Table IV shows the influence on physical properties of either the temperature of the electrolytic bath or the amount of current passed. An increase in temperature seems to increase the resistance to salt corrosion, while the number of coulombs passed (which controls the thickness of the polymer film) improves that resistance until the coating is between 10-15 μm thick. As regards the influence of the medium on physical properties, it must be mentioned that in nearly methanolic solvent (85%) only thin films (1-2 μm) are obtained, by a low current yield. During the electrolysis these films rapidly passivate the substrate, but when submitted to physical tests, neither give (making due allowance for their thinness) improved protection to the metal nor benefit from curing. The reason for this is discussed below.

Composition of the coating material.—The elemental compositions of either the soluble or the insoluble fractions are not far from the theoretical provisions of an allylsubstituted polyoxyphenylene, although some nitrogen is present (see Table V). With respect

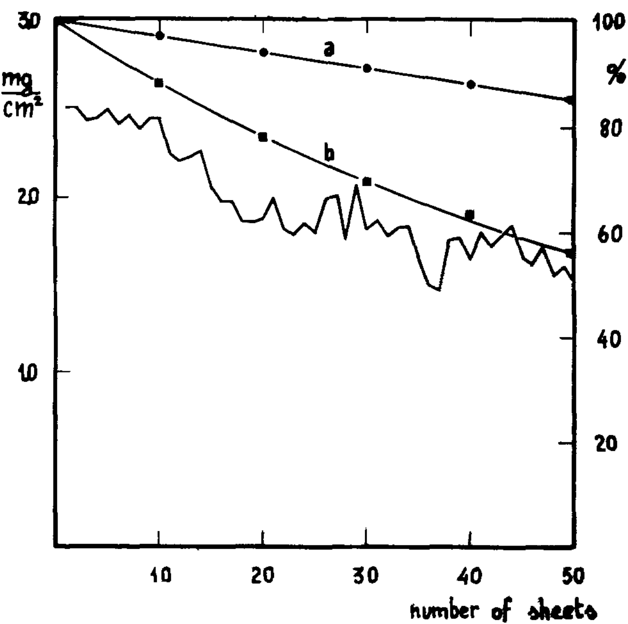

Fig. 4. Left-side scale: polymer yield (mg/cm²) obtained after a fixed electrolysis time as a function of the number of the samples coated. Right-side scale: curve a, volume decrease (%); curve b, o-allylphenol decrease (%).

to this fact it must be noted that the amount of nitrogen (which derives from the amine) is many times higher in the coatings obtained from phenol (2.5-6%). Similarity for both the soluble and insoluble fractions also exists in the infrared and mass spectroscopy patterns. The second technique, after pyrolysis of the samples at $t \geq 260°C$ and ionization by a 70 eV electron beam, mainly shows peaks of the structure:

The anodization solution had the standard composition.

On comparing infrared spectra obtained from samples before and after thermal curing, the following variations may be outlined: (*i*) The uncured samples show three bands in the range 3000-2840 cm^{-1}, typical of allyl C-H stretching, and a sharp band at 1640 cm^{-1}, which may be ascribed to $-HC{=}CH_2$ stretching; (*ii*) in the cured samples, the morphology of the bands between 3000-2840 cm^{-1} changes, although the respective ν do not. At the same time the band at 1640 cm^{-1} becomes very feeble, and a new absorption appears between 1750-1650 cm^{-1} (maximum at 1715 cm^{-1}), which may be ascribed to C=O.

Different results are obtained from the thermogravimetric analysis when the experiments are performed in either nitrogen or air. Under N_2 a slow weight loss takes place up to pyrolysis conditions: at 285°C an exothermic reaction occurs (by DTG). Under air, the weight of the samples increases from 140°C, the reaction reaching its maximum at 170°C; pyrolysis occurs at 230°C.

An oxidative cross-linking is thus strongly supported as the main curing process. It must also be noted that since the polymer has a T_G at 328 K, it passes through a viscous quasi-melting state in the oven before reacting with oxygen.

Discussion

In order to explain the results shown by o-allylphenol, it seems useful to summarize the mechanism of *in situ* coating formation.

In the electrochemical coupling of phenoxide anions, the anode substitutes the copper salt amine complex catalyst (6)

catalyst or ze

For the chemical polymerization the exhausted (reduced) copper catalyst is continuously restored (oxidized) by oxygen; electrochemically the continuity of the oxidation is provided by the anodic potential. The polymerization reaction is not limited to head-to-tail coupling, but also involves the ortho positions: For this reason 2,6-dimethylphenol is usually used for obtaining technologically useful linear polymers (6). We have also shown (2) that during anodic coupling of phenol in the presence of amines,[4] a side reaction frequently takes place between quinol-ether polymeric (I) intermediates (6-8) and amine according to the following scheme

I

Base

$Ar = -[C_6H_4O-]_n C_6H_5$

[4] The amine has a fundamental role as inhibitor of Fe oxidation in the anodic formation of polyoxyphenylene coatings onto Fe sheets (2).

Table V.

	Elemental analysis		
	C	H	N
Theoretical composition	81.2	6.7	—
Soluble fraction	79.2	5.31	0.70
Insoluble fraction	77.8	4.65	0.78

The reaction with amines is favored by the electron-attracting ortho substituents which increase the electrophilicity of quinol-ether meta positions. It is probable that other nucleophilic molecules or ions such as OH^- may attack the same positions. In this last case, the newly formed phenolic group might be engaged in the oxidative coupling, thus contributing strongly toward cross-linking. As regards o-allylphenol, the o-allyl group reduces the occurrence either of coupling in ortho or attack in meta by amine and OH^-. Branching and cross-linking are therefore strongly reduced with respect to phenol polymers. The linearity of the chains leads to two consequences: Uncured coatings have good solubility; and in the oven, before curing, the coating material may melt, thus achieving complete and homogeneous spreading onto the substrate.

However, the same should also hold for other alkyl substituted phenols, whereas we have observed the formation of poorly adhering coatings from, for instance, 2,6-dimethylphenol. The reason for the peculiar behavior of o-allylphenol is thus to be found in a strong interaction of the allyl group with the substrate, which causes adsorption of the monomer and bonding to the metal of the polymer as it is formed.

These considerations seem strongly supported by the following macroscopic evidence:

1. High voltages are tolerated during deposition. This fact is also related to the linearity of chains which, swollen by solution, do not cause excessive electric resistance.

2. There is strong adhesion of the polymeric material to the substrate. Such adhesion (which may also be related to the morphology of the chains as determined by the allyl group) cannot be due to some product of the oxidative cross-linking because films dried below 100°C adhere strongly. In addition the reactivity of the allyl group allows thermal curing, whereby the molecular complexity is increased so as to obtain good resistance to chemical and physical agents.

3. Furthermore, since polyoxyphenylene chains are cross-linked in this way through nonrigid bridges composed of several aliphatic carbon atoms, the cured coatings retain sufficient elasticity to cope with any stress or deformation of the substrate.

Concluding Remarks

From the low electrical resistance of the wet films (Fig. 1) it may be deduced that "throwing power" is rather low. Indeed by varying some experimental conditions (*e.g.*, by increasing either temperature or methanol percentage) throwing power may increase, but the benefits generally are lower than the disadvantages. From this point of view, therefore, *in situ* electropolymerization of allylphenol is at a disadvantage compared to classical electrophoretic coatings. Another hindrance to practical applications is the fact that inorganic pigments cannot be entrapped in the film during its *in situ* formation. Such pigments often contribute significantly to the life of the electrophoretic coatings.

The advantages of preparing the polyoxy-(allyl)-phenylene coatings by the electrolytic process presented in this paper are: (*i*) good corrosion resistance

of the coatings; (*ii*) simplicity of the electrolytic process; (*iii*) stability of the solutions (the electrophoretic bath instead is a metastable colloidal system); (*iv*) strong adhesion, which likely originates from interactions existing *ab initio* between monomer and substrate (for this same reason the substrate does not require, apart from cleanness, any particular pretreatment); and (*v*) good ability of bonding organic overpaintings.

Substrate Effects on Zinc Deposition from Zincate Solutions

I. Deposition on Cu, Au, Cd and Zn

M. G. Chu,* J. McBreen,* and G. Adzic*[,1]

Brookhaven National Laboratory, Department of Energy and Environment, Upton, New York 11973

ABSTRACT

The deposition of zinc on Cu, Au, and Cd from alkaline zincate solutions has been investigated using cyclic voltammetry, potential pulse methods, x-ray diffraction, and scanning electron microscopy. Deposits on Zn were examined by scanning electron microscopy and x-ray diffraction. In the case of Au and Cu approximately a monolayer of zinc is formed in the underpotential deposition region prior to bulk deposition. The respective underpotential shifts of Au and Cu are 0.45 and 0.22V and are in good agreement with the difference in work function between zinc and the substrate. Electrodeposited zinc forms an undetermined surface brass phase on Cu and two alloys (Au_3Zn and $AuZn_3$) with Au. The deposits on all substrates are oriented preferentially parallel to the basal plane.

In a recent study of inorganic oxide additives in pasted zinc electrodes it was found that in many cases the oxide was reduced to the metal prior to deposition of zinc (1). Thus the effect the additives have on the zinc electrode could be due to a substrate effect. Accordingly, an investigation of zinc deposition on various substrates was carried out. Work on Ag substrates has been reported (2). In this case zinc deposition is a complex process involving underpotential deposition, alloy formation, and growth of bulk zinc.

Most morphological studies on zinc electrodeposition have been carried out on either Zn (3-9) or Cu (10-13) substrates. Detailed treatment of deposition habits on single crystal Zn has been carried out in both sulfate (10) and zincate (4, 9) electrolytes. In the latter case at low overvoltages (50 mV) layered deposits were found. There have been two detailed studies of zinc deposition on single crystal Cu from sulfate solution (10, 11). The zinc deposits are of the layered or ridge type with an orientation parallel to the basal plane. Oxley and Fleischman studied zinc deposition on Zu, Cu, Ag, and Cd under conditions of activation control and diffusion control (14, 15). In the case of diffusion-controlled deposition the initiation period for dendrite growth appeared to be a function of the substrate. In the case of activation-controlled deposition the weight of nonadherent deposit for 27C of Zn/cm^2 varied with the substrate according to Cu $>$ Zn $>$ Ag $>$ Cd. For an identical quantity of deposit under diffusion control the weight of nonadherent deposit decreased in the order Cu $>$ Ag $>$ Zn $>$ Cd. Cadmium-plated current collectors have been used in zinc-ferrocyanide (16) and nickel-zinc batteries (17).

Despic (13) has investigated the deposition of zinc on Cu and Au in sulfate solutions. In both cases he found underpotential deposition of zinc and a low nucleation overvoltage for bulk deposition. Kolb, in his review (18), mentions underpotential deposition of zinc from sulfate solution on Au.

It is well known that copper turns to a gray color when coupled with zinc in alkaline solutions (19, 20). This apparently is due to alloy formation.

Even though it is known that the substrate greatly affects the adherency of zinc deposits in alkaline electrolyte and that in some cases there is evidence for

alloy formation with the substrate, no systematic study has been carried out on the effects of various substrates on zinc deposition. The purpose of the present work was to elucidate the reasons for the substrate effect on the morphology and dissolution behavior of zinc deposits in alkaline electrolyte.

In the present study the deposition of zinc on polycrystalline substrates of Cu, Au, Cd, and Zn was investigated using cyclic voltammetry, potential pulse methods, scanning electron microscopy, and x-ray diffraction. The data were analyzed for evidence of underpotential deposition of zinc, alloy formation, and deposit morphology and orientation.

Experimental

Cell.—The cell was the same as that used for deposition on Ag (2).

Working electrode.—Two types of working electrodes were used. One was a simple "flag" type sheet electrode (1 × 1 cm); the other was a machined disk electrode (0.686 cm^2). The electrodes were polycrystalline and were at least 99.998% pure. The preparation of the electrodes is given below. No common electrode preparation method could be used because of the differences in the metallurgical and chemical properties of the metals.

Copper.—Copper sheet electrodes were first immersed in dilute HNO_3 for a few seconds and then washed with triply distilled water. Copper disk electrodes were mounted in the holder and polished successively with 600 grit SiC paper, Microcut sheets (Buehler Limited), 5 and 0.5 μm alumina. The electrodes were then washed with triply distilled water prior to incorporation into the cell.

Gold.—Gold sheets were degreased in acetone and washed with triply distilled water.

Cadmium.—Cadmium sheet electrodes were first immersed in a solution of 75% fuming nitric acid and 25% water for 5-10 sec, then washed with triply distilled water. The cadmium disk electrodes were polished successively with 600 grit SiC and Microcut sheets and were rinsed with triply distilled water.

Electrolytes.—The electrolytes were prepared from triply distilled water, reagent grade KOH, and ZnO (New Jersey Zinc USP-19).

Electrochemical studies.—After assembly, the solutions were deaerated by bubbling nitrogen through the solution for 15 min prior to the start of measurements. The nitrogen was purified by passage through molecular sieves. The cyclic voltammetry studies were made in voltage envelopes that were more negative than −0.63V[2] for copper and −1.1V for cadmium. At no time, except for cyclic voltammetry on Au, did the voltage go into a potential region where the substrate could oxidize.

In the case of Cu and Au two types of potential step experiments were carried out. In one case electrodes were held initially at a potential of −1.0V and then pulsed to potentials between −1.1 and −1.25V for 100 sec. This was followed by an anodic pulse to −1.0V. The purpose of this potential profile was to quantify the charge associated with underpotential deposition of zinc. Measurement of the charge on the anodic pulse gives more accurate results because of the smaller contribution of hydrogen evolution to the total current. In the other experiments the electrodes were held initially at −1.0V and then pulsed to increasingly negative potentials between −1.30 and −1.46V for 100 sec. This was followed by an anodic pulse to −1.25V for 100 sec, followed by a second anodic pulse to −1.0V. The purpose of the latter potential profile was to quantify the charge associated with bulk zinc deposition and alloy formation. The cathodic potential which first yielded anodic charge on pulsing to −1.25V was taken to indicate the onset of zinc deposition. The difference between this potential and the Nernst potential is the nucleation overvoltage. In the case of Cd the potential profile was first to hold the electrode at −1.1V then pulse to potentials between −1.25 to −1.46V for 100 sec and a final pulse to −1.1V. In all the experiments particular care was taken to prevent dissolution of the substrate during the course of the experiments.

[2] All potentials are with respect to an Hg/HgO reference electrode in the same electrolyte.

Scanning electron microscopy and x-ray diffraction.—Sample preparation for the scanning electron microscopy and the x-ray diffraction studies was as follows: The zinc was deposited on the "flag" sheet electrodes until a required number of coulombs was deposited. The electrode was immediately removed from the electrolyte, washed repeatedly in distilled water, rinsed in acetone, air dried, and stored in a desiccator until mounted in either the scanning electron microscope or the x-ray goniometer. The x-ray diffraction pattern was determined using Cu-Kα radiation. The samples prepared for the morphology and deposit orientation studies were deposited from 8.4M KOH + 0.74M ZnO. Four samples on Cu, Au, and Cd substrates were prepared. The deposition conditions were 0.5 C/cm^2 at −1.40V, 2 C/cm^2 at −1.42V, 5 C/cm^2 at −1.44V, and 2 C/cm^2 at 15 mA/cm^2. On Zn only 2 C/cm^2 samples deposited at 15 mA/cm^2 were examined.

Results

Cyclic voltammetry.—Figure 1 shows cyclic voltammograms on Cu sheet in the voltage envelope −0.6 to −1.4V in 1M KOH + 10^{-3}M ZnO. There is a well-defined underpotential deposition pattern at −1.08V. There are two other dissolution peaks at −1.18 and −1.32V. On the anodic sweep there is a small cathodic current peak at −1.0V.

The cyclic voltammograms on Au were very dependent on the positive limit of the voltage envelope. When the positive limit was −0.45V no clear underpo-

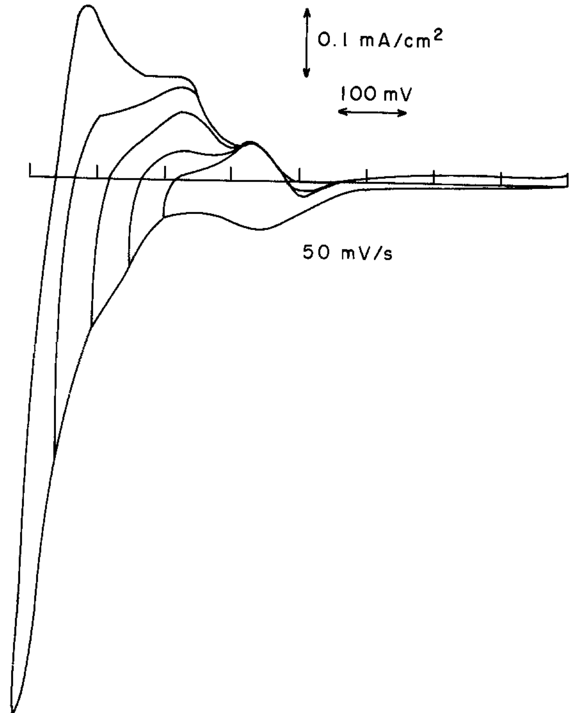

Fig. 1. Cyclic voltammograms on Cu sheet in 1M KOH + 10^{-3}M ZnO in the potential envelope −0.6 to −1.4V; sweep rate 50 mV/sec.

tential deposition pattern could be observed. However, when the positive limit was extended into the oxide region (Fig. 2) a clear underpotential deposition pattern was found at −0.85V. The results are very similar to those found by Despic in sulfate solutions (13).

Figure 3 is a cyclic voltammogram on Cd in 1M KOH + 0.08M ZnO in the voltage envelope −1.1 to 1.42V. There was no evidence of underpotential deposition or alloy formation. The current pattern can be ascribed simply to zinc deposition and dissolution.

Investigations were also carried out in 6M KOH + 0.8M ZnO and in 8.4M KOH + 0.74M ZnO. The overall features of the cyclic voltammograms were similar to those reported here.

Potentiostatic pulse studies.—Figures 4-6 show the current transients for cathodic and anodic pulses on Cu, Au, and Cd substrates in 8.4M KOH + 0.74M ZnO. All anodic pulses were at −1.25V.

Figure 7 shows a comparison of anodic stripping charges for two potentiostatic pulse profiles on Cu and Au in 8.4M KOH + 0.74M ZnO. The results indicate that in both cases at −1.25V approximately a monolayer of underpotential deposited zinc is formed prior to bulk deposition. In the case of bulk deposition most of the deposit is stripped at −1.25V. When deposition is carried out at more negative potentials, the second anodic pulse to −1.0V results in the dissolution of additional zinc (up to 30 monolayers).

Figure 8 shows the results on Cd. The results are consistent with simple deposition of zinc with a high nucleation overvoltage. Complete dissolution of the bulk deposit occurs at −1.25V and no additional anodic dissolution was observed at −1.1V.

X-ray diffraction.—In addition to the diffraction lines for Zn and Cu, the deposit on zinc had diffraction peaks at 2θ = 24.8°, 37.7°, 42.1°, and 57.7°. The strong diffraction peak at 42.1° could be attributed to the hexagonal Cu-Zn brass phase, and the peak at 37.7° to the γ brass phase. Unfortunately, the other strong reflections for these phases coincide with those of copper. In the case of the deposit on Au there were many reflection peaks that could not be attributed to Au or Zn. These were 2θ = 22.7°, 25.5°, 27.9°, 32.3°, 46.2°, 47.7°, 49.2°, 52.0°, 53.4°, 54.8°, 63.7°, and 67.3°,

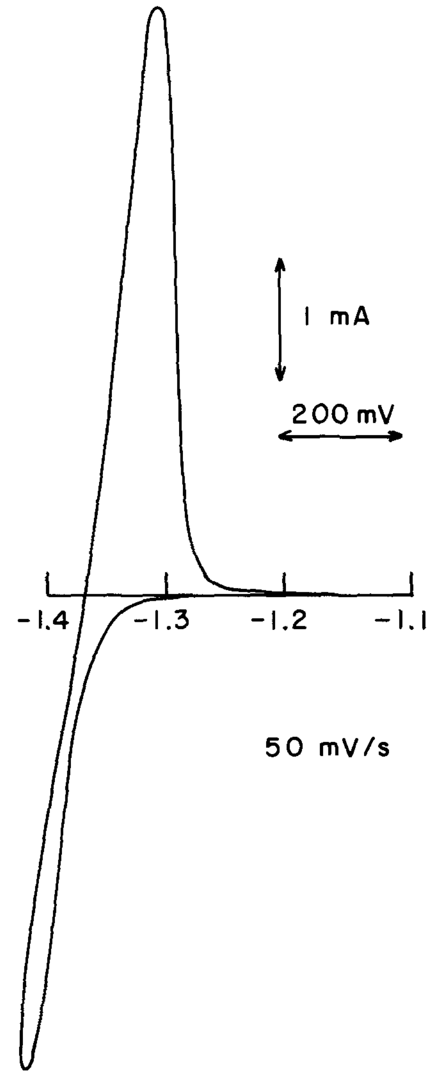

Fig. 3. Cyclic voltammogram on Cd disk (0.686 cm^2) in the 1M KOH + 0.08M ZnO in the potential envelope −1.1 to −1.42V; sweep rate 50 mV/sec.

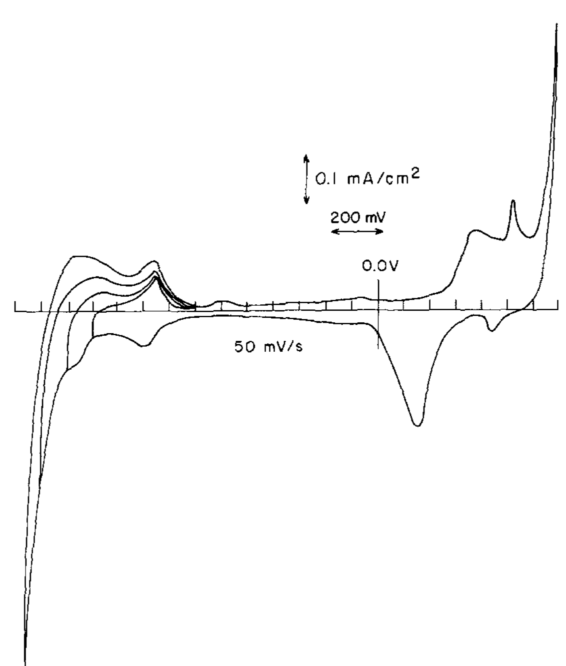

Fig. 2. Cyclic voltammograms on Au sheet in 1M KOH + 10^{-3}M ZnO in the potential envelope 0.7 to −1.35V; sweep rate 50 mV/sec.

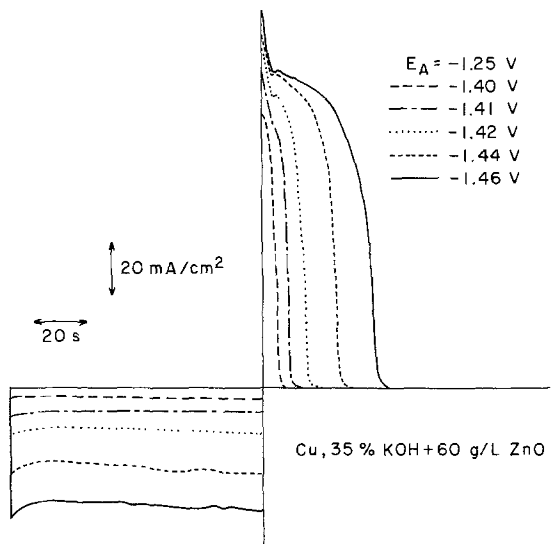

Fig. 4. Current transients for zinc deposition on Cu sheet at various potentials for 100 sec, followed by an anodic stripping pulse at −1.25V.

Some of the peaks (22.7°, 27.9°, 32.3°, 47.7°, and 49.2°) could be attributed to the cubic γ_1-$AuZn_3$ phase (49.2°, 52.0°. 53.4°, 54.8°, and 67.3°) while others could be attributed to the tetragonal α-Au_3Zn phase. The diffrac-

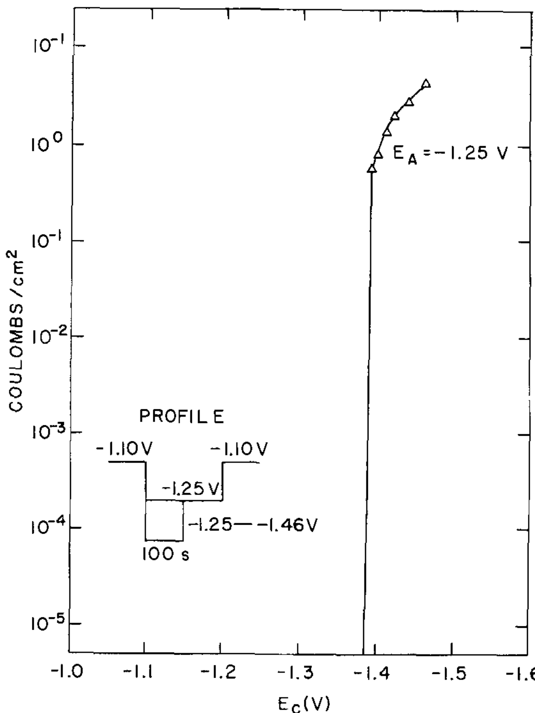

Fig. 8. Anodic stripping charge vs. deposition potential for zinc and Cd sheet in 8.4M KOH + 0.74M ZnO. Potential profile is given in figure. Deposition time, 100 sec.

tion peak at 46.2° is common to both phases. In the x-ray pattern for the deposit on Cd only reflections that could be attributed to either Cd or Zn were found.

Deposit orientation and morphology.—The deposits on all four substrates had an orientation that was preferentially parallel to the basal plane. The morphology of the deposits on Cu, Au, and Cd are shown in Fig. 9-11. On Cu, Au, and Cd the deposit consisted of hexagonal platelets. On Cd the platelets were layered and more compact than those of Cu. On Zn the morphology was identical to that found by Bockris *et al.* (9) and the orientation was parallel to the basal plane. Deposit orientation and morphology did not vary with the deposition conditions investigated.

Discussion

Quantitative treatment of the cyclic voltammograms and the cathodic current transients is essentially impossible because of the unknown contribution of the hydrogen evolution reaction. Nevertheless the electrochemical results yield valuable information which complements the results of the scanning electron microscopy and x-ray diffraction analysis.

Underpotential deposition of zinc.—The results in Fig. 1, 2, and 7 indicate that approximately a monolayer of underpotential deposited zinc is formed on Au and Cu, at −1.25V, prior to bulk deposition. If one takes the underpotential shift as the difference between the bulk and monolayer stripping peaks (18), then the respective underpotential shifts on Au and Cu are 0.45 and 0.22V. These are in good agreement with the difference in work function between zinc and the substrate (18). According to Trasatti (21) the work function for Cd is lower than that of Zn and in agreement with the empirical relationship (18); no underpotential was observed on Cd.

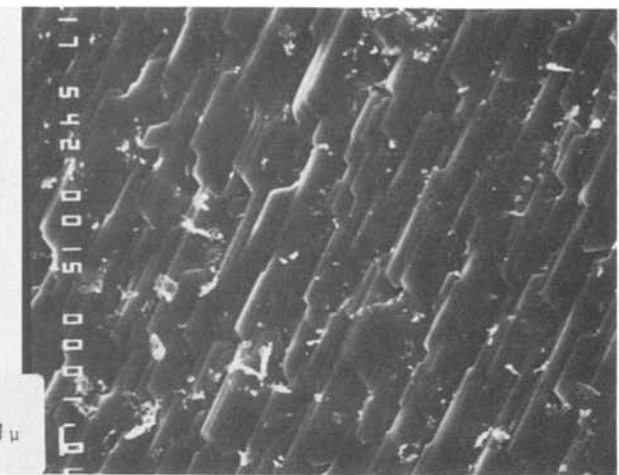

Fig. 11. Scanning electron micrograph of zinc deposit on Cd sheet. Deposit conditions were 2 C/cm^2 at 15 mA/cm^2 from 8.4M KOH + 0.74M ZnO. Magnification 5400×.

The cyclic voltammogram on Cu (Fig. 1) is fairly complex. Apart from the underpotential deposition pattern with a current peak at −1.08V, there is a shoulder on the cathodic current scan between −1.2 and −1.35V. On going to more negative potentials, an anodic current peak develops at −1.18V. When the cathodic scan goes into the zinc deposition region, a third anodic peak appears at −1.32V. This behavior is very similar to that found for cadmium deposition on Au in acetate buffered $CdSO_4$ electrolyte (22). The cathodic current shoulder between −1.2 and −1.35V and the anodic peak at −1.18V can be ascribed to alloy formation in the potential region between the Nernst potential and the underpotential deposition region. The anodic peak at −1.32V can be ascribed to dissolution of bulk zinc.

One peculiar feature of the cyclic voltammogram on Cu is the small cathodic current at −1.0V on the anodic sweep. This can be explained by the inhibition of hydrogen evolution by the adsorbed zinc layer. Such inhibition by underpotential deposited layers is well known (23, 24). On the anodic sweep, when the layer is stripped, hydrogen evolution occurs and the current makes an excursion into the cathodic region at approximately −1.0V.

The behavior of zinc on Au is very similar in some respects to zinc on Cu. In addition to underpotential deposition of zinc, there is evidence for alloy formation as the cathodic scan is extended to potentials between the underpotential deposition region and the Nernst potential. Underpotential deposition of zinc on Au is enhanced by extending the cyclic voltammograms into the oxide region. This may be due to a reordering of the Au surface. Also, it has recently been found that the adsorption behavior of metals can be modified by extended polarization at a preset potential (25). One proposed mechanism is that the adsorption behavior is modified by adsorbed or absorbed oxygen. A similar mechanism may apply here.

Bulk deposition and alloy formation.—As in the case of Ag (2), there is no discernible nucleation overvoltage for zinc deposition on Cu and Au substrates (Fig. 7). Similar results were found by Despic (13, 26) for zinc deposition on Cu and Au in sulfate solutions. However, in this present case there is evidence for alloy formation between the underpotential deposition potential and the Nernst potential, and this may account for the apparent absence of a nucleation overvoltage.

The cyclic voltammetry, potential pulse studies, and x-ray diffraction analysis confirm alloy formation in the case of both Cu and Au. In the case of Cu diffraction peaks that could be attributed to either a γ-brass or a hexagonal Cu-Zn brass phase were observed. The overlap of the other strong lines of these phases with those of copper precluded unequivocal determination of the alloy phase. In the case of Au the situation is much clearer since several diffraction peaks could be uniquely attributed to either the $AuZn_3$ or the Au_3Zn phase. These two alloys are probably found at different depths in the substrate. The results in Fig. 7 indicate the formation of an alloy to a depth of at least 30 monolayers in both cases.

The cyclic voltammetry, potential pulse, and x-ray analysis measurements on Cd are consistent with simple zinc deposition with a high nucleation overvoltage. The absence of alloy formation is in agreement with the finding that the solubility of Zn in Cd is practically nil at 100°C (27).

Deposit morphology and orientation.—The basal orientation of the deposit on Cu is in agreement with that found on single crystal copper in sulfate solutions and with that found when zinc is condensed on Cu from the vapor phase (28). The hexagonal growth habit is typical for growth of a hexagonal close-packed crystal structure oriented parallel to the basal plane (29). Visual inspection of the scanning electron micrographs of the deposits obtained on Cu, Ag (2), and Cd indicates that the density of the zinc deposit

increases in the order Cu > Ag > Cd. This is the order of decreasing peak current for the anodic stripping pulse at −1.25V (Fig. 7). It is also the order of increasing deposit adherency that was found by Oxley and Fleischman (14, 15). Copper substrates in particular encourage the growth of an active hexagonal deposit with many kink sites and edges. This encourages the growth of a deposit whose surface area increases with thickness. This also results in an increase in the dissolution activity of the deposit with increasing thickness.

Summary

1. Approximately a monolayer of zinc is formed on polycrystalline Cu and Au prior to bulk deposition. There is excellent agreement between the underpotential shift and the difference in work function between the substrate and zinc.

2. Alloy formation of zinc with the substrate was found in the case of Cu and Au. Copper forms an undetermined brass phase, and Au forms Au_3Zn and $AuZn_3$.

3. Bulk deposition proceeds without any detectable nucleation overvoltage on Cu and Au. On Cd the nucleation overvoltage is high. In all cases the deposits are preferentially oriented parallel to the basal plane.

Substrate Effects on Zinc Deposition from Zincate Solutions

II. Deposition on Pb, Tl, Sn, and In

J. McBreen,* M. G. Chu,* and G. Adzic*,[1]

Brookhaven National Laboratory, Department of Energy and Environment, Upton, New York 11973

ABSTRACT

The deposition of zinc on Pb, Tl, Sn, and In has been investigated using cyclic voltammetry, potential pulse methods, x-ray diffraction, and scanning electron microscopy. There is no evidence of underpotential deposition on any of the substrates and the nucleation overvoltage is 30-40 mV. Thallium forms a surface alloy with zinc and there is evidence that zinc diffuses into Pb. In the case of Sn and Tl the deposit had an intermediate orientation and on Pb and In the deposit was oriented perpendicular to the basal plane. Deposit orientation has been correlated with the degree of mismatch of zinc with the substrate. The morphology of the zinc was dense on all substrates and there was no evidence for the hexagonal type of deposit that is usually found on Zn and Cu.

The deposition of zinc on Sn and Pb has been investigated by Oxley and Fleischman (1, 2). They found that the deposits were more adherent than on Cu, Ag, or Cd, with the best adherency being on Pb.

There is an extensive literature on the effect of Pb and Sn ions on zinc deposits in alkaline electrolyte (3-7). Initial work was carried out by Kudryatzev (3). Since then several investigators have confirmed that Pb (4-6) and Sn (7) ion additions inhibit zinc dendrite growth. It has also been shown that Pb ion additions affect the specific area of the zinc deposit, suppress self-discharge, and improve the mechanical and discharge characteristics of the electrodes (5). The effect of Pb ion additions on zinc deposits in aqueous zinc chloride and zinc sulfate electrolytes has been investigated (8, 9). In both cases additions of Pb ions change the deposit and promote zinc growth perpendicular to the basal plane.

In recent years there have been several reports on the effect of PbO, Tl_2O_3, SnO_2, $SnCl_2$, H_2O, In_2O_3, and $In(OH)_3$ additions to the pasted battery zinc electrodes (10-13). It has been found that in the case of PbO and Tl_2O_3 additions to zinc electrodes in nickel-zinc cells that the oxides are reduced to the metal prior to zinc deposition on the first charge (13). The mechanism by which these additives modify the electrode has been attributed to a substrate effect.

The present study was part of an investigation of substrate effects on zinc deposition on several metals from zincate solution. The techniques used were cyclic voltammetry, potential pulse methods, scanning electron microscopy, and x-ray diffraction.

Experimental

Cell.—The cell for the electrochemical studies is described elsewhere (15).

Working electrode.—Two types of working electrodes were used. One was a simple "flag" type sheet electrode (1 × 1 cm); the other was a machined disk electrode (0.686 cm^2). The electrodes were polycrystalline and were at least 99.998% pure. The preparation of the Pb, Tl, In, and Sn electrodes is given below; no common electrode preparation method could be used.

Lead.—Lead sheet was first immersed in a solution of 20% hydrogen peroxide and 80% glacial acetic acid for 15 sec, then washed with triply distilled water (14). The lead disk electrodes were first polished with 600 grit SiC paper and then chemically etched in a solution of 80% glacial acetic and 20% hydrogen peroxide for 15 sec. Finally the electrode was rinsed with methanol.

Thallium.—The preparation of thallium sheet was the same as that for lead sheet electrode. The thallium disk electrodes were polished with 600 grit SiC and then washed in 6*N* KOH followed by a rinse in triply distilled water.

Indium.—Indium electrodes were first washed in acetone and rinsed with triply distilled water.

Tin.—Tin sheet electrode was only washed with triply distilled water. The tin disk electrodes were first polished with 600 grit SiC paper and then washed with triply distilled water.

Electrolytes. —The electrolytes were prepared from triply distilled water, reagent grade KOH, and ZnO (New Jersey Zinc USP-19).

Electrochemical studies.—After cell assembly, the solutions were deaerated by bubbling nitrogen through the solutions for 15 min prior to the start of measurement. The nitrogen was purified by passage through molecular sieves. The cyclic voltammetry was made in voltage envelopes that were more negative to −0.84V for Pb, −0.9V for Tl, −1.15V for In, and −1.2V for Sn. At no time did the voltage scan go into a potential region where the substrate could oxidize. Double cathodic-anodic pulse measurements were made in an effort to quantify the amount of the deposit, determine the nucleation overvoltage, and obtain further evidence for alloy formation. This procedure consisted of a cathodic pulse for 100 sec at increasingly negative potentals between −1.25 and −1.46V followed by an anodic pulse at −1.25V for 100 sec and a final pulse to a potential slightly negative of the dissolution potential of the substrate. In the case of Pb, Tl, In, and Sn, the respective potentials of the final anodic pulses were −1.0, −1.0, −1.19, and −1.15V. The cathodic deposition potential which first yielded an anodic charge at −1.25V was taken to indicate the onset of zinc deposition. The difference between this potential and the Nernst potential is the nucleation overvoltage. Any additional dissolution that occurred on stepping to potentials more positive to −1.25V was ascribed to zinc that had alloyed or diffused into the substrate.

Key words: electrodeposition, alloy, SEM.

Scanning electron microscopy and x-ray diffraction.—Sample preparation for the scanning electron microscopy and the x-ray diffraction studies was as follows. The zinc was deposited on the "flag" sheet electrodes at a fixed potential until a required number of coulombs was deposited. The electrode was immediately removed from the electrolyte, washed repeatedly in distilled water, rinsed in acetone, air dried, and stored in a desiccator until mounted in either the scanning electron microscope or the x-ray goniometer. The diffraction pattern was determined using Cu-Kα radiation. The sample prepared for the morphology and deposit orientation studies was deposited from 8.4M KOH + 0.74M ZnO. Four samples on each substrate were prepared. The deposited conditions were 0.5 C/cm^2 at -1.40V, 2 C/cm^2 at -1.42V, 5 C/cm^2 at -1.44V, and 2 C/cm^2 at 15 mA/cm^2.

Results

Cyclic voltammetry.—Figure 1 is a cyclic voltammogram on a Pb disk electrode in 1M KOH + 0.08M ZnO in the potential envelope -0.83 to -1.45V. The cathodic current has a distinct nucleation loop with no zinc deposition occurring on the cathodic sweep till a potential of -1.4V is reached. Cyclic voltammograms with negative limits at -1.43V displayed one anodic current peak at -1.28V. When the negative limit was extended to -1.45V a second anodic peak appeared at -1.35V (Fig. 1); when the limit was -1.55V a third anodic peak appeared at -1.3V. Results in Fig. 2 show the effect of various voltage arrests on the anodic behavior of the cyclic voltammogram. Figure 3 shows cyclic voltammograms for thallium in 1M KOH + 0.08M ZnO in the voltage envelope -0.9 to -1.4 and -1.45V. There is no evidence of underpotential deposition on Tl. At -1.4V there is no zinc deposition. At 1.45V there is deposition and a very distinct nucleation loop. Figure 4 shows cyclic voltammograms for more negative limits down to -1.65V. When the negative limit is -1.65V another anodic peak is observed -0.8V. The main feature of zinc deposition on Tl is that there is no underpotential deposition; there is evidence of a nucleation overvoltage for zinc deposition. The behavior of Sn is shown in Fig. 5. There is no evidence of underpotential deposition or alloy formation. Almost identical results were found on In substrates.

Potentiostatic pulse studies.—Figures 6-9 show the current transients for cathodic and anodic pulse on Pb, Tl, Sn, and In substrates (1 × 1 cm) in 8.4M KOH + 0.74M ZnO. Cathodic pulses vary from -1.40 to -1.46V. All anodic pulses were at -1.25V.

Figures 10 and 11 show the anodic stripping charge for various potentiostatic pulse profiles in 8.4M KOH + 0.74M ZnO for Pb, Tl, In, and Sn, respectively. On Pb and Tl substrates, most of the dissolution of bulk deposit occurs at -1.25V; the remainder of the deposit is stripped at -1.0V. On In and Sn substrates, all of the dissolution of bulk deposit occurs at -1.25V; no dissolution was observed at the higher potential.

X-ray diffraction result.—In the case of the Tl sample prepared for morphology and deposit orientation studies strong diffraction peaks at 2θ = 23.5°, 26°, 27.2°, 31°, 38.5°, and 48.5° were observed. In the case of Pb, In, and Sn, all the diffraction peaks could be attributed to either zinc or the substrate.

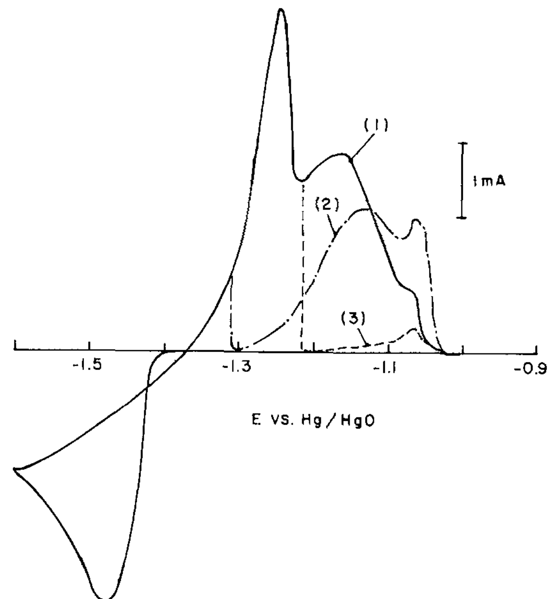

Fig. 2. Cyclic voltammograms on Pb disk (0.686 cm^2) in 1M KOH + 0.08M ZnO; sweep rate 10 mV/sec. (Curve 1) continuous cyclic voltammograms, (curve 2) with a 5 sec anodic arrest at -1.3V, (curve 3) with a 5 sec anodic arrest at -1.21V.

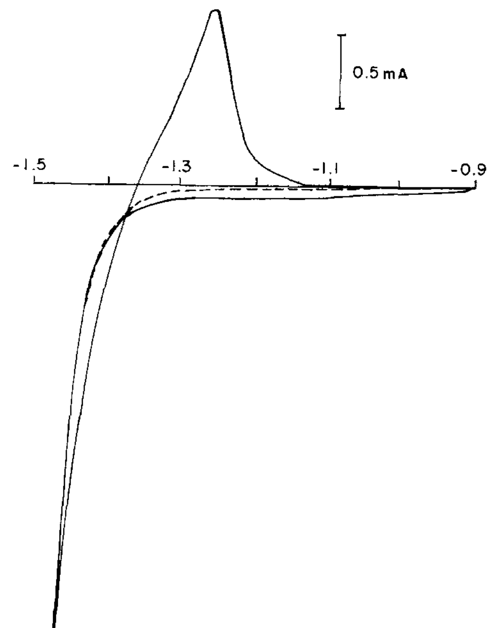

Fig. 3. Cyclic voltammograms for Tl disk (0.686 cm^2) in 1M KOH + 0.08M ZnO; broken line for a negative limit at -1.4V; solid line for a limit at -1.45V. Sweep rate 100 mV/sec.

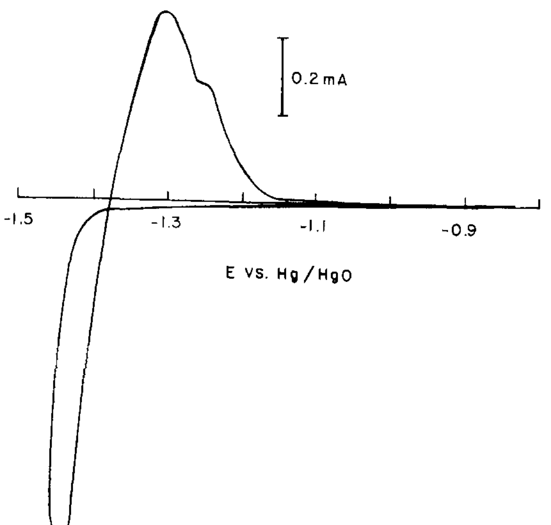

Fig. 1. Cyclic voltammogram on Pb disk (0.686 cm^2) in 1M KOH + 0.08M ZnO; sweep rate 100 mV/sec. Negative limit -1.45V.

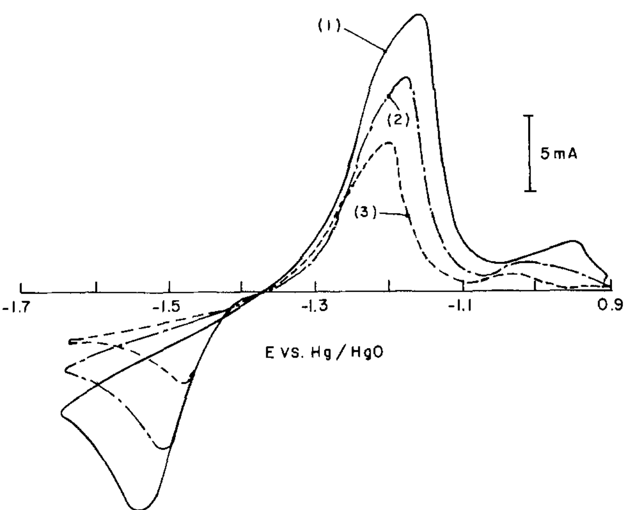

Fig. 4. Sweep rate dependence of cyclic voltammograms on Tl disk (0.686 cm^2) in 1M KOH + 0.08M ZnO. Sweep rates: (curve 1) 100 mV/sec, (curve 2) 50 mV/sec, (curve 3) 20 mV/sec.

Deposit orientation and morphology.—The zinc deposits on both Pb and In were oriented perpendicular to the basal plane. On Tl and Sn the deposit had an intermediate orientation. Figures 12 to 15 show scanning electron micrographs of zinc deposits on each substrate. There is no evidence of the hexagonal structures found on Ag (15), Cu and Cd (16). On In and Sn the deposits had a very dense appearance.

Discussion

Zinc deposition.—No underpotential deposition was observed on any of these substrates. This is to be expected since the work function for Sn is only 0.05 eV higher than that of zinc and for the other metals is considerably lower (17). The nucleation overvoltage is high on all metals. Thallium was the only material with which zinc formed an alloy. This was confirmed by the additional anodic peak, at approximately

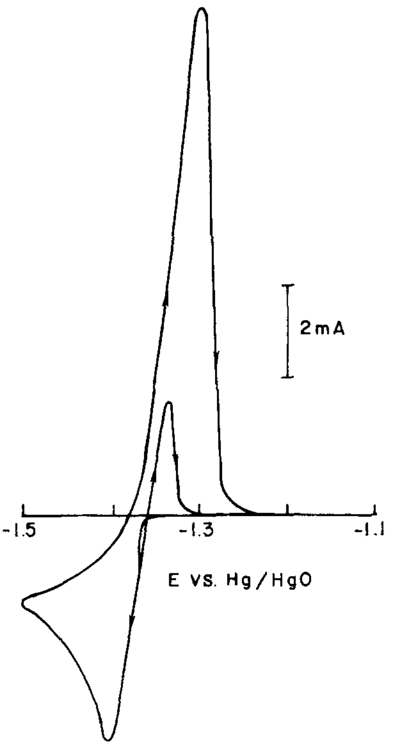

Fig. 5. Cyclic voltammograms on Sn disk (0.686 cm^2) in 1M KOH + 0.08M ZnO; sweep rate 50 mV/sec.

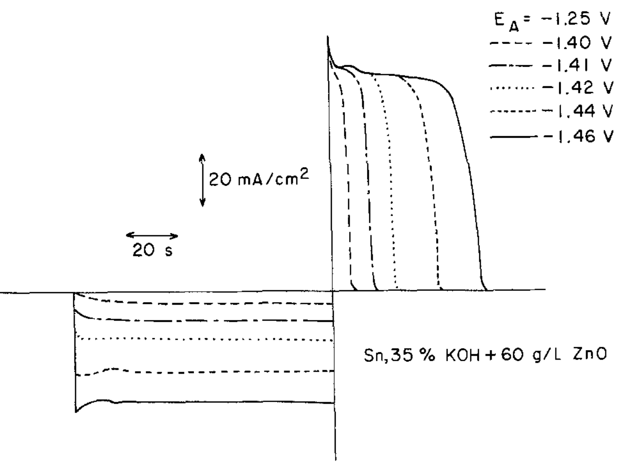

Fig. 8. Current transients for double cathodic/anodic pulse experiments on Sn sheet in 8.4M KOH + 0.74M ZnO. Deposition potentials are indicated on the figure. Anodic pulses were to −1.25V.

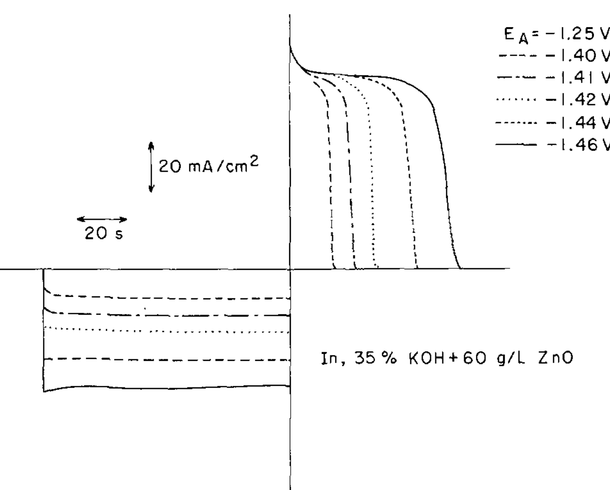

Fig. 9. Current transients for double cathodic/anodic pulse experiments on In sheet in 8.4M KOH + 0.74M ZnO. Deposition potentials are indicated on the figure. Anodic pulses were to −1.25V.

−1.0V, in the cyclic voltammograms (Fig. 5). The double anodic pulse also showed additional dissolution on going to −1.0V. This additional dissolution was observed on the cyclic voltammograms at slow sweep rates and in the potential pulse measurements after holding the electrode at −1.25V for periods as long as 300 sec. Thus it could not be ascribed to residual passivated zinc. In addition, the x-ray diffraction results showed several diffraction peaks that could not be ascribed to either Zn or Tl. No literature data for x-ray patterns of Zn-Tl alloys could be found.

The cyclic voltammetry results (Fig. 4 and 5) and the double anodic pulse measurements (Fig. 11) indicate that alloy formation of zinc with Tl is quite different than alloy formation with Ag (15), Au or Cu (16). There is no evidence for alloy formation at potentials positive to the Nernst potential. Actually the cyclic voltammogram displays a nucleation loop (Fig. 4) and no zinc is deposited at potentials more positive

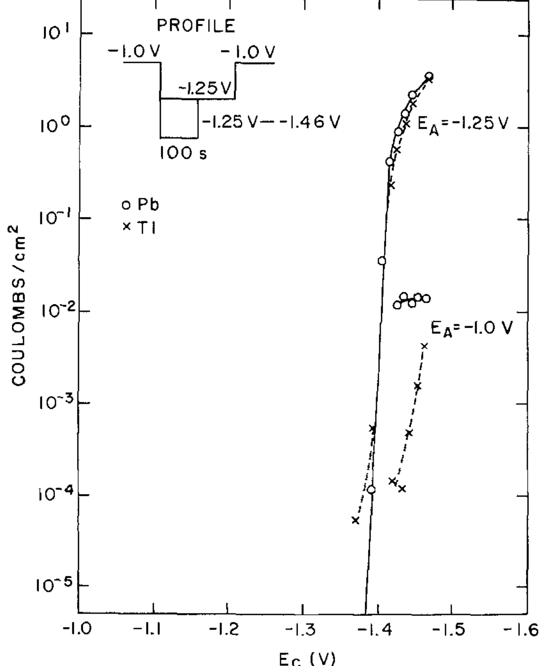

Fig. 10. Anodic stripping charge *vs.* deposition potential for Pb and Tl sheet in 8.4M KOH + 0.74M ZnO. Deposition time was 100 sec. Potential profiles are indicated on the figure.

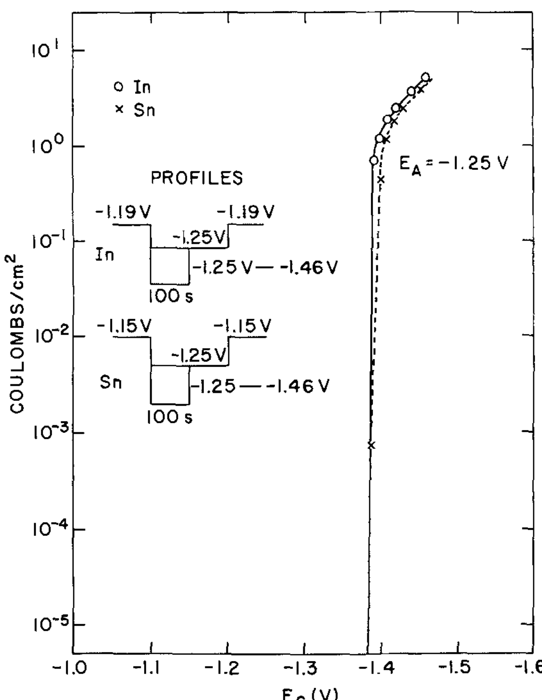

Fig. 11. Anodic stripping charge *vs.* deposition potential from Sn and In sheet in 8.4M KOH + 0.74M ZnO. Deposition time was 100 sec. Potential profiles are indicated on the figure.

to −1.4V. Apparently the presence of bulk zinc is required on the Tl surface before alloy formation. There is a possibility that in the case of Ag, Au, and Cu, the underpotential deposited layer catalyzes alloy formation at potentials positive to the Nernst potential. It is difficult to quantify the amount of alloy formation from the double anodic pulse measurements. On pulsing to −1.25V, the current tailed off (slowly) over a long period of time (Fig. 7). This may be due to some alloy dissolution at −1.25V after stripping the bulk deposit.

The behavior of zinc on Pb is very complex as indicated by the cyclic voltammetry and potential pulse measurements. The behavior was similar in some respects to that observed with substrates that alloyed with zinc. However, no Pb-Zn alloy is known and the x-ray diffraction data showed only reflections for Pb and Zn. The cyclic voltammograms indicate that there are at least three dissolution processes. This could be rationalized on the basis of dissolution of nonepitaxial

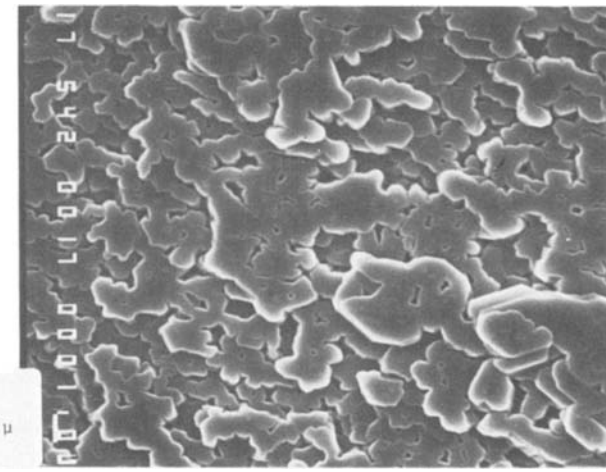

Fig. 12. Scanning electron micrograph of a zinc deposit on Pb sheet. Electrolyte was 8.4M KOH + 0.74M ZnO. Deposition conditions were 2 C/cm² at 15 mA/cm². Magnification 5400×.

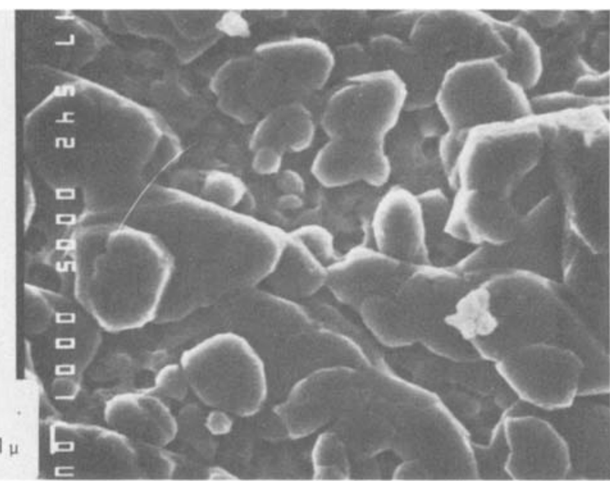

Fig. 13. Scanning electron micrograph of a zinc deposit on Tl sheet. Electrolyte was 8.4M KOH +0.74M ZnO. Deposition conditions were 2 C/cm^2 at 15 mA/cm^2. Magnification 5400×.

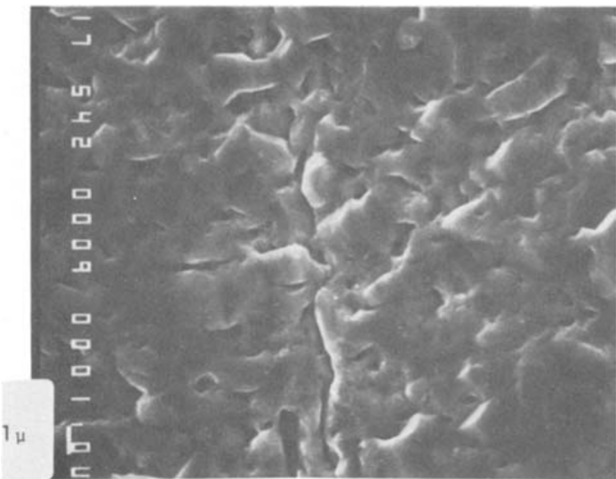

Fig. 14. Scanning electron micrograph of zinc deposit on Sn sheet. Electrolyte was 8.4M KOH + 0.74M ZnO. Deposition conditions were 2 C/cm^2 at 15 mA/cm^2. Magnification 5400×.

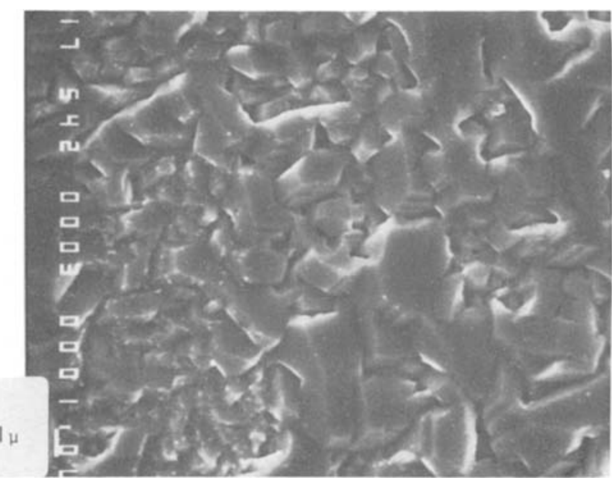

Fig. 15. Scanning electron micrograph of zinc deposit on In sheet. Electrolyte was 8.4M KOH + 0.74M ZnO. Deposition conditions were 2 C/cm^2 at 15 mA/cm^2. Magnification 5400×.

growth, epitaxial growth, and zinc that diffuses into the lead. The concept of the dissolution of epitaxial and nonepitaxial growth has been invoked to explain the dissolution of Cd deposits on Cu (18), and a similar mechanism may be operative here. It is known that the diffusivity of Zn in Pb is abnormally high (19, 20). It is about six orders of magnitude higher than the self-diffusion of Pb in Pb. Extrapolation of the data of Ross *et al.* (19) indicates a diffusivity of 8.24×10^{-11} cm^2 sec^{-1} for Zn in Pb at 25°C. If one assumes that the area under curve 3, Fig. 3 is due to dissolution of zinc that diffuses into Pb, then the amount of Zn in the substrate is 1.4×10^{-3}C. The total zinc that diffuses into the Pb is given by

$$Q = 4\mathbf{F}AC_o \left(\frac{Dt}{\pi} \right)^{1/2}$$

where **F** is the Faraday constant, A the electrode area, D the diffusivity of Zn in Pb, C_o the concentration of zinc directly beneath the Pb surface, and t the time the substrate was covered with Zn (21). The total time t, including the arrest time, was 78 sec. This yields a value of C_o of 0.06 atom percent Zn in Pb, a value that is reasonably close to the theoretical solubility of Zn in Pb (22).

The electrochemical behavior of the zinc deposit on In and Sn was unique in that the deposit activity does not increase with deposit thickness (Fig. 9 and 10). The limiting discharge current on stepping to −1.25V does not change with thickness. This would indicate that the surface area of the zinc remains constant as the deposit grows. This may be a feature associated with epitaxial growth perpendicular to the basal plane. The stripping current behavior also differed from that of Pb and Tl in that there was no tailing of the current. This is consistent with no interaction of the zinc with the substrate bulk.

Deposit morphology and orientation.—The zinc deposits on Pb, Tl, In, and Sn differed from those found on Ag (15), Cu, Au, Cd, and Zn (16) in that the deposits were not oriented parallel to the basal plane. Consequently the deposits did not display the usual hexagonal platelets that are obtained from growth in a direction parallel to the basal plane.

The only correlation that can be made is that substrates with atomic radii close to that of zinc encourage growth parallel to the basal plane, and substrates with atomic radii much larger than zinc encourage growth perpendicular to the basal plane. The latter deposits tend to be more dense. Table I summarizes data on the interatomic distances in the substrates investigated (23) and give the degree of mismatch with the basal plane spacing of zinc. It is best to compare substrates that do not form alloys with zinc such as Cd, Sn, In, and Pb, since alloy formation certainly must rearrange the atoms of the substrate. In going from Cd to Sn to In and Pb the deposit changes from a basal to an intermediate and then to a perpendicular orientation. According to Finch and his co-workers (24), the critical mismatch is about 15%. This appears to be the case here.

Summary

1. The nucleation overvoltage for zinc on Pb, Tl, Sn, and In in alkaline zincate solutions is 30-40 mV.

Table I. Substrate interatomic distance in comparison to interatomic distances in the zinc basal plane

Metal	Interatomic distance (A)	Differences with interatomic distance of Zn in basal plane (%)
Cu	2.556	−4.1
Ag	2.889	8.4
Au	2.883	8.1
Cd	2.979, 3.293	11.78
Sn	3.02, 3.17	13.32
In	3.24, 3.37	21.57
Tl	3.401, 3.456	29.68
Pb	3.500	31.3
Zn	2.665, 2.912	

2. Thallium is the only metal that alloys with Zn during deposition.

3. As opposed to the deposits found on Ag, Cu, Au, Cd, and Zn, the deposits were not oriented parallel to the basal plane. On Sn and Tl the deposit had an intermediate orientation and on In and Pb the deposit was oriented perpendicular to the basal plane. Deposit orientation and morphology has been correlated with the degree of mismatch of Zn with the substrate.

Electrodeposition of Silicon from Solutions of Silicon Halides in Aprotic Solvents

A. K. Agrawal* and A. E. Austin*

Battelle, Columbus Laboratories, Columbus, Ohio 43201

ABSTRACT

Amorphous silicon has been electrodeposited from nonaqueous baths using $SiHCl_3$ as the silicon source. A typical bath composition was 1.0M $SiHCl_3$ in propylene carbonate containing 0.1M tetrabutyl ammonium chloride as the supporting electrolyte. Deposits were made potentiostatically at around −2.5V *vs.* Pt reference at temperatures 35°-145°C under an argon atmosphere. A variety of materials including Pt, Ti, Ti-6Al-4V alloy, n-Si, and indium-tin oxide coated fused silica were used for the substrate. The as-deposited silicon contains some hydrogen bonded as SiH_2 or SiH. The quality and hydrogen content of the deposits are controllable by selecting the proper bath composition and operating temperature. The electrodeposition process offers an inexpensive route for producing α-Si films for possible solar cell applications.

The successful development of low cost solar cells for large-scale terrestrial power generation calls for new technology for attaining required cost reductions of 30-fold from the present. Amorphous silicon films produced by various vapor phase deposition processes are being actively considered for solar cell applications (1). We investigated electrodeposition as a process for producing silicon directly on low cost metal substrates. As is well known, silicon cannot be electrodeposited from aqueous electrolytes because of hydrolysis of its salts and very large negative potentials

* Electrochemical Society Active Member.

Key words: amorphous silicon, solar cell, electrodeposition, nonaqueous bath.

required for the cathode. The use of a wide range of nonaqueous organic solvents was investigated. Appropriate media were found to be solutions of silicon halides in dipolar aprotic organic solvents that are essentially anhydrous (2). The process yielded amorphous silicon of 1-5 μm thickness on a variety of substrates. Process details, deposit quality, and composition of the electrodeposited α-silicon are discussed here.

System Development

Initially a number of solutes (silicon source—chloro and bromo silanes mainly), nonaqueous solvents, and supporting electrolytes (tetraalkyl ammonium salts) were investigated for the process. The screening was done by cyclic voltammetry experiments and followed by electrodeposition onto a platinum or Ti-6Al-4V substrate [see Ref. (2)]. After extensive trials the most suitable choices for the solute, solvent, and supporting electrolyte were trichlorosilane, propylene carbonate (PC), and tetraalkyl ammonium chlorides, respectively. The main considerations in the selection were stability of various components in the bath at operating cathode potentials in the anticipated temperature range of 35°-150°C, and the product quality.

Although $SiHCl_3$ is quite soluble (>1M) in PC, the $SiHCl_3$ is barely ionized in the solvent. As a result the solution conductivity is extremely low (35 μmho cm^{-1}) for an efficient operation of the cell. Tetraalkyl ammonium chlorides were therefore added to the cell to increase the conductivity of the bath and thereby reduce the operating cell voltages.

Cyclic voltammetry.—Preliminary cyclic voltammetry experiments were done on platinum electrodes in PC with tetrabutyl ammonium chloride (TBAC) as the supporting electrolyte but without any $SiHCl_3$ present. This was done to check the inertness of the bath and also to determine the safe working potential range. In the voltagrams no current waves, either cathodic or anodic, were observed in the potential range +0.8 to −3.0V *vs.* Pt. This indicated an absence of reactions and proved the inertness of the bath. However, when the scanning was extended beyond the above potentials, in separate experiments, large current waves resulted at both ends. These waves were due to the breakdown of the bath constituents. The potential range beyond −3.0V *vs.* Pt was therefore considered unsafe for the cell operation but safe between +0.8 and −3.0V *vs.* Pt. Chloride ion oxidation starts beyond +0.8V *vs.* Pt.

A cyclic voltagram for $SiHCl_3$ in PC and TBAC is shown in Fig. 1. Two reduction waves at cathodic potentials near −1.2 and −2.3V *vs.* Pt are evident. During scanning in the positive direction from the most negative potential −2.7V *vs.* Pt, no anodic waves corresponding to either of the cathodic waves were observed. This implies that the cathodic reactions are highly irreversible. The first wave at −1.3V *vs.* Pt is thought to be from the reduction of trace amounts of HCl present in the bath. This HCl results from a reaction between $SiHCl_3$ and H_2O, which finds its way as a trace impurity in PC or TBAC. In the second cycle the first wave completely disappeared, probably because of an exhaustion of HCl from the bath. Formation of HCl by hydrolysis of chlorosilanes, *e.g.*, $R_3SiCl + H_2O \rightarrow R_3SiOH + HCl$, and the reduction of HCl on electrolysis in nonaqueous solvents have been reported by Corriu *et al.* (3).

The second wave in the voltagram in Fig. 1 is from the reduction of $SiHCl_3$ to α-Si. The current peak is located at −2.3V *vs.* Pt. Repeated cycling of the potential between +0.8 and −2.7V *vs.* Pt produced a gradual shrinking of the peak and also a slight negative shift of the peak potential in successive cycles. These changes are thought to be from a buildup of α-Si deposit on the substrate during each cycle and the resulting *IR* drop therein. The presence of only a strong single peak, after the HCl removal, suggests that the reduction of $SiHCl_3$ is essentially a one-step process. Multiple peaks corresponding to stage-wise reduction of $SiHCl_3$ were never observed.

Experimental

All experiments including screening experiments were done inside a dry glove box under an argon atmosphere. Initially a reagent grade PC after careful drying over molecular sieves and purification by vacuum fractional distillation was used for the solvent. The distillate was kept at all times under an argon atmosphere. Gas chromatographic analysis of the distillate gave a maximum of 10 ppm H_2O and 100 ppm propylene glycols. The conductivity of the distillate was 0.5-1.0 μmho. Later, high purity, very low water, glass distilled PC from Burdick and Jackson Laboratories was used in all experiments, without any further treatment. Cyclic voltammetry results and the quality of deposits with the latter PC justified its use. Trichlorosilane used as solute was from Silar Corporation. Tetraalkyl ammonium chlorides, *i.e.*, tetraethyl (TEAC), tetrapropyl (TPAC), TBAC, tetrapentyl (TPnAC), and tetrahexyl (THAC) were obtained from the Ventron Corporation and these were purified by recrystallization under argon atmosphere according to the procedures described in Mann (4).

Electrodeposition experiments were carried out potentiostatically in Teflon cells using an internal platinum reference electrode. A Teflon cell of 15 ml capacity used with 2 cm diam substrates is shown in Fig. 2. The counterelectrode was made from vitreous carbon, whereas a variety of substrates were used for the cathode, including Pt, Ti-6Al-4V alloy, commercially pure titanium, n-silicon, and transparent indium-tin oxide on fused silica. All metallic substrates were mechanically polished to a mirror smooth finish for

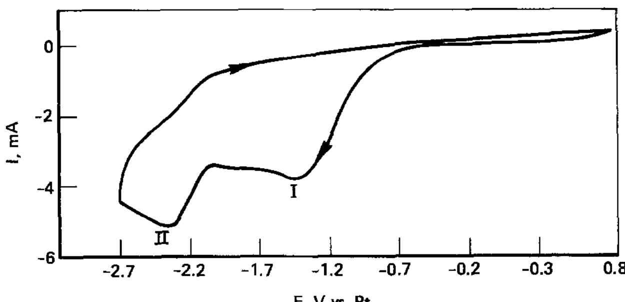

Fig. 1. A cyclic voltammogram of platinum substrate at 35°C in PC containing 0.1M TBAC and 0.2M $SiHCl_3$.

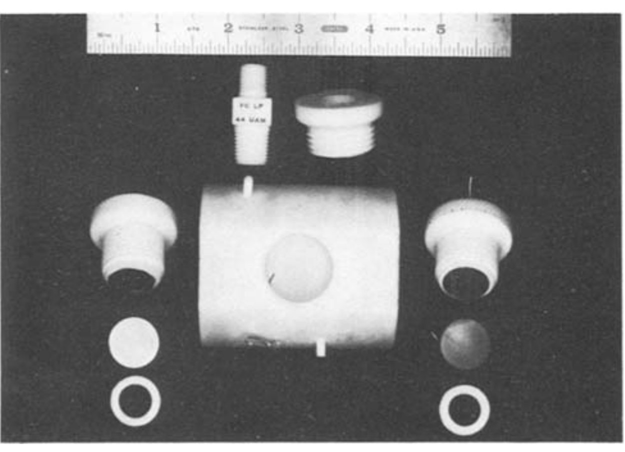

Fig. 2. A Teflon cell used in electrodeposition experiments shown disassembled.

use as a cathode. These were cleaned with deionized water and rinsed off with acetone prior to use. A deposition potential around −2.5V *vs.* Pt was used in most of the experiments.

Deposits were made at 35°-145°C. Experiments above 35°C required a heated pressure chamber for the cell because of the high volatility of $SiHCl_3$ (bp 33°C). For runs at high temperatures the Teflon cell after assembling and filling with the solution was sealed in the chamber. The chamber was then pressurized with argon. The pressure was maintained at 20-30 psi (140-210 kPa) above the vapor pressure of $SiHCl_3$ at the operating temperature of the cell, *e.g.*, 110 psig (800 kPa) for a 90°C run. This prevented the loss of $SiHCl_3$ from the cell.

During deposition the cell current was monitored, and in most cases a digital integrator was also used to show the cumulative charge passed at any time. Deposit thickness was calculated using Faraday's law assuming 4 electron transfer reduction, 100% current efficiency, and a deposit density of 2.0 g/cm^3. The thickness was checked in a few instances by weight gain of the substrate and a measurement of the tapered section of the deposit with SEM. A good correspondence between the calculated thickness and measured thickness supported the assumptions.

Results and Discussion

In very early experiments a tank-type 300 ml capacity bath was used as a cell. The bath was reused 3 or 4 times for the deposition without changing the solution but after replenishing the $SiHCl_3$. It was noticed that the starting currents in subsequent runs, under identical operating conditions, were smaller than in the previous runs. It was reasoned that some by-product is generated during the $SiHCl_3$ reduction. This by-product adsorbed on the cathode surface in competition with the active $SiHCl_3$ species and hindered the reduction process. As a result, the practice was changed to using a fresh bath for each deposit. However, in order to save on expensive chemicals the cell design was changed and the volume was reduced to ~15 ml solution for a 2 cm diam substrate. All the results described here are for the later practice using the new cell.

A typical deposit made on Ti-6Al-4V substrate at 35°C is shown in Fig. 3. A typical bath contained 0.1M TBAC and 0.25M $SiHCl_3$. The starting currents in general were 2-5 mA/cm^2, but decayed rapidly after about 0.5 min at a rate proportional to $t^{-1/2}$ to t^{-1} (where t is time) with thickening of the deposit (see Fig. 4). The drop in current with time was partly due to the *IR* drop in the growing film, and for the rest the reasons are not completely understood at this time. A 1 μm thick deposit required more than 1000 min. The process was subsequently improved to give better yields. The effect of process variables, such as solute concentration, temperature, and the size of cation in the supporting electrolyte are discussed below. The supporting electrolyte used in most of the experiments was TBAC at 0.1M concentration unless mentioned otherwise.

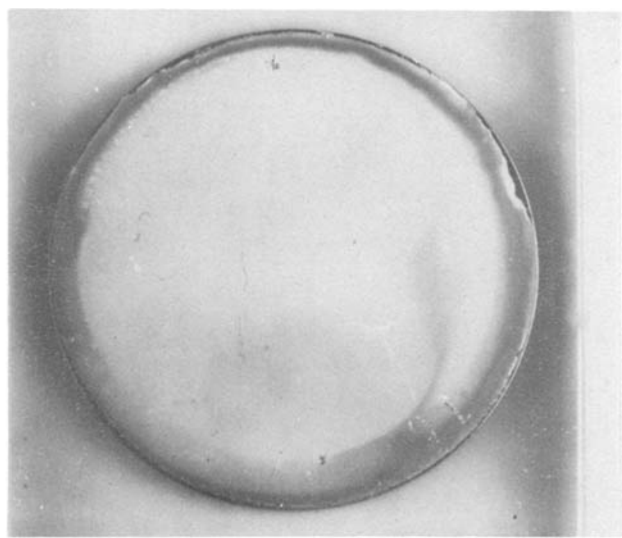

Fig. 3. Photomacrograph of silicon deposit on titanium alloy (4×).

Temperature.—Increasing the temperature above 35°C resulted in a higher starting current which remained higher during the course of deposition. The electrodeposition currents for two temperatures of 35° and 70°C are shown in Fig. 4 for comparison. It should be noted in the figure that although the current for the 70°C run is higher by at least a factor of two over most of the deposition period, the rate of decay for the two runs is almost identical. The identical nature of two curves suggests that the deposition process in both cases is the same. The activation energy for the process was calculated from the Arrhenius plots of i *vs.* $1/T$ shown in Fig. 5, for the temperature range 35°-90°C. Three time intervals 0.1, 1, and 100 min were chosen for the calculations, but all three gave the same value of activation energy 2 ± 0.2 kcal. The low activation energy for the process suggests that the rate-determining step is probably an electrosorption process. Higher temperatures usually resulted in thicker and smoother deposits. Deposit thickness of ~1 μm could be obtained in about 1000 min by operating the cell at 70°C, as opposed to ~0.5 μm at 35°C.

Solute concentration.—The solute concentration in the bath in the range 0.1-1.0M had a significant effect on the rate of current decay as well as on the quality of deposit. The rate of decay, particularly in the first 10 min, was considerably retarded with increasing $SiHCl_3$ concentration. Consequently a deposit of 1 μm thickness could be produced in about an hour or less with 1.0M $SiHCl_3$ in the bath at 50°C or higher. The deposits were also more uniform and smoother in texture than those made with lower concentrations of $SiHCl_3$. Concentrations above 1M $SiHCl_3$ offered no further improvements.

Although the rate of current decay was affected by the solute concentration, the starting current changed little with the increasing $SiHCl_3$ concentration. The starting current was strictly dependent upon the type of substrate used for the cathode.

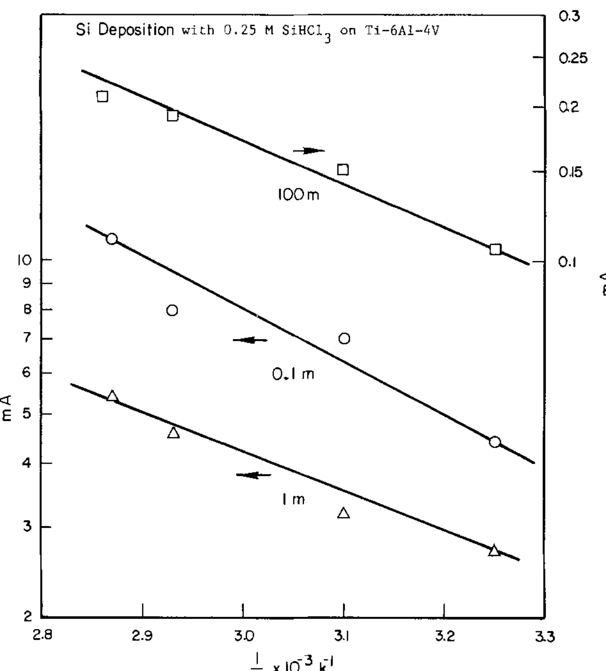

Fig. 5. Arrhenius plots of I vs. $1/T$ at 0.1, 1, and 100 min

Supporting electrolyte.—From the low activation energy and the current decay behavior during the deposition, it was hypothesized that the process is adsorption controlled. It was, therefore, concluded that by changing the cation size of the supporting electrolyte in the bath, the deposition rate and the quality of the deposit, particularly the morphology, could be controlled. As a result, silicon deposition was experimented using different supporting electrolytes of the tetraalkylammonium chloride series. The tetraalkylammonium chlorides used in the experiments were TEAC, TPAC, TBAC, TPnAC, and THAC. The concentration of the supporting electrolyte in each of the experiments was kept constant at 0.1M. The nominal bath temperature was 35°C and the $SiHCl_3$ concentration 0.5M.

The morphology of the Si deposit and the deposition current decay both were strongly affected by the size of the cation in the bath. In general, the deposits were coarser with increasing cation size; with smaller cations TEAC and TPAC the deposits were very smooth, at 2000 magnification with SEM no separate nodules could be detected. With THAC, the deposits were extremely coarse and loosely adherent to the titanium substrate. The adherence appeared to improve with lowering of the cation size in the bath.

The starting current on the Ti substrate in all the cases was 2.6 ± 0.2 mA/cm², irrespective of the cation size. However, after a few monolayers of Si deposition the current decay was greatly affected by the cation size. The smaller the cation in the bath, the higher was the rate of current decay. The current decay with TEAC was so rapid that deposit thickness was limited to only ~0.3 μm before the deposition rate reached to nearly zero (~0.01 mA/cm²) value. With THAC, on the other hand, the rate of decay was very small, and the current stayed with deposition at about 1 mA/cm². The starting current of 2.6 mA/cm² appears to be controlled only by the number of active sites available on the Ti substrate for the adsorption of active $SiHCl_3$. It is only after the first few monolayers that the cation size of the supportive electrolyte became important.

In order to improve the morphology of electrodeposited silicon, mixed supporting electrolytes of TBAC and TPAC were tried in the bath. Typical experiments with the mixed TBAC and TPAC electrolyte were made at 50°C and cathode potential of −2.6V *vs.* Pt. The total concentration of the mixed electrolyte in the bath was always maintained at 0.1M with 1.0M $SiHCl_3$. The TPAC:TBAC compositions tried were 1:100, 10:100, 50:50, 100:10, and 100:1. The optimum composition for TPAC:TBAC was found to be 100:10. With this TPAC:TBAC ratio good deposits of about 1 μm could be obtained in less than 2 hr. With any other mixture the rates were significantly lower.

The nodule size in the deposits in general decreased with the increasing proportion of TPAC in the mixture. For comparison purposes, four deposits from different bath compositions are shown in Fig. 6. The lower two of the deposits in Fig. 6 are from pure electrolytes TPAC and TBAC, whereas the upper ones are from 10:100 TPAC to TBAC and 10:100 TBAC to TPAC ratios. The deposit from the bath with 10:100 TBAC to TPAC ratio is fine grained and smoother in comparison to the others. Table I gives the deposit thickness and their resistivity, as measured in the solution, from different electrolyte mixtures. The resistivity generally increased with decreasing nodule size and increasing smoothness.

Composition and properties.—Silicon deposits were analyzed for composition with EDAX, Auger spectrometer, and SIMS. The EDAX analysis showed no other metallic element besides Si. Transfer of specimens from the deposit dry box to the Auger chamber resulted in surface oxidation of deposits. This produced insulating film on the specimen surface, and subsequently presented problems with Auger analysis because of the electron charging. Auger analysis after argon sputtering showed Si_{LL} peak at 92 eV. Analyses with SIMS indicated Si, oxygen (≡3% SiO), and less than 0.01% of trace impurities C, Mg, Al, K, and Na in the deposits. Chlorine was not detected with either SIMS or Auger in any of the deposits analyzed.

The deposits contain some hydrogen, which is driven off on annealing with a threshold at 350°C and a peak of evolution at 470°C. The amount of hydrogen in the deposits varied with the deposition tem-

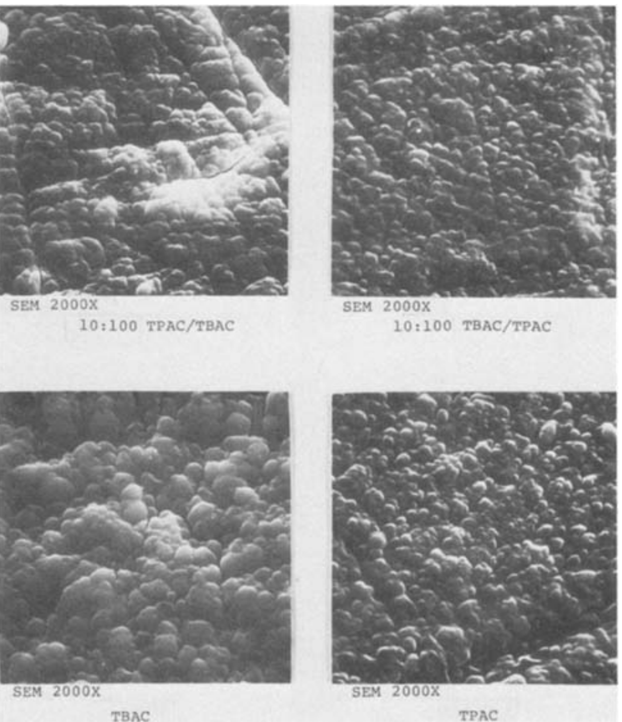

Fig. 6. Micrographs of silicon deposits made with varying supporting electrolyte ratio of TBAC and TPAC on titanium substrate at 50°C.

Table I. α-Si characteristics from mixed TBAC and TPAC electrolyte baths

Ratio TBAC:TPAC	Thickness (μm)	Resistivity[a] (Ω-cm × 10^7)
0:100	0.36	12
1:100	0.68	12
10:100	0.91	1.5
50:50	0.51	7.5
100:10	1.36	3.9
100:1	1.07	2.3

[a] Resistivity as measured in deposition cell using a Wayne-Kerr bridge.

perature. The hydrogen in deposits made at 35°C was determined by thermal evolution in mass spectrometer, whereas other deposits were analyzed by nuclear reaction with ^{15}N beam (5). The hydrogen content was estimated to be 35% in deposits made at 35°C, 20% at 50°C, and only 16% at 90°C.

There is indication from infrared spectra that the hydrogen in deposited silicon is chemically bonded in the form of SiH, SiH_2, and SiH_3, mostly as SiH_2 (6, 7). The nature of bonding changes from SiH_2 to SiH as the temperature of the deposition bath is raised; the change was detected by a shift in the *IR* absorption spectra at 2100 cm^{-1} and appearance of absorption band at 650 cm^{-1}. The *IR* absorption spectra of electrodeposited silicon was interpreted in the light of work by Lucovsky *et al.* (8) with amorphous silicon produced by other techniques.

The electrodeposited silicon showed photoconduction as well as photovoltaic properties. The nature of hydrogen bonding in the deposits and some of their photoelectric properties are subjects of another paper (9).

Amorphous nature of the deposits was determined with x-ray diffraction and transmission electron diffraction. X-ray diffraction of silicon deposits produced no crystalline pattern but only a broad diffused band, indicative of amorphous material. Transmission electron diffraction at 100 kV of free silicon films that were lifted off from the substrate, gave also diffused rather than a crystalline pattern. At 100 kV any microcrystallinity of the order of 10-20Å would have been easily revealed. For the present purposes, the deposited material is therefore considered amorphous.

Conclusions

Amorphous silicon can be deposited from a nonaqueous bath containing PC as solvent, $SiHCl_3$ as solute, and tetraalkyl ammonium chlorides as the supporting electrolytes. The deposit growth is nodular 1-3 μm in size. An increase in bath temperature ($35° \leq T \leq 145°C$) and solute concentration ($0.1 \leq C \leq 1.0M$) favors faster deposition rates, more uniform and smoother deposits. Nodule size and therefore smoothness can also be controlled by using a mixed supporting electrolyte from the tetraalkyl ammonium chloride series.

As deposited α-silicon contains some bonded hydrogen as SiH_2 or SiH. The hydrogen is driven off on annealing at temperatures ~470°C. The electrodeposition process offers an inexpensive route for producing α-Si films for possible solar cell applications.

Resistance to Flow of Current to Scratched Electrodes

H. J. Pearson,[1] G. T. Burstein,* and R. C. Newman

Department of Metallurgy and Materials Science, University of Cambridge, Cambridge CB2 3QZ, England

ABSTRACT

The electrolyte resistance to flow of current to a scratched electrode is calculated assuming the scratch to be shallow and represented by a rectangular planar strip. The resulting equation agrees with experimentally measured ohmic resistances to long, narrow rectangular strip electrodes. Also presented are corrections to the previously published formula for the ohmic resistance to a disk electrode due to finite dimensions of the counterelectrode and the electrochemical cell for systems with radial symmetry.

Rapid mechanical scratching or abrasion of potentiostatically controlled metal electrodes in aqueous electrolytes provides a method of examining the electrochemical properties of metal surfaces initially free from oxide films (1-10). Under external potential control, initially passive electrodes can react at very high anodic current densities on scratching before reverting to the passive state. Important features of an experimental device for studying scratched electrodes are a rapid rate of bare surface generation, an accurately known bare surface area, and minimal surface heating during abrasion. These criteria are satisfied most closely by a device which creates a single narrow shallow scratch on a rotating disk electrode (6-10). The purpose of the present paper is to consider the effects of electrolyte resistance during electrochemical reactions at scratched electrodes under potentiostatic control, where the current passing on the scratched surface flows to a counterelectrode. The related problem of the open-circuit potential distribution across a scratch in a passive film has been investigated by Doig and Flewitt (11) and Melville (12). However, the use of similar open-circuit results to criticize the soundness of the potentiostatic scratching technique (11) is not valid since the current distribution in the two cases is quite different. Many potentiostatic scratching experiments are performed on specimens whose overall surfaces are not coated: the area of exposed metal carries a slow steady-state reaction. Ohmic potential changes occurring around the scratch due to high current densities from the scratch itself can interfere with measurements of scratch current densities. This has been observed when the electrode as a whole is active or carries a readily reducible oxide film (7, 9)).

Newman (13) has presented a calculation of the ohmic potential drop due to current flow between a rotating disk electrode embedded in an insulating surface and a counterelectrode at infinity. He solves the Laplace equation for the potential distribution by transforming to rotational elliptic coordinates (oblate spheroidal coordinates). This exact method of solution is only possible because of the symmetry of the problem and is not available for more general electrode geometries. Here we show that knowledge of the approximate form of the current distribution near the electrode leads to accurate expressions for the ohmic potential drop for various electrode shapes, in particular a thin strip of finite length representing a scratch in a passive film. The technique also allows calculation of the corrections required for counterelectrodes of finite size and distance from a rotating disk working electrode. Confirmation of the calculations is obtained by measuring the ohmic resistance to segments of narrow strip electrodes using a double galvanostatic pulse technique.

Mathematical Model

Consider a plane counterelectrode situated at a position $z = 0$ (where z is the axis perpendicular to the planes of the counter and working electrodes), and a plane working electrode of given geometry embedded in an insulating plane at $z = d$. The Laplace problem for the ohmic component of the potential given by

$$\nabla^2\phi = 0 \qquad [1]$$

may be considered as having the following boundary conditions

$$\phi = 0 \text{ at } z = 0 \qquad [2a]$$

$$\frac{\partial \phi}{\partial z} = \frac{1}{\sigma} f(x, y) \text{ at } z = d \qquad [2b]$$

where x and y are the axes parallel to the counter and working electrode surfaces. $f(x, y)$ is zero on the insulated portion of the plane $z = d$ and represents the current distribution at the surface of the working electrode. The exact value of $f(x, y)$ is such that the value of ϕ is constant on the surface of the electrode. However, calculation will proceed by assuming forms of $f(x, y)$ close to, but not necessarily identical to, the real expression. The first class of geometries that we consider will use an infinite plane counterelectrode at $z = 0$. A further idealized calculation will yield estimates for the corrections due to finite counterelectrode and cell size. The model deals first with the disk electrode as considered by Newman (13) and proceeds to an electrode geometry representing that of a finite, long, narrow, rectangular scratch.

Disk working electrode with plane counterelectrode of infinite size.—Here the boundary value problem is solved by Fourier-Bessel transform in the radial direction. Details are given in Appendix A. For comparison with the results of Newman (13) we consider two current distributions on the disk electrode of radius a

$$f(x, y) = ai_0(a^2 - r^2)^{-1/2} \text{ for } r < a \qquad [3a]$$

$$f(x, y) = i_0 \text{ for } r < a \qquad [3b]$$

where

$$x^2 + y^2 = r^2 \qquad [4]$$

The distribution represented by Eq. [3a] is the same as that for the exact problem solved with the counterelectrode and probe at infinity. Equation [3b] is an artificial distribution included to show the relative insensitivity of the ohmic resistance to the precise form of the current distribution on the electrode. For $d >> a$ Eq. [3b] gives

* Electrochemical Society Active Member.

[1] Present address: Department of Applied Mathematics and Theoretical Physics, University of Cambridge, Cambridge, England.

Key words: disk working electrode, plane counterelectrode, rectangular strip working electrode.

$$R = \frac{V}{I} \approx \frac{1}{4a\sigma}\left(1 - 2\beta\frac{a}{d}\right) \quad [5]$$

where $\beta = \ln(2/\pi) = 0.2206$. This gives a small correction to the result of Newman (13)

$$R = \frac{1}{4a\sigma} \quad [6]$$

due to the finite distance of the counterelectrode. For Eq. [3a] the potential varies across the disk. Taking the potential at the center of the disk as representative we find

$$R_o = \frac{V_o}{I} = \frac{1}{\pi a\sigma}\left(1 - 2\beta\frac{a}{d}\right) \quad [7]$$

Taking the potential at the edge of the disk as representative we find

$$R_a = \frac{V_a}{I} = \frac{2}{\pi^2 a\sigma}\left(1 - 2\beta\frac{a}{d}\right) \quad [8]$$

Thus any suitable average of Eq. [7] and [8] gives a similar result to Eq. [5], for example

$$R = \frac{1}{2a\sigma}\left(\frac{1}{\pi} + \frac{1}{\pi^2}\right) = \frac{1}{3.6a\sigma} \quad [9]$$

A constant current distribution also clearly gives a reasonable value for the ohmic resistance.

Disk working electrode with plane counterelectrode of finite size.—This uses a disk-shaped counterelectrode of radius p, coaxial with the working electrode and distance d from it. For this case we also define the cell as a coaxial cylinder of radius c. Using cylindrical polar coordinates (r, θ, z) the Laplace Eq. [1] is solved subject to the following boundary conditions

$$\frac{\partial\phi}{\partial z} = \frac{1}{\sigma} f(r, \theta) \text{ at } z = 0, d \quad [10a]$$

$$\frac{\partial\phi}{\partial r} = 0 \text{ at } r = c \quad [10b]$$

This now restricts current flow to within the finite cell and specifies the current distribution on the counter and working electrodes. The problem given by Eq. [1] and [8] with distribution of the form [3a] is solved in the manner given in Appendix B using a Fourier-Bessel series expansion. The solution is

$$R = \frac{d}{\pi\sigma c^2} + \frac{1}{\pi\sigma}\sum_{n=1}^{\infty}\frac{1}{\lambda_n^2 J_o^2(\lambda_n)}\left[\frac{\sin(\lambda_n a/c)}{a} + \frac{\sin(\lambda_n p/c)}{p}\right] \quad [11]$$

where the λ_n are the positive solutions of the equation $J_1(\lambda_n) = 0$. The first term on the right-hand side of Eq. [11] is simply the electrolyte resistance within the cylindrically shaped cell. The second and third terms are the end corrections for the finite size of the working and counterelectrodes, respectively. For $a/c << 1$ the second term is the resistance found previously for the disk electrode with c and d infinite (section above). The first and third terms, being independent of a, should represent a good estimate of the correction for finite cell geometry for small scratches as well as disk electrodes and, hence, will be negligible for small scratches. Note that for $p/c = 0.5$ the third term is half the first term.

Rectangular strip working electrode and plane counterelectrode.—We now consider the ohmic resistance to flow of current between a finite length rectangular strip electrode (length $v = 2b$, width $w = 2a$, $b > a$) and a planar counterelectrode. This shape of working electrode is selected since it most accurately represents a rectangular scratch of negligible depth in a metal surface. Details of the calculation are given in Appendix C for the following current distributions analogous to those used above

$$f(x, y) = ai_o(a^2 - x^2)^{-1/2}, \quad -a \le x \le a, \quad -b \le y \le b \quad [12a]$$

$$f(x, y) = i_o, \quad -a \le x \le a, \quad -b \le y \le b \quad [12b]$$

For distribution [12a] we have for $d >> b > a$

$$R = \frac{1}{2\pi\sigma b}\ln\{2[(1 + b^2/a^2)^{1/2} + b/a]\} \quad [13]$$

For the additional inequality that $b >> a$, Eq. [13] simplifies to

$$R = \frac{1}{2\pi\sigma b}\ln(4b/a)$$

For current distribution [12b], and for $d >> b >> a$

$$R = \frac{1}{2\pi\sigma b}[\ln(2b/a) + 1] \quad [14]$$

Equation [13] will be used for comparison with the experimentally determined ohmic resistances (see below).

Experimental

The apparatus used for scratching potentiostatically controlled rotating disk electrodes has been described previously (6-10). The electrochemical cell used for measurement of the ohmic potential drop was similar in design and dimensions; its internal diameter was 10.5 cm and its capacity 1000 cm^3.

The working electrodes were designed to simulate rectangular scratches and were made in the following way. Rotating electrodes were prepared in which the edges of copper foils of various thicknesses were exposed to the electrolyte, as shown in Fig. 1. Three foil thicknesses were used: 39, 126, and 936 μm. The foils were set in epoxy resin so that the rectangular edges were exposed, with the insulating resin forming the rotating disk (8 mm diam). Surfaces were abraded to a 1200 grit finish, cleaned ultrasonically, and degreased. Different lengths of the resulting straight, narrow, rectangular strip copper electrodes were exposed by applying a thin mask of lacquer to insulate varying proportions of the electrode length. Rotation at 33 Hz was used for convenience to remove bubbles adhering to the working electrode surface; however, electrode rotation had no effect on the measured ohmic potentials.

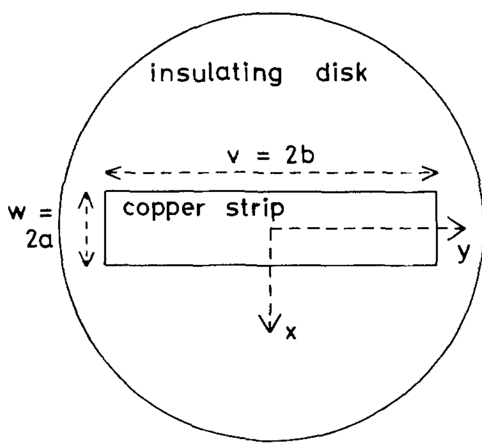

Fig. 1. Schematic diagram of rectangular strip electrode embedded in an insulating rotating disk.

The counterelectrode was a circular platinum disk of 5 cm diam mounted symmetrically below the working electrode surface at a distance of 6 cm. A small hole cut through the center of the counterelectrode allowed a Luggin probe to emerge through it from the bottom of the cell. The probe tip of ~1 mm internal diameter was positioned 4 cm vertically below the working electrode surface. This probe distance is effectively infinite within this cell geometry. Potentials were measured with respect to a saturated calomel reference electrode.

Electrolytes were prepared from analytical grade reagents and distilled water. Their conductivities were measured to ±2% with a conductivity bridge (Wayne-Kerr B642 Auto-Balance Universal Bridge).

The ohmic resistances were measured using a double galvanostatic pulse technique, delivered from a potentiostat (Wenking Type OPA 69, response time 1 μsec) programmed to operate as a galvanostat. Square current pulses were generated by feeding the output of a waveform generator (Chemical Electronics Type WG 01) into the potentiostat. Double current pulses, each of 3 msec duration, were used, both in the anodic direction. The initial current density was zero, and the first pulse (A) was adjusted to give an anodic current density of ~2 A cm^{-2}. The second pulse (B) was adjusted to increase the anodic current density to ~4 A cm^{-2}. Pulse A allowed fast electrode processes such as double layer charging to approach completion; the instantaneous potential change, which occurred as a result of the current pulse B, was used as a measure of the ohmic potential drop in the electrolyte. This was checked by measuring the ohmic potential drop as a function of the current amplitude of pulse B for constant electrode length and width, demonstrating that the relationship was indeed ohmic (see below). Electrode response to the double pulse was stored in a transient recorder (Datalab Type DL 905) and displayed oscillographically. The working electrode was resurfaced between measurements to prevent significant recession of the metal surface into the epoxy resin mount due to anodic dissolution.

All experiments were performed at 291 ± 2 K.

Results and Discussion

Figure 2 shows the relationship between the measured potential change ΔE, due to current pulse B and the pulse amplitude ΔI, for constant amplitude of pulse A. The relationship is ohmic and the slope gives the electrolyte resistance R (25.3Ω measured from Fig. 2; 23.9Ω calculated from Eq. [13]). Figure 2 also shows one measurement for a different amplitude of pulse A, which yields a similar value of R.

The resistance to flow of current through an acetate buffer solution (0.75M HOAc, 0.75M NaOAc) to rectangular electrodes of three different widths, w ($= 2a$), is plotted as a function of inverse electrode length v^{-1} ($v = 2b$) in Fig. 3. The solid lines in Fig. 3 represent the theoretical electrolyte resistance predicted from Eq. [13] using the measured electrolyte conductivity. Deviation from the predicted behavior occurs for the widest electrode (w = 936 μm) for $v^{-1} > 0.4$. This represents the condition $v/w = b/a < 2.5$ and is, in fact, expected from Eq. [13], which is not symmetrical in a and b. Apart from this the experimental data are in excellent agreement with the theoretical predictions. Similar behavior is shown in Fig. 4 for different electrolytes of several conductivities: again significant deviation from the predicted behavior occurs only for $v/w < 2.5$.

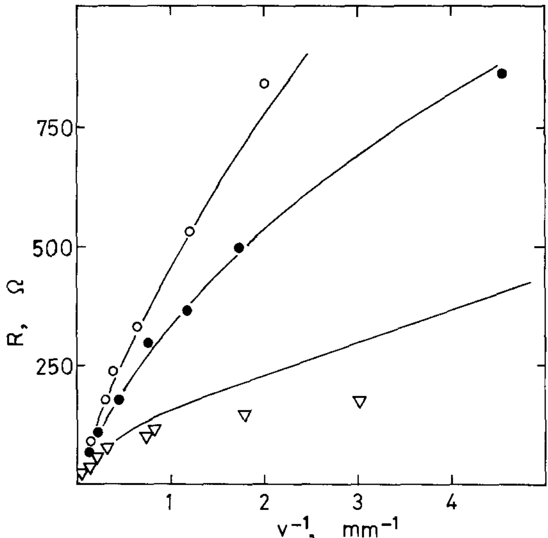

Fig. 3. Electrolyte resistance as a function of electrode length for 0.75M HOAc, 0.75M NaOAc, $\sigma = 3.3\ \Omega^{-1}\ m^{-1}$. ○, w = 39 μm; ●, w = 126 μm; ▽, w = 936 μm. The lines shown are the theoretical lines calculated from Eq. [13].

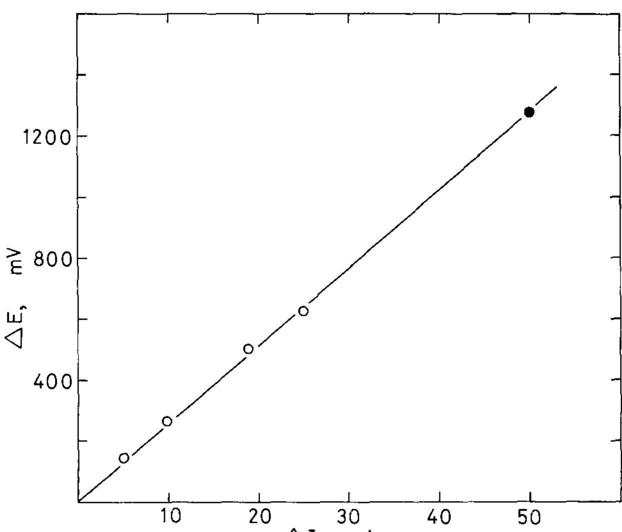

Fig. 2. Measured potential change as a function of applied current pulse (B) amplitude (○). Also shown is one point (●) from pulse A. Electrolyte: 1M KOH, $\sigma = 15.4\ \Omega^{-1}\ m^{-1}$. Strip electrode, w = 39 μm, v = 5.48 mm.

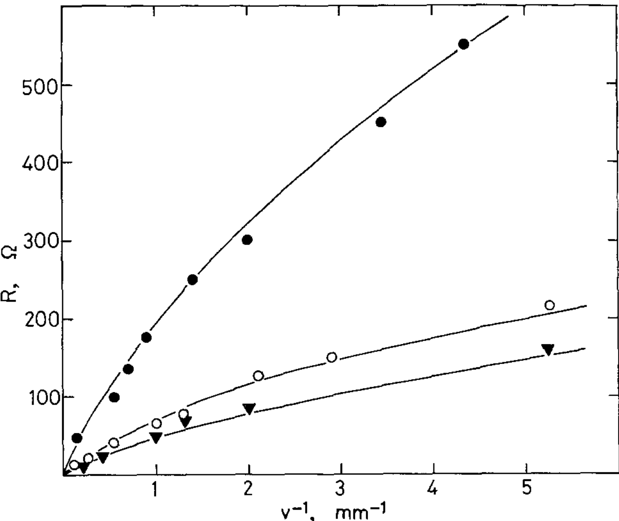

Fig. 4. Electrolyte resistance as a function of electrode length. ●, 0.53M $(NH_4)_2SO_4$, $\sigma = 7.0\ \Omega^{-1}\ m^{-1}$, w = 58 μm; ○, 1M KOH, $\sigma = 15.4\ \Omega^{-1}\ m^{-1}$, w = 126 μm; ▼, 1M H_2SO_4, $\sigma = 32.8\ \Omega^{-1}\ m^{-1}$, w = 39 μm .The lines shown are the theoretical lines calculated from Eq. [13].

The predicted dependence on electrode width using Eq. [13] is shown in Fig. 5 for $b >> a$ ($v >> w$), and agreement is obtained with the measured data. Measurements were also made in several different electrolytes as a function of solution conductivity, and these are shown in Fig. 6 together with the theoretical lines from Eq. [13]. The graph shows that the measured resistance is indeed inversely proportional to the electrolyte conductivity, and the data are in accord with Eq. [14]. Figure 6 also shows that the measured ohmic potentials lie across the electrolyte and are not due to any surface film on the electrode.

However, in electrolytes in which a highly resistive film grows on the metal surface during current pulse A, one would expect the measured ohmic resistances to be higher than those predicted from Eq. [13] by an amount equal to the ohmic resistance of the film. Two such cases are shown in Fig. 7. In both of these electrolytes (1M K_2CO_3, pH 11.6 and 0.5M K_2CO_3, 0.5M $KHCO_3$, pH 9.8) the copper electrode surface was green after galvanostatic pulsing, owing to formation of a copper carbonate film. In both these cases the measured resistances were considerably higher than those predicted from Eq. [13]. Furthermore, successive galvanostatic double pulses in these electrolytes without resurfacing the electrode between measurements gave ohmic resistances which increased with the number of pulses, showing that film thickening occurred. Whether this increased resistance is due to the film lattice itself or to the electrolyte resistance within pores in the film is not known. Clearly, however, a working electrode which does not produce salt films in carbonate electrolytes, such as Pt or Au, could be used to determine the ohmic resistances of these solutions.

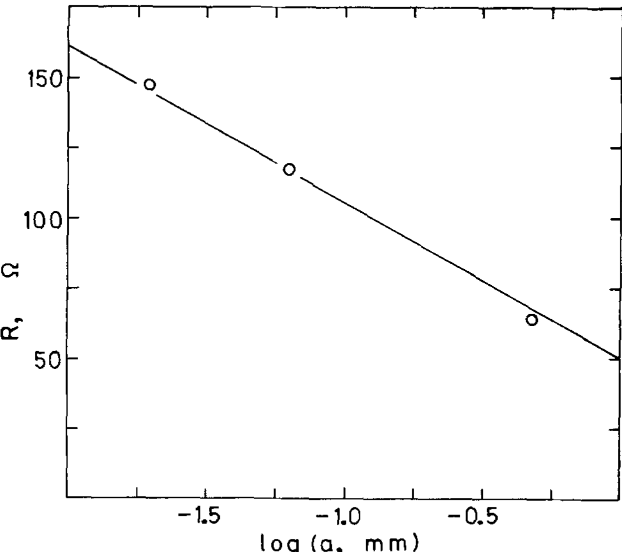

Fig. 5. Dependence of electrolyte resistance on width of strip electrode for constant length (4.0 mm). 0.75M HOAc, 0.75M NaOAc, $\sigma = 3.3\ \Omega^{-1}\ m^{-1}$. The line shown is that calculated from Eq. [13].

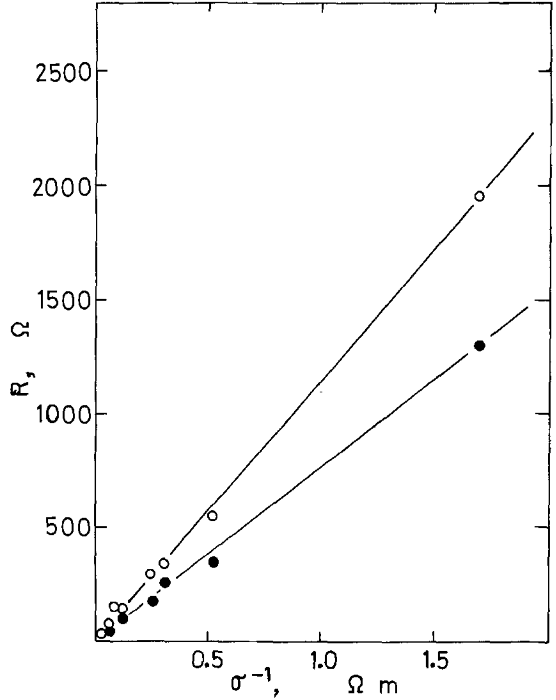

Fig. 6. Electrolyte resistance as a function of conductivity for $v = 1.6$ mm. ○, $w = 39\ \mu m$; ●, $w = 126\ \mu m$. The lines shown are calculated from Eq. [13].

It is clear from Eq. [13] (and Eq. [14]) that for a rectangular scratch in a rotating disk electrode the minimum ohmic potential drop across the electrolyte is achieved when the scratch length and width are both minimum, since the total current I ($= vwi$) decreases more rapidly with decrease in scratch area than does R, and thus the product IR also decreases. Practical limitations on the scratch area, however, arise from the ability to detect very small current transients arising from very small scratches. The technique which has been employed in recent experiments to scratch rotating disk electrodes (6-10) used a diamond stylus assembly which was allowed to fall under its own inertia onto the disk creating a long (~2 mm), narrow (~40 μm) scratch at a distance of ~2 mm from the center of the disk, at a rate determined by the electrode rotation rate. This has simplified the calculation by imposing the inequality $b >> a$ (see above). It also ensures that the scratch is of constant width, thereby approximating rectangularity. The ends of the scratch, which are the contact-making and contact-breaking regions, are tapered: Under the above conditions they comprise only ~5% of the total scratch area. As b approaches a, not only must Eq. [13] be used in its full form, but the scratch ceases to be approximately rectangular, and the equation becomes inaccurate. Thus a long narrow scratch, of sufficiently large area to provide a detectable current transient, provides the most quantifiable reaction

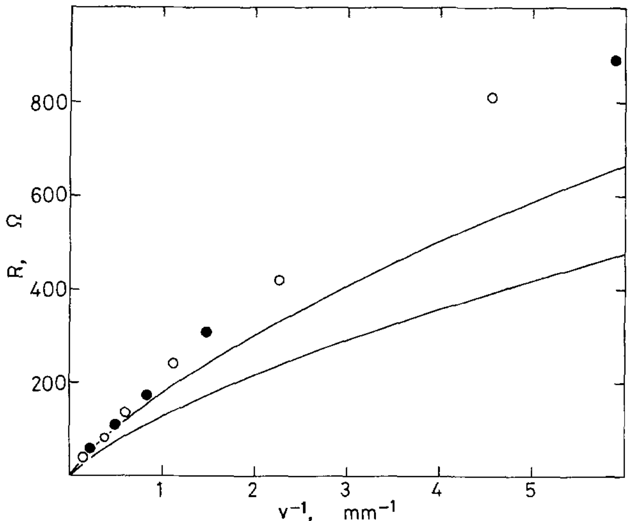

Fig. 7. Measured resistance as a function of electrode length (for $w = 39\ \mu m$) for carbonate electrolytes. ○, upper line: 0.5M K_2CO_3, 0.5M $NaHCO_3$, $\sigma = 8.2\ \Omega^{-1}\ m^{-1}$. ●, lower line: 1M K_2CO_3, $\sigma = 11.4\ \Omega^{-1}\ m^{-1}$. The lines shown are calculated from Eq. [13].

parameters of the freshly generated metal surface. The model described above also assumes that the scratch has no depth. For the experiments described (6-10) the scratch depth of ~ 3 μm was small compared with the width, and was thus negligible.

Doig and Flewitt (11) have criticized the scratched electrode technique using calculations made for the ohmic potential drop to a scratch in a metal surface under open-circuit conditions. In that case the current from the scratch as anode flows to the unscratched area of the same specimen acting as cathode. It is fallacious to apply that calculation directly to a potentiostatically controlled scratched disk, however, since the current now flows to a counterelectrode and not to other parts of the working electrode. That this is so is demonstrated by the ability to record a current transient: if all the current from the scratch flowed to other parts of the working electrode no transient would be detectable. Doig and Flewitt showed that for a scratch current density of 0.3 A cm^{-2} flowing from a scratch 10 μm wide to the surrounding unscratched metal surface in a solution of conductivity 10 Ω^{-1} m^{-1} the ohmic potential drop could be as high as 500 mV. However, under the potentiostatic conditions actually used in these experiments, and with a scratch length of 2 mm, Eq. [13] gives the ohmic potential drop as only 6 mV.

APPENDIX

A. Disk Working Electrode with Plane Counterelectrode of Infinite Size

The problem to be solved is

$$\nabla^2 \phi = 0 \qquad \text{[A-1]}$$

$$\phi = 0 \quad \text{for} \quad z = 0 \qquad \text{[A-2]}$$

$$\left.\frac{\partial \phi}{\partial z}\right|_d = \frac{1}{\sigma} f(r) \quad \text{for} \quad r < a$$
$$= 0 \quad \text{for} \quad r > a \qquad \text{[A-3]}$$

In cylindrical polar coordinates (r, θ, z) we have axial symmetry and may take

$$\phi = \int_0^\infty A(k) J_0(kr) \sinh(kz)\, dk \qquad \text{[A-4]}$$

where J_0 is the zero order Bessel function of the first kind. This form of ϕ satisfies [A-1] and [A-2]; the transform $A(k)$ is determined by [A-3] through the relation

$$\left.\frac{\partial \phi}{\partial z}\right|_d = \int_0^\infty k A(k) J_0(kr) \cosh(kd)\, dk$$

Inverting this expression gives

$$\sigma \cosh(kd) \cdot A(k) = \int_0^a r f(r) J_0(kr)\, dr$$

which is then substituted in [A-4] to give an expression for ϕ.

(*a*) For

$$f(r) = a i_0 (a^2 - r^2)^{-1/2}$$

then

$$\sigma A(k) = \frac{a i_0}{\cosh(kd)} \frac{\sin(ak)}{k}$$

thus

$$\sigma \phi(r, d) = i_0 a \int_0^\infty \frac{\sin(ak)}{k} J_0(kr) \tanh(kd)\, dk$$

In order to find the ohmic drop we evaluate V/I, where V is the potential at the disk electrode, given by $\phi(O, d)$ and I is the total current flowing. The latter is given by

$$I = \int_0^a 2\pi r f(r)\, dr = 2\pi a^2 i_0$$

Evaluating V we have

$$\sigma \phi(O, d) = i_0 a \int_0^\infty \frac{\sin(ak)}{k} \tanh(kd)\, dk \qquad \text{[A-5]}$$

For $d >> a$, that is to say, the counterelectrode many disk radii away from the working electrode, $\tanh(kd)$ differs from unity, while $(\sin(ak))/k$ is given to a good approximation by the constant value a. So we may write [A-5] as

$$\sigma \phi(O \cdot d) = i_0 a \int_0^\infty \frac{\sin(ak)}{k} dk - i_0 \int_0^\infty a^2 (1 - \tanh(kd))\, dk + i_0 a O\left(\frac{a}{d}\right)^3$$
$$= i_0 a \left[\frac{\pi}{2} - \ln \frac{2a}{d} + O\left(\frac{a}{d}\right)^3\right]$$

$$R = \frac{V}{I} \approx \frac{1}{4a\sigma}\left[1 - \frac{2 \ln 2}{\pi}\left(\frac{a}{d}\right)\right]$$

and the correction for the finite counterelectrode distance to the Newman result (13)

$$R = (4a\sigma)^{-1}$$

is of the order a/d $(<< 1)$ as might be expected. $O(a/d)^3$ represents all terms of order $(a/d)^3$.

(*b*) For $f(r) = i_0$

by similar arguments to above

$$\sigma \phi(O, d) = a i_0 \int_0^\infty \frac{J_1(ak)}{k} \tanh(kd)\, dk$$
$$\approx a i_0 \left(1 - \ln \frac{2a}{d}\right)$$

and so

$$R_0 = \frac{1}{\pi a \sigma}\left(1 - \ln \frac{2a}{d}\right)$$

Also

$$\sigma \phi(a, d) = \frac{2 a i_0}{\pi}\left(1 - \ln \frac{2a}{d}\right)$$

whence

$$R_a = \frac{2}{\pi^2 a \sigma}\left(1 - \ln \frac{2a}{d}\right)$$

B. Disk Working Electrode with Plane Counterelectrode of Finite Size

The problem to be solved is

$$\nabla^2 \phi = 0 \qquad \text{[B-1]}$$

$$\frac{\partial \phi}{\partial z} = \frac{1}{\sigma} f_1(r) \quad \text{at} \quad z = d$$
$$= \frac{1}{\sigma} f_2(r) \quad \text{at} \quad z = 0 \qquad \text{[B-2]}$$

$$\frac{\partial \phi}{\partial r} = 0 \quad \text{at} \quad r = c \qquad \text{[B-3]}$$

A suitable representation of ϕ satisfying [B-1] and [B-3] is

$$\sigma \phi = A_0 z + \sum_{n=1}^\infty \left[A_n \exp\left(-\frac{\lambda_n z}{c}\right)\right.$$

$$+ B_n \exp\left(\frac{\lambda_n z}{c}\right)\Bigg] J_o\left(\frac{\lambda_n r}{c}\right) \quad \text{[B-4]}$$

where the λ_n's are the positive roots of $J_1(\lambda_n) = 0$. We take

$$\begin{aligned} f_1(r) &= i_o a (a^2 - r^2)^{-1/2} && \text{for } r < a \\ &= 0 && \text{for } c > r > a \\ f_2(r) &= i_o a^2 p^{-1} (p^2 - r^2)^{-1/2} && \text{for } r < p \\ &= 0 && \text{for } c > r > p \end{aligned}$$

Then, as in Appendix A

$$\sigma A_o = \frac{2a^2 i_o}{c^2}$$

$$\sigma A_n = \frac{2i_o}{\lambda_n^2 J_o^2(\lambda_n)} \; \frac{\dfrac{a^2}{pc}\sin\left(\dfrac{\lambda_n p}{c}\right)\exp\left(-\dfrac{\lambda_n d}{c}\right) - \dfrac{a}{c}\sin\left(\dfrac{\lambda_n a}{c}\right)}{1 - \exp\left(-\dfrac{2\lambda_n d}{c}\right)}$$

$$\sigma B_n = \frac{2i_o}{\lambda_n^2 J_o^2(\lambda_n)} \; \frac{\dfrac{a^2}{pc}\sin\left(\dfrac{\lambda_n p}{c}\right)\exp\left(\dfrac{\lambda_n d}{c}\right) - \dfrac{a}{c}\sin\left(\dfrac{\lambda_n a}{c}\right)}{\exp\left(\dfrac{2\lambda_n d}{c}\right) - 1}$$

for $n = 1, 2, 3 \ldots.$

If $d/c > 1$ and a/p is not too small, then the first term in the expansion for A_n and the second term in the expansion for B_n are both small and may be ignored, giving

$$R = \frac{\phi(d, 0) - \phi(0, 0)}{I} = \frac{d}{\pi\sigma c^2} + \frac{1}{\pi\sigma}\sum_{n=1}^{\infty}\frac{1}{\lambda_n^2 J_o^2(\lambda_n)}\left[\frac{\sin\left(\dfrac{\lambda_n a}{c}\right)}{a} + \frac{\sin\left(\dfrac{\lambda_n p}{c}\right)}{p}\right]$$

C. Rectangular Strip Working Electrode and Plane Counterelectrode

The problem to be solved is

$$\nabla^2\phi = 0 \quad \text{[C-1]}$$

$$\phi = 0 \quad \text{at} \quad z = 0 \quad \text{[C-2]}$$

$$\frac{\partial\phi}{\partial z} = \frac{1}{\sigma} f(x, y) \quad \text{at} \quad z = d \quad \text{[C-3]}$$

The rectangular strip is given by $|x| \leq a$, $|y| \leq b$; $f(x, y) = 0$ outside these limits.

The solution is found in terms of a double Fourier transform in x and y

$$\sigma\phi = \frac{1}{4\pi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} A_1(k_1) A_2(k_2) \exp i(k_1 x + k_2 y) \sinh(kz) dk_1 dk_2$$

where

$$k^2 = k_1^2 + k_2^2$$

This form satisfies [C-1], [C-2], and [C-3] and yields

$$f(x, y) = \frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \exp i(k_1 x + k_2 y) \, A_1(k_1) A_2(k_2) k \cosh(kd) dk_1 dk_2 \quad \text{[C-4]}$$

(*a*) Suppose the current density on the rectangular strip is constant, i_o

$$I = 4abi_o$$

Inverting [C-4] gives

$$A_1(k_1) A_2(k_2) k \cosh(kd) = i_o \int_{-a}^{a}\int_{-b}^{b} \exp -i(k_1 x + k_2 y) \, dxdy = 4i_o \frac{\sin(k_1 a)}{k_1}\frac{\sin(k_2 b)}{k_2}$$

Therefore

$$\sigma\phi(0, 0, d) = \frac{i_o}{\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{\sin(k_1 a)}{k_1}\frac{\sin(k_2 b)}{k_2}\frac{\tanh(kd)}{k} dk_1 dk_2$$

To evaluate this integral we transform to polar coordinates: $k_1 = k \sin\theta$, $k_2 = k\cos\theta$, $dk_1 dk_2 = kdkd\theta$, and note that only a very small error is made by putting $\tanh(kd) = 1$. Then

$$\sigma\phi(0, 0, d) = \frac{4i_o}{\pi^2}\int_0^{\infty}\int_0^{\pi/2}\frac{\sin(ak\sin\theta)\sin(bk\cos\theta)}{k^2\cos\theta\sin\theta} dkd\theta$$

The k integration gives

$$\frac{\pi b}{2\sin\theta} \qquad a\sin\theta > b\cos\theta$$

$$\frac{\pi a}{2\cos\theta} \qquad a\sin\theta < b\cos\theta$$

leading to a final answer of

$$\sigma\phi(0, 0, d) \approx \frac{\pi}{2} a i_o \left[\ln\left(\frac{2b}{a}\right) + 1\right]$$

for a long thin strip, where $b >> a$. This gives

$$R = \frac{1}{2\pi\sigma b}\left[\ln\left(\frac{2b}{a}\right) + 1\right]$$

(*b*) For the more realistic current distribution

$$f(x, y) = a i_o (a^2 - x^2)^{-1/2}, \quad |x| < a, \quad |y| < b$$

the calculation is similar, with $(\sin(k_1 a))/k_1$ replaced by $J_o(ak_1)$. The final result for this case is

$$R = \frac{1}{2\pi\sigma b}\ln\left\{2\left[\left(1 + \frac{b^2}{a^2}\right)^{1/2} + \frac{b}{a}\right]\right\}$$

for $d >> b > a$.

LIST OF SYMBOLS

a	radius of disk-shaped working electrode; half-width of strip working electrode
$A(k)$	transform of potential
A_n	coefficient in expansion for potential
b	half-length of strip working electrode
B_n	coefficient in expansion for potential
c	radius of cylindrical cell
d	distance between working and counterelectrodes
E	electrode potential
i	current density
I	current
J_o	zero order Bessel function
J_1	first order Bessel function
k	wave number
O	terms of order . . .
p	radius of counterelectrode
r	polar coordinate
R	resistance
v	length of strip working electrode
V	potential difference
w	width of strip working electrode
x	cartesian coordinate
y	cartesian coordinate
z	polar, cartesian coordinate
β	$\ln(2/\pi)$
θ	polar coordinate
λ_n	positive roots of equation $J_1(\lambda_n) = 0$
σ	electrolyte conductivity
ϕ	potential

Conductivity of Beta-Alumina Highly Doped with Iron

John H. Kennedy and Susan M. Stuber

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

Complex plane impedance diagrams were used to determine the ionic conductivity of Fe-doped β-alumina over the composition range $Na_{1.3}Al_{9.86}Fe_{1.14}O_{17.15}$ (10% Fe by weight) to $Na_{1.3}Al_{7.18}Fe_{3.82}O_{17.15}$ (30% Fe by weight). The influence of starting material [Fe_2O_3, $Fe_2(C_2O_4)_3 \cdot 6H_2O$, $Fe(C_2O_4) \cdot 2H_2O$, $Fe(NO_3)_3 \cdot 9H_2O$] upon grain boundary and bulk properties was studied. The ionic conductivity of all doped materials increased over that of undoped β-alumina. The best materials obtained resulted from doping with $Fe(C_2O_4) \cdot 2H_2O$. At the 10% doping level, bulk conductivity reached a maximum coinciding with a minimum in activation energy. Electronic conductivity was investigated by a "floating" blocking technique. The electronic conductivity was small at the 15% dopant level, representing $<10^{-3}$% of the total conductivity, but increased rapidly and at the 30% dopant level was $\sim$0.1% of the total conductivity. Preliminary Mössbauer studies showed a steady increase in the Fe(III)/Fe(II) ratio as dopant levels increased.

A previous study of β-alumina doped with small amounts of iron [*ca.* 2 weight percent (w/o)] investigated the oxidation states and site symmetry of the iron dopant and concluded that both Fe(II) and Fe(III) were present after air sintering (1). Conductivity results for iron-doped β-alumina containing up to 8 w/o Fe showed an increase in bulk conductivity up to 4 w/o Fe while 8 w/o material was of lower density and conductivity when the same sintering conditions were used (2). It becomes apparent that sintering conditions must be adjusted as the dopant level changes in order to achieve the maximum density and conductivity particularly when higher doping levels are attempted.

In the present study iron doping of 10-30 w/o has been carried out, and changes in bulk and grain boundary conductivity are reported. The influence of starting material and sintering conditions on the properties of the sintered pellets has also been studied. It was anticipated that high doping levels of iron in β-alumina could be attained because Fe_2O_3 and Al_2O_3 form solid solutions across the whole composition range and β-alumina analogs of the type $MFe_{11}O_{17}$ are also known (3, 4).

Experimental

Sodium β-alumina (Alcoa XB-2 "Superground") was doped with iron using Fe(III) nitrate, Fe_2O_3, Fe(II) oxalate, and Fe(III) oxalate as starting materials. In some of the samples investigated, Na_2CO_3 was added as a starting material in order to see the influence on the final Na^+ concentration. The presence of Na_2CO_3 seemed to have no effect on the outcome. However, the important factor for maintaining sample control with regard to Na^+ concentration involved a fresh packing of coarse β-alumina powder surrounding the pellets. All samples were packed in 300 mesh β-alumina during sintering. Details of the doping and firing procedures have been published previously (1).

Pellets of approximately 1.27 cm diam and 0.2 cm thickness were isostatically pressed and then sintered. Sintering time and temperature necessary to yield highest density material (typically 3.15-3.25 g/cm^3) were determined for each iron concentration. Material of the highest density invariably also exhibited the highest conductivity. In general, 0-10 w/o Fe material could be sintered at 1600°C for 3 hr while 15-25 w/o Fe was sintered at 1540°C for 3 hr. Recent measurements with more highly doped iron (>25%) indicate that sintering temperature must be decreased to about 1500°C to achieve optimum results. When pellets are fired at too high a temperature they shrink to a small diameter but are porous and are of low density, mechanical strength, and conductivity. All samples were fired in air.

The sintered disks were prepared for electrode deposition by polishing with successively finer grades of silicon carbide paper. Finishing was accomplished by polishing with 9, 6, and 3 μm diamond impregnated lapping wheels. The polishing solvent was ethanol. The polished samples were then ultrasonically cleaned in acetone. The disks were then heated at 300°C for 24 hr before electrodes were applied.

Electrodes were deposited on the disks by a Technics, Incorporated Hummer Sputtering and Deposition instrument using a gold target. The electrodes were nominally 2.5 μm thick.

Complex impedance/admittance diagrams were recorded between 25° and 325°C by placing the sample in a furnace which was inside a helium-filled glove box (Overly P-100). Accurate temperature control

Key words: complex plane analysis, Fe-beta-alumina, solid electrolyte.

was achieved by a digital setting Eurotherm controller. Measurements from 10^{-4} to 10^{+6} Hz were made using a Schlumberger-Solartron 1174 Frequency Response Analyzer interfaced to a Hewlett-Packard 9845-S desktop computer. Most often impedance measurements were taken directly and inversion of the data to the admittance mode, if desired, was part of the 9845 program. The computer was programmed to accept measurements from the frequency response analyzer in the a,b (cartesian coordinates) mode and generally 16 data points per decade of frequency were taken, although this feature was programmable. In addition to tabulating the results, the program output was in the form of a complex plane plot which could then be fit to a series of semicircles and straight lines by curve fitting routines (5). An example is shown in Fig. 1.

A correction program was incorporated to compensate for inductive and capacitive effects observed at high frequency (10^5-10^6 Hz). The signal across the sample was normally 100 mV but other signals may be selected as part of the computer program.

X-ray diffraction patterns were obtained using a diffractometer to determine percentage of β''-alumina present.

Sodium analysis was accomplished by dissolving the samples in boiling, concentrated phosphoric acid and analyzing the solution by atomic absorption. Exchangeable sodium was also determined by ion exchanging the samples with molten $AgNO_3$ and measuring the mass change (2).

Results

An equivalent circuit which approximates polycrystalline β-alumina has been reported (2, 6) which allows the calculation of bulk and grain boundary effects from complex plane diagrams. Values reported here were determined using the techniques reported previously (2) plus computer program curve-fitting routines developed since the previous study (5).

The conductivity in all doped samples increased compared to undoped β-alumina. However, differences were observed depending on the starting material used for doping. Densities, sodium content, conductivities, and activation energies were all sensitive to the starting composition. Because firing resulted in decomposition of all starting materials to the oxide form but the observed final Fe(II/III) ratio was dependent on firing conditions, these differences were attributed to differences in particle size and attainment of homogeneity. In general it was found that doping with Fe(II) oxalate gave pellets with the highest density and conductivity at each doping level investigated. Therefore, results with this particular dopant starting material will be emphasized. Results are shown in Table I for all Fe(II) oxalate compositions. In addition, other materials with data of particular interest discussed in the text are also presented.

A maximum bulk conductivity, σ_b, was observed at ~10 w/o Fe followed by a steady decrease in the conductivity values up to the highest levels investigated to date (30 w/o). At the same time the activation energy for bulk conductivity was a minimum at the 10 w/o doping level. These trends can be seen in Fig. 2 and Fig. 3. At first it was thought that the decrease in conductivity reflected less-than-optimum sintering conditions as was experienced for early work with 8 w/o iron doped β-alumina (2). However, densities near theoretical were obtained for several samples and all attempts to improve the density and conductivity over those shown in Table I have failed.

Table I. Properties of Fe-doped β-alumina

Nominal composition dopant	Nominal formula (iron as +3)	Density (g/cm^3)	% Na AA	% Na Ag exch.	$\beta:\beta''$ (%)	Fe(III)/Fe(II)	$\sigma_{b\ 25°}$ $(\Omega\ cm)^{-1}$	$\sigma_{b\ 300°}$ $(\Omega\ cm)^{-1}$	$\sigma_{gb\ 25°}$ $(\Omega\ cm)^{-1}$	E_a (bulk) (kcal/mol)	$E_{a(gb)}$ (kcal/mol)	σ electronic $(\Omega\ cm)^{-1}$

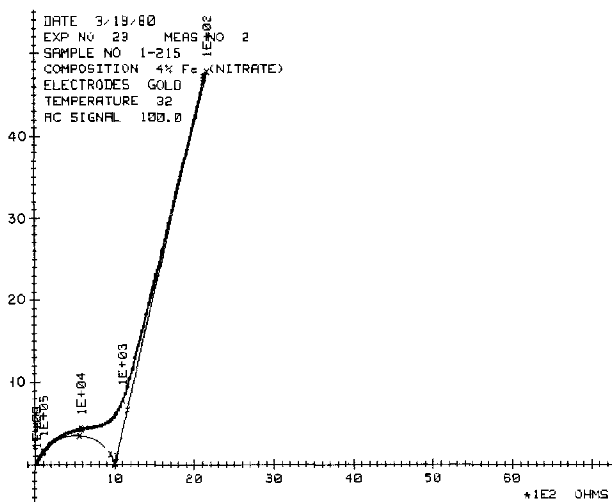

Fig. 1. Impedance diagram showing experimental data and mathematical fitting into semicircle and straight line components.

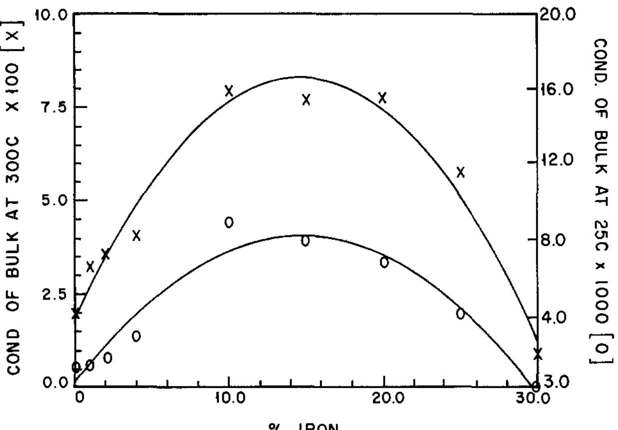

Fig. 2. Bulk conductivity at 25° and 300°C as a function of iron content.

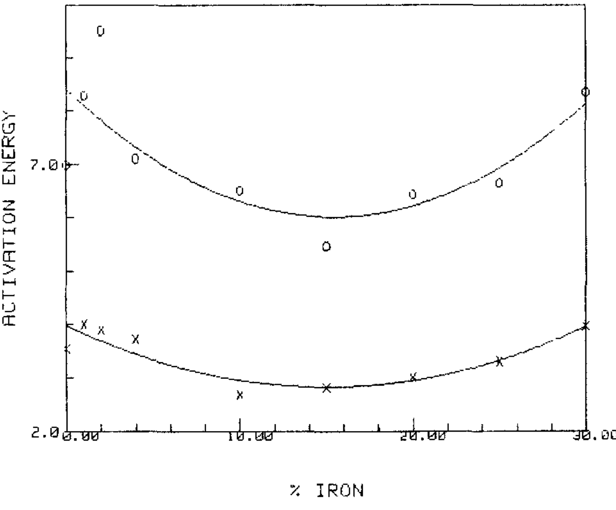

Fig. 3. Activation energy of bulk (X) and grain boundary (○) as a function of iron content.

The grain boundary conductivity also reached a maximum in the same doping region as the bulk conductivity but the actual peak value was observed at 15 w/o Fe as shown in Table I and Fig. 4. The activation energy showed the same small trend toward lower values in the 10-20 w/o doping region as did the activation energy for bulk conductivity.

Grain boundary contribution to the total resistance of a sample at 300°C was so small that measured

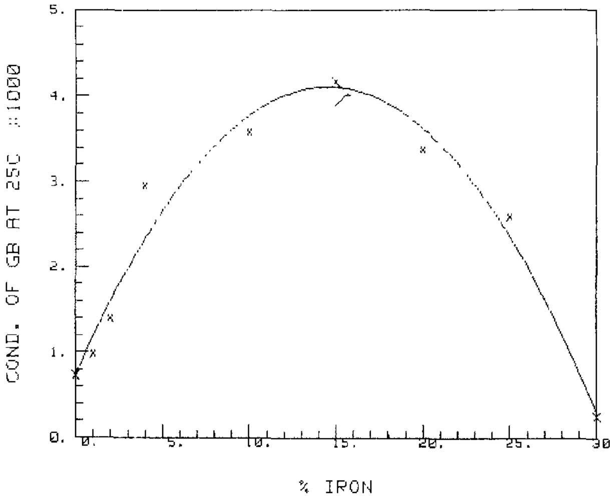

Fig. 4. Grain boundary conductivity at 25°C as a function of iron content.

values are not very meaningful. The cross-over temperature above which bulk resistance was the dominant factor occurred a little above room temperature (<80°C for most materials). Below this temperature grain boundary resistance was greater than the bulk resistance.

Admittance diagrams in the 10^{-2}-10^{-4} Hz frequency range gave no evidence for the existence of any appreciable electronic conductivity, *i.e.*, the lowest frequency semicircle had a real-axis intercept of zero mhos (infinite resistance) within experimental accuracy (Fig. 5). This conclusion was supported by d-c measurements with gold blocking electrodes (Fe-doped β-alumina is not stable in the presence of sodium so that the traditional Wagner blocking technique was not possible). A reasonably stable steady-state current was reached after 1-2 days at each applied voltage, and a plot of current *vs.* applied voltage is shown in Fig. 6. The slope of the line indicated a resistance of $2.3 \times 10^6 \Omega$ which translated to a conductivity value of 1.2×10^{-7} $(\Omega\text{-cm})^{-1}$ for 15% Fe-doped β-alumina. Since true equilibrium may not have been reached, this probably represents a maximum value for electronic conductivity in this "floating" system (*i.e.*, no reference potential as in a Wagner blocking technique). The bulk conductivity for this material was 7.9×10^{-3} $(\Omega\text{-cm})^{-1}$ at 25°C so that electronic conductivity contributed $<10^{-3}$% of the total conductivity. As can be seen from Table I the

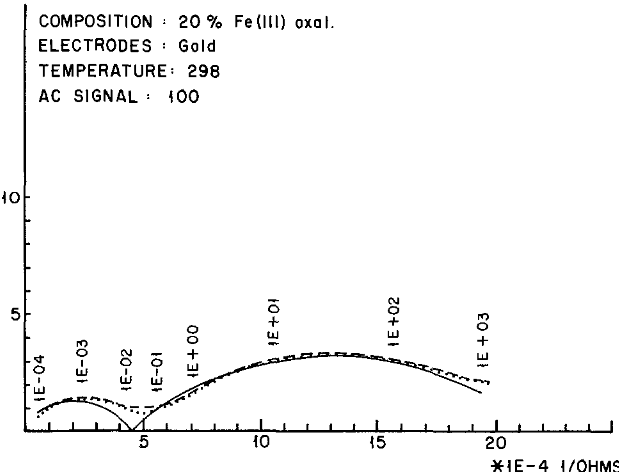

Fig. 5. Admittance diagram for 20% Fe in β-alumina doped from Fe(III) oxalate. Low frequency intercept of zero (within experimental uncertainty) gives no evidence for electron hopping.

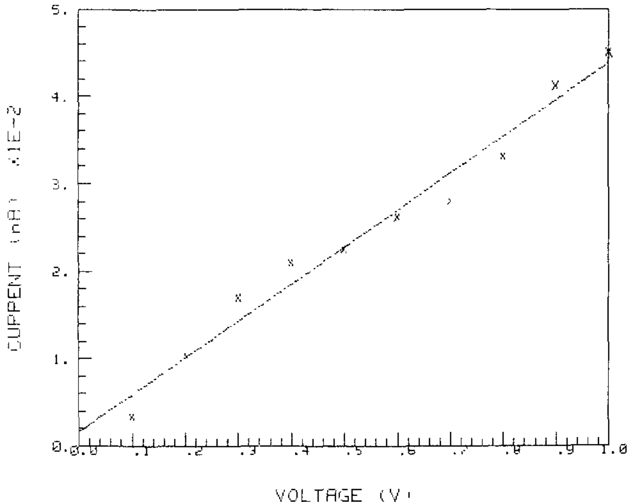

Fig. 6. Plot of current vs. applied voltage for 15% Fe in β-alumina doped from Fe(II) oxalate.

percentage electronic conductivity increased rapidly to nearly 0.1% when the iron content reached 30%. Roland reported (7, 8) that electronic conductivity in iron-doped β-alumina was significant at these doping levels and projected that at 53 w/o Fe electronic conductivity would equal ionic conductivity. Results from this study show that the percentage electronic conductivity does increase with increasing Fe content but the point at which $t_i = t_e$ would not be reached until at least 60 w/o Fe were present assuming the observed trend continued. This point will be discussed further later on.

A critical factor in the electrochemical properties of iron-doped β-alumina is the Fe(III)/Fe(II) ratio. It is well known that metal ions in the plus two oxidation state tend to increase the conductivity of β-alumina, probably by incorporating more conductive Na^+ and/or by decreasing the concentration of O^{2-} interstitials needed for charge compensation. A Mössbauer study of low iron doping showed the existence of both Fe(II) and Fe(III) in nearly equal proportions (1). A more accurate calculation based on peak areas attributable to Fe(II) and Fe(III) shows that the Fe(III)/Fe(II) ratio was about 1.7 at the 2.95 w/o doping level. Higher doping levels also showed the existence of Fe(II), but preliminary results indicated that the Fe(III)/Fe(II) ratio increased to 4 at 20 w/o Fe and to 7 at 25 w/o Fe. Details of the Mössbauer study will be published later. Similar results showing an increase in the Fe(III)/Fe(II) ratio at higher doping levels were also reported by Burzo and Ardelean in their work with iron-doped glasses (9).

Another factor which was considered to play a role in the electrochemical properties of Fe-β-alumina was the possible presence of β″-alumina. Low doping levels of Fe reported previously showed only single phase β-alumina (1, 2). However, Mg^{2+} stabilizes the β″-form and perhaps other M^{2+} ions could play the stabilizing role to produce compositions of the type $Na_{2-x}M_{1-x}{}^{2+}Al_{10+x}O_{17}$. X-ray diffraction patterns of β-alumina doped with at least 10 w/o Fe generally indicated the presence of the β″-phase. The amount of β″-phase remained small even at high doping levels which may be a result of the small amount of Fe(II) in highly doped Fe-β-alumina. Amounts of β″-phase estimated from diffraction line intensities are given in Table I. The technique for estimating β/β″ involved comparing diffractometer peak heights for the following d-spacings: $d = 2.039$ and $d = 1.939$ for β compared to $d = 1.978$ for β″; $d = 2.687$ and $d = 2.514$ for β compared to $d = 2.605$ for β″. The peak heights were normalized to the peak heights reported for pure β and β″-alumina. It should be noted that the material showing the highest bulk conductivity [10 w/o from iron(II) oxalate] also contained the highest concentration of β″-alumina.

Discussion

Previous work involving M(II) doping showed that conductivity increases correlated well with M(II) content and also with sodium content (2). One possible charge compensation mechanism involves replacement of an Al(III) by an M(II) in the spinel block with incorporation of an additional sodium ion in the conduction plane. When β-alumina is doped with iron, some of the iron is present as Fe(II) and, therefore, this mechanism would be possible. However, unlike other plus two metal dopants such as Mn, Co, and Ni, the sodium content did not continue to increase as the dopant level increased (2). In Table I it can be seen that with higher doping levels the sodium content did not correlate well with doping level and, if anything, was no higher than undoped β-alumina.

These results are not unexpected when one considers the Mössbauer results. As the dopant level increased the percentage Fe(II) decreased so rapidly that the concentration of Fe(II) in 25 w/o Fe was less than in 20 w/o Fe (3 *vs.* 4%). The maximum concentration of Fe(II) probably occurred in the 10-20 w/o region which correlates well with conductivity.

Another charge compensation mechanism involves a decrease in blocking oxide interstitials as the M(II) concentration increases. One would predict a decrease in activation energy for this mechanism and no necessary change in sodium content. As can be seen in Fig. 3, the lowest activation energies were observed with 10-20 w/o Fe, but, if anything, a slight increase at low doping levels compared to undoped β-alumina [data taken from Ref. (2)]. Thus, it appears that at low doping levels (<5 w/o Fe) a significant amount of Fe(II) is present which incorporates additional sodium ions resulting in an increase in bulk conductivity. At higher doping levels the amount of Fe(II) reaches a maximum in the 10-20 w/o region and this doping is at least partially charge compensated by a decrease in oxide interstitials leading to a lower activation energy. At doping levels >20 w/o Fe the amount of Fe(II) drops, and the conductivity begins to fall as the activation energy begins to increase.

This simple picture is clouded by the presence of β″-phase. One would expect a higher conductivity for β″-form compared to β, and this may account for some of the increased conductivity in the 10-20 w/o region. However, β″-phase was also found in the 30 w/o material so that the previous argument involving Fe(II) concentratiaons probably predominates.

The increasing electronic conductivity at high doping levels most likely reflects the shorter average distance between iron atoms. If an electron hopping mechanism exists it would be necessary to maintain a significant amount of Fe(II) in the structure at high doping levels. It was shown in a previous study (1) that Fe(III) may be reduced to Fe(II) in β-alumina by treatment with 90% N_2/10% H_2 at 1200°C. An increase in the Fe(II) content at high doping levels may result in a substantial increase in electronic conductivity making these materials potentially valuable mixed conductors. The Fe(III)/Fe(II) ratio is most probably a sensitive function of sintering temperature and sintering atmosphere and this fact could explain the higher electronic conductivity values reported by Roland (7, 8). However, no information on the Fe(III)/Fe(II) ratio is available for his materials. At present we are continuing these studies of β-alumina highly doped with iron to investigate the possibility of increasing the electronic conductivity (and possibly the ionic conductivity as well) by increasing the amount of Fe(II).

Effects of Cadmium Impurities on the Electrowinning of Zinc

F. R. Foulkes,* J. W. Smith, R. Kalia, and D. W. Kirk*

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A4

ABSTRACT

A study was carried out on the effect of cadmium, a major impurity in commercial zinc electrolytes, on the zinc plating current efficiency in acid sulfate baths. The synthetic electrolyte (200 $g \cdot dm^{-3}$ Zn^{++} and 0-100 $mg \cdot dm^{-3}$ Cd^{++}) was continuously circulated through the electrolysis cell. The electrolysis was carried out with a current density of 480-490 $A \cdot m^{-2}$ at 37°C. Hydrogen overpotential, potential sweep, atomic absorption, x-ray diffraction, and electron microscopy were used to determine the effect of cadmium on the behavior of the zinc plate. The results indicate that cadmium may either increase or decrease the zinc plating current efficiency. For Cd^{++} less than 20 $mg \cdot dm^{-3}$, increasing cadmium concentrations in the electrolyte reduce the hydrogen overpotential and the zinc plating current efficiency. For Cd^{++} greater than 20 $mg \cdot dm^{-3}$, increasing cadmium concentrations cause a refinement in the structure of the zinc plate with subsequent increase in the hydrogen overpotential and in the zinc plating current efficiency. The incorporation of cadmium into the zinc plate neither significantly alters the crystal orientation of the deposit nor alters the hydrogen evolution mechanism.

