percent (a/o) and the fcc solid solution transforms into Pd_3Sn (27 a/o Sn) which also has the fcc structure. The lattice parameters for pure Pd and for Pd_3Sn are $a = 3.89$ and 3.97, respectively. Above *ca.* 30 a/o the orthorhombic compounds such as Pd_2Sn, $PdSn_2$ (or pseudotetragonal), and $PdSn_4$ are reported except for the composition range around 40 a/o in which the compound of Pd_3Sn_2 has the hexagonal structure. Therefore, the samples "A" and "D", although their diffraction rings are broadened by some stannic compounds in the surface layer on active sites, may consist of fcc Pd-Sn alloys having less than 27 a/o Sn. In contrast to "A" and "D" the commercial samples "E" and "F" may have the surface layer of Sn-rich compounds on active sites, which might be produced by aging process which would increase the size of the colloidal particles in catalyst solution. The aging effect will be discussed later.

Electron diffraction patterns after the acceleration process.—The typical results of sample "D" after acceleration with various kinds of accelerators are demonstrated in Table III, corresponding to the electron micrographs in Fig. 1, respectively. Electron diffraction patterns can be explained as fcc only in the cases of NaOH and H_2SO_4 accelerators. The accelerators NaOH and H_2SO_4 remove the surface layers on the active nuclei effectively and the sodium hydroxide which gives the finest remaining particles can show the bare conditions of catalytic nuclei which consists of Pd-Sn alloy of fcc structure. The electron diffraction pattern with HCl accelerator (D-HCl) whose electron micrograph shows rearranged uniform and small particle contribution can be apparently explained as tetragonal structure and it might be attributed to some products of chloride or changes of the lattice from fcc Pd-Sn alloy. The electron diffraction patterns with ammonates (D-NH_4OH and D-NH_4BF_4) which can be seemingly explained as orthorhombic structure might be due to some Pd-ammonia complexes, and it seems to be supported by the results of the coagulation of the particles shown in Fig. 1. Therefore, the electron diffraction patterns of the most characteristic two accelerators (*i.e.*, NaOH and NH_4BF_4) are shown in Fig. 3. In the case of NaOH accelerator [Fig. 3(a)] all catalysts give the electron diffraction patterns of fcc structure, while in the case of NH_4BF_4 [Fig. 3(b)], all patterns show the non-fcc structure which can be apparently explained as orthorhombic. Therefore, the results after NaOH acceleration are considered to show the bare active nuclei and the results after NH_4BF_4 acceleration are considered to be produced by the different surface conditions from the usual active sites, which may result from some ammonate compounds such as Pd-ammonia complexes. Since it can be concluded that the electron diffraction patterns after NaOH acceleration process give the information of bare catalytically active nuclei, the discussion about the active sites or nuclei is considered to be advanced with the results after the NaOH acceleration process. In the cases of "A" and "D" the diffraction rings change from broad to sharp rings, and the change may be caused by the removal of Sn-rich surface layer of particles. The change from non-fcc to fcc in the case of the commercial samples seems to correspond to the fact that the catalytic active sites of fcc structure appear after removing the surface layer consisting of Pd-Sn alloy of orthorhombic structure whose Sn content is much higher than that of fcc structure. Cohen and Meek (6b) pointed out that the lattice constant for Pd-Sn alloy of Pd-rich region of fcc structure can be changed from $a = 3.89$ (pure Pd) to 3.97 (Pd_3Sn) with the increase in Sn concentration. Only in the two cases of sample "A" activation and F-NaOH acceleration in Table IV does the lattice constant not fall in this range, namely, it is smaller than that of pure Pd ($a = 3.89$) (see Table IV). Though a lattice constant smaller than that of pure Pd is not usually expected, it might be caused by the facts that the surface particles contain many defects and/or charged metal atoms, and that the surface energy in minute particles is lower than that of the bulk conditions. The amorphous conditions of the surface particles suggest that they contain many defects. The XPS results previously shown (2) derived the conclusion

Table III. Dependence of acceleration on the crystal structure of Pd-Sn core

D	D-NaOH	D-HCl	D-H_2SO_4	D-NH_4OH	D-NH_4BF_4
fcc $a = 3.986$	fcc $a = 3.949$	non-fcc	fcc $a = 3.937$	non-fcc	non-fcc

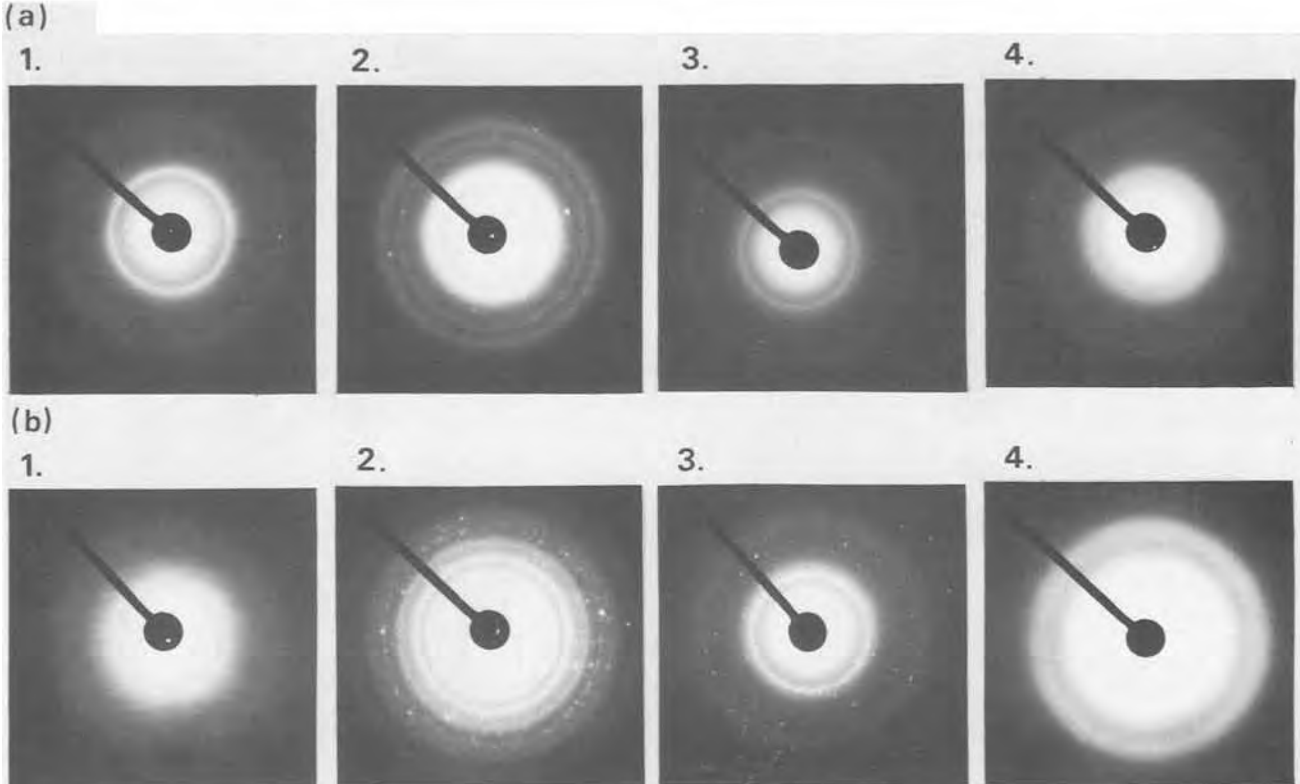

Fig. 3. Electron diffraction patterns of various samples on collodion film after acceleration. (a): accelerator 1M NaOH, (b): accelerator 1M NH_4BF_4. Each number is the same as in Fig. 2.

that the high activity catalyst shows shifts in binding energies of Pd and Sn toward the metals and that the acceleration process causes the chemical shifts for Pd and Sn to occur toward the metals with lower binding energies. The possibility of lower activity catalysts of "A" and "F" containing many charged metal atoms can be inferred from the XPS conclusion. The change of lattice parameter from 3.986 to 3.949 in the case of sample "D" is considered to be caused by the removal of an Sn-rich surface layer of Pd-Sn alloy, while in the case of sample "A," the change from 3.719 to 3.878 may be due to the removal of a surface layer which contains many charged metal atoms.

The effect of aging on the catalyst solution was observed in our experiments, for example, catalyst "D" gave the major change of lattice parameter from $a = 3.766$ to 3.986 with aging approximately for 3 ~ 4 weeks. The aging effect was also reported by Feldstein *et al.* (3) and it was confirmed that the aging effect on the copper deposit is to render the product similar to that employing an improved conventional sensitizer. It seems to be concluded that the aging effect changes the charged metal atom to the metallic state and that it produces the distribution of well-formed colloidal particles in solution.

Finally, the activated surface conditions can be regarded as that the catalytically active sites consisting of Pd-Sn alloy have the fcc structure with various concentrations of Sn in the Pd-rich region, and that the active cores are usually covered with Sn-rich surface layers which stabilize the colloidal particles in solution. The accelerator usually removes the surface layer to give the active core with fcc structure, however, the accelerator of the ammonate group renders the activity lower by producing some Pd-ammonia complexes which give the catalytically low activity.

Table IV. Dependence of activation and/or acceleration on the crystal structure of Pd-Sn core

Acc \ Act	A	D	E	F
Activation only	fcc $a = 3.719$	fcc $a = 3.986$	non-fcc	non-fcc
NaOH	fcc $a = 3.878$	fcc $a = 3.949$	fcc $a = 3.917$	fcc $a = 3.796$
NH_4BF_4	non-fcc	non-fcc	non-fcc	non-fcc

Acknowledgments

The authors would like to thank Professor Dr. Tadashi Yoshida, Waseda University, Dr. Takashi Furuoya, and Mr. Yoji Suganuma, Basic Technology Research Laboratories, Nippon Electric Company, for their encouragement of this research and Dr. Masaki Miyahara, Waseda University, for his useful discussion. They are also greatly indebted to the Kurata Research Grant from the Kurata Foundation and the Research Fund of Waseda University for financial support.

$Ga_xIn_{1-x}P$ (n) ($0 \leq x \leq 1$) Semiconducting Alloys Studies in Photoelectrochemical Cells

A. M. Redon* and J. Vigneron

Laboratoire d'Electrochimie Interfaciale du C.N.R.S., 92190 Meudon-Bellevue, France

ABSTRACT

The $Ga_xIn_{1-x}P$ (n) ($0 \leq x \leq 1$) alloys are very interesting semiconducting compounds for solar energy conversion purposes as their bandgaps vary from 1.30 to 2.25 eV. The studies are performed in acidic pH (pH ~ 1) (0.5M KCl + 0.1M HCl), as the photocurrents observed are only stable in this medium. The photodecomposition gives rise to the formation of $In(OH)_3$ and $Ga(OH)_3$ which are soluble products at low pH, but insoluble at higher pH. A maximum efficiency is obtained with the reducing agent Fe^{2+}. This result was interpreted as depending on the relative positions of the bands. A maximum efficiency was also observed for the composition $x = 0.36$ in all the media investigated. This was interpreted as a change in the different parameters of the alloys.

Recently, there has been much interest in utilizing semiconducting electrodes for solar energy conversion purposes by the photoassisted electrolysis of water, or for chemical storage by means of electrochemical reactions with redox systems.

In fact, by illuminating an n-type electrode with photon energy of incident light greater than the bandgap, holes are produced in the valence band, and then, as a result of the electric field at the semiconductor electrolyte interface, they migrate to the surface where they can react with species in solution (1-3). Thus, it should be easy, with suitable semiconductor electrodes, to oxidize water to oxygen by means of solar energy.

For this purpose, many semiconducting electrodes have been investigated. But photocorrosion remains an important problem. Generally more stable materials in aqueous solutions have a large bandgap energy. In fact, compounds with small bandgaps have little cohesion energy, so that the photodecomposition potential is often lower than the potential associated with oxygen evolution. So photodecomposition generally occurs preferentially (4-5).

In this work, semiconducting alloys (n) ($Ga_xIn_{1-x}P$) ($0 \leq x \leq 1$) are considered. These compounds are very interesting because their bandgaps, which vary from 1.30 eV (InP) to 2.25 eV (GaP), cover the whole visible solar spectrum.

Some previous studies were made with these materials. First, they were investigated with physical methods, such as electroreflectance, cathodoluminescence, and optical transmission (6-9). Then, the flatband potential and the concentration of majority carriers were determined by means of electrochemical impedance measurements and compared with the results obtained in the absence of any electrolyte (10-11).

In previous work, these compounds were used as electrodes in photoelectrochemical cells, in the absence of any redox system (12-13), and some fundamental physical properties, such as the bandgap energy, the transition mode, and the diffusion length of minority carriers, were deduced and compared with those found in literature (6-9).

While GaP compounds have been studied a great deal by photoelectrochemistry (14-19), studies on InP electrodes are more recent and not so extensive (20-23). But to our knowledge, there are no papers up to now on $Ga_xIn_{1-x}P$ compounds on photoelectrochemical studies, except those realized in this laboratory.

* Electrochemical Society Active Member.

Key words: semiconductors, photoelectrochemistry, stabilization, solar energy, solar cell.

The results obtained with various redox systems in the same aqueous electrolyte (0.5M KCl + 0.1M HCl, pH = 1), are given here.

The main purpose of this work is to determine the reducing agents and the composition associated with a maximum efficiency for the conversion of solar energy into electricity.

Experimental

Apparatus.—The apparatus consisted of a 150W xenon lamp and a Jobin Yvon HRS 2 monochromator. The light is chopped with a PAR 121 in order to eliminate the dark current.

Cyclic voltammetry curves are performed with the aid of a Fabelle potentiostat controlled by a voltage scan generator Wenking VSG 72.

Electrodes.—The photoanodes used are n-type $Ga_xIn_{1-x}P$ polycrystalline alloys ($0 \leq x \leq 1$). They are doped with sulfur at a concentration ~ $10^{17}/cm^3$, at 300°K, for all the compositions (9, 11, 12). The percentage in Ga and In was determined with an electron microprobe.

The ohmic nature contact to the semiconductor is insured by diffusion of tin. Before the experiment, the surfaces of the electrodes exposed to the light, and in contact with the electrolyte, are mechanically polished with diamond paste (1 μm < grain size < 25 μm), and then etched with a 2% bromine-methanol solution. But, after this treatment, dark currents and photocurrents slowly decrease, probably due to some modification of the surface. So, this etching with bromine-methanol was not done before each experiment, but only before the first one; an electrochemical polishing of the electrodes was performed with many cyclic voltammetric sweeps.

Electrode areas were determined by numerical integration on a photograph.

Electrolyte.—All the experiments in this work were performed at pH = 1, in 0.5M KCl + 0.1M HCl. In basic, and neutral pH, photocurrents are not stable, due to electrode decomposition. Interpretation of these results is discussed in the following.

The reducing agents Ti^{3+}, Ce^{3+}, Fe^{2+}, and the hydroquinone were then introduced into the cell. In these different media, the cyclic voltammograms are recorded in the dark and under a monochromatic light in order to compare the efficiencies of the different compounds in electrolyte alone and with reducing agents. These efficiencies are determined by the ratio between photocurrents by unit area, and the diode current obtained at the same place as the photoelectrode, after the electrolyte. So the absorption of the electrolyte is taken into account.

The sweep rate chosen for all the recording is v = 10 mV/sec.

Samples were always positioned very carefully in the same place to achieve a maximum photocurrent. This was realized, by fixing the cell into a plate which can be rotated around three axes and displaced following these three directions.

Results

Current potential curves under a monochromatic light.—Without a redox system.—With n-type semiconductors, in the absence of any redox system, it is easy to observe an anodic photocurrent at more positive potentials due to oxygen evolution or decomposition of the electrode.

The shapes of the curves on Fig. 1, can be explained very well by the relative differences between the parameters of the compounds (absorption coefficient α, diffusion length L_p of the minority carriers) (12). In fact, following Gärtner's theory (24), and with relative values of αL_p and the width of the depletion layer, the saturation voltage in the intensity-potential curves goes to lower values of the anodic potential. ($\alpha_{GaP} \sim 10^2$ cm^{-1}, $\alpha_{InP} \simeq 10^4$ cm^{-1}, $\overline{L}_{pGaP} \sim 2.7$ cm, $\overline{L}_{pInP} \sim 0.9$ cm).

On Fig. 2, we can see the different efficiencies obtained as a function of the wavelength of the incident light, and for the same polarization of the electrodes (V = 1 V/SCE) in the electrolyte alone. All the results refer to the unit area of the electrode. Photocurrent values are corrected from the intensity of the xenon lamp spectrum and for the response of the photodiode. For this, a P.D.P. 11 computer was utilized.

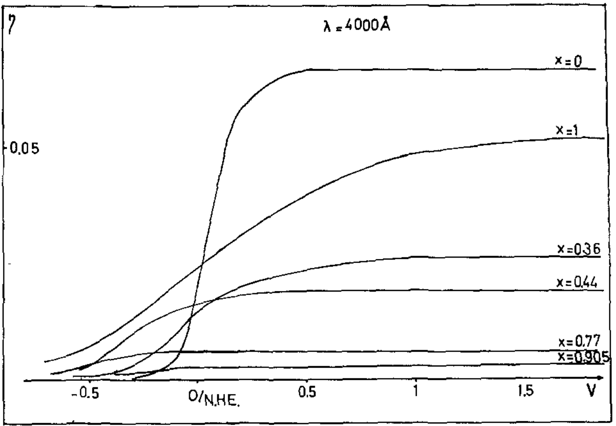

Fig. 1. Efficiencies for different compositions x of the alloys, in 0.5M KCl + 0.1M HCl (pH = 1.2) vs. the applied electrode potential values are corrected from the area of the electrodes. Wavelength of the incident light is λ = 4000Å.

The photoaction spectra does not vary with sample history, or with different portions of the same sample. They only depend on the composition of each sample.

With reducing agents.—The different efficiencies are then observed in the presence of several reducing agents under monochromatic illumination.

On Fig. 3 the efficiencies are given *vs.* applied potential, and with the reducing agents, at the same concentration (10^{-3}M) and with the same base electrolyte (pH = 1.2). The composition investigated here is x = 0.77, and the wavelength chosen λ = 500 nm.

Ga x In 1-x P=f(λ) 0.5M KCl+HCl (pH=1.2)

1 —— x=0.
2 —— x=0.36
3 —— x=0.44
4 —— x=0.77

Fig. 2. Efficiencies for the different compositions x vs. the wavelength of the incident light. Electrode potential V = + 1 V/NHE. All the values are corrected for the area of the electrodes.

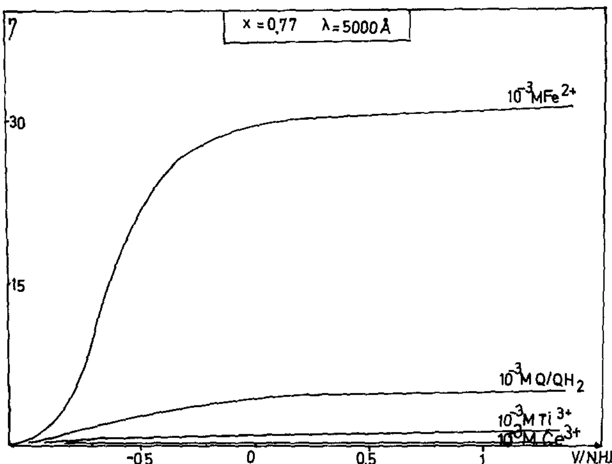

Fig. 3. Efficiencies *vs.* applied potential at $\lambda = 5000Å$ for $Ga_{0.77}In_{0.23}P$ in the presence of: $10^{-3}M$ Fe_2SO_4, $10^{-3}M$ hydroquinone, $10^{-3}M$ $TiCl_3$, $10^{-3}M$ $CeCl_3$ and base electrolyte.

If the intensity varies with the composition, and the redox system, the shapes of the curves remain the same and so they are not drawn here, consequently a comparison between the different alloy compositions are given in the base electrolyte (Fig. 4a). On Fig. 4b, we can see that the photocurrent depends on the composition of the electrode, the normalization to the maximum photocurrent being realized. On Fig. 5a and b, the magnitude of the photocurrents is given *vs.* the composition of the electrodes, with different reducing agents investigated and with the hydroquinone.

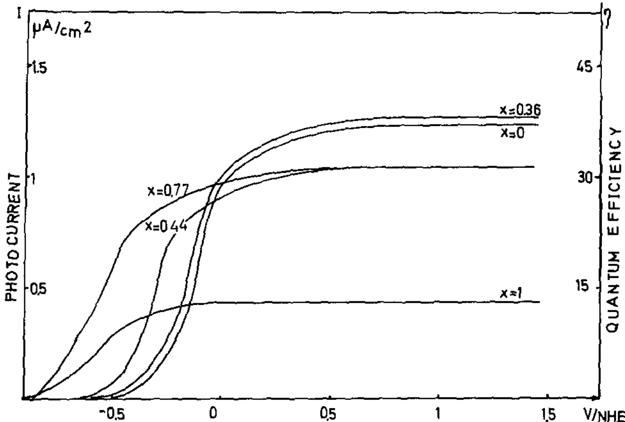

Fig. 4a. Efficiencies for $\lambda = 4000Å$, in the base electrolyte, for the different compositions *x vs.* the applied potential.

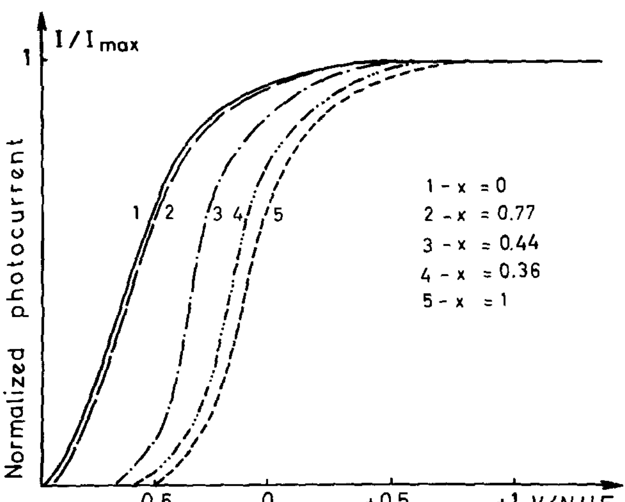

Fig. 4b. Normalized intensities relatively to the maximum photocurrent of each curve.

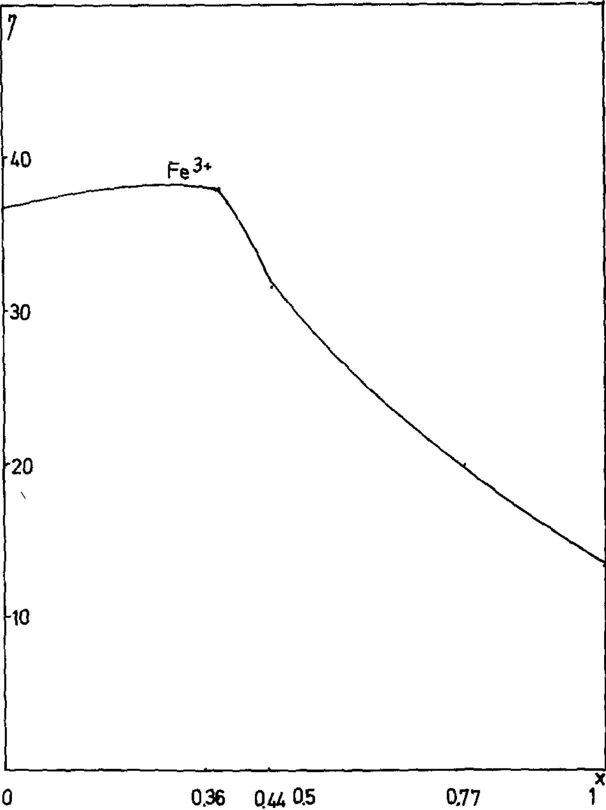

Fig. 5a. Efficiencies obtained *vs.* the composition *x* of the alloys in $10^{-3}M$ Fe^{2+}. Wavelength of the incident light is $\lambda = 5000Å$ and the applied potential $V = 1.7$ V/NHE.

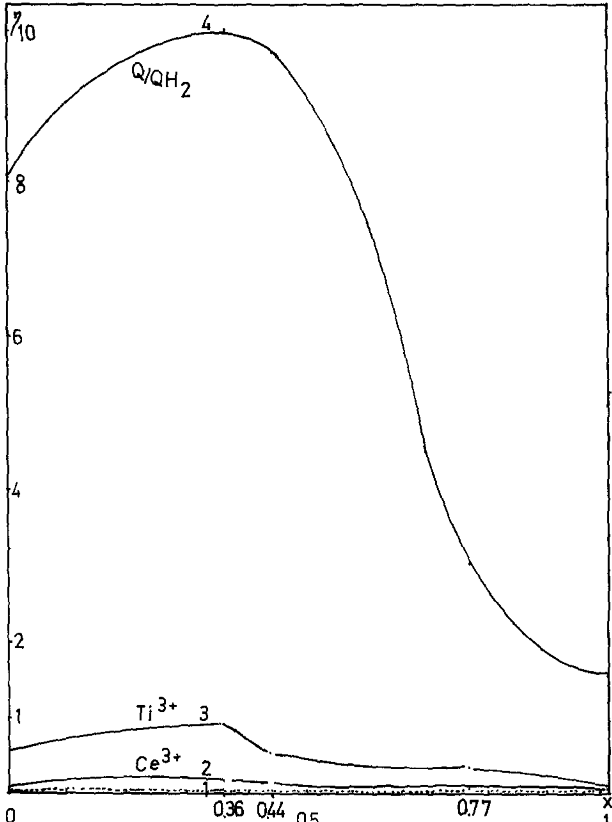

Fig. 5b. Efficiencies obtained *vs.* the composition *x* of the alloys in different media: curve 1, electrolyte alone; curve 2, $10^{-3}M$ Ce^{3+}; curve 3, $10^{-3}M$ Ti^{3+}; curve 4, $10^{-3}M$ Q/QH_2. Wavelength of the incident light $\lambda = 5000Å$. Applied polarization $V = 1.7$ V/NHE.

Results obtained show that maximum efficiency is always obtained in all media for the same composition $x = 0.36$ (bandgap 1.72 eV).

Discussion

In order to discuss results obtained in the base electrolyte it is necessary to know the position of the bands of the compounds studied, relative to the Gibbs energy of the decomposition reactions, Fermi levels associated with the electrolysis of the water (Fig. 6), and redox reactions (Fig. 7).

At negative potentials, cathodic currents correspond not only to the protons reduction, but also to the cathodic decomposition of the electrodes. Reactions involved are the following (12)

$$GaP + \frac{3}{2} H_2 \rightleftarrows Ga + PH_3 \ (V_{dnGaP} = -0.46 \text{ V/NHE})$$

$$InP + \frac{3}{2} H_2 \rightleftarrows In + PH_3 \ (V_{dnInP} = -0.29 \text{ V/NHE})$$

V_{dn} is the potential associated with the cathodic decomposition at pH = 1.

The reactions of anodic decomposition of the electrodes, giving rise to anodic currents, are the following (12, 25, 26)

$$InP + 6H_2O \rightleftarrows In(OH)_3 + H_3PO_3 + 3H_2 \ (V_{dpInP} = -0.31 \text{ V/NHE})$$

$$GaP + 6H_2O \rightleftarrows Ga(OH)_3 + H_3PO_3 + 3H_2 \ (V_{dpGaP} = -0.35 \text{ V/NHE})$$

V_{dp} is the potential associated with the anodic decomposition at pH = 1. These values show that anodic, as well as cathodic, decomposition occurs at negative potentials relative to the 0 V/NHE and that InP decomposes more easily than GaP, as values of decomposition potentials are lower.

After holding a $Ga_xIn_{1-x}P$ alloy several hours at anodic potentials in the electrolyte alone (pH = 1), under a maximum light intensity, the solution was analyzed by colorimetry (27) in order to detect indium and gallium. Both elements were detected. Moreover, the surface of the electrodes was covered with

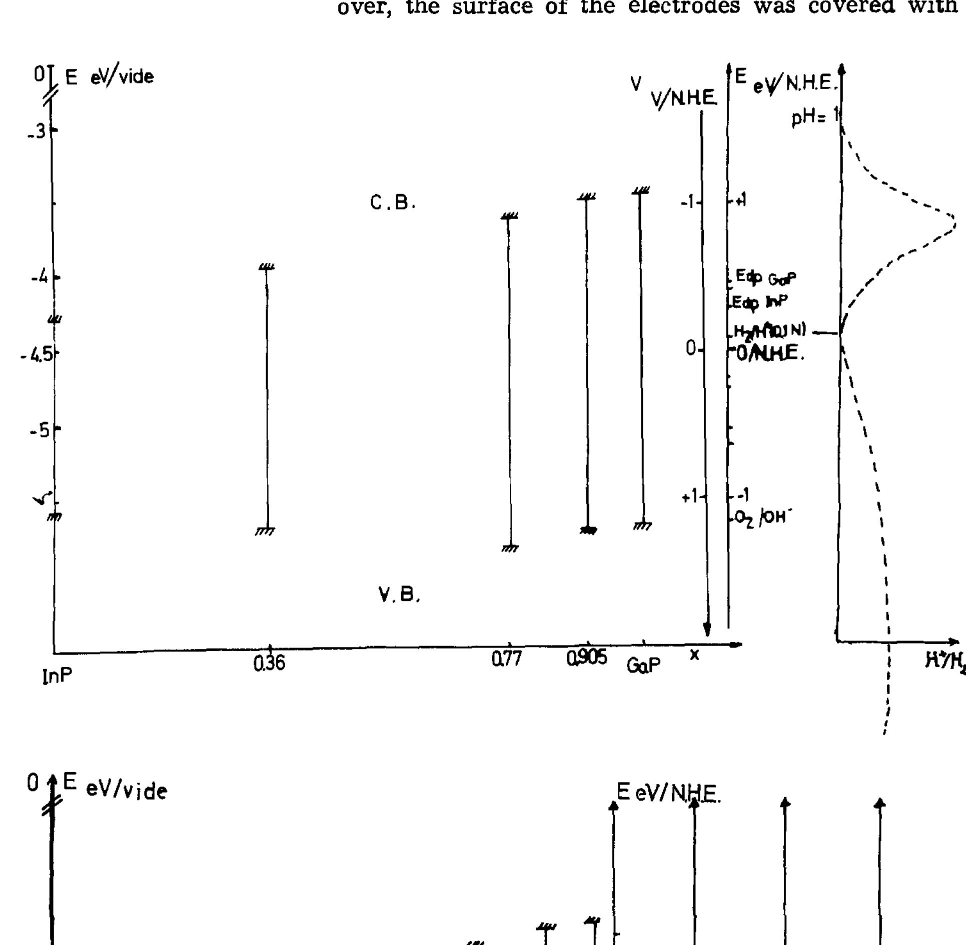

Fig. 6. Position of the anodic decomposition potentials of the crystals, and Fermi levels associated with the electrolysis of the water, relatively to the bands of the $Ga_xIn_{1-x}P$ compounds ($0 \leq x \leq 1$, n-type).

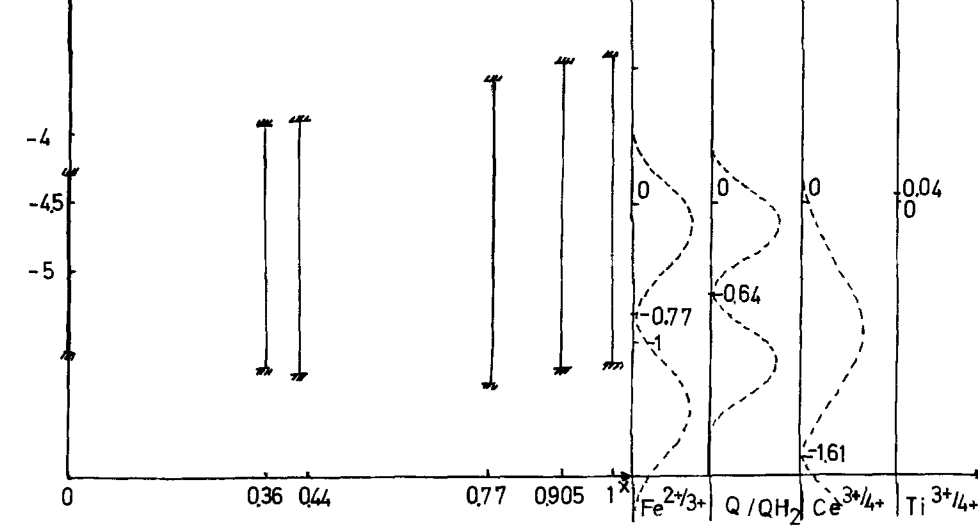

Fig. 7. Band diagram of the $Ga_xIn_{1-x}P$ compounds and distribution of the different redox couples used.

a gray substance which probably was due to the formation of $In(OH)_3$ and $Ga(OH)_3$.

So, photocurrent obtained at anodic potentials is probably due to both oxygen evolution and anodic decomposition.

Then, if the Fermi levels of the redox reactions are considered, relative to the bandedges at the surface, Fig. 7 can explain our experimental results.

As we can see by comparison of Fig. 3 and 7, reducing agents having a Fermi level near the valence band must give rise to higher photocurrents. This is in accordance with experimental results: quantum efficiencies are greater with Fe^{2+} than with Q/QH_2 or Ti^{3+}. Moreover, since the Fermi level of Ce^{3+} is below the valence band, the anodic photocurrent is very small.

But, the widths of the different redox couples used can also be taken into account to interpret this result, Table I (28).

A diagram of the bands of our semiconductors may be arranged relative to the electronic distribution of redox reactions (Fig. 6-7).

The redox system with highest overlap of its filled levels with the edge of the valence band are expected to give larger photocurrents if the different efficiencies obtained in this work are compared to position and distribution of the different redox couples investigated.

A maximum efficiency is obtained for the composition $x = 0.36$ ($E_g = 1.72$ eV). This result can be associated with a change in the behavior of the compound. In fact, with the composition there is change in the optical transition mode (12), and the absorption coefficient is very different ($\alpha = 10^4$ cm^{-1} for InP and $\alpha = 10^{+2}$ cm^{-1} for GaP). As we can see, this result is obtained for all the reducing agents used.

Conclusion

In this paper, we explore the efficiencies of photocells realized with $Ga_xIn_{1-x}P$ alloys ($0 < x \leq 1$), n-type, at $pH = 1$, with and without Ce^{3+}, Ti^{3+}, Fe^{2+}, and Q/QH_2 at the same concentration, 10^{-3}M. In the electrolyte alone, there is a substantial decomposition of the electrode, as well in the dark as under the light.

With the different reducing agents investigated, it appears a maximum efficiency with Fe^{2+}. This result agrees with the relative positions of the bands of the alloys and the Fermi levels of the redox couples investigated.

Another important result is that a maximum efficiency is obtained with all the reducing agents used for the composition $x = 0.36$ of the alloys. This probably is due to the evolution of the different parameters of the compounds: diffusion length of minority carriers, width of the depletion layer, absorption coefficient, and transition mode.

Acknowledgments

The authors wish to thank Dr. J. Bourneix for the fabrication of the $Ga_xIn_{1-x}P$ compounds, and Mme. De Mende for the mounting of the electrodes. We would also like to acknowledge helpful discussions with Dr. Parsons and Dr. H. Tributch. This work was performed with support from D.G.R.S.T. Contract No. 6501617.

Lattice-Gas Treatment of Supercritical Phase Behavior in Fluid Mixtures

L. A. Kleintjens and R. Koningsveld

Central Laboratory DSM, 6160 MD Geleen, The Netherlands

ABSTRACT

Recently, Trappeniers *et al.* have shown that gas-gas demixing phenomena can be described qualitatively with the lattice-gas model in its simplest form. We have tried to develop this treatment into a quantitative theory with the least possible number of parameters. The extended model has proven to permit a fairly accurate description and prediction of supercritical fluid phase behavior in a number of systems. The applicability of the model is illustrated with experimental data on the system methane/water which shows gas-gas demixing of the second kind.

Lattice models have frequently been used in the description of phase behavior of liquid mixtures. One of the assumptions underlying such treatments is the equality of the partial specific volumes of the components in all liquid phases at constant pressure and temperature. In gas-liquid and supercritical fluid equilibria the densities of the phases may differ a great deal and the conventional rigid-lattice model is less suited for describing such phenomena.

This problem is circumvented in the lattice-gas model which introduces randomly distributed vacancies in the lattice. The density of a system or phase can be reproduced easily by adjustment of the concentration of vacancies. The model was developed by Mermin (1) and by Mulholland and Rehr (2) for one-component systems on the basis of the hole theory of liquids devised by Altar (5), Cernuschi and Eyring (4), Frenkel (3), and others.

Trappeniers *et al.* (6, 7) extended the theory combining Guggenheim's (8) two-component lattice model with the lattice-gas treatment and were able to give a qualitatively correct description of the various forms in which gas-gas demixing occurs. The more-component lattice-gas model has also been used by a number of authors for other purposes (9-12). Quantitative descriptions allowing predictions of phase behavior, however, have so far been very rare. In this paper we analyze how Trappeniers' treatment can be extended into a quantitative predictive description of fluid phase behavior, retaining the simplicity of the model and introducing the smallest possible number of adjustable parameters.

Pure Substances

In the lattice-gas model a pure substance is conceived as a binary mixture composed of occupied and vacant lattice sites in which the vacancies contribute to the entropy but not to the internal energy. Temperature and pressure changes cause variations in the concentration of vacancies (holes) but v_o, the volume per lattice site (also hole size), is constant. We further assume only nearest neighbor interactions to contribute significantly to the interaction energy.

Since we want to describe phase behavior of supercritical systems the model should be valid for liquids and gases alike. Gas-liquid equilibrium in a pure substance is considered as a fluid 1-fluid 2 equilibrium where the two fluid phases differ in hole concentration only. A change in hole concentration alters the number of contacts between occupied sites and thereby the total internal (nearest-neighbor interaction) energy.

Key words: equation of state, supercritical fluids, hole theory, lattice-gas description.

Following the recipe of Trappeniers and co-workers (6, 7) we extend the treatment applying a suggestion of Staverman (13). We drop the rigid-lattice condition that each site will have the same number of nearest neighbors (lattice coordination number) and assign an interacting-surface area σ_1 to the molecules. Likewise a surface area σ_o can be assigned to the vacancies, which serves as a unit to relate σ_1-values also. The adjustable parameter thus arising is the surface-area ratio ρ_1 ($= \sigma_1/\sigma_o$) which, however, must have a value within a range imposed by the tolerances of the model. Such a relaxation of the rigid-lattice model has also been introduced by other authors (9, 11, 14, 15) and has proven to be very useful when dealing with various thermodynamic properties. Recently we noticed the same in the description of liquid-liquid phase behavior of linear and branched polyethylene solutions (16, 17).

A further extension we found useful consists of allowing the molecules to occupy more than one lattice site and even permitting broken numbers for the occupancy. By now the lattice has become an abstraction serving merely as a framework for convenient derivation of usable thermodynamic relations. Such a procedure has already been suggested in general terms by Rowlinson (18). All this leads to the following expression for ΔF, the Helmholtz free energy of mixing N_o holes and N_1 molecules of substance 1, occupying m_1 sites each (19)

$$\Delta F/N_\phi kT = \phi_o \ln \phi_o + \phi_1 m_1^{-1} \ln \phi_1 + \phi_o\phi_1[\alpha_1 + g_{11}(1-\gamma_1)(1-\gamma_1\phi_1)^{-1}] \quad [1]$$

where ϕ_o, ϕ_1 = volume fractions of vacancies and occupied sites, $g_{11} = -\frac{1}{2} w_{11}\sigma_o/kT$; $\phi_o = N_o/N_\phi$; $\phi_1 = N_1m_1/N_\phi$; $N_\phi = N_o + N_1m_1$, w_{11} = interaction energy of adjacent molecules 1 per unit surface area, σ_o, σ_1 = surface areas of holes and molecules; $\sigma_1/\sigma_o = \rho_1$, $\gamma_1 = 1 - \rho_1$, and kT has its usual meaning.

In the application of Eq. [1] to vapor-liquid equilibrium data we found that a purely empirical entropy correction parameter α_1 must be included. The other parameters, though adjustable, have a clear physical meaning which allows their magnitude to be estimated. The number of sites m_1 occupied by a molecule 1 is related to v_o by

$$d_1 = \phi_1 M_1/v_o m_1 \quad [2]$$

where d_1 and M_1 stand for density and molar mass of substance 1.

Expressions for experimentally accessible quantities can be derived from Eq. [1] by standard procedures. For instance, the pressure is obtained by applying

$$p = (\partial\Delta F/\partial V)_{T,N1}$$

which leads to

$$-pv_o/kT = \ln \phi_o + (1 - m_1^{-1})\phi_1 + \phi_1^2[\alpha_1 + g_{11}(1 - \gamma_1)^2(1 - \gamma_1\phi_1)^{-2}] \quad [3]$$

Within the model the total volume V is given by $V = N_\phi v_o$. Introduction into Eq. [3] and series development of the logarithmic term shows Eq. [3] to reduce to Boyle's law at low gas density ($\phi_1 << 1$) and to a virial series in reciprocal volume at higher densities.

Vapor-liquid equilibrium conditions are the equality of pressure (defined by Eq. [3] and of the chemical potential of component 1 in the two phases (denoted by ′ and ″). The chemical potential follows from

$$\mu_1 = (\partial\Delta F/\partial N_1)_{T,V}$$

and the equilibrium condition

$$\mu_1' = \mu_1''$$

yields a relation between the concentrations of occupied and empty lattice sites in the two phases

$$m_1^{-1}\ln(\phi_1'/\phi_1'') = \phi_o''^2[\alpha_1 + g_{11}(1-\gamma_1)(1-\gamma_1\phi_1'')^{-2}] - \phi_o'^2[\alpha_1 + g_{11}(1-\gamma_1)(1-\gamma_1\phi_1')^{-2}] + (1 - m_1^{-1})(\phi_1'' - \phi_1') \quad [4]$$

This equation, together with Eq. [3] in $p' = p''$, allows calculation of ϕ_1' and ϕ_1'' and, by Eq. [2], of the densities d_1' and d_1'' of the phases.

Expressions for the spinodal (limit of thermodynamic stability) and the gas-liquid critical point are derived from $(\partial^2\Delta F/\partial\phi_1^2)_{T,V} = 0$ and $(\partial^3\Delta F/\partial\phi_1^3)_{T,V} = 0$, respectively (7, 19). We obtain

$$(1/\phi_o) + (1/m_1\phi_1) = 2g_{11}(1-\gamma_1)^2(1-\gamma_1\phi_1)^{-3} + 2\alpha_1 \quad \text{(spinodal)} \quad [5]$$

and

$$(1/\phi_o^2) - (1/m_1\phi_1^2) = 6g_{11}\gamma_1(1-\gamma_1)^2(1-\gamma_1\phi_1)^{-4} \quad \text{(critical point)} \quad [6]$$

The parameters in Eq. [1]-[6] can be calculated from the gas-liquid critical point (p_c, T_c, d_c) of the substance by a suitable combination of Eq. [2], [3], [5], and [6]. Since the interaction energy term g_{11} usually showed a temperature-dependence departing slightly from that indicated in Eq. [1] additional data are needed, *e.g.*, from vapor-liquid equilibrium at another temperature, to establish this dependence which can be described with

$$g_{11} = g_{110} + g_{111}/T \quad [7]$$

We have done so with a number of pure substances and found the present treatment to lead to good reasonable descriptions of gas-liquid densities in a wide range of pressure and temperature. Examples, referring to CH_4 and H_2O, are shown in Fig. 1. Close to the critical point more or less serious deviations between data and calculated curves can be seen. This may either indicate a need for further refinement of the model [see, *e.g.*, Ref. (11) or (20)] or point to nonclassical critical behavior that is clearly not covered by the present procedure. We leave this question open because the aim here is to describe fluid phase behavior in a general way which proves well possible with the outlined simple model.

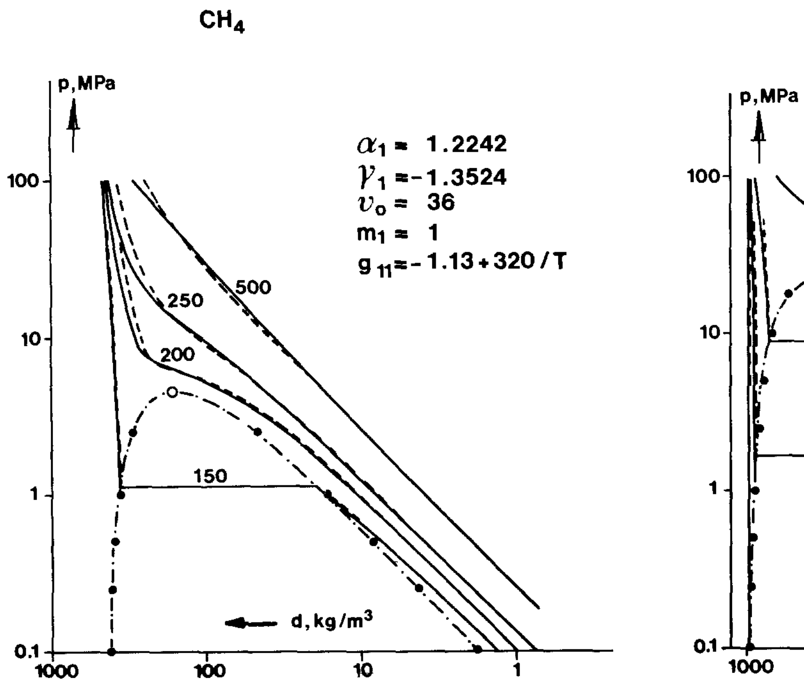
Binary Mixtures

The Helmholtz free-energy expression for a binary mixture—vacancies and two kinds of sites (1 and 2)—can be derived along analogous lines; it reads

$$\Delta F/N_\phi kT = \phi_o \ln \phi_o + \phi_1 m_1^{-1}\ln\phi_1 + \phi_2 m_2^{-1}\ln\phi_2 + \phi_o\phi_1[\alpha_1 + g_{11}(1-\gamma_1)q^{-1}] + \phi_o\phi_2[\alpha_2 + g_{22}(1-\gamma_2)q^{-1}] + \phi_1\phi_2[\alpha_m + g_m(1-\gamma_2)q^{-1}] \quad [5]$$

where $q = 1 - \gamma_1\phi_1 - \gamma_2\phi_2$; $\gamma_1 = 1 - \rho_1$; $\gamma_2 = 1 - \rho_2$.

The sets of parameters (α_1, g_{11}, ρ_1, m_1) and (α_2, g_{22}, ρ_2, m_2) can be deduced from pure-component data as indicated above, and the binary mixture then calls for two more parameters, *viz.* α_m and g_m. These can be derived from vapor-liquid or fluid-fluid critical data on the mixture. To avoid the need of designing mixing rules for v_o, and the consequent uncertainties introduced when derivatives with respect to concentration are taken, we postulate that all constituents in a mixture shall have the same v_o, independent of the composition of the system. There will be as many values of ρ as there are components and these values



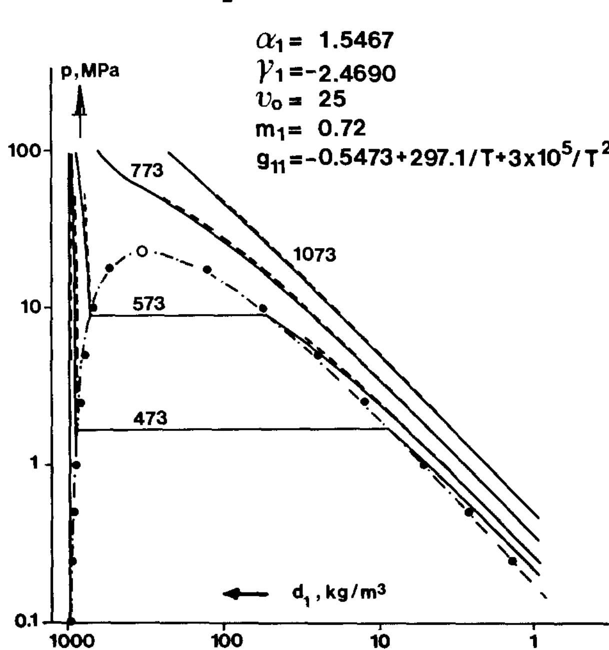


Fig. 1. pVT diagrams for indicated temperatures in °K. Calculated; one phase densities (—) and gas-liquid coexistence densities. Experimental (literature) data; smoothed isotherms (- - - -), gas-liquid coexistence (●) and critical point (○).

may differ, in accordance with the shapes of the various molecules.

Expressions for chemical potentials, spinodal, and critical point can be derived straightforwardly from Eq. [5]. The resulting equations being complex we only state the binary analogue of Eq. [3] here, Ref. (19) contains a full report. The equation for the pressure now reads

$$-pv_o/kT = \ln \phi_o + (1 - m_1^{-1})\phi_1 + (1 - m_2^{-1})\phi_2 + (\alpha_1\phi_1 + \alpha_2\phi_2)(\phi_1 + \phi_2) - [\alpha_m + g_m(1 - \gamma_2)q^{-2}]\phi_1\phi_2 + [g_{11}(1 - \gamma_1)\phi_1 + g_{22}(1 - \gamma_2)\phi_2](q - \phi_o)q^{-2} \quad [6]$$

A set of binary critical data (T_c, p_c, $x_{2,c}$) can be used for the calculation of α_m and g_m, after which the complete phase diagram of the fluid 1-2 mixture can be computed and compared with experimental data. The mole fraction of the second component x_2 is given by

$$x_2 = [1 + (\phi_1 m_2/\phi_2 m_1)]^{-1} \quad [7]$$

The calculated curves can be represented as isotherms on a ternary diagram; Fig. 2 shows an example referring to the system CO_2/CH_4. The pressure varies along the curves but is obviously equal at both ends of a tie line which represent coexisting phase compositions in terms of ϕ_1, ϕ_2, and ϕ_o. Equation [7] then serves to convert the lattice-site fractions ϕ into mole fraction numbers and isothermal $p(x_2)$ plots can thus be constructed from the calculated curves in Fig. 2 and compared with the actual situation. For one of the isotherms in Fig. 2 this comparison is made in Fig. 3. The agreement between experiment and prediction can be considered satisfactory particularly in view of the fact that the only information used on the mixture was the critical point. The situation is comparable to that encountered with pure substances where the critical point supplies the essential information for reasonable to good descriptions of liquid/vapor densities.

The system CH_4/H_2O exhibits gas-gas demixing of the second kind (21-23). This involves the occurrence of two miscibility gaps in $p(x_2)$ isotherms at temperatures just under the critical temperature of water. One of these is of the upper-critical-miscibility type with a maximum critical pressure, the other, located at higher pressures, is a lower critical miscibility gap with a minimum critical pressure. Determination, as above, of α_m and g_m from some upper critical data proved to suffice for an essentially correct

description of the full phase diagram, including the gas-gas lower-critical miscibility gap. "Ternary" isotherms calculated for this system are illustrated in Fig. 4 and compared with experimental $p(x_2)$ sections in Fig. 5. The calculated curves are spinodals and comprise a narrower $p(x_2)$ region than the corresponding coexistence curves, as they should do. The location of the calculated spinodals is in good agreement with that of the experimental coexistence curves.

Discussion

The aim of the present study was the development of adequate equations describing fluid-fluid phase be-

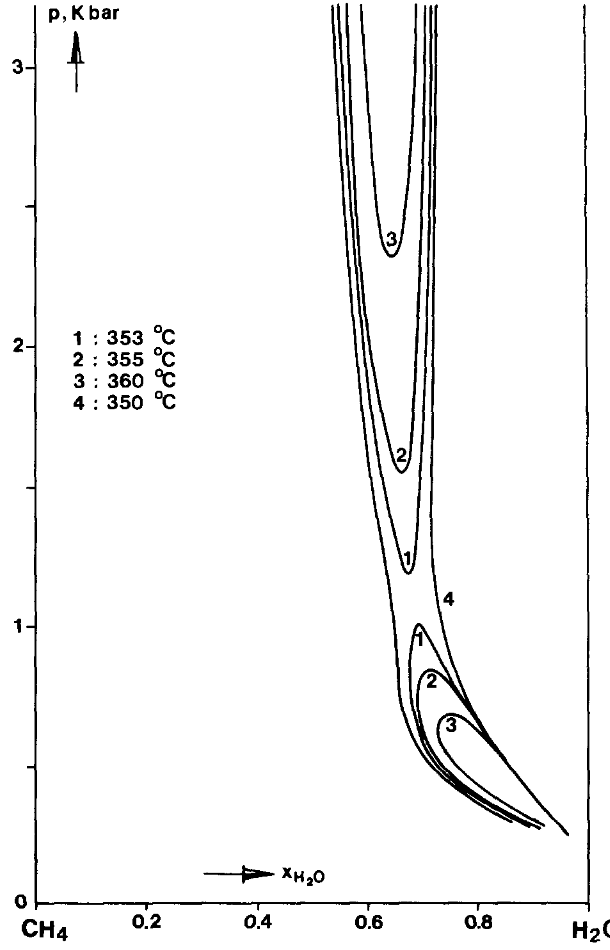

Fig. 4. Spinodals calculated with $v_O = 25$, $m_{CH_4} = 1.35$, and $m_{H_2O} = 0.72$ at indicated temperatures in °K.

havior and involving a minimum number of adaptable parameters. Using the two-component lattice-gas model as a starting point we found the introduction of interacting-surface-area ratios to relax the lattice model sufficiently without undue increase in number of adjustable parameters. As yet we did not ascertain whether this favorable situation is either brought about or limited by an important assumption underlying all our calculations, *viz.* the independence of the lattice cell volume v_0 of concentration, temperature, and pressure. This assumption was made to avoid the need to draw up arbitrary mixing rules for v_0, and thus to reduce the number of purely empirical parameters. It should be noted, however, that the choice of the number of lattice sites m, occupied by molecules, fixes the value of v_0 for a substance. Intuitively one would object to values of m deviating considerably from unity when small molecules like CO_2 are concerned. The values we used for v_0 on a number of substances and systems (about 20 cm^3/mole) agree fairly well with the equilibrium value estimated by Frenkel (3).

The surface-area ratios ρ, number of occupied lattice sites m, and cell volume v_0 are parameters open to appraisal on physical grounds. This is also true for the parameter g which is related to the interaction energy between adjacent molecules. It proved necessary, however, to correct the entropy of mixing terms in the Helmholtz free energy expressions (logarithmic terms in Eq. [1] and [5]) with merely empirical parameters (α and g_{110}) which have to be accepted at face value. Yet, the fact that the ΔF expressions developed here can be fitted so well to experimental data gives some credence to the mathematical form of the equations. It is probably the interacting surface-area ratio which mainly provides for the versatility of the present treatment.

In this study we derived values for the various parameters from a minimum number of experimental data, in order to be able to test the predictive value of the procedure. Alternatively, one might optimize the parameters using all experimental data available and thus possibly obtain better descriptions. Apart from phase-equilibrium data, the present objective, one could also use compressibilities and thermal expansion coefficients. This is a subject of current study.

Manuscript submitted April 16, 1980; revised manuscript received June 10, 1980. This was Paper 548 presented at the St. Louis, Missouri, Meeting of the Society, May 11-16, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Publication costs of this article were assisted by the Central Laboratory DSM.

Pressure Dependence of the Oxygen Electrode

Eddie Morild[1] and Jan E. Ølmheim

Department of Chemistry, University of Bergen, N-5014 Bg-U, Bergen, Norway

ABSTRACT

A commercial oxygen electrode (YSI 5750) has been calibrated from 1 to 1500 bar. The theory of the pressure dependence of the electrode processes, the oxygen fugacity, and the membrane permeability is presented. A short treatment of the use of the electrode in measuring kinetic processes under pressure is also given. The activation volume for the diffusion through the membrane has been found to be 58 ± 2 cm³ mole⁻¹. The diffusion is always the rate-determining step. When the increase in oxygen fugacity with pressure is not taken into consideration, the observed activation volume is 25 ± 2 cm³ mole⁻¹.

It is of general interest to learn how oxygen is produced and consumed in different environments and under different circumstances. By means of the Clarck oxygen electrode, *in situ* measurements can be continuously performed all over the earth, and also down to depths of 10^4m in the oceans. In principle, all kinds of oxygen exchange in chemical and biological systems can be studied with this electrode at high pressures. But the electrode itself is influenced by pressure to such an extent that a thorough calibration is necessary before use. Nevertheless, some earlier workers have made detailed investigations both of the oxygen content of old bottom seawater and of the respiration of biological organisms without this calibration. It is a drawback that the processes taking place at the electrode are complex and not properly known as functions of pressure. A calibration is therefore necessary and suffices when supplied with data on the high pressure oxygen partial pressure. The instruction note states: "The membrane passes oxygen at a rate proportional to the pressure difference across it. Since oxygen is rapidly consumed at the cathode, it can be assumed that the oxygen concentration under the membrane is zero. Hence, the force causing the oxygen to diffuse through the membrane is proportional to the absolute pressure of oxygen outside the membrane. If the oxygen pressure increases, more oxygen will diffuse through the membrane and more current flows through the sensor. A lower pressure results in less current." This is all perfectly true at ordinary pressures, say, to a few atmospheres. But we shall see that it is no longer true at high pressure. We seek here to develop the theory of this electrode at high pressure as far as possible and present the calibration curve up to more than 10^3 bar.

Experimental

The oxygen electrode (cathode) used is a Yellow Springs Instrument Company (YSI) 5750 nonstirring B.O.D. bottle probe, a complete voltammetric system. The oxygen cathode (Fig. 1) is a thin circular gold foil covered with a 0.001 in. FEP Teflon permeable membrane stretched over the sensor system. This isolates the sensor elements from the environment, but allows gases to enter. The reference electrode in lower middle is a silver/silver chloride electrode with half-saturated KCl as electrolyte and also functions as anode. When a polarizing voltage of 0.8V is applied across this sensor system, oxygen that has passed through the membrane reacts at the cathode, causing a current to flow. The probe current with air as medium at 30°C is 19μ, according to specifications. A small problem was caused by the pressure difference over the membrane due to the compression of the inner electrolyte volume. Some irregularities followed, and the membrane was often damaged. Usually, this was avoided by not fastening the membrane too tight. Another type of dissolved oxygen probe (YSI 5739) has a pressure compensating system with an electrolyte bypass through a vent on the side of the probe to the inside of the membrane. In this way there is no buildup of pressure across the membrane.

For proper functioning of the electrode, stirring is required. This was achieved magnetically, by enclosing the small beaker above an electromotor equipped with a bar magnet within a Teflon tube as shown in Fig. 2. The oxygen probe was brought into the beaker through a rubber stopper, ensuring that no air bubbles were trapped between the solution and the stopper.

The pressure chamber was made of steel, with an inside diameter of 3.5 cm and 30 cm depth. The whole chamber was filled with hydraulic oil and surrounded by a thermostatted oil bath. The electrode system was immersed in the oil with electrical connections through the lid. Control of the stirring rate at high pressure was obtained by measuring the rotation frequency with an oscilloscope coupled in parallel with the electromotor. The rate was reduced to about one-fifth at 1000 bar, due to viscosity increase of the oil, and this had to be compensated by an increased voltage. The temperature of the thermostatted chamber was maintained at 25.0° ± 0.1°C.

The pressure was generated by an Enerpac handpump system, and was known to ±10 bar at the highest pressures.

Oxygen content was determined by the Winkler method, using analytical reagent chemicals. As a check on the linearity of the response of the electrode system, it was standardized every day with three solutions: (*i*) distilled water, boiled with $Na_2S_2O_5$ to remove traces of oxygen (this fixed the zeropoint reading on the recorder), (*ii*) distilled water saturated with air at 5°C and allowed to stand for equilibration with air at 25°C, (*iii*) distilled water saturated with pure oxygen at 5°C and allowed to stand for equilibration

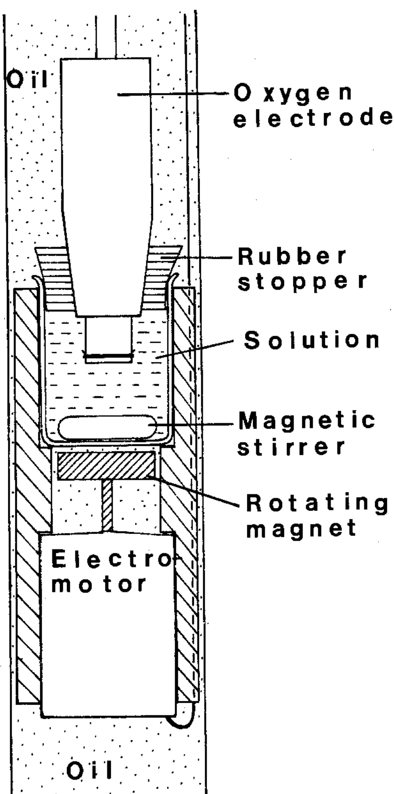

Fig. 2. Experimental setup during the high pressure calibration measurements. The electrode, beaker, and electromotor were immersed in the oil-filled pressure chamber.

with oxygen at 25°C. In both cases saturation was obtained by bubbling gas through the solution for 15 min.

Partial molal volume measurements of H_2O_2 were performed with a Paar DMA O2C digital densimeter. The accuracy was of the order 10^{-6}g cm^{-3}. All densities were measured with pure water and expressed relative to the density of water, 0.997075g cm^{-3} at 25.00°C. The temperature control was automatic, with a Hewlett-Packard quartz thermometer, and had an accuracy of $\pm 4° \times 10^{-3}$°C. The partial molal volume was determined from the equation

$$V = 1000(d_o - d_s)/md_od_s + M_s/d_s$$

where d_o is the density of water, d_s the density of the solution, m the molarity of the solution, and M_s the molecular weight of the solute. $V°(H_2O_2)$ at infinite dilution was obtained by extrapolation along the m-axis. The H_2O_2 used was Merck 30% hydrogen peroxide "Medizinisch Rein."

Membrane permeability of the Teflon membrane at high pressure was studied with the apparatus shown in Fig. 3. An oxygenated solution was brought into one compartment, and boiled, nearly oxygen-free solution was brought into the other compartment, separated by the membrane. Stirring was effected by an electromotor in each end. Diffusion was allowed for an hour at various pressures, and oxygen content was checked by means of the electrode before and after diffusion. Corrections were applied for the time of mounting and dismounting the pressure chamber system.

Theory

There are at least five different factors influencing the measured current when high pressure is applied. These will be treated in order, but first it must be emphasized that the analysis of charge-transfer reactions under pressure is difficult due to the indeterminacy of single electrode potentials. In principle, every rate process may be described in terms of the transition-state theory, assuming formation of an activated complex. Strictly, the volume of activation

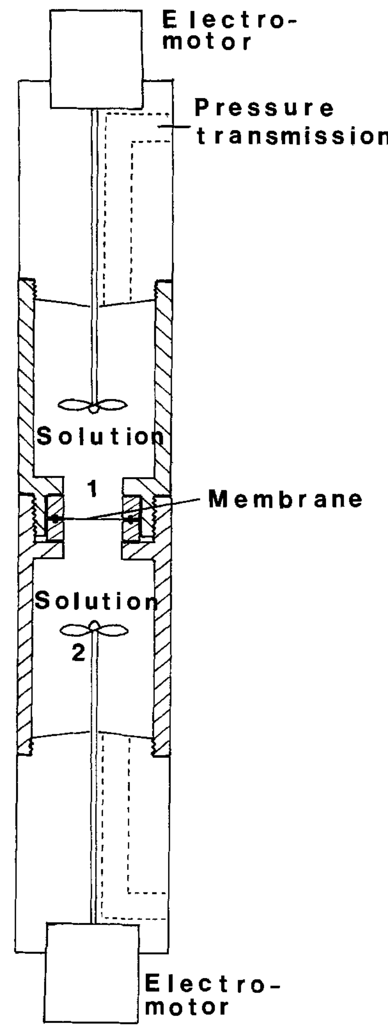

Fig. 3. Experimental setup for measurement of membrane permeability at high pressure. This compartment system was made of PVC and was completely filled with the two solutions, one oxygenated and one deoxygenated. The system was immersed in the oil-filled pressure chamber, and the pressure was transmitted through holes in the top and the bottom block.

$$\Delta V^{\ddagger} = RT\left(\frac{\partial \ln i}{\partial p}\right)_{T,\mu,\phi} \qquad [1]$$

is here indeterminate due to the inconstancy of the inner (Galvani) potential of the electrode participating in the charge-transfer process with current i (1). Nevertheless, we will use the quantity $\Delta V^{\ddagger}$ in search of a qualitative indication on the rate-determining process at high pressure.

Activation at the Au electrode.—The electrode reaction for the reduction of oxygen occurs via hydrogen peroxide which is a more or less stable intermediate (2)

$$O_2 + 2H^+ + 2e \rightarrow H_2O_2 \qquad [2]$$

This reaction is followed by a certain activation volume characteristic of the transition step in the electrode process. If this activation volume was large enough, this electrode process could in principle be rate determining at high pressure.

Activation at the Ag/AgCl electrode.—Because the current density at this electrode is small and the electrode surface relatively large, its influence on the overall process is probably negligible. Even if there were a large activation volume associated with the AgCl formation, it is very unlikely that this electrode process should be rate determining at high pressure.

Oxygen partial pressure change.—If we denote by k some effective rate-determining parameter at any pres-

sure, and the fugacity (partial pressure) of oxygen is f_{O_2}, then the current i flowing through the system is given by the simple proportionality

$$i = kf_{O_2} \quad [3]$$

This strict linearity is specified by YSI and has also been verified by us by means of Winkler titration of oxygen. The solubility of oxygen in terms of mole fraction x_{O_2} is related to the fugacity through Henry's law

$$f_{O_2} = Hx_{O_2} \quad [4]$$

H is Henry's constant, (H = 43,800 bar). Now, the mole fraction is pressure independent, but the fugacity increases with total pressure because Henry's constant is pressure dependent. (Or can be chosen to be pressure dependent, otherwise the pressure dependence must be projected into the activity coefficient, which for our purpose amounts to the same.) Taking the standard state of oxygen to be pressure independent and at 1 bar, the variation of Henry's constant with pressure follows the relation (3)

$$\left(\frac{\partial \ln H}{\partial p}\right)_T = \left(\frac{\partial \ln (f_{O_2}/x_{O_2})}{\partial p}\right)_T = \frac{V(O_2)}{RT} \quad [5]$$

with $V(O_2)$ as the partial molar volume of dissolved oxygen. This leads to the integrated form

$$\ln (f_{O_2}/x_{O_2}) = \ln H^\circ + pV(O_2)/RT \quad [6]$$

where H° is Henry's constant at the standard state. The fugacities $f_{O_2}(p)$ and $f_{O_2}(0)$ at the pressure p and at atmospheric pressure are then related by

$$\ln f_{O_2}(p) = \ln f_{O_2}(0) + pV(O_2)/RT \quad [7]$$

The partial molar volume $V(O_2)$ has been determined by Enns *et al.* (4) to 32.1 ± 0.2 cm³ mole, and is practically constant in the actual pressure interval.

Pressure dependence of cell potential.—The oxygen electrode can be represented by the electrochemical cell

$$O_2(\text{soln})|\text{membrane}|KCl(m)|Ag/AgCl|KCl(m)|Au \quad [8]$$

The overall reaction determined by this cell is

$$O_2 + 2H^+ + 2Cl^- + 2Ag \rightarrow H_2O_2 + 2AgCl \quad [9]$$

with the Nernst expression

$$\Delta\epsilon = \Delta\epsilon^o + \frac{RT}{2\mathbf{F}} \ln \frac{[H^+]^2[Cl^-]^2 f_{O_2}}{[H_2O_2]} \quad [10]$$

In the unbuffered solution, H⁺ ions will be produced from water by increased ionization with pressure

$$\left(\frac{\partial \ln K_w}{\partial p}\right)_T = -\frac{\Delta V_w}{RT} \quad [11]$$

$$\left(\frac{\partial \Delta\epsilon}{\partial p}\right)_T = \left(\frac{\partial \Delta\epsilon^o}{\partial p}\right)_T + \frac{RT}{\mathbf{F}}\left(\frac{\partial \ln K_w^{1/2}}{\partial p}\right)_T - \frac{RT}{2\mathbf{F}}\left(\frac{\partial \ln V}{\partial p}\right)_T + \frac{RT}{2\mathbf{F}}\left(\frac{\partial \ln f_{O_2}}{\partial p}\right)_T \quad [12]$$

Now using the relations

$$-n\mathbf{F}\left(\frac{\partial \Delta\epsilon}{\partial p}\right)_T = \left(\frac{\partial \Delta G}{\partial p}\right)_T = \Delta V \quad [13]$$

and

$$\kappa_T = -\left(\frac{\partial \ln V}{\partial p}\right)_T \quad [14]$$

Eq. [12] turns into

$$\Delta V = \Delta V^o + RT\left(\frac{\partial \ln K_w}{\partial p}\right)_T - RT\left(\frac{\partial \ln f_{O_2}}{\partial p}\right)_T - RT\kappa_T \quad [15]$$

which by means of Eq. [5] and [11] results in

$$\Delta V = \Delta V^o + \Delta V_w - V(O_2) - RT\kappa_T \quad [16]$$

The standard volume of reaction ΔV^o can be obtained from knowledge of all partial molar volumes in Eq. [8]

$$\Delta V^o = 2\rho_{AgCl}^{-1} + \tfrac{1}{2} V(H_2O_2) - 2\rho_{Ag}^{-1} - 2V(HCl) - V(O_2) \quad [17]$$

The pressure dependence of the cell potential can then be calculated.

Change of diffusion rate with pressure.—There is a diffusion of oxygen molecules through the Teflon membrane, and the measured current may be described by the oxygen gradient over the membrane

$$i = -D_c\frac{dc}{dx} = D_f\frac{f_{O_2}}{\delta} \quad [18]$$

where D_c and D_f are diffusion coefficients on concentration and fugacity scales, respectively. δ is the diffusion distance, the thickness of the membrane. The last term in Eq. [18] holds when the diffusion process is rate determining. In the case of homogeneous diffusion in solution we could have written

$$\left(\frac{\partial \ln i}{\partial p}\right)_T = -\frac{\Delta V_D^{\ddagger}}{RT} \quad [19]$$

where $\Delta V_D^{\ddagger}$ would have been the usual volume of activation due to the pressure dependence of the diffusion coefficient. Then, $\Delta V_D^{\ddagger}$ would be of the order of +(10-20) cm³ mole⁻¹, so that diffusion rate would be reduced with pressure. Considering the diffusion problem with the dropping mercury electrode, Hills (5) argues that the product $cD^{1/2}$ is not appreciably pressure independent. So in the present problem we have to consider the change in membrane permeability, with unknown $\Delta V^{\ddagger}$, along with changes in f_{O_2} and δ

$$\left(\frac{\partial \ln i}{\partial p}\right)_T = \left(\frac{\partial \ln D_f}{\partial p}\right)_T + \left(\frac{\partial \ln f_{O_2}}{\partial p}\right)_T - \left(\frac{\partial \ln \delta}{\partial p}\right)_T \quad [20]$$

From the diffusion measurements under pressure we are only able to measure the combined effect of the first and last term of the rhs of Eq. [20]

$$\left(\frac{\partial \ln k}{\partial p}\right)_T = \left(\frac{\partial \ln D_f/\delta}{\partial}\right)_T = -\frac{\Delta V_k^{\ddagger}}{RT} \quad [21]$$

If the diffusion is rate determining, the measured current change with pressure should be described by the relation

$$\left(\frac{\partial \ln i}{\partial p}\right)_T = -\frac{\Delta V_i^{\ddagger}}{RT} = -\frac{\Delta V_k^{\ddagger}}{RT} + \frac{V(O_2)}{RT} \quad [22]$$

corresponding to Eq. [3].

If the measured values of $\Delta V_i^{\ddagger}$ and $\Delta V_k^{\ddagger}$ does not satisfy Eq. [22], it is probable that one of the electrode reactions is rate determining. In this case, $\Delta V_k^{\ddagger}$ can be reinterpreted and calculated from

$$\Delta V_k^{\ddagger} = \Delta V_i^{\ddagger} + V(O_2) \quad [23]$$

Calibration and Use

In any case, a measurement of i *vs.* p yields a sufficient calibration of the electrode. Integration of Eq. [22] results in

$$\ln i(p) = \ln i(0) - \frac{p\Delta V_i^{\ddagger}}{RT} \quad [24]$$

and by using [3], we obtain

$$f_{O_2}(0) = (i(p)/k(0)) \exp (p\Delta V_i^{\ddagger}/RT) \quad [25]$$

Here $f_{O_2}(0)$ is the fugacity of oxygen measured at the pressure p, reduced to atmospheric pressure. The measured current at p is $i(p)$ and the proportionality constant in Eq. [3] is $k(0)$ at atmospheric pressure.

An interesting application of the oxygen electrode is its use as a probe of oxygen in kinetic process under pressure. Differentiating Eq. [3] with respect to time, we get

$$v_c = \frac{di}{dt} = k\frac{df_{O_2}}{dt} = kv_{O_2} \quad [26]$$

where v_c is the rate of current change and v_{O_2} is the rate of fugacity change. The oxygen-producing (consuming) process is characterized by a certain activation volume $\Delta V_{O_2}{}^{\ddagger}$, which is the interesting quantity. Then

$$\left(\frac{\partial \ln v_{O_2}}{\partial p}\right)_T = -\frac{\Delta V_{O_2}{}^{\ddagger}}{RT} \quad [27]$$

The logarithm of Eq. [26] is

$$\ln v_c = \ln k + \ln v_{O_2} \quad [28]$$

which by differentiation with respect to pressure yields

$$\left(\frac{\partial \ln v_c}{\partial p}\right)_T = \left(\frac{\partial \ln k}{\partial p}\right)_T + \left(\frac{\partial \ln v_{O_2}}{\partial p}\right)_T \quad [29]$$

The first term is characterized by an activation volume $\Delta V_c{}^{\ddagger}$, and then

$$\Delta V_{O_2}{}^{\ddagger} = \Delta V_c{}^{\ddagger} - \Delta V_k{}^{\ddagger} = \Delta V_c{}^{\ddagger} - \Delta V_i{}^{\ddagger} - V(O_2) \quad [30]$$

It is rather probable that the ln v_c *vs.* p curve is not a straight line, but of the general form

$$\ln v_c = a_o + a_1p + a_2p^2 + a_3p^3 + \ldots \quad [31]$$

so that

$$\left(\frac{\partial \ln v_c}{\partial p}\right)_T = a_1 + 2a_2p + 3a_3p^2 + \ldots \quad [32]$$

The correction necessary to find the curve of ln v_{O_2} *vs.* pressure is then

$$\left(\frac{\partial \ln v_c}{\partial p}\right)_T - \left(\frac{\partial \ln k}{\partial p}\right)_T = a_1 + \frac{\Delta V_i{}^{\ddagger}}{RT} + \frac{V(O_2)}{RT} + 2a_2p + 3a_3p^2 + \ldots \quad [33]$$

and at last

$$\ln v_{O_2}(p) = \ln v_{O_2}(O) + \left[a_1 + \frac{\Delta V_i{}^{\ddagger}}{RT} + \frac{V(O_2)}{RT}\right]p + a_2p^2 + a_3p^3 + \ldots \quad [34]$$

Results

To calculate the standard volume of reaction, ΔV^o in Eq. [17] we need the molar volume of H_2O_2, which has not been found in the literature. From density measurements on a dilution series of aqueous H_2O_2, $V(H_2O_2)$ was determined by extrapolation to infinite dilution, Fig. 4. The volume was found to be $V(H_2O_2) = 22.8 \pm 0.4$ cm^3 mole^{-1}.

From known values of the density of solid Ag and AgCl (6), the partial molar volumes of HCl (7) and O_2 (4), we found

$$\Delta V^o = 2 \cdot 25.8 + 22.8 - 2 \cdot 10.3 - 2 \cdot 17.9 - 32.1 = -18.1 \text{ cm}^3 \text{ mole}^{-1}$$

Then the pressure dependence of the standard potential is

$$\left(\frac{\delta \Delta\epsilon^o}{\delta p}\right)_T = \frac{\Delta V^o}{2F} = 9.3 \cdot 10^{-6} \text{ V bar}^{-1}$$

which means that the potential increases 9.3 mV with a pressure increase of 10^3 bar.

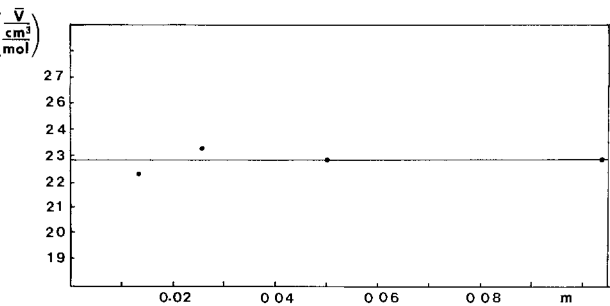

Fig. 4. Concentration (molality) dependence of the partial molal volume of H_2O_2.

The overall volume change, considering dissociation and compression, is given by Eq. [15]

$$\Delta V = -18.1 - 22.1 - 32.1 - 1.1 = -73.4 \text{ cm}^3 \text{ mole}^{-1}$$

where $\Delta V_w{}^o$ is taken from Ref. (8). This represents a pressure dependence of the equilibrium potential

$$\left(\frac{\delta \Delta \epsilon}{\delta p}\right)_T = 38.5 \cdot 10^{-6} \text{ V bar}^{-1}$$

This means an increase of 38.5 mV at 1000 bar. Now, the polarographic process is a nonequilibrium situation and the calculated values cannot be directly applied here. However, a polarographic study of this system (9) has shown that potential changes of less than 100 mV result in negligible changes in current, because the current-voltage curve has a plateau centered at the applied voltage. It is therefore reasonable to believe that the change in current due to indirect effects of pressure on the polarization voltage can be neglected. Figure 5 is a plot of ln i *vs.* p for different oxygen fugacities. The lower curve, No. 1, represents the oxygen fugacity in air-saturated water and No. 3 represents about half oxygen-saturated water. No. 2 represents an intermediate between these and No. 4 represents water saturated with oxygen from enzymatic degradation of H_2O_2 to O_2 under a pressure of 33 bar. With the possible exception of curve No. 1, they are all linear with pressure and have a slope

$$\left(\frac{\delta \ln i}{\delta p}\right)_T = -\frac{\Delta V_i{}^{\ddagger}}{RT} = -1.013 \cdot 10^{-3} \text{ bar}^{-1}$$

which yields a volume of activation, $\Delta V_i{}^{\ddagger} = 25.1$ cm^3 mole^{-1}. Now the volume change of the rate-determining process, deduced from Eq. [23] can be calculated

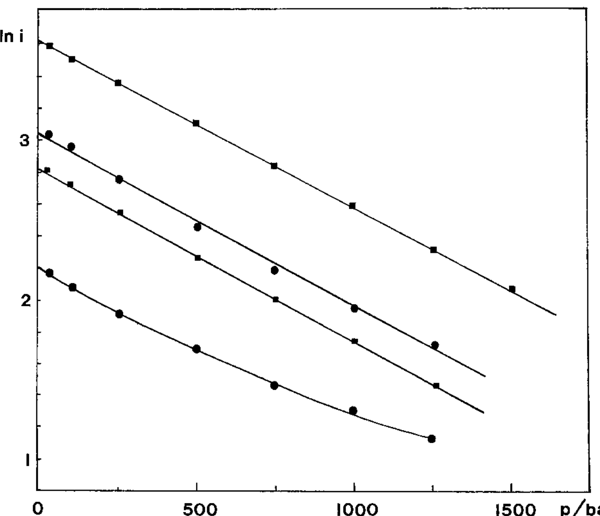

Fig. 5. Plot of the logarithm of the measured current *i*, as a function of total hydrostatic pressure *p*. See text.

$$\Delta V_K^{\ddagger} = 25.1 + 32.1 = 57.2 \text{ cm}^3 \text{ mole}^{-1}$$

This is the volume change that results when it is taken into account that the oxygen fugacity increases with pressure. All other factors being constant, the current should increase when the oxygen fugacity is increased. When this is not so, it must be because the other processes going on have a total pressure dependence that more than compensates for the effect of the fugacity increase. The result from the studies of the membrane permeability as a function of pressure is shown in Fig. 6. The ordinate is the logarithm of a relative measure of the amount of oxygen that has permeated the membrane during 1 hr. The initial slope of the curve corresponds to a volume change which can be interpreted as the activation volume for the diffusion process in the membrane. The oxygen flux j through the membrane has a pressure dependence given by

$$\left(\frac{\partial \ln j}{\partial p}\right)_T = \left(\frac{\partial \ln D_f/\delta}{\partial p}\right)_T + \left(\frac{\partial \ln f_{O_2}}{\partial p}\right)_T$$

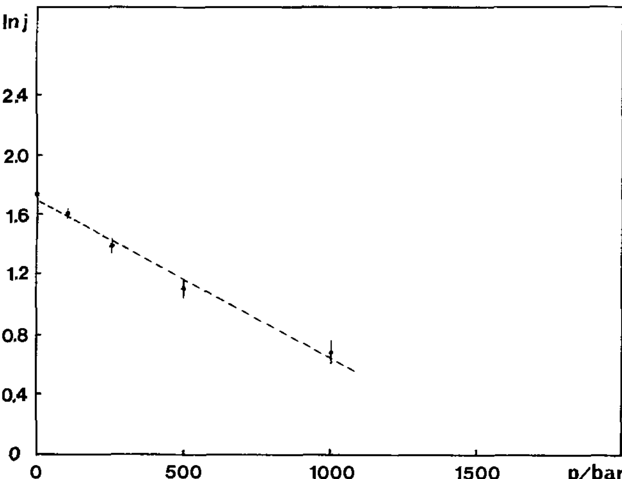

Fig. 6. Plot of the logarithm of the oxygen flux j through the Teflon membrane, as a function of total hydrostatic pressure p.

associated with the volume changes

$$\Delta V_j^{\ddagger} = \Delta V_K^{\ddagger} - V(O_2)$$

The average value of the slope was found to be $\Delta V_j^{\ddagger} = 26$ cm^3 mole^{-1} and this leads to the value $\Delta V_K^{\ddagger} = 58$ cm^3 mole^{-1}. This is an appreciable pressure dependence, and it is clear that the membrane diffusion is rate determining. The experimental uncertainty here is about ± 2 cm^3 mole^{-1}, so this value is in good agreement with the value 57.2 cm^3 mole^{-1}. Then, as could be expected, the whole electrode is operating under total mass transfer control also at high pressure. The pressure effects on the Au and the Ag/AgCl electrodes are screened by the effect on the membrane and cannot be observed.

Oxygen Evolution on $La_{1-x}Sr_xFe_{1-y}Co_yO_3$ Series Oxides

Y. Matsumoto, S. Yamada, T. Nishida, and E. Sato*

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishi-icho 2753, Utsunomiya, Japan

ABSTRACT

$La_{1-x}Sr_xFe_{1-y}Co_yO_3$ series oxides with perovskite-type structure were synthesized and were examined as the electrode for the oxygen evolution reaction in alkaline solution. The oxides except for $SrCoO_{2.5}$, $LaFeO_3$, and their neighbors were suitable for the electrode with respect to high conductivity. The catalytic activity for the oxygen evolution reaction increases along the direction from $LaFeO_3$ to $SrCoO_3$ in composition. It is concluded that the following two conditions are desirable for the perovskite-type oxide with high catalytic activity for the oxygen evolution reaction: (*i*) the oxide has a broad σ^* band and (*ii*) the transition metal cation in the oxide exists as the higher oxidation state. In addition, it was found that the catalytic activity of $La_{0.2}Sr_{0.8}Fe_{0.2}Co_{0.8}O_3$ is the highest in the oxides prepared in this study.

Some of the perovskite-type oxides with high electronic conductivity show good catalytic activity for the oxygen evolution reaction (1-3) and the oxygen reduction (4-7). In particular, the perovskite-type oxides containing Co, Fe, and Ni ions in the lattice are excellent in catalytic activity for the oxygen evolution reaction in alkaline solution (1-3). For example, the overvoltages of the partly substituted $SrFeO_3$ with Ni and Co ions are very low for the oxygen evolution reaction (3). The catalytic activity will be mainly determined by the σ^* band formation of the M-O-M in the lattice which enhances electron transfer from the chemical species, OH^-, into the electrode surface

* Electrochemical Society Active Member.

Key words. oxygen evolution, perovskite-type oxide, electrocatalysis.

(1). In addition to the electron transfer step, chemical reaction steps are also in the process of the oxygen evolution reaction. For the chemical reaction step such as

$$SOH + OH^- \rightarrow SO^- + H_2O$$

the higher oxidation state of the transition metal ion in the perovskite-type oxide is preferable to the lower oxidation state as shown in the previous paper (2), where S stands for the transition metal ion on the surface.