The effects of metallic ion impurities on the electrowinning of zinc from acidic sulfate solutions have been the subject of a large number of investigations (1-3). Metallic impurities are known to affect the current efficiency, deposit morphology, and product purity. In general, metal impurities more noble than zinc and having less negative hydrogen overvoltages tend to reduce the current efficiency (4) and accelerate the rate of dissolution of the electrodeposited zinc in both acidic and alkaline media (5, 6). Although lead is a more noble metal, lead ions are recognized to either increase or not affect the zinc plating current efficiency (1, 7). This effect is attributed to a more negative hydrogen overvoltage on lead [−1.09V for Pb, −0.75V for Zn in H_2SO_4 at 16°C and 1 $A \cdot m^{-2}$ (8)]. Similarly, magnesium also is known to retard the corrosion of zinc (9).

Cadmium also has a large hydrogen overvoltage, but there is disagreement in the literature concerning its effects on zinc electrodeposition. It has been reported that cadmium increases (10), does not affect (11), and decreases (1, 7) the current efficiency. It also has been reported that cadmium retards zinc corrosion (12-14) as well as accelerates it (15). The present work was undertaken to clarify the effects of cadmium impurities on the electrowinning of zinc.

Experimental

Cell.—The experimental cell (Fig. 1) was constructed of Lucite. The grooves in the side walls permitted the maintenance of a uniform and reproducible electrode gap of 3.7 cm. The electrical connections were sealed at the gastight lid, so that the rate of hydrogen evolution during deposit dissolution could be measured using a soap-bubble flowmeter at outlet G when the spent electrolyte outlet (F) was closed.

The cathodes were cut from 0.35 mm thick aluminum foil. Before use, they were treated for 2 min with 2.0M NaOH solution, washed with distilled water, treated with 0.05M H_2SO_4 solution, washed again with distilled water, and dried in an oven at 100°C. This cathode pretreatment procedure was found to be essential in order to obtain reproducible results. The backs, edges, and upper faces of the cathodes were masked with "invisible sellotape." By so decreasing the effective area of the cathode compared with that of the anode, a uniform deposit was obtained. The anode,

made from lead containing 2% silver, was anodized in 2M H_2SO_4 for 1 hr at 360 $A \cdot m^{-2}$ before use.

Reagents.—The electrolyte was prepared by dissolving Fisher certified $ZnSO_4$[1] and H_2SO_4 in double distilled water to yield a solution containing 62 $g \cdot dm^{-3}$ Zn and 200 $g \cdot dm^{-3}$ free acid. Cadmium sulfate (Analar, B.D.H.) was used for making a stock solution containing 2.0 $g \cdot dm^{-3}$ Cd^{++} which was further diluted as required to be added as 5 cm^3 aliquots to 500 cm^3 of zinc electrolyte.

Measurements.—A cathodic current density of 480-490 $A \cdot m^{-2}$ was maintained during all the electrodeposition experiments. Cathodic voltages were measured against a saturated calomel electrode (SCE)[2] using a Corning *pH* meter, Model 7. Fresh electrolyte was pumped to the cell at a constant rate of 2.0 $cm^3 \cdot min^{-1}$ using a Teflon-lined solution metering pump. The temperature of both the cell and electrolyte was maintained at 37° ± 1°C in a constant temperature bath.

Unless otherwise specified, the electrolysis was carried out for 90 min. For current efficiency determinations the cathode was removed from the cell immediately after a run, washed with distilled water, dried at 60°C, and weighed to constant weight. For cathode dissolution experiments the pump was shut off immediately after the electrolysis, the cell outlet closed, and the rate of hydrogen evolution measured with a soap-bubble gas flowmeter.

The current efficiency determinations were reproducible to ± 0.3%, while the time required to dissolve the deposit in a sulfuric acid solution varied by ± 10 min for apparently identical plates.

Results and Discussion

The effect of cadmium on the zinc plating current efficiency is shown in Fig. 2. The electrolyte contained 200 $g \cdot dm^{-3}$ H_2SO_4 and 62 $g \cdot dm^{-3}$ Zn^{++} with varying cadmium concentrations. It can be seen from

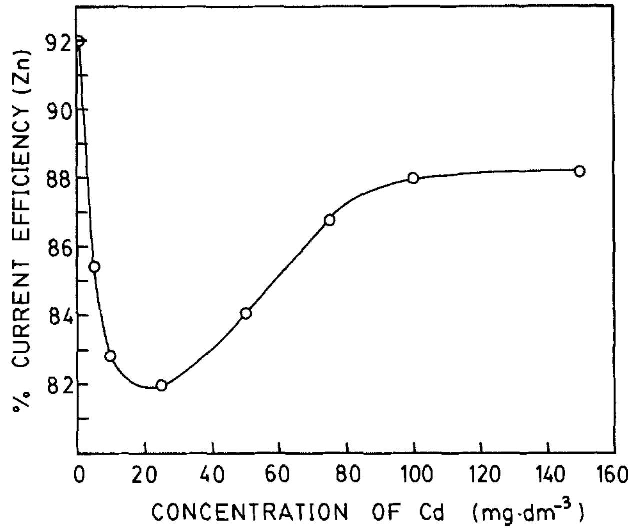

Fig. 2. Effect of cadmium concentration on zinc plating current efficiency. Electrolyte: H_2SO_4 200 $g \cdot dm^{-3}$, Zn 62 $g \cdot dm^{-3}$. Temperature 37°C.

the figure that the current efficiency has a minimum at about 20-25 $mg \cdot dm^{-3}$ Cd^{++}. Increasing cadmium concentrations to this level causes a decrease in the zinc plating current efficiency, while increasing cadmium concentration above this level causes an increase in the zinc plating current efficiency. This behavior is undoubtedly the cause of some of the confusion concerning cadmium effects on current efficiency. In the range 0-20 $mg \cdot dm^{-3}$ Cd^{++}, Kerby and Ingraham (1) reported a decrease in the zinc plating current efficiency from 92% to 80% with increasing cadmium concentration. Similarly Nikiforov (16) has reported increasing current efficiency with decreasing cadmium concentration for concentrations less than 6 $mg \cdot dm^{-3}$. These observations are in agreement with our work.

For a greater concentration range Turomshina and Stender (9) reported no change in the zinc plating current efficiency with 10 $mg \cdot dm^{-3}$ Cd^{++}. As can be seen from Fig. 2, the current efficiency is very sensitive to small concentrations of Cd^{++} and a small concentration of Cd^{++} impurity would result in there being no apparent difference in the current efficiency with the 100 $mg \cdot dm^{-3}$ Cd^{++} solution. Figure 2 also shows that at concentrations greater than ~100 $mg \cdot dm^{-3}$ cadmium does not seem to greatly alter the current efficiency and it is possible to speculate that the reduction in zinc plating current efficiency reported by Turomshina and Stender (9) for a 1000 $mg \cdot dm^{-3}$, Cd^{++} was the result of increased cadmium plating.

Since the major competing reaction with zinc deposition at low impurity levels is hydrogen evolution, the effect of cadmium on the hydrogen overpotential was studied. Zinc deposits from the electrolytes containing various cadmium concentrations were immersed in a sulfuric acid bath (200 $g \cdot dm^{-3}$ without Zn^{++} or Cd^{++} present) at 37°C. The cathodic potentials required to yield a current density of 480 $A \cdot m^{-2}$ were recorded. Using the calculated value for the reversible hydrogen potential for this solution at 37°C (−0.2576V *vs.* SCE; see Appendix A), the hydrogen overpotentials were calculated and the results plotted in Fig. 3. The results show that the magnitude of the hydrogen overpotential η_c displays a maximum for the zinc deposit obtained from an electrolyte containing 20 $mg \cdot dm^{-3}$ Cd^{++}. It is clear that the minimum for the zinc plating current efficiency observed in Fig. 2 is related to the maximum in the hydrogen overpotential observed in

[1] Impurities: ≤ Fe 0.0003%, Pb 0.0008%, As 0.2 ppm, Mn 1 ppm.
[2] All voltages are reported *vs.* SHE unless otherwise noted.

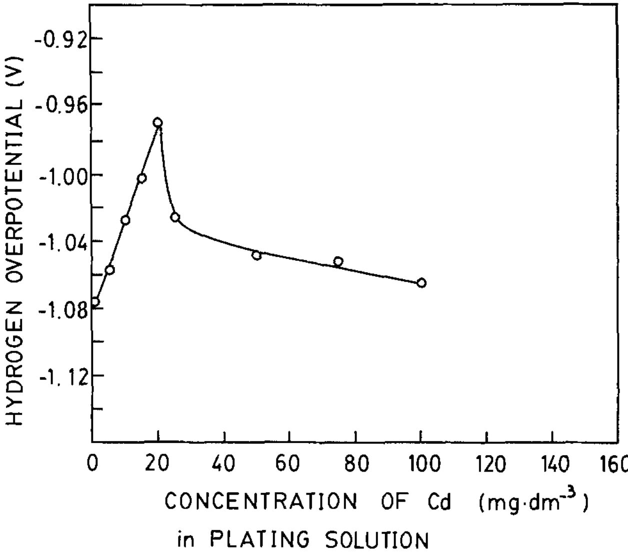

Fig. 3. Hydrogen overpotential for zinc plated from solutions containing various cadmium concentrations. Electrolyte: 2M H_2SO_4. Temperature = 37°C. E_{rev} = -0.2576V. Current = 480 $A \cdot m^{-2}$.

Fig. 3. At low cadmium concentrations ($\leq$20 mg · dm^{-3}) increasing cadmium concentrations cause a decrease in the magnitude of the hydrogen overpotential and hence cause an increase in the rate of hydrogen evolution. This results in a lower zinc plating current efficiency. Conversely, increasing cadmium concentrations greater than 20 mg · dm^{-3} cause an increase in the magnitude of the hydrogen overpotential which improves the zinc plating current efficiency as observed in Fig. 2.

In order to elucidate the effect of cadmium on the hydrogen overpotential of the zinc deposits, polarization profiles were measured for pure zinc and pure cadmium plates electrodeposited from solutions without added impurities and tested in a sulfuric acid electrolyte without Zn^{++} or Cd^{++} present. The results are shown in Fig. 4. For current densities less than 10 A · m^{-2} the profile for zinc remains horizontal at the potential -0.75V. This portion of the curve reflects the equilibrium potential of 0.76V for the reaction $Zn^{++} + 2e^- \rightarrow Zn$ at 35°C. At greater current densities the evolution of hydrogen begins. From 30-800 A · m^{-2} a second linear region is found. The Tafel slope of -0.105 results from the kinetics of the hydrogen evolution reaction on zinc. The transfer coefficient, α, calculated from the Tafel slope is 0.58 and indicates that $H_3O^+ + e^- \rightarrow H_{ads} + H_2O$ is the rate-determining step (17). This finding is in agreement with that of other workers (6, 18-20). Measurement of the hydrogen evolution transfer coefficient in pure sulfuric acid solutions for zinc plates obtained from solutions with cadmium concentrations from 0 to 100 mg · dm^{-3} produced an average transfer coefficient of 0.498 with a deviation of $\pm$ 0.078. These measurements show that the transfer coefficient does not change significantly with the addition of cadmium to the plating bath. Thus the rate-determining step for the hydrogen evolution reaction does not change with the addition of cadmium to the plating bath and cannot be the cause of the maxima observed in Fig. 2 and 3.

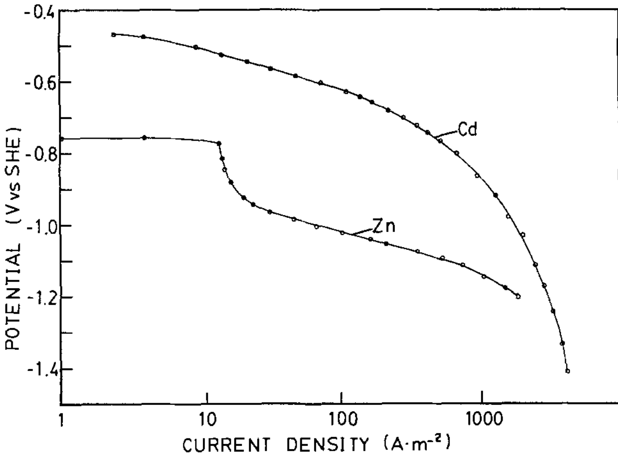

Fig. 4. Polarization plot of pure zinc plate and pure cadmium plate from solutions containing only zinc or cadmium ions, respectively. Electrolyte: 200 g · dm^{-3} H_2SO_4. Temperature = 37°C.

The polarization plot in Fig. 4 reveals that higher current densities can be sustained on pure cadmium plate than on pure zinc plate for the same potential. There is some variance in the literature concerning this point. Values of hydrogen overpotential on zinc and cadmium in 2*N* H_2SO_4 at 25°C are reported to be 0.926 and 1.211V at 500 A · m^{-2}, respectively (21). Mantell (22) gives values of 1.06 and 1.22V at 100 A · m^2 for zinc and cadmium in 2*N* H_2SO_4 at 25°C. These indicate that cadmium has the greater overpotential in contrast to that shown in Fig. 4. However, hydrogen bubble overvoltages reported by Glasstone (23) for Zn and Cd are 0.70 and 0.48V in 1*N* sulfuric acid at room temperature. More recent data by Pickett (24) at 25°C give values of 0.94 and 0.90V at 100 A · m^{-2} for Zn and Cd, respectively. These differences may reflect the effect of different impurity levels in the zinc and cadmium plates. From the experimental results of Fig. 4 it is clear that, for the zinc and cadmium plates obtained from the synthetic electrolytes, zinc has a higher hydrogen overpotential than cadmium. The approximate exchange current densities estimated from Fig. 4 (by extrapolation of the linear portion of the *V vs.* log *i* plot) are 0.4 and 1.5 A · m^{-2} for zinc and cadmium, respectively, again indicating that the hydrogen is more easily evolved on cadmium than on zinc. While these values are quite different from theoretical exchange current densities, they are in good agreement with those reported (0.2 A · m^{-2}) by Lowenheim (8). The results indicate that for plating baths in the absence of other deliberate impurity additions, the incorporation of cadmium into the zinc plate should cause an increase in the hydrogen evolution rate. Thus the zinc plating current efficiency should decrease with increasing cadmium content in the zinc plate. This would explain the initial decrease in the current efficiency observed in Fig. 2. To confirm that cadmium was being incorporated into the zinc plate, the zinc deposits were analyzed for their cadmium content.

The results of the atomic absorption analysis are shown in Fig. 5. In order to ensure complete ionization of the sample, ionization was carried out using either a flame or a graphite furnace. Comparable results were obtained in either case. It is clear from Fig. 5 that the percent of cadmium in the deposit increases monotonically with cadmium concentration in the electrolyte. The increase is linear for cadmium concentrations less than $\simeq$ 50 mg · dm^{-3}. This behavior simply demonstrates that at these concentrations cadmium is under limiting diffusion current control. Calculations (see Appendix B) show that the limiting diffusion currents are: $i_{H^+} \simeq$ 17,000 A · m^{-2}; $i_{Cd^{++}} \simeq$ 0.6 A · m^{-2} (maximum at a concentration of 100 mg · dm^{-3}); $i_{Zn^{++}} \simeq$ 670 A · m^{-2}. Thus under these conditions, the partial current for cadmium plating ($i_{Cd^{++}}$) is proportional to the cadmium concentration in the bulk of the electrolyte (25).

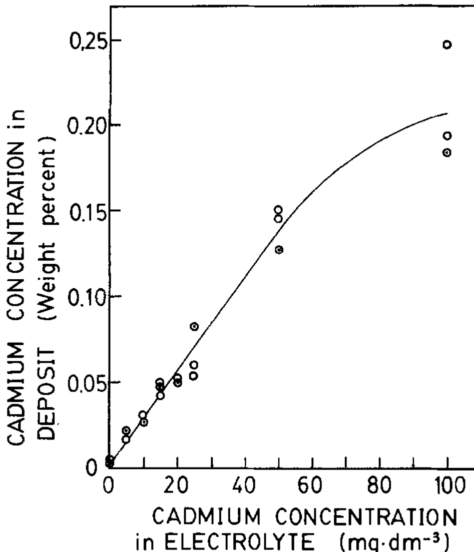

Fig. 5. Cadmium content of zinc plate from electrolytes with various cadmium concentrations, by atomic absorption analysis. Deposits from electrolyte: 200 g · dm^{-3} H_2SO_4, 62 g · dm^{-3} Zn. Current density 480 A · m^{-2}. Temperature 37°C. Sample ionization, by flame ⊙; by graphite furnace ○.

An increase in cadmium concentration in the electrolyte results in a zinc plate with a greater cadmium content, which promotes the hydrogen evolution reaction and decreases the zinc plating current efficiency. While this explains the current efficiency and overpotential behavior at low cadmium concentrations ($\leq$ 20 mg · dm^{-3}) seen in Fig. 2 and 3, the behavior at greater cadmium concentrations ($>$ 20 mg · dm^{-3}) is not explained by this model.

In order to study other possible changes in the reaction, cyclic potential sweep measurements were conducted for the zinc plates in a sulfuric acid bath (200 g · dm^{-3}). Some typical potential scans are shown in Fig. 6. A relatively high sweep rate (100 mV · sec^{-1}) was used to reduce the effect of changing surface area during the measurement. The samples were masked so that the same geometrical area was represented. From the potential scans it is clear that there are no hydrogen adsorption peaks. This is consistent with the fact that hydrogen does not strongly adsorb on zinc (6). The composition of the plate does, however, affect the rate of hydrogen evolution at any potential. In Fig. 7 the variation of the cathodic current density with plate composition is shown at various potentials. These measurements were conducted at room temperature (23°C) and again show that a maximum cathodic current density (hydrogen evolution rate) is found for the zinc plates obtained from solutions with 20 mg · dm^{-3} Cd^{++}. No obvious changes in the hydrogen evolution reaction mechanism are apparent from these measurements. To determine whether any macroscopic change in the zinc deposit was caused by changes in the cadmium content, scanning electron micrographs were taken. The results are shown in Fig. 8. It is clear from the photographs that a certain amount of grain refinement does take place with increasing cadmium content. This grain refinement of the zinc plate has also been reported by Mackinnon, Brannen, and Kerby (26) for increasing cadmium content in industrial acid sulfate baths. Other changes in zinc plate morphology from the presence of impurities have also been reported. The concentration of lead in the plating solution has been shown to alter both morphology and orientation (27). Antimony and glue additions will likewise alter the surface plate characteristics (4). In addition to impurities, overpotential

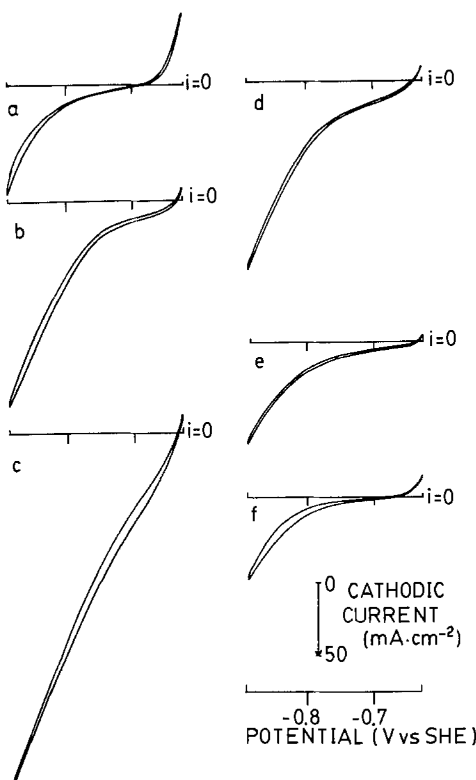

Fig. 6. Potential sweep profiles of zinc plates. Electrolyte: H_2SO_4 200 g · dm^{-3}. Temperature = 22.5°C. Sweep rate = 100 mV · sec^{-1}. Zinc plates obtained from synthetic industrial electrolyte containing 200 g · dm^{-3} H_2SO_4, 62 g · dm^{-3} Zn, and (a) 0 mg · dm^{-3} Cd; (b) 15 mg · dm^{-3} Cd; (c) 20 mg · dm^{-3} Cd; (d) 25 mg · dm^{-3} Cd; (e) 50 mg · dm^{-3} Cd; (f) 100 mg · dm^{-3} Cd.

can have an important role in the type of crystal growth (28). The work of Vagramyan, Leach, and Moon indicated that at low overpotentials metal deposition causes crystal growth to take place along close-packed crystal directions while at higher overpotentials more random growth occurs. X-ray diffraction patterns of the zinc plates were measured to determine whether there were any changes resulting from the differences in cadmium content. The analysis of the patterns showed no change in the orientations with the exception of the weakening of the (102) with greater cadmium concentrations. The preferred

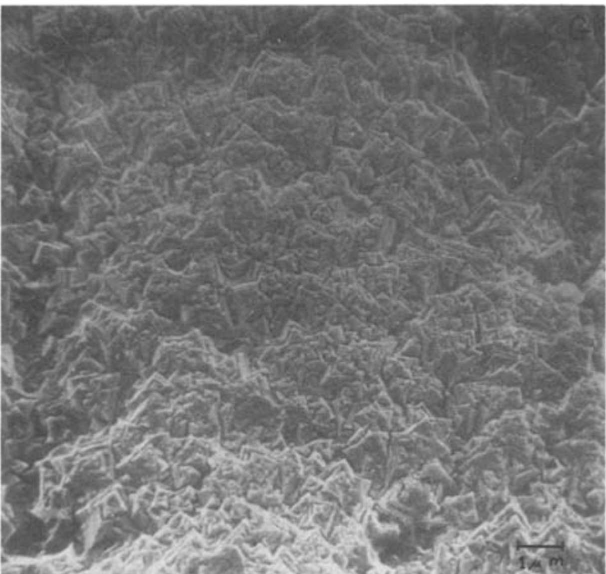

Fig. 8. Scanning electron micrographs of deposit morphology. Zinc deposit from solution containing 200 g · dm^{-3} H_2SO_4 + various cadmium concentrations. Temperature ≈ 37°C. Current density 480 A · m^{-2}. A, 0 Cd^{++}; B, 10 mg · dm^{-3} Cd^{++}; C, 15 mg · dm^{-3} Cd^{++}; D, 20 mg · dm^{-3} Cd^{++}; E, 25 mg · dm^{-3} Cd^{++}; F, 50 mg · dm^{-3} Cd^{++}; G, 100 mg · dm^{-3} Cd^{++}.

orientations (112), (002), and (103) were not affected, but the patterns from the zinc plates with greater cadmium concentrations were more continuous with less spread in the diffraction bands. This change resulted from the fine grain size at higher cadmium concentrations. Changes in crystal structure orientation can be ruled out as the cause of the increase of hydrogen overpotential with cadmium concentration.

One change that is apparent (from Fig. 8) with increasing cadmium concentrations is the increase in the number of crystallites and finer grain size in the zinc plates. The change in crystallite size causes a change in the surface area of the sample. Based on a fixed geometrical area, a decrease in the surface area would result in an increase in the current density and hence a greater apparent overpotential. It is partially due to this effect that shiny platinum has a greater hydrogen overpotential than platinized platinum. From the scanning electron micrographs in Fig. 8 it is clear that increasing cadmium concentrations cause smoother deposits and hence the surface roughness factor should decrease. The variation of overpotential with surface morphology has been studied by Bockris and Raxumney (29). They found that the transition in surface morphology from large pyrimidal crystal structures to finer polycrystalline structures was accompanied by an increase in overpotential. During zinc deposition, increasing overpotential has been found to cause smaller crystallites (28). For the deposition of copper, the magnitude of the increase of the overpotential was reported to be ≃120 mV (29). From Fig. 2, the increase in the magnitude of the hydrogen overpotential is about 92 mV and therefore it is not unreasonable to assign the cause of the increase to the change in morphology of the zinc plates. Although the change in morphology does not affect the reaction mechanism (since the transfer coefficient did not change with zinc plate composition), the exchange current density could be affected. The hydrogen exchange current density depends on surface activity as well as on the effective surface area. If surface area change is ignored for the moment, a decrease in the exchange current density would increase the overpotential. The decrease in the exchange current density could be caused by the transition to fine grain deposits (29). Thus three factors must be considered to explain the overpotential behavior. The first is the co-deposition of cadmium with zinc. This initially results in a surface with a greater hydrogen exchange current density. The second factor is the increased number of nucleation sites resulting from the cadmium co-deposition. This results in a finer grained deposit. The third factor is the decrease in the hydrogen exchange current density resulting from the change in surface morphology. Thus a maximum would be expected in the hydrogen exchange current density for the zinc deposit with increasing cadmium content. Support for this behavior is given in Fig. 9. The hydrogen exchange current density determined from potential sweep data in sulfuric acid (200 g · dm^{-3} without Zn^{++} or Cd^{++} present) at 22.5°C is plotted against cadmium concentration in the plating bath. An average of 10 runs was used for each point. A distinct maximum is formed at 20 mg · dm^{-3} Cd^{++}. Although data from potential sweeps at 100 mV · sec^{-1} must be viewed with some caution, the relative behavior of the zinc deposits is clear. An advantage of the data from the potential sweeps is that there is little area change during the course of the measurement. From Fig. 9 the exchange current density does increase initially with increasing cadmium content up to about 20 mg · dm^{-3} Cd^{++}. At greater cadmium concentrations the exchange current density decreases as a result of the change in morphology (finer deposits) and the decrease of the effective area. The magnitude of the change in the exchange current density is much larger than would be predicted by a surface area changes and must be primarily due to the increase of activity of the fine grained deposits.

Conclusions

The effect of cadmium on the zinc plating current efficiency in acid sulfate baths is dependent on cadmium concentration. At less than about 20 mg · dm^{-3} Cd^{++}, increasing cadmium concentrations lower the zinc plating current efficiency by decreasing the hydrogen overpotential on the zinc plate. This effect is superseded at greater cadmium concentrations by the refinement of the zinc plate and subsequent in-

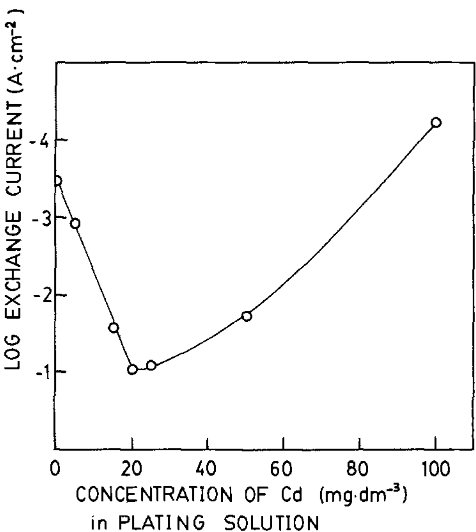

Fig. 9. Hydrogen exchange current density for zinc plated from electrolytes containing various cadmium concentrations. Data from potential sweep measurements. Electrolyte H_2SO_4 200 g · dm^{-3}. Temperature ≈ 22.5°C. Sweep rate = 100 mV · sec^{-1}. (Average of 10 runs per determination.)

crease of the hydrogen overpotential as a result of the morphology change and surface area decrease. The incorporation of cadmium into the zinc plate does not cause any significant change in the crystal orientations of the zinc plate nor does it alter the mechanism of hydrogen evolution.

APPENDIX

A. Theoretical Hydrogen Voltage

Electrolyte

$$= 200\ \text{g} \cdot \text{dm}^{-3}\ H_2SO_4 + 62\ \text{g} \cdot \text{dm}^{-3}\ Zn^{++}$$

$$\text{pH} = 0.35$$

$$H^+ + e^- \rightleftarrows \tfrac{1}{2} H_2$$

$$\epsilon_H = \epsilon_H^\circ - \frac{RT}{\mathbf{F}} \ln \frac{(P_{H_2})^{1/2}}{a_{H^+}}$$

$$= -\frac{RT}{\mathbf{F}} \ln (P_{H_2})^{1/2} + \frac{2.303\,RT}{\mathbf{F}} \log_a H^+$$

at $P_{H_2} = 1$ atm, $\epsilon_H = -0.0215$V *vs.* SHE at 37°C and at 37°C SCE $= 0.2361$V *vs.* SHE (30) and $(\epsilon_H)_{37^\circ C} = -0.2576$V *vs.* SCE.

The contribution of the liquid junction potential for the SCE in this solution is estimated as follows. The Planck-Henderson theory (31) gives

$$E_j \simeq \left(\frac{2.303\,RT}{\mathbf{F}}\right)\left[\frac{\Sigma_i\,\lambda_i (M_{i_S} - M_{i_R})}{\Sigma_i\,\lambda_i |Z_i|\,(M_{i_S} - M_{i_R})}\right] \log\left[\frac{\Sigma_i\,\lambda_i |Z_i| M_{i_R}}{\Sigma_i\,\lambda_i |Z_i| M_{i_S}}\right]$$

where E_j = liquid junction potential, λ_i = equivalent conductivity for ion i, M_{i_R} = concentration of ion i in reference electrolyte, M_{i_S} = concentration of ion i in solution, and Z_i = charge on ion.

The concentrations of the $[H^+]$, $[HSO_4^-]$, $[SO_4^=]$, and $[Zn^{++}]$ are calculated in Appendix B, $[K^+]$ and $[Cl^-]$ are assumed to be completely dissociated at saturation at 37°C.

Equivalent ion conductivities (λ_i) at infinite dilution +37°C were obtained by graphical interpolation of data given by Quist and Marshall (32).

Walden's Rule was used to extend the data to the concentrated solutions. From this the above equation yields the value $E_j \simeq 0.0183$V indicating that the overpotentials may be in error by this amount.

B. Limiting Current Density Calculations

Electrolyte 2.04M H_2SO_4 + 0.948M $ZnSO_4$ at 37°C pH = 0.35. The limiting current densities may be estimated from the equation (17)

$$i_{lim} = \frac{ZFDC^\circ}{(1-t)S}$$

where Z is the charge on the ion, $\mathbf{F}$ is Faraday's constant, D is the diffusion coefficient, C° is the concentration of the ion in the bulk of the solution, t is the transport number, and S is the diffusion layer thickness.

The concentrations of $[SO_4^=] + [HSO_4^-]$ were calculated knowing the dissociation constant for H_2SO_4.

For 2M H_2SO_4, $[SO_4^=] = 0.7$, $[HSO_4^-] = 1.3$, $K_2 = 7.24 \times 10^{-3}$ at 37°C (33, 34)

$$K_2 = \frac{\gamma_{H^+} \cdot \gamma_{SO_4^=}}{HSO_4^-} \cdot \frac{(H^+) \cdot (SO_4^=)}{(HSO_4^-)}$$

$$\simeq 0.01 \frac{(H^+) \cdot (SO_4^=)}{(HSO_4^-)}$$

$$[H^+] = 1.92,\ [HSO_4^-] = 2.17,\ [SO_4^=] = 0.821,$$

$$[Cd^{++}] \simeq 0,\ [Zn^{++}] = 0.948$$

The transport number

$$t_i = \frac{i_i}{i_T} = \frac{Z_i C_i \lambda_i}{\Sigma\, Z_i C_i \lambda_i}$$

using $\lambda_{i37^\circ C}{}^\circ$ [equivalent conductivity ($\Omega^{-1} \cdot m^2$ equiv.$^{-1}$)] $t_{H^+} = 0.60$, $t_{Zn^{++}} = 0.10$, $t_{Cd^{++}} \simeq 0$, $t_{HSO_4^-} = 0.17$, $t_{SO_4^=} = 0.13$ and using $\delta \simeq 0.03$ cm, *i.e.*, boundary layer thickness with some stirring from gas evolution

$$i_{H^+} \simeq 17{,}000\ \text{A} \cdot \text{m}^{-2},\ i_{Zn^{++}} \simeq 670\ \text{A} \cdot \text{m}^{-2}$$

for

$$[Cd^{++}] = 5\ \text{mg} \cdot \text{dm}^{-3}\ i_{Cd^{++}} \simeq 3 \times 10^{-2}\ \text{A} \cdot \text{m}^{-2}$$

$$[Cd^{++}] = 100\ \text{mg} \cdot \text{dm}^{-3}\ i_{Cd^{++}} \simeq 0.6\ \text{A} \cdot \text{m}^{-2}$$

Despite the assumptions in using λ_i° for λ_i and a diffusion layer thickness 0.03 cm it is clear that Cd^{++} will be diffusion controlled.

Effects of the Brine Impurities on the Cell Performance of the Diaphragm-Type Chlor-Alkali Cell

F. Hine,* M. Yasuda,* and K. Fujita[1]

Nagoya Institute of Technology, Nagoya 466, Japan

ABSTRACT

A laboratory cell equipped with the deposited asbestos diaphragm was operated with impure brine to investigate the effects of the hardness on the cell performance. The concentration distribution of NaOH in the diaphragm was established by three factors: diffusion, migration, and the hydraulic flow. It is pointed out that the migration flux was larger than the diffusion flux under the operating conditions of the diaphragm cell.

The amalgam process is best for producing chlorine and pure caustic. However, no new constructions using amalgam cells are being announced at present, and many amalgam cell plants are being converted to diaphragm cells, especially in Japan, due to environmental concerns with mercury pollution (1). It is estimated that now about 70% of the world production of chlorine and caustic comes from diaphragm cells.

Although the diaphragm cell process has a long history, innovations were delayed by a poor market for the impure caustic and the relatively high consumption of energy, both electricity and steam.

Recently, the invention of dimensionally stable anodes (DSA) by Beer (2), and the development of the modified asbestos diaphragms (3, 4), for example, the HAPP of Hooker and the TAB of Diamond Shamrock, have brought a new phase in diaphragm-type chlor-alkali technology.

The d-c electric power for cell operation and steam for evaporating the weak caustic liquor are major energy requirements, thus the overall consumption of energy by these factors must be minimized.

Consumption of electric power could be optimized by the reduction of several factors: the anode overvoltage (2, 5); the cathode overvoltage, (6-11); the solution *IR* drop, especially the bubble effects of chlorine and hydrogen gases (12-24); and the *IR* drop through the diaphragm (16). This paper deals with this last factor.

The brine is fed to the electrolytic cells after purification and under pH control, if necessary. Even so, the hardness (Mg^{2+} and Ca^{2+}) in the anolyte may plug the porous diaphragm, resulting in a gradual increase in the cell voltage for long-time operation. This also decreases the brine flow rate because the hydraulic resistance of the porous diaphragm increases.

The transport of OH^- through the diaphragm is by diffusion, migration, and hydraulic flow. All these factors are affected significantly by plugging of the diaphragm with precipitates. This causes changes in the operating conditions affecting cell performance (17).

In this paper the limitations on hardness of the feed brine based on experimental results of an accelerated test are discussed. The transport phenomena of NaOH through the diaphragm was also studied.

Experimental

A small "Lucite" cell as shown in Fig. 1 was used. A titanium sheet, 2 cm long, 2 cm wide, and 0.5 mm thick, coated with a thermally deposited mixture of RuO_2 and TiO_2 was used as the anode. The cathode was made of Ni sheet (2 × 2 cm). A modified asbestos mat was used as the diaphragm. Chrysotile fiber [5g of Hooker, Grade H-1, 0.4g of E-CTFE powder (Allied Chemical, "Halar 5004"), and a small amount of surfactant in 2*M* NaOH] was vacuum-deposited on a steel mesh, dried at 120°C for 1 hr, peeled off from the mesh, then heated at 270°C for 3 hr for setting. The thickness was about 4 mm, and the effective area was 19.6 cm^2 (5 cm diam).

Two Luggin-Haber probes were located about 0.5 mm from the diaphragm to measure the *IR* drop. A

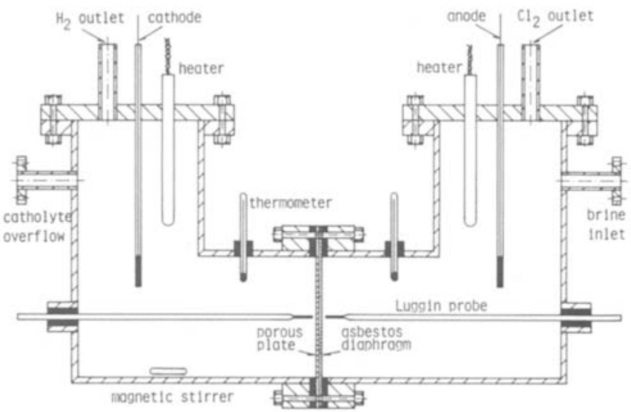

Fig. 1. An experimental electrolytic cell

* Electrochemical Society Active Member.
[1] Present address: Niihama Works, Sumitomo Chemical Industry Company, Niihama, Japan.
Key words: current efficiency, flow rate, diffusion, electrical resistance, migration.

saturated calomel electrode, Hg/Hg_2Cl_2/satd. KCl (at 30°C), was used as a reference electrode for the anode Luggin, and a mercuric oxide electrode, Hg/HgO/3.5m NaOH (at 30°C), was employed for the cathode Luggin.

Electric heaters were located in both the anode and the cathode compartments to maintain the solution temperature. A magnetic stirrer was located under the cathode compartment.

A saturated NaCl solution, 5.1m NaCl prepared with pure salt and distilled water, in the brine reservoir (*ca.* 50 liters) was pumped up to the level tank (*ca.* 10 liters) located about 3m above the cell. The brine was fed to the anode compartment at a given rate. The electrolytic solution passed through the diaphragm and flowed out of the cathode compartment to the catholyte reservoir by gravity.

Chlorine liberated at the anode was collected in a gas holder (*ca.* 5 liters) located about 3.5m above the cell and was sent to an absorption column containing caustic soda solution. Hydrogen generated at the cathode was purged to the air after a water wash.

The required amounts of $MgCl_2$ or $CaCl_2$ were added to the brine reservoir to investigate the effects of these brine impurities.

The rate of feed brine was adjusted to yield a 50% decomposition with respect to pure brine. The flow rate decreased and the NaOH concentration in the catholyte increased when an impure brine was fed to the cell.

The current density was kept constant during each experiment.

The amperage and the *IR* drop were recorded continuously whereas the flow rate of the electrolyte was measured at certain intervals, say every 30 min. The catholyte effluent was titrated every 24 hr. Thus the current efficiency for production of caustic soda (C.E. in percent) was calculated by Eq. [1]

$$\text{C.E.}(\%) = \frac{\text{Practical amount of NaOH produced}}{\text{Theoretical amount of NaOH to be produced}} \times 100 \quad [1]$$

A three-compartment cell illustrated in Fig. 2 was employed to determine the diffusion and migration of OH^-. The cell was equipped with a cation exchange membrane ("Nafion 390") between the anode compartment and the center compartment to eliminate transport of OH^- and Cl^- as well as hydraulic flow of the electrolytic solution. Each compartment has a volume of about 300 cm. The alkali strength in the cathode compartment was kept constant at 2.2m NaOH during the experiment, whereas 5m NaCl (pH $\simeq$ 2) was fed to the center compartment at the start-up time. The NaOH concentration in this room increased with time due to diffusion of OH^-. Thus the "superficial" diffusion coefficient of OH^- through the diaphragm can be evaluated.

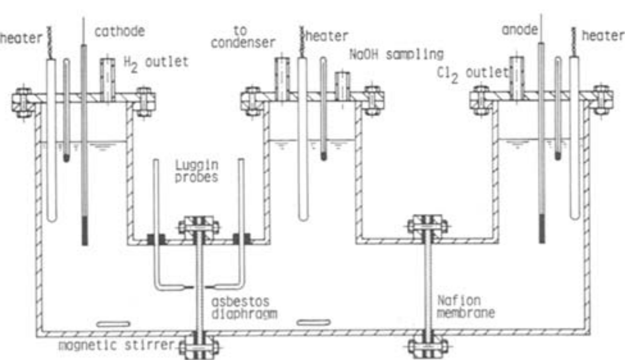

Fig. 2. A three-compartment electrolytic cell

The electrolyte level was equalized to avoid a hydraulic pressure between adjacent compartments. A reflux condenser was located on the top of each compartment to minimize the change of the solution composition by evaporation.

The anode, cathode, and reference electrodes were the same as for the cell shown in Fig. 1.

The potential drops between the Luggin probes were recorded continuously. The electrolytic solutions in the three compartments were titrated at intervals to obtain the transport of OH^-. The *p*H of the anolyte was unchanged during the experiments.

The diaphragm thickness was varied: 1.2, 2.4, and 4.8 mm. The material was the same as in the cell in Fig. 1. The current density (0 ~ 25 A/dm^2) and the solution temperature (30° ~ 90°C) were varied.

Results and Discussion

Effects of the brine hardness.—It was confirmed that the flow rate of brine, the *IR* drop, the NaOH concentration, and the current efficiency were unchanged for 10 days or more when the purified brine was fed to the electrolytic cell.

Figure 3 shows the results obtained during electrolysis of brine containing 100 mg/liter Mg^{2+} at 10 A/dm^2 current density. For three days, all the data were unchanged during the electrolysis of a pure brine. When an impure brine was fed to the anode compartment of the cell, the flow rate decreased with time due to plugging of the diaphragm, which results in a rise in the caustic strength in the catholyte. Also the *IR* drop increased gradually. The current efficiency decreased, presumably due to the enhancement of diffusion. Similar results would be obtained with impure brines containing different amount of the hardness, either Mg or Ca.

On the other hand, the *IR* drop decreased, as shown in Fig. 4, when the brines containing hardness of a high concentration were electrolyzed at relatively high current densities. The caustic strength of the catholyte increased considerably. A signficant reduc-

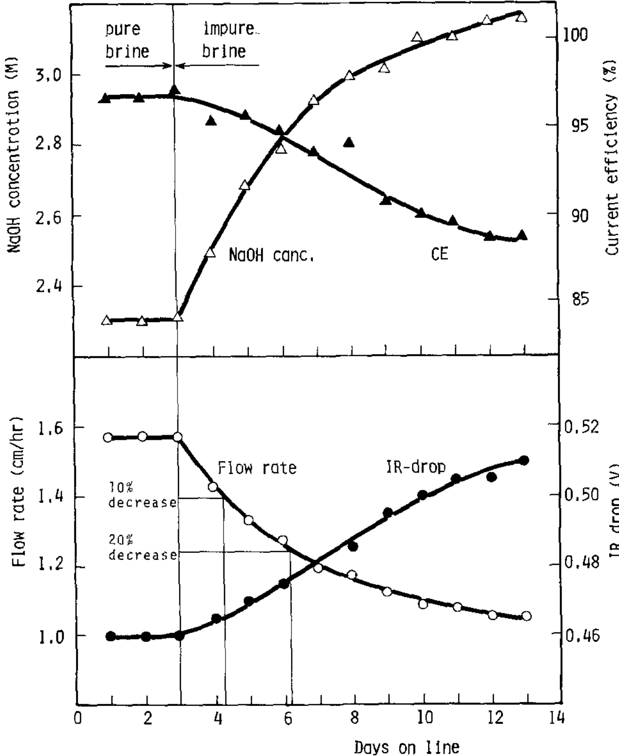

Fig. 3. Flow rate, *IR* drop, NaOH concentration, and current efficiency. Conditions: current density = 10 A/dm^2; Mg^{2+} concentration = 100 mg/liter.

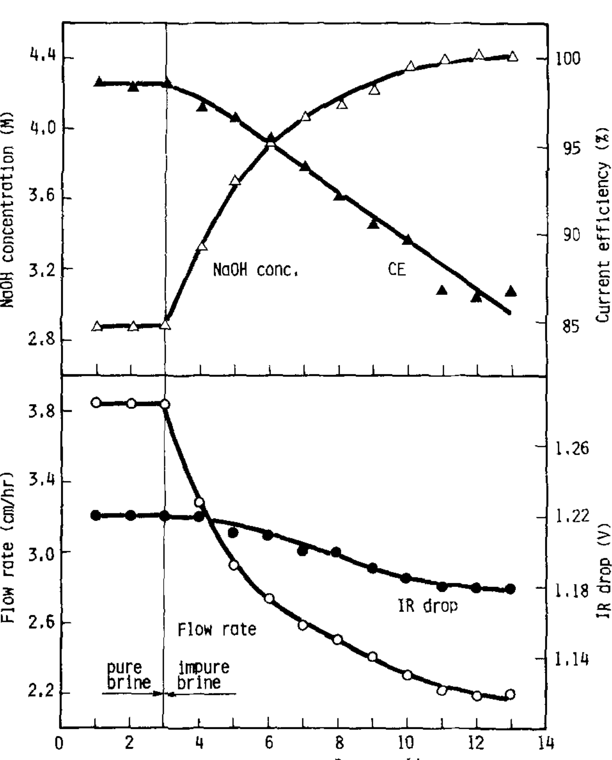

Fig. 4. Flow rate, IR drop, NaOH concentration, and current efficiency. Conditions: current density = 30 A/dm²; Mg^{2+} concentration = 80 mg/liter.

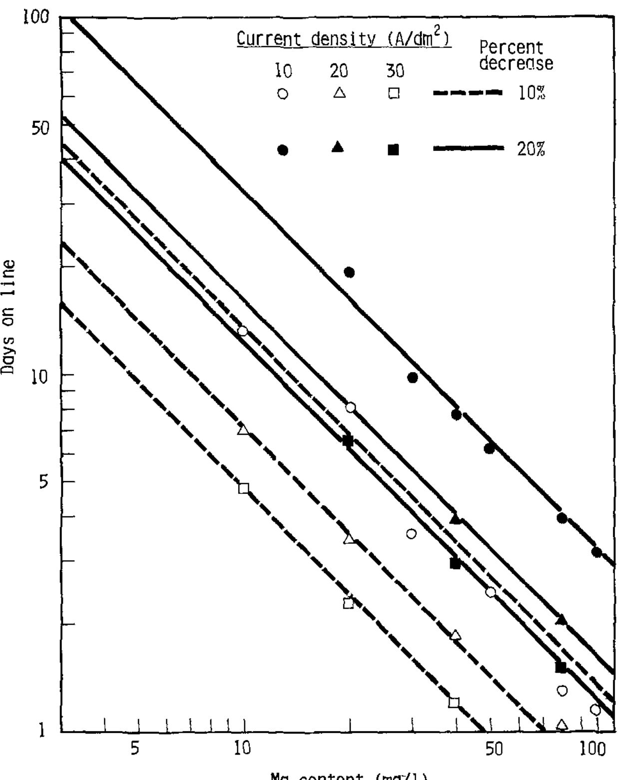

Fig. 5. Days on line vs. Mg content as functions of the percent reduction of the brine flow and the current density.

tion in the electrical resistivity of the diaphragm is due to a rise in the caustic strength (see Table I). The brine flow, the NaOH concentration, and the current efficiency are affected by the brine hardness, but the *IR* drop depends on the solution composition in the diaphragm and the operating temperature rather than on the clogging of the diaphragm.

Since the flow rate of electrolyte decreases gradually with time due to plugging, and influences the cell performance, it can be used as a parameter for evaluating the effects of hardness in feed brine. In Fig. 3, for example, the flow rate decreased by 10% for 1.3 days and by 20% for 3.2 days after switching the feed brine.

The diaphragm of the laboratory cell was plugged more quickly compared to commercial cell operation since the feed brine contained Mg^{2+} at a relatively high concentration (100 mg/liter) in this experiment. The operable period is, of course, extended when the brine hardness is decreased. Figure 5 illustrates the operable period *vs.* Mg content based on the accelerated test with relatively high contents of Mg in the feed brine (10 ~ 100 mg/liter). Experiments were conducted, using the galvanostatic method, at 10, 20, and 30 A/dm². The dotted line shows the 10% decrease of the flow rate and the solid line the 20% decrease. It is clear that the operable period is reciprocally proportional to the Mg content. Plugging occurs quickly at high current densities since the flow rate of the brine is large to yield a given decomposition (50%); but the product of period (d) and current (i) was almost constant (Table II). Magnesium in the feed brine precipitates as hydroxide and is collected or filtrated on the asbestos mat. Magnesium hydroxide is a typical compressible precipitate (18, 19), and hence the rate of brine flow may decrease appreciably within a short time if the pressure drop is high. Since the pressure differential through the diaphragm is small, say one tenth of the brine filter, the effect of the compressibility of precipitate on the flow rate seems to be small.

Figure 6 illustrates similar results for Ca in the feed brine, which are essentially the same as for Mg. However, it is important that the $i \times d$ increases with an increase in the current density (see Table II), probably due to a different mechanism of plugging of the diaphragm by Ca precipitate than by Mg precipitate. Although these results were obtained by the accelerated test by electrolysis of brines containing a very high hardness concentration, they agreed

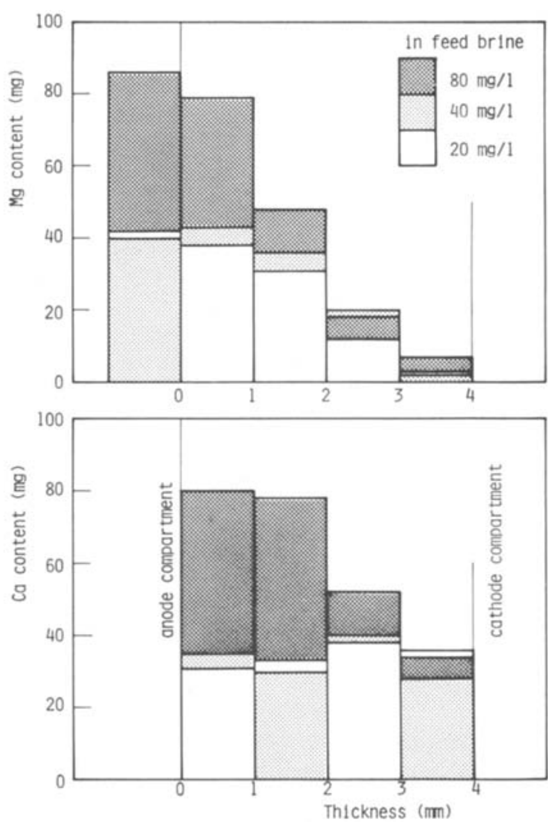

Fig. 7. Distribution of magnesium and calcium precipitates in the diaphragm (5 cm diam and 0.4 cm thick) after electrolysis.

well with our plant experiences. In practical operation, the brine level is varied in accordance with the permeability of the diaphragm so as to keep the flow rate and, hence, the percent decomposition constant. The flow rate of the brine containing 2.5 mg/liter Ca through a commercial diaphragm cell operated at 31 A/dm^2 would decrease by about 20% when the brine level is unchanged for 100 days of operation, which agrees with Fig. 6.

In conclusion, we believe that Fig. 5 and 6 are applicable as a guide to commercial cell operation.

The concentration distributions of Mg and Ca in the diaphragm were determined since their behavior seems to differ. A diaphragm mat after electrolysis was sliced into four equal sections (1 mm thick each). Each segment was immersed in dilute HCl (1 ~ 3N HCl depending on the amount of precipitate), and the Mg content in the filtrate was measured by atomic absorption spectrochemical analysis. Because a small amount of Mg from the chrysotile fiber is dissolved by the acid solution, this effect was calibrated for. A large amount of magnesium hydroxide is deposited in the first and the second segments on the anode side as shown in Fig. 7 since the asbestos mat became completely alkaline due to back-migration of OH^-. On the contrary, Ca was precipitated more uniformly throughout the porous mat.

Since the Mg content in the brine was high, an amount of $Mg(OH)_2$ was deposited on the surface of diaphragm, whereas Ca did not do so. This is clearly a filtration mechanism associated with chemical reaction. According to chemical analysis, the catholyte contained 0.2 ~ 0.5 mg/liter Mg or 1.5 ~ 2.5 mg/liter Ca, due to leakage since the brine hardness was significantly higher.

MacMullin states in a private letter that "magnesium deposits on the diaphragm surface facing the anodes and penetrates to a lesser extent in the calcium. Calcium is deposited throughout the diaphragm and Hine's work indicates that at low value of calcium might be expected that calcium washed through. Magnesium hydroxide is considerably less soluble than calcium hydroxide."

Permeation of the brine without electrolysis.—Experiments without electrolysis were conducted so as to separate diffusion from migration of alkali. The catholyte consisting of NaCl and NaOH was circulated between the reservoir (*ca.* 60 liters) and the cathode compartment to keep the solution composition constant. The hydraulic head between the anolyte and the catholyte was kept constant at 60 cm, which corresponded to the flow rate required for electrolysis of pure brine at 50% decomposition and 15 A/dm^2. A small current (1 A/dm^2) was switched on briefly at certain intervals to determine the *IR* drop through the diaphragm.

As is shown in Fig. 8, the flow rate decreased gradually, and the electric resistance of the diaphragm became larger due to plugging, whereas the anolyte *p*H was unchanged during experiment. The phenomena were the same for electrolysis, but blocking was rapid because of a different distribution of precipitates in the mat as shown in Fig. 9. Both Mg and Ca deposited closely to the cathode side.

Since Mg^{2+} deposits as $Mg(OH)_2$, the concentration distribution of Mg indicates the OH^- distribution in the porous mat. Consequently, the experimental results would show that the contribution of migration for an overall permeation of alkali during electrolysis is significant compared with diffusion.

Experiments with a three-compartment cell.—An example of the results obtained with the three-compartment cell (Fig. 2) is shown in Fig. 10. The NaOH concentration in the cathode compartment and in the center compartment increased almost proportionally to the time of electrolysis.

It is well known that the diffusion flux under steady-state conditions is represented by the equation

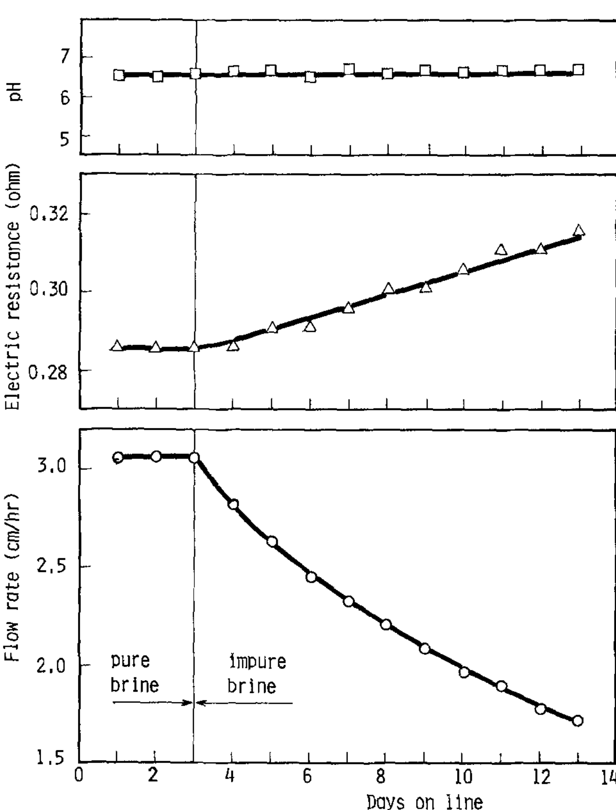

Fig. 8. Flow rate, electric resistance of the diaphragm, and the pH of anolyte at zero current. Mg^{2+} concentration = 50 mg/liter.

$$j = -DA\frac{dC}{dx} \quad [2]$$

Assume that dC/dx is equal to $\Delta C/L$, where ΔC is the difference of the OH^- concentration between two sides. Thus the diffusion coefficient D can be obtained by Eq. [2].

Figure 11 shows the Arrhenius plots for diffusion. The activation energy is evaluated to be about 3 ~ 4 kcal/mol.

It is well known that the diffusion coefficient for electrolytes at room temperature is in the order of 10^{-5} cm^2/sec (20) whereas the experimental results in Fig. 11 show it to be in the order of 10^{-6} cm^2/sec because of limitations of mass transport through the diaphragm. The diffusion flux through the porous medium depends on the formation factor, F_c, of the medium

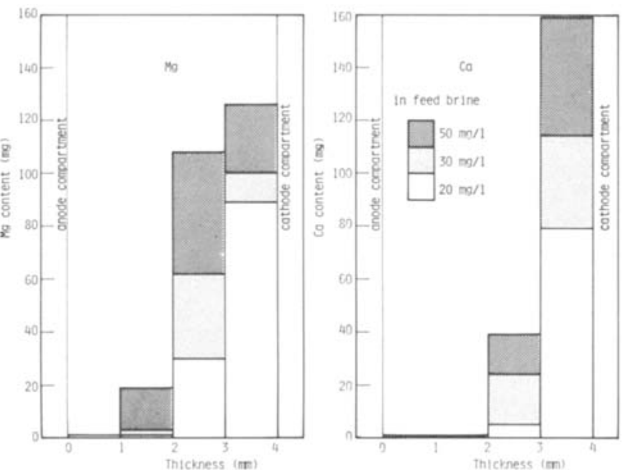

Fig. 9. Distribution of magnesium and calcium precipitates in the diaphragm (5 cm diam and 0.4 cm thick) without electrolysis.

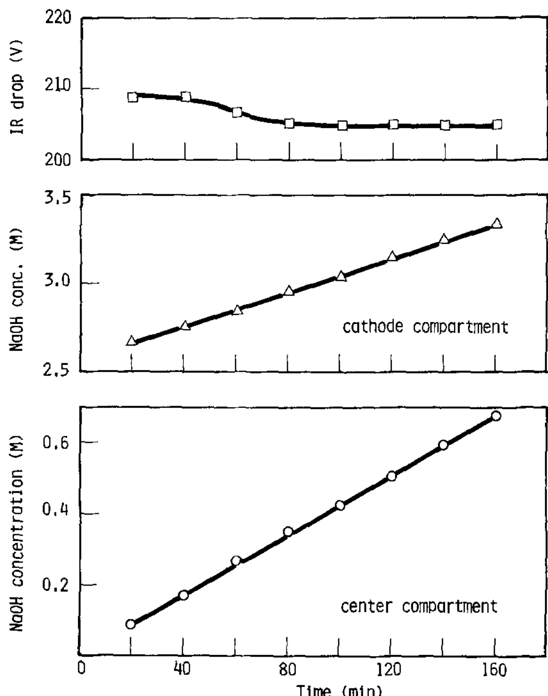

Fig. 10. NaOH concentration and IR drop as functions of the time of electrolysis. Conditions: diaphragm thickness = 2.4 mm. Temperature = 70°C. Current density = 20 A/dm^2.

$$F_c = \frac{D^\circ}{D} = \frac{\chi^2}{\epsilon} \quad [3]$$

An equation for D° *vs.* t(°C) was established by the method of least squares. The data listed in the International Critical Tables (20) were employed. Thus D° at 30°C was calculated to be 1.88×10^{-5} cm^2/sec, compared to 0.55×10^{-5} cm^2/sec for D (see Fig. 11).

Substituting these data into Eq. [3]

$$F_c = \frac{1.88}{0.55} \simeq 3.42$$

On the other hand, F_c can also be obtained by the ratio of the specific resistances as follows (17)

$$F_c = \frac{\rho}{\rho_0} \quad [4]$$

where ρ is the superficial resistivity of the porous medium in $\Omega \cdot cm$ and ρ_0 is the resistivity, also in $\Omega \cdot cm$, of the electrolyte. From Fig. 10, the electric resistance of a porous diaphragm of 19.6 cm^2 in area and 0.4 cm

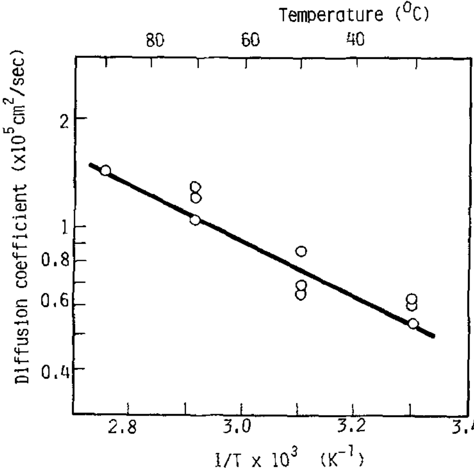

Fig. 11. Diffusion coefficient as a function of the temperature

thick filled with 2.5m NaCl is estimated to be 0.28Ω. Therefore

$$\rho = \frac{0.28 \times 19.6}{0.4} \simeq 13.72\ \Omega \cdot \mathrm{cm}$$

The specific resistance of 2.5m NaCl is 3.79 Ω · cm (see Table I). Thus, we have F_c as follows

$$F_c = \frac{13.72}{3.79} \simeq 3.62$$

It is clear that both calculations agree well with each other.

Mass transport through the diaphragm.—The mass transport problems through the diaphragm in chlor-alkali cells have been investigated by many authors [see Ref. (17)].

Stender *et al.* have calculated the mass transport of OH^-, j_{OH} (24)

$$j_{OH} = -D\frac{dC}{dx} + UC \qquad [5]$$

$$U = \frac{\mathbf{F}}{RT}\frac{D}{\kappa}i - v \qquad [6]$$

Integrating Eq. [5] with the boundary conditions

$C = C^\circ$ at $x = 0$ (at cathode side)

and

$C = 0$ at $x = \delta$ (at anode side)

Equations [7] and [8] are obtained

$$j_{OH} = \frac{C^\circ U}{1 - \exp\left(-\frac{U\delta}{D}\right)} \qquad [7]$$

and

$$\frac{C}{C^\circ} = \frac{1 - \exp\left(-\frac{U}{D}(\delta - x)\right)}{1 - \exp\left(-\frac{U}{D}\delta\right)} \qquad [8]$$

where the thickness of the alkaline zone δ is assumed to be equal to the thickness of diaphragm L. Also the current efficiency for OH^- is

$$\mathrm{C.E.}(\%) = \frac{1}{1 + \frac{U}{v}\left(1 - \exp\left(-\frac{U\delta}{D}\right)\right)^{-1}} \times 100 \qquad [9]$$

When a thin diaphragm is employed, $U\delta << D$. Therefore

$$\mathrm{C.E.}(\%) = \frac{1}{1 + \frac{D}{v\delta}} \times 100 \qquad [10]$$

When $U > 0$, the C *vs.* x curves become convex as shown in Fig. 12 (see Eq. [8]). When $U < 0$, on the other hand, the curves are concave. Assume that $D = 10^{-5}$ cm²/sec, $\delta = 0.5$ cm, $v = 10^{-3}$ cm/sec, $\kappa = 0.5$ mho/cm, $T = 373$ K, and $i = 0.2$ A/dm², therefore for practical operation, we have

$$\frac{U\delta}{D} \simeq -7$$

Consequently, the C *vs.* x curves are clearly concave, and the reduction of current efficiency is controlled by migration and diffusion of OH^-.

The flux of alkali through a unit area of the diaphragm ($A = 1$ in Eq. [2]) in a three-compartment cell, j_{OH}, can be represented by the sum of the diffusion flux, $j_{OH}(d)$, and the migration flux, $j_{OH}(m)$, since there is no flow of brine

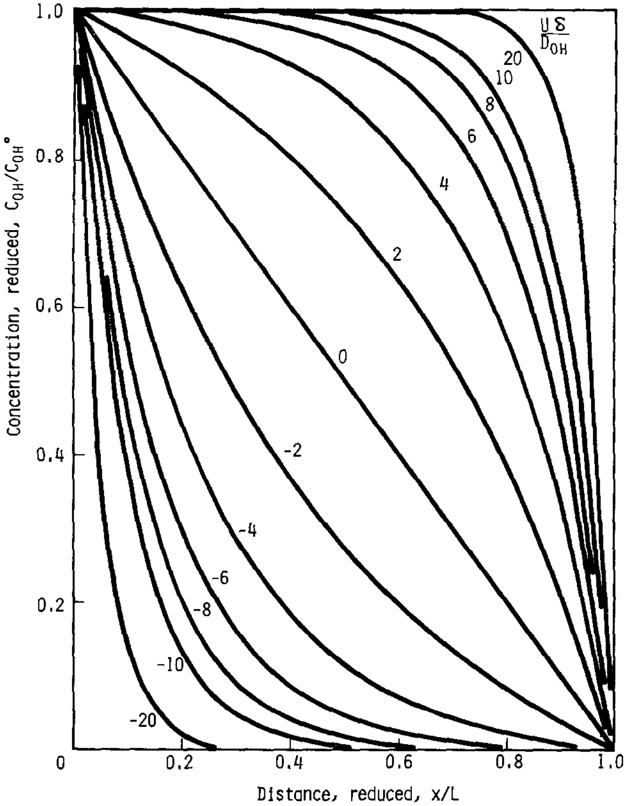

Fig. 12. Distribution of the NaOH concentration in the diaphragm

$$j_{OH} = j_{OH}(d) + j_{OH}(m) \qquad [11]$$

$$j_{OH}(d) = -D\frac{dC}{dx} \qquad [12]$$

$$j_{OH}(m) = \frac{\mathbf{F}}{RT}\frac{D}{\kappa}Ci = -\frac{\mathbf{F}}{RT}DC\frac{d\phi}{dx} \qquad [13]$$

Assuming that

$$\frac{dC}{dx} = \frac{C}{\delta} \text{ and } \frac{d\phi}{dx} = \frac{\Delta\phi}{\delta}$$

we have

$$K = \frac{j_{OH}(m)}{i_{OH}(d)} \simeq \frac{\mathbf{F}}{RT}\Delta\phi \qquad [14]$$

where K is the ratio of $j_{OH}(m)$ to $j_{OH}(d)$. The diffusion flux $j_{OH}(d)$ can be obtained by experiment without electrolysis, whereas the OH^- flux during electrolysis is the sum of $j_{OH}(d)$ and $j_{OH}(m)$. Thus $j_{OH}(m)$ can be evaluated. Factor K, calculated by Eq. [14], is listed in Table III and is in good agreement with experiment. The K is proportional to the IR drop, but the line in Fig. 13 is independent of other factors.

Since the IR drop through the diaphragm in practical cells is 0.3 ~ 0.4V, $j_{OH}(m)$ is one order of magnitude greater than $j_{OH}(d)$. Therefore, $j_{OH}(m)$ must be minimized to improve the current efficiency. Operation at high temperatures is feasible for this purpose because D and κ increase. Use of a thin diaphragm decreases K since $j_{OH}(d)$ increases, whereas $j_{OH}(m)$ remains constant because $\Delta\phi/\delta$ is unchanged.

At high current densities, both $\Delta\phi$ and K become large. On the other hand, the flow rate of the brine is increased proportionally to the current density to keep the brine decomposition constant. Since the effect of the flow rate on the current efficiency is larger than that of other factors under operating conditions, operation at high current densities, say 25 ~ 35 A/dm², is desirable to improve the current efficiency.

Conclusion

The performance of diaphragm-type chlor-alkali cells is related closely to the transport phenomena of OH^- and the physicochemical properties of the diaphragm. The overall mass-transfer through the diaphragm is composed of the diffusion flux, the migration flux, and the hydraulic flow. Of these, diffusion and migration have been discussed in this paper.

The concentration distribution of alkali in the diaphragm without electrolysis differs greatly from that with electrolysis because the migration flux is significantly large. Also the OH^- concentration distribution varies with the current density for the same reason.

Hardness in the feed brine deposits in the porous diaphragm and affects the electrical conduction and mass transport through the diaphragm. Cell performance as measured by the current efficiency and the cell voltage becomes less favorable as the diaphragm is plugged. The limits of hardness in the feed brine have been discussed with the results obtained by an accelerated test involving electrolysis of brines containing high hardness concentrations.

Growth of Thick Anodic Oxide Films on Nickel in Borate Buffer Solution

B. MacDougall* and M. J. Graham

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R9

ABSTRACT

Anodic galvanostatic charging of nickel in pH 7.65 borate buffer solution produces a finely porous oxide film which is distinctly different from the passive film of NiO. The porous film which is probably NiOOH can grow to thicknesses in excess of 1000Å. It is reduced to a lower oxidation state during galvanostatic reduction, giving a distinct cathodic potential arrest. The oxide, however, remains on the surface during the cathodic treatment and reapplication of the anodic charging current results in an anodic arrest that is almost the mirror image of the cathodic arrest. The reversible conversion charge increases with increasing time of polarization in the O_2 evolution region, in conjunction with an increase in porous film thickness as determined by x-ray emission and Auger electron spectroscopies. In fact, the conversion charge is a close monitor of porous film thickness over a wide range of thicknesses and has been used to study film growth kinetics as a function of temperature, charging rate, and prior electrode treatment. The kinetics of porous oxide growth are interpreted in terms of an outer porous film growing on top of an inner compact film, the latter probably being the passive film. It is suggested that breakdown and repair events in the compact inner film generate the Ni^{2+} which is incorporated into the porous film, and that the stability of the passive film thus determines the growth rate of the porous film. This model explains the influences of temperature and electrode surface condition on oxide growth rate as well as the existence of breakaway-type kinetics and its dependence on charging rate.

The anodic oxidation of nickel in the passive potential region has been extensively studied in a variety of electrolytes, *e.g.*, borate buffer solution (1-3) and neutral and acid sulfate solutions (1, 4-22). The composition of the passive oxide film formed in neutral and acid solutions is generally thought to be NiO with a maximum thickness reported anywhere from 12Å (4, 13, 23, 24) to 18Å (1, 9). In borate electrolyte, considerably thicker oxide films can be grown at potentials in the oxygen evolution region (1-3, 25, 26). The oxide formed in this potential region is a higher oxide of nickel, probably NiOOH (26). Unlike the passive film of NiO, this oxide gives a distinct galvanostatic reduction arrest which is believed to be associated with its conversion to a lower oxide of nickel, *e.g.*, $Ni(OH)_2$ (or NiO). Subsequent anodic charging of the lower oxide also gives a distinct potential arrest as the lower oxide converts back again to the higher oxide (1, 27). This electrochemical conversion reaction is smilar to that proposed for charging and discharging the nickel electrode in the nickel alkaline battery (27, 28), and while extensive research has been published in this area [cf., for example, (29)], little work has appeared concerning the kinetics and mechanism of anodic growth of thick conversion oxide films on nickel surfaces by direct oxidation of the metal. The present investigation considers the factors influencing the growth kinetics of thick anodic oxide films on nickel in pH 7.65 borate buffer solution, and a model will be suggested for the mechanism of film growth.

Experimental

Polycrystalline specimens, 1 × 2.5 × 0.02 cm thick, were prepared from Materials Research Corporation zone-refined nickel sheet of 99.996% purity (4). They were degreased with benzene, chemically polished, electropolished for 2 min at 23°C in a 57 volume percent sulfuric acid solution at 0.5 A cm^{-2}, and then annealed at 800°C in a vacuum of 10^{-8} Torr. The specimens were again electropolished immediately before use in an experiment. Potentials quoted in this paper are referred to the saturated calomel electrode which is 0.245V with respect to the standard reversible hydrogen electrode. Electropolished nickel electrodes were galvanostatically anodized without cathodic reduction of the prior oxide film. Solutions were deaerated pH 7.65 borate buffer, and were analyzed for Ni^{2+} by carbon rod atomic absorption spectroscopy, the lower limit of detection by this method being 0.2 $\mu g\ cm^{-2}$ (sample area = 5 cm^2; cell volume = 50

ml). X-ray emission (30, 31) and Auger electron spectroscopies (Physical Electronics Incorporated Model 590) were used to determine oxide film thicknesses.

Results

Cathodic and anodic galvanostatic charging profiles.—Figure 1 shows the cathodic and anodic charging profiles for electropolished nickel electrodes anodized for various times at 80 μA cm^{-2} in the oxygen evolution region [potentials >0.95V (25, 26)]. Anodic charging generates a species which, when the charging polarity is switched from anodic to cathodic, undergoes reduction and gives a distinct potential arrest at ~0.75V. When reduction of this species is complete, the potential rapidly shifts into the hydrogen evolution region. Upon immediate reapplication of the anodic charging current, an anodic arrest occurs at about the same potential as the cathodic arrest; the cathodic and anodic arrest charges are equivalent. Oxides formed at potentials in the passive region do not give rise to this reversible arrest since the ~12Å thick passive film of NiO (4, 13, 23, 24) is inert to both conversion to a higher oxide of nickel and to cathodic reduction. During anodic charging in the oxygen evolution region, a very finely porous (26) higher oxide of nickel is generated, perhaps NiOOH as has been previously suggested by a number of workers (1, 3, 27). The charge-consuming reaction would thus be associated with interconversion of the nickel ion in the oxide between the 3+ and 2+ oxidation states *e.g.*, by a reaction such as

$$NiOOH + H^+ + e \rightarrow Ni(OH)_2$$

The term "conversion charge" will denote the cathodic arrest charge associated with this reaction.

To investigate the kinetics of the conversion reaction, a constant quantity of higher oxide was formed (*e.g.*, by anodizing at 80 μA cm^{-2} for 24 hr at 25°C) and this was reduced and reoxidized at charging rates of 4, 80, and 200 μA cm^{-2}. The conversion charge was constant (6.6 ± 0.3 mC cm^{-2}) at all three charging rates indicating that the conversion reaction is a rapid, reversible process under activation rather than diffusion control. A fixed quantity of porous oxide gives the same conversion charge at all electrolyte temperatures from 5° to 45°C so that the kinetic results obtained for growth of the conversion oxide at different temperatures may be directly compared.

Oxide film examination.—The degree of hydration of oxides in the above conversion reaction is still open to question. Electrodes removed from solution in the oxidized state were blue-black in color, but this coloration slowly disappeared and the oxide film eventually became transparent. (This is exactly what happens when an oxidized electrode is cathodically reduced in solution, *i.e.*, the dark color becomes less distinct during the cathodic conversion arrest and at the end of the arrest the film is transparent.) Because the films change with time, difficulties are presented in attempting phase identification of the oxide in the oxidized state; reflection electron diffraction of a thick oxide film did confirm, however, the presence of β-NiOOH in addition to NiO. Oxide films in the reduced state examined by electron diffraction and Auger spectroscopy appeared to be NiO rather than $Ni(OH)_2$. It may be, though, that the porous film in the reduced state is $Ni(OH)_2$, but that this species dehydrates in the vacuum system, *i.e.*, $Ni(OH)_2 \rightarrow NiO + H_2O$. In any event, the conversion reaction of $Ni^{3+} \rightarrow Ni^{2+}$ involves a 1-electron transfer, and assuming a current efficiency of 100%, the amount of oxide can be estimated from the conversion charge. The conversion charge increases with increasing time in the oxygen evolution region (Fig. 1), and thus the measured conversion charge can be used to determine the kinetics of porous oxide growth, provided that the relationship between conversion charge and quantity of porous oxide is constant over a wide range of film thicknesses. To check this, electrodes anodized at 80 μA cm^{-2} for 30 min and 24 hr (at 25°C) were removed from the solution and analyzed for oxygen content. The conversion charges for the 30 min and 24 hr treatments were 2.2 mC cm^{-2} and 6.6 mC cm^{-2}, respectively, compared with an increase in oxygen content (as determined by x-ray and Auger techniques) from 0.54 (±0.05) to 1.27 (±0.13) μg oxygen cm^{-2} (25). This increase in oxygen thus correlates reasonably well with the conversion charge increase. The relationship holds even for very thick films (≡ 10 μg oxygen cm^{-2}), indicating that the oxide growth kinetics can be determined from galvanostatic charging experiments.

Kinetics of porous oxide growth.—Figures 2 and 3 show the increase in conversion charge with time of anodic charging at 4, 80, and 200 μA cm^{-2} for electrolyte temperatures of 5° 25°, and 45°C. It is immediately evident that the temperature at which the oxide is grown plays a much more important role than

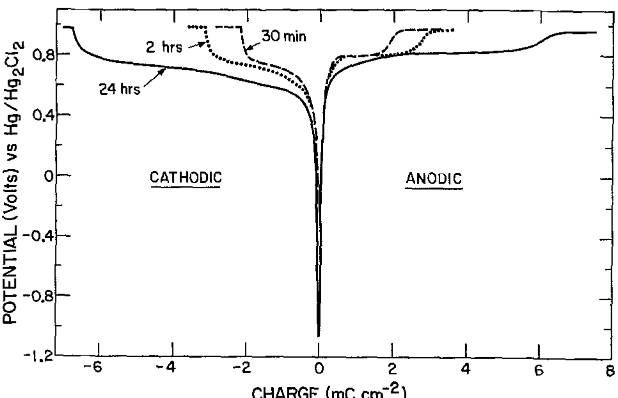

Fig. 1. Cathodic and anodic galvanostatic charging profiles, at 80 μA cm^{-2}, for nickel electrodes anodized at 80 μA cm^{-2} for various times in the O_2 evolution region: (- - -) 30 min; (···) 2 hr.; (——) 24 hr. The charging current was switched from cathodic to anodic as soon as the potential shifted into the H_2 evolution region (*i.e.*, −1.06V); for comparison, the profiles are centered at the point of transition from cathodic to anodic charging.

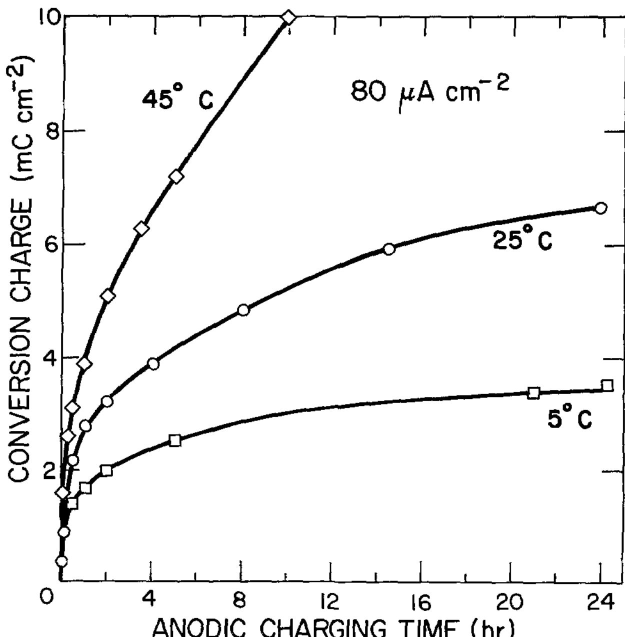

Fig. 2. Increase in conversion charge with time of anodic charging at 80 μA cm^{-2} at various temperatures: (—□—) 5°C; (—○—) 25°C; (—◇—) 45°C.

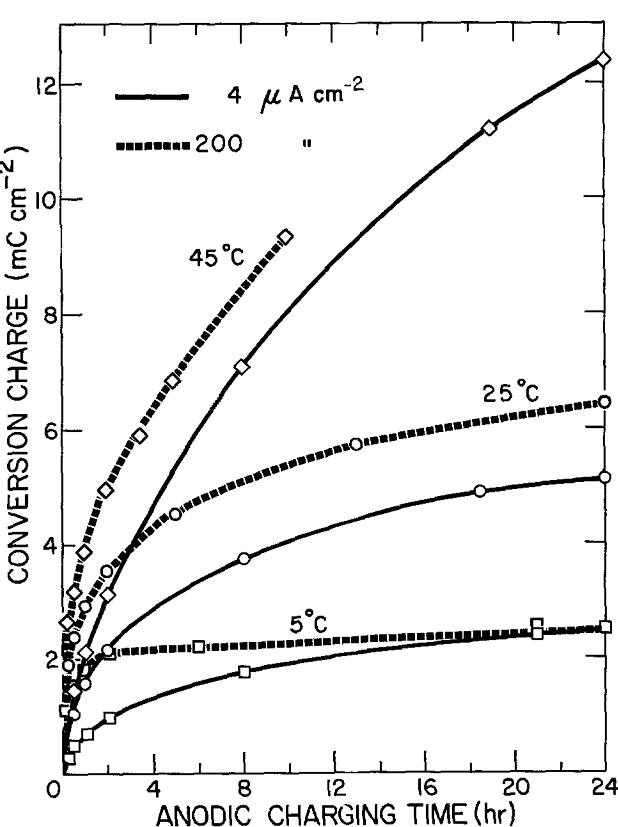

Fig. 3. Increase in conversion charge with time of anodic charging at 4 (——) and 200 (- - -) μA cm^{-2} at various temperatures. (—□—) 5°C; (—○—) 25°C; (—◇—) 45°C. The conversion charge was determined by cathodic charging at 80 μA cm^{-2}.

the anodizing current. Obviously, the current efficiency for oxide growth is higher at the lower charging rate, but the values are $\leq 1\%$ at all charging rates and temperatures with most of the charge being consumed by oxygen evolution (25). When the film is sufficiently thick, breakaway-type kinetics are observed with the oxide growth rate increasing rapidly (Fig. 4 and 5). It is also seen in Fig. 5 that oxide growth is much faster on etched nickel (electropolished and then etched for 60 sec in 5% HNO_3) than on electropolished nickel.

Discussion

Previous electrochemical and Auger results suggest that the conversion oxide has a porous structure, and that the porosity is on too fine a scale to be detected by electron microscopy (25). It is difficult to explain the conversion charge kinetic curves (Fig. 2-5), where the rate slows and then increases dramatically, on the basis of growth processes of the porous oxide alone. A more reasonable model of the oxidation

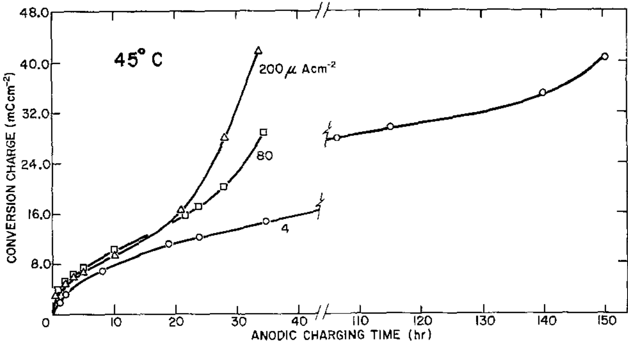

Fig. 4. Increase in conversion charge with time of anodic charging at 45°C using different charging rates: (—○—) 4 μA cm^{-2}; (—□—) 80 μA cm^{-2}; (—△—) 200 μA cm^{-2}.

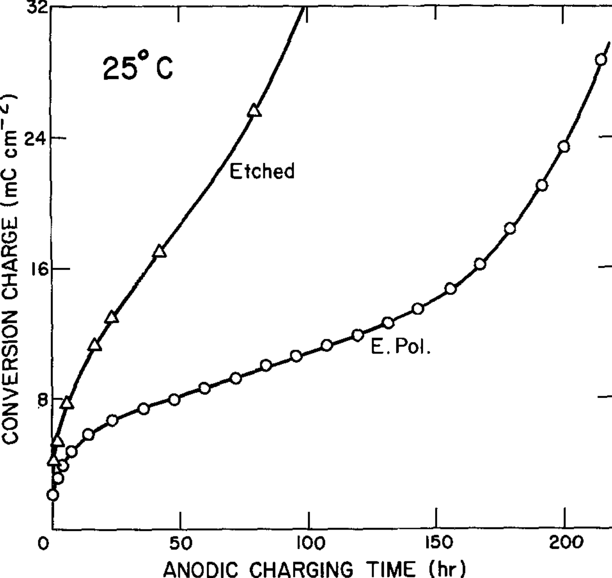

Fig. 5. Increase in conversion charge with time of anodic charging at 80 μA cm^{-2} at 25°C for electropolished nickel (—○—) and etched nickel (—△—). Etching was in 5% HNO_3 for 60 sec.

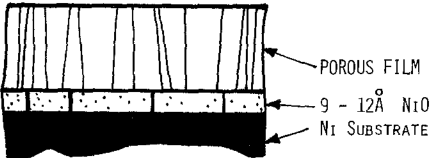
mechanism would involve the presence of a compact oxide film beneath the outer porous film. It is suggested that the compact film is the 9-12Å passive film of NiO as illustrated schematically in Fig. 6. It is known from previous work that the passive oxide has a defect character and the local breakdown of the film, in the passive potential region, generates Ni^{2+} in solution. In the oxygen evolution potential region, the Ni^{2+} arising from passive film breakdown could be oxidized to a higher oxide of nickel and this would give rise to the porous film, perhaps by the reaction

$$Ni^{2+} + 2H_2O \rightarrow NiOOH + 3H^+ + e$$

An alternative reaction would be

$$2Ni^{2+} + 3H_2O \rightarrow Ni_2O_3 + 6H^+ + 2e$$

which has a reversible potential of 0.2V (*vs.* Hg_2Cl_2). In the proposed model for porous film formation, growth would be controlled solely by the frequency of breakdown events in the passive film which would depend on the stability of the passive film as well as



$Ni + H_2O \longrightarrow NiO + 2H^+ + 2e$ — PASSIVATION

$NiO + 2H^+ \longrightarrow Ni^{2+} + H_2O$ — BREAKDOWN AT DEFECTS

$Ni \longrightarrow Ni^{2+} + 2e$ — METAL DISSOLUTION

$Ni^{2+} + 2H_2O \longrightarrow NiOOH + 3H^+ + e$ — POROUS FILM GROWTH

OR

$2Ni^{2+} + 3H_2O \longrightarrow Ni_2O_3 + 6H^+ + 2e$

$NiOOH + H^+ + e \longrightarrow Ni(OH)_2$ — CONVERSION

Fig. 6. Schematic illustration of the growth of the thick porous film on top of the compact passive flim of NiO. The reaction sequence indicates the possible mechanisms for growth and conversion of the porous film.

the electrolyte environment. It is known that the state of perfection of the passive film increases and the anodic corrosion current (due mainly to $Ni \rightarrow Ni^{2+} + 2e$) decreases with time of anodization after a potential step into the passive region, the decrease being rapid at first and then quite slow (24). It may be that the initial rapid decrease of anodic current with time correlates with the initial slowing down of the oxide growth kinetics in the oxygen plateau region (Fig. 2-4). That is, as the passive film becomes more perfect, less Ni^{2+} is generated so less porous film can form. The linear-type kinetics (cf. Fig. 5, E. Pol.) could be associated with the passive film reaching a virtual steady state of perfection and therefore having a constant breakdown frequency, after some time of anodization in the oxygen region. This would correlate with the almost constant corrosion current in the passive potential region after long times of potentiostatic holding. The results then suggest that the changes in the corrosion current with time of potentiostatic holding in the passive potential region are similar to the changes in the nickel dissolution current in the oxygen plateau region during galvanostatic oxidation.

The breakaway kinetics (Fig. 4 and 5), observed after the porous film has reached a significant thickness, can be explained by a localized pH decrease at the base of the porous film, *i.e.*, in the vicinity of the passive film. This arises because the oxidation reaction generates protons which must diffuse out from the body of the porous film for pH equilibration. When the porous film is too thick, the protons are not able to diffuse out rapidly enough for pH equilibration, so that a local decrease in pH occurs [cf. (32)-(35)]. The frequency of breakdown events at the passive film is highly dependent on the solution pH with the result that a decrease in pH causes this frequency to increase. This results in more rapid generation of Ni^{2+} and consequently a more rapid growth of the porous film. Growth kinetics at 4, 80, and 200 $\mu A\ cm^{-2}$ support this interpretation (Fig. 4), breakdown occurring at a lower porous film thickness at 200 $\mu A\ cm^{-2}$ since the higher charging current is generating a more rapid, local pH change. At 4 $\mu A\ cm^{-2}$, a much thicker oxide film is required before breakaway-type kinetics are observed.

This model of porous oxide film growth readily explains the previously noted thickness anisotropy[1] from grain to grain on polycrystalline nickel electrodes (25). It has been established in a number of earlier papers that the defect character of the passive oxide film is highly dependent on the crystal orientation of the substrate (23), the passive film on some grains being more defective than on others. Thus, with a polycrystalline sample, those grains with the most defective passive film will have the highest growth rates for the porous film. The rate of the porous film growth on a particular metal grain is therefore a monitor of the stability of the passive film on that grain.

The proposed model also explains the observations regarding temperature, anodic charging rate, and the influence of surface pretreatment on porous oxide growth kinetics. With increasing temperature, the porous film growth rate increases dramatically (Fig. 2 and 3). To quantify this increase with increasing electrolyte temperature, the extensive linear-type growth region can be used (cf. for example, Fig. 5). Growth kinetics for the porous film in this region are (charging rate 80 $\mu A\ cm^{-2}$): 0.6Å hr^{-1} at 25°C and 5.5Å hr^{-1} at 45°C. This compares with an increase of the corrosion current in the passive potential region from 0.01 $\mu A\ cm^{-2}$ at 25°C to 0.1 $\mu A\ cm^{-2}$ at 45°C. Thus, the increase in the porous film growth rate with temperature follows the increase in current measured in the passive potential region, a result to be expected if the dual oxide model is correct. The observation that the anodic charging rate has little influence on the growth kinetics of the porous film is also to be expected since the anodic charging current should have little or no influence on the defect character of the underlying passive film. With increased anodic current, the oxygen plateau potential shifts in the anodic direction and the extra charge is consumed by oxygen evolution. The influence of surface pretreatment on the growth rate of porous films (Fig. 5) is understandable in terms of the much less stable prior oxide film on etched nickel (36). Since the prior oxide is less stable, the anodic corrosion current is higher with more Ni^{2+} available for incorporation into (and therefore growth of) the porous film. In the proposed model where the passive film persists beneath the porous oxide, any factor which increases the corrosion rate of the passive film also increases the growth rate of the porous film.

[1] This thickness anisotropy is also evident during cathodic charging of a thick, dark porous film; the oxide on some grains becomes transparent long before that on other grains.

Summary

Anodic galvanostatic charging of nickel in pH 7.65 borate buffer solution produces a finely porous oxide film whose thickness is dependent on the time of charging and the electrolyte temperature. The anodically formed porous film is probably β-NiOOH which undergoes a facile cathodic reduction to a lower oxidation state, likely $Ni(OH)_2$. The conversion from the higher to lower oxide, and vice versa, gives a distinct galvanostatic arrest structure; the arrest charge is related to the quantity of porous oxide and can thus be used to study the kinetics of porous film growth. The kinetics are explained by a model which suggests that the compact passive film persists beneath the porous film and controls the latter's growth. Factors which increase the corrosion rate of the passive film (*e.g.*, increasing temperature and different surface pretreatment) also increase the growth rate of the porous film, suggesting that breakdown and repair events in the underlying passive film provide Ni^{2+} which is anodically incorporated into the porous film. In fact, the measured corrosion current of the passive film appears to directly determine the growth rate of the porous film.

ABSTRACT

The stability of single crystal CdSe photoelectrodes in polysulfide electrolyte is shown to be a function of the etching treatment used. This is explained by changes in real electrode surface area caused by different etchants, leading to a variation in real photocurrent density. The effect of photocurrent density on stability is measured, and used to semiquantitatively explain the observed variation in stability with etching. The effect is shown to be consistent for three different crystal faces, and is extended to polycrystalline electrodes.

Since the earliest reports showing that polychalcogenide electrolytes can stabilize n-Cd-chalcogenides as photoanodes in a photoelectrochemical cell, PEC, (1-3), it has becomes apparent that this stability is very ill defined. For example, the stability of the CdSe/polysulfide system has been reported to vary between minutes (4) to months (5). The variables which have been shown to affect the degree of stability are: electrode crystal structure and exposed crystal face, electrolyte composition, stirring, and photocurrent density (5-8).

In the CdSe/$S_x^=$ system it has been shown that stabilization of the photoanodes is connected with the exchange of Se from the CdSe by S from the electrolyte leading to a polycrystalline CdS layer on top of the CdSe (1,4-6, 9-11). Under favorable circumstances cell output is stable because the CdS layer stops growing after reaching a certain thickness (probably less than ~100Å), at which point Se/S exchange is replaced by S/S exchange. If, however, Se/S exchange continues, even at a much reduced rate, the CdS layer continues to grow. This thicker layer will start to impede the transfer of minority carriers from the bulk solid to the solution phase, leading to increased deactivation. The resistance to the transfer of the minority carriers can be due to blocking by the higher bandgap CdS layer and/or reduced electrical conductivity of this layer. However, the similar stability behavior of CdS, where such a blocking layer is not expected, suggests that the degradation in output is due primarily to the increased polycrystallinity of the surface CdS layer, leading either to trapping and recombination of holes at the grain boundaries (8, 10, 11) or if the surface layer is porous and inactive, impeding the dissolution of

* Electrochemical Society Active Member.

Key words: CdSe photoelectrodes, photoelectrode surface area, photoetching.

photogenerated S [which is the rate-determining step (12)] away from the active surface through the porous CdS layer (8, 9).

Therefore photocorrosion is related to the competition between several possible reactions by the photogenerated holes: oxidation of polysulfide from the solution (the desired reaction); oxidation of the freshly formed CdS layer, which renews the solid/solution interface; or oxidation of the CdSe itself, which is the photocorrosion reaction and leads to increased S/Se substitution, and eventually, degradation of the output. Any change in conditions which facilitates the overall electrochemical oxidation of polysulfide and removal of the reaction photoproducts from the surface, should change the balance of the competitive reactions in favor of decreasing exchange, and thus increasing stability. We have shown that polycrystalline electrodes are more stable than single crystal ones, and explain this by the higher real surface area of the less smooth polycrystalline electrodes, leading to a lower real photocurrent density (5) which has previously been shown to cause increased stability (6). This follows from the competitive nature of the possible reactions (13); if the photocurrent density is not too high, the oxidation of polysulfide (actually the dissolution of S from the surface) can occur as fast as (or faster than) the hole flux to the surface. At higher photocurrent densities (*i.e.*, greater hole fluxes), if the overall polysulfide oxidation step cannot keep up with the arrival of holes at the surface, we expect degradation according to the principles previously discussed.

This picture is, however, too simple, and the purpose of the work reported here is to investigate more fully than previously the effect of real surface area of CdSe photoelectrodes, together with the influence of several etching treatments, on the output stability of these electrodes in polysulfide electrolyte. By trying to achieve a picture, that is as complete as possible, of the various factors influencing the output stability of such PEC's, it may become feasible to manipulate the variables influencing these factors in such a way so as to achieve stable PEC's with output stability under normal day/night conditions, that is constant for years.

Experimental

All the CdSe crystals were cut from the same boule, which was "as-grown" (from Dr. W. Giriat, IVIC, Caracas), with an approximate resistivity of 15 Ωcm. Crystals were cut along the (0001), (10$\bar{1}$0), and (1120) faces. All orientations were checked by x-ray diffraction. Using the anomalous dispersion factors the (0001) face was shown to be the Cd-one (14). Polycrystalline CdSe electrodes were prepared by painting an aqueous slurry of CdSe (Alfa 99.999%) mixed with a $ZnCl_2$ flux onto a Ti substrate. and annealing 10 min at 630°C in argon (15). Single crystal electrodes were all polished to a mirror finish using alumina polishing suspension down to 0.3 μm. The different etching treatments on these polished electrodes were, all at room temperature:

1. Dip in 4% Br_2 in MeOH for 5 sec; rinse with polysulfide ($S_x^=$) and then with water. Repeat. Br_2/MeOH.
2. Dip in CrO_3:HCl:H_2O in 6:10:4 w/w ratio, for 5 sec; rinse with $S_x^=$ and then with water. Repeat. "CrO_3."
3. Dip in fresh aqua regia, 15 sec; rinse with $S_x^=$, then with water. Repeat. AR.
4. AR followed by "CrO_3," *i.e.*, as 3, followed by 2.
5. AR followed by photoetch, *i.e.*, as 3, followed by illumination in HNO_3:HCl:H_2O (0.3:9.7:90) electrolyte, short circuited to a carbon counterelectrode in the same electrolyte, under AMI illumination for 4-5 sec; then rinsing in S_x^{2-} and H_2O (16). The polycrystalline electrode was etched for 4-5 sec in 3% HNO_3 in HCl (aqua regia was too vigorous an etchant for these thin layers), rinsed in S_x^{2-} and water, and photoetched as above.

The electrolyte in all cases was 1M each KOH, Na_2S, and S in deionized water. The experiments were all carried out using the same bulk solution stored under argon. Each stability run was obtained using a fresh quantity of this solution. The stability runs were carried out potentiostatically under essentially short-circuit conditions using Pt counter and reference electrodes. The cell was thermostated in a water bath at 35°C, and no stirring was employed. Illumination was by a stabilized quartz-iodine lamp, and illumination was controlled to give the required photocurrent density in all cases. In some cases, where the photocurrent density initially increased with time for constant illumination, which often happens in this system, the illumination intensity was reduced slightly to maintain the initial current, (otherwise a meaningful comparison could not be made).

Results and Discussion

It has been shown previously (6) that the (0001) face of a CdSe crystal is less stable as a photoanode in S_x^{2-} than the (11$\bar{2}$0) face. Since we wished to compare the effect of change in surface roughness by use of different etchants, which could preferentially expose planes other than that initially chosen, we had to verify that the various etchants did not expose any crystal face(s) preferentially. Therefore, we investigated three different faces, namely (0001), (10$\bar{1}$0), and (11$\bar{2}$0), assuming that, if preferential exposure of a more stable face did occur upon etching, the dependence on etchant of these three faces would be different. Figures 1 and 2 show the photocurrent densities of these faces after the various etching treatments, as a function of time, plotted on a logarithmic scale. The (0001) and (10$\bar{1}$0) faces behaved identically (within experimental error). The interesting result is that, in spite of entirely different stabilities of the (11$\bar{2}$0) face on the one hand and the (0001) and (10$\bar{1}$0) faces on the other hand, they respond very similarly to the various etching treatments. Stabilization by a factor of ~50 is obtained when going from the entirely smooth surface to one that has been photoetched. This behavior indicates that we are not dealing with preferential exposure of more or less stable faces by the different etchants used.

To correlate these results with the effects of the various etchants on the real surface area, we show in

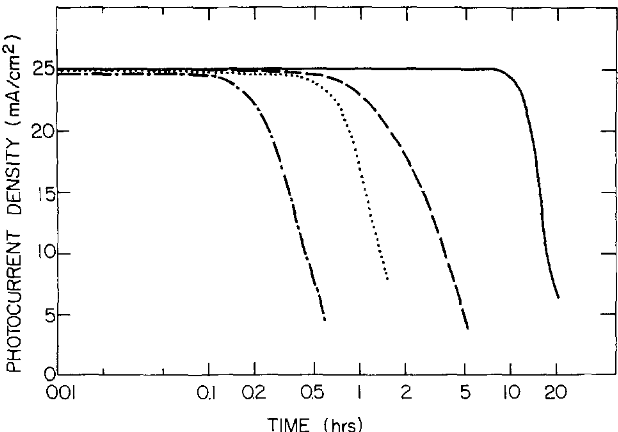

Fig. 1. Output stability of the (10$\bar{1}$0) face of a CdSe crystal in a polysulfide electrolyte (1M each KOH, Na_2S, and S) at 35°C. —·—·— Polished and Br_2/MeOH (for (0001) face) or "CrO_3" (for (10$\bar{1}$0) face) etched; . . . . . . aqua regia (AR) etch followed by "CrO_3" etch; - - - - - - AR etch; ——— AR etch followed by photoetch. An essentially identical picture was obtained for the (0001) (Cd) face.

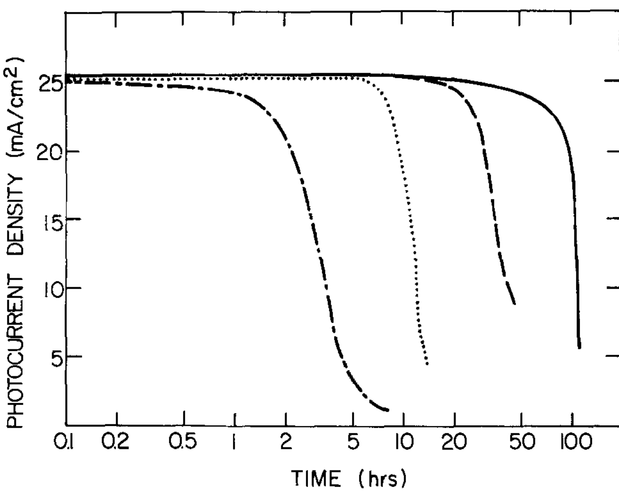

Fig. 2. As Fig. 1, but for the (11$\bar{2}$0) face

Fig. 3-11 SEM pictures of the surfaces of the 3 faces, each after 3 different etching treatments. (SEM pictures of the Br_2/MeOH or "CrO_3" only, etches are not shown, since these surfaces were all mirror-smooth, and featureless under the SEM.)

Figures 3, 4, and 5 show AR + Br_2/MeOH, AR, and AR + photoetch for the (0001) face of CdSe. We can see an increase in surface roughness going from Fig. 3 to 5. Figures 6, 7, and 8 [for the (10$\bar{1}$0) face] and 9, 10, and 11 [for the (11$\bar{2}$0) face] show precisely the same trend, although the etch patterns vary from one face to another. Figure 12 shows a photograph of the (1120) crystal face with 3 differently etched regions. Even such a visual observation of the surface shows the strikingly different effects of different etchants.

Thus, the increase in stability in going from left to right in Fig. 1 and 2 correlates with an increase in surface area, in agreement with our reasoning given previ-

ously on the basis of the difference between single crystal and polycrystalline CdSe.

Although we have not yet developed a method, reliable enough to measure these variations in surface area quantitatively (but diffuse reflectance together with photoacoustic measurements do show some promise in this respect), and in any case, such measurements would be of limited value, since an increase in real surface area by a certain factor need not reflect an in-

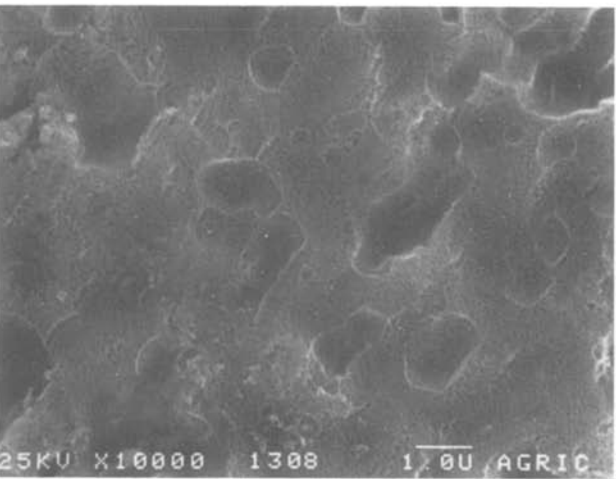

Fig. 11. SEM micrograph of (1120) face after AR + photoetch

crease in the active surface area by the same factor, it is of interest to see if such variation is sufficient to explain the effect of stability. Figure 13A shows the effect of photocurrent density on stability for the smooth, Br_2/MeOH etched, (0001) face (we have given the x-axis in time, and not coulombs, in order to facilitate comparison with other figures). In Fig. 13B these and similar data are used to show directly the dependence of the amount of photocharge that can be passed, as a function of initial photocurrent density.

Because of the long measuring times at lower current densities, the curve could not be extended in this direction. But based on general experience we expect the curve to straighten out and to give a practically infinite lifetime at some finite lower (<10 mA/cm^2) current density. The strong dependence of stability on the initial photocurrent density, also described in Ref. (6),

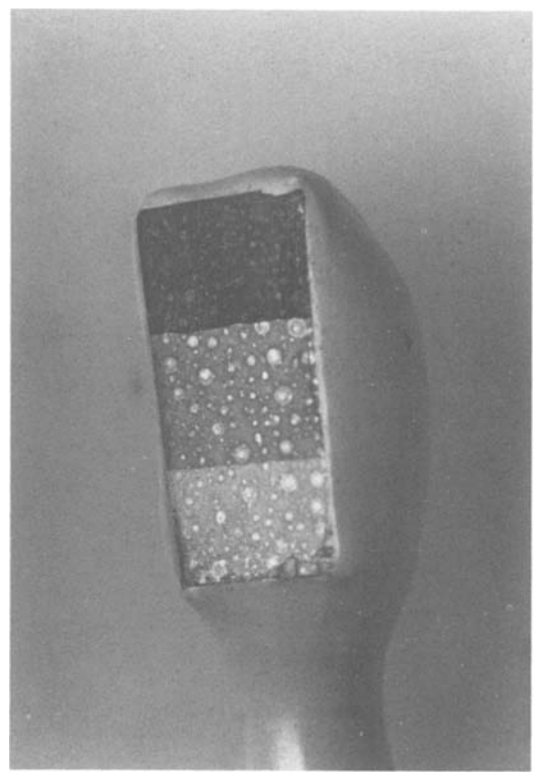

Fig. 12. Photograph (10× magnification) of a (11$\bar{2}$0) face of a CdSe crystal. The three different regions are obtained after: AR followed by "CrO_3" etch (lightest region); AR etch alone (middle region); and AR followed by photoetch (darker region).

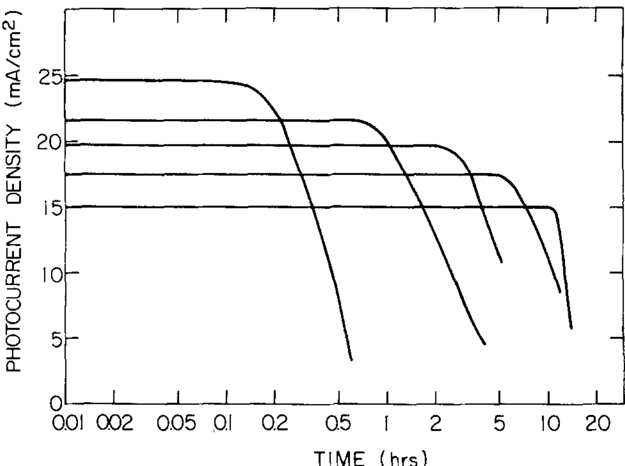

Fig. 13A. Effect of photocurrent density variation (by varying illumination intensity) on stability of polished, and subsequently Br_2/MeOH etched, (0001) CdSe crystal at 35°C.

can be seen clearly. Using Fig. 13A we can understand the results shown in Fig. 1 and 2. Those were obtained at an initial current density of 25 mA/cm². We see from Fig. 13A that a roughness factor of ~1.6 (24.5 mA/15 mA), which would decrease real current density to ~15 mA/cm², would increase the lifetime by a factor of about fifty. The SEM pictures in Fig. 3-11 show that the range of roughness factors resulting from the different treatments are probably much higher and the most logical explanation for the increased stability is therefore this increase in surface area with concurrent decrease in real current density.

As mentioned earlier, the increase in active surface area need not be the same as the increase in real surface area, and will probably be smaller, since the presence of small pores of other surface irregularities may lead to transport problems which could partially offset

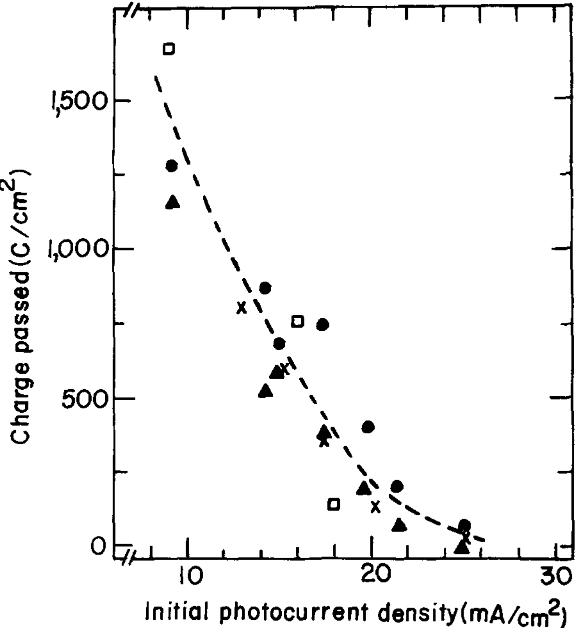

Fig. 13B. Dependence of the amount of photocharge, that can be passed through a CdSe electrode (as in 13A) until destabilization, on the initial photocurrent density. The data are from Fig. 13A (●, ▲) and similar ones obtained with crystals cut from the same boule (×, ○). ●, ×, □: Only photocharge passed until the current density decreases to 5 mA/cm² is taken into account, because of varying behavior and long measuring times at lower current densities. ▲: As ●, but for the photocharge passed at constant current density (= initial current density), *i.e.*, while the electrode is 100% stable.

the gain due to increased surface area. This makes it very difficult to treat the above effect in any more quantitative detail.

Since our original reasoning for the effect of surface area on stability came from the comparison between single crystal and thin layer polycrystalline CdSe (5), it is of interest to see how the most stable form of a single crystal photoetched (11$\bar{2}$0) face compares in stability with photoetched thin layer electrodes. This is shown in Fig. 14. Note the high photocurrent densities used here (50 mA/cm²) in order to measure a degradation in a reasonably short period of time. While there is a definite difference in stability between the two electrodes, the difference is considerably less than that noted earlier in comparing polycrystalline CdSe with the AR-etched (0001) face of CdSe, for what are now obvious reasons. The main difference is in the slow and diminishing rate of deactivation of the polycrystalline electrode, compared with the single crystal. This slow rate of deactivation is characteristic of our polycrystalline electrodes. It may be due to the very large degree of surface irregularity of these electrodes (see Fig. 15). Some areas will be photoelectrochemically more active than others. Thus, the more active ones may deactivate first, since the local current density at them will be relatively high. As the photocurrent falls,

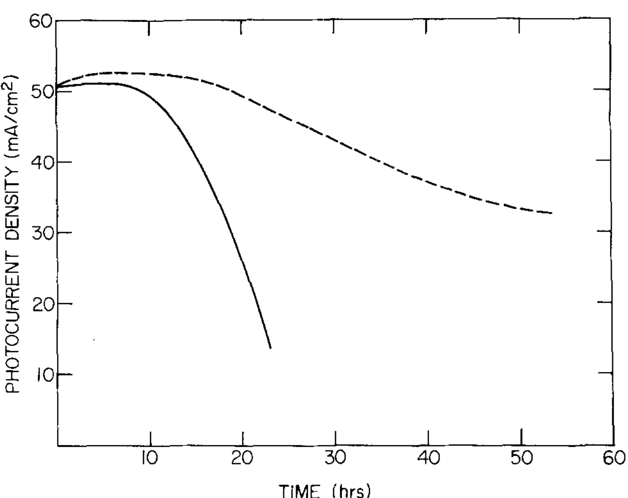

Fig. 14. Comparison of stability of thin layer polycrystalline painted CdSe (3% HNO_3 in HCl etch followed by photoetch) (broken line), and (11$\bar{2}$0) face of single crystal CdSe (AR followed by photoetch) (solid line).

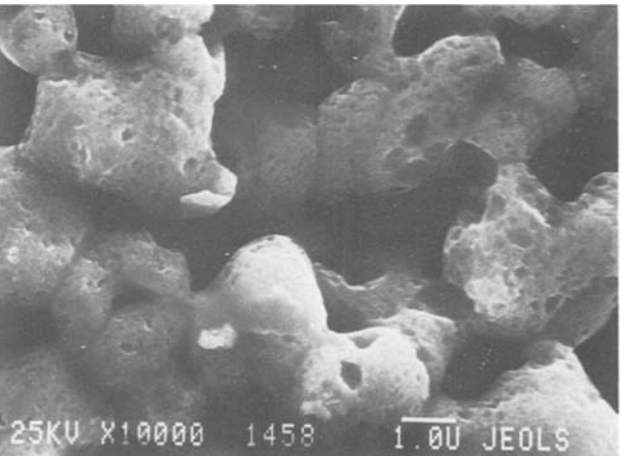

Fig. 15. SEM micrograph (10,000× magnification) of a painted polycrystalline CdSe electrode after 3% HNO_3 in HCl etch and use in $S_x^=$ solution.

the previously less active areas now become (relatively speaking) the most active, but at a lower current density, hence a slower rate of deactivation. While this explanation is admittedly rather simplistic, it can serve as a basis for explaining the slow and decreasing rate of deactivation of polycrystalline electrodes.

It should be noted that the electrolyte used here (1M each OH^-, S^{2-}, S) is far from being the most stabilizing electrolyte for this system. Therefore, the stability results shown here should not be interpreted as reflecting the maximum attainable stability of this system. In a more stabilizing electrolyte, the stability will in fact be much greater (8).

Although not the main point of this study, it is of interest to attempt to understand the difference in stability of the various faces. A possible reason may be found by considering the number of bonds that have to be broken to free a Cd^{2+} ion from the surface. In the $(11\bar{2}0)$ plane there are two in-plane bonds and one into the bulk phase. The $(10\bar{1}0)$ plane has only one in-plane bond and one or two into the bulk phase, while the (0001) plane has no in-plane bonds but one or three into the bulk phase. Thus, one could argue that the $(11\bar{2}0)$ plane is more stable since always three bonds need to be broken in order to free a Cd ion. If this is so, then the decomposition potential of a semiconductor photoelectrode must be dependent on the crystal face exposed. The different bonding at the surface may also influence the electrochemical reaction through different surface-solute interaction, and thus change the relative energetics of the two competing processes. In this case, the decomposition potential need not necessarily change. Finally, if photocorrosion is connected with the diffusion of Cd^{2+} through the bulk to the surface, such as has been reported to occur for CdTe photoanodes (17), then the varying stability of different faces may be due to varying rates of diffusion (or migration in the space charge layer) of the Cd^{2+} in the different crystal directions.

According to the strong dependence of lifetime on current density, we might expect the electrode at constant illumination to be less stable at short circuit than at maximum power, because of the higher current density passed. But according to our experience this is not true and we find that at constant illumination, most of our electrodes are more stable at short circuit than at maximum power. We shall deal with this interesting phenomenon in a subsequent publication. Suffice here to note that apparently, current density is not the only parameter influencing stability, but the electrode potential under the actual working conditions plays a role as well. In view of the rate-determining dissolution of sulfur, it is likely that changes in electrode potential influence the stability through variations in surface potential (or changes in the Helmholtz layer), rather than simply by a change in band bending.

The Relationship of Transport Properties and ^{1}HNMR Spectra to the Structure of Molten Methylpyridinium Halides

Department of Chemistry, Bowling Green State University, Bowling Green, Ohio 43403

ABSTRACT

The equivalent conductance, viscosity, and ^{1}HNMR spectra of several molten symmetric and asymmetric methylpyridinium halides were measured as a function of temperature. From these measurements, correlations between structure, spectra, and transport properties were made. From these correlations conclusions about the dynamics of motion in these and in other organic melts were drawn.

Molten pyridinium salts alone or in combination with molten aluminum halides are of considerable importance as the electrolyte in batteries and as the solvent for synthetic and mechanistic studies of organic and inorganic compounds. In recent years they have also become important as a possible heat storing media in solar heating and air conditioning systems as well as solvents for coal solubilization and decomposition reactions (1). In addition to these practical considerations, molten pyridinium salts offer a convenient vehicle for understanding the nature of the molten state because their relatively low melting points make them accessible to NMR techniques as well as to conventional transport measurements. This, combined with the myriad different pyridinium salts that are easily synthesized, makes it possible to observe the effects of small structural changes, such as moving a methyl group from the 4 to the 3 position on the pyridine ring, on both transport and spectral properties. From these effects a qualitative understanding of molecular motion in these and probably other molten organic liquids can be obtained.

In an earlier study (2) we reported the equivalent conductance, Λ, of 4-methylpyridinium bromide to be about 8% lower than the conductance of N-methylpyridinium bromide over approximately the same temperature range. We attributed this surprising result to complex formation in the 4-methyl salt which reduces the number of charge carriers per unit volume relative to the N-methyl salt. The complex probably forms by means of hydrogen bonding between the nitrogen proton and the bromide ion and this, of course, cannot occur in the N-methyl salt (3-5). The ^{1}HNMR spectrum of 4-methylpyridinium bromide showed no line width broadening greater than 0.02 ppm, over a nearly 50° temperature range, indicating the barrier to complex formation is less than about 40 kJ/mol (1). There is, however, a change in proton chemical shift, as the anion changed from Br^- to Cl^-, that correlates well with the conductance data and this is discussed later. Herein we extend our investigation to include other symmetrical methylpyridinium salts as well as the asymmetrical methylpyridinium halides. We also assess the nature of the complex species in 4-methylpyridinium chloride and in 4-methylpyridinium bromide and estimate the magnitude of their association constants. In addition, we comment on the mechanism of molecular motion in methylpyridinium melts.

Experimental Details

All transfer operations were carried out in a dry box in which N_2 gas was circulated over molecular sieves to remove water. A fiber optic light pipe was used to conduct light into the Dow Corning 710 oil which served as the heat bath. The flexible light pipe greatly facilitated the density and viscosity measurements. The bath was held constant to ± 0.1°C. A Varian CFT-20 NMR machine with variable temperature capability was used to obtain the ^{1}HNMR spectra.

The preparation of the salts, conductivity measurements, density measurements, viscosity measurements, and ^{1}HNMR techniques are all described in detail elsewhere (6-9).

Results

The density, ρ, the specific conductance, κ, the viscosity, η, and the ^{1}HNMR spectra of molten 2-methylpyridinium chloride (2-mepyr/HCl), 2-methylpyridinium bromide (2-mepyr/HBr), 3-methylpyridinium chloride (3-mepyr/HCl), and 3-methylpyridinium bromide (3-mepyr/HBr) were measured as a function of temperature over an approximately 50°C temperature range. These salts, together with their melting points, are shown in Fig. 1. The η's of 4-methylpyridinium bromide and chloride as well as the η of N-methylpyridinium chloride (N-mepyr/Cl) were measured as a function of temperature. The κ of molten 4-mepyr/HCl was also measured as a function of temperature. The values of ρ used to compute η and Λ for the symmetric salts were taken from an earlier study (7). The ^{1}HNMR spectra of the three molten 4-methylpyridinium halides were obtained relative to an external standard of either $(CH_3)_2SO$ or $(CH_3)_2SO_2$. Figure 2 shows the spectrum of 4-mepyr/HI at 172°C relative to $(CH_3)_2SO_2$. Figures 3 and 4 show the spec-

tra of 2-mepyr/HCl and 3-mepyr/HCl, respectively, at 100°C relative to DMSO. There was no discernable peak narrowing or chemical shift change as a function of temperature greater than 0.02 ppm in any of the melts so only one spectrum of each cation need be shown.

Table I lists the chemical shifts, δ, for the several asymmetric methylpyridinium salts studied, relative to a standard of DMSO. Table II lists the δ's for the symmetric methylpyridinium salts relative to an external standard of $(CH_3)_2SO_2$. The $(CH_3)_2SO_2$ peak is 0.45 ppm downfield from DMSO. Table III lists the densities of the asymmetrical melts.

Figure 5 is a graph of ln η *vs.* T^{-1} for the four asymmetric salt melts and it should be noted that there is a slight, but distinct, curvature in the plots. Figure 6 shows the ln η *vs* T^{-1} behavior of the symmetric melts and here the graphs are linear over the temperature

Salt	a	$-(b \times 10^3)$	Temperature range (K)
2-mepyr/HCl	1.334	0.5657	363-408
2-mepyr/HBr	1.711	0.7279	350-395
3-mepyr/HCl	1.329	0.5525	374-419
3-mepyr/HBr	1.690	0.6890	370-415

range studied. Figure 7 shows ln Λ *vs.* T^{-1} for the four methylchlorides while Fig. 8 is a plot of ln Λ *vs.* T^{-1} for the four methyl bromide isomers. It is obvious from Fig. 7 that N-mepyr/Cl is a much better conductor than the 4-methyl salt and that this unexpected phenomenon first observed in the bromide melts is even more pronounced in the chloride melts.

Discussion

To validly compare properties of one melt with those of another, the melts must be in the same state. In order to ensure they are in the same state, a reference state must be agreed upon. Historically, most authors, including us, have used the salt's normal melting point, T_M, as the reference state and compared properties at a convenient multiple of T_M. This is tantamount to saying that each salt is in the same state if it is the same relative distance into its liquid range on a p *vs.* T plane. This, of course, assumes that the start of the liquid range is T_M, but recent evidence has called this assumption into question, especially for complicated salts like the methylpyridinium halides (10).

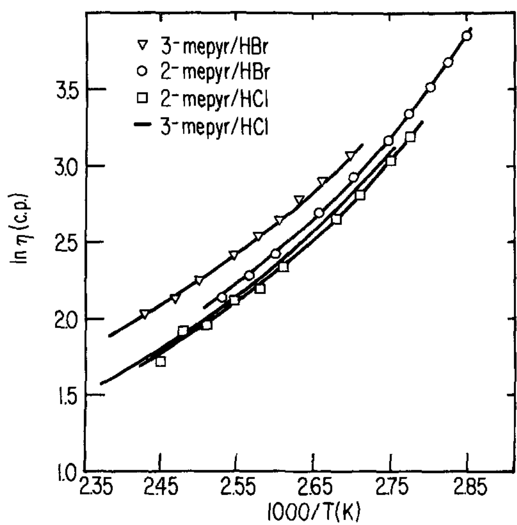

Fig. 5. Log of the viscosity (in cp) vs. 1000/*T* for each of the asymmetric methylpyridinium halides.

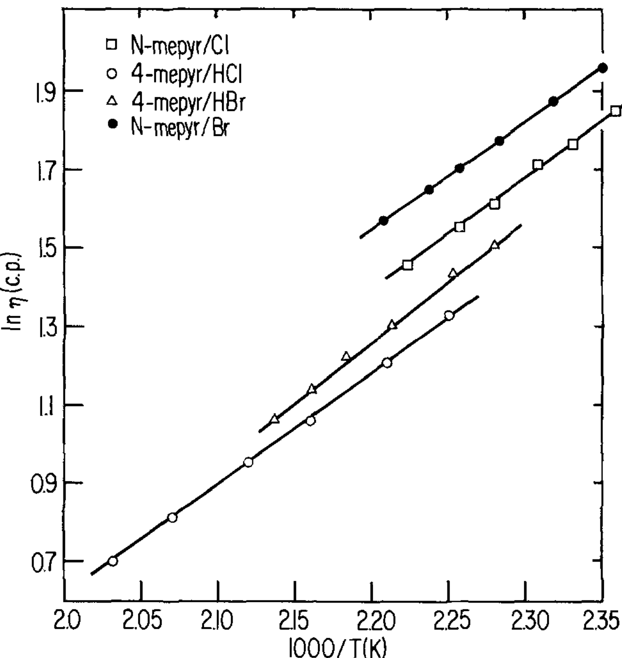

Fig. 6. Log of the viscosity (in cp) *vs.* 1000/*T* for each of the symmetric methylpyridinium halides.

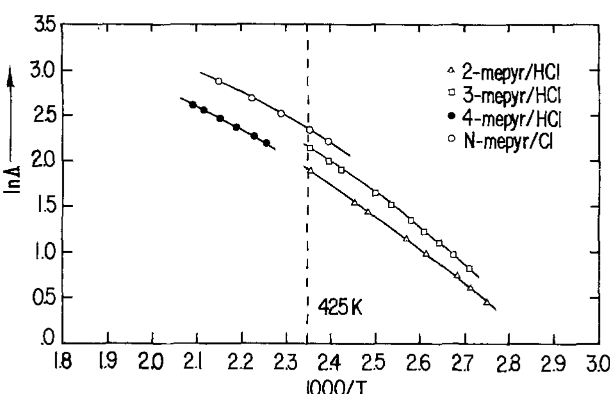

Fig. 7. Log of the equivalent conductance *vs.* 1000/*T* for the four methylpyridinium chlorides.

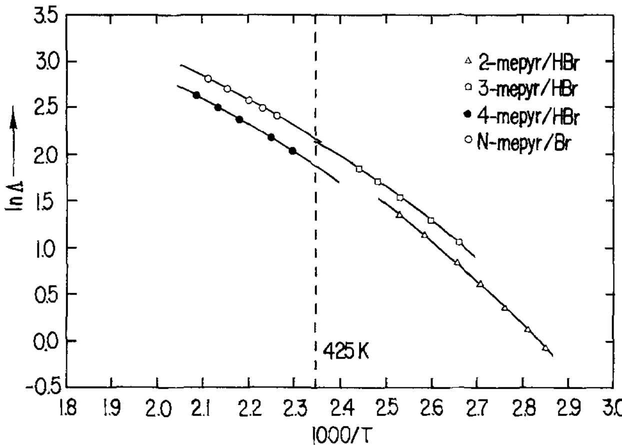

Fig. 8. Log of the equivalent conductance *vs.* 1000/*T* for the four methylpyridinium bromides.

For these systems, a more appropriate standard state is either the boiling point, T_b, or the glass transition temperature, T_g. Since we do not know the T_g's for our salts and many of them dissociate before they boil, we have selected a "common temperature" of 425 K as the reference state.

Table IV lists viscosities, densities, equivalent conductances, and Walden products of the eight salts at 425 K. This choice of reference implies that all of the compounds have the same liquid range and, *mutatis mutandis,* that T_g is a more reliable approximation to the start of the liquid state than is T_M.

Enough evidence from measurements of the liquid ranges of disubstituted benzenes exists to support our choice of reference state. To site one example, the o-, m-, and p-fluorotoluenes boil at 388, 387, and 385 K, respectively, have T_g's of 120, 122, and 123 K, respectively, but have T_M's of 211, 185, and 216 K, respectively (10).

Evidence for the existence of complex species.—Comparing the equivalent conductance of an N-methyl salt with the equivalent conductance of the corresponding 4-methyl salt, over the entire temperature range, indicates that the N-methyl salt is the better conductor. Because isomers are being compared, and the N-methyl melts are slightly more dense than the 4-methyl melts, suggesting motion is relatively more restricted, the most plausible explanation for this difference in Λ is that there are fewer charge carriers per unit volume in the 4-methyl salts than in the corresponding N-methyl salts because complex species are present. The alternative explanation, that there are the same number of charge carriers per unit volume, but they move slower, is still possible, but based on the spectroscopic data and observed viscosities is far less likely. The formation of a complex almost certainly involves hydrogen bonding between the nitrogenic proton and the halide ion, which means we should obtain further evidence for the existence of a complex from the ^{1}HNMR spectra of the three 4-methylpyridinium ions (Fig. 2 and Table II). In these melts the ring and methyl protons are deshielded more by the I^- than by Br^-, and more by Br^- than by Cl^-, so that there is actually a sign reversal of δ for CH_3 relative to the dimethylsulfone external standard. On the contrary, the nitrogenic proton is deshielded more by the Cl^- than by the Br^- and more by the Br^- than the I^-. This dramatic change in chemical shift order correlates very well with the conductivity data and is compelling evidence for believing that the $N\text{-}H^+$ forms a stronger hydrogen bond with Cl^- than it does with Br^-. It probably does not hydrogen bond to I^- at all (5). In an isolated methylpyridinium ion, the proton is well shielded by the nitrogen's lone pair of electrons, presumably located in an sp^2 orbital. The halide ion strongly attracts this proton, partially dislodging it from the protection of its shielding electrons, and causes it to resonate at a lower frequency. This phenomenon is more pronounced in the Cl^- melts than in the Br^- melts due to the larger charge to volume ratio in Cl^- than in Br^-. This same trend is present in the asymmetric chlorides and bromides as well. The reasons why the ring protons respond to the halide differently are still not perfectly clear, but it is very likely that hydrogen bonding is not the major factor. Probably exigencies of packing are responsible for the observed chemical

Table IV. Transport properties, densities, and Walden products of the four isomers of methylpyridinium chloride and the four isomers of methylpyridinium bromide at 425 K

Isomer	Λ ($cm^2(\Omega$ equiv.$)^{-1}$)	η (cp)	ρ (g/cm^3)	$\Lambda\eta$
2-mepyr/HCl	6.68	3.90	1.093	26.1
3-mepyr/HCl	8.58	3.87	1.094	33.2
4-mepyr/HCl	6.61	5.06	1.094	33.5

2-mepyr/HBr	7.76	4.78	1.401	37.1
3-mepyr/HBr	8.41	6.65	1.397	55.9
4-mepyr/HBr	6.55	5.41	1.405	35.4
N-mepyr/Cl	9.00	7.27	1.445	65.4

shifts. The crystal structure of pyridinium iodide indicates the I^- is sandwiched between the π clouds of two pyridinium rings (11) and it is not unlikely that this sort of structure would tend to persist in molten 4-mepyr/HI. On the other hand, the Cl^- ion, by virtue of its strong tendency to form hydrogen bonds with the nitrogenic proton, will reside much of the time at the $N\text{-}H^+$ end of the molecule, as it does in solid pyridinium/HCl (12). The Br^- will occupy an intermediate position, on the average. This means the I^- ion perturbs the pyridine ring current more than the Br^- and the Br^- perturbs it more than the Cl^-. The ring current, which diamagnetically shields protons, will be least effective in the iodide, next least effective in the Br^- melts, and most effective in the Cl^- melts at shielding protons on neighboring molecules; hence the observed order of deshielding of the ring protons and CH_3 groups (13). These phenomena taken together, account for the observed chemical shifts in a qualitative way and when correlated with the conductivity data yield fairly decent evidence for the existence of some sort of complex species in these melts.

The N-H⁺ contribution to the conductivity.—Before discussing the nature of the complex, we comment on the protonic contribution to the conductivity. It is obvious that the 2- and 3-methylpyridinium chlorides have about the same viscosities, but the 3-methyl salt's equivalent conductance is 22% greater. The most likely reason for this, since the molecular dimensions, densities, and molecular geometry are so similar, is that there is a greater protonic contribution to the conductivity of the 3-methyl salt, than to the conductivity of the 2-methyl salt (3, 4, 14). The 3-methylpyridine is less basic than the 2-methylpyridine (15), so its proton is held less tightly and can make a greater contribution to the conductivity. The $-CH_3$ group at the 2 position of the ring would also interfere with facile proton transfer (or complex formation for that matter) thus further reducing the proton's contribution to the 2-methyl salt's conductivity. A similar protonic contribution is probably occurring in the bromide melts, as well, though here it seems less pronounced. At this point it is unclear if an actual Grotthuss mechanism occurs (Fig. 9b), in which there is a transfer of charge or virtual movement without an actual proton diffusion, or a hopping mechanism occurs, in which a given proton hops from site to site, and during one of its excursions reaches an electrode. Nevertheless, there is almost certainly some protonic contribution to the conductance and this contribution seems to be greater in the chloride melts than in the bromide melts.

The nature of the complex species and equilibria in the melts.—The spectroscopic and conductivity data suggest that in melts containing $N\text{-}H^+$, an equilibrium of the sort

$$\text{mepyr/H}^+ + X^- \rightleftharpoons \text{mepyrH}^+X^- \rightleftharpoons \text{mepyr} + HX \quad [1]$$

is present with the proton oscillating within its double minimum potential well. This sort of equilibrium has been suggested by Shuppert and Angell to exist in pyridinium HCl melts (4). Since neither spectral measurements nor chemical analysis has turned up any evidence of free methylpyridine or HX, we think these species are present in very low concentration and consequently the principal equilibrium is simply

$$\text{mepyr-H}^+ + X^- \rightleftharpoons \text{mepyrH}^+ \ldots X^- \quad [2]$$

A rough estimate of the association constant, K_A, for 4-mepyrH$^+$ . . . X^- can be made using the following line of reasoning. If there were no complex formation in the 4-methyl melts, their conductivities would be similar to those of the corresponding N-methyl melts because the respective molecular sizes, densities, and

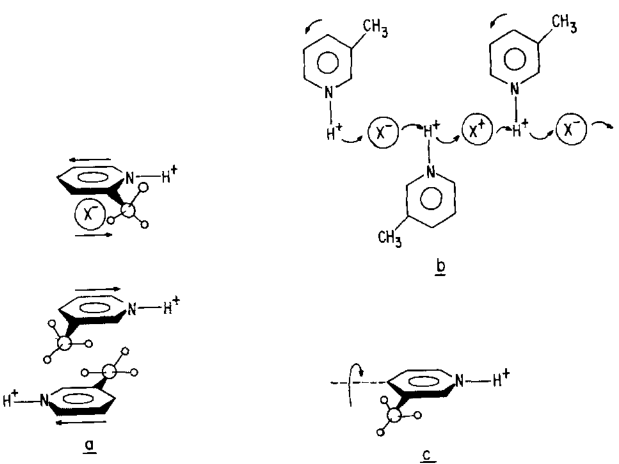

Fig. 9. Contributions to molecular motion in methylpyridinium melts. a, Methyl groups interfering with each other as ions pass each other (in plane); b, possible Grotthuss mechanism; c, out of plane rotation about the C . . . N axis.

symmetries are similar. We therefore assume that to a first approximation the measured Λ's for the N-methyl salts are the Λ's the corresponding 4-methyl salts would have if they were completely dissociated. We next attribute the lower conductance of the 4-methyl salts to formation of the complex species described by Eq. [2]. The degree of dissociation can be approximated, as it is in the case of weak electrolyte solutions, by the Arrhenius notion.

$$\alpha \approx (\Lambda_{4\text{-meth}}/\Lambda_{N\text{-meth}})_{425\text{ K}} \quad [3]$$

K_A is then given by the expression

$$K_A = \frac{[\text{4-mepyrH}^+ \ldots X^-]}{[\text{4-mepyr-H}^+][X^-]} = \frac{1-\alpha}{c\alpha^2} \quad [4]$$

where c is the average concentration in moles per liter at 425 K. It is possible to further correct the $\Lambda_{4\text{-meth}}$ for protonic contribution by assuming this protonic contribution is roughly the same as it is in the 3-methyl melt. The protonic contribution to the 3-methyl melt's conductance is estimated in the following manner. If the difference in conductivity between the 3-mepyr melts and the corresponding 2-mepyr salts is mostly due to the protonic contribution, and if this contribution is negligible in the 2-methyl salts for the reasons mentioned earlier, then at T_c the protons contribute 1.90 $(\Omega\text{ equiv.})^{-1}$ cm^2 to the 3-mepyr/HCl conductance and 0.65 $(\Omega\text{ equiv.})^{-1}$ cm^2 to the 3-mepyr/HBr conductance. Subtracting these values from the appropriate $\Lambda_{4\text{-meth}}$'s gives a corrected conductance $\Lambda'_{4\text{-meth}}$ which contains only contributions from the methylpyridinium ion and the halide ion. The value of Λ' for the chloride is 4.71 cm^2 $(\Omega\text{ equiv.})^{-1}$ and for the bromide it is 5.90 cm^2 $(\Omega\text{ equiv.})^{-1}$. Values for K_A, α, and ΔG, the free energy of complex formation, are listed in Table V.

Although the method for estimating the K_A's is somewhat convoluted, the values obtained give at least correct order of magnitude association constants. The greater basicity of the 4-methylpyridine than the 3-methylpyridine almost certainly reduces the protonic contribution to the 4-methyl melt's conductivity, but this is compensated for because if there

Table V. Association constants for 4-mepyr/HCl and 4-mepyr/HBr

Salt	α	K_A	ΔG (kJ/mol)
4-mepyr/HCl	0.448	3.81×10^{-2}	3.4
4-mepyr/HBr	0.655	9.9×10^{-3}	8.2

were no labile protons and no hydrogen bonding the conductance of the 4-methyl salt should be a bit higher than that of the N-methyl salt (which serves as the Λ_0 in the Arrhenius equation) because of lower density. Moreover, the K_A of the Br^- melt is smaller than that of the Cl^- melt, as is expected based on the differences in charge density of the halide. These K_A's represent a significant complex ion contribution to the structure of the 4-methyl chloride and bromide melts and certainly will influence transport properties.

Comparison between asymmetric and symmetric salts.—The most obvious difference between the symmetric and asymmetric isomers of a given salt is the melting point; the symmetric salts melting considerably higher than the corresponding asymmetric salts (this difference also persists in the iodide melts) (16). A second difference is that the ln η *vs.* T^{-1} graphs for the asymmetric salts exhibit some curvature while the ln η *vs.* T^{-1} graphs for the symmetric melts are linear.

In contrast to these differences, both symmetric and asymmetric salts of a particular halide ion have similar viscosities at a common temperature. For example, at the standard temperature, 425 K, which is just above the high temperature end of the asymmetrical salt's liquid range, and just below the symmetrical salts' melting point, 4-mepyr/HCl has an extrapolated η of about 4.5 cp whereas the 2- and 3-mepyr/HCl have η's equal to about 4.6 cp. The conductivities of the salts are also relatively unaffected by symmetry *per se*. For instance, the conductances of 2- and 4-methylpyridinium chloride lie on essentially the same curve. Taking these data in the aggregate, we conclude that symmetry, *per se*, has relatively little effect on transport properties or spectral properties, but manifests itself mainly through differences in observed melting points and protonic contributions to the melt's conductivity. Far and away, a more significant factor in determining relative values of transport properties is the presence or absence of hydrogen bonding. This conclusion is in sharp contrast to one reached earlier (8, 9) where we suggested symmetry, rather than H-bonding, was the most important factor in determining transport properties in pyridinium melts. Our earlier conclusion was arrived at using a melting point reference state, and the difference between the two conclusions dramatically illustrates the importance of the particular reference state used.

The role of hydrogen bonding.—We can now assemble the diverse results of our experiments into a fairly coherent pattern and assess the contribution of hydrogen bonding to structure and to ionic motion.

The equivalent conductance of the symmetrical chloride and bromide melts decreases 37% and 27%, respectively, when the methyl group is moved from the nitrogen to the 4 position of the ring. At the same time η decreases 19% and 25%, respectively. The only plausible explanation for these results is the one we suggested earlier and that is that complex formation reduces the number of charge carriers per unit volume thereby lowering the conductivity. These same complexes reduce the melt's viscosity by, in effect, lowering interionic friction and shortening the length of the hydrogen-bonded species along the C_4-N-H^+-X^- axis relative to the separated ions (17, 18). Therefore, the H-bonded salts are poorer conductors, but less viscous than the N-methyl melts.

Undoubtably, additional factors are also contributing to the differences in transport properties between the two types of melt. For example, within the time frame of diffusional motion, the N-methyl melt may still have vestiges of its crystal structure in which the halide ion is above and to one side of the ring (as it is in the N-mepyr/I crystal (19). This fluctuating asymmetry will increase the interionic friction due to one melt layer interfering with another and consequently increase the viscosity relative to the hydrogen bonded melts. However, these factors are difficult to isolate and seem much less important than hydrogen bonding itself.

We think the fact that the corresponding N-H^+ containing chlorides and bromides have such similar Λ's is one more indication of the importance of hydrogen bonding. The Cl^- ion forms stronger hydrogen bonds than the Br^- ion, and consequently has its mobility considerably reduced. What might be considered "normal" behavior is exhibited by the N-methyl salts, in which there is a 14% decrease in Λ between the Cl^- and the Br^- melts and a 13% decrease between the Br^- and I^- melts (2, 16).

Details of ionic motion and melt structure.—The principal charge carrier in all of the pyridinium melts studied is the halide ion. This is consistent with our earlier results and those of King and co-workers (20, 14, 2). Attractive forces and steric factors dominate, hence the relatively low ratio of about 1.1 for E_η to E_Λ and the likely, very little if any, expansion upon melting. Bloom and Reinsborough (21) found Pyr/HCl expands only 2% on melting and preliminary results in our laboratory indicate 3-methylpyridinium chloride actually contracts when it melts. This should be contrasted with typical inorganic salts which expand 15-25% on melting and have E_η/E_Λ ratios of between 2 and 5 (22, 23).

It is difficult to identify particular modes of motion that are favored over others because there is no special difference between symmetrical and asymmetrical salts with regard to their transport properties and relatively little difference between viscosity and conductivity with regard to energies of activation. The best one can say is it looks as if inplane rotation, or rocking back and forth about an axis perpendicular to the plane of the molecule, may be favored over out of plane rotation (Fig. 9c). In other words, the cations translate as rotating or rocking weighted disks rather than rotating weighted cylinders. The reason for arriving at this conclusion is that all of the cations sweep out about the same area, but the asymmetric cations sweep out considerably larger cylindrical volumes, rotating out of plane (9c), than do the symmetric cations. Since the asymmetric ions require greater volumes, and space is at a premium, they should have higher viscosities and higher energies of activation. This is contrary to our experimental results. Because the planar area of the disklike cation is considerably greater than half the area of an edge, and because only one end is charged, the ion is prevented from freely rotating. Consequently it is unlikely that the cations are translating as rotating spheres as are the halide ions.

The E_η/E_Λ ratio of $\sim$1.1 further implies that viscosity and conductivity meet with the same sort of barriers. (24). Ions are moving past each other, Fig. 9a, and it matters little whether two cations pass each other or a cation and anion pass each other, the energies required are quite similar.

Errors and comparison with other workers.—Comparing our proton chemical shifts in the 2-mepyr/HCl melt with the chemical shifts in the same melt reported by Angell and Shuppert (25) we agree within experimental error on the location of the α, β, γ, and methyl peaks, but differ by -0.85 ppm on the N-H^+ chemical shift, ours being 16.2 ppm and theirs being 17.05 corrected to TMS. One possible reason for this discrepancy is that a trace of water may still be present in our melts, but not in theirs. This water molecule would tend to lie on, or near, the N-H^+ and shield it

from the magnetic field. On the other hand, they used an internal standard of $(CH_3)_4NCl$ which exchanges with H^+ and with other CH_3^+ groups (25), but also increases the Cl^- concentration which would deshield the N-H^+ proton and cause it to resonate at lower frequencies. There does not seem to be any other melt spectra in the literature to compare our data with. Our melting point of 89°C for 2-methylpyridinium chloride is identical to the one reported by Angell, Hodge, and Cheeseman for the same compound and our specific conductances are within ±2% of theirs (3). Our conductivity data for the N-mepyr/Cl is within ±2% of the values reported by King and co-workers (20).

Overall, we estimate our equivalent conductance data to be correct to ±2% and our viscosity data to be accurate to ±3%. Our analyses of the pyridinium salts were *in* all cases 99±%.

Perhaps the largest error in this study is the assumption that all the melts have the same liquid range, but since no conclusion depends on an exact knowledge of T_g or T_b, this error should not seriously affect our conclusions

Conclusion

By systematically varying the structure of the methylpyridinium cation and changing the anion, correlations between structure, spectra, and transport properties in molten pyridinium salts can be made in a relatively simple and straightforward manner. From these correlations, several conclusions can be reached about the structure of the melt and its relation to transport properties. The conclusions drawn are the following:

1. Hydrogen bonding exerts a strong influence on transport properties, species present, and melt structure.

2. Symmetry of the cation, *per se*, has little influence on either melt structure or transport properties.

3. The anion is the principal charge carrier in the methylpyridinium melts.

4. There are complex species in the 2-, 3-, and 4-methylpyridinium chloride and bromides.

5. There is probably a protonic contribution to the conductivity of those melts in which the N-H^+ is present. The protons move either through a Grotthuss mechanism or through a hopping mechanism.

6. In the molten pyridinium halides, and probably in molten organic salts generally, attractive forces dominate over repulsive forces, and there is very little free space, hence the E_η/E_Λ ratio of 1.1.

The Kinetics and Mechanism of the Electroreduction of Sulfur Dioxide in Nonaqueous Media

I. Reduction in Solutions of Tetraethylammonium Perchlorate in N,N-Dimethylformamide

ABSTRACT

Polarographic studies of the electroreduction of sulfur dioxide in dimethylformamide containing 0.1M tetraethylammonium perchlorate have shown that at 20°C, the mechanism of electroreduction is given by the reactions

$$SO_2 + e \rightleftharpoons SO_2^- \quad [1]$$

$$SO_2 + SO_2^- \rightleftharpoons S_2O_4^- \quad K_2 \quad [2]$$

$$2SO_2^- \rightleftharpoons SO + SO_3^{2-} \quad K_{13} \quad [13]$$

The standard rate constant for the electron transfer reaction [1] has been found to be 1.0 ± 0.2 cm/sec. This rate of electron transfer is very fast, being of the same order of magnitude as that observed for reduction of aromatic hydrocarbons (21). The association constant, K_2, for reaction [2] has been found to be 8400 ± 2000 dm^3 mol^{-1}. This is an order of magnitude larger than the association constant measured in bulk solution using ESR spectroscopy (20). In addition to formation of the complex, $S_2O_4^-$, the results show that a second follow-on reaction is also important. Evidence is presented that this follow-on reaction is the disproportionation of SO_2^- to form SO and SO_3^{2-}. The equilibrium constant for this reaction has been found to 0.6 ± 0.4. The dimerization of SO_2^- to form dithionite is not important during the initial stages of reduction at room temperature and over the range of SO_2 concentration (1×10^{-4}-5×10^{-3}) used in these experiments. However, at low temperatures, the formation of dithionite is favored.

In recent years considerable effort has gone into the development and commercialization of the lithium-sulfur dioxide battery. While these efforts have resulted in successful exploitation of this battery system, there remain a number of environmental (1) and safety (2) problems to be solved.

By contrast, work reported on the basic chemistry and electrochemistry of the reduction of sulfur dioxide has been limited. While it is generally agreed that the major product formed during the discharge of the lithium-sulfur dioxide battery is lithium dithionite, previous work has indicated that the reduction mechanism is influenced by the choice of solvent and electrolyte.

It is generally agreed that the initial one-electron transfer step

$$SO_2 + e \rightleftharpoons SO_2^- \quad E_1^\circ \quad [1]$$

is followed by one or more follow-on reactions. In N,N-dimethylformamide (DMF), a stable, blue paramagnetic product is formed (3-7) which has been ascribed to a complex of the form

$$SO_2^- + xSO_2 \rightleftharpoons (SO_2)_xSO_2^- \quad K_2 \quad [2]$$

The number, x, of neutral SO_2 molecules in the complex has been the subject of some controversy. Thus, Dinse and Mobius (5) concluded that $x = 2$ by measuring the ratio of the concentrations of $(SO_2)_xSO_2^-$ and SO_2^- using ESR spectroscopy. On the other hand, Rinker and Lynn (4) concluded that $x = 1$. The recent work of Kastening and Gostisa-Mihelcic (6) which was based on ESR measurement of the $[(SO_2)_xSO_2^-]/[SO_2^-]$ ratio coupled with direct electrochemical measurement of the SO_2 concentration has shown that the complex has the stoichiometry $S_2O_4^-$ (*i.e.*, $x = 1$). This is also in agreement with kinetic measurements made by the same authors (8). K_2 was determined to be 230 dm^3 mol^{-1} at 25°C. The larger value of $x = 2$ obtained by Dinse and Mobius appears to be the result of their failing to correct for the change in the bulk SO_2 concentrations after electrolysis. However, since details of the experiments are not given in their paper this cannot be confirmed.