Therefore, as for the oxygen evolution reaction on the perovskite-type oxide electrode with high conductivity, (*i*) the σ^* band formation and (*ii*) the higher oxidation state of the metal ion in the oxide will be desirable for high catalytic activity. In this paper, the catalytic properties of $La_{1-x}Sr_xFe_{1-y}Co_yO_3$ series oxides with perovskite-type structure for the oxygen evolution reaction in alkaline solution are studied and the above two conclusions for the catalytic property are deduced from the variation of the catalytic activity with x and y. The oxide electrocatalyst with the highest catalytic activity in this series of oxides is $La_{0.2}Sr_{0.8}Fe_{0.2}Co_{0.8}O_3$.

Experimental

$La_{1-x}Sr_xFe_{1-y}Co_yO_3$ series oxides were synthesized by using La_2O_3, $SrCO_3$, CoO, and Fe_2O_3 as the starting materials. These materials were stoichiometrically mixed with an agate mortar and then heated at 1000°C for 2 hr in air. The mixtures were reground and heated at 1250°-1300°C for 6 hr in air. The materials were shown to be synthesized perovskite-type oxides by x-ray analysis with the scanning rate 2θ/min = 0.5°/min. The powders were pressed into tablet form with 100 kg/cm², followed by sintering at 1350°C for 1 hr. The compositions of the perovskite-type oxides are represented as ABO_3 in this paper, although the prepared oxides have some oxygen ion vacancies in the lattice, especially for the oxides having a large amount of Sr. The specific resistivities at room temperature were measured by the four-probe method. The type of the conductivity of each sample at room temperature was determined by the temperature dependence of the resistivity. The types of the semiconductivity, n or p, were judged from the signs of the measured thermoelectric power. The thermoelectric power was measured by a digital voltmeter. In this measurement, the sintered rod samples ($10 \times 2 \times 2$ mm) were used and the one tip was heated (~100°C). The electrodes were prepared in the same manner as described in previous papers (1-3). The current densities shown in this paper are indicated by the apparent ones based on geometrical area.

The solution was pre-electrolyzed 1M KOH. An Hg/HgO electrode was used as the reference electrode and electrode potentials cited in this paper are referred to this electrode. The main electrochemical test was made by the potential sweep method with the sweep rate of 500 sec/V at 25°C. The Tafel slopes were obtained from the polarization curve under steady state in the same manner as described in previous papers (1-3).

Results

The synthesized oxides, except for $SrCoO_3$, consisted of a single phase of the perovskite-type structure. The oxides synthesized in the present study are denoted by the symbol of a circle in Fig. 1, which shows the phase diagram giving the composition region of the cubic crystal system in $La_{1-x}Sr_xFe_{1-y}Co_yO_3$. In this figure, $SrCoO_3$ is not of the perovskite-type structure and exists as $SrCoO_{2.5}$ in composition (8). The shaded parts indicate the cubic system and the other region was the tetragonal or the rhombohedral system except for $SrCoO_{2.5}$. The phase diagram for the resistivity is shown in Fig. 2. The oxides with $y \geqq 0.2$ and $x = 1$ could not be so tightly sintered and the sintering was impossible in the region of $0.6 \leqq y < 1$

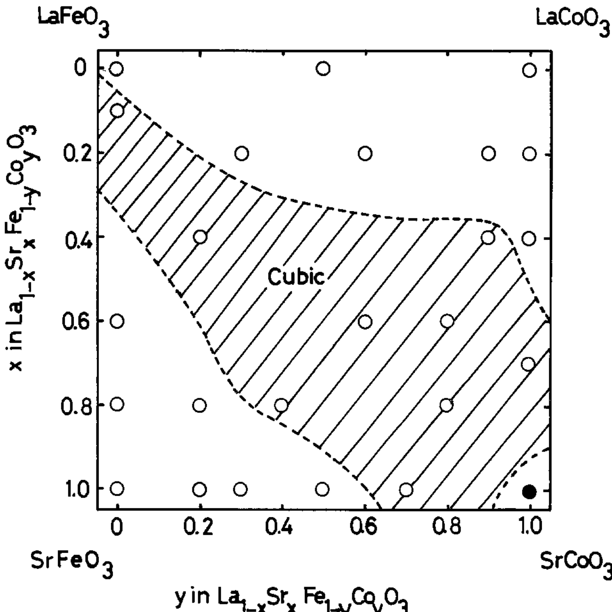

Fig. 1. Composition region of cubic crystal system in the phase diagram of $La_{1-x}Sr_xFe_{1-y}Co_yO_3$ oxides. The shaded parts indicate the cubic crystal system. The circles denote the compositions of the oxides prepared in this study. ● denotes other structure.

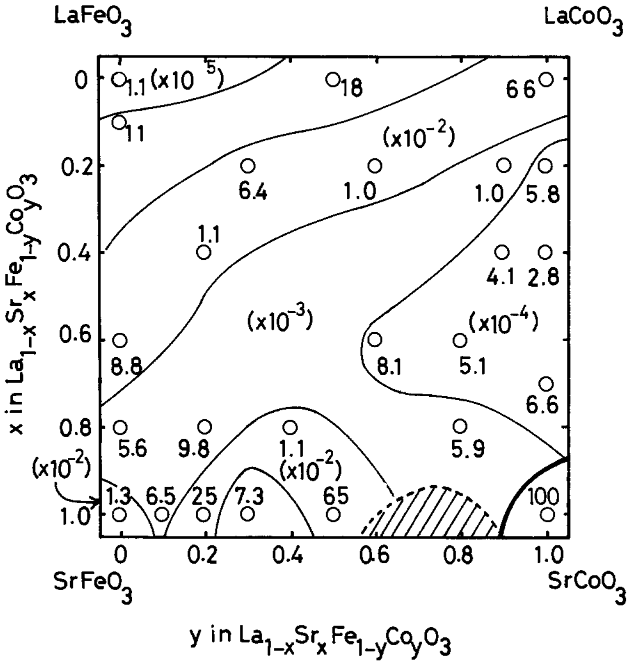

Fig. 2. Distribution of resistivity at room temperature. The unit for the each value in the figure is Ω · cm. The shaded parts indicate the composition region of the oxides impossible for sintering.

for the case of $SrFe_{1-y}Co_yO_3$ series oxides. The shaded parts in this figure indicate the composition region where sintering is impossible. The resistivities of $La_{1-x}Sr_xCoO_3$ (8) and $La_{1-x}Sr_xFeO_3$ decrease with an increase of x, since the partially filled π^* or σ^* band comes to be formed, with an increase of M^{4+} ion to bring a large interaction with the O^{2-} ion in the lattice (9). The d orbitals of the Co ion overlap more largely with the s, p orbitals of O^{2-} ion than those of the Fe ion in the lattice of the perovskite-type oxide, leading to a large contribution to the formation of the σ^* and π^* bands. Therefore, in the case of $LaFe_{1-y}Co_yO_3$, the resistivity decreases with an increase of y (10). It follows from the above results and the theories that the resistivity is expected to decrease with the increases of x and y, *i.e.*, along

the direction from $LaFeO_3$ to $SrCoO_3$, in composition. In the region surrounded by $LaCoO_3$, $La_{0.2}Sr_{0.8}FeO_3$, and $LaFeO_3$, the above expected result was qualitatively obtained as the figure shows, but not in the other region. The unexpected result in the latter region is based on the oxygen ion vacancies formed in the lattice. The oxygen ion vacancies lead to a decrease of the conductivity because of the vanishing of the interaction between the transition metal ion and the oxygen ion, M-O-M, in the lattice. There exists a large number of oxygen ion vacancies in the lattice for the oxides in the composition region having large x values. The amount of oxygen ion vacancies is qualitatively determined by the electrochemical technique described in the following section. The high resistivity of $SrCoO_{2.5}$ is assigned to the other structure in which the perfect oxygen octahedra around Co ions do not exist. After all, $La_{1-x}Sr_xFe_{1-y}Co_yO_3$ series oxides are suitable for electrode materials of low resistivity except for $SrCoO_{2.5}$, $LaFeO_3$, and their neighbors.

Figure 3 shows the type of the conductivity of the $La_{1-x}Sr_xFe_{1-y}Co_yO_3$ series oxides, which was determined by the thermoelectric power. Strictly speaking, $La_{0.4}Sr_{0.6}Fe_{0.2}Co_{0.8}O_3$ only showed metallic conductivity and the other oxides showed semiconductivity. However, the thermoelectric powers of the oxides in the shaded parts are small, in line with the low resistivity of the oxides in this part as shown in Fig. 2. Therefore, these oxides are denoted as "semi-metal" in this figure. The semiconducting type converts at about $x = 0.5$ from p type (in the region of $x < 0.5$) to n type (in the region of $x > 0.5$), except for $SrFe_{0.7}Co_{0.3}O_3$ and $SrCoO_{2.5}$. The ratio of La to Sr ion may be responsible for the type of semiconduction in the $La_{1-x}Sr_xFe_{1-y}Co_yO_3$ series oxides, but the type of semiconduction has no effect on the catalytic properties for the oxygen evolution reaction described in the following section. In any case, the semiconducting property, especially rectification, was not observed in the electrochemical tests, because of the degeneration of the surface due to a large number of surface states formed on the sintered disk samples.

Electrochemical properties.—Figure 4 shows the voltammogram of $La_{0.2}Sr_{0.8}Fe_{0.2}Co_{0.8}O_3$ electrode in 1M KOH at 25°C. The other oxide electrodes, except for

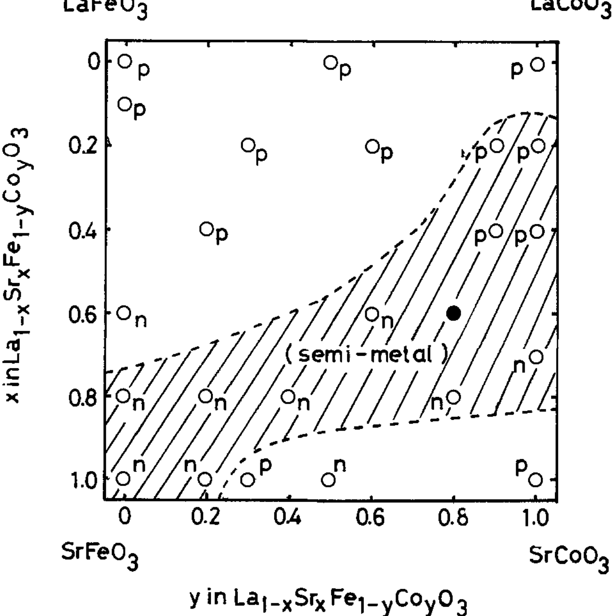

Fig. 3. Type of the conductivity. ● denotes the metallic conductivity. The shaded parts indicate "semi-metal" with small thermoelectric power.

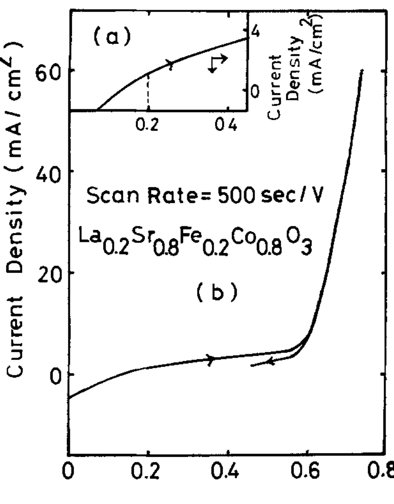

Fig. 4. Potential sweep voltammogram of $La_{0.2}Sr_{0.8}Fe_{0.2}Co_{0.8}O_3$ electrode in 1M KOH at 25°C: (a) is the figure magnifying (b) in the potential range between 0 and 0.45V.

$LaFeO_3$, also showed voltammograms similar to Fig. 4. The voltammogram was taken in a restricted potential region between 0V and the potential at which the oxygen evolution current density exceeds about 65 mA/cm². The plateau oxidation current observed prior to the oxygen evolution current [see (a) in Fig. 4] is assigned to the following oxidation reaction of the electrode

$$La_{1-x}Sr_xFe_{1-y}Co_yO_{3-\delta} + 2\delta OH^- \rightarrow La_{1-x}Sr_xFe_{1-y}Co_yO_3 + \delta H_2O + 2\delta e^-$$

The oxygen ion vacancies formed in the oxide surface region are filled with oxygen ion in the OH^- by the above electrochemical reaction. The phase diagram for the current densities at 0.2V [see (a) in Fig. 4] produced by the above electrochemical oxidation reaction of the oxide is shown in Fig. 5. In the composition region with large x value in $La_{1-x}Sr_xFe_{1-y}Co_yO_3$ series oxides, a high current density was observed, showing that the oxides in this composition region have a large amount of oxygen ion vacancies in the lattice. This is in line with the resistivity as described in the previous section.

Figures 6 and 7 show the phase diagrams for the overvoltages (η) of the oxygen evolution reaction at 40 and 60 mA/cm², respectively, which were determined from the voltammograms measured under the same conditions as Fig. 4. From the contour line of the overvoltages, in general, the catalytic activity increases with increases of x and y, *i.e.*, along the direction from $LaFeO_3$ to $SrCoO_3$ in composition. The catalytic activity of the $La_{0.2}Sr_{0.8}Fe_{0.2}Co_{0.8}O_3$ electrode was the highest in the oxide electrodes studied in the present paper as the figures show. However, the possibility will exist from the tendency of the contour lines that the catalytic activity of $SrCoO_3$ with perovskite-type structure is the highest in this series of oxides, if preparation is possible. The variations of the potentials with time during anodic polarization at 100 mA/cm² for the $La_{0.2}Sr_{0.8}Fe_{0.2}Co_{0.8}O_3$ electrode is shown in Fig. 8. The electrode potential slowly rises during 35 hr, but becomes almost invariant after 40 hr. $La_{0.2}Sr_{0.8}Fe_{0.2}Co_{0.8}O_3$ electrode, therefore, is good for use over long periods. Since there is little dissolution of this electrode, this oxide and its neighbors are suitable as anode materials in alkaline solution.

Discussion

The mechanism for the oxygen evolution reaction on the perovskite-type oxides in alkaline solution is proposed as follows (1-3, 11)

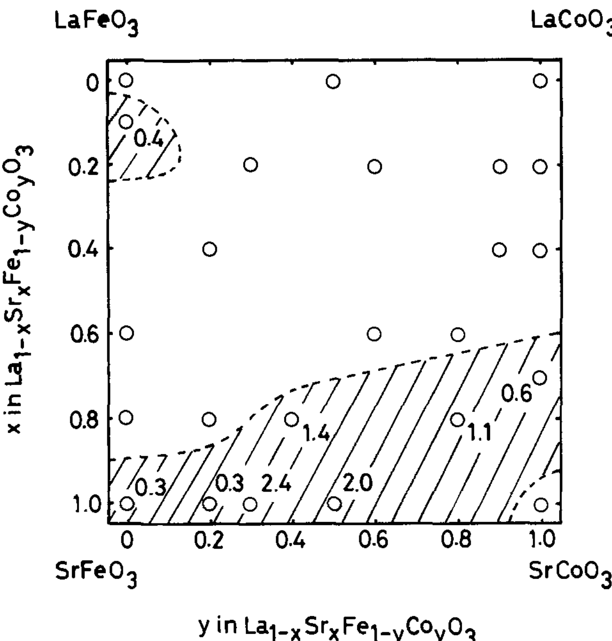

Fig. 5. Distribution of oxidation current density of electrodes at 0.2V (vs. Hg/HgO). The unit is mA/cm^2. The shaded parts indicate the composition region of the oxides giving the oxidation currents.

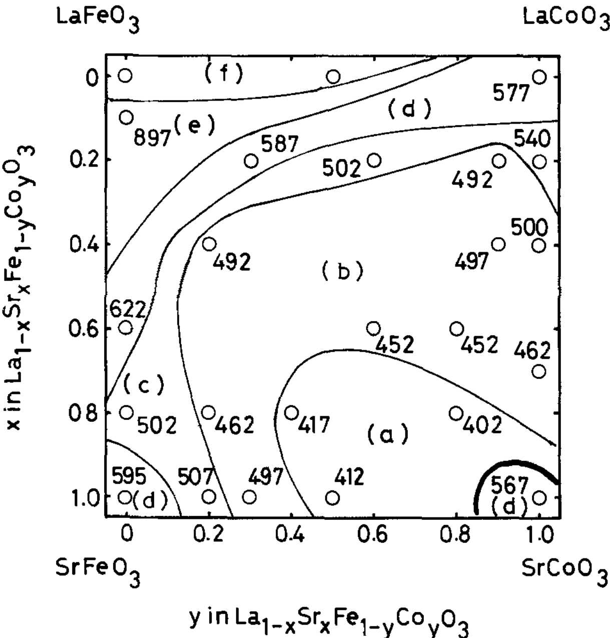

Fig. 6. Distribution of overvoltage (η) at 40 mA/cm^2. The unit is mV. (a) $\eta \leqq 450$ mV; (b) 450 mV $< \eta \leqq 500$ mV; (c) 500 mV $< \eta \leqq 550$ mV; (d) 550 mV $< \eta \leqq 650$ mV; (e) 650 mV $< \eta \leqq 900$ mV; (f) $\eta > 900$ mV.

$$S + OH^- \rightarrow SOH + e^- \quad [1]$$

$$SOH + OH^- \rightarrow SO^- + H_2O \quad [2]$$

$$SO^- \rightarrow SO + e^- \quad [3]$$

$$2SO \rightarrow 2S + O_2 \quad [4]$$

where S stands for the transition metal ion on the surface as described already. The rate-controlling step is the second step in the above process for the $SrFeO_3$ and $La_{1-x}Sr_xCoO_3$ electrodes (1, 2). The third step is rate controlling for the $SrFe_{0.9}Co_{0.1}O_3$, $SrFe_{0.9}Ni_{0.1}O_3$, and $SrFe_{0.9}Ti_{0.1}O_3$ electrodes (3), and the first step is rate controlling for the $La_{1-x}Sr_xMnO_3$

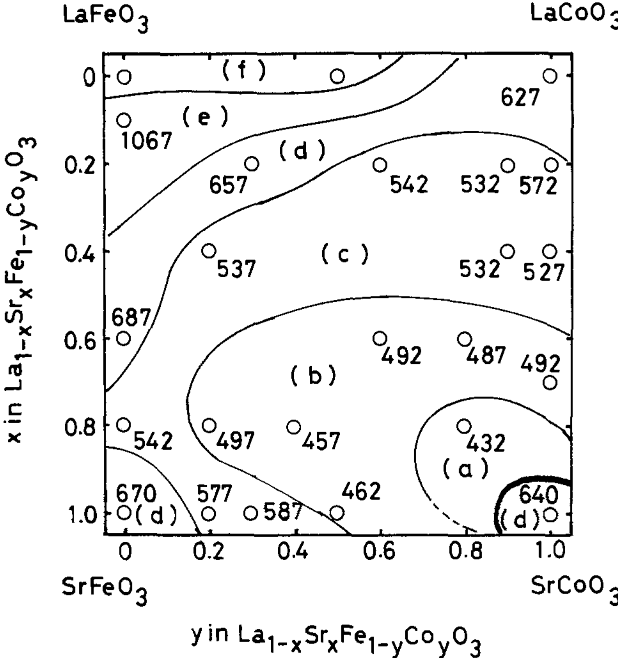

Fig. 7. Distribution of overvoltage (η) at 60 mA/cm^2. The unit is mV. (a) $\eta \leqq 450$ mV; (b) 450 mV $< \eta \leqq 500$ mV; (c) 500 mV $< \eta \leqq 600$ mV; (d) 600 mV $< \eta \leqq 700$ mV; (e) 700 mV $< \eta \leqq 1100$ mV; (f) $\eta > 1100$ mV.

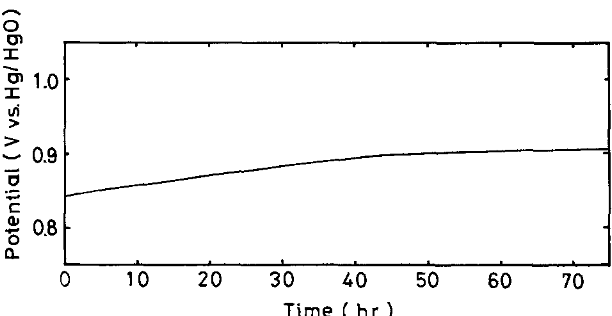

Fig. 8. Potential-time curve under anodic polarization of $La_{0.2}Sr_{0.8}Fe_{0.2}Co_{0.8}O_3$ electrode in 1M KOH at 100 mA/cm^2 at 25°C.

and $SrFe_{0.9}Mn_{0.1}O_3$ electrodes (3, 11) as described in the previous papers. The values of the Tafel slopes of $La_{1-x}Sr_xFe_{1-y}Co_yO_3$ series oxides for the oxygen evolution reaction are in the range of about 45-80 mV/decade except for $SrFe_{0.7}Co_{0.3}O_3$ and its neighbors as shown in Fig. 9. Under the assumption of Langmuirian adsorption conditions, this result suggests that the rate-controlling step is the second or third step for the $La_{1-x}Sr_xFe_{1-y}Co_yO_3$ electrodes (12). The resistivities of $SrFe_{0.7}Co_{0.3}O_3$ and its neighbors are relatively high, as Fig. 2 shows, and a large amount of oxygen ion vacancies exist in these oxides. Although the oxygen ion vacancy is electrochemically filled with oxygen ion, the bond strength between the newly filled oxygen ion and the transition metal ion in the lattice will be weak. Therefore, a relatively large barrier, such as a depletion layer, will be formed in the surface region of these oxides, leading to the large Tafel value.

The rates of the first and the third steps are mainly determined by the σ^* band width, that is, the rate of electron transfer increases with the increase of the σ^* band width. The d-electron configurations of $LaFeO_3$, $SrFeO_3$, $LaCoO_3$, and $SrCoO_3$ are shown in Fig. 10. In the case of $SrCoO_3$, the d-electron configuration is given for the ideal stoichiometrical $SrCoO_3$ with perovskite-type structure. The σ^* band width increases with increase of x for the

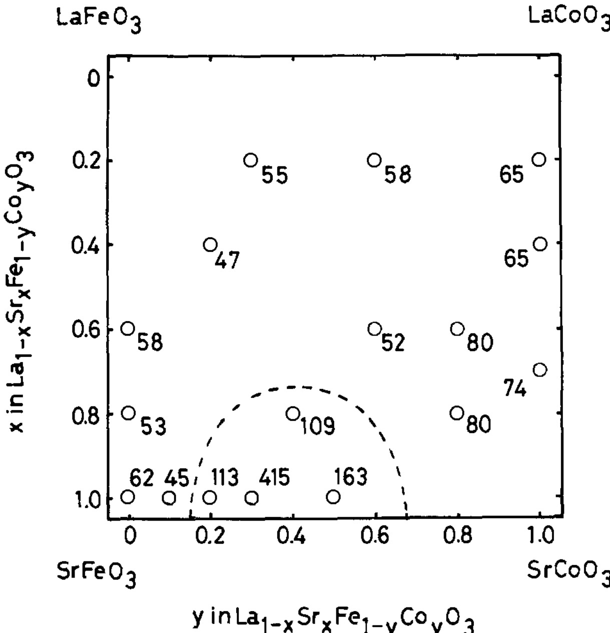

Fig. 9. Distribution of Tafel value for the oxygen evolution reaction. The unit is mV/decade.

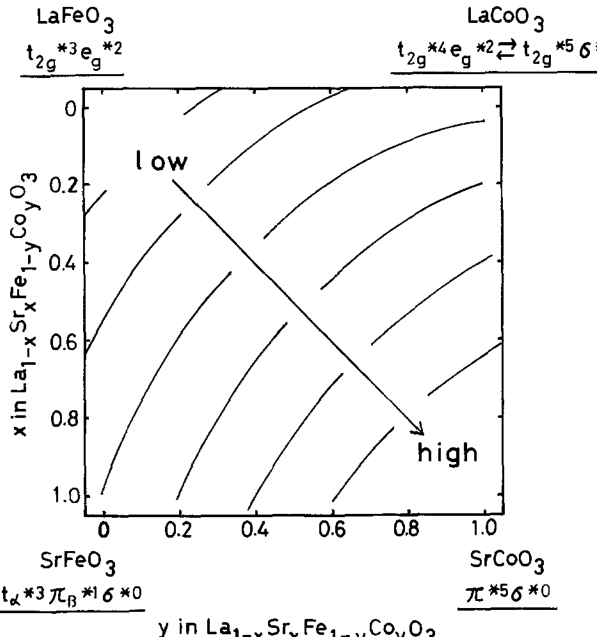

Fig. 10. Model of tendency of catalytic activity and d-electron configurations. The contour line for the activity is arbitrary.

$La_{1-x}Sr_xFeO_3$ and $La_{1-x}Sr_xCoO_3$ series oxides and increases with increase of y for the $LaFe_{1-y}Co_yO_3$ series oxides. This leads to the conclusion, as a matter of course, that the σ^* band width of the $La_{1-x}Sr_xFe_{1-y}Co_yO_3$ series oxides also will increase with the increases of x and y, *i.e.*, along the direction from $LaFeO_3$ to $SrCoO_3$ in composition. As a result, the rates of the first and third steps increase with increases of x and y. On the other hand, for the second step, the rate is determined by the positive charge density of the transition metal cation, that is, the rate increases with the increase of the amount of Sr, leading to the increase of quadrivalent cation in the lattice, as proposed in the previous paper (2).

Consequently, the rate of the oxygen evolution reaction will increase with the increases of x and y for $La_{1-x}Sr_xFe_{1-y}Co_yO_3$ series oxides, since the rate-controlling step will be either the second or the third step as the Tafel slopes suggest. Therefore, if the σ^* band width of $SrFeO_3$ is almost the same as that of $LaCoO_3$, the contour line of the catalytic activity in Fig. 10 is qualitatively suggested. In this figure, the contour line is arbitrary, and the activity increases along the direction from $LaFeO_3$ to $SrCoO_3$ as shown by the arrow. This phase diagram is consistent with the experimental results of Fig. 6 and 7 in the qualitative tendency of the catalytic activity except for $SrCoO_{2.5}$, $SrFeO_3$, and their neighbors. The high resistivity and the low activity of $SrCoO_{2.5}$ are based on the nonperovskite-type structure, in which the d-electron configuration will not be suitable for these properties. In the cases of $SrFeO_3$ and its neighbors, the σ^* band width may be different from expectation.

If $SrCoO_3$ with perovskite-type structure could be prepared in some way, the catalytic activity would be the highest of this series of oxides. Considering that the dissolution of $SrCoO_3$ would be small according to the mechanism described in the previous paper (2), sintered $SrCoO_3$ with perovskite-type structure must be a superior catalyst for the oxygen evolution reaction in alkaline solution. At the present stage, $La_{0.2}Sr_{0.8}Fe_{0.2}Co_{0.8}O_3$ is the best electrocatalyst of the oxides investigated in this study.

An Electrochemical Instrumentation System for Agriculture and the Plant Sciences

W. Gensler

Department of Electrical Engineering, University of Arizona, Tucson, Arizona 85721

ABSTRACT

The basic technique in this system is the placement of a noble metal probe invasively in the stems, petioles, or peduncles of higher plants. A reference electrode is placed in the soil. The time history of the potential arising between these two electrodes, termed an electrophytogram, can be related to the physiological status of the plant. The potentials arising in this circuit vary from 200 to 500 mV relative to a silver chloride electrode. The variations in the potential are coherent and highly reproducible. There are six broad categories of potential-time variation. The system has been tested under laboratory and field conditions wherein the potential data is stored locally or is transmitted via an rf telemetry link to a central site for analysis. The system is capable of long term, remote monitoring at low labor intensity under laboratory or field conditions.

The basic objective of this system is the determination of the physiological status of plants by a continuous, direct, *in vivo,* electrical measurement. In essence, the technique consists of placing a noble metal electrode invasively in the plant tissue. A second electrode is placed in the root environment. The bioelectrochemical electropotential arising from this circuit is monitored, plotted, and interpreted in terms of the status of the plant, the plant-soil continuum, and environmental conditions. Figure 1 illustrates the technique in schematic form.

There are several aspects of the measurement circuit that must be stressed. First of all, the measurement is made under normal conditions, that is, there is almost no disturbance of the crop canopy, nor the structure of the individual plant. The measurement is as passive as possible. An absolute minimum amount of energy is extracted from the plant by the measuring circuitry. The galvanic circuit path giving rise to the electropotential consists of the measuring probe-tissue interface, the stem and/or main trunk, the roots, the root-soil interface, the soil, and the soil-reference electrode interface. The measured potential at the output of the two electrodes arises from the electrode interfaces, plus any series galvanic potentials in the circuit path. The measurement is usually made every 15 min, 24 hr a day for almost the entire life of the plant.

Typical d-c levels range from 200 to 500 mV relative to a silver chloride electrode in the soil. A-C variations of 100 mV are common, variations as high as 250 mV have been observed. The potential is plotted to yield a time history of the potential variation. This time history has been termed an electrophytogram, or EPG (1). The ultimate objective of the system is the derivation of numerical indexes of plant water and growth status based on the electrophytogram information.

General Methods and Materials

The noble metal probe consists of a palladium rod, 250 microns in diameter and approximately 8 to 10 mm long. The electrode is inserted tangentially or at an angle to the tissue surface to a depth of 1.5-2.5 mm. Penetration depth normally carries the probe well into the secondary xylem. The electropotential between the measuring probe in the tissue and the reference electrode in the soil is monitored with a high impedance amplifier. The amplifier output is converted to digital form for further processing, transfer, and storage. The following discussion is principally addressed to the transduction aspects of the measurement technique since the electrical data processing is relatively conventional.

The probe-wire connection and the wire leading from the probe is of first-order importance and must be handled with great care. Many connection methods have been attempted under both laboratory and field conditions. The optimum technique up to the present time consists of stripping away 3-4 cm of insulation from a No. 30 (7×38) stranded wire; cutting away all but two of the strands, twisting these strands, and wrapping them mechanically around the probe at a 90° angle to the long axis of the probe and 1 mm below the end of the probe. The wires are then soldered to the probe. The probes can be cleaned and taken to the field in plastic bags for connection to the buried wires and ultimate connection to the plant.

The reason for this care is necessitated by two problems encountered principally under field conditions. Tests have shown that solar radiation impinging on the insulated wire results in a rise in temperature of the metal wire of as much as 6°C. This leads to

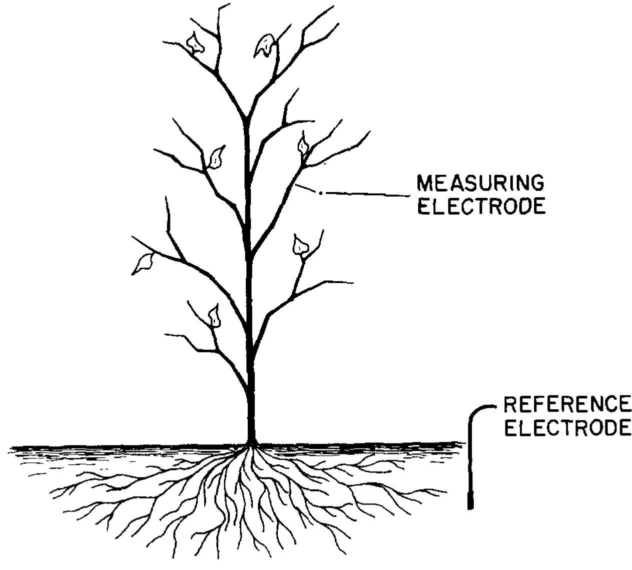

Fig. 1. Basic electrode arrangement of the electrophytogram technique.

Key words: agriculture, potential, electrophytogram, instrumentation, electrochemical.

an abnormal influx of heat energy into the probe-tissue interface. Further testing has indicated that a 3 cm length of uninsulated wire between the insulation and the probe permits heat transfer from the wire to the environment and a very considerable decrease in the elevated temperature of the probe. The decrease in thermal mass as well as the increase in thermal resistance as a result of using two strands further lessens this abnormal heat transfer. The second reason for this procedure arises from the need for mechanical isolation of the probe from the wire to insure proper healing and normal information transfer. Wind loading and mechanical movement of the plant requires mechanical isolation of the probe. The use of only two strands of No. 38 wire and the presence of substantial slack between the probe and main wire produces the required electrical connection at a minimum mechanical connection. The angle of approach of the wire to the probe decreases any "cantilever effect" of the probe by the wire The main wire itself is attached to the plant with strips of self-adhesive nylon mesh. With proper care in the handling of the lead wire, the plant will form a callous around the probe entry point firmly bonded to the metal surface. This will yield a probe-tissue interface below the surface that appears normal and gives no evidence of necrosis over long intervals of time. Microscopic examination has indicated the tissue ultimately will grow in an invaginated manner around the probe.

The success in achieving a stable probe-tissue interface depends on the age and type of tissue. *Lycopersicon esculentum* (tomato), *Kalonchoë blossfeldiana*, and *Gossypium hirsutum* (cotton) readily accept the probe at all ages. *Carya pecan* (pecan) appears to accept the probe only before the tissue becomes woody. It is very difficult to penetrate the woody secondary xylem since palladium is a soft metal.

The amount of energy and power which can be sustained by the plant during the measurement is difficult to assess since the electropotential source has no simple Thevinen equivalent circuit. A crude model of the measuring circuit would consist of a current dependent voltage source in series with a relatively low output resistance. Under field conditions, the energy required to charge the wires has been estimated to exceed the energy required to drive the amplifier. For this reason, No. 30 and No. 32 wire have been used to carry the electropotential signal. Further reduction in energy drain has been achieved by carrying the leads in buried conduit. This further reduces the wire to soil capacitance and at the same time protects the leads from mechanical damage under field conditions. The maximum distance between the probe and the amplifier tested up to the present time has been 40m. The input impedance of the amplifier must remain above $10^9\Omega$ (2). The published values of amplifier input impedance have little meaning because of surface resistivities of wire insulation, amplifier packages, and mounting boards under the extreme humidity variations encountered under field conditions. Teflon mounts, sealed enclosures, and dessicant within the enclosures have been employed to reduce surface leakage. These precautions have been found to be necessary when the electronic equipment operates in the middle of a "lake" during flood irrigation.

Acquisition time to determine the electropotential has been limited to approximately 2 sec/measurement. During this interval, the electropotential is measured three times. The use of triple redundancy has been found to be a very valuable means of determining system and/or probe malfunction. Resolution of 1 mV has been routinely obtained under field conditions.

The kinetics of the electropotential variations are such that a sampling rate of 12-15 min is sufficient to obtain an indication of the timing of most of the variations. This means the upper bound on the bandwidth of electropotential variations is approximately 2.0 radians/min (3).

Since the subject of reference electrodes is such an extensive one, the detailed discussion of its characteristics is given in the Appendix.

It is interesting to note that the d-c electropotential levels measured with a hydroponic root environment do not differ from those encountered with several soil types under field conditions. This would indicate the magnitude of the potential contribution of the circuit path from the reference electrode to the roots is relatively unaffected by both the root-soil interface and the soil.

Several generations of electronic techniques have been employed. The present acquisition sites have between 32 and 64 channels. In addition to the electropotential data, the temperature, humidity, photosynthetically active radiation level, reference electrode, and electronic equipment status are monitored The equipment operating at the remote sites is entirely solar powered.

Signal processing circuitry is conventional. However, extreme care must be taken to electrically isolate the transduction circuit from line driven equipment. Optoisolators, magnetic amplifiers, fiber optic links, relays, and battery driven amplifiers have all been employed to achieve electrical isolation of the transduction circuit in growth chambers as well as in the field.

Field measurements were initiated in the spring of 1977. During the 1978 and 1979 growing seasons, electropotentials and associated environmental readings were obtained via a 120 km rf telemetry net wherein the data was transmitted directly to the University of Arizona Campus for computer processing. Figure 2 shows one of the field test sites. The methods of probe placement and data acquisition were tested with cotton and pecans. They have been found operable within the scope of normal commercial agronomic operations

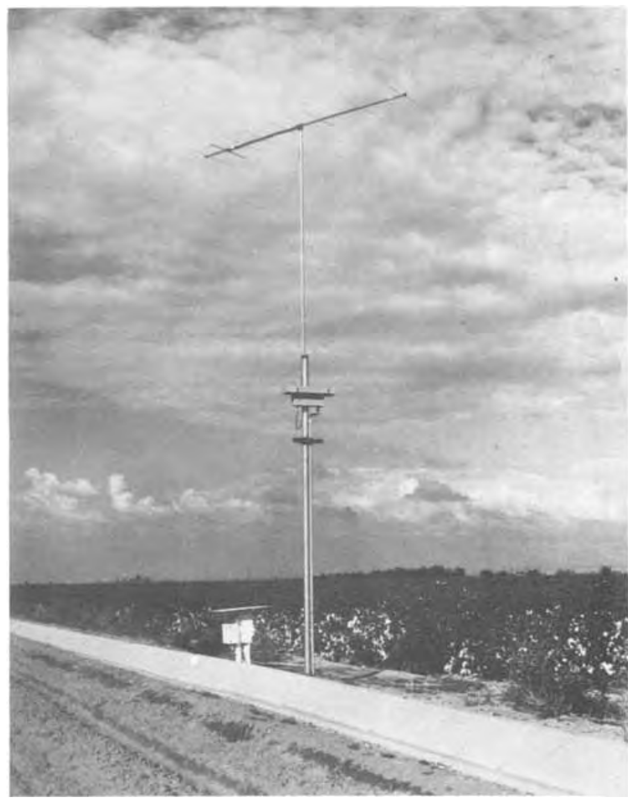

Fig. 2. Commercial cotton field test site showing data acquisition equipment and radio frequency telemetry equipment. Avra Valley, Southern Arizona.

such as ripping, plowing, cultivation, and irrigation. The system is capable of remote, long term, multiplexed measurements of electropotential and associated environmental data at low labor intensity.

Categories of Potential Variation

The potentials measured are coherent and highly reproducible. An examination of the phytograms yields a variety of potential pulses and long duration time shifts in potential level. There are six relatively distinct categories of potential variations. Each of these is briefly described.

Healing potentials are observed immediately after the penetration of the probe into the tissue (4, 5). The potential drops precipitously. The potential then rises in a roughly exponential manner during the healing process and levels off at a stable equilibrium value. The magnitude of the rise is 200-300 mV. Under growth chamber conditions at low light intensities and moderate temperature conditions, the 90% rise point is attained in about 3 days. In the field, the rate of rise is in the order of 8 hr at similar magnitudes. The healing response is extremely consistent. A rewounding response of the same basic form, but of faster duration, is observed when an impulsive mechanical stress is applied to the probe lead wire.

A hypothesis of healing has been developed based on the drop in potential with wounding and then the monotonic rise in potential during the healing process. The basic electrochemical principle invoked is the correlation of more negative oxidation-reduction potentials with the presence of more highly reduced reactants. The initial decrease in potential is caused by a sudden increase of electron availability at the wound site as a result of a mixing of hitherto separated reactants. This enhanced electron availability or reducing power is then consumed in an ordered manner as manifest by the monotonic rise in potential during the subsequent healing reaction.

Transition potentials arise at dawn and dusk. These potentials occur for approximately 1 hr following the light transition. They have been studied almost exclusively under laboratory conditions wherein it is possible to expose the plants to a definitive, short duration light transition. Under field conditions, the change in light intensity is very slow at dawn and dusk and it is difficult to separate out a potential variation which can be attributed exclusively to a light disturbance. The transition potentials do not appear to be related to short term growth, but there is a correlation of the magnitude of the transition potential with the 24 hr growth rate (1).

Diurnal potentials are potentials which occur with the normal 24 hr time cycle. Figure 3 illustrates a typical diurnal potential which has been observed in *Kalanchoë blossfeldiana.* The cyclic waveshape shows the sharp transition potential notches at light transition points and the subsequent shift in d-c potential several hours after the light transition. The potential is a manifestation of an endogenous rhythm as seen by the fact that the rhythm continues for approximately 2 cycles after the onset of continuous darkness. The potential variation has been correlated with *p*H changes in the leaves, the variations can be induced by shifting the plant from long (12/12 hr) days to short (8/16 hr) days (unpublished results). This has led to the hypothesis that this potential variation is a measure of the shift from C3 to crassulacean acid metabolism in *Kalanchoë blossfeldiana.*

Water-related potentials have been observed in two forms (6). In the first, there is an immediate drop in d-c level by the addition of water in the root zone. This potential is believed to be due to a change in the potential of the root-soil interface. The second form of water-related potential has been observed in the field following irrigation. The potential shows no response in the short term, but a very dramatic burst of electropotential activity after a period of at least one day.

The fifth category of observed potential variations are high frequency oscillations. These oscillations have a frequency of 1-6 radians/hr and a peak to peak magnitude of a few millivolts to as high as 20-30 mV. They come in bursts lasting from a few hours to as long as several days.

Nocturnal potentials have been observed under field conditions only. Figure 4 shows a typical nocturnal potential observed in the peduncle of *Carya Pecan.* These occur in the absence of any observable external environmental disturbance. They are believed to be related to water status.

The separation of potential variations into these relatively distinct categories does not imply that the origin of the potentials are mutually exclusive. The distinctions have grown out of observations of the electrophytograms under externally induced environmental disturbances such as light or water. Internal regulatory or developmental mechanisms can and do give rise to potential disturbances as seen in the diurnal potential waveshape in Fig. 3 and the nocturnal potential waveshape in Fig. 4. Sharp changes in potential level occurred under constant light conditions and constant or nearly constant temperature conditions.

With the exception of the healing potential, the entire range of potential variations follows a definite pattern insofar as the potential variations are characterized by an upper bound. Variations are normally a drop and return to an upper bound. Figure 3 shows an example of this relatively general observation. The diurnal potentials and nocturnal potentials also illustrate this phenomenon.

Electropotential measurements have been made extensively under growth chamber and field conditions. The magnitude of the potential variations observed in field conditions are substantially greater than those encountered in growth chambers. It is very difficult to attribute an origin to this difference since the environmental conditions, age, and type of plant studied all vary. The d-c electropotential levels encountered in the lab and the field are the same. The magnitudes of healing potentials are also the same. One encounters the same d-c levels if the root environment is a hydroponic nutrient solution or soil.

The previous discussion has concerned individual potential variations arising from a single probe. Be-

cause the electrophytogram technique is a macroscopic measurement, it is possible to implant probes at many locations in the same plant. Figure 5 shows the locations of multiple probes in the fruiting branch of cotton during the 1978 growing season. An example of the comparative phytograms from the peduncle of the apical boll and the petiole of its companion leaf is shown in Fig. 6. There is a striking similarity in the potential variation even though the probes are approximately 3-5 cm apart on opposite sides of a fruiting branch.