In addition to the formation of the complex species, $S_2O_4^-$, dimerization of the SO_2^- to form dithionite has also been shown to be important (9)

$$2SO_2^- \rightleftharpoons S_2O_4^{=} \quad K_3 \quad [3]$$

Reaction [3] is the major follow-on reaction in dimethylsulfoxide solution, the value of K_3 being 10^5 dm^3 mol^{-1} at 55°C.

In view of the potential importance of studies of the basic electrochemistry and chemistry of the reduction process in helping to resolve some of the remaining

Key words: high energy density batteries.

problems of the primary lithium-sulfur dioxide battery and in indicating directions for further improvement of the system (*e.g.*, the development of a rechargeable Li/SO_2 battery), we have recently undertaken a systematic study of the effect of solution composition on the kinetics and mechanism of the electroreduction of sulfur dioxide in nonaqueous media. In this paper, we describe results that we have obtained for the electroreduction of SO_2 in solutions of 0.1M tetraethylammonium perchlorate (TEAP) in DMF. Additional work on the effect of solvent and electrolyte on the kinetics and mechanism of the electroreduction of SO_2 will be described in another paper as will results of simultaneous electrochemical-electron spin resonance measurements.

Experimental

Current-potential data were obtained using a PAR Model 170 Electrochemistry System. All measurements were made in a jacketed 3-electrode glass cell. The working electrode was normally a dropping mercury electrode except in the cyclic voltammetric experiments where a hanging mercury drop electrode was used. The counterelectrode was a platinum cylinder and the reference electrode a silver wire in a solution of 0.05M $AgNO_3$ and 0.05M TEAP in DMF. This solution was changed daily because of photoreduction of the Ag^+. The solution in the reference electrode compartment was isolated from the working solution by fritted glass disks.

Kinetic data for the electron transfer process were obtained using the phase sensitive a-c admittance method described previously (10). Admittance data were obtained as a function of d-c potential in the vicinity of the d-c half-wave potential over the frequency range from 160 to 1050 Hz using a 10 mV (peak-to-peak) a-c signal. Pulse polarographic measurements were also made for many of the systems. In these experiments, a potential pulse is applied for 45 msec at the end of the drop life, the average current being measured during the final 5 msec.

The procedures followed for purifying and drying the DMF (Aldrich Spectrophotometric grade) and TEAP (Eastman) have been described previously (10-12). Anhydrous SO_2 was used as received from Matheson. A stock SO_2 solution was prepared by bubbling SO_2 in DMF. The concentration of the stock SO_2 solution (~0.5M) was determined by titration. All solvents, salts, and stock solutions were stored in a controlled atmosphere glove box (Vacuum Atmospheres Limited) where the argon atmosphere was continually purged of oxygen and water. Further dilution of the stock SO_2 solution to prepare the working solutions (0.1-5 mM) was carried out in the glove box and all solutions were bubbled with argon to remove traces of oxygen. The experiments were conducted in the same glove box. The temperature of the cell was maintained constant by passing methanol, controlled at the desired temperature, through an outer jacket surrounding the working compartment of the cell.

Results

Cyclic voltammetry.—Reduction of sulfur dioxide in a 0.1M TEAP/DMF solution gives a well-defined cyclic voltammogram as shown in Fig. 1. The presence of a follow-on reaction is indicated by the appearance of more than one oxidation peak on the reverse sweep and the ratio of the peak anodic to the peak cathodic currents for the reduction reaction which is less than one (13). These results are in qualitative agreement with those reported earlier by Martin and Sawyer (3).

D-C polarography.—In order to study the reduction process in more detail, d-c polarographic measurements were made as a function of both SO_2 concentration and temperature. These polarograms are broader than is expected for a simple one-electron transfer

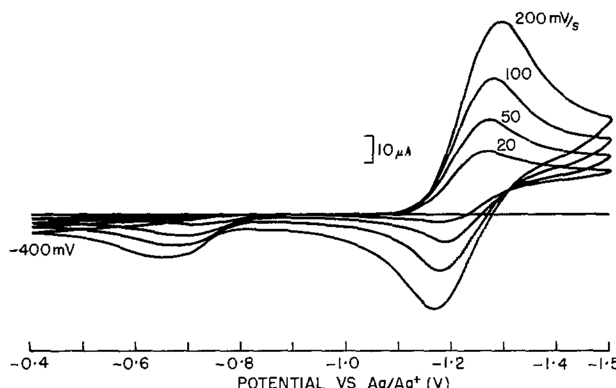

Fig. 1. Cyclic voltammogram for the reduction (forward sweep) of 10^{-2}M SO_2 at a hanging mercury drop electrode in N,N-dimethylformamide containing 0.1M tetraethylammonium perchlorate with varying sweep rates as indicated.

reaction, plots of log $(i/i_d - i)$ having nonlinear slopes greater than 59 mV per decade. In addition, the half-wave potential is dependent both on SO_2 concentration and temperature.

The effect of concentration on the half-wave potential is shown in Fig. 2 and on the plots of log $(i/i_d - i)$ *vs.* E in Fig. 3. It is seen that, as the concentration is increased, there is a positive shift of the half-wave potential and a marked increase in the curvature of the log $(i/i_d - i)$ plots. There is also a linear variation of the limiting current, i_d, with concentration. The half-wave potential and shape of the polarograms were found to be independent of drop time in the range from 1 to 5 sec.

Figure 2 also shows that decreasing the temperature causes a positive shift of the half-wave potential. As one might expect, there is also a marked decrease in the limiting current. The plots of log $(i/i_d - i)$ *vs.* E (Fig. 4) show that the polarograms are sharpened as the temperature is decreased.

A-C polarography.—A-C admittance measurements were made on each of the SO_2 solutions in order to measure the rate of electron transfer (10). Above 0°C, the a-c admittance data give good Randle's plots (Fig. 5). At lower temperatures deviation from linearity is observed. Analysis of the a-c data allows (10) both the standard rate constant for the electron transfer reaction and the diffusion coefficient to be determined (see Table I). In calculating these parameters, allowance has been made for the fact that, at the standard electrode potential, $E_1°$, the SO_2 concentration is less than half the bulk SO_2 concentration as a result of the follow-on reaction. The actual concentration was determined from the d-c polarograms.

The a-c peak potential (as measured from the peak of the out-of-phase component of the a-c admittance) was found to be 20-50 mV negative with respect to the half-wave potentials from d-c polarography and independent of concentration and temperature, having a constant value of −1.30V against the Ag/Ag^+ reference electrode.

Pulse polarography.—Pulse polarography was used to study the reduction process for times intermediate between those used for the d-c and a-c measurements.

Table I. A-C polarography analysis

Temp (°C)	k_s (cm sec⁻¹)	D (cm² sec⁻¹) × 10⁶
30	1.2	8.68
25	1.0	6.76
20	0.9	5.23
10	0.7	3.03
0	0.5	1.69
−10	0.4	0.90

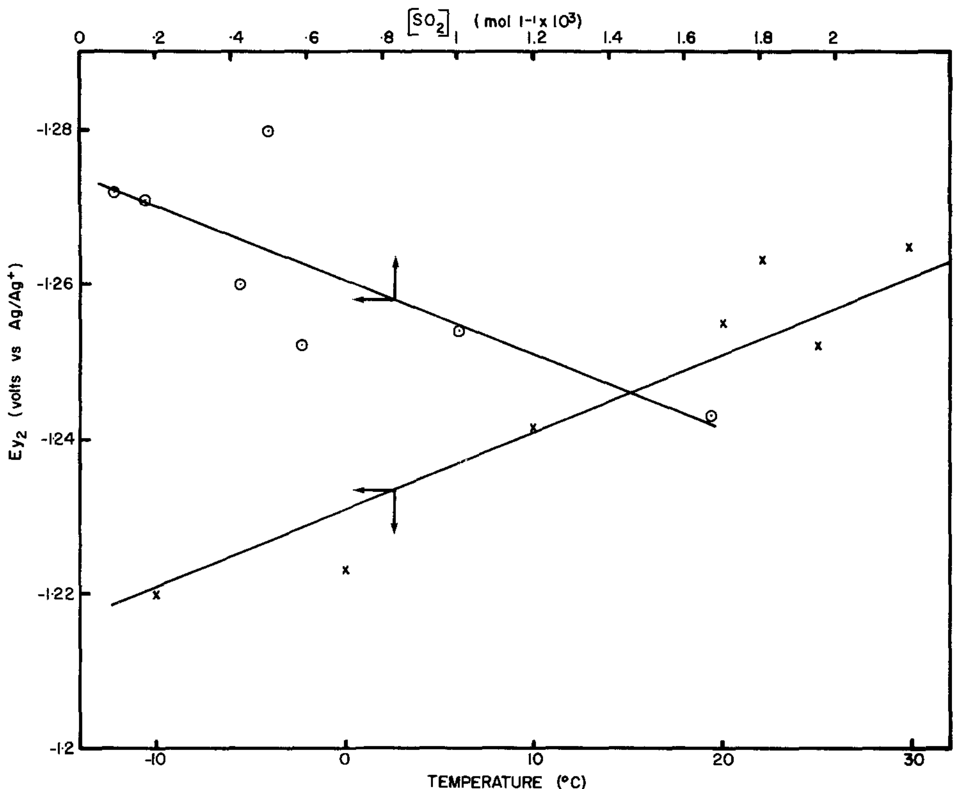

Fig. 2. Effect of reactant concentration and temperature on the half-wave potential for the electroreduction of SO_2 in the same solution as Fig. 1.

More specifically, the current was sampled at the end of a 45 msec pulse. This can be compared with times in the 1-6 msec range used in the a-c measurements and the 2 sec drop time used for most of the d-c measurements. Pulse polarography measurements were made using both cathodic and anodic sweeps.

Pulse polarograms obtained for solutions of SO_2 in 0.1M TEAP/DMF using a negative sweep give half-wave potentials which are negative with respect to the d-c half-wave potentials. In addition, the plots of log $(i/i_d - i)$ *vs.* E (Fig. 6) are more linear and have slopes closer to 59 mV per decade.

When the potential is swept positively from a point on the reduction wave, the pulse polarogram has two distinct waves (Fig. 7): one at -1.3V and one at -0.7V. The relative heights of the two waves depend both on concentration and initial potential. Table II gives the heights of the two waves as a function of initial potential for several different concentrations of SO_2. At the higher concentrations ($\geq 10^{-3}$M) a slight

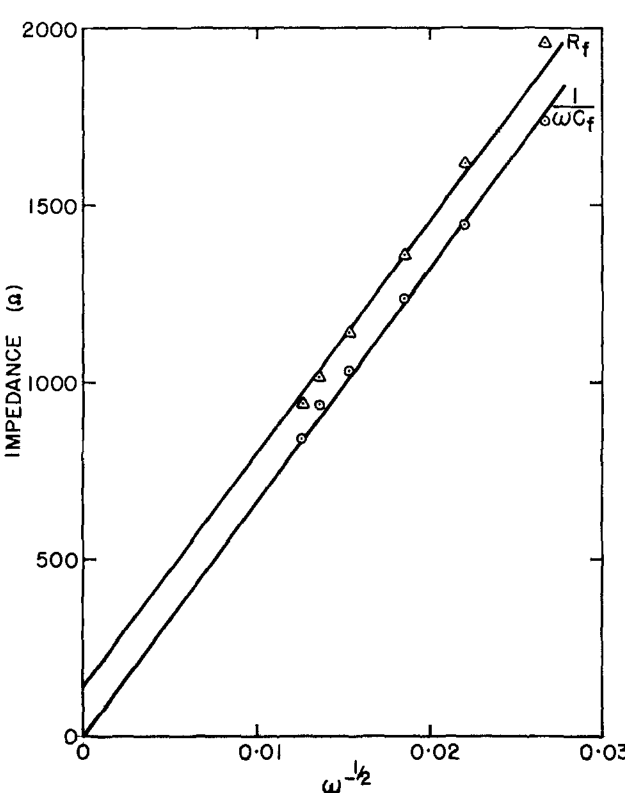

Fig. 5. Randle's plot of a-c admittance data for the electroreduction of 10^{-3}M SO_2 in the same system as Fig. 1.

maximum is observed in the wave at −0.7V suggesting that weak adsorption is taking place (14).

Discussion

As discussed earlier, previous work has shown that the SO_2^- produced in the primary electron transfer step can undergo the two follow-on reactions [2] and [3]. In the discussion that follows, the experimental results are discussed initially in terms of reactions [1] to [3] assuming $x = 1$ (*i.e.*, the complex is assumed to have the stoichiometry $S_2O_4^-$).

Information regarding the mechanism of the electroreduction of SO_2 in TEAP/DMF solutions can be obtained by comparing the experimental polarograms with theoretical predictions based on the proposed mechanism. In our description of the shape of the d-c polarograms, we assume that reactions [2] and [3] are

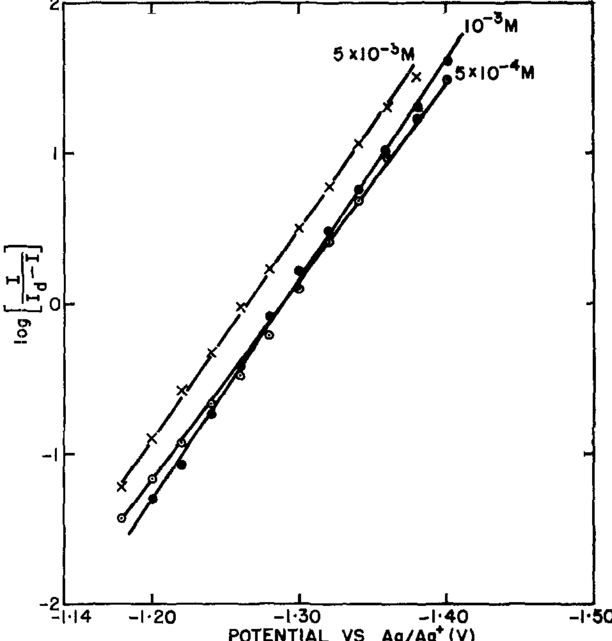

Fig. 6. Plots of log $[i/i_d - i]$ against potential for pulse polarographic data obtained with varying SO_2 concentrations as indicated. Other conditions as in Fig. 1.

at equilibrium.[1] This assumption is supported by the observation that the measured half-wave potentials are independent of drop time. The present approach differs from that of Bonneterre and Cauquis (9) who have described their cyclic voltammetric and rotating disk studies of the reduction of SO_2 in dimethylsulfoxide in terms of dimerization of SO_2^- using a reaction layer approximation. If it is assumed that the Nernst and Ilkovič equations hold, then the following general expression can be derived (see Appendix) which describes the shape of the d-c polarogram

$$E - E_1^\circ = \frac{RT}{\mathbf{F}} \ln \left\{ \frac{1}{2}\left(\frac{i_d - i}{i}\right) \left\{ \left(1 + K_2\left(\frac{i_d - i}{i}\right)\right) + \left[\left(1 + K_2\left(\frac{i_d - i}{i}\right)\right)^2 + \frac{4K_3 i}{g}\right]^{1/2} \right\}\right\} \quad [4]$$

[1] This assumption is not valid on the time scale used for the a-c, pulse polarographic, and cyclic voltammetric measurements.

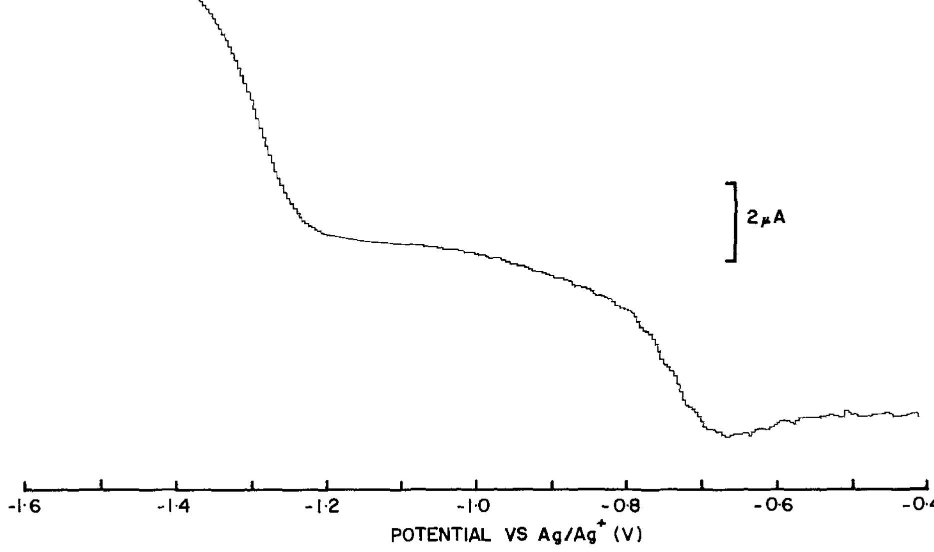

Fig. 7. Pulse polarogram for the oxidation of the reduction products of a 10^{-3}M SO_2 solution with an initial potential for the positive sweep of −1.6V *vs.* the reference electrode. Other conditions as in Fig. 1.

where i_d is the limiting current and g the Ilkovič constant.

It is of interest to consider the simpler situations where either reaction [2] or [3] predominates.

When $K_3 = 0$ (*i.e.*, complex formation is the dominant follow-on reaction), Eq. [4] can be simplified to give

$$E - E_1° = \frac{RT}{\mathbf{F}} \ln \left\{ \left(\frac{i_d - i}{i} \right) \left[1 + K_2 \left(\frac{i_d - i}{g} \right) \right] \right\} \quad [5]$$

In this case it can be shown that the follow-on reaction [2] causes a shift of the polarogram to positive potentials and broadens the wave so that plots of $\log (i/i_d - i)$ *vs.* E have slopes greater than 59 mV per decade.

If, on the other hand, it is assumed that dimerization of SO_2^- according to [3] is the major follow-on reaction (*i.e.*, $K_2 = 0$), then Eq. [4] can be simplified to give

$$E - E_1° = \frac{RT}{\mathbf{F}} \ln \left\{ \frac{1}{2} \left(\frac{i_d - i}{i} \right) \left(1 + \sqrt{\frac{4K_3 i}{g}} \right) \right\} \quad [6]$$

In this case, a positive shift of the polarograms is also predicted, but the polarographic waves are sharpened so that slopes of less than 59 mV per decade are obtained from plots of $\log (i/i_d - i)$ *vs.* E.

It follows that the qualitative behavior of the d-c polarograms (Fig. 3) obtained for the reduction of SO_2 in 0.1M TEAP/DMF solutions at room temperature corresponds to the predictions based on Eq. [5].

The experimental shift of the half-wave potential with respect to the standard potential for the SO_2/SO_2^- couple can be compared with theoretical predictions. Thus substituting the relationships that, at the half-wave potential

$$i = \frac{i_d}{2} = \frac{g[SO_2]°}{2} \quad [7]$$

then, from Eq. [5], the dependence of the half-wave potential on SO_2 concentration can be written

$$E_{1/2} - E_1° = \frac{RT}{\mathbf{F}} \ln \left(1 + \frac{K_2[SO_2]°}{2} \right) \quad [8]$$

Thus, a plot of $\exp((E_{1/2} - E_1°)\mathbf{F}/RT)$ against $[SO_2]°$ should be linear with a slope of $K_2/2$ and unit intercept. A value of $E_1° = -1.30$V is obtained[2,3] from the peak potential of the out-of-phase component of the a-c admittance. Figure 8 shows values of $\exp((E_{1/2} - E_1°)\mathbf{F}/RT)$ plotted against $[SO_2]°$. From the slope, a value of $K_2 = 8400 \pm 2000$ dm^3 mol^{-1} is obtained for the association constant for reaction [2]. On the other hand, the intercept is found to be 2.5 ± 0.8, that is, not unity as predicted by Eq. [8]. The large value of the intercept suggests that some other reaction is contributing to the shift of the half-wave potential.

Some support for this conclusion is obtained from the pulse polarographic experiments. Regarding the two distinct waves observed on the positive sweep, the first at -1.3V is ascribed to the oxidation of SO_2^-. The second wave at -0.7V has been ascribed previously by Martin and Sawyer (3) and ourselves (15) to oxidation of the complex species $S_2O_4^-$. As mentioned previously, the relative heights of these two waves are dependent on both SO_2 concentration and initial potential (Table II). From these results it is seen that the relative intensity of wave 2 with respect to wave 1 decreases with increasing SO_2 concentration instead of increasing linearly with increasing SO_2 concentration as one would anticipate on the basis of $S_2O_4^-$ being formed by reaction [2]. In addition, an estimate of the standard potential $E_2°$ for $S_2O_4^-$ oxidation can be obtained from the association constant K_2. On the basis of fundamental thermodynamics, the standard potential for the reaction

$$2SO_2 + e \rightleftharpoons S_2O_4^- \quad E_2° \quad [9]$$

is given by

$$E_2° - E_1° = \frac{RT}{\mathbf{F}} \ln K_2$$

Assuming $K_2 = 8400$ dm^3 mol^{-1}, it is found that standard potential for the $2SO_2/S_2O_4^-$ couple is 226 mV more positive than that for the SO_2/SO_2^- couple whereas a 600 mV difference is observed between the two oxidation waves in the pulse polarogram.

For these reasons it is concluded that the assignment of the wave at -0.7V to oxidation of $S_2O_4^-$ is incorrect. The failure to observe an oxidation wave for $S_2O_4^-$ can be explained by reaction [2] being sufficiently labile that the $S_2O_4^-$ is completely removed during the 45 msec pulse due to oxidation of the SO_2^- (reaction [2]).

The wave at -0.7V must therefore be ascribed to the oxidation of another product produced during the reduction of sulfur dioxide. Since this reaction causes a potential shift that is independent of SO_2 concentration, it is concluded that the reaction is first or pseudo-first order. The following suggestions can be made:

(*a*) Formation of a cation complex

$$TEA^+ + SO_2^- \rightleftharpoons TEA \cdot SO_2 \quad [10]$$

(*b*) Formation of an anion complex

$$ClO_4^- + SO_2^- \rightleftharpoons (ClO_4 \cdot SO_2)^{2-} \quad [11]$$

(*c*) Formation of a solvent complex

$$DMF + SO_2^- \rightleftharpoons (DMF \cdot SO_2)^- \quad [12]$$

(*d*) Disproportionation

$$2SO_2^- \rightleftharpoons SO + SO_3^{2-} \quad K_{13} \quad [13]$$

The formation of a complex between SO_2^- and either the cation or the anion of the supporting electrolyte (reactions [10] and [11]) can be eliminated since the ratio of the two waves in the anodic pulse polarogram has been found to be independent of the concentration of the supporting electrolyte. The two waves were also observed at the same potential in hexamethylphosphoramide indicating that the reaction does not involve formation of a complex with the solvent. However, the results are consistent with a disproportionation of the SO_2^- according to reaction [13]. In this scheme the wave at -0.7V can be attributed to the oxidation of SO_3^{2-}. If it is assumed that the equilibrium for this reaction is established slowly compared to the 45 msec

Table II. Pulse polarography—anodic sweeps

$[SO_2]$ mol dm^{-3} × 10^{-3}	Initial potential volts *vs.* Ag/Ag$^+$	wave 2 / wave 1
5.0	−1.4	0.31
1.67	−1.6	0.54
1.0	−1.6	0.61
0.70	−1.6	0.77
0.58	−1.6	0.56
0.5	−1.6	0.60
	−1.36	0.58
	−1.24	1.0
	−1.20	1.83
0.20	−1.6	0.93
0.167	−1.6	0.79
0.10	−1.4	1.18

[2] The assumption is made that the diffusion coefficients for SO_2 and SO_2^- are equal.

[3] As discussed later in the paper, on the time scale used for the a-c measurements, the follow-on reaction is sufficiently slow that the reaction can be considered as a simple one-electron transfer reaction. In this case, the peak of the out-of-phase component of the a-c admittance will occur when the surface concentrations of $[SO_2]$ and $[SO_2^-]$ are equal. The situation in this case is similar to that described by Fawcett and Lasia (10).

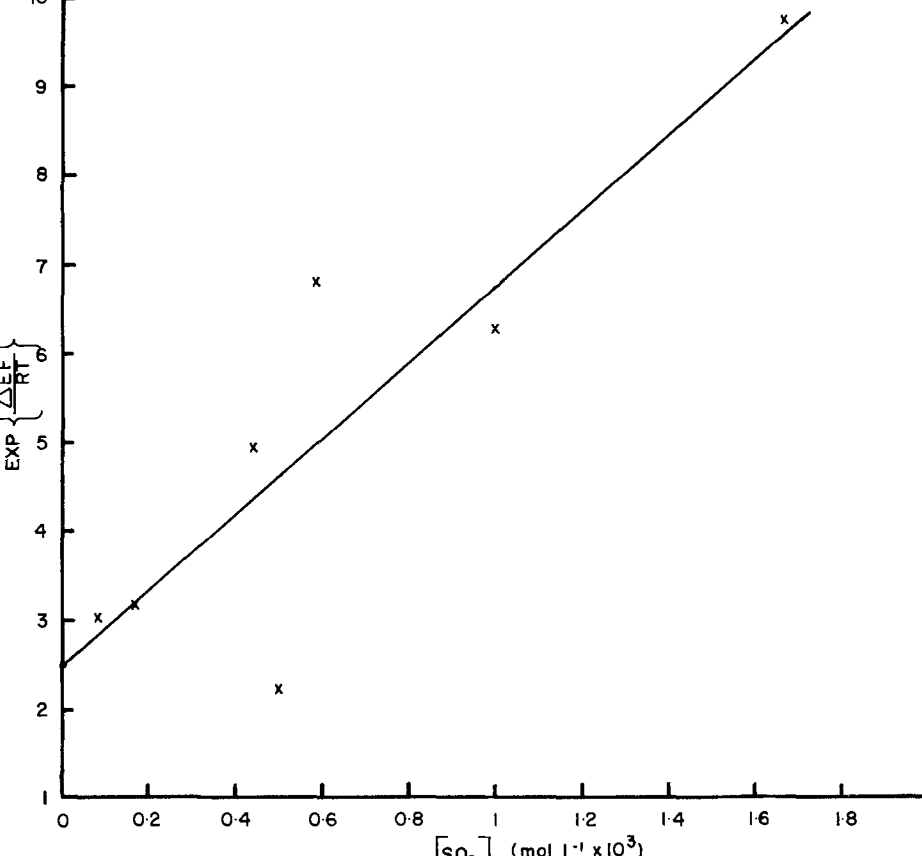

Fig. 8. Graphical determination of the association constant K_2 and the disproportionation constant K_{13} according to Eq. [15] from plots of the exponent of the shift in half-wave potential from the standard potential against the bulk SO_2 concentration.

pulse then it is clear that two oxidation waves corresponding to oxidation of SO_2^- and SO_3^{2-} will be observed. In addition, at low SO_2 concentrations where the formation of the $S_2O_4^-$ complex is negligible, the ratio of the SO_3^{2-} wave to the SO_2^- wave should be constant.

As the SO_2 concentration is increased, the ratio of the SO_3^{2-} wave to the SO_2^- wave should decrease because the contribution that the complex makes to the SO_2^- wave will increase. This is observed experimentally where the ratio of the two waves goes from 1.2 in a 10^{-4}M SO_2 solution to 0.3 in a 5×10^{-3}M SO_2 solution. Using data for the free energy of formation of Li_2SO_3 and SO_3, it has been estimated (16) that $E°$ for the system $2Li + SO_3 \rightarrow Li_2SO_3$ is ~3.7V. The corresponding value for $2Li + 2SO_2 \rightarrow Li_2S_2O_4$ is about 3.0V. This indicates that the oxidation wave for SO_3^{2-} should occur approximately 700 mV more positive than the oxidation wave for SO_2^-. This is in reasonable agreement with the experimentally observed potential shift (600 mV).

The SO formed in reaction [13] is expected to further disproportionate (17) to form elemental sulfur and SO_2. This mechanism is supported by the work of Rinker and Lynn (18) who have shown that both sulfite and elemental sulfur are formed during the reduction of SO_2 in DMF at sodium amalgam. Similar reactions have been postulated for the decomposition of dithionite in aqueous media (19). Experiments to measure the oxidation potential of SO_3^{2-} directly were unsuccessful because of the low solubility of the available sulfite salts.

It is easily shown that, when the disproportionation reaction is included in the reaction scheme, the shape of the d-c polarogram is given by the expression

$$E - E_1° = \frac{RT}{\mathbf{F}} \ln \left[\left(\frac{i_d - i}{i} \right) \left(1 + 2K_{13}^{1/2} + K_2 \left(\frac{i_d - i}{g} \right) \right) \right] \quad [14]$$

and the corresponding shift in half-wave potential by the relationship

$$E_{1/2} - E_1° = \frac{RT}{\mathbf{F}} \ln \left(1 + 2K_{13}^{1/2} + K_2 \frac{[SO_2]°}{2} \right) \quad [15]$$

Equation [15] is of the same general form as Eq. [8]; however, in this case a plot of exp $(E_{1/2} - E_1°)\mathbf{F}/RT)$ against $[SO_2]°$ should give a linear plot with intercept $1 + 2K_{13}^{1/2}$ and a slope equal to $K_2/2$ as before. From the experimental intercept (Fig. 8) of 2.5 ± 0.8, a value of $K_{13} = 0.6 \pm 0.4$ is obtained. At low concentration the ratio of the two waves in the anodic pulse polarogram should be approximately $1/K_{13}^{1/2}$. Using the value of $K_{13} = 0.6$ obtained above, it is seen that the ratio of the two waves should be about 1.3 at low SO_2 concentrations. Experimentally, a ratio of 1.2 is observed for a 10^{-4}M solution, the lowest concentration measured.

An estimate of K_2 can also be obtained by measuring the surface concentration of SO_2 at the equilibrium potential. As a result of the follow-on reactions, the surface concentrations of SO_2 and SO_2^- are less than half of the bulk concentration at the standard potential. It can be shown (Appendix) that the following relationship holds

$$K_2 = \frac{[SO_2]° - 2(1 + K_{13}^{1/2})[SO_2]_{E=E_1°}}{[SO_2]^2_{E=E_1°}} \quad [16]$$

It follows that a plot of $[SO_2]°/[SO_2]_{E=E_0}$ against $[SO_2]_{E=E_0}$ should give a straight line with slope equal to K_2 and intercept $2(1 + K_{13}^{1/2})$. A plot of these data are shown in Fig. 9 from which the estimates $K_2 = 2400 \pm 2000$ and $K_{13} = 0.4 \pm 0.1$ are obtained. The value for K_{13} is in agreement with the potential shift analysis, but the K_2 value does not agree with the previous estimate. On the whole, however, we feel the potential shift analysis is more reliable as it is less affected by distortions which occur on the upper part

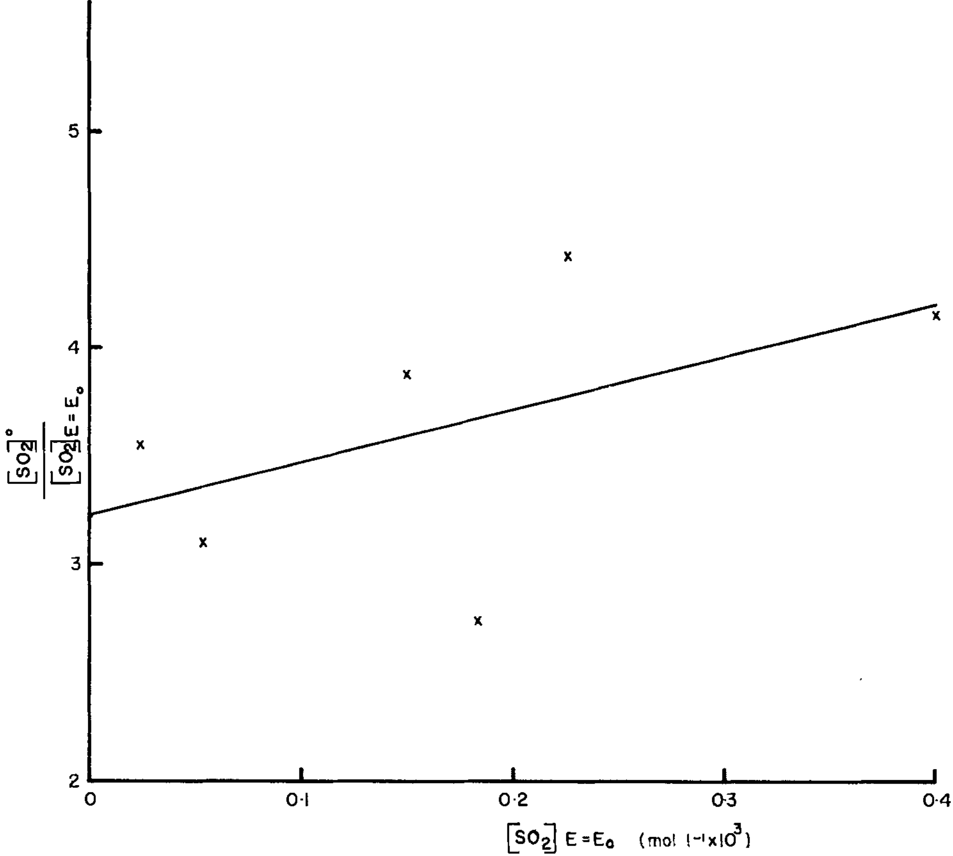

Fig. 9. Graphical determination of the association constant K_2 and the disproportionation constant K_{13} from a plot of the ratio of the bulk SO_2 concentration $[SO_2]^\circ$ to the SO_2 concentration at the electrode surface at the standard potential $[SO_2]_{E=E0}$ against $[SO_2]_{E=E0}$ according to Eq. [16].

of the wave and which become more significant as the SO_2 concentration is increased. This distortion is probably due to a second reduction process.

The values of K_2 obtained from these measurements are at least an order of magnitude higher than the value of 600 dm^3 mol^{-1} determined by Laman *et al.* (20) in TEAP solutions and of 230 dm^3 mol^{-1} determined by Kastening *et al.* (6) in tetraethylammonium bromide solution using ESR spectroscopy.

The reason for the large difference in the value of K_2 obtained by the two methods is not clear. It is interesting to note, however, that ESR transients measured using a constant current pulse (20) can only be simulated if the larger (*i.e.*, electrochemical) value of K_2 is used. This suggests that the ESR measurement underestimates the value of K_2 for some reason.

As the temperature is decreased, considerable changes occur in the reaction mechanism. Positive shifts in the half-wave potential along with a sharpening of the d-c polarogram all point to an increasing contribution of the dimerization reaction (reaction [3]) to the reduction mechanism as the temperature is lowered. This suggestion is confirmed by the observation that the intense ESR signal due to the paramagnetic complex $S_2O_4^-$ in a partially reduced 0.05M SO_2 solution completely disappears when the sample is cooled to 77 K. At room temperature, our own results as well as those of Kastening and Gostisa-Michelcic (6) indicate that the contribution of the dimerization reaction is not significant. From Ref. (6) it can be shown from the ratio of the two paramagnetic species and the SO_2 concentration measured after electrolysis that very little if any of the SO_2^- formed during the initial stages of the electroreduction of SO_2 dimerizes to form $S_2O_4^=$ at room temperature.

Dithionite is, of course, the major product when the electroreduction is carried to completion (*i.e.*, one electron per SO_2 molecule). In addition, other complex species such as $S_3O_6^{2-}$ have been observed by Martin and Sawyer (3) during the later stages of the electroreduction.

Analysis of the d-c polarographic limiting current data yields a diffusion coefficient of 1.52×10^{-5} cm^2 sec^{-1} at 20°C. A least squares fit of the limiting current data as a function of temperature yields an activation energy of 8.5 ± 0.3 kJ mol^{-1} for the diffusion process.

Analysis of the pulse polarograms recorded using a cathodic sweep (Fig. 6) show clearly that the follow-on reactions have much less influence on the shape of the pulse polarogram than on the d-c polarogram. Thus, the half-wave potentials are closer to the standard electrode potential and plots of $\log (i/i_d - i)$ against E are much more linear and have slopes closer to 59 mV. Systematic deviations remain, however, indicating that one or more of the follow-on reactions are fast enough to influence the shape of the pulse polarograms.

In order to obtain information on the kinetics of the electron transfer reaction, phase sensitive a-c admittance measurements were made. For temperatures above 0°C, the a-c admittance data give linear Randle's plots as shown in Fig. 5. These results indicate that, under these conditions, the follow-on reaction is sufficiently slow that the reaction can be considered as a simple one-electron transfer reaction on the time scale used for these measurements. In addition, the half-wave potentials are considerably more negative than those determined from d-c polarography and are independent of concentration. These results indicate that, by using a-c polarography, the primary electron transfer step can be studied without interference from follow-on reactions. The observation that deviations from linearity are observed in the Randle's plots for frequencies less than about 160 Hz in the 10^{-3}M solution provides a crude estimate of the half-life of the SO_2^- radical which must be about 10 msec under these conditions. The influence of the SO_2 concentration on the rate of conversion of SO_2^- into $S_2O_4^-$ can be seen by the fact that deviations from linearity are observed at higher frequencies as the concentration of the SO_2 is increased.

The results indicate that the electron transfer rate is very fast. At 25°C, $k_s = 1.0 \pm 0.2$ cm/sec. The uncer-

tainty in determining k_s is high as rates of this order of magnitude are at the limit of the a-c admittance technique. Analysis of the effect of temperature on the rate of electron transfer allows an activation energy of 20.4 kJ/mol to be determined. Electron transfer rates for the electroreduction of aromatic hydrocarbons are of the same order of magnitude (21) as those measured for the reduction of SO_2.

APPENDIX

Shape of the d-c Polarogram

In describing the shape of the d-c polarogram it is assumed initially that:

(*a*) The mechanism of reaction is as follows

$$A + e \rightleftharpoons A^- \quad \text{electron transfer} \quad [A\text{-}1]$$

$$A + A^- \rightleftharpoons A_2^- \quad K_2 \quad \text{complex formation} \quad [A\text{-}2]$$

$$2A^- \rightleftharpoons A_2^{2-} \quad K_3 \quad \text{dimerization} \quad [A\text{-}3]$$

(*b*) That reactions [A-2] and [A-3] are in equilibrium; therefore

$$K_2 = \frac{[A_2^-]}{[A]\,[A^-]} \quad [A\text{-}4]$$

and

$$K_3 = \frac{[A_2^{2-}]}{[A^-]^2} \quad [A\text{-}5]$$

(*c*) That the A/A^- couple determines the electrode potential and that the Nernst equation holds

$$\frac{[A]}{[A^-]} = P = \exp\left\{\frac{(E - E_0)\mathbf{F}}{RT}\right\} \quad [A\text{-}6]$$

(*d*) That the Ilkovič equation holds; it follows that

$$i = g\,([A]^\circ - [A]_0) \quad [A\text{-}7]$$

and

$$i_d = g[A]^\circ \quad [A\text{-}8]$$

where $[A]^\circ$ is the bulk SO_2 concentration and $[A]_0$, the concentration at the surface.

(*e*) That the system is at steady state (*i.e.*, flux in = flux out); thus

$$g_A\{[A]^\circ - [A]_0\} = g_A[A^-]_0 + 2g_{A_2^-}[A_2^-]_0 + 2g_{A_2^{-2}}[A_2^{-2}]_0 \quad [A\text{-}9]$$

and assuming

$$g_A = g_{A^-} = 2g_{A_2^-} = 2g_{A_2^{-2}} = g \quad [A\text{-}10]$$

we then find that

$$\frac{i_d}{g} = [A]^\circ = [A]_0 + [A^-]_0 + [A_2^-] + [A_2^{2-}] \quad [A\text{-}11]$$

Substituting [A-4] to [A-10] into [A-11] we find that

$$\frac{i_d}{g} = \frac{(i_d - i)}{g} + \frac{(i_d - i)}{gP} + K_2\frac{(i_d - i)^2}{g^2P} + K_3\frac{(i_d - i)^2}{g^2P^2} \quad [A\text{-}12]$$

The equation for P is

$$P = \frac{1}{2}\left\{\frac{i_d - i}{i}\right\}\left\{\left(1 + K_2\frac{(i_d - i)}{g}\right) + \left[\left(1 + K_2\frac{(i_d - i)}{g}\right)^2 + \frac{4K_3 i}{g}\right]^{1/2}\right\} \quad [A\text{-}13]$$

From [A-6]

$$E - E_0 = \frac{RT}{\mathbf{F}}\ln P \quad [A\text{-}14]$$

The above expression describes the shape of the polarogram in the general case where both reactions [A-2] and [A-3] are important. It is also of interest to consider the special cases where:

(*a*) $K_3 = 0$ (*i.e.*, complex formation is the dominant follow-on reaction). In this case, Eq. [A-4] can be simplified to give

$$E - E_0 = \frac{RT}{\mathbf{F}}\ln\left[\left(\frac{i_d - i}{i}\right)\left(1 + K_2\frac{(i_d - i)}{g}\right)\right] \quad [A\text{-}15]$$

At the half-wave potential $i = i_d/2$. Substitution of this relationship into [A-15] allows the following relationship to be obtained for the shift of the half-wave potential with respect to the standard potential

$$E_{1/2} - E_0 = \frac{RT}{\mathbf{F}}\ln\left(1 + \frac{K_2[A]^\circ}{2}\right) \quad [A\text{-}16]$$

Measurement of the shift of the half-wave potential thus allows K_2 to be determined.

An estimate of K_2 can also be obtained from the concentration of A at E_0 which can be obtained from the d-c polarogram using the Ilkovič equation at $E = E_0$, $P = 1$ and $[A]_{E0} = [A^-]_{E0}$. Substitution into [A-11] thus yields

$$[A_2^-]_{E0} = [A]^\circ - 2[A]_{E0} \quad [A\text{-}17]$$

therefore

$$K_2 = \frac{[A_2^-]}{[A]\,[A^-]} = \frac{[A]^\circ - 2[A]_{E0}}{[A]^2_{E0}} \quad [A\text{-}18]$$

(*b*) $K_2 = 0$ (*i.e.*, dimerization is the major follow-on reaction). In this case Eq. [14] can be simplified to give

$$E - E_0 = \frac{RT}{\mathbf{F}}\ln\left\{\frac{1}{2}\left(\frac{i_d - i}{i}\right)[1 + (1 + \sqrt{4K_3 i/g})]\right\} \quad [A\text{-}19]$$

The Kinetics and Mechanism of the Electroreduction of Sulfur Dioxide in Nonaqueous Media

II. Effects of Electrolyte and Solvent on the Mechanism of Reduction

ABSTRACT

The effect of solvent and supporting electrolyte on the mechanism of the electroreduction of SO_2 has been studied using polarography. It has been found that both the solvent and the electrolyte have a strong influence on the course of the reduction process. The reduction proceeds via the free radical intermediate $S_2O_4^-$ in systems containing large cations but leads directly to $S_2O_4^=$ when the system contains small cations. In addition, it has been shown that the stability of the $S_2O_4^-$ decreases with increasing basicity of the solvent. These effects have been interpreted in terms of ion pairing in the system.

The reduction of sulfur dioxide is industrially important for both the operation of the newly developed (1) high energy density lithium/sulfur dioxide battery and for the manufacture of dithionite salts (2) which are used in large quantities as an industrial reducing agent. In a previous paper (3), polarographic studies of the electroreduction of SO_2 in 0.1 mol dm^{-3} solutions of tetraethylammonium perchlorate (TEAP) in N,N-dimethylformamide (DMF) have been described. In agreement with earlier work (4-8) it was found that, in this medium, the reduction process proceeds via a stable, blue paramagnetic complex of SO_2 and SO_2^- having a 1:1 stoichiometry. Both ESR (9) and Raman (10) spectroscopic studies indicate that this species is a loosely bonded charge transfer complex. The polarographic studies have shown that the initial stages of the electroreduction process in 0.1 mol dm^{-3} TEAP/DMF can be explained in terms of the following reactions

(a) Electron transfer

$$SO_2 + e \rightleftharpoons SO_2^- \qquad [1]$$

(b) Complex formation

$$SO_2 + SO_2^- \rightleftharpoons S_2O_4^- \quad K_{a1} = 8400\ \mathrm{dm^3\ mol^{-1}} \qquad [2]$$

and

(c) Disproportionation

$$2SO_2^- \rightleftharpoons SO + SO_3^{2-} \quad K_d = 0.6 \qquad [3]$$

At later stages of the reduction process a red complex that has been ascribed (4) to the complex species $SO_2 \cdot S_2O_4^{2-}$ and finally dithionite are formed (10).

There are indications, however, that the choice of solvent and electrolyte has an important effect on the reduction mechanism. For example, Bonneterre and Cauquis (11) concluded that the major follow-on reaction in dimethylsulfoxide solution is the dimerization of SO_2^- to form dithionite according to the reaction

$$2SO_2^- \rightleftharpoons S_2O_4^{2-} \quad K_{a2} \qquad [4]$$

In the present paper, we report results of studies that we have carried out to examine the effects that both the solvent and the electrolyte have on the mechanism of the electroreduction of sulfur dioxide in nonaqueous media.

Experimental

The electroreduction of dilute solutions ($\sim 10^{-3}$ mol dm^{-3}) of sulfur dioxide has been studied using three different solvents and six different supporting electrolytes. The solvents, which were chosen for their different solvating abilities, included N, N-dimethyl formamide (DMF) (Aldrich Spectrophotometric grade), acetonitrile (AN) (Aldrich Spectrophotometric grade), and hexamethylphosphoramide, HMPA, (Sigma). The

* Electrochemical Society Active Member.

Key words: sulfur dioxide, high energy density batteries.

supporting electrolytes, which were chosen for variation of cation size, included tetraethylammonium perchlorate (TEAP) (Eastman), tetrabutylammonium perchlorate (TBAP) (Eastman), potassium perchlorate (Fisher), sodium perchlorate (Analar), and lithium perchlorate (Research Inorganic Chemical Company). The procedures followed for purifying and drying the solvents and salts have been described previously (12-14).

All potential measurements given in this paper were measured against a reference electrode that consisted of a silver wire in a solution of 0.05 mol dm^{-3} $AgNO_3$ and 0.05 mol dm^{-3} TEAP in the solvent being used for the experiment. The reference electrode solution was changed daily due to photodecomposition of Ag^+ in DMF. Other details of the electrochemical methods used to make the electrochemical measurements have been described in the first part of this study (3). Electron spin resonance measurements were made using a Varian E-Line spectrometer. The electrochemical ESR cell used for these measurements was similar to that designed by Goldberg and Bard (15). This cell was filled and sealed in the glove box to exclude moisture and air and ESR measurements were then made after partial electrolysis of the solution.

Results and Discussion

Effects of cation on the mechanism of reduction in DMF.—The results to be described in this section show that the mechanism of reduction of SO_2 becomes more complex when supporting electrolytes other than TEAP or TBAP are used in DMF solvent.

A comparison of the cyclic voltammograms in different electrolytes shows a transition from a quasi-reversible reduction in TBAP and TEAP to an irreversible reduction when a small cation such as Li^+ is used. The cyclic voltammograms of SO_2 in TBAP are almost identical to those presented earlier for TEAP (3). These voltammograms show a quasi-reversible peak at −1.3V and a minor oxidation peak at about −0.7V, the latter being ascribed (3) to the oxidation of SO_3^{2-} produced from reaction [3]. When $LiClO_4$ is used as electrolyte (Fig. 1), the reduction reaction is essentially irreversible, the SO_2 being removed rapidly by a follow-on reaction. In this case, there is evidence for the formation of an additional major product which is oxidized at more positive potentials (−1.0V). Only a small oxidation peak is observed at −0.7V. In TEAP and $LiClO_4$ solutions, a linear relationship is observed between i_p, the peak current of the reduction wave, and $\nu^{1/2}$ where ν is the sweep rate.

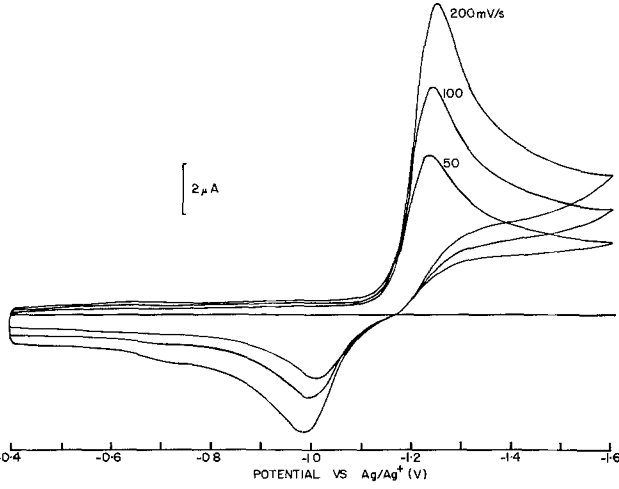

Fig. 1. Cyclic voltammograms for the reduction (forward sweep) of 10^{-3} mol dm^{-3} SO_2 at a hanging mercury drop electrode (HMDE) in N,N-dimethyl formamide (DMF) containing 0.1 mol dm^{-3} $LiClO_4$ with varying sweep speeds as indicated.

The cyclic voltammograms of SO_2 in 0.1 mol dm^{-3} $KClO_4$ and $NaClO_4$ (Fig. 2 and 3) are more complex. The distinct prewave and large oxidation wave on the reverse sweep seen in $KClO_4$ solution is characteristic (16) of product adsorption.

For both $NaClO_4$ and $KClO_4$, $i_p/\nu^{1/2}$ decreases with increasing ν. This behavior is ascribed to product adsorption in both electrolytes. This suggestion is confirmed by d-c and pulse polarographic measurements as discussed later. Because of product adsorption, interpretation of the number and position of the oxidation peaks observed in $KClO_4$ and $NaClO_4$ is difficult. Qualitatively, however, it appears that the cyclic voltammogram of SO_2 in $KClO_4$ most closely resembles that in TEAP while the voltammogram in $NaClO_4$ more closely resembles that in $LiClO_4$.

In order to study the reduction process in more detail, d-c polarographic measurements were also made on all of the solutions. Both the shape and the half-wave potential were dependent on the nature of the base electrolyte. This is illustrated in Fig. 4 where plots of log $(i/i_d - i)$ *vs.* E are presented. The half-wave potentials and limiting current constants, based on maximum currents, are given in Table I.

The d-c polarogram of SO_2 in TBAP is virtually identical with that in TEAP which has been described in detail previously (3). The d-c polarographic data are consistent (3) with the reduction proceeding via reactions [1]-[3] in both electrolytes.

The shape of the d-c polarogram for SO_2 in $LiClO_4$ or LiBr is quite different (Fig. 4) from that described above for SO_2 in TEAP. In this case, the follow-on reaction causes the polarogram to be sharpened so that plots of log $(i/i_d - i)$ *vs.* E have a slope of about 45 mV per decade, the half-wave potential

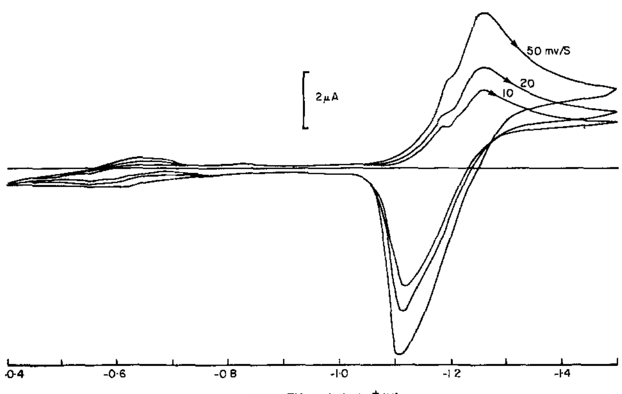

Fig. 2. Cyclic voltammograms for the reduction of 10^{-3} mol dm^{-3} SO_2 at an HMDE in DMF containing 0.1 mol dm^{-3} $KClO_4$ with varying sweep speeds as indicated.

being −1.18V. The effects of temperature on the half-wave potential and limiting current constant are shown in Table II.

This behavior is consistent (3) with a change of mechanism so that dimerization of the SO_2^- to form dithionite (reaction [4]) becomes the major follow-on reaction, *i.e.*

$$2SO_2^- \rightleftharpoons S_2O_4^{2-} \quad K_{a2} \qquad [4]$$

Dithionite is known (17) to be the major product in the discharge of the lithium/sulfur dioxide battery.

If it is assumed that reaction [4] is at equilibrium on the time scale used to make the d-c polarographic measurements and that the Nernst and Ilkovič equations hold then the shape of the d-c polarogram is described (3) by the equation

$$E - E^\circ = \frac{RT}{\mathbf{F}} \ln \left\{ \frac{1}{2} \left(\frac{i_d - i}{i} \right) \left(1 + \sqrt{\frac{4K_{a2}}{g}} \right) \right\} \qquad [5]$$

where E° is the standard electrode potential for the SO_2/SO_2^- couple, i_d is the limiting current, and g is the Ilkovič coefficient. At the half-wave potential, Eq. [5] reduces to

$$E_{1/2} - E^\circ = \frac{RT}{\mathbf{F}} \ln \left\{ \frac{1}{2} (1 + \sqrt{2K_{a2}[SO_2]^\circ}) \right\} \qquad [6]$$

Taking the value of $E^\circ = -1.30V$ estimated from a-c polarographic measurements as described later, then from the half-wave potential of −1.18V at 24°C a value of 23.3×10^6 dm^3 mol^{-1} is obtained for K_{a2}.

ESR measurements support this change in reduction mechanism in changing from TEAP to $LiClO_4$ solutions. In $LiClO_4$ solutions no paramagnetic intermediates are detected even at relatively high SO_2 concentrations ($\sim 10^{-2}$m). Under similar conditions an intense ESR signal is detected (6, 7, 9) for the polarographic complex $S_2O_4^-$ in TEAP solutions. The measurement of diffusion-limited currents for the reduction of SO_2 in TEAP and $LiClO_4$ also reflects the difference in reduction mechanism. In TEAP the limiting currents (and hence the apparent diffusion coefficient of SO_2) are significantly lower (Fig. 5) than the $LiClO_4$ solutions. This is undoubtedly caused by the scavenging of SO_2 by SO_2^- to form $S_2O_4^-$.

Interpretation of the d-c polarograms for SO_2 in $KClO_4$ and $NaClO_4$ solutions is more difficult. In both systems distinct adsorption prewaves are observed. This is in agreement with the cyclic voltammogram for SO_2 in $KClO_4$ solutions which also showed effects due to product adsorption (Fig. 1). At 53°C, the polarogram for the reduction in $NaClO_4$ solution shows a distinct kinetic maximum. From the cyclic voltammetric and d-c polarographic data, it appears that the situation in $KClO_4$ and $NaClO_4$ solutions is intermediate between that in TEAP and $LiClO_4$. It is thus probable that both $S_2O_4^-$ and $S_2O_4^=$ are formed by reactions [2] and [4] in these solutions. Pulse polaro-

graphic measurements support this conclusion. Using a negative potential sweep, the pulse polarogram for SO_2 in all of the electrolytes consists of a single wave that gives a linear plot of log $(i/i_d - i)$ *vs.* E (Fig. 6). It is seen that there is a regular increase in slope of these curves from 68 to 46 mV per decade in going from TEAP to $LiClO_4$. This change of slope can be attributed to the shift in mechanism from formation of the free radical complex $S_2O_4^-$ in TEAP to the formation of dithionite in $LiClO_4$. The theoretical description of the shape of the d-c polarogram when both reactions [2] and [4] contribute has been given previously (3). It can be shown that this gradual change of slope is consistent with the transition from one product to the other (*i.e.*, $S_2O_4^-$ to $S_2O_4^{2-}$).

The pulse polarographic data obtained using a positive potential sweep from various points on the reduction wave provide some information regarding the reaction mechanism. As has been discussed in detail previously (3), the pulse polarogram of SO_2 in TEAP solutions obtained using a positive potential sweep shows two distinct waves, one wave at $-1.3V$ that is attributed to the oxidation of SO_2^-, and a second wave at $-0.7V$ that is attributed to oxidation of SO_3^{2-}. The failure to detect a wave due to oxidation of $S_2O_4^-$ was attributed to the labile equilibrium that exists between SO_2^- and $S_2O_4^-$. It is believed that this equilibrium is sufficiently rapid that all of the $S_2O_4^-$ is depleted through oxidation of SO_2^- before the current is sampled at the end of the 45 msec pulse.

The anodic pulse polarograms of SO_2 in $KClO_4$ (Fig. 7) and $NaClO_4$ are more complex, the polarograms exhibiting large maxima. This behavior has been described by Flanagan and co-workers (18) who have shown that this effect is caused by product adsorption. This is in agreement with the d-c polarographic and cyclic voltammetric results which have also indicated that product adsorption is taking place as discussed previously. It is interesting to note that, when the initial potential is set just at the foot of the d-c polarogram, a small wave at $-0.7V$ is observed. This indicates that the disproportionation of SO_2^- to form SO_3^{2-} takes place in these solutions as well.

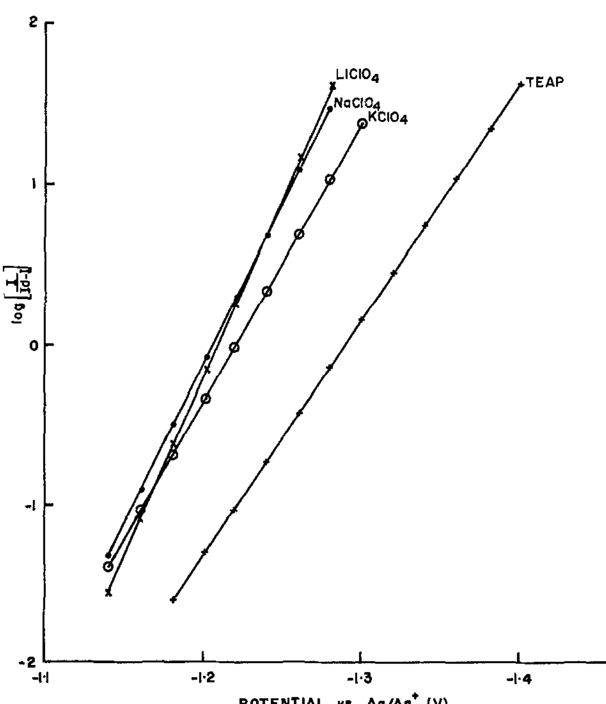

Fig. 6. Plots of log $(i/i_d - i)$ against electrode potential on the basis of pulse polarographic data for the electroreduction of SO_2 in DMF containing different electrolytes as indicated.

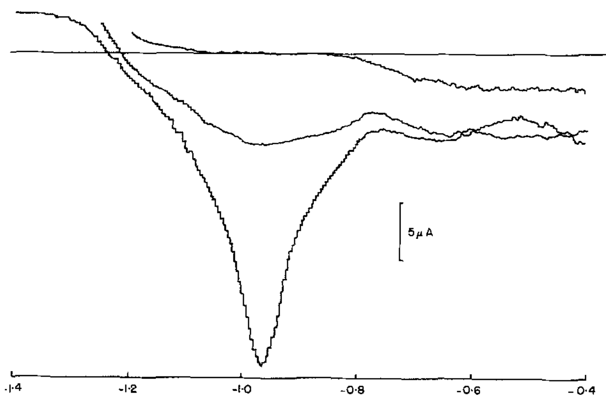

Fig. 7. Pulse polarogram for the oxidation of the reduction products of a 10^{-3} mol dm^{-3} SO_2 in DMF containing 0.1 mol dm^{-3} $KClO_4$ with initial potential as indicated.

In $LiClO_4$ solutions (Fig. 8), the anodic pulse polarogram shows three distinct waves at -1.3, -1.0, and $-0.7V$. At $-1.3V$ the net current flowing is cathodic indicating that the SO_2^- produced in the primary reduction is completely removed during the 45 msec pulse. The major oxidation wave occurs at $-1.0V$ and probably results from oxidation of dithionite which is thought to be the major product from the follow-on reactions. A small wave is also observed at $-0.7V$ indicating that some SO_3^{2-} is also produced.

The experiments described above indicate that the electrolyte cation has a strong influence on the course of the electroreduction process. Thus, in TEAP solutions, the reduction process proceeds via the free radical complex $S_2O_4^-$ as well as a red complex that has been ascribed to $SO_2 \cdot S_2O_4^{2-}$ on route to dithionite on complete electrolysis. In $LiClO_4$ solutions, on the other hand, dithionite is formed directly by dimerization of SO_2^-. The influence of electrolyte cation on the mechanism of reduction can be explained in terms of the effect of ion pairing on the position of the various equilibria (19). It appears that the formation of dithionite is favored when strong ion pairing occurs in solutions containing a small cation such as lithium. On the other hand when a large cation such as TEA^+ is used and ion pairing is expected to be weak, the formation of the complex species is favored. With Na^+ and K^+ in solution, the degree of ion pairing is expected to be intermediate between these two extremes.

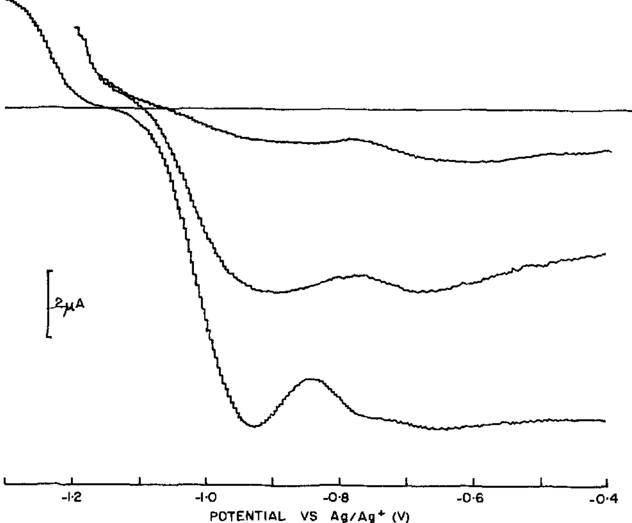

Fig. 8. Pulse polarogram for the oxidation of the reduction products of 10^{-3} mol dm^{-3} in DMF containing 0.1 mol dm^{-3} $LiClO_4$ with initial potential as indicated.

Effects of solvent on the mechanism of reduction.—As mentioned previously, the electroreduction of sulfur dioxide has been studied in three different solvents (DMF, HMPA, and AN) of varying solvating ability to examine the effect of solvent on the mechanism of reaction. Measurements have been made in each of these solvents using TEAP, $NaClO_4$, and $LiClO_4$ as electrolyte.

The d-c polarographic data for the reduction of SO_2 in 0.1 mol dm^{-3} solutions of TEAP in each of the three solvents are shown in Fig. 9. The shapes of the log $(i/i_d - i)$ plots are very similar in HMPA and DMF. On the other hand, in AN a marked broadening of the curve occurs at negative potentials similar to that seen at high SO_2 concentrations in DMF (3). It is possible that this broadening is due to a second reduction process such as the direct reduction of $S_2O_4^-$. It was also noted that there is a fairly large variation in limiting current which can be related to the variation in diffusion coefficient due to a corresponding variation in solvent viscosity.

The general features of the polarograms in all solvents with TEAP as electrolyte suggest that the reduction of SO_2 in these systems proceeds via reactions [1]-[3]. In this case the shift in the half-wave potential can be related (3) to the equilibrium constants K_{a1} and K_d by the relationship

$$E^{1/2} - E^\circ = \frac{RT}{\mathbf{F}} \ln \left\{ 1 + 2 K_d^{1/2} + \frac{K_{a1}}{2} [SO_2]^\circ \right\} \quad [7]$$

where $[SO_2]^\circ$ is the bulk SO_2 concentration.

Using the method described earlier (3), the disproportionation constant K_d was determined to be 1.5 in HMPA. The pulse polarogram for SO_2 in AN (Fig. 10) obtained using a positive potential sweep is quite different than that obtained in DMF or HMPA. In AN, a fairly weak broad wave is observed at about -0.85V which is absent when the initial potential is held at the foot of the reduction wave. This indicates that SO_3^{2-} is not produced in this reaction and that $K_d = 0.0$ in AN. The broad wave at -0.85V is tentatively assigned to the oxidation of $S_2O_4^-$.

An estimate of the standard potential for the process $SO_2 + e \rightleftharpoons SO_2^-$ was obtained from the peak

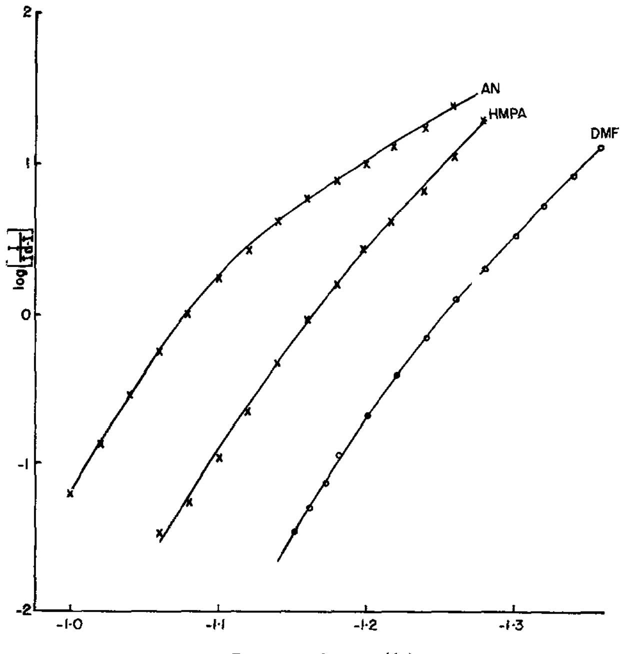

Fig. 9. Plots of log $(i/i_d - i)$ against electrode potential on the basis of d-c polarographic data for the electroreduction of SO_2 in various solvents as indicated containing 0.1 mol dm^{-3} TEAP.

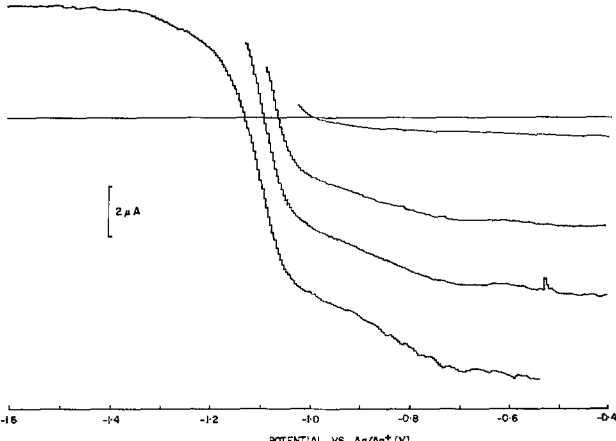

Fig. 10. Pulse polarogram for the oxidation of the reduction products of 10^{-3} mol dm^{-3} SO_2 in AN containing 0.1 mol dm^{-3} TEAP with initial potential as indicated.

potential of the out-of-phase component of the a-c admittance. Using the measured d-c polarographic half-wave potentials and Eq. [7], values of K_{a1} = 0, 8400, and 17,000 dm^3 mol^{-1} are obtained in HMPA, DMF, and AN, respectively. From these results, it is seen that the solvent has an important effect on the stability of the complex and thus the reaction mechanism. These results provide further evidence of the importance of ion pairing in determining the position of equilibrium among the various components of the reacting system. As the basicity of the solvent decreases (20) (HMPA > DMF > AN) the ability of the cation in the system to interact with negatively charged components of the reaction system increases; thus, it appears that the negatively charged complex $S_2O_4^-$ is most stable in AN where it can most strongly interact with the cation, in this case, TEA^+.

The electroreduction of SO_2 was also studied in 0.1 mol dm^{-3} solutions of $LiClO_4$ and $NaClO_4$ using each of the three solvents. In these electrolytes, the experimental results are complicated by the apparent kinetically limited reduction in HMPA and extremely strong adsorption of product in AN. Because of these complications, very few conclusions regarding the effect of solvent on the reaction mechanism could be reached. Perhaps the most revealing results are the data obtained by pulse polarography recorded using a negative sweep with 0.1 mol dm^{-3} $LiClO_4$ electrolyte (Fig. 11). From these curves it is concluded that the formation of dithionite is the major follow-on reaction in AN and DMF. In HMPA (Fig. 11) the slope of the log $(i/i_d - i)$ plot is much larger ($\sim$ 91 mV per decade) and the half-wave potential is considerably more positive than that measured using d-c polarography. It is suggested that this behavior is the result of a kinetic limitation of the reduction of SO_2 in this system.

The very strong product adsorption that occurs in AN leads to some curious results. In $LiClO_4$ or $NaClO_4$ solutions, it is not possible to record a d-c polarogram because the electrode becomes blocked by the adsorbed product. As shown in Fig. 12, the normal pulse polarogram recorded in 0.1 mol dm^{-3} solution of $LiClO_4$ in AN using an anodic sweep also shows dramatically the effects of adsorption. In this case a large adsorption peak is observed at very positive potentials rather than the normal oxidation waves seen when HMPA or DMF are used as the solvent (Fig. 12). This gives the normal pulse polarogram a very unusual appearance.

Conclusions

These studies have indicated that the choice of solvent and electrolyte has a major effect on the

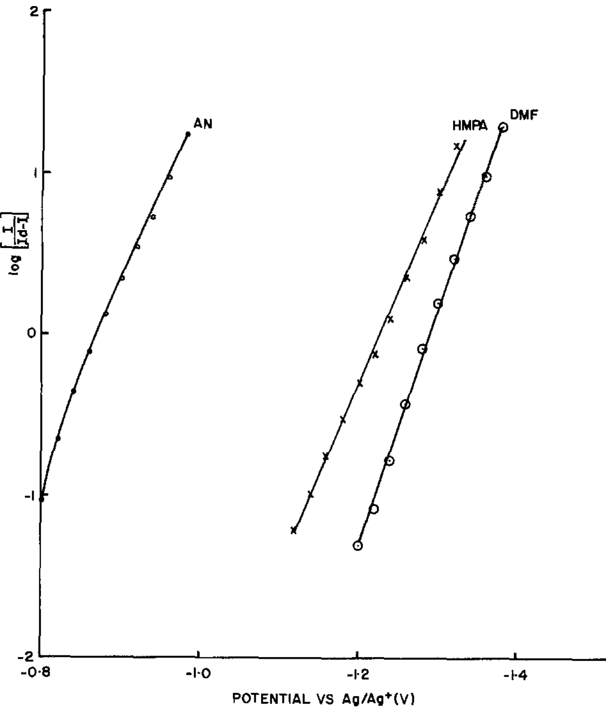

Fig. 11. Plots of log ($i/i_d - i$) against electrode potential on the basis of pulse polarographic data for the electroreduction of SO_2 in various solvents as indicated containing 0.1 mol dm^{-3} $LiClO_4$.

mechanism of reduction of sulfur dioxide in nonaqueous media. The influence of solvent and electrolyte on the reaction mechanism can be interpreted in terms of ion pairing in the system.

In DMF solution, it has been shown that, in solutions containing a large cation such as TEA^+ which leads to relatively weak ion-pairing, the reduction process proceeds via the free radical complex $S_2O_4^-$ during the initial stages of electrolysis. When a small cation such as Li^+ is used, on the other hand, dithionite is formed directly by dimerization of the primary reduction product SO_2^-. In addition, it has been shown that the stability of $S_2O_4^-$ decreases with increasing basicity of the solvent.

Electrocatalysis for Chlorine Electrode Reaction on RuO_2 Electrode in $NaAlCl_4$ Melt

I. Uchida,* H. Urushibata, and S. Toshima

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980, Japan

ABSTRACT

In molten $AlCl_3$-NaCl with near equimolar compositions, electrocatalysis of the chlorine electrode reaction ($2Cl^- = Cl_2 + 2e^-$) on RuO_2 electrodes has been investigated at 175°C. Melt-stable RuO_2 electrodes were prepared by a thermal decomposition method on semiconductive SnO_2 films deposited on Pyrex substrates. Tafel relationships for chlorine evolution and reduction were studied as functions of pCl($= -\log a_{Cl^-}$) and partial pressure of Cl_2, and several kinetic parameters including reaction orders with respect to Cl^- and Cl_2 were determined. The mechanistic analysis based on the theoretical kinetic derivatives revealed that the chlorine electrode reaction on RuO_2 obeys a Volmer-Tafel type mechanism under the activated Temkin condition: $Cl^- = Cl_{ad} + e^-$ (fast), $Cl_{ad} + Cl_{ad} \rightleftarrows Cl_2$ (slow). The exchange current density at the standard condition (pCl = 1.1, P_{Cl_2} = 1 atm) was 132 ± 22 $\mu A/cm^2$, and this figure was found to be 15-20 times larger than that on glassy carbon electrodes. The difference of this electrocatalytic activity was ascribed to the mechanistic difference between the two electrode materials and not to the difference of electrode roughness. Capacity data to check this viewpoint were also presented.

Electrocatalysis of the chlorine electrode reaction in molten salt systems is of special interest from the viewpoint of developing molten salt batteries and electrolytic metal winning processes. The only anode material available so far is carbon, which is not sufficiently stable in chloroaluminate melts, showing considerable swelling and disintegration (1, 2). In previous works (3, 4), we have shown that Sb-doped tin oxide acts as stable working electrodes for chlorine evolution. Highly doped SnO_2 having carrier densities of the order of 10^{20} cm^{-3} behaves as an electron-tunneling electrode which allows the electron to pass through the space charge layer formed at the semiconductor/melt interface (5). The comparative study carried out on SnO_2 and glassy carbon (GC) electrodes showed that the polarization behavior for chlorine evolution on SnO_2 increasingly approached that on GC with increasing carrier density (4). In this case, however, electrocatalytic activity would not be expected for SnO_2 electrodes because the electron tunneling process governs the chlorine evolution. Considering that SnO_2 can be utilized as a catalyst support and a current collector, we have proposed the possibility of developing DSA-type, SnO_2-based electrocatalysts usable in melts by applying the oxide-coating techniques employed in the production of DSA.

DSA-type electrodes used for the electrolysis of brine have a multilayer structure consisting of the upper layer of electrocatalyzers such as RuO_2 and the intermediate layer of titanium dioxide acting as the catalyst support which is formed on the underlying titanium substrate (6), and their physicochemical properties and electrochemical behavior have been studied extensively (7-12). Specially for chlorine evolution, a number of studies have been carried out with various electrochemical techniques (13-17). Iwakura *et al.* studied the reaction mechanism and catalytic activity for chlorine evolution on several kinds of metal oxides (RuO_2, IrO_2, MnO_2 etc.) on the basis of crystal field theory (18, 19). Kazarinov *et al.* reported the double layer structure on Ru-Ti oxide anodes in various electrolyte solutions (20), and Rolison *et al.* investigated the electrochemical behavior of RuO_x electrodes in organic solvents (21). Although there are so many works concerning ruthenium oxide anodes, no workers have reported the electrocatalytic effect of ruthenium oxide on chlorine evolution in molten salt systems.

One of the problems for the use of so-called DSA-type anodes in chloride melts is the instability of Ti substrates. If the oxide anode has a pinhole or a crack and Ti metal comes into contact with melt, anodic dissolution of Ti will take place vigorously. To avoid this problem, ruthenium oxide used in this work was prepared on SnO_2 films on Pyrex substrates. With the electrodes thus prepared, we examined the electrocatalytic effect for chlorine evolution and the reduction in this melt system at 175°C and carried out the mechanistic study using kinetic parameters collected under various conditions. In comparison with the kinetic behavior of the chlorine electrode reaction on glassy carbon electrodes in the same melt system (22), the salient feature of ruthenium oxide as the electrocatalyzer has been demonstrated.

Experimental

Melt preparation.—The AR grade NaCl and $AlCl_3$ which was rendered iron free by sublimation were mixed under a dry nitrogen atmosphere. After melting the mixture, a sequence of purification procedures (HCl gas treatment, Al displacement, and preelectrolysis) was performed as described previously (23, 24).

Electrodes.—Ruthenium oxide was prepared on Sb-doped tin oxide films with thermal decomposition of $RuCl_3$. The SnO_2 films were prepared on rectangular Pyrex glass plates by a spray method using tin(IV) chloride solution containing 5 mol percent (m/o) $SbCl_3$ (23). A dilute n-propanol solution of $RuCl_3 \cdot 3H_2O$ (0.02M) was applied to the thin SnO_2 film by the dip coating method, and then the liquid film of $RuCl_3$ on the SnO_2 substrate was dried in an oven at 120°C for 30 min and heated in air at 500°C for 20 min. This procedure was repeated 20 times to attain uniform coating of the oxide film, and finally the electrode thus prepared was annealed for 10 hr at 500°C in air.

Visual inspection showed that the SnO_2 film was covered with a blue-black, compact layer with satis-

* Electrochemical Society Active Member.

Key words: fused salts, Tafel slope, electrocatalysis, anode.

factory uniformity. SEM observation revealed a pore-free structure, and x-ray analysis showed the presence of all the principal RuO_2 peaks in comparison with those of ASTM cards (File No. 21-1171). The underlying SnO_2 film acts as a catalyst support as well as a current collector. The adhesion of RuO_2 to SnO_2 was proved quite satisfactory. No damage was observed when the electrode was subjected to gentle scraping or thermal shocks.

The electrical contact with the electrode was made through a gold layer which was printed on the SnO_2 film by using a gold paint (C-5040, Sumitomo Mining Company). The unnecessary part of the oxide surface and the gold contact were insulated with a thick layer of Teflon coating (30-J, Mitsui Fluorochemical Company). These techniques were described in previous paper (23). Details of the electrode construction are shown in Fig. 1. Hereafter this type of electrode is called the SnO_2-based RuO_2 electrode.

Prior to experiments, the electrode surface was slightly polished with fine alumina powder (0.3 μm, Buehler Limited) and degreased with a methanol solution of NaOH. Then, it was soaked in a mixed acid of concentrated HNO_3 and H_2SO_4 for 1 hr and washed thoroughly with distilled water. After the above surface conditioning, the electrode was dried in an oven (120°C) for 12 hr.

Glassy carbon electrodes (GC) were sealed into Pyrex tubes as described previously (25). Their surface conditioning was similar to that of the RuO_2 electrode. The counterelectrode was a W sheet with a large area.

Two types of reference electrodes, whose constructions were described previously (22), were used: the Al reference electrode confined in a Pyrex bulb (membrane type) and the chlorine electrode on a large area GC rod under an atmospheric pressure of chlorine (gas electrode type). The melt composition of the reference room was an NaCl-saturated $NaAlCl_4$ melt. All the potentials quoted without description are given with respect to the gas electrode.

Apparatus and procedures.—Experiments were performed in a Pyrex vessel at 175°C. The electrochemical cell assembly equipped with gas delivering systems (N_2 and Cl_2) and a temperature control system were essentially the same as that in previous works (22, 23). Nitrogen gas was rendered oxygen free by passing it through heated copper fibers and drying it with anhydrous $Mg(ClO_4)_2$ and P_2O_5. Chlorine gas was dried by passing it through concentrated H_2SO_4 and anhydrous $Mg(ClO_4)_2$. The gas delivering system had a gas mixing chamber where N_2 and Cl_2 were mixed at a desired ratio. The gas mixture was blown into the melt for 1 hr and allowed to flow over the melt during the experiments. The gases sampled from the mixing chamber were subjected to iodometry for determination of the partial pressure of chlorine (22).

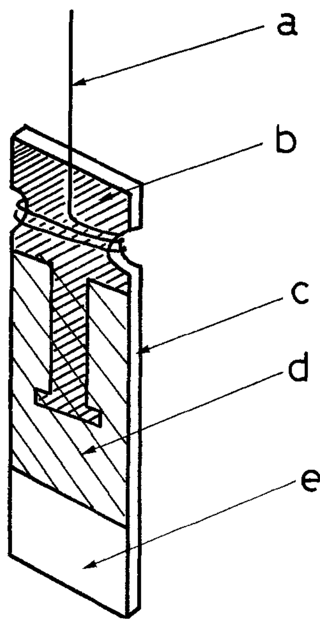

Fig. 1. Electrode construction of the SnO_2-based RuO_2 electrode. a, Au lead; b, printed Au layer; c, Pyrex; d, SnO_2-based RuO_2 covered with Teflon; e, SnO_2-based RuO_2 electrode surface.

The concentration of chloride ion depends on the melt composition (NaCl + $AlCl_3$). At the equimolar composition, chloride ion activity determined by the acid-base equilibrium of Eq. [3] is $10^{-2.54}$ ($-\log a_{Cl^-} = 2.54 = p$Cl) (29). The highest activity of Cl^- (pCl = 1.1) is attained in the melt saturated with NaCl (49.75 m/o $AlCl_3$) which is used as the standard state in this melt (29). All the measurements carried out in this work were, therefore, started with this standard condition, and then pCl was changed by partial electrolysis. Part of chloride ion in the cell compartment which was separated from a counterelectrode with a fritted disk was removed coulometrically by chlorine evolution, and the exact pCl value was determined from the shift of chlorine electrode potential. The use of the off-gas reaction to change pCl and of the gas electrode as a pCl indicator electrode were described previously (22).

Measurements of voltammograms and differential capacities were carried out as described previously (22-24). For measurements of Tafel relationships, a logarithmic amplifier (Philbrick Nexas, 4350) was used for curve tracing. Tafel plots were always started from the rest potentials with a scan rate of 1 mV/sec and were recorded on an X-Y recorder (Watanabe Denki, WX 4401).

Results and Discussion

Electrode roughness.—Many workers observed large background current levels of the order of several mA/cm^2 in aqueous systems with their RuO_2 electrodes prepared on Ti substrate (8-12), ascribing the anomaly to electrode roughness. The surface roughness is an important factor in calculation of the exchange current density, which is a measure of the electrocatalytic activity to be examined in this study. In order to check the roughness of our RuO_2 electrodes prepared on SnO_2, the differential capacity and background cyclic voltammograms were measured and compared with those of metal electrodes as shown in Fig. 2 and 3. The anodic limit of the melt is chlorine evolution taking place at potentials positive to *ca.* 2.1V *vs.* Al, and we have the double layer region at less noble potentials. The capacity value of the SnO_2-based RuO_2 electrode in the double layer region was 25-30 $\mu F/cm^2$ on the basis of geometric area, which is comparable to those of Pt and W electrodes, while the GC showed large discrepancy. Fellner *et al.* reported that the double layer capacity on Hg electrodes in the melt at 160°C is 14-20 $\mu F/cm^2$ at a potential range from 0.1 to 0.7V *vs.* Al (26). Adopting Fellners' value as a true capacity of the double layer, we may conclude that the roughness factor of our RuO_2 electrode is 1.5-2.0, while that of GC is 6-8. This feature was confirmed by the background voltammograms shown in Fig. 3.

The background current levels for GC observed in the double layer region were several times as large as those for the RuO_2 electrode, whereas the anodic current due to chlorine evolution increased more rapidly on the RuO_2 electrode than on GC despite its lower roughness, indicating the marked catalytic activity of the RuO_2 electrode. It is widely accepted that the roughness of Ti-supported RuO_2 electrodes largely

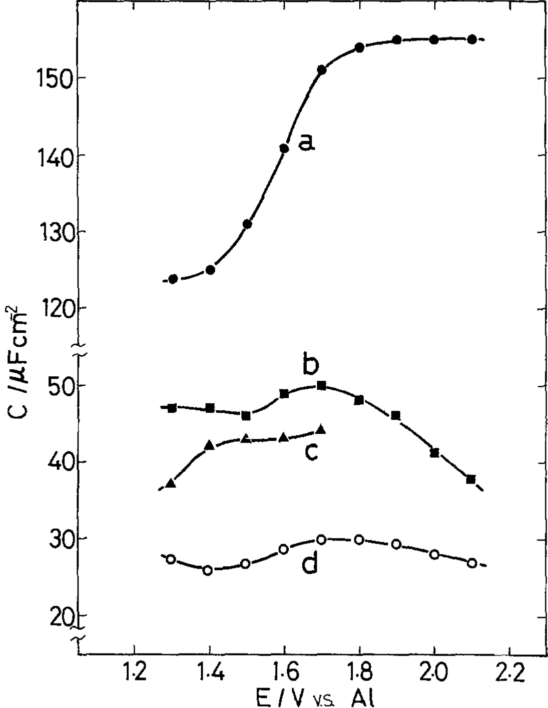

Fig. 2. Capacity *vs.* potential curves for different electrode materials in the melt of $pCl = 1.1$ at $f = 1$ kHz. a, GC; b, W; c, Pt; d, SnO_2-based RuO_2.

depends on coating methods and annealing conditions (7-12). The estimated values of their roughness factor show large scattering; below 10 (21) and 8-20 (10) for compact RuO_2 electrodes and 60-200 (10) and above 200 (9) for porous RuO_2 electrodes. Rolison *et al.* prepared Ti-supported RuO_x electrodes with low roughness factors below 10 and observed low background current levels less than 100 $\mu A/cm^2$ (21), which are comparable to the background current levels obtained in this work. Similarly low current levels were also observed in aqueous solutions with SnO_2-based RuO_2 electrodes (27). All the evidence collected with SEM observation, capacity measurements, and background voltammograms, therefore, indicates that the real surface area of our RuO_2 electrode is not considerably different from the geometric area, the ratio of the real to the geometric area being estimated to be two at most. The causes of the low roughness can be attributed partly to the optically flat surface of the Pyrex substrate, the use of dilute coating solutions (0.02M $RuCl_3$), and the relatively long annealing time (10 hr at 500°C).

Comparison of Tafel plots between SnO_2-based RuO_2 and GC electrodes.—Figure 4 shows the Tafel plots for chlorine evolution and reduction in the melt of $pCl = 1.1$ on (a) GC and (b) RuO_2 electrodes. At low overpotentials chlorine evolves from free chloride ions whose activity is specified by the pCl value, and the current plateau is ascribed to the diffusion process of Cl^- (28), because the limiting value depends on pCl, irrespective of electrode materials. The cathodic limiting current is due to the diffusion of Cl_2 (22), depending on the partial pressure of Cl_2.

There are two overall reactions concerning chlorine evolution

$$Cl_2 + 2e^- = 2Cl^- \quad [1]$$

$$2Al_2Cl_7^- + Cl_2 + 2e^- = 4AlCl_4^- \quad [2]$$

The standard potential of reaction [2] is located at 0.62V positive to the potential of reaction [1] ($pCl = 1.1$, $p_{Cl_2} = 1$ atm) according to the thermodynamic calculation using the equilibrium constant ($K = 1.06 \times 10^{-7}$) of the following acid-base reaction (29)

$$2AlCl_4^- = Al_2Cl_7^- + Cl^- \quad [3]$$

In the present study, we are concerned with reaction [1], which is the primary reaction taking place at low pCl and low overpotentials.

The polarization behavior obtained during reverse scanning is not shown in Fig. 4 for simplicity. Deep scanning ($\eta \sim 500$ mV) resulted in so-called hysteresis curves and subsequent scanning showed different results. However, those changes in the polarization easily recovered to the original one by agitating the bulk melt, and irreversible changes indicating surface degradation were not observed. The hysteresis effect is ascribed to the change in pCl at the electrode surface.

The chlorine evolution on semiconductive SnO_2 electrodes is less reversible than that on GC as reported previously (4). Hence, the reversible be-

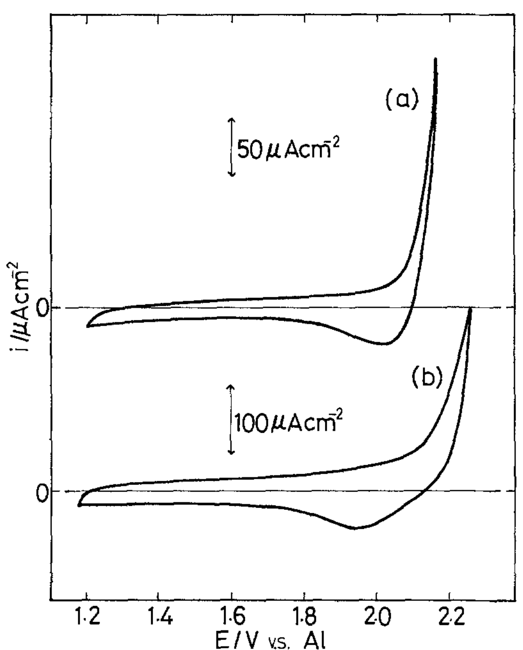

Fig. 3. Background cyclic traces in the melt of $pCl = 1.1$ at $v = 50$ mV sec^{-1}. (a) SnO_2-based RuO_2 electrode, (b) GC electrode.

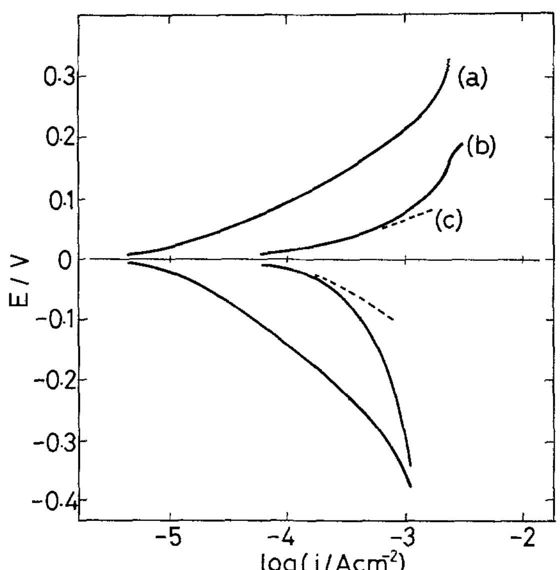

Fig. 4. Comparison of Tafel plots between SnO_2-based RuO_2 and GC electrodes in the melt of $pCl = 1.1$ under an atmospheric pressure of Cl_2. (a) GC electrode, (b) SnO_2-based RuO_2 electrode, (c) curve (b) corrected for concentration overvoltages.

havior of curve (b) is obviously ascribed to the activity of the electrocatalyzer prepared on SnO_2. Because of the improved reversibility, the Tafel region of the RuO_2 electrode is narrow and largely curved, showing a great participation of the diffusion process. In order to obtain kinetic parameters, the concentration overvoltage was corrected with the conventional method described by Vetter (30). The dotted line in Fig. 4 shows the corrected Tafel plots. The anodic (b_+) and cathodic (b_-) Tafel slopes were 72 ± 8 and −105 ± 8 mV/decade, respectively, and the exchange current density (i_o) based on the geometric area was 132 ± 22 $\mu A/cm^2$ for several experiments. The i_o value on GC was 8.9 $\mu A/cm^2$ based on the geometric area, being in good agreement with the previous result, 8.6 ± 0.8 $\mu A/cm^2$ (22). Comparing the two i_o's it is seen that the former value is 15 times larger than the latter value, or more if taking into account the higher roughness of GC electrodes. The electrocatalytic activity of the RuO_2 electrode is therefore quite noticeable.

The reaction mechanism on RuO_2 electrode.—For the overall reaction [1], the following elementary reactions have been proposed (1, 22, 31-33)

overall

$$2Cl^- = Cl_2 + 2e^-$$

$$Cl^- = Cl_{ad} + e^- \quad [4]$$

$$Cl_{ad} + Cl^- = Cl_2 + e^- \quad [5]$$

$$Cl_{ad} + Cl_{ad} = Cl_2 \quad [6]$$

Using the stoichiometric number (ν) defined by reaction [7], one can specify possible combinations of the above elementary reactions

$$\nu = \frac{nFi_o}{RT}\left(\frac{\partial E}{\partial i}\right)_{E\to 0} \quad [7]$$

Near-equilibrium polarization behavior (*i vs. E*) obtained in the melt of $pCl = 1.1$ is shown in Fig. 5, the so-called polarization resistance, $(\partial E/\partial i)_{E\to 0}$, being easily determined. The ν value calculated from the i_o and the n (= 2) values was 0.94, being close to unity. Therefore, the reaction mechanisms corresponding to the fact that $\nu = 1$ are three combinations of them

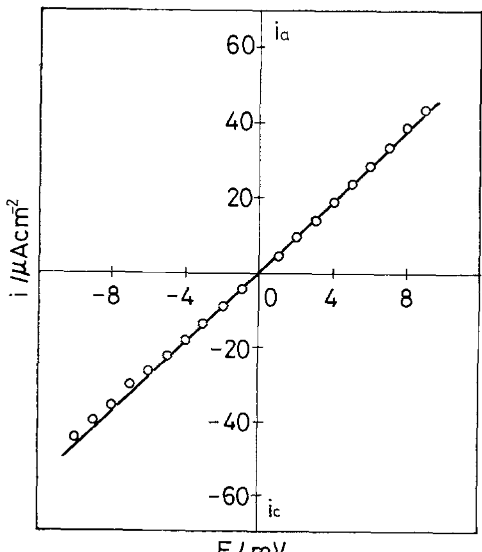

Fig. 5. Micropolarization behavior of SnO_2-based RuO_2 electrode in the melt of $pCl = 1.1$ under $P_{Cl_2} = 1$ atm.

(A) fast, reaction [4] + slow, reaction [5]

(B) fast, reaction [4] + slow, reaction [6]

(C) fast, reaction [5] + slow, reaction [4]

The rate equations for the above reaction schemes have to involve some adsorption isotherm which the adsorbed intermediate obeys. Langmuir, nonactivated Temkin, and activated Temkin isotherms are applied in formulating the rate equations, and then the theoretical kinetic parameters are subjected to comparison with the experimental values to determine which reaction scheme is the most probable. Mechanistic analysis based only on Tafel slopes, however, would fail in the determination because some of the isotherms yield the same Tafel slope for the different schemes. In connection with this, kinetic analyses based on reaction orders are quite informative. In a previous study (22), the reaction orders with respect to Cl^- and Cl_2 played decisive roles in determining the reaction mechanism of chlorine electrode reaction on GC electrode in the melt.

Figures 6 and 7 show the dependence of Tafel plots on pCl and P_{Cl_2} (partial pressure of Cl_2), where the concentration overvoltages are corrected for each plot. Cathodic Tafel plots showed slightly curved features which were presumably due to experimental uncertainty of the cathodic diffusion current (i_{dc}). The correction term $(1 - i/i_{dc})$ is very sensitive to the i_{dc} value because available i values are limited only to one order range below the i_{dc}. Using those data, we can obtain six kinetic parameters; three reaction orders of i_o, i_a, and i_c with respect to Cl^-, and also similar three parameters with respect to Cl_2. The former three parameters were calculated from Fig. 8, where anodic current values (i_a) at $E = 0.105V$, cathodic current values (i_c) at $E = -0.030V$, and i_o values are plotted against $-pCl$ ($= \log a_{Cl^-}$) at a constant P_{Cl_2} (= 1 atm). The latter ones were obtained from Fig. 9 where i_a and i_c at $E = \pm 0.080V$ and i_o were plotted against partial pressures of Cl_2 at a constant pCl (= 1.1). The reaction orders thus collected are summarized in Table I.

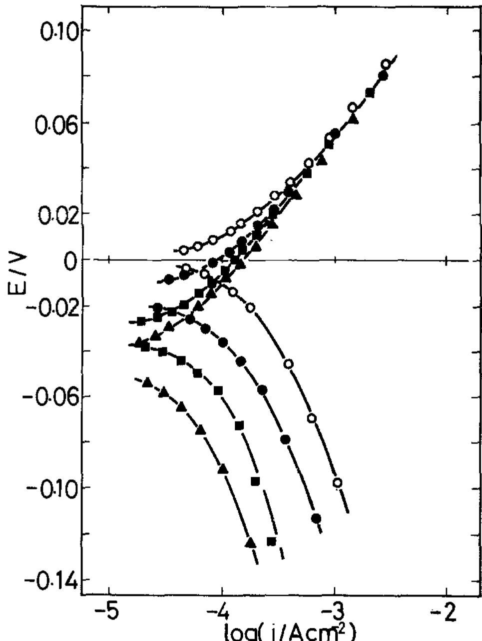

Fig. 7. P_{Cl_2} dependence of Tafel plot for chlorine electrode on SnO_2-based RuO_2 in a $NaAlCl_4$ melt of $pCl = 1.1$ at 175°C. (○) $P_{Cl_2} = 1$ atm, (●) $P_{Cl_2} = 0.52$ atm, (■) $P_{Cl_2} = 0.22$ atm, (▲) $P_{Cl_2} = 0.11$ atm.

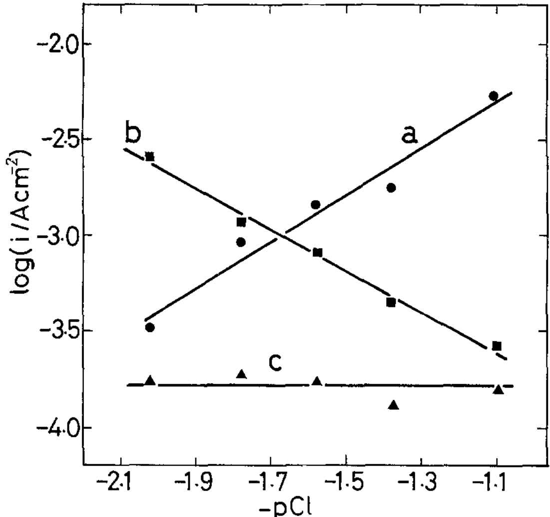

Fig. 8. pCl dependence of current (i) under a constant P_{Cl_2} (= 1 atm). a, Anodic current densities at $E = 105$ mV; b, cathodic current densities at $E = -30$ mV; c, exchange current densities.

The data shown in Table I were inspected first from the viewpoint of the i_o derivatives, which must be the most reliable parameters because their definition does not involve any arbitrary choice of electrode potential. The theoretical i_o derivatives with respect to pCl and P_{Cl_2} are tabulated in Table II for the mechanism (A), (B), and (C) with the three adsorption

Table I. Experimental reaction orders with respect to Cl^- and Cl_2 on a RuO_2 electrode in $NaAlCl_4$ melt at 175°C

$(\partial \log i_o/\partial \log a_{Cl^-})_{P_{Cl_2}}$	0
$(\partial \log i_o/\partial \log P_{Cl_2})_{pCl}$	0.6
$(\partial \log i_a/\partial \log a_{Cl^-})_{E, P_{Cl_2}}$	1.2
$(\partial \log i_c/\partial \log a_{Cl^-})_{E, P_{Cl_2}}$	−1.1
$(\partial \log i_a/\partial \log P_{Cl_2})_{E, pCl}$	0
$(\partial \log i_c/\partial \log P_{Cl_2})_{E, pCl}$	1.0

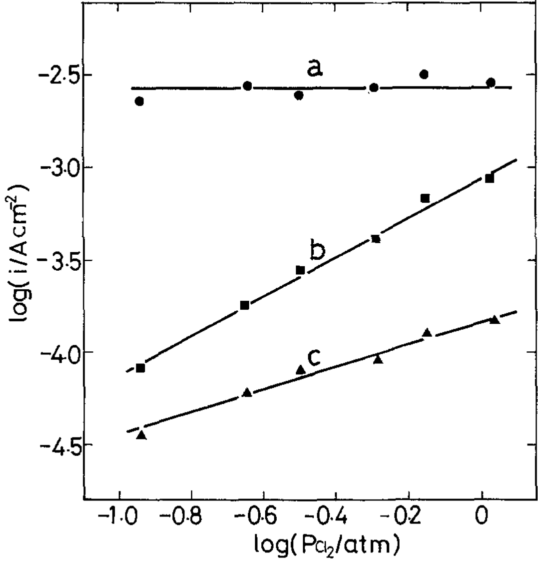

Fig. 9. P_{Cl_2} dependence of current (i) at a constant pCl (= 1.1). a, Anodic current densities at $E = 80$ mV; b, cathodic current densities at $E = -80$ mV; c, exchange current densities.

isotherms. The table was constructed on the bases of our calculations described previously (22) and literature (34). Since the experimental i_o derivatives are 0 with respect to Cl^- and 0.6 with respect to Cl_2, it is seen at first glance that mechanism (B) under the activated Temkin isotherm is the most probable scheme.

The validity of the Temkin condition can be seen in the anodic and cathodic reaction orders with respect to Cl^-. Table III shows both theoretical reaction orders for mechanism (B) with the different isotherms (22, 35). Apparently, only the activated Temkin isotherm gives a tendency consistent with the results shown in Table I. This mechanistic conclusion was also confirmed by comparison between the theoretical and experimental reaction orders with respect to Cl_2. As shown in Table IV, the former values for the anodic and cathodic processes are 0 and 1, being in excellent agreement with the experimental values.

For mechanism (B) under activated Temkin condition, the following rate equation is derived (22, 36), assuming a quasi-equilibrium state for the fast process, reaction [4]

$$\text{fast,} \quad Cl^- \underset{k_{-4}}{\overset{k_4}{\rightleftarrows}} Cl_{ad} + e^-$$

$$\text{slow,} \quad Cl_{ad} + Cl_{ad} \underset{k_{-6}}{\overset{k_6}{\rightleftarrows}} Cl_2$$

$$i = 2\mathbf{F}k_6(K_4)^{2(1-\beta)}a_{Cl^-}{}^{2(1-\beta)} \exp[2(1-\beta)fE] - 2\mathbf{F}k_{-6}(K_4)^{-2\beta}a_{Cl^-}{}^{-2\beta}P_{Cl_2} \exp(-2\beta fE) \quad [8]$$

where $K_4 = k_4/k_{-4}$, $f = \mathbf{F}/RT$, β is the symmetric factor of the adsorption process, and E is the potential difference from the reference electrode. Neglecting the backward reaction, we obtain Tafel relationships for the anodic and cathodic processes

$$\ln i_a = \ln(2\mathbf{F}k_6) + 2(1-\beta)\ln(K_4) + 2(1-\beta)\ln(a_{Cl^-}) + 2(1-\beta)fE \quad [9]$$

$$\ln i_c = \ln(2\mathbf{F}k_{-6}) - 2\beta\ln(K_4) - 2\beta\ln(a_{Cl^-}) + \ln(P_{Cl_2}) - 2\beta fE \quad [10]$$

The kinetic derivatives shown in Table IV are easily obtained from reactions [9] and [10]. Some of the reaction orders involve the parameter β, which is usu-

Table II. The theoretical reaction orders (i_o derivatives) with respect to Cl^- and Cl_2 in the chlorine electrode reaction

Mechanism	Langmuir $\theta \simeq 0$		Langmuir $\theta \simeq 1$		Nonactivated Temkin		Activated Temkin	
	x	y	x	y	x	y	x	y
(A)	0.5	0.75	0.5	0.25	0.5	0.75	0.5	0.5
(B)	0	1	0	0	0	1	0	0.5
(C)	0.5	0.25	0.5	−0.25	0.5	0.25	0.5	0

In calculations, symmetry factor of electron transfer step (α) and adsorption step (β) were assumed as 0.5. $x = (\partial \log i_o/\partial \log a_{Cl^-})_{P_{Cl_2}}$, $y = (\partial \log i_o/\partial \log P_{Cl_2})_{pCl}$.

Table III. The theoretical reaction orders with respect to Cl^- for mechanism (B) under different adsorption isotherms

Reaction order	Langmuir $\theta \simeq 0$	Langmuir $\theta \simeq 1$	Nonactivated Temkin	Activated Temkin*
$(\partial \log i_a/\partial \log a_{Cl^-})_{E, P_{Cl_2}}$	2	0	2	1
$(\partial \log i_c/\partial \log a_{Cl^-})_{E, P_{Cl_2}}$	0	−2	0	−1

* $\beta = 0.5$.

Table IV. Theoretical Tafel slopes and reaction orders for mechanism (B) under activated Temkin condition

$(\partial \log i_o/\partial \log a_{Cl^-})_{P_{Cl_2}}$	0
$(\partial \log i_o/\partial \log P_{Cl_2})_{pCl}$	$1 - \beta$
$(\partial \log i_a/\partial \log a_{Cl^-})_{E, P_{Cl_2}}$	$2(1 - \beta)$
$(\partial \log i_c/\partial \log a_{Cl^-})_{E, P_{Cl_2}}$	-2β
$(\partial \log i_a/\partial \log P_{Cl_2})_{E, pCl}$	0
$(\partial \log i_c/\partial \log P_{Cl_2})_{E, pCl}$	1
$(\partial E/\partial \log i_a)$	$1/2(1 - \beta)f'$*
$(\partial E/\partial \log i_c)$	$-1/2\beta f'$

* $f' = F/2.3RT$.

ally regarded as 0.5 as assumed in the foregoing sections. Thus the β value, which can be calculated with the data shown in Table I, may be used to evaluate the consistency of our conclusion. The calculated β was 0.4 from the i_o derivative, and 0.4 and 0.55 from the reaction orders with respect to Cl^-. Using the average value of β (= 0.45), we can also calculate the theoretical Tafel slopes; $b_+ = 80.9$ mV and $b_- = -98.9$ mV, being in good agreement with the experimental results ($b_+ = 72 \pm 8$ mV and $b_- = -105 \pm 8$ mV). Thus there is no inconsistency in our mechanistic analysis.

The polarization behavior of the RuO_2 electrode shown in Fig. 4 is again represented in a different manner, taking into account the presented reaction mechanism. The rate equation [8] can be rewritten as follows

$$i/[1 - \exp(-2f\eta)] = i_o \exp[2(1 - \beta)f\eta] \quad [11]$$

where η is the overvoltage. In this case the reference electrode is the reversible chlorine electrode (pCl = 1.1, P_{Cl_2} = 1 atm), hence $\eta = E$ for the condition of Fig. 4. Since the backward reaction is not omitted in reaction [11], the plot of $\log \{i/[1 - \exp(-2f\eta)]\}$ *vs.* η describes the polarization behavior corrected for the backward reaction rate over a broad range of current density (37) and gives a straight line with the slope of $2(1 - \beta)\mathbf{F}/2.3RT$. Figure 10 shows this relationship in a potential range where the concentration overvoltage can be negligible. The β value (= 0.45) obtained from the slope and the i_o value at $\eta = 0$ again coincided with the above values.

Consequently, the chlorine electrode reaction on RuO_2 in $NaAlCl_4$ melt with near equimolar compositions occurs according to a Volmer-Tafel mechanism, where the Tafel reaction (atom-atom recombination) is a rate-determining step for both anodic and cathodic reactions. This mechanism is in contrast with that on GC, which obeys a Volmer-Heyrovsky type mechanism involving the Heyrovsky reaction (atom-ion recombination) as a rate-determining step, *i.e.*, mechanism (A) as revealed previously (22). Mechanisms (A), (B), and (C) are analogous to the mechanism of hydrogen electrode in aqueous systems. It is widely accepted that in acidic solutions the hydrogen evolution on highly catalytic substrates such as Pt obeys the Volmer-Tafel mechanism, while the Volmer-Heyrovsky mechanism prevails on other metals such as Au and Ni, giving smaller exchange current densities (38). Similar kinetic correlation seems to be applied to chlorine evolution in aqueous systems. Several authors suggested that the rate-determining step of the chlorine evolution is the Tafel reaction on RuO_2 electrodes (6, 16, 39) and the Heyrovsky reaction on vitreous (39) and graphite electrodes (40). The electrocatalytic activity of RuO_2 electrodes in the melt, which is associated with the Tafel reaction, may be understandable from this phenomenological aspect.

Conclusions

Ruthenium oxide electrodes have a noticeable electrocatalytic effect on the chlorine electrode reaction in molten $NaAlCl_4$. The exchange current density at the standard conditions (pCl = 1.1, P_{Cl_2} = 1 atm, at 175°C) is 132 ± 22 $\mu A/cm^2$, while the corresponding i_o on GC is 8.9 $\mu A/cm^2$. The chlorine evolution obeys a Volmer-Tafel type mechanism under the activated Temkin condition

$$Cl^- = Cl_{ad} + e^- \quad \text{(fast)}$$

$$Cl_{ad} + Cl_{ad} \rightleftarrows Cl_2 \quad \text{(slow)}$$

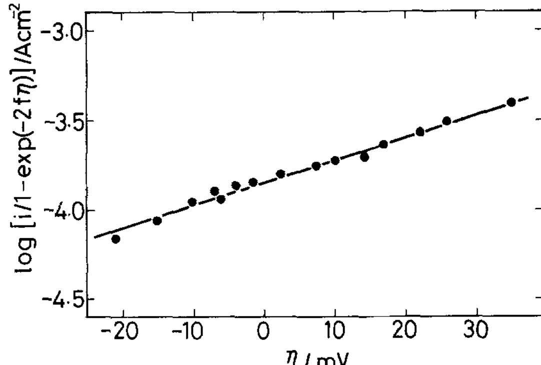

Fig. 10. Polarization behavior of SnO_2-based RuO_2 electrode corresponding to the data of Fig. 4. The data were plotted according to Eq. [11].

The rate-determining step is the combination (Tafel) reaction. The chlorine reduction also obeys the same mechanism in the reverse direction.

Acknowledgment

Part of the experimental data has been obtained by Mr. Isao Sato during his undergraduate research training.

Electrochemical Photovoltaic Cells Based on n-GaAs in Propylene Carbonate

M. E. Langmuir,* P. Hoenig, and R. D. Rauh*

EIC Laboratories, Incorporated, Newton, Massachusetts 02158

ABSTRACT

Electrochemical photovoltaic cells (EPC's) have been characterized based on n-GaAs and propylene carbonate electrolytes. Photovoltages are limited to ~0.7V due to electrode corrosion and lack of specific adsorption by the redox systems studied. Polarization of photo and counterelectrodes, resulting from low redox solubilities and electrolyte conductivities, are responsible for lower fill factors and short-circuit photocurrents for nonaqueous compared to aqueous EPC's. Potentially, these losses can be offset by higher voltages and long-term stabilities, particularly if specifically adsorbing redox couples can be found.

Nonaqueous electrolytes hold the promise of enhancing long-term stability in electrochemical photovoltaic cells (EPC's). In this paper we characterize n-GaAs, propylene carbonate (PC) based EPC's with regard to limitations on photovoltage and photocurrent.

Propylene carbonate has been chosen as a representative solvent for its wide anodic and cathodic stability range, and because we have established procedures for

* Electrochemical Society Active Member.

Key words: photoelectrochemistry, propylene carbonate, gallium arsenide.

its effective drying and purification (1). In addition, PC supports a stable Li^+/Li reference electrode (2) which is simple to use and which can be employed without danger of solution contamination. We note, however, that the low conductivity of PC electrolytes (relative to H_2O) probably prevents its use in practical devices as currently conceptualized. Nevertheless, the aspects of photoelectrochemical operation discovered in PC can be generalized to other nonaqueous systems.

We will first ask: What are the limits to the photovoltage in such a cell? In the ideal two-electrode EPC, the counterelectrode senses the rest potential of the solution and is thus equivalent to V_{redox}. The photoelectrode has a maximum onset voltage corresponding to its flatband potential, V_{FB}, leading to the relation

$$V_{oc} = V_{FB} - V_{redox} \qquad [1]$$

This simple relation is fundamental to EPC operation. The relation is meaningless, however, if the redox couple in the cell is not oxidized or reduced by the photoelectrode so as to stabilize it against photocorrosion. Thus, we further specify the limiting photovoltage in a stable cell by

$$V_{oc}\,(\max) = V_{FB} - V_c \qquad [2]$$

where V_c is the anodic or cathodic corrosion potential of the photoanode or photocathode, respectively. One of the potential advantages of nonaqueous solvents is to allow the maximization of Eq. [1] through the maximization of Eq. [2] assuming that corrosion reactions are rendered more difficult than in H_2O.

Two factors appear to complicate the use of Eq. [1] as a simple predictor for cell design. The first is that V_{FB} is influenced by the redox couple when specific adsorption occurs. For example, in the aqueous-based CdX/X_n^{-2}, X^{-2} cells ($X = S$, Se, or Te), V_{FB} is shifted negative by such adsorption (3). Most documented cases of this kind of influence on V_{FB} occur in protic media due to acid-base equilibria involving surface OH or XH groups (4). Thus, we might be able to test Eq. [1] in aprotic media like PC without this additional variable.

The other complicating factor involves the observation that half-cell photovoltages equivalent to V_{FB} are often unattainable. In solid-state Schottky barrier devices, this is often ascribed to the intermediacy of "surface states" (5). The latter may be viewed as surface-bound redox centers which act as very efficient captors of electrons or holes. As a result, such centers "pin" the Fermi level, thus restricting the photovoltage. It may be possible to modify, chemically, such states. Improvements in cell operation due to certain semiconductor etching treatment, oxidation, hydrogenation, or treatment with Ru^{+3} have been ascribed to such surface-state modification (6-9). Recent observations by Wrighton, Bard and co-workers suggest Fermi level pinning at some semiconductor liquid junctions (10).

The other major question regarding cell operation concerns the factors which influence the photocurrent. The effects on photocurrent yields of redox potential, interaction of the electrolyte with the electrode surface states, and the doping, orientation, and crystalline quality of the photoelectrode are little understood. Surface states can, for example, influence the voltage onset and sharpness of the rise of photocurrent-voltage curves. Recombination via the surface has been used to explain the so-called "foot problem" in EPC *i-V* curves, characteristic of inefficient electrodes with low fill factor (3, 11).

Experimental

Materials preparation and handling.—Several different redox couples were employed in this study. Acetyl ferrocene (acFc), ferrocene (Fc), and NN'-tetramethyl-p-phenylenediamine (TMPD) were sublimed before use. I_2 was also sublimed *in vacuo* before use. Both KI and tetrabutylammonium bromide (Eastman) were dried *in vacuo* over P_2O_5. Bromine (Ventron, ultrapure) was used as received. The propylene carbonate (PC), $LiAsF_6$ electrolyte preparation and purification were described previously (1).

All manipulations were carried out in an Ar-filled glove box containing <10 ppm H_2O. The $acFc^+$, Fc^+, and $TMPD^+$ were produced by electrolysis of acFc, Fc, and TMPD solutions at constant current. Concentrations were verified spectrophotometrically.

Electrochemical cell and reference electrode.—Most experiments were carried out in a demountable thin layer photoelectrochemical research cell shown in Fig. 1. The cell has a liquid path length of ~0.4 mm. Irradiation occurs through an optically transparent electrode of tin oxide (NESA) or indium-tin oxide (NESATRON).

The electrodes are mounted in a Macor machinable glass block. Filling was carried out in the glove box (<10 ppm H_2O, Ar atmosphere) through the holes containing the demountable Pt electrodes. The photoelectrode is provided with an ohmic contact and a Ni lead wire and is sealed into the block using an epoxy cement previously tested for solvent compatibility. All the desired electrochemical and photoelectrochemical measurements can be made in this cell. Typically, one of the Pt electrodes served as a reference electrode, placing V_{redox} at 0 volts in each cell.

As the supporting electrolyte in the cells was $LiAsF_6$, we were able to calibrate the internal reference electrode *vs.* Li^+/Li (in a separate measurement), since PC is compatible with Li metal. The Li^+/Li potential is known *vs.* aqueous SCE in a variety of nonaqueous solvents. The liquid-junction corrected value of $E^\circ(Li^+/Li)$ is $-2.94V$ *vs.* $(SCE)_{aq}$ in PC (12). The potentials of some of the specific redox solutions in PC which we have employed are listed in Table I.

Electrode materials.—All investigations were carried out on the <100> face of an n-GaAs crystal (0.11 Ω-cm, partially Zn compensated) of 0.07 cm^2 area. Usually the n-GaAs surface was etched prior to each experiment according to the procedures of Kohl and Bard (13), which produced a shiny surface with a nonuniform distribution of etch pits (etch A). In several experiments on the effects of surface preparation on n-GaAs photoelectrodes, the matte etching procedure of Parkinson, Heller, and Miller was employed, which produced a high area, nonreflective surface (etch B). Etch B followed by treatment for 30 sec in a 0.01M $RuCl_3$, 0.1M HNO_3 solution is denoted as etch C.

Photoelectrochemical measurements.—Illumination of the working electrode was achieved with a 150W xenon lamp, the output of which was passed through a water filter with Pyrex windows. Light intensity was measured using an EG&G Model 450 Radiometer/

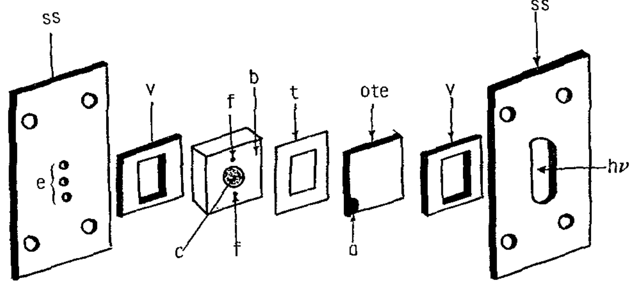

Fig. 1. Demountable thin layer photoelectrochemical research cell. The crystal (c) is mounted in a Macor block (b), which also contains holes (f) for filling and auxiliary wire electrodes. The optically transparent counterelectrode (OTE) is separated by a Teflon spacer (t), and has an Ag epoxy reinforced electrode contact (a). The package is confined using Viton rubber spacers (v) and stainless steel front and back plates (ss) with holes for electrodes (e). The plates are secured with bolts and wing nuts through the four corner holes.

Photometer at a constant distance from the source. The cell was then always placed at that distance. The intensity was adjusted using various neutral density filters. Although the Xe source yields an imperfect representation of the solar spectrum, it is a convenient white light source and is used here to compare results under typical broad band radiation.

Current-voltage curves were obtained with a Wenking LT73 potentiostat. A function generator specially designed for voltammetry provided a linear voltage scan with a preset starting voltage and adjustable scan rate. The current-voltage curves were measured on an X-Y recorder.

Half-cell measurements were made with respect to one of the Pt internal reference electrodes, using the window OTE as the counterelectrode. For solar cell measurements, the OTE was either shorted to the Pt reference electrode, or was used as both the counter and reference electrode. Both configurations gave equivalent results.

Linear sweep voltammograms of the redox couple on n-GaAs were obtained for different light intensities using a Pyrex filter to eliminate the u.v. component below 320 nm of the 150W Xe arc spectrum. The scan rate was 20 mV/sec for all cases. The reported data are not corrected for reflection or light absorption by the OTE or the solution and therefore give a true picture of the efficiency of the cell operated as a solar cell. Measurements of output stability of the solar cells were made at the potential yielding the maximum power on the cell's figure of merit *i-V* curve.

Results and Discussion

Factors influencing the photovoltage.—A typical series of current-voltage curves are shown in Fig. 2 for the cell

n-GaAs | PC, 0.01M $LiAsF_6$ Fc^+/Fc (0.007/0.063M) | optically transparent electrode

In this cell, which contains a rather dilute redox electrolyte, the mechanisms of current and voltage control are evident. In the dark, no anodic current flows. However, a dark cathodic current is observed with an onset of around −0.2V[1] *vs.* Pt/redox. The magnitude of this current is proportional to the concentration of oxidized species. Its onset is considerably positive of the flatband potential of n-GaAs (see below).

The positive onset of dark current with respect to V_{FB} is indicative of a process involving the tunneling of electrons from the conduction band through the space charge region. We have measured this onset as a function of V_{redox}. In Fig. 3, the voltage onset of dark current (V_{dark}) is plotted *vs.* V_{redox}, both on the aqueous SCE scale. In the region from 0 to +1V *vs.* SCE, V_{dark} is directly proportional to V_{redox}. This result would be consistent with a surface-state controlled barrier potential, which would render $V_{FB} - V_{redox}$ independent of V_{redox}. It is also possible that the dark reaction occurs via a few metal-like areas on the crystal surface.

Returning to Fig. 2, we see next that, on irradiation, an anodic photocurrent is produced. The onset of photocurrent at each intensity corresponds to the open-circuit voltage, V_{oc}. It occurs at the voltage where dark and photocurrents are exactly equal. Thus, the dark current-voltage behavior of the photoelectrode is important in determining the open-circuit voltage of the cell. If V_{dark} always occurred at the same potential, we might hope to adjust V_{redox} to minimize the dark current effect. This is, however, not the case, as seen in Fig. 3.

Even though a dark current always opposes the photocurrent, regardless of V_{redox}, cells studied here with large separations between V_{redox} and the apparent flatband voltage (see below) still have larger open-circuit voltages. In Fig. 4, the open-circuit photovoltages of these cells are plotted *vs.* V_{redox}. Note that these are photovoltages of two-electrode cells in which the counterelectrode is the OTE. The measurements were made at a high light intensity, where the photovoltage exhibits saturation. For the couples studied, the variation of V_{oc} at saturation is quite linear with V_{redox} for any given crystal and surface preparation. For crystals cut from the same slice, but for different runs of the same polishing/etching regime, photovoltages are reproducible to about ±10%.

[1] Electrochemical measurements were made in both two- and three-electrode configurations. For the cell featured in Fig. 2, the counterelectrode has been shown to be more polarizable than the n-GaAs, and due to its larger area has a negligible contribution to the total cell polarization at the current levels employed. In other systems where the redox reactions have kinetic limitations, such as in I_3^-/I^- cells, this is not always the case.

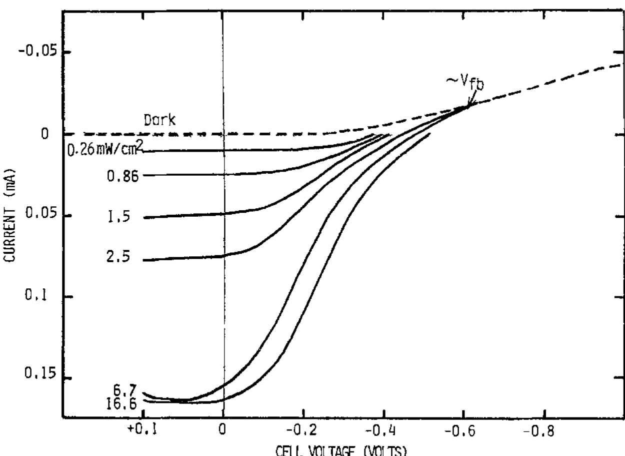

Fig. 2. Current vs. voltage at various light intensities for the photoelectrochemical cell n-GaAs (0.07 cm^2)|Fc^+(0.007M), Fc (0.063M), $LiAsF_6$(0.1M), PC|NESATRON OTE. Light source is an Xe arc, Pyrex filter.

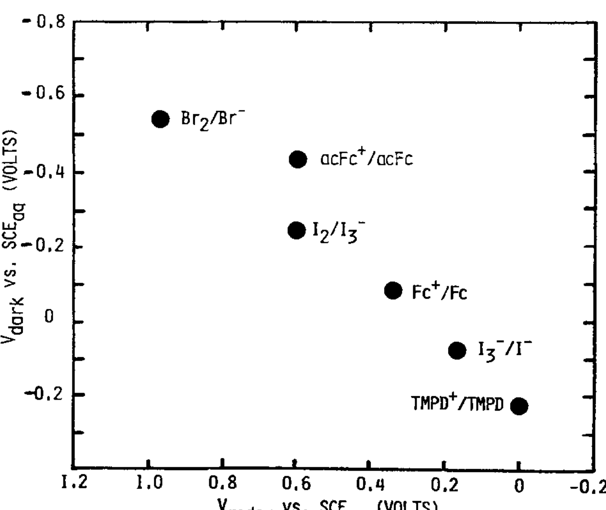

Fig. 3. Variation of voltage onset of cathodic dark current (V_{dark}) with redox potential (V_{redox}) for the half-cell n-GaAs|redox couple, 0.1M $LiAsF_6$, PC.

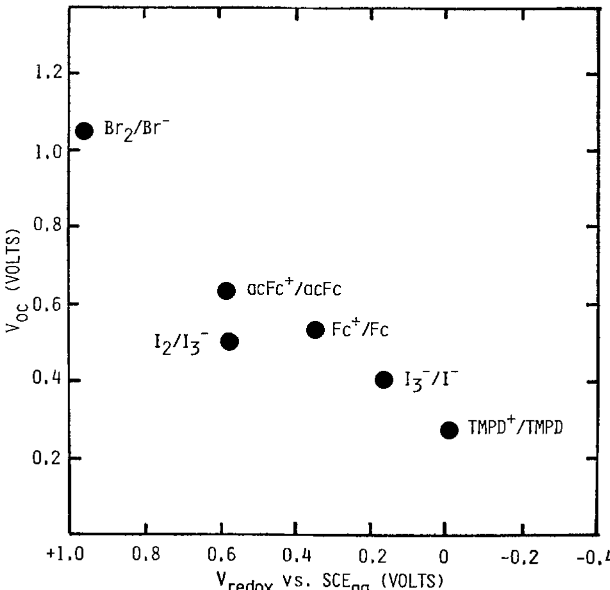

Fig. 4. Variation of open-circuit voltage (V_{oc}) with redox potential (V_{redox}) for the photoelectrochemical cell n-GaAs redox couple, 0.1M $LiAsF_6$, PC|NESA OTE. Illumination is 150W Xe source, 55 mW/cm².

An important point concerning photovoltages in photoelectrochemical cells is illustrated by the case of the Br_2/Br^- couple, which is an exception to the above discussion. With Br_2 present, GaAs corrodes even in the dark according to the reaction

$$2GaAs + 3Br_2 \rightarrow 2Ga^{+3} + 6Br^- \quad [3]$$

Hence, the redox couple is ineffective in stabilizing the semiconductor. In these cases, the cell exhibits a voltage in the dark, approximately given by the difference $V_{redox} - V_c$. This bucking voltage acts in series with the photovoltage, which is now $V_{FB} - V_c$. The difference $V_{FB} - V_{redox}$ can be made large by choosing any redox couple, but the resulting photovoltages cannot be related to the band bending in the photoelectrode unless it is established that the redox couple is indeed photoelectrochemically oxidized or reduced.

In Fig. 5, V_{oc} and V_{dark} of the semiconductor are summarized along with V_{redox}, but with all potentials presented on the aqueous SCE scale. It is seen that V_{oc} under high light intensities is about -0.2V for the n-GaAs half-cell regardless of the redox couple in solution. This either represents the flatband potential of n-GaAs, or is the effective potential of a surface level which, when reduced at more negative potentials, is totally effective in quenching the photocurrent.

Also shown in Fig. 5 are the values of V_{oc} for each cell at the lowest light intensity used, 0.26 mW/cm².

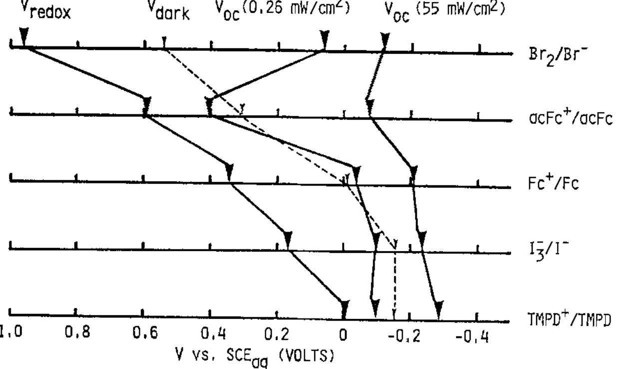

Fig. 5. Diagram showing variations of V_{dark} and V_{oc} at low and high light intensity, with redox couple potential for n-GaAs photoelectrochemical cells in PC.

Except for the case of Br_2/Br^-, these are close to the voltage onsets of cathodic dark current. The trend is toward a larger difference between high and low intensity V_{oc}'s with increasingly positive V_{redox} (discounting, again, Br_2/Br^-). The slopes $dV/d(\log I)$ in the linear region of these plots are revealed in Table II. In a classical photodiode, this slope is 59 mV, but in these cells it is usually somewhat larger. This phenomenon has been noted recently by Sakata *et al.* (14) for some other photoelectrochemical cells. They assign a value of δ to the ratio 59 mV/($dV/d(\log I)$). A small value of δ means that the photocurrent is effective in overcoming the dark current, as is certainly expected under conditions of large band bending. In general, the onset of dark current is more likely to determine the onset of photocurrent at low intensity. However, the onset of photocurrent tends toward V_{FB} at saturation. Hence, measurements made at low intensity are more likely to show "Fermi level pinning," since V_{dark} is proportional to V_{redox} (Fig. 3).

One major issue to be resolved in these and other n-GaAs cells is the true position of the flatband potential. Capacitance-voltage analysis obtained in the dark indicates a flatband potential for n-GaAs in PC of -1.1 ± 0.2V *vs.* SCE, in agreement with Kohl and Bard in acetonitrile (13), although considerable frequency dependence characterizes the slope of the Mott-Schottky plots. However, other estimates of V_{FB} can be made by observing the intersection of dark and light *i-V* curves (cf. Fig. 2) or by measuring the bias voltage at which the instantaneous photovoltage, obtained using a pulsed dye laser, is zero (Fig. 6). Both methods give a V_{FB} of about -0.2V *vs.* SCE. In addition, the plot of V_{oc} *vs.* V_{redox} shown in Fig. 4 extrapolates to the same value of V_{FB}. Comparison with Table II indicates that, if the more positive values of V_{FB} are accepted, then the redox couples employed all have potentials lying within the n-GaAs gap. If the value of -1V is accepted, then several of the couples lie beneath the valence bandedge, and it would be surprising if they could react with photogenerated holes.

We have tested the stability of the n-GaAs cell with all the couples and found over several hours operation at 1 mA/cm² that only the Br_2/Br^- cell shows significant degradation of photocurrent or change in electrode surface morphology as determined by microscopic examination. Furthermore, in all cases except Br_2/Br^-, the photoelectrochemical oxidation of the redox species can be observed visually at the n-GaAs surface. Although this does not prove total stabilization, it does indicate that hole transfer to the reduced redox species is by far the dominant process except with Br^-. Experiments with just Br^- in the electrolyte show no visual evidence of Br_2 production at the irradiated n-GaAs surface.

Therefore, the accumulated results cast doubt on the validity of *C-V* measurements for predicting V_{FB} in this case. It is possible that surface states accessible only at potentials <-0.2V *vs.* SCE influence the capacitance at cathodic voltages, leading to anomalously negative values for V_{FB} determined in this manner.

Photocurrents, fill factors, and cell efficiencies.—The other important features of Fig. 2 are related to the photocurrents. For light intensities of up to 2.5 mW/

cm², the photocurrents are limited by the number of photons absorbed by the n-GaAs and thus by the number of holes produced. At the higher intensities, the photocurrents become limited by the supply of ferrocene to the electrode surface. An approximation of the steady-state diffusional current is given by Eq. [4] (16)

$$i(\text{mA/cm}^2) = \frac{1000nFCD}{d} \quad [4]$$

where d is the electrode separation (~0.04 cm), C is the concentration (in mols/cm³), and D the diffusion coefficient. In the present case, $C = 6.3 \times 10^{-5}$ mols cm^{-3} and 10^{-5} is a reasonable value for D (15). The resulting limiting current is ~1.5 mA/cm². Experimental results of the limiting photocurrents observed for oxidation of 0.05M I^- and 0.032M acFc at n-GaAs are plotted as a function of light intensity in Fig. 7.

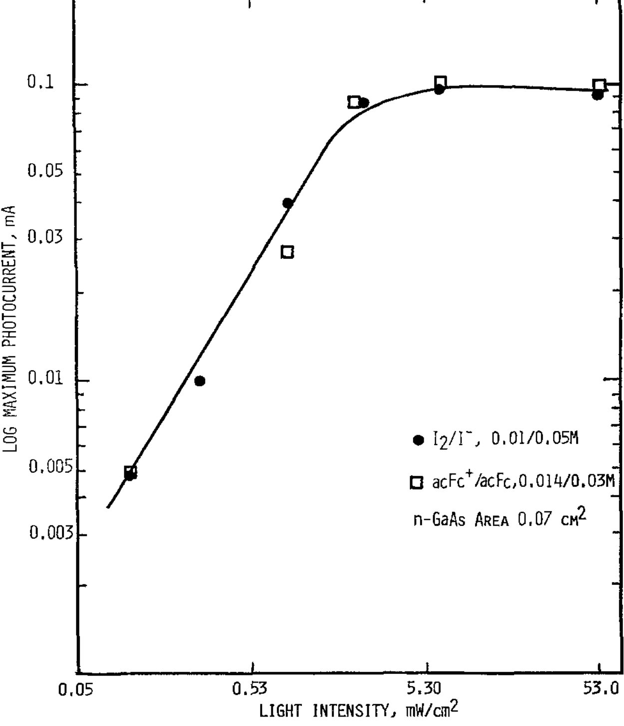

Fig. 7. Limiting photocurrent as a function of light intensity for n-GaAs in PC, 0.1M $LiAsF_6$, redox couple, NESA counterelectrode.

The diffusion-limited current density in both cases is ~1.4 mA/cm², attained at light intensities >5 mW/cm² for these concentrations, close to that predicted by Eq. [4].

The fill factor or "squareness" of the current-voltage curves in the region between 0 volts and V_{oc} is an important variable in determining cell efficiencies. As shown in Fig. 8, contributions to the final curve arise from polarizations at the photoelectrode and counterelectrode, as well as from solution resistance. The production of photocurrent is also sensitive to the efficiency of light absorption and to lifetime of minority carriers. Cells based on n-GaAs/propylene carbonate, Fc^+/Fc (0.007/0.063M) have been tested in which we have varied the counterelectrode, the concentration of supporting electrolyte, and the surface treatment of the n-GaAs. Some of the results are summarized in Table III, and indicate some of the limitations of the present system.

All cells listed in Table III exhibited diffusionally limited currents at high light intensities. Efficiencies in the range where currents were limited only by the hole flux, *i.e.*, 0-2 mW/cm² white light, were 4-8% while efficiencies at solar intensities were <1%. Kohl and Bard (13) have reported the same type of decrease in efficiency with increasing intensity for n-GaAs/acetonitrile-based systems. Short-circuit photocurrents were enhanced by 25-30% by employing a black matte etched GaAs surface rather than a reflective shiny surface. Another increase in photocurrents was observed by decreasing the sheet resistance of the optically transparent counterelectrode. NESA glass (SnO_x, 150 Ω-cm) gave short-circuit currents which were about 50% less than the more conductive, though ~20% less transmissive, NESATRON ($SnO_x \cdot In_2O_{3-x}$, 5 Ω-cm). Fill factors and efficiencies were also enhanced in the NESATRON cells, despite a reduction in voltage which may relate to NESATRON's higher optical absorption. An attempt to decrease the surface recombination velocity by adsorbing Ru^{+3} on the n-GaAs surface proved unsuccessful (surface treatment C, in the table). In the original work by Heller and co-workers, a pretreatment in Se^{-2}/Se_n^{-2} aqueous electrolyte was employed (6, 7). We have demonstrated in other work that such pretreatment is also necessary for observation of the Ru^{+3} effect in nonaqueous electrolytes (17).

At high light intensity, concentration polarization develops for all these cells over the first minute of cell operation. This effect is demonstrated in Fig. 9 for a cell based on 0.007M Fc^+, 0.063M Fc, and is due, at least in part, to the limiting concentration of Fc achievable in PC. The wavelength of the incoming light has a significant effect on the cell efficiency. This is due to the wavelength dependence on solution and semiconductor absorbances, as well as that of photocurrent production due to differences in light penetration depth into the semiconductor. For the GaAs cell, sev-

eral experiments were done with monochromatic light using a 765 nm interference filter and a power of 0.9 mW/cm². At this wavelength, absorbance by Fc^+ is small, and the cell action spectrum is nearly maximized. As shown in Fig. 10, instantaneous conversion efficiencies of 14% were obtained, followed by relaxation to a somewhat lower steady-state value of 9% due to electrode polarization. These values are comparable with those reported by Kohl and Bard for GaAs in acetonitrile using red light. White light from the Xe source of the same intensity gave ~6.6% conversion efficiency.

Conclusions

Measurements of n-GaAs photoelectrodes with a variety of redox couples in PC electrolytes have indicated several limiting factors in EPC devices. Photovoltages were sensitive to the position of V_{redox}, but were limited to $<\sim 0.7V$ by decomposition of the semiconductor. Redox couples which lie too positive of V_{FB}, are likely to act as etchants; indeed, Br_2 is a common etchant for GaAs. Furthermore, the redox couples explored in this work appear not to have adsorptive effects on the onset of photocurrent, which occurred at a common potential of $\sim -0.2V$ *vs.* SCE in all the PC-based systems. In aqueous solutions, negative shifts of V_{FB} due to adsorption of redox species can provide an

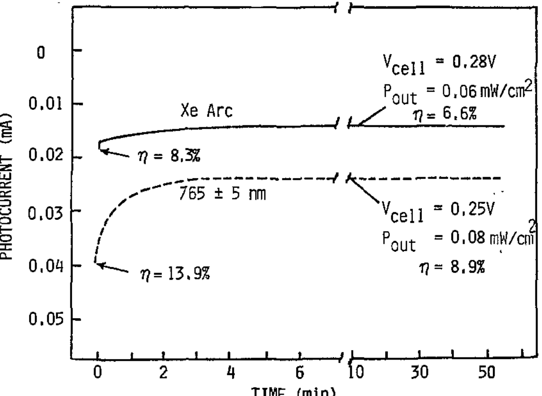

Fig. 10. Output and stability of photoelectrochemical cell n-GaAs (0.07 cm²)|Fc+ (0.007M), Fc (0.063M), LiAsF₆ (0.5M) PC| NESATRON OTE under white light (——) and monochromatic (- - -) illumination of 0.9 mW/cm². Cells operated at voltages (V_{cell}) yielding maximum power.

increased range of photovoltages, *e.g.*, n-GaAs/aqueous Se_2^{-2}, Se^{-2} devices. Although more positive-lying redox couples can stabilize GaAs in PC than in water (*e.g.*, ferrocene, I_3^-), photovoltages are no greater in the nonaqueous systems due to the lack of such adsorptive effects. Nevertheless, nonaqueous systems do have the advantage of allowing a wider variety of stabilizing redox couples than aqueous solutions. We anticipate that less noxious electrolytes than alkaline Se_2^{-2}/Se^{-2} can be developed in nonaqueous systems.

We have shown that efficiencies degrade seriously with increasing light intensity in PC-based electrolytes. We assume these losses to be related to limited redox electrolyte solubility and low electrolyte conductivity. Such losses are accumulated at both cell electrodes and are manifested as reductions in short-circuit currents and fill factors. We note that even the most conductive nonaqueous electrolytes, such as those based on acetonitrile, are still at least ten times more resistive than their aqueous counterparts. Nevertheless, if high photovoltages can be achieved in nonaqueous systems because of their increased stabilizing range, then high efficiencies can be achieved even with reduced currents, *i.e.*, $P_{max} = 10$ mA/cm² $\times$ 1V, rather than $P_{max} = 20$ mA/cm² $\times$ 0.5V. However, surface adsorbed redox couples in nonaqueous electrolytes or other semiconductor surface modifications may be necessary to achieve such high voltages.

Photoelectrochemical Evaluation of the n-CdSe/Methanol/Ferro-Ferricyanide System

Rommel Noufi,*[,1] Dennis Tench,* and Leslie F .Warren*

Rockwell International, Microelectronics Research and Development Center, Thousand Oaks, California 91360

ABSTRACT

Factors limiting the short-circuit photocurrent for the n-CdSe/methanol/ferro-ferricyanide system to 17.5 mA/cm^2 have been identified. The principal limiting factor is apparently specific adsorption of hexacyanoferrate species on the electrode surface, which occurs at higher redox couple concentrations and slows the overall charge transfer process. Ion pairing also occurs, resulting in a low mass transport rate (smaller diffusion coefficients and increased solution viscosity), and probably enhances the degree of specific adsorption.

In a previous publication (1), the systematic development of a nonaqueous ferro-ferricyanide electrolyte for stabilization of n-CdSe photoanodes was described. Selection of the solvent was discussed in terms of inherent stability provided, the rate of the redox reaction, the tendency toward specific adsorption of the redox species, and the equilibrium potential of the redox couple with respect to the flatband potential (attainable open-circuit voltage). Results were presented for cells of the type n-CdSe/methanol, $Fe(CN)_6^{3-/4-}$/Pt which had been operated for up to 700 hr at 6 mA/cm^2 with no detectable degradation in either the electrode surface or the photoresponse.

Although the $Fe(CN)_6^{3-/4-}$/methanol system itself was subsequently found to be photolytically unstable (substitution for cyanide slowly occurs), additional work was warranted since this system serves as a prototype for stabilizing nonaqueous redox electrolytes. In the present paper, the factors limiting the attainable photocurrent for n-CdSe in this system are discussed.

Electrolyte Preparation

Tetraethylammonium ferricyanide was prepared by the metathesis of $Ag_3Fe(CN)_6$ with Et_4NBr (where Et = ethyl) in methanol (2), recrystallized twice from an acetonitrile-acetone mixture, and then subjected to high vacuum to remove traces of solvent. Tetraethylammonium ferrocyanide was prepared as an off-white crystalline powder by anaerobic neutralization of $H_4Fe(CN)_6$ (3) with excess Et_4NOH (Southwestern Analytical Chemicals) in water, treated *in vacuo* to remove the solvent, and recrystallized from an i-propanol/acetone mixture in an inert atmosphere. This chemical procedure for preparing the air-sensitive $(Et_4N)_4Fe(CN)_6$ is faster and less tedious than the electrochemical synthesis used previously (1). Tetraethylammonium fluoroborate was precipitated from a solution of Et_4NBr and 48% fluoroboric acid in ethanol by addition of i-propanol, and was then recrystallized twice from ethanol. The methanol solvent (Baker Analyzed) was refluxed over Mg, and then fractionally distilled under an inert atmosphere.

Electrodes

Reference electrodes were isolated in a separate compartment which was connected to the main cell through a medium glass frit. Both Ag/AgCl and saturated calomel reference electrodes were used with comparable results.

The Pt disk electrode (0.13 cm^2) used to study the kinetics of the $Fe(CN)_6^{3-/4-}$/Pt reaction was mounted concentric and flush with the end of a 12 mm diam Kel-F cylinder by hot pressing. After mounting, the electrode was polished on successively finer aqueous alumina powder slurries to 1 μm particle size, and was then cleaned ultrasonically in water. Before each use, the electrode was further cleaned by immersion in boiling concentrated nitric acid.

The n-CdSe electrodes (0.18 cm^2 × 1 mm thick) were cut from rods supplied by Cleveland Crystals, Incorporated (Cleveland, Ohio) and had from 10^{16} to 10^{18} carriers/cm^3. Ohmic contacts were made with an In-Ga alloy. Before use, n-CdSe electrodes were polished to 0.05 μm particle size, then etched in 3*M* nitric acid or a 1:25 mixture of concentrated nitric and hydrochloric acids (with comparable results). For long-term studies, n-CdSe electrodes were mounted in Kel-F by hot pressing. Results for electrodes mounted in silicone adhesive/sealant (Dow Corning Corporation, Midland, Michigan) were comparable.

[1] Present address: Solar Energy Research Institute, Golden, Colorado 80401.

Key words: semiconductor photoanodes, nonaqueous solvents, performance characteristics.

Electrochemical Measurements

All electrochemical measurements were made in Pyrex glass cells inside an inert atmosphere dry box using a PAR Model 173 Potentiostat/Galvanostat in conjunction with a PAR Model 175 Universal Programmer. The effects of solution resistance were always eliminated by electronic *iR* compensation. Electrodes were illuminated by a tungsten-halogen lamp through a quartz window. The illumination intensity was measured with a Pyroelectric Radiometer (Molectron, Sunnyvale, California).

Results and Discussion

Performance characteristics were measured for n-CdSe photoanodes in methanol solutions as a function of the ferro-ferricyanide redox couple concentration. The best output parameters (5.5% conversion efficiency, FF = 0.47) were obtained for electrodes with 5×10^{16} carriers/cm^3 in solutions containing 0.25*M* each of chemically prepared $Fe(CN)_6^{3-/4-}$ species. A typical power curve is shown in Fig. 1. The measured open-circuit voltage is very close to the maximum value expected for this system (0.7V). Photocurrent measurements as a function of light intensity indicated that the maximum stable short-circuit current is 17.5 mA/cm^2 in stirred solutions and 7.5 mA/cm^2 in unstirred solutions (at 95 mW/cm^2). Transient photocurrents were larger at higher light intensities but rapidly decayed to the steady values. Currents of 17.5 mA/cm^2 were passed for as long as 2 hr.

Possible causes for such photocurrent limitations include decreased redox reaction rate and/or inadequate mass transport of the redox species in the electrolyte caused by ion pairing and/or specific adsorption of one or both of the electroactive species. The inherent electrode kinetics for the ferro-ferricyanide couple in methanol were studied by cyclic voltammetry at a rotating Pt disk electrode (4). Kinematic viscosity measurements were made as a function of the redox couple concentration so that the relative effects of changes in the fluid flow characteristics, reactant diffusion coefficients, and electron transfer rate could be ascertained. The dependence of the photocurrent for n-CdSe photoanodes on light intensity was determined in both the methanol/ferro-ferricyanide and the established aqueous polysulfide systems as a means of detecting solid-state limitations.

Figure 2 shows plots of the diffusion-limited currents (i_L) for the ferro-ferricyanide reaction at a rotating Pt disk electrode as a function of the redox couple concentration. For both the anodic and cathodic branches, i_L goes through a maximum at about 0.15*M* $Fe(CN)_6^{3-/4-}$. Also, at concentrations above 0.05*M*, specific adsorption becomes significant, as indicated by higher Tafel slopes (180-250 mV/decade) than obtained at lower concentrations (~120 mV/decade). The decrease in i_L at higher concentrations could result from a decrease in the diffusion coefficient of the hexacyanoferrate species, stemming from increased ion pairing, and/or an increase in the electrolyte viscosity. That i_L is practically diffusion limited at all redox couple concentrations is shown by the Levich plots (4) in Fig. 3.

Figure 4 shows plots of the diffusion coefficients for the $Fe(CN)_6^{3-/4-}$ species (calculated from the Levich equation) and the electrolyte kinematic viscosity (measured with a Cannon-Fenske viscometer) *vs.* the redox couple concentration. The viscosity is practically constant at low $Fe(CN)_6^{3-/4-}$ concentrations but increases sharply at about 0.2*M*, which corresponds approximately to the maximum in the diffusion-limited current for the redox reaction (0.15*M*). However, the diffusion coefficient decreases by almost an order of magnitude (from 28×10^{-6} to 3×10^{-6} cm^2/sec) from 0.01 to 0.1*M* $Fe(CN)_6^{3-/4-}$, indicating that considerable ion pairing occurs even at relatively low redox couple concentrations. Ion pairing of hexacyanoferrate species with tetraalkylammonium cations in solvents with low acceptor numbers has also been detected polarographically (2).

The relative effects of the electrolyte kinematic viscosity (ν) and the diffusion coefficients (D) in reducing the diffusion-limited currents can best be seen by plotting $D^{2/3}$ and $\nu^{-1/6}$, which are the terms appearing in the Levich equation (4)

$$i_L = 1.94 \times 10^7 C_R D_R^{2/3} \nu^{-1/6} \omega^{1/2}$$

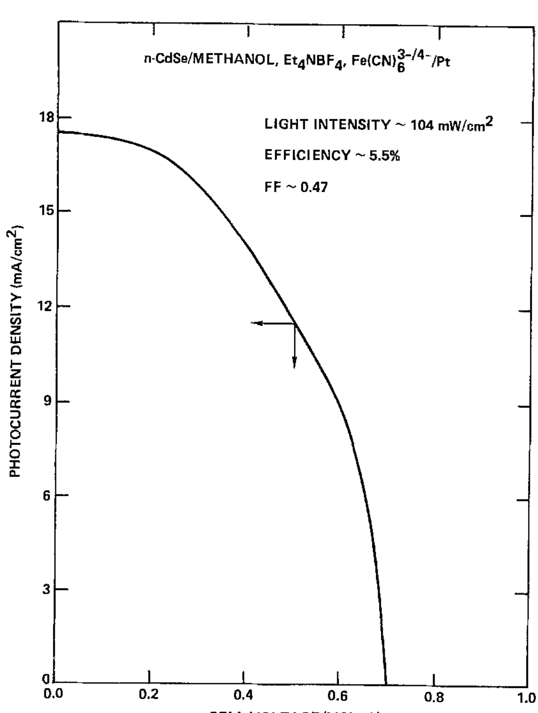

Fig. 1. Photocurrent density *vs.* voltage for the cell n-CdSe/methanol, 0.25*M* $Fe(CN)_6^{3-/4-}$, 0.1M Et_4NBF_4/Pt under illumination at 104 mW/cm^2.

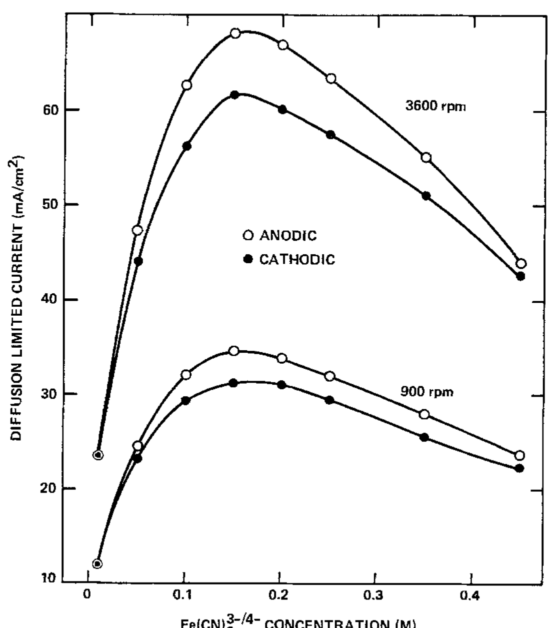

Fig. 2. Diffusion-limited currents *vs.* the $Fe(CN)_6^{3-/4-}$ concentration for a rotating 0.13 cm^2 Pt disk electrode in methanol/0.1*M* Et_4NBF_4 electrolyte containing equal concentrations of the oxidized and reduced species. The scan rate was 20 mV/sec and i_L was determined at an overvoltage of 1.00V in each case.

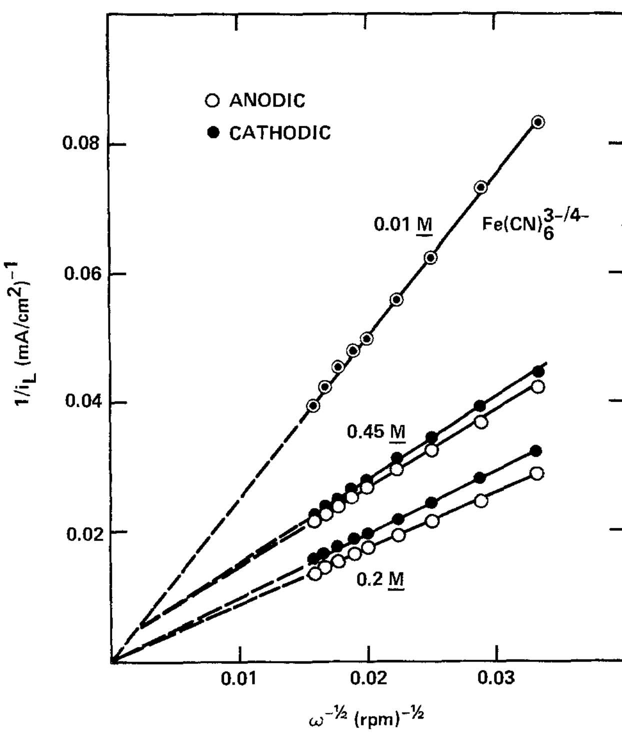

Fig. 3. Levich plots (4) for the $Fe(CN)_6^{3-/4-}$ reaction at a rotating Pt disk electrode in methanol/0.1*M* Et_4NBF_4 (conditions same as for Fig. 2).

where i_L is in mA/cm^2, C_R is the concentration of reactant in mol/ml, D_R is the reactant diffusion coefficient in cm^2/sec, ν is the electrolyte kinematic viscosity in cm^2/sec, and ω is the disk electrode rotation rate in rpm. Such plots are shown in Fig. 5, where $\nu^{-1/6}$ is seen to decrease linearily and relatively slowly (note scale difference) with $Fe(CN)_6^{3-/4-}$ concentration,

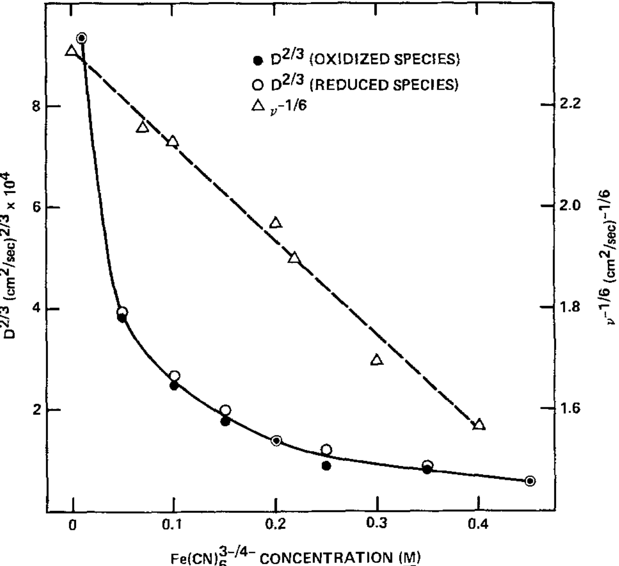

Fig. 5. Plots of $D^{2/3}$ and $\nu^{-1/6}$ for the data in Fig. 4

whereas $D^{2/3}$ decreases sharply to about 0.1*M* and then more gradually. Thus, the decrease in i_L at concentrations above 0.15*M* results from a combination of the effects of $\nu^{-1/6}$ and $D^{2/3}$.

Plots of the short-circuit photocurrent at single crystal n-CdSe photoanodes in 0.25*M* $Fe(CN)_6^{3-/4-}$/methanol and in aqueous polysulfide electrolyte *vs.* light intensity are shown in Fig. 6. The linear plot (passing through the origin) for the aqueous system indicates that solid-state limitations are not predominant. Therefore, the nonlinearity in the methanol/$Fe(CN)_6^{3-/4-}$ plot and the upper limit of 17.5 mA/cm^2 for the steady-state photocurrent are apparently associated with electrolyte effects. The data can be adequately explained by assuming the occurrence of strong specific adsorption of a ferricyanide species, which is the product of the photoelectrochemical redox reac-

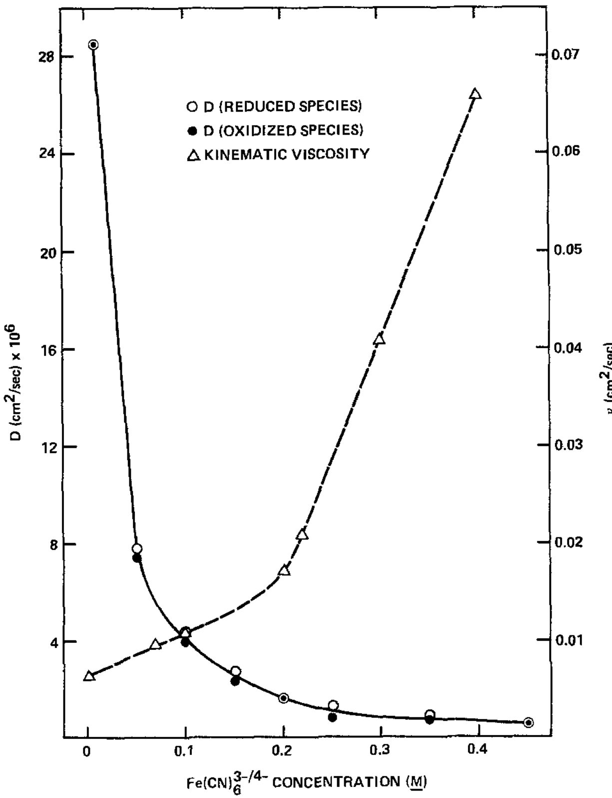

Fig. 4. Plots of the diffusion coefficients (*D*) of $Fe(CN)_6^{3-/4-}$ species and the kinematic viscosity of 0.1*M* Et_4NBF_4/methanol solutions as functions of the $Fe(CN)_6^{3-/4-}$ concentration.

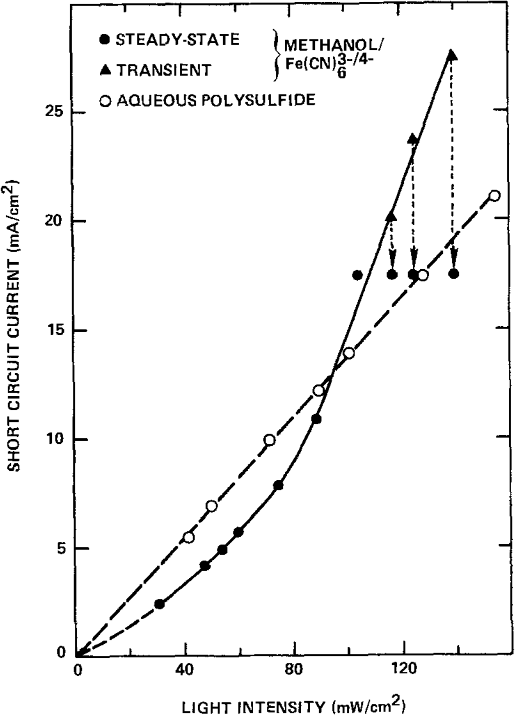

Fig. 6. Short-circuit currents vs. light intensity (tungsten-halogen lamp) for n-CdSe electrodes in 0.25*M* tetraethylammonium $Fe(CN)_6^{3-/4-}$/0.1*M* Et_4NBF_4/methanol and in aqueous 2.2*M* Na_2S/0.1*M* S/0.1*M* NaOH electrolytes.

tion. Thus, at the lower light intensities, for which the currents are lower, the reaction rate is under mixed electron transfer/product desorption control, *i.e.*, the rates of electron transfer (which is determined by the availability of photoholes in the semiconductor) and product desorption are comparable. As the light intensity (and consequently the current) is increased, the electron transfer rate increases and product desorption becomes the slow reaction step. In this case, higher currents can be passed for a short time but product accumulation on the electrode surface ultimately limits the current to a constant value determined by the rate of desorption. This model is consistent with the transient photocurrents (at the higher light intensities) decaying to the steady-state value (Fig. 6), and with the higher Tafel slopes (on Pt) for higher redox couple concentrations. The adsorbed species may be either the ferricyanide species normally present in solution or some reaction intermediate, and it may be ion paired since the viscosity data indicate that ion pairing is prevalent at $Fe(CN)_6^{3-/4-}$ concentrations above 0.1*M*. Note that specific adsorption is known to also occur for the aqueous polysulfide system but would not affect the linearity of the corresponding plot in Fig. 6 if adsorption/desorption is fast compared to the electron transfer step, which involves two electrons.

Summary and Conclusions

The photocurrent for n-CdSe photoanodes in the methanol/ferro-ferricyanide system is limited to 17.5 mA/cm^2, apparently by specific adsorption of ferricyanide redox species. Ion pairing in this system also has a pronounced effect on the redox couple diffusion coefficients and the electrolyte viscosity at higher redox couple concentrations. Such factors would be expected to be of general importance in photoelectrochemical cells employing nonaqueous electrolytes.

Kinetics of Electroless Copper Plating

V. Mass Transport at Cylindrical Surfaces

Francis M. Donahue*

Department of Chemical Engineering, The University of Michigan, Ann Arbor, Michigan 48109

In a previous communication, properties of mass transport in electroless copper plating baths were presented for the common case of linear transport (1). Since some studies have been performed on cylindrical samples (2-4), it is worthwhile to determine the effects of this geometry on mass transfer phenomena.

The steady-state mass balance for a transporting species, "j," for cylindrical geometry in the absence of a homogeneous reaction and with concentration variation only in the radial direction is

$$\frac{d^2c_j}{dR^2} + \frac{1}{R}\frac{dc_j}{dR} = 0 \qquad [1]$$

The boundary conditions for the case considered here are

$$c_j = c_{sj} \quad \text{at} \quad R = R_o \qquad [2a]$$

and

$$c_j = c_{bj} \quad \text{at} \quad R = R_o + \delta \qquad [2b]$$

The solution of Eq. [1] for these boundary conditions is

$$c_j = c_{bj} + (c_{sj} - c_{bj}) \frac{\ln\left(\frac{R_o + \delta}{R}\right)}{\ln\left(\frac{R_o + \delta}{R_o}\right)} \qquad [3]$$

The flux of the transporting species at the sample-solution interface is

$$N_j = -10^{-3}D_{jm}(dc_j/dR)_{R=R_o} \qquad [4]$$

Differentiating Eq. [3] and setting $R = R_o$, the flux becomes

$$N_j = (10^{-3}D_{jm}/\delta)(c_{sj} - c_{bj}) \frac{\delta/R_o}{\ln(1 + \delta/R_o)} \qquad [5]$$

Comparing Eq. [5] with Eq. [1a] of Ref. (1) shows that the flux at a cylindrical sample reduces to that for linear transport when the ratio of the boundary layer thickness to the sample radius is less than 0.1.

* Electrochemical Society Active Member.
Key words: mass transport, baths, plating.

The boundary layer thickness for rotating cylinders can be computed from the macroconvection mass transfer coefficient (1) and the diffusivity. The boundary layer thickness for the cylinders used by Dumesic and co-workers (3) at the lowest rotation speed (150 rpm) was computed using Donahue's corrected value of the macroconvection mass transfer coefficient (1) and their diffusivity for cupric ion. Since the ratio, δ/R_o, was less than 0.01, the flux of cupric ion was correctly described by the authors in terms of the linear transport equation.

When microconvection controls the transport process (*e.g.*, in the absence of forced convection, but the presence of gas evolution), the boundary layer thickness is a function of the plating rate (1), *i.e.*

$$\delta = 0.026\, r_p^{-0.53} \quad [6]$$

Insertion of Eq. [6] in Eq. [5] provides some insight into the roles of plating rate and sample radius under these conditions. However, it is more convenient to define an "effective" mass transfer coefficient, k_{cj}', by

$$k_{cj}' = \frac{10^3 N_j}{c_{sj} - c_{bj}} \quad [7]$$

or, from Eq. [5]

$$k_{cj}' = \frac{D_{jm}/R_o}{\ln (1 + \delta/R_o)} \quad [8]$$

which can be rearranged to

$$\frac{k_{cj}'}{D_{jm}} = \frac{1/R_o}{\ln (1 + \delta/R_o)} \quad [9]$$

where the right-hand side of the equation is a function of the plating rate and sample radius and independent of the transporting species. Figure 1 shows the behavior of the left-hand side of this equation as functions of sample radius and plating rate. From this figure one concludes that the stationary cylinders of Dumesic and co-workers (3) exhibited linear transport even at the lowest plating rates. On the other hand, the wire samples of Donahue and co-workers (2, 4), *i.e.*, $R_o = 0.016$ cm, exhibit substantial deviation from the linear transport line even at the highest plating rates. Therefore, when computing interfacial concentrations, they cannot use the linear transport equations given previously (1), but must use Eq. [5].

Electrodeposition of Palladium on Iron and Steel for Electrochemical Hydrogen Permeation Studies

R. Driver*

CSIRO Division of Applied Physics, Sydney, Australia 2070

In the highly sensitive electrochemical technique for studying hydrogen permeation in metals (1, 2), a thin test membrane acts as a bipolar electrode in a two-compartment cell. A fraction of the hydrogen produced at the cathodically polarized (inlet) side diffuses through the membrane and is oxidized as it reaches the anodically polarized (exit) side. To obtain meaningful permeation rate data, it is necessary to ensure that ionization of hydrogen at the exit surface occurs much faster than the competing, nonelectrochemical, hydrogen atom recombination reaction, and that the measured ionization current is free of any spurious components associated with anodic dissolution or passivation of the exit surface.

* Electrochemical Society Active Member.

Key words: membrane, permeation, metals.

In principal, these objectives may be achieved by coating the exit surface with a very thin layer of palladium, an inert and highly permeable material which has virtually no effect on the overall rate of hydrogen transport. Electrolytic deposits have usually been employed, but descriptions of the plating methods are both meager and conflicting and very little attention has apparently been directed at monitoring the thickness or integrity of the coatings. As pointed out by Heidersbach *et al.* (3), there is wide variation in existing hydrogen permeation data and this could be due partly to poor control of the palladium deposits applied to membrane exit surfaces.

The present work was undertaken to establish a simple and reliable laboratory method for obtaining good quality palladium electrodeposits on iron and steel, the materials most commonly used in hydrogen diffusion studies. A simple porosity test was used to determine the minimum deposit thickness for complete coverage. The chemical factors underlying the operation of the plating bath are discussed briefly.

Experimental

Sample preparation.—Plating experiments were performed on coupon specimens of surface area 4-10 cm^2, cut from Johnson Matthey "Specpure" iron sheet, 1.0 mm thick, and from bright mild steel sheet, 0.78 mm thick. After degreasing in hot petroleum (bp 100°-120°C), any rust or oxide bloom was removed by treatment with a commercial acid-based rust remover, or alternatively, by appropriate pickling in 0.5M H_2SO_4. The former procedure had the advantage of leaving a brilliantly clean surface, almost free of etching. The samples were then rinsed in distilled water, dried with alcohol, and finally polished with steel wool.

Plating solution.—The alkaline plating electrolyte was prepared from palladium diammine dinitrite, $Pd(NH_3)_2(NO_2)_2$ ("Palladium P Salt"), using the composition recommended by Hedrich and Raub (4), *i.e.,* 0.1M $Pd(NH_3)_2(NO_2)_2$, 100 g/l NH_4NO_3, and 10 g/l $NaNO_2$, with addition of sufficient ammonia to adjust the *p*H between 8 and 10. It is convenient to dissolve the palladium complex in ammonia solution before adding the other constituents. The solution is then diluted approximately to volume and *p*H adjusted (using graduated indicator paper) either by further addition of ammonia or by warming the solution to expel the excess. The question of the optimum bath *p*H is discussed later. The same bath may be prepared just as conveniently by substituting 0.1M palladium nitrate, $Pd(NO_3)_2$, for the nitrite complex, in which case the required sodium nitrite concentration is 24 g/liter.

Electroplating procedure.—Experiments to establish a satisfactory plating procedure were performed in a simple beaker cell. The current source was a Wenking Model POS73 scanning potentiostat operated in galvanostatic mode with an external control resistor. The anode was a sheet of bright platinum foil, the area of which was comparable with that of the cathode specimen. The cell was first filled with 0.5M H_2SO_4 and the specimen was activated by anodic polarization at 5 mA/cm^2 for 30 sec. The cell and electrodes were then rinsed quickly with dilute ammonia to ensure complete removal of hydrogen ions, the plating solution introduced, and deposition commenced immediately, without stirring, at a current density of 20 mA/cm^2. The current was maintained at this value for 30 sec, and then reduced uniformly at 0.5 mA/cm^2 sec to a constant value of 5 mA/cm^2 and deposition continued for a further 18 min. Plated specimens were dried with alcohol, and the coating thickness was determined from the gain in mass. All experiments were conducted at 22°C.

Porosity test.—Porosity was assessed using a method based on the Ferroxyl test for detecting pinholes in tinplate (5). Specimens were just submerged in a solution containing 0.2M $K_3[Fe(CN)_6]$ and 0.0025M KCl. Exposed iron is rapidly attacked, and within a few minutes, the presence of pores is revealed by telltale spots of "blue rust" formed by reaction between ferrous and ferricyanide ions.

Results and Discussion

Although various plating solutions have been mentioned for palladium (6), the above formulation is better suited to laboratory applications and under appropriate conditions is capable of yielding smooth deposits with a high gloss, even from an unstirred bath. The given procedure yielded pore-free coatings 1.5-1.6 μm in thickness for a total plating time of about 19 min, corresponding to a current efficiency of 55-60% (at 100% current efficiency, the Pd deposition rate at 5 mA/cm^2 is 0.138 μm/min). Deposits generally displayed some porosity at thickness < 1.3 μm, although this could be as little as 1-2 pores/cm^2 at about 1 μm. Sample cleanliness is essential for the attainment of pore-free deposits. Except in the case of extremely thin foil specimens, a palladium coating of about 2 μm will not materially affect the hydrogen permeation kinetics.

The relatively high initial current density was designed to obtain more or less complete coverage as soon as possible. This procedure was prompted by the gradual formation of an unidentified precipitate containing iron during deposition attempts at current densities < 1 mA/cm^2. Initial plating densities exceeding 20 mA/cm^2 are not recommended, as the deposit structure may suffer due to increasing hydrogen content (7). The follow-up plating density of 5 mA/cm^2 was chosen to maximize current efficiency and to minimize the degree of hydrogen ion buildup at the anode, the effects of which are discussed later.

With this bath, discharge of palladium takes place from the tetrammine palladium (II) ion, formed according to the equilibrium

$$Pd(NH_3)_2(NO_2)_2 + 2NH_3 \rightleftharpoons [Pd(NH_3)_4]^{2+} + 2NO_2^-$$

and hence the performance is very dependent on the *p*H. As the *p*H is lowered, the tetrammine gradually reverts to the insoluble diammine complex and palladium deposits (7) obtained at *p*H 7-8 reportedly contain occluded $Pd(NH_3)_2(NO_2)_2$. This can eventually lead to blistery coatings at *p*H < 7. As the *p*H increases, reduction of the $[Pd(NH_3)_4]^{2+}$ ion occurs at more negative potentials which favor discharge of hydrogen. These effects determine the recommended operating range of *p*H 8-9. Since the bath loses ammonia continuously on exposure to the atmosphere, regular *p*H checks are essential.

The low current efficiency of this bath, even under optimum conditions of *p*H and current density, is apparently due to reduction of nitrite and/or nitrate ions (4), rather than hydrogen discharge, which only becomes important at high *p*H or at current densities >30 mA/cm^2. The efficiency of the unstirred bath also depends on the palladium concentration, which should be maintained fairly close to the recommended value of 0.1M. When the palladium content had been depleted by 20-30%, the observed current efficiency dropped below 50%, and more importantly, deposits of given thickness were significantly more porous than those from a relatively fresh solution. Efficiency and performance were fully restored by appropriate evaporation. Alternatively, the bath may be replenished by addition of the palladium complex dissolved in dilute ammonia. In the absence of proper *p*H control, the bath can be depleted very rapidly by crystallization of $Pd(NH_3)_2(NO_2)_2$ on the anode, where the dis-

charge of hydroxyl ions causes a substantial drop in local pH, *i.e.*

$$2\,OH^- \rightarrow O_2 + 2H^+ + 4e$$

followed by

$$[Pd(NH_3)_4]^{2+} + 2NO_2^- + 2H^+ \rightarrow Pd(NH_3)_2(NO_2)_2 + 2NH_4^+$$

At 5 mA/cm^2, crystallization was only observed at pH $\leq$ 8, but higher current densities might be expected to exacerbate this problem.

Conclusion

Good quality palladium electrodeposits on iron and steel may be readily obtained from an unstirred bath at room temperature. Complete coverage and passivation of these substrates requires an electroplated coating >1 μm and preferably 1.5-2 μm thick. A palladium layer of these dimensions will not affect the rate of hydrogen transport through ferrous specimens. The coatings should be individually checked for porosity as this could vary with different substrates.

Dependence of Flatband Potentials of n-TiO_2 on Electrolytes and Electrolyte Concentrations

James R. Wilson and Su-Moon Park*

Department of Chemistry, University of New Mexico, Albuquerque, New Mexico 87131

The flatband potential of a semiconductor electrode is an important parameter in designing a photoelectrochemical cell. The importance of the flatband potential of a given semiconductor material in locating energy levels of the conduction and valence bands (1-3), and for predicting its stabilities has been discussed elsewhere (4-6). Flatband potentials have been reported to be dependent on the pH of the medium (1, 3). The pH dependency of flatband potentials has been characterized by a straight line with a slope of 59 mV/pH according to the equation

$$E_{FB} = E_{FB}^\circ - 0.059\ pH$$

where E_{FB}° is the value at pH = 0. The pH dependency is ascribed to the adsorption of the hydroxyl ion at the electrode surface (1), which in turn is dependent on the pH of the medium.

In the present note, we report the effect of electrolytes and electrolyte concentrations on the flatband potential of an n-TiO_2 electrode. This study was carried out on the assumption that electrolyte species other than the hydronium or hydroxyl ion could also be the potential determining species at the semiconductor-electrolyte interface.

Reagents used were of reagent or analytical reagent grade and obtained from Baker, Eastman Organic, Mallinkrodt, or Merck. Most reagents were used as received, but a few salts were recrystallized from double distilled water. A Princeton Applied Research (PAR) 175 Universal Programmer, a PAR 173 potentiostat-galvanostat, and a PAR 176 I/E converter have been used to control the potential at the working electrode and to record the photocurrent. A Tectronics Model 5115 storage oscilloscope was used to record faster measurements such as the capacitance current produced by applying a small triangular a-c signal (± 10 mV) superimposed on a d-c bias potential. An Oriel 450W Xe arc lamp powered by an Oriel 8540 Universal power supply was used as a light source. Monochromatic light was produced by an Oriel 7240 monochromator (bandpass = 20 nm). The illumination intensity was measured with the International Light Model 700 Radiometer. The pH was monitored by a Cambridge 5-700 combination electrode with a Sargent-Welch Model NX Digital pH meter. The photocurrent was recorded on a Houston Model 2000 X-Y recorder.

The electrolyte concentration was controlled by dispensing small volumes of a concentrated electrolyte solution from a buret. This has the advantage of maintaining the same electrode position in the solution throughout the experiment.

An n-TiO_2 electrode, furnished by Dr. Mike A. Butler, Sandia Laboratories, was cut from a large single crystal perpendicular to the c-axis. The TiO_2 electrode was doped in a quartz tube furnace under the hydrogen atmosphere at 450°C for 2 hr, whenever necessary. The electrode thus doped had a donor density of $\sim 1.0 \times 10^{19}/cm^3$, as measured from the slope of a Mott-Schottky plot (1, 2).

Due to the irreproducibilities encountered in flatband potential measurements by the Mott-Schottky method (7, 8), a photoresponse method (9) was used. This method is based on a measurement of the photocurrent (I) as a function of the applied potential (E). From the I-E measurements, a plot of I^2 *vs.* E was obtained. The flatband potential was then obtained from the intercept of the E-axis. Since the results obtained from this method were found to be affected by experimental parameters such as the voltage scan rate and the wavelengths of light illuminated (10), we employed a scan rate of 1 mV/sec and a wavelength of 360 nm for electrode illumination. The illumination intensity was about 0.71 mW/cm^2. In order to check the reproducibility of this method, the pH dependency of the flatband potential was obtained; an extremely well-correlated straight line with a slope of −53 mV/pH was observed.

* Electrochemical Society Active Member.

Key words: flatband potential, complexation effect, n-TiO_2.

Of eight inorganic salts studied, only one showed a slight concentration effect on the flatband potential. Compounds such as NaCl, KCl, NaI, KNO_3, Na_2SO_4, K_2SO_4, and $NaClO_4$ did not show any effects. The values of flatband potentials of TiO_2 were the same in solutions of these salts and independent of their concentrations. Addition of NaH_2PO_4 to water moved the flatband potential to a more positive value, which would be expected from the resultant change in *p*H. While the flatband potential varied slightly with NaH_2PO_4 concentration, E_{FB} values corrected against the corresponding change in *p*H were constant.

The fact that most inorganic salts did not exert any effects on flatband potentials indicates that both cations and anions of the salts studied did not show significant specific adsorption toward the electrode material. A small change in the flatband potential when NaH_2PO_4 was added has been ascribed to the change in *p*H due to the hydrolysis of the salt. Thus, we decided to perform the same study for complexing agents. Complexing agents used were NaCN, sodium citrate, ethylenediaminetetraacetic acid (EDTA), and 8-hydroxyquinoline. Of these, neither NaCN nor sodium citrate showed any significant effects, while EDTA and 8-hydroxyquinoline did. The effect of the concentration of EDTA on the flatband potential of n-TiO_2 is shown in Fig. 1. Note that the measurements were made in solutions of *p*H's 11 and 12. The intercept of the two curves shown in Fig. 1 was identical with the E_{FB} values that were obtained at $pH = 11$ and 12 without EDTA present for its *p*H-dependence studies. The effects shown in Fig. 1 were not observed at lower *p*H's. This indicates that the dissociated form (Y^{4-}) of EDTA (H_2Y^{2-}) according to the equilibrium reaction

$$H_2Y^{2-} \rightarrow 2H^+ + Y^{4-}$$

is important as a potential determining species at the electrode surface. Indeed, when the shift in the flatband potential is normalized by dividing it by the molar concentration of the dissociated form of EDTA ($[Y^{4-}]$), it was approximately constant with about 9% average deviation. The normalized shift thus calculated was ~0.36 V/*M* Y^{4-}. The fact that Y^{4-} is a potential determining species also implies that the complexation of Y^{4-} with surface ions may be responsible for the observed results.

For 8-hydroxyquinoline, the results were similar. No effects were observed at low *p*H, whereas the flatband

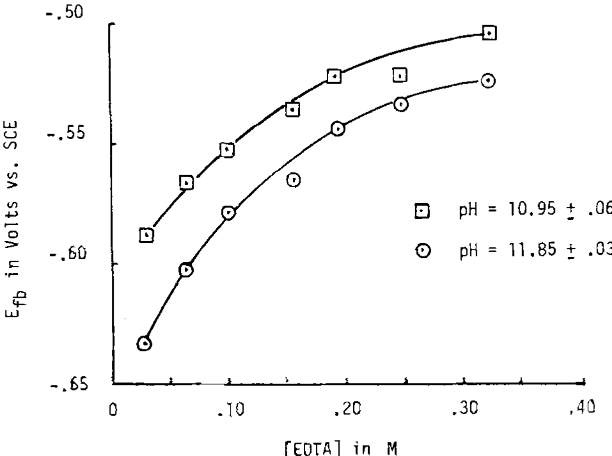

Fig. 1. The flatband potential of an n-TiO_2 electrode as a function of the EDTA concentration. Wavelength of light illuminated was 360 nm.

potential shifted to a more positive direction at high *p*H, where hydroxide on the 8-hydroxyquinoline (8-HQ) molecule would be dissociated. The shift in the flatband potential was to the extent of 0.14V at a 8-hydroxyquinoline concentration of 27 mM. At a higher 8-HQ concentration, no photocurrent was observed.

We attribute the observed behavior to the complexation of donor ions such as Ti^{3+} at the semiconductor surface. When EDTA or 8-hydroxyquinoline is present in the solution, the dopants at the surface may be complexed, shifting the energy levels of the electron donor ions. We believe that the surface complexation affects the energy level of the semiconductor more than of the solution side. This will shift the flatband potential in a more positive direction. The complexation effect was more dramatic for 8-HQ, probably because it forms the insoluble complex (precipitate), possibly blocking the electrode surface.

The reason that the addition of cyanide and citrate did not affect the flatband potential may be that these ions are not strong enough complexing agents toward Ti^{3+}. It is readily predicted that both EDTA and 8-hydroxyquinoline would be stronger complexing agents than citrate and cyanide for Ti^{3+}, although no quantitative data except for EDTA are available in the literature (11). Further work is in progress in our laboratory along the lines described.

Photoactivity of Polycrystalline α-Fe_2O_3 Electrodes Doped with Group IVA Elements

John H. Kennedy,* Menahem Anderman, and Ruth Shinar

Department of Chemistry, University of California, Santa Barbara, California 93106

Success in obtaining significant photocurrents with polycrystalline, SiO_2-doped α-Fe_2O_3 photoanodes (1) gave rise to a study of the photoelectrochemical properties of other group IVA elements as dopants. Recently, photochemical properties of SnO_2- and CaO-doped α-Fe_2O_3 electrodes were investigated elsewhere (2) but only 1 and 5% doping levels were studied.

In the present work α-Fe_2O_3 material was mixed with 0.002-5 atomic percent (a/o) GeO_2 and SnO_2 and with 0.01-5 a/o (initial composition) PbO_2. Emission spectroscopy and x-ray diffraction were used to check the initial and final doping levels and for the possible presence of two-phase materials. Photoelectrochemical results were compared to those obtained at Si(IV)- and Ti(IV)-doped α-Fe_2O_3 electrodes.

Experimental

Electrodes were prepared from high purity, 99.999% α-Fe_2O_3 (Alfa Products) by mixing with the dopant powder, pressing, and sintering as described elsewhere (1). The dopants were Alfa Products 99.9% GeO_2, B and A 99% SnO_2 or Alfa Products 99.9% SnO_2, and Research Organic/Inorganic Chemical Corporation 95% PbO_2 or Apache 99.9% PbO_2.

Pressed pellets were sintered at 1250°-1370°C for 3-40 hr. Table I summarizes the dopant concentrations, sintering temperatures, and sintering times needed to prepare the best electrodes. The electrodes were 1.29 cm diam when initially pressed but some shrinking occurred during sintering so that final electrodes were $\sim$1 cm^2.

Electrical connections were made using silver epoxy as previously described (3). Densities were 75-90% of the theoretical value, and resistances measured at 1 kHz with a conductivity bridge were usually 50-2500Ω.

Samples containing Ca^{2+} (starting material: Matheson, Coleman & Bell $CaCO_3$) and Pb^{2+} (starting material: Mallinckrodt, Analytical Reagent PbO) were also prepared. 0.5 a/o Ca^{2+}-doped α-Fe_2O_3 pellets were sintered at 1370°C for about 15 hr and at 1330°C for 70 hr. In both cases the resistances were very high ($>$200 kΩ). 0.5 a/o Pb^{2+}-doped electrodes were sintered at 1370°C for 5 hr. Resistances were $\sim$2 kΩ.

Pellet weight was checked before and after sintering. Differences between starting and final dopant concentration were also determined by emission spectroscopy. Both powders and ground sintered pellets of pure and doped α-Fe_2O_3 were analyzed by a Norelco x-ray diffractometer.

The cell arrangement, and optical and electrochemical measurement procedures were described previously (1). Lamp intensity was measured with a Yellow Springs Instrument Company Kettering Model 65A radiometer, and the photocurrent spectra were normalized to the lamp output spectrum. When using a monochromator light intensities in the range 350-560 nm were 4-18% mW/cm^2. The lamp intensity at the electrode surface was about 300 mW/cm^2 when no monochromator was employed. This was reduced to about 180 mW/cm^2 when a filter was used (pass light $<$540 nm).

Results

No loss of weight during sintering was observed in the case of pure α-Fe_2O_3, Si^{4+}-, Sn^{4+}-, and Ge^{4+}- (sintered at 1300°C) doped electrodes, but some loss of weight was observed in Ge^{4+}-doped pellets sintered at $\sim$1350°C, probably due to some evaporation of GeO_2 at high sintering temperatures (4).

A significant weight loss was observed in the Pb^{4+}-doped pellets as expected, since PbO_2 decomposes at 290°C and PbO, the final decomposition product, melts at 888°C and evaporates appreciably (4).

Emission spectroscopy confirmed the above results. Si^{4+}-, Ge^{4+}-, and Sn^{4+}-concentrations in the ground pellets (after sintering) were the same, within experimental error, as in the mixed powders (before sintering). In the case of Ge^{4+}-doped pellets a reduction in the final concentration of the dopant was observed when sintered at relatively high temperatures. For example, the final doping level of the 0.5 a/o Ge(IV) sample sintered at 1350°C for 13 hr was $\sim$0.1 a/o. It should be kept in mind that emission spectroscopy is not a highly accurate analytical technique but significant differences between initial and final composition could be readily observed. For the lead-doped electrodes only low levels of lead ($\sim$200 ppm) were observed in the final sintered pellets independent of initial concentration, sintering temperature, or sintering time.

X-ray patterns of ground sintered pellets indicated the existence of single phase α-Fe_2O_3 even at doping levels of 5 a/o GeO_2 and SnO_2. On the other hand, x-ray diffraction of the starting mixtures containing as little as 0.5 a/o GeO_2 and SnO_2 clearly showed the presence of dopant phases along with α-Fe_2O_3. Also, no evidence for the presence of other phases was found for electrodes containing up to 2 a/o SiO_2.

Most of the photoactivity experiments were carried out on low doping level electrodes. High doping levels were used mainly to check for possible weight loss during sintering and for the presence of two-phase materials.

To ensure homogeneity in the electrodes some pellets were sintered at elevated temperatures for very long periods ($>$3 days) compared to the time required to obtain pellets of relatively low resistance. No noticeable change in the photoactivity could be observed by the long sintering cycle. In addition, some sintered samples were ground and resintered. Occasionally densities were slightly improved but no significant changes in the photoactivity were observed.

Photocurrent density *vs.* applied potential at 400 nm for α-Fe_2O_3 electrodes doped with group IVA elements is shown in Fig. 1. The indicated doping levels are those of the final electrodes. Initial concentration for the lead-doped electrode is given in parentheses.

The photocurrent was measured in 1F NaOH. Results for 0.05 a/o Ti^{4+}-doped electrodes are also shown for comparison. Dark currents in the range shown were always lower than 8 μA/cm^2. As can be seen the elec-

Table I. Composition and sintering conditions for group IVA-doped α-Fe_2O_3 electrodes

Dopant	Doping level (a/o)	Sintering temperature, °C	Sintering time, hr
SiO_2	0.25-2	1350	20-30
GeO_2	0.002-0.01	1300	5-20
SnO_2	0.002-0.01	1300-1370	8-15

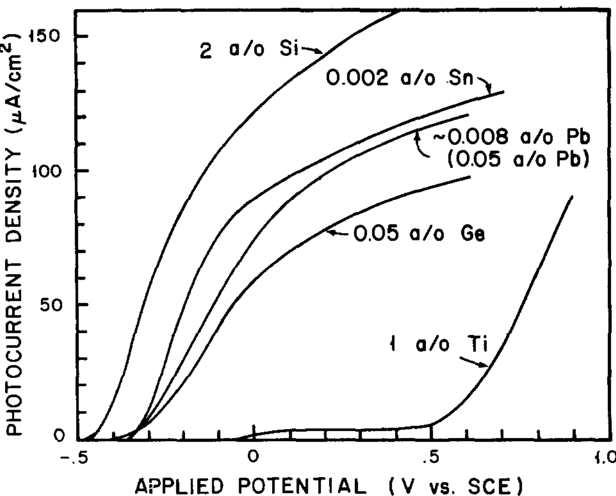

Fig. 1. Photocurrent density as a function of applied potential at 400 nm for α-Fe_2O_3 electrodes doped with group IVA elements and with TiO_2. Solution: 1F NaOH.

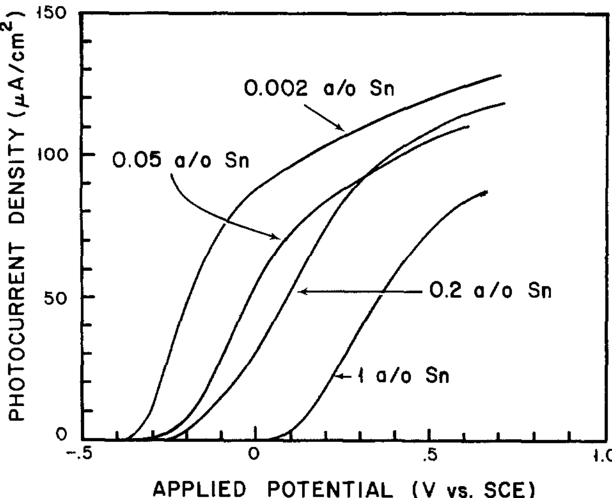

Fig. 3. Photocurrent density as a function of applied potential at 400 nm for α-Fe_2O_3 electrodes doped with various amounts of Sn(IV). Solution: 1F NaOH.

trodes doped with group IVA elements exhibited significant photocurrents even at 0V *vs.* SCE in a basic solution. The highest photocurrents at relatively low potentials (<0.5V *vs.* SCE) were observed at 2 a/o Si^{4+}-doped electrode. Although there were differences in photocurrents at low applied potentials among the different electrodes the photocurrent plateau values reached at higher potentials (~1V *vs.* SCE) were about the same for nearly all electrodes.

Figure 2 shows the spectral response for the photocurrent (quantum) efficiency in 1F NaOH for several electrodes. In general there was no significant difference between the effect of GeO_2 and SnO_2 as dopants. Both of the lower doping levels 0.002-0.01 a/o showed higher photocurrent densities at 0V *vs.* SCE than those obtained at higher (>0.05 a/o) doping levels. At doping levels >1 a/o the photocurrents at 0V *vs.* SCE were negligible for both dopant types. This doping level effect is demonstrated in Fig. 3 for Sn(IV)-doped electrodes. It should be noted that this effect was not observed for SiO_2-doped electrodes and we did not succeed in preparing TiO_2-doped electrodes at a level lower than 0.05 a/o. Photoelectrochemical performance of all electrodes reported was stable for long periods (>3 days at 0.4-1.8 mA) of irradiation. The onset of photocurrent spectral response (~bandgap) of all group IVA-doped electrodes was the same within experimental error. A value of ~2.2 eV was obtained by plotting $(\eta h\nu)^{1/2}$ *vs.* $h\nu$, where η is the photocurrent (quantum) efficiency. An example for SiO_2- and GeO_2-doped electrodes is shown in Fig. 4.

The turn-on voltage for several SiO_2-, GeO_2-, and SnO_2-doped electrodes was measured as a function of *p*H as shown in Fig. 5 for the SiO_2- and GeO_2-doped electrodes. Straight lines were obtained for each electrode with slopes in the range of −(60-68) mV/*p*H. These results were within experimental error of −59 mV/*p*H, the value expected for the *p*H dependence of the flatband potential. Although the turn-on voltage does not correspond exactly to the flatband potential (3) the *p*H dependence is usually identical. The turn-on voltage shifted to negative potentials as the dopant level decreased, as can be seen in Fig. 3 for Sn(IV)-doped electrodes.

It had been observed previously (1, 5) that dipping Si(IV)- and Ti(IV)-doped electrodes in 1F KI at *p*H 9 improved photocurrents observed in strong base solution. However, dipping Ge(IV)- and Sn(IV)-doped electrodes did not significantly improve the photocurrent. Soaking in KI solution appears to be effective only for electrodes showing less than optimum photoactivity perhaps by removing surface recombination sites. It should be noted that undoped high purity α-Fe_2O_3 was highly resistive and exhibited no photocurrent during the tenure of our experiments.

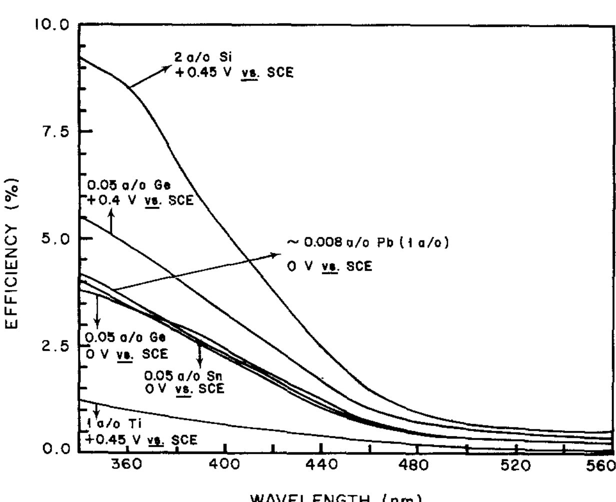

Fig. 2. Spectral response for photocurrent efficiency (uncorrected for reflection losses at the cell window and the electrode surface) of doped α-Fe_2O_3 electrodes in 1F NaOH.

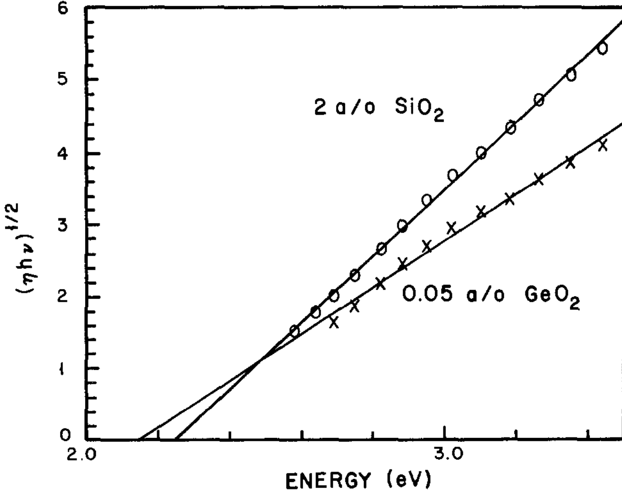

Fig. 4. $(\eta h\nu)^{1/2}$ *vs.* $h\nu$. (o): 2 a/o Si(IV); (x) 0.05 a/o Ge(IV)-doped α-Fe_2O_3 electrodes. E_g: 2 a/o Si(IV) = 2.25 eV; 0.05 a/o Ge(IV) = 2.15 eV.

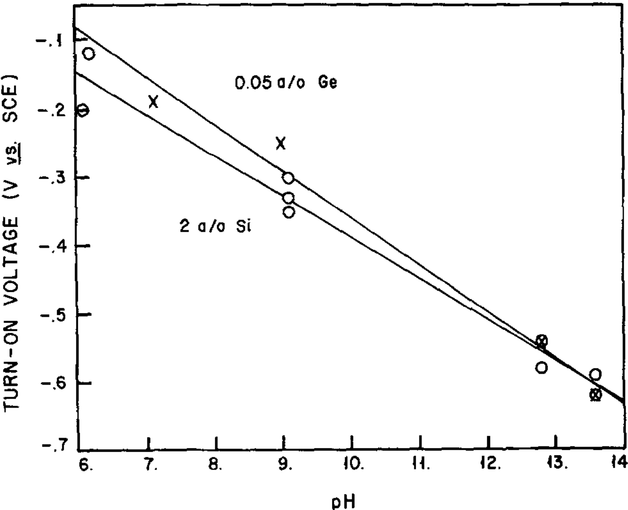

Fig. 5. Turn-on voltage *vs.* pH. (o): 2 a/o Si(IV); (x): 0.05 a/o Ge(IV)-doped α-Fe_2O_3 electrodes. Slopes: 2 a/o Si(IV) = −60 ± 3 mV/pH; 0.05 a/o Ge(IV) = −68 ± 5 mV/pH.

Discussion

It appears that all IVA elements are effective dopants for α-Fe_2O_3 photoanodes. This is consistent with the general aliovalent doping concept that the +4 ion introduces an electron into the conduction band

$$\text{M (IV)} \longrightarrow \text{M (IV)}_{\text{Fe}} + e_{cb}'$$

One could argue that group IVB elements should be equally effective whereas the experimental evidence indicates that titanium is not as effective as silicon. The difference may lie in the additional energy levels introduced by the aliovalent metal ion centers present. A $Ti_{Fe}^{\cdot}$ center may trap an electron to form Ti_{Fe}^{x}, *i.e.*, a Ti(III) ion. Such centers may also act as electron hole recombination sites thereby decreasing photocurrent efficiency. Lower members in group IVB may not display this behavior, and recently Horowitz (6) showed that single crystal Fe_2O_3 doped with ZrO_2 was more effective than titanium doping.

A second conclusion is that photocurrent decreases at a given applied potential as the doping level increases as shown in Fig. 3 for SnO_2-doped electrodes. This is expected when one considers the effect of donor density on space charge layer thickness. As the donor density increases the space charge layer becomes thinner and fewer photons are absorbed in the space charge region. Photons may still be absorbed at a greater depth in the Fe_2O_3 electrode but hole mobility is so low that few reach the space charge region to be driven to the surface. The apparent shift in turn-on voltage to more anodic values with increasing doping level is not expected although this point was observed and discussed in a previous paper (3).

However, it must be kept in mind that the dopant may play other roles besides introducing electronic defects especially at high doping levels. For example, they may act as traps and recombination centers leading to lower photocurrent efficiency at high doping levels.

The results with lead-doped electrodes are more difficult to explain because the final oxidation state is not +4 as with the other dopants. In fact, doping with PbO gave electrodes with photoelectrochemical properties similar to PbO_2-doped electrodes. Doping with a +2 ion could lead to p-type material although doping with Ca(II) produced only highly resistive electrodes. However, the behavior of lead-doped α-Fe_2O_3 electrodes indicates that it is n-type like other members of group IV. Because doping levels need not be high, and in fact, better performance is observed with lower doping levels (Fig. 3) it may be that traces of Pb(IV) account for the photoelectrochemical behavior. Fredlein and Bard (7) also observed n-type behavior for single crystal α-Fe_2O_3 grown from a PbO melt. The Pb content was 1-10 a/o, but photocurrents were small unless heat-treated. These authors assumed that lead was present as Pb(IV) because the electrodes were n-type. All electrodes were stable for long periods of illumination with many electrodes being studied over periods of several weeks with no significant change in photoelectrochemical properties.

Environmental Stability and Failure Mechanisms of Chromated Lead/Tin Alloy Joints Bonded with an Ethylene-Acrylic Acid Copolymer

I. Acidic Conditions

Fumio Yamamoto, Shinzo Yamakawa, and Makoto Wagatsuma

Nippon Telegraph and Telephone Public Corporation,
Ibaraki Electrical Communication Laboratory, Tokai, Ibaraki 319-11, Japan

ABSTRACT

The environmental stability and the failure mechanisms of a cathodically chromated lead/tin (38/62) alloy joint bonded with an ethylene-acrylic acid (EAA) copolymer have been investigated in acidic solutions. Immersion of the joint in acidic solutions causes rapid decrease in peel strength and finally interfacial separation. ESCA analysis of the peeled surfaces shows that this decrease in peel strength is due to an interfacial degradation between the chromate film and the underlying alloy (consisting both of lead and tin phases). The retention time, during which a joint retains the initial peel strength, decreases with increasing anode current density of the alloy in acidic solutions or with decreasing polarization resistance. This result suggests that the interfacial failure at the chromate-alloy interface results from anodic dissolution of the underlying alloy. A failure mechanism of the chromated alloy joint in acidic solutions has been proposed: The degradation at the chromate-alloy interface occurs through rapid anodic dissolution of the lead phase and slow anodic dissolution of the tin phase.

The long-term exposure of metal joints bonded with ethylene-acrylic acid (EAA) copolymers to humid environments causes the loss in joint strength (1-4). We have reported that cathodic chromate treatments of lead/tin alloys greatly enhances the environmental stability of the alloy joints bonded with an EAA copolymer and that the joint strength is kept unchanged in distilled water for more than 2 years (5, 6). However, these joints seem to have poor environmental stability in acidic solutions since both lead and tin metals are rapidly corroded in acidic solutions (7). This paper is concerned with the environmental stability in acidic solutions and the failure mechanisms of a cathodically chromated lead/tin alloy joint bonded with an EAA copolymer.

Experimental

The preparation of T-peel specimens consisting of adherend (0.5 mm)-adhesive (0.2 mm)-adherend (0.5 mm) and the T-peel testing were described elsewhere (5). The adherend used was a cathodically chromated lead/tin (38/62) alloy. The adhesive used was an EAA copolymer (1) supplied by Union Carbide Company (melt index 50 g/10 min, acrylic acid content 20 weight percent, density 0.96 g/cm^3, glass transition temperature 31°C). To evaluate the environmental stability of the joints, the peel specimens were immersed in acidic solutions, and the T-peel strength was measured at 25°C immediately after immersion. The pH range of the solutions was 0.8-5.6, and the temperature range was 20°-70°C. The acidic solutions were 2-$HOCOC_6H_4COOK$-HCl (pH 0.8, 2.5, and 3.2), CH_3COONa-HCl (pH 4.5), 2-$HOCO_6H_4COOK$-NaOH (pH 5.0), and CH_3COOH-CH_3COONa (pH 5.6) buffers.

The corrosion resistance of untreated and chromated alloy sheets in acidic solutions were evaluated from anode current density (I_p) by a potentiostatic method or from polarization resistance (R_p) (8-10) by a coulostatic method (11-15). The potentiostatic measurements were made using a Hokuto potentiometer, and the anode current density was measured at an overpotential of 50 mV under nitrogen gas. The surface area of untreated and chromated alloy sheets used as the working electrodes was *ca.* 2 cm^2. A platinum sheet of *ca.* 2 cm^2 and a saturated calomel electrode were used as the counter and reference electrodes, respectively. The anode current density decreased with time of applying overpotential and leveled off after 30-60 sec. The leveled-off anode current density was recorded as an I_p value. The coulostatic measurements were made using a Hokuto galvanostat connected with a pulse generator (pulse width 10 μsec) without removing dissolved oxygen. The overpotential-time curves were displayed on a storage oscilloscope. The amount of charge density applied was 0.1-0.3 μC/cm^2, and the induced initial overpotentials were in the range 2-10 mV. The polarization resistance calculated from the overpotential-time curves decreased with

Key words: ESCA, anodic dissolution, interfacial degradation, metal-polymer joint.

water immersion of alloy sheets and leveled off after *ca.* 20 min immersion. The leveled-off polarization resistance was recorded as an R_p value. To check the validity of the R_p values measured by the coulostatic method, R_p values of alloy sheets in various acidic solutions were also measured from polarization curves. In this case, R_p values were calculated using $R_p = \beta_a\beta_c/I_o(\beta_a + \beta_c)$, where β_a and β_c are anodic and cathodic Tafel slopes, respectively, and I_o is corrosion current density. The R_p values measured from the coulostatic measurements were in agreement with those from the polarization curves within an error of 20%. The amount of oxides on the alloy surfaces was measured by electrolytic reduction in an aqueous solution of 0.1 mol/liter NH_4Cl at a constant current density of 90 $\mu A/cm^2$ under nitrogen gas, in the same way as in the previous work (5).

The original chromated alloy and EAA surfaces before bonding and the fractured surfaces of the joints were analyzed by x-ray photoelectron spectroscopy (ESCA). ESCA spectra were recorded on an A.E.I. ES 200 spectrometer using Al $k\alpha_{1},\alpha_{2}$ radiation. Typical operating conditions were: x-ray gun, 10 kV, 20 mA; pressure in the sample chamber, 1×10^{-7} Torr. The binding energies were calibrated with respect to the carbon 1s electron peak at 284.9 eV due to residual pump oil on the sample surface. Electron probe x-ray microanalysis (XMA) was also used for the surface analysis of chromated alloy sheets. XMA was carried out using a Shimazu EMX-SM7. XMA data were taken at a probe operating voltage of 15 kV and a sample current of 1 nA.

Results and Discussion

Chromate films on a lead/tin alloy surface.—Figure 1 shows an SEM micrograph and lead and tin images of a lead/tin (38/62) alloy surface cathodically chromated for 5 sec. The presence of a chromate film on the alloy surface was not detected by XMA analysis because its film thickness was much thinner (*ca.* 100Å) (5) than the XMA sampling depth (several micrometers), whereas it was detected by ESCA and IMA (ion microanalyzer) (5). From the lead and tin images (Fig. 1), it is apparent that the alloy surface consists both of lead and tin phases. The XMA analysis showed that the tin content in the lead phase and the lead content in the tin phase were less than a few percent.

It is well known that most chromate films deposited on metals have considerable cracks (16). Figure 2 shows the changes in oxygen 1s ESCA spectrum of the chromated alloy surface with heating. The chromated alloy sheet was heated in ESCA chamber for 20 min at each temperature, and ESCA spectra from its alloy surface were measured immediately at the same temperature. The intensity of oxygen 1s decreases with increasing heating temperatures and after heating at 180°C reaches *ca.* 70% of that heated at 60°C. The disappeared oxygen 1s peak at 532.3 eV has been assigned to adsorbed oxygen or water by Ansell *et al.* (17). Figure 3 shows the changes in the amount of alloy oxides of the chromated alloy surface with heating for 20 min at each temperature. The amount of oxides on the chromated alloy surfaces corresponds to that of the underlying alloy oxides at cracks of the chromate film. The amount of oxides increases gradually with heating at temperatures of more than 100°C and then increases rapidly with the rupture of chromate film due to the melt of the underlying alloy at *ca.* 183°C. These results indicate that many cracks, which are probably formed by contraction in volume due to escaped water, are present in the chromate film on the alloy surface heated at temperatures of more than 100°C. Since chromated alloy joints were prepared by heating for 5 min with a hot press at 120°C (5), the chromate film in the joints should have many cracks.

Bond durability.—Figure 4 shows the changes in peel strength with immersion in a CH_3COONa-HCl buffer (pH 4.5) for a chromated alloy joint. Figure. 5 shows the change in peel strength retention time (during which the initial peel strength is kept unchanged) with immersion temperature. The peel strength retention time decreases with increasing immersion temperature and was only 5 days at 70°C. On the other hand, the peel strength retention time of the chromated alloy joint immersed in distilled water at 50°C was more than 2 years (6). Apparently, the joint deteriorates more rapidly in the acidic solution than in distilled water. SEM observations of fractured surfaces showed that the small areas or spots of peel strength $\simeq$ 0 kg/cm, different in peel strength from the surrounding area of peel strength which was 6.0-6.5 kg/

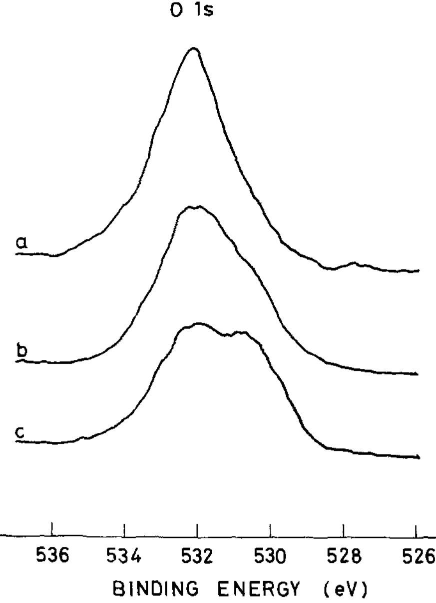

Fig. 2. Changes in oxygen 1s ESCA spectrum with heating for a chromated alloy surface. The alloy was heated in ESCA sample chamber for 20 min at each temperature. Heating temperatures were: (a) 60°C, (b) 120°C, (c) 180°C.

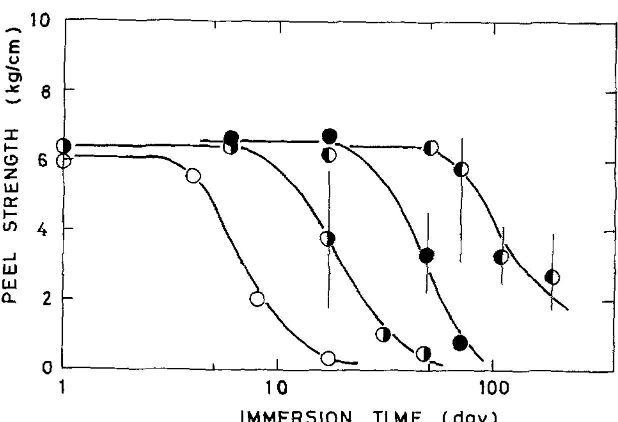

Fig. 4. Changes in peel strength with immersion in a CH_3COONa-HCl buffer (pH 4.5) for a chromated lead/tin (38/62) alloy joint bonded with an EAA copolymer. Immersion temperatures were: (◐) 40°C, (●) 50°C, (◑) 60°C, (○) 70°C.

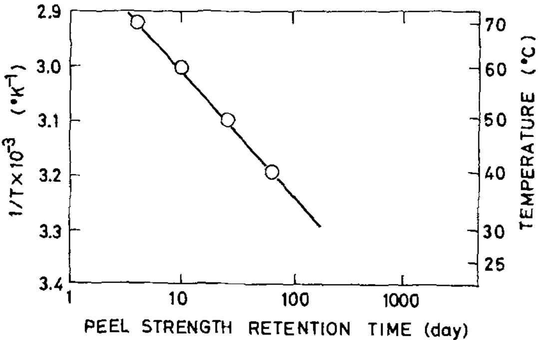

Fig. 5. Arrhenius plot for peel strength retention time of a chromated alloy joint in a CH_3COONa-HCl buffer (pH 4.5).

cm, appeared over the whole part of the interface, the area and number of the spots increased gradually with immersion, and then finally an interfacial separation occurred.

Table I summarizes the peel strength retention times of the chromated alloy joint in various acidic solutions. In most cases, the peel strength retention time decreases with decreasing *p*H of acidic solutions. However, there are some exceptions: the peel strength retention time in a CH_3COONa-HCl buffer (*p*H 4.5) at 50°C and that in a 2-$HOCOC_6H_4COOK$-HCl buffer (*p*H 3.2) at 50°C.

Locus of failure.—Figure 6 shows ESCA spectra of fractured chromated alloy and EAA surfaces of chromated alloy joints peeled with low peel strength after immersion in a CH_3COONa-HCl buffer (*p*H 4.5), together with those of original chromated alloy and EAA surfaces. Each fractured surface peeled with low peel strength after immersion in the other buffers showed ESCA spectra similar to those in Fig. 6. The fractured alloy surface shows the increase in tin intensities (metal peak, 484.3 eV; oxide peak, 486.5 eV), the decrease in oxygen intensity (532.3 eV), and the disappearance of chromium oxide (577.0 eV). On the other hand, the fractured EAA surface shows the decrease in carbon intensity (285.0 eV), the remarkable increase in oxygen intensity, and the appearance of tin and chromium oxides. Apparently, the exposure of tin and chromium oxides on the fractured EAA surface is due to the transfer from the chromated alloy surface. Further, the remarkable increase in oxygen intensity on the fractured EAA surface is due to the transfer of the chromate film from the alloy surface. On the other hand, the increase in tin intensities on the fractured alloy surface is probably due to exposure of the underlying lead/tin alloy by the transfer of the chromate film to the EAA surface. These results indicate that the failure occurs between the chromate film and the underlying alloy, although it is not clear whether the failure occurs at the chromate-underlying alloy oxide layer interface, in the alloy oxide layer, or at the alloy oxide layer-alloy metal interface. On the other hand, the water absorption of the EAA copolymer was as low as *ca.* 0.44 w/o in the *p*H 4.5 buffer at 50°C. This value

Table I. Peel strength retention time in various acidic solutions

Acidic solution	pH	Temperature (°C)	Peel strength retention time (days)
2-$HOCOC_6H_4COOK$-HCl buffer	0.8	50	30
2-$HOCOC_6H_4COOK$-HCl buffer	2.5	50	40
2-$HOCOC_6H_4COOK$-HCl buffer	3.2	50	40
CH_3COONa-HCl buffer	4.5	70	4
CH_3COONa-HCl buffer	4.5	60	10
CH_3COONa-HCl buffer	4.5	50	26
CH_3COONa-HCl buffer	4.5	40	64
2-$HOCOC_6H_4COOK$-NaOH buffer	5.0	50	>900
CH_3COOH-CH_3COONa buffer	5.6	70	75
CH_3COOH-CH_3COONa buffer	5.6	40	600

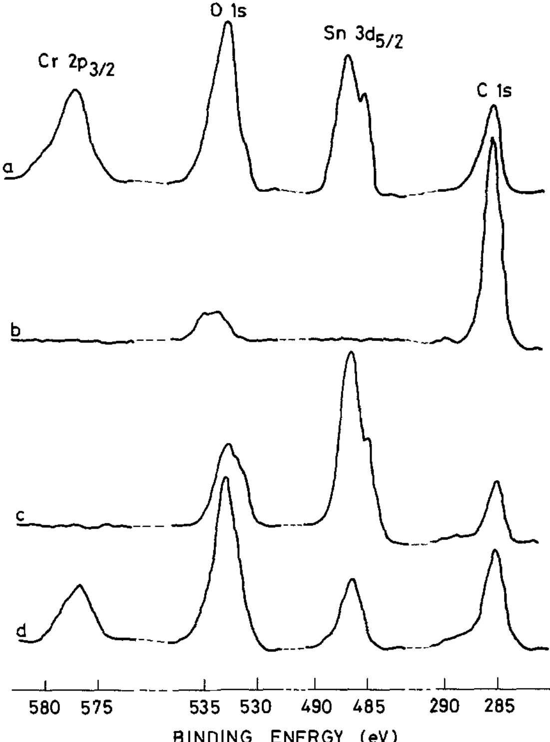

Fig. 6. ESCA spectra of original chromated alloy (a) and EAA (b) surfaces and fractured chromated alloy (c) and EAA (d) surfaces of a chromated alloy joint peeled with low peel strength after immersion in a CH_3COONa-HCl buffer (*p*H 4.5).

was nearly equal to that (0.36 w/o) in distilled water. Therefore, the mechanical properties of EAA copolymer such as stress-strain and failure behavior were not affected by immersion in acidic solutions. As a result, as long as the failure occurred cohesively in the EAA copolymer, the initial peel strength was kept unchanged (6). Thus, the decrease in peel strength occurs in acidic solutions with the change in locus of failure from the EAA copolymer to the chromate-underlying alloy interface.

Relationship between bond durability and alloy corrosion.—It seems likely that the interfacial failure between the chromate film and the underlying alloy in acidic solutions is due to anodic dissolution of the underlying alloy. To clarify the relation between the decrease in peel strength and the chromated alloy corrosion, the anode current density (I_p) from the potentiostatic method and the polarization resistance (R_p) from the coulostatic method were measured for untreated and chromated alloys in acidic solutions, in which immersion tests of chromated alloy joints were carried out. Figure 7 shows the changes in I_p value with immersion temperature for untreated and chromated alloy sheets in a CH_3COONa-HCl buffer (*p*H 4.5). On both the surfaces, the I_p value increases with increasing immersion temperature. The I_p values on chromated alloy are *ca.* 1/500 times those on untreated alloy. Since the chromate film itself is corrosion-resistant, the I_p values measured on chromated alloy surfaces mean those on regions uncovered with the chromate film [*e.g.*, grain boundaries (5) and cracks in the chromate film]. The I_p values on untreated and chromated alloy surfaces show the same temperature dependence (Fig. 7). This fact also supports the view that the I_p value on chromated alloy surfaces measures a leak current density from the underlying alloy. Therefore, the corrosion properties of chromated alloys depend on both the area uncovered with the chromate film and the corrosion of the underlying alloy itself. In this paper, since the chromate treatment was carried out under the same conditions, the area uncovered with the chromate film is thought to be the same for all chromated samples. Accordingly, since the corrosion resistance of the chromated alloy can be related to that of untreated alloy, the I_p and R_p values of untreated alloy in acidic solutions were compared with the peel strength retention time of chromated alloy joints in acidic solutions.

Figures 8 and 9 show log-log plots of I_p and R_p of untreated alloy *vs.* peel strength retention time for chromated alloy joints at various immersion temperatures in various acidic solutions. In spite of the use of different acidic solutions and different immersion temperatures, the peel strength retention time is inversely proportional to the I_p value and proportional to the R_p

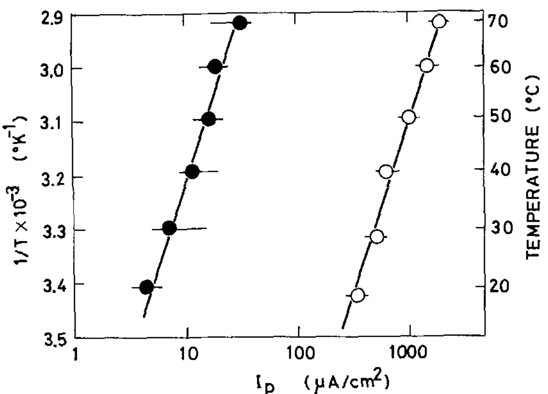

Fig. 7. Arrhenius plots for I_p values of untreated (○) and chromated (●) alloy sheets in a CH_3COONa-HCl buffer (*p*H 4.5).

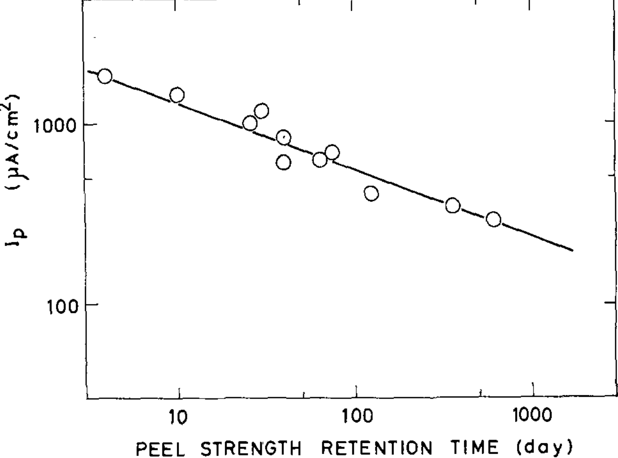

Fig. 8. Log-log plot of I_p vs. peel strength retention time of chromated alloy joints at various immersion temperatures in various acidic solutions.

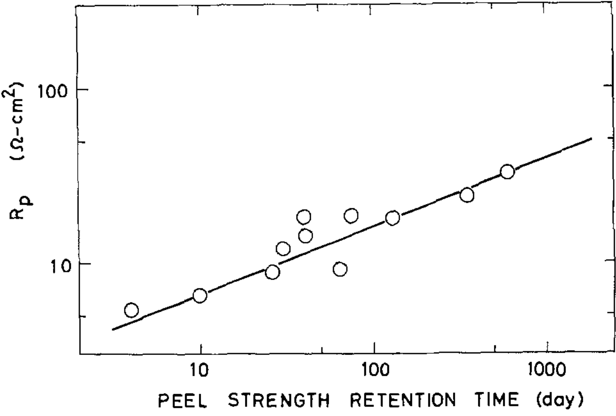

Fig. 9. Log-log plot of R_p vs. peel strength retention time of chromated alloy joints at various temperatures in various acidic solutions.

value. In other words, the peel strength retention time increases with decreasing anodic dissolution of the underlying alloy, *i.e.*, decreasing I_p value or increasing R_p value. Thus, it is concluded that the decrease in peel strength is due to the anodic dissolution of the underlying alloy.

Failure mechanism in acidic solutions.—Figure 10 shows a schematic diagram of chromated lead/tin alloy-EAA interfaces degraded in acidic solutions. The alloy surface consists both of lead and tin phases (Fig. 1). Since the lead phase was corroded more rapidly than the tin phase when untreated alloy sheets were immersed in acidic solutions, the lead phase-EAA interface of chromated alloy joints are assumed to degrade rapidly in acidic solutions by anodic dissolution of lead according to the reaction.

$$Pb + 2H^+ \rightarrow Pb^{2+} + H_2$$

Therefore, the joint strength of chromated alloy joints is due mainly to interfacial forces at the tin phase-EAA interfaces. In chromated alloy joints immersed in acidic solutions, hydrogen ions diffuse into the adhesive joints along the lead phase-chromate film interfaces and reach the tin phase-chromate film interfaces. At the same time, hydrogen ions may diffuse through the EAA copolymer, pass through the cracks (Fig. 2) of chromate film, and then reach the tin phase-chromate film interfaces. Subsequently, at the tin phases in contact with the chromate film, the growth of tin oxide layer and the anodic dissolution occur gradually according to the reaction

$$Sn + 2H^+ \rightarrow Sn^{2+} + H_2$$

The decrease in peel strength occurs simultaneously with anodic dissolution of the tin phases. After complete anodic dissolution of all the tin phases in contact with the chromate film, interfacial separation occurs between the chromate film and the underlying alloy. In conclusion, the environmental stability of chromated lead/tin alloy joints in acidic solutions depends on the corrosion properties of the tin phase in acidic solutions, and the failure of chromated alloy joints proceeds with anodic dissolution of the tin phases.

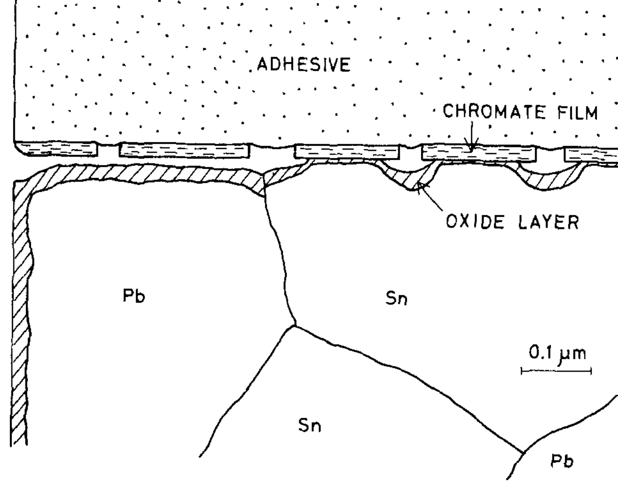

Fig. 10. Schematic diagram of chromated lead/tin alloy-EAA interfaces degraded in acidic solutions.

The I_p and R_p values of untreated alloy were 1.0 $\mu A/cm^2$ and 3.2 $k\Omega\text{-}cm^2$ in distilled water, respectively. It is estimated from Fig. 8 and 9 that the peel strength retention time of chromated alloy joints is more than 10 years in distilled water. This estimation is in fair agreement with an experimental result (6) that the decrease in peel strength of chromated alloy joints does not occur even after immersion in distilled water for 2 years.

Environmental Stability and Failure Mechanisms of Chromated Lead/Tin Alloy Joints Bonded with an Ethylene-Acrylic Acid Copolymer

II. Alkaline Conditions

Fumio Yamamoto, Shinzo Yamakawa, and Shinji Tsuru

Nippon Telegraph and Telephone Public Corporation, Ibaraki Electrical Communication Laboratory, Tokai, Ibaraki 319-11, Japan

ABSTRACT

The environmental stability and the failure mechanisms of a cathodically chromated lead/tin (38/62) alloy joint bonded with an ethylene-acrylic acid (EAA) copolymer (20 weight percent acrylic acid) have been investigated in alkaline solutions. The environmental stability has been compared with that of the alloy joint bonded with an ethylene-ethyl acrylate copolymer grafted with acrylic acid (EEA-g-AA). The peel strength of the EAA joint decreases rapidly with immersion in alkaline solutions. This decrease in peel strength results from stepwise swelling of the EAA adhesive layer from the edges of the joint to the inside, which swelling occurs by alkaline ions diffusing into the joint inside. On the other hand, the decrease in peel strength of the EEA-g-AA joints occurs from stepwise interfacial degradation from the joint edges, with no swelling of the EEA-g-AA adhesive layer. The interfacial failure mechanism is discussed in comparison with that of the EAA joint.

Cathodically chromated lead/tin alloy joints bonded with an ethylene-acrylic acid (EAA) copolymer have high peel strength in dry conditions (1) and show high environmental stability in distilled water (2). However, immersion of the joints in acidic aqueous solutions causes a rapid decrease in peel strength and finally an interfacial separation (3). This decrease in peel strength is due to an interfacial degradation or failure between the chromate film and the underlying alloy. This interfacial failure is due to anodic dissolution of the underlying alloy. In alkaline solutions, on the other hand, lead/tin alloys are corroded since both lead and tin are amphoteric metals (4). Therefore, it is interesting to see whether the interfacial failure of lead/tin alloy joints occurs in alkaline solutions via the same mechanism as that in acidic solutions or via the other failure mechanism. This paper is concerned with the environmental stability in alkaline solutions and the failure mechanism of a cathodically chromated lead/tin (38/62) alloy joint bonded with an EAA copolymer used in previous papers (1-3). The failure mechanism in alkaline solutions is compared with that of the alloy joint bonded with an ethylene-ethylacrylate copolymer grafted with acrylic acid (EEA-g-AA).

Experimental

The preparation of T-peel specimens consisting of adherend (0.5 mm)-adhesive (0.2 mm)-adherend (0.5 mm) and the T-peel testing were described elsewhere (1). A cathodically chromated lead/tin (38/62) alloy sheet was used as the adherend. An EAA copolymer sheet (EAA-1), used in previous works (1-3), was used as the adhesive in this work, together with an ethylene-ethyl acrylate copolymer grafted with acrylic acid (EEA-g-AA). The EEA copolymer, supplied by Nippon Unicar Company, was homogeneously grafted with acrylic acid in benzoyl peroxide-containing xylene solutions at 120°C under nitrogen gas (5). The properties of ethylene copolymers investigated in this work are given in Table I. To evaluate the environmental stability of the joints, the peel specimens were immersed in alkaline solutions at temperatures of 40°-70°C, and the T-peel strength was measured at 25°C immediately after immersion. The alkaline solutions used were: H_3BO_4 + KCl-NaOH (pH 8.0 and 8.5), $NaHCO_3$-NaOH (pH 10.0), Na_2HPO_4-NaOH (pH 11.0), and KCl-NaOH (pH 12.0 and 13.0) buffers, and 0.1*N* NaOH solution (pH 14.0). The locus of failure of these joints was determined from analysis of the fractured surfaces by x-ray photoelectron spectroscopy (ESCA) and scanning electron microscopy (SEM).

Results and Discussion

Water immersion test.—Figure 1 shows the changes in peel strength with immersion at various temperatures in an $NaHCO_3$-NaOH buffer (pH 10.0) for an EAA-1 joint. Figure 2 shows the changes in peel strength with immersion in various alkaline solutions at 50°C for the same EAA-1 joint. The peel strength decreases rapidly at relatively high *p*H values and temperatures as in acidic solutions (3). The peel strength retention time (during which the initial peel strength is kept unchanged) decreases with increasing immersion temperature or *p*H of alkaline solutions. Figure 3 shows the changes in peel strength in various alkaline solutions at 50°C for an EEA-g-AA joint. The peel strength retention time also decreases with increasing *p*H of alkaline solutions. However, the peel strength retention times of the EEA-g-AA joint is

longer than those of the EAA-1 joint when both the joints are immersed in the same alkaline solution; the EEA-g-AA joint is more stable in alkaline solutions than the EAA-1 joint.

Locus of failure.—The peel strength of the EAA-1 joint decreases as rapidly in alkaline solutions as in acidic solutions. However, the progress of the interfacial failure in alkaline solutions has been found to be significantly different from that in acidic solutions. Immersion of the joint in acidic solutions causes first the small areas or the spots of peel strength $\simeq 0$ kg/cm over the whole part of the interface, next the increases in the area and the number of the spots, and finally an interfacial separation (3). In alkaline solutions, on the other hand, the failure initiates from the edges of the joint in contact with the alkaline solutions and proceeds into the joint inside with water immersion. Figure 4 shows SEM micrographs of fractured chromated alloy and EAA surfaces of the EAA-1 joint peeled after immersion in an $NaHCO_3$-NaOH buffer (pH 10.0). The SEM micrographs show a distinct front of failure on both the peeled surfaces. On the peeled alloy surface, the part of smooth surface corresponds to the undegraded region of the joint inside, which was peeled with a high peel strength similar to the initial peel strength. The part of rough surface corresponds to the degraded region of the joint edges, which was peeled with a low peel strength of *ca.* 0 kg/cm. The rough surface topography results from the residual adhesive, which had been transferred from the adhesive side to the alloy side through the cohesive failure of the adhesive layer. On the other hand, on the peeled EAA side, remarkable swelling of the EAA adhesive was observed on the degraded region. The front of swelling coincided approximately with the front of the interfacial degradation. The undegraded EAA surface, peeled with high peel strength, shows a rough surface topography similar to that peeled in dry conditions (1). This rough topography results from plastic deformation of the adhesive.

Figure 5 shows ESCA spectra of the fractured chromated alloy and EAA surfaces corresponding to those of Fig. 4, together with those of original chromated alloy and EAA surfaces. The degraded parts of both the peeled surfaces show an overall ESCA spectrum similar to that of the original adhesive surface, although there is a slight ESCA peak of tin. This ESCA result and the presence of the residual adhesive on the degraded alloy surface (Fig. 4a) indicate that the failure of the degraded region of the joint occurs within the adhesive when the joint is peeled. On the

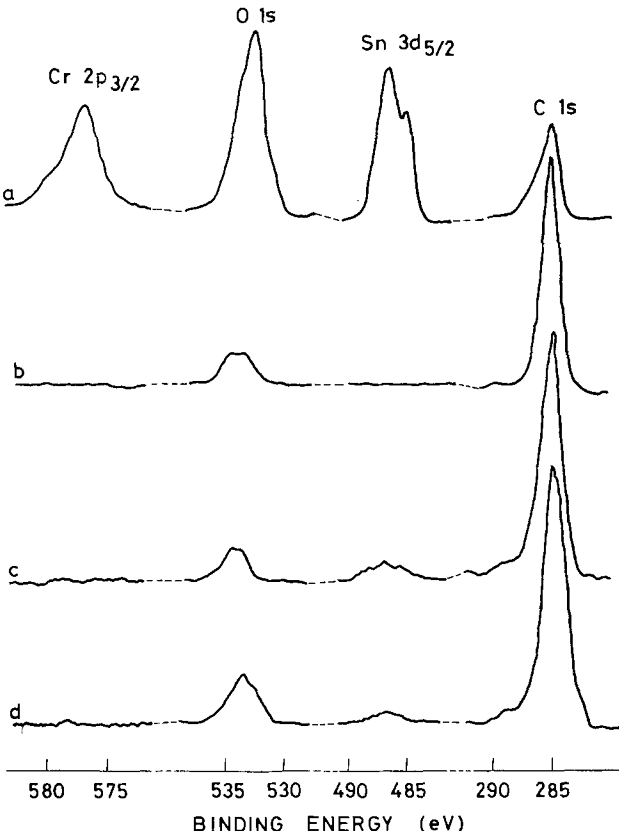

Fig. 5. ESCA spectra of original chromated alloy (a) and EAA (b) surfaces and fractured chromated alloy (c) and EAA (d) surfaces of an EAA-1 joint peeled with low peel strength after immersion in an $NaHCO_3$-NaOH buffer (pH 10.0).

other hand, peeled alloy and EAA surfaces of the dry joint (1) and the undegraded region of immersed joints showed ESCA spectra similar to those (c, d) of Fig. 5. This result indicates that the locus of failure in the dry joint or in the undegraded region of the joint inside, in which the initial peel strength is kept unchanged, also is the cohesive failure of the adhesive itself. In other words, both the undegraded and degraded regions of the EAA-1 joint result in cohesive failure within the adhesive in spite of the significant difference in peel strength. This fact suggests that the decrease in peel strength of EAA-1 joints results from the decrease in mechanical or cohesive strength of the EAA adhesive, but not from anodic dissolution of the underlying alloy (3, 6-8) and from displacement of the adhesive by water (9).

Failure mechanism of EAA-1 joints in alkaline solutions.—The anode current density (I_p) (3) at an overpotential of 50 mV and the polarization resistance (R_p) (3) of a lead/tin (38/62) alloy in the alkaline solutions used were of the order of 100 $\mu A/cm^2$ and 500 Ω-cm^2, respectively. The estimated peel strength retention time in alkaline solutions, which was obtained from the above I_p and R_p values using the relation between peel strength retention time and I_p or R_p in Fig. 8 or 9 of the previous paper (3), is more than 10 years. In fact, however, the joint degrades rapidly in alkaline solutions; the measured peel strength retention time is of the order of 10-100 days (Fig. 1 and 2). This disagreement indicates that anodic dissolution of the underlying alloy is not the prime cause for the joint deterioration in alkaline solutions, although it is the prime cause for the joint failure in acidic solutions.

Table II shows water absorption test results of EAA-1 and EEA-g-AA copolymer sheets (used as adhesives in this paper) immersed in an $NaHCO_3$-NaOH

buffer (pH 10.0) in the temperature range 40°-70°C until there was not further increase in weight. Table III shows those immersed in three buffers of pH 8.5-12.0 at 50°C. Tables II and III also include those of two other EAA copolymers (EAA-2 and EAA-3) containing lower acrylic acid contents. EAA-1 sheets show much higher water absorption values than those of EAA-2, EAA-3, and EEA-g-AA sheets, corresponding to its high acrylic content [20 weight percent (w/o)]. Furthermore, the water absorption of the EAA-1 copolymer increases with increasing immersion temperature and pH of alkaline solutions. Also, it was observed that EAA-1 sheets were significantly swollen and became mechanically weak at relatively high water absorption, whereas EAA-2, EAA-3, and EEA-g-AA sheets were not swollen. The significant swelling of EAA-1, which is probably due tu ionization or dissociation of carboxyl groups in the copolymer, also indicates that the deterioration of EAA-1 joint in alkaline solutions occurs with decreasing mechanical strength of the bulk EAA due to its remarkable swelling.

Figures 6 and 7 show the degraded depth from the edges of T-peel specimen *vs.* the square root of immersion time in an $NaHCO_3$-NaOH buffer (pH 10.0) at various temperatures and in various alkaline solutions at 50°C, corresponding to Fig. 1 and 2, respectively. The degraded depth corresponds to the region peeled with low peel strength of *ca.* 0 kg/cm and to the swollen region of the EAA-1 adhesive layer. In other words, the degradation or failure front of the interface coincides with the swelling front of the EAA-1 adhesive layer. In an $NaHCO_3$-NaOH buffer (pH 10.0) at 40° and 50°C (Fig. 6 and 7) and in an H_3BO_4 + KCl-NaOH buffer (pH 8.5) at 50°C (Fig. 7), the degraded depth is proportional to the square root of immersion time. This result indicates that failure of the EAA-1 joint occurs with swelling of the EAA adhesive layer by alkaline ions diffusing into the joint inside through the adhesive layer.

On the other hand, in an $NaHCO_3$-NaOH buffer (pH 10.0) at 60° and 70°C (Fig. 6), in a 0.1*N* NaOH solution (pH 14.0) at 50°C, in a KCl-NaOH buffer (pH

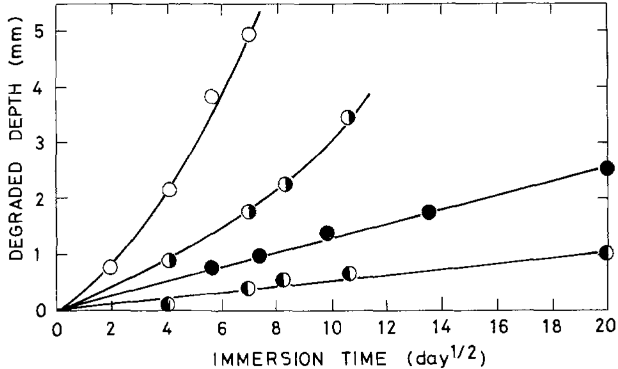

Fig. 6. Degraded depth from the edges of T-peel specimen vs. the square root of immersion time. An EAA-1 joint was immersed in an $NaHCO_3$-NaOH buffer (pH 10.0) at various temperatures: (◐) 40°C; (●) 50°C; (◑) 60°C; (○) 70°C.

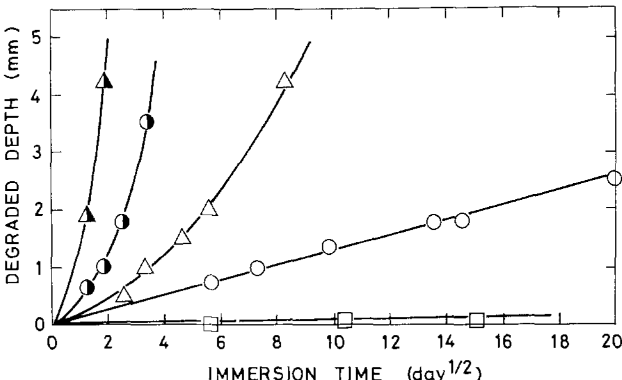

Fig. 7. Degraded depth from the edges of T-peel specimen vs. the square root of immersion time. An EAA-1 joint was immersed at 50°C in various alkaline solutions: (▲) 0.1N NaOH solution, pH 14.0; (◑) KCl-NaOH buffer, pH 12.0; (△) Na_2HPO_4-NaOH buffer, pH 11.0; (○) $NaHCO_3$-NaOH buffer, pH 10.0; (□) H_3BO_4 + KCl-NaOH buffer, pH 8.5.

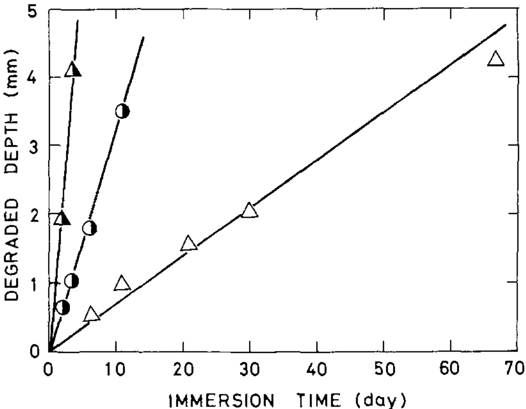

Fig. 8. Degraded depth from the edges of T-peel specimen vs. immersion time. An EAA-1 joint was immersed at 50°C in various alkaline solutions: (▲) 0.1N NaOH solution, pH 14.0; (◑) KCl-NaOH buffer, pH 12.0; (△) Na_2HPO_4-NaOH buffer, pH 11.0.

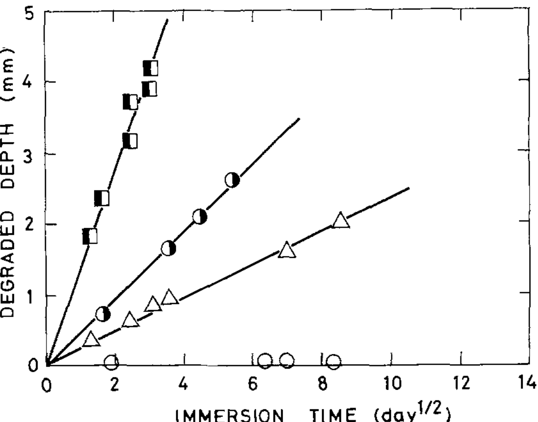

Fig. 9. Degraded depth from the edges of T-peel specimen vs. the square root of immersion time. An EAA-g-AA joint was immersed at 50°C in various alkaline solutions: (◧) KCl-NaOH buffer, pH 13.0; (◑) KCl-NaOH buffer, pH 12.0; (△) Na_2HPO_4-NaOH buffer, pH 11.0; (○) $NaHCO_3$-NoOH buffer, pH 10.0.

12.0) at 50°C, and in an Na_2HPO_4-NaOH buffer (pH 11.0) at 50°C (Fig. 7), the degraded depth deviates from the linear relation with the square root of immersion time and accelerates with immersion time. In these cases, the two adherends were bent outside from each other by a remarkable swelling of the EAA copolymer adhesive (see Tables II and III) sandwiched by the two adherends. This waved swelling caused gaps between the adherend and the adhesive. Although the degraded depth values in Fig. 7 deviate from the linear relationship with the square root of immersion time, they give linear lines when replotted against immersion time (Fig. 8). This linear relationship indicates that alkaline solutions easily reach the failure front of EAA joints (or the swelling front of EAA adhesive layer) through above-mentioned gaps between the adherend and the adhesive.

Failure mechanism of EEA-g-AA joint in alkaline solutions.—The water absorption of EEA-g-AA sheets having a low acrylic acid content is low in alkaline solutions (Table II) and does not increase appreciably with increasing pH of alkaline solutions (Table III), whereas that of EAA-1 sheets is high and increases appreciably with increasing pH. The EEA-g-AA sheets are not swollen in alkaline solutions, whereas the EAA-1 sheets are appreciably swollen. These results indicate that alkaline ions diffuse into the bulk EAA-1, but do not diffuse into the bulk EEA-g-AA copolymer. However, it has been observed that the failure of the EEA-g-AA joint also initiates from the edges of the joint and proceeds gradually into the joint inside in a manner similar to that of EAA-1 joint. Figure 9 shows the relation between the degraded depth from the edges of T-peel specimen and the square root of immersion time in various alkaline solutions at 50°C. The degraded depth is proportional to the square root of immersion time. The bulk EEA-g-AA copolymer sheet has low water absorption values in these alkaline solutions, and its use as an adhesive results in no gap between the adherend and the adhesive. All the results suggest that the rate of the joint failure also is controlled by diffusion of alkaline ions along the alloy-adhesive interface.

Based on the well-documented phase structures of multiphase polymers such as block and graft copolymers, polymer blends, and interpenetrating networks (10), it is reasonable to assume that the grafted poly(acrylic acid) within EEA-g-AA undergoes phase separation. The presence of the grafted poly(acrylic acid) phase domains at the alloy-adhesive interface is responsible for the high peel strength ($\geqq$ 4 kg/cm) of the chromated alloy-EEA-g-AA joint (Fig. 3), because the base EEA copolymer before grafting gives only low peel strength (*ca.* 0.5 kg/cm). In analogy with the above-mentioned failure mechanism of EAA-1 joints, it is tempting to assume that the decrease in peel strength of alloy-EEA-g-AA joints in alkaline solutions occurs with swelling of the poly(acrylic acid) domains at the interface by alkaline ions diffusing into the joint inside along the interface. We discuss in more details the failure mechanism of EEA-g-AA joints in a later paper.

Kinetics for the Reaction of Hydrogen with a Plutonium-1 Weight Percent Gallium Alloy Powder

Jerry L. Stakebake

Rockwell International, Golden, Colorado 80401

ABSTRACT

Kinetics for the reaction of hydrogen with plutonium-1 w/o gallium were measured using powder prepared "*in situ*." The rates obeyed a first-order rate law and were independent of temperature from −29° to 355°C. A pressure dependence proportional to $P^{1/2}$ was observed at pressures less than 1 kPa. From 1 to 70 kPa the pressure dependence rapidly decreased. Total pressure dependence could be accurately described by a Langmuir equation. Results indicate an adsorption-controlled reaction at low pressures and a reaction-controlled process at high pressures.

Plutonium hydride is frequently employed as an intermediate for preparing the metal or nitride powder and as such plays an important role in the nuclear industry. Even though a number of experimental studies have been carried out to describe the physicochemical properties of the plutonium-hydrogen system, several areas are still poorly defined. Earlier studies (1-7) have described in detail the equilibrium behavior and thermodynamic properties of plutonium hydride. Much less information, however, is available on the kinetics of the reaction of hydrogen with plutonium. Some kinetic data for the reaction of hydrogen with plutonium coupons have been reported by Bowersox (8, 9) and Colmenares *et al.* (10). A recent report (11) has also described the decomposition kinetics of plutonium hydride in both the two-phase region below $PuH_{0.95}$ and in the nonstoichiometric region between $PuH_{1.95}$ and PuH_3. Much of the early experimental kinetic data were influenced by oxide films on the metal coupons which increased the importance of hydride nucleation in the reaction. Hydrogen diffusion also plays a role in coupon hydriding and this process is likewise not understood. Therefore, additional work is required in order to fully understand the kinetics of plutonium hydriding as well as the factors which influence the kinetics.

Hydrogen reacts rapidly and exothermally with plutonium metal. The reaction is, however, strongly influenced by impurities in the gas phase hydrogen or on the plutonium metal surface. When impurities are present the reaction is characterized by a period of inhibition followed by a nucleation process on the plutonium surface. Elimination of the effect of impure hydrogen can be accomplished through gas purification techniques. Oxide films on the surface are more difficult to eliminate. To accomplish this successfully the sample must be prepared *in situ* without exposure to air. The problem of a surface film contaminant was dealt with in another way by Bowersox (8, 9). Plutonium coupons were heated under vacuum to about 300°C. During such a treatment the PuO_2 surface film is converted to PuO or more likely a Pu (C,O) phase (12). This material is catalytic and enhances the dissociation of hydrogen thus promoting the hydriding reaction. When plutonium coupons were treated in this manner, hydride nucleation sites were rapidly generated and inhibition caused by the oxide film was nearly zero. The problem with this type of approach was that the true plutonium-hydrogen reaction was not being studied. The approach used in the present investigation was to purify the hydrogen gas and then prepare a plutonium powder *in situ*. This procedure results in a relatively clean sample with a high surface area.

A second problem in measuring plutonium hydriding kinetics arises from the exothermal nature of the reaction. The heat of formation of plutonium hydride varies from −38 to −50 kcal/mol depending on the composition of the hydride (3). Self-heating of the sample during reaction makes it difficult to obtain isothermal kinetic data. Use of a heat sink bonded to the plutonium coupon can alleviate the problem to a degree (8, 9). However, this was not practical in the present investigation. The significance of not maintaining strictly isothermal conditions will be discussed later.

This paper describes the results from an investigation of the hydriding kinetics of a plutonium-1 weight

Key words: adsorption, corrosion, metals.

percent (w/o) gallium alloy powder. The metal powder was used because it could be prepared with a clean surface and any bulk hydrogen diffusion effects would be minimal. Measurements were carried out over a temperature range of $-29°$-355°C and at hydrogen pressures of 20 Pa to 67.96 kPa. Kinetic data were evaluated with the reaction model used for uranium powder (13).

Experimental

Materials.—Plutonium metal used in this investigation was a plutonium-gallium alloy which was stabilized in the delta phase. The gallium concentration was 1.03 w/o. There was a total of 1335 ppm of metallic impurities including 855 ppm of americium. Americium is present as a radiolytic decay product of plutonium-241. Coupons for this study were machined to a thickness of 3 mm from cast rods. Individual samples weighed about 1.5g. They were cleaned by mechanically polishing the surface and immediately loaded on the vacuum microbalance.

Ultrapure hydrogen (99.999%) and argon (99.999%) were used in this investigation. These gases were introduced into the system through a bed of uranium hydride to further minimize oxygen contamination. However, surface reactions between hydrogen and the stainless steel walls of the vacuum system still produced some water vapor contamination.

Apparatus.—The experimental apparatus used for this investigation has been described in detail elsewhere (13). A Cahn Model 100 microbalance was incorporated into a stainless steel vacuum system. Minimum pressures attainable were in the 10^{-6} Pa (10^{-8} Torr) range. Hydrogen pressures during reaction were controlled with a Granville-Phillips pressure controller and could be varied from 10^{-4} Pa to 10^{5} Pa. Pressures were measured with an ionization gauge or a capacitance manometer. Sample temperatures were varied with a resistance heater controlled with a power proportioning programmer. The thermocouple for measuring the sample temperature was located beside the sample and inside the vacuum system. Output from the microbalance, thermocouples, and pressure meters were collected with a data acquisition system and processed using a computer.

Procedure.—Plutonium powder was prepared by hydriding and then dehydriding a 1.5g plutonium coupon. Hydride sites were nucleated on the coupon by exposure to 6.65 kPa of hydrogen at 20°C for 2 min. Bulk hydriding was then performed slowly in 67 Pa of hydrogen at 20°C. Although slow, this process produced the highest surface area for the powder. Dehydriding was accomplished by heating the sample at 450°C under vacuum. The objective during dehydriding was to attain a reasonable rate and still minimize any sintering of the powder. Surface areas for the powders were calculated from the argon adsorption isotherm, obtained at -196°C, using the BET (14) method. Powder hydriding rates were then measured over a range of temperatures ($-29°$-355°C) and pressures (0.020-67.96 kPa). Following each run the sample was dehydrided at 450°C and reused for the next hydriding run. A total of fifteen different plutonium samples were used throughout the course of this investigation.

Reaction Kinetics

The reaction model used to describe the reaction of hydrogen with plutonium metal powder is called the "Progressive Conversion" model (15). This model assumes that once hydrogen is adsorbed on the surface diffusion into the bulk is very rapid and not rate determining. Thus, the reaction takes place uniformly throughout the particle and not strictly at the metal/hydride interface. The general reaction equation is

$$W_t = W_m\{1 - [1 + k(n-1)M_o^{(n-1)}t]^{1/1-n}\} \quad [1]$$

where W_t = hydrogen reacted in time, t; W_m = total hydrogen reacted; k = rate constant; n = order of the reaction; and M_o = milligram atoms of metal initially available. In the special case where the reaction is first-order ($n = 1$), Eq. [1] becomes

$$W_t = W_m\,(1 - e^{-kt}) \quad [2]$$

This equation was used throughout this study to evaluate rates of reaction.

Results and Discussion

Plutonium powder characterization.—Gallium metal present in this plutonium alloy powder is nonreactive with respect to hydrogen. The role of gallium is to stabilize the plutonium in the delta phase. This metal phase is more reactive with respect to hydrogen than the room temperature alpha phase found in pure plutonium. The most logical reason for the increased reactivity is the greater metal-metal atomic spacing in the delta alloy. In this structure the f-electrons are more localized and are not involved in metallic bonding (16). Thus, it has been proposed that they are available for the rapid chemisorption of hydrogen during the hydriding reaction (17). One initial concern was that gallium would become segregated during the hydriding/dehydriding cycles. This would result in a mixture of alpha and delta phase material. X-ray diffraction analysis of the metal powder showed that the metal was in the delta phase and there was only a trace of alpha plutonium. Apparently the gallium remains uniformly distributed throughout the powder.

When the initial hydriding of a plutonium coupon was carried out in 26.6 kPa of hydrogen at 200°C the reaction was very rapid. Powder formed in this manner contained large particles (Fig. 1). Additional hydriding and dehydriding did not reduce the particle size because of the high temperature (450°C) required for dehydriding. For this investigation the initial coupon was nucleated in 6.65 kPa of hydrogen at 20°C for about 2 min. During this stage about 1% of the total reaction took place. The remainder of the coupon hydriding was carried out at 20°C in 67 Pa of hydrogen over a period of about 5 hr. Powder formed by this method was finer and more uniform than that prepared by rapid, high temperature hydriding (Fig. 2).

Particle sizes of the powder used were measured with a Quantimet 720 particle analyzer. The particle size distribution is shown by a log-normal plot in Fig. 3. The count mean diameter (CMD) was 5.0 μm, while the standard deviation, σ_g, was 13.4. Total surface areas

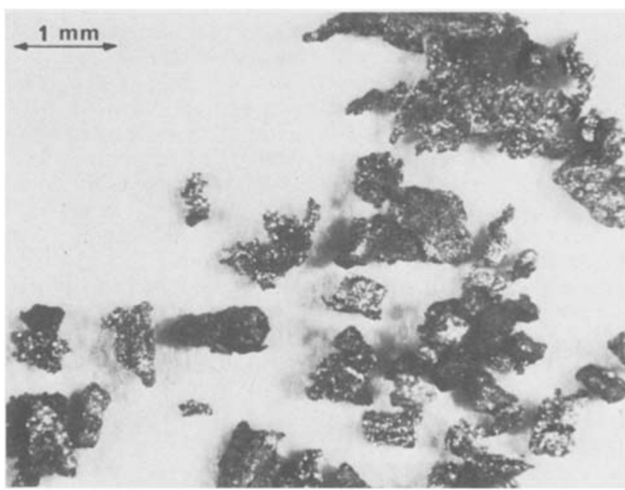

Fig. 1. Plutonium-1 w/o gallium powder prepared at 200°C in 26.6 kPa of hydrogen.

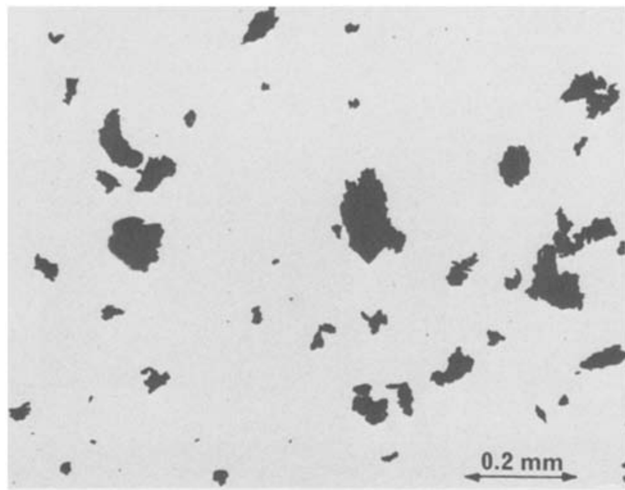

Fig. 2. Plutonium-1 w/o gallium powder prepared at 20°C in 0.067 kPa of hydrogen.

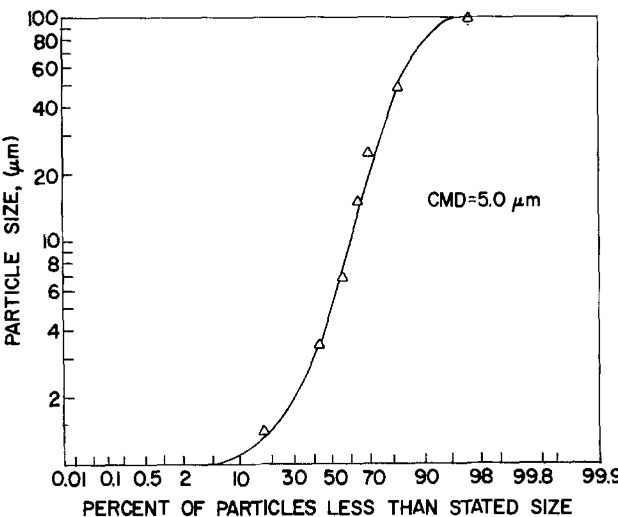

Fig. 3. Log-normal size distribution of plutonium alloy powder. The count median diameter for the particles was 5.0 μm and the geometric standard deviation σ_g was 13.4.

of the samples were measured with the BET (14) technique using argon adsorption at −196°C. The surface area of this powder was calculated to be 0.16 m^2/g. All of the powders used in this study had surface areas on the order of 0.1-0.2 m^2/g. This range was too small to establish any surface area dependence for the reaction.

Kinetic evaluation of powder hydriding.—The applicability of the "Progressive Conversion" model discussed earlier was evaluated under all of the conditions of this investigation. A typical evaluation is illustrated in Fig. 4. This particular hydriding run was made at an initial temperature of 30°C in 1.06 kPa of hydrogen. Because of the heat of reaction the average temperature of this run was 130°C. It is evident that both Eq. [1] and [2] fit the data quite well. Using Eq. [1] the rate constant, k, was 1.60 min^{-1} and the calculated order was 0.91. Equation [2] for a first-order reaction produced a rate constant of 1.46 min^{-1}. For the purpose of this investigation all data were evaluated using Eq. [2].

Effects of temperature on powder hydriding.—Hydriding of plutonium metal released significant amounts of heat. With the experimental set-up being used, this heat could not be dissipated and the net result was an increase in sample temperature. This effect is shown in Fig. 5. Because of the rapid heat release thermal

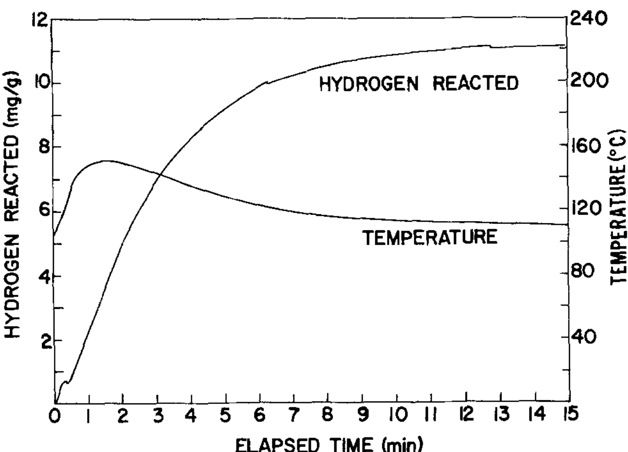

Fig. 5. Exothermic behavior of plutonium powder hydriding at 100°C in 0.067 kPa of hydrogen.

gradients were established between the sample and the wall of the chamber. These gradients, which were most pronounced at low pressures and temperatures, are believed to cause the discontinuities observed in Fig. 4 and 5 through their effect on the microbalance. Discontinuities have been observed at about 0.1-0.2 min after the start of a run for all experiments at temperatures less than 140°C and pressures less than 1.33 kPa.

When the main purpose of an investigation is the measurement of reaction rates, the inability to maintain isothermal conditions could present a problem. Table I summarizes data obtained over a range of temperatures for two pressure levels, 0.067 and 26.6 kPa (0.5 and 200 Torr). Temperatures being reported

872	26.60	48	184	129 ± 30	2.42

were gas-phase temperatures measured next to the sample. Because of the significant self-heating during reaction, an average temperature was calculated for each run. In the first set of experiments at 0.067 kPa, an attempt was made to hold the temperature near its maximum. With the exception of the low temperature runs 833 and 834, heat was supplied to the sample with a furnace and temperature programmer. The effectiveness of this approach is shown by the standard deviations of the temperature. This technique was not used for the higher pressure experiments. The lack of temperature programming coupled with reaction rates which were nearly five times larger resulted in significantly higher standard deviations for the average temperatures.

Since actual powder temperatures were unknown, no attempt was made to evaluate the temperature dependence for powder hydriding using the Arrhenius equation. Examination of the gas-phase temperatures shown in Table I indicate that temperature apparently has little effect on the hydriding rate. This is indicative of a very small activation energy. Additional work is required, however, to measure actual powder temperatures and to evaluate the nonisothermal kinetics.

Studies made with plutonium coupons have shown some temperature dependence. Activation energies have been reported to range from 2 to 6 kcal/mol (8-10, 18). Since in the case of bulk coupons such processes as nucleation and diffusion play a significant role, activation energies may be associated with these processes and not the direct reaction between plutonium and hydrogen.

Effects of hydrogen pressure on powder hydriding rates.—Experimental runs were conducted at pressures of 20 Pa (0.15 Torr) up to 67.96 kPa (510 Torr). Temperatures were nonisothermal and the variation during the investigation ranged from an average of −29° to 355°C. Earlier in this discussion it was shown that hydriding rates were essentially independent of temperature. Only a slight inverse temperature dependence was noted at higher pressures, *e.g.,* 26.6 kPa. This type of behavior was attributed to the role of adsorption at low temperatures and hydride decomposition at high temperatures. The decomposition reaction becomes significant at about 350°C (11). Because of this temperature influence at the temperature extremes, runs at temperatures less than 0°C or greater than 350°C were not used in evaluating pressure effects on hydriding rates.

Data from all runs at various pressures are listed in Table II. These data were analyzed using the equation

$$k_{hyd} = k_0 P^n \qquad [3]$$

where k_{hyd} is the first-order rate constant, P the hydrogen pressure in kPa, k_0 is a constant, and n is the order of the hydrogen pressure dependence. A plot of the data using this equation is shown in Fig. 6. A discontinuity is noted at about 1 kPa (8 Torr) indicating the pressure dependence might be evaluated for two pressure ranges. For the pressure range 0-1 kPa (0-8 Torr) n is equal to 0.45 while for pressures greater than 1 kPa n is 0.11.

In the low pressure region the rate is proportional to $P^{1/2}$. This relationship is typical for dissociative adsorption of hydrogen. For pressures greater than 1 kPa the pressure dependence of the reaction is proportional to 0.11 or very nearly equal to zero. This type of behavior is similar to the Langmuir adsorption isotherm and suggests that hydrogen adsorption may play a major role in the overall hydriding kinetics.

Using Langmuir's kinetic derivation (19) for the adsorption isotherm, θ is the fraction of the surface covered with hydrogen and $1 - \theta$ is the fraction bare. If hydrogen is adsorbed dissociatively

861	67.96	2.21	108 ± 20

$$H_2(gas) \overset{K}{\rightleftharpoons} H(chem) + H(chem) \qquad [4]$$

The rate of adsorption may then be written as

$$v_1 = k_1 P (1 - \theta)^2 \qquad [5]$$

and the rate of desorption is

$$v_{-1} = k_{-1}\theta^2 \qquad [6]$$

At equilibrium the rates are equal and

$$\frac{\theta}{1-\theta} = \left(\frac{k_1 P}{k_{-1}}\right)^{1/2} = (KP)^{1/2} \qquad [7]$$

Upon rearranging Eq. [7] becomes

$$\theta = \frac{(KP)^{1/2}}{1 + (KP)^{1/2}} \qquad [8]$$

The pressure dependence of the surface coverage is shown in Fig. 7. At high pressures θ is independent of pressure while at low pressures $\theta \approx (KP)^{1/2}$.

In considering the hydriding of plutonium powder

$$Pu + H(chem) \xrightarrow{k_2} PuH_2 \qquad [9]$$

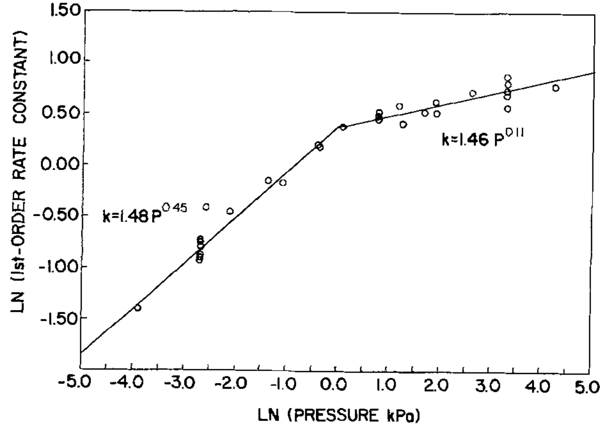

Fig. 6. Effect of hydrogen pressure on plutonium powder hydriding rates with temperatures varying between 5° and 315°C.

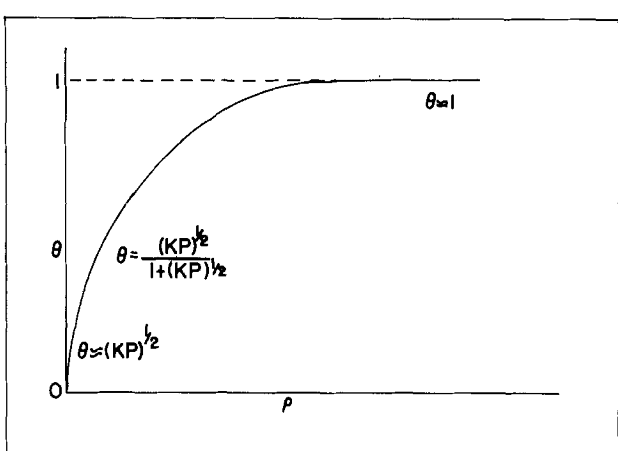

Fig. 7. Variation in surface coverage as a function of pressure for Langmuir-type adsorption.

the temperatures were kept sufficiently low so that the reverse decomposition reaction was negligible. The rate of hydriding has been found to follow a first-order process. If the rate of hydriding is proportional to the hydrogen surface coverage the first-order rate is

$$k_{hyd} = k_2\theta \quad [10]$$

or

$$k_{hyd} = \frac{k_2(KP)^{1/2}}{1 + (KP)^{1/2}} \quad [11]$$

The relationship given in Eq. [11] has exactly the same form as seen in Fig. 7. At pressures less than 0.02 kPa $(KP)^{1/2} < 1$, Eq. [11] becomes

$$k_{hyd} = k_2(KP)^{1/2} \quad [12]$$

where the rate of hydriding is proportional to $P^{1/2}$ and adsorption is rate determining. At high pressures (>1000 kPa) where $(KP)^{1/2} > 1$ Eq. [11] becomes

$$k_{hyd} = k_2 \quad [13]$$

Under these conditions the hydriding rate is equal to k_2 and is independent of hydrogen pressure. This behavior has been observed for the hydriding of plutonium-1 w/o gallium powder as illustrated in Fig. 6.

Equation [11] can be tested for the hydriding of plutonium powder by rearranging to the form

$$\frac{P^{1/2}}{k_{hyd}} = \frac{1}{k_2K^{1/2}} + \frac{P^{1/2}}{k_2} \quad [14]$$

Plotting $P^{1/2}/k_{hyd}$ against $P^{1/2}$ gives a straight line with the slope $1/k_2$. Such a plot is shown in Fig. 8. From an evaluation of the data k_2 was found to be 2.69

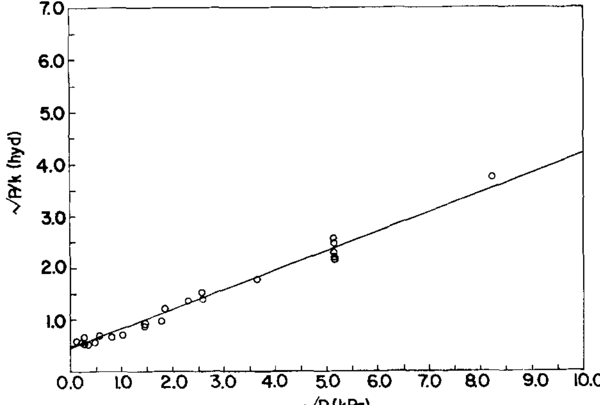

Fig. 8. Modified Langmuir plot for the pressure dependence of plutonium-1 w/o gallium hydriding rates on the hydrogen pressure.

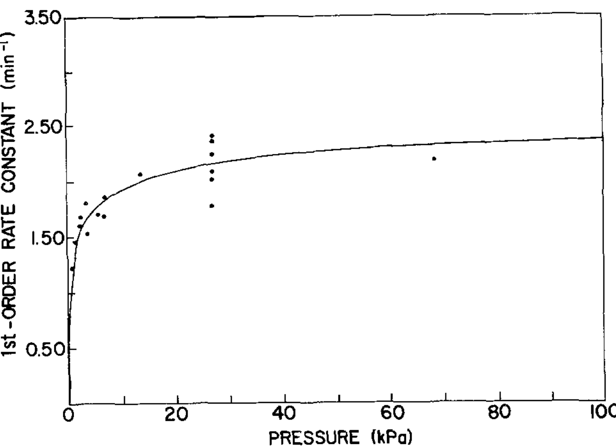

Fig. 9. Variation of experimental and predicted plutonium-1 w/o gallium powder hydriding rates with pressure.

min^{-1} and K was equal to 0.66 kPa^{-1}. Using these constants hydriding rates have been predicted over the pressure range 0-100 kPa. Results are shown by the solid line in Fig. 9. Predicted rates obtained from Eq. [11] are in good agreement with the experimental values from 0 to 70 kPa.

Conclusions

The reaction kinetics for the hydriding of plutonium-1 w/o gallium were measured using a metal powder prepared "*in situ*." This technique successfully minimized oxide formation which introduces a predominant hydride nucleation and growth step in the reaction sequence. Powder hydriding was found to be independent of temperature from −29° to 355°C. Hydriding rates exhibited a hydrogen pressure dependence which could be described by a modified Langmuir equation. At pressures less than 1 kPa rates were proportional to $P^{1/2}$ indicating dissociative adsorption of hydrogen was rate controlling. Above 1 kPa the pressure dependency decreased with complete independence being predicted at about 1000 kPa. In the high pressure region the rates are reaction controlled.

Effects of Heat-Treatment on Indium-Tin Oxide Films

F. T. J. Smith* and S. L. Lyu

Eastman Kodak Company, Research Laboratories, Rochester, New York 14650

ABSTRACT

Highly conductive and transparent films of indium-tin oxide have been sputter-deposited from an oxide target. The effects of annealing in oxidizing or reducing atmospheres on the electrical and optical properties of these films have been determined. The electron concentration and related optical properties are reversible functions of the oxygen partial pressure in the annealing atmosphere. The form of this relationship is consistent with a defect model in which most of the Sn dopant is present in neutral complexes with interstitial oxygen. The Hall mobility and refractive index are changed irreversibly by annealing as a result of subtle changes in film structure.

Highly transparent and electrically conducting thin films are useful in a wide variety of applications, for example, transparent Joule heating elements, infrared-reflecting coatings transparent in the visible, and transparent electrodes allowing optical and electrical access to solid-state devices. The oxides of Cd, In, Sn, and Sb have usually been found to have the best combination of properties (1). In particular, films of indium oxide containing some tin oxide are widely used where sheet resistances of less than 10 Ω/sq are required.

Films of indium-tin oxide (ITO) can be prepared by spray hydrolysis, but for most electronic applications, sputtering, evaporation, or chemical vapor deposition methods are necessary to achieve the required uniformity. Sputtered films have been prepared by using either conventional sputtering from hot-pressed oxide targets (2) or reactive sputtering from metal targets (3). With oxide targets the optimum composition has been reported to be 5-20 mol percent (m/o) SnO_2 in In_2O_3 (4).

The properties of these films are sensitive to the preparation conditions, in particular the oxygen partial pressure in the sputtering atmosphere (5). Film properties can also be modified by annealing in either oxidizing or reducing atmospheres. It would therefore be desirable to develop an understanding of the effects of film structure and stoichiometry on electrical conductivity and optical transmission. This has been achieved to some extent for pure In_2O_3 films (6, 7). In the presence of Sn, however, the situation is much more complex. Precipitation of metallic clusters (8) or possibly an Sn_3O_4-like phase (9) has been reported in some situations. Although the presence of tin leads to a higher conductivity, it is not clear what its role is or what the mechanism is for the changes in conductivity observed when these films are annealed.

We will present results obtained for films deposited by rf sputtering from a hot-pressed oxide target. Deposition parameters have been optimized to yield films having high electrical conductivity and transparency. We will not describe the dependence of film properties on sputtering parameters in detail, since our results are similar to those reported previously (10). Instead, the results of annealing ITO films at various partial pressures of oxygen will be discussed. We will show that, if the films are not reduced to the point of producing a metallic phase, the effect of annealing on conductivity is a reversible function of oxygen partial pressure. These changes in conductivity can be interpreted in terms of the formation of neutral clusters of tin with interstitial oxygen. Annealing also affects the optical properties of these films, in some cases reversibly, as a result of their relationship to the free-carrier concentration.

Experimental Methods

An rf diode sputtering system was used (Fig. 1). It has two notable features. First, the target is placed below the substrate so that material sputtered upward is collected. Second, the substrates were loaded through an evacuable load lock, thus avoiding exposure of the target to the atmosphere and preventing adsorption of moisture by the target material, which is somewhat hygroscopic. As a result the run-to-run reproducibility was very high after initial outgassing and presputtering of new targets. The sputtering chamber is a stainless steel cylinder pumped by an oil diffusion pump with a cold trap. System pressures of 1×10^{-7} to 5×10^{-8} Torr were typically obtained between runs. During sputtering, a throttle valve of fixed diameter was used to limit pumping speed, and both argon and

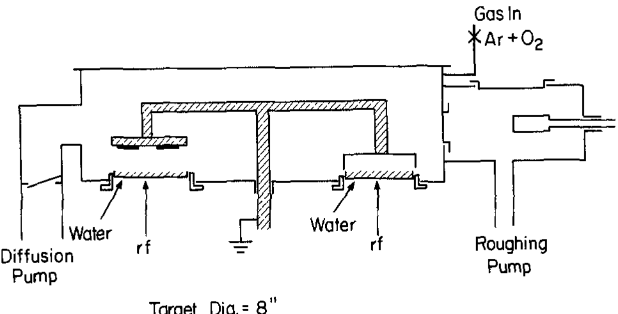

Fig. 1. RF diode sputtering system

oxygen of high purity were introduced to the chamber through metering valves.

A 20 cm diam hot-pressed disk of In_2O_3 containing 9 m/o of SnO_2 was used as a target. This was bonded to a water-cooled copper plate. The substrates were clamped into recesses in a 3 mm thick aluminum disk which in turn was bolted to a 12 mm thick copper plate. This plate acted as a heat sink. Either the substrates or a stainless steel shield could be rotated into position over the target. The target-to-substrate distance was 3.5 cm. To stabilize the system, presputtering onto the stainless steel shield was always done for 30 min before deposition onto the substrates. With a new target, presputtering for 8-12 hr was necessary before film properties became reproducible from run to run. An increased outgassing rate was observed during the first few hours of this procedure.

Polished fused quartz disks 5 cm in diameter and 0.05 cm thick were used as substrates. These were cleaned using ammonia-hydrogen peroxide and hydrochloric acid-hydrogen peroxide mixtures (11).

Optical measurements were made at near-normal incidence using a Cary 14 two-beam spectrophotometer in the visible and near-infrared region and a Beckman AR10 spectrophotometer in the 2-10 μm range. Sheet resistances were measured using a four-point tungsten probe, and both sheet resistance and Hall coefficients were measured by the van der Pauw method. Good agreement ($\pm 5\%$) was found between the two methods for sheet resistance. For the van der Pauw measurements the films were etched into a cloverleaf pattern by using conventional photolithography with hot hydriodic acid as an etchant (12). Silver paste contacts were used.

The measurements were made using a-c current and a d-c magnetic field of 4.3 koe. In some cases electrical measurements were made at high temperatures at various oxygen partial pressures, also by the van der Pauw method. To do this the samples were enclosed in a quartz tube in a furnace placed between the poles of an electromagnet. Mixtures of argon with traces of oxygen were passed through the tube, and the oxygen concentration in the exit gas was measured with a commercial solid-state oxygen meter. For these high temperature measurements, pressure contacts were made by spring-loaded nickel wires. Film thickness was measured by using a profilometer to determine the average height of an etched film edge. Annealing was done in a horizontal tube furnace. The annealing ambient was established by placing the samples in a quartz tube and flowing the appropriate gas over them at ~0.5 cm/sec.

Results and Discussion

A series of films 5000-10,000Å thick were deposited while sputtering parameters such as gas composition and pressure, power, and substrate-target spacing were varied so as to optimize film properties. That is, these parameters were varied to obtain the highest ratio of visible-wavelength transmission to sheet resistance for films in this thickness range.

Films sputtered in an atmosphere containing a few percent of oxygen had a high resistivity. For example, films ~7000Å thick deposited at a power of 500W in an argon plus 5% oxygen atmosphere at a total pressure of 2×10^{-2} Torr had a sheet resistance of $2\text{-}5 \times 10^3$ Ω/sq. In contrast, films of this thickness deposited in pure argon under the same conditions had a sheet resistance of ~5 Ω/sq. Sheet resistance decreased with increase in sputtering power, as reported previously (10). Thus the sheet resistance of films ~7000Å thick deposited from pure argon at 2×10^{-2} Torr decreased from ~9 Ω/sq at 200W to ~4 Ω/sq at 600W.

Repeated presputtering and deposition in pure argon gradually reduced part of the target surface, as evidenced by the development of a very dark metallic appearance. Films deposited from such a target had sheet resistances a factor of two or more higher than those from a fresh target surface obtained by abrading away the darkened surface layers. Similar observations have been reported elsewhere (2). Presputtering at a reduced power of 300W in a 50% O_2 plus 50% Ar atmosphere prevented this darkening, apparently by reoxidation of the target surface. Presputtering was therefore always carried out under these conditions for 30 min before each deposition run. Changing the presputtering atmosphere to pure argon for 1-10 min before film deposition had no effect on film properties. Several hours of deposition in pure argon were required before significant reduction of the target occurred, so that only minor changes in target condition would be expected during a single deposition run.

On the basis of these results, all subsequent films were deposited at 500W in a pure argon atmosphere, pressure 2×10^{-2} Torr, after presputtering in an argon-oxygen mixture as described. The oxygen flow was stopped ~3 min before deposition was begun. With this procedure, sheet resistances were reproducible to within $\pm 5\%$ from run to run. Figure 2 shows the sheet resistance of deposited films and the optical transmission at 500 nm, after averaging interference fringes, both as functions of the total deposition time. Under these conditions the deposition rate was 8.5 Å/sec, so that the film thickness increased from 5100Å after 10 min to 30,600Å after 60 min. The sheet resistance correspondingly decreased, reaching a value of less than 1 Ω/sq after 60 min. The transmission, on the other hand, increased for the first 25 min of deposition and at this point was limited only by the reflectivity of the film. The decrease in transmission of thicker films is presumably due to bulk absorption adding to reflection losses. The decrease at short times is not understood.

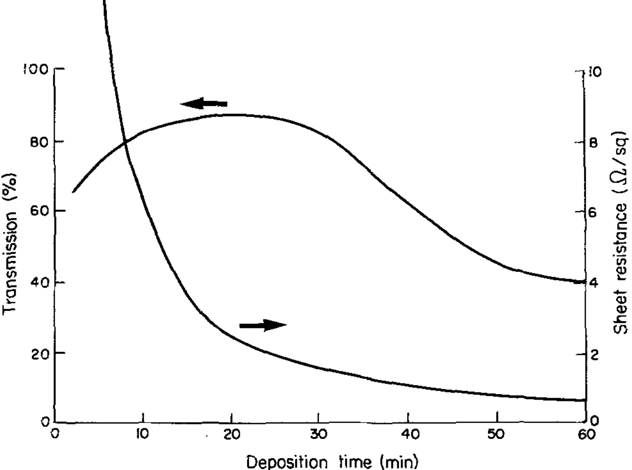

Fig. 2. Dependence of sheet resistance and transmission at 500 nm on total deposition time in 2.0×10^{-2} Torr Ar at 500W power.

If the higher resistivity of films deposited in Ar-O_2 mixtures were due only to differences in carrier concentration resulting from differences in oxygen content, it should be possible to bring all films to the same resistivity by equilibrating them with the same oxidizing or reducing atmosphere. This should take place at a temperature sufficient to allow rapid oxygen diffusion within the bulk of the film. In fact, when films were annealed at 200°C, the resistivity did change and equilibrium was reached within ~30 min. Figure 3 shows the sheet resistance of a relatively resistive film as a function of time at 200°C in nitrogen containing ~20 ppm of oxygen. This film was deposited in an Ar + 5% O_2 mixture. The equilibrium sheet resistance for several films is shown in Fig. 4 as a function of anneal conditions. These data were obtained using films ~8000Å thick deposited in pure argon, giving an as-deposited sheet resistance of 3.5 Ω/sq (curves a), and at oxygen levels of 5% (curves b) and 10% (curves c), resulting in as-deposited sheet resistances of ~2200 and 7000 Ω/sq, respectively. The coated disks were cleaved into halves, and the halves were annealed in either N_2 + 200 ppm O_2 (broken lines in Fig. 4) or N_2 + 10% H_2 + 50 ppm H_2O (solid lines). Anneals were carried out for 30 min at 100°C and repeated at 100°C intervals above this. The sheet resistances decreased with increasing anneal temperature, approaching each other and reaching a minimum at 300°-500°C. At higher temperatures the sheet resistance increased rapidly and the films acquired a dark metallic appearance, indicating reduction of the oxides to a metallic phase. The fact that all samples did not reach the same resistivity indicates that simple differences in initial oxygen stoichiometry do not entirely explain the increase in resistivity for films deposited at the higher oxygen levels. Differences in structure were therefore looked for which could explain these differences in resistivity.

Figure 5 is an SEM picture of the surface of a film ~8000Å thick. This particular film was deposited in pure Ar, but an apparently identical surface morphology is seen for films sputtered in Ar-O_2 mixtures. The films consist of crystallites 1000-2000Å in diameter which form the rounded hillocks seen in Fig. 5. This structure is very similar to that reported by Fraser and Cook (2) for d-c-sputtered films. Cleaved cross sections of similar films were also examined by SEM. Although this instrument was operating near the limit of resolution, a columnar grain structure could be seen with grain boundaries extending perpendicularly from tthe film surface to the substrate. X-ray diffraction spectra show the films to have the bcc In_2O_3 structure. All films had a predominantly [100] texture with a lesser tendency to a [111] orientation. The O_2 level in the sputtering atmosphere had no effect on this surface appearance or orientation. Both [111] (2) and [100] (4) orientations have been reported. The lattice parameter was 10.17Å for all ITO films, as compared with 10.12Å for In_2O_3 deposited from a pure In_2O_3 target in the same system. Fan *et al.* (5) found tthe lattice parameter a = 10.23Å for highly transparent films and an apparently different phase with a = 10.15Å in dark films deposited at low oxygen level. These authors used a target containing 15 m/o SnO_2 compared with 9 m/o in the present work. The present films presumably correspond with their transparent films, the re-

duction in a from 10.23 to 10.17Å resulting from the reduced Sn concentration. Anneals at 400°C in either N_2 or O_2 for 30 min had no effect on either the surface appearance or the x-ray diffraction patterns of any of the films. Thus the differences in resistivity (Fig. 4) for films deposited at various oxygen levels and then all annealed at 400°C in the same atmosphere apparently result from differences in structure which are beyond the resolution of the methods we have used.

Hall coefficient measurements were made to characterize further the effects of annealing on low resistivity films. All films were n-type. The carrier concentration n was obtained from the Hall coefficient R, using the expression $R = r/ne$. The Hall factor r has been approximated by unity in view of the high electron concentrations. In any case, the absolute value of n is not critical to interpretation of the results. In early experiments it was observed that for a given film, if it was not reduced to a metallic phase, *e.g.*, by heating in hydrogen at temperatures above 400°C, n is a reproducible function of the annealing atmosphere. For example, a series of anneals were carried out at 400°C on a single film ~12,000Å thick under reducing, then oxidizing, and then again reducing conditions. The results are given in Table I. Annealing in reducing conditions increased n as compared with the as-deposited film. Annealing in oxygen reduced n to below its initial value. Subsequent anneals in mildly oxidizing, neutral, and reducing conditions increased n until it reached essentially the same value it had after the first anneal in reducing conditions. These changes in n could not be attributed to changes in the film or grain boundary structure, since such changes would not be reversible. On the other hand, the mobility decreased in most instances after annealing in either oxidizing or reducing atmospheres; this could be attributed to structural changes.

To determine whether surface effects are important to the annealing behavior, as has been suggested (13), measurements were made on films of various thicknesses. If the observed changes in n were due to a surface phenomenon, they would decrease in magnitude linearly with increases in film thickness. Figure 6 shows n for films ranging in thickness from ~3000 to ~18,000Å. Results for both as-deposited films and films annealed at 400°C for 30 min in N_2 + 5% H_2 are shown. Before annealing, the results are quite strongly dependent on the film thickness. This is probably due to relatively small changes in the actual oxygen partial pressure during sputtering. An initial adsorption of oxygen from the sputtering atmosphere followed by a gradual release has been reported (5) in a similar system. At some point an optimum oxygen level was apparently reached, giving rise to the maximum in n observed. This variation is almost totally removed by the anneal, indicating the result of such anneals to be a bulk effect for these films. However, note that, although the dependence of n on deposited-film thickness can be removed by annealing, variations in doping level from substrate to surface could exist. It has been reported that the surface of as-deposited ITO films may be tin-rich (9). This could be true for our annealed films but only if the tin-rich layer increased in

Table I. Results of a series of anneals at 400°C on an ITO film 12,000Å thick

Atmosphere	Time (min)	Electron concentration (cm^{-3})	Mobility (cm^2/Vsec)
As deposited		5.69×10^{20}	27.9

thickness linearly with increases in total film thickness so that the average value of n remained constant, the result shown in Fig. 6.

To summarize these observations, n is uniquely determined by the temperature and composition of the annealing ambient for a particular film, if it is not reduced enough to cause a phase change, for example, by annealing under strongly reducing conditions above 450°C. Furthermore, the changes in n caused by annealing result from a bulk effect. To determine n as a function of the oxygen partial pressure p_{O_2}, conductivity and Hall coefficient were measured by the van der Pauw method at high temperatures while samples were held in a flowing argon-oxygen mixture. The range of temperatures over which measurements could be made was small, because below 250°C changes occurred too slowly and above 450°C the films were easily reduced and darkened or developed cracks after a few hours at high temperature. Figure 7 shows equilibrium values of n as a function of p_{O_2} at 320° and 400°C for a film 8300Å thick. The mobilities at these temperatures were 15.3 and 14.3 cm^2/Vsec, respectively, and were independent of n. Over a wide range of p_{O_2}, n is proportional to $p_{O_2}{}^{-m}$. Measurements at intermediate temperatures overlap these but are of the same form with $m = 0.14 \pm 0.01$. The same type of relationship but with $m = 0.166$ has been reported for pure sintered In_2O_3 powder above 600°C (13). The values of n reported for pure In_2O_3 are, however, several orders of magnitude below those shown in Fig. 7 for a tin-doped film.

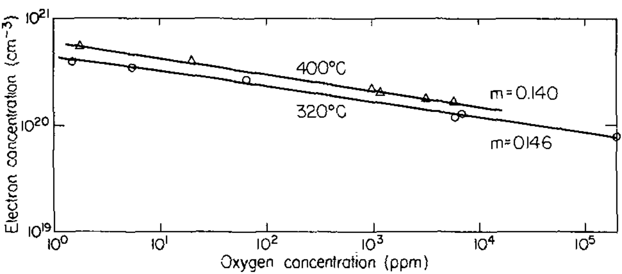

Fig. 7. Equilibrium carrier concentration as a function of oxygen partial pressure for a film 8300Å thick. Lines show fit to $n \sim p_{O_2}{}^{-m}$ with values of m given.

In undoped In_2O_3 this behavior was attributed to the presence of oxygen vacancies which act as doubly ionized donors and are the dominant contributors to n (13). In the present case this is obviously not the situation since the presence of Sn in the lattice has increased n substantially. On the other hand, if all of the Sn simply substituted for In and donated one electron, then n would be equal to the total tin concentration, *i.e.*, $n = [\dot{Sn}_{In}] = [Sn]_T \simeq 1.4 \times 10^{21}/cm^3$, and independent of p_{O_2}. In fact, the measured values of n are much less than the total tin concentration, as noted previously for tin concentrations above a few percent (14). In the In_2O_3 structure, O^{2-} ions occupy only ¾ of the tetrahedral interstices formed by the In^{3+} ion lattice. It might be expected, therefore, that additional oxygen ions could be accommodated easily into the remaining interstices and act as double acceptors to compensate any Sn^{4+} ions introduced onto In^{3+} sites. The oxygen partial pressure would then influence n through the reaction

$$O_I'' \rightleftharpoons 2e + \tfrac{1}{2} O_2 \quad [1]$$

$$K_1 = \frac{n^2 p_{O_2}^{1/2}}{[O_I'']} \quad [2]$$

Since $n << [Sn]_T$, *i.e.*, $n << 1.4 \times 10^{21}/cm^3$ over the range of our measurements, most of the $\dot{Sn}_{In}$ is compensated, therefore, $2[O_I''] \simeq [Sn]_T$. Substituting this into Eq. [2] gives

$$n \simeq \left(\frac{K_1[Sn]_T}{2}\right)^{1/2} p_{O_2}^{-1/4} \quad [3]$$

Obviously the value of $m = 1/4$ predicted by this model does not agree with our results. Making the assumption that interstitial oxygen can accept only one electron leads to $n \sim p_{O_2}^{-1/2}$, in even worse agreement with experiment. On the other hand, if the Sn^{4+} ions form pairs in association with the extra oxygen ion to form a neutral complex of local stoichiometry Sn_2O_4, this could be reduced at low oxygen levels to give pairs of $\dot{Sn}_{In}$ donors

$$\{(2Sn_{In})O_I\}^* \rightleftharpoons 2\dot{Sn}_{In} + 2e + \tfrac{1}{2} O_2 \quad [4]$$

$$K_2 = \frac{[\dot{Sn}_{In}]^2 n^2 p_{O_2}^{1/2}}{[\{(2Sn_{In})O_I\}]} \quad [5]$$

Since most of the Sn is not electrically active, $[\{(2Sn_{In})O_I\}] \simeq [Sn]_T/2$, and since on the other hand $\dot{Sn}_{In}$ is the dominant donor, $n \simeq [\dot{Sn}_{In}]$. Substituting these approximations into Eq. [5] gives

$$n \simeq \left(\frac{K^2[Sn]_T}{2}\right)^{1/4} p_{O_2}^{-1/8} \quad [6]$$

i.e., $m = 0.125$, in reasonable agreement with the value 0.14 ± 0.01 obtained from our high temperature measurements. Clusters of more than two Sn^{4+} ions may be expected at higher Sn levels until a distinct separate SnO_2 phase is formed. The fact that the conductivity of films deposited at a high oxygen level can never be increased by annealing to as high a value as for films deposited in pure argon could be attributed to a much greater degree of formation of large SnO_2-like complexes of this type during deposition as a result of the greater oxygen ion availability. Fan *et al.* (5) have shown in detail the effect on n of oxygen level in the sputtering atmosphere. They report n to decrease very steeply with increases in oxygen partial pressure in the region where highly transparent single phase deposits were obtained, also indicating the formation of neutral complexes under oxidizing conditions.

All films were highly transparent in the visible region. The transmission spectrum for a film ~8000Å thick (Fig. 8) shows an absorption edge at 300-350 nm and interference fringes at longer wavelengths. Figure 8 also shows the spectrum after this film was annealed in N_2 + 10% H_2 at 400°C for 30 min. This anneal increased n from 5.76 to $11.2 \times 10^{20}/cm^3$. It also reduced the optical transmission, shifted the absorption edges, and shifted the interference fringes. Transmission was reduced as a result of any anneal in either oxidizing or reducing atmospheres. The refractive index, calculated from the spacing between interference fringes, was also reduced by any annealing procedure. Figure 9 shows the refractive index for both the as-deposited and annealed films of Fig. 8. The reduction in index resulting from annealing is surprisingly large.

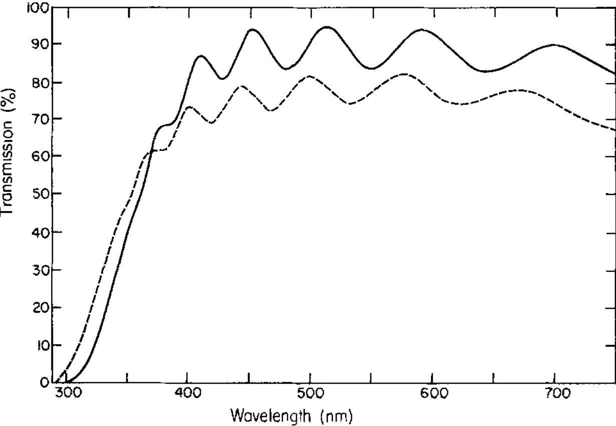

Fig. 8. Transmission spectrum for film ~8000Å thick, as-deposited (solid line) and after 30 min anneal at 400°C in N_2 + 10% H_2 (broken line).

The shift in the short-wavelength absorption edge depended on the nature of the annealing atmosphere in the same way that n does, *i.e.*, anneals in reducing and oxidizing atmospheres gave shifts in opposite directions. Figure 10 shows the shifts in the absorption edge of a single film resulting from a series of anneals and the electron concentrations resulting from each anneal. At values of α above 10^3 cm^{-1}, the square of the absorption coefficient is linearly proportional to the photon energy. A relationship of this sort is expected for direct allowed transitions and has been reported for pure In_2O_3 films (15). By extrapolating the linear regions to zero absorption coefficient, values of the apparent direct gap were obtained. Figure 11 shows these results as a function of electron concentration. A linear relationship is observed between $n^{2/3}$ and the apparent gap, as would be expected if this shift can be attributed to the Moss-Burstein effect (16). In the case of parabolic bands the shift $\Delta E = \frac{h^2}{8m}\left(\frac{3n}{\pi}\right)^{2/3}$. If the effective electron mass m_e is much smaller than the effective hole mass, then $m \simeq m_e$. With this assumption, the data of Fig. 11 give $m_e = 0.64\ m_o$. This

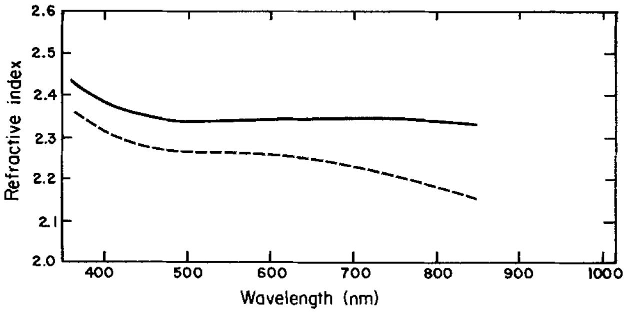

Fig. 9. Refractive index of film ~8000Å thick, as deposited (solid line) and after 30 min anneal at 400°C in N_2 + 10% H_2 (broken line).

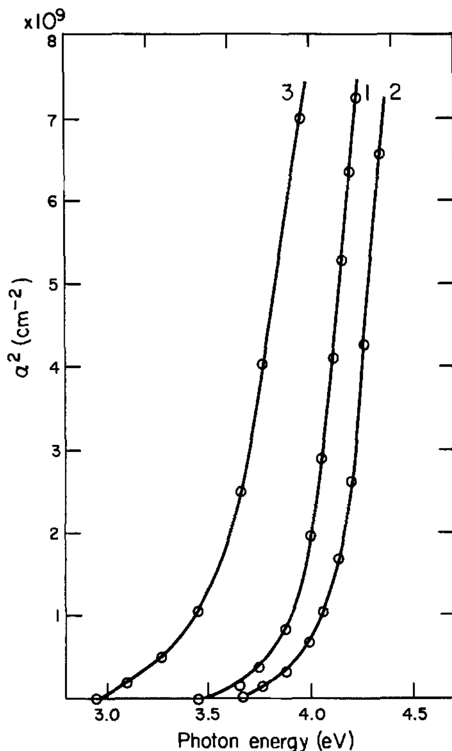

Fig. 10. Energy dependence of square of absorption coefficient for film ~8000Å thick. Curve 1: as deposited, $n = 5.76 \times 10^{20}$/cm³; curve 2: after 30 min 400°C anneal in N_2 + 10% H_2, $n = 11.2 \times 10^{20}$/cm³; curve 3: after 150 min 400°C anneal in O_2, $n = 1.96 \times 10^{20}$/cm³.

can be compared with somewhat lower reported values of 0.54 m_o (14) and 0.5 m_o (17) obtained by varying the Sn concentration to vary n. Since Sn doping at the high levels used would be expected to shift the absorption edge to shorter wavelengths (as a result of the alloying effect), by an amount proportional to the Sn concentration (Vegard's law) this method would be expected to underestimate m_e. Recently a value of 0.55 m_o was reported by others also using the annealing method to vary n (18).