Discussion

The use of the noble metal probe results in a measurement of the electropotential status of the extracellular electrolyte at the probe-tissue interface. Assuming no algebraic cancellation of potentials along the circuit path, the d-c levels encountered are reasonable since the plant is very likely not going to maintain its extracellular fluid at a high energy level. By using multiple probes one can establish a partial common circuit path between the reference electrode and the measuring probes. Variations in potential along this common path are easily observable when examining the simultaneous phytograms of each probe. For example, a malfunction in the reference electrode will show up as a change in potential of all the probes at the same time and of the same magnitude. This has led to the conclusion that the electropotential variations in most cases are believed to be due to the conditions at the measuring probe-tissue interface (2).

Fig. 5. Multiple probe technique applied to the fruiting branch of *Gossypium hirsutum*. Probes are placed in the stem, peduncles, and petioles for simultaneous recording.

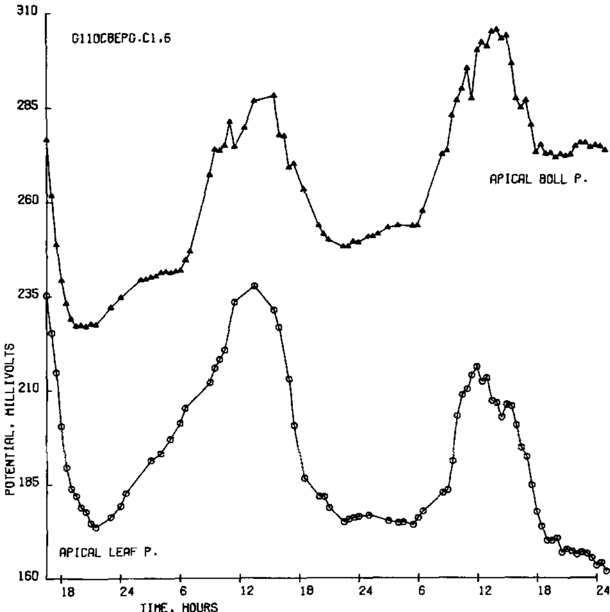

Fig. 6. Simultaneous electrophytogram of the apical boll peduncle and companion leaf petiole in a fruiting branch of *Gossypium hirsutum*.

There are a number of problems with the technique that must be recognized. First, of all, the physiological origin or origins of the potential variations have not been determined. Second, the spatial origin of the potential is not well defined. The probe surface is an equipotential surface bathed in a heterogeneous electrolyte. The d-c potential and potential variation can arise from a variety of sources: a change in reactants, a change in reactant concentration, pH level, or possible electrostatic influence. In addition, some of the observed changes may be due to conditions along the circuit path other than at the measuring probe-tissue interface.

While the variations in potential are coherent, consistent, and reproducible, the d-c values exhibit a wide range of values. This range is present even under stringent probe cleaning techniques and similar placement methods.

The simplicity of the probe renders the interpretation difficult. It is possible to assert that the probe measures the potential status of the fluid adjacent to its interface. Furthermore, the measurement is extracellular. But the transition from a measured galvanic potential to a biochemical or biophysical origin is a difficult one.

Another serious problem associated with the technique is the need for long-term data acquisition to remove or lessen the influence of multiple uncontrollable environmental disturbances.

The number of probes required to assess physiological status is presently unknown. The answer to the question of probe numbers is dependent on a more fundamental question: where in the plant should the probes be placed to obtain the maximum information? The probe locations shown in Fig. 5 are directed to answering the question of obtaining the maximum information with the minimum number of probes.

Given these problems, if the potential variations can be related to specific physiological activity, then the potential can be used as an easily acquired, nondestructive measure of such activity. Furthermore, each plant has definite electropotential characteristics. The electropotential activity may be used as a means of genetic selection. The electropotential can be monitored from juvenality to senescence.

With regard to field usage of the electrophytogram system, the most labor intensive operation in monitoring field crops is the need to bury the lead wires in the fall and raise them again in the spring. This procedure is required to prevent the destruction of the wires during mechanical harvesting in the fall and soil preparation in the spring. All electrical equipment in the field must be buried at least 60 cm below the surface to clear the ripping operation. The raising of the cables must be delayed until after mechanical seeding because of the equipment involved. Portable equipment would obviate this problem but requires more electrical complexity and also introduces a security problem.

It has been found necessary to run the lead wires directly along the line of plant main stems. The tractor tolerances are such that only about 5-10 cm of undisturbed soil exists on each side of the stem line. The wires cannot be seen by the tractor operator.

Furthermore, it is not feasible to require special care on the part of the tractor operator in the region of the probes.

The telemetry antennas have been found to present no problem to airborne crop dusters.

The ultimate hardware and software configuration of the system is dependent on the crop type, irrigation practice, and the size of the agricultural unit. For example, in a section (259 hectares) of cotton planted in smaller subunits to stagger the water demand, the system would consist of semiportable acquisition pods capable of acquiring the primary data and transmitting it a maximum of 1.5 km to an intermediate transfer center. The data would be stored and subsequently transferred via a long distance rf link to a central processing site for evaluation and formulation of numerical indexes. In discussions with growers it is apparent that the mass of electropotential data must be presented in very quickly assimiliated form. Numerical indexes derived from the electropotential data is the most logical form of presentation.

In summary, the electrophytogram system is a technique for remotely monitoring the physiological status of plants under laboratory or field conditions for long intervals of time at low labor intensity. Coherent, reproducible electropotential variations can be observed at various locations in the individual plant. The major problem at the present time is the determination of the physiological origin of these variations. Once this origin is established, the EPG should provide insight into the fundamental physiology of the plant in laboratory studies and provide a quantitative backup to agricultural decision making under field conditions.

APPENDIX

The Reference Electrode

The interpretation of the electrophytogram is heavily dependent on the assumption of a constant galvanic potential between the return wire to the amplifier and the bulk soil. Furthermore, the comparison of phenomena which occur days and even months apart requires long term stability in the reference electrode potential. The electrode assembly described below is employed to maintain a constant interfacial potential and at the same time permit a continuous assay of the potential.

Figure A-1 illustrates the basic technique in schematic form. In essence, the assembly consists of an AgCl concentration cell in which the soil functions as part of the galvanic current path. Electrode assembly A is an AgCl electrode employing a 0.5M potassium chloride electrolyte. The electrolyte wets a KCl-saturated polyacilamide salt bridge. The acrilamide salt bridge in turn wets a porous ceramic plug, the outer surface of which is in contact with the soil.

Electrode assembly B is a duplicate of electrode assembly A except a 1.0M KCl electrolyte is employed. Either electrode may be employed as the reference electrode although it is customary to use electrode assembly B as the reference electrode in the electrophytogram transduction circuit because of the resultant electronic simplicity (single rail amplifiers can be employed).

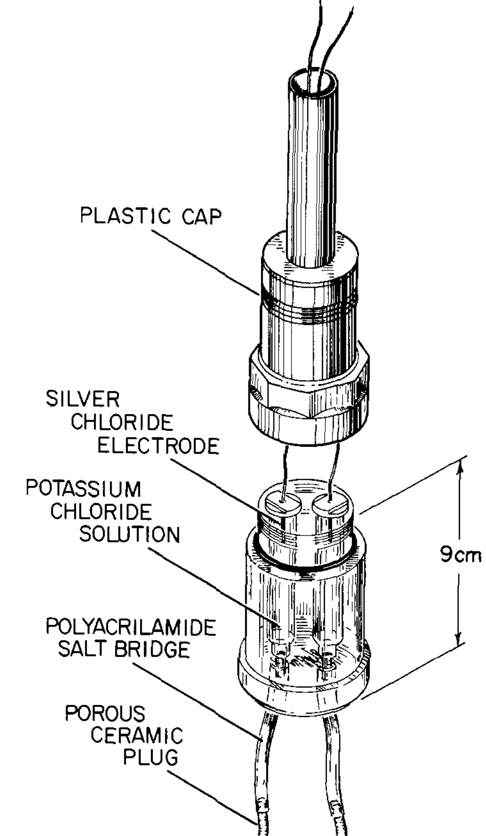

Fig. A-1. Reference electrode assembly

If electrode assembly B functions as the reference electrode, then electrode assembly A becomes an electrode used to monitor the stability of the main reference electrode. The manner in which it does this can be seen by an examination of the circuit path. The concentration cell circuit path begins at the copper wire of assembly B, passes through the chloridized silver electrode into the 1.0M electrolyte, through the acrilamide gel and porous plug, across the ceramic-soil interface, through the soil, and then into electrode assembly A in a reverse manner. There are two ceramic-soil interfaces which in practice have been separated by at least 15 cm of soil. The assumption is made that changes in the interfacial potential at these interfaces will not "track" or produce algebraically similar potential variations. If this is the case, and it is highly probable, then any change of galvanic potential at any interface or series element will show up as a potential change in the two copper wires.

Employing these principles, electrodes of the type shown in Fig. A-1 have been built and tested. A potential of between 12-18 mV results when the electrodes are buried 1m below the surface. The overall variation in potential for a given electrode is approximately 4 mV and it is felt that some of this variation is due to the soil temperature difference in Southern Arizona between summer and winter. Electrodes of this type have been in continuous service for as long as fifteen months at the time of this writing.

Soil type does not appear to influence the potential. The units have been tested only in normal farmland as opposed to drier desert soils. It is assumed that wetting of the ceramic comes from soil moisture since the polyacrilamide gel passes almost no fluid.

The location of the reference electrode is not significant in measuring plant potentials. The maximum distance between the plant and the reference electrode that has been employed up to the present time is 20m. The insensitivity of this distance to the potential reading is reasonable since the impedance level of soil

is not more than 100's of ohms while the impedance level of the electronic amplifier is at least $10^{10}\Omega$.

It is also interesting to observe that the soil itself, a very rich mixture of redox reactants, yields a highly stable circuit path between the two ceramic plugs.

The Suppression of GaAs Photocorrosion in Aqueous Solutions by Sulfonated Anthraquinones

F. Decker[1] and B. A. Parkinson*

Ames Laboratory, USDOE, Iowa State University, Ames, Iowa 50011

ABSTRACT

The water soluble organic redox couples 1, 5-anthraquinone disulfonate (1, 5 AQD) and 2, 6-anthraquinone disulfonate (2, 6 AQD) were investigated as possible redox reagents for use in the stabilization of GaAs electrodes in semiconductor liquid junction solar cells. The redox potentials and electron transfer kinetics of these anthraquinones measured at various *p*H's on a rotating glassy carbon electrode indicated that the reduced form of the couple could effectively compete with photocorrosion reactions for photogenerated holes on a GaAs surface in basic electrolytes. A rotating GaAs disk-glassy carbon ring electrode was constructed and the collection at the ring electrode of the photooxidized product from the illuminated semiconductor was measured. Competition between light flux, mass transport of the reducing agent, and photocorrosion reactions, as well as redox couple adsorption, were measured at the rotating electrode. The long term stability of illuminated cells containing these redox species was investigated and photocurrent spectra were measured. The importance of redox couple adsorption in the stabilization of semiconductor surfaces in liquid junction cells is assessed.

The n-GaAs/1M KOH, 0.8M K_2Se 0.1M K_2Se_2/C semiconductor liquid junction solar cell is presently the most efficient cell of this type for both single crystal (1) and polycrystalline (2) gallium arsenide. There is considerable room for improvement of both long term stability and energy conversion efficiency, however. The selenide solutions used in these cells are colored, air sensitive, and highly toxic, properties which would make a suitable substitute attractive. Bard (3) and others (4, 5) are attempting to use nonaqueous solvents to avoid the photocorrosion reactions which involve water and to make available a wider range of organic and organometallic redox couples for use in these cells, however the limited solubility of many of these couples has precluded their use at light intensities near or above solar levels (3). The difficulty of permanently removing water from the organic solvents and the additional expense they would add to cell construction are other problems associated with the use of these solvents. Our approach was to take anthraquinone, which Bard (3) has shown stabilizes the GaAs surface at low light intensities in acetonitrile, with sulfonate groups attached to the molecule to make it more water soluble. In some solutions the requirement of fast electron transfer kinetics to the solution redox species is satisfied by anthraquinones. Rapid kinetics are necessary to avoid overpotential losses in the cell and to effectively compete with photocorrosion reactions for photogenerated holes at the semiconductor surface.

Rotating electrode techniques are particularly suited for the investigation of the interactions between dark reactions, photocorrosion, mass transport of redox couples, and light flux at semiconductor electrodes (6, 10). We have employed rotating disk and ring disk electrodes of glassy carbon and gallium arsenide to elucidate the interaction of photochemical and electrochemical processes in gallium arsenide photoelectrochemical cells containing disulfonated anthraquinones. The wavelength response and long term stability of the photocurrent in these systems were investigated. An experiment which demonstrates the adsorption of these redox couples on GaAs is also presented.

Experimental

Electrodes.—GaAs crystals obtained from Laser Diode Laboratories were silicon-doped with a carrier density of 2×10^{17} cm^{-3} and a resistivity of 0.01 Ω-cm. The (100) face with a back ohmic contact was attached by means of silver epoxy to a copper wire (stationary electrodes) or to a steel shaft (rotating electrodes). Both types of electrodes were then insulated with epoxy and, in the case of the rotating electrodes, machined to a cylindrical form. (The geometric parameters of the rotating GaAs disk/glassy carbon ring in cm are $r_1 = 0.195$, $r_2 = 0.325$, and $r_3 = 0.595$.) The GaAs electrodes were etched in 1:1 H_2SO_4-30% H_2O_2 before each test. The reference electrode was Ag/AgCl and the counterelectrode was a carbon rod or platinum gauze.

Materials and Techniques.—Anthraquinone-1, 5 and -2, 6 disulfonic acids as the disodium salt (Aldrich Chemical Company) were purified by repeated recrystallization from water. Stock solutions of the purified reagent were prepared at concentrations close to saturation, around 40 and 30 mM for the 1, 5 and 2, 6, respectively, at ambient temperature. Solutions of the anthraquinones in different supporting electrolytes were electrolyzed at Pt gauze (in base) or a large area carbon electrode (in acid). Since these solutions

Key words: semiconductor, mass transport, energy conversion.

are air sensitive the photoelectrochemical cell experiments were run in the electrolysis cell which was being flushed with nitrogen or, alternatively, the electrolyzed solution was transferred to a second cell under anaerobic conditions. The light sources were a 10 mW He-Ne laser, beam-expanded to cover the electrode for the efficiency measurements, and a 100W quartz-halogen lamp, for the RRDE experiment. For the long term runs and the photocurrent spectrum measurements the illumination was through an optical flat on the bottom of the cell. The laser power was measured with a Metrologic radiometer.

Results

The electrochemical behavior of a 50% reduced solution of 1, 5-AQD and 2, 6-AQD on a rotating glassy carbon electrode as a function of the electrolyte *p*H is shown in Fig. 1. The inset of the figure shows that the potential of the couple shifts negative as the *p*H is made more basic at very close to the theoretical rate of 59 mV/*p*H unit for the reaction written in Eq. [1]

$2H^+ + 2e^- +$ (anthraquinone: O, A, B / B, A, O) ⇌ (anthrahydroquinone: OH, A, B / B, A, OH) [1]

1, 5 $A = SO_3^-$ $B = H$ 2, 6 $A = H$ $B = SO_3^-$

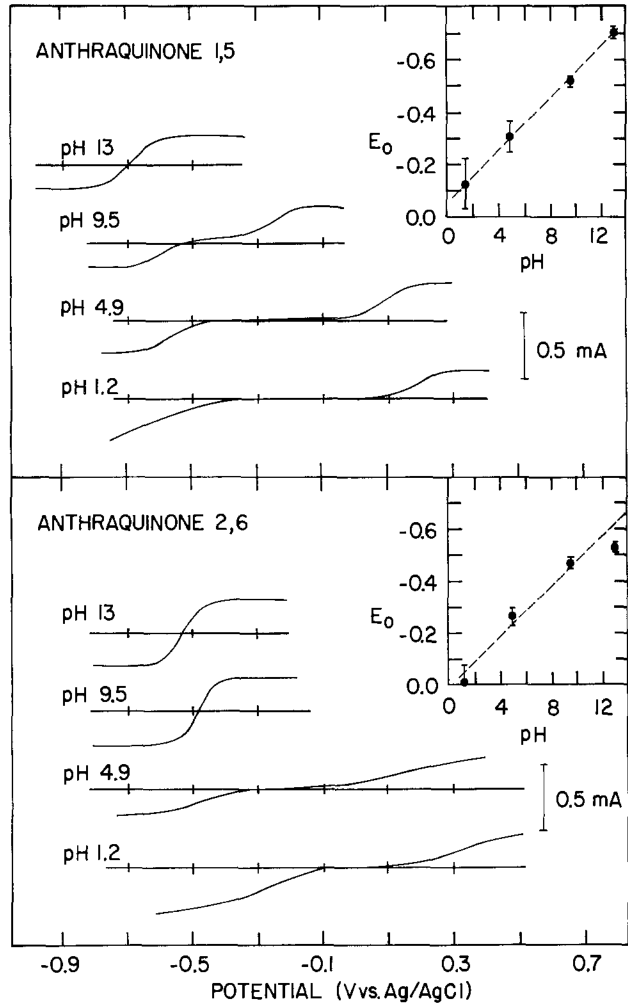

Fig. 1. Electrochemical behavior of a 50% electrolyzed solution of the anthraquinones used in this study at a rotating glassy carbon disk electrode (1000 rpm) in aqueous electrolytes: *p*H 13 0.1M NaOH; *p*H 9.5 0.2M ammonia buffer; *p*H 4.9 0.2M acetate buffer; *p*H 1.2 0.2M $HClO_4$. The insets show the equilibrium redox potential as a function of *p*H.

The potentials shown in Fig. 1 are in good agreement with values reported by Furman and Stone (7) at a dropping mercury electrode in 10% ethanol solutions.

The coalescence of the oxidation and reduction waves in basic solutions indicates that the electron transfer rate is faster than in acid. The potential of the 2, 6 AQD in highly basic electrolytes falls below the line extrapolated from more acid *p*H's which indicates that no protonation step occurs upon reduction of this molecule in very basic solution.

Table I shows the results with 1, 5-AQD and 2, 6-AQD in an n-GaAs liquid junction cell at two monochromatic illumination intensities and different *p*H. The data in Table I was taken with the GaAs surface in the "shiny" etch (8) condition due to the greater ease of reproducing this surface. A good "matte" etch would increase the short-circuit current and efficiency by up to 50% (8). The table shows that the best cells made from either couple are at *p*H ~ 9 even though the redox potential and electron transfer rate constant would appear to be more favorable in more basic solutions. This is because at *p*H 12 the predominant form of the reduced quinone in solution is the highly colored dianion which absorbs an appreciable fraction of incident radiation. An intriguing aspect of Table I is that the open-circuit voltage (OCV) of a cell is dependent on the solution *p*H for 2, 6-AQD and independent of *p*H for the 1, 5-AQD couple. In Fig. 2 the cell voltage at constant monochromatic intensity at the semiconductor is plotted *vs.* the redox potential of the anthraquinone solution.

A slope of zero, as drawn for 1, 5 AQD in Fig. 2, might be expected if the flatband potential of the electrode and the redox potential of the solution were shifting in the same direction at the same rate as the *p*H of the solution is changed. Gomes and Cardon have measured flatband potential shifts of about 56 mV/*p*H unit for n-GaAs in various buffers (9). However this shift has been attributed to protonation of surface oxides, a process which may be influenced by redox couple adsorption which will be discussed later in this paper.

The data in Table I does not yield any information about the stability against photocorrosion of the cells and rotating electrodes were used for this purpose. Figure 3 shows the interaction of corrosion and redox couple mass transport at a rotating glassy carbon ring-gallium arsenide disk electrode under constant white light illumination from a tungsten halogen lamp. The dotted lines show the photocorrosion current for the gallium arsenide electrode with no redox couple in the solution and the ring current at −0.9V shows no

Table I. Open-circuit potential (V_{oc}), short-circuit current (I_{sc}), fill factor (ff), and monochromatic (632.8 nm) power efficiency (η) of different n-GaAs/10 mM anthraquinone in 0.2M aqueous electrolyte/carbon cells.

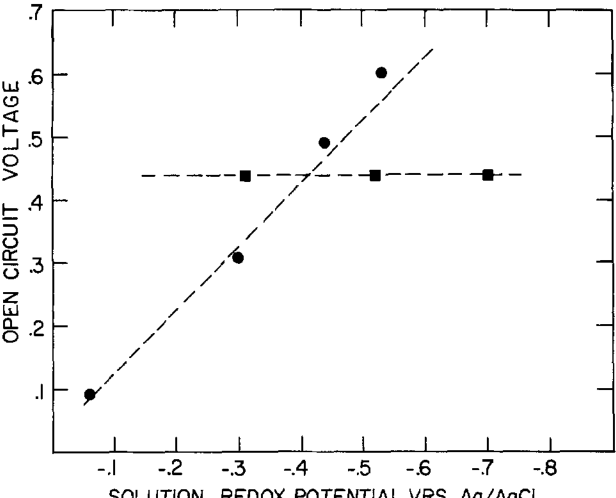

Fig. 2. The open-circuit voltage generat-d plotted with respect to the solution redox potential at a constant illumination intensity (1 mW 632.8 nm) for an n-GaAs electrode in a 10 mM solution of —2, 6 anthraquinone disulfonate (●) and —1, 5 anthraquinone disulfonate (■).

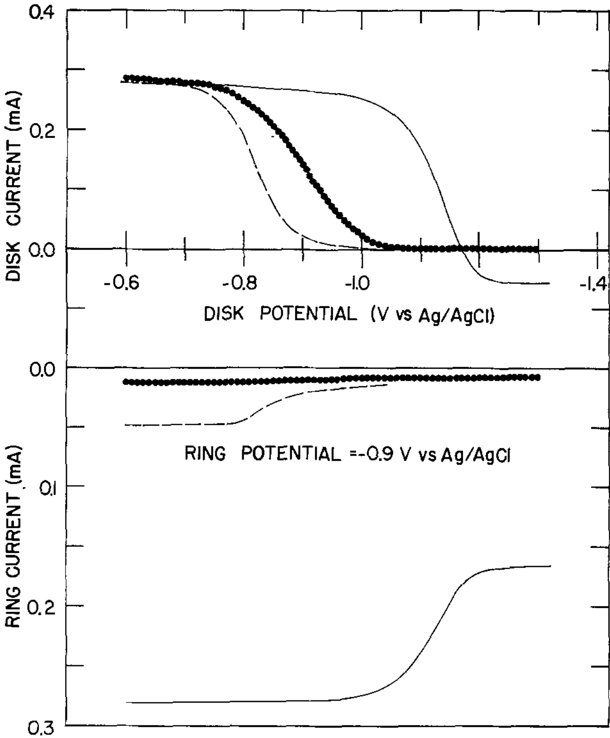

Fig. 3. Current-voltage behavior of a rotating glassy carbon ring-illuminated n-GaAs disk electrode in verious electrolytes. Dotted lines—0.2M ammonia buffer; dashed lines—0.2M ammonia buffer + 4 mM hydroquinone; solid lines—0.2M ammonia buffer + 4 mM 2, 6- AQD. Illumination was from a 150W tungsten lamp. Rotation speed 1500 rpm. scan rate 5 mV/sec.

collection of photocorrosion products at this potential. When hydroquinone is added to the solution (the dashed lines) the photocorrosion reaction is shifted in a positive direction by about 0.1V and the photo-oxidized product can be reduced at the ring electrode. The percentage of stabilization can be calculated from the limiting current and the collection efficiency of the electrode to be about 25% which is consistent with a number reported by Memming (10). The solid lines show the disk and ring currents for an 80% reduced solution of 4 mM 2, 6 AQD. The photocurrent onset in now about 200 mV more negative than the photocorrosion reaction and the ring current (which is superimposed on a background of unreduced bulk 2, 6 AQD) shows an increase in current which is within experimental error equal to the disk current multiplied by the collection efficiency, indicating that virtually all the photogenerated holes are reacting with the redox couple.

The rotation speed dependence of the currents shown in Fig. 4 demonstrates the separation of the 2, 6 AQD wave from the corrosion wave when the mass transport of 2, 6 AQD is less than the hole flux. The stable plateau of the ring current at the lower rotation speeds demonstrates that the photo-oxidation of 2, 6 AQD is continuing at a mass transport limit even at potentials where the gallium arsenide disk is undergoing a simultaneous photocorrosion. The greater than 200 mV separation of the 2, 6 AQD wave from the photocorrosion indicates the effectiveness of this redox couple for suppression of gallium arsenide photocorrosion. Similar results are obtained with 1, 5 AQD, however the potential difference between anthraquinone photo-oxidation and the photocorrosion reaction is about 150 mV. Miller has observed similar behavior on rotating GaAs electrodes with photo-oxidation of selenide; however, in this case, the photocorrosion products (As^{3+} and Ga^{+3}) interfere with the polyselenide before it can be reduced at the ring electrode (6).

The photocurrent spectra of cells containing the hydroquinone form of 2, 6 AQD and 1, 5 AQD in pH 9.5 ammonia buffer and selenide/polyselenide in 1M KOH are compared in Fig. 5. The predominate form of the anthraquinone in this pH range is the monoprotonated anion ($AQDH^-$) which is lightly colored but absorbs strongly in the blue region of the spectra. A photoresponse spectrum for the selenide/polyselenide couple at its usual concentration is also shown and indicates that the anthraquinone couples transmit a larger fraction of the incident light, albeit at these lower concentrations.

The long term stability under illumination of cells containing 1, 5 AQD and 2, 6 AQD was investigated in *p*H 9.5 solutions. The GaAs electrode was rapidly corroded when illuminated at solar irradiation inten-

sities in stirred solutions containing 20-40 mM of the reduced anthraquinone. Apparently the mass transport of the redox couple at these concentrations is not large enough to compete with corrosion reactions at air mass one intensities. This is not surprising in light of the fact that GaAs cells at these intensities require an excess of 0.3M selenide ion to reduce the ratio of corrosion current to the total current to below 0.01 (11). Also the results of a simple diffusion calculation based on the Sand equation predicts that currents of ~ 20 mA/cm^2 cannot be sustained with the concentration of the redox couple below 0.05M.

Upon extended illumination of the GaAs at lower intensities, two different types of behavior are shown by —1, 5 AQD or 2, 6 AQD. In some cells the power output at 100 μA/cm^2 was stable over a period of days while other cells had an immediate but gradual loss of output without apparent corrosion. Once the cell output had decayed significantly the original output could not be restored even upon repeated etching in the sulfuric acid-hydrogen peroxide etchant or by treatments with methanol. The formation of a blocking surface film by the anthraquinones (12), impurities, or photochemical products (13) is probably responsible for this behavior. The formation of robust insulating surface films on platinum electrodes by the oxidation of phenolic compounds is well established (12). Subtle surface structure differences which influence the film nucleation could be an explanation for the fact that some electrodes passivate and others do not.

Chronocoulometric measurements by Anson and Epstein of the adsorption at mercury electrodes from solutions of 10^{-5}-10^{-3}M in 2-anthraquinone monosulfonate have established the existence of approximately monolayer coverages on the surface (14). They reported only a small electrode charge and potential dependence of the adsorption. except at very negative potentials. This indicates that the adsorption is driven mainly by the hydrophobicity of the large organic molecule. Considering these results the adsorption on GaAs electrodes of the molecules in this study (2, 6-AQD and 1, 5-AQD) can certainly be expected especially in solutions of more than millimolar concentration.

The adsorption of the reduced form of 1, 5-AQD on gallium arsenide can be demonstrated by an experiment the results of which are shown in Fig. 6. The gallium arsenide disk electrode is potentiostatted in the absence of light at various potentials in a solution containing the reduced form of 1, 5 AQD. Unlike a metal electrode at these potentials, the absorbed or bulk anthraquinone cannot be oxidized in the dark at the semiconductor surface. At time T_1 the

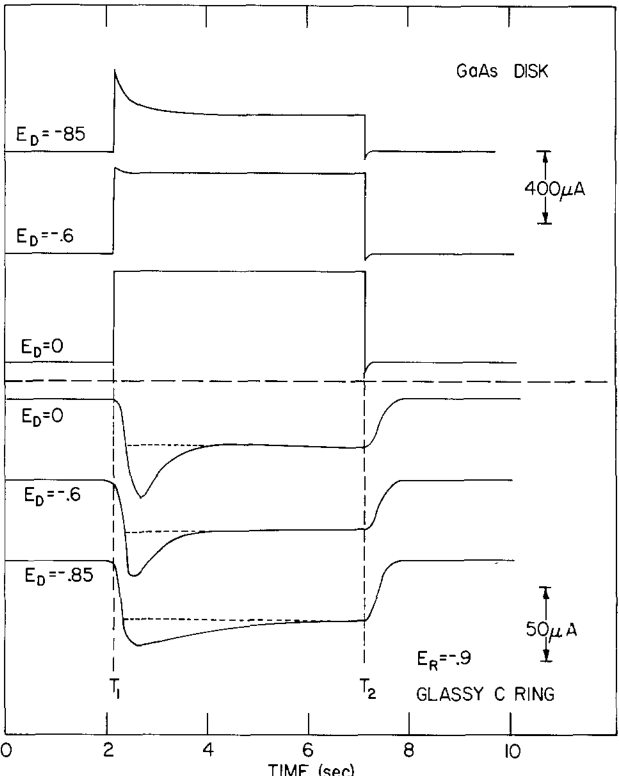

Fig. 6. Current response at a rotating n-GaAs disk-glassy carbon ring electrode to a pulse of ~50 mW/cm^2 white light (T_1 to T_2) at various disk potentials with a rotation speed of 540 rpm in a solution of 0.2M ammonia buffer with 6 mM of reduced 1, 5-AQD.

disk is illuminated and quickly reaches a steady-state current, while a peak of current is seen at the ring electrode which is held at a potential where the photo-oxidized anthraquinone can be reduced (−0.9V). The light induced hole flux in these experiments is higher than the reductant mass transfer which results in corrosion however an initial stabilization of the surface results due to the surface excess of the anthraquinone. The steady-state ring current, which decays after the light is turned off at T_2, represents the fraction of stabilization of the GaAs surface by this redox couple under steady-state conditions (~25%). Photocorrosion products from the disk do not influence the ring current at this ring potential (see Fig. 1).

Integration over time of the excess current (above the dotted lines in Fig. 6), and correcting for the collection efficiency of the electrode, yields a charge which corresponds to a surface coverage of about 30×10^{-10} moles/cm^2.

A monolayer of sulfonated anthraquinone, as determined experimentally or by geometric considerations, is about 1.5×10^{-10} moles/cm^2 (14) so the coverage of the adsorbed reduced 1, 5 AQD in the collection experiment corresponds to about 20 monolayers at all the potentials where measurements were made. This coverage resulted from an accumulation for about 30 sec before the light pulse.

Discussion

Although the cells examined in this study are not stable at solar illumination levels we feel that they are still interesting from several viewpoints. The use of organic redox couples allows fine tuning of the redox potential of a molecule by purposeful substitution on an existing carbon framework or by altering the framework of the redox center(s) in the molecule. The contrasting behavior of the open-circuit voltage for very similar molecules shown in Fig. 2 is a good example of how subtle changes in a molecule can produce dramatically different behavior in a photo-

electrochemical cell. Also organic redox couples also have the potential to be synthesized very cheaply.

Photodegradation of organic redox couples by the ultraviolet component of sunlight (13) may be a disadvantage for their use in practical cells, however the use of antireflection coatings, which are usually composed of wide bandgap semiconducting materials absorbing much of the ultraviolet light on the cell windows, may solve this problem. The long term thermal stability of organic redox couples may also be a problem with many compounds.

The other problems associated with the redox couples (1, 5 AQD and 2, 6 AQD) used in this study are lack of solubility, absorbance of blue light (Fig. 5), and blocking film formation. The first problem might be overcome by the use of a more soluble sulfonic acid salt or by the addition of additional sulfonic acid groups to the molecule (1, 2, 5, 6 anthraquinone tetrasulfonic acid). The solution absorbance would become unimportant if a blackwall illumination of the cell is adopted. In this configuration a layer of semiconductor on the order of the space charge layer thickness is deposited on a transparent substrate and illuminated through the substrate rather than the solution. In such a cell the very negative redox potential and fast electron transfer kinetics of the highly colored anthraquinone dianions may be exploited. Recent advances on blackwall illumination of thin film CdSe cells (15) are encouraging in this regard.

Adsorption of the redox couple at the semiconductor-electrolyte interface is very important for stabilizing the semiconductor against photocorrosion. Preventing polymerization of quinones on the GaAs surface will probably be difficult. Recent studies concerning the electroanalytical detection of phenols which have demonstrated techniques for the *in situ* removal of similar films from platinum electrodes are encouraging (16). The photo-oxidation and desorption of the reduced 1, 5 AQD as shown in Fig. 6 is a good example of how a surface excess of the redox couple initially stabilizes the electrode against photocorrosion. If the adsorption kinetics of the redox couple are fast and the bulk concentration is high enough, this stabilization could be expected to continue even at high light intensities. The importance of adsorption is also demonstrated by the difficulty experimenters have encountered in preparing a stable regenerative liquid junction cell using redox couples such as Fe^{+2}/Fe^{+3} (10) and $Fe(CN)_6^{-4}/Fe(CN)_6^{-3}$ (17) which are not expected to be strongly chemisorbed at surfaces. Ginley and Butler have demonstrated the importance and extent of sulfide adsorption on the cadmium chalcogenides (18). Using capacity measurements Tyagai (19) has also shown sulfide strongly interacts with the CdS surface and also reported an apparent lack of $Fe(CN)_6^{-4}$ adsorption on this semiconductor. Indeed the most successful cells reported at this writing have used the highly surface active polysulfide (20, 21), polyselenide (1, 2), or triodide (22) ions. The stabilization of a silicon surface against oxide passivation in aqueous solutions by chemically bonded ferrocenes (23) is another example of the importance of an expeditious reaction of highly energetic holes to form a stable surface species and thus protect the surface from undesirable reactions. However an extreme can be reached if the adsorbed layer gets too thick and becomes insulating as in some of the long term experiments in this study.

The photoelectrochemical desorption with collection experiment (Fig. 6) has potential of being a useful technique for measuring redox couple adsorption at semiconductors. The current transients resulting from the illumination of a semiconductor disk electrode are very difficult to quantitatively interpret because they are a combination of currents due to space charge layer charging, faradaic reactions of adsorbed and transported redox couple, and corrosion. The ring potential is held constant at a potential where corrosion products do not react so the current transient measured is due only to the photoreacted redox couple. Peaks of current above the steady-state current can then be interpreted as arising from the photoreaction of the redox couple adsorbed on the disk electrode. Further studies of the extent, kinetics, and potential dependence of redox couple adsorption on semiconductor surfaces, using this and other techniques, are underway in this laboratory.

Oxide Ion Titrations in Molten NaCl with the Zirconia Electrode

Kurt H. Stern*

Chemistry Division, Naval Research Laboratory, Washington, D.C. 20375

ABSTRACT

Stabilized zirconia electrolytes can be used to titrate O^{2-} into and out of molten NaCl. Relations between the oxide activity in the melt and the charge passed through the ceramic have been derived and verified. The technique is applicable to the purification of melts and the determination of oxide solubility products.

Zirconia stabilized with several percent CaO, MgO, or Y_2O_3 is finding increasing use in a variety of applications at high temperatures. All of these depend on the fact that charge transport through this material occurs by migration of oxide (O^{2-}) ions (1). Electrochemical applications may be divided into equilibrium methods in which the stabilized ZrO_2 (SZ) is used as part of an indicator electrode, and nonequilibrium methods in which a sensible amount of charge is passed through the material.

Indicator electrodes made of SZ have been used to: (*i*) measure O_2 partial pressure in gases (2), (*ii*) measure solubility of O_2 in metals (2), (*iii*) measure the dissociation pressures of solid oxides (2), (*iv*) measure the oxide activity in molten salts (3-5) and glasses (6).

The transport of O^{2-} through SZ under an applied potential has been used to: (*i*) operate an oxygen fuel cell (2), (*ii*) change the O_2 content of gases (7, 8), (*iii*) measure the diffusivity of O_2 in metals (9), (*iv*) titrate oxygen into metals (9).

Most of the applications depend on two properties of SZ: (*i*) at an interface of the type $O_2(M)|SZ$, the potential-determining process is

$$1/2\ O_2(g) + 2e \rightleftarrows O^{2-}\ (\text{in SZ}) \qquad [1]$$

where M is an inert metal such as platinum. Studies of such interfaces have shown that the process is readily reversible, at least at temperatures above 500° (2); (*ii*) applications involving the measurement of O^{2-} activities in molten salts depend on the equilibrium

$$O^{2-}\ (\text{in SZ}) \rightleftarrows O^{2-}\ (\text{melt}) \qquad [2]$$

The reversibility of these processes under potentiometric conditions (very small currents) can be regarded as established. In this case the "zirconia electrode," which can be described as

$$O_2(g)\ (Pt)\,|SZ|\,O^{2-}\ (\text{in melt}) \qquad [3]$$

functions as an O^{2-}-specific electrode for which the half-cell reaction is given by the sum of reactions [1] and [2]

$$1/2\ O_2(g)\ (Pt) + 2e \rightleftarrows O^{2-}\ (\text{in melt}) \qquad [4]$$

Thus, the zirconia electrode functions operationally as does the glass electrode for H^+, although the mechanisms responsible for the potential-determining reactions are not entirely analogous.

Reaction [4] has so far been applied only potentiometrically (3-5, 10, 11). Although the oxygen gas electrode ($O_2(Pt)|O^{2-}$ (in melt)) has also been used in oxide-containing melts, the advantages of the zirconia electrode are (*i*) specificity to the O^{2-} ion (no response to O_2^{2-} and O_2^-), and (*ii*) the oxygen gas pressure over the melt can be varied independently of the operating O_2 pressure of the electrode. Construction of the electrode and its potentiometric applications in molten salts have been described elsewhere (3-5, 10, 11).

The purpose of the present paper is to report on the exploration of the "kinetic" properties of the zirconia electrode. If the electrode behaves reversibly, as indicated by reaction [4], and if the temperature is sufficiently high for the conductivity of the ceramic to be appreciable, it should be possible to titrate O^{2-} ions into and out of melts by the application of an applied potential between the $O_2|(Pt)$ electrode attached to one side of the zirconia and a suitable counterelectrode. The resulting change in the O^{2-} activity of the melt is measured by a cell which has been described in detail elsewhere (5, 11). NaCl was used as the molten salt medium since the chemistry of oxides dissolved in it had been studied previously (5).

Experimental Procedure

All experiments were carried out in a controlled atmosphere glove box (Vacuum Atmospheres Corporation) with moisture and CO_2 content in the ppm range with the O_2 content set (O_2-He mixtures) for each experiment. NaCl was vacuum-dried at 500° for several days. Melts were contained in high purity (99.8%) Al_2O_3 crucibles. These crucibles are subject to slight corrosion by alkaline melts, but only when the Na_2O concentration approaches 1 mole percent (m/o). Since the Na_2O concentrations in this work are less than that by one to two orders of magnitude, corrosion is not significant.

For experiments in which changes in the Na_2O activity of the melt were to be detected, the measuring cell can be written as

$$Ag|AgCl(10\ m/o),\ NaCl\underset{|\text{mullite}|}{|Na^+|}NaCl,\ Na_2O|SZ|O_2(Pt) \qquad [5]$$

for which the cell reaction is

$$2Ag + 1/2\ O_2 + 2NaCl = 2AgCl + Na_2O \qquad [6]$$

and

$$E_{\text{cell}} = E^\circ - (RT/2\mathbf{F})\ln\left[\frac{a^2_{AgCl}a_{Na_2O}}{P_{O_2}a_{NaCl}^2}\right]$$
$$= E^{\circ\prime} - (RT/2\mathbf{F})\ln a_{Na_2O} \qquad [7]$$

where all the constant terms in the brackets have been absorbed into E°.

The cell used for the electrolysis experiments can be written as

$$O_2(Pt)\,|SZ|NaCl,\ Na_2O||NaCl|Pt \qquad [8]$$

The platinum counterelectrode was not studied in detail and may not behave reversibly. This was not considered significant since the pinhole liquid junc-

* Electrochemical Society Active Member.

Key words: ceramics, molten salts, coulometry.

tion prevents mass transport of reaction products into and out of the counterelectrode compartment and since substitution of the liquid junction by an Na^+-conducting mullite membrane gave exactly the same results, and in this case reaction products are confined inside the membrane. Therefore, all composition changes in the $NaCl-Na_2O$ melt must be produced by charge transport through the zirconia.

Potentials were measured with high impedance poteniometers (Orion 801 and PAR 136). Most coulometric titrations were carried out at constant current (Keithley 225 current source), usually at 10 mA, in series with an electronic coulometer (Koslow Model 541). Since most experiments turned out to be rather long, charge passed and emf's measured were recorded automatically at intervals on a Digitem recorder.

Results

Some information on the current-voltage characteristics of electrode [3] was obtained by measuring the current as a function of voltage applied to cell [8]. As can be seen in Fig. 1, the behavior is slightly nonohmic above 0.1V. 0.13V is the OCV against the Pt counterelectrode. The points represent the current 1 min after each change of voltage. The curve is independent of the direction of the current. One matter of interest is the current flow which the electrode can sustain (by reaction [4]) without undergoing irreversible processes, such as the reductions of the ZrO_2 itself. Examination of the electrode after electrolysis showed no such deleterious effects of the voltage and current span used.

In order to explore the coulometric applications of the zirconia electrode, cell [8] was put in series with a voltage or current source and a coulometer. The following observations were made:

(*i*) When the zirconia electrode is made the anode, current flows only in a direction consistent with reaction [4] from right to left (oxidation); when the electrode is made the cathode, reaction [4] goes from left to right (reduction).

(*ii*) For current passage in either direction, the current decreases with time at constant voltage, but eventually comes to a constant value.

(*iii*) The electrode is highly "polarized" by the passage of current in either direction, *i.e.*, after the applied voltage is removed, the OCV decays for several hours toward the value which would have been observed with an electrode through which no current had been passed. Therefore, the same electrode cannot be used for both electrolysis and as an indicator electrode.

This last observation necessitated use of a dual electrolysis and measurement system in order to study the relation between the charge passed through the zirconia and the resulting oxide activity changes in the melt. As described previously, cell [5] was used for the measurement of oxide activity, and cell [8] for the electrolysis. By interfacing the potentiometer measuring the emf of cell [5] and the coulometer measuring the charge Q passing through cell [8] with a data logger, both quantities could be measured and recorded simultaneously.