The optical properties in the infrared depend strongly on n. Figure 12 shows the transmission and reflection spectra of an as-deposited film ~4000Å thick having $n = 3.8 \times 10^{20}$/cm³. As discussed in detail

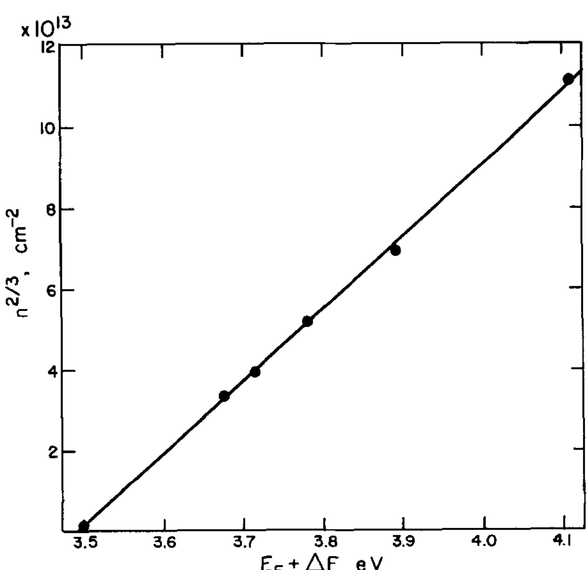

Fig. 11. Dependence of absorption edge on $n^{2/3}$

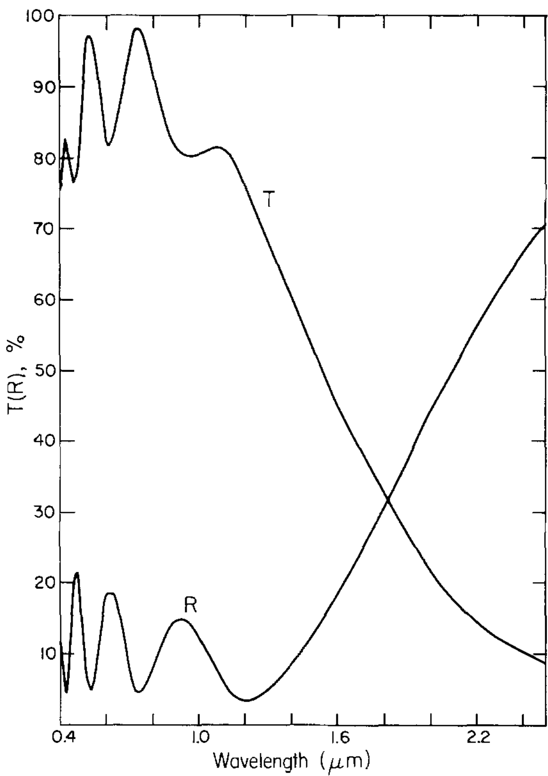

Fig. 12. Transmission T and reflectivity R in the infrared for a film ~4000Å thick with $n = 3.8 \times 10^{20}$/cm³.

previously (10, 14), free-carrier absorption dominates the optical properties at wavelengths longer than the plasma wavelength, which is ~1.8 μm for this particular film.

From the reflectivity and transmission data for both as-deposited and $N_2 + H_2$ annealed films, the value of the optical absorption coefficient α was calculated over a range of photon energies of 0.5-4.5 eV (Fig. 13). Both the Moss-Burstein shift at higher energies and

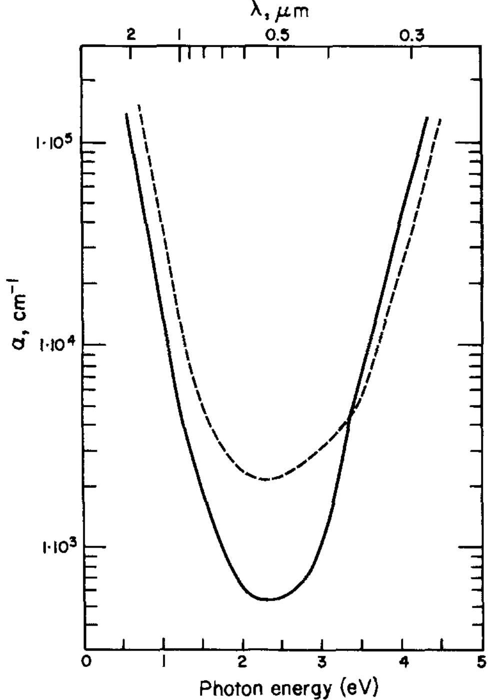

Fig. 13. Absorption coefficient α as a function of photon energy for as-deposited films (solid line) and after 30 min 400°C anneal in N_2 + 10% H_2 (broken line).

the opposite shift at low energies due to the change in plasma frequency are illustrated.

Conclusions

Highly conductive and transparent films of ITO can be deposited from an oxide target by maintaining the target surface in an oxidized condition but depositing films from a pure argon ambient. The electron concentration in these films and properties which depend on it, such as the absorption edges, are affected reversibly when the films are annealed in mildly reducing or oxidizing conditions. This behavior can be rationalized in terms of the formation of neutral complexes of Sn with oxygen interstitials. Other properties, such as the electron Hall mobility and the refractive index, change nonreversibly, apparently because of permanent structural changes.

ABSTRACT

The image contrast of color television tubes is reduced by the diffuse reflection of ambient light at the tube face. A recent method used to compensate this effect makes use of color filters, which are transparent to the phosphor light and absorb the rest of the visible spectrum. The subject of this paper is an investigation of the fundamental optical capability of the color filter concept. The main emphasis is placed on the sandwich system, involving a filter layer between the phosphor layer and the screen glass. Experiments were performed on 5×5 cm^2 test samples, using a spectrophotometer for the reflection measurements and a scanning electron microscope for measuring the phosphor light output. They yield a gain in brightness contrast performance (BCP) of 15-28% for combinations of red or blue phosphors with commercially available inorganic filter pigments. The corresponding increase of brightness can be twice as high if the contrast is held constant. Model calculations, assuming isotropic light scattering within the powder layers and linear superposition of multiple reflections between adjacent layers, show good agreement with the experimental results. Ideal square filters yield a BCP gain of 100-120%, whereas a shift of real phosphor spectra or filter spectra along the wavelength axis only yields a gain of a few percent. The conclusion drawn is that the inorganic filter pigments used set a practical limit to the gain in BCP that can be achieved with the color filter concept. Some results on mixtures of phosphors and filters are included. The experimentally found BCP gain amounts to about 7-10%, *i.e.*, only about one-half of the sandwich gain. A simplified model leads to approximately the same values. The different optical behavior of a color pigment in sandwich and mixture arrangements is apparently due to differences in the effective optical path length for ambient light and phosphor light.

Brightness and contrast are important parameters determining image quality in color television. Both can be improved by an enhanced light output. A further improvement of contrast, *i.e.*, the ratio of useful (image) light to disturbing (reflected ambient) light becomes possible by lowering the tube reflection. This can be achieved, for example, by blackening the screen glass or by filling the empty space between phosphor areas with a black powder. A third method, which has recently come into use (1-3), involves spectral filtering. Each of the three phosphors (red, green, and blue) is combined with a suitable filter material, which is transparent in the spectral region of phosphor emission and absorbent in the rest of the visible spectrum. In this way the phosphor light is hardly if at all attenuated, while the ambient light is strongly reduced after being reflected at the tube face.

The color filter concept is explained in more detail in Fig. 1. In a normal, nonfilter tube (on the left) high-energy electrons out of the vacuum penetrate into the phosphor layer, where they are absorbed and generate visible light, which reaches the observer through the glass of the screen. The thin aluminum backing functions as a definite electrode and serves as a mirror for the visible light. In the sandwich-type filter tube an additional filter layer is placed between each phosphor layer and the screen glass, which must be traversed by the phosphor light as well as by the light from the surrounding. These filter layers, usually inorganic color pigments, have to be applied with exactly the same geometry as the three-color phosphor dots or lines.

A filter effect similar to the sandwich arrangement can be achieved by mixing each phosphor with its corresponding color pigment. The mixture-type filter tube is preferred in practice because of its technological simplicity. Besides contrast improvement, the color filter concept offers the advantage of enlarging the selection of phosphors, because unsuitable chromaticity coordinates can to some extent be corrected by the filter. The quality gain as a result of color filtering is usually (1) expressed in terms of the brightness contrast performance (BCP), which is defined for the red, green, and blue color components, respectively, as follows

$$\mathrm{BCP} = \left(\frac{B}{\sqrt{R}}\right)_{\substack{\text{with}\\\text{filter}}} \Big/ \left(\frac{B}{\sqrt{R}}\right)_{\substack{\text{without}\\\text{filter}}} \qquad [1]$$

Here B stands for the tube brightness per color and R

Key words: cathodoluminescence, inorganic, reflectance, solids.

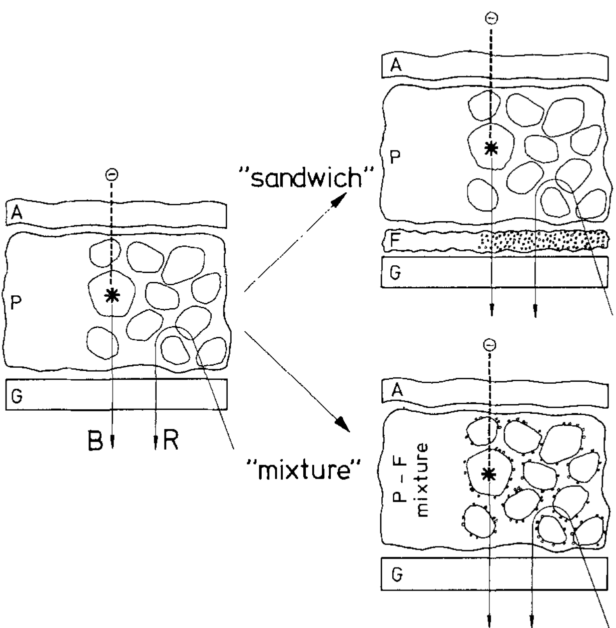

Fig. 1. Filter concept. Light-generating system of a normal, *i.e.*, nonfilter tube (left) and of filter tubes with sandwich or mixture arrangement (right). A = aluminum, P = phosphor, F = filter, G = glass.

denotes the diffuse reflection of the tube for white ambient light, with the specular reflection at the first glass surface excluded. Both B and R are measured with a photopic detector.

The subject of this paper is an investigation of the fundamental optical capability of the color filter concept in color television. The main emphasis is on the sandwich system, results of which have not yet been published. Though somewhat less advantageous for fabrication than the mixture, the sandwich can be regarded as a model system with a more easily understandable mode of operation.

The measurements of the complete color filter systems are assisted by optical model calculations, based on spectrometer measurements on simplified systems, *i.e.*, pigment layers on glass in the case of a sandwich and thick powder layers of pigmented phosphor in the case of a mixture. In the case of the mixture, satisfactory agreement between theory and experiment has not yet been achieved, probably because of greater complexity and additional interaction between phosphor and pigment particles. In the sandwich case, which generally shows greater BCP gains, reasonable agreement between theory and experiment is obtained. This agreement supports further predictions of the theory, *i.e.*, selection of suitable color pigments and their appropriate concentration ranges and an estimate of the theoretical limits of the color filter concept.

Experimental

Sample preparation.—All experiments were made with small test samples of 5×5 cm^2 with clear glass slides as substrates. Layers of phosphor or pigment were prepared by several techniques, the simplest one being sedimentation of a particle suspension in an organic liquid. Electrophoretic deposition is used especially for pigment suspensions, applying charging additives and an upward electrical field. In the lacquer technique some polymer, *e.g.*, nitrocellulose, is incorporated in the suspension, so that a lacquer film can be prepared by centrifuging. Polyvinylalcohol plus ammonium dichromate (pva, adc) is another example of a lacquer material, which can be photohardened in the usual way (4), thereby facilitating the preparation of sandwiches.

Mixtures are prepared by coating the surface of the phosphor particles with pigment. The adherence of the pigment particles (typical diameter 0.1 μm) on the phosphor particles (diameter about 5-10 μm) is usually improved by the addition of latex. On top of the phosphor layer an aluminum film about 0.2 μm thick is evaporated, supported by an auxiliary nitrocellulose film. Finally all volatile, organic components are removed by baking out at 430°C.

Investigated pigments are commercially available types of cobalt blue, ultramarine blue, cobalt green, green chromium oxide, cadmium red, and red iron oxide. Standard blue/green/red phosphors are used: $ZnS:Ag/(Zn,Cd)S:Cu$ or $Y_2SiO_5:Tb/Y_2O_2S:Eu$.

Optical measurements.—The light paths shown in Fig. 1 are only schematic. In reality pigment as well as phosphor particles strongly scatter light. Reliable measurements of their optical properties can therefore only be performed with goniophotometers or with spatially integrating detectors. We used the Zeiss DMR 21 automatic spectrophotometer including a 150 mm diam integrating sphere.

The measurements consisted of reflection of complete color filter systems of sandwich or mixture type (compare Fig. 1), reflection and transmission of pigment layers on glass slides, and reflection of pigmented phosphor in 5 mm glass cuvettes (so-called R_∞). Reflection values are related to the reflectivity of the $BaSO_4$ standard. If necessary the influence of the cover glass is eliminated, according to the theory in the section on Theory Sandwich.

Measurements usually extend from 380 to 800 nm wavelength. With respect to phosphor emission and eye sensitivity the range from 700 to 800 nm is of less importance, but it serves as an additional control, providing nearly absorption-free regions. The continuous measurement values are digitized every 10 nm and fed into a computer.

Brightness measurements.—The brightness of the "glass-filter/phosphor-Al film" samples under cathode-ray excitation was measured in a scanning electron microscope (type: Philips PSEM 500). The excitation conditions were chosen in such a way as to simulate a "TV-like" phosphor load see (Table I). The light output, *i.e.*, the brightness, was measured with a photopic detector (type: Osram-Si-V_λ cell), the spectral sensitivity of which is well matched to the "eye sensitivity." This detector was incorporated into the PSEM and mounted close to the sample.

Theory Sandwich

The optical action of a sandwich-type color filter tube takes place in the four-layer sandwich glass-filter-phosphor-aluminum (GFPA); compare Fig. 1. The main experimental variations concern the F-part. Because of the difficult preparation of a GFPA sandwich, an FG sandwich is a much more favorable test sample. In the following a model is presented, which

Table I. Conditions of electron beam excitation

	PSEM 500	30 AX tube
High voltage*	25 kV	25 kV
Beam current	0.1 μA	300 μA
Spot diameter	30 μm	1.5 mm

Number of lines	62.5	625
Line frequency	15 kHz	15 kHz
Current density* in the spot	$\sim 1.4 \times 10^{-2}$ A/cm^2	$\sim 1.7 \times 10^{-2}$ A/cm^2
Excitation time*, †	0.42 μsec	0.2 μsec

* Parameters relevant for comparison of PSEM 500 with 30 AX tube.

† Excitation time per phosphor element and frame scan, calculated from spot diameter divided by line frequency and length of scanned area.

allows the evaluation of the BCP of a GFPA sandwich from reflection and transmission measurements of an FG sandwich.

The model involves (*i*) the interrelation between the optical properties of single layers and sandwiches; (*ii*) averaging according to the eye sensitivity V_λ, the phosphor emission spectrum E_λ, and the ambient illumination N_λ; and (*iii*) normalizing of "tube with filter" relative to "tube without filter." Assumptions are (*a*) one-dimensional calculation, *i.e.*, no lateral or angular effects; (*b*) addition of light intensities, *i.e.*, no interference effects, which should be allowed for diffusely scattering phosphor and pigment layers; and (*c*) no optical contact between glass and powder layer, in other words a small gap between them.

Let ρ_1, ρ_2, τ_1, and τ_2 be the reflection and transmission of two homogeneous layers. If the two layers are combined to form a sandwich, a geometric series of multiple reflections between adjacent surfaces occurs (see Fig. 2a). The overall transmission τ_{12} and reflection ρ_{12} therefore follow

$$\tau_{12} = \tau_1\tau_2(1 + \rho_1\rho_2 + \rho_1^2\rho_2^2 + \ldots) = \tau_1\tau_2/(1 - \rho_1\rho_2) \quad [2]$$

$$\rho_{12} = \rho_1 + \rho_2\tau_1^2(1 + \rho_1\rho_2 + \rho_1^2\rho_2^2 + \ldots) = \rho_1 + \rho_2\tau_1^2/(1 - \rho_1\rho_2) \quad [3]$$

From Eq. [2] and [3] it is evident that the overall transmission is commutative, but not the overall reflection, *i.e.*

$$\tau_{12} \equiv \tau_{21}, \quad \rho_{12} \not\equiv \rho_{21} \quad [4]$$

If the single layers are not homogeneous, but have a reflection which depends on the direction of light incidence, Eq. [3] has to be replaced by

$$\rho_{12} = \rho_1' + \rho_2\tau_1^2/(1 - \rho_1\rho_2) \quad [3a]$$

ρ_1 and ρ_1' being the reflection of layer No. 1 from the right and the left side, respectively.

The properties of a single layer can be determined from the sandwich properties by resolving Eq. [2] and [3], *e.g.*

$$\rho_1 = (\tau_2^2\rho_{12} - \rho_2\tau_{12}^2)/(\tau_2^2 - \rho_2^2\tau_{12}^2) \quad [5]$$

$$\tau_1 = \tau_2\tau_{12}(1 - \rho_2\rho_{12})/(\tau_2^2 - \rho_2^2\tau_{12}^2) \quad [6]$$

A different problem arises if layer No. 1 is a planar light source. The transmission of light emitted by this light source through a filter layer (No. 2) in front of it follows similarly (see Fig. 2b) as

$$\tau_{(1)2} = \tau_2(1 + \rho_1\rho_2 + \rho_1^2\rho_2^2 + \ldots) = \tau_2/(1 - \rho_1\rho_2) \quad [7]$$

Equation [2], [3], and [7] can be extended for more than two layers by splitting, *e.g.*

$$\tau_{123} = \tau_{12/3} = \tau_{12}\tau_3/(1 - \rho_{21}\rho_3) \quad [8]$$

with τ_{12}, ρ_{21} according to Eq. [2] and [3]. The kind of splitting has no influence, *i.e.*, $\tau_{12/3} \equiv \tau_{1/23}$.

The reflection of the TV-sandwich GFPA is obtained by splitting into GF and PA

$$\rho_{GFPA} = \rho_{GF} + \rho_{PA}\tau_{GF}^2/(1 - \rho_{FG}\rho_{PA}) \quad [9]$$

based on Eq. [3a]. ρ_{GF} is calculated from ρ_{FG} and τ_{FG} using Eq. [5] and [6]. By the same kind of splitting, for the transmission of the planar light source AP through the sandwich FG (in front of it) it follows from Eq. [7] that

$$\tau_{(AP)FG} = \tau_{FG}/(1 - \rho_{FG}\rho_{PA}) \quad [10]$$

Tube reflection R and relative brightness T are obtained by spectral averaging

$$R = \int \rho_{GFPA}V_\lambda N_\lambda d\lambda / \int V_\lambda N_\lambda d\lambda - r \quad [11]$$

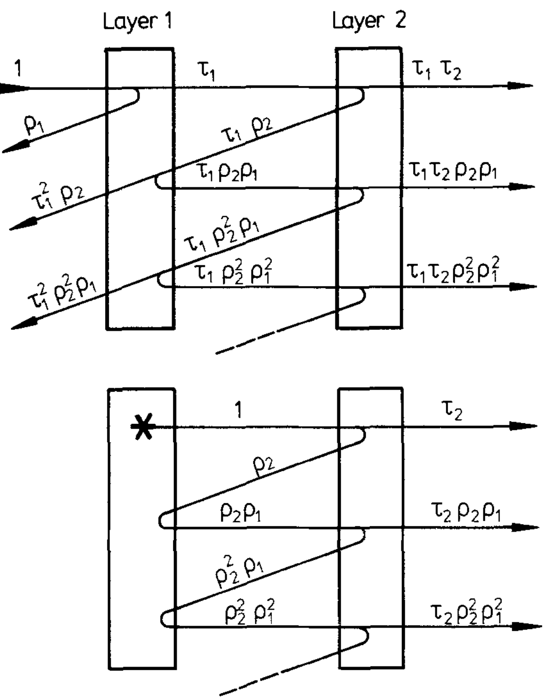

Fig. 2. Light intensities induced by multiple reflections in a sandwich. (a, top) τ_{12} and ρ_{12}, (b, bottom) $\tau_{(1)2}$.

$$T = \int \tau_{(AP)FG}V_\lambda E_\lambda d\lambda / \int V_\lambda E_\lambda d\lambda \quad [12]$$

The specular reflection r at the first glass surface usually amounts to 0.04. T is proportional to brightness **B**, so that on the grounds of definition [1] BCP becomes

$$\mathrm{BCP} = \left(\frac{T}{\sqrt{R}}\right)_{\text{with filter}} \Big/ \left(\frac{T}{\sqrt{R}}\right)_{\text{without filter}} \quad [13]$$

The screen "without filter" forms a three-layer sandwich GPA, which can be evaluated similarly to GFPA. Its characteristic values R and T are determined by ρ_{PA} and by the glass properties ρ_G and τ_G, which are connected with internal glass transmission ϑ and first surface reflection r

$$\rho_G = r + \vartheta^2(1 - r)^2 r/(1 - r^2\vartheta^2) \quad [14]$$

$$\tau_G = (1 - r)^2\vartheta/(1 - r^2\vartheta^2) \quad [15]$$

The computer model described permits the introduction of artificial filter-phosphor combinations as well. Several cases are of interest: (*i*) Real spectra of filter or phosphor may be shifted along the wavelength axis in order to obtain better coincidence. (*ii*) Square filters represent the ideal case. With suitable cut-on and cut-off wavelengths they form the theoretical limit of the color filter concept. (*iii*) A further idealization results from narrow-band or even monochromatic phosphors.

The chromaticity coordinates, X, Y of the three television phosphors must obey international standards. Since the chromaticity may be influenced by color filters, a control is necessary. For this purpose X and Y of each phosphor-filter combination are calculated in the known way by forming three integrals of $E_\lambda \cdot \tau_{(AP)FG}$ multiplied by the three color-matching functions, followed by normalization (5). Small color variations can quantitatively be expressed in multiples of "just noticeable difference," represented by the so-called MacAdam ellipse (6) in the X,Y plane.

Results

Results are given for the measured optical properties of the subsystem "filter glass" (FG), the calculated optical properties of the complete system "glass-

filter-phosphor-aluminum" (GFPA) including the model BCP, and the experimentally determined BCP. Figures 3 and 4 show two typical examples of red pigments Cd(S,Se) and α-Fe_2O_3. In Fig. 3a transmission τ_{FG} and reflection ρ_{FG} spectra of thin pigment layers on glass are to be seen. Because of the scattering nature of the pigment particles the curves of transmission and reflection closely resemble each other, *i.e.*, in regions with low absorption both transmission and reflection are high, and vice versa.

Figure 3b shows the reflection ρ_{GFPA} of the complete sandwich GFPA and the transmission $\tau_{(AP)FG}$ of the light source AP through the filter FG in front of it. They are calculated from Fig. 3a assuming a constant

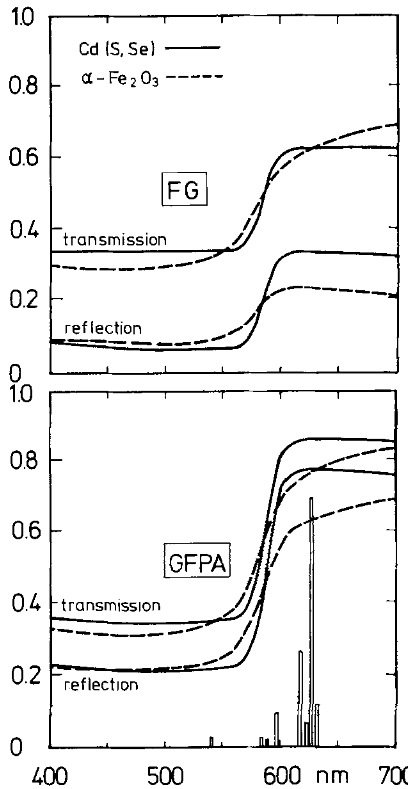

Fig. 3 (a, top) τ_{FG} and ρ_{FG} of two red pigment layers on glass, measured in a spectrometer; (b, bottom) $\tau_{(AP)FG}$ and ρ_{GFPA} calculated from (a), together with E_λ of red phosphor Y_2O_2S:Eu.

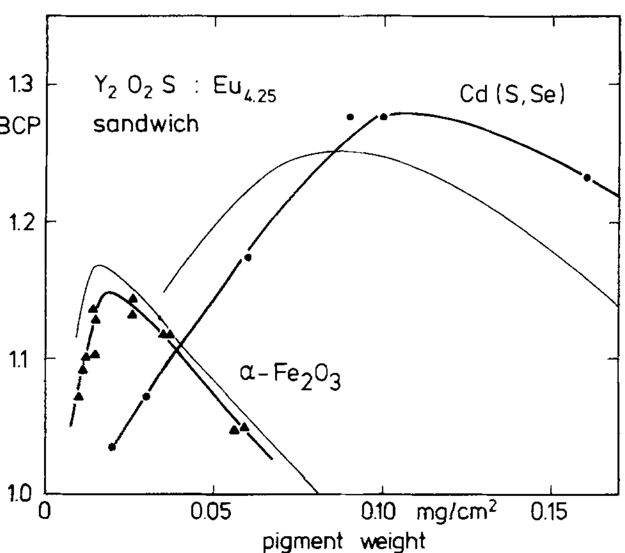

Fig. 4. BCP as a function of pigment weight in a sandwich filter system. The two red pigments are cadmium red and iron oxide. Thin lines refer to model calculations.

Table II. Theoretical *R*, *T*, and BCP values of color filter sandwiches with two typical red pigments*

Filter	mg/cm²	*R*	*T*	BCP
Cd(S,Se)	0.099	0.323	0.800	1.25
α-Fe_2O_3	0.016	0.306	0.727	1.17
No filter	—	0.763	0.984	1

* Calculated on the basis of spectrometer measurements of pigment layers on glass substrate.

ρ_{PA} = 0.80 and no glass blackening. The main feature is a steepening of the absorption edges due to the mirror action of the PA-double layer. Averaging with the emission E_λ of $Y_2O_2S:Eu_{4.25}$ phosphor and a "white" ambient light N_λ delivers theoretical values for the tube reflection *R*, relative brightness *T*, and BCP, listed in Table II.

The superior behavior of Cd(S,Se) pigment compared to α-Fe_2O_3 pigment, evidently caused by the steeper absorption edge, appears correspondingly in the thickness dependence of BCP (Fig. 4, thin lines). Experimental BCP values of complete color filter sandwich systems, determined by reflection and brightness measurements, are included in Fig. 4. They exhibit good agreement with the theoretical values for both maximum BCP and optimum filter thickness.

An example for a blue pigment is shown in Fig. 5 and 6, arranged as for Fig. 3 and 4. A cobalt blue layer of 0.22 mg/cm² thickness in combination with E_λ of ZnS:Ag phosphor yields model values $R = 0.350$, $T = 0.869$, and BCP = 1.30. Figure 5b contains additionally the measured reflection curve of a complete sandwich with a comparable thickness of 0.21 mg/cm². The agreement with the calculated ρ_{GFPA} is satisfactory; larger deviations below 420 nm originate in the assumption of a constant ρ_{PA}. Still better agreements can be achieved by taking into account a slight glass absorption and the angular dependence of glass reflection.

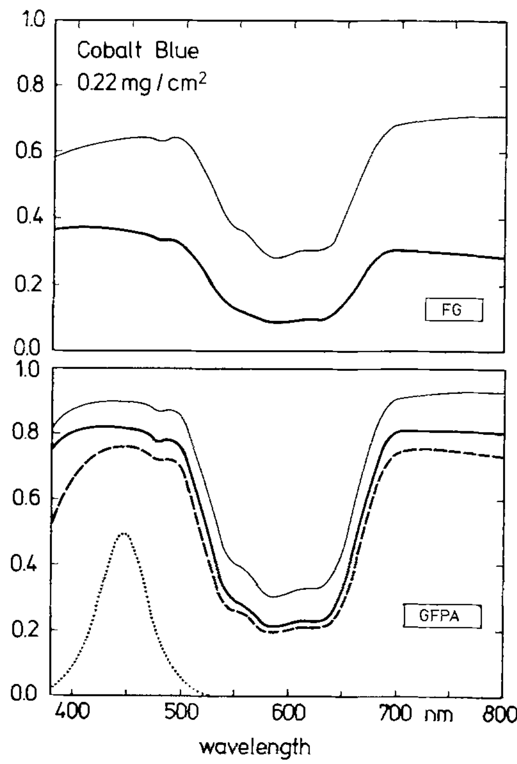

Fig. 5. (a, top) τ_{FG} (thin line) and ρ_{FG} of a cobalt blue layer on glass, (b, bottom) $\tau_{(AP)FG}$ (thin line) and ρ_{GFPA} calculated from (a), together with E_λ (dotted line) of blue phosphor ZnS:Ag. The thick dashed line is the measured reflection ρ_{GFPA}.

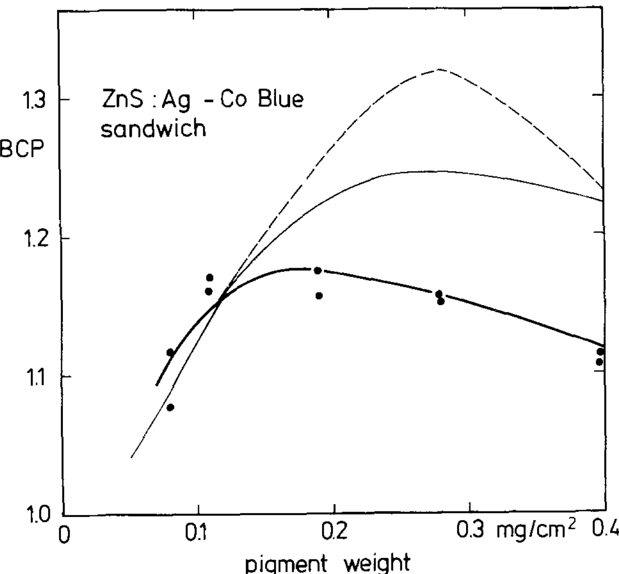

Fig. 6. BCP as a function of cobalt blue pigment weight in a sandwich filter system. The two thin, dashed and full lines refer to model calculations, based on differently deposited pigment layers.

The thickness dependence of BCP is plotted in Fig. 6, for both model calculations and experimental values. The agreement is not so good as with the two red pigments, which may be an effect of pigment processing. The strong influence of preparation technique can be seen by comparing the two thin lines: the dashed and the full ones correspond to different methods of depositing the pigment.

Figure 7 presents results of a green pigment. In this example a layer of 0.06 mg/cm^2 cobalt green in combination with the green phosphor (Zn,Cd)S:Cu yields $R = 0.520$, $T = 0.764$, and BCP $= 0.94$, *i.e.*, only a loss. There is little hope of finding a filter-phosphor combination with a clear BCP gain, either with line-emitting or broad-band phosphors, simply because of the high eye sensitivity in the green spectral region.

The results obtained so far with color filter sandwiches are summarized in Table III, the BCP maxima of real filter-phosphor combinations ranging from 1.15 to 1.45. Among the blue pigments cobalt blue is exceeded by ultramarine blue. Unfortunately, however, the latter has poor temperature stability. As expected, idealized square filters offer much higher BCP gains, as illustrated in Fig. 8. While the usual green phosphor (Zn,Cd)S:Cu even with an ideal square filter exhibits only 1.09, the line-emitting green phosphor Y_2SiO_5:Tb with a 20 nm square filter yields a surprisingly high BCP of 1.65. Narrow-band phosphors with the ability to transmit their whole light output through 10 nm square filters would offer BCP values of 3.39, 2.74, and 4.02 for the red, green, and blue regions, respectively.

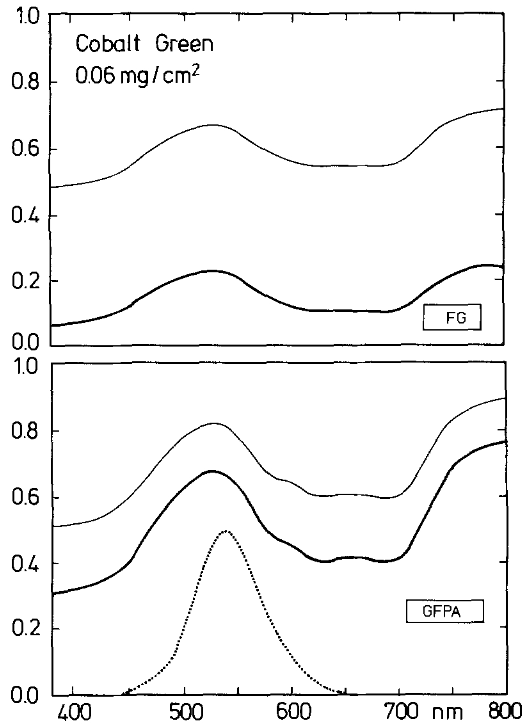

Fig. 7. (a, top) τ_{FG} (thin line) and ρ_{FG} of a cobalt green layer on glass; (b, bottom) $\tau_{(AP)FG}$ (thin line) and ρ_{GFPA} calculated from (a) together with E_λ of green phosphor (Zn,Cd)S:Cu (dotted line).

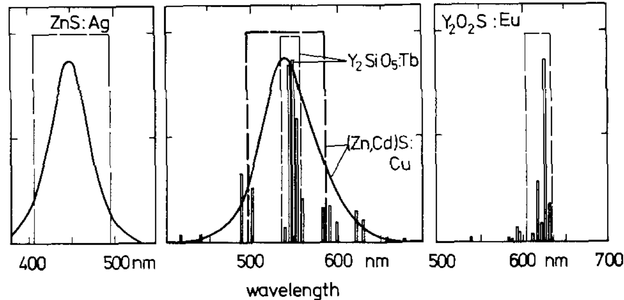

Fig. 8. Emission spectra E_λ of blue, green, and red phosphors, together with transmission τ_F of ideal square filters.

The influence of the pigment on the phosphor chromaticity is expressed in the changes ΔX, ΔY of the chromaticity coordinates (see Table III). Up to optimum pigment thicknesses there is only a small shift, providing a slight expansion of the accessible color triangle toward the purple line [about 1 or 2 steps of "just noticeable difference" (6) for the two blue pigments and about 3 or 4 steps for the two red pigments, respectively, exceeding the standardized E.B.U. toler-

* Filter-induced chromaticity displacements ΔX and ΔY according to CIE 1931 (5).

ances (7) by no more than a factor of 2]. On the other hand, this shift can be used to compensate the green shift of certain high efficiency red or blue phosphors. For example, Y_2O_2S phosphor with 3 instead of 4.25% Eu exhibits a chromaticity displacement ($\Delta X = -0.0093$, $\Delta Y = 0.0086$), which is largely canceled by 0.13 mg/cm² Cd(S,Se).

Pigment as well as phosphor materials frequently exist in the form of mixed crystals, and compositional variations can be simulated by shifting real spectra along the wavelength axis. Our model calculations reveal, however, that no essential BCP improvements can be obtained in this way. In the case of filter variation, BCP increases by only about 1% at the most. Shifting of phosphor spectra yields up to 5% additional BCP gain, but at the cost of an intolerable chromaticity change ($\Delta X = 0.015$, $\Delta Y = -0.033$ for ZnS:Ag).

Discussion

The experimentally determined BCP of sandwich-type filter tubes ranges from about 1.15 to 1.25 for commercially available red or blue pigments. Up to now no gain has been found for the green color. The filter-induced chromaticity changes exceed the perception threshold only slightly. They can be used either for a slight increase of color gamut or for the green shift compensation of certain high efficiency phosphors.

Reasonable agreement is obtained between experiments and sandwich model calculations, regarding both maximum BCP value and optimum pigment layer thickness. From this fact the other model predictions acquire a higher probability, too. The model thus helps one in making a selection from among numerous commercial pigments. Those presented belong to the best ones according to model calculations.

Another important model prediction concerns the wavelength shifts of real spectra. Only about 1% additional BCP gain appears to be possible, unless excessive chromaticity displacements take place. Therefore, essential improvements cannot result from variations of mixed crystals. The most important point is the slope of absorption edges. In this respect commercial pigments are probably optimized, because in accordance with color theory (8) the most saturated colors are those with rectangular spectral characteristics, the so-called optimal colors. The conclusion is therefore drawn that the present filter pigments form a practical limit and essentially higher BCP gains are not to be expected.

Ideal square filters yield BCP values of 2-2.2 for the red and the blue, *i.e.*, a gain of 100-120%, while the portion achieved by real filters amounts to about 1/4 to 1/3. This is another indication of the limiting character of the present pigments, since square responses are, of course, quite unrealistic. A further, even more utopian BCP improvement results from narrow-band phosphors with 10 nm square filters.

For all three stages, *i.e.*, real filters, square filters, and narrow-band phosphors with 10 nm square filters, the same sequence green, red, and blue of increasing BCP is observed. This is evidently due to the increasing wavelength distance (about 15, 70, 105 nm) from the maximum of eye sensitivity, which facilitates the discrimination between passband and rejection band. At the third stage, however, differences between green, red, and blue would disappear if the bandwidth approaches zero. In this case, with $T = 0.984$ and $R = 0.037$, BCP arrives at its absolute limit 4.55, as long as antireflection coatings are excluded.

As already stated, blackening of screen glass is frequently used for contrast improvement. From Eq. [7] one can see that brightness or relative brightness T is approximately proportional to glass transmission τ_G. From Eq. [3] it follows that tube reflection R varies approximately as a function of τ_G^2. So indeed contrast, which is proportional to B/R, increases approximately as $1/\tau_G$, but at the cost of a loss in B. On the other hand, BCP, forming a kind of geometric means of contrast and brightness, to a first approximation does not depend on τ_G, since τ_G and square root of τ_G^2 cancel out.

A given BCP gain can lead to different results, depending on the choice of τ_G. If, for example, τ_G of the filter tube is increased so that R (with filter) equals R (without filter) then B (with filter) becomes B (without filter) times BCP. Alternatively, τ_G of the filter tube can be chosen so that contrast remains constant, whereby the brightness ratio becomes approximately BCP squared. As the BCP criterion cannot decide which of these alternatives is to be preferred, we propose a new criterion, as demonstrated in Fig. 9. Relative brightness T is plotted as a function of tube reflection R. The curve is obtained by variation of internal glass transmission ϑ from 1 (*i.e.*, no glass blackening) to 0 (total glass blackening). The absolutely best combination of T and R is no doubt $T = 1$ and $R = 0$.

We now put forward the hypothesis that a real combination (T, R) is the better the shorter its distance from the "ideal point" ($T = 1$, $R = 0$). From this the optimum ϑ for the tube without filter turns out to be $\vartheta_{op} = 0.66$, corresponding to $\tau_G = 0.61$, which agrees surprisingly well with the quality maximum known from practice. For sandwich filter tubes with 0.03 and 0.1 mg/cm² Cd(S,Se), ϑ_{op} equals 0.79 and 0.89, respectively, agreeing with the experience that the more filter elements (color pigments or also black matrix between phosphor areas) are already present, the lower the optimum glass blackening. Of course, this is not an absolute criterion, which would require detailed physiological knowledge, but it can help one to find a reasonable compromise between brightness and contrast, especially if supplemented by empirical calibration points.

Outlook for Mixture Systems

Typical results of mixture-type color filter systems are shown in Fig. 10. BCP of the combination α-Fe_2O_3

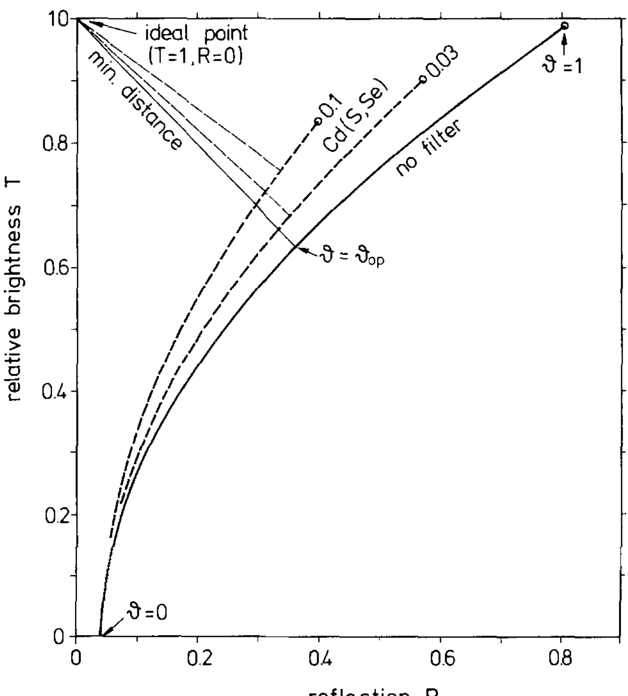

Fig. 9. Relative brightness T vs. reflection R (inclusive specular component) for a nonfilter tube and two sandwich filter tubes with 0.03 and 0.1 mg/cm² Cd(S,Se), calculated from τ_{FG} and ρ_{FG} measurements by variation of the internal glass transmission ϑ. At $\vartheta = \vartheta_{op}$ the distance from the ideal point passes through a minimum.

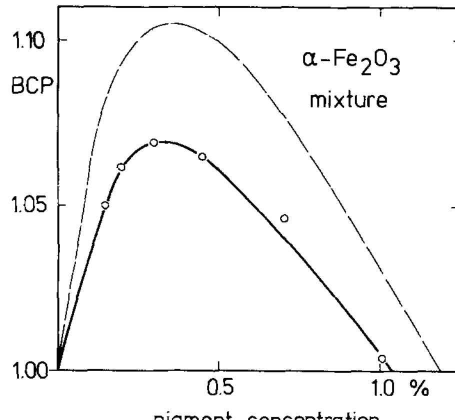

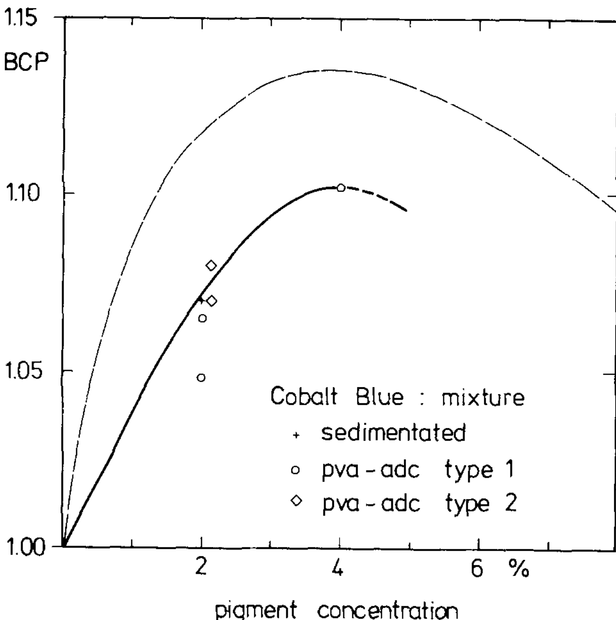

Fig. 10. BCP as a function of pigment concentration in a mixture filter system. The dashed lines refer to model calculations. (a, top) Red pigment α-Fe_2O_3; (b, bottom) cobalt blue.

with Y_2O_2S:Eu phosphor reaches 1.07 at about 0.3% pigment concentration. For cobalt blue with ZnS:Ag phosphor a maximum BCP value of about 1.1 is achieved at about 4% pigment concentration. In both examples the mixture yields only about half the BCP gain of the sandwich (see Fig. 4 and 6, and Table III).

Converted to the phosphor layer thicknesses of about 3.5 mg/cm^2 for the red and 3 mg/cm^2 for the blue, the optimum pigment concentration corresponds to layer thicknesses of about 0.12 mg/cm^2 for cobalt blue and 0.01 for α-Fe_2O_3, which are again only about half of the optimum thickness values of the sandwiches. This implies that at low pigment quantities the BCP of sandwiches and of mixtures rises in approximately the same way, but that the BCP of sandwiches continues it rise up to about twice as high a pigment quantity as with mixtures.

A qualitative explanation for this behavior can be derived from electron absorption by the filter pigment instead of the phosphor, which occurs in mixtures only. But in view of the low actual pigment concentration it is clear that this mechanism is not sufficient. The main cause is probably the simple fact that the filter layer in a sandwich system has to be crossed twice by the ambient light, but only once by the phosphor light, whereas in a mixture system the paths for both kinds of light are approximately equal. For a final understanding the different mechanisms of light scattering in sandwiches and mixtures have to be taken into account. In mixtures with a small pigment concentration the optical interaction between phosphor and pigment proceeds mainly by scattering at the phosphor particles, which are large compared to the light wavelength. In sandwiches the filter-relevant light scattering happens among subwavelength pigment particles within the pigment layer.

The essential experimental findings can be reproduced by a simplified empirical model, the results of which are included as dashed lines in Fig. 10. It is assumed that light generation takes place only in a thin surface region of the phosphor layer adjacent to the aluminum film. By formally regarding the layer with the phosphor-filter mixture as a filter layer and combining a virtual light-emitting layer with the aluminum film, it is possible to treat a mixture-type color filter system with the same computer program as the sandwich.

Transmission and reflection of this type of "filter" layer are determined on the basis of the Kubelka-Munk theory (9), which enables a weakly absorbing, scattering material to be described with the aid of an absorption coefficient K and a scattering coefficient S. Measurements of R_∞, the reflection of an "infinitely" thick powder layer, yield the ratio K/S. S can be evaluated, for example, from reflection measurements of layers with different finite thicknesses. S depends, as stated above, mainly on the phosphor. This is confirmed by our measurements, which give values of about 500 cm^2/g for the blue phosphor and 400 cm^2/g for the red one, nearly independent of pigment addition and wavelength. So a relatively simple measurement of R_∞ is generally sufficient to obtain a reasonable prediction of the BCP of a complete mixture system.

Conclusion

The action of color filters in color television tubes can be understood with the help of relatively simple models, especially in the case of sandwiches. BCP gains up to about 25% have been obtained in sandwiches with commercial filter pigments. This appears to be a practical limit, which could not be essentially exceeded. Mixture-type color filters, though more favorable for production, exhibit only about one-half of the sandwich BCP gain.

Fujitsu Laboratories Limited, 1015 Kamikodanaka, Nakahara-ku, Kawasaki, Japan

ABSTRACT

The properties of phosphorus-doped molybdenum silicide as a gate electrode, interconnecting material, and impurity diffusion source for LSI's have been studied. The phosphorus-doped molybdenum silicide films were deposited by co-sputtering using specially designed Mo and Si targets in a PH_3/Ar atmosphere. PH_3 decomposed to P and H_2 during sputtering and the phosphorus combined with Mo and Si. Typically, a phosphorus concentration of 1.5×10^{21} cm^{-3} in the films was used. As-deposited films (Mo/Si $\leqq$ 0.5) had amorphous structure and high resistivity. After the films were annealed at temperatures above 800°C, they became polycrystalline and resistivity was decreased. The resistivity of the film with a Mo/Si ratio of 2 to 1 was 7.5×10^{-5} Ω-cm with annealing at 1000°C in N_2. Phosphorus was able to diffuse from the doped molybdenum silicide films to the Si substrate during annealing in O_2. After high temperature annealing up to 1100°C, the contact resistance between the molybdenum silicide and the silicon substrate was below 2×10^{-6} Ω-cm^2. The reliability of doped molybdenum silicide gate MOSFET's is as good as polysilicon gates and the threshold voltage shift is within ±20 mV under stress conditions of 2.5 MV/cm for 1000 hr at 150°C.

As LSI device dimensions continue to decrease, the conductivity of the polysilicon used for interconnections and gates is beginning to limit the circuit performance.

Previous investigators have explored the use of refractory metals such as Mo and W for gate electrodes and interconnections in MOSFET circuits (1-6). These metals have significantly higher conductivity than polysilicon, but do not have the ability to withstand the chemical reagents and oxidizing ambient used in LSI fabrication.

In order to overcome these disadvantages, the refractory metal silicides, such as $MoSi_2$ and WSi_2, have been proposed because of their resistance to oxidizing ambient and chemical reagents (7-11). It has been reported that the contact resistance between the molybdenum silicide and the silicon substrate was increased by high temperature annealing, but this problem has never been solved completely (12, 13). Moreover, as the contact region cannot be doped through the silicide, it must be doped prior to gate electrode deposition. Sometimes, a slight shift of threshold voltage appears due to the mobile ions in the oxide films when silicide is used as the gate electrode (7).

We have developed phosphorus-doped molybdenum silicide films in order to overcome just these problems. This film has several advantages for LSI fabrication.

In this paper we discuss the properties of these phosphorus-doped molybdenum silicide films, the composition of films, the behavior of the phosphorus in the films, the electrical properties of the contact between the silicide and the silicon substrate, and MOS device characteristics.

Deposition of Phosphorus-Doped Molybdenum Silicide Film

The phosphorus-doped molybdenum silicide film was deposited by a d-c magnetron co-sputtering technique. A conceptual diagram is given as Fig. 1. The deposition was performed from specially designed Si and Mo targets as shown in Fig. 2. A larger proportion of the Mo target (99.95%, 150 mm diam) was covered with fan-shaped high-purity Si.

The chamber was pumped down to 4×10^{-7} Torr (5.3×10^{-5} Pa) and backfilled to sputtering pressure, 6×10^{-3} Torr (0.8 Pa), by introducing Ar and PH_3. Typically, PH_3 partial pressure of 1.1×10^{-3} Torr (0.15 Pa) was used. The ratio of Mo to Si in the deposited films could be varied by changing the positions of the Si and the sputtering pressure. The phosphorus concentration is varied by controlling the ratio of PH_3 and Ar in the sputtering gas. The deposition rate was 10-15 Å/sec and d-c power was 160-220W.

Crystal Structure

Silicide films of various Mo/Si ratios were deposited on the thermally grown SiO_2. The Mo/Si ratio in the film was measured by Rutherford backscattering using $^4He^+$ ions at 330 keV and $^3He^{++}$ ions at 300 keV. Structure information was obtained using x-ray diffraction techniques. When the Mo/Si ratio was lower than 0.5 as-deposited films were an amorphous structure. The amorphous film became a polycrystalline structure after high temperature annealing. The relation between annealing temperature and x-ray diffraction traces is shown in Fig. 3. The Mo/Si ratio in this film was 0.45 (Mo:Si = 1:2.2). This figure shows that the silicide film is crystallized at annealing temperatures above 800°C and exhibits a tetragonal $MoSi_2$ structure (JCPDS cards 6-0681).

On the other hand, as-deposited films with Mo/Si ratios higher than 0.5 were crystallized a little as shown in Fig. 4. Figure 4(a) shows the Mo_3Si phase for an Mo/Si ratio of 2.7, and Fig. 4(b) shows $MoSi_2$ (hexagonal structure) for an Mo/Si ratio of 0.9. After annealing above 800°C, the $MoSi_2$ structure changes from hexagonal to tetragonal.

X-ray diffraction traces for various Mo/Si ratios are shown in Fig. 5. The silicide films on SiO_2 were annealed at 1000°C for 20 min in N_2. Figure 5(a) shows the simple phase Mo_3Si for an Mo/Si ratio of 2.7 (Mo:Si = 1:0.37). When the Si ratio in the film is increased, the film produces Mo_5Si_3 and $MoSi_2$, as shown in Fig. 5(b) for an Mo/Si ratio of 0.9 (Mo:Si = 1:1.1). The $MoSi_2$ phase is for an Mo/Si ratio of 0.5 (Mo:Si = 1:2) only, as shown in Fig. 5(c). When the Mo/Si ratio falls 0.35 (Mo:Si = 1:2.9), as in Fig. 5(d), the film has the $MoSi_2$ phase only.

Composition of the Films

The depth concentration profile of the samples before and after annealing was obtained by Rutherford

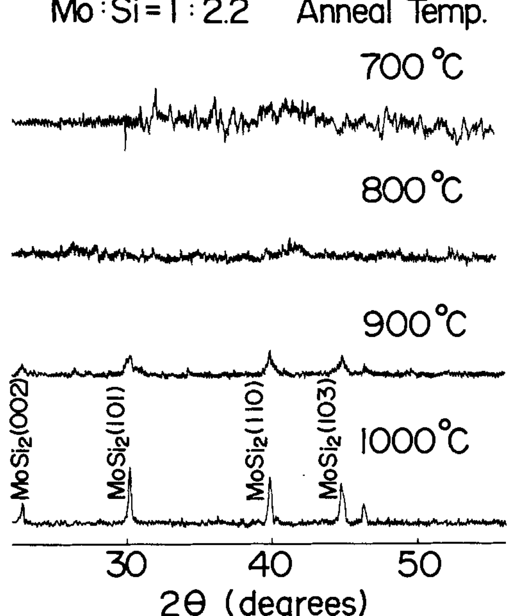

Fig. 3. X-ray diffraction traces as a function of the annealing temperatures. The Mo/Si ratio is 0.45.

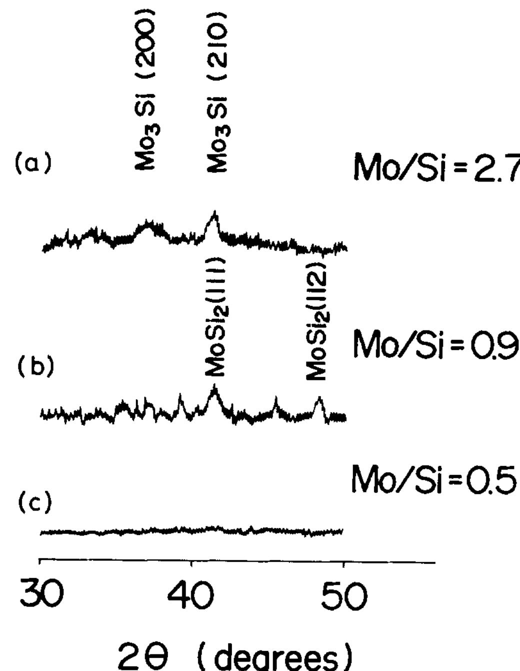

Fig. 4. X-ray diffraction traces of as-deposited films for various Mo/Si ratios: (a) 2.7, (b) 0.9, and (c) 0.5.

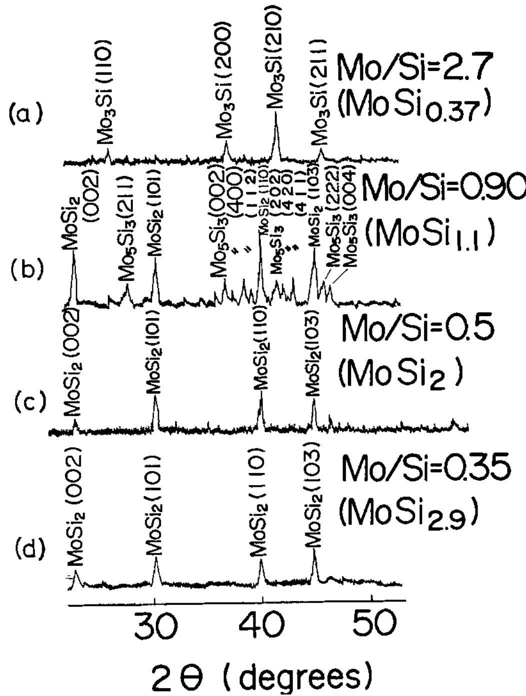

Fig. 5. X-ray diffraction traces of annealed films for the various Mo/Si ratios. The films were annealed at 1000°C for 20 min in N_2.

backscattering spectra analysis. The silicide films deposited on SiO_2 and Si were annealed for 20 min at 1000°C in N_2. The Mo/Si ratios of the samples were 0.35 (1:2.9) and 0.82 (1:1.2) for Si-rich silicide and Mo-rich silicide films, respectively, as compared to $MoSi_2$. The film thickness was 780Å.

Figure 6 shows the backscattering spectra of the sample before and after annealing. The sample was Si-rich silicide film deposited on SiO_2. In the spectra of the annealed sample, the center of the Mo spectra is slightly higher than one side, and the shoulder is broad. This indicates that the ratio of Mo decreased slightly at both the silicide surface and at the silicide/SiO_2 interface. A model of this is shown in the upper right-hand corner of Fig. 6.

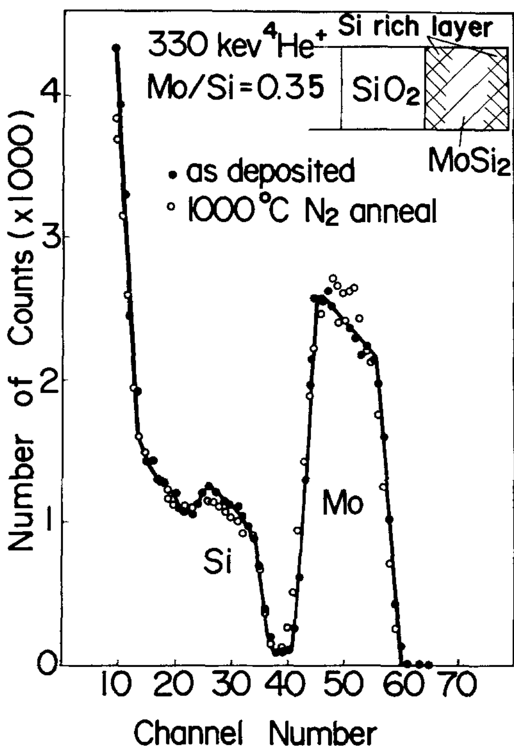

Fig. 6. Backscattering spectra of the thin film on SiO_2 before and after annealing at 1000°C for 20 min in N_2. The Mo/Si ratio is 0.35.

Figure 7 shows the backscattering spectra of the Si-rich silicide on Si before and after annealing. After annealing, the presence of the phase is confirmed by the height of the respective "step" in the backscattering spectra, indicating a region with a 1:2 Mo/Si ratio. The width of the Mo spectra is decreased and the interface between the silicide and Si moves toward the surface after annealing. This indicates that excess Si in the film is precipitated at the silicide/Si interface and the film is recrystallized as a double layer of $MoSi_2$ and Si, as shown in the upper righthand corner of Fig. 7.

The spectrum of the Mo-rich silicide film on SiO_2 is shown in Fig. 8. This spectrum shows that the ratio of Mo increases at the surface and at the silicide/Si interface, and the Mo/Si ratio at the middle of the film approaches $MoSi_2$ after high temperature annealing. A model of this is shown at the top of Fig. 8.

The spectra of the Mo-rich film on Si are shown in Fig. 9. The spectrum of the annealed film indicates that Si diffuses into silicide from the Si substrate and forms a 1:2 Mo/Si ratio. The film thickness increases until the composition changes to $MoSi_2$ as shown in Fig. 9.

These backscattering spectra indicate the following results. The composition profile of the as-deposited sample is uniform from the silicide surface to the silicide/SiO_2 or Si interface. The composition profiles of the films on Si change to 1:2 Mo/Si ratio after annealing. On the other hand, the composition profiles of the films on SiO_2 vary from the middle of the film to the surface or the silicide/SiO_2 interface. The middle of the films approaches 1:2 Mo/Si ratio.

Behavior of Phosphorus in Molybdenum Silicide Films

The sputtering gas was analyzed by a mass analyzer. The mass spectra of the sputtering gas are shown in Fig. 10. Before sputtering, H_2O, P, PH_1, PH_2, PH_3, and Ar signals were observed in the atmosphere. During sputtering, P, PH, PH_2, and PH_3 signals disappeared, and the H_2 signal increased. Thus, it is clear that PH_3 gas decomposes into P and H_2, and the phosphorus is combined with Mo and Si during the deposit.

Phosphorus-doped molybdenum silicide films with various Mo/Si ratios were deposited on thermally grown SiO_2. The film thickness was about 3000Å. The phosphorus concentration was measured by neutron activation analysis (14). The doped silicide films on SiO_2, were irradiated for 6 hr in the center of a nuclear reactor at a flux of 3.7×10^{12} n/cm^2 · sec. Subsequently the phosphorus was chemically separated and then precipitated. The precipitate was β-counted several times during the next 30 days to determine the amount of radioactive P-32. The weight of phosphorus in the film was measured through this radioactive tracing process.

Figure 11 shows the relation between the phosphorus concentration in the as-deposited films and the Mo/Si ratio when the film was deposited by sputtering under PH_3 at 1.1×10^{-3} Torr. When the Mo/Si ratio is less than 0.5, the phosphorus concentration in the film is about 1.5×10^{21} cm^{-3}. When the Mo/Si ratio is greater than 0.5, the phosphorus concentration decreases. These films were slightly crystallized as described in the previous section. The phosphorus concentration may be related to the crystallization of as-deposited films. When the total pressure was 6×10^{-3} Torr and the PH_3 partial pressure was below 1.1×10^{-3} Torr, the phosphorus concentration appeared to be proportional to the exponent of the PH_3 partial pressure as shown in Fig. 12.

The doped silicide films were annealed in O_2 and N_2 from 800° to 1000°C for 20 min. The phosphorus concentration in the film was measured by neutron activation analysis. Figure 13 shows the relation between the phosphorus concentration and the annealing temperature. When annealing above 900°C in N_2, the phosphorus concentration decreases to a level of 2.5×10^{18} cm^{-3} at 1000°C for 20 min. On the other hand, in O_2 annealing, the phosphorus concentration remained almost the same as before annealing. Moreover, when the doped silicide film covered with CVD SiO_2 of 2000Å was annealed in N_2, the phosphorus concentration was almost the same as before annealing. Therefore, thermal oxide film formed by O_2 annealing on the silicide prevents the out-diffusion of phosphorus from the doped film.

The chemical state of phosphorus was investigated by x-ray photoelectron spectroscopy (XPS).

Typical XPS spectra of phosphorus 2p core level in the doped silicide film is shown in Fig. 14. For comparison, XPS spectra of phosphorus in the doped molybdenum film, doped polysilicon film, and phosphorus evaporated film are also shown in Fig. 14. All spectra were calibrated by the carbon C_{1S} as a line at 285.0 eV. The doped molybdenum film was deposited on SiO_2 by sputtering with red phosphorus on the Mo targets. The

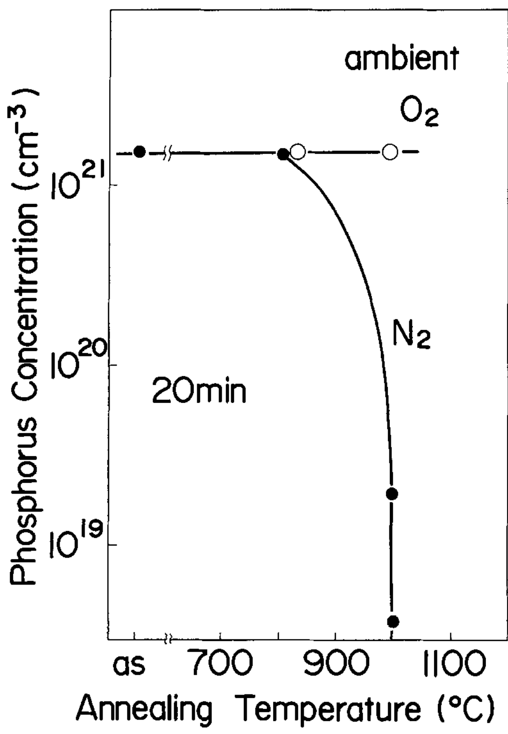

Fig. 13. Phosphorus concentration in the film after annealing in N_2 and O_2.

doped polysilicon was deposited by CVD with PH_3, SiH_4, and N_2 gas at 700°C. The phosphorus film was evaporated on SiO_2 from a red phosphorus source with a tungsten heater. The phosphorus spectra in as-deposited silicide film has a peak at 129.5 eV (E_1), as shown in Fig. 14. The peak value of phosphorus 2p in doped molybdenum film and doped polysilicon was observed to be the same. The peak value of phosphorus 2p in the evaporated phosphorus film is 130.1 eV (E_2), as shown in Fig. 14. This value is the same as that for red phosphorus as reported by Pelavin (15).

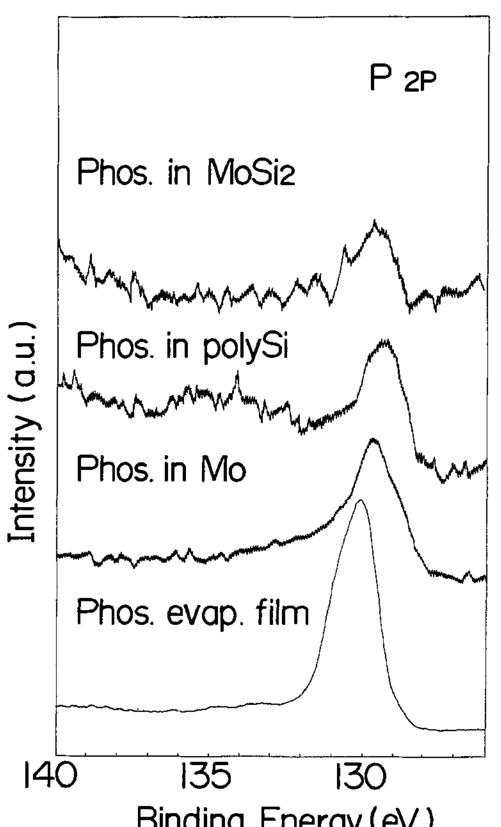

Fig. 14. X-ray photoelectron spectra of the phosphorus 2p electron core level in the doped molybdenum silicide film, doped polysilicon film, doped molybdenum film, and phosphorus evaporation film.

This chemical shift is not fully understood. The peak value of phosphorus in molybdenum film and in doped polysilicon is the same as in the doped silicide film, but is different from that of red phosphorus. Therefore, it is thought that the phosphorus in the film was incorporated interstitially, as in phosphorus implanted into SiO_2 (16).

Figure 15 shows the phosphorus 2p spectra of the film before and after annealing. The film was annealed at 1000°C for 20 min in O_2 and was etched off the thermally grown SiO_2 on the silicide. The annealed film displays the two peaks such as E_1 (129.5 eV) and E_2 (130.1 eV).

The line shape of spectra E_2 is corresponding to red phosphorus. This indicates that some phosphorus in the film may be gathered at the grain boundary after high temperature annealing because the film was crystallized. Then the phosphorus formed the metallic state of red phosphorus. These two peaks are tentatively interpreted as due to the interstitial state (corresponding to E_1) and metallic state (corresponding to E_2) of phosphorus.

Phosphorus Diffusion into Si Substrate

Phosphorus-doped molybdenum silicide was deposited on p-type (100) Si and the diffusions were performed in O_2 at the nominal diffusion temperature. The thickness of the films was 3000Å, the Mo/Si ratio was 0.45 (Mo:Si = 1:2.2), and the phosphorus concentration was 1.5×10^{21} cm^{-3}. The phosphorus concentration profiles were determined by the incremental sheet resistivity method using the anodic oxidation technique. The profiles for various diffusion times at 900°C and various diffusion temperatures for 20 min are shown in Fig. 16 and 17, respectively.

These profiles are similar to those obtained from other diffusion sources such as doped polysilicon (17), or PSG. High surface concentrations are obtained with relatively low temperature diffusion. XPS and Auger analysis confirmed that sufficient phosphorus is always supplied at the silicide/Si interface and a high surface concentration is obtained. Therefore, this is a very attractive technique for fabricating MOS LSI's.

Ohmic Contact with Si Substrate

The major advantage of polysilicon gate technology is the excellent ohmic contact between the gate electrode and the Si substrate in a buried contact. The same advantage is required if silicide gate technology

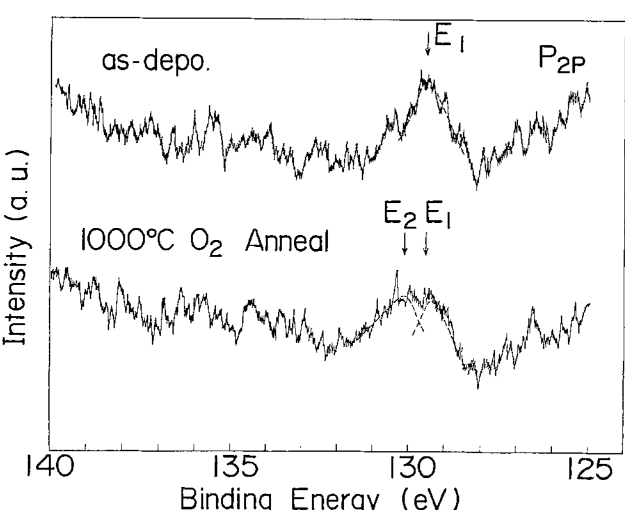

Fig. 15. X-ray photoelectron spectra of the phosphorus 2p electron core level in the films before and after annealing.

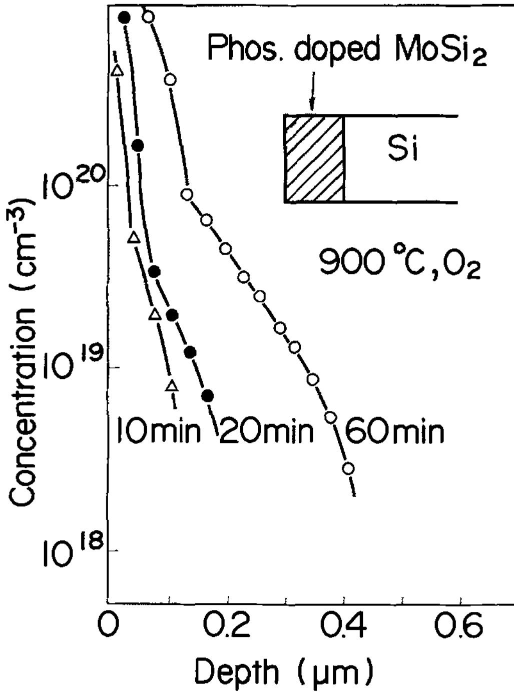

Fig. 16. Phosphorus depth profiles diffused from doped molybdenum silicide into Si substrate at 900°C for 10, 20, and 60 min in O_2.

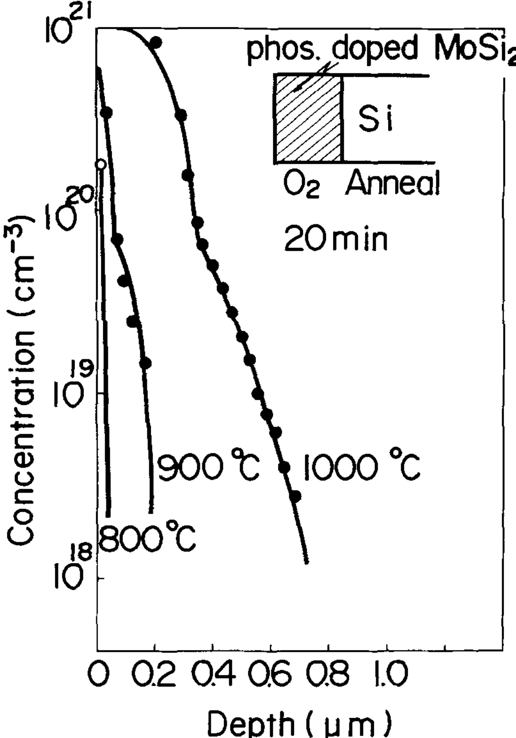

Fig. 17. Phosphorus depth profiles diffused from doped molybdenum silicide into Si substrate at 800°, 900°, and 1000°C for 20 min in O_2.

is to replace polysilicon technology. However, the contact resistance between the molybdenum silicide and Si often becomes high due to a highly resistive layer formed during annealing at the silicide/Si interface (12) or related to film deposition and stress (13).

The measured contact resistance between the silicide and silicon n^+ layer is shown in Fig. 18 as a function of annealing temperature in O_2. The Mo/Si ratio in the film was 1:2.0 ($MoSi_2$). The contact resistance was measured by a 1000 contact hole chain with a contact area of 4×4 μm^2. The contact resistance between

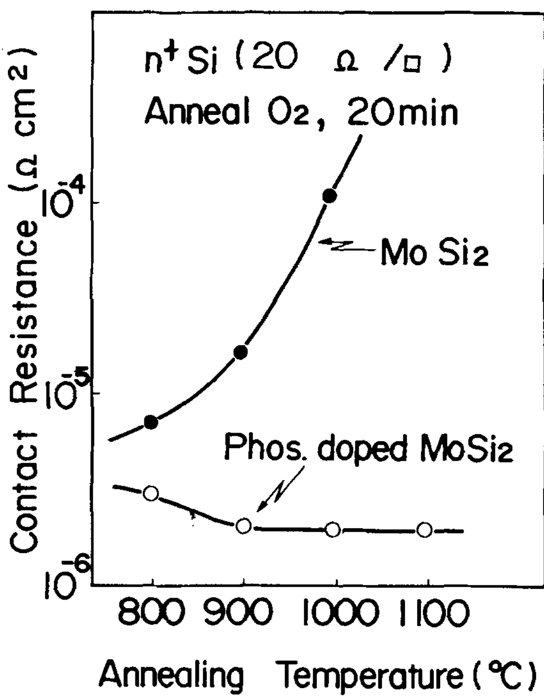

Fig. 18. Contact resistance between the molybdenum silicide and the n^+ Si after annealing for 20 min in O_2.

nondoped silicide and the n^+ Si layer increased with higher annealing temperatures, while the contact resistance of the doped silicide and the n^+ Si layer was below 2×10^{-6} Ω-cm, up to 1100°C. These results may be explained as follows. When the nondoped silicide/Si was annealed at high temperature, the donor impurity of the Si surface decreased and a highly resistive layer was formed at the silicide/Si interface. The presence of enough phosphorus in the doped silicide films prevented the formation of a high resistive layer, even after annealing at temperature up to 1100°C.

Resistivity

The effect of the Mo/Si ratio on film resistivity was evaluated. The resistivity of as-deposited films is quite high. As the annealing temperature increases, the resistivity decreased. The relation between the resistivity of annealed films and the Mo/Si ratio is shown in Fig. 19. The films were annealed for 20 min at 1000°C in N_2. The resistivity decreases as the Mo/Si increases. The resistivity of $MoSi_2$ is 7.5×10^{-5} Ω-cm. This value is lower than that of $MoSi_2$ obtained from hot press targets. Because hot press targets have a significant level of impurities such as carbon, oxygen, and alkali ions, its impurities raise the film resistivity (18, 19).

Phosphorus concentration had no influence on the resistivity of the films.

MOS Device Characteristics

V_{FB} dependence on the Mo/Si ratio.—Using various Mo/Si ratios for the gate electrodes, MOS diodes having a 5×10^{-3} cm^{-2} gate area were fabricated on thermally oxidized p-type (100) Si, with 1×10^{16} cm^{-3} doping density. The gate oxide was 400Å thick and was grown in dry O_2 at 1000°C.

The samples were annealed at 1000°C in N_2 for 20 min to reduce the resistivity and to crystallize the film, and then annealed at 450°C in forming gas (5% H_2, 95% N_2) for 30 min to minimize surface states.

Capacitance was measured as a function of gate voltage at a frequency of 1 MHz. The flatband voltage, V_{FB}, was measured from the C-V plot. The V_{FB} of the silicide gate is shown in Fig. 20 as a function of the Mo/Si ratio. The figure also shows the V_{FB} of the molybdenum and n^+ polysilicon gate. The V_{FB} of the MOS

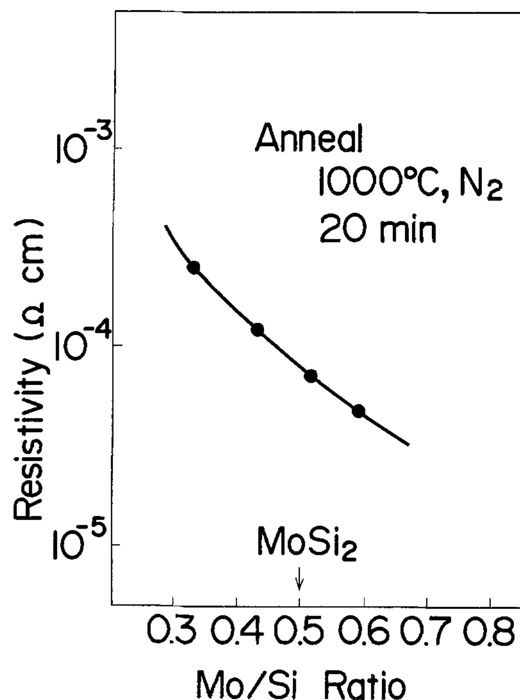

Fig. 19. Resistivity of the molybdenum silicide films as a function of the Mo/Si ratios. The films were deposited on SiO_2 and annealed for 20 min at 1000°C in N_2.

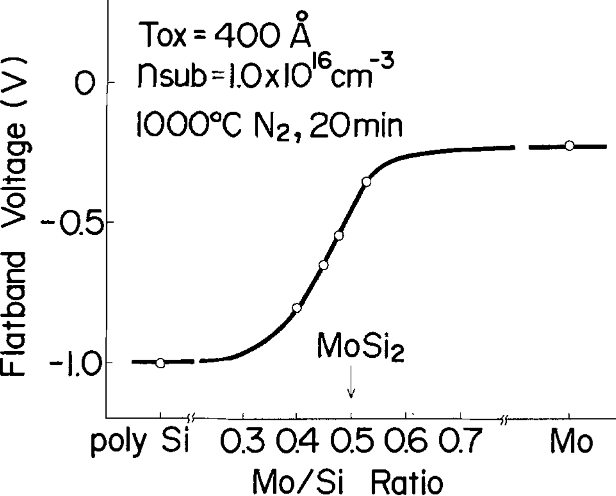

Fig. 20. Flatband voltage for various Mo/Si ratios after annealing for 20 min at 1000°C in N_2.

diode gradually increases from −1.0 to −0.2V as the Mo/Si ratio increases. When the Mo/Si ratio decreases, the V_{FB} of the annealed silicide gate rises to the value for an n^+ polysilicon gate. If the Mo/Si ratio increases, V_{FB} approaches the value for a molybdenum gate. The V_{FB} of the $MoSi_2$ gate is −0.45V.

From measuring with the quasi static *C*-*V* method (20), the surface state density in the midgap was found to be below 3×10^{10} eV^{-1} cm^{-2} and was constant for various Mo/Si ratios. Further, the fixed charge in the oxide did not vary with different Mo/Si ratios. Thus, the V_{FB} shifts observed for the MOS diodes were mainly due to the difference of the effective work function for molybdenum silicide. As described in the previous section, the excess Si or Mo in the silicide films on the SiO_2 moves toward the silicide/SiO_2 interface and then forms an Si-rich or Mo-rich layer after high temperature annealing. It is confirmed that the effective work function of the silicide films is determined by the Mo/Si ratio at the silicide/SiO_2 interface, however, this phenomenon is not completely understood.

Mobile ions.—Mobile ions in the gate oxide were measured by the triangular voltage sweep (TVS) method with a temperature of 230°C and voltage sweep velocity of 33 mV/sec (21). The mobile ion density as a function of annealing temperature for nondoped and phosphorus-doped silicide gates is given in Fig. 21. The Mo/Si ratio in this test was 1:2.

Mobile ion density was about 1×10^{11} cm^{-2} in the nondoped silicide gates annealed below 900°C, and density decreased to 5×10^{10} cm^{-2} after 1000°C annealing. Mobile ion density of doped silicide gates annealed above 900°C in O_2 were below the TVS sensitivity level ($<10^9$ cm^{-2}). After high temperature annealing, phosphorus diffuses slightly from the doped silicide to the SiO_2 surface, and its oxide surface layer includes phosphorus and had a strong mobile ion gettering effect as in a phosphosilicate glass.

Reliability of MOSFET's.—MOSFET's were fabricated using doped silicide for the gate electrode. The Mo/Si ratio was 1:2 ($MoSi_2$), a 7 Ω-cm CZ p-type Si wafer was used as the substrate, and the gate oxide thickness was 400Å. The doped silicide film of 3000Å was deposited and patterned by plasma etching. Arsenic was ion-implanted in the source and drain regions, and CVD SiO_2 film of 8000Å was deposited for surface passivation. The doped $MoSi_2$ was annealed at 1000°C for 20 min together with activation of the source and drain implanted layers. Aluminum-containing silicon was metallized through contact holes and annealed at 400°C for 10 min in forming gas.

The current-voltage characteristics of the MOSFET's are shown in Fig. 22. Effective channel length and width are (a) 20 and 100 μm, and (b) 2 and 19 μm, respectively. Threshold voltage, V_{th}, for long channel (20 μm) is 0.5V and for short channel (2 μm) is 0.3V. Size effect of V_{th} is observed for channel lengths smaller than 3.0 μm.

The V_{th} shifts of the MOSFET after bias and temperature stress (BT stress) are listed in Fig. 23, where + and − indicate the gate bias polarities with respect to source, drain, and substrate. The test MOSFET had a channel length of 20 μm and width of 100 μm. The electric field was ±2.5 MV/cm and the temperature was 150°C. After ±BT stress for 1000 hr, shifts of V_{th} were within ±20 mV. Nonionic V_{th} shifts were not observed under these stress conditions. Effective electron mobility was 620 $cm^2/V \cdot sec$ and had no influence before and after BT stress. This indicates that the phosphorus-doped $MoSi_2$ gate MOSFET is very stable, as in the polysilicon gate structure.

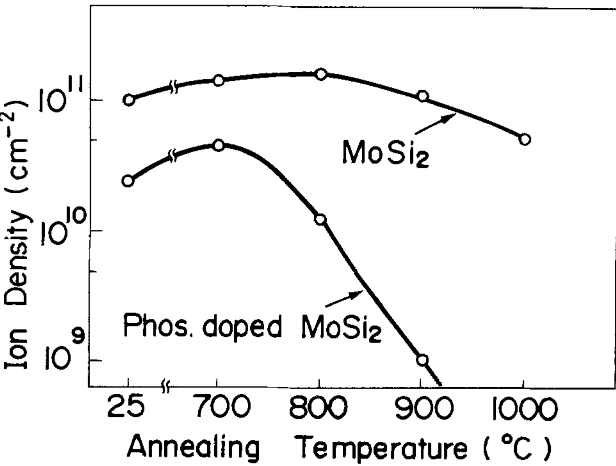

Fig. 21. Mobile ion density in the gate oxide films as a function of annealing temperatures.

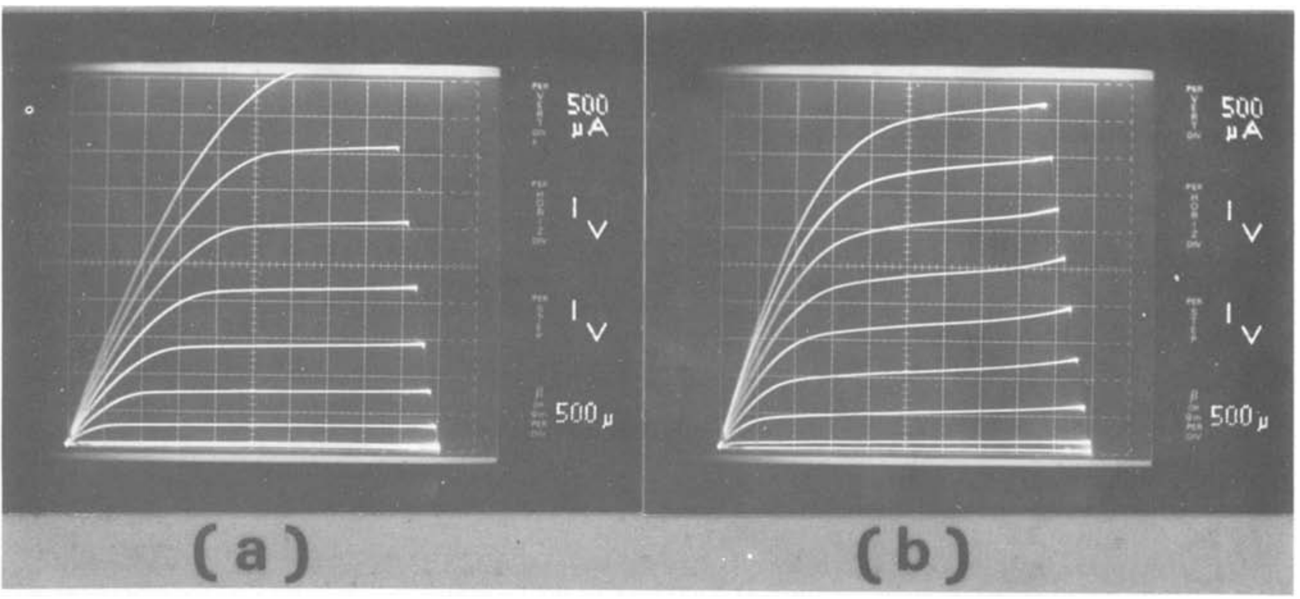

Fig. 22. Current-voltage characteristics of the phosphorus-doped molybdenum silicide gate MOSFET's. Effective channel length and width are (a) 20 and 100 μm, (b) 2 and 19 μm, respectively.

Conclusion

Phosphorus-doped molybdenum silicide was deposited by co-sputtering Mo and Si in Ar containing PH_3. PH_3 was decomposed to P and H_2, and the phosphorus combined with Mo and Si. As-deposited films (Mo/Si $\leq$ 0.5) exhibited amorphous structure and the resistivity was high. At high annealing temperatures the films became polycrystalline and resistivity was decreased. After annealing at 1000°C for 20 min, the resistivity of film with an Mo/Si ratio of 1:2 was 7.5×10^{-5} Ω-cm. This value is one order of magnitude lower than that of polysilicon. As the proportion of Si increases in the film, the resistivity also increases.

After high temperature annealing, the excess Si in Si-rich silicide film on SiO_2 and the excess Mo in Mo-rich silicide on SiO_2 move to the surface and the silicide interface both. At these locations, Si-rich or Mo-rich silicide layers were formed.

The silicide films on Si with various Mo/Si ratios are changed in composition to a $MoSi_2$ after high temperature annealing.

When the silicide is covered with SiO_2, phosphorus can diffuse from the films into the Si substrate as in doped polysilicon, so the contact region need not be doped prior to gate electrode deposition.

Good ohmic contact between the phosphorus-doped molybdenum silicide and Si substrate is maintained because the phosphorus prevents the formation of a highly resistive layer at the silicide/Si interface during high temperature annealing. Contact resistance was below 2×10^{-6} Ω-cm² after annealing at temperatures up to 1100°C.

V_{th} shifts are within ±20 mV under stress conditions of ±2.5 MV/cm for 1000 hr at 150°C and mobile ions in the film were no longer detectable after annealing. The reliability of phosphorus-doped molybdenum silicide gate technology is comparable to polysilicon gate technology.

These important advantages make doped molybdenum silicide material technology a viable alternative to polysilicon in LSI fabrication.

Shaping of Bulk Semiconductor Samples by Photolithography and Chemical Etching

J. S. Blakemore, R. S. Mand,[1] and E. H. Wishnow

Oregon Graduate Center, Beaverton Oregon 97006

ABSTRACT

Semiconductor bulk samples, suitable for characterization of electronic properties, have been made by simultaneous deep patterned mesa etching from opposing faces of polished wafers. Outlines of the samples to be produced were delineated by areas of hard-baked photoresist on those faces, with mirror-image masks aligned for the two opposing faces. Sample outlines thus created included the well-known "bridge-shaped" and "clover-shaped" forms used for electrical characterization. The etching action was quenched when canyons etched from the two faces met, releasing individual sample shapes. An $H_2SO_4/H_2O_2/H_2O$ etch was used in making GaAs samples, from polished wafers of (100), (110), (111), and (211) orientations; wafers of thickness in the range 0.2-0.5 mm could be used without excessive undercutting. Preliminary results are reported for silicon samples made by this method, using an $HNO_3/HF/H_2O$ etch.

Numerous techniques have been developed for the characterization of (nominally homogeneously doped) bulk semiconductor materials (1). When the electrical resistivity is moderate (no more than a few hundred Ω cm), some basic properties of isotropic monocrystalline materials can be assessed with reasonable accuracy from measurements on a bulk ingot or sliced complete wafer, using contactless or temporary probe methods. However, many characterization methods require a bulk sample of specific size and shape. There are special problems associated with the interpretation of data for an anisotropic solid (2, 3), for material with inhomogeneous doping (4), or for a porous ceramic sample (5). However, the concern of the present work was simply to arrive at desired sample shapes for isotropic monocrystalline semiconductors, with a primary interest in semi-insulating GaAs.

Intricate sample shapes can be produced, in principle, by mechanical, chemical, and electrochemical methods of attack. For the high resistivity GaAs of interest to us, electrochemical attack by spark erosion cutting was not possible. This method has been used for highly conducting semiconductors 6), though is more traditionally thought of as a method for shaping metallic samples (7).

Mechanical shaping techniques include use of a diamond cut-off wheel, string saw, airborne abrasive particle stream, and ultrasonic impact cutter head. For semiconductors which do not cleave excessively readily (such as Ge and Si), complex sample shapes have been made in many laboratories using a liquid slurry of abrasive particles, directed by an ultrasonic tool with a "cookie-cutter" impact head (8). Since a thin GaAs wafer is prone to cleavage on {110} planes, impact cutting is much less attractive for that material, if the desired sample shape is to include arms with narrow necks. We have been able to use mechanical methods for making bulk GaAs samples in simple shapes such as a filamentary one without sidearms; but attempts to use impact cutting for shapes with narrow sidearms had relatively poor success.

At that point, we were encouraged (by Dr. P. K. Bhattacharya) to attempt sample shaping by unusually deep mesa etching, using photolithographic delineation for the areas to be protected from etching. A shallower version of this is, of course, a common procedure for electrical isolation of a thin conducting layer on a semi-insulating substrate (9), or one separated from the underlying material by a p-n junction.

This paper reports on a procedure we have found satisfactory for making GaAs samples, with simultaneous mesa etching from the opposing faces of a wafer of thickness up to approximately 0.5 mm. The etching action produced an array of "canyons" into the two faces. The etching action was quenched when the canyons from the opposing faces met, an event signalled by the release of individual sample shapes.

Some samples have similarly been made of silicon, and Fig. 7 and 8 will show the appearance of these. Whereas the procedure for GaAs has become a routine in this laboratory, that for silicon is preliminary and not optimized.

Some Useful Sample Shapes

The simplest shape for measurements of the basic electronic transport parameters of a semiconductor (conductivity, Hall effect, etc.) is an elongated filamentary bar, of uniform cross section. If this cross section is rectangular, then the rectangular parallepiped

[1] Present address: School of Applied Physics, University of Bradford, Bradford, England.

Key words: sample shape, mesa etching, gallium arsenide, silicon.

shape can be simply made with a series of cuts by a diamond wheel or string saw. That shape was used in Pearson and Bardeen's 1948 investigation (10) of carrier transport in doped silicon, with electroplated areas on ends and sides for current contacts and potential probes.

It is advantageous to have potential contacts removed from the region of current flow. This led to the adoption of more intricate sample shapes, often cut by impact grinding (8) through a parallel-faced wafer. Among these shapes one of the most useful has been the "bridge-shaped" one; a filamentary bar with sidearms. Those sidearms were "dumb-bell" shapes as utilized and illustrated by Pearson and Suhl (11) and by Debye and Conwell (12). Such dumb-bell shapes can provide large areas for minimization of contact resistance, though are not necessary if the contacting procedure provides an adequately small specific contact resistance, in Ω-cm^2.

Figure 1 illustrates a bridge-shaped sample we have made by the procedure of photolithography and chemical etching described in the present paper. The sample shape of Fig. 1 uses simple rectangular sidearms; the shape analyzed by Jandl *et al.* (13) as a "double-cross." Jandl *et al.* showed that relatively short rectangular arms could permit adequate isolation of the contact pad areas from the current flow in the main bar. Thus current density and electric field strength are essentially constant throughout the volume being analyzed, for a bridge-shaped or double-cross sample of semiconductor material which is isotropic and uniformly doped.

In contrast, some other geometries cause the equipotential surfaces to be markedly nonplanar, and unequally spaced. That is not a problem for some semiconductor materials, particularly if measurements are to be made exclusively of low field transport in the dark. However, some semiconductors are less tolerant of field nonuniformity, especially if high electric fields and/or a photoconductive response is to be involved.

The sample shapes most commonly used for which the field pattern is markedly nonuniform are based on the theorem of van der Pauw (14, 15) for the resistance of a flat sample with peripheral contacts. These shapes include the simple rectangular slab with corner contacts (16), the "Greek cross" (17), and the "clover" shape[2] that van der Pauw proposed and illustrated (14, 15). Figure 2 illustrates a clover-shaped sample of GaAs, made by the method described in the present paper, and prior to the evaporation of Au:Ge contact areas in the outer corners.

[2] This shape has attracted many names in the ensuing literature, including "iron cross," "papal cross," "Maltese cross," and others.

Experimental Procedures for GaAs Samples

As noted in the introduction, the procedure we evolved consisted of removal of unwanted bulk material surrounding designated sample outlines by chemical etching, this action proceeding from both faces of a wafer simultaneously. Meanwhile, the sample areas themselves were protected with hard-baked photoresist. This section describes the procedure as evolved for making GaAs bulk samples of satisfactory outline shape and profile.

Many factors determine the outcome when parts of a semiconductor wafer are protected by photoresist, and adjacent unprotected portions are chemically etched. Thus, etching may be carried out in a plasma chamber, or in a liquid. Our work as reported here used aqueous etches.

The etching rate in aqueous solution depends on the strength and freshness of the ingredients, on the solution temperature, and often on crystal orientation (18, 19). Highly preferential etching can sometimes be turned to advantage; thus, Otsubo *et al.* (20) used citric acid/peroxide etches into {100} GaAs to create flat-bottomed holes, and grooves of "tsuzumi" (hand-drum) profile. [An even more dramatic anisotropy of the etching rate has been demonstrated in the work of Kendall (21) with {110} silicon, using KOH-based etches to make deep narrow grooves.] However, our preference was for an etch that would work with more or less facility for GaAs wafers of various orientations.

The etch composition and strength that we have found particularly useful for the present purpose with GaAs of various orientations has been (2)H_2SO_4-(1)H_2O_2-(1)H_2O, used in the temperature range 70°-80°C. Iida and Ito (22) showed that the $H_2SO_4/H_2O_2/H_2O$ system includes some compositions that are highly selective, but found that the above-mentioned composition gave good polishing action for most low index planes of GaAs with, of course, an inferior response for the gallium (111A) plane. This has been our experience also. When the above-cited etch composition is used at 80°C for a (111) GaAs wafer, the attack rate on the (111A) plane is only about 30% slower than on

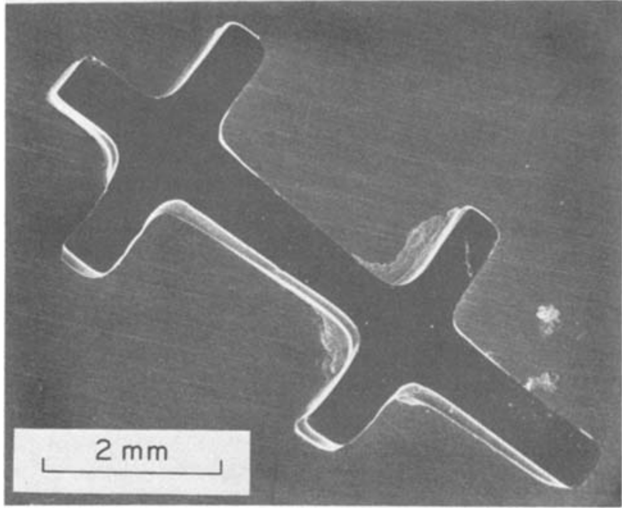

Fig. 1. A bridge-shaped sample of chromium-doped semi-insulating GaAs, created from a polished 0.45 mm thick wafer of (211) orientation, by etching inwards from both faces while the designated sample area was protected by photoresist. Etching was carried out in (2)H_2SO_4-(1)H_2O_2-(1)H_2O at 80°C.

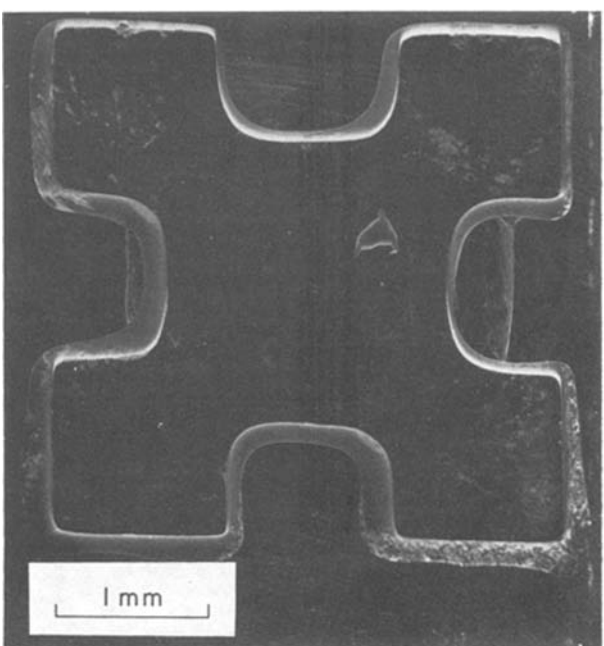

Fig. 2. A clover-shaped sample of semi-insulating GaAs, made by the same method as the sample of Fig. 1. The polished starting wafer here was of (100) orientation, 0.53 mm thick.

the (111B) plane (7 μm per min, compared with 10 μm per min), but microscopic examination of a partly consumed wafer shows the attacked (111A) surface to be much more pitted than the opposite face.

Figure 3 illustrates the effect of various etching times on the total thickness reduction of wafers with orientations of (100), (110), (111), and (211), determined from microscopic measurement of the decrease of distance between bottoms of opposing etched canyons. These measurements, the consequences of using the above-cited etch at 80°C, correspond to an etching rate of some (10 ± 1) μm/min for fresh etch acting on a GaAs surface with any orientation other than (111A). That rate, and the reduction of some 30% for (111A), is in general agreement with the findings of Iida and Ito (22) for etching rate *vs.* composition, orientation, and temperature. Figure 3, and similar results obtained with other wafers, shows no signs of any pre-etching induction period. Provided the etching solution is freshly prepared, and of large enough quantity so that reaction products do not slow the action, then etching reduces thickness at an essentially linear rate until sample separation occurs. For a wafer 0.5 mm thick, this requires about 25 min for most orientations, and perhaps 28-30 min for a {111} wafer.

The wording of the preceding paragraph was chosen to indicate that reliable etching at a constant rate was obtained when the etch (*i*) was used fresh, and (*ii*) was of volume sufficient to minimize the effects of dissolved etching products on the continuation of the process. Thus, for a part-wafer of area 5 cm^2 and thickness 0.5 mm, one may need to etch away about 0.75g of GaAs to separate out individual samples. It would be our practice not to attempt this with less than 100 ml of mixed etch, with vigorous stirring of the etch throughout to minimize the buildup of etch products near the surfaces under attack.

Since the procedure required that a wafer remain in the etch for a time of up to half an hour at a temperature of 70°-80°C, it was extremely important that the photoresist over designated sample areas adhere as strongly as possible. That called for some changes from the photoresist procedures normally encountered in

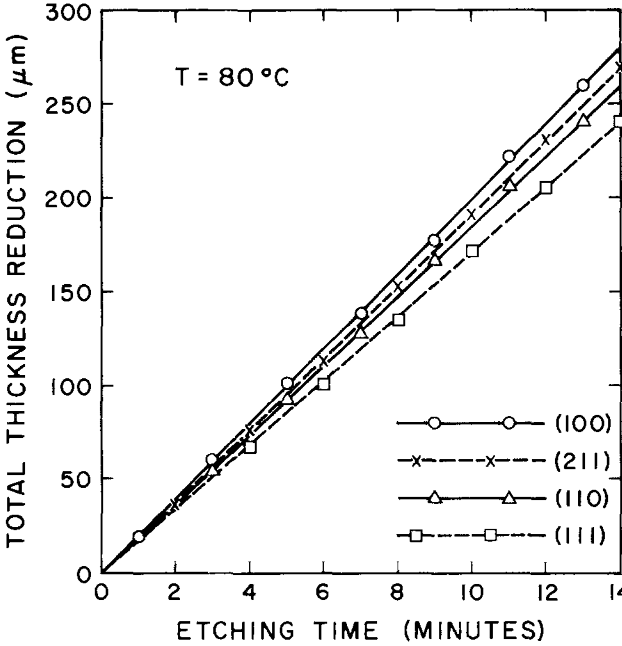

Fig. 3. Total reduction in wafer thickness (sum of amounts thinned from opposing sides) vs. etching time, for GaAs in (2)H_2SO_4-(1)H_2O_2-(1)H_2O at 80°C. These are representative data for wafers etched in large quantities of the etchant, with ample stirring, so that effects of etchant exhaustion and/or poisoning were minimized. The results for (100), (110), and (211) are all essentially the same. The total thinning rate is smaller for (111) wafers because of the slower attack rate for the (111A) face.

the integrated circuit industry, where etch depths are typically no more than a few micrometers, and etch durations quite short.

Our objectives of etching completely through wafers up to a considerable thickness also placed requirements on the layout of any sample shape on the mask, that this allow for inevitable undercutting. Resist adhesion and undercutting are related, since any tendency of the resist to "lift off" around the edges will open up new territory for undercutting.

Figure 4 shows part of a (211) GaAs wafer bearing a repetitive array of hardened photoresist areas (each of the van der Pauw clover shape) after etching for 1 min. The unprotected areas have been etched to a depth of some 10 μm. It will be observed that the resist has curled up from one corner, and is showing signs of doing so at two adjacent corners. That lack of adherence is unacceptable in view of the 20 or more minutes of additional etching time that would be necessary to complete separation of samples from each other.

The results of etching a wafer for a longer period of time are exemplified by the almost edge-on view shown in Fig. 5. The wafer here was of (100) orientation, patterned on both faces with photoresist, etched at 80°C for 7 min, and cleaved to permit study of the profiles of the canyons etched from the opposing faces. Note in Fig. 5 that (*i*) overhanging ledges of photoresist jut out above the canyon walls, (*ii*) the canyon

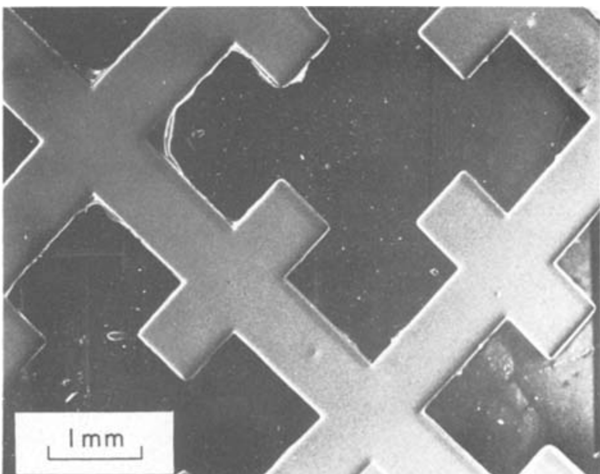

Fig. 4. Part of a repetitive pattern for making clover-shaped samples, as formed into hardened resist areas on the surface of a (211) GaAs wafer. One minute in the $H_2SO_4/H_2O_2/H_2O$ etch has removed some 10 μm of material from the unprotected areas. Note that poor adherence of the photoresist for this wafer has already led to curling back from some outer corners.

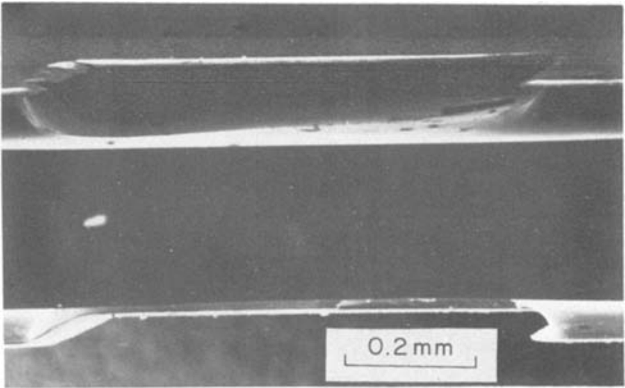

Fig. 5. An edge-on view of a 400 μm thick (100) GaAs wafer, which had been (a) patterned with hardened resist so that resist edges would lie along <011> directions, (b) etched at 80°C for 7 min, and then (c) cleaved to permit the edge-on view.

floors are essentially flat and parallel, and (*iii*) the canyon walls curve in a manner appropriate for complete nonselectivity of etching action. Somewhat to our surprise, we have found the canyon wall shapes to curve in essentially the same fashion for any (100) wafer (whether the edges of the resist are aligned with <010> or <011> types of orientation), and also for wafers of other orientations including (111).

The literature provides ample citations for etch pits produced in GaAs [and other zincblende structure solids such as InSb (23)] which show marked facets of preferential etching. Thus Iida and Ito (22) showed that slow action of an $H_2SO_4/H_2O_2/H_2O$ etch on (100) could produce a flat-bottomed pit of trapezoidal cross section (overhanging canyon walls) when the edge of the resist-protected area was parallel to <010> or <001>. We have not observed this to happen with the relatively speedy etching action of the 2:1:1 composition at 80°C. With any orientation of the wafer and any alignment of the mask pattern, the canyon wall shows a curved profile such as that in Fig. 5. Incidentally, that figure shows undercutting to have proceeded by some 40 μm at a stage when the canyon floor lies some 75 μm below the original wafer surface plane.

Through the courtesy of M. Pope and M. Wright, photographic masks were made for us through which photoresist could be exposed. These masks had repetitive patterns for sample shapes (such as bridge-shape and clover-shape). It was necessary to have pairs of masks which were mirror images of each other, so that a matched pair placed to sandwich a prepared wafer would register the same pattern on both surfaces of that wafer. A simple mechanical fixture was constructed which enabled the pair of masks to be aligned with respect to each other, in respect of x, y, and θ.

Mask pairs of these kinds were made with opaque/transparent patternings suitable for use with positive resist, and additional pairs of the converse opacity for use with negative resist. Our first crude attempts at sample separation were made using a negative resist[3] on the wafer faces, and were (not surprisingly) accompanied by frequent failures owing to resist detachment during the lengthy etching. There can be little doubt that the procedure can be made to work perfectly well with negative resist applied and baked properly; but we have not persisted with this approach. For since it happened that we were successful rather soon in persuading positive resist[4] to stay in place until etching was complete, all our subsequent work has been based on the positive resist approach. Thus, for this we have been using masks with opaque areas where designated sample areas are to be protected from the etching action.

Photoresist as used in the integrated circuit industry is applied typically by spinning, with a resist layer thickness of perhaps 1 μm, and an emphasis on the ability to create narrow linewidths (24). Our requirements were quite different. High spatial resolution was not important, but a tenacious and adherent resist layer on both faces was very important. These requirements were met most readily by dip coating of suitably prepared wafers, at a temperature ($T \approx 20°C$) and viscosity that would provide a hardened film thickness in the range 12-17 μm.

Our wafer preparation now requires that both faces of the wafer be polished. That admittedly involves extra work, but we have found that undercutting progresses more slowly under photoresist that is firmly adherent to a polished face.

Thus the procedure as it has evolved comprises mechanical polishing of both faces, degreasing, baking dry at 90°C, cooling to room temperature, photoresist application by dip coating, a 1 hr "soft bake" at 90°C, cooling to 25°C, exposure to u.v. radiation through a matched pair of facing masks, development in diluted (Shipley AZ-351) resist developer, water rinse, air dry, and then a 2 hr "hard bake" at 160°C. When cooled for handling, the wafer is then ready for etching.

Two physical arrangements have been used for etching. In one of these, the wafer (and its eventual daughter samples) is supported above a glass frit in the etching solution, while bubbled nitrogen gas is supplied from below to provide agitation. The other arrangement uses a magnetic stirrer within the beaker of etch on a hotplate. (The latter arrangement simplifies positive control of the temperature.) The clover-shaped sample of Fig. 2 happened to have been made using the first of these systems, while the bridge-shaped sample of Fig. 1 was made using the magnetic stirring system.

The clover-shaped sample of Fig. 2 came from a wafer 0.53 mm thick. Thus one might expect the periphery of the top and bottom sample surfaces to retreat by some 200-250 μm if etching and undercutting were completely isotropic. A comparison of this sample with mask dimensions shows that the upper periphery has actually been cut back by (215 ± 10) μm. However, Fig. 6 shows a magnified edge-on view of one corner of this sample, and one may see that the cusped profile protrudes by only $\sim$100 μm. This was obtained by allowing the etching to continue for some 30 sec after the first sample was seen to "calve" from the parent wafer. Now such a sample would normally have the resist stripped from top and bottom faces (with acetone and/or Shipley 1112A "photoresist stripper"), and then be etched over its entire surface prior to contacting, in order to remove the mechanical damage associated with the prior polishing procedures. That additional etching would further reduce the peripheral protuberance before the sample was ready for electrical measurements.

A clover-shaped sample with a protuberant profile as just described and illustrated is in technical violation of a requirement of van der Pauw's theorem (14, 15), that a sample be of constant thickness over its entire current-bearing area. However, a protuberance of the size described appears to involve an error in the analysis of van der Pauw resistivity and Hall measurements of less than 3% by direct measurement; an error in the (expected) sense of making the resistivity (using van der Pauw's expression) appear slightly low. That estimate of the error involved was obtained by first measuring a sample as resulting from

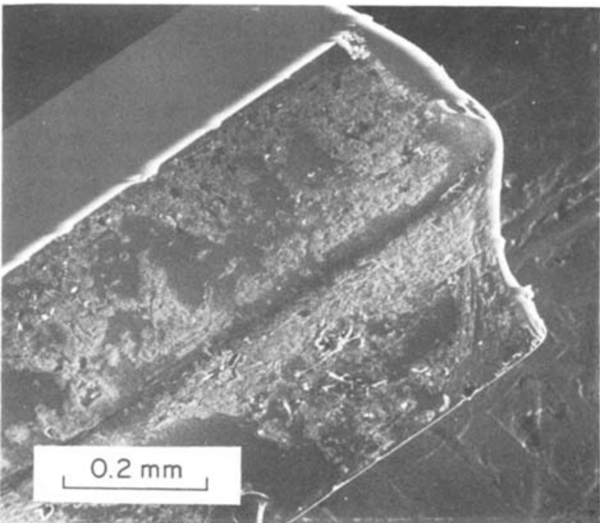

Fig. 6. A magnified edge-on view of one corner of the clover-shaped sample of Fig. 2. This shows details of the edge profile resulting from undercutting prior to sample separation, and the partial rounding off of this cusped protuberance during an additional 30 sec of etching after separation.

[3] MOS-Grade Negative Photoresist, available from KTI Chemicals, of Sunnyvale, California.
[4] AZ-1350J Positive Resist, available from the Shipley Company, of Newton, Massachusetts.

the photolithography/etching process, and then using an abrasive particle stream to "trim up" the re-entrant portions of the sample periphery.

The GaAs bridge-shaped sample of Fig. 1 shows similar imperfections of profile. In that case, these would be enough to require that the usual conversion [$\sigma = (L/wt)(I/V)$] from resistance to bulk conductivity be modified to take account of the slightly nonrectangular cross section of the bar. Whereas the bridge sample of Fig. 1 has a thickness $t = 0.45$ mm, we have usually resorted to thinner wafers when the desire was for Hall data with GaAs bridges of more nearly perfect geometry. Of course, a sample shape and profile such as that of Fig. 1 is perfectly adequate for photoconductive or various relative measurements.

Thus, for most of our purposes in measuring GaAs of resistivity up to the semi-insulating range, the procedure as described above needs little further optimization.

Preliminary Results with Silicon Samples

A procedure for making silicon samples by simultaneous etching from both sides of a masked wafer has not been tested by us so far beyond the stage of crude feasibility. Results we obtained show that the etch we used, of (2)HNO_3-(2)HF-(1)H_2O composition (25), was not ideal for this purpose.

Figure 7 shows a clover-shaped silicon sample, made from a (100) wafer that had been polished on both faces, equipped with patterned photoresist as described in the previous section, and etched in the HNO_3/HF/H_2O solution until individual samples separated. With the etch brought to a temperature of 30°C prior to the introduction of the wafer, separation of individual samples from a wafer ~0.4 mm thick would occur in approximately 3 min. As is well known (19, 25), this is a fast-acting etch.

It will be apparent from Fig. 7 that the periphery of this sample (of 0.37 mm thickness) was undercut much more severely than for the GaAs samples previously illustrated. The extent of the undercutting is shown clearly in the enlarged edge-on view Fig. 8 provides of one corner of that sample. In this instance, etching action was quenched with water as soon as possible after the release of individual samples was spotted, thus the cusp tip was not appreciably eroded. However, note also in Fig. 8 that the edge of the sample blends toward the upper and lower surface faces in convex arcs. This shows that the etching action had preferentially attacked the wafer/photoresist interface.

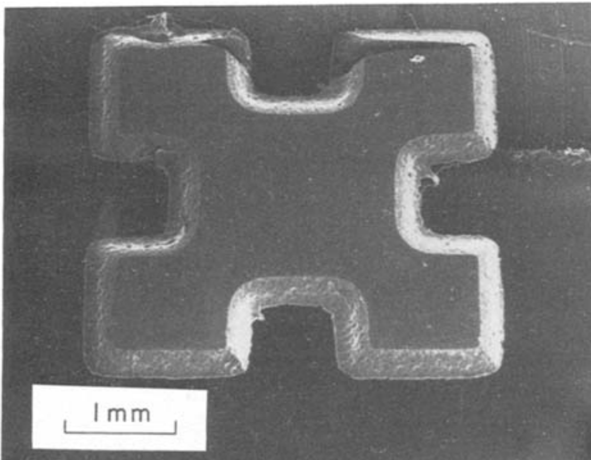

Fig. 7. A silicon clover-shaped sample, made by photomasking and chemical etching of a polished (100) wafer 370 μm thick. Etching was carried out in (2)HNO_3-(2)HF-(1)H_2O at $T \approx 30$°C, and sample separation occurred (with severe undercutting as may be seen) after etching from both faces simultaneously for 150 sec.

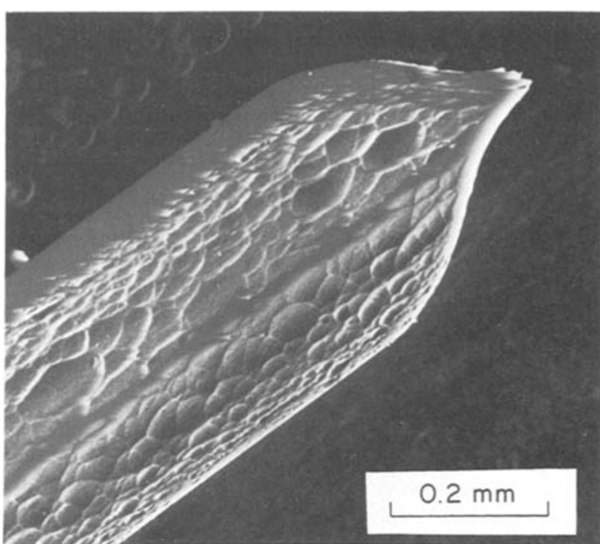

Fig. 8. An enlarged edge-on view of one corner of the silicon sample of Fig. 7. The convex curvature of the edge surface adjacent to the top and bottom faces indicates that the etch had preferentially attacked the (SiO_2-rich) silicon surface under the edge of the resist layer.

That preferential attack is inherent in the mechanism by which an etch of the HNO_3/HF/H_2O family attacks silicon (19, 25), because the inevitable SiO_2 layer on the silicon surface is attacked by HF, the complexant in the mixture. That promotes undercutting, and lift-off of the photoresist shapes. When we have attempted to make silicon samples, but with the etch solution cooled, to slow down the reaction rate, the photoresist has always lifted off before the canyons from the two faces have had an opportunity to meet.

Thus one can envisage preferable etching approaches for making silicon samples. One possibility is that the wafer might first receive a quick dip in HF (to remove SiO_2 from the exposed areas), then be rinsed, and placed for an extended period in an etch (such as an alkaline one) that has a preference for dissolution of Si itself rather than SiO_2.

Acknowledgments

We wish to thank Morgan Pope and Mel Wright of Tektronix, Incorporated, for their splendid cooperation in making masks patterned to meet our various needs. We should also like to thank Pallab Bhattacharya and Robert Rugh for helpful discussions. This work has been supported in part by the National Science Foundation, through Grant DMR 79-16454.

Parameter Dependence of RIE Induced Radiation Damage in Silicon Dioxide

L. M. Ephrath,* D. J. DiMaria, and F. L. Pesavento

IBM T. J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Radiation damage in silicon dioxide films exposed to reactive ion etching (RIE) in CF_4 has been investigated. Capacitance-voltage ((*C-V*) and photocurrent-voltage (photo *I-V*) techniques were used to monitor charge trapping and location after the films were incorporated into MOS capacitors. Blanket etched films were used to study the trapping characteristics of bulk, neutral, radiation-induced traps as a function of position in the reactor, rf peak-to-peak voltage, and pre-RIE high temperature annealing. The trapping characteristics of films etched in a $CF_4 + H_2$ mixture were also studied. Oxide films etched in $CF_4 + H_2$ show reduced trapping when compared with oxides etched in CF_4. The ability of gate electrode materials to shield an underlying oxide during RIE was also tested. It was determined that aluminum and n^+ polysilicon are effective in shielding oxide from RIE induced radiation damage.

Reactive ion etching (RIE) is a directional, dry etching technique that has been used in our laboratory to fabricate micron dimension FET logic and array chips (1, 2). RIE is used at several levels of processing including definition of recessed oxide isolation, polysilicon gate electrodes, and contact holes to polysilicon and diffused regions. Extensive use of RIE is required for the delineation of fine lines and openings with no undercut of the etch mask. RIE is, however, carried out in a radiation environment; substrates are subjected to bombardment by electrons, ions, and photons. For this reason, experiments have been carried out to determine the effect of RIE on the reliability of devices. RIE induced trapping was characterized by exposing a blanket oxide film to RIE, incorporating the etched oxide into an MOS device, and injecting charge into the conduction band of the oxide by avalanche injection. The numbers and cross sections of the traps, the density of trapped charge, and the centroid of the trapped charge distribution were determined by *C-V* and photo *I-V* techniques (3). Three distinct trapping sites were observed (4). The first was a buildup of positive charge at the silicon-silicon dioxide interface. These positive trapped charges present a coulombic capture cross section for electrons in the range of 10^{-12} and 10^{-13} cm^2 and have a density of about 10^{12} positive charges/cm^2. These trapped positive charges are believed to be holes which were generated initially by ionization across the bandgap of the oxide. Some of the free positive charges in the silicon dioxide valence band are subsequently trapped at pre-existing sites near the interfaces. The second type of trapping site is created by ion implantation damage within about 5 nm of the surface. These traps are observed only when a nonetching gas such as O_2 is used to clean the surface. Presumably, an etching gas such as CF_4 removes its damage as it is produced leaving only a residual when etching is stopped. The third type of trap is a neutral trapping center. These sites are distributed approximately uniformly throughout the bulk of the oxide. The electronic capture cross sections of these traps are between 10^{-14} and 10^{-17} cm^2 and their density is between 10^{11} and 10^{12} cm^{-2}. These traps are very similar to those observed by Aitken, Young, Pan, and Ning (5-7) for oxides exposed to much higher energy radiation than in the present case (20-25 keV x-rays or electrons). In the comparatively low energy environment of RIE, the occurrence of trapping in the bulk suggests, by process of elimination, the involvement of photons which are sufficiently energetic to penetrate the oxide. Ion energies are not sufficient to penetrate the oxide, and energetic electrons would not reach the cathode because of its negative bias. High energy photons, though, would be created in the reactor when secondary electrons which are accelerated across the cathode dark space strike ground planes. Photons generated by secondary electrons in an rf sputtering configuration have been shown to degrade the stability of MOS devices (8). Secondary electrons vary in energy depending on when they are emitted during the rf cycle, but some may have energies corresponding to the full peak-to-peak voltage. Photon energies, then, could also approach this value. The trapped positive charge and the ion implantation damage were not studied beyond their initial characterization (Table I).

Table I. Summary of trapping center data

Trapping center	Cross section (cm^2)	Density (cm^{-2})	Source	Anneal T°C
Positive charge	10^{-12}-10^{-13}	10^{12}	Photons	400
Implantation damage	10^{-14}-10^{-18}	10^{13}	Ions	1000
Neutral center	10^{-14}-10^{-17}	10^{11}-10^{12}	Photons	600
Background	10^{-17}	10^{12}	—	—

The trapped positive charge is annealed at a low temperature of 400°C on the aluminum gated structures used in this study. The implantation damage can be eliminated by dip etching the oxide since the damage is confined to the surface or by avoiding the use of a nonetching gas. The neutral traps, however, are present throughout the bulk of the oxide and an anneal of 600°C or more is required for their removal. Thus, they must be avoided or annealed before aluminum metallurgy is in place.

In the present study, the RIE parameter dependence of the neutral traps was studied. The RIE parameters that were varied include position of substrate in the reactor, rf voltage, and composition of etching gas. Finally, the ability of gate electrode materials to shield an underlying oxide from RIE radiation damage was evaluated by etching oxide films masked with aluminum or n^+ polysilicon patterns.

Experimental

RIE system.—The reactive ion etching system used in this work is shown in Fig. 1. The substrates were loaded onto an 18 cm diam aluminum plate. The aluminum plate was mechanically and electrically connected to the water-cooled copper rf cathode. A perforated anode plate which is attached to the grounded chamber was placed 3.3 cm from the cathode in order to prevent backsputtering of aluminum sputtered from the substrate holder. A perforated anode plate was used so that wafers could be monitored visually during etching, and also to ensure an adequate and uniform supply of etchant in the vicinity of the wafers. The chamber was evacuated with a 6 in. oil diffusion pump and then backfilled with 40 sccm CF_4 to establish a dynamic pressure of 3.33 Pa (25 milliTorr). During etching, 0.25 W/cm^2 is delivered to the cathode. Under these conditions, the peak-to-peak voltage is 800V. The d-c voltage at the cathode is approximately one-half of the peak-to-peak voltage (9). The etch rate of silicon dioxide in CF_4 is about 50 nm/min.

Sample preparation.—Dry silicon dioxide films of 150 nm thickness were grown on boron-doped, <100> orientation, 0.1-0.5 Ω-cm resistivity p-type silicon substrates. The oxide films were then exposed to a CF_4 or $CF_4 + H_2$ plasma to etch approximately 50 nm of silicon dioxide. The wafers were then cleaned to remove metals and hydrocarbons from the surface of the oxide

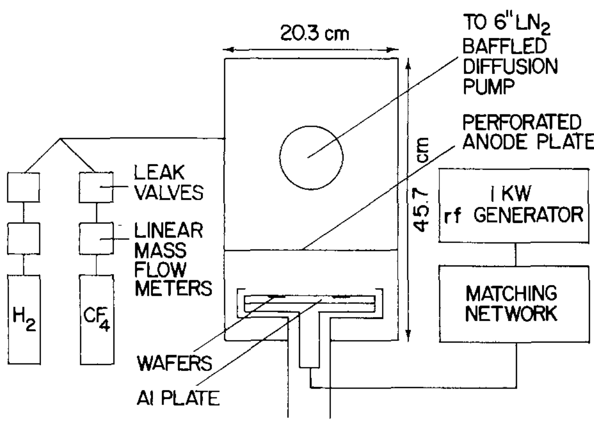

Fig. 1. Schematic of RIE reactor

in alkali and acid peroxide solutions using a procedure similar to that used by Irene (10), but without HF. Some wafers received a buffered HF dip at this point in order to remove ~10 nm from the surface of the oxide. After cleaning, some wafers were annealed in an N_2 ambient for 30 min. Annealing temperatures ranged from 600° to 1000°C. Circular aluminum dots, 13.5 nm in thickness and 5.2×10^{-3} cm^2 in area, were then evaporated in vacuum from resistively heated tantalum boats or rf heated crucibles. Finally, the backs of the wafers were stripped and metallized, and a forming gas anneal at 400°C for 20 min was carried out.

Techniques.—To investigate the enhanced electron trapping characteristics of silicon dioxide layers exposed to plasmas in an RIE system, avalanche injection (11, 12) and internal photoemission (13-15) techniques were used to inject electrons from the contacts of the MOS structures into the oxide. The experimental apparatus for avalanche injection (16) and internal photoemission (17) have been described in other publications. As the electrons traverse the film in the presence of an applied electric field, some of the carriers are trapped into sites created during RIE. This trapping is not particularly sensitive to the mode of carrier injection: avalanche injection from the silicon or internal photoemission from the aluminum or silicon. The trapping rate is not particularly sensitive to the average field in the oxide layer which is consistent with the weak field dependence of the capture process for radiation induced neutral traps recently reported by Ning (7). This weak field dependence is in contrast to the strong field dependence of electron capture on trapped holes (3, 7, 18).

The buildup of this trapped charge is sensed through the internal electric field it creates near the contacts by the capacitance-voltage (C-V) (19, 20) and photocurrent-voltage (photo I-V) (18, 21, 22) techniques which are well described in the literature. The voltage shifts between the C-V curves depend on the product $\bar{x}Q$ where Q is the charge per unit area and $\bar{x}$ is the centroid of trapped charge in the oxide layer measured with respect to the aluminum-oxide interface (19, 20). The voltage shifts between photo I-V data for both positive and negative polarity allow separate determination of $\bar{x}$ and Q (18, 21). The combination of the C-V and photo I-V techniques can also be used to separate silicon-silicon dioxide interface trapping from bulk oxide trapping (18, 21, 22). Also by studying charge buildup as a function of time, electron capture cross sections σ_c and areal trap densities N_t can be determined (3). These quantities ($\bar{x}$, Q, σ_c, and N_t) are used to characterize the different traps created by the exposure to RIE plasmas in the following sections. Only a very small amount of trapping was seen for the charging conditions used on samples fabricated in an identical manner, but not exposed to RIE (4). The results were reproducible for different locations within a sample, and for samples fabricated over a time span of several months.

Results and Discussion

RIE parameter dependence.—It was suggested earlier that the neutral traps are created in the relatively low energy environment of RIE by photons. To substantiate this view, substrates were loaded onto the grounded perforated plate with the oxide film facing away from the cathode. In this way, the oxide film is no longer subjected to bombardment by energetic ions. The oxide film is also protected from secondary electrons from the cathode by the silicon substrate. The oxide film is, however, still exposed to photons that are created when secondary electrons strike the walls of the reactor. A plot of the volume density of trapped charge as a function of avalanche injection time (Fig. 2) shows that the oxide etched

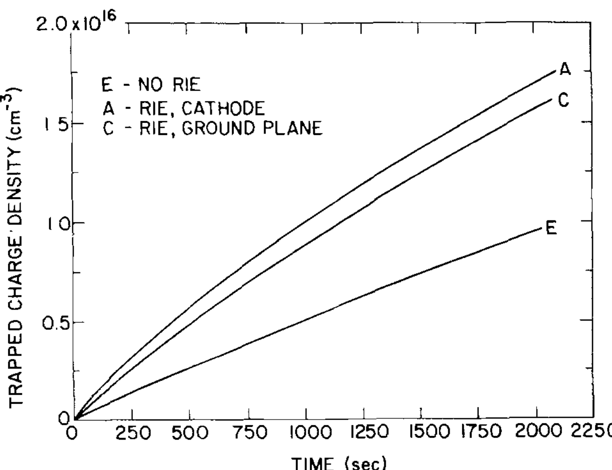

Fig. 2. Volume trapped charge density as a function of avalanche injection time for oxides exposed to RIE on the electrode and on a ground plane. Constant avalanche current = 8×10^{-9}A.

by RIE and the oxide exposed only to energetic photons show enhanced trapping relative to that measured in the control. Data points are taken at 44 sec intervals and so are represented by a solid line. The error bars included for data plotted against an expanded scale in Fig. 7 are representative of data shown in Fig. 2-6.

In the second experiment, the rf power was varied in order to vary the rf peak-to-peak voltage. Etch times were increased as voltage was decreased so that the amount of oxide removed was constant. The purpose of this experiment was to determine whether the introduction of traps exhibited a threshold in the regime of power and pressure that is appropriate for RIE. As can be seen in Fig. 3, enhanced trapping was observed for all oxides etched by RIE even though rf peak-to-peak voltage was reduced by more than a factor of two, from 730 to 330V. Thus, radiation damage is not avoided by etching for longer times at lower rf voltages. It is not possible to carry out RIE at lower voltages. RIE requires low pressures to maintain vertical etching and a low pressure discharge could not be sustained at voltages below 330V. It is possible, however, to reduce voltage if the requirement for directional etching is suspended. For the third experiment, pressure was increased to simulate plasma etching. Oxygen was added to CF_4 so that a direct comparison could be made with oxides etched in a commercial barrel plasma etcher. The pressure of the CF_4 + 20% O_2 etching gas was increased to 0.5 Torr which results in an rf peak-to-peak voltage of 120V. The trapping data (Fig. 4) show that neutral traps are not created during plasma etching or during etching under plasma etching-like conditions in the RIE reactor. For completeness, an oxide was etched by low pressure RIE in the $CF_4 + O_2$ mixture to assure that the addition of O_2 was not the significant factor. As expected, this oxide shows the presence of neutral traps with a trap density that is approximately equal to that of an oxide etched in CF_4.

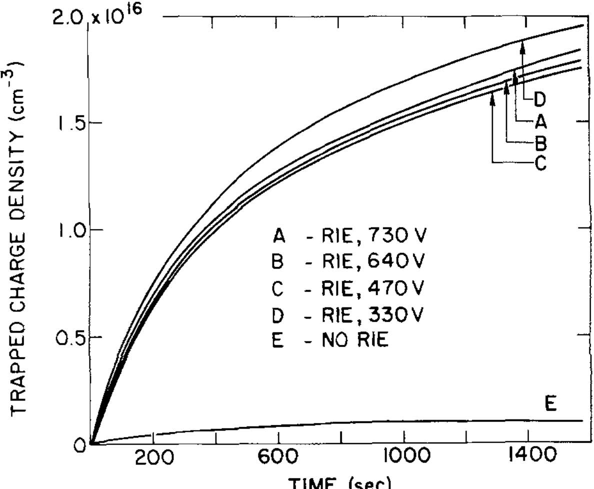

Fig. 3. Volume trapped charge density as a function of avalanche injection time for oxides exposed to RIE with rf peak-to-peak voltages between 730 and 330V. Constant avalanche current = 2×10^{-9}A.

The fourth and last experiment carried out with blanket etched oxide films was to add H_2 to CF_4. This experiment was suggested by speculation that the neutral traps were created by breaking or relaxing bonds in the lattice of the oxide (6). If correct, the diffusion of atomic hydrogen into silicon dioxide might anneal neutral traps in a way that is analogous to the reduction in dangling bond density in amorphous silicon by atomic hydrogen (23). The data in Fig. 5 show that the addition of H_2 does lead to a significant reduction in trapped charge when compared with an oxide etched in CF_4 alone. A peak-to-peak voltage of 810V was measured. This value is slightly higher than that measured during RIE in CF_4. While the effect of adding H_2 is reproducible and consistent with annealing of traps by atomic hydrogen, it was not possible to reduce trap density by introducing hydrogen in other ways. Trapping was not reduced by exposing oxides to a hydrogen plasma before or after RIE in CF_4 or by annealing oxides in forming gas (90% N_2/ 10% H_2) at 1000°C before RIE in CF_4.

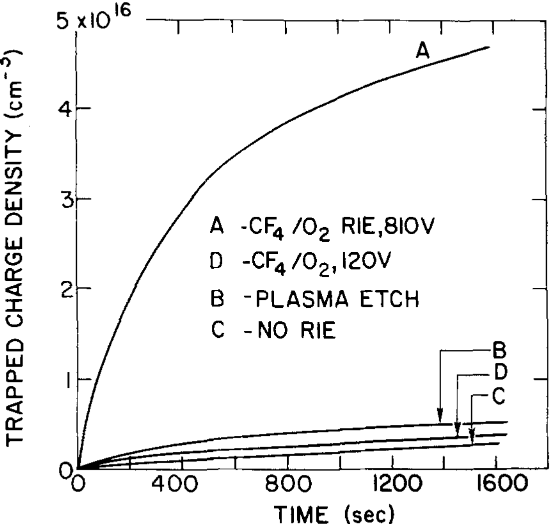

Fig. 4. Volume trapped charge density as a function of avalanche injection time for oxides exposed to RIE in $CF_4 + O_2$ and plasma etching in RIE and barrel-type plasma reactors. Constant avalanche current = 2×10^{-9}A.

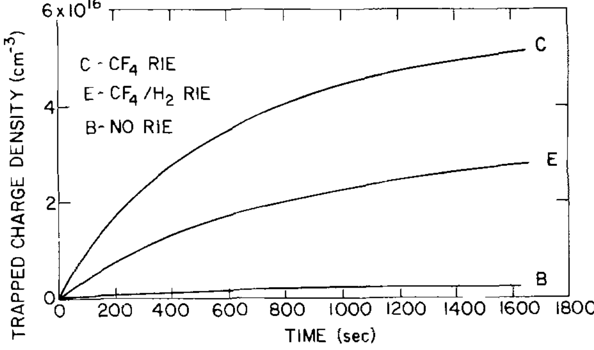

Fig. 5. Volume trapped charge density as a function of avalanche injection time for oxides exposed to RIE in CF_4 and $CF_4 + H_2$. Constant avalanche current = 2×10^{-9}A.

Gate shielding.—The purpose of experiments carried out with blanket oxide films is to understand the nature and parameter dependence of the neutral traps. During FET processing, however, the gate oxide is covered by the material that is used as a gate electrode. With this fact in mind, the ability of polysilicon and aluminum to shield an underlying gate oxide from the introduction of neutral traps was tested.

The procedure used to fabricate the samples begins with the same cleaning and oxidation steps described earlier. After the oxide was grown, a 350 nm thick film of silicon was deposited by chemical vapor deposition on some substrates and then doped n^+ by the deposition and drive-in of $POCl_3$. The polysilicon plus 50 nm of oxide was etched using patterned photoresist to delineate 32 mil diam dots. On other oxidized substrates, 32 mil diam, 400 nm thick aluminum dots were evaporated by resistive heating. 50 nm of oxide was then etched by RIE. Appropriate control wafers were included to determine background trapping in the oxide, to provide a reference for the degree of shielding by the gate electrode, and to provide a comparison with wet etching of polysilicon. The data in Fig. 6 show that 400 nm of aluminum does shield the oxide. The shielded oxide exhibits the same increase in trapped charge density as the control, while the unshielded oxide again shows enhanced trapping. The trapping data for oxides covered by polysilicon plus resist during RIE also show that the oxide has been effectively shielded (Fig. 7). The trapped charge density for the reactive ion etched structure is shown on an expanded scale with the trapped charge density obtained for a structure that was wet etched. The two samples show the same low density of trapped charge. In fact, the trapped charge density measured for both samples is approximately half that measured on similar structures with aluminum electrodes. This reduction is attributed to a decrease in background oxide trapping as a result of the high temperature deposition and doping of the polysilicon films. Other differences in plots of the trapped charge density as a function of the avalanche injection time on the Al-gated controls (compare Fig. 2 and 6 with Fig. 3, 4, and 5) are due to differences in the magnitude of the avalanche current used.

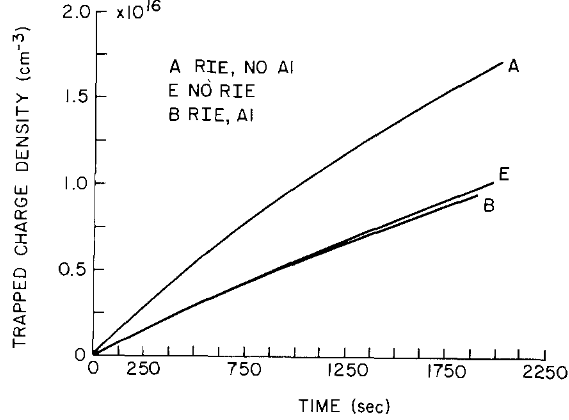

Fig. 6. Volume trapped charge density as a function of avalanche injection time for oxides exposed to RIE with and without an aluminum etch mask. Constant avalanche current = 8 × 10^{-9}A.

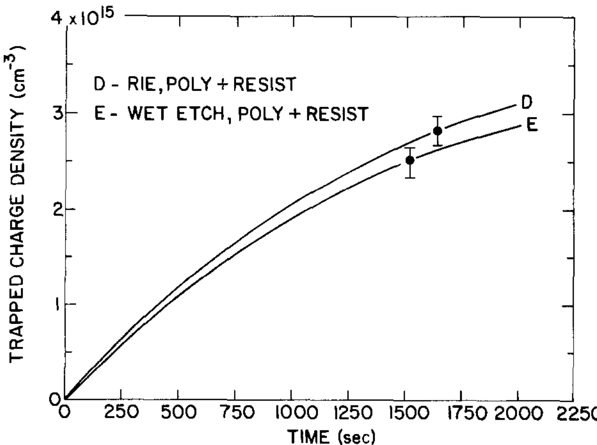

Fig. 7. Volume trapped charge density as a function of avalanche injection time for oxide after RIE of polysilicon electrode. Sample in which polysilicon was wet etched serves as a control. Constant avalanche current = 8 × 10^{-9}A.

Summary

The parameter dependence of neutral traps introduced during RIE has been investigated under worst case conditions of blanket etching and also with a gate electrode in place. During blanket RIE of silicon dioxide, neutral traps are created. These traps are removed by a 600°C anneal and so are of concern only if an RIE step occurs after aluminum metallurgy is in place. The trap density is reduced by adding H_2 to the etching gas. Neutral traps were not introduced when the reactor was operated under plasma etching-like conditions. Finally, it is concluded that oxide is effectively shielded during RIE by a polysilicon or aluminum gate electrode.

ABSTRACT

In this paper the Rutherford backscattering technique combined with channeling is used to study the stoichiometry and perfection of molecular beam epitaxial layers of InAlAs and InGaAs. Corroborative evidence from SIMS and Auger profiling are used to supplement the RBS studies.

In recent years molecular beam epitaxy (MBE) has emerged as a valuable tool for the growth of electronic quality epitaxial layers of many compound semiconductors (1, 2). The improvement of layer quality depends critically on the development of analytical techniques with which to characterize the material properties. These include parameters such as mobility, conductivity, doping profile, deep level densities and energy levels, and crystal perfection. In this paper we consider the application of Rutherford backscattering (RBS) in evaluating the structure and quality of molecular beam epitaxial InGaAs and InAlAs layer structures. We also consider the use of ion beam channeling for the measurement of crystal perfection, with particular interest in the interfaces between heteroepitaxial MBE layers. RBS has many limitations in the present context including: (*i*) Poor sensitivity in the measurement of light elements such as aluminum in matrixes incorporating relatively heavy atoms such as indium; and (*ii*) the inability to resolve neighboring atoms in the periodic table (*i.e.*, such as gallium and arsenic). In order to resolve any ambiguities arising from these limitations, complementary studies have been conducted with secondary ion mass spectrometry (SIMS) and sputter/auger profiling.

Experimental Procedures

Lattice matched $In_{0.53}Ga_{0.47}As$ layers were grown on (100) InP substrates by MBE. Substrates were heat cleaned *in situ* under stabilizing arsenic fluxes at 505°C for 2 min (3). A concentric double cell was used for gallium and indium to improve the spatial and depth composition uniformity of InGaAs layers, while separate aluminum and indium cells were used for growth of InAlAs alloys. Lattice mismatching to InP substrates measured by x-ray diffraction were $\Delta a/a_o < 1 \times 10^{-3}$ for InGaAs and $\Delta a/a_o < 2 \times 10^{-3}$ for InAlAs. Layers grown on GaAs substrates were not lattice matched. Typical substrate temperatures (T_s) = 490°C for InGaAs and T_s = 510°C for InAlAs. Low field electron mobilities of unintentionally doped InGaAs layers were as high as $\mu_{300} = 8800$ cm²/Vsec with $n_{300} = 1 \times 10^{16}$ cm^{-3} and $\mu_{77} = 15{,}000$ cm²/Vsec with $n_{77} = 8.5 \times 10^{15}$ cm^{-3}, while unintentionally doped InAlAs layers were of high resistance ($\rho > 3 \times 10^{-3}$ Ω cm). Single crystal epitaxial aluminum layers were grown on some of the samples (below 120°C) without exposure to air to obtain Schottky barriers.

The basic principles underlying the RBS/channeling techniques have been discussed extensively in the literature (4-7) and consequently, only a brief summary will be provided here. A collimated beam of 2-2.5 MeV He^+ ions is directed onto the crystal surface and the energy distribution of particles scattered through an angle θ degrees is measured using a surface barrier nuclear particle detector. This energy spectrum of the backscattered ions yields information on the mass and depth distribution of the scattering ions (5). When the ion beam is incident in a random crystal direction, the near surface composition of the crystal may be deduced from the Rutherford scattering law (6). The relative concentration N_A and N_B of species A and B may be deduced from the respective yields Y using the approximate equation (5)

$$\frac{N_A}{N_B} = \frac{Y(A)}{Y(B)} \cdot \frac{[S]_A}{[S]_B} \left(\frac{Z_B}{Z_A}\right)^2 \quad [1]$$

where Z_A and Z_B are the atomic numbers for the atoms A and B and the $[S]$ terms are the compound stopping powers in the crystal for scattering from the species A or B, respectively, given by the expression (5)

$$[S]_A = k_A{}^2[S]_{in} + \frac{[S]_{out}}{\cos(\theta)} \quad [2]$$

$k_A{}^2$ is the kinematic factor for the atoms A (or B) and θ is the scattering angle defined in the inset of Fig. 1. The stopping powers $[S]_{in}$ and $[S]_{out}$ correspond to the ingoing and scattered beam. For the compounds used in this work $[S]$ was obtained from the stopping powers of the elements concerned by the use of the Bragg law (4, 8).

Results and Discussion

The straightforward use of RBS in the measurement of the elemental composition (8) was of value to the present study. Figure 1 shows a spectrum obtained for random incidence from an $In_xAl_{(1-x)}As$ layer 1.5 μm thick (x = 0.4) grown on GaAs. The random spectra were obtained by aligning the crystals to the <100> axis and then carefully misaligning to find a random direction. In this figure we show both the compound (raw) RBS spectrum obtained by scatter-

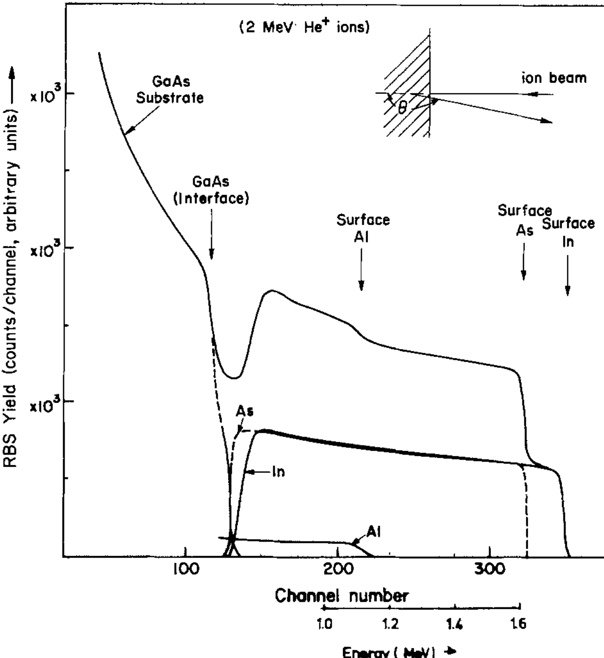

Fig. 1. Rutherford backscattering spectrum (RBS) obtained from an $In_xAl_{1-x}As$ crystal ($x = 0.4$) grown on a GaAs substrate. (Incident helium ion energy $E_i = 2.0$ MeV scattering angle $\theta = 168°$.) Both the composite spectrum and its component parts are shown.

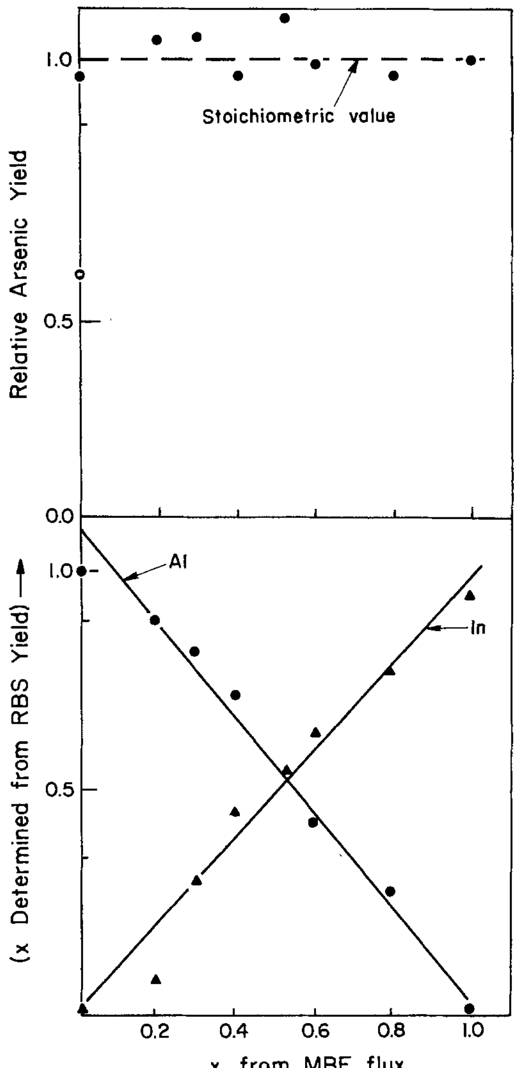

Fig. 2. A summary of the results obtained from a series of crystals grown with the value of x in $In_xAl_{1-x}As$ varied from 0 to 1. The upper graph shows the normalized (stoichiometric value = 1.0) arsenic concentration as a function of x. In the lower graph the RBS values of x for indium and $(1 - x)$ for aluminum are plotted as a function of the predicted MBE flux values.

ing 2 MeV He^+ ions through 168°, together with the individual component spectra from the indium, arsenic, and aluminum and the substrate GaAs. In order to estimate the component spectra, a simple iterative procedure (9a) based upon the work of Ref. (9b) was used. For each component spectrum an increase in yield with depth was obtained by normalizing the surface yield of each of the spectra to unity and using the Rutherford scattering relationship [*i.e.*, yield α (energy)$^{-2}$] to generate the depth dependence of the spectrum. In InAlAs grown on GaAs, for example, the GaAs substrate spectrum would be extracted first. The procedure described above would then be used for the In spectrum, followed by the As and finally the Al spectra. The heavier indium atoms give the clearest near-surface spectrum, while the much lighter aluminum spectrum superimposed on the relatively large background is more difficult to resolve and hence has the largest uncertainty. From this spectrum the value of x from the indium spectrum and $(1 - x)$ from the aluminum spectrum may readily be obtained.

RBS spectra have been obtained for a range of $In_xAl_{1-x}As$ samples with x ranging between 0 and 1. The values of x and $(1 - x)$ and the arsenic concentration obtained from the corresponding RBS spectra are shown by the circular and triangular points in Fig. 2 as a function of the values predicted from the molecular beam cell fluxes. The full lines are the best straight lines through the experimental points. The arsenic concentration is stoichiometric (*i.e.*, at 50%) in all the layers grown with x varied between 0 and 1. This is as expected from thermodynamic considerations. Observation of the indium concentration again confirms that the x values measured by RBS agree well with those estimated from the MBE flux monitor (3). The one departure from this behavior is that of a layer with $x = 0.2$ (Fig. 3); here RBS estimates a value near to $x = 0.1$, which is confirmed by repeated measurements at different areas over the crystal surface. Another interesting feature of this spectrum is the appearance of a surface indium peak where the local x value rises to near the predicted $x = 0.2$. The reproducibility of the surface indium peak across the surface, confirms that it is not a local segregation of indium [as would be expected with spitting from the indium or aluminum source (10)]. The surface indium peak in this case arises from the surface accumulation of indium [or preferential incorporation of Al(Ga)] in the nucleation stages, during growth at high substrate temperatures or low As_4 fluxes. Further confirmation comes from SIMS studies (Fig. 3 inset) where results show that the indium concentration falls by about 10% at about 0.5 micron inside the surface. The spatial uniformity of the surface indium accumulation was also confirmed by the SIMS studies. (Note that the very high arsenic yield near to the surface is an artifact of the present SIMS technique possibly associated with residual surface oxide persisting during the erosion process.) In comparison with the SIMS profiles, RBS spectra are relatively easy to interpret and they yield quantitative data. However, the problem of obtaining an aluminum profile from the spectrum shown in Fig. 3 is not tractable, making complementary SIMS profiles invaluable.

The ability of the backscattering technique to measure indium profiles is again indicated in Fig. 4(a) which shows an RBS spectrum of a 1.5 μm lattice matched InGaAs crystal grown on an InP substrate. The indium profile extracted from this spectrum shows two regions of different composition, one at the surface

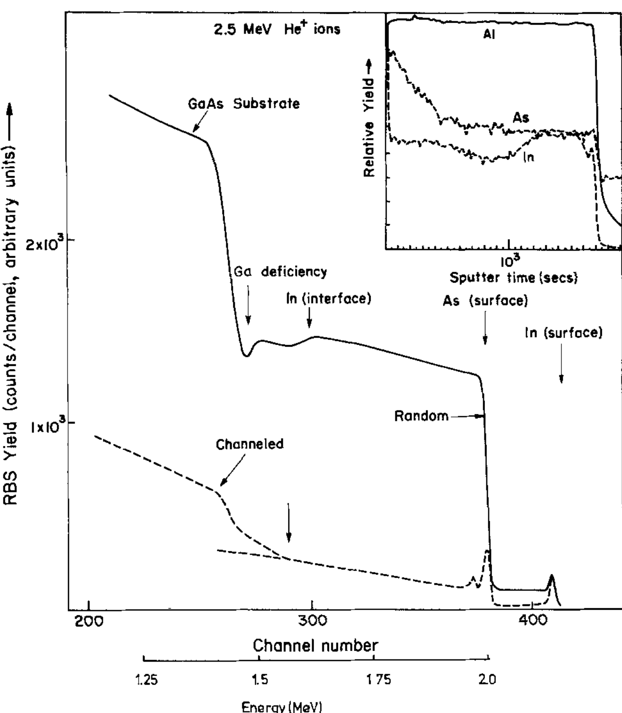

Fig. 3. RBS spectrum from an InAlAs crystal ($x = 0.2$) grown on a GaAs substrate. In this case $E_i = 2.5$ MeV and $\theta = 170°$. Both the channeled <100> and random spectra are shown. Also shown in the inset is the corresponding SIMS profile.

and a second peak approximately 0.3 μm inside the crystal. This indium fluctuation was the result of indium surface segregation at the relatively high growth temperature (489°C). This was done to determine the upper temperature limit to the growth and to identify the growth problems that occur in this high temperature regime. We note that the surface indium concentrations indicate an almost 100% increase over the bulk indium value. Note also that the close proximity of the gallium and arsenic atomic masses makes it difficult for the profiles to be separated unambiguously from this spectrum. The reverse situation, namely a drop in indium concentration at the surface, was associated with an instability in the indium effusion cell temperature control and is clearly shown in Fig. 4(b) where the indium concentration in InAlAs falls from the value corresponding $x = 0.8$ to $x = 0.72$. Note

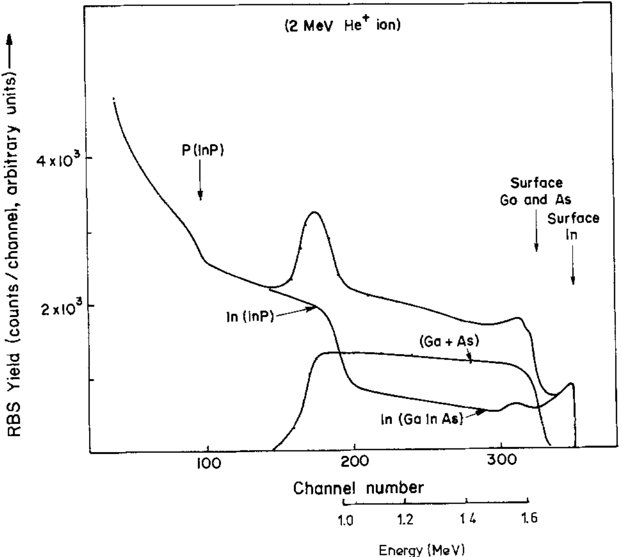

Fig. 4(a). RBS spectrum from an InGaAs crystal grown lattice matched to an InP substrate. ($E_i = 2$ MeV (He ions) $\theta = 168°$.)

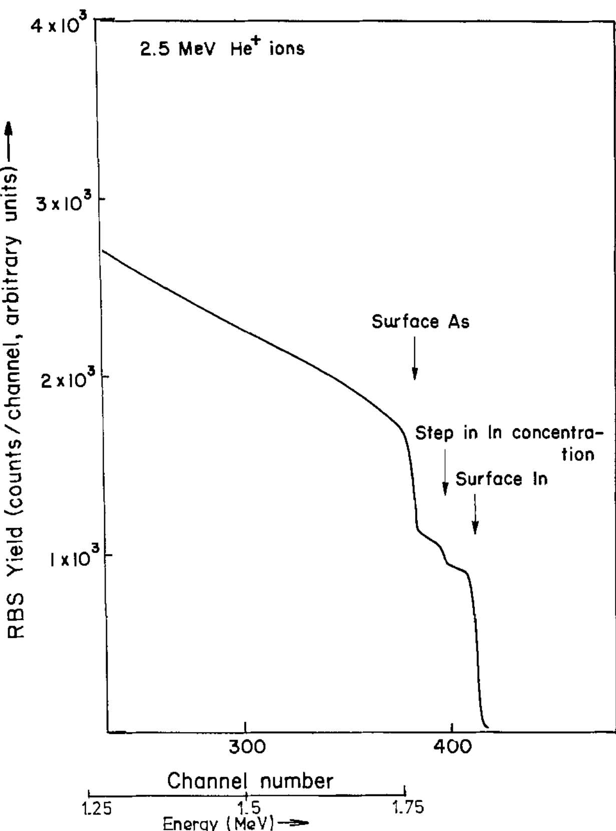

Fig. 4(b). RBS spectrum from an InAlAs crystal ($x = 0.8$) grown on a GaAs substrate. ($E_i = 2.5$ MeV, $\theta = 170°$.)

also that it becomes more difficult to identify fluctuations unambiguously where the indium and arsenic spectra overlap.

In some potential device applications where the device active layer is of a composition that does not lattice match that of the substrate used, it is necessary to grade the ratio of the component elements to reduce mismatch strain and strain induced defects etc. (*i.e.*, x in $In_xAl_{1-x}As$). Such structures provide good test vehicles for material characterization techniques. RBS alone can provide information on the compound composition and its depth dependence. When complemented by channeling measurement, however, information on crystal quality may also be obtained. This latter point is discussed later. The crystal analyzed in Fig. 5(a) is an $In_xAl_{1-x}As$ sample where x was stepped down from 1.0 at the interface in 20% steps to 0 at the surface. To avoid oxidation of the AlAs surface region a thin InAs layer was deposited on the top surface. This is seen as the near surface peak at the high energy end of the spectrum of Fig. 5(a). From the main spectrum the indium yield is readily obtained by extracting the arsenic profile, which is known to be a constant from thermodynamic considerations and is also confirmed from sputter Auger and SIMS profiling studies. The indium profile lies close to that predicted by the growth parameters and is again confirmed by the Auger and SIMS results. The steps in the composition are apparent only for In_x (x stepped from 1.0 to 0.8) which is also confirmed by Auger sputtering profiles. The 20% steps from $x = 0.8$ down to $x = 0$ are reduced due to mismatch strain-induced interdiffusion at the high growth temperature (480°C). This strain becomes apparent in the channeling measurements discussed later in this paper. It is interesting to note that the Auger sputter profiling of the inverse layer structure (*i.e.*, where x was stepped in 20% increments from 0 at the interface to 1.0 at the surface) grown at 375°C [inset shown in Fig. 5(b)] shows discrete steps, although this is not observed on the cor-

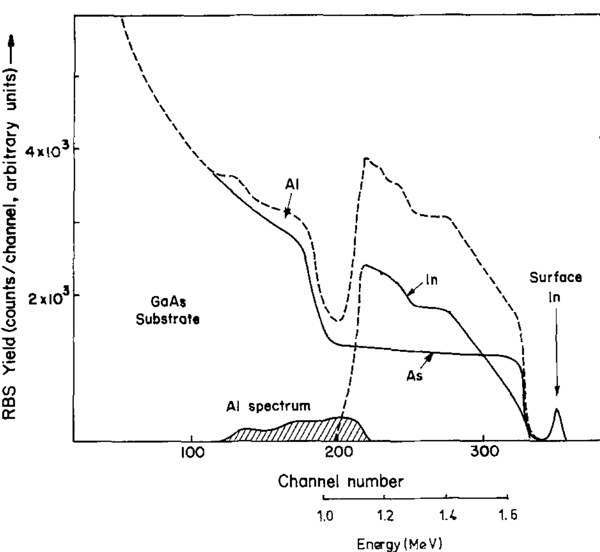

Fig. 5(a). RBS spectrum from an InAlAs crystal where the indium concentration x is varied from 1.0 at the interface in 20% steps to 0 at the surface. The AlAs surface is protected from oxidation by the growth of a thin InAs layer. [E_i = 2.0 MeV (He) and θ = 168°.]

responding RBS spectrum as the ion beam energy and incident angle were not optimized for the best depth resolution. The RBS spectrum again illustrates the difficulty of extracting the aluminum profile. The extracted indium and aluminum signals are compared to the Auger profiled results in Fig. 5(b) inset. Here both techniques confirm the relative integrity of the individual alloy layers and interface regions when grown at the lower temperature.

So far we have considered only the basic RBS technique. The following considers the use of the channeling process (6) to investigate bulk layer crystal quality and more importantly the crystalline perfection of interfaces. Figure 6 shows two RBS spectra obtained for aligned and random incidence from a multilayer structure consisting of an InGaAs (2500Å)/InAlAs (1000Å)/InP (substrate). Using the channeling technique there are two basic measures of crystal quality, the minimum yield χ_{min} and the dechanneling rate $\alpha (= d\chi_{min}/dz)$ where z is the depth of the penetration

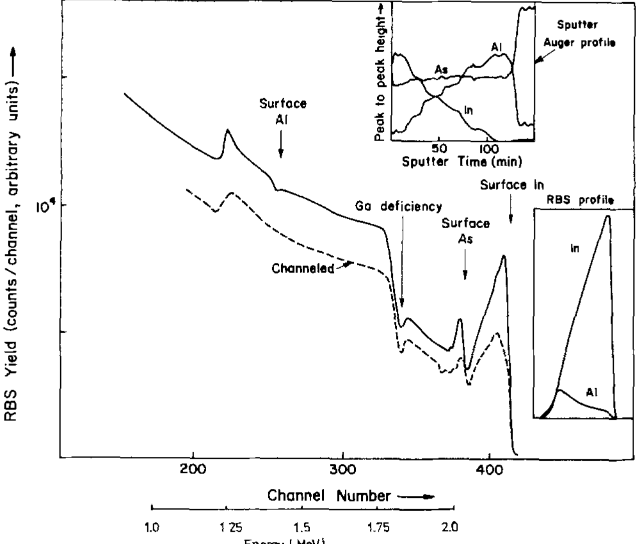

Fig. 5(b). The channeled (<100> axis) and random spectra from an $In_xAl_{1-x}As$ crystal where the indium concentration x is varied from 0 at the interface in 20% steps to 1.0 at the surface. [E_i = 2.5 MeV (He ions), θ = 170°.] Also shown in the inset is the corresponding sputter Auger profile.

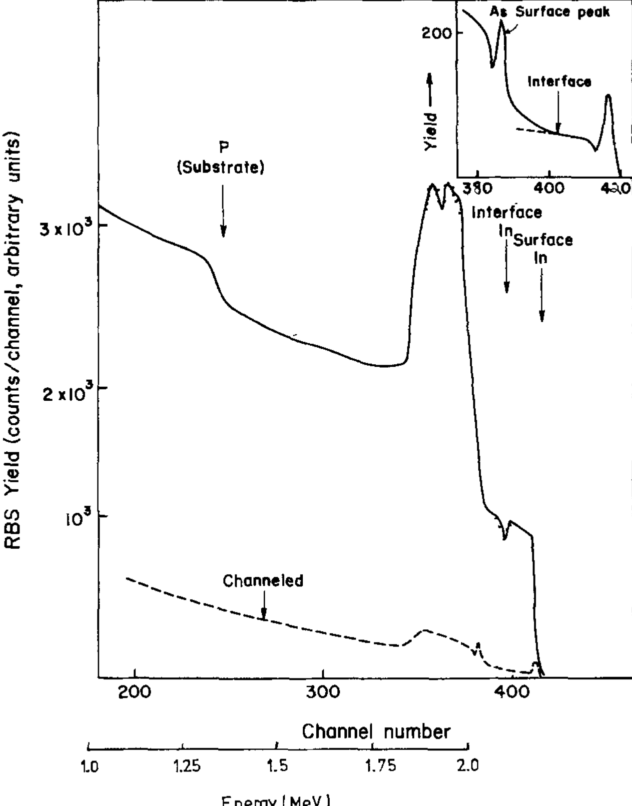

Fig. 6. The RBS spectrum for channeled and random incidence from an InGaAs/InAlAs/InP crystal, where the two epitaxial layers are grown lattice matched to the InP. [E_i = 2.5 MeV (He ions), θ = 170°, axis for channeling <100>.] The inset shows an enlarged version of the near surface channeled spectrum.

in the crystal (11). These parameters provide only a relative measure of crystal quality. In order, therefore, to provide a standard we note that for channeling along the <100> axis in a good quality GaAs layer values of $\chi_{min} \simeq 0.04$ and $\alpha \simeq 10^{-4}$ (nm)$^{-1}$ are typical. For the crystal shown in Fig. 6 (*i.e.,* channeling along the <100> axis) we obtain near surface values of $\chi_{min}(In) = 0.04$ and $\alpha(In) = 5 \times 10^{-4}$ (nm)$^{-1}$. The minimum yield shows excellent agreement with the best GaAs experimental results (12). In the case of the dechanneling rate α, this result is a factor five larger than that typical of premium grade GaAs. However there are two reasons why this is reasonable. In the first instance dechanneling is a much more sensitive parameter than the minimum yield. Wood and Morgan (12), for example, have observed fourfold increases in α in GaAs epitaxial layers at a growth interface. A second important consideration arises from the disparity in the atomic numbers of the component atoms—indium, arsenic, and aluminum. A large disparity gives rise to a much larger intrinsic dechanneling rate. In the case of planar channeling, computer simulation (13) results show that this factor alone could result in a 300% increase in going from GaAs to a material such as InAlAs. In view of these considerations it is concluded that the value of $\alpha = 5 \times 10^{-4}$ (nm)$^{-1}$ is comparable to those obtained for high-grade epitaxial layers and indicates that the uppermost InAlAs layer exhibits a high degree of perfection, justifying the care in lattice matching to the substrate InP.

A second interesting feature of these spectra may be more clearly seen in the inset to Fig. 6, which shows an enlarged plot of the near surface indium peaks (*i.e.,* the indium in the InAlAs and the InGaAs). At the interface between these two layers the indium channeling curve undergoes an abrupt transition resulting in a fourfold increase in the dechanneling parameter

α(In) (*i.e.*, α increases from 5×10^{-4} to 20×10^{-4} $(nm)^{-1}$). This indicates that the lattice structures are strained at the interface, presumably a result of imperfect matching, local segregation, or diffusion of group III elements within the alloy sublattice across the interface. It is clear that such strain can result in undesirable deep levels which could adversely affect the performance of FET's made from such layers. Further clarification of the interface strain may be gained from the random spectrum of Fig. 6. At the interface the indium yield decreases indicating that a deficiency of indium occurs during the transition from the growth of InGaAs to InAlAs. The indium deficiency at the interface is further evidence for accumulation of indium in these two ternary alloys growing under conditions of low As_4 fluxes or high temperature substrates. The total indium deficiency at the interface corresponds to a total equivalent of 1.5 monolayers of pure indium. Because of the limited depth resolution (~200Å) it is not known how localized this deficiency is.

A third measure possible from a channeling spectrum is the area under the surface indium, gallium, and arsenic peaks (9). These peaks give the ratio of unscreened components in the surface disordered layer. From the <100> channel spectrum shown in the inset of Fig. 1 we obtain a value of $N(\text{In})/N(\text{Ga} + \text{As}) = 0.63$ which is significantly larger than the expected bulk value of 0.36. One of the difficulties of this measurement is that the Ga and As peaks cannot be separated and hence the source of the nonstoichiometry cannot be identified. Before leaving the topic of interfaces we note in the random spectrum in Fig. 3 that there exists a dip in the gallium yield when InAlAs is grown on a GaAs substrate which is explained by an Al/Ga exchange and redistribution reaction during growth of the first few atomic layers of any aluminum-containing alloy or compound on any gallium-containing alloy or compound. It is also observed that the dechanneling curve in Fig. 3 undergoes an abrupt increase as the interface between InAlAs and the GaAs substrate is approached. This is presumably a result of the interface strain expected since this interface is not lattice matched. The dechanneling results indicate that this strain extends some 2000Å into the epitaxial layer.

In order to further investigate the value of channeling measurements, studies have been carried out on the range of samples studied earlier (*i.e.*, those with $In_xAl_{1-x}As$ for x ranging from 0 to 1). The clear trend in these results is that the best channeling (*i.e.*, lowest χ_{min}) was obtained in crystals with $x \simeq 0.5$ (*i.e.*, the InP lattice matched system). We note also that layers grown on GaAs (not lattice matched) give poorer channeling. For example, in the case of $x = 0.8$ [Fig. 4(b)] the crystal structure is so poor that it is very difficult to observe any channeling dips with any degree of certainty. The same conclusions may be drawn for other crystals with variable x [Fig. 5(b)], the near surface $\chi_{min}(\text{In}) = 0.52$, confirming that the crystallinity is very poor.

Another example of the value of this technique is shown in Fig. 7 in the spectrum from a lattice matched layer of InGaAs/InP. This layer exhibited a very low mobility compared to normal. The reason for this low mobility is apparent from the RBS spectra shown in Fig. 7. Consider first the random spectrum. This shows a series of peaks in the indium concentration culminating with a large surface accumulation (*i.e.*, a 15-20% increase over the average bulk value). These oscillations occur and can be seen even when the indium and GaAs spectra overlap. Clearly any variation in indium concentration must be matched by a complementary change in the gallium. Of particular interest is the

[3] The background correction procedure used to extract the surface peaks was that described by Morgan and Wood in Ref. (11).

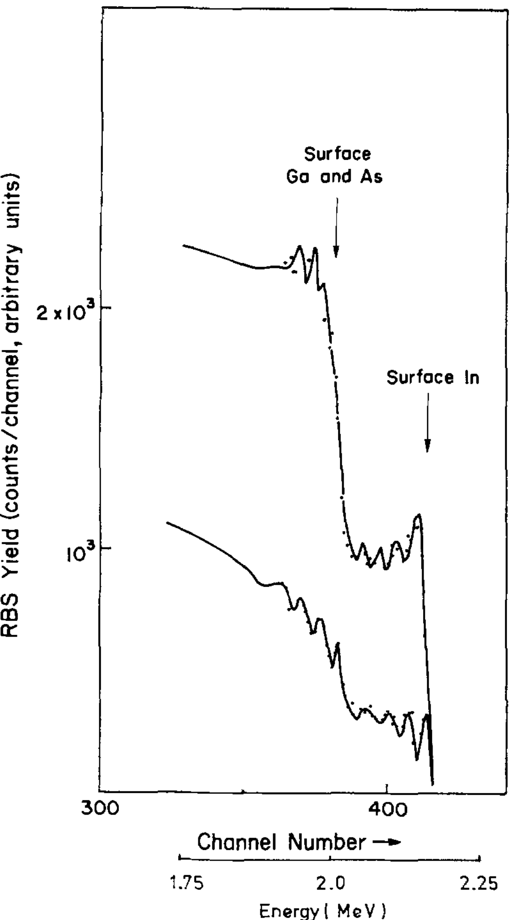

Fig. 7. RBS spectrum of an InAlAs grown on a GaAs substrate [$E_i = 2.5$ MeV (He ions), $\theta = 170°$.]

channeled spectrum; here the oscillations are greatly amplified (*i.e.*, a maximum of 100% change). The reason for this greater sensitivity lies in the nature of the channeling process. The channeled component of the beam is screened from violent collisions. However, when the indium concentration increases, the channel becomes distorted and some channeled ions are no longer screened, resulting in the increased backscattering. In this way the effect of the indium fluctuations are amplified (*i.e.*, 10% variation in the random RBS spectrum becomes a 100% change).

Conclusions

Both random and channeling RBS have been used with complementary sputter Auger and SIMS techniques to study epitaxial InAlAs and InGaAs multilayer structures on (100) InP and GaAs substrates.

Results indicate that at higher temperatures or reduced arsenic fluxes indium accumulates on the surface during growth of both InGaAs and InAlAs alloys. The net effect is to leave an indium deficiency at near substrate layer interface regions. The effect was confirmed by observing depth fluctuations of the In/Ga ratio in layers grown with intentionally fluctuating arsenic fluxes. A further effect seen only by RBS was the preferential exchange of aluminum for gallium at the nucleation stage of InAlAs on GaAs substrates or on InGaAs layers.

Acknowledgments

The authors are grateful to L. Rathbun for the sputter Auger data, to G. Morrison for SIMS data, and to Ms. Elma Weaver and Mrs. C. Edmondson for preparation of the typescript. We also acknowledge Dr. J. M. Poate (Bell Laboratories) and Professor G. Carter (University of Salford, UK) for the use of their RBS machines and the planning committee of NRRFSS for permission to use the MBE machine.

Plasma Oxide FET Devices[1]

A. K. Ray* and A. Reisman*

IBM T. J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Plasma oxidation techniques described in this issue (1, 2) by the authors were employed alone, or in conjunction with thermal oxidation processes in the fabrication of n-channel polysilicon gate field effect transistors. Horizontal dimensions were delineated using optical lithography, and ranged from 2.5 μm minimum dimensions up, to enable assessment of device parameters. The characteristics of 500°C plasma oxidized structures were compared to those fabricated in a conventional manner at 1000°C. Gate oxides were 35 nm thick and field planar oxide regions were 350 nm thick. Using wafers of a given resistivity, the thick and thin oxide thresholds of plasma oxide structures were higher than their thermal counterparts due, it is believed, to the absence of surface boron depletion in plasma oxidized regions. In line with this, threshold sensitivity to substrate bias (substrate sensitivity) was greater in plasma oxidized structures for a given starting background substrate doping level. Also because of the absence of impurity spreading, the sheet resistivity of n^+ junctions was higher in plasma oxidized structures. Aside from doping level effects which can be advantageously accommodated for by appropriate device design, plasma oxidized devices are otherwise quite comparable to their thermal counterparts. They exhibit obvious device design and process control attributes due to shorter processing time at high temperatures, *i.e.*, absence of oxidation induced stacking faults, confinement of junctions, and absence of surface impurity depletion. In n-channel devices, the absence of boron depletion during plasma oxidation has enabled the fabrication of surface and junction ion-implanted devices with lower boron doses and lower substrate sensitivity.

In the fabrication of micron or submicron device structures, there is an increasing interest in the use of lower processing temperatures to minimize impurity redistribution and defect generation effects. Oxidation is a key process in semiconductor device fabrication. High temperature oxidation is accompanied in addition to the problems mentioned above by surface depletion of impurities (3), oxidation enhanced diffusion (4), generation of stacking faults (4, 5), and so-called bird's beak generation (6). In Parts I and II the authors have described a low temperature plasma oxidation process (1, 2) in which uniform thickness oxides exhibiting excellent physical and electrical properties can be grown on 57 mm diam silicon wafers. In the process described, an oxygen plasma is generated at pressures above 10 mTorr in an electrodeless fused silica reaction chamber using a 3 MHz rf generator and a 1 kW power output. The system is pumped continuously during oxidation and the oxygen pressure is varied by varying the oxygen flow rate. Silicon wafers are placed on either side of an rf coil, mounted perpendicular to the direction of gas flow, with the silicon surfaces to be oxidized facing away from the plasma. Oxide grows primarily on the silicon surfaces facing away from the plasma, while much thinner oxide grows on the silicon surfaces facing the plasma. The temperature of the wafers during plasma oxidation is about 500°C, and is measured by a Chromel-Alumel thermocouple placed adjacent to the wafers. The plasma oxides can be grown at rates less than, equal to, or greater than that obtainable via dry thermal oxidation processes at 1000°C, depending upon oxygen partial pressure, wafer position relative to the rf coil, temperature, and generator output power. The high-low thickness uniformity of the grown oxide was better than ±5% and the standard deviation was of the order 1-3%. The etch rate and refractive index

Key words: silicon, oxygen plasma, boron depletion, substrate sensitivity.

of the as-grown plasma oxides were comparable to thermal oxides grown at 1000°C. The as-grown oxides exhibited large negative flatband voltages with high interface trap density (3×10^{12}/cm^2 eV). However, after a conventional low temperature postmetallization anneal (400°C, 20 min, forming gas), the interface charge and trap densities decrease to 6×10^{10}. The electrical breakdown strength (3-4 MV/cm) was somewhat lower than the thermal counterpart. However, after a postoxidation heat-treatment at 1000°C for 15 min in dry O_2, followed by 5 min in Ar, the breakdown strength improved to 7-8 MV/cm and the interface charge and trap densities dropped further to the 2×10^{10}. The properties of plasma grown oxides after a short anneal at 1000°C are thus comparable to the thermal oxides grown at 1000°C. The thickness change associated with this annealing treatment is less than 5 nm. In addition, boron depletion effects are absent, as are oxidation-induced stacking faults and bird's beak effects (2). Elimination of the bird's beak is due solely to the fact that an oxide pad is not required under the oxidation mask to avoid defect generation during the low temperature plasma oxidation. Based on these results, the present study was conducted to evaluate plasma oxides in terms of polycrystalline silicon insulated gate FET device characteristics.

Experimental Techniques

Polysilicon gate FET devices were fabricated using optical lithographic techniques in conjunction with the plasma oxidation process alone, or in combination with thermal oxidation. For the present studies, plasma oxide growth rates considerably faster than 1000°C dry oxidation rates were employed. For example, 35 nm gate oxides were grown in 5 min and 350 nm field oxides were grown in 330 min. The comparable times for dry thermal oxidations at 1000°C would have been 38 and 1220 min, respectively. The plasma oxides were all grown at 500°C, 30 mTorr system partial pressure, 1 kW generator output power, and a generator frequency of 3 MHz. As mentioned, the growth of these plasma oxides occurs on the surfaces of the wafers facing away from the plasma which was described earlier (2). No external bias was applied to the wafers. There were three oxidation steps involved in the device fabrication; field isolation oxidation, gate insulator oxidation, and simultaneous source-drain: gate electrode oxidation. Four groups of wafers, two in each group, were employed in the experiments. These included: (A) wafers with plasma field, plasma gate insulator, and plasma source-drain: gate electrode oxidations, (B) wafers with plasma field, plasma gate insulator oxidations, and thermal gate electrode: source-drain oxidation, (C) wafers with plasma field oxidation, thermal gate insulator, and thermal gate electrode: source-drain oxidations, and (D) control wafers with thermal field, thermal gate insulator, and thermal source-drain: gate electrode oxidations. In order to keep the device fabrication process as simple as possible, no field or channel tailoring implants were employed in this first series of experiments, and source and drain regions were formed by diffusion. In addition, field regions were planar (as opposed to semi-ROX configurations). 0.5 Ω-cm p-type ($B \sim 3.2 \times 10^{16}$/cm^3) Czochralski grown silicon wafers were used as substrates. About 350 nm of blanket field oxides were grown over the entire wafer using either plasma or thermal oxidation techniques as the starting point. Field regions were subsequently defined using standard photolithographic techniques. Gate oxides (35 nm) were then grown using plasma or thermal oxidation processes. Wafers with plasma gate insulators were given a postoxidation heat-treatment at 1000°C for 15 min in dry O_2 followed by 5 min in Ar. As mentioned before, this heat-treatment reduces the interface traps and charge density, and improves the breakdown strength of plasma oxides. During this postoxidation heat-treatment, as mentioned, about 5 nm of thermal SiO_2 is grown in addition to the 30 nm of plasma gate oxide already present on the wafers. If the postoxidation annealing of the plasma oxides is conducted only in an inert atmosphere (argon), the interface electrical properties of the oxides are essentially equivalent to those obtained using the procedure described (2). The breakdown strength of the oxides following inert gas annealing does not improve however, although it is still adequate for device applications. Our normal procedure is to use the two-step annealing procedure so as to obtain the higher breakdown strength oxides. Wafers with conventional thermal oxides received a 1000°C, 5 min Ar postoxidation heat-treatment. After growing field and gate oxides, about 350 nm of undoped polysilicon films were deposited over the wafers and subsequently doped with phosphorus. Polysilicon gate electrodes, source, and drain regions were defined by photolithography. Source and drain were then formed by phosphorus diffusion. Following source-drain diffusion, 100 nm of oxides were grown over these regions using plasma or thermal oxidation processes. Subsequent device fabrication steps, *e.g.*, CVD SiO_2 deposition (250 nm), PSG formation, contact metallurgy, pre (500°C, 30 min, forming gas) and post (400°C, 20 min, forming gas) metallization anneals were common to all wafers.

Results and Discussions

Threshold voltage comparisons of FET devices were made using a standard *I-V* technique. Measurements were made on devices with a 10.8 μm channel length and an 89.5 μm channel width, unless otherwise specified. About ten devices on each wafer were measured to obtain the average threshold voltage. Figure 1 shows the *I-V* characteristics of FET devices in wafer type A which were fabricated using only plasma oxidation steps. Threshold measurements were made with a source-substrate bias of -1V with the source grounded and 0.1V applied between the source and drain. The threshold voltage as determined from the straight line portion of the curves was 0.88 ± 0.07V. Figure 2 shows the *I-V* characteristics of FET devices in control wafer, type D. The threshold voltage of FET devices made by conventional processes was 0.74 ± 0.065V. Comparing slopes of the straight lines in Fig. 1 and 2, it is seen that the channel transconductance of FET devices fabricated with plasma oxidation processes is essentially the same as those fabricated by conventional thermal techniques. The thermal oxide devices exhibited lower threshold voltages, but the spread in threshold voltages is essentially the same for the two types of wafers. This spread is quite

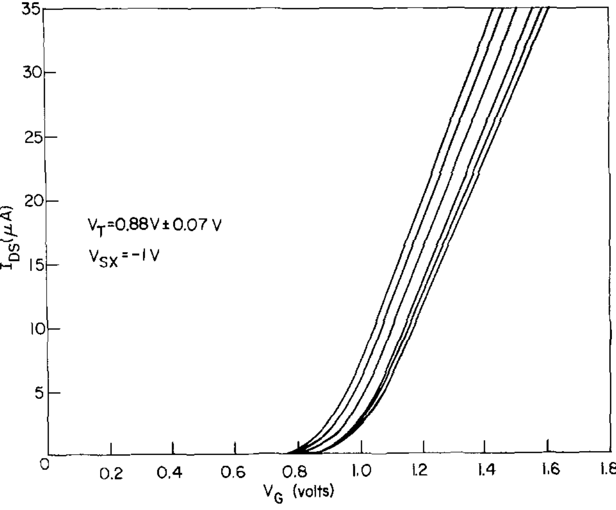

Fig. 1. *I-V* characteristics of FET devices fabricated using only plasma oxidation steps.

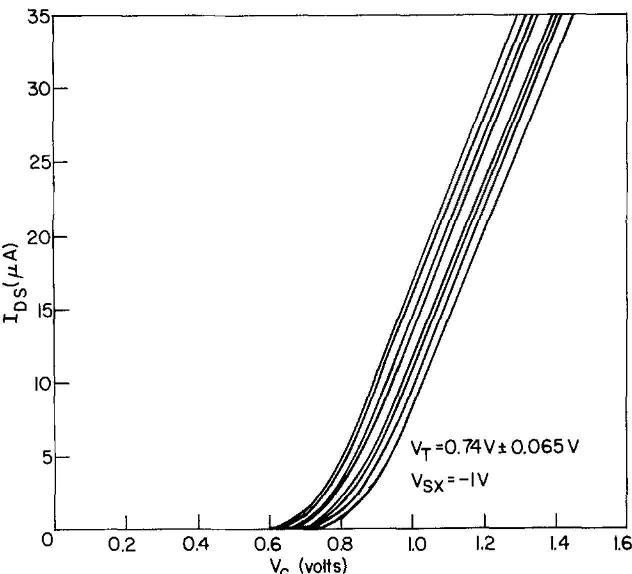

Fig. 2. *I-V* characteristics of FET devices fabricated using only thermal oxidation steps.

common in devices which do not have channel implant tailoring and is due to bulk doping variations. Figure 3 shows the variation of the threshold voltage with channel mask length for the four types of wafers being examined. The effective channel length for each device size which would differ from the mask length by a value Δl could not be determined from the mask set employed, because the device width was different for each channel length. The channel etch tolerance for all devices should, however, be the same and the Δl value would depend then on junction diffusion spreading in each wafer type. Consequently, the comparison of similar devices in Fig. 3 is of less value than device-to-device comparison along each curve, and the relative position of one curve to the others. Devices on all the wafers showed the expected short channel effect below $L = 3.5$ μm. The straight line portions for the wafer types A and B may have a slight upward slope, because the large devices ($L = 50.8$ μm, $W = 508$ μm) in both wafer types A and B exhibit thresholds of 1.1-1.2V compared to values around 0.88V for somewhat smaller devices (L = 10.8 μm, W = 89.5 μm). Corresponding devices on wafer types C and D, both of which have thermal gate insulators show no such effect. If we now examine the curves for wafer types C and D of Fig. 3, it is seen that devices on wafer type D appear to show a lower threshold than corresponding devices on wafer type C. This is believed to be due to surface boron depletion (7) in wafer type D which underwent thermal field oxidation as compared to wafer type C which underwent plasma field oxidation. Since wafer types C and D both received a thermal gate insulator oxidation sequence, the relative threshold difference cannot be due to gate insulator thickness difference between them. This was verified via *C-V* measurements on capacitor pads present on the device wafers on which flatband values were also determined to insure that the difference could not be attributed to difference in insulator charge levels. More definitive boron depletion experiments which confirmed the above are discussed more fully below.

Figure 4 shows the variation of thin oxide threshold voltage as a function of substrate bias voltage. It is seen that the control wafer D exhibits slightly lower substrate sensitivity than the plasma oxidized devices. This is also consistent with the existence of a boron depletion effect in the control wafers. The boron depletion effect is even more pronounced in the substrate sensitivity curves for Al gated thick oxide devices (Fig. 5). Thermal thick oxide devices (D) have much lower thresholds compared to plasma thick oxide devices (A, B, and C), again consistent with boron depletion effects in the former. The slight variation in thresholds of thick plasma oxide devices in wafer types A, B, and C is probably due to variation in oxide thickness (493, 507, and 509 nm, respectively) or bulk substrate doping level variations.

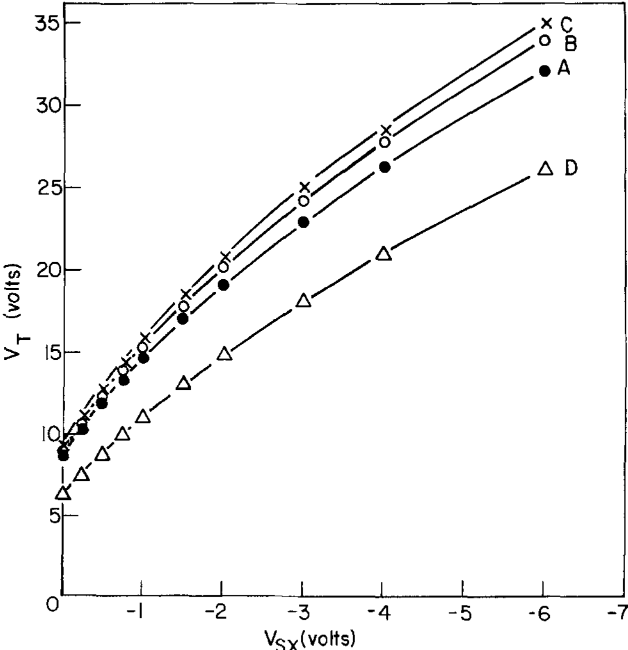

Fig. 5. Variation of thick oxide threshold voltage as a function of substrate bias voltage.

The absence of boron depletion effects during plasma oxidation was confirmed via pulsed C-V measurements on polysilicon gated capacitors in separate experiments. 350 nm of SiO_2 was grown on 2 Ω-cm p-type ($B \sim 8 \times 10^{15}/cm^3$) silicon wafers using either plasma oxidation at 500°C or thermal oxidation at 1000°C. These thick oxides were grown to enhance boron depletion effects, if present, as they would be in a conventional field oxidation. The thick oxides were then stripped off, and thin oxides (35 nm) were grown on the same wafers by plasma or thermal oxidation processes. Polysilicon gated capacitors were formed on this thin oxide, and the boron concentration profile near the Si-SiO_2 interface was determined via the pulsed C-V technique. Figure 6 shows the boron concentration profile near the Si-SiO_2 interface after plasma oxidation, indicating the absence of boron depletion effects. Figure 7 shows the boron concentration profile after thermal oxidation. The boron concentration gradually decreases from its bulk value as the Si-SiO_2 interface is approached. In Fig. 6 and 7 the profile is shown to within $2L_D$ of the Si-SiO_2 interface, (L_D = Debye length), because at $<2L_D$ the pulsed C-V data are not considered reliable. The sheet resistivity of n^+ junctions for devices with thermal source-drain: gate electrode oxidation was lower (30 Ω/□) than devices with plasma source-drain: gate electrode oxidation (41 Ω/□). This is an indication of the formation of deeper junctions during the thermal source-drain: gate electrode oxidation step at the higher temperatures employed, since the same doping cycle was used for all the wafers during initial source-drain formation. The sheet resistivity of polysilicon gate electrodes (25 Ω/□) was essentially the same for all wafers.

The results of the first device test run led to the fabrication of a second device test run to test semi-ROX plasma field oxides against thermal field oxides. Plasma oxidation was used only to grow field oxides in this test run with the gate oxides being grown thermally at 800°C. During the gate oxide growth at 800°C, we would expect minimal surface boron depletion. The absence of boron depletion during plasma oxide growth should enable the fabrication of ion-implanted devices with lower boron field doses than that used in conventional processing. The use of lower boron doses in field ion implantation should also result in lower junction capacitance and lower substrate sensitivity. Field ion implantation conditions were chosen so as to obtain the same thick oxide thresholds for the plasma and thermal thick oxide devices with −0.75V on the substrate. For the plasma field oxides, boron implantation dosage was 1.15×10^{12} and 80 keV while that for thermal field oxides was 7.5×10^{12} and 65 keV. About 450 nm of semi-ROX plasma field oxides were grown on wafer type E at 550°C, 15 mTorr system pressure, and 1 kW generator output power in 6.5 hr. 200 nm of MgO on top of 5 nm of SiO_2 was used as an oxidation mask. About 450 nm of thermal field oxides were grown on wafer type F at 950°C. As mentioned above, gate oxides (22.5 nm) were grown on all wafers by thermal oxidation at 800°C. Channel tailoring ion implantation ($B \sim 1.1 \times 10^{12}$, 34 keV) was employed in this test run, and source-drain regions were formed via ion implantation. Other device fabrication steps were essentially the same as described before. Figure 8 shows the thick oxide thresholds for polysilicon gate plasma (wafer E) and thermal (wafer F) thick oxide devices as a function of substrate voltage. At −0.75V substrate bias voltage, the threshold for the thermal thick oxide devices is about 1V higher than the plasma oxide devices. It is seen from Fig. 8 that the plasma oxide devices have much lower substrate sensitivity compared to the thermal oxide devices because of the lower boron dosage required for field ion implantation. It is thus possible to obtain desired threshold voltage accompanied by lower substrate sensitivity in plasma oxide devices by adjusting ion implantation conditions, since no boron is lost to the grown oxide via a boron depletion effect.

Since the thin oxides in both types of wafers were grown thermally at 800°C, and same channel tailoring ion implantation was used, we expected the thin oxide threshold voltages to be the same for both wafers. Figure 9 shows the variation of thin oxide threshold voltage as a function of substrate bias voltage for the two types of wafers. Thin oxide devices have similar thresholds and substrate sensitivity. Threshold measurements were made on devices with nominal dimensions (L = 10.8 μm, W = 89.5 μm). Since plasma field oxides were grown at much lower temperature compared to thermal field oxides, there will be less

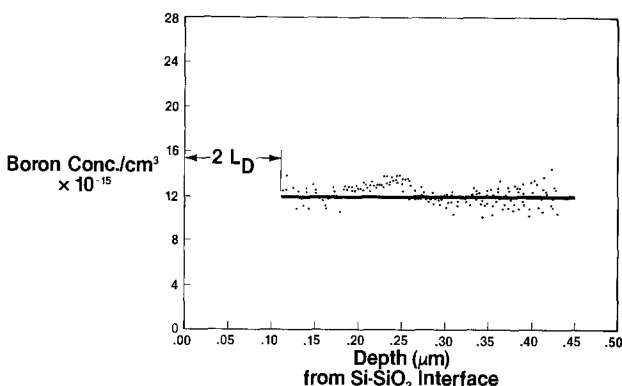

Fig. 6. Boron concentration in silicon as a function of depth from the Si-SiO_2 interface after plasma oxidation.

dopant redistribution in plasma oxidized structures and as a consequence, the boron concentration near the semi-ROX edges may be less for plasma field oxides compared to thermal field oxides. This could lead to leakage along the width of an FET channel often called "sidewalk leakage." This effect would be more pronounced for narrow width devices. In order to examine this phenomenon, the subthreshold characteristics of thin oxide FET devices with nominal dimensions $L = 3.18$ μm and $W = 3.18$ μm were determined. Figure 10 shows the subthreshold I-V characteristics of FET devices with plasma (E) and thermal (F) field oxides. Both devices exhibit similar subthreshold behavior with no indication of abnormal leakage current, *i.e.*, normal subthreshold conduction characteristics are observed.

Conclusions

The characteristics of FET devices fabricated using plasma oxidation processes were found to be normal and comparable to devices fabricated in conventional manner. With a given starting substrate resistivity, the threshold voltages of plasma oxide devices are higher than thermal oxide devices because of the absence of boron depletion effects during plasma oxidation. A higher observed substrate sensitivity of plasma oxide devices is also consistent with the absence of the boron depletion effect. The higher sheet resistivity of n^+ junctions in plasma oxide devices is presumably due to the formation of shallower junctions because of the lower source-drain:gate electrode oxidation temperature. The doping level employed during source-drain formation can be adjusted for desired junction sheet resistivity. It has been demonstrated

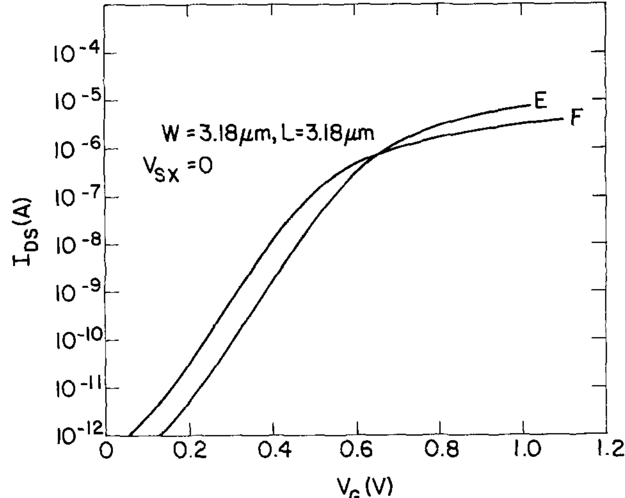

Fig. 10. Subthreshold I-V characteristics of thin oxide FET devices with plasma and thermal field oxides.

that a required threshold voltage and lower substrate sensitivity in the field regions can be achieved in plasma oxide devices by using lower dosage implants, since no excess boron is lost to the grown oxide via a boron depletion effect. A similar but smaller effect would occur in the channel regions. In general, then, plasma oxide devices have advantages over thermal oxide devices in terms of lower processing temperatures, absence of defects, absence of surface dopant depletion and junction depth containment, as well as minimization of "bird's beak" phenomena.

A Modified SEM Type EB Direct Writing System and Its Application on MOS LSI Fabrication

Y. Iida* and K. Mori

Nippon Electric Company, Limited, Basic Technology Research Laboratories, Takatsu-ku, Kawasaki 213, Japan

ABSTRACT

A modified SEM type electron beam exposure machine adopts an auto-registration function and it is converted to a direct writing purpose system. One-chip-one field and chip-by-chip registration scheme is adopted to increase the field size and to eliminate stage-related problems, such as laser interferometric control complexity and stage movement slowness. 2 μm rule 64 k ROM, shrunk to 4/10 from the original design, is used as a device for testing the developed EB system capability. 0.8 μm high, 2 μm wide, L-shaped step made from bulk Si is used as registration marks and ±0.1 μm of 2 level overlay accuracy is achieved. Although no special optimization or device design modification is done on the shrinkage, the device fabricated by all EB direct writings and dry etching process shows no noticeable difference in electric functions from one made by photolithographic (DSW) processes. The system is stable without intensive maintenance jobs and overlay accuracy through the process (7 exposing levels) is better than ±0.25 μm, although the registration mark structure is changed by the fabrication processes. It becomes clear that this kind of direct writing machine is very useful for research of EB lithography and the LSI development.

Master mask fabrication using electron beam exposure has become usable on the factory level. A raster scanning machine is most popular for this purpose (1-3).

However, it is not clear yet which is the best system for direct writing and there is no commercial machine used for production. For a while the electron beam direct writing machine was used as an experimental or LSI development purpose tool, due to the small throughput from its serially exposing nature but quick turn around time. The system under these circumstances should have the following characteristics to compete with ever improving photolithographic machines (4): (*i*) Achievability of highly accurate reregistration, even though the wafer is distorted (5) and the registration mark is degraded by the fabrication processes; (*ii*) reasonable throughput to fabricate developing devices; (*iii*) high stability and high uptime ratio; and (*iv*) connection to computer aided design system is possible.

To satisfy (*i*), a vector scanning electron beam exposure is one of the best ways, because of its scheme to register the writing pattern on a chip by chip basis, using registration marks on each chip corner. If chip by chip registration is possible, necessary stage movement accuracy becomes less and reregistration could be realized even without laser interferometric control. It also reduces the EB system cost and complexity.

About (*ii*), a one-chip-one field strategy for large field would be one of the better choices, since it can reduce the stage movement time, which could be a large part of exposing time after the advent of high resolution high speed DAC for steering the electron beam. While this technique results in bigger writing field distortion, if all the exposure is accomplished by the same machine, there should not be any problem including overlaying.

To satisfy (*iii*), magnetic field scan and separation of main scan and correction for reregistration are important. About (*iv*), PG-3000 format[1] could be an interface.

The system developed in this research is a vector scanning type using prelens double deflection correction for registration and postlens main scanning. Field size is relatively large, 5 mm. It can accommodate various developing test devices like 64 K ROM, 4 k static RAM, 256 k bubble device, SAW device, etc. It could give important information for larger scale integration, which is often an ally of these devices (6). A testing tool selected for clarifying the system characteristics through its direct writing application is a 64 k ROM which simply reduced the conventional 5 μm rule into the 2 μm rule. Emphasis was placed on determining degradation in registration marks on the wafer by the process chosen to fabricate the 64 k ROM. The technologies used in the process were not only a direct writing, but reactive sputtering in combination with beam resists.

System Description

A vector scan electron beam system[2] is modified for direct writing by the adoption of auto-registration system. A block diagram of the system is shown in Fig. 1. The electron beam column has a main postlens magnetic scanning coil and an additional small prelens double deflection coil for registration purposes. Main scan is achieved by a combination of positioning purpose high accuracy 16 bit DAC and fill-in mode high speed 12 bit DAC. Accelerating voltage is set at 20 kV, but is adjustable from 2.5 to 30 kV. A tungsten filament is used for its high stability. Also, a single crystal LaB_6 is used sometimes for tests. The modified machine is balanced to operate at an equivalent 0.5 MHz data rate with electron resist sensitivities of 5 $\mu C/cm^2$ for W filament and 30 $\mu C/cm^2$ for single crystal LaB_6. The column can provide a minimum beam diameter less than 500Å at 56 mm working distance. Typical probe size used for this work is 0.25-0.40 μm. Beam blanking is electrostatic. A scintillator system is used to provide video signals for setup and registration. Registration has been accomplished in two stages.

First, the wafer is roughly registered in the stage movement direction and writing field, using large wafer registration mark. Next, the writing field is finely and automatically registered on a chip by chip basis using chip registration mark. Figures 2 and 3 show the wafer setting errors in shift and rotation, respectively, without preregistration to the cassette. Both errors

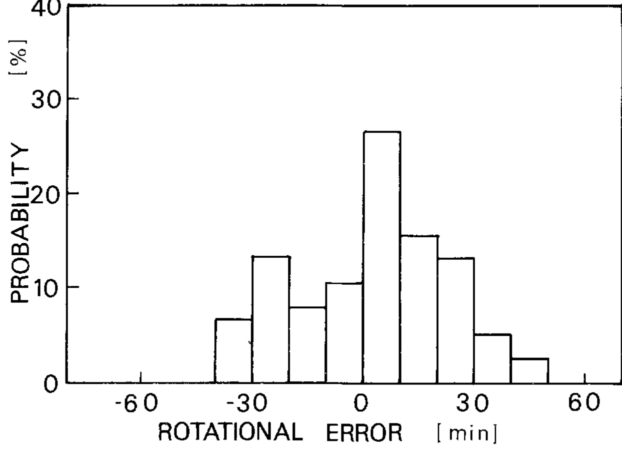

Fig. 3. Wafer setting error (rotation)

include that of wafer to cassette and that of cassette to column. They are fundamentally gaussian distribution. From the data, the auto-registration system correction range was designed to shift ±150 μm and rotate ±2.5° at maximum. Field size is adjustable ±2%. Any correction is accomplished by 12 bit multiplication DAC in X and Y directions, separately. Resolutions are 0.073 μm in shift, and 0.045 and 0.039 μm at the field corner in rotation and magnification, respectively. Drive amplifier for registration correction has high level response, close to 10 MHz. After registration pattern writing commences, the system can select a data file to expose, and multiple chip fabrication is possible aiming at small volume but quick fabrication.

Patterns are exposed in serpentine, rectangular, or raster format with pattern generation providing several primitive shapes such as rectangles, parallelograms, and triangles. Proximity correction has not been included, because of the relatively large design rule employed.

Writing Method and Hysteresis

To minimize the settling time, jumping distance from one pattern to another is restricted through subfield sorting (7). For this method, a basketweave shift between subfields is the best (8). However, it causes a hysteresis error at the connection point of each subfield stripe. This error comes from magnetization of stage parts in the column by leakage field.

This problem is partially alleviated by shielding with Permalloy, as shown by the dotted line in Fig. 4. However, a system aiming at a large field, like the present one, cannot escape from the error completely. Stripe raster shift should be adopted. Using this method, the error is completely eliminated. A drawback is that longer settling time (typically 20 times the subfield jump time) is needed when the subfield is shifted from one corner to the other of a stripe. It is, however, only 10 msec (field jump settling time) × 20

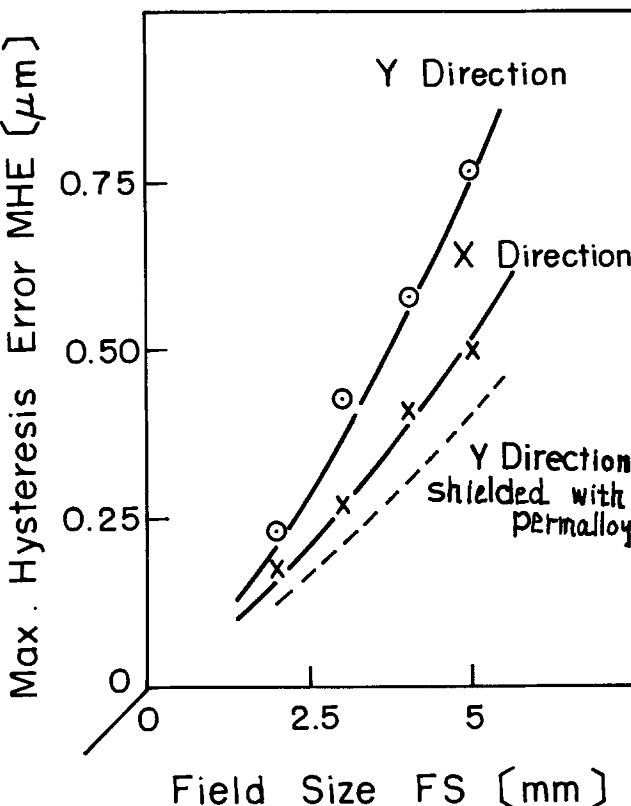

Fig. 4. Maximum hysteresis error as a function of field size

(number of stripes), making 200 msec. There is no problem compared with writing time, typically 3 min/chip for 64 k ROM.

Pattern Data Preparation

The pattern data are first created in an interactive computer aided design (CAD) system, and are output in PG-3000 format. The shapes are sorted to minimize long jumps between shapes using a large computer system (ACOS-700).

Consequently, pattern writing time will contain minimum overhead necessary for settling the deflection system. This is achieved by first sorting the chip data into subfields through which the writing will progress in a stripe raster fashion.

The typical size of a subfield is 1/20 of the field size. Within a subfield, the shapes are connected to compact the data. The resulting set of sorted records is then translated into code in the format required by the modified E-beam machine. Typical CPU time to treat 100 k data is about 10 min.

Resist Process

A key to this work is the resist system, which must provide high durability against reactive sputter etching and adequate sensitivity. Commercial availability of resists might be another important factor in order to make the fabrication process reliable. AZ-2400[3] was chosen as a positive electron resist (9) and NER-1 was chosen as a negative electron resist. The former is a well-known photoresist. The latter is made from narrow molecular weight dispersion polystyrene, which is easily available as molecular weight standard synthesized by living polymerization. Selection of negative resist molecular weight is important. The higher the molecular weight is, the greater the severity of the swelling problem and the "kissing" problem between lines, while soaking in the developer. A 4:1 tetrahydrofuran-ethanol mixture was selected as a low swelling developer. However, the smaller the molecular weight, the stronger the tensile stress and the more

[3] Shipley Company, Newton, MA.

Table I. Direct writing resist characteristics

RESIST	NER-1(polystyrene)			AZ-2400
TYPE	NEGATIVE			POSITIVE

ETCH RATIO (MATERIAL/RESIST)	4.3	2.1	6.5	2.8
TYPICAL PATTERN	1 μm			SiO_2 Az 2.5 μm

severe the distortion in the L-shaped pattern results. This is due to the polymer cross-linking by exposure and concomitant volume shrinkage.

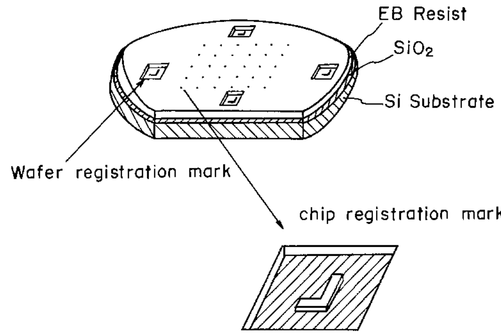
Relatively large 600 k molecular weight was chosen to optimize swelling and shrinking problems. It is called NER-1. Table I shows a summary of characteristics for both resists.

Linewidth Control and Registration Mark

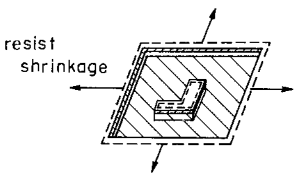
All EB direct writing process is practically usable when the device patterns are directly etched by EB resist mask; without metal mask transfer step the registration mark is compatible with the process. Delineation accuracy values, when using SiO_2, Si_3N_4, poly-Si, and Al are ±0.15, ±0.15, ±0.15, and −0.25 ± 0.15 μm, respectively. It is achieved by using reactive sputter etching (10) and highly durable EB resist against dry etching mentioned above.

For accurate registration, it is desirable to fabricate registration marks using electron beam exposure. The registration marks used in this work are 0.8 μm high silicon pedestals, which are completely compatible with the silicon process. The fabrication process is illustrated in Fig. 5. There are several advantages to the process: (*i*) There is no foreign material like refractory metal, CVD poly-Si, etc.; (*ii*) the resist area for the registration mark is small and resist deformation caused by dry etching does not affect pattern accuracy.

1. Electron Beam Exposure and Development



2. Dry Etching of SiO_2 and Si



3. Remove resist and wash out SiO_2

Fig. 5. Si pedestal registration mark fabrication process with EB resist mask and dry etching.

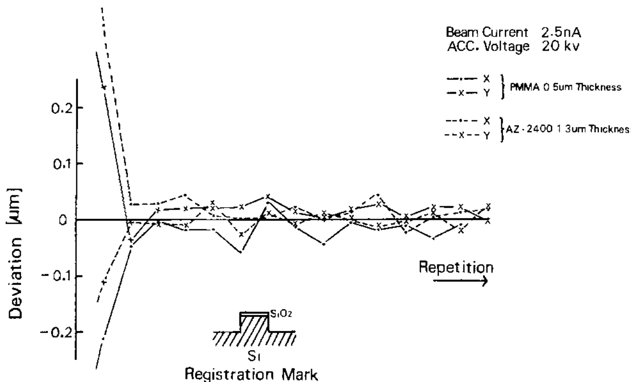


Fig. 6. Deviation in detected position from desired position

The larger the continuous resist area, the more critical the pattern deformation or positional shift. (*iii*) Device area; cleanliness is protected by the SiO_2 during the process. The SiO_2 is etched away after the process. Figure 6 shows the X direction and Y direction detection accuracy for the registration mark coated by different thickness resists. There is no notable difference between them. After two scans, the detection accuracy is better than 0.1 μm. Though the reason for relatively large error in the first scan is not clear, it could be because of resist deformation by the first beam scan. It is desirable to practice dummy scanning before the detection. Figure 7 shows an example of the two layer registration accuracy for the 5 mm field. Since the system has field distortion, the registration condition shown by the arrows is slightly different for different positions. They are, however, within ±0.1 μm.

1	-112.8	93.4	-12.9
2	27.6	-112.9	-25.2

Fig. 7. 5 mm field overlay accuracy

Direct Writing Process and the Function of the Fabricated Device

The direct writing process is fundamentally an n-channel polysilicon MOS process. Figure 8 shows key steps in the etching process. Table II shows exposure and doping processes. After registration mark patterning, device areas were isolated by boron diffusion in the field and by the local oxidation of silicon (LOCOS). Threshold voltages for driver enhancement transistor and load depletion transistor are adjusted by boron ion and arsenic ion implantations, respectively. Gate insulator thickness was 400Å; 5000Å CVD polysilicon was used as gate metallization. The polysilicon was covered by 1600Å CVD Si_3N_4. Arsenic ions were implanted to form the self-aligned source and drain. Wafers were annealed at 1000°C in a steam atmosphere to form the sidewall insulator of the polysilicon gate and thick silicon dioxide on the source and drain by heavily doped arsenic enhancing oxidation. After Si_3N_4 removal, phosphorous was thermally diffused into the polysilicon. Double layers of phosphorous silicate glass and CVD SiO_2 were used as an insulator. PSG made it possible to topographically smooth the device surface, preventing discontinuing the Al metallization and thin SiO_2 eliminated the wetting and poor resist adhesion problems of PSG. Contact holes were etched into the double layer to write ROM information. Phosphorous-doped polysilicon 0.2 μm thick and 1.2 μm Al

were continuously deposited and etched as interconnectors. Annealings to remove the irradiation damage were carried out in H_2 atmosphere at 450°C.

Figure 9 shows an overall view of the fabricated 64 k ROM and enlarged views. The 2.5 μm contact hole is centered in 3 μm width Al metallization. It is clear that the registration mark is kept well through the fabrication processes. Details are discussed in the following section.

Figure 10 shows a function of the device fabricated by all E-beam direct writing. As can be seen, the rise-time for the fall time of the signal are unbalanced. It was, however, assumed that the input and output buffer is not optimized, although high reduction (4/10) has been accomplished. The same design rule device, fabricated by photolithographic process (DSW), has shown very similar results (11).

Overlay Accuracy

Table III shows an example of overlay accuracy through the process. The Vernier method was adopted to measure the accuracy. On the table, for example, GR-load shows overlay accuracy for load I/I pattern on the guard ring pattern.

The overlayed pattern always has little X and Y shift and distribution. The shift error origin is not clear, but the registration mark structure change caused by unbalanced resist or material coating of the mark are considered reasons. Similar phenomena are often discussed on Al metallization coverage.

Table III. Overlay accuracy through the all EB direct writing process

	X [μm]		Y [μm]	
	$\bar{X}$	σ	$\bar{Y}$	σ
GR-Load	-0.02	0.13	-0.05	0.13
GR-D.Contact	0.12	0.03	-0.04	0.12
GR-Gate	0.13	0.06	0.07	0.12
Gate-Contact	0.08	0.08	0.02	0.03
Contact-Al	0.07	0.07	0.09	0.06

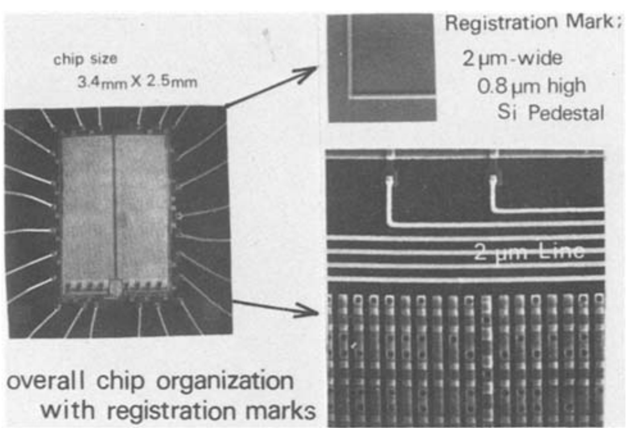

Fig. 9. Overall and magnified view of 64 k ROM

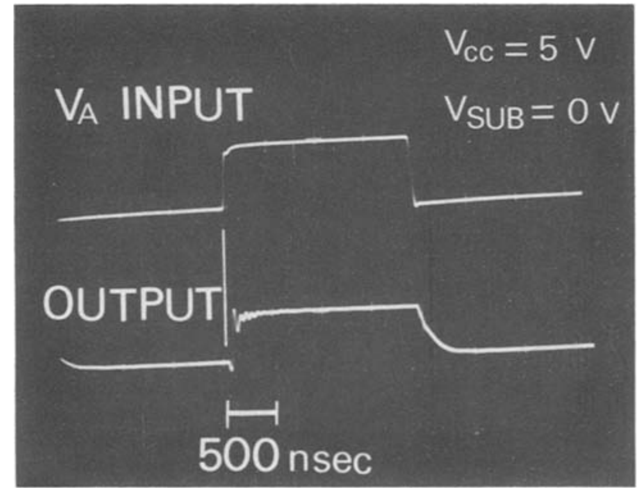

Fig. 10. An example of output waveform

Even considering shift and distribution, the results shows that the system well satisfied the required ±0.25 μm overlay accuracy, using registration mark damaged by various coating and etching processes.

Conclusion

The systems described here are a fundamentally modified SEM machine, not those machines which could be fabricated only by a huge company laboratory. The systems are easily modified to research fundamental electron optics and new strategy to write pattern, such as double deflection correction, hysteresis, and stripe scanning. It has, however, enough capability to fabricate LSI such as 64 k ROM by all direct writing process. The beam is focused into a small diameter area, less than 500Å.

The system could be used for quick fabrication of a wide variety of devices, like bubble memories, Josephson circuits, GaAs FET, etc. It is also used for new resist evaluation, research in physics related to electron beam damage, electron scattering, and delineation limitation.

ABSTRACT

X-ray lithography has been applied to fabricate n-MOS devices such as transistor matrixes, ring oscillators, and MOS capacitors. A propagation delay time as low as 200 psec/gate, and about 0.12 pJ power-delay product were obtained from the ring oscillator with 0.7 μm effective gate length. From the threshold voltage measurements of the transistor matrixes, it was found that the standard threshold voltage deviation in MOSFET's with 1.5 μm effective gate length in a chip and the deviation in a wafer were as low as 5 and 7 mV, respectively.

X-ray lithography has been expected to be useful as a fine pattern replicating technique, because of its high resolution and productivity. Recently, a high power x-ray lithographic system using a water-cooled rotating Si anode for x-ray source and a beam vibration method for mask alignment has been developed and its performance was demonstrated (1, 2). An SiN/SiO_2/SiN sandwich structure membrane mask (3) has also been developed and was applied to fabricate poly-Si gates in ring oscillators (2).

In this experiment, MOS devices have been fabricated using the above-mentioned x-ray lithographic system for four mask levels. The present paper describes the x-ray lithography process followed by dry etching, and also the device characteristics.

X-Ray Lithography Process

The IC chips which have been fabricated in this experiment contain transistor matrixes, ring oscillators, and MOS capacitors. Of the five lithographic steps, local oxidation of silicon (LOCOS) (4), gate, contact hole, and metallization were processed by x-ray lithography. Only the channel doping step was processed by photolithography. In order to examine the x-ray exposure influences on the devices, a few wafers in the lot were processed by photolithography through all lithographic processes.

A water-cooled rotating Si anode x-ray source was operated at 20 kW (20 kV, 1A) electron beam input power, which generates about 6×10^{-5} W/Sr SiKα x-ray radiation.

Key words: fine pattern, x-ray mask, dry etching, transistor matrixes.

X-ray masks (3) consisting of an SiN (0.2 μm)/SiO_2 (1.0 μm)/SiN (0.2 μm) sandwich structure were prepared by CVD for SiN and by rf-sputtering for SiO_2, respectively. The membranes have as high as 85% transparency for both the SiKα line and visible light. X-ray absorber patterns, consisting of a 0.8 μm thick gold, were fabricated by a double lift-off method (5), in which 1.2 μm thick polyimide spacer patterns are used for gold plating masks.

Details of the x-ray lithographic levels are shown in Table I. In three mask levels, *i.e.*, LOCOS, gate, and metallization, negative resist SEL-N[1] has been used. Figure 1 shows a scanning electron micrograph of 2 μm gate patterns exposed in a 0.8 μm thick SEL-N. The SEL-N patterns show trapezoidal cross sections. This is caused by the swelling of SEL-N patterns in a developer followed by shrinking in rinsing solution and postbaking process. The swelling magnitude changes,

[1] SEL-N is produced by Somar Industy Corporation, in Japan.

Table I. X-ray lithographic levels

Level	Film	Resist	Etching method	Gas	Etch rate ratio (film/resist)
LOCOS	SiO_2	SEL-N (0.7 μm)	Wet etching	—	—
Gate	Poly-Si (0.4 μm)	SEL-N (1.0 μm)	Reactive sputter etching	$CBrF_3$	3.5
Contact	PSG (0.8 μm)	FBM (1.0 μm)	Reactive sputter etching	C_2F_6	1.3
Metallization	Al (0.8 μm)	SEL-N (1.5 μm)	Plasma etching	CCl_4	1.0

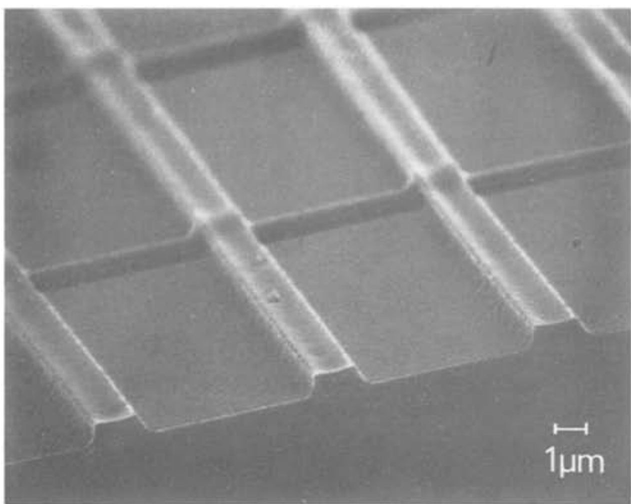

Fig. 1. Scanning electron micrograph of 2 μm gate patterns exposed in a 0.8 μm thick SEL-N.

depending on the resist volume, and also on the kind of developer. In this experiment, methyl alcohol was used for developer, which resulted in rather small swelling. However, in contact hole level, negative resists, including SEL-N, are hard to use because of the large resist-covered area that leads to conspicuous swelling (narrowing or plugging up of the contact holes). In this level, therefore, a positive resist poly hexafluorobutyl metacryrate (FBM) (6) was used, which showed little swelling in the developer. A scanning electron micrograph of 4 μm wide contact holes, exposed in a 1.3 μm thick FBM, is shown in Fig. 2. FBM contact holes preserved squarish shoulders, and the side walls were inclined from the surface at 75 degrees.

Dry etching has been employed for constructing gates, contact holes, and wiring. The etching method after each lithographic step is presented in Table I with gases used, and film to resist etch rate ratio. A scanning electron micrograph of 2 μm poly-Si gates etched by reactive sputter etching (7) is shown in Fig. 3. Side walls of the poly-Si gates show 45° ~ 50° tilts, which reflect SEL-N pattern profile used for etching mask. Figure 4 is an SEM photograph, which indicates good step coverage of the poly-Si gate at the 0.5 μm guard ring projection.

Figure 5 shows the appearance of aluminum metallization in the transistor matrix after plasma etching. Although the etch resistance of SEL-N against plasma etching using CCl_4 is the same as that of aluminum, a considerably thick (~1.5 μm) SEL-N resist layer is required for x-ray exposure of the metallization level, because the decrease in the resist thickness at the shoulder of contact holes is significant. In this case, 0.8 μm thick, 3 μm wide, 2 μm gap aluminum metallization is successfully fabricated, as shown in Fig. 5.

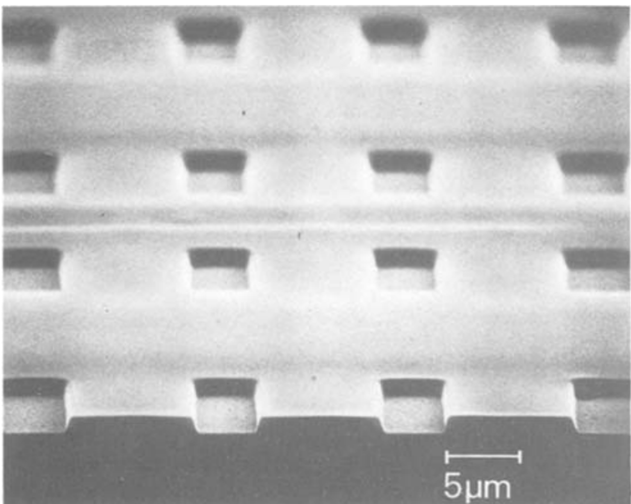

Fig. 2. Scanning electron micrograph of 4 μm wide contact holes exposed in a 1.3 μm thick FBM.

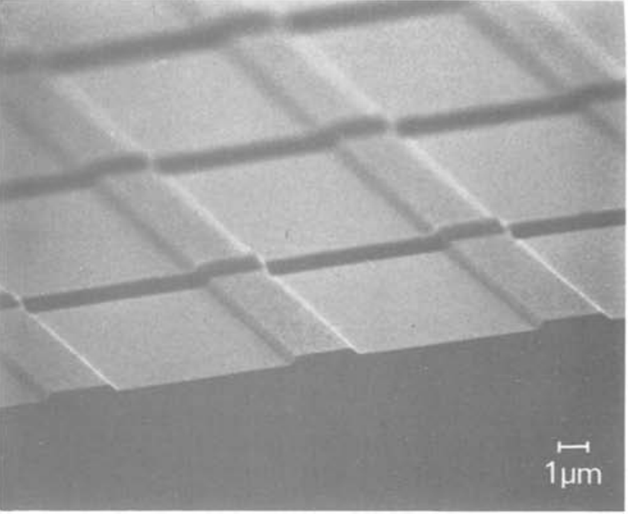

Fig. 3. Reactive sputter etched 2 μm poly-Si gates

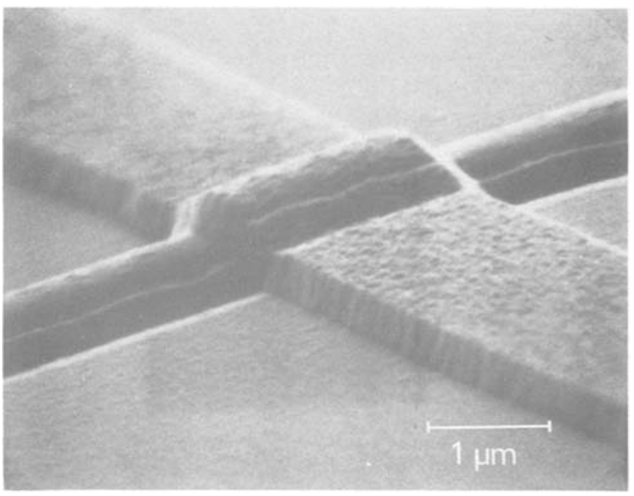

Fig. 4. Scanning electron micrograph showing good step coverage at the 0.5 μm step.

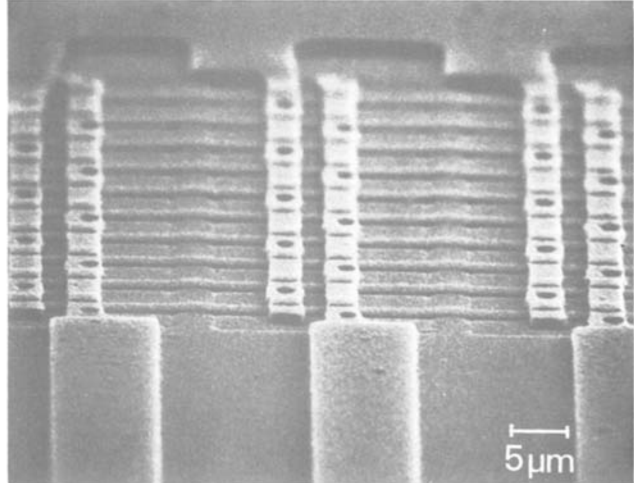

Fig. 5. 3 μm wide aluminum metallization in a transistor matrix

The x-ray masks were aligned to the wafer using the beam vibrating method (1, 8). The alignment marks on the wafer were made by preferential etching using hydrazine solution. It was found that the S/N of this mark was not changed through the five lithographic processes. Therefore, the same mark was used for all lithographic processes without any protection. The total alignment error by the above-mentioned method was found to be less than 0.3 μm (2σ) in a 2 in. diam wafer, from measurements using vernier patterns which were made in each lithographic process.

Device Characteristics

An example of the threshhold voltage (V_{th}) distribution for transistor matrixes with 1.5 μm effective gate length is shown in Fig. 6. The upper numeral in each of the sixteen squares shows V_{th}, the average values of the V_{th} of 120 FET's in the transistor matrix. The lower numeral shows σ_o, the standard deviation in the V_{th}. The average value of σ_o, over all chips in the wafer, represented by $\bar{\sigma}_o$, is 5.0 mV. The standard V_{th} deviation in the wafer, σ_1 is 6.7 mV. Other wafers show a similar tendency. These results show highly uniform characteristics in devices made by x-ray lithography followed by dry etching.

Figure 7 is a photomicrograph of the ring oscillator fabricated by x-ray lithography. The ring oscillator is a 31-stage E/D mode unit with a fan-in and fan-out ratio of 1. Effective channel length is 0.7 μm in the driver transistors, and 2.3 μm in load transistors.

The output waveform for the ring oscillator at V_{dd} = 5V is shown in Fig. 8. The oscillation period is 12.5 nsec, which corresponds to 202 psec/gate propagation delay time. The power-delay product is about 0.12 pJ/gate.

The C-V curve for the MOS capacitor, fabricated using x-ray lithography for four mask levels and that by using photolithography for all mask levels, is shown in Fig. 9. Both MOS capacitors have the same design, and have been made in the same lot, except for the lithographic processes. There was no special annealing process after the x-ray lithographic process. Figure 9 shows that there is no x-ray radiation-induced damage in the MOS capacitor, when every standard process is over. It is reported, however, that the C-V curves from MOS capacitor irradiated by AlKα (8.3Å) shift from the original state (9-11). It is considered that, in the present experiment, radiation-induced damage was annealed out at the high temperature processes, such as impurity diffusion, oxidization, and CVD.

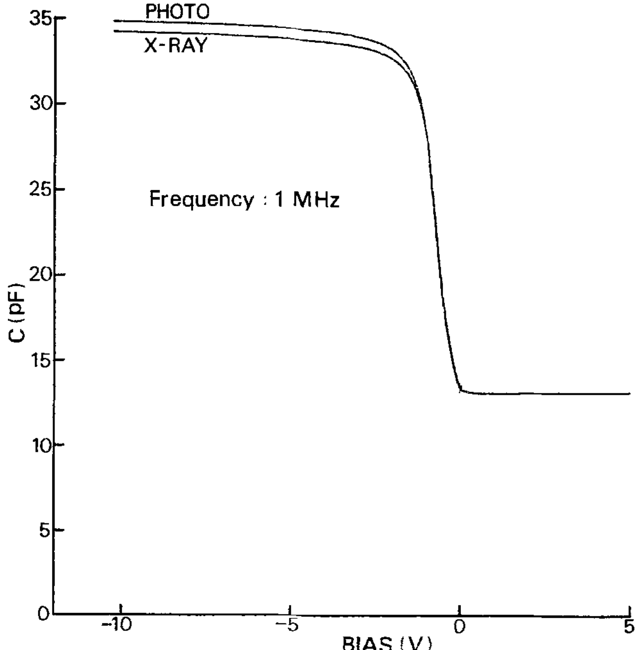

Fig. 9. C-V curve for MOS capacitor fabricated by x-ray lithography and that by photolithography.

Conclusions

MOS devices, such as transistor matrixes with 1.5 μm effective channel length, ring oscillators with 0.7 μm effective channel length, and capacitors for C-V

measurements, have been fabricated using x-ray lithography, including automatic mask alignment.

Results obtained from the present study are as follows.

1. High contrast x-ray masks with 0.8 μm thick gold patterns have been prepared on $SiN/SiO_2/SiN$ membrane by double lift-off method.

2. Alignment marks made by preferential etching work well through all mask processes without any protection.

3. High registration accuracies, better than ±0.3 μm (2σ) on 2 in. wafers, were realized.

4. Dry etching is successfully applied to fabricate poly-Si gates, PSG contact holes, and aluminum metallizations.

5. Standard deviation in V_{th} as low as 5 mV in a chip, about 6.7 mV in a wafer, was realized.

6. Propagation delay time reaching 202 psec/gate, and the power-delay product of 0.12 pJ/gate were obtained from the ring oscillator.

7. No x-ray exposure damage in devices has been observed from the C-V measurements, without any special annealing after the x-ray lithography processes.

Acknowledgment

The authors wish to thank Drs. S. Asanabe, D. Shinoda, and H. Muta of Basic Technology Research Laboratory, Nippon Electric Company, Limited, and Drs. S. Yamazaki and S. Nakayama of Musashino Electric Communication Laboratory, N.T.T. for their discussions and encouragement. The members of Polymer Section of Electric Communication Laboratory, N.T.T. are also thanked for the supply of FBM resists.

Manuscript submitted Feb. 10, 1981; revised manuscript received April 17, 1981.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.

Publication costs of this article were assisted by Nippon Electric Company, Limited.

Measurement of the Diffusion Coefficient of Gallium in Molten Germanium

E. D. Bourret,[1] J. J. Favier, and O. Bourrel

Laboratoire d'Etude de la Solidification, Centre d'Etudes Nucleaires de Grenoble, 85X, 38041 Grenoble Cedex, France

ABSTRACT

The diffusion coefficient of ^{72}Ga in molten germanium has been measured at $T = 1219$ K using the shear-cell technique. The concentration profile was obtained from the intensity of the γ-emission detected in the range 0.740-0.900 MeV. The diffusion coefficient was found to be 2.1×10^{-8} m^{2}sec^{-1} at this temperature.

The accurate determination of diffusion coefficients of solute in the liquid phase (D_L) is becoming more and more important for the understanding of solidification in metallurgical processes as well as in crystal growth. Up to now, very few measurements of these coefficients have been made (1). In the germanium-gallium system, the lack of data for D_L has been pointed out by different authors (2, 3). In order to relate the diffusion phenomenon to the segregation during solidification, an accurate value of the diffusion coefficient near the solidus temperature is badly needed. This is of prime importance for determining the type of mass transport which took place during the growth of Ge-Ga crystal in a microgravity environment (2, 4). This paper reports the measurements of D_L at 1219 K.

The melting point of pure germanium is $T_m = 1210.4$ K.

Experimental Procedure

Measurements were made using the shear-cell technique developed by Potard *et al.* (5). The shear-cell consists of several graphite disks mounted coaxially in which three off-center holes (1.5 mm diam) are drilled to form three capillaries when they are aligned. As shown in Fig. 1, solvent and solvent + solute metals were kept separate until an experiment was begun by aligning the upper and the lower capillaries in a vertical position. After diffusion, the disks were rotated so that the liquid columns were sheared. This last rotation of the disks avoids subsequent change of concentration due to solidification; thus there was no need for quenching the samples. Upper capillaries were filled with pure germanium and lower capillaries contained the dilute alloy germanium-gallium. Diffusion occurs from bottom to top for preventing additional

Key words: shear-cell technique, gallium, diffusion.

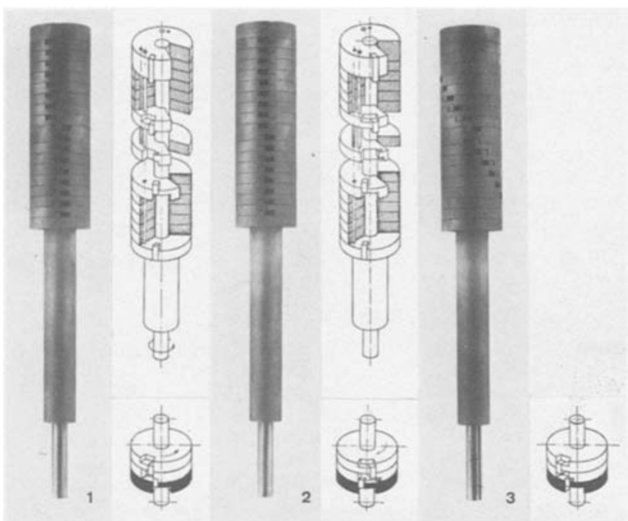

Fig. 1. The shear-cell: 1, filling; 2, diffusion; 3, shearing

effects due to segregation of gallium. Densities of gallium and germanium are, respectively, 5.91 and 5.32 g/cm^3. In order to obtain a direct and precise concentration measurement of the samples, ^{72}Ga was used as a radioactive tracer. Under irradiation by thermal neutrons, gallium of normal isotopic composition, which contains 39.8% of ^{71}Ga, produces ^{72}Ga. ^{72}Ga emits β^- particles with a maximum energy of 2.54 MeV, followed by γ-emission with a maximum energy (96%) of 0.835 MeV. One gram of gallium was irradiated for 700 sec under a neutron flux of 1.6×10^{19} nm^{-3} sec^{-1}.

The active gallium was then melted with pure germanium to obtain a Ge-Ga alloy containing about 600 ppm of Ga.

Diffusion occurs at 1219 K, a "stabilizing" gradient of 100 K m^{-1} being maintained between the bottom and the top of the cell to reduce convection.

Results

A practical diffusion time was determined from theoretical considerations to be 20 min. A preliminary experiment, using nonactive gallium, confirmed that this time was correct. The gallium was found to diffuse over 4 disks. Concentration measurements which were made, in this case, by x-ray fluorescence cannot be used to evaluate the diffusion coefficient since, due to the small size of the samples, the surface of integration is very small and induces large experimental errors. In the shear-cell configuration, the boundary value problem is that of diffusion between a pair of semi-infinite solids. A solution of Fick's second law $\left(\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2}\right)$, with the boundary conditions $C = C_0$ at $x > 0$ at $t = 0$ and $C = 0$ at $x < 0$ at $t = 0$ is given by

$$C(x,t) = \frac{C_0}{2}\left(1 + \text{erf}\,\frac{x}{2\sqrt{Dt}}\right)$$

Knowing x, t, and $C(x,t)$, D is given by

$$D = \frac{1}{4b^2t}$$

b being the slope of

$$\text{erf}^{-1}\left(\frac{2C}{C_0} - 1\right) = \frac{x}{2\sqrt{Dt}}$$

The gallium concentration is proportional to the intensity of the γ-rays emitted with an energy in the range 0.740-0.900 MeV. Each measurement was corrected to account for the weight of the sample and the intensity of the ^{72}Ga peak as a function of time ($t_{0.5}$ = 51,000 sec for ^{72}Ga). If the intensity of the source at t is I_t, then at $t + \Delta t$, it will be

$$I_{t+\Delta t} = I_t \exp(-\lambda \Delta t) \quad [1]$$

λ being the disintegration constant, $\lambda = 0.693/t_{0.5}$. The mean intensity during Δt is

$$\overline{I} = I_t \frac{1}{\Delta t}\int_0^{\Delta t} \exp(-\lambda t)\,dt \quad [2]$$

and then

$$I_t = \overline{I}\,\frac{0.693\,\Delta t/t_{0.5}}{1 - \exp(-0.693\,\Delta t/t_{0.5})} \quad [3]$$

The intensity represents the accumulated counts per time units. Every measurement is corrected using a reference time; in this case, the reference time is $t = 0$ at the beginning of the countings.

Another correction is made to account for the dead time of the detector. To account for the dead time, an apparent half-life is determined using the decreasing curve of the activity of ^{72}Ga ($\log N = -\lambda t$) (Fig. 2). This curve exhibits three different slopes corresponding to three apparent half-lives, as shown in Table I. The apparent half-lives are used to calculate the intensity of accumulated counts per time unit (Eq. [3]). The concept of apparent half-lives is used because the correlation (Table I) with straight lines is good enough so that specific corrections for each count rate according to Fig. 2 are not necessary and the corrective calculations are then simplified. Finally, the diffusion coefficient obtained from the measurements reported in Fig. 3 is $D_L = 2.1 \times 10^{-8}$ m^{2}sec^{-1} at $T = 1219$ K. The coefficient of determination for the straight line is 0.999.

In earlier studies, Schmidt and Verhoeven (6) measured this diffusion coefficient at $T = 1303$ K. The method used was the capillary-reservoir technique and led to the value of 2.4×10^{-8} m^{2}sec^{-1}.

Considering an activation energy of 0.32 eV given by Kodera (3), this value, corrected to 1219 K, becomes 2.0×10^{-8} m^{2}sec^{-1}, which is in good agreement with our direct measurements at this temperature.

The shear-cell technique is a very appropriate one for direct measurement of the interdiffusion coefficient in the vicinity of the liquidus temperature (less than 10 K above) and should be used before investigating

A Mathematical Assessment of Chemical Diffusion Measurements in Transition Metal Oxides

François Morin*

Institut de Recherche d'Hydro-Québec, Varennes, Québec, Canada J0L 2P0

ABSTRACT

The relaxation method lends itself to the measurement of chemical diffusion coefficients in transition metal compounds. By means of various mathematical calculations, it is shown that the significance of experimental results can be greatly improved. A better insight into the interrelations between physical parameters like nonstoichiometry, defect mobility, and electrical conductivity should be gained by proper consideration of various experimental parameters. The effects of many parameters such as slow surface reaction, large departure from stoichiometry, and varying defect mobility, are reviewed. The electrical conductivity is perfectly equivalent to weight measurements when properly applied to relaxation experiments. Moreover, in some cases, it may contain some specific information regarding the interrelation between electronic and ionic defects.

Chemical diffusion in transition metal compounds is a common phenomenon. It has already been associated with various important physical processes like oxide growth and sintering of ceramics. There is also a renewal of interest in the search for new battery electrode materials. Various formalisms have already been developed in order to describe the basic mechanisms involved in the course of chemical diffusion (1-7), most of them largely based on C. Wagner's transport theory. Besides, most of our point defect theory originates from Wagner and Schottky (8). Wagner *et al.* also applied the simple mass action law to point defects for several oxides (9-11). This last approach was considerably developed and also described with a convenient notation by Kröger and Vink (12-13). There are a few widely accepted examples, like CoO and Cu_2O, where the diffusion and the point defect theories merge in a simple manner (14). Such a simple picture is also commonly transferred to other compounds.

Several controversial arguments were set forth in the recent years, regarding either coulombic interactions (15) or the prevalent existence of clustered de-

* Electrochemical Society Active Member.

Key words: defects, dielectrics, diffusion, kinetics.

fects (16-17) and nonrandom walk diffusion (18). In view of those complex considerations, the usual treatment of experimental data looks rather crude. Any comparison of experimental data with a more sophisticated theory would be faced with a crucial problem regarding the actual precision of those data. Thus, experimental diffusion phenomena would require a degree of accuracy that is neither intrinsically available for certain types of experiments nor has been completely evaluated in a peculiar experimental method.

The relaxation method might be one of the most suitable means for studying chemical diffusion with both a high precision and a simple procedure. The compound is first equilibrated with the outer atmosphere, whether pure oxygen or an oxidizing-reducing mixture. The compound must thus possess a nonnegligible electronic conductivity. The chemical activity of that atmosphere is suddenly changed from its original value to a different one and the evolution of the defect within the compound is normally recorded as a variation in weight or electrical conductivity *vs.* time. Dünwald and Wagner (19) also formulated the analytical solutions for various sample shapes such as plates, cylinders, and spheres. An equivalent solution has been described by Newman for brick-shaped samples (20). A few comprehensive reviews on the subject are available (21-23). The precision commonly reached with the relaxation method might suffice normally if the aim were simply to verify a largely accepted diffusion mechanism coupled with a very simple defect model. However, if one wants to make full use of this method, further consideration must be given to the various sources of error. Certain criteria have already been suggested by J. B. Wagner *et al.* (21, 23, 24) such as the equivalence between oxidation and reduction runs, the effect of gradated sample sizes or diluted atmospheres for nonnegligible surface reactions, and also some preference for thermogravimetry instead of electrical conductivity. Such criteria deserve a complete mathematical analysis of all experimental parameters as has already been described (25). The basic simplicity of relaxation experiments is not an impairment of the significance of their results. Analysis of the relaxation method is considerably refined and more completely described here.

The Relaxation Technique and Its Analytical Solution

The chemical diffusion coefficient $\tilde{D}$ is unequivocally defined by Fick's first law

$$j_i = -\tilde{D} \cdot \frac{\partial c_i}{\partial x} \quad [1]$$

where c_i is the concentration of the chemical species, but can also sometimes be considered as a point defect concentration, and j_i is the flux of the same species. In the case of a transient concentration state, the preceding equation becomes, according to the mass conservation law

$$\frac{\partial c_i}{\partial t} = \frac{\partial}{\partial x}\left(\tilde{D} \cdot \frac{\partial c_i}{\partial x}\right) \quad [2]$$

which is equivalent to Fick's second law of diffusion. If $\tilde{D}$ is concentration independent, Eq. [2] then reads

$$\frac{\partial c_i}{\partial t} = \tilde{D} \cdot \frac{\partial^2 c_i}{\partial x^2} \quad [3]$$

The following set of time and boundary conditions fully describes the normally expected conditions for relaxation experiments

$$c_i(x, 0) = c_o \quad \text{at} \quad t = 0$$
$$c_i(0, t) = c_f \quad \text{at} \quad t > 0$$

where c_o is the initial equilibrium concentration within the sample, c_f is the final equilibrium concentration, and x is the length along the diffusion axis. Equation [3] can be extended to a three-dimensional case. According to Newman (20), the concentration c_i in a prism with overall dimensions equal to $2a_1$, $2a_2$, and $2a_3$ is expressed by the following relation

$$c_i(X, T) = c_o \cdot f(X_1, T_1) \cdot f(X_2, T_2) \cdot f(X_3, T_3) \quad [4]$$

where

$$f(X, T) = \frac{2}{\pi} \sum_0^\infty \frac{(-1)^n}{n + ½} \cdot \exp\{-T(n + ½)^2\pi^2\} \cdot \cos\{(n + ½)\pi \cdot X\}$$

$$T = \frac{\tilde{D}t}{a^2}$$

$$X = x/a$$

The reduced coordinate X varies from zero to one while T varies from zero to infinity. The average concentration $\bar{c}$ is a more readily accessible parameter than the local concentration $c_i(X, T)$ so that

$$\bar{c} = c_f - (c_f - c_o) \int_0^1 \int_0^1 \int_0^1 f(X_1, T_1) \cdot f(X_2, T_2) \cdot f(X_3, T_3) \cdot dX_1 \cdot dX_2 \cdot dX_3 \quad [5]$$

Again, $\bar{c}$ can be transformed to a dimensionless parameter

$$c_r = (c_f - \bar{c})/(c_f - c_o) \quad [6]$$

By introducing Eq. [6] into Eq. [5] and integrating

$$c_r = g(T_1) \cdot g(T_2) \cdot g(T_3) \quad [7]$$

where

$$g(T) = \frac{2}{\pi^2} \sum_0^\infty \frac{1}{(n + ½)^2} \cdot \exp\{-T \cdot (n + ½)^2 \cdot \pi^2\}$$

For equilibration runs, c_r is usually interpreted in terms of weight or electrical conductivity variation *vs.* time. Therefore, both a relative weight W_r and a relative electrical conductivity have to be defined

$$\sigma_r = (\sigma_f - \bar{\sigma})/(\sigma_f - \sigma_o) \quad [8]$$

$$W_r = (W_f - W)/(W_f - W_o) \quad [9]$$

In most cases, W_r can be shown to be strictly equivalent to c_r. But σ_r is identical to c_r only when a linear relationship between σ and c_i is obeyed and when the average conductivity is measured perpendicular to the diffusion axis. Any approximation of Eq. [7] or any actual departure from the ideal case should be assessed in comparison with that solution. A correction parameter, $\Delta\tilde{D}/\tilde{D}$ is accordingly defined

$$(\Delta\tilde{D}/\tilde{D}) = (\tilde{D}_{true} - \tilde{D}_{apparent})/\tilde{D}_{apparent} \quad [10]$$

so that

$$\tilde{D}_{true} = \tilde{D}_{apparent}\,[1 + (\Delta\tilde{D}/\tilde{D})]$$

The significance of $\tilde{D}_{true}$ and $\tilde{D}_{apparent}$ is two-fold. First, if all conditions are fulfilled for the exact application of Eq. [7], $\tilde{D}_{true}$ is derived directly from that equation and $\tilde{D}_{apparent}$ comes out from the approximations usually encountered with the same equation. Second, if any departure from the ideal relaxation case occurs, $\tilde{D}_{true}$ is then derived from a more appropriate exact numerical solution. Then, $\tilde{D}_{apparent}$ comes out from the normal analytical equation since that equation is often assumed to still correctly apply to the experimental case.

A Detailed Approach to Various Errors on $\tilde{D}$

There are several potential error sources associated with the relaxation method. The precision of $\tilde{D}$ and, consequently, its physical significance can be enhanced only if those error sources are properly identified and controlled. The most common ones are listed in Table I. Mathematical handling is straightforward for types one and two while numerical integration is required for the third type. It has been found convenient to illustrate each case numerically. Generally speaking, values of $\Delta\tilde{D}/\tilde{D}$ can be extrapolated readily up to about 10%. All errors do not add up necessarily, but the maximum uncertainty criterion may prove to be useful for type two. Not all the error sources mentioned in Table I lend themselves to a global statistical analysis based on the least squares fit. Some of those errors always behave in a systematic manner. Others would vary randomly from one relaxation run to another, but would systematically affect any single experiment. The graphical representation of $\tilde{D}$ *vs.* c_r bears much significance in finding potential error sources and also in evidencing unexpected phenomena. Consequently, a normalized representation of $\Delta\tilde{D}/\tilde{D}$ *vs.* c_r has been developed and is used throughout the present analysis.

Mathematical approximations.—The most common tendency when handling a large number of relaxation data within any single run, is to use a linearized graphical fit of these data and to measure the resulting slope. Equation [7] does not lend itself readily to that operation unless some approximation is made. In fact, the summation represented by $g(T)$ rapidly reduces to its first term as c_r tends toward zero. Hence, a linear relationship between ln c_r and T should work properly at low c_r values (19-21) and it also corresponds to the common practice. For the three-dimensional case

$$\tilde{D}t = \frac{\ln(512/\pi^6) - \ln(c_r)}{\frac{\pi^2}{4}\left(\frac{1}{a_1^2} + \frac{1}{a_2^2} + \frac{1}{a_3^2}\right)} \quad [11]$$

Analogous relationships can also be easily deduced for one- and two-dimensional processes. By comparing such equations with the reference analytical equation, one gets the results shown in Fig. 1. One-, two-, and three-dimensional approximations, such as in Eq. [11], are illustrated by means of specific examples. All corresponding curves were identified with their respective dimensional ratios. The worst approximation usually pertains to the three-dimensional equation. Under certain unfavorable geometrical conditions, Eq. [11] would even lose all of its original sense.

Another common approximation consists of neglecting either one or two diffusion axis out of the three possible ones. This is illustrated in Fig. 2. Equation [7] has been successively applied to the full and to the approximated sample geometries. The last figure appearing in any one ratio, corresponds actually to the neglected dimension. In contradistinction with Fig. 1, the correction factor $\Delta\tilde{D}/\tilde{D}$ never completely disappears. Only for the most favorable cases does it remain within acceptable limits.

Table I. Identification of most common error sources in relaxation experiments

Classification	Description
1. Mathematical approximations	Reduction to a two- or a one-dimensional diffusion process Reduction to a simple logarithmic equation
2. Experimental uncertainties	Uncertainties on c_o, c_t, and $\bar{c}$, respectively Uncertainties on time and dimensions Uncertainties on temperature and partial pressure
3. Nonanalytical conditions	Slow surface reaction Initial gas exchange period Large departure from stoichiometry; moving boundaries Concentration dependent mobility Temperature and pressure fluctuations during reequilibration

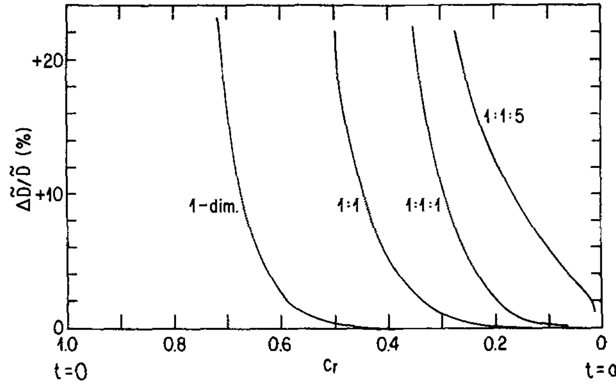

Fig. 1. Validity range for the use of a simple logarithmic relationship between c_r and T. One-, two-, and three-dimensional cases are considered.

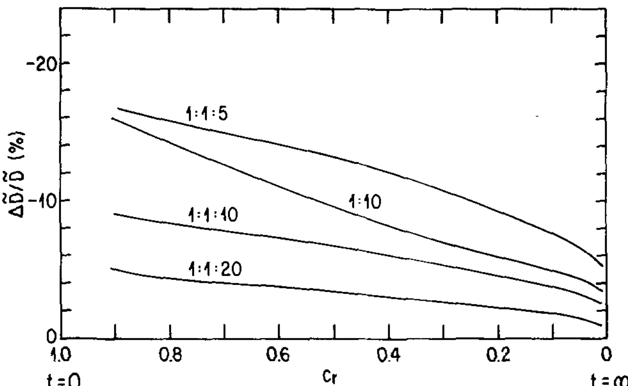

Fig. 2. Application of the full analytical equation, reduced to a two- or a one-dimensional diffusion process. The last figure, for any ratio, corresponds to the specifically neglected sample dimension.

Actual uncertainty on c_r.—Most of the accuracy of $\tilde{D}$ relies on a precise determination of c_r during the reequilibration process. A crude estimate of the uncertainty of $\tilde{D}$, due to c_r, is a mathematical derivation of the reference equation and is shown in Fig. 3, mainly reflecting the mathematical behavior of Eq. [7]. Based on this behavior, it is often believed that the best pre-

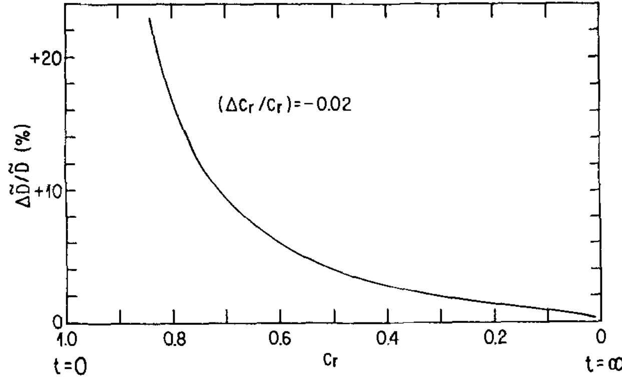

Fig. 3. Effect of the relative uncertainty $\Delta c_r/c_r$ on the correction factor $\Delta\tilde{D}/\tilde{D}$, for a one-dimensional diffusion process.

cision of $\tilde{D}$ might be obtained for the lowest c_r values, *i.e.*, the longest diffusion times. However, the overall uncertainty of c_r is normally not constant due to its definition given by Eq. [6]. In fact, the relative concentration c_r is the combination of three experimentally independent variables: c_o, the initial defect concentration, $\bar{c}$, the evolving average defect concentration and c_f, the final defect concentration. An optimum c_r range for the determination of $\tilde{D}$ becomes evident when those three terms are dealt with separately as in Fig. 4. That range is more or less defined by the flattened portion of those three curves. It should vary somewhat from one experimental case to another but, roughly speaking, it will extend from about $c_r = 0.55$ to $c_r = 0.1$. By averaging within such a region, the precision of $\tilde{D}$ values will be increased.

Other experimental parameters.—In Eq. [7], the uncertainty of T is rather simply estimated more directly by considering $\tilde{D}$, t, and a^2 and adding the uncertainties for those terms together. A high degree of accuracy can be readily achieved on the measurement of time except for the absolute determination of the origin $t = 0$ at the startup of the experiment. Mathematically speaking, that uncertainty is readily calculated. In practice, however, there is some risk that the lack of precision on $t = 0$ be inadvertently used as a fitting parameter for the whole experimental curve. Slow pressure changes are more specifically dealt with later on. The expected uncertainty of $\tilde{D}$ due to sample dimensions is very easily deduced for the simplest cases. For a one-dimensional diffusion process, it is equal to $2(\Delta a/a)$, and equal to $6(\Delta a/a)$ for a perfectly cubic sample. $\Delta a/a$ is the uncertainty on one single dimension. For any intermediate sample geometry, $\Delta\tilde{D}/D$ would stand somewhere between the two former values.

Finally, $\tilde{D}$ is also intrinsically influenced by temperature, and more occasionally, by partial pressure. With a perfect constancy of these two parameters during any single run, the uncertainty of $\tilde{D}$ is limited to the lack of precision on temperature. It is rather insensitive to an exact absolute value of the partial pressure. For example, $\tilde{D}$ varies by about 0.9% for a 1°C variation in CoO at 1000°C. Much greater attention should be paid to the temperature or the partial pressure fluctuations during the course of a single reequilibration experiment; c_r is then appreciably affected through its experimentally fluctuating $\bar{c}$ and c_f components. The surface concentration c_f is instantaneously modified while $\bar{c}$ is influenced more progressively. The true diffusion coefficient is only slightly affected compared to the estimated $\tilde{D}$. That also explains why the usefulness of the experimental data become severely limited at c_r close to zero, *i.e.*, at the largest values of t.

Departure from the analytical solution.—The third type of error, in Table I, is related to the occurrence of nonanalytical experimental conditions. Mathematical solutions for various specific sets of conditions can be developed by means of numerical analysis and, more precisely, with Crank-Nicholson's method (26). Little would normally be added to our present aims by dealing with two and three diffusion axes. Emphasis is placed on the one-dimensional process. Two- and three-dimensional diffusional processes are expected to behave in quite an analogous manner and this has been checked already for a few cases.

Initial partial pressure modification.—According to Eq. [7], the surface concentration must be abruptly modified at time $t = 0$, which is a condition difficult to achieve. The gas handling operation is a time-consuming process and slow surface reactions are also likely to occur. The use of pure oxygen appreciably simplifies the rapid establishment of new partial pressures, but limits the physically achievable partial pressure ranges. In many circumstances, gas mixtures must be employed, which implies either an additional gas flushing or gas sweeping operation. A specific example is depicted in Fig. 5. The greatest effect on $\Delta\tilde{D}/\tilde{D}$ appears immediately after emptying out the gas mixture. More explicitly, the value $T = 0.0015$ is approximately equivalent to $t = 10$ sec for a 1 mm thick CoO sample at 1000°C. For the quite common case where no flushing operation is used, the gas composition changes only very progressively, in a more or less logarithmic manner, even with a rapid switching between different mixtures. This process can be accelerated by faster sweep rates, but with an appreciable penalty on thermogravimetric measurement accuracy. Close attention to the initial partial pressure modification is especially important with faster reequilibrating compounds.

Slow surface reaction.—At the beginning of the relaxation process, the incoming defect flux in the first few layers of the solid sample is, theoretically, extremely large. The surface reaction may not be fast enough to accommodate such a flux, with the resultant occurrence of some deviation from the true surface equilibrium concentration. This departure from the ideal reequilibration process vanishes more or less rapidly as the relaxation process goes on, but the actual determination of $\tilde{D}$ remains affected for longer times. In the following somewhat simplified model, the surface reaction rate is assumed to be proportional to the surface concentration departure from equilibrium

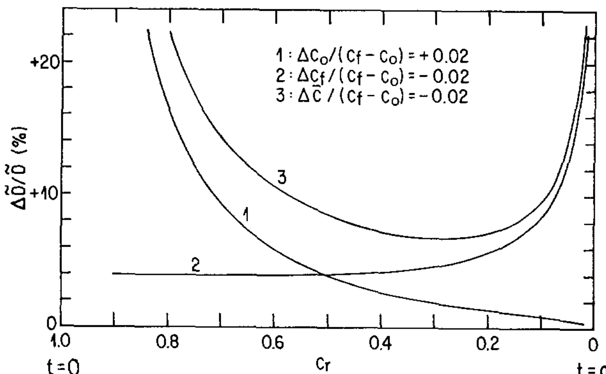

Fig. 4. Reconsideration of the uncertainty on c_r in view of its experimental components c_o, c_f, and $\bar{c}$ for a one-dimensional diffusion process.

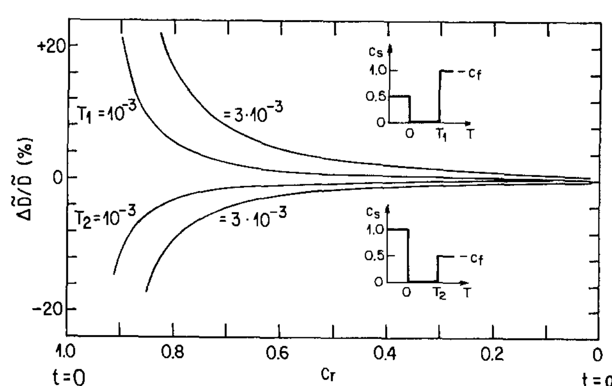

Fig. 5. Effect of a gas emptying operation for two distinct cases. c_s is the instantaneous surface concentration.

with the outer atmosphere. Hence

$$j(0, t) = A\{c_i(0, t) - c_f\} \quad [12]$$

By combining with Fick's first equation

$$\left(\frac{\partial c_i}{\partial x}\right)_{x=0} = B \cdot \{c_i(0,t) - c_f\} \quad [13a]$$

where C is defined as $(c_i - c_o)/(c_f - c_o)$. Consequently

$$\left(\frac{\partial C}{\partial x}\right)_{x=0} = B\{1 - C(0,t)\} \quad [13b]$$

where $j_i(0,t)$ is the flux at the gas-solid interface, A is a constant specific to the gas mixture, and B is equal to $(A \cdot a/\tilde{D})$. Equation [12] is analogous to the drying process already discussed by Newman (27) and the wustite surface reaction model used by Landler and Komarek (28) for a combined surface and volume rate-limited process. Other models have also been described and discussed at some length (29-31). But the main purpose of the present approach is to quantify the effect of a surface rate-limited reaction on the determination of $\tilde{D}$ rather than identifying the exact surface mechanism responsible for that rate-limiting action. Equation [13b] has been introduced as a boundary condition for the numerical integration of Fick's second law. The results for $\Delta\tilde{D}/\tilde{D}$ are shown in Fig. 6. To scale up the phenomenon, various values were attributed to B, *e.g.*, $B = 25$ leads to a limiting surface flux equal to the flux that would be theoretically observed at $c_r = 0.976$ in the absence of a slow surface reaction. Since the individual curves uniquely depend on the magnitude of B, the present numerical solution is concentration independent. In contradistinction to Fig. 5, and to the error on the estimation of time at $t = 0$, there is a largely persistent effect of the surface reaction on $\tilde{D}_{\text{apparent}}$, even at very low c_r values.

Oxidizing-reducing mixtures like H_2/H_2O and CO/CO_2 are quite susceptible to the kind of phenomenon presently discussed. Experimental results on wustite have been discussed at some length by J. B. Wagner *et al.* (24). Even pure oxygen should theoretically not be overlooked for a partly surface rate-limiting action.

Large stoichiometric variations.—Several compounds like FeO, MnO, and UO_2 exhibit large departures from stoichiometry. Large concentration variations have often been applied to those compounds for relaxation experiments. On fundamental grounds, the effect of a large stoichiometric variation within any single relaxation experiment is two-fold: (*i*) the outer crystal surface cannot be considered any more as a fixed boundary, in the case of a mobile cationic sublattice; and (*ii*) there should be a stress-induced effect due to the concentration gradient. Case one must be numerically integrated. The apparent value of σ_r (see Eq. [8]), *i.e.*, its value obtained without correcting the initial sample dimensions for the continuously advancing boundaries, departs from the actual value of σ_r or, else, c_r. It can be shown that

$$c_r = 1 - (a_f/a)[1 - (\sigma_r)_{\text{app}}] \quad [14]$$

where a is the instantaneous sample dimension and a_f, the final one. Weight and apparent conductivity variations vary in exactly the same way, so that a strictly equivalent equation also holds for W_r. The correction to be brought *vs.* c_r, to compensate for the departure from the true $\tilde{D}$ value, is shown in Fig. 7. The other effect, concerning internal stresses in the course of diffusion, has been theoretically discussed at some length elsewhere (32-33). Practically speaking, there is no absolute need for large stoichiometric variations except for more sensitivity in a few thermogravimetric experimental procedures.

Concentration-dependent diffusion coefficient.—The eventual defect mobility variation, which has sometimes been reported for transition metal compounds (22, 34), is a rather controversial problem. That phenomenon is likely to be accompanied by either a change in the defect nature or by defect interactions. Taking into account the sole effect of $\tilde{D}$ variation and numerically integrating Fick's second law lead to the results shown in Fig. 8. In that solution, $\tilde{D} = f(c_i)$ was defined as follows

$$\tilde{D}(c_i) = \tilde{D}_{\text{min.}} + (\tilde{D}_{\max} - \tilde{D}_{\text{min.}}) \cdot (c_i/c_{\max}) \quad [15]$$

Because $\tilde{D}$ is concentration dependent and should likewise vary continuously during the course of the re-

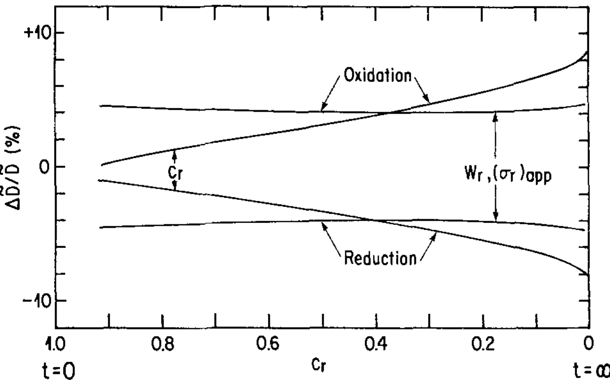

Fig. 7. Description of a large departure from stoichiometry in MeO_{1+y}. Here, y varies between 0 and 0.05.

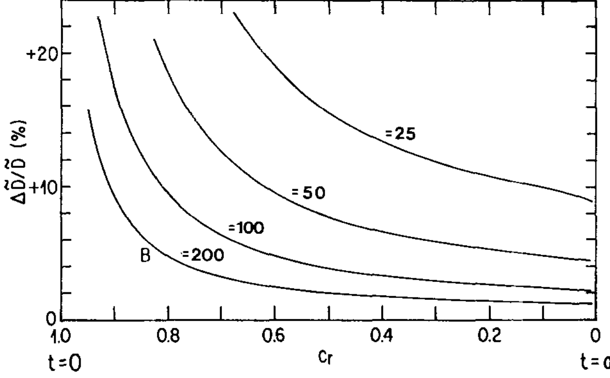

Fig. 6. Effect of a slow surface reaction on $\Delta\tilde{D}/\tilde{D}$. B is used here as a scaling parameter and it is proportional to the surface reaction rate constant.

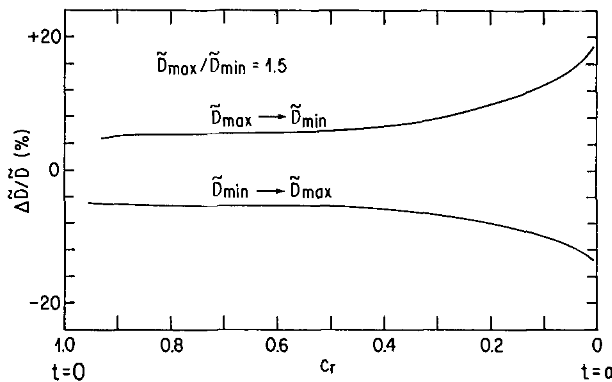

Fig. 8. Study of a chemical diffusion coefficient linearly dependent on concentration.

laxation process, $\tilde{D}_{true}$ is arbitrarily taken as equal to its arithmetic mean, $(\tilde{D}_{max} + \tilde{D}_{min.})/2$. Whenever the correction factor $\Delta\tilde{D}/\tilde{D}$ is applied to the analytically calculated $\tilde{D}$ values, the corrected $\tilde{D}$ value becomes identical to the preceding arithmetic mean. From Fig. 8, the analytical $\tilde{D}$ values should be slightly biased either positively or negatively depending on reequilibration being an oxidation or a reduction process. The expected analytical deviation during the course of a single experiment is somewhat smothered both by the actual diffusion process and by the use of the arithmetical average on $\tilde{D}$. A true $\tilde{D}$ variation *vs.* concentration would consequently be more easily detected by several small successive concentration changes over a desired range, instead of a single large concentration variation.

Thermogravimetric and Electrical Conductivity Measurements

One last and major point of interest in relaxation experiments is the physical means used in measuring the concentration evolution within the sample. Weight and electrical conductivity are the most suitable and the most widely used physical properties. The preference for either of these must be discussed on its respective merits. Theoretically speaking, one major advantage in using weight is that it always relates more directly to a chemical component activity than conductivity would, in agreement with a perfectly general thermodynamical formulation of diffusion. However, structural interpretation of defects is usually done currently, hence invalidating the preceding argument. Experimentally speaking, thermal noise, simple buoyancy, and gas flow effect limit the useful sensitivity of weight measurements. These factors can be quite well controlled in carefully designed experiments. An additional difficulty may come from the initial gas handling procedure associated with a rapid weight variation. The accuracy of thermogravimetric measurements depends on the magnitude of the absolute concentration change. Weight variations are thus easily recorded for large stoichiometric changes but at the same time, they become rather less sensitive at low defect concentrations.

For the counterpart, electrical measurements can intrinsically be made very precise so that their accuracy is usually limited by external factors like temperature and partial pressure control. The relative error made in conductivity measurements being generally constant, makes them very suitable for extended defect concentration ranges. The electrical conductivity is related to c_e, the free electron concentration or else the electron hole concentration in the following way

$$\sigma_e = \mu_e \cdot q_e \cdot c_e \quad [16]$$

where μ_e is the electron mobility, q_e is the elementary charge, and the mobility μ_e is normally considered to be constant. The mobility is quite often temperature dependent, but to a much lesser degree than the departure from stoichiometry. Four different conductivity types have been accordingly distinguished in Table II. The first two types, showing a linear relationship between electronic and ionic defects, are readily compatible with relaxation experiments. Type IV is the main exception to the use of electrical conductivity measurements. The conditions for types I and II do not need to be strictly obeyed to be used for relaxation experiments because the electrical conductivity is intimately related to defect concentration and to defect nature. In fact, σ only needs to be unequivocally related to the departure from stoichiometry. The effect of an eventual nonlinear relationship between σ_r and c_r can be readily evaluated by numerical integration of

Table II. Electrical conductivity in nonstoichiometric compounds in relation to the relaxation method

Conductivity type	Example	Ref.
I. Electrical conductivity is directly proportional to departure from stoichiometry; electronic mobility is temperature dependent	CoO	(36)
II. Electrical conductivity is directly proportional to departure from stoichiometry; electronic mobility is temperature independent	MnS	(36)
III. Electrical conductivity is dependent on nonstoichiometry; a mixed defect state prevails for a certain oxygen activity range.	MnO	(37)
IV. Electrical conductivity is identified with metallic conduction; it is independent of nonstoichiometry	NbO	(38)

that relationship. A power law between equilibrium values of σ and c_i is taken here as an example

$$\sigma = \text{constant} \cdot c_i^r \quad [17]$$

In this type of equation, c_i is normally dealt with as a defect concentration. The present treatment partly resembles that described by Campbell and O'Keeffe (35), and r can either be thought of as an arbitrary exponent or it can be deduced from already existing experimental data on σ and c_i. For example, $r = 3/4$ may also be interpreted in terms of n_σ equal to 4 and n_X equal to 3. One other example is that of r equal to 0.5. Again, that may also correspond to $n_\sigma = 8$ and $n_X = 4$ in Me_2O. Typical calculations, reported in Fig. 9 and 10, have been performed for various r and c_f/c_o ratios. Oxidation and reduction processes are identified by c_f/c_o greater or smaller than unity, respectively. These results can also be summarized as follows:

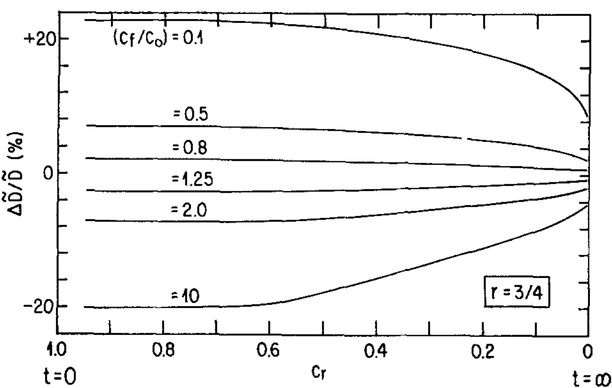

Fig. 9. Nonlinear dependency between electrical conductivity and concentration. The effect is shown for various concentration ratios, during both oxidation and reduction runs.

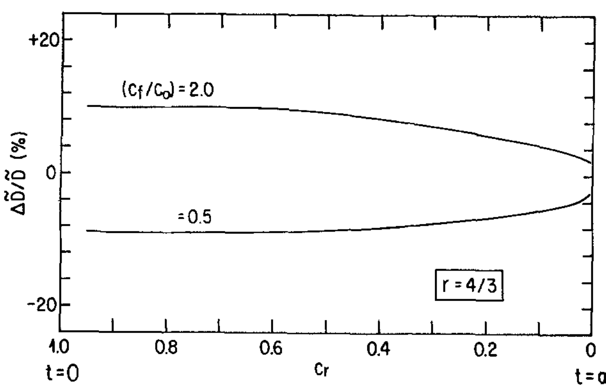

Fig. 10. Nonlinear dependency between electrical conductivity and concentration. Effect of an inverted power law coefficient on the correction factor $\Delta\tilde{D}/\tilde{D}$.

1. The effect on $\Delta\tilde{D}/\tilde{D}$ is most important during about the first half of the relaxation run; it diminishes asymptotically at the very end of the experiment.
2. The greater the departure of r from unity, the greater the correction factor $\Delta\tilde{D}/\tilde{D}$; $\Delta\tilde{D}/\tilde{D}$ reverses sign when r goes from $r < 1$ to $r > 1$.
3. $\Delta\tilde{D}/\tilde{D}$ increases with increasing c_f/c_o departure from unity; that effect is symmetrical for low enough $\Delta\tilde{D}/\tilde{D}$ values.
4. The nonlinearity effect on $\tilde{D}$ tends to become negligible as r or c_f/c_o tend toward unity.

Other empirical relationships between σ and c_i have also been tested. The observations are quite analogous to those previously formulated. Therefore, the $\Delta\tilde{D}/\tilde{D}$ behavior is not specifically tied to a peculiar relationship, but is generally dependent on (*i*) the degree of curvature between σ and c_i, combined with the magnitude of the concentration change and on (*ii*) the absolute sign of that curvature.

Finally, Fig. 11 is an exact representation of the most generally accepted defect model in cuprous oxide. Neutral cation vacancies are assumed to be the major defects and electrical conduction would come from the simultaneous and minor existence of electron holes and singly ionized cation vacancies (14). The present calculations provide the guidelines for correcting eventual relaxation experiments in Cu_2O or for probing the actual existence of the preceding model.

In brief, the effect of a nonlinear relationship between σ and c_i is predictable. The calculations involved in that process can either be used to correct diffusion coefficient measurements or, inversely, to detect the existence of a nonlinear relationship between those two fundamental parameters.

Electrode configuration.—The electric conductivity technique should normally be quite attractive. Nonetheless, there is a very common source of discrepancies which is directly related to the electrode configuration. For relaxation experiments, there should be two basic types of electrode configuration as illustrated in Fig. 12. According to type a, the electric current is perfectly parallel to the diffusion axis through the whole sample. Hence, the average conductivity is related to the average defect concentration by the following equation

$$\bar{\rho} = \text{constant} \cdot \int_0^a (1/c_i) \cdot dx \qquad [18a]$$

or, since $\bar{\sigma} = 1/\bar{\rho}$

$$\bar{\sigma} = \text{constant} \Big/ \int_0^a (1/c_i) \cdot dx \qquad [18b]$$

where $\bar{\rho}$ is the average sample resistivity. The electrode is simultaneously assumed to be perfectly porous and perfectly conducting. In type b, the current flow is strictly perpendicular to the diffusion axis and the electrodes are assumed to be completely impervious to diffusion. Hence

$$\bar{\sigma} = \text{constant} \cdot \int_0^a c_i \cdot dx \qquad [19a]$$

or

$$\bar{\sigma} = \text{constant} \cdot \bar{c} \qquad [19b]$$

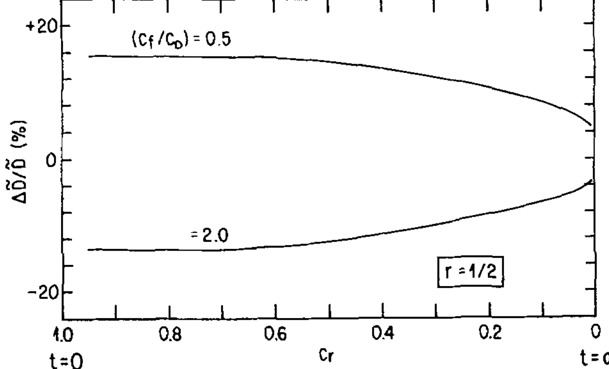

Fig. 11. Characterization of the cuprous oxide model behavior during relaxation runs with electrical conductivity.

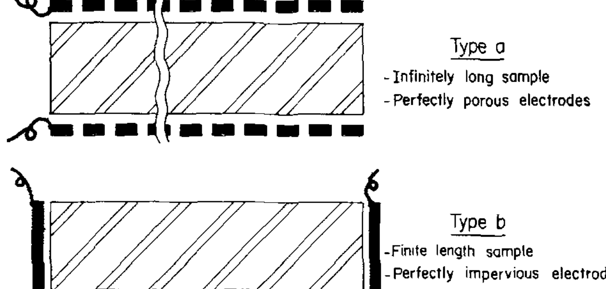

Fig. 12. Idealized electrode arrangements for relaxation runs

The two preceding sets of equations represent a perfectly linear relationship between σ and c_i. The difference between Eq. [18b] and [19a] is obvious. Thus, directly substituting c_r for σ_r would lead to erroneous results in the first case. Regarding type a configuration, the assumption that the electrode layer is perfectly porous is hardly feasible. Type b is to be preferred. The use of electric conductivity measurements would thus be limited to one- and two-dimensional processes. Any intermediate configuration would lead to a nonohmic interpretation of the measurements. Wrapping the diffusion samples with electrode wires at a finite length from one another is one such case. It leads to at least partially incorrect results unless a full specific mathematical treatment is allowed for it. Such a treatment would be rather lengthy and cumbersome. The electrode configuration suggested here is simpler and more reliable.

Final Comments

The relaxation method has been discussed here from the experimentalist's point of view. All calculations were based on a very few fundamental equations or else on very simple assumptions. These calculations were developed to let the relaxation method gain more potential regarding the study of defect diffusion and point defect behavior in transition metal compounds. The actual significance of $\tilde{D}$ has not been discussed outside its basic definition given by Eq. [1]. That would naturally be the next important step in discussing present diffusion theories.

A graphical representation of $\tilde{D}$ *vs.* c_r is suggested to give a better statistical weight to all data during any single experiment and to make use of all the information contained within any data set. Several numerical examples have been worked out in order to obtain more specific ideas about the actual effects of the most common error sources. Those examples were mostly done in dimensionless parameters so that they might be transferred to the practical design or assessment of experiment. Moreover, an optimum range for c_r that would lead to more accurate $\tilde{D}$ values has been indicated.

The electrical conductivity measurements applied to the reequilibration method were thoroughly discussed. As long as there is a nonstoichiometric dependency of electrical conductivity, this measurement technique appears to be useful for all defect concentration ranges. Large concentration changes should generally be avoided. Nevertheless, the electrical conductivity may then, on the base of preceding calculations, be a useful

means of detecting some eventual nonlinear relationship between σ and c_i.

Finally, experimental papers on the relaxation method are still very representatively described by Childs *et al.* (23). Quite surprisingly, there is only a limited number of works in the field and there is ample room for further experimental development. The most useful aspect of the present mathematical analysis is in redesigning relaxation experiments so that not only more precise and reproducible data are made available, but also the experimental observations keep in pace with the constantly developing defect theory. In that sense, relaxation experiments have been performed recently on CoO and they are reported extensively elsewhere (39). Not only do we observe a clear tendency for $\tilde{D}_{CoO}$ to vary with the oxygen activity but any discrepancy with previous assumptions on $\tilde{D}_{CoO}$ is explained by the present analysis.

ABSTRACT

In order to explain the differences experimentally observed in the chemical vapor transport of titanium diboride by various transporting agents we have used thermodynamics to model the process. Two different calculating methods have been undertaken. The first one is based upon the consideration of the transport process as two successive thermodynamic equilibria whose chemical compositions have been obtained by minimization of the Helmholtz free energy. The second one refers to the Richardson and Noläng model and accounts for the mass transport by calculating the flux functions of the vapor phase constituents. The comparison between experiments and results of each calculating method shows that the two models give fuller information, contribute to a satisfactory explanation of the experiments, and allow one to chose available transporting agents.

In order to grow titanium diboride single crystals of a relatively large size (about a few millimeters), we have undertaken a set of chemical vapor transport experiments in sealed tubes using a great variety of transport agents:[1] halogens, hydrogen halides, titanium and boron halides, tellurium tetrachloride. While doing these long-lasting experiments we could reveal very different behaviors for each transport agent (1, 2). This is the set of results we use to test predictive models based upon thermodynamic considerations. Two different types of approaches are tested in this way. As both use the minimization of a thermodynamic function of the system, their simultaneous implementation is very easy. The comparative study of their respective pros and cons points out how pertinent a simultaneous use of both models is in predicting the transport phenomenon in closed tubes.

Experimental

Experiments have been carried out in silica sealed tubes (6 mm diam 100 mm long, and 12 mm diam 100 mm long). The starting materials are industrial titanium diboride powder (> 99%), halogen, and halides. The quantities are about 300 mg of TiB_2 (an excess) and 6×10^{-4} mol of t.a. per 10 cm^3. The tube is air evacuated to 10^{-5} Torr for 6 hr then sealed under low pressure transport agent. The ampuls are heated by electric horizontal furnaces in temperature gradient of 10 deg. cm^{-1} for one month.

Experiments have been carried out for nine transport agents and transport was observed except in the case of TiI_4. The transport occurs from the cold to the hot end of the tube with some t.a., from the hot to the cold end with the others. Table I gives the experimental observations with an average evaluation of the amount transported in each case.

Chemical analyses have been made by spectrophotometric measurements on the transported crystals. They show a variation in the boron-titanium ratio when changing the transport agent.

After cooling of the ampul, in most cases the tube was unpolished showing an etching of silica at the source end. Gaseous or liquid halides remain on the tube and except in the case of tellurium halides no solid compound other than TiB_2 appears at the sink end.

First Thermodynamic Model: Equilibria in Closed Tubes

The model consists in decomposing the transport process into two successive equilibria. The first one is at the source end of the tube at temperature T_1 taking into account the powdery titanium diboride, the transport agent, and the silica of the tube. The composition of this system at equilibrium is determined by minimization of the Helmholtz free energy.[2] The gas phase of this equilibrium causes the transport.

The second equilibrium system consists of the gas phase taken at the sink end of the tube together with silica at T_2 temperature. A second minimization of the Helmholtz free energy gives the composition of the sink system at equilibrium.

Table I. Data and results for TiB_2 transported from T_1 to T_2

	t.a.	T_1 (K)	T_2 (K)	TiB_2 transported (mg/month)
$T_2 > T_1$	I_2	1125	1225	50
	BI_3	1050	1200	50
	HCl	1075	1225	10
$T_2 < T_1$	$TeCl_4$	1255	1125	150
	$TeBr_4$	1255	1125	150
	BBr_3	1235	1105	150
	Cl_2	1270	1125	20
	$TiBr_4$	1320	1270	10
	$TiCl_4$	1300	1190	0

[1] t.a. in the following text.

[2] The computer program used for the minimization is a slightly modified version of the one used for the minimization of the Gibbs free energy (3).

Such systems are of great complexity because of the number of chemical reactions which are feasible between halogen, titanium, boron, silicon, and oxygen but the number of constituents is not limited in the calculation method. The only limit is the knowledge of the thermodynamic values of all the compounds. All the values used in the calculations are reported at the end of the text in the Appendix.

The Helmholtz free energy is minimized; that is, the very one which falls to a minimum at equilibrium in a sealed tube (under constant V and T). Let us consider a system involving Γ phases, each phase itself involving N_γ constituents. The Helmholtz free energy is

$$F = G - PV$$

after the Euler's theorem

$$G = \sum_{i=1}^{N_\gamma} n_i \overline{G}_i$$

with $\overline{G}_i = \left(\frac{\partial G}{\partial n_i}\right)_{P,T} = \mu_{i\gamma}{}^{\circ} + RT \ln P_i$ (for one gaseous species for example

$$\frac{F}{RT} = \sum_{\gamma=1}^{\Gamma} \sum_{i=1}^{N_\gamma} n_i{}^\gamma \left[\frac{\mu_{i\gamma}{}^{\circ}}{RT} + \phi_\gamma \ln P_i + (1 - \phi_\gamma) \ln a_i{}^\gamma \right] - \frac{1}{RT} \sum_{\gamma=1}^{\Gamma} \sum_{i=1}^{N_\gamma} \phi_\gamma n_i{}^\gamma RT$$

$$\frac{F}{RT} = \sum_{\gamma=1}^{\Gamma} \sum_{i=1}^{N_\gamma} n_i{}^\gamma \left[\frac{\mu_{i\gamma}{}^{\circ}}{RT} + \phi_\gamma \left(\ln \frac{RT}{V} + \ln n_i{}^\gamma - 1 \right) + (1 - \phi_\gamma) \ln a_i{}^\gamma \right]$$

with $n_i{}^\gamma$ = mols of the ith species in γth phase; $\mu_{i\gamma}{}^{\circ}$ = standard chemical potential of the ith species in the γth phase; $\phi_\gamma = 1$ if a gaseous phase; $\phi_\gamma = 0$ if nongaseous phase; $a_i{}^\gamma$ = activity of the ith species in the γth nongaseous phase; and V = volume of the tube.

The nongaseous phases are assumed to be pure, their activity is taken equal to 1, and the chemical potential gradients are contingent on the temperature. The gaseous compounds are assumed to follow the ideal gas law.

The compositions of the two equilibria have been calculated for the following conditions: temperature gradient 1200-1300 K (or vice versa), transport agent 6×10^{-4} mol, volume of the tube 10 cm^3 and with five series of transport agents: (*i*) halogen Cl_2, Br_2, I_2; (*ii*) hydrogen halides HCl, HBr; (*iii*) tellurium halides $TeCl_4$; (*iv*) titanium halides $TiCl_4$, $TiBr_4$, TiI_4; (*v*) boron halides BCl_3, BBr_3, BI_3.

The set of calculations provides a number of indications. The whole set of numerical results gives too many tables, so we have limited the presentation to one series of transporting agents, the boron halides for example (Table II). This table shows the complexity of the vapor phase and the non-negligible role of silica; as to the presence of titanium diboride at the sink it means the suitability of the chosen temperature gradient (if the gradient is not in the good direction we do not obtain TiB_2 at the sink).

In the order to determine the amount of TiB_2 expected at the sink when the equilibrium state has been reached, we have reported in Table III the calculated values which indicate the tendency of the system to transport TiB_2, together with experimental results when obtained. The poor agreement between the two sets of results is obvious. So, while $TiCl_4$ is

Σ SiXn: number of mols of all silicon halides.
Σ N: total mol number of the gaseous phase.

expected to work a hundred times better than BI_3, it is the latter which produces experimental transport.

In Table IV the relative importance of the silicon halides in the vapor phase is reported. These values represent maximum limits of silica etching never reached in facts because of the passivation of the tubes.

So this first model gives the appropriate transport direction, accounts for the silica etching, but does not enable us to anticipate the importance of mass transport. In such experiments in which weak transport occurs (few milligrams a month), it seems interesting to implement a method which optimizes, or at least provides indications about the speed of transport; that is the reason why we refer to the Richardson and Noläng model.

Second Model

In his thesis (6) Richardson has demonstrated (4, 5) the influence on the transport rate of all the vapor species, even when they had very low partial pressures. Moreover, when studying the transport of SnO_2 by iodine and sulfur (4), he points out the competition between two tin halides that constitutes a case similar to ours in which the titanium is present in the gas phase as TiX_3 and TiX_4, both responsible for the transport of TiB_2 (in a few cases TiX_2 also appears).

We have applied this model to our systems to predict the rate of chemical transport. The principal assumptions are that the gaseous diffusion follows the laminar flow model, that the system has reached a steady state, and that the total pressure is equal to the average value of the pressures at sink and source calculated by the first method. Then, the reactions of the walls of the ampul are assumed infinitely kinetically hindered so that the fluxes are position independent. It is therefore necessary to neglect all the products of reactions with silica. The Gibbs free energy of the systems TiB_2/t.a. is minimized at the assumed pressure successively at source and sink temperature. The results of these minimizations for a number of transport agents experimentally tested are reported in Tables V-XII, the compositions of the equilibria are given as partial pressures (atm) for the gaseous species and number of mols for the solid ones. These partial pressure values allow us to obtain the flux functions of the various species.

In the approximation of the experimental model the flux function of a species can be written as

$$\phi_i = \frac{1}{RT}\left(\frac{P_o}{P}\right)\left(\frac{\overline{T}}{T_o}\right)^{\alpha} \left[\overline{P}_i\left(\sum_i \lambda_{ir}\frac{\Delta P_i}{\Delta T} \Big/ \sum_i \lambda_{ir}\overline{P}_i\right) - \frac{\Delta P_i}{\Delta T}\right] = \frac{1}{RT}\left(\frac{P_o}{P}\right)\left(\frac{\overline{T}}{T_o}\right)^{\alpha}[f(i)]$$

with

$$\overline{P}_i = \frac{P_{i1} + P_{i2}}{2}$$

mean partial pressure value between the two equilibria

$$\frac{\Delta P_i}{\Delta T} = \frac{P_{i2} - P_{i1}}{T_2 - T_1}$$

$$\overline{T} = \frac{T_1 + T_2}{2}$$

α is a constant used in the relationship $\overline{D} = \overline{D}_o\ (P_o/P)$

$(T/T_0)^\alpha$ to describe the temperature and total pressure variation of the diffusion coefficient. Its value lies between 1.5 and 2.

λ_{ir} is the stoichiometric coefficient of the rth element in the i species where r is present only in the vapor phase (here r is the halogen). The relation between ϕ_i and the flux of the i species is

$$J_i = \bar{D}_0 \phi_i \frac{\Delta T}{\Delta x}$$

in which Δx is the length of the tube and $\bar{D}_0$ the mean diffusion coefficient; this single average value replaces the diffusion coefficients D_0.

Richardson and Noläng (4, 5) wished to optimize the flux function, in this paper we shall only compare the values of this function for different transport agents.

The transport of TiB_2, for the titanium part, being due to TiX_3 and TiX_4, we can write

$$\phi[TiB_2] = \phi[TiX_3] + \phi[TiX_4] = \frac{1}{RT}\left(\frac{P_0}{P}\right)\left(\frac{\bar{T}}{T_0}\right)^\alpha [f(TiX_4) + f(TiX_3)]$$

The different values obtained (Table XIII) show that, with the exception of BBr_3, the functions ϕ of the halides have opposite signs. Therefore, there is a competition between them and only one is responsible for the transport.

A means of comparison of the transport agents in spite of the different values of $\bar{P}$ and D_0 is the consideration of the ratio

$$R = -\frac{\text{flux of the transporting halide}}{\text{flux of the second halide}}$$

When the ratio tends toward 1 (equal fluxes), infinitely slow transport is expected. The values of R for the various transport agents are reported in Table XIII against the amounts experimentally transported. There is now a very good agreement between the two series of results except for $TeCl_4$ and Cl_2.

These two transport agents will be studied together with $TiBr_4$ and $TiCl_4$, all of them producing an R value close to 1. Let us consider the case of Cl_2: For that carrier, just like for $TiCl_4$ and $TeCl_4$, there appears neither boron (unlike the cases of BI_3, BBr_3, and I_2) nor $BHCl_2$ (unlike the case of HCl) and, as Cl_2 acts only as a solvent and is completely consumed, the relation between the partial pressures results in

$$P_{[TiCl_3]} + P_{[TiCl_4]} = \frac{1}{2} P_{[BCl_3]}$$

and

$$P_{[BCl_3]} = \frac{2}{3} P_{total}$$

The model assumes the same pressure at source and sink and, in the absence of chemical potential gradient, transport becomes impossible. The same phenomenon occurs in the case of $TeCl_4$ (with transport of tellurium in the process). In the cases of $TiBr_4$ and $TiCl_4$, transport can be described by the equation

$$9TiX_4 + \langle TiB_2 \rangle \rightleftarrows 10\,TiX_3 + 2BX_3$$

and as we started from TiX_4, we necessarily have

$$P_{[TiX_3]} = 5P_{[BX_3]}$$

which gives for the flux functions

$$\phi_{[TiX_3]} = 5\phi_{[BX_3]}$$

now

$$\phi_{[TiB_2]} = \phi_{[TiX_3]} + \phi_{[TiX_4]} + \frac{1}{2}\phi_{[BX_3]}$$

In the absence of solid boron we shall have

$$\phi_{[TiX_4]} = -4{,}5\,\phi_{[BX_3]}$$

and

$$\frac{\phi_{[TiX_3]}}{\phi_{[TiX_4]}} = \frac{5}{4{,}5} = -1{,}11 \quad \text{(cf., Table XIII)}$$

These few equations explain why the Richardson model predicts no transport in these cases. To understand why two of these transport agents still give experimental transport, it is necessary to come back to the first model and to consider Table IV showing the side reactions with silica of the tube. In the case of $TiCl_4$ and $TiBr_4$, there is almost no attack so that the restraints on the partial pressures remain and, as predicted, there is no transport. On the contrary, in the case of Cl_2 and $TeCl_4$, silicon halides are formed by attack of the tube, and the restraints fall down, and the transport becomes possible.

Conclusion

The application of thermodynamics and flux functions, while pointing out their limitations, provides a useful insight into investigating transport system.

The grouping of the two submitted models brings an approach of the complicated chemical processes which occurs. From that approach we deduce the transport direction and the importance of the wall etching as well as its influence on the transport. Lastly, it allows one to make *a priori* choice between the different transport agents.

Vacuum Plasma Electron Beam Melting of Reactive and Refractory Metals and Their Alloys

One Step Melting of Low Oxygen Content Titanium Scrap by Using VPEB

ABSTRACT

Vacuum plasma electron beam (VPEB) melting with a hot hollow cathode gives satisfactory results for recovery of low oxygen content titanium scraps and Zircaloy-2 scraps. The yield of relatively high vapor pressure elements, such as Cr, can be controlled easily to meet with the tolerance. The VPEB has a high energy density and purification effect which is similar to that of high voltage electron beam melting. Power input of the VPEB to a target of a molten pool is by far more stable and the yield of materials throughout the melting of reactive and refractory metals and their alloys is quite satisfactory compared to those of high voltage EB or the vacuum arc melting process. The VPEB process is also safer, easier to operate, and suitable for automation. Three examples of VPEB application at VMC-ULVAC are described in this paper.

A simple recycle process of reactive metal and alloy scrap to sound ingots is aimed at. Low oxygen content, loose-shape titanium scraps (Fig. 1), the chemical composition of which is shown in Table I, are melted by using VPEB. Oxygen content of the VPEB melted ingots satisfied the high quality level of JIS Grade-1 specification. One-step melting of high purity reactive metal scrap by using VPEB is feasible both technologically and economically.