Figure 2 illustrates an experiment in which O^{2-} was electrolyzed out of a melt containing some added Na_2O. The measured emf changes very little until $\sim$100 μequ had been passed through the zirconia. The curve then steepened progressively until a limiting slope was reached. The duration of this experiment was $\sim$20 hr. Current reversal resulted in an increase of O^{2-} in the melt, as indicated by the emf.

In this case the emf at first changes very little with increasing Q, and then approaches a limiting slope of $RT/2\mathbf{F}$. Both observations are consistent with the equations derived in the Appendix. A more detailed analysis is being published elsewhere (12).

Since the above-described experiments showed that O^{2-} ions could be coulometrically titrated into a melt through zirconia, it seemed reasonable to see if this technique could be applied to determining the solubility product of a metal oxide. The procedure consisted of dissolving 2×10^{-3} μequ CuCl in $\sim$100g NaCl and adding O^{2-} through the zirconia, as described above. After the addition of CuCl the emf of cell [5] changed from $\sim$200 to 560 mV, showing that the addition of Cu^+ decreased the oxide activity in the melt by $\sim$3 orders of magnitude, presumably

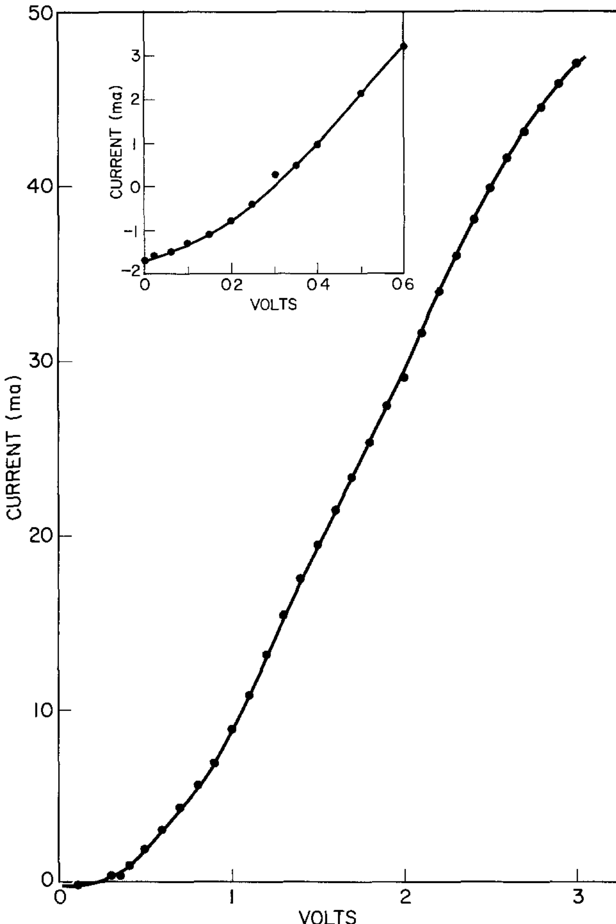

Fig. 1. Current-voltage characteristics of electrode [3], measured with cell [8]. P_{O_2} (zirconia reference) = 1 atm. Helium atmosphere above melt.

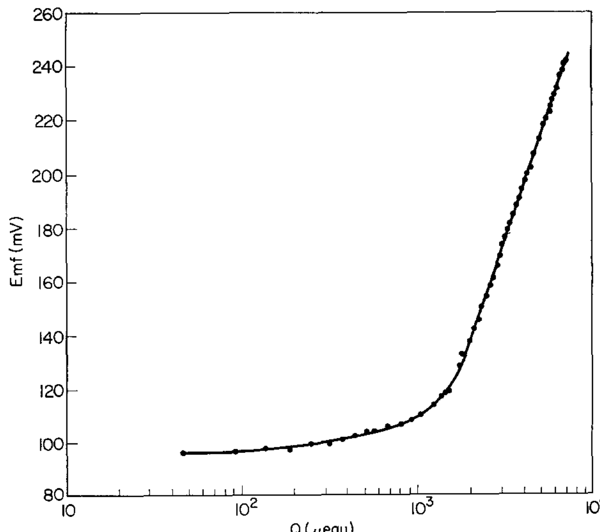

Fig. 2. Electrolysis of O^{2-} out of an Na_2O-NaCl melt at 830°C. Current = 10 mA, 20% O_2 above melt.

because some Cu_2O was being precipitated. The relation between E and Q during the titration is shown in Fig. 3. The curve is typical of potentiometric titrations resulting in the precipitation of an insoluble compound, Cu_2O in this case. The steepest portion of the curve is close to the endpoint expected on the basis of the precipitation of Cu(I) as Cu_2O. The method is thus applicable to the determination of solubility products of slightly soluble oxides in molten salts. A more detailed exploration of this application will be described elsewhere (13).

Discussion

The purpose of this paper is to report a new application of stabilized zirconia: the coulometric titration of O^{2-} ions into and out of molten salts. The experiments described show how such titrations can be carried out. The E *vs.* ln Q curves obtained are consistent with the equations derived in the Appendix.

Electrolyzing O^{2-} out of a melt can be used to purify it of a dissolved oxide. The lower limit of attainable oxide concentration is expected to be the solubility of the zirconia itself, although lower concentrations could be obtained if (*i*) the electrolyzing cell is withdrawn from the melt immediately after cessation of the electrolysis, and (*ii*) a nonoxide crucible, *e.g.*, platinum, is used.

It should also be emphasized that the measuring zirconia electrode responds to changes in the O^{2-} activity, whereas the coulometric zirconia passes equivalents. In dilute melts, the activity coefficients are most likely constant and thus activities are proportional to equivalents; but the situation is more complicated for solubility products. The solubility product of an oxide Mo is defined as

$$Ksp = a_{M^{2+}} \cdot a_{O^{2-}}$$

but $a_{M^{2+}}$ is set by the thermodynamics of the MCl_2-NaCl system, whereas $a_{O^{2-}}$ is related to that of the Na_2O-NaCl system. Thus, equality of activities does not necessarily imply equality of concentrations.

APPENDIX

The relation between charge passed and the measured emf can be derived as follows:

It is known (5) that in molten NaCl, oxide and peroxide ions are in equilibrium. The equilibrium constant for the reaction

$$Na_2O + 1/2\ O_2 = Na_2O_2 \quad [A\text{-}1]$$

is 3.1 at 1100°K (5). At constant P_{O_2}, the ratio

$$[Na_2O_2]/[Na_2O] = K_eP_{O_2}{}^{1/2} = K_e' \quad [A\text{-}2]$$

where the brackets denote mole fractions. Since the electrolysis is slow, it is reasonable to assume that this equilibrium is maintained.

Case I. Electrolysis of Na_2O into the melt.—Let $[Na_2O]_o$ and $[Na_2O_2]_o$ equal the initial Na_2O and Na_2O_2 concentrations, respectively, at equilibrium. These concentrations may be impurities or result from prior addition of Na_2O. They can be calculated from the emf of cell [5], *i.e.*, Eq. [7], if $E°$ and the activity coefficients are known.

For Q equivalents electrolyzed into the melt, $Q/2$ moles O^{2-} will initially form. The initial O^{2-} concentration is then $Q/2n$, where n = number of moles of solvent, and it is assumed that the melt is very dilute. Some fraction X of this O^{2-} concentration is converted to $O_2{}^{2-}$ when the melt comes to equilibrium. The new equilibrium concentrations of Na_2O and Na_2O_2 then are

$$[Na_2O]_e = [Na_2O]_o + Q/2n - X \quad [A\text{-}3]$$

$$[Na_2O_2]_e = [Na_2O_2]_o + X \quad [A\text{-}4]$$

Substitution of [A-3] and [A-4] into [A-2] gives

$$X = \frac{K_e'Q}{2n(K_e' + 1)} \quad [A\text{-}5]$$

Therefore

$$[Na_2O]_e = [Na_2O]_o + \frac{Q}{2n(K_e' + 1)} \quad [A\text{-}6]$$

Substituting [A-6] into [7] gives the relationship between E and the charge passed

$$E = E°'' - (RT/2\mathbf{F}) \ln \left\{ [Na_2O]_o + \frac{Q}{2n(K_e' + 1)} \right\} \quad [A\text{-}7]$$

where the activity coefficient of Na_2O has been absorbed into $E°'$. One sees from the form of [A-7] that $dE/d \ln Q$ will be small for small Q, since then $[Na_2O]_o$ will exceed the term in Q. When the second term in the bracket becomes much larger than the first, the limiting slope $dE/d \ln Q = -RT/2\mathbf{F}$ will be reached, in agreement with experimental observation.

Case II. Electrolysis of Na_2O out of the melt.—The same assumptions are made as for Case I. As Na_2O is electrolyzed out of the melt the equilibrium [9] is maintained and therefore

$$[Na_2O]_e = ([Na_2O]_o - Q/2n)/K_e' + 1) \quad [A\text{-}8]$$

Therefore

$$E = E°'' - (RT/2\mathbf{F}) \ln[([Na_2O]_o - Q/2n)/K_e' + 1)]$$

In this case the measured emf remains nearly constant in the beginning of the electrolysis and asymptotically approaches infinity at $Q/2n$ approaches $[Na_2O]_o$. Although the curve in Fig. 2 shows the expected flat portion, followed by a steeper section, the latter appears linear, rather than steepening as expected. The reasons are not clear.

Electrodeposition of CdSe Films from Selenosulfite Solution

M. Skyllas Kazacos* and B. Miller*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A route to CdSe film formation by reduction of selenosulfite ion in the presence of cadmium-EDTA complex has been devised. The as-deposited product is free from the selenium contamination characteristic of prior methods and also shows better n-type photoactivity in sulfide-polysulfide cells. The interfacial reactions have been clarified by rotating ring-disk electrode and related techniques. Electrochemical control of the process is shown to be simple.

Photoactive CdSe films have been electrodeposited both cathodically and anodically, the former with selenious acid-cadmium ion solutions (1) and the latter with Cd anodes in selenide media (2). Such methods would be attractive for the production of low cost, large area photoelectrochemical cells. Anodic n-CdSe layers have the advantage of fairly good as-formed photoresponse but are restricted in growth by the transport of cadmium ions through the film. Cathodic deposition of CdSe is not limited in thickness as only electron transport to the solution interface is required, but post-thermal treatment is necessary to develop respectable photoactivity (1). In the cathodic method, millimolar solutions of SeO_2 (H_2SeO_3) are reduced in the presence of relatively high concentrations of $CdSO_4$ to yield a film of CdSe at the cathode surface. Layers up to several microns have been achieved with good adherence on a Ti substrate after a 600°C anneal (1). Higher SeO_2 concentrations result in electrode passivation due to the formation of a red insulating layer of Se.

A recent study of the reduction of selenious acid and CdSe formation (3) in H_2SO_4 solution has shown that the initial cathodic reaction involves an overall transfer of six electrons

$$H_2SeO_3 + 6H^+ + 6e \rightarrow H_2Se + 3H_2O \quad [1]$$

The H_2Se formed may react by

$$2H_2Se + H_2SeO_3 \rightarrow 3Se + 3H_2O \quad [2]$$

yielding elemental selenium. This step competes with the desired deposition of CdSe

$$Cd^{+2} + H_2Se \rightarrow CdSe + 2H^+ \quad [3]$$

The rate of the chemical reaction [2] is dependent on the concentration of H_2SeO_3 and is sufficiently rapid at high H_2SeO_3 concentrations so that the net process taking place at the surface of the electrode is

$$H_2SeO_3 + 4H^+ + 4e \rightarrow Se + 3H_2O \quad [4]$$

Plating of CdSe from dilute H_2SeO_3 solutions minimizes the level of selenium codeposited in the cathodically generated films (3). However, even at low H_2SeO_3 concentrations, contamination of the CdSe films with excess selenium cannot be eliminated. This results usually in mixed n- and p-type behavior in photocurrent spectra, and even dominant p-type response in white light, for the as-formed film (3). In addition, this poor photoresponse makes a postannealing process at elevated temperature essential, both for the improvement of poor crystallinity and for the vaporization of excess Se from the films (1).

A process for cathodic generation of CdSe not subject to codeposition of Se would allow either elimination or modification of the presently essential annealing stage. Ideally, the room temperature cathodic product would have the n-type response of the anodic films without meeting the passivity which limits the latter to crystallite sizes and thicknesses less than visible light absorption depths. Since the main problem in the reduction method (1) arises from the interaction between the starting material H_2SeO_3 and the electron transfer product, H_2Se, we have sought a route to cathodic selenide generation avoiding higher valent selenium species or other active oxidant capable of reacting with selenide.

We find the reduction of selenosulfite, $SeSO_3^{-2}$, suited to this purpose. Selenosulfite is readily prepared *in situ* by the dissolution of elemental selenium in excess sulfite by

$$Se + SO_3^{-2} \leftrightarrow SeSO_3^{-2} \quad [5]$$

Selenide can be generated from this ion by the reaction (4)

$$SeSO_3^{-2} + 2e \rightarrow Se^{-2} + SO_3^{-2} \quad [6]$$

The photoelectrochemical behavior of CdSe electrodes prepared by carrying out reaction [6] in the presence of cadmium species was examined. Rotating disk and ring-disk electrode methodology was applied to ascertain the nature of the reactions taking place.

* Electrochemical Society Active Member.

Key words: energy conversion, semiconductor, voltammetry.

Experimental

Voltammetric study of the reduction of selenosulfite in 1M NH_3/NH_4^+ buffer was carried out using gold and cadmium rotating disk and silver-cadmium rotating ring-disk electrodes, the construction and electronics of which have already been described (5). Sinusoidal hydrodynamic modulation (SHM) experiments were also performed with the apparatus previously reported (6).

A silver ring-cadmium disk electrode with disk, inner ring, and outer ring radii of 0.238, 0.253, and 0.320 cm, respectively, was used. The theoretical geometric collection efficiency, N (7), was 0.383.

Approximately 5 mM Na_2SeSO_3 solutions were prepared by shaking 0.1M Na_2SO_3 and weighed powdered selenium in 1M NH_3/NH_4^+ buffer until the selenium dissolved. The high concentration of Na_2SO_3 and the use of ammonium buffer were necessary to achieve 5 mM, as the equilibrium constant of reaction [5] is around unity (8). Thus a pH 10 medium assists dissolution from

$$Se + HSO_3^- \rightleftarrows SeSO_3^{-2} + H^+ \quad [7]$$

The $SeSO_3^{-2}$ and SO_3^{-2} ions (or their protonated forms) do not oxidize Se^{-2} (or its protonated form), as happens for H_2SeO_3 in reaction [2]. Thus selenium contamination of CdSe is not expected, both because there is no obvious mechanism of its generation and, further, it is soluble in excess sulfite. An ammonia buffer was initially chosen as this ligand allows the necessary cadmium ion solubility in base to attempt deposition of CdSe films.

All solutions were prepared with triply distilled water and reagent grades of Na_2SO_3, NH_4OH, NH_4Cl, $CdSO_4$, and EDTA (ethylenediaminetetraacetic acid). The rotating disk electrodes were examined in a standard three-compartment cell. All potentials are referred to a saturated calomel electrode unless otherwise specified.

CdSe films were prepared on stationary vertical ¾ in. titanium disks in magnetically stirred solutions as well as on gold and cadmium rotating disk electrodes. The Ti surfaces were degreased with acetone and etched in 5% HF, prior to use (9). The metal disk edges were protected by epoxy mounting after film deposition and any annealing step, before observing photoresponse characteristics under 100W tungsten-halogen lamp illumination at white light levels producing the equivalent of about AM1 solar short-circuit current with single crystal n-CdSe cells.

Results and Discussion

Reduction of $SeSO_3^{-2}$ in NH_3/NH_4^+ buffer.—The cathodic behavior of selenosulfite in 0.3M $NaNO_3$ at a dropping mercury electrode has been ascribed to Se^{-2} formation in a single two-electron step at a half-wave potential of $-1.06V$ *vs.* SCE (4). Figure 1 presents the typical behavior of a gold disk electrode in 2 mM $SeSO_3^{-2}$-0.1M Na_2SO_3 in 1M NH_3/NH_4^+ buffer solution. A single reduction wave can be observed starting near $-1.0V$ *vs.* SCE. Curve 2 of Fig. 1 shows the corresponding SHM response which was obtained by superimposing a 1 Hz sinusoidal variation of $\Delta\omega^{1/2}$ on the rotation speed $\omega^{1/2}$ and extracting the corresponding Δi_ω value. The near superposition of the $\Delta i_\omega \times \omega^{1/2}/\Delta\omega^{1/2}$ and i curves indicates that the process obeys the Levich equation and that the $SeSO_3^{-2}$ reduction reaction is convective diffusion controlled. The SHM response plateau is also seen to continue unchanged into the H_2 evolution region, indicating no further stage of reduction for $SeSO_3^{-2}$ can be detected. (Hydrogen evolution at gold is irreversible and, since it is not limited here by convective diffusion of an electroactive species to the electrode surface, it is insensitive to ω variation.)

In order to verify that the species Se^{-2} was being generated during the reduction of $SeSO_3^{-2}$, a cadmium disk-silver ring electrode experiment was performed (the substitution of Cd for Au in the disk does not alter the reduction process here). The silver ring was potentiostatted at $-0.4V$ *vs.* SCE while the cadmium disk was scanned negatively from approximately $-0.8V$. Under this ring condition a mass transfer limited film formation reaction

$$2Ag + Se^{-2} \rightarrow Ag_2Se + 2e \quad [8]$$

can be used to detect Se^{-2} generation at the disk in the manner applied to S^{-2} (10). An anodic ring current corresponding to the cathodic disk reaction was observed as in Fig. 2. Visual examination of the ring electrode after cycling the disk between -0.8 and $-1.5V$ showed the presence of a black deposit of Ag_2Se on the silver surface. If the species Se^{-2} (HSe^-) is being generated at the disk electrode from $SeSO_3^{-2}$ by reaction [6], then the ratio of ring to disk current, i_R/i_D, should be given by N since $2e$ are involved per Se^{-2} in both disk and ring reactions. Figure 3 shows the i_R *vs.* i_D trace during the disk reduction wave of Fig. 2(b). The initial slope of 0.309 is in adequate agreement with the calculated N, considering that the disk current contains an increasing component of electrolyte reduction with negative potential scan, producing curvature in the trace.

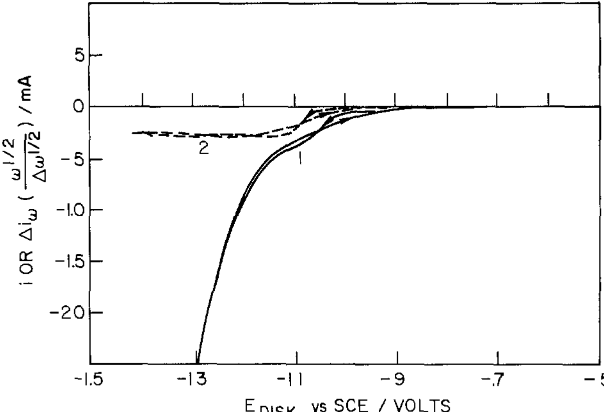

Fig. 1. Curve 1: Controlled potential sweep cycle of 0.175 cm² gold disk in 2 mM Na_2SeSO_3-0.1M Na_2SO_3-1M NH_3/NH_4^+ at 10 mV sec^{-1} scan rate. Curve 2: Modulated component of disk current for potential scan of Curve 1. Central rotation speed ω = 1600 rpm; modulation amplitude, $\Delta\omega^{1/2}$ = 2 rpm$^{1/2}$, modulation frequency, f = 1 Hz.

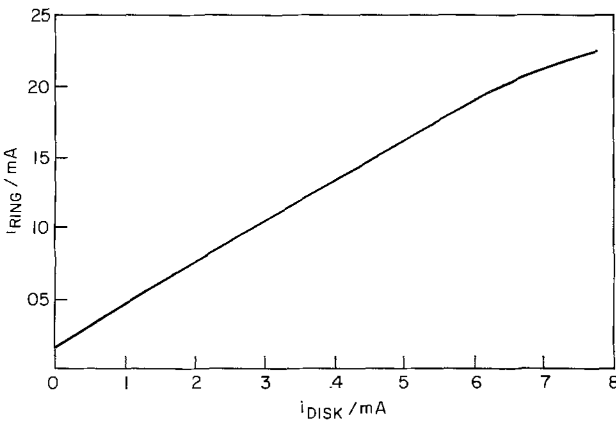

Fig. 3. Ring current vs. disk current trace corresponding to data of Fig. 2.

CdSe film deposition.—The above evidence establishes Se^{-2} as the product of $SeSO_3^{-2}$ reduction in NH_3/NH_4^+ buffer at a gold or cadmium electrode. Importantly, this reaction does not appear to be complicated by subsequent redox reactions as was the case in the H_2SeO_3/Se^{-2} system (3). Thus, carrying out the reduction in the presence of cadmium ions should permit forming a CdSe film at the surface of the electrode without the problem of selenium contamination found with H_2SeO_3 as selenide source. The situation is complicated, however, by the reduction potential of Cd^{2+} in NH_3/NH_4^+, which is positive with respect to the potential of the $SeSO_3^{-2}$ reduction, as seen in the curves of Fig. 4(a) and 5(a). The deposition of Cd metal under these circumstances is evidenced by its oxidative redissolution, essentially unaffected by $SeSO_3^{-2}$ being absent [Fig. 4(a)] or present [Fig. 5(a)]. The corresponding SHM traces in these figures show the convective-diffusion controlled Cd(II) reduction and the partially kinetically controlled anodic response (11) on positive-potential going scan. In order to generate Se^{-2} in the presence of Cd(II), an additional complexing agent for Cd^{+2}, stronger than NH_3, is necessary to shift the potential for Cd(II) reduction to more negative values, while at the same time not interfering with the selenosulfite reduction. The success of EDTA addition for this purpose is illustrated in Fig. 4(b) and 5(b) for Cd^{+2} in NH_3/NH_4^+ and Cd^{+2} + $SeSO_3^{-2}$ in NH_3/NH_4^+, respectively.

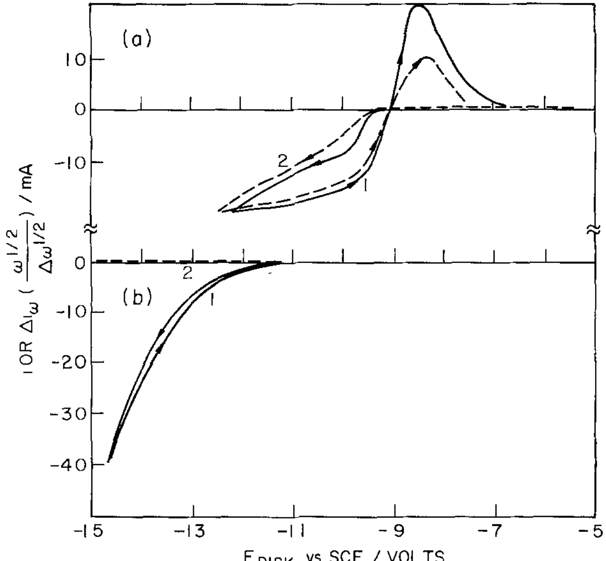

Fig. 4. (a) Curves 1 and 2: As for Fig. 1, except solution is 2 mM $CdSO_4$-1M NH_3/NH_4^+. (b) Curves 1 and 2: As for (a), except 0.01M EDTA added.

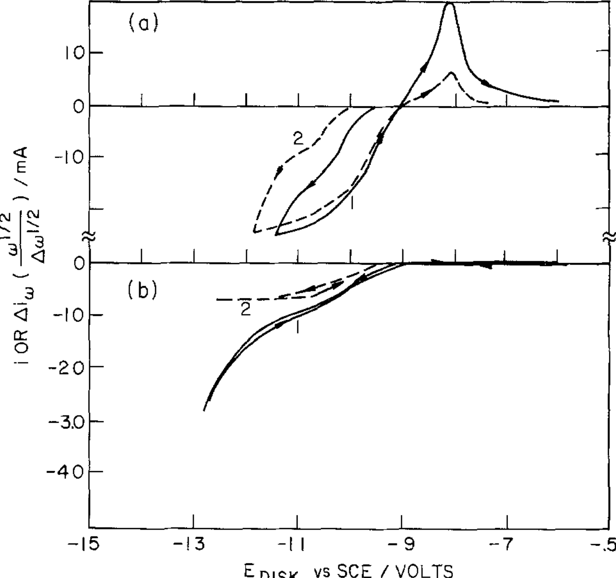

Fig. 5. (a) Curves 1 and 2: As for Fig. 1, except solution is 2 mM Na_2SeSO_3-2 mM $CdSO_4$-0.1M Na_2SO_3-1M NH_3/NH_4^+. (b) Curves 1 and 2: As for (a), except 0.01M EDTA added.

In Fig. 4(b), the EDTA complex of Cd(II) is no longer reducible over the potential range up to supporting electrolyte reduction, evidenced both by no SHM response and no anodic dissolution on positive scan. The curves in Fig. 5(b) are virtually identical to those of Fig. 1 and 2, for a solution containing no cadmium. Under the conditions of Fig. 5(b) then, the desired situation of Se^{-2} generation in the presence of Cd(II) species is achieved. The stability of the Cd-EDTA complex is insufficient to prevent the formation of the very insoluble CdSe, qualitatively shown by the black film on the electrode in a Fig. 5(b)-type experiment.

A number of CdSe films were prepared on gold, cadmium, and titanium substrates from solutions consisting of 5 mM Na_2SeSO_3 + 0.1M Na_2SO_3 + 0.2M $CdSO_4$ + 0.2M EDTA in 1M NH_3/NH_4^+ [EDTA always kept just in excess of Cd(II)]. The relatively high Cd-EDTA complex concentrations were found necessary to precipitate the film at the electrode surface in an adherent form. The metal electrodes were held at −1.1 to −1.2V *vs.* SCE, during which time the current ranged from 0.5 to 1.0 mA/cm². For vertically mounted disks the solution was magnetically stirred; the other electrodes were rotated. Deposition times of 1-4 hr were employed to achieve calculated film thicknesses of 1.5-12 microns. The solution was replaced after the current dropped below 0.5 mA/cm².

The electrodes obtained as above were examined for photoresponse in a cell with a 1M Na_2S_2 + 1M NaOH-0.07M Se solution (12) and a carbon counterelectrode. The values of short-circuit photocurrents (I_{sc}) and open-circuit photopotentials (V_{oc}) under white light ranged from 0.25 to 3.1 mA/cm² and 0.1 to 0.55V, respectively. A selection of these data appear in Table IA. There were no distinct differences in the behavior of films deposited on gold, cadmium, or titanium disks. The thickness of the CdSe film, however, does have an effect on both the I_{sc} and V_{oc}, as shown in the curves of Fig. 6, which appears significant beyond the scatter evidenced in Table IA. However, the range of results does not presently allow evaluating this relation more quantitatively. The dark current levels probably vary with residual porosity in the film as deposited and after transfer from the forming to testing solution.

To place these electrodeposited film results in the perspective of the behavior of an aqua regia etched (12) single crystal n-CdSe electrode, cell curves as

Table I. Characteristics of 6 μm electrodeposited CdSe films

A. As deposited Substrate

	Ti			Cd		Au			
Electrode	1	2	3	4	5	6	7	8	9
V_{oc}, V	0.41	0.39	0.38	0.38	0.31	0.55	0.13	0.35	0.41
I_{sc}, mA cm^{-2}	0.6	3.1	0.8	0.4	0.3	0.2$_5$	1.0	3.1	0.7

B. Following 10 min at 600°C in N_2* Substrate—Ti

Electrode	10	11	12	13
V_{oc}, V	0.49	0.33	0.45	0.33
I_{sc}, mA cm^{-2}	2.0	1.1	2.0	2.0

* Four additional specimens in this sequence lost film adherence and were not measured.

those in Fig. 6 were obtained for both types under the same illumination. These results indicate film short-circuit currents typically 1/5 of that of single crystals and equivalence to 1% AM2 solar conversion efficiency, given the 7% (12) found for the crystals in this cell.

The effect of heat-treatment on the performance of the films was briefly investigated. Some of the electrodes deposited on Ti were annealed at 600°C for 10 min under an argon atmosphere (9). These were then epoxy mounted and current-voltage plots obtained. The electrodes subjected to the heat-treatment exhibited ranges in photocurrent and photovoltage similar to those of untreated disks and no consistent improvement in performance could be related to this step (Table IB). In fact, a slight deterioration in the appearance of the films was usually apparent, in particular shrinkage, flakiness, and poorer adherence, leading to total failure of perhaps half the specimens before cell testing.

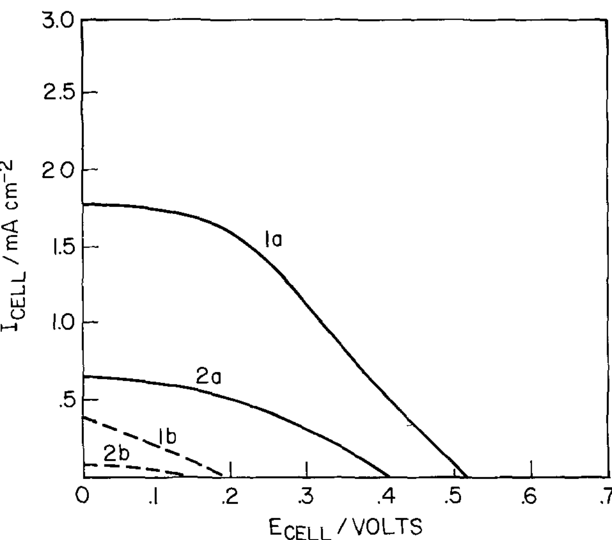

Fig. 6. Curve 1(a): Output power characteristic for 6 micron CdSe film on Ti substrate in 1M Na_2S-1M S-1M NaOH-0.07M Se under illumination. Curve 1(b): As for 1(a) but no illumination. Curve 2(a): As for 1 (a) but for 1.5 micron CdSe film. Curve 2(b): As for 2(a) but no illumination.

Another direction requiring further investigation is the effect of etching on the electrodeposited films. Preliminary etching experiments with 1 HNO_3-4 HCl-5 H_2O solutions at room temperature suggest that cell currents could be initially improved by as much as a factor of two, but concurrent overall degradation of the thin films makes the results inconclusive. A milder surface treatment would be needed.

Summary

The reduction of $SeSO_3^{-2}$ ion to Se^{-2} has been demonstrated by a variety of rotating disk electrode techniques. In a solution in which the $SeSO_3^{-2}$ is stable to dissociation into Se^o and cadmium ion is complexed strongly enough to be reduced at more negative potentials than $SeSO_3^{-2}$, CdSe films may be generated by a surface precipitation process. The film is clearly n-type and photoactive, and, in our experience (3), a better photoanode in the as-deposited condition for the $S^{-2}/S_x^{-2}|C$ cell than that produced from H_2SeO_3 reduction where Se^o contamination appears an intrinsic problem.

Conditions of concentration and mass transfer are not nearly so critical in the $SeSO_3^{-2}$ process as they are in H_2SeO_3 reduction because of the intermediacy of Se^o in the latter. The electrochemical control of the $SeSO_3^{-2}$ route to CdSe is relatively simple. The reactions and precautions as understood for CdSe film formation could be applied to doping such photoelectrodes or producing other selenides. Surface treatment for optimizing the photoanodic behavior of the film and an annealing procedure to improve its crystallinity remain to be established.

The Sulfospinel-Lithium Battery System: Initial Study of Three Sulfospinels

M. Eisenberg*

Electrochimica Corporation, Mt. View, California 94040

The discovery that chalcospinels (*e.g.*, sulfospinels) of certain transition metals can make useful reversible cathode materials in an aprotic electrolyte battery system was recently reported (1, 2). These face-centered cubic materials represent sulfur equivalents of the well-known oxospinels of a general formula $M_1^{II}M_2^{III}S_4$, where M_1 and M_2 denote divalent and trivalent metal ions. This communication describes additional tests on $CuCo_2S_4$-Li cells as well as several new sulfospinels, in the preparation of which nickel and iron were used in place of cobalt as the trivalent transition metal ion.

Experimental Studies and Results

All sulfospinel materials discussed in this paper have been synthesized from metal powders or simple sulfides in quartz furnaces by a method described previously (1). Experimental studies were carried out on partial "C" cells employing cathodes 1.3 × 5 in. long supported on nickel grids and coiled with a 6 in. lithium anode. Polypropylene separators were used in between. A crimped seal was produced on the cylindrical cells in an argon dry box. Subsequently cell tests could be carried out in a normal laboratory atmosphere. A typical discharge of a cell with a $CuCo_2S_4$ cathode is illustrated in Fig. 1 for an 8 hr rate of discharge (0.63 mA/cm^2).

Figure 1 shows the initial discharge of a freshly assembled cell and its subsequent charge. The horizontal scale also indicates delivered capacity in terms of electrons per mole. As can be seen, there is a relatively prompt drop during the first hour to a voltage level of 1.55V after which the cells discharge remarkably linearly. Linearity is preserved at least over the range of two electrons per mole. The same is also true during the charge as shown from the upper curve of Fig. 1.

The experimental slope of the discharge curve is 0.165V/$\bar{e}$/mole. It should be noted that this slope is under discharge conditions for a complete cell including polarized potentials of both cathode and anode. (It is not a plot of the open-circuit cathode potential *vs.* lithium take-up for which the slope should be 0.059 V/$\bar{e}$/mole in accordance with the Nernst equation for the emf of a pure concentration cell.) A greater slope should be expected even for the cathode alone, since its polarization can be expected to increase as discharge proceeds and the take-up of lithium causes a decrease in the intrinsic conductivity of the sulfospinel.

This initial study included the first preparations of the sulfospinels of nickel and iron (in addition to copper). These were the first synthetic efforts and optimum conditions for their preparation still remain to be determined. However, some encouraging results in comparison to $CuCo_2S_4$ have been obtained as illustrated in Table I which summarizes the initial cycling results (8 cycles) for 8 groups of partial C-cells consisting of 3 cells each.

All cells were connected in series and operated on the same cycling circuit. In this manner the same amount of charge was passed through all of them and they all experienced the same cycling history. Since the amount of active cathode material varied slightly from group to group, the number of moles per cell varied somewhat and, consequently it was more useful to express the depths of discharge in terms of electrons per mole. For the discharges this ranged from 1.87 to 2.73 $\bar{e}$/mole. Since electrochemical reversibility has clearly been established and n-butyl lithium titrations indicate the preservation of the face-centered cubic structure of the sulfospinel (and possibly even up to 3 electrons per mole) (1), it was considered conservative to designate a 2 electron per mole discharge to correspond to a 100% depth of discharge (DOD) corresponding to 167 mA-hr/g in case of $CuCo_2S_4$.

The following observations can be made on the basis of the results given in Table I:

1. The $CuCo_2S_4$ cell (group No. 2) showed typical satisfactory behavior. An initial scan to 3.12 mA/cm^2 (equivalent to a 1.6 hr rate) cell voltage was 1.0V and a 2$\bar{e}$/mole 10 hr rate discharge yielded an end-voltage of 1.45V (average value). The recharge of 2$\bar{e}$/mole required an end-voltage of 2.70V.
2. The two $CuNi_2S_4$ groups (No. 6 and 7) showed (for slightly greater depth of discharge and charge) desirable higher discharge end-voltages and particularly lower charge end-voltages of 2.34V.
3. Substituting one of the Ni by Fe in the sulfospinel appears to increase the starting discharge voltage, lowering its end-voltage. It substantially increases the charging end-voltage which is undesirable.

Table I. Cell cycling performance of new sulfospinel cathode materials

Groups 17-28—10 hr rate (0.5 mA/cm²) charge and discharge									
				1D Scan Volts at		Disch 7D		Charge 8C	
Sub. gp. No.	Cathode	Batch	Mole/cell × 10^3	1.25	3.12 (mA/cm²)	V-range	e/mole	V-range	e/mole
−2	$CuCo_2S_4$	13B	7.5	1.88	1.40	2.20-*1.45*	2.03	1.82-*2.70*	2.0
−6	$CuNi_2S_4$	3A	5.6	1.85	1.38	2.16-*1.57*	2.73	1.80-*2.39*	2.96
−7	$CuNi_2S_4$	3B	7.4	1.88	1.52	2.18-*1.48*	2.07	1.92-*2.34*	2.15
−5	$CuNiFeS_4$	1	6.5	1.51	1.10	2.60-*1.28*	2.35	1.75-*3.60*	2.32
−3	$CuFe_2S_4$	4A	4.6	1.42	1.08	2.10-*1.12*	2.40	1.60-*3.10*	2.01
−4	$CuFe_2S_4$	4B	7.3	1.46	1.09	2.45-*1.33*	2.10	1.70-*3.60*	2.07
−8	$CuFe_2S_4$	5	8.2	1.51	1.12	2.55-*1.36*	1.87	1.75-*3.46*	1.84
−9	$CuFe_2S_4$	6	7.8	1.75	1.34	2.52-*1.38*	1.96	1.76-*3.42*	1.93

4. The $CuFe_2S_4$ groups (No. 3, 4, 8 and 9) show similarly lower end-voltages on discharge and particularly higher end-voltage on charge (3.1-3.6V) which is symptomatic of greater kinetic irreversibility for charge acceptance.

Conclusions

The sulfospinels are a new promising group of cathode materials for high energy ambient temperature cells. Their utility in high temperature lithium cells has also been established (3), but so far for an initial discharge only. Since they are good electrical conductors, they provide the basis for a high rate capability.

Their reversible cycling behavior appears due to an interstitial migration of lithium into the face-centered cubic structure. This is based on the x-ray confirmation (1) that the face-centered cubic structure is retained when up to 3 lithium equivalents are introduced per mole of sulfospinel by the n-butyl lithium titration.

Of the compounds presented in this paper, $CuCo_2S_4$ and $CuNi_2S_4$ appear most promising. The somewhat poorer results obtained for $CuFe_2S_4$ may be due to a poor preparation. Further studies of these compounds, especially of the x-ray structure before and after discharge or charge, are now indicated for future optimization of the preparation methods.

Manuscript submitted Oct. 16, 1979; revised manuscript received May 30, 1980. This was Paper 27 presented at the Los Angeles, California, Meeting of the Society, Oct. 14-19, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Simultaneous Discharge of Two Reacting Species under Pulsed Current Conditions

K. Viswanathan,*,[1] M. A. Farrell Epstein, and H. Y. Cheh*

Department of Chemical Engineering and Applied Chemistry, Columbia University, New York, New York 10027

In recent years there has been considerable interest in the application of pulsed current to electrodeposition processes. One of the questions addressed is whether or not higher mass transfer rates are possible under pulsed conditions. Viswanathan *et al.* (1-4) examined the mass transport behavior under various periodic currents and potentials and concluded that for a single reaction occurring at the electrode surface, it is impossible to exceed the d-c electrolysis rate by any non-d-c methods. However, in a number of alloy as well as single metal deposition processes, two or more reactions can occur simultaneously (5). It is therefore interesting to examine the effects of applying non-d-c electrolysis to a system where two reactions occur. Recently, Haynes (6) has discussed current efficiencies under pulsed condition. Unfortunately, several assumptions made by Haynes are of doubtful validity (7).

This study involves the use of a simple model to demonstrate the point that pulsed current can be beneficial in certain instances. Consider two irreversible reactions occurring simultaneously at an electrode surface. Reaction [1] produces an unwanted by-product while reaction [2] produces the desired substance. Assume also that reaction [1] is kinetically favored over reaction [2]. In other words, reaction [2] will not proceed until the applied current density exceeds the limiting current density of reaction [1]. To simplify the analysis, the reacting species are assumed to have equal diffusivities and bulk concentration. These assumptions can be relaxed to suit specific situations under consideration. Because of the irreversible nature of these assumed reactions, the current density is zero for each reaction during the off-period of the pulse.

Under d-c conditions, the current density for reaction [2] is zero when the applied current density is equal to or less than the limiting current density for reaction [1]. Based on the assumptions stated previously, both reactions have equal limiting current densities and the limiting current density for reaction [2] is reached when the applied current density is twice the d-c limiting current density for reaction [1]. The d-c current efficiency for reaction [2], $(\eta_2)_{d\text{-}c}$, is given by

* Electrochemical Society Active Member.
[1] Present address: Hooker Development Center, Niagara Falls, New York 14302.
Key words: pulsed electrolysis, current efficiency, mass transfer.

$$(\eta_2)_{d\text{-}c} = \frac{\begin{pmatrix}\text{Applied d-c}\\ \text{current density}\end{pmatrix} - \begin{pmatrix}\text{d-c limiting current density}\\ \text{for reaction [1]}\end{pmatrix}}{(\text{Applied d-c current density})} \times 100 = \frac{i_{d\text{-}c} - (i_{d\text{-}c})_{1,1}}{i_{d\text{-}c}} \times 100 \quad [1]$$

where $i_{d\text{-}c}$ is the applied d-c current density and $(i_{d\text{-}c})_{1,1}$ is the d-c limiting current density for reaction [1]. Obviously, the maximum value for the current efficiency for reaction [2] is 50% when $i_{d\text{-}c}$ is equal to 2 $(i_{d\text{-}c})_{1,1}$. It is therefore apparent that in order to approach the 50% current efficiency for reaction [2], one must apply a current density whose magnitude should be close to 2 $(i_{d\text{-}c})_{1,1}$. On the other hand, one realizes that as the limiting current density of reaction [2] is being approached, the quality of the electrodeposit generally deteriorates rapidly (8). To better utilize the applied current density, it would be beneficial to reduce the fraction of current density which is consumed by reaction [1]. A possible way to accomplish this task is by the application of a pulsed rather than a d-c current. This advantage can be explained by the following consideration.

In order to enhance the current efficiency of reaction [2], one should apply a current which is considerably higher than the limiting current density for reaction [1]. Under pulsed current conditions, the pulsed limiting current density, $(i_p)_{1,1}$, can be calculated by the method described by Cheh (9). The pulsed limiting current density has been defined to be the applied current density which causes the concentration of the reacting species to drop to zero at the end of the on-period during a pulse cycle. In contrast to d-c conditions, if a pulsed current with a magnitude of 2 $(i_p)_{1,1}$ is applied, reaction [2] will proceed under conditions not completely controlled by mass transfer. This is because reaction [1], being kinetically favored, will proceed at a current higher than $(i_p)_{1,1}$. The concentration of the reacting species for reaction [1] will drop to zero during the pulse instead of at the end of the pulse. The highest current that reaction [1] can achieve is given by the intermittent potential case (4), which corresponds to the situation where the concentration of the reacting species drops to zero instantaneously at the onset of a pulse. This is a limiting case. For the concentration of a reacting species to drop to zero instantaneously, one must apply an infinite current density initially. In reality, a high current density is needed for a short period of time at the onset of the on-period. The overall current density for reaction [1] during the on-period is nevertheless close to the limiting current density of reaction [1] for the intermittent potential case, $(i_{int})_{1,1}$. The calculation of $(i_{int})_{1,1}$ has been presented recently by Viswanathan *et al.* (4).