Figure 2 illustrates a VPEB one-step recycle furnace. A schematic drawing of the furnace is shown in Fig. 3. By using a 200 mm diam water-cooled copper crucible and an ingot pulling mechanism, a 1m length of titanium ingot (weight 130 kg) is produced. Melt stocks of titanium scraps, which are represented in Table II, are charged to a material feeding chamber and moved over the lip of the crucible. An 18 in. gate valve is attached to the furnace for semicontinuous feeding of the melt stock. A 20 in., 8 m^3/sec oil ejector pump, a 1 m^3/sec mechanical booster pump, and a rotary piston pump with a capacity of 7 m^3/min are equipped in series. A d-c power supply of 100V and 3 kA maximum output is used as the VPEB power source.

Figure 4 illustrates the melting operation. An example of operating parameters are represented in Table III. Figure 5 illustrates the surface of the one-step melted titanium ingot. Table IV represents the

purity grade titanium wire is also shown as the reference.

A low oxygen content 200 mm diam titanium ingot can be produced by VPEB one-step melting. Results are shown as follows: (*i*) The increase of the oxygen content level by one-step melting is less than 100 ppm. (*ii*) The melting rate of titanium one-step melting is 0.2 kg/kA · min. This value is acceptable in practical application. (*iii*) Variations of pressure, voltage, and current are very small so that extremely stable operation continues throughout melting. (*iv*) Argon gas consumption for VPEB discharge is small and can be neglected. It is, however, possible to recycle the argon, if required. (*v*) Operating experience has proved that the VPEB process is economically advantageous.

paper, however, a new process for direct recovery of Zircaloy scrap is proposed. Surface-cleaned Zircaloy scraps are converted in a specially designed vacuum plasma electron beam furnace to an electrode for vacuum arc remelting which is a part of a conventional process. Sufficient mechanical strength and electrical conductivity are the two factors required with the VPEB processed electrode, while compensation for chromium loss (Fig. 6) during the melting was considered. The result of the development work is satisfactory and the new process can be a big improvement.

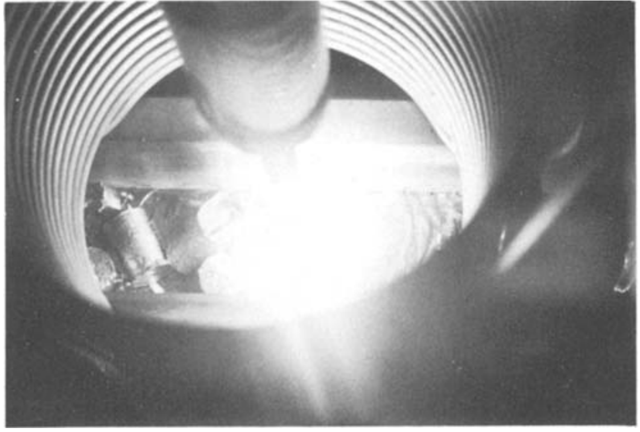

Fig. 9. VPEB melting of Zircaloy scrap for electrode

Figure 7 illustrates the specially designed VPEB scrap recovery furnace. Scraps are laid on a water-cooled copper hearth which has dimensions suitable for electrode to successive VAR. The hearth is movable back and forth in the vacuum chamber while VPEB bombards the surface of the scraps. A simple scanning mechanism is equipped for the VPEB gun. A chromium charging mechanism feeds the necessary addition of chromium granules following the first melt down. A larger charging mechanism feeds Zircaloy scraps over the first melt for additional second melting as is illustrated in Fig. 8. VPEB melting in this ap-

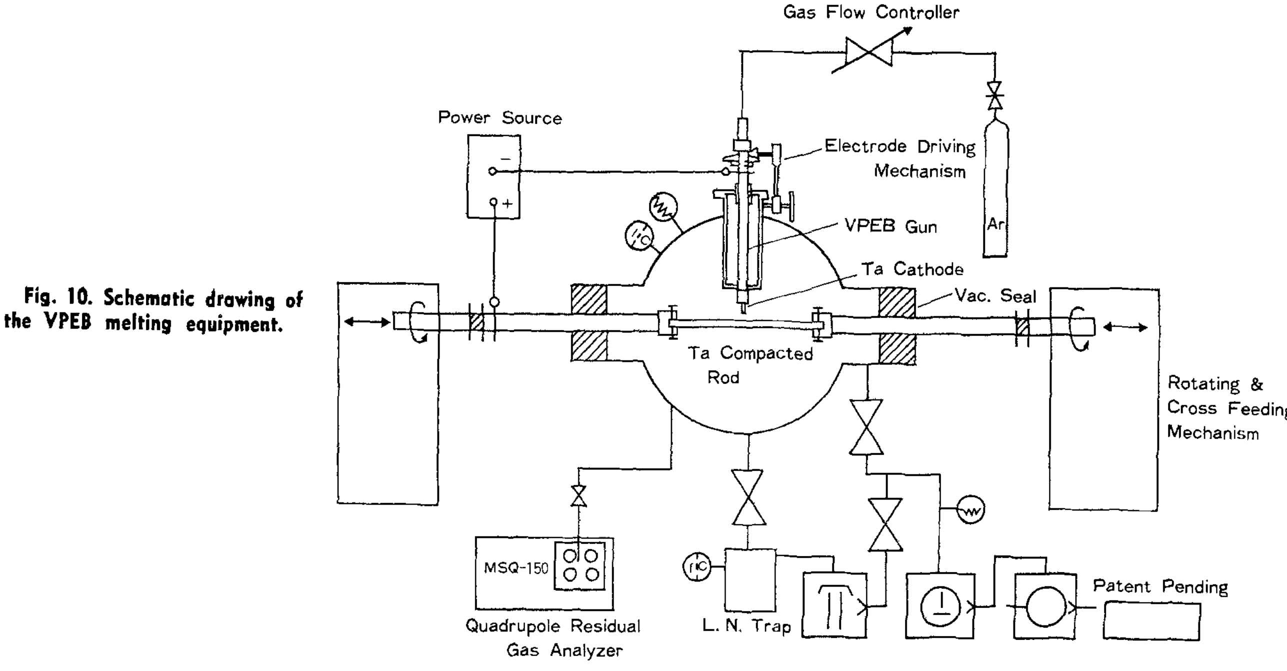

Fig. 10. Schematic drawing of the VPEB melting equipment.

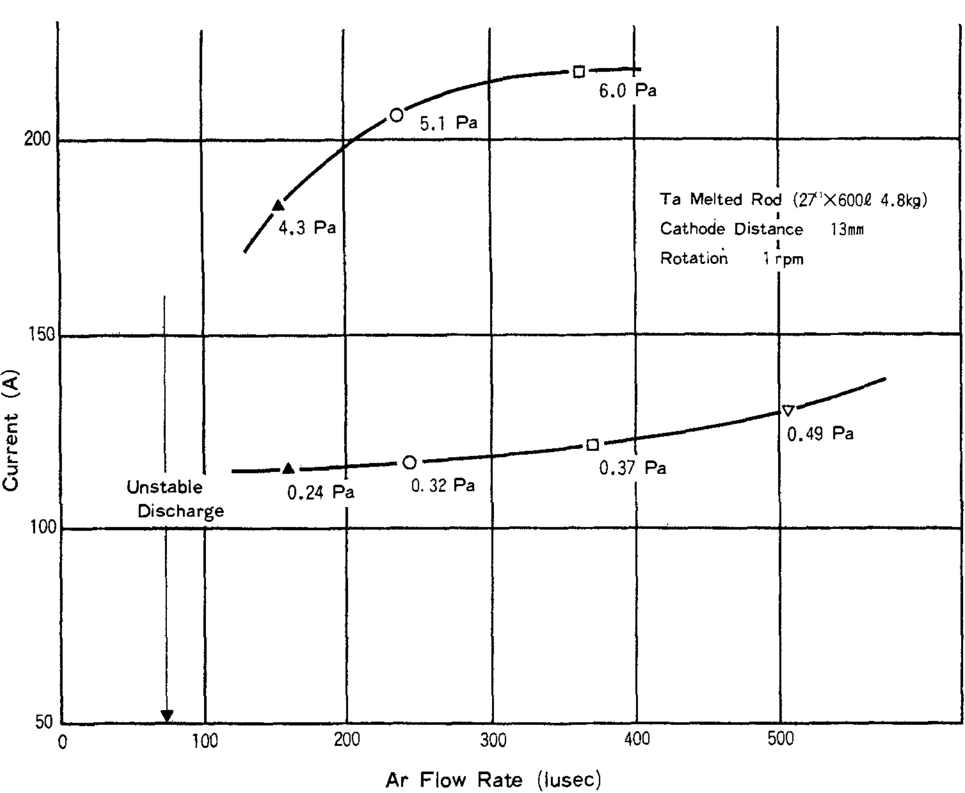

Fig. 11. Minimum current for Ta melting.

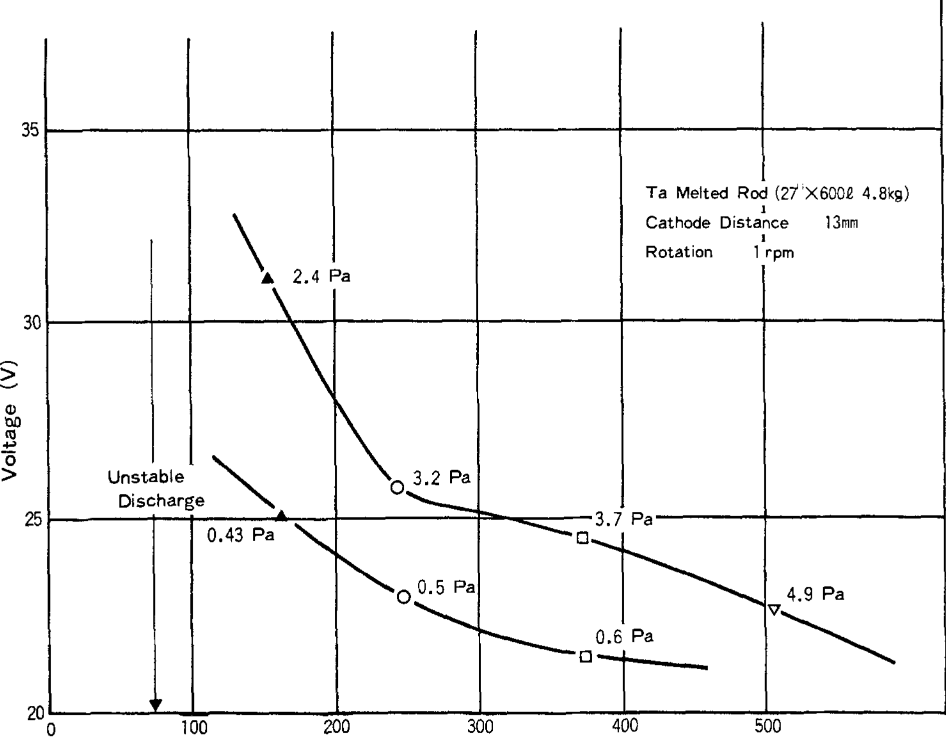

Fig. 12. Corresponding voltage for Ta melting.

plication is aimed at joining scraps to a satisfactory electrode, so a complete melt down of the charge is not required. Figure 9 illustrates melting operation. An example of the operating parameters are represented in Tables VII and VIII. Table IX represents the parameters for successive VAR operation. Table X represents the results of chemical analysis of the finished ingot.

The addition of chromium is not required at least for several recyclings. This is a favorable result for actual production. Chromium loss as a whole is kept small because of the relatively short thermal history of the electrode. However, it will be required to add chromium if, for example, all scraps charged are of chips and thin sheets.

The VPEB is considered to be the ideal heat source for the direct recovery of Zircaloy scraps. VPEB is operable at low voltage and medium to high vacuum. There is no danger of damage to the water crucible with sufficient power density to melt down refractory metals. Power input can be controllable and maintained constant for as much time as is required. Practically any shape of raw stock can be charged.

Melting Tantalum by Using VPEB

Tantalum ingot is conventionally produced by using either a vacuum arc (VA) furnace or high voltage electron beam (HVEB) furnace. A vacuum sintering (VS) furnace has been an alternative for producing smaller rod shapes. An example of VPEB melting,

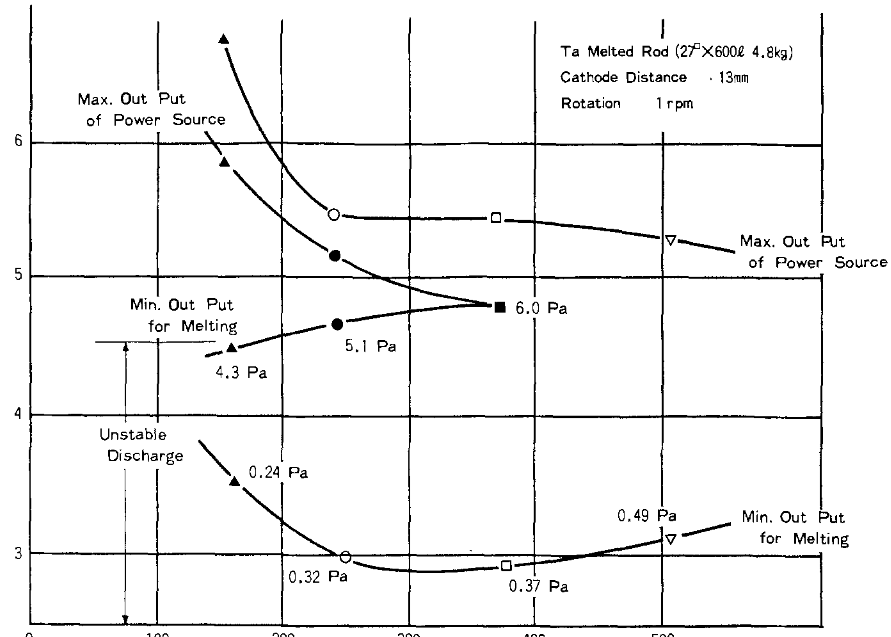

Fig. 13. Electrical power input vs. operating flow rate.

which is new, economical, versatile, easy for maintenance and operation, and produces a similar grade of purification to that of HVEB, is presented in this paper.

Figure 10 illustrates a schematic of the equipment. Melting and purification of a tantalum rod or ingot by using the VPEB is aimed at. A mechanical drive gives rotation and push-pull transfer motion to the tantalum rod through vacuum-tight seals while VPEB melts the surface. A quadrupole residual gas analyzer (RGA) is used for dual purpose: monitoring the purity of background environment and gaseous or vapor composition degassed during the melting. Partial pressure of any active gases or vapors which may react with hot tantalum must be kept below a certain level. Argon pressure to keep VPEB is roughly between 3×10^{-1} and 10 Pa measured in the vacuum chamber. Figures 11 and 12 illustrate the minimum current and corresponding voltages required for melting the tantalum surface, respectively. Shift of operating pressure was made by changing pumping speed and argon flow rate.

Figure 13 represents electrical power input *vs.* operating flow rate. Table XI summarizes a comparison of operating parameters at the two typical conditions. Details of basic experiment and data were published elsewhere (1, 2). Table XII represents some of the purification effects obtained for surface melting of powder compacts 22 mm $\phi \times 500$ mm L, 76% density made by hydrostatic compaction of 100 mesh Ta. Carbon powder was additionally mixed for the No. 02 series in order to promote oxygen removal by CO reaction. The result indicates that partial pressure of H_2O and the total pressure played a major role in this case. Figures 14 and 15 represent monitored gas composition during the processing.

A new product, SMTR (3) (surface melted tantalum rod) is an example of optimized use of VPEB. The SMTR has pure, dense, and sound surface made by VPEB melting while the inside (central portion) of the rod is composed of sintered smaller density tantalum. Figure 16 represents an example of the process flow. Figure 17 illustrates the purification effect at the surface. Figure 18 illustrates radial density variation from the surface to the center. Average density before and after surface melting is 76% and 88%, respectively. The fabricated square rod 5 × 5 mm cross section and annealed at 1200°C 1 hr showed mechanical properties represented in Table XIII, which is, by far, over the specification JIS H4701. Similar surface treat-

ber should be paid due consideration with respect to gas flow pattern and electrical field distribution. Magnetic confinement can improve concentration of the plasma, with additional expense.

In summary, application of VPEB requires careful design of system. Operation of VPEB, however, has big advantages in reliability (stability) and safety over VA or HVEB. VPEB is usable for producing both large ingots and small diameter rods starting from powder compact, sponges, or any shape of raw stock. It is also usable for controlled heating which varifies application in a variety of heat-treatments. Energy density at a target surface can be as high as 10^4 kW/cm^2, which is sufficient for surface melting of refractory metals and alloys. VPEB can often be an alternative short-cut process of an existing production line; valuable for rationalization or saving labor, energy, and thus cost.

Acknowledgments

The authors are indebted to Mr. H. Takei and his group, ULVAC Corporation, for the design and manufacture of the VPEB scrap recycle furnace. Mr. K. Yoshida, Vacuum Metallurgical Corporation, gave helpful advice throughout this study.

The Formation of SiO_2 in an RF Generated Oxygen Plasma

I. The Pressure Range Below 10 mTorr

A. K. Ray* and A. Reisman*

IBM Thomas J. Watson Research Center, Yorktown Height, New York 10598

ABSTRACT

This paper deals with the formation of SiO_2 on silicon in an rf generated oxygen plasma in the pressure range below 10 mTorr. A companion paper describes the behavior of the oxide growth process in the pressure range above 10 mTorr. The oxide was formed in an open-tube pumped fused silica system without substrate biasing. Oxide formation rate was studied as a function of substrate temperature, conductivity type, resistivity, distance from the end of the plasma generating coil, oxygen pressure, and generator power output. Based on the results obtained on masked substrates, using the silicon-mask interface as a marker, it was determined that within the limits of experimental error, all the oxide formed in the pressure range studied was deposited on the surface and not a result of oxidation. The rate of deposition increased with increasing power, decreasing pressure, and decreasing wafer to plasma generation zone distance. This rate was temperature independent and was unaffected by substrate parameters. Excellent uniformity was obtained over 56 mm diam wafers, ±3-5%. The properties of the oxide deposited at 600°C and above are only slightly poorer than thermal oxides grown at 1000°-1100°C. They exhibit somewhat higher fixed charge and interface state density while the breakdown strength, etch rate, and refractive index are essentially the same as thermal oxides. A key observation of the plasma process conducted at pressures below 10 mTorr is that the oxide always forms on the silicon surface facing the plasma. This is opposite to the results obtained at higher pressures described in Part II of this study.

It is to be anticipated that as semiconductor devices are scaled to smaller dimensions, *i.e.*, less than 1 μm ground rules, currently employed chip processing temperatures will tend to become incompatible with desired device designs, because impurities present in shallow junctions and/or in surface threshold adjusting layers will tend to redistribute. The problem will be compounded further by surface depletion of im-

* Electrochemical Society Active Member.
Key words: silicon, plasma, oxidation, SEM.

purities during oxidation (1), oxidation enhanced diffusion effects (2), and the generation of substrate defects (2, 3). Two of the primary high temperature processes to be contended with are oxidation, and ion implantation damage annealing and activation.

As a first step in evolving a lower temperature processing sequence, the authors have focused on the oxidation process. One might assume, initially, that the lower the temperature at which one can conduct an oxidation process, the better. This is not necessarily true from a stress point of view. If, for example, the intrinsic stress at the oxide formation temperature tends toward zero, then any temperature excursions above this temperature will force the oxide into tension, making it susceptible to cracking at mask opening corners. To minimize this problem, oxidation processes should be conducted at the highest possible temperature consistent with impurity redistribution, surface depletion, and defect generation constraints.

High pressure and plasma oxidation processes both offer potential for use at lower temperatures. The high pressure approach (4, 5) is in current use, but for large areas (5) is conducted only in wet oxygen ambient atmospneres, and at moderate pressures, up to 25 atm. In dry oxygen, pressures in excess of 100 atm would be required (4) to achieve oxidation rates comparable to wet oxidation. Such a pressure-temperature combination is not achieved readily on a practical basis for a variety of technical reasons which will be discussed by us at a later time. Very high oxidation rates have, however, been reported using plasma anodization approaches (6-15) at temperatures as low as 170°C (12). Two general problems encountered in using plasma approaches have been the difficulty in achieving uniform growth over areas greater than 1-2 cm^2 (6, 7) and the generally poor electrical and defect characteristics of the oxides (7, 12). Partial resputtering of the grown oxides has been considered by Kraitchman (8) and others (12, 13), but none of the reports considered seriously the possibility of sputtering from the walls of the reaction chamber onto the wafer surface as an effect to be contended with. In addition, using presumably similar experimental techniques, different workers have obtained significantly different results. Lingenza (6) reported power and temperature dependencies, but no substrate bias voltage dependency on oxidation rate. He also found parabolic growth behavior for biased oxidations and nonparabolic growth in unbiased oxidations. Skelt and Howells (7) and Kraitchman (8), however, saw no temperature dependency, and Kraitchman implied that there was no power dependency. Furthermore, Kraitchman found parabolic growth behavior for both biased and unbiased oxidations, even when constant current biasing (as opposed to constant voltage) was employed. Pulfrey and Reche (12), on the other hand, observed linear kinetics in constant current anodizations.

The present study was prompted by the noted discrepancies among the reported results and by a desire to see if uniform growth could be achieved over large areas. In addition, it was desired to operate in an electrodeless system to avoid possible electrode sputtering contamination effects. It was felt also that the plasma and sample temperatures should be independently controllable to a degree at least, by separating the plasma generation and oxidation zones, and that the effects of temperature and power on both oxide quality and growth kinetics required better understanding. Independent temperature control was accomplished by separating the plasma generation and oxidation zones, with the sample being placed at predetermined distances from the plasma generation zone in a resistance-heated portion of a reaction chamber. Excited species drift from the plasma generation region to the oxidation zone at the drift velocity of the low pressure flowing gas.

This paper deals with the pressure regime below 10 mTorr while a companion paper, Part II, is concerned with the pressure regime > 10 mTorr for reasons which will become obvious.

Experimental Techniques

The experimental setup for plasma oxidation in the pressure regime below 10 mTorr is shown schematically in Fig. 1. Ultrahigh purity bottled oxygen (99.999%) was purified further by heating to 1000°C in a quartz chip bed to decompose any hydrocarbons present to CO_2 and H_2O. These contaminants were removed subsequently in a liquid nitrogen trap. The liquid nitrogen trap could be used to remove CO_2 and H_2O without liquefying the oxygen because the oxygen pressures employed (2-100 mTorr) were less than the vapor pressure of oxygen at the boiling point of nitrogen. The vapor pressures of CO_2 and H_2O at liquid nitrogen temperature are estimated to be of the order of 10^{-5} and 10^{-8} mTorr, respectively. For an operating pressure of 10 mTorr, this corresponds to maximum values of 1 ppm of CO_2 and 1 ppb of H_2O in oxygen, assuming equilibrium obtains. The purified oxygen was used to generate an oxygen plasma in the 80 mm ID, 100 cm long fused silica reaction chamber by a variable frequency (0.5-8 MHz) rf generator. All experiments were conducted at 0.5 MHz unless otherwise specified. Electrical coupling to the system was effected by a six turn coil of 0.25 in. OD Cu tubing placed around the reactor tube and connected to the rf generator by appropriate cables. In our experimental system, only the generator output power was known. An estimate of the power input to the plasma could not be made. Hence, a variation of the generator output power was considered as a variation of the power input to the plasma. The coupling mechanism was assumed not to change with power and pressure variations. The system was pumped continuously during the experiments, and the pressure in the chamber was controlled by regulating the oxygen mass flow into the reaction chamber using a mass flow controller. The pressure in the reaction chamber was measured by a thermocouple gauge located at the exit end of the reaction tube. In order to avoid coupling to the rf field, the thermocouple gauge was placed remote to the plasma generating region. Most of the silicon wafers used were 56 mm diam p-type with a nominal resistivity of 10 Ω cm. The wafers were cleaned prior to an experiment by a process described elsewhere (16). A wafer was placed, on a quartz sample holder, perpendicular to the direction of gas flow. The temperature of the wafer was, as mentioned above, varied and controlled by an external resistance heated furnace. The temperature of the wafer was measured by a Chromel-Alumel thermocouple placed adjacent to it. SiO_2 film thickness was measured using an IBM 7840 Film Thickness Analyzer (17). The IBM 7840 F.T.A. measures combined reflectance of the films and substrate in the wavelength range of 380-750 nm and computes the thickness of the film from the optical constants of

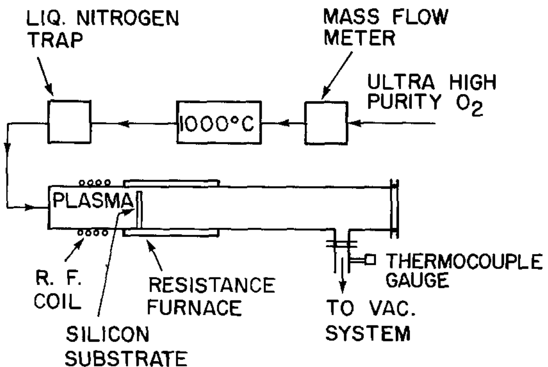

Fig. 1. Schematic diagram of the experimental plasma oxidation system.

the film and substrate. The film thicknesses measured by the F.T.A. were checked with the values obtained ellipsometrically and found to agree to better than ±5%. Since the IBM 7840 F.T.A. can be programmed to measure oxide thickness automatically at 21 predetermined locations over the entire wafer, and is much more rapid in use than the ellipsometric measurement available to us, it was used to gather the uniformity data. The electrical properties of plasma SiO_2 were determined by measurements of fixed charge density, surface-state density, and electrical breakdown strength in conventional fashion, *i.e.*, *C-V* measurements and ramp voltage breakdown measurements.

Results and Discussions

In an initial experiment, a silicon wafer was placed perpendicular to the direction of gas flow 20 cm downstream from the end of the rf induction coil. The temperature of the wafer was maintained at 650°C. An oxygen plasma was generated at 5 mTorr and a generator output power of 4.5 kW at 0.5 MHz. About 50 nm of SiO_2 was formed in 4 hr on the surface of the wafer facing the plasma. No SiO_2 was formed on the other side of the wafer. Thickness uniformity of the SiO_2 film formed was better than ±5%. Under the same conditions, but with increasing pressure in the chamber, the thickness of SiO_2 formed decreased significantly. Consequently, to study the effect of pressure on oxide formation, the generator output power was subsequently increased to 7 kW to increase oxide thickness to reasonable values. Figure 2 shows the thickness of SiO_2 formed in 4 hr as a function of system oxygen pressure at 7 kW. The pressure was changed simply by changing the rate of oxygen input to the system. Since pressure was found to vary linearly with oxygen input rate in the pressure range studied, the flow rate and, therefore, the linear gas stream velocity were constant. The oxygen flow rate was 2.1 scm^3/min at 30 mTorr pressure, and the linear gas stream velocity was 20 cm/sec. As seen in Fig. 2, the oxide thickness obtained after 4 hr shows two distinct regimes when plotted in log-log fashion. The oxide thickness decreases from 350 nm in 4 hr at 1.5 mTorr to 40 nm in 4 hr at 7 mTorr with approximately a 1.4 power dependency on pressure. Above 7 mTorr, the rate decreases much more slowly, *i.e.*, to the 0.1 power. Even with the high (7 kW) output power employed, the SiO_2 thickness at 30 mTorr is only 34 nm in 4 hr. If one wants rapid growth, it is evident from Fig. 2 that the operating pressure should be as low as possible in the experimental configuration described. An operating pressure of 2.5 mTorr was then chosen for the low pressure studies, because below 2.5 mTorr it was difficult to ignite and maintain an oxygen plasma. The behavior at this pressure is representative of the range up to about 10 mTorr. The variation of oxide thickness with position of the silicon wafer outside the confines of the rf coil was studied at 650°C, 2.5 mTorr and 4.5 kW generator output power. Figure 3 shows the data obtained in a 2 hr series of growth experiments. The oxide thickness decreases sharply with increasing distance up to 12 cm. At distances greater than 12 cm, the oxide thickness remains more or less constant. As the thickness uniformity was found to vary more in the region from 7-12 cm than in the region greater than 12 cm, a distance of 20 cm from the end of the rf coil was then chosen for most of the experiments. Experiments were also conducted with the wafer in a horizontal position. The rate of SiO_2 formation was greatly reduced compared to vertical mounting, and a significant SiO_2 thickness gradient was generated across the axial direction of the wafer.

The effect of generator output power on the thickness of oxide formed in 1 hr was studied at 650°C and 2.5 mTorr, the wafer being placed vertically at a distance of 20 cm from the end of the rf coil. With increasing power, the oxide thickness increases linearly with power up to 6 kW and above 6 kW, the oxide thickness increases as $(\text{power})^{4.5}$, Fig. 4, but as might be expected from the large slope of the curve, the thickness uniformity of the SiO_2 formed was poor at the higher power. An output power of 4.5 kW yields a reasonable oxide formation rate and good thickness uniformity. With the preceding as a basis for choosing a usable set of experimental conditions, the kinetics of SiO_2 formation were studied at 2.5 mTorr O_2 pressure, 4.5 kW of generator output power, and the silicon wafer placed vertically at a distance of 20 cm from the end of rf coil. Figure 5 shows the thickness of SiO_2 formed at 600°C as a function of time. It is seen from Fig. 5 that the oxide thickness varies linearly with time in the entire oxide thickness range up to 160 nm. Thermal oxidation of silicon at high temperatures in dry oxygen, of course, follows linear parabolic kinetics to a first approximation. The proposed model of a conventional thermal oxidation process (18) is that there are three basic steps: (*i*) the transfer of oxidant from the gas phase to SiO_2 at the gas-SiO_2 interface; (*ii*) the transport of oxidant through the SiO_2 to the Si-SiO_2 interface and (*iii*) the reaction of oxidant with Si to form SiO_2 at the Si-SiO_2 interface. In a film growth process, the step (*i*), depending on the temperature, linear gas stream velocity, and the film thickness, may or may not be rate limiting (19). In a conventional thermal oxidation process, step (*i*)

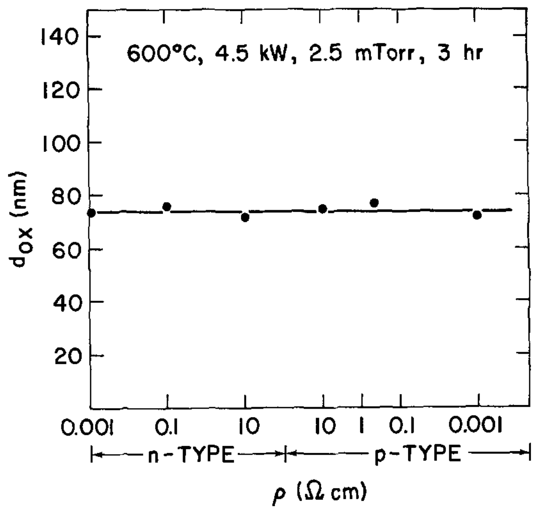

Fig. 7. Thickness of SiO_2 formed at 600°C in 3 hr for wafers of different resistivities.

is usually not rate limiting. The step (*ii*), if it is a diffusion-controlled process, follows parabolic kinetics. The third step determines the oxidation rate and follows linear kinetics. If step (*iii*) alone determines the rate of oxidation, then the rate of oxidation should depend on the temperature, the orientation, and the doping level of silicon wafers and should not depend on oxide thickness.

Figure 6 shows the thickness of SiO_2 formed at 600°C as a function of time for <111> and <100> orientated Si wafers. The rate of SiO_2 formation on <111> surfaces is seen to be the same as that on <100> Si wafers while both are seen to be linear with time. Oxide formation was found not to depend on silicon dopant concentration either. Figure 7 shows the thickness of oxide formed in 3 hr at 600°C for both p- and n-type wafers of different resistivities. Oxide formation rate was found to be independent of temperatures also. Figure 8 shows the thickness of SiO_2 formed as a function of time for three different temperatures. In another series of experiments, about 307.5 nm of dry thermal SiO_2 were first grown at 1000°C on Si wafers, and these wafers were then used as substrates for subsequent plasma experiments. Figure 9 shows the oxide thickness of these wafers as a function of time of ex-

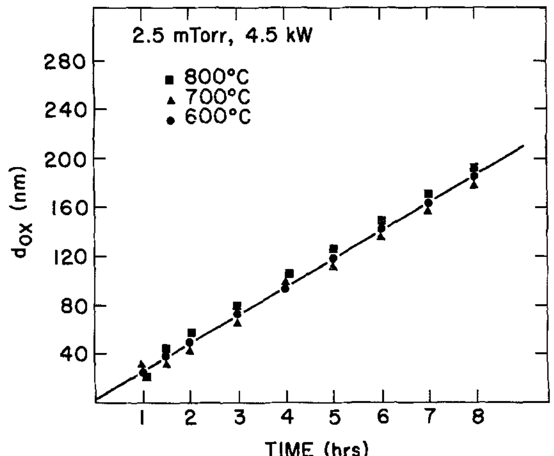

Fig. 8. Thickness of SiO_2 formed as a function of time at 600°C, 700°C, and 800°C.

posure to the oxygen plasma. The oxide thickness still increases linearly with time, and the rate of increase is the same as that observed for bare silicon wafers. The data for bare silicon wafers is taken from Fig. 8. From

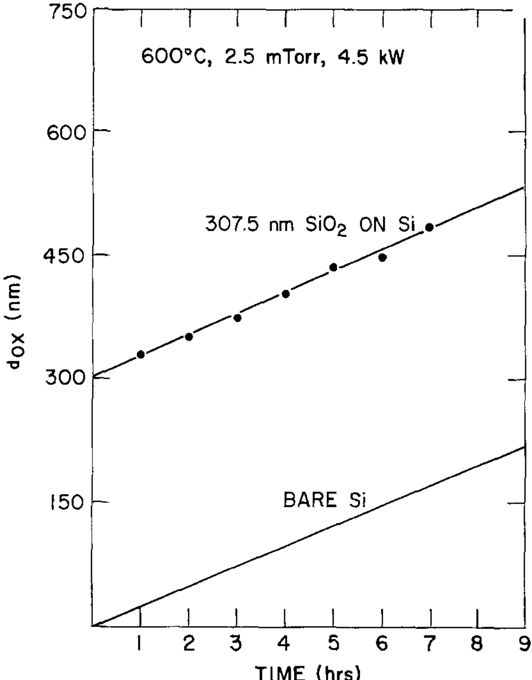

Fig. 9. Thickness of SiO_2 formed at 600°C as a function of time for starting silicon wafers with 307.5 nm of dry thermal SiO_2.

the above experimental results, it would appear that the second process does not determine the rate of formation of SiO_2 under the growth conditions studied. Furthermore, the temperature, wafer orientation, and resistivity independence of oxide formation rate made questionable the possibility that the linear kinetics observed are due to a combination of steps (*i*) and (*iii*) and raised the possibility that the oxide formed in our experiments was not the result of a reaction between silicon and oxygen, but was due to a deposition of SiO_2 in the fused silica reaction chamber at the high rf generator output power and low operating pressure employed. The possibility existed that SiO_2 or a silicon oxygen species, *e.g.*, SiO sputtered from the wall of the reaction chamber, could react with oxygen and deposit SiO_2 on the silicon wafers. In order to test this hypothesis, a silicon wafer was partially masked with Al (400 nm thick) and then exposed to the plasma under the standard set of conditions described. After about 800 nm of SiO_2 was formed, the wafer was cleaved, the Al was etched in dilute HCl, and the cross section was examined in an SEM. It is clear from the

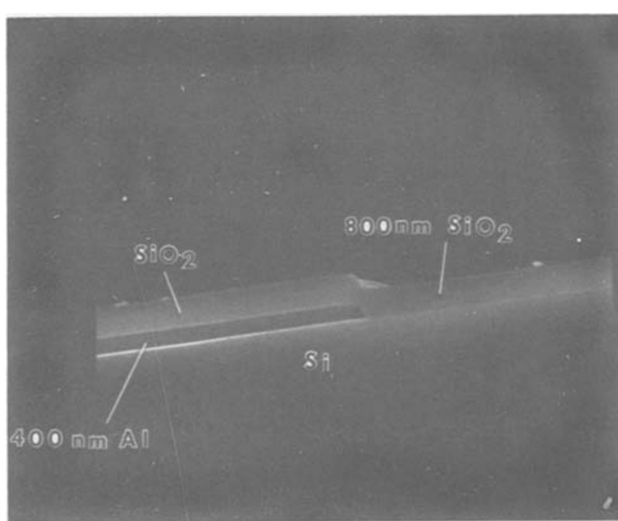

Fig. 10. SEM micrograph of the cross section of a silicon wafer after SiO_2 formation.

SEM micrograph (Fig. 10) that SiO_2 formed on both the exposed Si surface as well as over the Al, indicating that the SiO_2 is deposited oxide. Using the silicon-aluminum interface as a marker, it appears that very little, if any, silicon is oxidized during this process. Whether SiO_2 molecules are sputtered as such, and then deposited, or whether a species such as SiO is sputtered which reacts with oxygen homogeneously or at the silicon surface to form SiO_2 could not be determined. We consider the direct sputtering of SiO_2 to be unlikely since the properties of the deposited SiO_2 are quite different from those of conventionally sputtered silica (20). The refractive index of oxides deposited at 600°C and at lower temperatures was measured by ellipsometry at 632.8 nm and was in the range 1.461-1.465. The etch rate of the plasma deposited SiO_2 was comparable to that of dry thermal SiO_2 grown at 1000°C. The etch rates were compared by etching simultaneously the thermal and plasma oxides in 1:9 (49% HF:40% NH_4F) solution at room temperature. The etch rate was determined by measuring the change in oxide thickness during etching. The etch rates at room temperature were in the range of 74-76 nm/min. In order to evaluate the electrical properties of the plasma-deposited SiO_2, about 75 nm of plasma deposited was formed on 2 Ω cm p-type <100> oriented Si wafers at 600°C. No other high temperature heat-treatment was given to the oxide. Aluminum dots 32 mil in diameter were evaporated on the oxide through a metal mask. Aluminum was also evaporated on the back side of the wafers for electrical contact. A post-metallization anneal in forming gas at 400°C for 20 min was given to the capacitors. Figure 11 shows the high frequency *C-V* curve of these capacitors. The high frequency *C-V* curve was obtained at 1 MHz with a voltage ramping rate of 0.2 V/sec. Well-defined inversion and accumulation regions were obtained. The hysteresis effect observed between the inversion and accumulation regions may be due to the presence of a large number of surface states. Surface-state density measured by the quasi-state technique was about 10^{12}/cm^2 eV at midgap. With surface-state density so high, the expression for V_{FB} in terms of fixed positive charge becomes complicated. So effective charge density (Q_f) was calculated from the flatband voltage (V_{FB}) determined via the high frequency *C-V* curve according to the formula

$$V_{FB} = \phi_{ms} - \frac{Q_f}{C_{ox}}$$

where ϕ_{ms} = work function difference between Al and the semiconductor, taken as −0.7V for 2 Ω cm p-type silicon, C_{ox} = oxide capacitance per unit area, and Q_f = effective charge per unit area.

The calculated effective charge density from the V_{FB} is 1.3×10^{-3} C/m^2 which is equivalent to 8×10^{11}/cm^2 singly charged centers. A high temperature (1000°C) postoxidation heat-treatment was given to some wafers, but this did not reduce effective charge density appreciably. Electrical breakdown strength was measured on one hundred Al-SiO_2-Si capacitors in accumulation. Figure 12 is a histogram showing the

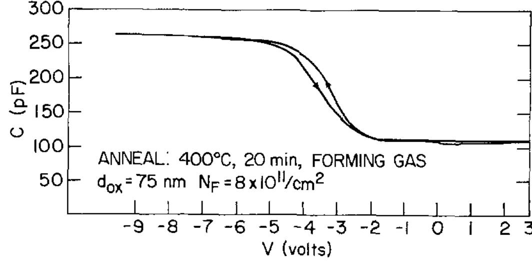

Fig. 11. High frequency *C-V* curve of plasma deposited SiO_2 capacitors after postmetallization anneal in forming gas at 400°C for 20 min.

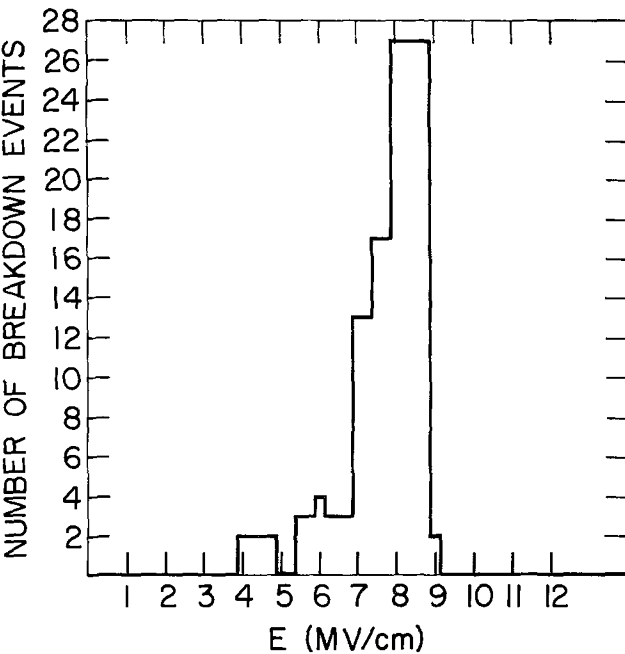

Fig. 12. Histogram showing the number of breakdown events at different breakdown strengths for one hundred plasma SiO_2 capacitors.

number of breakdown events at different breakdown strengths. The breakdown strength is high and there are few low field breakdown events.

Conclusions

From our experimental results, it can be concluded that the SiO_2 formed on the surface of a silicon wafer facing the plasma in a low pressure (<10 mTorr) oxygen plasma is deposited oxide. The deposited oxide is believed to be sputtered material from the wall of the quartz reaction plasma. The exact mechanism (sputtering or reactive sputtering) of SiO_2 formation is not clear. Since the properties of the deposited oxide bear more of a resemblance to thermal oxides grown at 1000°C than sputtered oxide, we believe that reactive sputtering is the mechanism of oxide formation. The rate of oxide deposition increases with increasing power input to the plasma and decreasing pressure and distance of the wafer from the plasma. The increase of oxide formation rate with decreasing pressure is due to the fact that at pressures less than 10 mTorr, wall sputter deposition appears to be the primary mechanism of oxide formation. The sputtering phenomenon leading to deposition rather than oxidation is a function of pressure only and does not depend on the distance of the wafer from the plasma generating zone. Clearly, however, the rate of deposition in such a process will depend on the distance. Very uniform deposits are obtained only under certain experimental conditions. The use of high power or positioning the wafer too close to the plasma results in less uniform deposits. The properties of the deposited oxide are probably related to the purity of the quartz reaction chamber. Refractive index, etch rate, and electrical breakdown strength of the oxides deposited at 600°C are comparable to those of thermal SiO_2 grown at 1000°C. Fixed charge and surface state densities are higher. Limited results indicate that the oxides deposited at lower temperatures have properties similar to those deposited at 600°C. This technique thus may have potential for forming passivation layers for interconnections where conventional high temperature CVD methods cannot be used. The companion paper that follows describes the plasma system behavior at pressures greater than 10 mTorr which is dramatically different from that described here.

The Formation of SiO_2 in an RF Generated Oxygen Plasma

II. The Pressure Range Above 10 mTorr

A. K. Ray* and A. Reisman*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

This paper describes the formation of SiO_2 in an rf generated oxygen plasma in the pressure range above 10 mTorr. The experimental setup used for this study is the same as that described in Part I of this study. Using the silicon-mask interface as a marker and examining the cross section of silicon wafers after oxide formation, it was concluded that the mechanism of oxide formation in the pressure range 10-100 mTorr is growth of SiO_2. A unique and unexpected result of the plasma process conducted at pressures greater than 10 mTorr is that oxide growth occurs primarily on the surface of the wafer facing away from the plasma, in sharp distinction to the observations made at pressures less than 10 mTorr where the oxide forms only on the surface facing the plasma. A key experimental parameter is the confinement of the plasma by the wafer which was observed only at pressures greater than 10 mTorr and at generator frequencies from 0.5 to 3 MHz. Oxide growth rate was studied as a function of pressure, power, frequency of the applied field, and substrate parameters to determine the optimum growth conditions. The etch rate, refractive index, stress, fixed charge, interface states, and breakdown strength of plasma oxides grown at 500°C compare very favorably to thermal oxides grown at 1100°C.

In Part I of this study (1), it was concluded that the SiO_2 formed in a low pressure oxygen plasma is a deposited oxide. The deposited oxide is believed to result from the sputtering of SiO_2 or an oxygen-silicon species from the wall of the fused silica reaction chamber. Because of the long mean free path at low pressures, it is possible for the sputtered material to deposit on a wafer placed as far as 20 cm from the plasma generating region. The sputter yield is therefore expected to be minimized with increasing pressure and decreasing power input to the plasma. In this paper, we describe the *in situ* oxidation of Si at higher pressures and lower power in the plasma system. The results are unique in that at elevated pressures, not only does deposition cease, but oxidation occurs primarily on the silicon surface facing away from the plasma.

Process and Kinetic Studies

When the operating pressure was increased to 30 mTorr and power output from the generator was reduced to 1 kW, no detectable SiO_2 was formed on a silicon wafer placed at a distance of 20 cm from the end of the rf coil. Consequently, for experiments in the high pressure regime (>10 mTorr), the wafer was placed closer (2 cm) to the coil. Under this condition, surprisingly, the plasma was confined by the wafer and the bulk of the SiO_2 was formed on the surface of the wafer facing away from the plasma (the wafer back side) while a much thinner oxide was formed on the surface facing the plasma (the wafer front side). The high-low thickness uniformity of the oxide formed on the back side was better than ±5% and the standard deviation was of the order of 1-3%. The thin oxide formed on the front surface was much less uniform. For example, on a 56 mm diam silicon wafer, there is a region around the wafer periphery where oxide thickness is considerably greater than in the central area. This region of greater oxide thickness increases with increasing oxidation time. After about 5 hr of oxidation at 540°C, there was a region 6 mm wide around the periphery where oxide thickness was about 200 nm as compared to an average oxide thickness of about 65 nm in the central area. During the same oxidation time, about 300 nm of SiO_2 was formed on the back side. An initial explanation for this observation that came to mind was that the oxide formed in equal amounts on both surfaces, but that the SiO_2 formed on the surface facing the plasma was resputtered. In addition, it was to be determined whether the oxide films formed were wall-sputtered oxides, as was the case at low pressures, grown oxides, or combinations of the two with resputtering complicating the picture. To resolve these questions, the results required analysis according to the schematic representation depicted in Fig. 1. In Fig. 1, the expected wafer cross section is depicted for the possible cases, *in situ* growth only,

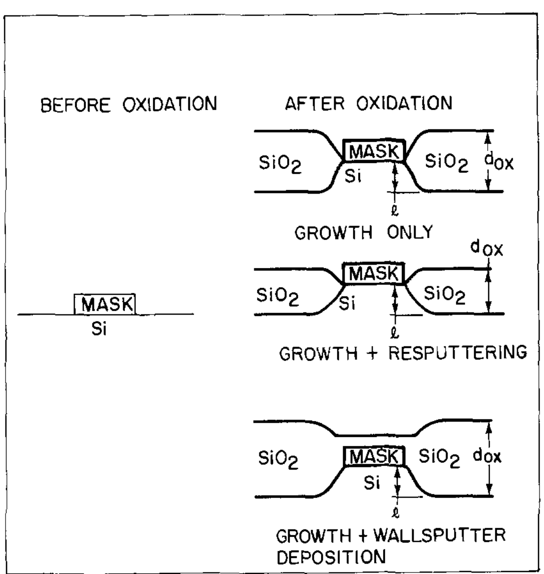

Fig. 1. Schematic representation of the cross section of a silicon wafer for the possible cases, growth only, growth + resputtering, and growth + wall-sputter deposition.

Key words: silicon, plasma, oxidation, SEM.

growth plus resputtering, and growth plus wall-sputter deposition. On the left-hand side of Fig. 1 the situation before oxide formation is shown where part of the silicon area is masked against oxide formation. Using the silicon-mask interface as a marker, it is possible to distinguish among the possible cases mentioned earlier. If the Si-SiO_2 interface is below the original silicon surface (silicon-mask interface), then clearly some of the SiO_2 at least is being formed by a growth mechanism because silicon is consumed from the substrate during the oxide formation process. The thickness of SiO_2 would be approximately twice the distance (l) of the Si-SiO_2 interface below the silicon-mask interface. This value should equal the measured oxide thickness (d_{ox}) if resputtering and deposition are both absent. If growth and resputtering take place simultaneously and the rate of resputtering is less than the rate of growth, then for the same amount of oxidation, as in the case above, the Si-SiO_2 boundary will be at the same distance (l) from the Si-mask interface, but the measured oxide thickness (d_{ox}) will be less than 2 (l) and there will be thickness asymmetry relative to the marker. If growth and wall-sputtering take place simultaneously, then oxide would form over the mask as well as on the silicon substrate. As a result, the apparent thickness of the masking layer would change after oxide formation, and the SiO_2 boundary would again be unsymmetrical with respect to the silicon-mask interface. If the resputtering rate is greater than the growth rate, no oxide would be detected and the unmasked silicon surface would drop below the silicon-mask interface. Finally, if all processes occur simultaneously, *e.g.*, deposition, oxidation, and resputtering, mask thickness would increase, and asymmetry around the mask level would result except in the unlikely event that the resputtering rate and deposition rate are identical. 200 nm thick MgO was used as a mask to examine these possibilities. The reason for selecting MgO as a mask is discussed later. Figure 2 is an SEM micrograph of the cross section of a silicon wafer after oxide formation on the MgO masked silicon surface which faces away from the plasma. It is evident from the picture that oxide formed on this surface is grown oxide and not deposited oxide. There is also no evidence of resputtering or wall-sputtering. Figure 3 shows the cross section of the wafer after oxide formation on the MgO masked silicon wafer surface which faces the plasma. Even though the oxidation was carried out for the same length of time as for the back side, the distance of the Si-SiO_2 interface from the original silicon surface is much less compared to that in Fig. 2, indicating that oxidation has taken place to a much lesser extent on the front surface. However, the oxide is symmetrical around the original silicon surface. Consequently, it may be concluded that the thinner oxide grown on the front surface is due to a reduced oxidation rate, and not due to growth plus simultaneous resputtering of oxide. Further, there is no evidence of deposition on either surface of the wafer. The difference in oxidation rate, for the back side and front side oxidations is believed to be due to self-biasing of the wafer in the plasma. This phenomenon is being examined currently and will be discussed when our experiments are completed. Further interesting observations are as follows.

When two silicon wafers are placed one behind the other, greater than 5 mm apart, the oxide thickness on the back side of the wafer closest to the plasma is uniform and significantly greater than that on the back side of the second wafer. For separation distances less than 5 mm, the oxide thickness uniformity on the first wafer degrades significantly. When the two wafers are placed in direct contact with each other, the back side of the second wafer only is oxidized. The design of the wafer holder was found to be critical for obtaining uniform oxide growth. In order to get uniform growth over an entire wafer, the wafer has to be mounted vertically and supported only at its base. Other mount-

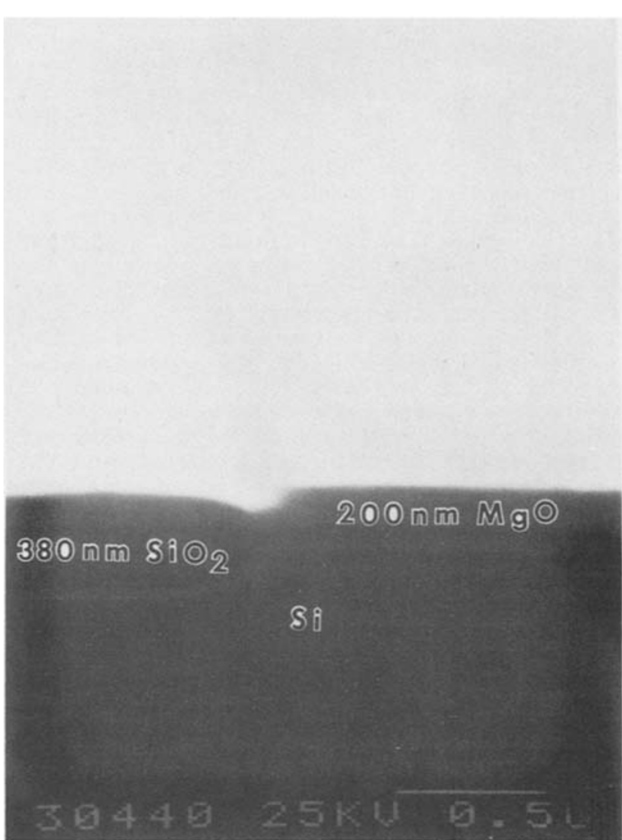

Fig. 2. SEM micrograph of the cross section of a silicon wafer after SiO_2 formation on an MgO masked silicon surface which faces away from the plasma.

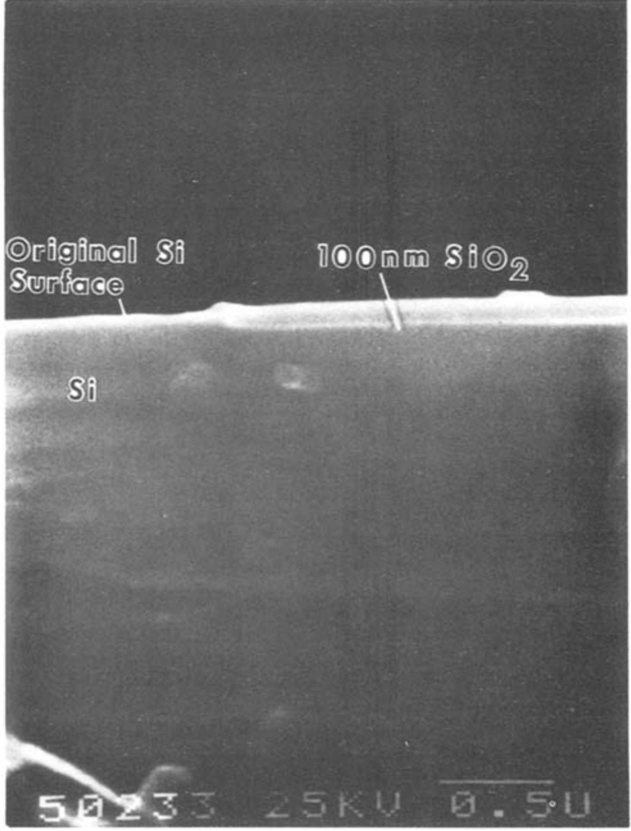

Fig. 3. SEM micrograph of the cross section of a silicon wafer after oxide formation of an MgO masked silicon surface which faces the plasma.

ing configurations, *e.g.*, horizontal placement, wafer support on its bottom and edges, etc. lead to nonuniform growth.

Our process of plasma oxidation involves placing the silicon wafer vertically perpendicular to the direction of the gas flow with the surface to be oxidized facing away from the plasma. This is true for a wafer located on either side of the rf induction coil. Thus, two wafers can be oxidized simultaneously using this plasma oxidation technique. The rate of oxidation is a strong function of the position of the wafer relative to the edge of the coil, decreasing sharply with increasing distance. For the experimental results to be discussed below, the wafer(s) was placed at a distance of 2 cm from the end of the rf coil. Since the wafer lies adjacent to the plasma generation region, the temperature of the wafer is determined to some extent by plasma heating. It takes about 15 min for the temperature of the wafer to stabilize when the plasma is ignited. To study the kinetics of oxidation at a particular temperature, the wafer was brought to an initial temperature using the resistance heat furnace and then a helium plasma was struck at the desired pressure. When the wafer temperature stabilized, the gas input was changed over to oxygen. The latter step takes about a minute. A control wafer was heated in a helium plasma for 30 min to determine whether any oxide is formed during the preheating stage due to contaminants. No detectable amount of SiO_2 formed. The temperature of the resistance heated furnace was varied to obtain the desired oxidation temperature, independent of the power used to generate the plasma. To study the kinetics of oxide formation on two surfaces of a wafer simultaneously, wafers polished on both sides were oxidized for different lengths of time. As mentioned before, the oxide thickness on the front side is less uniform. The average oxide thickness on the front side was computed from the thickness measurements on a 4 cm diam central area of the wafer. Figure 4 shows the thickness of oxide grown at 540°C on the back and front sides of a wafer as a function of time. Oxide thickness on the back side was about 4-5 times the oxide thickness on the front side. In order to analyze the kinetics of oxidation, the data was plotted as log d *vs.* log t (Fig. 5). Both curves follow essentially the same behavior. The oxide thickness appears to increase as t in the initial oxidation phase and as $t^{1/2}$ for longer oxidation times. It is interesting to note that for the back side of the wafer, the $t^{1/2}$ law is obeyed at an oxide thickness of 150 nm whereas for the front side, the $t^{1/2}$ law prevails at an oxide thickness of 40 nm. If neutral species are responsible for oxidation, then the onset of

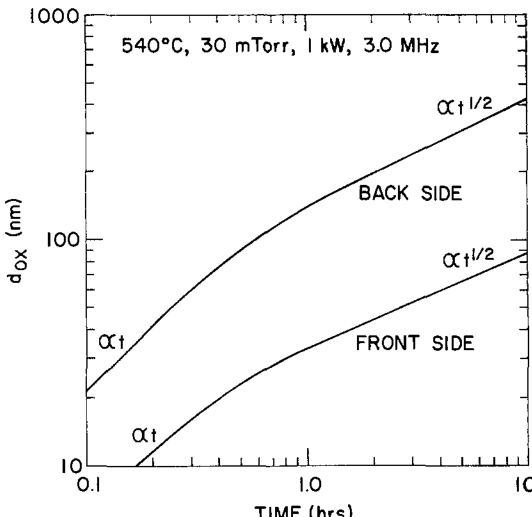

Fig. 5. Thickness *vs.* time for the data shown in Fig. 4 plotted as log d *vs.* log t.

a parabolic law for two different oxide thicknesses would imply that oxidation on the two surfaces is due to different species being responsible for oxidation on each side of the wafer. If we assume that plasma oxidation follows linear-parabolic kinetics (2), then in the parabolic regime $d_{ox} \propto C_o^{1/2}$ and in the linear regime $d_{ox} \propto C_o$ where d_{ox} is the oxide thickness grown in a fixed time and C_o is the concentration of oxidizing species in the gas phase. The two lines in Fig. 5 are more or less parallel indicating that the difference in the oxidation behavior of the two surfaces cannot be explained on the basis of different concentrations of oxidizing species present on either side of the silicon wafer. However, if the oxidizing species is charged, then in addition to the oxidizing species itself, the electric field (V/d_{ox}) would affect the rate of oxidation and the onset of parabolic behavior (3). V is the applied or built in potential difference across the oxide. Studies are in progress to examine such built in potentials and the role they play in the plasma oxidation mechanism.

Figure 6 shows the thickness of the oxide grown on the back side of a wafer in 1 hr at 425°C as a function of oxygen pressure in the reaction chamber. Below 10 mTorr, the oxide thickness is seen to increase sharply with increasing pressure while above 10 mTorr,

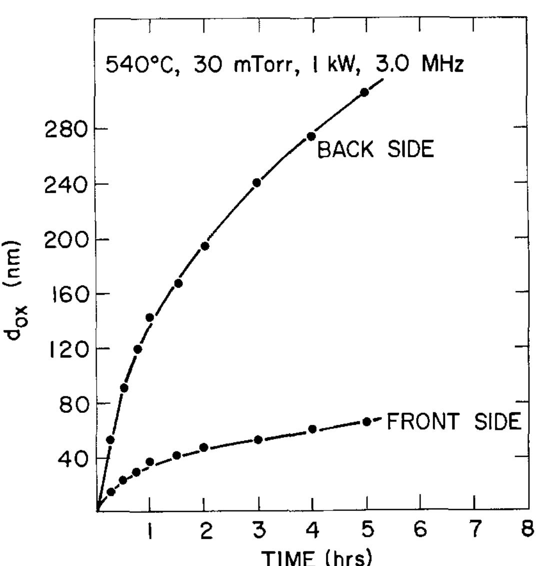

Fig. 4. Thickness of SiO_2 grown at 540°C on the back and front sides of a wafer as a function of time.

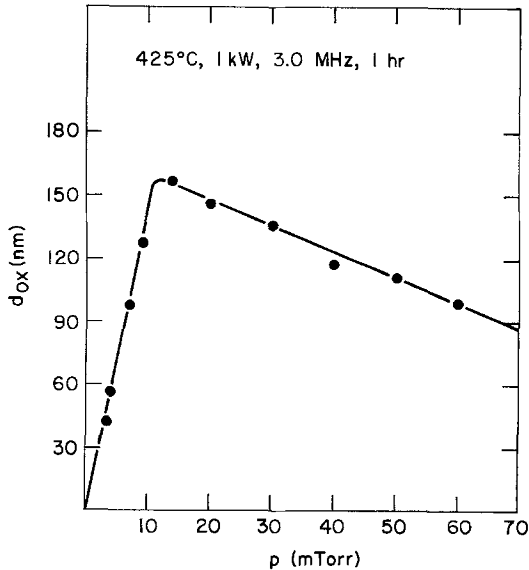

Fig. 6. Thickness of SiO_2 grown at 425°C as a function of oxygen pressure in the reaction chamber.

it decreases slowly with increasing pressure. The effect below 10 mTorr may be explained by the increase in concentration of the oxidizing species with increasing pressure and the effect above 10 mTorr may be explained by the loss of oxidizing species due to an increase in recombination rate with increasing pressure. It is to be recalled from the previous paper that at pressures less than 10 mTorr, when wall-sputtering is the primary mechanism for oxide formation, the rate of oxide formation on the front side of a wafer decreases with increasing pressure. This is a completely different phenomenon than that shown in Fig. 6, which refers only to the process of oxidation taking place on the back side of a wafer. Concomitant with the process of oxidation shown in Fig. 6, at pressures below 10 mTorr, deposition of oxide is taking place on the front side of a wafer in accordance with the discussion in Part 1. If an experiment is conducted, however, at pressures in excess of 10 mTorr, the front side deposition ceases and, of course, the process described in Fig. 6 continues to occur. One other point with respect to Fig. 6 which describes back-side oxidation is that the experiments were conducted at generator output powers in which the front-side deposition rate was very small compared to the rate of oxidation. This point is important because in the experiments to be described at a later date, it will be shown that the back-side oxidation rate is affected by the thickness of an oxide on the front side. One other important aspect of the pressure effect is at pressures less than 10 mTorr, the plasma is not well confined by the silicon wafer, while at pressures greater than 10 mTorr, the visible plasma is totally confined by the wafer. This confinement phenomenon which is striking to observe depends not only on the pressure but also on the frequency of the applied field. The confinement is readily obtained from 0.5 to 3 MHz and very difficult to obtain at 13.6 MHz. When confinement is not obtained, the back-side oxidation rate is dramatically decreased. Figure 7 shows the thickness of oxide grown as a function of time for two generator output powers. Since with increasing power from 1 to 2 kW, there is only a small increase in oxide thickness, most of our experiments were carried out with 1 kW power. The effect of the frequency of the applied field on the thickness of the grown oxide as a function of time is shown in Fig. 8. With increase in frequency from 0.5 to 3 MHz, there is about a 20% increase in oxide thickness. The higher frequency was used in most experiments to obtain higher growth rates. As shown in Fig. 9, the thickness of oxide grown in a fixed time experiment was found

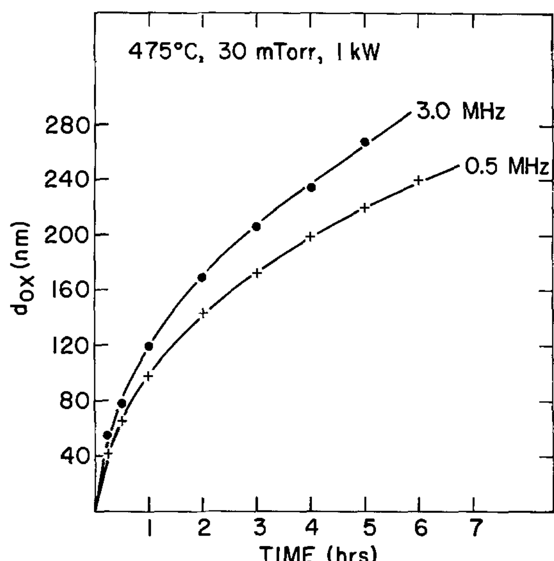

Fig. 8. Thickness of SiO_2 grown at 475°C as a function of time for applied field frequencies of 0.5 and 3 MHz.

not to depend on the resistivity of a silicon wafer. At these low oxidation temperatures, dopants are practically immobile and they are not expected to play a role in the oxidation rate. Oxide thickness as a function of time for <111> and <100> orientation silicon wafers is shown in Fig. 10. Oxide thickness was found to be independent of silicon orientation also, supporting the rate data which indicate a mass transport limited growth process. Since the linear regime, if at all present in our experiments, was probably confined to times less than 10 min, no distinction between the two silicon orientations was possible for the initial stage of the growth process. The effect of temperature on the thickness of oxide grown as a function of time is shown in Fig. 11. Temperature has more of an effect in the parabolic regime than in the initial regime. If we define a parabolic rate constant K_p as $d_{ox}^2 = K_p t$ for the parabolic regime, then the activation energy of K_p is found to be 0.16 eV compared to 1.3-2.3 eV (4, 5) observed for the thermal oxidation of silicon. This is, of course, expected in view of the low temperatures at which we are able to effect oxidation. It should be noted, based on the above, that at 540°C, growth rates comparable to dry thermal oxidation at 1100°C can be achieved by plasma oxidation, but the oxidation rate is strongly limited by the wafer distance from the plasma zone.

Masking Studies

Some interesting observations were also made when a mask material was used. Ligenza (6) reported using Al as an oxidation mask. However, in our case, Al oxidized preferentially to Si and the rate of silicon oxidation, when 50% of the wafer was uniformly masked with Al, was a factor of approximately three less than that of an unmasked silicon wafer. This behavior indicates a large sticking coefficient on the Al of the oxidizing species and is reminiscent of epitaxial growth behavior on Ge and ZnO reported previously by one of the authors (7-9). However, when MgO was used as a mask material, exposed Si areas oxidized at the same rate as that of a blanket silicon wafer. Si_3N_4 was also found to be an effective oxidation mask material and like MgO did not affect growth rate on unmasked surfaces. However, difficulty was encountered in etching Si_3N_4 preferentially to SiO_2 after plasma oxidation using this masking material. SIMS studies indicated that the surface of the Si_3N_4 is oxidized, probably to SiO_xN_y during plasma oxidation. The bird's beak effect described by Bassous *et al.* (10) was examined using 200 nm of MgO as a mask. After about 380 nm of plasma oxide was grown, the MgO was dissolved in a saturated ammonium oxalate solution at room temperature, and the Si-SiO_2 interface was examined using SEM. It is evident from Fig. 12 that the bird's beak effect is apparently absent in plasma oxidation. Si_3N_4 directly on top of silicon surface may minimize the bird's beak effect in conventional oxidation but the stress at the Si_3N_4-Si interface damages the underlying silicon at high temperatures. In order to avoid the generation of dislocations and other defects, a pad oxide must be used between the Si_3N_4 and the silicon surface. This pad oxide provides a diffusion path for oxidation and gives rise to a bird's beak. The ability to plasma oxidize silicon at lower temperatures enables one to place the oxidation mask in direct contact with silicon and thereby eliminate bird's beak formation.

Properties of Plasma Grown SiO_2

The properties of plasma SiO_2 grown at 500°C were studied and were compared to thermal SiO_2 grown at 1100°C. The results are summarized in Table I. The refractive indexes were determined at 632.8 nm using ellipsometry. The etch rates of plasma and thermal SiO_2 were compared by etching simultaneously the two types of oxide in 1:9 (40% HF:49% NH_4F) solution at room temperature. The stress (σ_F) at the Si-SiO_2 interface was calculated knowing the film thickness (t_f), substrate thickness (t_s), and the radius of curvature of the silicon substrate (R), using the formula

$$\sigma_f = \frac{E_s}{6(1-\gamma_s)} \frac{t_s^2}{t_f} \cdot \frac{1}{R}$$

where E_s = Young's modulus of the silicon substrate and γ_s = Poisson's ratio.

In order to get an accurate measurement of the radius of curvature, 7 mil thick wafers polished on both sides were used. About 450 nm of SiO_2 were grown by plasma oxidation or by thermal oxidation at 1100°C. Oxide was then etched from one surface of the wafers. The compressive stress in SiO_2 results in elas-

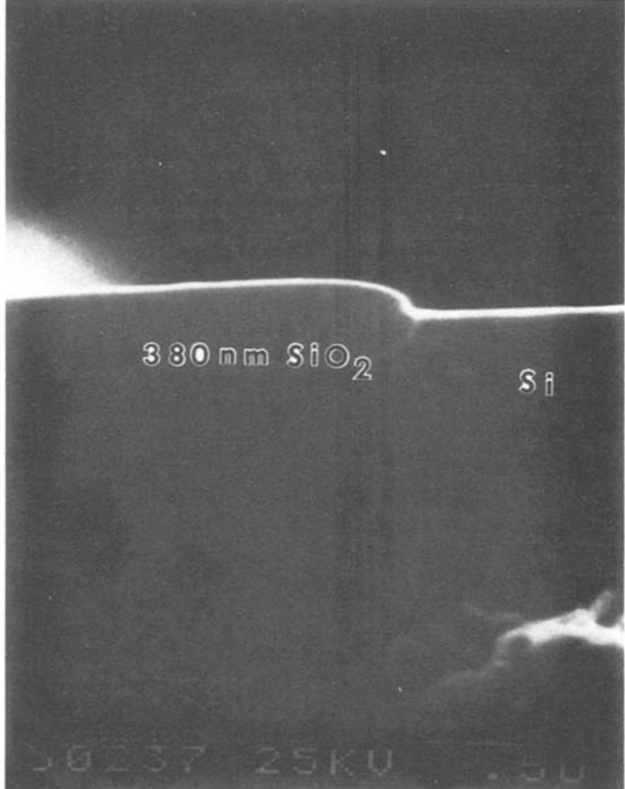

Fig. 12. SEM micrograph of the cross section of a silicon wafer after oxide growth showing the apparent absence of bird's beak effect.

Table I. Properties of plasma SiO_2 grown at 500°C compared to thermal SiO_2 grown at 1100°C

Properties	Plasma SiO_2 500°C growth temperature	Thermal SiO_2 1100°C growth temperature
Etch rate in 1:9 BHF (nm/min)	74-76	75
Refractive index	1.461-1.465	1.462
Stress (dynes/cm²)	1.5-1.6 × 10^9	3.1-3.4 × 10^9
Fixed charge (No./cm²)	2-6 × 10^{10}	2 × 10^{10}
Interface states (No./cm² eV)	2-6 × 10^{10}	2 × 10^{10}
Retention time (sec)	~100	>500
Breakdown strength (MV/cm)	4-8	10
Boron depletion	Absent	Present
Bird's beak effect	Absent	Present
Oxidation-induced defects	Absent	Present

tic bending of the wafer. The radius of curvature of the silicon wafer was determined by an automatic x-ray diffraction technique described by Segmuller *et al.* (11). The stress for plasma oxide was determined to be 1.5-1.6 × 10^9 dynes/cm² and that of thermal oxide was 3.1-3.4 × 10^9 dynes/cm². The difference in stress can be explained by the different growth temperatures and the subsequent cooling to room temperature. If we assume that strain at the Si-SiO_2 interface is proportional to the difference in thermal contraction of Si and SiO_2 during cooling from the growth temperature, and that the intrinsic stress at the growth temperature is negligible, then we can write strain $\propto$ $(\alpha_{Si} - \alpha_{SiO_2})\,\Delta T$ where α_{Si} and α_{SiO_2} are the coefficients of expansion of Si and SiO_2, respectively, and ΔT is the difference between the growth temperature and room temperature. Thus, the ratio of stress in plasma oxide (500°C) and thermal oxide (1100°C) is expected to be $(1100 - 23)/(500 - 23) = 2.27$, close to 2.1, the ratio of the experimentally determined stress values. Since the deformation in silicon is elastic in nature as evidenced by the absence of slip in the oxidized wafers, the rate of cooling from the growth temperature to room temperature is not important.

Fixed charge and interface-state density for oxides grown on <100> Si wafers were determined using high frequency and quasi-static C-V techniques. As-grown oxides exhibited large negative flatband voltages and high surface-state density (3 × 10^{12}/cm² eV). Figure 13 shows high frequency (solid line) and quasi-static (dotted line) *C-V* curves of Al-SiO_2-Si capacitors with only a standard postmetal anneal (400°C, 20 min, forming gas). No high temperature postoxidation heat-treatment was given to these capacitors prior to metallization nor were they premetal annealed at a lower temperature. The postmetal anneal fixed charge density calculated from the flatband voltage was 6 × 10^{10}/cm², and the surface-state density at midgap was found to be 6 × 10^{10}/cm² eV. When, in addition to the standard postmetallization anneal, a postoxidation heat-treatment (1000°C, 20 min, Ar) was given, both the fixed charge and surface-state density values dropped to 2 × 10^{10}. Another postoxidation heat-treatment at 1000°C for 15 min in dry O_2 followed by 5 min in Ar also reduced the fixed charge and surface-state density to the same value. However, the postoxidation heat-treatment in dry O_2 also improved the breakdown strength of plasma oxides considerably. A breakdown strength histogram on one hundred capacitors with different postoxidation heat-treatments is shown in Fig. 14. Plasma oxides without any postoxidation heat-treatment exhibited breakdown strengths of 3-4 MV/cm. The postoxidation heat-treatment at 1000°C in Ar did not change this breakdown histogram. However, after postoxidation heat-treatment in oxygen, the breakdown strength increased to 7-8 MV/cm. During the heat-treatment in oxygen, another 5 nm of thermal SiO_2 were formed in addition to the 35 nm of plasma oxide already present on the wafer. The improvement in breakdown strength cannot be accounted for by this additional 5 nm of thermal SiO_2. The improvement is also not due to the densification of SiO_2 at high temperature since the argon anneal at the same temperature did not improve breakdown characteristics. It is possible that some kind of stoichiometric change in plasma oxide takes place during annealing in oxygen. One aspect of our experimental technique which is suspect is the use of liquid nitrogen baffled mechanical pumping to maintain desired pressures during oxidation. This is accompanied unavoidably by oil back streaming which may incorporate carbon into the oxide films. The oxygen treatment may remove these defects.

In order to establish the presence or absence of oxidation-induced stacking faults and other defects, about 400 nm of plasma SiO_2 were grown on a silicon wafer, the oxide was subsequently stripped in BHF and the silicon surface was etched in Wright etch for 40 sec. The etched silicon surface was then examined using optical microscopy. No oxidation-induced stacking faults or other defects were observed. Plasma oxidation thus has definite advantages over thermal oxidation from the defect and bird's beak elimination point of view, both of which advantages arise because of the lower oxidation temperatures employed.

Conclusions

From the experimental results described in this paper, we can conclude that oxide formation in an oxygen plasma in the pressure range above 10 mTorr is solely due to silicon oxidation. The process of oxidation involves placing the wafer surface to be oxidized facing away from the plasma, close to the plasma generation region, and perpendicular to the direction of gas flow. The oxide thickness grown in a fixed time experiment increases with increasing power, temperature, frequency of the applied field, and decreases with increasing pressure and distance of the wafer from the plasma. Oxide thickness was found to be independent of the resistivity and crystallographic orientation of the wafer. The growth rate and properties of SiO_2 grown in an oxygen plasma at 500°C were comparable to thermal SiO_2 grown at 1000°-1100°C. Low fixed charge and interface-state densities were obtained following only a low temperature postmetallization anneal. Following a short postoxidation anneal in argon or oxygen, these values improved further by a factor of three. Breakdown strength improved considerably following a brief postoxidation heat-treatment at 1000°C in dry O_2, but not in argon. Bird's beak and oxidation-induced defects were both found to be absent in plasma grown oxides.

Preparation and Electrical Properties of V_2O_3 Single Crystals of Controlled Stoichiometry

S. A. Shivashankar,[1] R. Aragón,[2] H. R. Harrison, C. J. Sandberg, and J. M. Honig

Purdue University, West Lafayette, Indiana 47907

ABSTRACT

V_2O_3 crystals have been grown by the skull-melting technique and subsequently annealed in CO_2/CO atmosphere to produce crystals of controlled stoichiometry. Crystals were characterized by x-ray Laue back-reflection photography, lattice parameter refinement, polarized reflected light microscopy, neutron and gamma ray diffraction, and thermogravimetric analysis. Deviations from strict stoichiometry, $V_{2-y}O_3$, were found to follow the relation $y \sim f_{O_2}{}^{3/4}$ in the dependence on oxygen fugacity. The dependence of electrical resistivity on temperature was measured for two different samples, and the variation of the temperature of metal-insulator transition with sample composition was determined.

As is by now well recognized, V_2O_3 and its dilute alloys with other transition metal sesquioxides undergo a variety of spectacular metal-insulator transitions, which can be drastically altered by small changes in sample composition. Approximately 400 publications have been catalogued by us which deal with various aspects of this problem. It has also been known for some time that small departures from the 3/2 ratio of oxygen/vanadium considerably affect the physical properties of V_2O_3 or its alloys. While there is general agreement concerning the overall effects, various workers in the field differ from each other in their detailed findings. This points up the need for a method that permits precise control to be achieved over the exact oxygen stoichiometry. The object of the present publication is to report on progress in this particular area.

Key words: electrical properties of V_2O_3, preparation of V_2O_3 single crystals, annealing procedures for V_2O_3.

A variety of techniques have been used to obtain samples of nonstoichiometric vanadium sesquioxides; these may be briefly summarized as follows: For polycrystalline samples, treatment of V_2O_5 or of other vanadium oxides in CO_2/H_2 or CO_2/CO mixtures at high temperatures (1-3), generation of ceramic sintered bodies by reaction of V_2O_3 with a small quantity of V_2O_5 or of VO in evacuated quartz ampuls (4-8), reduction of VO_2 whiskers under a variety of low partial pressures of oxygen at 1500°C (9); for growth of single crystals, use of $TeCl_4$ or HCl as a chemical transport agent in a gradient furnace (5, 8, 10-12), and growth of bulk single crystals by the Verneuil flame-fusion technique (13, 14), utilizing different H_2/O_2 ratios, and by the Reed tri-arc technique (15, 16).

Physical investigations carried out on the resulting ceramic specimens include phase equilibria studies (1, 3, 4, 15, 17), heat capacity measurements at ordinary temperatures (9) and in the cryogenic temperature range (10), lattice parameter determinations by x-ray diffraction techniques (2, 5, 8, 11), magnetic susceptibility investigations (2, 4, 6, 8, 14), electrical resistivity

measurements (4, 5, 8, 11-14), Seebeck coefficient studies (13), optical measurements (9), electron microscope imaging (12), NMR and Mössbauer techniques (7, 8), and inelastic neutron spin-flip scattering investigations (7).

Growth of Single Crystals

The common deficiency in most of the techniques for growing single crystals is the lack of adequate control over the ambient. This is manifested in a recent investigation on V_2O_3 single crystals grown in this laboratory either by the Reed tri-arc technique (15, 16) or by CVT, using $TeCl_4$ as the transporting agent (16). With the aid of polarized reflected light microscopy Aragón (18) has demonstrated the occasional presence of higher oxide phase domains in these V_2O_3 single crystals, even though they appear to be single phase and homogeneous in x-ray diffraction patterns. To remedy this problem, and to obtain a homogeneous sample of precisely defined stoichiometry, thin slices cut from single crystalline boules were annealed in a variety of different CO_2/CO buffering atmospheres. By altering the CO_2/CO ratio one may precisely control the equilibrium fugacity of oxygen, f_{O_2}, and thereby achieve the variations in oxygen stoichiometry discussed below.

Single crystals of V_2O_3 were grown in a skull-melting apparatus; the principles, techniques, and operating procedures have been repeatedly described elsewhere (19-26). Provision was made for operation in a vacuum/gas chamber (volume $\sim$ 125 liters) for control of the ambient (25, 26). The charge for each skull-melter run consisted of approximately 500g of V_2O_3 powder obtained by reducing 99.9% Cerac/Pure V_2O_5 (placed in alumina boats) in flowing hydrogen at 1000°C for 10 hr. Traces of water present in the hydrogen used for reduction were removed by passing the gas over copper mesh at 0°C. A susceptor is required to initiate the melting of the V_2O_3 powder in the skull melter; it was found that a relatively small polycrystalline piece (10-20g) of previously produced V_2O_3 served this purpose very well. Two separate runs with CO_2/CO mixtures in the ratio of 25/75 were carried out, employing gas flow rates in the range 5-10 l/min at different stages of the melting process. Although these experiments had to be terminated early because of technical difficulties arising from the high electrical conductivity of V_2O_3 at elevated temperatures, single crystals as large as $10 \times 6 \times 5$ mm^3 were nevertheless obtained in the center of the boules. These crystals were singularly free of voids and cracks that often blemish V_2O_3 crystals grown by the tri-arc (Czochralski) technique. This material then served as the starting point for the annealing process described below.

Subsolidus Annealing Procedures

Specimens grown by the above process were annealed under controlled CO_2/CO atmospheres at temperatures below their melting point. Figure 1 provides information on the stability range of the various vanadium oxides; the upper part of this phase diagram is taken from the compilation by Okinaka *et al.* (27) of experimental results published by Katsura and coworkers (1, 3). The V_2O_3/VO/V boundaries were calculated by us from data on the free energies of formation collected by Reed (28). As the data incorporated in the phase diagram (Fig. 1) are taken from different sources, the phase boundaries as indicated are not considered to be precise. Included in this diagram is a set of well-calibrated f_{O_2} values corresponding to a variety of different CO_2/CO mixtures, as specified by Deines *et al.* (29). It is seen that as one lowers the ratio $r \equiv CO_2/(CO_2 + CO)$, the volume percentage of CO_2 in the mixture, from approximately 90% to about 5%, one should be able to generate V_2O_3 compositions bordering from the most oxygen-rich to the most oxygen-poor.

Most of the annealing runs were carried out at 1200°C in a horizontal resistance furnace 60 cm in length, under a typical gas flow of 20-50 cm/min. Provision was made for rapid quenching of the specimens at the end of the run in the controlled atmosphere. Gas flow was carefully regulated by utilizing two-stage regulators on the gas cylinders. The desired CO_2/CO ratio and mixing of the gases was achieved with a Matheson 7372 gas proportioner equipped with precision NRS flow-control valves. V_2O_3 single crystals, cut into thin plates by use of a low-speed diamond wheel saw, were placed in a silica tube plugged loosely with silica wool. Silica wool by its baffling action aids the equilibration of the sample with the flowing gas mixture. Calculations (30) based on estimated cation diffusion rate constants for Al_2O_3, Cr_2O_3, and Fe_2O_3 (31) showed that annealing times of $\sim$75-100 hr should suffice to generate a uniform oxygen stoichiometry in plates of 300 micron thickness of V_2O_3 at 1200°C. Annealing times of 75 hr were generally used.

A few runs were also carried out in a vertical resistance furnace at 1400°C; however, because of large temperature gradients and fluctuations the annealing conditions could not be regulated as closely.

Several annealing experiments were also carried out with solid buffers: VO/V_2O_3, Fe/FeO, FeO/Fe_3O_4, and Ni/NiO, corresponding to values of $\log f_{O_2}$ (atm) $=$ -21.4, -14.8, -12.3, and -10.1, respectively at 1000°C (32). Specimens to be annealed were cut into plates approximately 250 microns in thickness and placed in a silica tube with roughly five times their weight of the solid buffer mixture. The tube was then evacuated, sealed, and placed in a furnace at 1000°C for 100 hr, and finally quenched to room temperature.

Characterization

Samples were characterized by several different techniques.

X-ray Laue back-reflection photography.—Laue photography was used primarily to confirm that the dominant phase present in the annealed single crystals was the corundum V_2O_3 phase. At 1200°C the corundum phase covers the range $-7.7 \gtrsim \log f_{O_2} \gtrsim -14.7$ (nominal).

X-ray lattice parameter refinement.—Lattice parameters of annealed single crystals were determined and refined with an ENRAF NONIUS CAD-4 diffractometer, controlled by a PDP-8/e minicomputer. Molybdenum $K\alpha_1$ and $K\alpha_2$ radiation was used, with a graphite monochromator in the detector arm. Within the detection limit of roughly 2-5%, no extraneous phases were found in single crystals annealed under the conditions specified above.

Polarized reflected light microscopy.—Annealed single crystals were examined by polarized reflected light microscopy which is a sensitive technique for detecting extraneous phases. Samples annealed in the solid-solid buffer mixtures mentioned above showed evidence of phase segregation. By contrast, samples annealed under CO_2/CO proved to be consistently monophasic in the range $-7.7 \gtrsim \log f_{O_2} \gtrsim -14.7$ (nominal, 1200°C). All electrical measurements were carried out on single crystals annealed in these gaseous buffered atmospheres.

Neutron and gamma ray diffraction.—Skull-melter V_2O_3 crystals annealed in CO_2/CO have recently been examined by neutron and gamma ray diffraction (33). Compared to unannealed V_2O_3 grown by the tri-arc technique, these samples showed very much narrower and taller diffraction peaks. The annealed samples also proved to be of very homogeneous composition.

Thermogravimetric analysis.—The oxygen content of the samples annealed at various oxygen partial pressures was determined by thermogravimetric tech-

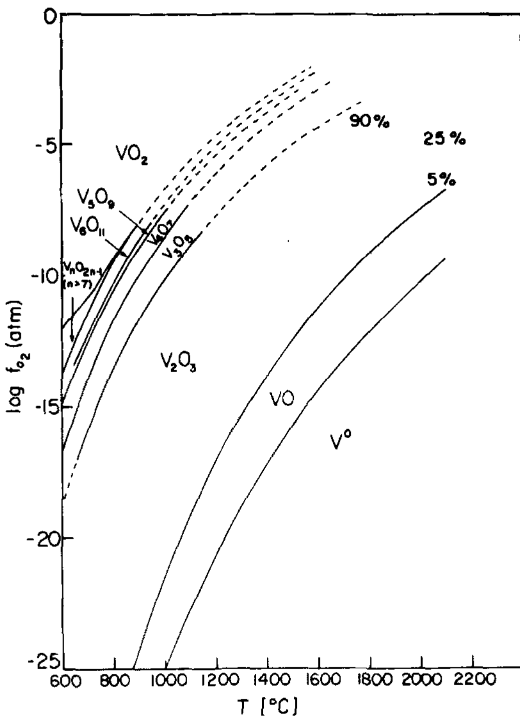

Fig. 1. Stability diagram of part of the V-O system in log f_{O_2}-temperature representation. Solid lines (with dashed extrapolations) are phase boundaries; dotted lines, CO_2/CO gas mixtures; numbers are volume percentages of CO_2, i.e., $CO_2/(CO + CO_2)$. Note melting point of V_2O_3 = 1967°C.

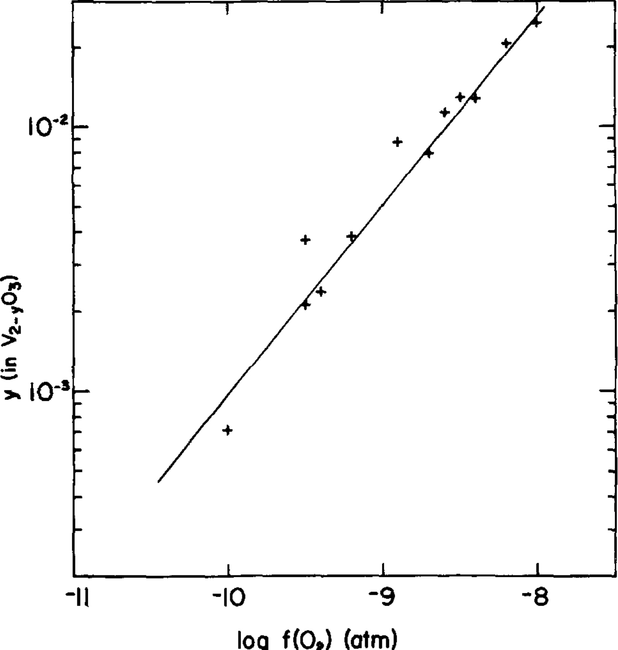

Fig. 2. Deviation from stoichiometry (y in $V_{2-y}O_3$) as a function of log f_{O_2} for V_2O_3 at 1200°C.

niques. A single crystal weighing approximately 200 mg was annealed at a series of different f_{O_2} in the range $-8.0 \gtrsim \log f_{O_2} \gtrsim -12.0$ at 1200°C for 80 hr, quenched at the end of each annealing run, and weighed with a precision of ± 1 μg. As a final step, the sample was annealed at a value of log $f_{O_2} = -11.0$ at 1200°C and reweighed; this is thought to correspond to the condition required to achieve stoichiometry (1). The sample was then oxidized in pure oxygen to V_2O_5 at 670°C in a du Pont 951 Thermogravimetric Analyzer. This instrument is capable of 0.4% accuracy in differential weight measurements. It was thus determined for the sample annealed at log $f_{O_2} = -11.0$ at 1200°C that the final composition was given by $V_{2-y}O_3$, with $y < 0.001$. From the mass determinations at the different f_{O_2} values it was possible to establish a correspondence between composition and equilibrium oxygen fugacity at a given temperature.

The results so obtained are shown in Fig. 2 as a plot of log y (in $V_{2-y}O_3$) *vs.* log f_{O_2} (oxygen fugacity) at 1200°C; least-squares fitting of the data yields a straight line with a slope of 0.74. This power law may be understood in terms of the simple point defect scheme (34)

$$V^{3+} + \frac{1}{4}O_2 = \frac{1}{3}V_V{}^x + V^{4+} + \frac{1}{2}O^{2-}$$

where, in the Kröger-Vink notation, $V_V{}^x$ denotes a neutral vanadium vacancy. This scheme predicts an equilibrium vacancy concentration

$$[V_V{}^x] = K(T)\,\frac{[V^{3+}]}{[V^{4+}]}\,f_{O_2}{}^{3/4}$$

where $K(T)$ is the equilibrium constant and concentrations are taken to be equivalent to the corresponding activities. This is equivalent to the observed relation $y \sim f_{O_2}{}^{3/4}$ (34, 35).

Electrical Measurements

We conclude with a brief report on the variation of the electrical properties of $V_{2-y}O_3$ with increasing y, prepared as described above. Figure 3 shows the variation of the electrical resistivity ρ with temperature T for samples with y = 0.0 and 0.017, displaying the sharp, first-order transition from metallic (M) to the antiferromagnetic insulating (AFI) phase. While the progressive lowering of the transition temperature (T_t) in $V_{2-y}O_3$ with increasing y has been previously reported (4, 8), new features emerge from the present investigation. Transition temperatures as low as 14 K have been observed, in contrast to the previously lowest transition temperature of ~50 K reported earlier

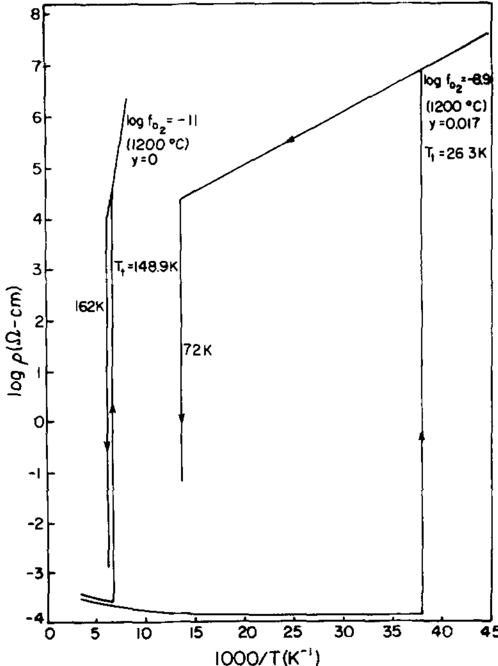

Fig. 3. Metal-insulator transition in $V_{2-y}O_3$ for single crystals of widely different stoichiometry, log ρ vs. 1/T. (a) y = 0.0, T_t = 152 K; (b) y = 0.017; T_t = 26 K.

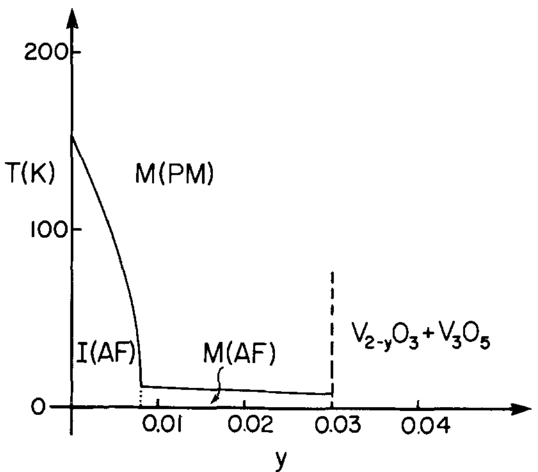

Fig. 4. Phase diagram for $V_{2-y}O_3$, T_t vs. y. M(PM) = metal (paramagnetic), M(AF) = metal (antiferromagnetic), I(AF) = insulator (antiferromagnetic).

(8). The resistivity discontinuity remains large for all y; indeed $\Delta\rho$ increases from about 10^8 Ω-cm at $y = 0$ ($T_t = 152$ K) to about 10^{12} Ω-cm at $y \simeq 0.017$ ($T_t = 14.0$ K). At the same time the hysteresis in the transition temperature (ΔT_t) increases from 12 to 63 K. Earlier studies showed constant values of $\Delta\rho$ and ΔT_t independent of the deviation from stoichiometry (8).

Figure 4 shows a phase diagram for $V_{2-y}O_3$ based on electrical resistivity measurements. This provides a modification of the phase diagram given by Ueda *et al.* (8), by extending the M-AFI boundary to ~11 K for $y \simeq 0.017$. T_t declines at first rather slowly with increasing y, until a range approaching $y \simeq 0.014$ is reached; there is then a precipitous decline in T_t with further departures from strict stoichiometry. The M-AFI transition disappears altogether at a critical value of $y \simeq 0.018$; for greater departures from the 3/2 ratio of O/V, the material remains metallic at all temperatures and undergoes antiferromagnetic ordering below 11 K. This AF ordering, investigated earlier by Ueda *et al.* (6) through Mössbauer studies, was confirmed in our present studies by the observations of anomalous behavior of electrical resistivity near the magnetic ordering temperature. A more detailed discussion of these findings will be provided elsewhere.

p-Type NiO as a Photoelectrolysis Cathode

F. P. Koffyberg* and F. A. Benko

Department of Physics, Brock University, St. Catharines, Ontario L2S 3A1, Canada

ABSTRACT

From an experimental study of p-type $Ni_{0.98}Li_{0.02}O$ as a cathode for the photoelectrolysis of water, we have determined its flatband potential [+0.1V (SCE) at a pH of 9.2] and its bandgap (3.47 eV, indirect). The electron affinity of NiO is only 1.4 eV, which is unusually small compared to most other oxides; this is due to the valence band being mainly nickel-3d type instead of the usual oxygen-2p type. The relevance of 3d valence bands to the performance of semiconducting photoelectrodes is discussed.

The photoelectrolysis of water using semiconducting electrodes has been the subject of intensive research recently (1, 2). For solar applications, electrode materials must have the following properties (apart from being good conductors): (*i*) A bandgap larger than 1.23 eV but smaller than 3 eV; (*ii*) a flatband potential which is sufficiently negative (for n-type photoanodes) or positive (for p-type photocathodes) so that a depletion layer of the proper sign is formed without the need for an external bias, and (*iii*) excellent chemical stability, both in the dark and under illumination. The last requirement limits the field of possible materials to oxide semiconductors. Nearly all oxide materials investigated so far have been n-type.

Stoichiometric NiO is an insulator, but it can be doped with lithium to give a good conducting p-type material. The conductivity mechanism has been a subject of some controversy, but an exhaustive review (3) of experimental data shows that the free holes move, with low mobility, in a narrow valence band made up mainly of 3d-type wavefunctions originating from the Ni^{2+} ions. Because of the low mobility, heavy doping is necessary to achieve acceptable conductivity; this, in turn, will produce narrow depletion layer widths so that the efficiency of an NiO photocathode is expected (and found) to be low. However, since both flatband potential (4) and bandgap data (5) are available, we thought it worthwhile to measure the properties of NiO as a photocathode.

In this paper we report the photocurrent-potential characteristics and the spectral quantum efficiency of $Ni_{0.98}Li_{0.02}O$. From the data we obtain the flatband potential and bandgap, which are in good agreement with the literature values. We then calculate the electron affinity of NiO, which is much smaller than the values reported for most other oxides; we propose tnat this is due to the d-type valence band. Finally, the implications of our results for the search for suitable solar photoanodes are discussed.

Experimental

Polycrystalline samples of $Ni_{0.98}Li_{0.02}O$ and $Ni_{0.95}Li_{0.05}O$ were prepared by thoroughly grinding NiO powder (Fischer Reagent Grade) moistened with the appropriate quantity of $LiNO_3$ solution. After drying, disks (area 1.2 cm^2, thickness 0.1 cm) were pressed and subsequently fired at 1000°C for 12 hr in air. The disks were then reground, re-pressed, and finally fired for 24 hr at 1450°C, during the final firing the disks were embedded in NiO(Li) powder to prevent lithium loss by evaporation. Disks so prepared had reproducible and stable photoelectrolytic properties. If the final firing was done at a lower temperature, then photocurrents slowly decreased in time; we ascribe this to lithium leaching. Qualitatively the polycrystalline samples with 2 and 5% Li, and a single crystal sample with 0.2% Li, showed the same behavior; the 2% Li samples (with a resistivity of 9 ± 1 Ωcm) showed the largest photocurrents, and all data reported are for this composition.

Experiments were performed in a one-compartment cell; solutions (from reagent-grade materials) were flushed continuously with hydrogen or oxygen. The counterelectrode was 7 cm^2 of platinized Pt. All potentials are with respect to SCE; measurements were made potentiostatically. Photocurrent measurements were made with pulsed light from a 150W xenon arc (0.81 W/cm^2 intensity at the sample); the time dependence was recorded with a digital storage oscilloscope. For the quantum efficiency (η) measurements the monochromatic light pulses were shaped such that only the instantaneous photocurrents were measured with a lock-in amplifier. For a given sample the η values were reproducible to ±3%, but variations of ±20% were found between different samples.

Results

On exposing the sample, in hydrogen-flushed 0.1M Na_2HPO_4 solution, pH = 9.2, to "white" xenon arc light the cell current increased within one msec to a maximum value; it then decayed relatively slowly to a smaller steady-state value. We define (Fig. 1) i_m as the instantaneous photocurrent and i_s as the steady-state photocurrent, both corrected for the dark current i_d. These currents are shown in Fig. 2 as a function of sample potential. This general behavior was observed in 0.1M phosphate solutions ranging in pH from 1 to 12, in 0.2M solutions of Na_2SO_3, Na_2HPO_3, Na_2CO_3, and in 0.01M KOH. Changing the counter-

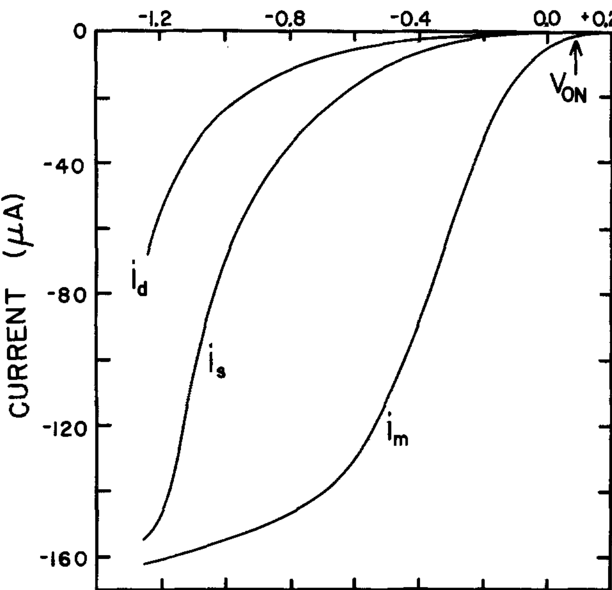

Fig. 2. The instantaneous photocurrent i_m, the steady-state photocurrent i_s, and the dark current i_d of $Ni_{0.98}Li_{0.02}O$ as a function of sample potential V(SCE). Electrolyte: 0.1M Na_2HPO_4, $pH = 9.2$, H_2 flushed.

electrode from Pt to metallic $La_{0.9}Sr_{0.1}CoO_3$ made no difference. Only in 0.01M KOH solutions flushed with oxygen was i_s much larger, approximately 90% of i_m in the potential range of 0 to -1.0V. In phosphate solutions the onset potential V_{ON}, defined where i_m equals 1 μA (Fig. 2) was equal to $+0.07 \pm 0.05$V (SCE) at $pH = 9.2$; it shifted regularly 0.056 ± 0.005 V/pH unit more positive with decreasing pH. The quantum efficiency η (defined as the ratio of the instantaneous photocurrent density and the incident photon flux) is shown as a function of the photon energy ($h\nu$) in Fig. 3. η is proportional to the optical absorption coefficient α if the depletion layer width and the minority carrier diffusion length are both smaller than α^{-1} (6); these conditions are met in our heavily doped samples. Then the bandgap E_g can be determined from a linear plot of $(\eta h\nu)^{1/n}$ *vs.* $(h\nu)$; the most linear plot was obtained with $n = 2$ (Fig. 4), indicating that the optical transition from the valence to the conduction band is indirectly allowed. E_g was found to be equal to 3.47 ± 0.04 eV (average for five samples).

Discussion

The value of the bandgap for NiO found by us is at the lower end of the range (3.4-3.7 eV) of values determined from absorption measurements (5). The spread in the reported values for E_g is probably due to the existence of strong crystal field absorption and lithium-induced optical absorption in the visible, which overlaps the bandgap absorption (7). These complications are unimportant for the photoelectrolysis experiment, which is sensitive only to that part of the overall absorption spectrum in which electron-hole pairs are produced by photon absorption.

At least two reactions are possible at the NiO cathode: hydrogen generation by photoelectrolysis and reduction of NiO according to $NiO + H_2O + 2e^- \rightarrow Ni + 2\,OH^-$. The decomposition potential for the latter reaction is -0.62V (SCE) at $pH = 9.2$; the rapid rise in the dark current i_d for sample potentials less than -0.9V (Fig. 2) suggest that there the NiO reduction contributes substantially to the cell current. However, in the potential range -0.9 to $+0.1$V the instantaneous photocurrent i_m is large with respect to i_d; we assume that here the dominant reaction is photoelectrolysis.

The rapid rise in the photocurrent, on exposing the sample to light, and its subsequent slow decay to a lower steady-state value have been observed previously for the n-type photoanodes TiO_2 and Fe_2O_3. Hardee and Bard (8) have proposed the following explanation for this behavior: On exposure to light an intermediate electrolysis product is formed by a fast forward (cathodic) reaction; this intermediate is unstable at the applied electrode potential and is subsequently re-oxidized in a slower back-reaction. The back-reaction slows down with increasing cathodic potential, so that at sufficiently negative potential i_s will be equal to i_m. This explanation may be valid for p-type NiO as well, but our experimental

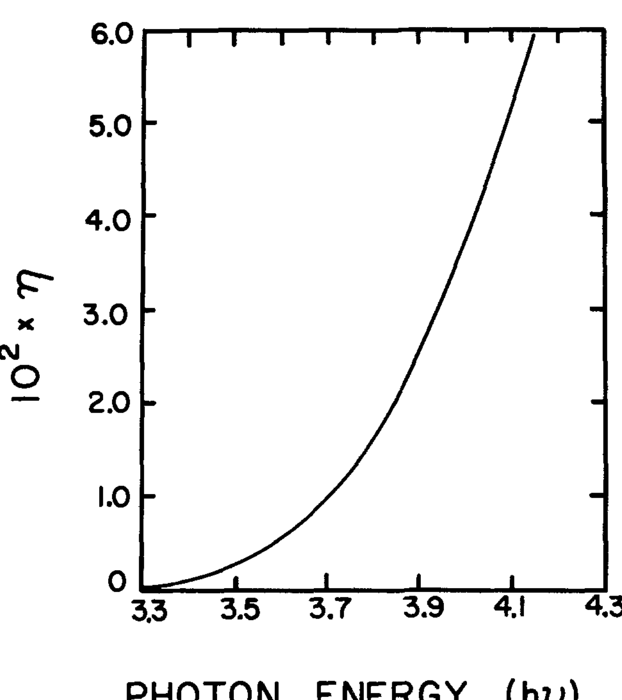

Fig. 3. The quantum efficiency η as a function of photon energy $h\nu$, at an electrode potential of -0.7V (SCE).

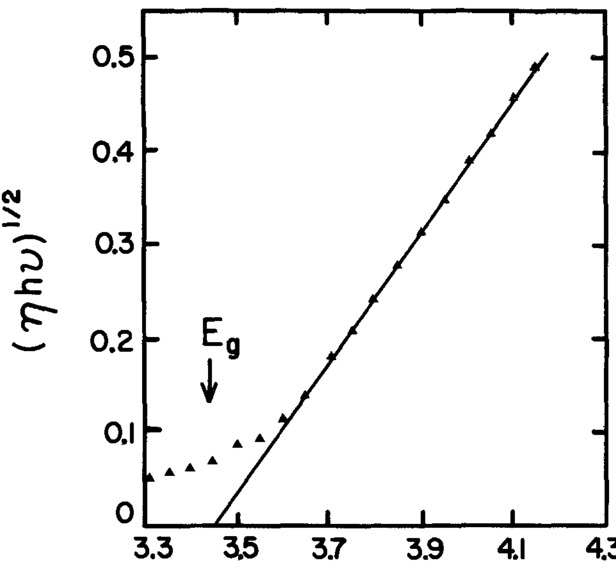

Fig. 4. Determination of the bandgap E_g for $Ni_{0.98}Li_{0.02}O$ from a plot of $(\eta h\nu)^{1/2}$ *vs.* $h\nu$.

results give no indication of the nature of the intermediate species. However, the i_m *vs.* V curve (Fig. 2) has the characteristic shape of a photoelectrolysis curve, and we take the flatband potential V_{FB} of NiO equal to or slightly more positive than the onset potential V_{ON}. At $pH = 9.2$, V_{FB} is therefore $+ 0.1 \pm 0.05$V (SCE).

A possible objection can be raised against this identification of V_{FB} with V_{ON}, since in some p-type materials [$LuRhO_3$ (9), GaP (10)] V_{ON} is not identical to V_{FB}. The clearest case is p-GaP, where V_{ON} is 0.7V more negative than the V_{FB} determined from a Mott-Schottky plot of the differential capacitance. This is due to the presence of an active electron-hole recombination center situated 0.7 eV above the valence band; evidence for this is a small maximum in the quantum efficiency spectrum at a photon energy 0.7 eV less than the bandgap energy. We consider it very improbable that a similar situation exists for NiO, for the following reasons. First, a careful search for a small maximum in η at photon energies less than E_g was a failure. Secondly, our V_{FB} value, extrapolated from $pH = 9.2$ to $pH = 1$ by 0.059 mV/pH unit, is $+0.58$V; this is very close to the value ($+0.64$V SCE) found previously (4) from a Mott-Schottky plot. Therefore we take $V_{FB} = +0.1$V at $pH = 9.2$.

We can now calculate the electron affinity EA of NiO from the relation (10)

$$EA = eV_{FB} - E_g + e\Delta E_F + eV_H + 4.74 \qquad [1]$$

Here ΔE_F is the energy difference between the Fermi level and the top of the valence band, and V_H is the potential drop in the Helmholtz layer due to absorbed H^+/OH^- ions; we take the SCE level 4.74 eV below vacuum (Fig. 5). ΔE_F, calculated (3) from the hole concentration and the hole effective mass ($6\ m_o$) is less than 0.1 eV for our samples, and can be neglected. In general V_H is pH dependent according to $V_H = 0.059$ (pH-P_o) where P_o is the pH of zero charge for the NiO-solution interface. From electrophoresis experiments (11) P_o has been estimated as 10.2 for NiO, with a probable accuracy of one pH unit. At $pH = 9.2$, V_H is therefore unlikely to be larger than 0.1V, and it can be neglected as well. Taking all uncertainties into account, we find therefore $EA = 1.4 \pm 0.2$ eV (Fig. 5).

In NiO the valence band is therefore located 4.9 eV below the vacuum level; for most other oxides the valence band lies 7.0-7.5 eV below vacuum (12, 13). This is due to the fact that in NiO the valence band is made up mainly from Ni-3d type wave functions (3), instead of O-2p wave functions as for most other oxides. Photoemission experiments (14) indeed show a p-bandedge approximately 2 eV below the d-bandedge. The O-2p band is therefore at its usual position of 7 eV below vacuum, but it is not the valence band in NiO.

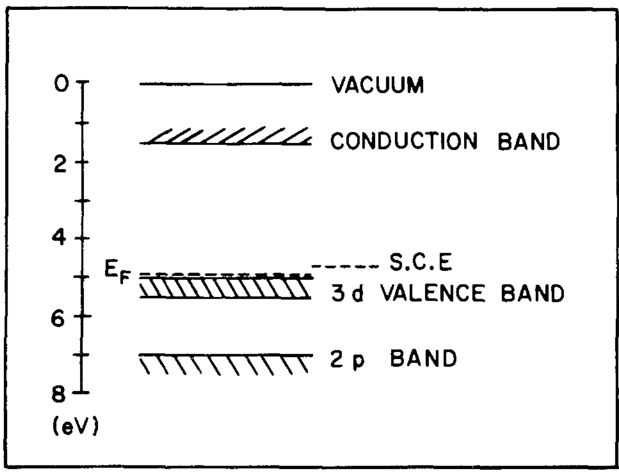

Fig. 5. Energy band scheme for NiO. The width of the 3d valence band is uncertain [Ref. (3)].

Butler and Ginley (15) have proposed a scheme to calculate both P_o and EA for a compound from the electronegativities of the constituent atoms. For NiO such a calculation leads to a predicted P_o of 8.5 (in fairly good agreement with the experimental value of 10.2), and an EA of 4.01 eV, (in contrast with the experimental value of 1.4 eV) which would place the valence band at 7.5 eV below the vacuum level. This is very close to the position of the O-2p band, and it suggests strongly that the predictions from the Butler and Ginley scheme will be correct for oxides with O-2p valence bands, but will be incorrect for materials with d-type valence bands.

It is clear from our results that p-type NiO is not a good photocathode for solar photoelectrolysis; although the spontaneous band bending is sufficiently large (0.8V), its large bandgap and the back-reaction render it unsuitable. However, materials which, like NiO, have $EA + E_g \simeq 5.0$ eV could be good photoanodes if they had n-type conductivity. For the presently known n-type oxide photoanodes the sum of EA and E_g seems to be 7-7.5 eV (12), so that materials with suitably small E_g do not operate spontaneously, but need an external bias to form the depletion layer. Our results show that n-type oxides with a 3d valence band could have the desirable combination of both small E_g and small EA, if the 3d valence band lies at least 2 eV above the O-2p band. Regrettably we cannot test this prediction with NiO, since it cannot be doped n-type.

From the review (2) of the data presently available, it is already clear that not all 3d semiconducting oxides will have suitable valence bands; for example, the oxides containing Fe^{3+} ($3d^5$) and Zn^{2+} ($3d^{10}$) ions have a valence band approximately 7 eV below vacuum. However, photoemission data for Cu_2O ($3d^{10}$) indicate a valence band 5.3 eV below vacuum (16); this value is confirmed by photoelectrolysis experiments on Cu_2O (17). Preliminary experiments by us on CuO ($3d^9$) also indicate a valence band at approximately 5 eV. Therefore, as a speculation, we suggest that oxides based on Cu^+, Cu^{2+}, Ni^{2+}, and possibly Co^{2+}, if they can be made n-type, may be promising materials for bias-free solar photoanodes.

Summary

The flatband potential of p-type NiO, determined from the potential dependence of the instantaneous photocurrent of an NiO/electrolyte/Pt cell, is $+0.1$V (SCE), in good agreement with the literature value; the NiO bandgap, determined from spectral quantum efficiency data, is 3.47 eV. Taken together, these two parameters indicate that the conduction band in NiO lies unusually high, only 1.4 eV below the vacuum level. This, in turn, is due to the fact that the valence band is made up of mainly 3d-type wavefunctions, instead of oxygen-2p type wavefunctions as is the case for the majority of oxides investigated so far. If materials with 3d valence bands can be made n-type, then they offer the possibility of constructing solar photoelectrolysis cells which would operate without an externally applied bias.

Investigations into the Electrochromism of Lutetium and Ytterbium Diphthalocyanines

David Walton, Brian Ely, and George Elliott

Marconi Research Laboratories, Great Baddow, Chelmsford, Essex, England

ABSTRACT

A comparison was made between the infrared, electronic, and electron spin resonance spectroscopic properties of lutetium and ytterbium diphthalocyanines, in the solid state as analytically pure powders, and after vacuum sublimation as thin deposited films. No significant differences were observed. Spectroscopic analysis of the sublimed films during electrochromic changes showed that the lutetium and ytterbium complexes behaved in a similar manner. Both gave identical variations in their electronic spectra with potential. Electron spin resonance data demonstrated that the oxidative color change is not associated with a change in paramagnetism, although the shape of the signal from the lutetium complex was altered upon oxidation. The ytterbium complex displayed no ESR signal before or after electro-oxidation.

Diphthalocyanine complexes of rare-earth elements are of interest in view of their electrochromic properties (1-3). The lutetium complex displays four colors (orange, green, blue, and purple), when an applied potential is varied between $\sim \pm 1.5$V (*vs.* aqueous Ag/AgCl reference) in a suitable electrolytic system. Similar results are obtained whether the complex is deposited as a thin film on an electrode surface (3) or in solution in dimethylformamide (4).

Recent investigations into the electrochromic changes of the Lu complex have concerned the variation in ESR spectrum of solutions in dimethylformamide (4), the charge transport phenomena during oxidation (5-7) and attempts to isolate the oxidized species (8). In this paper we wish to report the results of some electrochemical and spectroscopic studies made on lutetium and ytterbium diphthalocyanines. Comparisons are made between the infrared, visible, and electron spin resonance spectra of the analytically pure solids and sublimed films of the complexes deposited on to conducting glass for electro-optical devices. The voltammetry and the changes in the visible and electron spin resonance spectra of the deposited films during the electrochromic transformations are also investigated.

Experimental

Preparation.—The complexes are prepared by the reaction of the rare-earth acetate salt with excess of phthalonitrile, according to the method of McKay (9).

Key words: electrochromism, rare-earth diphthalocyanines, electronic spectra, electron spin resonance spectra.

The required product was isolated from the mix by extraction into chloroform. Solvent evaporation gave a green powder which was carefully washed with organic solvents (acetic anhydride, methanol, acetone) to remove traces of a persistent impurity.

The residual deep-green powder gave elemental analyses for the empirical formula M Pc_2H where M = Lu, Yb, and Pc = $C_{32}H_{16}N_8$.

Thus:

$LuPc_2H$	theoretical	C, 64.00;	H, 2.77;	N, 18.65%
	found	C, 64.15;	H, 2.79;	N, 18.57%
$YbPc_2H$	theoretical	C, 64.10;	H, 2.77;	N, 18.69%
	found	C, 64.01;	H, 2.79;	N, 18.85%

Yields 30-40%.

This procedure is advantageous since no lengthy chromatographic purification is employed, and the product is obtained in an unsolvated condition. The empirical formula is in agreement with the results of a recent x-ray structural analysis on neodymium diphthalocyanine (10) though the presence of the unique proton has not been established unequivocally, and its role in the bonding of the molecule is not clear.

Film deposition.—15 mg of the powdered diphthalocyanine complex was placed in a silica crucible, 15 cm above which a 50 cm^2 square of commercially available tin-oxide coated conducting glass was positioned. The conducting glass was a standard commercial product,

Nesa glass, of 80-100 Ω/square, supplied by PPG Industries Incorporated, Pittsburgh. The apparatus was evacuated to ~10^{-5} Torr and the crucible heated indirectly to ~450°C. Sublimation of the complex occurred, giving a uniform film, pale green in color, of thickness ~2000Å.

Apparatus.—Infrared spectra were recorded on Pye-Unicam Model SP3-100 spectrometer, and visible spectra on a Hitachi Perkin-Elmer Model 204, all recorded at room temperature. ESR spectra were recorded on a Varian Model E3 spectrometer. Film thicknesses were measured by the interference fringe method on a Reichert Zetopan research microscope.

Electrolyses were performed using a laboratory-built solid-state potentiostat, based on operational amplifier circuits, and operating in a conventional three-electrode mode. The working electrode comprised a slide of tin-oxide coated conducting glass with a working area 2 × 1 cm, upon which the diphthalocyanine complex had been deposited by sublimation. This was suspended in an aqueous electrolyte, containing either 5% Na_2SO_4 or 5% KCl, at *p*H 6-7, degassed with argon. An EIL standard aqueous silver/silver chloride reference electrode was employed in all instances. A suitable counterelectrode was a 1 cm^2 piece of platinum foil.

For cyclic voltammetry, the potential sweep was driven by a Commodore PET personal computer employing a Hewlett Packard 59303A digital to analogue converter working on an IEEE 448 bus through the external input of the potentiostat. Scans could be initiated at any intermediate potential between the preset positive and negative limits, and the potential could be varied linearly between the limits starting in either initial sweep direction. Current/potential curves were recorded on a Philips PM8131 X-Y recorder. Potentials were monitored on a Fluke series 8600A digital multimeter.

Electrolysis procedure.—The duration of electrolysis and the potential required varied with thickness of the diphthalocyanine film. Electrolyses were continued until the color change was complete. Similar results were obtained whether the potential was stepped directly to the final value or progressively varied to this value over a period of several seconds. Typically at +1.5V the initially green-colored film became orange over a period of a few seconds, with the passage of an electric current. The orange species was air stable over several hours. The slide could be removed from the electrolysis cell, washed with distilled water, dried in a stream of nitrogen gas, and placed in a spectrometer. By this means the ESR spectra of the oxidized species were recorded. By returning the slide to the electrolysis cell and maintaining a potential of ~ 0V, the green coloration returned. Reduction at ~ −0.8V gave a blue species. This was not air stable and returned uniformly to green over a period of a few minutes on removing from the cell. Further reduction at ~ −1.3V resulted in the formation of a deep purple coating. This also was unstable in air, and on removal from the cell it reverted uniformly to blue over a period of a few seconds, and then to green in a few minutes. The purple and blue species could also be converted to green within the electrolysis cell, in the absence of air, by the application of a small positive potential. To obtain the visible spectra of the reduced species, the electrolysis was performed in an especially adapted cell with windows of optical glass, placed directly in the beam.

All reagents and chemicals were of analytical grade, purified by conventional methods.

Results

Spectral properties of thin films of diphthalocyanine complexes.—The infrared, visible, and electron spin resonance spectra of sublimed films of the diphthalocyanine complexes were compared with the corresponding spectra of the solid powders and no significant differences were observed.

The infrared spectrum of a lutetium diphthalocyanine film sublimed directly onto a potassium bromide disk is given in Fig. 1. The ytterbium complex gives an almost identical spectrum. The characteristic peaks at 1320 cm^{-1}, 1112 cm^{-1}, and 724 cm^{-1} are observed in the nujol mulls of the powder samples. [The presence of absorptions at 2220 cm^{-1}, 1515 cm^{-1}, 1361 cm^{-1}, 760 cm^{-1}, and 631 cm^{-1} (sharp) in the crude product, obtained directly from chloroform extraction, shows the presence of a persistent impurity, removed by careful solvent washings.]

Comparison with other published infrared spectra shows a very close correspondence in the prominent lines for other rare earth complexes, as shown in Table I, which lists the results of MacKay *et al.* (9), Kirin *et al.* (11), Kirin *et al.* (12), Moskalev and Kirin (13), and Misumi and Kasuga (14). There are some discrepancies, for example, we do not find a line in the region of 1070-1078 cm^{-1}, and it is possible that this only appears in the blue form of the rare-earth complex. Some of the other workers have listed several other minor peaks, which we did not detect in our analysis. It is possible that some of the spectra could indicate the presence of impurities; a particular example is the spectrum published by Corker *et al.* (4), which would indicate a high proportion of the colorless persistent by-product which we found in our crude preparation, and also reported by MacKay *et al.* (9).

The visible spectrum of a green sublimed ytterbium diphthalocyanine film on conducting glass slide is shown in Fig. 2, curve (a), and displays a broad main peak at 668 nm, the half peak width being 55 nm, and a distinctive weak and broad peak at 463 nm. The shape of this spectrum is very similar to that of green solutions of the complex as powder dissolved in a range of organic solvents, though the peaks are narrower in solution. Thus, in chloroform: lutetium complex main peak 660.5 nm ($\epsilon = 1.71 \times 10^5$), half peak width 19 nm, and weak broad peak at 458 nm; ytterbium complex, 661 nm ($\epsilon = 1.59 \times 10^5$) half peak width 19 nm, 457 nm (weak). Solvatochromic effects do not appear to be pronounced in the visible spectra of the green complexes, and the wavelengths of maximum absorption, λ max, of the lutetium (ytterbium) complex in methanol solution is 657 nm (658 nm), and in dimethylsulfoxide solution is 661 nm (661.5 nm).

These solvents span a wide range of dielectric constants (Table II). These results suggest the ground and excited states of the transition to be similar in polarity, unlike, *e.g.*, merocyanine dyes where a change of dielectric produces a considerable shift in wavelength of maximum absorption (20).

The electron spin resonance spectrum of solid, analytically pure, lutetium diphthalocyanine powder at room temperature displays a single resonance at 3390G, the half peak width being 9.7G. This is slightly sharpened by cooling to liquid nitrogen temperatures, but no structure is observed. Similar structureless signals are obtained in chloroform and purified dimethylformamide solutions. The sharp single line at $g \sim 2$ indicates that the unpaired electron is located on the porphyrin ring and not on the metal.

When a sublimed film of lutetium diphthalocyanine on tin-oxide coated glass is suspended in the beam, the same signal is observed, though broader, the half peak width being 22.0G.

Ytterbium diphthalocyanine shows no ESR signal at all, whether in the solid state, in solution, or as a sublimed film.

Electrochemical transformations using cyclic voltammetry.—Figure 3 shows the current/potential curve for a sublimed film of lutetium diphthalocyanine on conducting glass, suspended in 5% aqueous sodium sulfate solution. Potentials are referred to aqueous silver/silver chloride, and the sweep rate was 10 mV/sec.

Curve (a) shows the first full oxidation/reduction cycle, starting with an initially green film at 0V. At +1.5V the color becomes orange and an oxidation current is passed. No reduction current is observed in this region upon scan reversal and the potential is swept to −0.2V before the green color reappears and a reduction current is observed. The shape and definition of these waves depend very much upon the sweep rate, and faster scan rates are unsatisfactory. The green/orange change is color reversible but the difference of ~1.7V between the oxidative and reductive reactions suggests that chemical processes are associated with the electron transfer reactions. Further reduction to −1.0V produces a blue coloration with the passage of a reduction current. Scan reversal produces an oxidation wave at −0.2V with the reappearance of the green color. These results are reproducible over several cycles.

Curve (b) displays the first blue/green reductive cycle, limiting the voltage sweep between 0 and −1.6V, starting from green at 0V, and demonstrates that this change is independent of the orange/green transformation. It is less sensitive to scan rates and good peaks of similar "quasi-reversible" shape are obtained at 140 mV/sec. There is a linear rise of current with scan rate, and a close to linear increase in the peak separation potential within the range of scan rates 10 mV/sec → 140 mV/sec.

Further reduction at potentials beyond −1.6V results in a purple coloration in the film, but an ill-

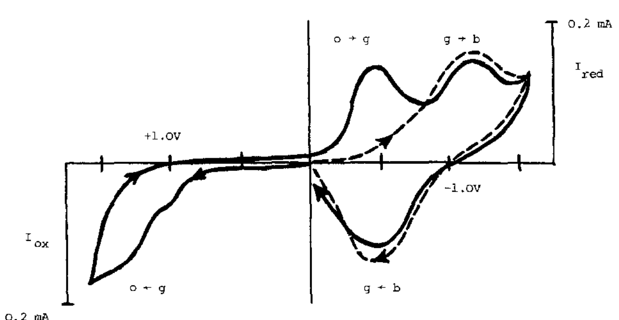

Fig. 3. Lutetium diphthalocyanine as sublimed film on conducting glass. Cyclic voltammetry in 5% aqueous KCl vs. aqueous Ag/AgCl reference, film thickness 2000Å, slide area ~2 cm^2. Scan rate 10 mV/sec, 1st cycle. Letters refer to color changes, g = green, o = orange, b = blue. (a) —— full oxidation reduction cycle: start 0V, initial sweep anodic. (b) - - - reduction cycle only: start 0V, initial sweep cathodic.

defined wave is observed together with current due to solvent breakdown and is not shown in the figure.

The above results are for a film thickness ~ 2000Å. Variations in the film thickness affect the voltammetry, particularly of the green/orange transformation.

Electronic spectra.—Figure 2 shows the visible spectrum of a single film of ytterbium diphthalocyanine sublimed on to conducting glass in (a) the initial green, (b) the oxidized orange, and (c) the reduced blue forms. All spectra were recorded *in situ* in an electrochemical cell fitted with optical glass sides, and the potentials employed were 0V, +1.5V, −0.8V, respectively (*vs.* aqueous Ag/AgCl reference, 5% aqueous KCl electrolyte). The results from the lutetium complex are very similar and the sets of data from both complexes are given in Table III.

These spectral changes are of a similar form to those obtained from electrochemical transformations of a solution of lutetium diphthalocyanine in carefully purified dimethylformamide (4). Purification of the solvent is necessary because green solutions of lutetium and ytterbium diphthalocyanines in dimethylformamide gradually become blue on standing in the absence of an electrode potential. The mechanism of this change is not clear though it has been reported that green solutions of gadolinium diphthalocyanine became blue upon the addition of base (9), and that Russian workers have added hydrazine to solutions of lutetium diphthalocyanine in DMF to improve solubility, giving deep blue solutions (8, 15, 16).

We have established that the addition of triethylamine to green solutions of lutetium and ytterbium diphthalocyanines in dimethylsulfoxide, methanol, acetone, and freshly purified dimethylformamide (vacuum distilled from anhydrous $CuSO_4$), produces an immediate blue coloration. It has not been shown with certainty that this base-produced blue color is due to the same species as that produced by electrochemical reduction. There are similarities in the electronic spectra of both species. The spectrum of the electroreduced blue species is given in curve (c) of Fig. 2. A distinctive twin peak is observed, that at shorter wavelength being more intense than that at long wavelength. A similar shape is observed in basified solutions though in these instances there is some distortion in the shape of the long wavelength peak, and also a weak "shoulder" at ~560 nm that is not present in the spectrum of the electrochemically reduced form. Comparative data for blue species in methanol, acetone, dimethylsulfoxide, and dimethylformamide solutions, compared to the electroreduced blue species as a thin film are given in Table IV. Blue solutions in the above solvents are air stable. Solutions in dimethylformamide have retained their color over several months, and evaporation yields dark crystals which are solvated (12). The electrochemically produced blue coloration in thin solid films is unstable in air, and returns to the green form over a period of a few minutes.

Color changes which parallel the electrochemical color changes can be induced by chemical oxidants and reductants. Figure 4 displays the visible spectra of a film of lutetium diphthalocyanine on a glass slide in (a) initially green form, (b) oxidized to orange after ~1 min in 4% (w/v) aqueous acidified ceric sulfate solution, (c) reduced to blue after ~ 1 min in a mixture of 2% sodium dithionite/2% sodium sulfite solution, (d) purple after 2 min in 4% aqueous sodium dithionite solution. The orange species is air stable but the blue and purple forms revert to green on removal from solution. The spectra were recorded in a cell with optical glass sides using a Grubb-Parsons experimental spectrometer based on a D2 monochromator unit. The data from the chemically reduced blue species are included in Table IV for comparison. The difficulty in arresting the reduction process at the blue stage reflects the difference between chemical reduction and electrochemical reduction, where a precise potential can be applied to achieve maximum effect in a system where species can exist in several oxidation states.

Electron spin resonance.—In the green form lutetium diphthalocyanine has a single ESR absorption [Fig. 5, curve (a) for a thin film on conducting glass]. Upon electro-oxidation at +1.8V in 5% aqueous sodium sulfate (w.r.t. aqueous Ag/AgCl reference) for several minutes, the absorption remains of similar amplitude but has become much sharper [Fig. 5, curve (b)]. The

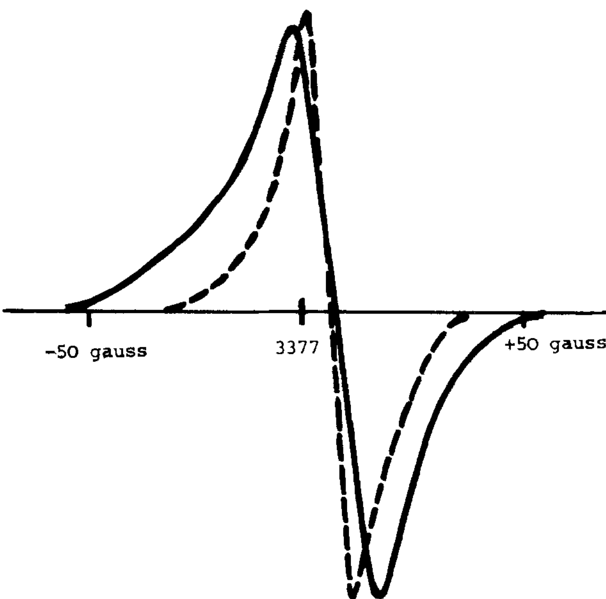

Fig. 5. Lutetium diphthalocyanine as sublimed film on conducting glass. Change of electron spin resonance spectrum with oxidation potential. (a) —— green form (~0V); (b) - - - orange form (~ +1.5V). (Electrolyte 5% aqueous Na_2SO_4, potentials vs. aqueous Ag/AgCl reference. Instrumental conditions: room temperature, modulation amplitude 5G, power 2 mW).

color of the film is orange. The color change is, therefore, not associated with a loss of paramagnetism in the system. If electro-oxidation is continued for 1 hr, a 30% loss in intensity of the sharp signal is observed, but on returning to the green form at 0V, the broader absorption reappears at its full intensity. The slide was removed from the electrochemical cell, washed, and dried before placing in the cavity of the spectrometer at room temperature.

In 5% aqueous KCl electrolyte a more rapid narrowing of the signal is observed, concomitant with the rapid appearance of the orange coloration. Further electrolysis for ~ ½ hr results in the total loss of the sharp signal, but, on returning to the green form at 0V the full intensity of the initial broad absorption is restored.

It seems that exhaustive electrolysis results in a total loss of signal. We have confirmed that this occurs in solutions of lutetium diphthalocyanine that are electro-oxidized in DMF/0.1M tetrabutylammonium tetrafluoroborate, as has been recorded (4), but the color change from green to orange is associated with a sharpening of the signal, not a loss of paramagnetism. This result is supported by the behavior of films of ytterbium diphthalocyanine. This complex is ESR inactive in the green form. It remains inactive after electro-oxidation to orange at +1.8V even after ~ 1 hr of electrolysis, though the color change occurs in less than 1 min. No change of paramagnetism occurs in this system.

Some comparative, but less detailed measurements were made on holmium and europium diphthalocyanines. Solid samples showed ESR signals that, compared with lutetium, were only 0.01 times the value in the case of holmium and 0.1 times the value in the case of europium; the ytterbium signal was virtually zero. Thin films of Ho and Eu did not show sufficiently large signals to enable differences to be observed between the green and orange forms of the complex, the glass substrate giving a small residual signal which masked the small responses due to the rare earth compounds.

Discussion

The observation of ESR signals from both the initially green and the electro-oxidized orange forms of lutetium diphthalocyanine is in accord with the evidence of Nicholson and Pizzarello (5, 6) who measured an approximately two-electron change from charge-transport data during electro-oxidation, employing aqueous sodium sulfate and potassium chloride electrolytes. These results do not necessarily conflict with those of Corker *et al.* (4) who reported that in dimethylformamide solution with tetrabutylammonium tetrafluoroborate support electrolyte, the electro-oxidation to a "yellow-red" species was concomitant with a loss of ESR signal and the removal of one electron, since the experimental conditions were different in this latter instance.

If the electro-oxidation is a multi-stage reaction in which the color change and modification of the ESR signal are distinct from the eventual loss of the ESR signal, then the relative rates of these processes may differ in solution compared to a solid film, particularly if ionic migration (5, 6) as well as electron transfer is important during the transformation. Furthermore, the behavior of lutetium diphthalocyanine in dimethylformamide solution appears to be complicated, and the nature of all species that may be present is not certain. Analytical data published by Kirin *et al.* (12) suggests that a blue product obtained from dimethylformamide solution may have the composition R_2Pc_3 3DMF, where R is the rare-earth atom.

The difference in behavior of the ESR signal in sodium sulfate solution as compared to potassium chloride solution is paralleled by the observations of Nicholson and Pizzarello (18) who also noticed a difference between these electrolytes. They showed that the propagation of the anodic reaction boundary in a thin film of lutetium diphthalocyanine depended on the nature of the ambient gas, and that the boundary ceased to move in sodium sulfate electrolyte if oxygen was excluded, but this was not true in potassium chloride electrolyte. It was concluded that oxygen was bound in the red form of the diphthalocyanine prepared in sodium sulfate electrolyte. Raynor *et al.* (19) have studied the origin of ESR signals in diamagnetic phthalocyanines of Zn, Ni, Pd, and Pt and have suggested that oxygen is the cause of a substantial part of the signal, but is not present as a simple radical with the unpaired electron localized on the oxygen. We conclude that the difference in ESR behavior of the lutetium complex in aqueous sodium sulfate and potassium chloride electrolytes may represent the differential uptake of oxygen following an initial two-electron change to the orange species. However, the existence of the original ESR signals in the green lutetium complex, and the much lower ESR responses from the holmium, europium, and particularly ytterbium complex are not easily explained by this simple model, and further work is required to elucidate the structure of these species.

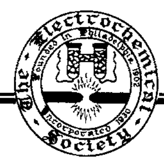
Technical Note



Excitation into Charge Transfer Band of Y_2O_2S:Eu

Lyuji Ozawa*

Matsushita Electric Industrial Company, Limited, Central Research Laboratories, Moriguchi, Osaka, Japan

This note describes the mode of excitation into the charge transfer band of Y_2O_2S:Eu phosphor. In general, the radiative transition impurities (*i.e.*, activator ions) in crystals can be optically excited in three ways; by (*i*) direct excitation into absorption of the ions (direct), (*ii*) excitation into associated activator-host absorption (*i.e.*, charge transfer band, CTB), and (*iii*) indirect excitation via absorption of host lattice (host), *i.e.*, radiative recombination of mobile electron-hole pairs (radiation-induced carriers) at activator ions. This can be seen comprehensively in excitation spectrum giving rise to luminescence. Figure 1 shows, for instance, the excitation spectrum of the Eu^{+3} luminescence line at 627 nm ($^5D_0 \rightarrow {}^7F_2$ transition) of Y_2O_2S:Eu; the spectrum consists of the small and narrow direct excitation lines ($4f^6$ transition), and a broad and strong CTB overlapped partially with a host band (shadowed). It has been believed that the CTB excitation belongs to the host excitation (1) because the CTB partially overlaps with the host absorption band and the hole photoconductivity has been suggested in Y_2O_2S:Eu under the CTB radiation (2). It has then been said that the CTB is an essential necessity to obtain the efficient cathodoluminescence phosphors (3). A question is raised as to whether the CTB belongs to the host excitation.

An experimental difficulty in determining the excitation mode of the CTB is that by either way of the photoexcitations, the activator ions emit the same characteristic activator luminescence even though the excitation mechanisms involved are quite different. Thus, the ambiguity always remains in the discussion of the CTB excitation if the study has been made with the measurements of the luminescence or excitation spectra alone. It has recently been shown that the concentration dependence (CD) curve of activator luminescence provides us with a powerful tool to clarify the excitation mode of activator ions (4). There are two excitation modes to be considered for the luminescence study in the first-order approximation: (*i*) direct excitation and (*ii*) indirect excitation through mobile carriers. The mode of the excitations can be clearly distinguished if the measurements of the CD curves are made on powdered phosphor

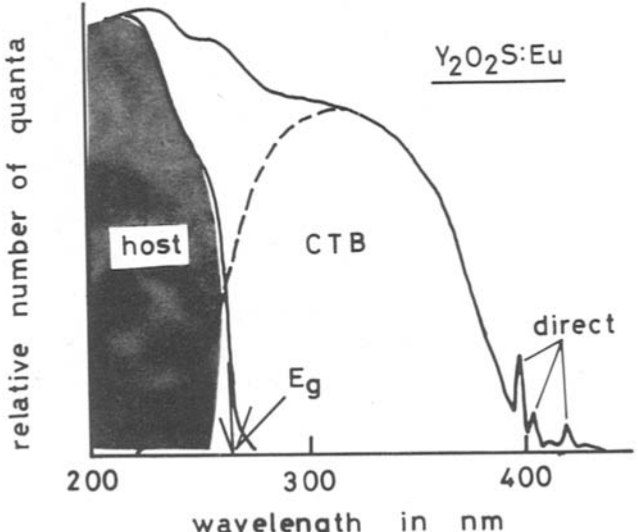


Fig. 1. Excitation spectrum of Y_2O_2S:Eu (0.01) giving rise to luminescence line at 627 nm ($^5D_0 \rightarrow {}^7F_2$ transition). The spectrum consists of host absorption band (host), charge transfer band (CTB), and direct excitation lines of Eu^{+3} (direct).

Key words: luminescence, phosphor.

screens. For direct excitation of activator ions, the time-averaged luminescence intensities from phosphor screen, obtained under constant intensity, has a linear dependence on activator concentration "C" in the concentration region where the concentration quenching mechanisms are neglected, and the normalized CD curve exhibits no crystal size effect (5). When the activator luminescence is due to the radiative recombination of the mobile carriers (created by host lattice absorption) at activator ions, the CD curve has two slopes, depending on C, in which C* at the discontinuity (*i.e.*, inflection of the curve) shows the crystal size effect due to the mobile carriers; C* decreases as the crystal size increases (4-6). We use this distinguishable different appearance in the CD curves to clarify the mode of the CTB excitation of Y_2O_2S:Eu.

Figure 2 shows the CD curves of the Eu^{+3} luminescence line at 627 nm of Y_2O_2S:Eu under irradiation of electron beam (CL), host-photoexcitation using the 200 nm radiation (PL-host), CTB excitation by the 320 nm radiation (PL-CTB), and direct photoexcitation using the 417 nm radiation (PL-direct). We used the 200 nm radiation for the PL-host to keep away from the entanglement of the CTB in the excitation. It can be seen that the CD curve of the PL-host is almost identical with that of CL, because the activator ions in both cases are predominantly excited through the mobile carriers created in the crystal (6). Both curves have two slopes and the value of C* shows the crystal size effect. The normalized curve for the PL-direct fits in with the theoretical curve of $C(1 - C)^{12}$ (unity slope below $C = 1 \times 10^{-2}$ and optimum $C = 8 \times 10^{-2}$) (5) and the curve exhibits no crystal size effect.

Referring the CD curves of the PL-host and PL-direct, it has been revealed that the mode of the CTB excitation actually belongs to the direct excitation. The CD curve for the CTB has unity slope, instead of two slopes, in the region below $C = 3 \times 10^{-3}$ and exhibits no crystal size effect. There is no evidence to show that the luminescence process at the Eu^{+3} is determined by the mobile carriers. The curve obtained clearly indicates that the CTB excitation falls under the category of direct excitation by incident radiation rather than the category through host-lattice excitation

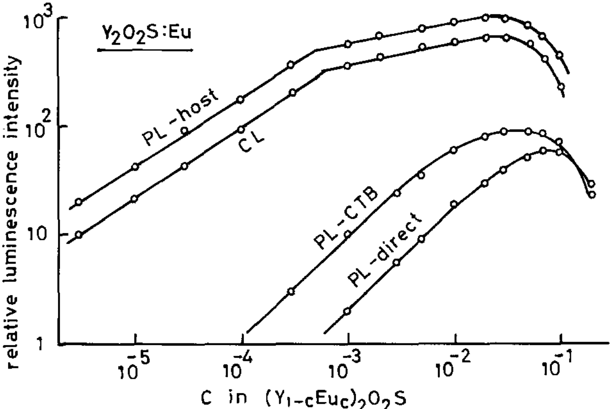

Fig. 2. Concentration dependence curves of Eu^{+3} luminescence of Y_2O_2S:Eu under irradiation of various excitation modes; electron beam (CL), host photoexcitation using 200 nm radiation (PL-host), charge transfer photoexcitation with 320 nm radiation (PL-CTB), and direct photoexcitation using 417 nm radiation (PL-direct).

Irradiation of the CTB radiation of Y_2O_2S:Eu probably creates an Eu^{+2} and a hole as a consequence of the electron (charge) transfer from anion (O^{-2} or S^{--2}) to Eu^{+3}. Since hole photoconductivity has been suggested in Y_2O_2S:Eu under irradiation of the CTB radiation (2), the Eu^{+2} may be stable at room temperature and does not release the electron; the luminescence may occur as the Eu^{+2} captures the the free hole (4). Because Eu ions in the crystal never move out from their occupied lattice sites during the luminescence process, the absorption (and subsequent luminescence) is definitely limited in the volume where the CTB radiation has been penetrated. In other words, the place at which the luminescence occurs is not determined by the free holes which move out from the location created. The penetration of the CTB radiation into the powdered phosphor screen is determined by $(\alpha + \beta)^{-1}$ where α and β are absorption and scattering coefficients, respectively. The value of α changes with C; *i.e.*, $\alpha = kC$ where k is expressed in cm^{-1} and depends only on the oscillator strength of the absorption. When the activator concentration is below 3×10^{-3}, $\alpha << \beta$, and the penetration volume is determined by β^{-1} and the cross section of the radiation beam; both are constant, resulting in the linear dependence of luminescence intensities on C (5). The penetration depth is decreased with increasing activator concentrations beyond 3×10^{-3} ($\alpha \not< \beta$); subsequently, the apparent optimum activator concentration moves to $C = 5 \times 10^{-2}$ (5).

The results of the CD curves suggest that the CTB and host absorption bands possibly occur at different levels, and the partial overlap in the excitation spectrum (Fig. 1) is not real; they are apparently overlapped. If it is so, the band model may be inadequate to explain the luminescence process of the Eu^{+3} in Y_2O_2S:Eu which has been considered (1, 3).

In conclusion, it has been shown that the excitation into the charge transfer band falls under the category of the direct excitation by the incident radiation, which the excitation is restricted in the penetration volume of the incident radiation. Therefore, it can be said that the presence of the charge transfer band is not essential to obtain the efficient cathodoluminescence phosphors. The efficient activator cathodoluminescence is predominantly due to the radiative recombination of the mobile electron-hole pairs at the activator ions, and the number of the electron-hole pairs created in the penetration volume would be about 100 times the number of the direct excitation of the activator ions by the incident electrons.

Manuscript received May 26, 1981.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.

Due to the Canadian postal disruptions, proofs of this article were not received in time for correction. Figure 2 was mislabelled, and should be replaced by the following

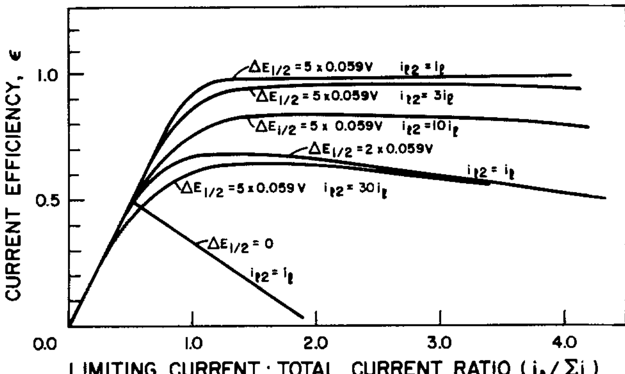

Fig. 2. Current efficiency variation for kinetic parameters characteristic of metal deposition in competition with hydrogen evolution, $(\alpha n)_1 = 2.0$ and $(\alpha n)_2 = 0.5$.

In the discussion of Fig. 1 and 2, case 1 should have stated that efficiency approaches the asymptotic value $\epsilon_\infty = 1$ when the current density is *much less than* the limiting current density, in situations where the transfer coefficient for metal deposition is less than that for the competing reaction.

Before Eq. [3], the requirement for a function describing current density should have read that it must vary in a monotonic fashion from case 1 to case 2, and that

$$\lim_{C \to \infty} \epsilon = \epsilon_\infty \quad \text{and} \quad \lim_{C \to 0} \epsilon = 0$$

In the discussion of Fig. 5, the statement concerning the dependence of current efficiency on $i_l/\Sigma i$ should have noted that it can be approximated by two straight-line portions at concentrations *above* 0.01M.

Determination of the Measurable Low P_{O_2} Limits of Oxygen Ion-Conducting Solid Electrolytes

T. A. Ramanarayanan*

Exxon Research and Engineering Company, Corporate Research-Science Laboratories, Linden, New Jersey 07036

Oxygen ion-conducting solid electrolytes based on ZrO_2 and ThO_2 are widely used for the measurement of oxygen chemical potentials in high temperature gaseous environments, melts and solid phases (1). These electrolytes have also applications in determining the kinetics of diffusion-controlled processes (2) and the rates of surface reactions (3).