Let us now proceed to calculate the current efficiency for reaction [2] under d-c conditions and compare it with the time-averaged current efficiency under pulsed conditions for the same number of coulombs passed in a given time period. Let the applied pulsed current density be 2 $(i_p)_{1,1}$ during the on-period of a pulse. The equivalent d-c current density is

$$i_{d\text{-}c} = i_p t_1/t_c = 2\,(i_p)_{1,1}\, t_1/t_c \quad [2]$$

where i_p is the applied pulsed current density, t_1 is the duration of the on-period, and t_c is the cycle time. The d-c current efficiency for reaction [2] can be calculated by substituting Eq. [2] into Eq. [1]

$$(n_2)_{d\text{-}c} = \frac{(2i_p)_{1,1}t_1/t_c - (i_{d\text{-}c})_{1,1}}{2(i_p)_{1,1}\, t_1/t_c} \times 100 \quad [3]$$

If we assume that reaction [1] proceeds at a current density $(i_{int})_{1,1}$, the current efficiency for reaction [2] by pulsed current is given by

$$(n_2)_p = \frac{\begin{pmatrix}\text{Time-averaged applied}\\ \text{pulsed current density}\end{pmatrix} - \begin{pmatrix}\text{Time-averaged intermittent}\\ \text{limiting current density}\\ \text{for reaction [1]}\end{pmatrix}}{(\text{Time-averaged applied pulsed current density})} \times 100$$

$$= \frac{2(i_p)_{1,1}t_1/t_c - (i_{int})_{1,1}t_1/t_c}{2(i_p)_{1,1}t_1/t_c} \times 100$$

$$= \frac{2(i_p)_{1,1} - (i_{int})_{1,1}}{2(i_p)_{1,1}} \times 100 \quad [4]$$

Since $(i_p)_{1,1}$ and $(i_{int})_{1,1}$ are functions of pulse characteristics and stirring (4, 9), a numerical comparison of $(n_2)_{d\text{-}c}$ and $(n_2)_p$ has to be carried out according to the following procedure. For various values of the dimensionless on- and off-periods defined by $\tau_1 = Dt_1/\delta^2$ and $\tau_2 = Dt_2/\delta^2$ where τ_1 and τ_2 are the dimensionless on- and off-periods, D is the diffusivity of the reacting species, and δ is the thickness of the Nernst diffusion layer, $(i_p)_{1,1}$ and $(i_{int})_{1,1}$ can be calculated by methods outlined by Cheh (9) and by Viswanathan *et al.* (4), respectively. These values are then used to calculate $(n_2)_{d\text{-}c}$ and $(n_2)_p$ by using Eq. [2] and [3]. Results from similar calculations are summarized in Table I.

For example, when $\tau_1 = 0.04$ and $\tau_c = 0.10$, $(i_p)_{1,1}/(i_{d\text{-}c})_{1,1} = 1.9825$ (9) and $(i_{int})_{1,1}/(i_{d\text{-}c})_{1,1} = 2.17$ (4). Therefore, according to Eq. [3], $(n_2)_{d\text{-}c} = [(2 \times 1.9825 \times 0.4 - 1)/(2 \times 1.9825 \times 0.4)] \times 100\% = 36.94\%$, and according to Eq. [4], $(n_2)_p = [(2 \times 1.9825 - 2.17)/2 \times 1.9825] \times 100\% = 45.25\%$.

These results clearly indicate that the maximum current efficiency for reaction [2] is 50% for a system with equal diffusivities, valency, and bulk concentration for both reacting species. This value is reached when one applies a d-c current density which is the sum of the d-c limiting current densities for both species. On the other hand, when the applied current is lower than the sum of the d-c limiting current densities, the current efficiency for reaction [2] under pulsed conditions is generally higher than that under d-c conditions. The faster the pulse, the higher is the current efficiency for reaction [2]. This is expected

Table I. Current efficiencies for reaction [2] by d-c and by pulsed electrolysis

τ_1	τ_2	$(n_2)_{d\text{-}c}$	$(n_2)_p$
1.000	0.000	50.00	50.00
0.800	0.200	40.50	44.50
0.600	0.400	27.20	40.98
0.400	0.600	6.87	38.87
0.100	0.000	50.00	50.00
0.080	0.020	47.05	48.20
0.060	0.040	43.07	46.84
0.040	0.060	36.94	45.25
0.020	0.080	24.24	43.94
0.010	0.000	50.00	50.00
0.008	0.002	49.07	49.42
0.006	0.004	47.81	48.84
0.004	0.006	45.87	48.43
0.002	0.008	41.86	47.64

because $(i_p)_{l,1}$ approaches $(i_{int})_{l,1}$ as the duty cycle approaches zero (4). It is also important to note that since $(i_{int})_{l,1}$ is the highest limiting current density among all non-d-c electrolysis, $(n_2)_p$ calculated by Eq. [3] provides the lower bound for the current efficiency for reaction [2] by pulsed electrolysis. The actual current efficiency for reaction [2] by pulsed electrolysis will be between the value calculated by Eq. [3] and 50%. Meanwhile, Viswanathan *et al.* (4) has shown that $(i_{int})_{l,1} \times t_1/t_2$ is always lower than $(i_{d\text{-}c})_{l,1}$. Thus, by applying a pulsed current, the time-averaged rate of pulsed electrolysis for reaction [1] is lower than that by d.c., thereby increasing the time-averaged rate of electrolysis and the current efficiency for reaction [2].

The Application of Linear Sweep Voltammetry to a Rotating Disk Electrode for a Reversible Reaction with Soluble Product

P. C. Andricacos* and H. Y. Cheh**

Department of Chemical Engineering and Applied Chemistry, Columbia University, New York, New York 10027

The theory of linear sweep voltammetry (LSV) in a stagnant system for a reversible reaction with soluble product was first worked out independently by Sevcik (1) and Randles (2). Subsequently, several authors (3-6) contributed to its further development. Reviews on the subject can be found in the classical paper by Nicholson and Shain (7) and in the monograph by Macdonald (8).

One of the advantages in performing LSV experiments in systems with controlled forced convection, such as that established by a rotating disk electrode (RDE), is that the effect of natural convection is suppressed even at low values of the Reynolds number. However, the application of LSV on an RDE has not been used extensively. One probable cause is the insufficient development of its theory.

In a recent paper (9), we applied the Nernst model of transient diffusion to an RDE, to obtain an analytical expression for the current transient associated with a reversible deposition (insoluble product) reaction. We have found that for slow dimensionless sweep rates, no current peaks are obtained. Instead, the current density increases monotonically with time to an asymptotic value equal to the diffusion limiting current density. However, as the dimensionless sweep rate is increased and after a relatively short transition region, peaks are obtained the behavior of which is the same for all practical purposes as those obtained in a stagnant system. As a result, the linear dependence of the peak current density on the square root of the sweep rate originally derived by Berzins and Delahay (10), is retained. In addition, the peak current density normalized with respect to the limiting current density has been shown to depend linearly on the square root of the dimensionless sweep rate. A particular advantage of this conclusion is that the correlation exhibits a weak dependence on the physical properties of the electrolyte.

In the present note, the LSV response of an RDE on which a reversible reaction with soluble product occurs, is analyzed. The same problem has been dealt with by Girina *et al.* (11) and by Fried and Elving (12), but to an insufficient detail. A review of the work of these authors has been provided elsewhere (9).

Consider the reaction

$$O + ne \rightarrow R \quad [1]$$

where both reduced and oxidized species are soluble. Assuming that the diffusion coefficients of O and R are equal to a common value D, a unique diffusion layer thickness, δ, has been derived by Levich (13)

$$\delta = 1.61 D^{1/3} \nu^{1/6} \omega^{-1/2} \quad [2]$$

where ν is the kinematic viscosity of the electrolyte and ω is the rotation speed of the RDE. If $c_O{}^b$ and $c_R{}^b$ are the bulk concentrations of O and R, respectively, the following dimensionless quantities can be introduced

$$C_O(\xi, \tau) = 1 - c_O(\xi, \tau)/c_O{}^b \quad [3]$$

$$C_R(\xi, \tau) = 1 - c_R(\xi, \tau)/c_R{}^b \quad [4]$$

$$\xi = x/\delta \quad [5]$$

$$\tau = Dt/\delta^2 \quad [6]$$

where C_O and C_R are dimensionless concentrations, and ξ and τ are dimensionless distance and time, respectively. Under the assumptions of the Nernst diffusion model discussed elsewhere (9), the diffusion of O towards the RDE surface is described by the following equations

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.

Key words: rotating disk, deposition, voltammetry.

$$\frac{\partial C_O}{\partial \tau} = \frac{\partial^2 C_O}{\partial \xi^2} \quad [7]$$

$$C_O(\xi, 0) = 0 \quad [8]$$

$$C_O(1, \tau) = 0 \quad [9]$$

$$\frac{\partial C_O}{\partial \xi}(0, \tau) = -\frac{i(\tau)}{i_{O,l}} \quad [10]$$

where $i(\tau)$ is the unknown current density and $i_{O,l}$ is the diffusion limiting current density defined as follows

$$i_{O,l} = n\mathbf{F}Dc_O{}^b/\delta \quad [11]$$

A similar set of equations describes the diffusion of R. The only difference is in Eq. [10], which reads

$$\frac{\partial C_R}{\partial \xi}(0, \tau) = \frac{i(\tau)}{i_{R,l}} \quad [12]$$

The resulting boundary value problems can be solved by the Laplace transform method. A simple computation in the Laplace domain followed by convolution yields the following relations

$$C_O(0, \tau) = \int_0^\tau \frac{i(\lambda)}{i_{O,l}} \times \theta_2(0, \pi i(\tau - \lambda))d\lambda \quad [13]$$

$$C_R(0, \tau) = -\int_0^\tau \frac{i(\lambda)}{i_{R,l}} \times \theta_2(0, \pi i(\tau - \lambda))d\lambda \quad [14]$$

$$\frac{i(\tau)}{i_{O,l}} = \int_0^\tau \frac{\partial C_O}{\partial \tau}(0, \lambda) \times \theta_3(0, \pi i(\tau - \lambda))d\lambda \quad [15]$$

$$i_{O,l}C_O(0, \tau) + i_{R,l}C_R(0, \tau) = 0 \quad [16]$$

where λ is a dummy variable of integration, and θ_2 and θ_3 are theta functions originally used for the solution of electrochemical diffusion problems by Tokuda and Matsuda (14-16). They are defined as follows (17)

$$\theta_2(0, \pi i(\tau - \lambda)) = 2\sum_{j=0}^{j=\infty} \exp(-(j + 1/2)^2\pi^2(\tau - \lambda)) \quad [17]$$

$$\theta_3(0, \pi i(\tau - \lambda)) = 1 + 2\sum_{j=1}^{j=\infty} \exp(-j^2\pi^2(\tau - \lambda)) \quad [18]$$

Equation [15] is important in that it provides an expression for the current density $i(\tau)$, once $\partial C_O/\partial\tau$ $(0, \lambda)$ is known. Furthermore, Eq. [16] is a relation between the dimensionless concentrations of O and R, derived by the elimination of the common integral between Eq. [13] and [14]. An expression for $\partial C_O/\partial\tau$ $(0, \lambda)$ can be obtained from the assumptions concerning the mechanism of reaction [1].

In an LSV experiment, the electrode potential, $E(t)$, is given by

$$E(t) = E_i - vt \quad [19]$$

where E_i is the initial potential and v is the sweep rate. For no current to flow initially through the system, E_i is taken to be the equilibrium potential of the electrode, computed from the Nernst equation and $c_O{}^b$, $c_R{}^b$. Since the reaction is reversible and assuming that it occurs in an ideal solution, we obtain

$$\frac{c_O(0, t)}{c_R(0, t)} = \frac{c_O{}^b}{c_R{}^b}\exp\left(-\frac{n\mathbf{F}}{RT}vt\right) \quad [20]$$

Introducing the dimensionless sweep rate, σ

$$\sigma = n\mathbf{F}v\delta^2/RTD \quad [21]$$

and the concentration ratio

$$\mu = c_O{}^b/c_R{}^b = i_{O,l}/i_{R,l} \quad [22]$$

Eq. [20] can be written in dimensionless variables as follows

$$\frac{1 - C_O(0, \tau)}{1 + \mu C_O(0, \tau)} = \exp(-\sigma\tau) \quad [23]$$

Combining Eq. [15] and [23] an expression for the normalized current density is obtained

$$\frac{i(\tau)}{i_{O,l}} = \frac{\sigma}{4}\left(1 + \frac{1}{\mu}\right)\int_0^\tau \frac{1 + 2\sum_{j=1}^{j=\infty} \exp(-j^2\pi^2(\tau - \lambda))}{\cosh^2((\ln\mu - \sigma\lambda)/2)}d\lambda \quad [24]$$

where the singularity at the upper limit can be removed by integration by parts.

Equation [24] can be used in principle for the computation of the current transient. However, further substitutions originally introduced by Matsuda and Ayabe (3) for the corresponding problem in a stagnant system can considerably simplify the calculations. Let

$$a = \ln\mu \quad [25]$$

$$\zeta = \sigma\lambda - a \quad [26]$$

$$\psi = \sigma\tau - a \quad [27]$$

Eq. [24] then acquires the following form

$$\frac{i(\psi)}{i_{O,l}} = (1 + e^{-a}) \times \frac{1}{4}\int_{-a}^{\psi} \frac{1 + 2\sum_{j=1}^{j=\infty} \exp(-j^2\pi^2(\psi - \zeta)/\sigma)}{\cosh^2(\zeta/2)}d\zeta \quad [28]$$

By using a transformation formula for θ_3 (17, 9) and defining a new variable, ρ, by

$$\rho = (\psi - \zeta)^{1/2} \quad [29]$$

Eq. [28] acquires its final form

$$\frac{i(\psi)}{i_{O,l}} = \sigma^{1/2}\Phi_{rde}(\psi, \sigma, a) \quad [30]$$

where Φ_{rde} is the current function defined as follows

$$\Phi_{rde}(\psi, \sigma, a) = (1 + e^{-a}) \times \frac{1}{2\pi^{1/2}}\int_0^{(\psi+a)^{1/2}} \frac{1 + 2\sum_{j=1}^{j=\infty} \exp(-j^2\sigma/\rho^2)}{\cosh^2((\psi - \rho^2)/2)}d\rho \quad [31]$$

The integral in Eq. [31] is well defined everywhere.

It would be interesting at this point to compare $\Phi_{rde}(\psi, \sigma, a)$ to the current function $\Phi_{st}(\psi, a)$ obtained by Matsuda and Ayabe (3) for the solution of the corresponding problem in a stagnant system. The expression derived by these authors in the present nomenclature is as follows

$$\Phi_{st}(\psi, a) = (1 + e^{-a}) \times \frac{1}{2\pi^{1/2}}\int_0^{(\psi+a)^{1/2}} \frac{1}{\cosh^2((\psi - \rho^2)/2)}d\rho \quad [32]$$

The most important difference between Eq. [31] and [32] is that the latter is not a function of the sweep rate. Indeed, given a value of a, Φ_{st} is only a function of ψ, whereas Φ_{rde} is still parametrized with respect to σ. One can also note that for small values of ρ or high values of σ, Eq. [31] and [32] tend to become identical.

The integral in Eq. [31] has been computed numerically by the use of Simpson's rule. Figure 1 shows a graphical representation of Eq. [31] for $a = 12.0$.

For small values of the dimensionless sweep rate, the current function increases monotonically from 0 to a steady-state value

$$\Phi_{\mathrm{rde}} \rightarrow \sigma^{-1/2} \quad \text{as} \quad \psi \rightarrow \infty \qquad [33]$$

For larger values of σ, a maximum is obtained, while the subsequent steady-state value is again described by Eq. [33]. Combining Eq. [30] and [33] we find that as $\tau \rightarrow \infty$, $i(\tau)/i_{\mathrm{O,l}} \rightarrow 1$. For $\sigma > 20$

$$\Phi_{\mathrm{rde,max}} = 0.446 \quad \text{at} \quad \psi = 1.1 \qquad [34]$$

Combining Eq. [30] and [34] we obtain

$$\frac{i_{\mathrm{p}}}{i_{\mathrm{O,l}}} = 0.446\,\sigma^{1/2}, \quad \sigma > 20 \qquad [35]$$

Maxima appear for $\sigma > 3$. Thus, the region $3 < \sigma < 20$ is the transition region. Figure 2 summarizes the dependence of $i_{\mathrm{p}}/i_{\mathrm{O,l}}$ on $\sigma^{1/2}$. In the region $10 < \sigma < 20$, deviation from Eq. [35] is less than 2%.

Equation [35] indicates that the peak current density, i_{p}, normalized with respect to the diffusion limiting current density, $i_{\mathrm{O,l}}$, is a linear function of the square root of the dimensionless sweep rate, σ, provided that σ is large enough. The slope is a constant, independent of any physical property of the system.

In terms of dimensional quantities, Eq. [35] can be written as

$$i_{\mathrm{p}} = 0.446\, n^{3/2}\mathbf{F}^{3/2}R^{-1/2}T^{-1/2}D^{1/2}c_{\mathrm{O}}^{\mathrm{b}}v^{1/2} \qquad [36]$$

Equation [36] is the same as the one describing the response in a stagnant system (3). However, the use of the RDE allows both Eq. [35] and [36] to be used for correlating results. As previously (9), Eq. [36] offers the advantage of the weak dependence on the physical properties of the electrolyte

$$\frac{i_{\mathrm{p}}}{i_{\mathrm{O,l}}} = 0.718\,(n\mathbf{F}v/RT\omega)^{1/2}(\nu/D)^{1/6} \qquad [37]$$

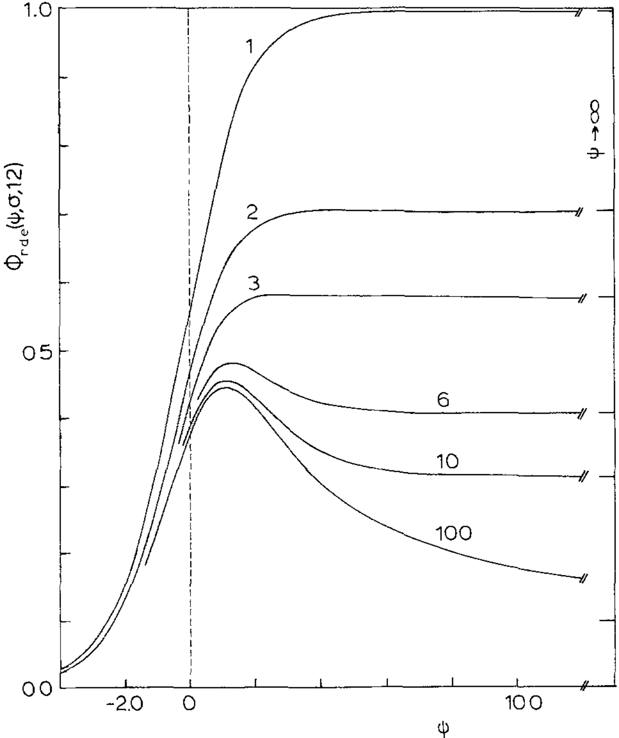

Fig. 1. RDE current function for a reversible reaction with soluble product, Eq. [31]. Numbers on lines indicate values of the dimensionless sweep rate.

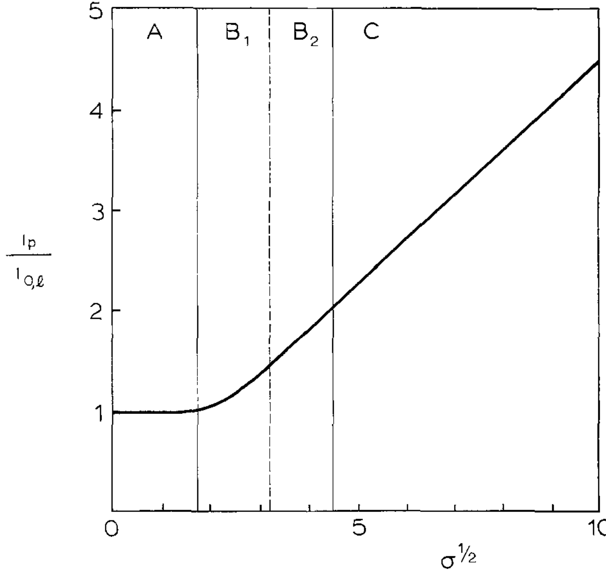

Fig. 2. $i_{\mathrm{p}}/i_{\mathrm{O,l}}$ vs. $\sigma^{1/2}$ correlation for a reversible reaction with soluble product occurring on an RDE under LSV conditions. A: region of no maxima; B_1 and B_2: transition region (B_2: less than 2% deviation from linearity); C: region of validity of Eq. [35].

The value of the overpotential at which the current peak appears, η_{p}, can be easily found to be

$$\eta_{\mathrm{p}} = -\frac{RT}{n\mathbf{F}}(1.1 + \ln \mu) \qquad [38]$$

The behavior of the current function is not affected by the value of a when the latter is greater than approximately 4. For instance, when $a = 4$ and within the region of validity of Eq. [35], the value of the peak overpotential is unaltered; however, the slope of the $i_{\mathrm{p}}/i_{\mathrm{O,l}}$ *vs.* $\sigma^{1/2}$ correlation is about 1% lower than the one predicted by Eq. [35].

Experimental investigations to verify the $i_{\mathrm{p}}/i_{\mathrm{O,l}}$ *vs.* $\sigma^{1/2}$ correlation have been conducted by Girina *et al.* (11) for the $Tl^{+}/Tl(\mathrm{Hg})$ reaction. In this case, the reaction product is soluble in the electrode. These authors also discuss the results of Fried and Elving (18) obtained for the oxidation of $\mathrm{Fe(CN)_6}^{-4}$. It should be noted that Girina *et al.* have erroneously assumed that the current peaks appear at $\sigma\tau \sim 1$. By assuming so, the dependence on μ has been eliminated erroneously.

Acknowledgment

The authors wish to thank Dr. Samuel Ruben for his generous endowment of a Bergen Davis Fellowship at Columbia University. One of us (P.C.A.) was the recipient of the Fellowship during the course of this work.

Manuscript received May 5, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Meso- and Dl- Diethyl 2,3-Diphenylsuccinate from the Electrochemical Reduction of Ethyl α-Bromophenylacetate

L. Rampazzo and A. Inesi

Institute of Chemistry, Faculty of Engineering, University of Rome, Rome, Italy

A variety of chemical methods for the preparation of the stereoisomeric *meso-* and *dl*-diethyl 2,3-diphenylsuccinates (I, II) have been developed (1-9). Other routes to $(PhCHCOOEt)_2$ are the electrochemical oxidation of the enolate of ethyl phenylacetate $PhCH_2COOEt$(III) (10, 11) and the photolysis of ethyl α-chlorophenylacetate (12). The purpose of this paper is to summarize some experimental observations related to the electrochemical reduction of ethyl α-bromophenylacetate (IV) on Hg in DMF-Et_4NClO_4 · 0.1M solutions, providing a synthetically useful preparation of *meso-* and *dl-* 2,3-diphenylsuccinates.

Additional experimental results on the electrochemical reduction of ethyl-α-bromophenylacetate on platinum and glassy carbon electrodes are also reported.

Experimental

Chemicals.—N,N-dimethylformamide (DMF) (RIEDEL-DE HAEN spectranal.) was treated with neutral Al_2O_3 for chromatography, which was previously heated for 3 hr at 600°C. The solvent was then passed through molecular sieves 4A (BDH) and distilled under nitrogen flux at 5 mm Hg. The product of the first distillation was collected over P_2O_5 and stored at 0°C in the dark. The water content of the purified DMF was not greater than 0.01% as measured by the Karl-Fischer titration. Polarographic grade Et_4NClO_4 (Carlo Erba) was vacuum dried at 60°C and used as the supporting electrolyte without additional purification. Bu_4NBr was Carlo Erba RS grade for polarography. Commercially available ethyl α-bromophenylacetate (K&K, 99.5%) was used as received. TLC on silica gel (eluent benzene) showed that it contained a trace of a product moving slower than IV. 3,4-xylenol and trifluoroacetic acid used in some experiments were reagent grade chemicals, BDH and K&K, respectively. Ethyl phenylacetate (K&K) was used for comparative purposes. All other chemicals used were commercially available and of the best purity.

Apparatus.—Conventional polarographic data were obtained with a three-electrode AMEL MOD 471 instrument. The reference electrode was a calomel-type as described by Fujinaga (13). Its potential, −0.059V *vs.* SCE, remained constant during several months; all potentials are quoted with respect to this reference electrode. The counterelectrode was a mercury pool. The dropping mercury electrode operated with a head of 70 cm. Two capillaries, 1 and 2, were used, giving values of $tg(1) = 4.01$ sec, $tg(2) = 5.01$ sec at open circuit, $tg(1) = 3.40$ sec, $tg(2) = 4.40$ sec at $E = -1.00V$; the Hg flux was $m(1) = 1.10$ mg $\times$ sec^{-1} and $m(2) = 1.36$ mg $\times$ sec^{-1}. An AMEL MOD 552 potentiostat equipped with an AMEL MOD 721 integrator were used in controlled potential electrolyses (c.p.e.) and coulometric experiments. A stirred mercury pool served at the cathode; the counterelectrode was a cylindrical platinum gauze immersed in the 0.1M Et_4NClO_4-DMF solution. A porous plug filled with methylcellulose and DMF-Et_4NClO_4 0.1M separated the counterelectrode from the test solution. Before each electrolysis, all solutions were deoxygenated with N_2 (PP), and nitrogen was passed over the solution during c.p.e.

A Bruker spectrospin operating at 90 MHz was employed to record NMR spectra, and all chemical shifts are reported in ppm downfield from TMS as internal standard. The solvent was $CDCl_3$. Mass spectrometric data for $(PhCHCOOEt)_2$ were obtained by direct insertion with an Hitachi-Perkin Elmer RMU-6 spectrometer at 70 eV. Infrared spectra were recorded on a Perkin-Elmer MOD 177 grating spectrophotometer using CCl_4 as solvent. Melting points were determined in glass capillaries with a BUCHI mp apparatus and are uncorrected. All electrochemical experiments were performed on freshly prepared solutions of IV. Preliminary experiments on the polarographic behavior revealed that ethyl-α-bromophenylacetate, when dissolved in DMF, can be slowly hydrolyzed by traces of water still present in the solvent. In fact, test polarograms were recorded on solutions which were from just prepared to five days old; the waves slowly changed in height on standing, and the Br^- ions determined the appearance of a characteristic anodic wave.

Voltammetric measurements on solid electrodes were performed using a pulsed electrode (14), which was assembled either with a platinum electrode of about 1 mm diam (PPE), or with a glassy carbon electrode of 3 mm diam (GCPE). Both electrodes were polished by conventional methods.

Controlled potential electrolysis.—C.p.e. of 2.78g of $PhCH_2BrCOOEt$ (IV) in 300 ml of DMF-0.1M Et_4NClO_4 using a mercury pool cathode at −1.500V was accomplished by adding the bromo-ester in small portions at a time, so that during electrolysis the concentration of IV to be reduced was never greater than 3×10^{-3}M.

Key words: d-c polarography, ethyl α-bromophenylacetate, diethyl 2,3-diphenylsuccinate, controlled-potential electrolysis, reductive coupling.

The maximum value of current intensity was about 0.6A; when the current value dropped to ca. 0.003A, electrolysis was interrupted and 810C were measured. At this time, no starting product or other substances reducible in the interval 0.00 to −2.700V were present in the solution, as ascertained by recording the polarogram. The electrolyzed solution was dried under vacuum ($t = 40°C$) to remove DMF; the product was extracted with ether, the ethereal solution was concentrated to a volume of about 20 ml. On cooling, a yellow-brown precipitate was formed; recrystallization from ethanol afforded 0.300g of colorless crystals melting at 139°-40°C [lit. (2, 8) for *meso* I: mp = 140°-1°C]. Infrared (I): ν_{max} (CCl_4): 1725, 1153, 700 cm^{-1} (all strong); the other medium-weak peaks at 3080, 3050, 3020, 2980, 1490, 1450, 1365, 1300, 1285, 1250, 1230, 1200, 1095, 1070, 1030, and 850 cm^{-1} matched the literature data (12). NMR (I): δ ($CDCl_3$)/ppm: 7.36 (multiplet, Ph); 4.37 (singlet, CH); 3.83 (quartet, J = 7.0 Hz, CH_2); 0.89 (triplet, J = 7.0 Hz, CH_3), according to literature data (5, 8) for *meso*-diethyl 2,3-diphenylsuccinate.

Mass spectrum of *I* ($t = 120°C$), m/e: 326 (M^+), 325 (M-H), 324 (M-2H), 281 (M-OEt), 280 (M-EtOH, metastable peak for the transition 326 → 280 at $m^* = 240.5$), 253 (M-COOEt), 252 (M-EtOH-CO, metastable peak for 280 → 252 at $m^* = 226.8$), 248 (M-H-PH), 235 (M-H-2 OEt), 224, 223, 207, 206, 195, and appropriate peaks at lower m/e.

The remaining ethereal solution was filtered, the solvent removed under vacuum, obtaining a yellow-brown substance which was crystallized from petroleum ether to white crystals (0.200g) melting at 74°-77°C [lit. (2, 8) for *dl* (II): 79°C]. The infrared spectrum was identical peak by peak to the spectrum of *meso* (I). NMR showed all peaks of *dl* (II) at δ/ppm ($CDCl_3$): 7.36 (Ph), 4.22 (singlet, CH), 4.14 (quartet, J = 7 Hz, CH_2), 1.17 [triplet, J = 7 Hz, CH_3, according to Ref. (8)], together with the peaks of I in minor amount, *i.e.* 75% *dl* and 25% *meso*.

The mother liquors of the two preceding crystallizations were collected, dried and recrystallized from petroleum ether to afford 0.25g of white crystals, mp 70°-110°C, of a mixture of 33.5% *meso*- and 66.5% *dl*-diethyl 2,3-diphenylsuccinate (NMR), as determined by the integrated peaks of the well-separated methyl triplets at δ = 0.89 and δ = 1.17 for I and II, respectively. No peaks between the signals of methine and phenyl- protons were apparent, indicating that no α-para dimers were present in detectable amounts.

Results and Discussion

Figure 1 (a, b, c) shows the polarograms for ethyl α-bromophenylacetate on a dropping mercury electrode in dimethylformamide containing 0.1M Et_4NClO_4, when the concentrations of IV are of the order of 10^{-4}M. If the concentration is raised over 10^{-3}M, a sharp maximum appears, followed by the normal diffusion current plateau. The presence of this maximum hides all the features between the ascending part of the first wave and the diffusion current. No significant deviation from diffusion control was observed on the polarographic waves; the limting currents were proportional to the concentration of IV in the range 10^{-4}-10^{-3}M, and to the square root of the height of the mercury reservoir. The two waves observed, with $E_{1/2} = -0.13V$ and −0.48V, respectively, show limiting currents in the ratio of about 2/1 for the same concentration range.

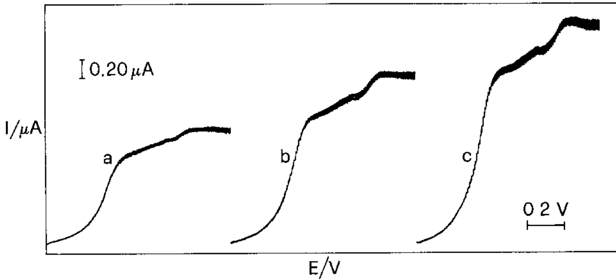

Fig. 1. Polarographic reduction waves of PhCHBrCOOEt (IV) in DMF-Et_4NClO_4 0.1M; curve a, C(IV) = 3.0 × 10^{-4}M; curve b, C(IV) = 5.0 × 10^{-4}M; curve c, C(IV) = 7.0 × 10^{-4}M. Each curve starts from E = 0.200V; E/V vs. the SCE as indicated in the experimental section; capillary 2.

Coulometric reduction of 2 × 10^{-3}M IV with a mercury pool cathode at $E = -1.8V$ gave n_{app} = 0.75-0.80 in repeated experiments; other polarographic and coulometric data are reported in Table I.

The effect of addition of 3,4 xylenol and trifluoroacetic acid (TFA) on the polarograms is shown in Fig. 2. The first reduction wave remains unaffected when 3,4 xylenol is added, whereas the second wave increases with increasing concentration of 3,4 xylenol, until a saturation value is obtained. Addition of TFA affects the height of the first wave, without shifting its half-wave potential, until about the same saturation value is obtained when excess TFA is added. It should be remembered that 3,4 xylenol is a weak acid in DMF; TFA is a strong acid in this solvent; the reduction wave of the latter, due to hydrogen discharge, is at $E_{1/2} = -1.48V$ (15). Polarographic and coulometric data for reduction of CHPhBrCOOEt in the presence of proton donors are collected in Table II.

As described in the experimental section, the isolated nonvolatile products of controlled-potential electrolysis of IV at a mercury pool cathode at −1.8V are *meso*- and *dl*-diethyl 2,3-diphenylsuccinate I and II, the overall relative ratio being 57.3% *meso*- and 42.7% *dl*. The overall current yield was about 60% after the working up of the electrolyzed solution. No effort was made to improve this procedure to optimize the yield, so it is likely that absolute yield would be better; moreover, commercially available PhCHBrCOOEt was used without further purification, so that nonreducible hydrolysis products could be present at the beginning of the electrolysis.

The products formation is clearly a consequence of the overall main electrode process

$$2PhCHBrCOOEt + 2e \xrightarrow[Hg,\ DMF]{E = -1.8V} 2Br^- + (PhCHCOOEt)_2 \quad [1]$$

meso and *dl*

The presence of dimers in the products of electrochemical reduction of monosubstituted halides has been

Table I. Polarographic and coulometric data for reduction of CHPhBrCOOEt in DMF containing 0.1M Et_4NClO_4

5[a]	1.56	0.85
38.4	max	0.75[d]

[a] Result obtained with capillary 1; all other data were obtained using capillary 2.

[b] Diffusion current constant, $I = \frac{i_{lim}}{m^{2/3}t^{1/6}C}$ μA × mM^{-1} × l × $mg^{-2/3}$ × $sec^{1/2}$.

[c] Number of F/mole obtained by coulometry at $E = -1.8V$.

[d] Low values of $n_{app} < 1$ at $C > 1$ mM/l were obtained by others in the one-electron reduction of carbon-halogen bond in DMF, *cf.* for example, C. M. McNamee, B. C. Willet, D. M. La Perriere, and D. G. Peters, *J. Am. Chem. Soc.*, 99, 183 (1977); a similar explanation may hold for the present case.

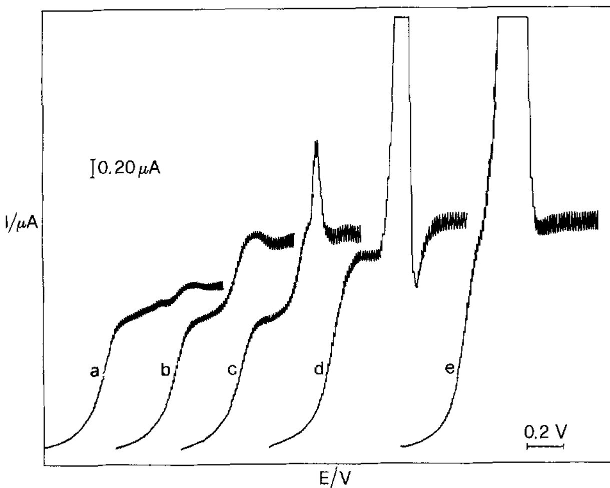

Fig. 2. Effect of 3,4-xylenol (HA) and trifluoroacetic acid (TFA) on the polarographic reduction waves of PhCHBrCOOEt (IV) 5.0×10^{-4}M in DMF-Et_4NClO_4 0.1M; curve a, C(acid) = 0.0; curve b, C(HA) = 2.5×10^{-4}M; curve c, C(HA) = 5.0×10^{-4}M; curve d, C(TFA) = 2.5×10^{-4}M; curve e, C(TFA) = 5×10^{-4}M. Each curve starts from E = 0.200V; capillary 2.

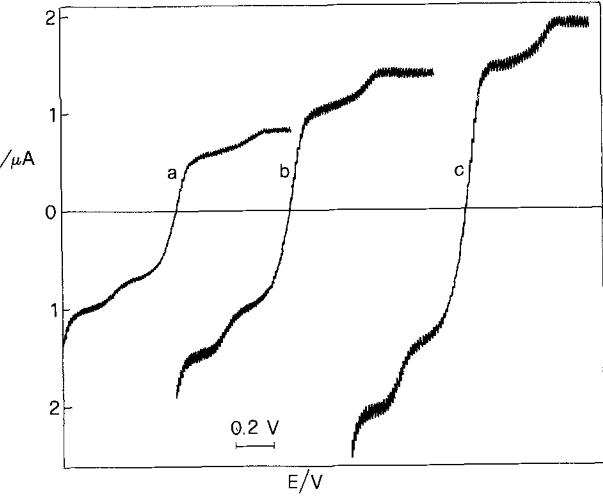

Fig. 3. Polarographic reduction waves of PhCHBrCOOEt (IV) in DMF-Et_4NClO_4 0.1M containing Bu_4NBr: curve a, C(IV) = 3×10^{-4}M; C(Bu_4NBr) = 3×10^{-4}M; curve b, C(IV) = 5×10^{-4}M; C(Bu_4NBr) = 5×10^{-4}M; curve c, C(IV) = 7×10^{-4}M; C(Bu_4NBr) = 7×10^{-4}M. Each curve starts from E = 0.450V vs. SCE; capillary 2.

reported (16) or suggested (17). Figure 3 shows the polarographic behavior of RBr in the presence of Bu_4NBr, C(RBr)/C(Bu_4NBr) = 1/1, at various concentrations of RBr. The same behavior is obtained with Et_4NBr instead of Bu_4NBr. If c.p.e. is performed at the potential of ~ −0.350V, *i.e.*, before the second wave, on a 3×10^{-3}M solution of RBr in aprotic DMF-0.1M Et_4NClO_4, the first wave disappears after about 0.6 F/mole RBr are passed. The second wave remains unchanged (Fig. 4), showing that it represents the reduction of a compound which is stable in the conditions of the experiments. The half-wave potential $E_{1/2}^{(2)}$, τ is consistent with that found for HgR_2 in various solvents (18). A subsequent c.p.e. on this solution, at −1.8V, showed $n_{app} \cong 0.6$. Direct reduction of RBr, $C = 3 \times 10^{-3}$M, at −1.8V showed $n_{app} \cong 0.9$. During the preparative c.p.e. performed at $E = -1.8V < E_{1/2}^{(2)}$, in aprotic DMF, the red color of carbanion R^- was observed.

The simplest mechanism which can explain the data on Hg is probably the following (19)

$$RBr + Hg + e \xrightarrow{E_1} RHg + Br^- \quad [2]$$

$$RHg \begin{cases} \xrightarrow{\text{slow}} \frac{1}{2} HgR_2 + \frac{1}{2} Hg \\ \xrightarrow[+e + H^+]{E_1} RH + Hg \end{cases} \quad [3]$$

$$R^- \begin{cases} \xrightarrow{+HA} RH + A^- \\ \xrightarrow{+RBr} R_2 + Br^- \end{cases} \quad [5]$$

The general pattern shown suggests that the electrochemical reduction of PhCHBrCOOEt should be

dependent on electrode nature. Typical d-c voltammetric curves for reduction of PhChBrCOOEt in DMF using glassy carbon and platinum electrodes are reported in Fig. 5 and 6. Voltammograms show one well-defined wave with $E_{1/2} = -1.04V$ for the vitreous carbon electrode. The height of the wave remains constant in the subsequent voltammograms. If excess 3,4-xylenol is added, the wave increases in height. At the platinum electrode, a wave with $E_{1/2} = -0.75V$ is observed, followed by a second wave with $E_{1/2} = -1.14V$. No further experiments with solid electrodes were performed, as we were interested mainly in determining the $E_{1/2}$ values of IV in DMF at electrodes different from mercury. Thus the PhCHBrCOOEt electrochemical characteristics are strongly dependent on electrode nature. Our results come into line with the conclusions made by Lambert *et al.* in their investigation of the carbon tetrachloride reduction at the glassy carbon electrode (20) as compared with the reduction of the same compound at the dropping mercury electrode.

After this work had been submitted, Bard and Merz (21) reported studies on the electrochemical reduction of some allyl halides in CH_3CN at mercury, platinum, and vitreous carbon electrodes. The special mode of electrochemical behavior of allyl bromide and iodide on mercury is interpreted in terms of a specific surface reaction of the halide with the mercury electrode (6), RBr + Hg $\rightleftarrows$ RHgBr. It appears that in the case of the allyl halides concerned and in the solvent employed, the equilibrium (6) lies far to the left, allowing direct transfer of electrons to allyl-HgX to occur at the potential of the first wave.

Control of Volume Resistivity in Inorganic-Organic Separators

Dean W. Sheibley* and Michelle A. Manzo

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio 44135

ABSTRACT

Control of resistivity in NASA inorganic-organic separators is achieved by incorporating small percentages of high surface area, fine-particle silica with other ingredients in the separator coating. The volume resistivity appears to be predictable from coating composition, that is, from the surface area of filler particles in the coating. The approach has been applied to two polymer-"plasticizer"-filler coating systems, where the filler content of each is below the generally acknowledged critical pigment volume concentration of the coating. Application of these coating systems to 0.0254 cm thick (10 mil) fuel-cell grade absestos sheet produces inexpensive, flexible, microporous separators that perform at least as well as the original inorganic-organic concept, the Astropower separator.

The usefulness of the inorganic-organic separators developed at the Lewis Research Center for alkaline batteries (*i.e.*, Ag-Zn, Ni-Zn, and Ni-Cd batteries) depends on an optimum balance of resistivity and microporous-structure uniformity. Over the past few years separators have been developed with longer cycle life, more uniform current density, greater flexibility, and lower cost than the original Astropower inorganic-organic separator.

The Astropower separator [Ref. (1)] and several other microporous separators contain relatively high filler volumes such that the amount of binder is insufficient to completely coat the filler particles and fill the interstices. That is, their filler volume is above the critical pigment volume concentration (CPVC) of 40-45 volume percent (v/o). These separators derive their ionic conductivity through the pathway created by the particle-to-particle contact of the fillers. Bozek (2) described the structure and function of the Astropower separator. Philipp and May (3) studied the reaction of the plasticizer with the electrolyte, the ionic resistivity of simulated inorganic-organic separators, and the zincate diffusion through various separators. Sheibley (4) discussed factors that influence the flexibility, resistivity, and zinc dendrite penetration rate of the Astropower separator and NASA improved inorganic-organic separators. A significant conclusion of that work was that the volume resistivity of the improved separators could be maintained in an acceptable range (10-25 Ω-cm) while keeping the volume percentage of fillers in the polymer below the CPVC (5). This also ensured good coating flexibility. Another significant conclusion of Ref. (4) was that the zinc dendrite penetration rate is controlled principally by the tortuosity produced by the presence of inert fillers in the coating. The acceptable range of resistivity was achieved by judicious selection of fillers that combined inertness and reactivity with the potassium hydroxide (KOH) electrolyte while providing a multiplicity of tortuous conduction paths. These paths were created by filling the spaces between larger particles with smaller particles (a filler packing effect).

Ion permeability of coatings rises very rapidly by several orders of magnitude at the CPVC (5). The key to film permeability below the CPVC in these improved inorganic-organic separators was the use of a proper polyester plasticizer. Philipp and May (3) pointed out that the plasticizer must be a polar compound that preferentially adsorbs on the filler particles, which are also polar compounds. Sheibley (4) showed that one of the products of the plasticizer reaction with the electrolyte must be a short-chain (two or three carbons) glycol. It was also shown that resistivity could be further improved by using an electrolyte-reactive filler in the coating.

This paper discusses the development of resistivity control in NASA microporous separators that contain filler volumes significantly less than the CPVC. First, the effect of filler volume on volume resistivity is shown for a typical inert filler. Then the effect of an electrolyte-reactive filler on volume resistivity is illustrated. Next, the effect on volume resistivity of combinations of fillers plus a selected organic additive (plasticizer) in the polymer is demonstrated. Finally, the incorporation of high surface area, fine-particle fillers is shown to be a predictable means of controlling resistivity.

Experimental Procedure

Preparation of coating mixture.—The coatings used for the separator materials were prepared by weighing an amount of polymer [either polyphenylene oxide[1] (PPO) or Kraton G[2] resin] into a ball mill, adding chloroform or another solvent, and then adding the weight of filler or filler plus organic additive (plasticizer) needed to provide the desired total volume percentage of filler in the resin. Before ballmilling, the Kraton G must be cut into solution with the

solvent in a high-shear mixer. After the materials were milled for 20 hr, chloroform was added to reduce the viscosity of the mixture to 15 to 16 sec as measured with a number 3 Zahn cup at ~22°C.

The fillers used in these studies were magnesium silicate (Microtalc), aluminum silicate (kaolinite), synthetic magnesium aluminosilicate (NAS-100), magnesium titanate (Mg_2TiO_4), natural calcium silicate (wollastonite), lead titanate, reprecipitated calcium silicate (Silene EF), and fumed silicon dioxide (Cab-O-Sil). The organic additives (plasticizers) were a polymeric polyester (P-9750), used with the PPO, and an epoxidized soya bean oil (Paraplex G-62), used with the Kraton G resin. The trade names and manufacturers of these fillers and additives are given in Table I. Coating compositions are given in Table II and discussed later.

Coating the asbestos substrate.—Fuel-cell-grade asbestos sheet 0.0254 cm thick (10 mils) and impregnated with 2 weight percent (w/o) PPO was the substrate for all experimental materials. The coating mixtures were applied to the asbestos with an adjustable knife-blade applicator with the blade height set typically 0.0254 cm above the substrate. Two layers were applied at a wet thickness of 0.0254 cm for each coating. The second layer was applied after the first had dried. In the laboratory coating method the substrate was held flat by means of a vacuum plate while the knife blade was pulled over the fixed substrate. On factory production equipment the knife blade was fixed and the substrate moved beneath it. The final dry coating thickness was 0.00762-0.01016 cm (3-4 mils) which gave a total separator thickness, including substrate, of 0.0330-0.0355 cm (13-14 mils).

Determination of volume resistivity.—Volume resistivities were measured with a test apparatus and procedure based on those described by Lander and Weaver in Ref. (6). In most cases, resistivities were measured on at least two samples to establish precision, which ranged from ±3 to ±6%. Measurements were made in ~45 w/o KOH at room temperature. The two samples (3.8 by 3.8 cm) of each material were pretreated by soaking them in 45 w/o KOH overnight at 90°-100°C. The test area in the conductivity cell was 0.95 cm². The dry thickness of the separator was used in calculating volume resistivity because it was difficult to measure the wet thickness of the separator once it was positioned in the resistivity cell and the cell halves were tightened together. The wet thickness of some separators is 25% greater than their dry thickness in an uncompressed state.

Determination of plasticizer associated with fillers.—The amount of plasticizer associated with the fillers was estimated from the ratio of plasticizer to PPO in the liquid phase. It is known (3) that the plasticizer (polar compound) is preferentially adsorbed on the fillers (also polar compounds), but the PPO is not. Any selective adsorption on the balls of the ball mill used to prepare the coatings should not affect the result because the surface of a ball is about 5×10^{-6} m² and the surface contribution from fillers was always at least 1m².

Samples of various coating mixtures were allowed to stand until all the filler particles had settled out and a relatively clear supernatant was left. The ratio of plasticizer to PPO in the supernatant was determined by infrared spectroscopy. A calibration curve was obtained from a series of solutions of known ratios; and a straight line was fit to the data by regression analysis.

The spectrometer used was a Beckman Model IR 18A. The samples were diluted 6:1 with chloroform and run against a chloroform blank in sodium chloride cells. The peak at 1595 cm^{-1} (distinctive for aromatic substituted compounds and easily measured) was used to determine the PPO content. The peak at 1725 cm^{-1} (carbonyl stretching) was used to determine the plasticizer content. A typical infrared spectrum is shown in Fig. 1. Table II contains information on the composition of formula X39NF. The precision of this method was estimated to be from 3 to 5%.

Measurement of filler surface area.—The specific surface area of the dry fillers was determined by the standard multipoint Braunauer-Emmett-Teller (BET) technique (7) with krypton and nitrogen gas adsorption. This work was performed by a contractor,[3] who used an Orr Model 2100 surface-area pore-volume analyzer.

Results and Discussion

The effect of filler volume content on volume resistivity was studied initially with various fillers in

[3] Micromeritics Instrument Corporation, Norcross, Georgia 30091.

PPO. Some fillers were reactive with the electrolyte; some were unreactive (inert). The fillers comprised a large range of particle sizes as well as different chemical compounds, both synthetic and natural. The effect was studied with and without a saponifiable organic additive (plasticizer) in the filler-PPO mixture. Table II presents information on PPO coatings discussed in this section. Table III presents data on particle sizes and surface areas of all fillers used in the PPO coatings (Table II) and in the Kraton G resin-base coatings (Table IV). Similar, but limited, studies on the volume content of fillers in Kraton G were also performed to establish that the resistivity results were not unique to PPO but were a more general result and usable with other resin-filler-plasticizer systems.

Effect of volume content of fillers in PPO on volume resistivity.—The volume resistivities of separators made with the fillers used in this evaluation are shown in Fig. 2. These fillers were milled into PPO-chloroform solutions without an organic additive. The curve for Microtalc in PPO shows a decreasing volume resistivity with increasing volume percent. This material has a surface area of ~3 m^2/g (Table III). The curve for synthetic magnesium aluminosilicate (NAS-100) in PPO is similar to that for Microtalc except that the larger surface area of NAS-100 (280 m^2/g, ~100 times greater than that of Microtalc) produces a correspondingly greater reduction in volume resistivity as filler volume content increases. The curve for P-9750 shows the effect of just a polyester plasticizer in PPO without any fillers. Since P-9750 is only slightly soluble in a dry PPO film [<10% by weight, (3)], it was assumed that when it was dispersed in the dry PPO film, it would segregate into discrete globules similar to filler particles. The plasticizer

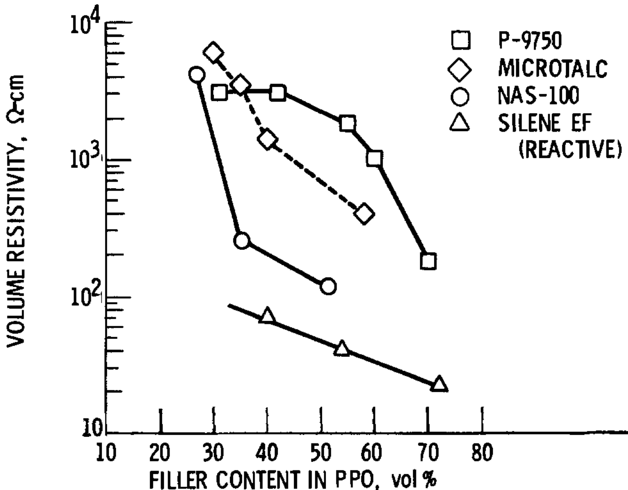

Fig. 2. Effect of filler volume content on volume resistivity, no plasticizer.

volume content without fillers had little effect on the volume resistivity until its volume percent was greater than 50% (greater than the CPVC). Reprecipitated (synthetic) calcium silicate filler (Silene EF), with a surface area of ~57 m^2/g (Table III), reacts with the electrolyte and leaves voids filled with gelatinous, hydrated calcium oxide. This curve is described in Ref. (4) and is shown here for comparison as typical of reactive filler formulations.

Effect of volume content of filler with organic additive (plasticizer) in PPO on volume resistivity.—The data in Fig. 3 provide an insight into the interaction that results from combining the proper (4) organic additive (P-9750) with an inert filler. Magnesium titanate (Mg_2TiO_4) has a surface area of approximately 3.5 m^2/g and a mean particle diameter of 1.7 μm, about the same as Microtalc (Fig. 2). However, the Mg_2TiO_4 with plasticizer results in a volume resistivity an order of magnitude lower than that for Microtalc without plasticizer (data from Table II for formulas X47NF, X37NF, and X39NF). As the filler surface area increases the resistivity decreases. When the filler volume percent exceeds the CPVC (~40-45%), the resistivity is lower than would be expected from a linear extrapolation of the other two points.

Figure 3 also shows the effect of a fixed amount of fine-particle fumed silicon dioxide (Cab-O-Sil) com-

Table III. Particle sizes and surface areas of reactive and inert fillers

	Particle size, μm	Surface area, m^2/g

	10.1	2317	61

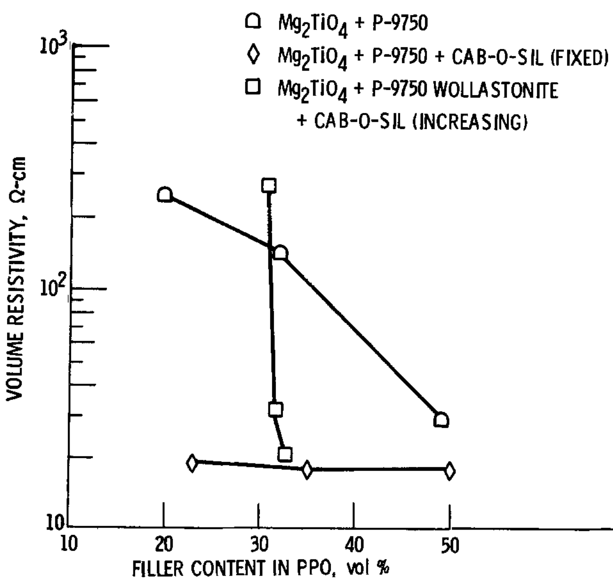

Fig. 3. Effect of volume content of filler plus organic additive (plasticizer) on volume resistivity.

bined with a larger amount of magnesium titanate with plasticizer. The curve represents the total for both fillers. The addition of electrolyte-reactive Cab-O-Sil, which has a mean particle size of 0.015 μm and a surface area of ~210 m^2/g (Table III), decreased the volume resistivity of Mg_2TiO_4 plus P-9750 by an order of magnitude. The data for formulas X31, X37, and X39 from Table II show that adding Cab-O-Sil increased the surface area significantly so that doubling the Mg_2TiO_4 content had little effect (20%) on surface area. Volume resistivity did not decrease significantly over the range investigated, even when the CPVC was exceeded (X39).

Figure 3 also shows the effect of an inert filler combination of magnesium titanate, natural calcium silicate (wollastonite P-15), and an increasing content of electrolyte-reactive Cab-O-Sil (0-3 v/o) with the plasticizer present. Data from Table II (formulas X47W, X47W1, and X47W2) show a pronounced drop in volume resistivity (445 Ω-cm to 21 Ω-cm) and at the same time a sharp increase in surface area (183 m^2/g to 1025 m^2/g) as the Cab-O-Sil content increased. The actual relationship of volume resistivity to filler surface area is described in detail later.

Effect of organic-additive (plasticizer) content on volume resistivity.—To more fully understand the role of the plasticizer and to estimate the thickness of the adsorbed layer on the filler particles, we attempted to measure the amount of P-9750 associated with the filler by using the ratio of P-9750 to PPO determined as described in the section Experimental Procedure. The calibration data, the regression line, and the results for the various formulas are shown in Fig. 4. The formulas are shown in Table II. Except for two points (X37 and X47W in Fig. 4), the data indicate that from 28 to 32 cm^3 of P-9750 remained in solution. The remaining 12-16 cm^3 are assumed to be associated with the settled filler particles.

From the surface areas given for the fillers in Table III, the total filler surface areas of the coating materials shown in Fig. 3 range from 1.8×10^6 to 1.5×10^7 cm^2. Since an average 14 cm^3 of P-9750 is assumed to be associated with the fillers, the organic-additive film deposited on the particles is 8-23 nm (80 to 230Å) thick. This is in the same range as the average pore size (5-15 nm)[4] for PPO-based separators as determined by water permeability (6) on KOH-soaked separators treated as described in the section Determination of Volume Resistivity.

The X47W point in Fig. 4, even though it is outside the range of the other points, is apparently consistent. The material (Table II) has a small calculated surface area (183 m^2/g) and would therefore be associated with less plasticizer. The calculated plasticizer layer is 3.2 nm thick, which could account for the high resistivity (445 Ω-cm) that was measured. The other outside point (X37) indicates a greater adsorption of plasticizer on the particles than for the other cases. There is no obvious or plausible explanation for it at this time.

[4] M. Reid of Lewis, Unpublished data (1977).

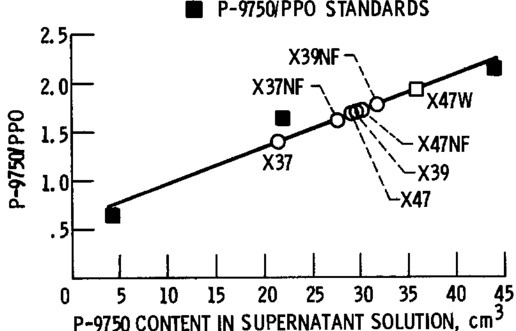

Fig. 4. Ratio of P-9750 to PPO as related to amount of P-9750 in supernatant solution.

BET measurements of separator pore size show a fairly sharp peak in the 2.5 nm region and a less well-defined region from 5 to 25 nm, the limit of the method. The smaller, 2.5 nm pores presumably are due to the pathway left by the evaporating solvent. Hence, it appears that ionic conduction through the separator depends primarily on the thickness of the ionic conduction pathway through and around the filler particles. This pathway is created by reaction of KOH with the adsorbed organic additive. A model of this pathway concept is shown in Fig. 5. Ion conduction is improved because pores are created by the reaction of fine-particle fillers with the KOH electrolyte. The pathways created by solvent evaporation probably also contribute. The reaction of the polymeric polyester (organic additive) with the KOH produces 1,2 propanediol and the potassium salt of azelaic acid. The diol, soluble in KOH, tends to improve volume resistivity while the salt presumably remains in the pathway as insoluble potassium azelate and further restricts the average diameter of the pathway.

Effect of filler surface area on volume resistivity.—The volume resistivity data in Fig. 3 show a marked dependence on the amount of fine-particle silica added to the coating formula. Figure 6 shows volume resistivity as a function of total filler surface area, in m^2/47g of PPO (with 47g of P-9750). The symbols are indentical to those in Fig. 3 and represent the same materials as well as X47 (circle) from Table II.

The two triangular points determine the line passing through the data points. This line was predicted from coefficients derived from a linear regression analysis of log (Ω-cm) as a function of total filler surface area in 47g of PPO (with 47g of P-9750). The correlation coefficient is −0.88. The fit is good considering that the data were taken from coating formulas containing from 1 to 3 fillers with varying surface areas. The two data points in Fig. 6 labeled X47W2 and X37 (Table II) demonstrate the proportional relationship of volume resistivity to the surface area of the fillers. The volume of Cab-O-Sil in X47W2 (1.9 cm^3) is 84% of that in X37 (2.28 cm^3). The surface area of X47W2 (1025 m^2/g) is 81% of that of X37 (1258 m^2/g), and the reciprocal volume resistivity of X47W2 (1/21 Ω-cm) is 84% of that of X37 (1/17.7 Ω-cm).

Effect of volume percentage of fillers in Kraton G on volume resistivity.—A more flexible separator system than could be obtained with PPO was desired for Ni-Zn cells. Based on results of 500 hr of immersion in 45% KOH at 105°-110°C, a Kraton G block copolymer was selected as the coating resin for this application.

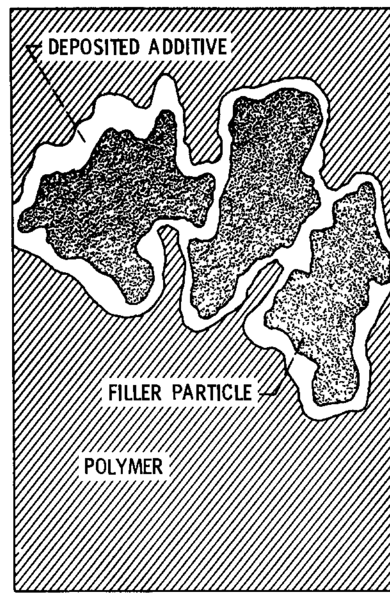

Fig. 5. Simplified ionic conduction model

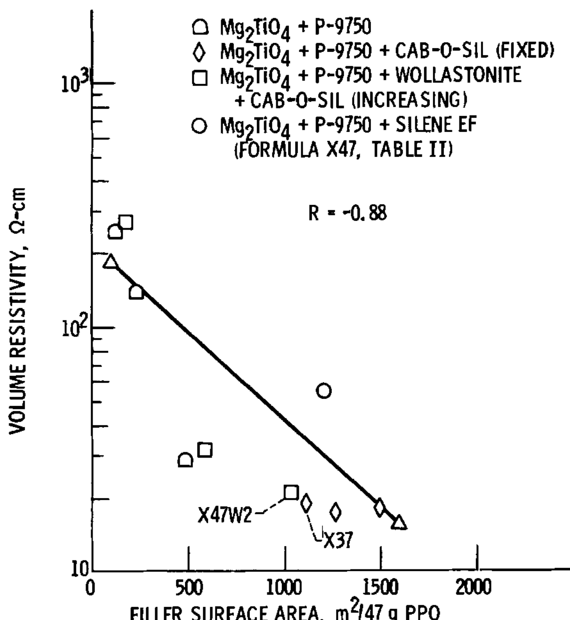

Fig. 6. Effect of total filler surface area on volume resistivity of PPO coatings.

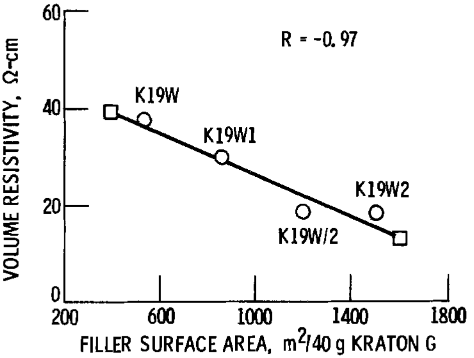

Fig. 7. Effect of total filler surface area on volume resistivity of Kraton G coatings.

Tests were performed to determine if the control of volume resistivity in PPO was more generally applicable to other polymer systems. An epoxidized soya bean oil plasticizer, Paraplex G-62 (a polar compound), was used with the Kraton G. One of its reaction products with KOH was ethylene glycol [Ref. (4), Table IV].

The effect on volume resistivity of the volume percentage of fillers in Kraton G (with no plasticizer) was studied. Table IV shows the effect of Silene EF and Cab-O-Sil on volume resistivity. These data indicate that 10.1 v/o of Cab-O-Sil is equivalent to 39.1 v/o of Silene EF. The effect is presumably due to the greater surface area of Cab-O-Sil. Table V shows the effect of adding the plasticizer to the polymer along with fillers; compare formulas K52, K53, and K51. The addition of a small volume percentage of Cab-O-Sil (formula K53, Table V) to the Silene EF mixture (formula K51) produced a substantial drop in volume resistivity.

This effect was then tested in actual separator coatings that applied the principle demonstrated in Fig. 3, that of increasing the amount of the fine-particle reactive silica in a coating mixture containing the Kraton G polymer, a plasticizer, and two unreactive fillers—lead titanate and natural calcium silicate (wollastonite).

These results are shown in Table V and Fig. 7. Formula K19W contains no Cab-O-Sil. Formula K19W2 contains twice as much as K19W1. The K19W/2 is a mixture of equal volumes of Silene EF and wollastonite, the total volume of which is equal to the volume percentage of wollastonite in the other formulas. The square points in Fig. 7 used to draw the curve represent two points predicted by the linear regression analysis of volume resistivity as a function of the surface area of fillers in 40g of Kraton G. The linear correlation coefficient for the regression analysis is −0.97.

These data show an effect similar to that observed with fillers and an organic additive to PPO. This method of resistivity control is therefore also useful and predictable in at least one other resin-plasticizer system and may be generally applicable.

Concluding Remarks

Small percentages of high surface area, fine-particle silica incorporated in coating systems where the filler content is below the critical pigment volume concentration have been shown to be a predictable means of controlling the volume resistivity of the coated substrate. Many of the formulas described in this paper have also been evaluated as separators in nickel-zinc and silver-zinc cells. Some of these cells have shown acceptable performance (9).

On High Temperature Oxidation of Chromium

I. Oxidation of Annealed, Thermally Etched Chromium at 800°-1100°C

K. P. Lillerud and P. Kofstad

Department of Chemistry, University of Oslo, Blindern, Oslo 3, Norway

ABSTRACT

Oxidation of annealed, thermally-etched chromium has been studied at different oxygen pressures ranging from 10^5 to $7 \cdot 10^{-2}$ Pa in the temperature range 800°-1100°C. A varied oxidation behavior is observed: at 10^5 Pa O_2 and 800°C the oxidation is approximately logarithmic, while above 900°C it is parabolic followed by repeated breakdowns and protective stages. At reduced oxygen pressures the oxidation behavior changes and becomes linear at the lower oxygen pressures. The different kinetics are correlated with properties of the Cr_2O_3 scales which may crack, wrinkle, or balloon depending upon the reaction conditions. Large compressive stresses are built up in the scales during oxidation and the ability of the scale to deform increases dramatically with decreasing partial pressure of oxygen. Under most conditions the oxide scales become detached from the metal substrate. It is concluded that volume diffusion and transport along cracks and grain boundaries contribute to the growth of Cr_2O_3 scales.

Chromium-bearing alloys owe their high temperature corrosion resistance to formation of protective layers of Cr_2O_3 (1-3). In spite of the importance in innumerable practical applications, the growth mechanism of Cr_2O_3 scales under various conditions is still in need of further clarification. This also applies to the defect structure and transport properties of Cr_2O_3 (4).

Although unalloyed chromium is not used as a constructional material, the reaction of chromium with oxygen at high temperatures has been extensively studied in order to characterize the reaction behavior and unravel the growth mechanism of Cr_2O_3 (5-18). This work extends such studies. This and the subsequent paper (19) deal with the oxidation behavior of annealed, thermally etched chromium at different oxygen pressures in the temperature range 800°-1100°C, properties of Cr_2O_3 scales, and the oxidation mechanism of chromium.

Literature Survey

The chromium-oxygen system.—Cr_2O_3 is the only solid chromium oxide that is thermodynamically stable at high temperatures. Cr_2O_3 has the corundum structure and can as such be grouped with oxides such as α-Al_2O_3, Fe_2O_3 a.o. This structure can be considered to consist of hexagonally close-packed oxygen atoms (ions) where the chromium atoms (ions) occupy two-thirds of the octahedral sites (4).

Solid CrO is a metastable oxide, but it can, for instance, be produced by partial decomposition of chromium oxalate (20). The oxide has been identified in chromium oxide layers on oxidized chromium by means of secondary ion mass spectrometry (21). Hagel (9) also reports in connection with studies of oxidation of chromium that in one exposure at 1100°C five lines for an unknown fcc compound of $a_0 = 4.02$Å were found. This may reflect CrO. The pattern could not be repeated on other samples treated in the same manner (9).

Key words: metals, corrosion, SEM, mass transport.

Higher oxides of chromium, *e.g.*, CrO_2, CrO_3, are only stable in solid form at low temperatures (22), and have as solids not been shown to be of importance in high temperature oxidation of chromium. However, volatile chromium oxide species may be important (23). CrO_3 is the important specie to consider in oxidizing atmospheres (15, 24-26). It evaporates from Cr_2O_3 in oxygen atmospheres: $1/2\ Cr_2O_3 + 3/4\ O_2 = CrO_3(g)$. Accordingly the evaporation rate is proportional to $p_{O_2}^{3/4}$ (24-26). Thus CrO_3 evaporation is important at "high" partial pressures of oxygen, *i.e.*, at atmospheric or near-atmospheric oxygen pressures, at high temperatures.

Oxidation of chromium in oxygen.—The high temperature reaction behavior of chromium in oxygen has been investigated at temperatures up to 1400°C (5-18). A number of publications report results of kinetic studies. Chromium exhibits protective oxidation behavior, *i.e.*, the reaction rate decreases with time.

The kinetics above 700°C are generally interpreted as parabolic. Reported values of corresponding parabolic rate constants are summarized in Fig. 1. A striking feature is that the k_p values vary by more than four orders of magnitude in the temperature range 1000°-1200°C. It may be noted that some investigators, and apparently depending on the pretreatment of specimens and reaction conditions, find periodic increases in the reaction rate and where the overall kinetics can be considered as a sequence of stages with protective behavior.

Below 700°C the reaction behavior changes. Young and Cohen (17) report that the oxidation in the temperature range 300°-600°C involved an initial logarithmic stage, which duration decreased with increasing temperature, followed by parabolic oxidation. The logarithmic rate constant exhibited a posi-

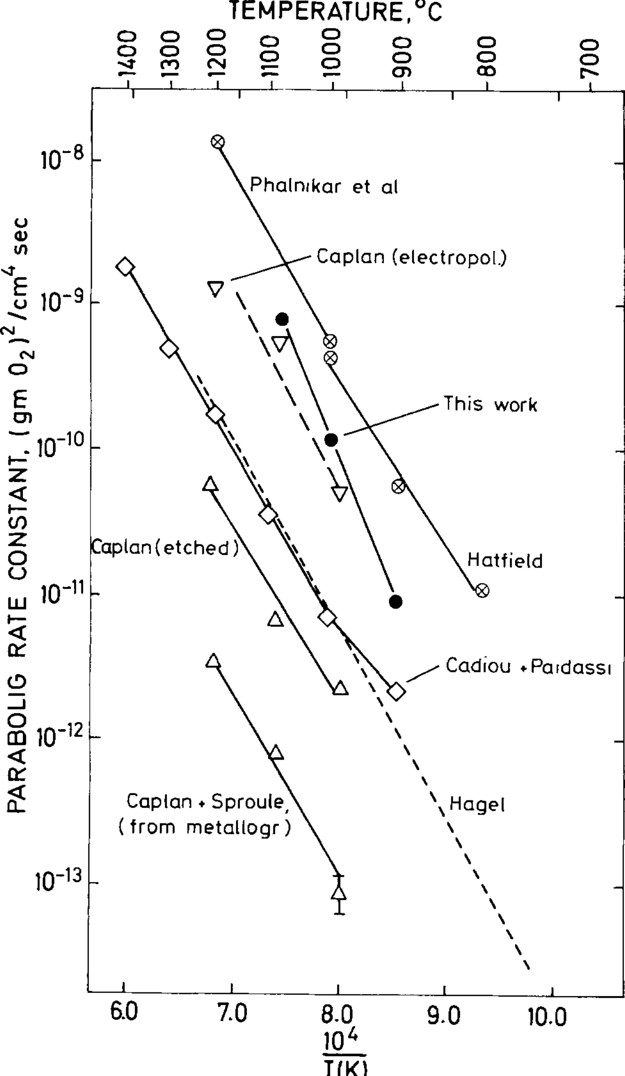

Fig. 1. Summary of reported parabolic rate constants for oxidation of chromium in oxygen in the temperature range 700°-1400°C. Results of this study on annealed, thermally etched chromium are also included. Studies by Hatfield (5), Phalnikar, Evans, and Baldwin (7), Hagel (9), Cadiou and Paidassi (10), and Caplan and Cohen (11, 14). Values of Gulbransen, and Andrew (6, 8), which are not included in the graph, are similar to those of Hagel.

tive pressure dependence, while the parabolic rate constant had a negative pressure dependence, *i.e.*, this rate constant increased with decreasing oxygen pressure. Such a pressure dependence cannot be explained in terms of a reaction governed by homogeneous diffusion through the scale (*e.g.*, Wagner mechanism), and a model is advanced where it is assumed that the concentration of adsorbed oxygen species is determined by an adsorption equilibrium on thin compact areas of the oxide scale, while the rate-determining growth occurred at areas with thicker porous oxide.

Much effort has been expended to explain the large discrepancies in oxidation rates at high temperatures. Various factors have been demonstrated or suggested as reasons for the differences.

An important factor is specimen preparation. This has particularly been demonstrated by Caplan *et al.* (11-14). The surfaces were prepared in different ways: abrading, electropolishing in various electrolytes, etching, and combinations of these. A general feature of these results is that electropolished specimens oxidize rapidly; for etched chromium some orientations oxidized rapidly, while others oxidize much slower. Nonuniform oxide layers exhibiting nodule growth, blistering, wrinkling, and multilayered ballooning are formed during the more rapid oxidation. Caplan *et al.* conclude that the growing Cr_2O_3 scales develop compressive stresses. The slower oxidation, which takes place on some etched orientations, involves formation of plane-parallel layers of Cr_2O_3 consisting of monocrystalline (and apparently stress-free) oxide. It may be noted that the smallest k_p values in Fig. 1 are evaluated from metallographic cross sections by measuring the oxide thickness on areas with such monocrystalline oxide-layers (14). All other k_p values represent overall k_p's determined from thermogravimetric measurements.

Caplan and Sproule (14) deduced that the monocrystalline oxide grows by cation lattice diffusion. Nonuniform growth in the form of nodules, blisters, and multilayered balloons are concluded to take place by a two-way transport: metal ion (lattice) diffusion outward and oxygen ion diffusion inward along grain boundaries. The periodic sequences in protective reaction kinetics reflect breakdown of the scale and formation of new protective oxide underneath. They have further shown that the oxide formed on "rapidly" oxidizing, electropolished chromium is fine-grained, and that this in turn facilitates a rapid transport (grain boundary diffusion) through the scale. During blistering and ballooning the oxide is separated locally from the metal. However, this does not affect the oxidation rate, as the vapor pressure and evaporation rate of chromium (at sufficiently high temperature) is high enough to sustain the supply of chromium at the underside of the separated oxide layer(s). Gulbransen and Andrew (8) have also pointed out that the high vapor pressure of chromium is an important factor in oxidation of chromium at high temperatures (> ~1000°C).

Evaporation of CrO_3 is particularly important at high temperatures (> ~1000°C) and high oxygen pressures (15, 24, 26). In thermogravimetric studies of chromium oxidation one measures the net difference between oxygen uptake and oxide evaporation. Depending upon the reaction conditions, CrO_3 may accumulate in the gas space surrounding the specimen, and the surrounding gas may serve as a barrier to the CrO_3 evaporation (24, 25). Thus the measured net weight change of oxidizing specimens will be different for static gas conditions and various degrees of gas flow, size of the reaction chamber, the temperature gradient in furnace, etc.

It has been suggested that differences in the impurity levels of the chromium metal used in different studies may be responsible for differences in reaction rates. However, it is difficult to find any clear-cut correlations between impurity contents and reaction rates. This should not necessarily be taken to mean that impurities are without any effects. Caplan and Sproule (14) have, for instance, demonstrated differences in the growth mechanism of Cr_2O_3 on chromium metal and Fe-25% Cr.

The observed reaction behavior may be affected by the experimental procedure. In various studies the specimen may as part of each run be rapidly heated in the reacting gas from room temperature to the reaction temperature, or alternatively be heated in high vacuum to the reaction temperature before admitting oxygen. With these procedures thin oxide films are formed either in air prior to introducing the specimen in the apparatus, or through the heating to the reaction temperature either in the reacting gas or "vacuum." The oxide films thus formed may have different thickness, grain size, and morphology, and as such represent different "pretreatments" of the specimen surfaces prior to the recorded experiments. A type of pretreatment which has not been emphasized in previous studies is whether the chromium specimens are annealed, used in hot-rolled condition without annealing, as electrolytically prepared metal, etc.

Despite the large discrepancies in the values of k_p there are surprisingly small differences in the values of the corresponding activation energies above about 700°C. The activation energy is approximately 250 kJ/mole (60 kcal/mole). However, at lower temperatures (<700°C) the observed activation energies are smaller, about 145-165 kJ/mole (16, 17).

Hagel (9) measured oxidation of chromium at 750° and 1100°C at oxygen pressures ranging from 10^2 to 1 Pa O_2. He observed no or but a small decrease in k_p with increasing p_{O_2}. Within the reproducibility of the results the smallest value of the exponent n in the relationship $k_p \propto p_{O_2}^{1/n}$ was estimated to be about 40.

Walters and Grace (18) studied the reaction rate at 700°-990°C in H_2/H_2O mixtures with partial pressures close to those of the decomposition pressure of Cr_2O_3. The parabolic rate constant was interpreted in terms of the relationship $k_p \propto p_{O_2}^{3/16}$, which is the expected relationship if the oxidation is governed by lattice diffusion of triply charged chromium vacancies as the predominant defect. It should be noted, however, that diffusion-controlled parabolic oxidation at oxygen pressures close to the decomposition pressure of the oxide will always yield a positive pressure dependence. In this case the measurements were not sufficiently accurate and reproducible to discriminate between different defect structure models [see, for instance, Ref. (4)].

Materials and Methods

Materials

Chromium metal.—The chromium metal was prepared electrolytically. The supplier (Koch-Light Laboratories) reported the metal to have a purity of 99.99+%. Spectrographic analysis gave the following results: Al-not detected (<0.005%), Fe-150 ppm, Mg-n.d. (<0.001%), Ca-10 ppm, Cu-16 ppm, Ti-n.d. (<0.01%), Si-n.d. (<0.005%). Vacuum fusion gas analysis gave: H-200 ppm and 0-4150 ppm.

The as-received metal was brittle and could not be mechanically worked. The specimens, measuring approximately 1 · 10 · 15 mm, were therefore prepared by spark induction. The brittleness was to a large extent caused by the hydrogen content. The hydrogen escaped by heating the specimen in high vacuum up to 560°C. After this treatment the metal was considerably less brittle.

Specimen preparation.—The many methods of surface preparation often suffer from some disadvantage (11-14). Mechanical polishing deforms a thin, outer layer of the metal, and this part of the metal may exhibit a different reactivity than the "bulk" layers (17). Electropolishing and etching give surfaces with relatively large topography, and furthermore the etchant and electrolyte may not be completely removed from the surface. By electropolishing the oxide film may possibly have unusual oxidation states as it is formed in applied electric field. In this work a new method of specimen preparation was used: thermal etching in high vacuum.

Prior to the thermal etching the specimens were mechanically polished with emery paper of grade 220. After extended polishing with the same polishing paper, removed chromium filled the pores and the surface roughness of the paper, and during the latter polishing stage chromium was polished against chromium. This gave a surface with no visible polishing stripes at 500×. The as-received metal was examined by the Guinier method. This gave broad, diffuse lines indicating that the electrolytically prepared chromium was highly microcrystalline.

The thermal etching was done by heat-treating the polished specimens in the reaction chamber in high vacuum (<10^{-3} Pa) at 1075°C for 20 hr. During this treatment the vapor pressure and the corresponding evaporation rate of chromium was so high that the thin, room temperature oxide film was removed and no new oxide was formed on the surface. The specimens lost weight at a linear rate, which at 1075°C mounted to 0.44 mg/cm^2 hr. During this 20 hr high vacuum annealing the outer 12 microns of the chromium specimen were removed. The annealing produced well-developed crystallites and sharp diffraction lines by the Guinier method.

Chromium vapor pressures were calculated from the linear rates of weight loss during chromium evaporation in high vacuum by means of the Hertz-Langmuir equation. Values obtained at different temperatures are in excellent agreement with previously reported vapor pressure values (6, 27).

The oxidation runs were made by adjusting the temperature in the furnace to the desired reaction temperature while maintaining high vacuum. During the temperature change the specimens continued to lose weight corresponding to the vapor pressure of chromium. After the new temperature equilibration, the reaction was started by introducing oxygen in the system.

By this treatment the deformed outer layer of the specimen was removed, and it is believed that the surface was essentially free from any oxide at the start of the reaction.

Oxygen gas.—The oxygen gas was dried over silicagel before being introduced into the reaction chamber, but no further attempts were made to purify the gas.

Methods

Balance, thermogravimetric measurements.—The thermogravimetric measurements were made with a magnetic levitation balance of Sartorius Type 4201. The apparatus was evacuated with a pair of diffusion and rotary pumps giving a high vacuum of <10^{-3} Pa as measured with an ion gauge located above the reaction chamber.

The reaction chamber consisted of a mullite tube, which was directly melted on to the borosilicate glass in the rest of the high vacuum system. The temperature was continuously monitored with Pt/Pt 10% Rh thermocouple located next to the suspended specimen in the constant temperature zone of the reaction chamber. The specimen was suspended with a 0.2 mm Pt thread. Oxygen was continuously pumped through the reaction chamber from the top to the bottom during the oxidation run.

The reacted specimens were characterized by means of optical metallography, scanning electron microscopy, and x-ray diffraction.

Experimental Results

Thermogravimetric Measurements

Results at 10^5 Pa O_2.—The results of the thermogravimetric measurements of oxidation of annealed, thermally etched chromium at 10^5 Pa (1 atm) O_2 and at 800°, 900°, 1000°, and 1075°C are summarized in a double logarithmic plot of weight gain *vs.* time in Fig. 2. The fully drawn lines represent the directly measured, net weight gain during oxidation. The reproducibility of parallel runs were within 2%.

Figure 2 illustrates some salient features of the oxidation behavior of thermally etched chromium: (*i*) the reaction rate at 800°C decreases much faster with time than for a parabolic behavior. As illustrated in the semilogarithmic plot [weight gain *vs.* log (time)] in Fig. 3, the reaction kinetics can be described as approximately logarithmic. (*ii*) Up to approximately 10 hr of oxidation the amount of oxidation is approximately the same at 800° and 900°C. This feature, and a distinct change in the reaction kinetics from 800° to 900°C, points to a marked change in the oxidation mechanism between 800° and 900°C. (*iii*) The reaction kinetics at 900°, 1000°, and 1075°C

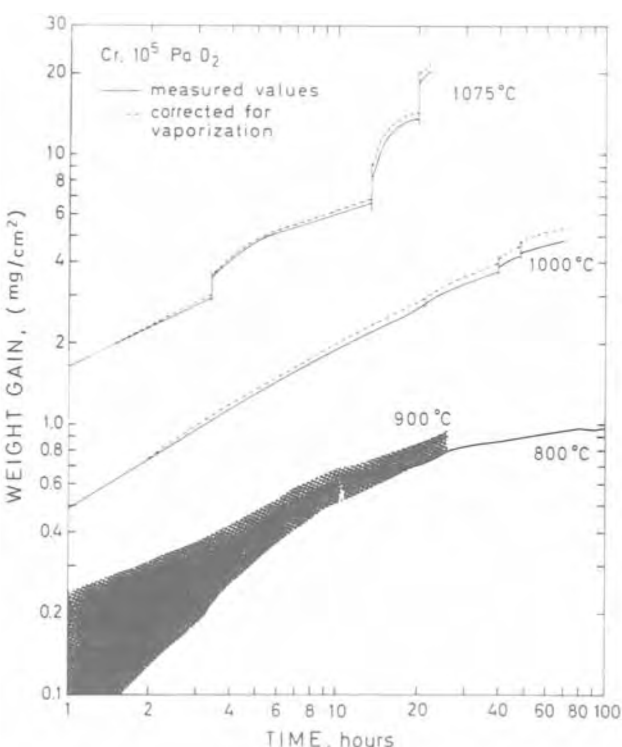

Fig. 2. Double-logarithmic plot (weight gain vs. time) of oxidation of thermally etched chromium at 800°, 900°, 1000°, and 1075°C and 10^5 Pa O_2. The fully drawn line shows the measured net weight gain during oxidation, while the stippled lines illustrate the total reaction by adding the weight loss due to CrO_3 evaporation to the net weight gain. The hatched regions indicate the uncertainties in the measurements (±0.1 mg) at low weight gains.

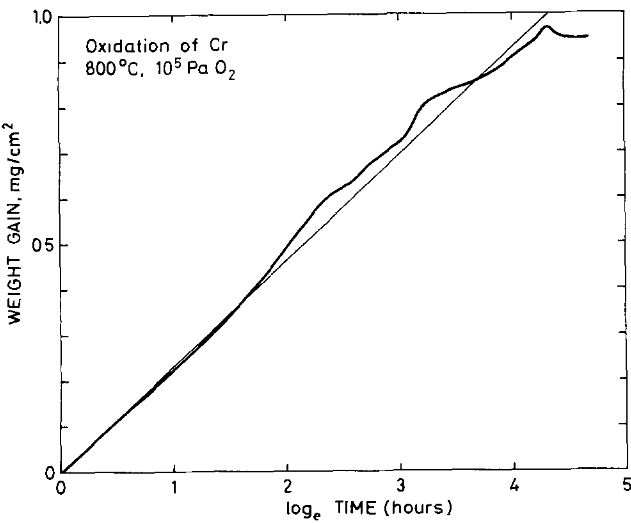

Fig. 3. Semilogarithmic plot [weight gain vs. log (time)] of oxidation of thermally etched chromium at 800°C and 10^5 Pa O_2.

can be described as approximately parabolic. This is further illustrated in Fig. 4 where the square of the weight gain is plotted as a function of time. But it may also be noted that the kinetics do not conform with an ideal parabolic rate. (*iv*) After extended oxidation (a weight gain of 2-3 mg/cm²) at 1000°C and 1075°C sudden increases take place in the oxidation rates, and the overall kinetics may be described as a sequence of stages with protective oxidation. This effect is much larger at 1075° than at 1000°C.

The parabolic rate constants during the initial oxidation at 900°, 1000°, and 1075°C corrected for oxide evaporation (see below) are included in Fig. 1. The values lie in the upper region of the previously re-

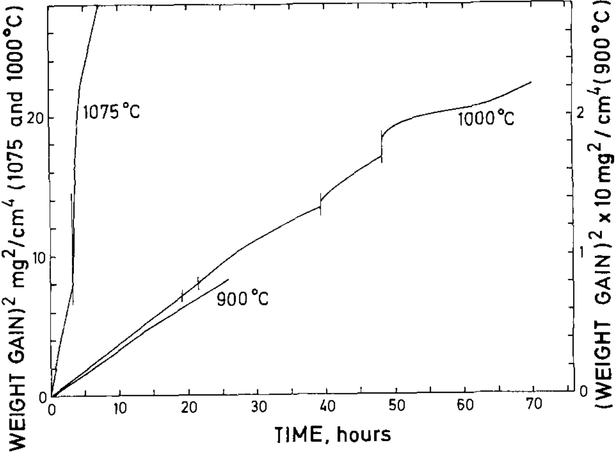

Fig. 4. Parabolic plot [(weight gain)² vs. time] of oxidation at 900°, 1000°, and 1075°C.

ported results. The activation energy as determined from these three points is 330 kJ/mole (78 kcal/mole), which is 30% higher than the average value from other studies. It should be noted that if values of k_p were evaluated from later stages of the reaction, as has been done in other studies (9, 10) somewhat lower values would have been obtained.

Oxidative vaporization of Cr_2O_3 during oxidation.—Oxidative vaporization of Cr_2O_3 as CrO_3 is significant during oxidation of chromium at high oxygen pressures and high temperatures. In order to correct the measured oxidation rates for this evaporative loss, the weight loss of a completely oxidized chromium specimen was measured at different temperatures and 1 atm O_2. The evaporation was followed for 24 hr at each temperature, and during each run a gas flow equal to that in the oxidation runs was maintained. The linear rates of weight loss at 1 atm O_2 were found to be $2.2 \cdot 10^{-2}$ mg/cm² hr at 1100°C, $6.7 \cdot 10^{-3}$ at 990°C, $2.1 \cdot 10^{-3}$ at 900°C. These results gave a straight-line relationship in an Arrhenius plot with an activation energy of 155 kJ/mole (37 kcal/mole). Extrapolation of these values gave a loss rate of $5 \cdot 10^{-4}$ mg/cm² hr at 800°C. These results have been used to correct the oxidation results to show the total rate of reaction at different temperatures. This is illustrated by the stippled lines in Fig. 2.

It is emphasized that these evaporation rates give no information about the thermochemistry of the reaction-controlled oxidation vaporization, but only provide information about the weight loss during the oxidation under the particular experimental conditions used. In the present study the oxygen atmosphere surrounding the specimens serves as a barrier to the free evaporation of CrO_3. The measured evaporation rates are much lower than calculated values for reaction-controlled vaporization at 1 atm O_2 as estimated from the data of Stearns *et al.* (6).

Results at reduced oxygen pressures.—800°C.—The results of thermogravimetric measurements at 800°C and oxygen pressures of 10^5 (760), $1.1 \cdot 10^3$ (8), 8 ($6 \cdot 10^{-2}$), and $6.7 \cdot 10^{-2}$ Pa O_2 ($5 \cdot 10^{-4}$ Torr) are shown in Fig. 5. The reaction kinetics at 10^5 Pa O_2 can be described as approximately logarithmic (Fig. 3). When the pressure is reduced to $1.1 \cdot 10^3$ and 8 Pa O_2, the initial period of rapid oxidation becomes shorter. This is followed by a period of slowly decreasing oxidation rate until the oxidation reaches the stage with essentially no oxidation.

With further reduction in oxygen pressure the oxidation kinetics are changed and can, within the sensitivity of the balance, be described as linear at $7 \cdot 10^{-2}$ Pa. It may be noted that the gas pressure is measured with gauges outside the furnace zone, and as molecular flow prevails in the reaction cham-

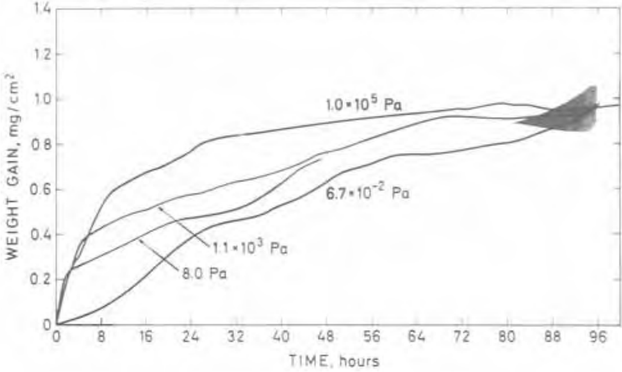

Fig. 5. Oxidation of thermally etched chromium at 800°C and oxygen pressures ranging from 10^5 Pa (760 Torr) to 6.7-7 · 10^{-2} Pa (~4.5 · 10^{-4} Torr). Weight gain of specimens (mg/cm^2) during oxidation as a function of time (hr). The hatched regions indicate the uncertainties in the weight gain measurements (±0.1 mg).

ber at this pressure, the real pressure at the specimen is slightly higher than indicated (28).

900°-1100°C.—When the temperature was increased to 900°C and further on to 1000° and 1075°C the studies revealed an unexpected change in the reaction behavior at different oxygen pressures.

At 900°-950°C the oxidation decreases slowly with decreasing partial pressure of oxygen in a manner similar to that at 800°C. At the lowest oxygen pressure, 7 · 10^{-2} Pa O_2, the oxidation is again approximately linear. However, as the temperature is increased to 1000° and 1075°C the oxidation is faster at oxygen pressures of 10^3-10^2 Pa than at 10^5 Pa. Furthermore, the kinetics are changed and can under these conditions be considered to be approximately linear within the time periods studied (up to 25 hr at 1075°C). On further reduction of oxygen pressure the oxidation rate again decreases with decreasing oxygen pressure and at the lowest pressure, 7 · 10^{-2} Pa O_2, the reaction is again linear. These features are illustrated in Fig. 6 and 7, which summarize results at 1000° and 1075°C, respectively.

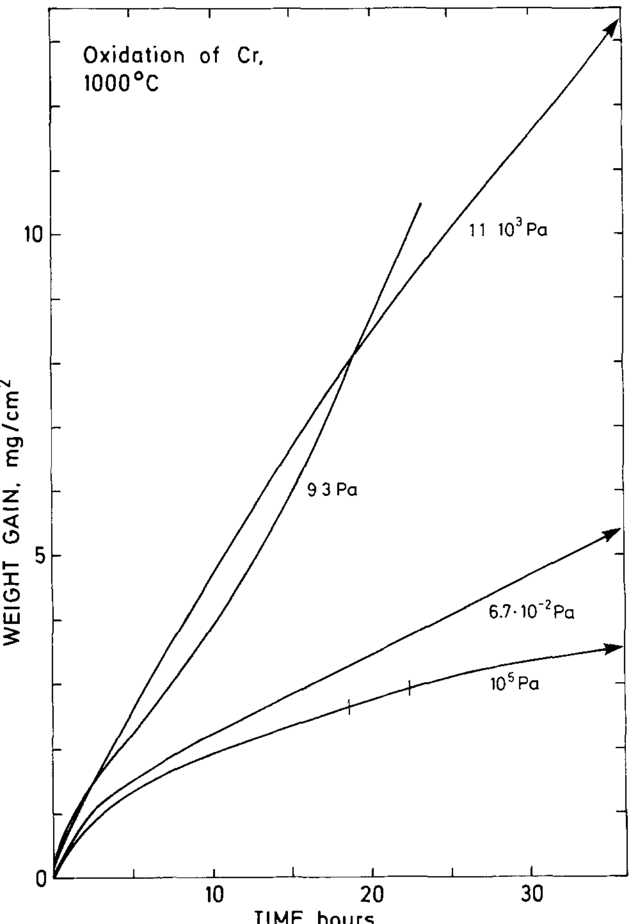

Fig. 6. Oxidation of thermally etched chromium at 1000°C and oxygen pressures ranging from 10^5 Pa to 7 · 10^{-2} Pa. Weight gain of specimens during oxidation as a function of time.

Characterization of Specimens

In most cases the most descriptive information on topography, morphology, and microstructure of Cr_2O_3 scales is obtained by examining fractured scales directly in the scanning electron microscope. Optical metallography and plane-polished cross sections often fail to uncover important details.

Oxide scales never spall at temperature. But specimens oxidized at atmospheric pressure at 800° and 900°C may exhibit violent spallation on cooling to room temperature. This is in all probability due to poor adherence of the scale to the metal substrate, growth stresses in the oxide, and the smaller thermal expansion coefficient of Cr_2O_3 compared to chromium metal.

Specimens reacted at 800°C.—Exposure at 1 atm O_2.—After oxide spallation only a few local areas are still covered with oxide scale. Figures 8 and 9 show examples of such fractured scales after oxidation at 800°C. Figure 8 refers to a specimen oxidized for 50 hr. The weight gain at this point was about 0.9 mg/cm^2, and the thickness of this layer is about 2 microns. At this stage, part of the scale is fine-grained, but also some larger grains are formed. These do not exhibit any crystal facets and also appear to consist of smaller crystallites. All in all, the morphology of the scale has similarities to that described by Young and Cohen (17) for chromium specimens (mechanically polished with subsequent electropolishing) oxidized for extended periods in oxygen at 300°-600°C.

These features may be compared with the morphology and microstructure of oxide scales after more extended oxidation as illustrated in Fig. 9a and b. These illustrations refer to a specimen oxidized for 127 hr, at which point the weight gain was about 1 mg/cm^2 and the oxidation rate was almost nil (Fig. 2). The scale is under these conditions highly protective. The larger grains have at this stage grown in number and size and the crystals have developed facets. Thus during the "logarithmic" oxidation the scales undergo recrystallization and crystal growth, and each oxide crystal tends to become more perfect. From these observations it can be concluded that the protective ability of the oxide is less dependent on the thickness of the scale than its morphology and microstructure and how well the crystals are developed.

Further examinations of Fig. 8 and 9 show that the scale is, at least partially, separated from the metal. No oxide can be detected on the metal after 127 hr of oxidation, and particularly Fig. 9 shows that the metal surface exhibits facets. From this it is concluded that there is a gap between the scale and the metal over most of the surface after prolonged oxidation. This is also probably a reason for the ease of spallation of the oxide on cooling.

Marker experiments were made at 800°C. A porous layer of gold (1-1.5 μm thick) was sputtered on one side of a few specimens. Such gold-sputtered specimens oxidized at the same rate as the ones without a gold layer. After oxidation for 24 hr the gold was located on the metal surface or at the inner layer of the oxide. However, there were indications that the gold influenced the morphology and microstructure of the scale in that plane-polished metallographic cross sections revealed more porosity on the unsputtered side than on the sputtered one.

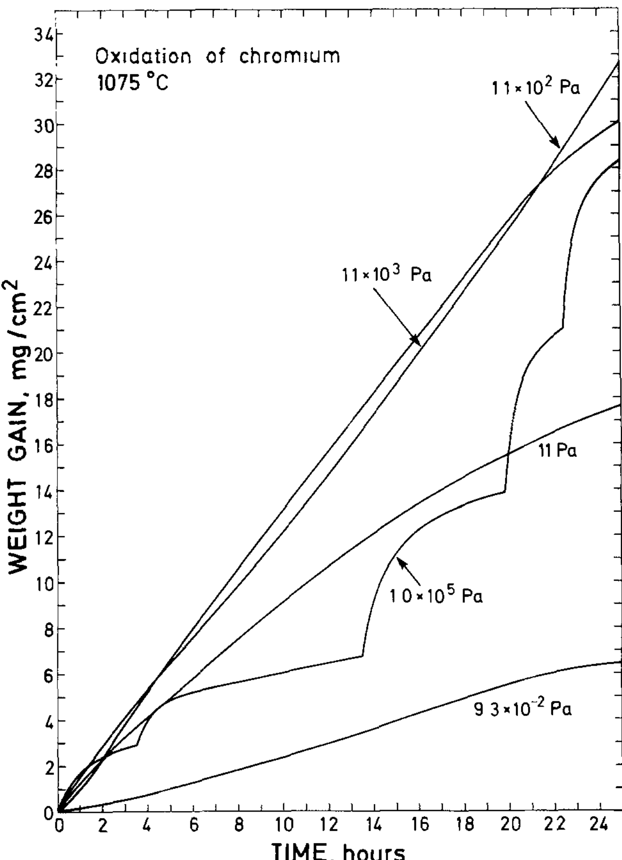

Fig. 7. Oxidation of thermally etched chromium at 1075°C and oxygen pressures ranging from 10^5 Pa to $7 \cdot 10^{-2}$ Pa. Weight gain of specimens during oxidation as a function of time.

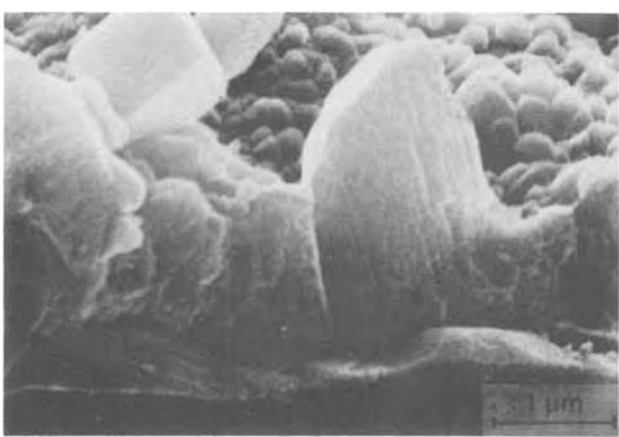

Fig. 8. Scanning electron micrograph of chromium specimen oxidized for 50 hr at 800°C and 10^5 Pa O_2. The picture shows a fractured edge of the scale with the chromium metal beneath.

Exposure at reduced oxygen pressures.—The morphology and microstructure of the scale changes markedly with oxygen pressure. On reducing the oxygen pressure to $1.1 \cdot 10^3$ Pa, marked changes in the scale are evident. This is illustrated in Fig. 10. On cooling to room temperature the scale has separated into 2-3 layers. The outer and middle layer of the scale exhibit large topography and adhere to each other in many places. The inner layer is flat and is separated from the other two layers. The crystallite size in the scale decreases inward through the layers of the scale, and for the inner layer the crystallite size is small and crystal facets can no longer be discerned.

On further reduction of the oxygen pressure to less than 10 Pa O_2 the scale is again single-layered and its microstructure resembles the inner layer in Fig. 10 (10^3 Pa O_2).

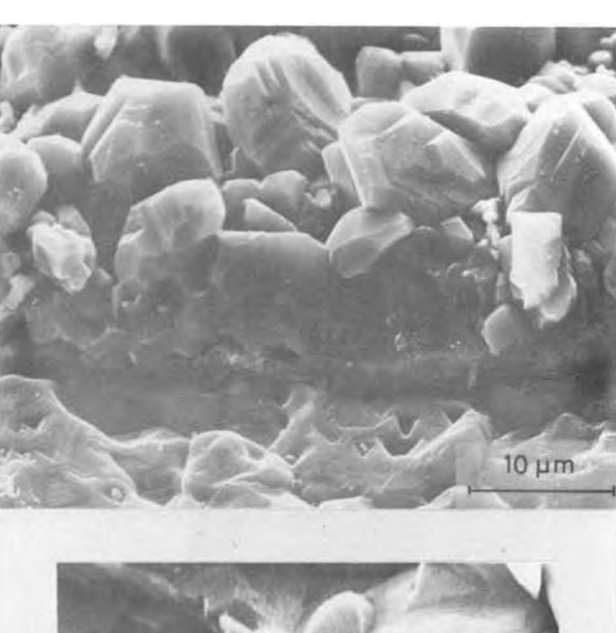

Fig. 9. Scanning electron micrograph of chromium specimen oxidized for 127 hr at 800°C and 10^5 Pa O_2. a shows a fractured edge of the oxide scale with the metal beneath, and b a detail of a at larger magnification showing the inner surface of the scale and the surface of the metal.

At $7 \cdot 10^{-2}$ Pa O_2 the morphology and microstructure of the scale is again markedly changed. Under these conditions the oxide grows as a single layer and is completely separated from the metal on the plane surfaces of the specimens. The scale neither cracks nor spalls on cooling to room temperature. Various features of the scale may be noted: the scale wrinkles and buckles. This feature is illustrated in Fig. 11a which shows the underside of the scale (facing the metal). By comparing with the surface appearance of the thermally etched metal before oxidation (Fig. 11b), it appears that the oxide scale has particularly deformed in areas where the oxide originally grew on the metal grain boundaries.

Figure 12a shows the fractured cross section of the scale. The oxide thickness is about 2 μm. An additional feature under these conditions is that whiskers are formed on the outer surface. This is illustrated in Fig. 12b. Crystal growth also takes place at the inner surface of the scale (facing the metal). This is further illustrated at a larger magnifications in Fig. 12c and d.

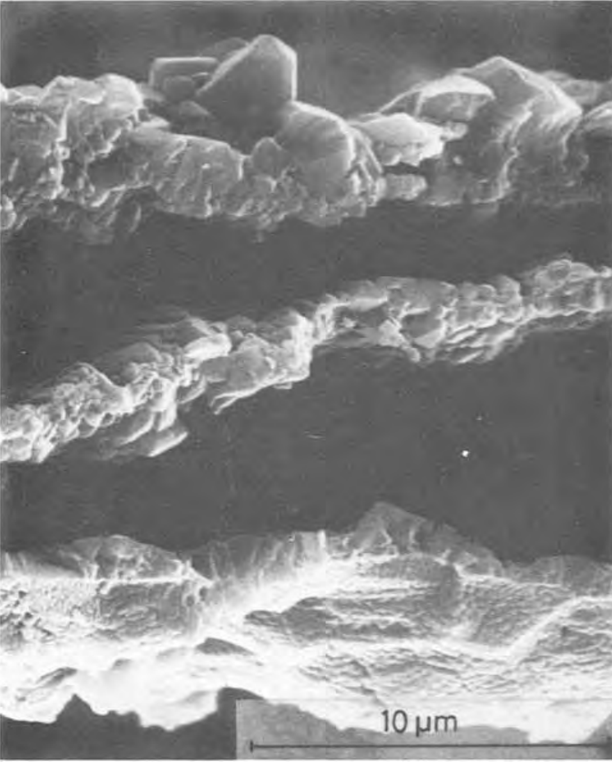

Fig. 10. Scanning electron micrographs of fractured scale of Cr_2O_3 after oxidation for 94 hr at 800°C and 10^3 Pa. The scale consists of three distinct layers.

All in all, the changes in topography, morphology, and microstructure of the scale with oxygen pressure points are important aspects of the properties of the oxide and the reaction mechanism. The results show that considerable growth stresses build up in the scale during its growth. These are partially alleviated by plastic deformation of the scale, and the oxide plasticity increases markedly with decreasing partial pressure of oxygen. The buckling and wrinkling of the scale and the large concurrent increase of the scale surface clearly suggests that the oxide not only grows in thickness, but also sideways (along the metal surface). This, in turn, suggests that the oxide, at least partially, grows within the scale probably as a result of countercurrent transport of the reactants.

Specimens reacted at 900°-1100°C.—Exposure at 10^5 Pa O_2.—At 900°-1075°C the initial oxidation is approximately parabolic. After extended oxidation at 1000° and 1075°C the kinetics involve a sequence of protective stages. It is reasonable to assume that this behavior reflects a periodic breakdown of the scale and formation of a new protective layer.

When the oxidation is stopped before the kinetics suggest any scale breakdown, the scales appear to be compact. But after more extended oxidation, and after one or more sequences of protective stages, fractured edges reveal some porosity in the scale. This is illustrated in Fig. 13a, which shows the fractured edge of the oxide scale on a specimen oxidized for 22 hr in 10^5 Pa at 1075°C. There is no clearly delineated layered structure which reflects each individual change in the kinetics; rather relatively large pores are distributed throughout the outer layer of the scale.

Figure 13b shows a detail of the surface of the metal and the inner surface of the scale. The metal surface is partly covered with oxide. But also here it is suggested that there has been a gap at temperature between the metal and the oxide scale over most of the surface. There is also considerable porosity in the oxide at the metal/scale interface.

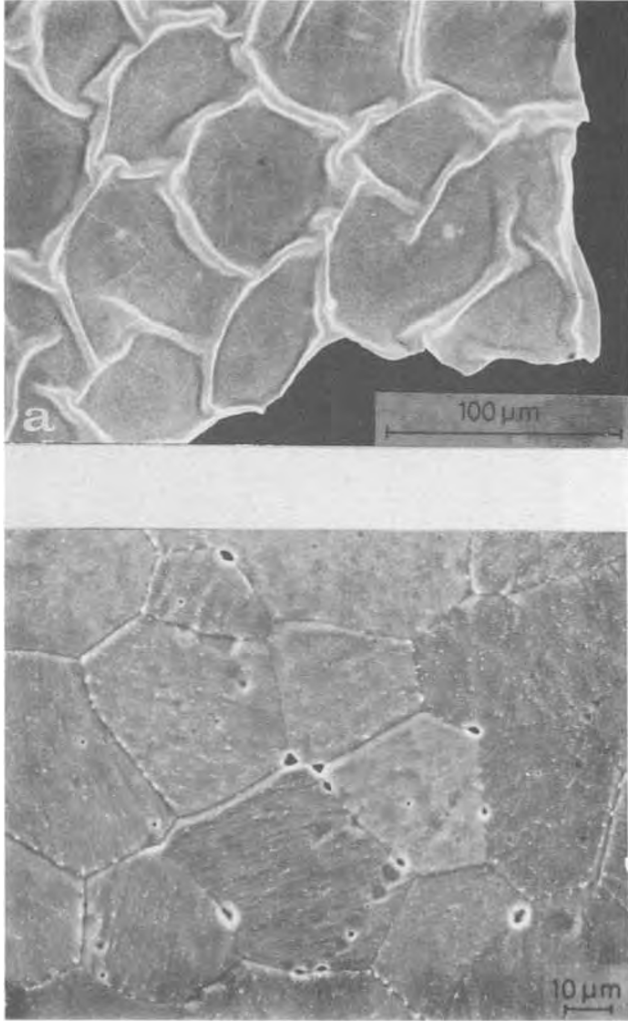

Fig. 11. (a) Scanning electron micrograph of fractured edge of Cr_2O_3 after oxidation for 3 hr at 800°C and $7 \cdot 10^{-2}$ Pa O_2; (b) scanning electron micrograph of surface of thermally etched and annealed chromium prior to oxidation.

After more extended oxidation at 10^5 Pa O_2 at and above 1000°C the individual oxide grains appear to be single crystals. This is illustrated in Fig. 14a, where oxide crystals from an area within the scale close to the inner surface are shown. The micrograph is taken from the specimen shown in Fig. 13. The individual crystals have a shape consistent with hexagonal structure. But it is also interesting to note that the shape of the crystals at the inner surface of the scale appear to reflect a cubic symmetry (Fig. 14b). This probably reflects the presence of a crystal layer different from Cr_2O_3. It is tentatively concluded that these crystals consist of CrO, as one of its modifications has the NaCl structure. X-ray diffraction studies were made directly on the inner surface of the scale, but these failed to reveal any diffraction lines other than those of Cr_2O_3. This may reflect that CrO is only present in small amounts or that CrO disproportionates or has been oxidized to Cr_2O_3 on exposure to the atmosphere.

It is also important to note that the Cr_2O_3 scales formed during extended oxidation at and above 1000°C, and involving one or more breakdowns of the scale, do not spall during cooling to room temperature. Although there is a loss of contact between the scale and the metal during cooling, the scales are retained on the specimens. This feature suggests that the breakdown of the scale alleviates growth stresses in the scale. Increased creep and plastic flow of the oxide

Fig. 12. with higher temperature will probably also be a contributing factor (19).

Exposure at reduced oxygen pressures.—The changes in the kinetics and oxidation rates when chromium is exposed to different oxygen pressures are directly associated with changes in the mode of oxide growth. Different aspects are illustrated by the scanning electron micrographs given in Fig. 15-22. In general the same features are observed at both 1000° and 1075°C.

There are marked differences in the surface appearance of specimens oxidized at different oxygen pressures. This is illustrated in Fig. 15a-c, which show scanning electron micrographs at low magnification of specimens reacted at 1075°C at 10^5, 130, and $7 \cdot 10^{-2}$ Pa O_2, respectively.

After oxidation at about 100 Pa O_2 the surface has an uneven appearance. It is best described and illustrated by a view at higher magnification. This is given in Fig. 16, which shows the fractured edge of the oxide on a specimen oxidized for 23 hr at 1000°C and 100 Pa O_2. The oxide is heavily buckled and deformed. This indicates that large growth stresses are produced during the scale growth. Compared to 10^5 Pa O_2, the oxide formed at this lower oxygen pressure is considerably more deformed and the stresses are partially alleviated by this process.

But closer examination also shows that the oxide cracks in numerous sites during oxidation. This is illustrated in Fig. 17a and b. Figure 17a shows a detail where cracking has occurred just before the oxidation was stopped. The cracking always occurs on the inside of the layer; when viewed from the outside there is no evidence of cracks. Figure 17b shows another detail where a crack has been healed by further deformation and secondary oxide growth.

The approximately linear kinetics observed under these conditions are concluded to reflect that a large number of cracks are being formed during the course of oxidation. The higher oxidation rate at this pressure range than at 10^5 Pa O_2 is probably due to penetration of oxygen gas at the cracks before these are healed. This is further corroborated by the fact that oxide crystals are being formed also on the metal surface under these reaction conditions. This may be seen in Fig. 16 and at a higher magnification in Fig. 18. It may be noted that the oxide crystals on the chromium metal surface have an external geometry characteristic of compounds with a cubic metal structure. The same cubic crystals were observed at 10^5 Pa, and are tentatively concluded to consist of CrO. These cubic oxide crystals are found in varying amounts at the chromium metal surface on all specimens examined in this work. But they are particularly observed in the pressure range with the relatively high oxidation rates caused by cracking of the scales (Fig. 16-18).

When the oxidation is carried out at even lower oxygen pressures (<about 100 Pa), the oxide scales grow detached from the larger, plane surfaces of the specimens. The scales bulge away from the metal surface; an example of this is shown in Fig. 16c. The scales exhibit a high degree of plasticity. A particularly remarkable example of this is shown in Fig. 19 which refers to a specimen oxidized at 1075°C and $7 \cdot 10^{-2}$ Pa O_2. In this case the scale has sagged giving the specimen a pear-shaped appearance.

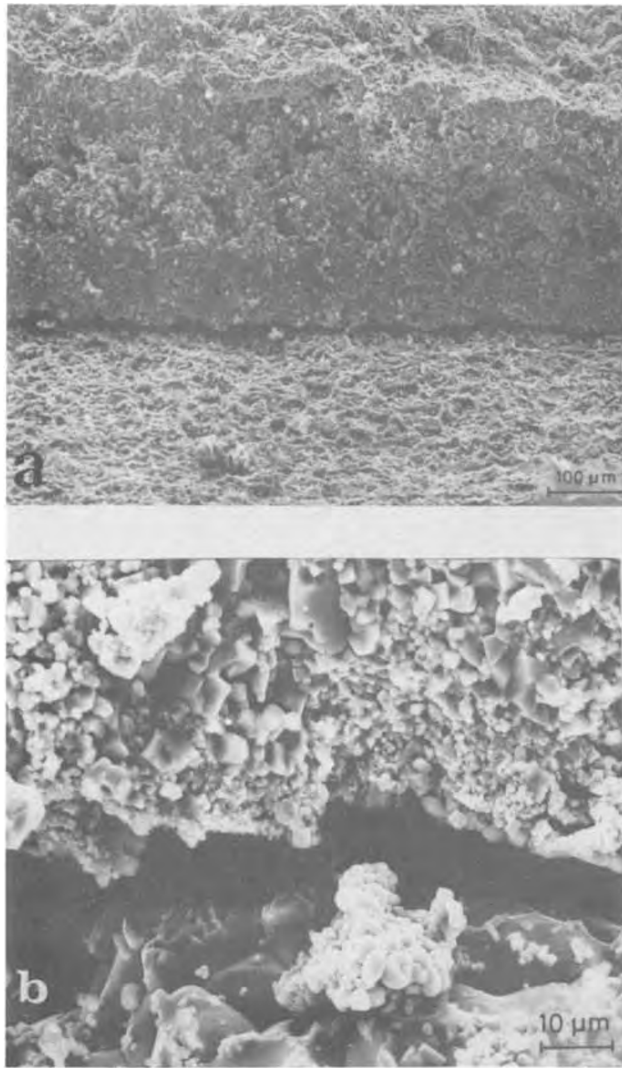

Fig. 13. Scanning electron micrograph of chromium specimen oxidized for 22 hr at 1075°C and 10^5 Pa O_2, (a) fractured edge of the oxide scale on the metal surface. The outer part of the scale contains appreciable porosity in the form of voids; (b) detail of (a) showing the inner surface of the scale and the surface of the metal.

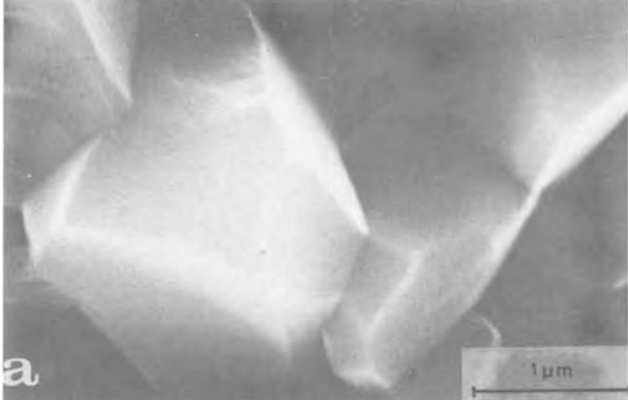
Figure 20a shows the cross section (fractured edge) of the scale from a specimen oxidized for 23 hr at 1075°C and $7 \cdot 10^{-2}$ Pa O_2. Such scales showed no evidence of cracking. The crystallite size changes gradually through the scale from relatively fine-grained at the outer surface (Fig. 20b) to more coarse-grained in the inner part of the scale (Fig. 20c). The fine-grained microstructure and smooth surface gave the specimens a shiny appearance.

For specimens oxidized at 1000° and 1075°C and at $7 \cdot 10^{-2}$ Pa O_2 single crystals of chromium metal were observed on the inner surface of the oxide scale. This feature is illustrated in Fig. 21a and b. This clearly illustrates the importance of chromium vapor transport across the gap between the metal and the bulging oxide scale. It may be noted that the chromium crystals are located at one end (the lower end) of the specimen. This feature, and the relatively large amount of chromium crystals, suggests that there has been a vapor transport of chromium as a result of a temperature gradient along the specimen. The amount of chromium crystals is too large to be explained by the condensation and crystallization of the chromium metal vapor present in the cavity between the metal and the oxide scale during cooling of the specimen to room temperature when the oxidation run was discontinued.



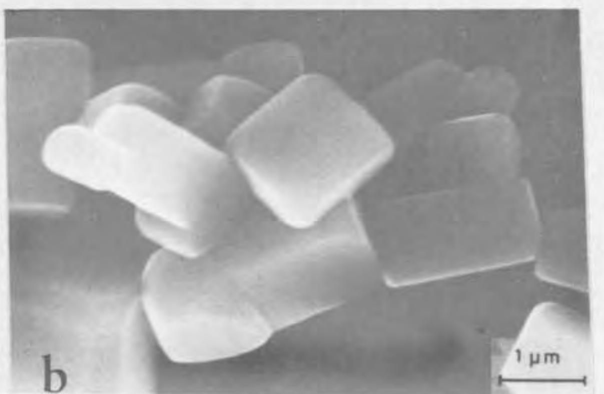


Fig. 14. Scanning electron micrograph of chromium specimen shown in Fig. 13; (a) detail of crystal morphology a few crystal layers away from the inner surface; (b) detail of crystal morphology of crystals at inner scale surface.

It was furthermore found that threadlike oxide crystals or whiskers were formed on some areas of the inner surface of the scale. This is illustrated on Fig. 22a. At these areas the inner crystal layer had poorly developed crystals. In other areas, however, this type of oxide growth was almost absent, and here the crystal facets were better developed. This feature is illustrated in Fig. 22b.

Discussion

In this work the oxidation of annealed, thermally etched chromium has been studied in the temperature range 800°-1100°C at different oxygen pressures ranging from 10^5 to $7 \cdot 10^{-2}$ Pa. During the thermal etching the specimens are stress-relieved, and approximately 12 μm of the outer layer of the specimens were removed through chromium evaporation prior to the start of the oxidation. This pretreatment gives remarkably reproducible results. It is different from previously reported studies where a number of other pretreatments have been used: mechanical polishing, electropolishing, etching, etc. Such pretreatments have been demonstrated to have large effects on subsequent oxidation behavior (11-15).

This study shows that chromium exhibits remarkable changes in the oxidation behavior when exposed to different oxygen pressures, particularly at and above 1000°C. Important general features are that large stresses develop in the scale during the oxide growth and that the ability of the scale to deform plastically increases dramatically with decreasing partial pressure of oxygen. The Cr_2O_3 scales may crack, wrinkle, or balloon depending upon the reaction conditions. On prolonged oxidation oxide scales become detached from the metal substrate.

A major change in the kinetics takes place between 800° and 900°C. At 10^5 Pa O_2 and 800°C the kinetics may be described as approximately logarithmic. At

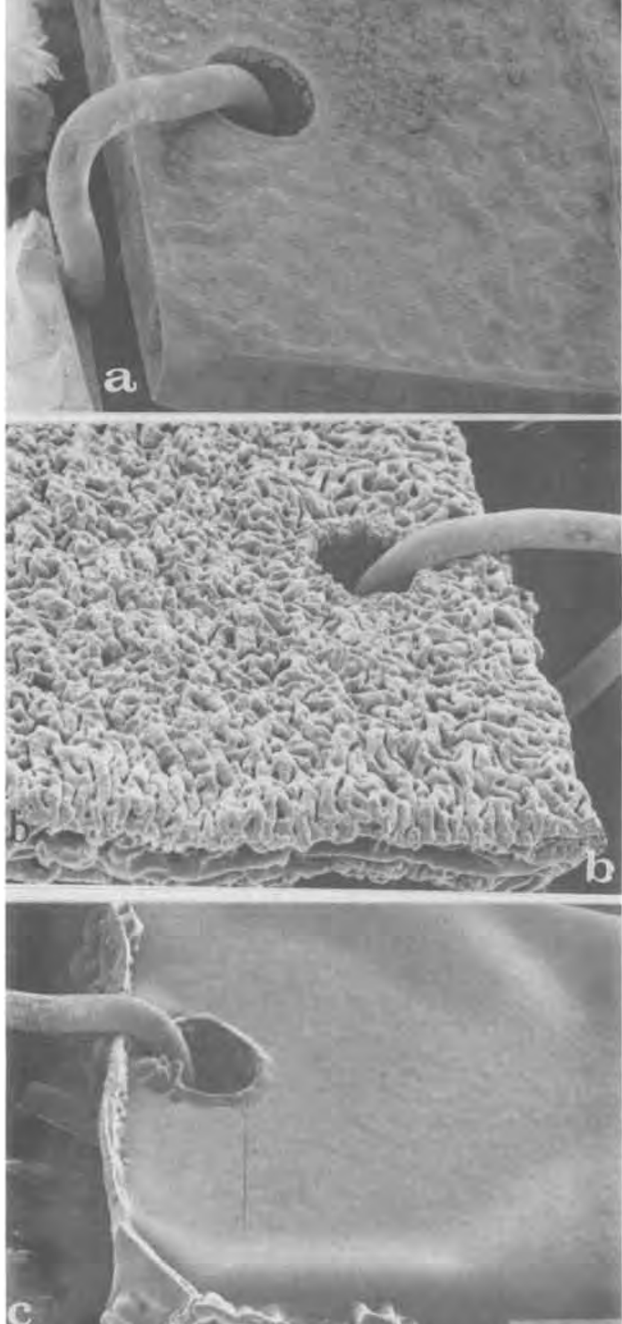

Fig. 15. Scanning electron micrographs (15×) of chromium specimens oxidized at 1075°C: (a) 10^5 Pa O_2 for 25 hr, (b) 130 Pa O_2 for 43 hr, (c) $7 \cdot 10^{-2}$ Pa O_2 for 72 hr.

900°C the oxidation is approximately parabolic within the time periods studied. This also applies to the initial oxidation at 1000° and 1075°C, but with increasing oxide thickness the oxidation exhibits abrupt changes which reflect cracking and breakdown of the scale. New protective oxide is formed, and the overall oxidation takes the form of a sequence of protective oxidation stages. The oxide scale formed under these conditions exhibits but small ability to deform plastically. It may also be noted that the oxidation at 800°C is much faster than would be expected if the oxidation behavior at the higher temperatures were extrapolated to 800°C.

When the oxidation at 800°C is carried out at decreasingly lower oxygen pressures, the period of

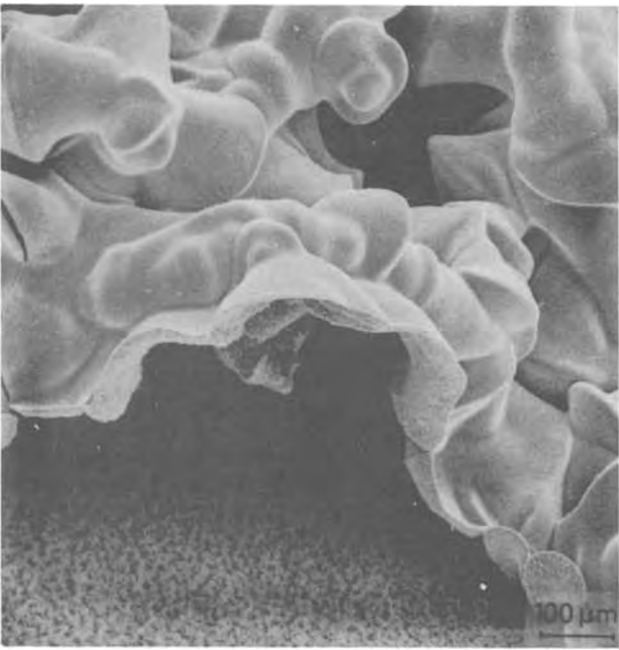

Fig. 16. Scanning electron micrograph of Cr_2O_3 scale after oxidation for 23 hr at 1075°C and 100 Pa O_2. The picture shows the buckled, heavily deformed outer scale and a fine-grained oxide on the metal surface.

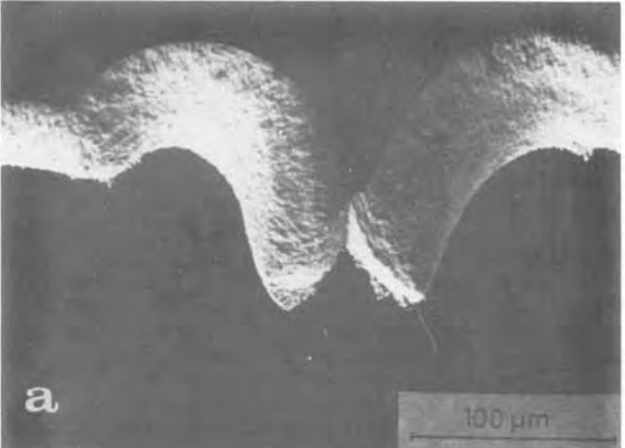

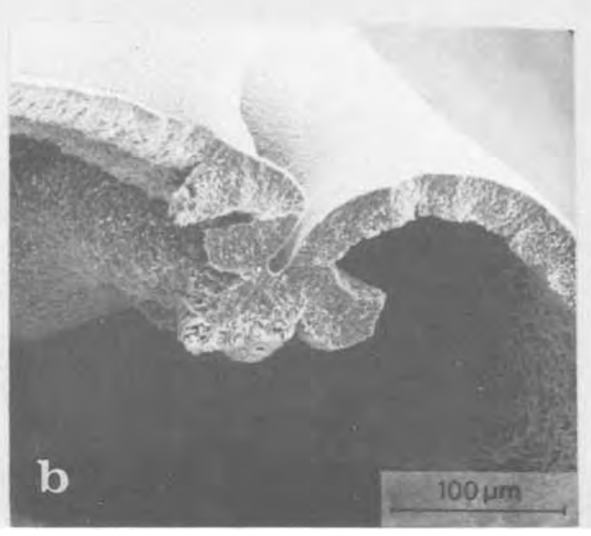

Fig. 17. Details of Fig. 16: (a) region where cracking has occurred just before oxidation was discontinued, (b) region where crack has been healed by further deformation and secondary oxide growth.

initial rapid oxidation becomes shorter. At pressures down to about 10 Pa the oxidation rate becomes slow and almost nil after extended oxidation. However, as the oxygen pressure is decreased to $7 \cdot 10^{-2}$ Pa the oxidation is approximately linear, and after extended oxidation may become faster than at the higher oxygen pressures. The oxide scale shows increasing ability to deform plastically with decreasing partial pressure of oxygen.

At and above 1000°C the oxidation increases as the oxygen pressure is reduced from 10^5 Pa to the pressure of about 100 Pa O_2. Under the latter conditions the oxidation rate is approximately linear. This is associated with the formation of a large number of cracks that are continuously and statistically formed and subsequently healed during the oxide growth. To some extent this allows oxygen penetration through the detached oxide scale and formation of new oxide at the metal surface.

As the oxygen pressure is further decreased the ability of the oxide to deform plastically becomes sufficiently large that the scale no longer cracks or breaks down. Rather, due to the large growth stresses, the oxide deforms and bulges away from the metal surface. The scale is single-layered and continuous. The oxidation is slower than at pressures of about 100 Pa O_2. At $7 \cdot 10^{-2}$ Pa O_2 the oxidation can be described as approximately linear. It is also to be noted that the oxide scale under these conditions is more fine-grained than at higher oxygen pressures.