In most applications of oxygen-conducting solid electrolytes, the ionic transference number of the electrolyte, t_{ion}, must be unity. At extremely low P_{O_2} values, the ionic transference number of the electrolyte is decreased by the introduction of excess electronic conduction. Thus, especially for low oxygen partial pressure measurements, there is a need to establish the low P_{O_2} limits (above which $t_{ion} > 0.99$) as a function of temperature. Since these low P_{O_2} limits are extremely sensitive to the presence of minute impurity levels in the electrolyte (4), the measurable low P_{O_2} limits can vary between two electrolytes of nearly identical chemical composition.

In the present communication, a simple experiment for the determination of the low P_{O_2} limits of an oxide-ion conducting electrolyte is discussed. The technique has been used for establishing the low P_{O_2} limits of ZrO_2 (∿5% CaO) solid electrolyte tube purchased from Degussa.

The electrochemical cell used in the present experiments may be represented as:

	O^{2-} ←		
⊖ H_2	ZrO_2 (5% CaO)	Air ⊕	[A]
P'_{O_2}	e^- →	P''_{O_2}	

in which the left hand electrode is extremely pure hydrogen. It would be nearly impossible experimentally to obtain a $P_{O_2} = 0$ in the hydrogen electrode. For one thing, even the best purification ensures only a finite extremely low P_{O_2} level. Secondly, a reaction between the H_2 gas and the quartz tube in which the electrochemical cell was placed is possible in principle:

$$SiO_2(s) + H_2 = H_2O + SiO(g) \qquad [1]$$

At a temperature of 1100°K, which is in the middle of the temperature range used in the current study, the equilibrium constant, K_1, for reaction [1] equals 2.05×10^{-16}. Assuming that both H_2O and SiO are generated by reaction [1] only, one can assume that $P_{H2O} \simeq P_{SiO}$. With this assumption, one calculates at 1100°K a P_{H2O} value of 1.43×10^{-8} atm. This amount of water vapor in H_2 would correspond to a P_{O_2} of 3.6×10^{-34} atm, which is extremely low. It is not suggested here that the reaction [1] proceeds to equilibrium, but only that even if it did, the P_{O_2} in the hydrogen stream would be very low.

According to Schmalzried (5,6), the Emf of cell A under these conditions is given by,

$$E = \frac{nRT}{4F} \ln \left[\frac{P_{\oplus}^{1/n} + P'^{\,1/n}_{O_2}}{P_{\oplus}^{1/n} + P''^{\,1/n}_{O_2}} + \frac{P_{\ominus}^{1/n} + P''^{\,1/n}_{O_2}}{P_{\ominus}^{1/n} + P'^{\,1/n}_{O_2}} \right] \qquad [2]$$

where n = 4 for a stabilized zirconia electrolyte, $P_{\oplus}$ and $P_{\ominus}$ refer to the P_{O_2} values at which the ionic conductivity of the electrolyte equals the positive hole conductivity and excess electronic conductivity respectively. As discussed by Schmalzried (5,6), for $P_{\oplus} \gg P''_{O_2} \gg P_{\ominus} \gg P'_{O_2}$, equation [2] reduces to

$$P_{\ominus} = P''_{O_2} \exp(-4\,EF/RT) \qquad [3]$$

Equation [3] applies to cell [A] and the $P_{\ominus}$ values can be determined from the measured open circuit Emf values as a function of

*Electrochemical Society Active Member.

temperature. From the P_θ values, the limiting low P_{O_2} values which can be measured using a ZrO_2 (~5% CaO) Degussa electrolyte can be calculated as follows.

The excess electronic transference number, t_e, of the electrolyte at low oxygen partial pressures is given by,

$$t_e = \frac{\sigma_e}{\sigma_e + \sigma_{ion}} \quad [4]$$

where σ_e and σ_{ion} are the excess electronic conductivity and ionic conductivity, respectively. For stabilized zirconia electrolytes, at a given temperature, σ_{ion} is a constant and $\sigma_e = \sigma_e^o P_{O_2}^{-1/4}$ where σ_e^o is a constant (1). Thus, Eq. [4] can be rewritten in the form,

$$\frac{1}{t_e} = 1 + k\, P_{O_2}^{1/4} \quad [5]$$

where $k = \sigma_{ion}/\sigma_e^o$. By definition, $P_{O_2} = P_\theta$, when $t_e = 0.5$. Upon substitution into Equ. [5],

$$k = (P_\theta)^{-1/4} \quad [6]$$

hence

$$\frac{1}{t_e} = 1 + \left(\frac{P_{O_2}}{P_\theta}\right)^{1/4} \quad [7]$$

If the lowest P_{O_2} value measurable with the ZrO_2-based electrolyte is denoted by $P_{O_2}^L$, then,

$$t_e = 0.01 \text{ for } P_{O_2} = P_{O_2}^L \quad [8]$$

Equation (8) corresponds to the generally agreed ionic transference number of >0.99 for an acceptable solid electrolyte. Upon substitution of Eq. [8] in Eq. [7],

$$P_{O_2}^L = 99^4\, P_\theta \quad [9]$$

The experimental cell arrangement used in the present study is shown in Fig. (1). A degussa ZrO_2 (~5% CaO) solid electrolyte tube (3/8" O.D. x 1/4" I.D.) was platinized over a 1" length on the inside and outside using platinum paste (Engelhard #6082). The paste was thinned with xylene and brushed on to the cleaned solid electrolyte surface. The coated portion was heated gradually to 800°C in a furnace, held at this temperature for one hour and furnace-cooled to room temperature. A series of four coatings was applied in this manner. Platinum lead wires were used to contact the inside and outside Pt paste. A slow stream of dry air was circulated through the inside of the electrolyte tube using a small alumina tube. The electrolyte tube was surrounded by an outer quartz tube. The outer surface of the electrolyte tube was exposed to a stream of high purity hydrogen. High purity hydrogen gas from a gas cylinder was further purified by passing through an Engelhard platinum catalyst (for conversion of any O_2 to H_2O); the water vapor was subsequently absorbed in a series of magnesium perchlorate towers.

The electrochemical cell was heated in a non-inductively wound tube furnace. A grounded Inconel tube was used around the quartz tube to eliminate stray Emfs. The cell was initially heated to a temperature of 750°C (± 1°C). The open circuit Emf developed across the cell was measured using a Hewlett Packard electronic voltmeter. The cell Emfs were observed to increase slightly with the flowrate of H_2; the flowrate dependence vanished beyond a certain flowrate. The actual flowrate where this occurred was not measured since no flowmeter was placed in the system. The flowrate independent Emf was taken to be the correct Emf value. An Emf reading was considered steady if the random variation over a two hour period was within ± 1 mV. Emf readings were taken at 50°C intervals up to 950°C.

The experimentally measured Emf values are shown as a function of temperature in Fig. 2. Shown in Fig. 3 are the P_θ values calculated using Eq. [3]. The temperature dependence of P_θ follows the expression:

$$\log P_\theta = 4.77 - \frac{35{,}130}{T} \quad [10]$$

Fig. 3 also contains the P_θ values reported by Patterson (7) and by Schmalzried (6) for the ZrO_2 (7 1/2% CaO) electrolyte. In Fig. 4, the limiting low P_{O_2} values, $P_{O_2}^L$, obtained using Eq. [9] have been plotted as a function of temperature. The temperature dependence of $P_{O_2}^L$ can be expressed by the relation:

$$\log P_{O_2}^L = 12.75 - \frac{35{,}130}{T} \quad [11]$$

Also shown in Fig. 4 are the limiting P_{O_2} values of the ZrO_2 (7 1/2% CaO) electrolyte according to Patterson (7). In Fig. 4 are

also shown the coexistence P_{O_2} values of two commonly used metal-metal oxide reference electrodes, the Fe-FeO electrode and the Cr-Cr_2O_3 electrode. It is readily seen that the Degussa ZrO_2 (5% CaO) electrolyte can accurately measure the P_{O_2} of the Fe-FeO electrode, but not the Cr-Cr_2O_3 electrode.

There are a few points which must be mentioned in connection with measurements involving cells of the type A. First of all, since the electrolyte exhibits some electronic conduction under conditions involved in measurements with cell A, even under open circuit conditions, there is electronic transport through the electrolyte from the low P_{O_2} side to the high P_{O_2} side. Such transport is accompanied by oxygen ion transport in the opposite direction. It is conceivable that the oxygen arriving at the left hand electrode of cell A by transport through the electrolyte raises the P_{O_2} at the left hand electrode/electrolyte interface locally. This effect should be more serious at low flow rates; at the higher flow rates, the oxygen is rapidly carried away in the hydrogen stream. This would in principle explain why the cell Emf would increase with flow rate in a certain range.

Another effect to be concerned about is the possibility of a chemical reaction between ZrO_2 and Pt at the left hand electrode where conditions are reducing. Meschter and Worrell (8) have determined the Gibbs' energy of formation of the intermetallic compound $ZrPt_3$ using electrochemical measurements involving a ThO_2-Y_2O_3 electrolyte. They have estimated that the reaction,

$$ZrO_2 + 3\ Pt + 2\ H_2 = ZrPt_3 + 2\ H_2O$$

is possible at 800°C at P_{O_2} values below $\sim 10^{-25}$ atm. No $ZrPt_3$ could be detected by X-ray diffraction on the platinized surface of the electrolyte tube after completion of experiments with cell A.

Shores and Rapp (9) have reported on the possibility of proton conduction in ThO_2 base electrolytes in the presence of H_2-H_2O environments. However, no such conduction has been reported for ZrO_2 based electrolytes. Wagner (10) found the solubility of water vapor in ZrO_2 containing 8 or 17% Y_2O_3 in the temperature range, 900°C-1000°C to be extremely small, of the order of 13-30 ppm. Thus, it is assumed in the present study that there is no significant proton conduction in the ZrO_2 (5% CaO) electrolyte.

Direct Observation of Surface States at the TiO_2 Electrolyte Interface

Withana Siripala and Micha Tomkiewicz*

Department of Physics, Brooklyn College of CUNY, Brooklyn, New York 11210

Relaxation Spectrum Analysis was suggested(1) as a general technique for mearsurements of charge accumulation modes and their corresponding relaxation times at the space charge layer of a semiconductor with strong emphasis on semiconductor liquid junction interfaces. Among all the reported results(2-4), none was, as yet, confirmed by an independent technique.

We wish to report here, evaluation of parameters of surface states that were observed on the surface of single crystal TiO_2 in contact with an aqueous electrolyte, using the Relaxation Spectrum Analysis technique and subband gap spectral response.

Fig. 1 shows the impedance spectrum of single crystal TiO_2 in contact with phosphate buffer. For detailed explanation of the experimental technique, the reader is referred to reference (1).

The equivalent circuit was found to consist of two parallel passive capacitive elements with distinctive relaxation times. The dependence of the capacitive elements on the electrode potential is shown in fig. 2. The space charge capacitance C_{sc}, obeys the Mott-Schottky relation over an extended range of potentials, from which the flatband potential and the doping level of the crystal were evaluated. The dependence of C_{ss} on the electrode potential, also shown in fig. 2., is more complex. It is dominated by a single gaussian distribution, centered around 0 V vs SCE. Similar behavior was found with surface states that were introduced on purpose by chemical modification of TiO_2(5-6) and by unmodified TiO_2 under certain surface preperation conditions[2]. The difference between the states observed here and those that were previously reported is that the relaxation times of the surface states in the previously reported examples were all fast and limited by the series resistance of the electrolyte. This resulted in our inability to distinguish the surface state capacitance from the space charge layer capacitance. The surface state capacitance in those reports was evaluated from the deviations of the observed capacitance from the expected Mott-Schottky behavior. In the present case the states are much slower and their relaxation time clearly distinguishable from that of the space charge layer. The possible origin of the gaussian distribution of the surface states was previously reported(5-6). From the maximum amplitude of the gaussian distribution coverage of $1.8 \times 10^{13}/\ cm^3$ was

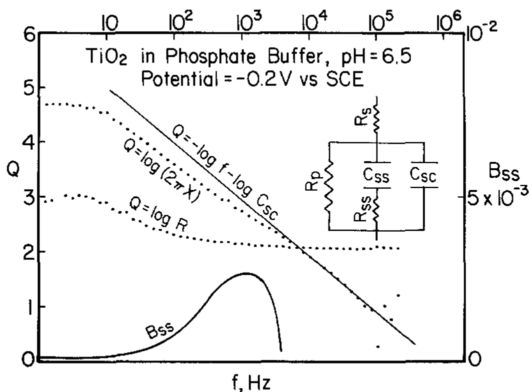

Fig. 1. Impedance response curves for n-type TiO_2 in 0.33 m phosphate buffer. On the right-hand corner is the equivalent circuit constructed from the curves in the manner explained on ref. (1). Area = 0.07 cm^2.

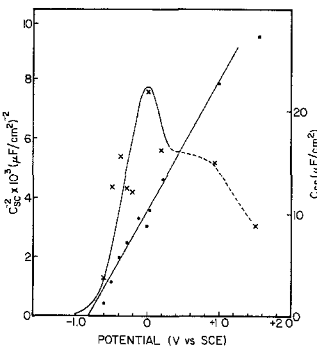

Fig. 2. Mott-Schottky plot of C_{sc} (left scale) and the variation of C_{ss} with potential (right scale). o - C_{sc} , X - C_{ss}
The solid lines are theoretically based on linear behavior of the Mott-Schottky plot and gaussian lineshape for C_{ss}.

---

* Electrochemical Society Active Member

estimated. From the potential of the maximum of the gaussian distribution and from the intercept of the Mott-Schottky plot, we can infer that the surface states are located around 0.8 eV from the bottom of the conduction band, or approximately 2.2 eV above the top of the valence band.

The influence of the surface states on the band gap light induced current voltage behavior will be discussed in the full manuscript which will follow this letter. Fig. 3 shows the spectral response of subband gap illumination with a clearly distinctive peak at 550 nm which is equivalent to photon energy of 2.2 eV. This can only be due to light induced electron ejection from the top of the valence band to the surface states. From fig. 1. it is observed that the states are relatively fast states with relaxation times in the millisecond range and can efficiently communicate with the bulk of the semiconductor.

Full analysis of these results, their implication on the photoelectrochemical behavior of TiO_2 and the relation between the surface states reported here and those that were reported in the literature will be discussed in subsequent publications.

Rechargeable Lithium/Vanadium Oxide Cells Utilizing 2Me-THF/$LiAsF_6$

K. M. Abraham,* J. L. Goldman,* and M. D. Dempsey

EIC Laboratories, Incorporated, Newton, Massachusetts 02158

ABSTRACT

Vanadium oxides of various compositions were synthesized and evaluated as rechargeable cathodes in cells of the type Li/2Me-THF/$LiAsF_6$/V-oxide, C. The most useful compositions were found to be $VO_{2.17}$, $VO_{2.19}$, and the Fe or the Cr substituted oxide of apparent composition, $M_{0.13}V_{0.87}O_{2.17}$. In high capacity cells, $VO_{2.17}$ exhibited a capacity of ~0.55 electrons/vanadium (e^-/V) at current densities of 0.5, 1, and 2 mA/cm^2 and 0.45 e^-/V at 4 mA/cm^2. The excellent rechargeability of this oxide in practical cells within cycling limits of 3.0 and 1.9V was demonstrated by extended cycling of a cell with an average cathode utilization of ~0.52 e^-/V in over 200 cycles. The first discharge of $VO_{2.19}$ resulted in a capacity of ~1 e^-/V at current densities as high as 2 mA/cm^2. In the first charge of this oxide a loss in capacity of 15-20% of the first discharge occurred even at charge current densities as low as 0.1 mA/cm^2. Moreover, in extended cycling, the capacity of this oxide slowly declined in early cycles, diminishing to ~0.70 e^-/V by about the 15th cycle and remaining fairly steady thereafter. These performance characteristics of $VO_{2.19}$ were reproduced in a 5 A-hr prismatic cell. Both types of oxide require carbon in the cathode for acceptable performance with the result that the oxides have only moderate volumetric energy densities. Incorporation of metals such as Cr or Fe into the vanadium oxide lattice appears to be a useful approach to the synthesis of new and useful cathode materials.

Lithium secondary battery technology has been actively pursued for more than 20 years (1). Some striking advances have been made in the past ten years. These have been made possible by the discoveries (2) of new organic solvent/Li salt systems in which the Li electrode can be recharged with high efficiency. Especially noteworthy are the EIC System (3), 2Me-THF/$LiAsF_6$, and the Exxon electrolyte (4), 1,3-dioxolane/$LiClO_4$. Unfortunately, the 1,3-dioxolane/$LiClO_4$ system shows a tendency to detonate upon impact and therefore has been abandoned (5). Recently, we have demonstrated 100-200 deep discharge cycles in high capacity Li/TiS_2 cells utilizing 2Me-THF/$LiAsF_6$ electrolyte (6).

Considerable progress has also been made in the development of rechargeable cathode materials (7). The most extensively studied and promising materials are solid-state cathodes which undergo intercalation or topochemical reactions with Li. Among these, only TiS_2 has received any significant developmental effort. Our recent studies (6) demonstrated the excellent reversibility and chemical compatibility of TiS_2 in practical Li cells utilizing 2Me-THF/$LiAsF_6$. Despite its impressive performance characteristics, TiS_2 does not have the energy density required for many potential applications of secondary Li cells. Therefore, new materials with improved energy densities are of great interest.

A potentially attractive group of materials are the transition metal oxides. Preliminary studies of several rutile and perovskite-related oxides have been carried out recently by Murphy and co-workers (8, 9). These studies have indicated that several vanadium oxides, particularly V_6O_{13}, are potentially attractive materials as high energy density cathodes for Li cells. The reaction of V_6O_{13} with n-BuLi results in an uptake of ~8Li per mol of V_6O_{13} leading to a theoretical specific energy of ~850 W-hr/kg (8). However, there has not been a clear demonstration of the performance characteristics of the oxide in practical cells. In view of the recent demonstration from this laboratory (3, 6) that 2Me-THF/$LiAsF_6$ is a highly desirable electrolyte for rechargeable Li cells, we have investigated in detail the performance characteristics of V_6O_{13} and related oxides in high capacity cells utilizing this electrolyte. The results are presented in this paper.

Experimental

Synthesis and Characterization of Vanadium Oxides

Stoichiometric V_6O_{13}; ($VO_{2.17}$).—The oxide was prepared according to the reaction shown in Eq. [1]

$$13V_2O_5 + 4V \xrightarrow{650°C} 5V_6O_{13} \quad [1]$$

In a typical preparation, an intimate mixture consisting of 11.82g (65 mmols) of V_2O_5 (Alfa-Ventron) and 1.02g (20 mmols) of powdered V (Alfa-Ventron, −325 mesh) was heated in an evacuated, sealed quartz tube for 24 hr at 650°C. An x-ray pattern of the dark powder was in satisfactory agreement with that reported by Wilhelmi *et al.* (10). Samples were

* Electrochemical Society Active Member.
Key words: battery cathodes, cycling, energy density.

also prepared using heating times 8 and 16 hr (11). Although all the samples exhibited very similar x-ray patterns, the relative intensities of the lines in the pattern of the 24 hr sample, listed in Table I, exhibited the best match to the data of Wilhelmi and co-workers. Therefore we consider the 24 hr sample to be the most desirable. This was further borne out by cycling data (*vide infra*). A scanning electron micrograph of the 24 hr sample is shown in Fig. 1. The material is highly crystalline, the crystals being 10-40 μm long and 5-10 μm wide. The crystal size distribution, however, varied from one preparation to the other and had no apparent effect on cathode utilization. This material will be referred to as V_6O_{13} (S).

Nonstoichiometric V_6O_{13}; ($VO_{2.19}$).—In a typical preparation, 17.33g NH_4VO_3 contained in a graphite boat were heated in a flowing argon atmosphere (flow rate, 450 cm³/min) with the following temperature regime: Initially the temperature was raised from 25° to 400°C in about ½ hr. The temperature was then increased to 450°C and the sample was kept at this temperature for another 2 hr. Finally, the material was annealed at 550°C for 1 hr. The dark product weighed 12.73g. The composition of the oxide was calculated to be $VO_{2.19}$. Its x-ray pattern (Table I) is very much similar to that of the stoichiometric oxide. The SEM of the material revealed it to be composed of 4-5 μm particles. The material will be referred to as V_6O_{13} (NS).

Other vanadium oxides from NH_4VO_3.—In optimizing the synthesis of $VO_{2.19}$ from NH_4VO_3, it was found that a very careful control of the Ar flow rate was of utmost importance in obtaining the desired product. The Ar flow rate controls the residence time of the liberated NH_3, the reducing agent which determines the V to O ratio in the oxide product. In different preparations with Ar flow rates significantly lower than 450 cm³/min,[1] oxides of the compositions $VO_{1.88}$, VO_2, $VO_{2.04}$, and $VO_{2.08}$ were obtained at the same temperature ranges. X-ray patterns of these oxides (11) were different from those of $VO_{2.19}$. All these oxides exhibited electrochemical characteristics inferior to those of $VO_{2.19}$ (*vide infra*).

Metal substituted vanadium oxides, ($V_{0.87}M_{0.13}O_{2.17}$); M = Cr, Mo, or Fe)[2].—Following the synthesis of $VO_{2.17}$ from V_2O_5 and V, metal substituted vanadium oxides with an overall metal to oxygen ratio of 1:2.17 were prepared by heating V_2O_5 (65 mmols) with Cr, Mo, or Fe (20 mmols) at 650°C for 24 hr. X--ray patterns of these materials are given in Table II. The SEM photograph of the iron derivative is shown in Fig. 2. These data confirmed the crystallinity of these materials.

[1] The Ar flow rate required to obtain $VO_{2.19}$ may vary with sample size and the container tube size.

[2] This formulation is based on analogy to the synthesis of V_6O_{13}(S) as shown in Eq. [1].

Lithium Cell Studies

The oxides were evaluated in cells of the type

$$Li/2Me\text{-}THF, LiAsF_6/V_6O_{13}, C$$

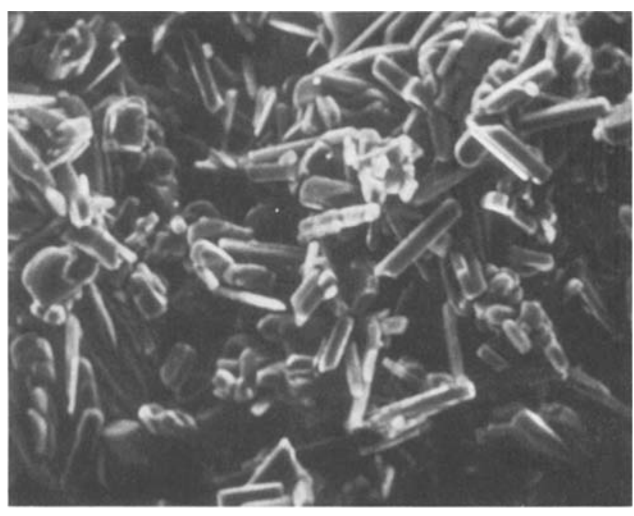

Fig. 1. SEM photograph of stoichiometric V_6O_{13}. Magnification 1000×.

Fig. 2. SEM photograph of Fe substituted vanadium oxide. Magnification 1000×.

Electrolyte preparation.—2-Methyltetrahydrofuran, 2Me-THF, obtained from Aldrich Chemical Company, was distilled over CaH_2 on a spinning band fractionating column (Perkin-Elmer 251) in an Ar atmosphere at a 5:1 reflux ratio. The middle 70% fraction was collected. The distilled solvent was treated with neutral alumina (Fisher Scientific Company) and a 1.5M $LiAsF_6$ electrolyte was prepared by adding an appropriate amount of $LiAsF_6$ (U.S. Steel Agri-Chemicals, electrochemical grade) to cooled (<0°C) 2Me-THF. The cooling is necessary to minimize possible decomposition (12). The solution was preelectrolyzed between two Li electrodes (~1 mA/cm² for ~16 hr) prior to use.

Cathode preparation.—The cathodes were prepared as pressed powder electrodes. An intimate mixture consisting of 70 weight percent (w/o) V_6O_{13}, 20 w/o C (Shawinigan 50% compressed), and 10 w/o Teflon was prepared in a blender. The mixture was pressed on either side of an expanded Ni screen (Exmet Corporation 5Ni7-4/0) at a pressure of 1000 lb/ in.². The electrodes typically had a thickness of 1-2 mm, depending on the loading capacities.

Test cells.—Most of the experiments were carried out in a prismatic glass cell (11). In these cells, the electrode package comprised one cathode flanked on either side by an Li electrode, wrapped in 1 mil thick Celgard 2400 (Celanese Corporation) separator. The Li electrode was fabricated from a 15 mil thick Li foil (Foote Mineral Company) by pressing the foil to one side of an expanded Ni screen. Each electrode had an area per side of 8 cm² (3.2 × 2.5 cm). The cell was completed with an appropriate amount of 2Me-THF/ 1.5M $LiAsF_6$.

Tests were also carried out in hermetically sealed laboratory cells (11). The electrode package in these cells comprised two cathodes and three anodes, arranged in an alternating fashion with Li forming the outer electrodes in the stack. The cell typically had a capacity of ~500 mA-hr based on a theoretical capacity of 1 e^-/V. The Li capacity was ~2.7 A-hr.

Large hermetically sealed prismatic cells (5 A-hr capacity) were constructed and tested with nonstoichiometric V_6O_{13} as the cathode materal. The cell contained a stack of rectangular electrodes. The cell can consisted of deep drawn stainless steel (SS-316) with the following dimensions: width, 5.76 cm; depth, 1.97 cm; height, 5.59 cm; wall thickness, 0.057 cm. The cover contained two glass-to-metal compression seals for electrical terminals. Other cell specfications were as follows: cathode: 16.1g nonstoichiometric oxide (70 w/o), 20 w/o C, and 10 w/o Teflon. Theoretical cathode capacity was 5 A-hr (based on 1 e^-/V). The cell had seven cathodes; each cathode was 5.0 × 3.75 cm per side; total area, 265 cm². The anode was 5.18g Li (20 A-hr). The cell had eight anodes; each was 5 × 3.75 cm. Total area was 265 cm². The separator was Celgard 2400, double wrap. The electrolyte was ~20g, 2Me-THF/1.5M $LiAsF_6$; the cell weight was 115g (about half of this weight is due to cell can and cover).

Cells were cycled galvanostatically or potentiostatically using standard instrumental techniques similar to those described previously (13, 14). For extended cycling of the cells, a microprocessor controlled galvanostat cycler, built in-house, was used. Data collection and retrieval were done with a Bascom-Turner Series 8000 Recorder equipped with microprocessor accessories.

Results and Discussion

Synthesis and Characterization of the Oxides

The synthesis of V_6O_{13} (S) was optimized and we found that heating for 24 hr at 650°C was the most desirable. Reduction reactions of V_2O_5 similar to those in Eq. [1] have also been carried out with Cr, Mo, or Fe to obtain what are believed to be the corresponding metal derivatives of V_6O_{13}, namely, $M_{0.78}V_{5.22}O_{13}$. Although the x-ray patterns of the mixed metal oxides have not been indexed, the absence of oxide phases corresponding to the metal reductants suggests these materials to be mixed metal oxides produced by the insertion of the metal reductants into the vanadium oxide lattice. The formulation suggested here for the mixed metal oxides are based on analogy to the synthesis of $VO_{2.17}$. Alternatively, the materials can be formulated as $M_xV_2O_5$, where x = ~0.31, as in the case of the previously reported $Fe_{0.33}V_2O_5$ (15). Indeed, our x-ray data for the Fe derivative closely resemble those for $Fe_{0.33}V_2O_5$. The structural similarities between V_6O_{13} and $Fe_{0.33}V_2O_5$ are discussed in Ref. (15). The noticeable differences in the x-ray patterns of the mixed metal derivatives shown in Table II seem to suggest that they are structurally not identical. It should be noted that structures such as $Na_{2-x}Mo_xV_6O_{15}$ have been identified (16) in which Mo^{+6} ions enter the oxide structure, substituting V^{+5} ions. The elaborate x-ray studies needed for the full structural characterization of the mixed metal oxides were beyond the scope present study since our work emphasized their electrochemical properties in Li cells. Nevertheless, the present work opens up possibilities for the synthesis of new and useful cathode materials.

The formation of $VO_{2.19}$ from NH_4VO_3 apparently follows the reactions depicted in scheme [2], with NH_3 reducing the initial decomposition product, $VO_{2.5}$

$$\left.\begin{array}{l} NH_4VO_3 \rightarrow \underbrace{VO_{2.5} + NH_3}_{\downarrow} + \tfrac{1}{2}H_2O \\ VO_{2.19} + \text{oxidation products of } NH_3 \end{array}\right\} \quad [2]$$

Because of the very complicated phase relations in the V-oxygen binary system, and the narrow compositional and stability ranges of the V_6O_{13} phase (17, 18), it is necessary to maintain a strict control of the residence time of the liberated NH_3 over the oxide to obtain the desired product. In our synthesis of $VO_{2.19}$, we achieved this by maintaining an Ar flow rate of 450 cm³/min. By maintaining Ar flow rates considerably lower than this, we have synthesized $VO_{1.88}$, VO_2, $VO_{2.04}$, and $VO_{2.08}$ whose x-ray pattern and electrochemical properties were significantly different from those of $VO_{2.19}$. Some of these lower oxides probably are not homogeneous oxide phases (17, 18). We also note that even with the optimized synthesis, different preparations of V_6O_{13} (NS) yielded materials with V to O ratios from 1:2.18 to 1:2.20.

The crystal structure of V_6O_{13} (S) was described by Wilhelmi and co-workers (10) and recently by Murphy and co-workers (8). This structure contains two perovskite cavities per V_6O_{13} structural unit. Each cavity contains 15 distorted square pyramidal sites which belong to two groups comprising 3 and 12 sites, respectively. It is not known how the slightly oxygen-rich structure of V_6O_{13} (NS) differs from that of V_6O_{13} (S). We have found that when V_6O_{13} (NS) is heated in vacuum at 650°C, it is converted to a more crystalline material whose electrochemical properties approach that of V_6O_{13} (S). In analogy with V_2O_5, which loses oxygen when heated at 600°C in vacuum (17), it is possible that heating of V_6O_{13} (NS) leads to the loss of the additional oxygens and transforms it to the more stable V_6O_{13} (S).

Discharge characteristics of NH_4VO_3 decomposition products.—The primary discharges of the oxides, $VO_{1.88}$, VO_2, $VO_{2.04}$, $VO_{2.08}$, and $VO_{2.19}$, obtained galvanostatically at 0.5 mA/cm², are shown in Fig. 3. The data indicate that the cathode capacities and the potentials at which the discharges proceed depend on

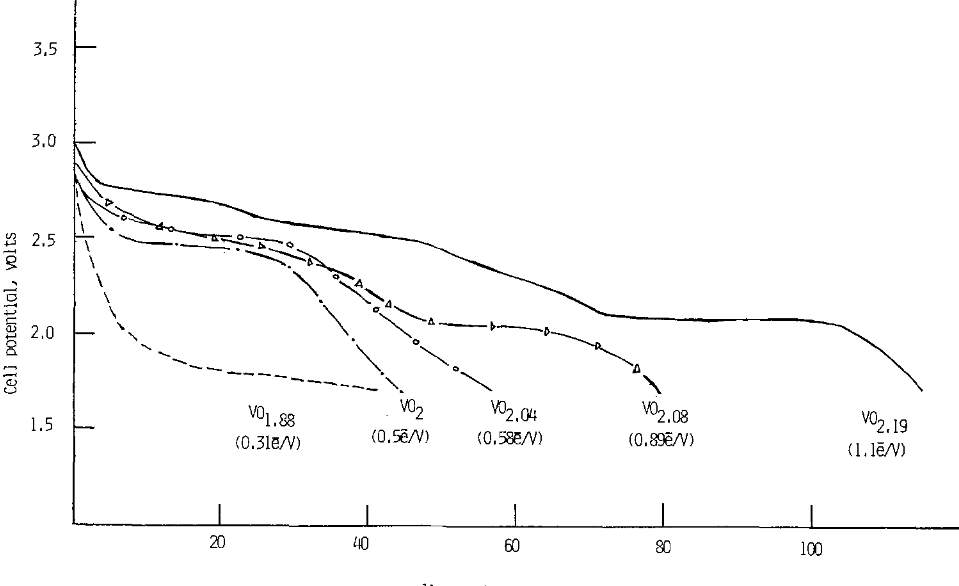

Fig. 3. Galvanostatic discharges of various vanadium oxides synthesized by the thermal decomposition of NH_4VO_3. Current = 8 mA (0.5 mA/cm²).

the composition of the oxide. Thus for $VO_{1.88}$, although the discharge begins at ~2.8V, the cell polarizes rapidly to ~1.8V, at which potential most of the discharge proceeds. The discharges of VO_2 and $VO_{2.04}$ show a voltage plateau at ~2.45V. The discharge curve for $VO_{2.08}$ shows two potential plateaus at ~2.45 and ~2.05V. The discharge of $VO_{2.19}$ is characterized by two voltage plateaus at ~2.70 and 2.50V, a downward sloping potential region at ~2.3V, and another plateau at 2.1V. The highest capacity is exhibited by $VO_{2.19}$ with 1.1 e^-/V to a 1.7V cutoff. The potential profiles observed here for $VO_{2.19}$ are identical to those reported by Murphy (8), for V_6O_{13}, prepared from NH_4VO_3.

Walk and Gore have studied the discharge characteristics of Li/V_2O_5 cells (19). In the first discharge of V_2O_5 about 20% of the capacity occurs at potentials above 3.0V. Thus the primary discharge characteristics of the oxides with their unique potential profiles appear to be useful in evaluating material purity.

Cycling behavior of V_6O_{13}(NS).—The first two cycles of a cell utilizing this oxide are shown in Fig. 4. The discharge proceeds in discrete potential steps, indicating that Li incorporation is accompanied by phase transitions of the oxide lattice. The discharge shows a fairly sharp cutoff to 1.9V with a capacity of ~1.0 e^-/V in the first discharge. In the first charge, typically only 80-85% of this capacity is recharged. The capacity in the second cycle is nearly 100% of that in the first charge.

The potential plateaus in the first discharge occur at the approximate Li compositions in $Li_xV_6O_{13}$ of $0 < x \leq 0.95$, $0.95 < x \leq 2.75$, $2.75 < x \leq 3.65$, and $3.65 < x \leq 6.05$. A capacity of nearly $4Li/V_6O_{13}$ is obtained at potentials >2.1V. This may involve the occupation of 2Li per cavity in the perovskite structure of the oxide. Of the additional two Li discharging at ~2.1V, one is probably taken up by each cavity. It should be noted that with nBuLi, nearly 8Li can be incorporated into V_6O_{13}(NS), suggesting that the maximum Li capacity in V_6O_{13}(NS) is 4Li per cavity (8, 11).

The 15-20% capacity loss in the first charge was independent of the current densities between 0.10 and 2.0 mA/cm². This fraction appears to involve mostly the capacity at the higher voltage regions, *i.e.*, primarily from the 2nd and 3rd phase regions. With continued cycling between 1.9 and 3.0V, the relative ratios of the capacities involved in the various phase regions of 2nd discharge are maintained. Because of the distinct changes in the potential profiles of the first and second discharges, we ascribe the capacity loss to Li which occupies irreversibly some sites in the oxide lattice. This is further substantiated by our observation that a similar irreversibility is not exhibited by V_6O_{13}(S); *vide infra.* It should be noted that prior studies from this laboratory have clearly demonstrated (3, 6, 12) the electrochemical stability of the electrolyte in the region of 1.9-3.0V.

Cycling behavior of V_6O_{13}(S) and related oxides.—The first two cycles of a cell utilizing V_6O_{13}(S) are shown in Fig. 5. The discharge proceeds in three distinct voltage steps corresponding to a capacity of ~0.55 e^-/V. The end of discharge is indicated by a very small plateau at ~2.0V and then a clear potential drop to 1.9V. In the present cell the three upper plateaus occur to the approximate Li compositions in $Li_xV_6O_{13}$ ternary of $0 < x \leq 0.75$, $0.75 < x \leq 1.5$, and $1.5 < x \leq 3.0$. Practically 100% rechargeability is observed in the first charge. Moreover, very few changes in the voltage profiles or capacities occur with continued cycling between voltage limits of 1.9 and 3.0V (*vide infra*).

Figure 6 compares the first cycles of three different samples of V_6O_{13}(S) obtained using heating times

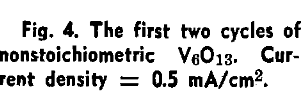

Fig. 4. The first two cycles of nonstoichiometric V_6O_{13}. Current density = 0.5 mA/cm².

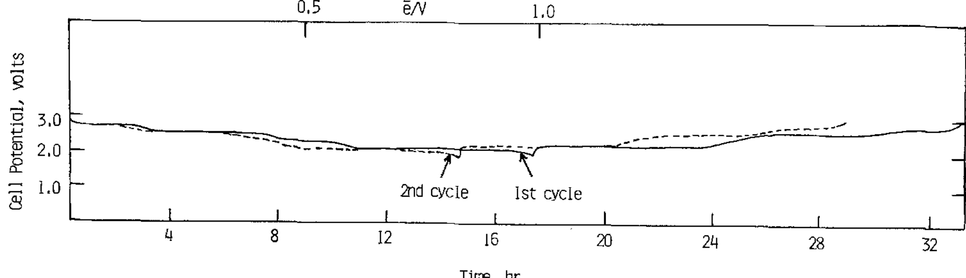

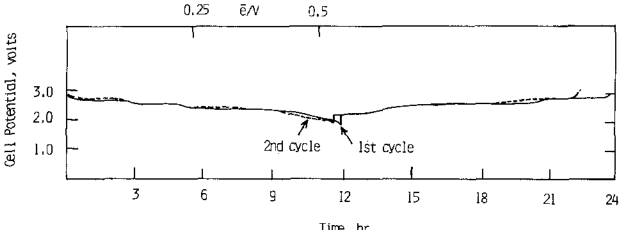

Fig. 5. The first two cycles of stoichiometric V_6O_{13}. Current density = 0.5 mA/cm^2.

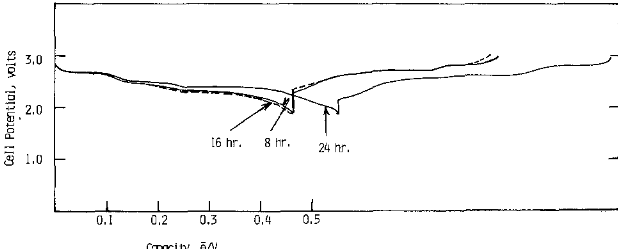

Fig. 6. The first cycles of V_6O_{13}(S) samples prepared at 650°C using heating times of 8, 16, and 24 hr. Current density = 0.5 mA/cm^2.

respectively of 8, 16, and 24 hr. There is very little difference in the potential profiles of the cycles of the three materials. However, the 24 hr sample exhibited the highest specific capacity. Moreover, the capacities of the 8 and 16 hr samples decreased with cycling while that of the 24 hr sample remained practically unchanged. The SEM data revealed the 24 hr sample to have the most uniform crystal size distribution. It was also found from x-ray data that although these materials had similar x-ray patterns, the relative intensities of the lines at 3.52 and 3.32Å showed a systematic variation with heating time, with the pattern of the 24 hr sample exhibiting the best match to the data reported by Wilhelmi (10). It appears that the inferior electrochemical performance, *i.e.*, the lower capacities and diminishing utilization with cycling, of the 8 and 16 hr samples are due to crystal imperfections. The nature of these crystal imperfections is not clearly understood, however. The effect of a heating time longer than 24 hr has not been evaluated in our studies.

The significant difference between the V_6O_{13}(S) and V_6O_{13}(NS) at ambient temperature is the absence of the plateau in the discharge of the latter at ~2.1V. Consequently, V_6O_{13}(S) exhibits approximately 0.33 e^-/V less capacity than V_6O_{13}(NS). The maximum capacity of the stoichiometric oxide determined by the nBuLi reaction is 4Li/V_6O_{13} or 0.66 e^-/V (7). This corresponds to the incorporation of 2Li per cavity in the oxide lattice.

The maximum capacity of 4Li per V_6O_{13}(S) at ambient temperature appears to be determined by kinetic factors. This was indicated by the observation that by discharging the cell at 60°C, an additional capacity of 0.33 Li/V was obtained with the extra capacity appearing at ~2.1V, as in V_6O_{13}(NS). However, the recharge at 60°C was only 85% of the discharge, *i.e.*, 0.72 e^-/V. This resembles the ambient temperature behavior of V_6O_{13}(NS) and suggests that similar irreversibility mechanisms are probably operative in both cases. When the cell was returned to room temperature, its behavior resembled that prior to the cycle at 60°C. But it appeared that the high temperature discharge had induced an irreversibility in the oxide with the result that the ambient temperature cathode utilization after the discharge at 60°C showed a declining trend, falling below 0.4 e^-/V after a few cycles.

Typical cycles of the cells containing the metal substituted vanadium oxides are depicted in Fig. 7 and 8, respectively. The first discharge of the Fe substituted oxide resulted in a capacity of 0.49 e^-/mol of total metal. The discharge, although it shows a close similarity to that of V_6O_{13}(S), does not exhibit well-defined potential plateaus as observed in the latter. The first recharge was nearly 100% efficient. With continued cycling there was very little change in the potential profiles of the cycles although the capacity gradually decreased with utilizations of 0.34 e^-/metal at the 15th and 0.24 e^-/metal at the 50th cycles. The close similarities in the potential profiles of the cycling of V_6O_{13}(S) and the Fe derivative seem to indicate that the two oxides have very similar crystal structures. Indeed, they have very similar x-ray patterns. Since the capacity of the Fe-V oxide was not better than that of VO(S), we did not investigate the mixed metal oxide in any great detail as a cathode material. The specific energy of the oxide corresponding to the first discharge is 320 W-hr/kg.

The first discharge of the Cr derivative to 1.9V proceeded at two major potential plateaus. The upper plateau region occurred at ~2.3V and involved a capacity of 0.56 e^-/mol of the total metal. The second plateau occurred at ~2V and involved a capacity of 0.22 e^-/total metal. In the first charge only the upper plateau region was rechargeable. In the second cycle, the discharge involved a capacity of 0.5e^- with a recharge efficiency of ~85%. With continued cycling, this capacity decreased, and the cathode utilizations were 0.42 and 0.33 e^- at the 16th and 38th cycles. The specific energy of the oxide corresponding to the second discharge was 350 W-hr/kg.

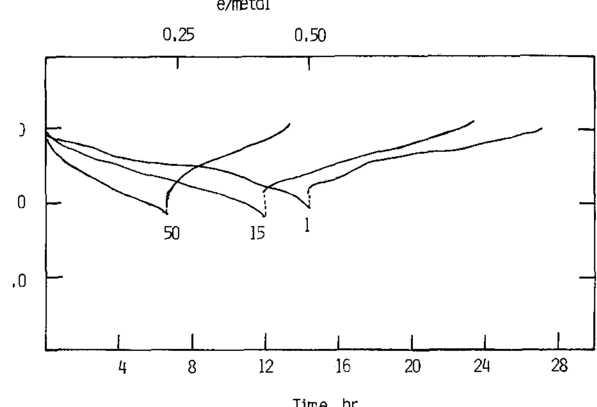

Fig. 7. Typical cycles of Fe substituted vanadium oxide cathode. Current density = 0.25 mA/cm^2.

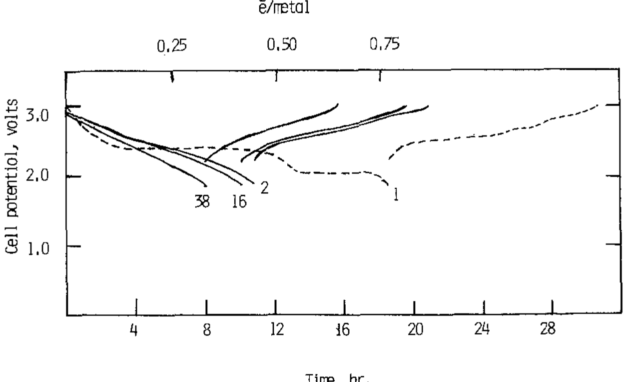

Fig. 8. Typical cycles of Cr-substituted vanadium oxide. Current density = 0.25 mA/cm^2.

The discharge capacity of the Mo oxide was only 0.2 e^-/mol of total metal. This low capacity, though practically not interesting, was quite reversible.

Attempts to modify the structure of V_6O_{13} by metal substitution resulted in new materials. Their electrochemical properties were not superior to those of V_6O_{13} itself. However, the results are promising. A systematic study is presently underway to further evaluate mixed metal oxides as cathode materials.

Rate-capacity behavior of V_6O_{13}.—Figure 9 shows the discharges of a 51 mil thick cathode utilizing V_6O_{13}(S) at current densities ranging from 0.5 to 8 mA/cm². The cathode, based on 1 e^-/V, had a capacity density of 20.9 mA-hr/cm². A capacity of ~0.55 e^-/V was obtained at current densities of 0.5, 1.0, and 2.0 mA/cm². At 4 mA/cm², the capacity was 0.45 e^-/V. With an Li cycling efficiency of 97%, the volumetric energy density, calculated using the practical electrode dimension is ~260 W-hr/dm³ at current densities ≤4.0 mA/cm². However, this does not take into account the volume required for the electrolyte.

Similar behavior was exhibited by V_6O_{13}(NS). At current densities ≤2.0 mA/cm², a capacity between 1 and 1.1 e^-/V was obtained in the first discharge. At 4 mA/cm², the initial cathode utilization was 0.87 e^-/V. As discussed in the next section these capacities decreased with cycling.

These results suggest that Li cells with V_6O_{13} cathodes potentially have high rate capabilities. An amount of ~20 w/o carbon in the cathode matrix appears to be sufficient for obtaining these high rate performances. The diffusion coefficient of Li^+ in V_6O_{13} seems not to have been determined. The present data suggest that it is quite high, probably approaching those found in layered compounds such as TiS_2 which exhibit high rate discharge capabilities in Li cells (20).

At lower temperatures, *i.e.* <0°C, the cells exhibited relatively poorer rate characteristics. For example, at 0°C, a cell with V_6O_{13}(S) and 2 Me-THF/1.5M $LiAsF_6$ exhibited a capacity of 0.41 e^-/V at 0.25 mA/cm², but practically no capacity at 0.5 mA/cm². Although not investigated in detail, it appears that at lower temperatures, the rate is primarily limited by the electrolyte.

Rechargeability of V_6O_{13}.—A detailed study (11) of the factors which affect the rechargeability of the vanadium oxides revealed the following: (*i*) High capacity cathodes utilizing both types of V_6O_{13} require carbon in the electrode matrix to obtain even an acceptable primary discharge. It was determined that an optimal amount of carbon which would permit high rate discharges was about 20% by weight of the cathode mix. (*ii*) Control of the lower voltage limit of cycling is of utmost importance especially with V_6O_{13}(NS) to avoid irreversible reduction of the oxides.

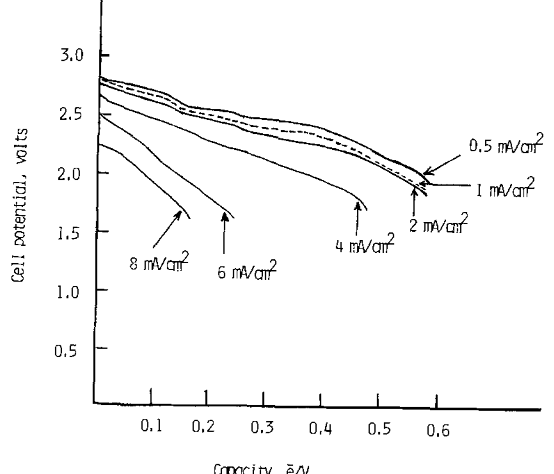

Fig. 9. Capacities of a Li/V_6O_{13}(S) cell at various current densities. Cathode has 313 mA-hr, 1 e^-/V capacity. Cathode thickness = 51 mils.

Potentiostatic discharges of cathodes utilizing V_6O_{13}(S) and V_6O_{13}(NS) were performed to evaluate the nature of electrode processes at potentials between 1.3 and 1.9V. Each cathode was initially discharged at 1.9V and then the potential was lowered to 1.3V at 0.1V intervals. At each potential the current was allowed to decay to <10 μA. The results are tabulated in Table III. The capacity at the 1.9V discharge corresponded to 1.17 e^-/V for V_6O_{13}(NS) and 0.71 e^-/V for the V_6O_{13}(S). At 1.8 and 1.7V only little additional capacities were obtained. At 1.6V, however, additional capacities of 1.49 e^-/V for V_6O_{13}(S) and 0.71 e^-/V for V_6O_{13}(NS) were found. This substantial difference seems to suggest that the discharge process at 1.6V is due to the cathode material and not the solvent. The electrolyte itself did not show any substantial current on a carbon electrode down to 1.3V (21). The integrated capacities of the two oxides for discharges at 1.9, 1.8, 1.7, and 1.6V were remarkably close being equivalent to ~14 e^-/V_6O_{13} formula. This would correspond to the reduction of all the V in the oxide to V^{+2}. The high capacity reduction at 1.6V in both of the oxides occurred at the low rate of ~0.06 mA/cm².

After the high capacity reduction the cathode exhibited little rechargeability even potentiostatically. Also, in agreement with the results of the potentiostatic studies, we found that the cathode performance degraded significantly during galvanostatic cycling with lower voltage limits ≤1.5V. The rate of degradation, however, was less in V_6O_{13}(S) than in V_6O_{13}(NS).

The average oxidation states of V in V_6O_{13}, $Li_4V_6O_{13}$, $Li_6V_6O_{13}$, and $Li_8V_6O_{13}$, respectively, are +4.33, +3.66, +3.33, and +3.0. Our data suggest $V^{+4.33} \rightleftarrows V^{+3.33}$ as the redox limits with least structural irreversibility.

V_6O_{13}(S) exhibits excellent rechargeability between cycling limits of 3.0 and 1.9V. Figure 10 shows a plot of cathode utilization *vs.* cycle number for a hermetically sealed laboratory cell utilizing V_6O_{13}(S). The cell with a cathode capacity density of 12 mA-hr/cm² and a total capacity of ~500 mA-hr, based on 1 e^-/V, was cycled at a current density of 1.0 mA/cm² for both discharge and charge. The average cathode utilization in over 200 cycles was ~0.52 e^-/V. Some typical cycles are shown in Fig. 11. The mid-discharge potentials show no change when going from the first to the 200th cycle, although the later discharges exhibit more of a linear, but sloping, voltage profile. The latter indicates that minor structural perturbations of the oxide lattice may occur in the cycling, but has no effect on its performance as a cathode. Indeed, when the current density was lowered to 0.5 mA/cm² at the 198th cycle, the capacity increased to 0.6 e^-/V and remained nearly constant in the next 10 cycles at the same rate. The cell was cycled 260 times before it was terminated. These cycles were obtained in a period of more than 5 months, indicating the excellent system compatibility at ambient temperature.

Table III. Potentiostatic discharges of V_6O_{13}

Oxide	Capacity (e-/V) at volts 1.9	1.8	1.7	1.6	Total capacity, e-/V
V_6O_{13}(S)	0.784	0.020	0.074	1.493	2.371
V_6O_{13}(NS)	1.160	0.173	0.342	0.707	2.383

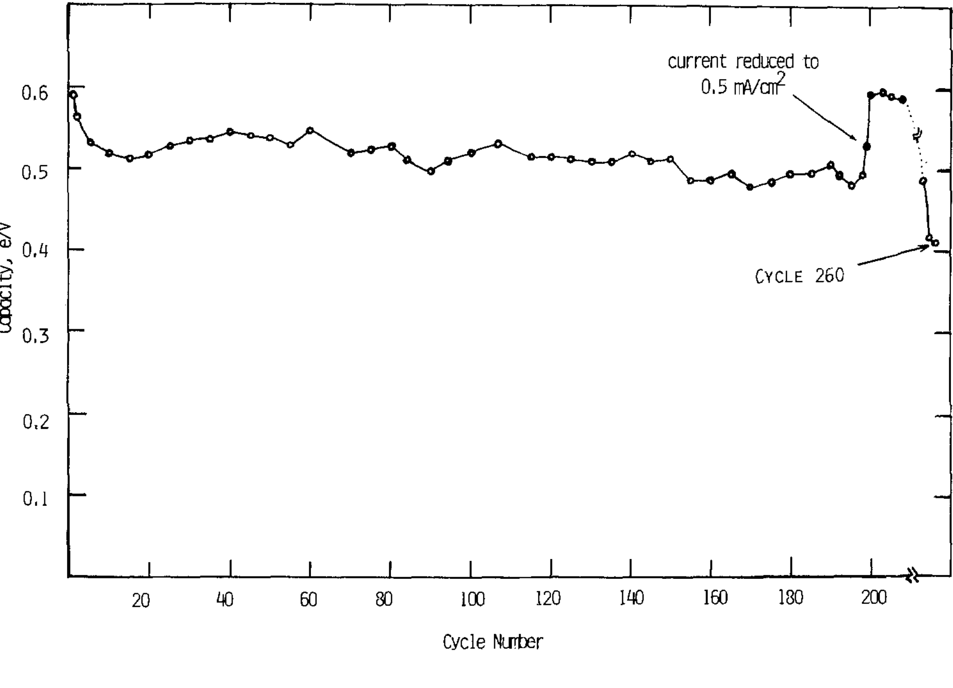

Fig. 10. Cathode utilization vs. cycle number for a hermetic laboratory test cell utilizing $V_6O_{13}(S)$. Current density = 1 mA/cm². Cathode area = 40 cm². Cathode capacity = 500 mA-hr (based on 1 e⁻/V).

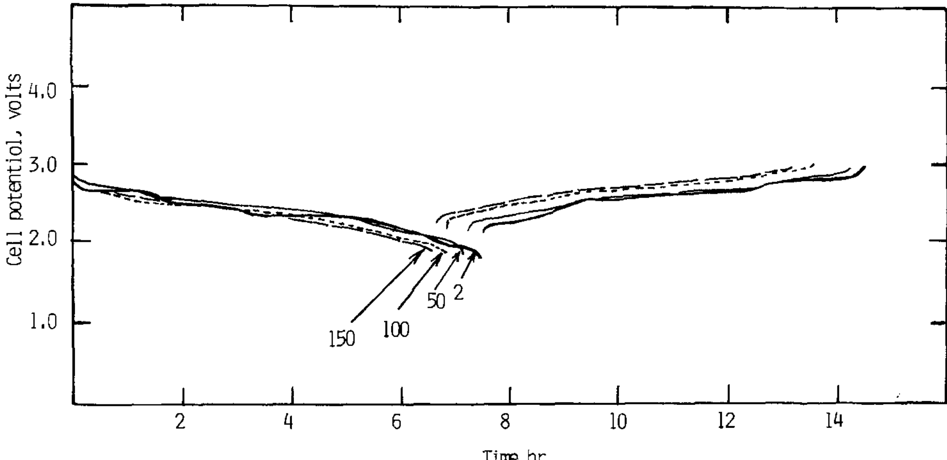

Fig. 11. Typical cycles of the cell shown in Fig. 10.

The Li cycling efficiency has exceeded 96%, as we found previously in Li/TiS_2 cells (6).

Figure 12 shows a plot of cathode utilization *vs.* cycle number for a cell with V_6O_{13}(NS). The cathode based on 1 e^-/V had a capacity density of 5.6 mA-hr/cm². In the first discharge at 1.0 mA/cm² the capacity was 1.1 e^-/V. In the second discharge the capacity decreased to 0.88 e^-/V. With further cycling the capacity showed a continued, but slow, decline, diminishing to ~0.65 e^-/V at the 19th discharge. There was very little change thereafter up to the 40th cycle. A probable reason for the decline in capacity in the early cycles may be related to the insulating characteristics of lithiated phases, $Li_xV_6O_{13}$, $x > 4$ (8). In each cycle a small fraction of the highly lithiated oxide phases probably gets isolated in the electrode matrix and loses electronic contact with the bulk of the material. The electronically isolated material is electrochemically not utilized. Supporting this view is the fact that after the second cycle the potential plateaus of the cycles remain the same despite the lower capacities (see below). The average capacity achievable in high capacity nonstoichiometric oxide cathodes appears to be ~0.7 e^-/V, corresponding to a specific energy of 450 W-hr/kg. The actual energy densities achieved in practical cells are discussed below.

With both of the oxides there were only small effects of discharge current densities up to 2.0 mA/cm² on cathode utilization. However, it appeared that good rechargeability is achieved with a charge current density of ≤1.0 mA/cm².

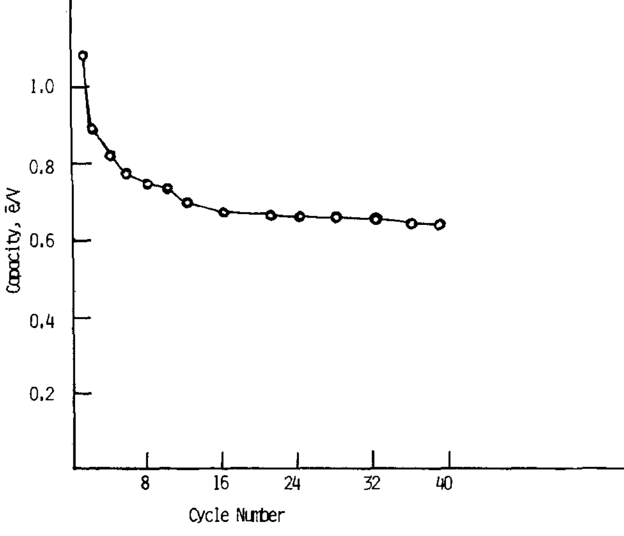

Fig. 12. Cathode utilization vs. cycle number for a cell utilizing V_6O_{13}(NS). Cathode area = 16 cm². Cathode capacity = 100 mA-hr (based on 1 e⁻/V). Current density = 1 mA/cm².

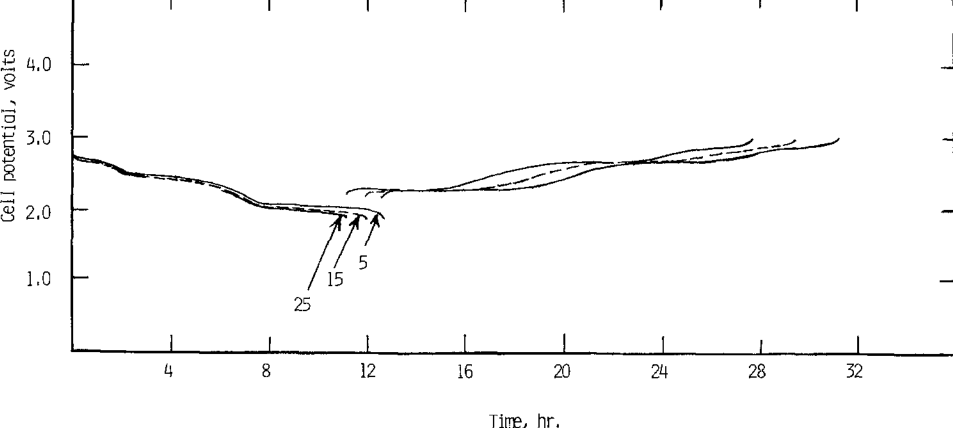

Fig. 13. Typical cycles of the 5 A-hr nominal capacity prismatic cell. Discharge current = 300 mA. Charge Current = 200 mA.

Performance characteristics of high capacity prismatic cells.—Approximately 5 A-hr capacity, hermetic prismatic cells were fabricated with V_6O_{13}(NS). Some typical cycles are shown in Fig. 13. The 5 A-hr nominal capacity cell reproduced the performance characteristics achieved in the small laboratory cells. For example, the capacity in the first discharge at a current of 140 mA (0.5 mA/cm^2) was 5.04 A-hr. The first charge at the same current was 83% efficient, with a capacity of 4.17 A-hr. From the second cycle onward the cell was cycled with currents of 300 mA for discharge and 200 mA for charge. The decrease in capacity with cycling in this cell occurred at a much slower rate than in the laboratory cell with V_6O_{13}(NS). The capacities were 3.66 A-hr in the 10th cycle, 3.51 A-hr in the 20th cycle, and 3.2 A-hr in the 40th cycle. The gravimetric and volumetric energy densities which correspond to these capacities are shown in Table IV. Testing of the cell was discontinued when it developed a partial short at the 45th cycle, manifested by a longer charge input than the previous discharge. The partial short results from dendrite penetration through the separator. We had previously identified this as a major failure mode also in 0.5 A-hr Li/TiS_2 cells (6). In the latter, however, this occurred at a much later stage in the cycling, *i.e.,* typically after 100-150 deep discharge cycles.

Conclusions

Specific capacities, potential profiles, and rechargeabilities of vanadium oxide cathodes are highly dependent on the oxide composition. The compositions, $VO_{2.17}$ and $VO_{2.19}$ have properties suitable for fabricating rechargeable, nonaqueous Li cells. Whereas the specific capacity of $VO_{2.17}$ is lower than that of $VO_{2.19}$, it cycles more reversibly. Performance characteristics identified in low capacity laboratory cells can be reproduced in high capacity practical cells. The system Li/2Me-THF/$LiAsF_6$/V_6O_{13} has acceptable stability at ambient temperature for many practical applications, as evidenced by extended cycling studies.

Table IV. Energy densities* achieved in a hermetically sealed prismatic cell†

	1st discharge	2nd discharge	10th discharge	20th discharge	40th discharge
Capacity, A-hr	5.04	4.07	3.66	3.51	3.2
Gravimetric energy density, W-hr/kg	102	81	73	70	64
Volumetric energy density, W-hr/dm^3	183	146	131	126	115

* About half of the cell weight (115g) is due to the can and cover. Cell volume = 64 cm^3.
† The cell utilizes nonstoichiometric V_6O_{13} with 5 A-hr (1 e-/V) capacity.

A performance-limiting characteristic of these cells was identified to be irreversible reduction processes at potentials below 1.7V. In a high capacity (5 A-hr) prismatic cell utilizing $VO_{2.19}$, a specific energy of 102 W-hr/kg and an energy density of 183 W-hr/dm^3 were achieved. These energy densities were reduced by 17% in the second discharge and ~30% in the 20th discharge. With the highly reversible $VO_{2.17}$, based on the same cell design, the specific energy would be ~60 W-hr/kg and the energy density would be ~115 W-hr/dm^3.

The two major factors limiting the volumetric energy densities are the amount of carbon required for fabricating an acceptable cathode and the amount of Li required to achieve a specified number of cycles. Considerable improvements in volumetric energy density may be possible by the use of metallic conductive additives to the V_6O_{13} and by improvements in the Li cycling efficiency.

Insoluble Sulfide Positive Electrodes for Organic Electrolyte Lithium Secondary Batteries

Fred W. Dampier*[,1]

EIC Corporation, Newton, Massachusetts 02158

ABSTRACT

The behavior of CuS, NiS, SiS_2, MnS_2, and FeS as positive electrodes for rechargeable Li cells was investigated using a 1M $LiAsF_6$/THF electrolyte. Of these sulfides CuS gave the best performance delivering 1.6 and 0.98 eq/mol of CuS at 1 mA/cm^2 after 4 and 20 cycles, respectively. These capacities translate into specific energies of 348 and 211 W-hr/lb based on the weight of CuS and actual cell voltages. It was found that both NiS and SiS_2 can be cycled for 40 cycles but the capacities were not adequate for battery applications. Deterioration of the Li electrode due to reaction of the Li with the electrolyte and reduction of the electrolyte on the CuS electrode below ~1.5V appear to be the main factors limiting the cycle life of the Li-CuS cell.

Monosulfides of the transition metals such as CuS and NiS have been extensively studied as positive electrodes for primary Li/organic electrolyte cells (1-7). Primary Li-CuS batteries have been developed by several manufacturers (1, 6) and 112 W-hr/lb has been achieved (1) for D-size cells. The monosulfides previously have been considered of minimal reversibility because of the low solubility of alkali and other metal sulfides in organic electrolytes (9) and their lack of a crystal structure favoring intercalation of Li^+ similar to TiS_2 (8). However, when exploratory work (10) with a CuS positive electrode revealed that the Li-CuS cell is reversible, it was decided to investigate the behavior of CuS and other insoluble sulfides as positive electrodes.

In this paper results are presented of an investigation of the behavior of CuS, NiS. SiS_2, MnS_2, and FeS positive electrodes in rechargeable Li cells. The selection of these sulfides for investigation was made on the basis of the specific energy calculations presented in Table I, cost, elemental abundance, and previous work reported in the literature (1, 2, 9). The results have been evaluated primarily in terms of the merits of each material for practical application in high energy density rechargeable batteries.

Experimental

Cell construction.—The cells consisted of two Li negative electrodes (3.5 × 3.5 cm) on either side of the sulfide positive electrode, separated by two layers of a 0.025 mm thick polypropylene separator (Celgard 2400). Cells were assembled by wrapping the positive electrode in a "U" fold of two layers of separator, then sandwiching the wrapped electrode between two Li electrodes. The element was then inserted into a rectangular glass cell case (inside $L \times W \times H$: 4.5 × 1.5 × 7.0 cm), using polypropylene shims to insure a snug fit.

The Li electrodes (3.5 × 3.5 cm) were prepared by pressing a layer of 0.38 mm thick Li foil (Foote Mineral Company) on both sides of a 0.08 mm thick 3 Ni10-3/0 grid (Exmet Corporation). Either pressed powder or Teflon bonded positive electrodes were used depending on the properties of the sulfide active material and the purpose of the particular test. Pressed powder sulfide positives were prepared following a procedure described earlier (7) by pressing a blend of 50% active material, 45% graphite (No. 1651, Southwestern Graphite Company) and 5% polyethylene powder (Microthene FN-500, U.S. Industrial Chemicals) onto a 3 mil thick Ni5-4/0 grid.

The Teflon bonded positive electrodes (2.54 × 2.54 cm) were prepared by pressing a mixture of 50% sulfide active material, 50% Shawinigan carbon black, and du Pont No. 30 Teflon dispersion on an Exmet 5

Table I. Specific energies of insoluble sulfide positive electrodes

Compound	Eq. wt.*	No. of electrons	E°**	W-hr/lb
A. Complete reduction				
NiS	52.32	2	2.02	469
CuS	54.74	2	2.23	495
FeS	50.89	2	1.97	471
MnS	50.44	2	1.36	328
MnS_2	66.47	4	2.00	366
Ag_2S	130.84	2	2.28	212
VS	48.40	2	1.50	376
CoS	52.44	2	1.97	457
B. Partial Reduction to monosulfide				
SiS_2	53.10	2	2.27	520
TiS_2	63.00	2	1.87	361
MnS_2	66.52	2	2.65	484
FeS_2	66.98	2	2.83	514

* Includes weight of required Li.
** The cell potentials were computed from the free energies of formation at 25°C tabulated by Gibson and Sudworth (19), except for FeS_2 where the NBS (26) value was used.

Key words: lithium, organic electrolytes, energy storage, tetrahydrofuran.

Ni5-5/0 grid and sintering the dried (overnight at 105°C) electrodes at ~300°C for 20 min under flowing argon. The procedure was similar to the one described earlier by Holleck and co-workers (11).

Electrolyte preparation.—Tetrahydrofuran (THF) (MC/B, Chromatoquality) was dried by passage through a glass column (height, 38 cm) filled with Linde 4A molecular sieves. The solvent was then passed through a second 38 cm column of fresh sieves, to achieve a water absorption capacity equivalent to a 76 cm column. Lithium hexafluoroarsenate ($LiAsF_6$, electrochemical grade) was obtained from United States Steel, Agri-Chemical Division, and was used as-received.

The preparation of the electrolyte and the construction of cells were all carried out in an argon-filled glove box with a relative humidity maintained at less than 0.002% (0.5 ppm), as measured by a dew point hygrometer (Alnor Instrument Company, Niles, Illinois).

Positive electrode materials.—The CuS, SiS_2, and FeS used to prepare positive electrodes were obtained commercially from Fisher, Atomergic Chemetals, and Fisher, respectively. However, the NiS and MnS_2 used in the present work were synthesized.

Nickel sulfide (α-NiS) was formed by dissolving 146g of $NiSO_4 \cdot 6H_2O$ (Harshaw) in 600 ml of distilled H_2O to which 100 ml of 14M NH_4OH was added followed by 170 ml of 24% $(NH_4)_2S$ solution (Fisher Certified). The NiS precipitate was filtered and washed until the washwater gave a negative test with dimethylgloxime (0.16 μg detection limit). The precipitate was then dried at 120°C for 48 hr in a tube furnace flushed with N_2.

Manganous disulfide, MnS_2 (Hauerite) was prepared using the procedure developed by Biltz and Weichmann (12). In brief, 5g of $MnSO_4 \cdot H_2O$ (Fisher, Certified) was dissolved in 20 ml of water then 20 ml of a boiling potassium polysulfide solution was added. The potassium polysulfide solution was prepared by dissolving 25g of anhydrous K_2S (Fisher) in 100 ml of water, bringing the solution to a boil, then adding 25g of sulfur (Ventron Corporation) in small portions over a 20 hr period. The slurry thus obtained was evaporated to dryness under vacuum in a glass tube, sealed, then heated to 170° ± 10°C. After 60 hr at this temperature the tube was broken open and the product was collected, washed first with 1 liter of hot water then with methanol without exposing it to air. Excess S was next removed from the MnS_2 by treatment with CS_2 in a Soxhlet extractor for 24 hr. Finally the compound was vacuum dried for 24 hr over NaOH at 100°C and transferred under vacuum into the glove box.

Results and Discussion

Copper sulfide.—The capacity change as a function of cycle number for Li-CuS cells using a 1M $LiAsF_6$/THF electrolyte and discharged to 1.5 and 1.45V are shown in Fig. 1 and 2, respectively. Over 300 cycles were obtained for the Li-CuS cell described in Fig. 2 by replacing the Li electrodes and the electrolyte after cycles 41 and 204. Since the capacity was greatly improved for more than 30 cycles each time the cell was refurbished, there is no indication that a cycling limit was reached for the CuS electrode even after 300 cycles. Examination of disassembled cells indicated that the capacity loss on cycling was probably due primarily to deterioration of the Li electrode. However, other factors which will be discussed later such as electrolyte reduction at the CuS electrode toward the end of discharge also appear to be involved.

The CuS electrodes used in cells 1-3 were of the Teflon-bonded type described earlier and contained 49% CuS in cells 1 and 2 and 73% CuS in cell 3. The nominal capacities of the electrodes were calculated

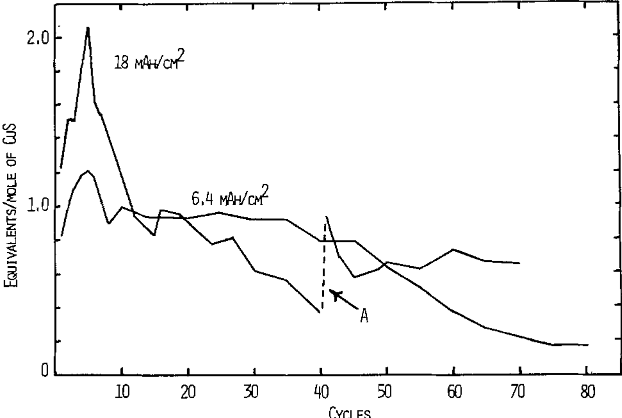

Fig. 1. Capacity changes of Li-CuS cells as a function of cycle number. $i_D = i_C = 1.0$ mA/cm². Voltage limits: 1.5V on D, 2.9V on C. Nominal capacities 6.4 and 18 mA-hr/cm² for cells 1 and 3, respectively. Li electrodes and electrolyte replaced at point A.

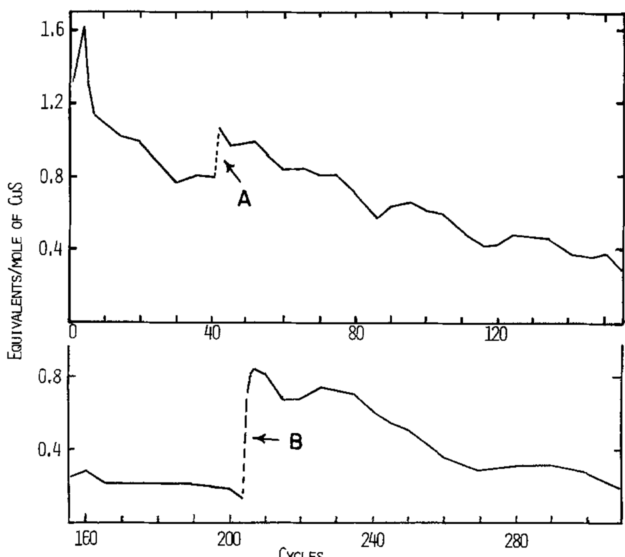

Fig. 2. Capacity changes of an Li-CuS cell as a function of cycle number. $i_D = i_C = 1.0$ mA/cm². Voltage limits: 1.45V on D and 2.90V on C. Nominal capacity cell 2, 8.4 mA-hr/cm². A, B—Li electrodes and electrolyte replaced.

on the basis of a 1.0 eq/mol CuS utilization and 6.45 cm².

The decline in capacity with cycle life observed for the Li-CuS cell as shown in Fig. 1 demonstrates that with $LiAsF_6$/THF the cell cycles well with little loss in capacity for about 35 cycles, after which the capacity rapidly falls. This same basic trend is seen in Fig. 2 although the voltage limits are slightly different and the Li electrodes were replaced. The voltage limits for cell 1 (Fig. 1) were initially 1.5V on discharge and 3.0V on charge, but near the end of the fifth charge, the cell potential suddenly became erratic and failed to reach an endpoint, behavior typical of dendrite shorting. The charging voltage limit was then set at 2.90V and no further problems with dendrite shorting were encountered.

Because the Li-CuS cell has a long sloping discharge curve extending below 1.3V at 1 mA/cm² (Fig. 3) it was thought that a 1.50V discharge cut-off might needlessly sacrifice capacity. Thus, for cell 2 the discharge cut-off was extended to 1.45V and as Fig. 2 shows, considerable extra capacity was obtained without any sacrifice in cycle life.

During cycling, the charge time for the Li-CuS cell was approximately 30% shorter than the discharge time for the first four cycles yielding A-hr efficiencies

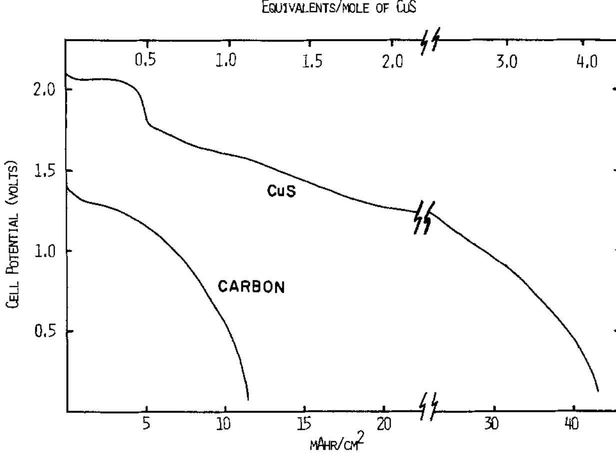

Fig. 3. Electrolyte decomposition compared at Teflon-bonded carbon black and CuS electrodes. $i = 1.0$ mA/cm^2; 1M $LiAsF_6$/THF, CuS electrode capacity 20.4 mA-hr/cm^2 at 1.0 eq/mol CuS.

greater than 100% (see Fig. 4 and Table II). Since it is known from previous voltammetric work (13) that 1M $LiAsF_6$/THF resists reduction down to the Li potential on a Ni working electrode, the only explanation remaining to account for the extra discharge capacity is that the electrolyte is either being reduced on the CuS or the carbon black added to the electrode to increase its conductivity.

To determine the extent of electrolyte reduction at CuS and Shawinigan carbon black, Teflon-bonded electrodes made of each of these materials were discharged to 0.10V *vs.* Li. The results which are presented in Fig. 3 show that below 1.4V much more electrolyte is reduced on CuS than on carbon. Since a greater capacity would be expected at the carbon black electrode with its high surface area and porosity, it seems likely that CuS or one of its reduction products may be a catalyst for the reduction of $LiAsF_6$/THF. This conclusion is reinforced by the fact that of the other oxide and sulfide positives which have been investigated in Li cells such as TiS_2, SiS_2, and MnO_2 all except NiS give A-hr efficiencies less than 100% as would be expected. Electrolyte decomposition has also been observed by Eichinger (5) at sintered Ni and CuS in $LiClO_4$/DMF.

Although electrolyte reduction at the CuS electrode near the end of discharge may lead to some minor deterioration of the CuS electrode, the major factor reducing cycle life of the Li-CuS cell appears to be deterioration of the Li electrode. The Li electrodes removed from Li-CuS, cell No. 2 after 41 cycles were found to be shiny except for the part opposite the CuS positive which was dark brown. Although the Li in this dark area opposite the CuS electrode was heavily corroded, when the surface film was scratched away it was found that considerable Li remained and the 0.38 mm thick foil was in no place consumed through to the Exmet grid. However, when cell No. 2 was disassembled after 205 cycles the Li electrodes were found to consist of a paste-like mixture of brown precipitate and small Li granules (<0.5 mm) down to the Exmet grid with no trace of the original Li foil. The interelectrode space and the separator also contained an appreciable quantity (~0.5g) of a brown precipitate which may be similar to the $Li_{1.2}F_{1.2}As_{0.66}O_{1.1}$ polymer reported by Koch (13, 14). These observations suggest that cell No. 2 was only capable of very shallow cycles by cycle 204 because the Li electrode had deteriorated to such an extent that all the Li foil was consumed and the Li granules which remained were electrically isolated from the current collector by a coating of reaction products. The large increase in the cycling capacity of cell No. 2 after cycle 205 when the cell was reassembled with new Li electrodes further confirms that the cycle life of the cell was limited primarily by failure of the Li electrode.

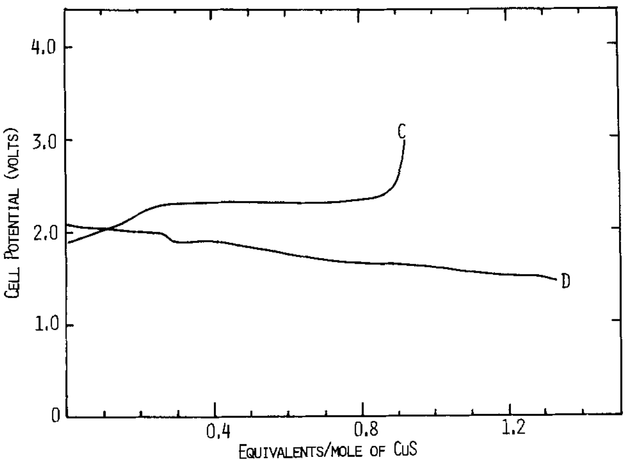

Fig. 4. Charge-discharge curves of the Li-CuS cell for the first cycle. Cell 2, $i_D = i_C = 1.0$ mA/cm^2.

Table II. A-hr efficiencies during cycling for Li-CuS and Li-NiS cells*

Cycle No.	CuS A-hr efficiency (%)	NiS A-hr efficiency (%)
1	138	123
2	—	110
3	140	111
4	119	119
5	107	114
6	106	117
7	103	118
10	92	113
20	101	144
30	90	110
40	104	142

* CuS efficiencies for cell No. 2.

Knowing the amount of Li originally present on the Li electrodes, Q_o, the amount of Li plated during the 162 cycles from cycles 42 to 204, Q_p, the coulombic cycling efficiency of the Li electrode, E can be computed for cell No. 2 using the relation

$$\bar{E} = 1 + \frac{Q_r - Q_o}{Q_p} \quad [1]$$

where Q_r is the amount of Li foil remaining on the grid of the Li electrode at the end of the experiment. For cell No. 2, $Q_r = 0$, $Q_o = 568$ C/cm^2, $Q_p = 2480$ C/cm^2, therefore from Eq. [1] the average cycling efficiency of the Li electrode, $\bar{E}$ was 77% from cycles 42 to 204. This is comparable with the 88.0% average Li cycling efficiency obtained by Koch and co-workers (15) for the Li electrode in half-cells with 1.5 $LiAsF_6$/THF electrolyte cycled at 5.0 mA/cm^2 to a depth of 1.1 C/cm^2. It is likely that the somewhat lower average efficiencies observed for the Li/CuS cell were due to the greater cycle depth and the larger number of cycles. Thus the limited cycle life of the Li/CuS cell observed in the present study is due to the failure of the Li electrode and can be accounted for in terms of the known inefficiency of the Li electrode in $LiAsF_6$/THF found in the earlier work in half-cells. Neither failure of the CuS positive electrode nor electrolyte reduction at the positive electrode appear to be factors limiting the cycle life although they may cause the gradual decline in capacity observed with increasing cycle number.

The thick coating of brown precipitate found on the separator of cell No. 1 when it was disassembled was analyzed using the method described by Koch (14). After three washings with distilled H_2O using a centrifuge and drying (2 hr at 110°C), 0.45g of solid was obtained for analysis. Although infrared spectra (KBr pellet) of the material showed a much weaker absorption peak at 795 cm^{-1} than expected, characteristic octahedral crystals of As_2O_3 were obtained when the brown solid was heated to 400°C in a capillary tube. From these and other analytical tests it was concluded that the brown precipitate found coating the separator from cell No. 1 was similar to the $Li_{1.2}F_{1.2}As_{0.66}O_{1.1}$ polymer described by Koch (14) produced by the reduction of $LiAsF_6$/THF electrolyte at the Li electrode during cycling.

In principle, analysis of the CuS electrode and the electrolyte for other electrolyte reduction products would lead to an understanding of the effect of electrolyte reduction at the positive electrode on cycle life. However, such studies were not carried out because it was clear that the low cycling efficiency of the Li electrode (*i.e.*, 77%) was the major problem and that future efforts should be directed toward the search for electrolytes with greater anodic stability.

Typical charge-discharge curves for the Li-CuS cell at 1.0 mA/cm^2 are shown in Fig. 3 and 4. The distinct plateau which occurs at ~0.28 to 0.5 eq/mol suggests a simple stepwise reduction of CuS to Cu_2S as postulated by previous workers (3). However, examinations in our laboratory (16) of the CuS used in the present work (Fisher, ACS reagent) by modal analysis (grain counting with a petrographic microscope) revealed that the CuS contained ~89% CuS as covellite and 10% Cu_2S as chalcocite. Investigations (17, 18, 22) of the structure of covellite using x-ray diffraction techniques have shown that it is not a simple cupric salt but a more complex compound which could be represented as $Cu_4^{I}Cu_2^{II}(S_2)_2S_2$ in which only one-third of the Cu is present as Cu(II).

The cathodic reduction of covellite is obviously a very complex process and although numerous reactions are possible the following reaction steps are tentatively suggested on the basis of the limited amount of data presently available

$$Li + 1/2\ Cu_4^{I}Cu_2^{II}(S_2)_2S_2 \rightarrow 1/2\ Cu_6^{I}(S_2)_2S + 1/2\ Li_2S \quad [2]$$

$$Li + 1/6\ Cu_6^{I}(S_2)_2S \rightarrow Cu + 1/3\ Li_2S_2 + 1/6\ Li_2S \quad [3]$$

$$Li + 1/2\ Li_2S_2 \rightarrow Li_2S \quad [4]$$

The equilibrium potentials of reactions [2] and [3] *vs.* Li^+/Li were estimated as 2.40 and 2.04V, respectively, using the potentials calculated from the tabulated values of the free energies of formation (19) for the reduction of CuS and Cu_2S by Li. From voltammetric studies in DMSO (20) it appears that reaction [4] occurs at approximately 1.99V *vs.* Li^+/Li. However, the work of Rauh and co-workers (10, 21) in THF indicates that the reduction of disulfide is kinetically difficult and substrate dependent and may proceed at much lower potentials at rates greater than ~0.5 mA/cm^2.

The discharge curve for CuS given in Fig. 4 shows a first plateau ending at 0.28 eq/mol which corresponds to a utilization efficiency of 93% based on reaction [2] taking into account that the CuS active material was ~89% covellite. On the other hand, for the Li-CuS cell described in Fig. 3 the first discharge plateau ended at 0.5 eq/mol which is higher than the 0.30 eq/mol expected. This increased capacity could be due to uneven distribution of CuS in the paste or changes in the covellite produced during sintering at 300°C but the exact cause of the increase is not known.

Crystallographic studies (17, 22) have indicated that CuS as covellite has an ABAACA type layer structure but the S-S distance between A layers is so short [*i.e.*, 2.09Å (17)] that a strong covalent bond would be assumed rather than van der Waals bonding as in TiS_2 (8). Thus an intercalation type discharge-charge mechanism appears unlikely for covellite. The plateau observed in the discharge curve suggests a heterogeneous discharge mechanism such as postulated in reactions [2]-[4] but it is possible that the reaction mechanism could include both displacement and topotactic steps. To determine the overall reaction mechanism for the covellite electrode it is clear that extensive x-ray studies will be required. Such studies were beyond the scope of the present investigation.

Nickel sulfide.—The capacity change as a function of cycle number for the Li-NiS cell using an $LiAsF_6$/THF electrolyte is compared in Fig. 5 with results for the Li-CuS cell. The Li-CuS cell is clearly far superior both in terms of cycle life and capacity. The NiS cell described in Fig. 5 used a Teflon-bonded electrode (1.1 mm thick) containing 30% NiS and 70% carbon black with a nominal capacity of 6.1 $mA\text{-}hr/cm^2$ calculated on the basis of a 1.0 eq/mol utilization. Pressed powder NiS electrodes (41 $mA\text{-}hr/cm^2$) were also tested but they cycled poorly, the utilization dropping below 0.2 eq/mol by the eighth discharge.

Similar to TiS_3 (23), NiS gives a high utilization on the first discharge but fails to accept sufficient charge to duplicate the discharge performance during the second and following cycles. Since the discharge curve for the Li-NiS cell shows a single long plateau at ~1.6V at 1 mA/cm^2 (see Fig. 6), the capacity is highly dependent on the value of the discharge cut-off potential. Thus, when a Li-NiS cell was discharged to a 1.04V cut-off, a capacity of 2.0 eq/mol was obtained, part of which was probably due to reduction of the electrolyte toward the end of discharge. Another indication of electrolyte reduction, as described earlier for CuS, are A-hr efficiencies greater than 100%. A comparison of the A-hr efficiencies for NiS and CuS in Table II shows that the A-hr efficiencies are somewhat smaller for NiS but they remain well above 100% much longer than CuS where they stabilize near 100% after about 10 cycles.

Charge-discharge curves typical for the Li-NiS cell at 1.0 mA/cm^2 are shown in Fig. 6. The discharge curve for NiS has only a single plateau which would be expected since Ni(I) has no appreciable degree of stability. However, the potential fails to show a sharp

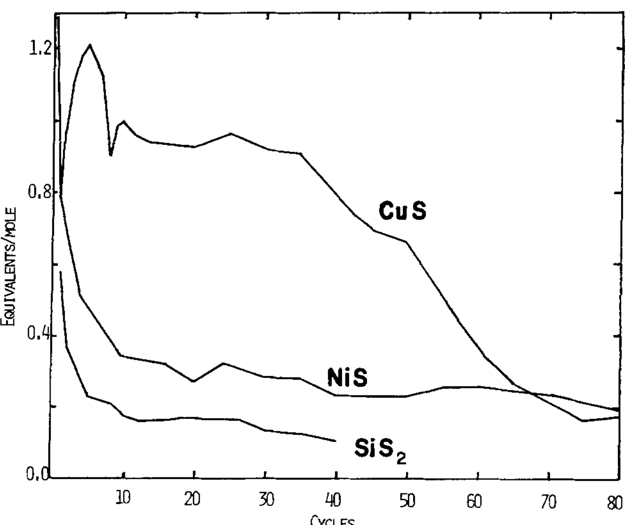

Fig. 5. A comparison of the cycling performance of Li cells with CuS, NiS, and SiS_2 positive electrodes, $i_D = i_C = 1.0\ mA/cm^2$. CuS results are for cell 1.

upturn indicating the end of charge, even for cells charged to 3.80V.

Since the α-NiS used in the present work was synthesized in our laboratory using a procedure similar to the one described by Jasinski and Burrows (2) and later used by Pistoia (25), it is noteworthy that our NiS cells outperformed the earlier cells [*e.g.*, 1.28 compared to 0.88 and 0.49 eq/mol to a 1.5V cut-off for the cells in Ref. (2) and (25), respectively]. The greater capacity of our cells can be attributed in part to the use of $LiAsF_6$/THF which is much more conductive and less viscous than the $LiClO_4$/PC and $LiClO_4$/EC used in the earlier work.

Silicon disulfide.—The cycling performance for the Li-SiS_2 cell using an $LiAsF_6$/THF electrolyte is shown in Fig. 5. Compared to CuS which gives almost ten times the capacity after ten cycles, the SiS_2 electrode is of marginal interest for practical batteries. The SiS_2 electrodes used in this study were of the pressed powder type (0.9 mm thick) described earlier and were 40% SiS_2, 54% graphite, and 6% polyethylene. Pressed powder SiS_2 electrodes were used because the preparation of Teflon-bonded electrodes involves the use of a water paste and SiS_2 hydrolyzes very rapidly to form H_2S and SiO_2.

The A-hr efficiencies calculated for the Li-SiS_2 cell described in Fig. 5 were all less than 100%. Thus SiS_2 does not appear to act as a catalyst for the reduction of the $LiAsF_6$/THF electrolyte even down to a 1.0V discharge cut-off. The SiS_2 (rhombic) used to prepare the electrodes is reported (24) to have a layer structure but it is not known if the bonding between the layers is van der Waals favoring Li intercalation or covalent.

Typical charge-discharge curves for the Li-SiS_2 cell are shown in Fig. 7. The peculiar peak in the first charge curve at 0.22 eq/mol remains well defined for the first 15 cycles after which it weakens until it disappears after 30 cycles. From observations of the SiS_2 as it was received from the manufacturer in large lumps, it was evident that it was a heterogeneous mixture about 90% SiS_2 and 10% impurities. Thus the plateaus in the charge-discharge curves are probably due to the heterogeneous nature of the active material.

Manganese disulfide.—The MnS_2 which was synthesized was evaluated using pressed powder electrodes (45.2% MnS_2, 50.1% graphite, 4.6% polyethylene) to avoid the possibility of MnS_2 decomposition if a Teflon-bonded construction was used. The open-circuit potential of the Li-MnS_2 cell was 3.29V immediately after it was assembled which is higher than the 2.65V OCP predicted in Table I. However, when an Li-MnS_2 cell was discharged at 1.0 mA/cm² the potential dropped to 2.35V within 30 sec, and to 1.45V after 5 min. On recharge the potential rose to the 4.00V charge limit

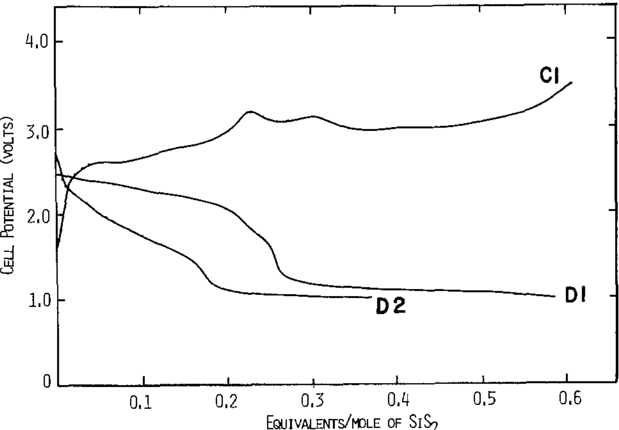

Fig. 7. Charge-discharge curves for an Li-SiS_2 cell, $i_D = 1.0$ mA/cm², $i_C = 0.75$ mA/cm². Voltage limits: 1.0V on D, 3.80V on C.

within 4 min at 1 mA/cm². The second discharge was no better than the first, the potential dropping to 1.57V after 3 min. The capacity of the MnS_2 electrode tested was 13 mA-hr/cm² based on a 1.0 eq/mol utilization. Thus, the first discharge amounted to a utilization of only 0.013 eq/mol which indicates that MnS_2 is for all practical purposes electrochemically inert.

Ferrous sulfide.—When an Li-FeS cell with FeS as β-pyrrhotite was discharged at 1.0 mA/cm² the potential fell from the 3.16V OCV to 1.47V in 18 min. On recharge at 1.0 mA/cm² the potential rose to the 2.90V limit within less than 2 min. The capacity of the Teflon-bonded FeS electrode was 3.4 mA-hr/cm² based on a 1.0 eq/mol utilization. Thus the first discharge yielded only 0.18 eq/mol to a 1.45V voltage limit which indicates that β-pyrrhotite is not a practical electrode material for room temperature Li batteries. Even when the current density was lowered to 0.10 mA/cm² after two cycles, the utilization for the third cycle was still only 0.12 eq/mol.

These results for the FeS electrode are of some interest because they demonstrate that at 0.1 mA/cm² negligible reduction of the $LiAsF_6$/THF electrolyte occurs down to 1.45V on either FeS or carbon since the electrode contained 50% carbon black. Furthermore, because the electrode could not be charged below 2.90V, the results for FeS clearly demonstrate that little capacity can be obtained by cycling just the electrolyte on carbon. These findings, along with others previously discussed, provide further evidence that the CuS electrode is intrinsically reversible during deep cycling.

Conclusions

The specific energies achieved during cycling for the five insoluble sulfides which were investigated are compared in Table III. Out of this group only CuS per-

Table III. Specific energies achieved for various insoluble sulfides as positive electrodes for rechargeable lithium batteries*

$VO_{2.156}$ (28)	2.4	0.16	~325	—	—	285(C5)	255(C35)

* The specific energies were calculated using actual cell potentials and only the weight of the positive electrode active materials omitting the weight of the Li anode, carbon, grids, and hardware. $E_{1/2}$ is the mid-discharge potential.

formed sufficiently well to merit consideration for use in practical Li secondary batteries. Although $VO_{2.186}$ clearly outperformed both CuS and TiS_2 in terms of specific energy for the first 35 cycles, the only available data (28) are for small thin $VO_{2.186}$ electrodes (*i.e.*, 1.3 cm^2, 1.9 mA-hr/cm^2) discharged at very low rate. The TiS_2 electrode gives excellent cycle life at moderate rate, but recent (28) performance gains compared to earlier work (23, 29) appear to be the result of improved methods of electrode fabrication and the choice of electrolyte. Since the active material loading for the TiS_2 electrode described in Table III was not reported (28), it is somewhat difficult to compare the TiS_2 data with the present results for CuS which were obtained using electrodes with loadings up to 18 mA-hr/cm^2 that were not optimized. However, even with the available information, it is clear that CuS will continue to merit consideration for rechargeable batteries because of its high specific energy, ready availability, and its low cost compared with other positive electrode materials.

The main problem with the CuS positive electrode does not appear to be the intrinsic reversibility of CuS but rather the decline in capacity observed during cycling with electrodes with practical loadings. It has been concluded from chemical analysis and inspection of Li electrodes from failing cells that deterioration of the Li electrode due to reaction of Li with the electrolyte is the major cause of the capacity decline seen during cycling.

Reduction of the $LiAsF_6$/THF electrolyte on the CuS electrode toward the end of discharge also limits the cycle life of the Li-CuS cell but it is a much less serious problem. In principle, electrolyte reduction at the CuS electrode could be greatly reduced and the cycle life improved by raising the discharge cut-off from 1.45 to 1.55V or higher. However, the Li-CuS cell has a discharge curve with a long plateau extending below 1.55V and any gain in cycle life would involve some sacrifice in capacity. A more fundamental solution to the problem of capacity decline would be the selection of an electrolyte more resistant to reduction at the Li electrode than $LiAsF_6$/THF.

Cathode-Limited $Li/SOCl_2$ Cells

K. A. Klinedinst*

GTE Laboratories, Incorporated, Power Sources Center, Waltham, Massachusetts 02254

ABSTRACT

The ambient temperature discharge characteristics of cathode-limited $Li/SOCl_2$ cells have been investigated at discharge rates ranging over five orders of magnitude (from about 2 $\mu A/cm^2$ to about 0.5 A/cm^2). The cell voltages and discharge capacities (per unit cathode volume) are compared as a function of discharge current density. The use of alternative cathode materials which catalyze the electroreduction of $SOCl_2$ is discussed, as are the dependencies of the average load voltage and the cathode utilization efficiency upon cathode thickness at high discharge rates. The relationship between the interelectrode spacing and the high rate discharge characteristics of cathode-limited $Li/SOCl_2$ cells has also been investigated.

Various aspects of the ambient temperature discharge characteristics of cathode-limited $Li/SOCl_2$ cells have previously been reported (1-3). (A cathode-limited cell is one whose discharge terminates due to the exhaustion of the carbon black cathode capacity.) Presented here are the results of an investigation of the discharge characteristics of cathode-limited $Li/SOCl_2$ cells in which the effects of varying discharge rate, cathode thickness, cathode composition, and interelectrode separation have been explored.

Experimental

Description of the cells and test procedures.—The electrolyte was a 1.5-1.8M solution of $LiAlCl_4$ in $SOCl_2$. The anodes were cut from a 0.76 mm thick sheet of lithium metal. Unless otherwise indicated, the cathodes contained 91% Shawinigan acetylene black and 9% PTFE and ranged in thickness between 0.025 and 1.3 mm. The thinnest cathodes (0.025-0.280 mm thick) were supported upon sheets of 0.127 mm thick nickel foil. Expanded nickel screen was used as the current collector for the thicker cathodes. Unless otherwise specified, nonwoven glass fiber paper 0.127 mm thick was used as the separator material. The electrodes and electrolyte have been described in more detail in a preceding paper (1).

Two different cell constructions were employed. For cells discharged at rates above 0.1 mA/cm^2, the cells were contained within sealed glass envelopes. The details of the construction of these glass envelope cells have been described previously (1). For cells discharged at rates below 0.1 mA/cm^2, the long discharge times required the use of a different cell construction. At these lower rates, AA-size stainless steel cylindrical cans were used to contain the cells. The lithium anode was first pressed onto the inside wall of the can. Next, a cylinder of porous glass separator paper was placed within the can. Finally, a 13 cm^3 sheet of cathode material was shaped into a cylinder and inserted into the center of the can. Nickel metal lead wires were welded to the can and to the cathode substrate, and the can containing the cell was completely immersed within a pool of electrolyte contained within a glass tube. A glass cap was sealed to the tube through which passed two metallic feedthroughs which had been welded to the nickel lead wires. Every cell contained large excesses of both lithium and $SOCl_2$.

The cells were all discharged to termination across constant loads, the voltages being recorded as a function of time by the use of a datalogger. From two to four cells were discharged at each rate. Reported below are the averaged results obtained from each set of duplicate tests. All of the cells were discharged at room temperature (between 22° and 25°C).

Scanning electron microscopy.—The spent cathodes were removed from the cells discharged at rates below 0.1 mA/cm^2. Disassembly of the cells was carried out in an inert atmosphere. Any adhering $LiAlCl_4$ salt was washed from each cathode by a brief immersion in excess distilled propylene carbonate. After drying, the now brittle cathodes were "flexed" so as to cause them to fracture into a number of pieces. These segments of spent cathode material were mounted and transferred to a JSM-U3 scanning electron microscope without exposure to the air. After the sample chamber had been evacuated, the cathode cross sections were examined microscopically.

Data analysis.—The cell voltage *vs.* time data were first transcribed to graph paper from the datalogger tapes. The average discharge voltages (E_{avg}) were obtained by averaging over each discharge curve to the point at which the voltage began to decline rapidly. The average discharge rate (I_{avg}) was calculated by dividing E_{avg} by the constant load (R). The current density was calculated by dividing I_{avg} by the geometric surface area of cathode (A). The discharge duration (t) was taken to be the time elapsed from the beginning of the discharge to the point at which the cell voltage had reached 90% of E_{avg}. In order to compare cathodes of different thicknesses, the discharge duration was normalized by dividing by the cathode thickness (T). The discharge capacity (C) was obtained by a graphical integration of the discharge curve from the beginning of the discharge to the point at which the cell voltage had reached 90% of E_{avg}. (The capacity is expressed below per unit cathode area and per unit cathode thickness.) The time required for the voltage on load to drop from 90% of E_{avg} to 70% E_{avg} divided by the discharge duration has been taken as a measure of the relative rate of voltage decline at the end of the approximately linear portion of the discharge curve.

Results and Discussion

The $Li/SOCl_2$ cell is characterized by a high open-circuit voltage (about 3.650V) and by the fact that, when discharged under constant load or constant current conditions at moderate rates, the voltage on load remains relatively constant until close to the end of the discharge when a relatively rapid voltage decline is observed. However, the higher the discharge rate, the larger is the voltage range spanned during the initial, linear portion of the discharge curve.

This effect is demonstrated in Fig. 1 which contains typical discharge curves for cells discharged with average current densities ranging from a few micro-

* Electrochemical Society Active Member.

Key words: cathode, discharge, polarization, capacity, catalysis.

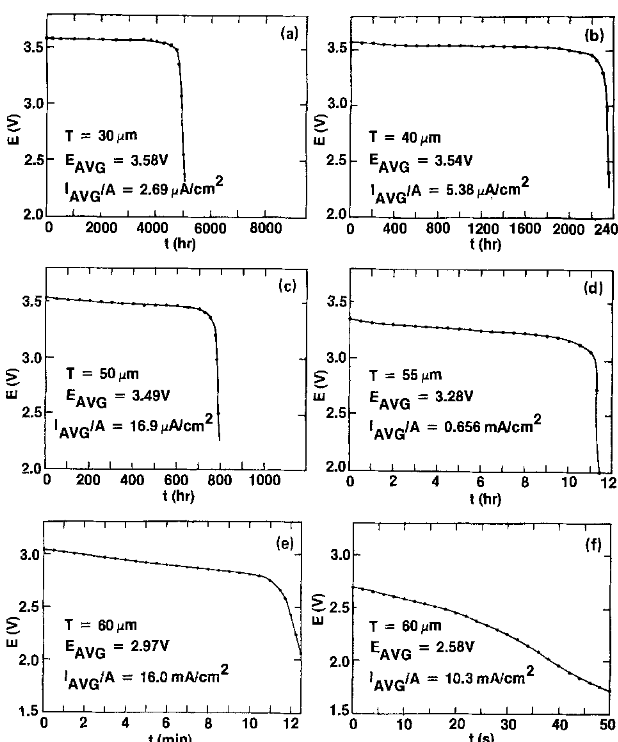

Fig. 1. $Li/SOCl_2$ cell discharge curves

amps per cm^2 to more than a tenth of an amp per cm^2. The data plotted in Fig. 1(a) through 1(f) are summarized in Table I in which are listed the average current densities, the average discharge voltages, and the voltage range spanned during the first 80% of the discharge.

Additionally, as shown in Fig. 1, the increasing discharge rate results not only in an increase in the slope of the approximately linear portion of the discharge curve, but also in a decrease in the relative rate of voltage decline at the end of the approximately linear portion of the curve. The time required for the voltage on load to drop from 90% of E_{avg} to 70% of E_{avg} expressed as a percentage of the discharge duration has been taken as a measure of this characteristic of the $Li/SOCl_2$ discharge curve. It has been found that, at very low rates (between 2 and 20 $\mu A/cm^2$), the time required for E to drop from 0.9 E_{avg} to 0.7 E_{avg} is, on the average, about 4% of the discharge duration. At intermediate rates (between 0.3 and 10 mA/cm^2), the time required for E to decrease from 0.9 E_{avg} to 0.7 E_{avg} is, on average, about 9% of the discharge duration. However, at high discharge rates (between 10 and 200 mA/cm^2), the time required for E to drop from 0.9 E_{avg} to 0.7 E_{avg} is about 30% of the discharge duration. These observations can be conveniently summarized by noting that, as the average discharge rate increases, the average voltage on load decreases and the approximate shape of the discharge curve changes from that of a step function to that of a downward ramp.

The average voltage on load is plotted as a function of the logarithm of the average current density in Fig. 2 for discharge rates ranging from 2.7 $\mu A/cm^2$ to 0.21 A/cm^2. Over this range of discharge rates, E_{avg}

Table I. $Li/SOCl_2$ cell polarization characteristics

I_{avg}/A (A/cm^2)	E_{avg} (V)	ΔE (V)
2.69×10^{-6}	3.58	0.02
5.38×10^{-6}	3.54	0.05
1.69×10^{-5}	3.49	0.07
6.56×10^{-4}	3.28	0.14
1.60×10^{-2}	2.97	0.20
1.03×10^{-1}	2.58	0.25

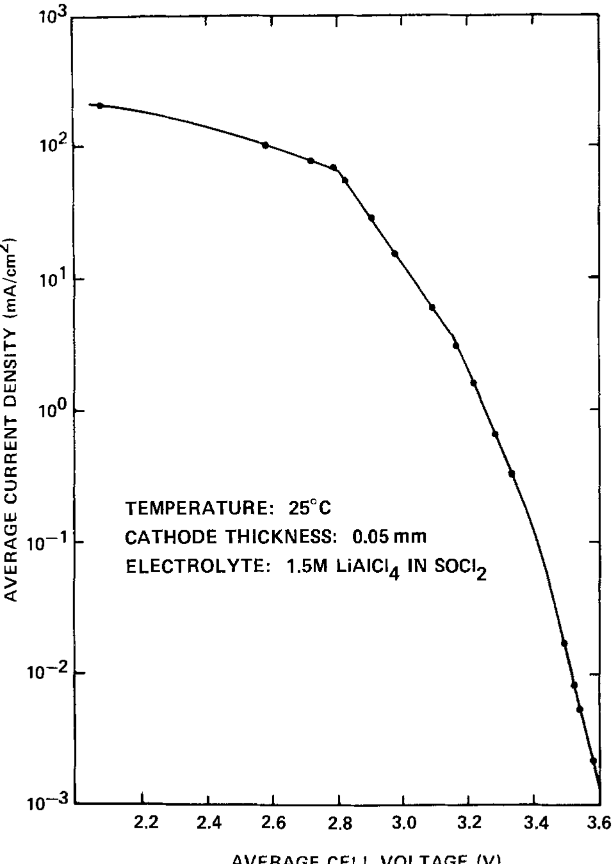

Fig. 2. $Li/SOCl_2$ cell polarization curve

varies from 3.58V (close to the open-circuit voltage) to 2.07V. Pronounced changes in slope are observed to occur at current densities of about 3 and 60 mA/cm^2.

The discharge duration per unit cathode thickness is plotted as a function of the average current density on a log-log scale in Fig. 3. Each point on this graph corresponds to a point in the preceding log current density *vs.* cell voltage plot (Fig. 2). Again, notice the pronounced changes in slope occurring at current densities of about 3 and 60 mA/cm^2. The linearity of the log current density *vs.* log discharge duration plot is an example of a general relationship first expressed by Peukert (4). (In this equation, α and β are constants.)

$$It^{\alpha} = \beta \quad [1]$$

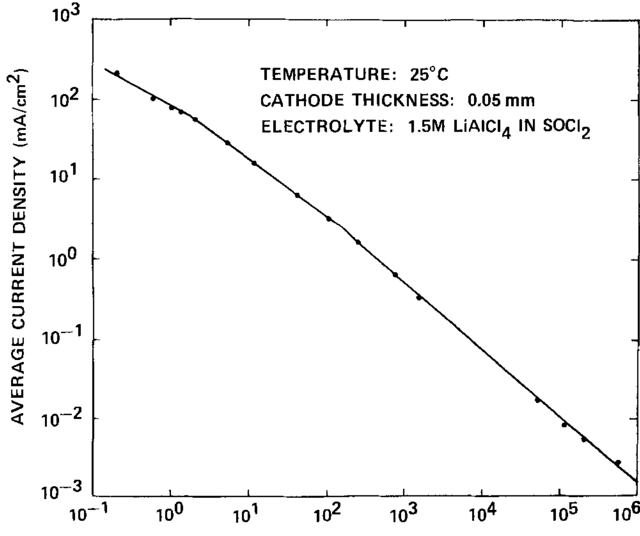

Fig. 3. $Li/SOCl_2$ cell discharge duration vs. discharge rate

More recently, it has been observed that the Peukert equation can be used in general to describe the discharge behavior of primary as well as secondary batteries (5). Such batteries characteristically deliver a limiting capacity at low rates. Thus, Peukert-type equations are not generally useful to express the discharge behavior of primary batteries at low discharge rates. However, the cells described here did not display a limiting capacity even at rates in the microamp per cm² range.

The relationship between the current density and the discharge duration (per unit cathode thickness) corresponding to the three segments of the Peukert plot defined by the two above-mentioned changes in slope can be expressed as follows (where the units of I are amperes per cm² and those of t/T are seconds per micrometer of cathode thickness).

For 3×10^{-6} A/cm² $\leq I \leq 3 \times 10^{-3}$ A/cm²,

$$I(t/T)^{0.84} = 0.167 \quad [2]$$

For 3×10^{-3} A/cm² $\leq I \leq 6 \times 10^{-2}$ A/cm²,

$$I(t/T)^{0.72} = 0.0954 \quad [3]$$

For 6×10^{-2} A/cm² $\leq I \leq 2 \times 10^{-1}$ A/cm²,

$$I(t/T)^{0.52} = 0.0846 \quad [4]$$

The data presented in Fig. 3 can be equivalently expressed by plotting the logarithm of the current density *vs.* the discharge capacity per unit cathode volume. Thus, in Fig. 4 the discharge capacities (in units of mA-hr per cm² of cathode area for a 50 μm cathode thickness) are plotted as a function of the logarithm of the current density for discharge rates between 2 μA/cm² and 0.2 A/cm². When the data are plotted in this fashion, the absence of a limiting capacity at low discharge rates is even more striking. In fact, at very low rates the measured capacities are much larger than would be predicted from an extrapolation of the higher rate data.

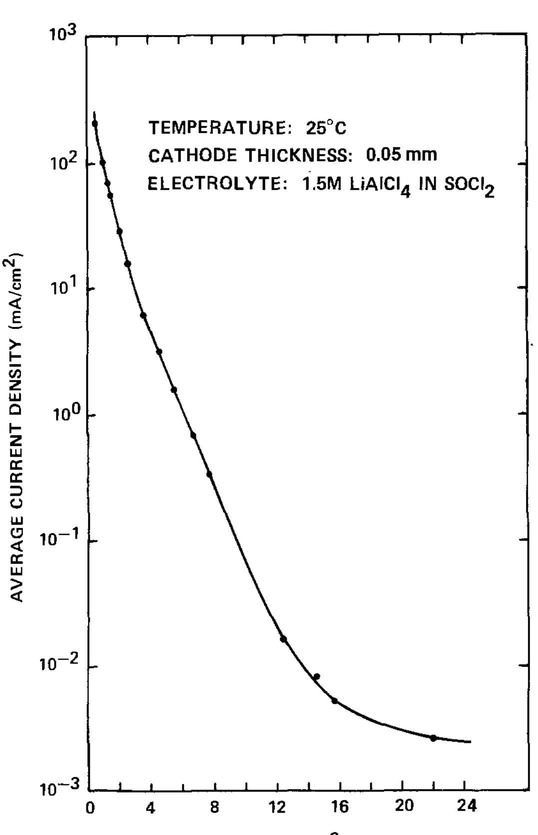

Fig. 4. Li/SOCl2 cell discharge capacity vs. discharge rate

The generally accepted overall Li/SOCl2 discharge reaction can be written as (6)

$$4Li + 2SOCl_2 \rightarrow 4LiCl + S + SO_2 \quad [5]$$

The S and SO_2 are soluble in the excess $SOCl_2$ electrolyte. However, the negligible solubility of the LiCl causes it to precipitate within the porous carbon black cathode as it is formed therein. Thus, the limiting capacity of a cathode-limited cell should be calculable from the amount of LiCl that can be contained within the cathode pores.

Scanning electron micrographs of the edges of spent cathode material were used to determine the thicknesses of the fully discharged cathodes. The cathodes from the cells discharged at the 2.7 μA/cm² rate were found to have increased in thickness from about 30 μm to about 55 μm during the 9 month discharge period. Assuming the entire pore volume of the expanded cathodes to be filled with crystalline LiCl, a cathode initially 50 μm thick would, after being so expanded, yield a capacity of about 11 mA-hr per cm² of geometric surface area—half the electrical capacity actually obtained. This observation suggests that, at least for discharge rates in the microamp per cm² range, the commonly accepted discharge reaction may not apply and that much less LiCl (or other insoluble discharge product) is formed per mole of oxidized metallic lithium than is formed at higher rates. Alternatively, given enough time, it may be possible for the LiCl reaction product to dissolve and be deposited upon surfaces other than within the porous cathode.

As shown in Fig. 2, cathode-limited Li/SOCl2 cells with thin PTFE bonded carbon cathodes polarize to a relatively small degree when discharged at current densities no higher than a few milliamps per cm² of geometric surface area. However, much more severe polarization is encountered at higher discharge rates, the more severe the greater the current density. Thus, alternative cathode materials have been sought by the use of which improved performance characteristics might be attained at moderate to high discharge rates (2, 7, 8).

As shown in Fig. 5 and 6, sizable increases in both cell operating voltage and discharge capacity have been realized by enriching the carbon voltage and discharge capacity have been realized by enriching the carbon black cathode with 9 weight percent (w/o) finely divided metallic platinum. In particular, as shown in Fig. 5 for discharge rates between 1 and 150 mA/cm², between 200 and 300 mV improvements in cell operating voltage may be achieved by the use of such cathodes. Moreover, as shown in Fig. 6, sizable increases in discharge capacity (from 50 to 100%) have also been found to result from the use of such platinum-enriched cathode materials.

Even with the use of catalytic cathode materials, however, Li/SOCl2 cells often exhibit limiting currents considerably below those that would be required to satisfy certain applications. It is true that, as shown in Fig. 7 for the standard cathode material, somewhat higher load voltages may be achieved by increasing the cathode thickness. However, the higher the discharge rate and the greater the cathode thickness, the smaller is the improvement in polarization to be gained by a given increase in thickness. This effect is demonstrated in Table II in which the average load voltage is listed as a function of cathode thickness for Li/SOCl2 cells discharged at 25°C with the standard 1.8M $LiAlCl_4$ electrolyte, with standard carbon black cathodes, and at a constant 58 mA/cm² rate. As shown, an increase in cathode thickness beyond about 0.25 mm has no significant effect upon cell polarization at this moderately high discharge rate.

The effect of increasing cathode thickness upon cathode utilization efficiency parallels the relationship be-

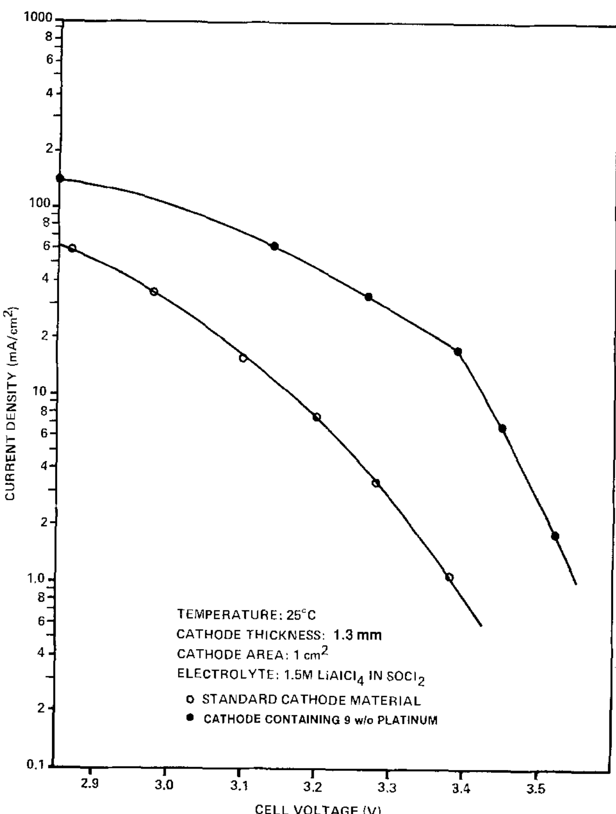

Fig. 5. Li/$SOCl_2$ polarization curves with standard and platinum-enriched cathode materials.

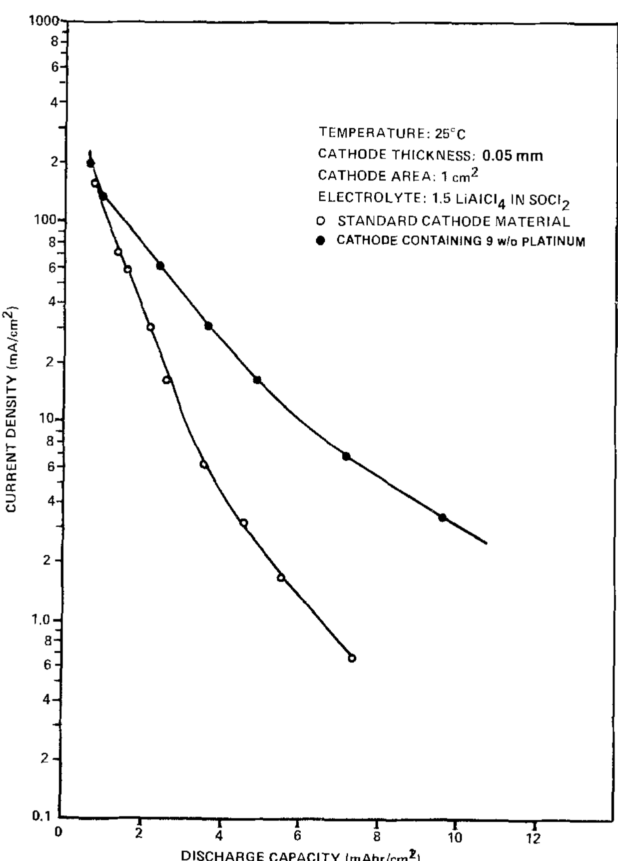

Fig. 6. Li/$SOCl_2$ discharge capacity vs. discharge rate with standard and platinum-enriched cathode materials.

tween cathode thickness and polarization. The discharge capacity per unit cathode volume (for a 1 cm^2 geometric cathode surface area) is plotted *vs.* the cath-

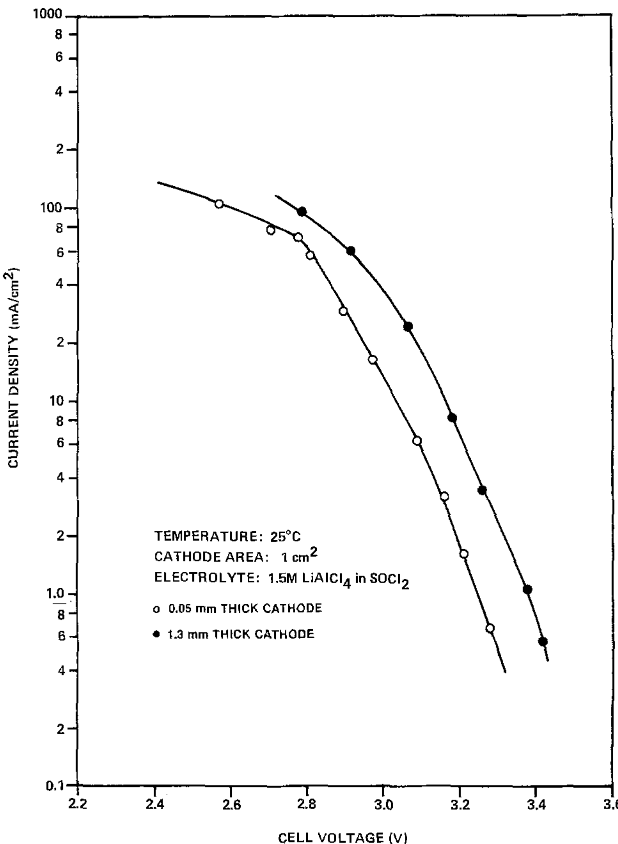

Fig. 7. Li/$SOCl_2$ polarization curves with 0.05 and 1.3 mm cathode thicknesses.

ode thickness in Fig. 8 for Li/$SOCl_2$ cells discharged at 25°C with the standard electrolyte, with standard carbon black cathodes, and at a 30 mA/cm^2 discharge rate. As shown, the cathode utilization efficiency decreases steadily with increasing cathode thickness, the most rapid variation in utilization efficiency occurring with thicknesses less than about 0.15 mm. Thus, the thicker the cathode, the less efficiently is the added cathode pore volume utilized in the storage of solid discharge products. [This effect is also demonstrated in the Peukert-type plot contained in Fig. 6 of Ref. (1) for current densities ranging between 3 and 100 mA/cm^2.] The rapid decrease in utilization efficiency with increasing cathode thickness reflects the fact that the higher the discharge rate, the more the LiCl discharge product tends to be preferentially deposited near to the surface of the cathode which faces the lithium anode (1, 9). Thus, the higher the discharge rate, the more the portion of the cathode nearest the anode is utilized more effectively than are the interior portions of the cathode.

Both of the observed effects, the relative insensitivity of the load voltage to cathode thickness and the reduction in cathode utilization efficiency with increasing thickness, result from the same cause—the relatively poor conductivity of the 1.8M $LiAlCl_4$ electrolyte solution (2×10^{-2} Ω^{-1} cm^{-1} at 25°C). As the cathode is traversed from the side facing the lithium anode to the interior, the *I-R* losses accumulate, effectively

30	2.88 ± 0.01
40	2.88 ± 0.01

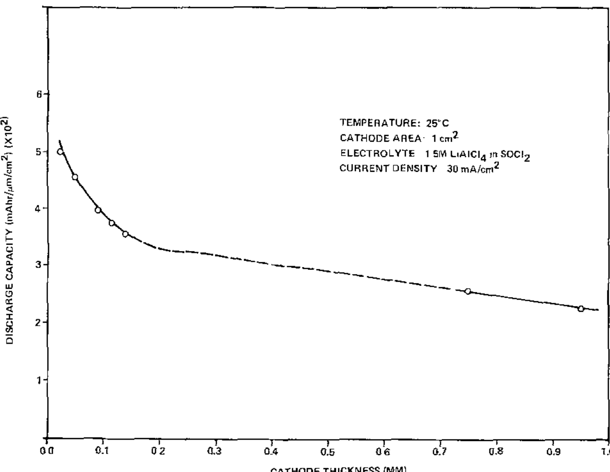

Fig. 8. Li/$SOCl_2$ cathode utilization vs. cathode thickness

negating the reduction in overvoltage that would otherwise result from a reduction in the specific current density (the discharge rate per unit of real cathode surface area). Moreover, as the precipitating LiCl builds up within the cathode pores, the more severe these *I-R* losses become. Thus, the higher the current density, the more the discharge reaction tends to concentrate toward the side of the cathode nearest the anode. The resulting preferential buildup of LiCl at the entrances to the cathode pores further magnifies the *I-R* losses leading to an even less uniform cathode utilization profile. It is this ever worsening mass transport situation which is responsible for the change in shape of the discharge curve with increasing discharge rate and for the steep decline in discharge capacity that accompanies an increase in discharge rate.

In order to demonstrate the magnitude of the effect of solution *I-R* losses upon the high rate performance characteristics of cathode-limited Li/$SOCl_2$ cells as well as to determine quantitatively the importance of interelectrode spacing in the determination of these characteristics, the following experiments were performed. Li/$SOCl_2$ cells with 0.050 mm thick standard carbon black cathodes and with the standard 1.8M $LiAlCl_4$ electrolyte were discharged at 25°C across 4, 7, and 10Ω loads. Five thicknesses of glass fiber separator paper were used, the approximate thicknesses being 0.068, 0.14, 0.21, 0.34, and 0.45 mm. Glass-coated metal weights were used to ensure good interfacial contact between the cell components. Thus, the interelectrode separation was established by the separator thickness. At least two cells containing each of the five thicknesses of separator paper were discharged to termination across each of the three constant loads. The average load voltages and discharge rates are compared in Fig. 9.

In general, the greater the interelectrode spacing, the lower was the average load voltage at constant current density. Similarly, the apparent limiting current decreased markedly with increasing interelectrode spacing. However, the discharge capacities were found to be independent of the interelectrode separation. Qualitatively similar results were obtained when the entire series of experiments was repeated at 65°C.

Perhaps the most striking result of these measurements is the linearity of the Tafel plot obtained with the 0.068 mm interelectrode spacing, indicating that the intrinsic limiting current determined by the kinetics of the Li/$SOCl_2$ discharge reaction is well in excess of 500 mA/cm² at room temperature, with a cathode thickness of only 0.05 mm, and in the absence of any catalytic cathode materials.

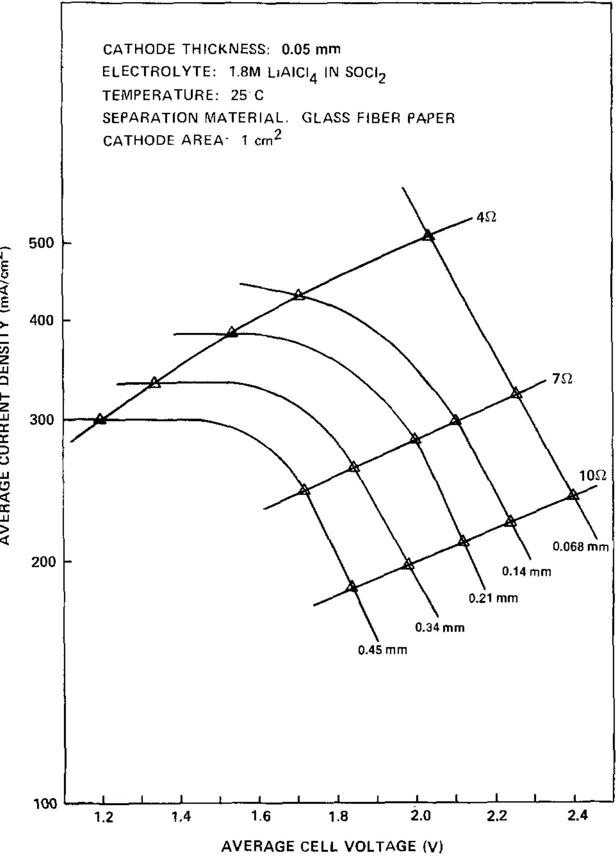

Fig. 9. Li/$SOCl_2$ polarization curves with varying separator thicknesses.

Summary

The ambient temperature discharge characteristics of cathode-limited Li/$SOCl_2$ cells have been investigated at discharge rates ranging over five orders of magnitude (from about 2 μA/cm² to about 0.5 A/cm²). The discharge characteristics of these cells have been summarized and compared. As the average discharge rate increases, the average voltage on load decreases and the approximate shape of the discharge curve changes from that of a step function to that of a downward ramp. Contrary to expectations, no limiting capacity was found, even at discharge rates as low as a few microamps per cm². Further, the cells discharged at the lowest current density so far examined (about 2.7 μA/cm²) exhibited capacities twice those expected assuming the validity of the commonly accepted overall discharge reaction.

Sizable increases in both cell operating voltage and discharge capacity have been realized by enriching the carbon black cathode with finely divided metallic platinum which catalyzes the electroreduction of the $SOCl_2$. Improvements in the high rate discharge characteristics of cathode-limited Li/$SOCl_2$ cells can also be accomplished by increases in cathode thickness. However, the magnitudes of these improvements are limited by solution *I-R* losses which become increasingly severe the higher the discharge rate and the greater the discharge duration. These solution resistance effects are also responsible for the rapid decline in average load voltage that results from an increasing interelectrode spacing at high discharge rates. It has been shown that, at room temperature and in the absence of any catalytic cathode materials, the intrinsic limiting current determined by the kinetics of the Li/$SOCl_2$ discharge reaction is well in excess of 500 mA/cm².

Effects of Deep Cycling on Lead Positive Plates

C. P. Wales* and A. C. Simon*,[1]

Naval Research Laboratory, Washington, DC 20375

ABSTRACT

Characteristics of the active material in lead positive plates were determined by light and electron microscopy, and by surface area analysis as the plates were cycled. Average size of $PbSO_4$ in discharged plates gradually decreased with cycling. Some PbO_2 usually remained within the $PbSO_4$ crystals. Capacity loss was mainly caused by large areas developing where the PbO_2 did not reduce on discharge. The rate of capacity loss decreased from 1.7 to 0.9% per cycle as discharge current density increased from 125 to 2000 A/m^2 (3 hr to 4 min discharge rates). Capacity loss was only 0.3% per cycle at 18 A/m^2 (24 hr rate) which suggests a different reaction mechanism. Surface area of the active material increased as discharge current density increased. The values for charged and discharged surface areas tended to approach each other with cycling.

Energy constraints in the USA have caused an increased focus on the use of electric vehicles. This interest has directed our attention to the effects of power demands on the lead-acid battery and to the question of the differences in electrode microstructure that might be produced by different rates of discharge. As the first stage of our investigation, the effect of different rates of discharge on the negative electrode was studied (1). In the present work the investigation has been extended to the positive plate.

Formed positive plates may have various structures depending on paste composition, treatment, and forming conditions. Despite the initial differences, plates cycled the same way are converted to practically the same microstructure after cycling, with the structure being a function of current density and mode of operation (2). Current density has a large effect on positive electrodes of lead-acid batteries because the rate at which reactions take place is governed by diffusion and crystallization processes, with the reaction mainly involving dissolved Pb^{++} ions rather than solid-state reactions (3). Other important factors that affect structure are the temperature and the proportions of α-PbO_2 and β-PbO_2 in the plate (4, 5).

Discharges begin with nucleation of $PbSO_4$ on PbO_2 surfaces that are in contact with the electrolyte. Further growth of $PbSO_4$ depends on dissolution of nearby PbO_2 and deposition of $PbSO_4$ on the surface of the $PbSO_4$ (6). Particles of inactive PbO_2 that remain within the $PbSO_4$ at the end of a discharge form a conductive network and serve as nuclei for crystallization of the PbO_2 during charge (6, 7).

Experimental

The positive and negative plates used in this study were commercial plates of the type used in automotive batteries. The active materials had not been formed. Positive plate size was 144 × 122 × 1.75 mm, not including the tabs. The grids were 4% antimony-lead. Before putting a positive plate in use, active material pellets were removed to outline seven equal areas as described earlier (1). Approximately 61.6g of unformed active material remained, which was 64% of the amount originally present.

Experimental cells and procedures were generally the same as in our negative electrode study (1), except that the cells contained one positive plate and two negative plates. The forming charge began within 30 sec after a positive plate was put into 1.150 sp gr acid. A positive plate was formed 18 hr at 50 A/m^2 followed by 22.5 hr at 20 A/m^2. Then the acid was adjusted to 1.255 sp gr and maintained at 1.250-1.260 during the cycling. The two negative plates in a cell had a much greater capacity than the one positive plate and were formed separately.

Positive plates were discharged at 18, 125, 500, or 2000 A/m^2 geometric area. This resulted in discharges lasting, respectively, 24 hr, 3 hr, 0.5 hr, and 4 min during the first six cycles. Final cell potentials were 1.8, 1.75, 1.5, and 1.0V. A particular positive plate was always discharged at the same current density for its entire life. Adjustments to cell current were made after removal of each sample, so that positive plate current density remained constant. Capacity discharges were done at cycles 1-6 and every 10 cycles thereafter. In all other cycles the positive plates were discharged to 80% of the previous capacity discharge. Cycling was done at room temperature (19°-25°C). Charges

were always done at 31.25 A/m², except for the forming charge.

Samples cut from the positive plates were washed 45-60 min in distilled water and then dried at 60°C. Fractured cross sections of the active material were examined using an AMR Model 1000 scanning electron microscope. Other plate portions were impregnated with plastic, cut into cross sections, polished, and examined by optical microscopy. The BET surface area was determined with a Micromeritics Model 2205 surface area analyzer, using about 5g of active material broken into pieces that were 5 mm or smaller. The material was degassed 40 min at 100°C in argon before analysis.

Results and Discussion

Figure 1 shows the change in discharge capacity with cycling. Values for the first 26 cycles are averages of results from two or three positive plates that were cycled independently. Individual measurements deviated by an average of 2.3% from the values in Fig. 1. Values given for cycles 32-76 are individual measurements. When capacity declined rapidly as a plate approached failure the discharge potential sometimes reached the cut-off value and a plate would be 100% discharged before the next regularly scheduled capacity discharge. Capacities are compensated for the removal of samples and are given as if the quantity of active material used at cycle 1 had remained constant. Capacity and structure changed more rapidly with the deep discharges used in the present work than they would have changed if SAE cycles had been used.

During the early cycles the capacity varied inversely with current density, as one would expect (Fig. 1). All three positive plates cycled at 125 A/m² showed a much greater rate of capacity loss than did the plates cycled at the other current densities. Plates discharged at 18 A/m² maintained their capacity much longer than plates discharged at 125-2000 A/m². The difference between the capacity obtained at cycles 30-50 when using 125-2000 A/m² and the capacity when using 18 A/m² suggests that a change in discharge mechanism occurred between 18 and 125 A/m².

Figure 2 gives capacities as a percent of the capacity obtained at cycle 1. If part of the active material becomes inactive after a certain number of cycles, then capacity would be expected to decrease more rapidly when cells were cycled at the lower current densities because a larger proportion of the active material is reduced as current density is decreased. In agreement with this, Fig. 2 shows that the rate of capacity loss did increase as discharge current density decreased from 2000 to 125 A/m². At 18 A/m², however, the trend is reversed and the capacity loss is significantly lower. This suggests strongly that the discharge is

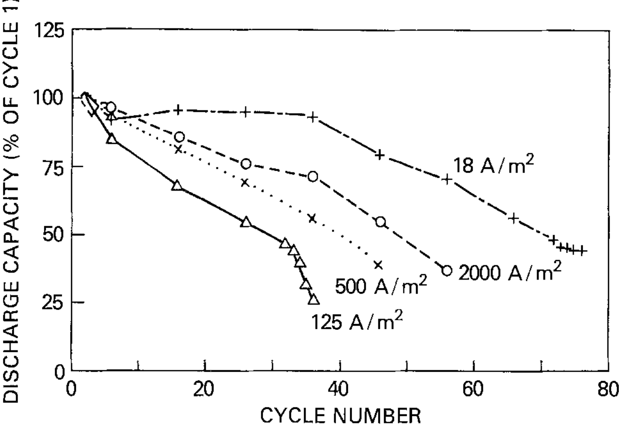

Fig. 2. Positive plate capacity relative to the capacity at cycle 1. For clarity the individual values at cycles 1-5 are omitted.

limited by a different mechanism at 18 A/m² than at 125-2000 A/m². At the lowest current density used in this work the reaction apparently had sufficient time so that diffusion processes did not limit cell capacity.

The rate of capacity loss was 0.3% per cycle for discharges at 18 A/m². This is the same as the rate of loss when negative plates were cycled at 18 A/m² (1). The positive plates lost capacity at about 1.7, 1.2, and 0.9% per cycle when discharged at 125, 500, and 2000 A/m² (Fig. 2). These values are all higher than the 0.7% per cycle loss obtained when negative plates were cycled at 125-2000 A/m² (1).

The changes in positive plate potentials during discharge are shown in Fig. 3. Potentials were lower in the first part of a discharge at cycle 1 and in the early cycles than they were at later cycles. The cycles between 1 and 26 gave potentials intermediate between those shown in Fig. 3. Polarization of the active material increased when current density was increased. The increased polarization was indicated in Fig. 3 by the lowered potential during the first half of a discharge, and by a decrease in the amount of discharge that was obtained before the potential began to fall rapidly.

Since the negative plates in the experimental cell had considerably more capacity than the positive plates, the negative plates only varied a few hundredths of a volt during the course of a discharge. Therefore, approximate cell potentials can be obtained by adding 0.96, 0.96, 0.95, and 0.89V, respectively, to the values shown in Fig. 3 for discharges at 18, 125, 500, and 2000 A/m².

Structure of discharged plates.—The effect of discharge current density on $PbSO_4$ crystal size was im-

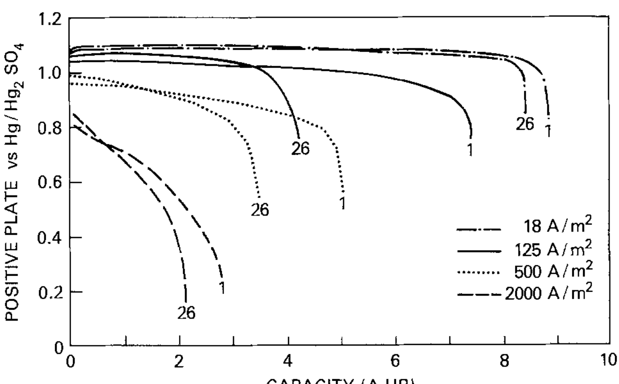

Fig. 3. Discharge potentials between the positive plate and the Hg/Hg_2SO_4 reference electrode. Potentials are shown for cycles 1 and 26 at four rates of discharge. The current density used at cycle 1 was repeated in all subsequent discharges.

mediately evident after a single discharge of the positive plates. Scanning electron microscope photographs of fractured cross sections after discharges are shown in Fig. 4 and 5. The $PbSO_4$ size varied inversely with current density. The major changes in $PbSO_4$ crystal size with cycling are summarized in Table I for the first 26 cycles. The size ranges were based on measurements of SEM photographs. To help minimize sampling error, the photographs were usually taken from at least three different samples of each electrode, and from two electrodes that were independently given the same cycling treatment. Although most of the active material was in the range of sizes given in Table I, one could also find particles outside these ranges.

The average size of the $PbSO_4$ gradually decreased with cycling, particularly in the early cycles (Table I). When using the lower discharge rates of 18 and 125 A/m^2 the size decrease occurred over a longer number of cycles. Samples taken later than cycle 26 from positive plates discharged at 125-2000 A/m^2 contained the same size $PbSO_4$ as was found at cycle 26 (Table I). However, at 18 A/m^2 average $PbSO_4$ size slowly decreased for about another 20 cycles although remaining in the 5-10 μm range.

Some PbO_2 was always present in the discharged plates, and can be seen in Fig. 4 and 5. The amount of PbO_2 remaining at the end of a discharge increased as discharge current density increased (compare Fig. 4 and 5). The increased PbO_2 reflects the lower discharge capacity obtained at the higher currents. The amount of PbO_2 in discharged electrodes also increased as the number of cycles increased. At the end of cycle 6 discharge at 125-2000 A/m^2 most of the $PbSO_4$ was obscured by a PbO_2 covering. As the cycling continued fewer and fewer $PbSO_4$ crystals were visible at the end of a discharge because of the increasing presence of PbO_2. After discharges at 18 A/m^2, much

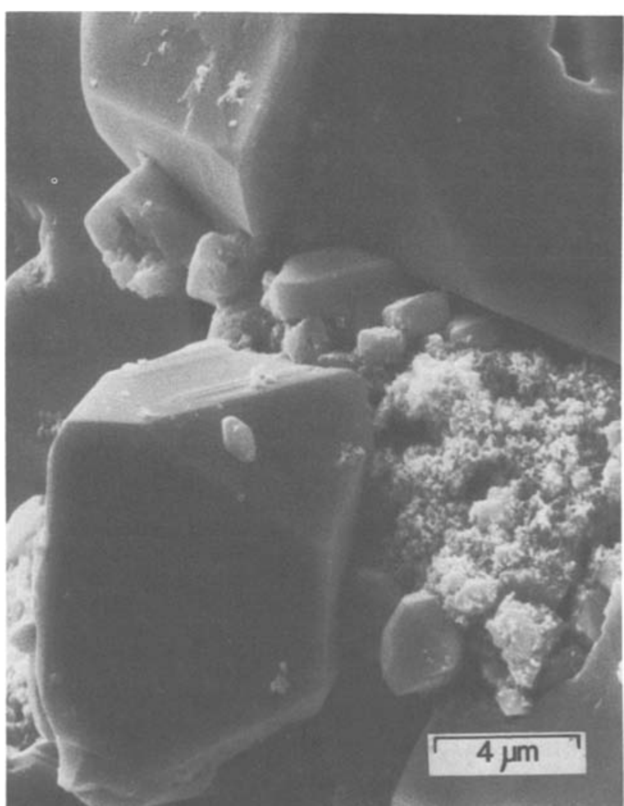

Fig. 4. Positive active material at the end of cycle 1 discharge at 18 A/m^2, the 24 hr rate. The smallest particles are PbO_2. Medium size and large crystals are $PbSO_4$.

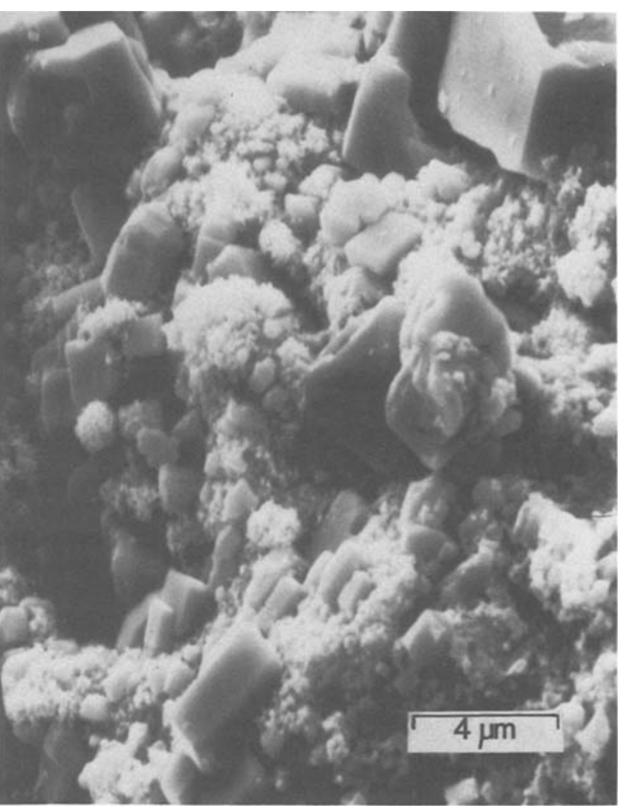

Fig. 5. Positive active material at the end of cycle 1 discharge at 2000 A/m^2, the 4 min rate. Note the smaller $PbSO_4$ size and increased amount of PbO_2 compared to Fig. 4.

less PbO_2 was present and the amount of PbO_2 increased more slowly with cycling.

The examination of electrode cross sections by optical microscopy revealed some things not evident from examination by the scanning electron microscope and confirmed others. The first discharge of the positive plates produced closely packed $PbSO_4$ (Fig. 6). The $PbSO_4$ crystals often contained PbO_2, with the amount of PbO_2 within the $PbSO_4$ increasing as discharge current increased. The SEM examinations gave no hint of the large amount of PbO_2 inside the $PbSO_4$ crystals. These PbO_2 particles play an important part in the recharge process (6, 7). As the cycling was continued, the active material gradually changed its consistency (Fig. 7).

During discharges at 18 and 125 A/m^2 the PbO_2 was reduced to $PbSO_4$ at sites throughout the electrode. Although electrodes discharged at 125 A/m^2 had the same structure at the outer layers as in the interior at cycle 1, there was a tendency for large particles to form in the interior of the electrode as cycling at 125 A/m^2 continued. Electrodes discharged at 18 A/m^2 did

Table I. Range of sizes that were common for $PbSO_4$ crystals in discharged positive plates (μm)

not develop a difference between the outer layers and the interior. When using discharges at 500 or 2000 A/m², the $PbSO_4$ formed mainly near the surfaces of the electrode with some areas in the interior showing no reduction of PbO_2. Bode *et al.* reported similar results for the effect of discharge current density on $PbSO_4$ content (8). The areas shown in Fig. 6 and 7 were in the outer 30% of the plate, the regions where most of the reduction and oxidation took place when discharges were done at 500 A/m². Diffusion became an increasingly limiting factor at the higher current densities. The amount of PbO_2 remaining in the center of a discharged plate was largest for 2000 A/m². Even after 56 cycles using 2000 A/m² as the discharge rate, some of the central areas still had PbO_2 apparently unchanged since the forming charge.

The amount of PbO_2 that remained at the end of a discharge gradually increased with cycling. Large areas developed where the active material consisted entirely of PbO_2 at the end of a discharge. For example, after cycle 26 discharge at 125 A/m², an estimated 30-40% of the active material remained in the form of areas of PbO_2 without $PbSO_4$. Even at 18 A/m² about 15-25% of the active material consisted of separate PbO_2 areas at the end of cycle 26 discharge. After cycle 1 discharge at 18 or 125 A/m², no large areas consisting only of PbO_2 were found, although much PbO_2 remained within the $PbSO_4$ crystals.

At the higher discharge current densities, the development of increasing amounts of inactive PbO_2 in the outer layers was partly offset by a gradual attack on the PbO_2 in the interior, the PbO_2 which had taken little part in discharges at the early cycles. As a result, the amount of PbO_2 in the interior gradually decreased with cycling. This active material in the interior must have prevented capacity from falling as rapidly as would have taken place if all of the active material had been used at cycle 1.

The amount of void space in discharged active material increased as discharge current density increased. At any given current density the amount of voids also increased with cycling. The increase in porosity that occurred in 26 cycles can be seen by comparing Fig. 7 with Fig. 6. Because PbO_2 occupies a smaller volume than $PbSO_4$, the increase in void space is attributed to the larger amount of PbO_2 in discharged electrodes.

The decrease in discharge capacity with cycling appeared to result from failure of PbO_2 to reduce to $PbSO_4$, rather than from $PbSO_4$ not oxidizing on charge. Increasingly large amounts of PbO_2 remained at the end of a discharge as capacity decreased, while the amount of $PbSO_4$ in a charged electrode remained low. Loss of active material from the plates was not a major factor during the first half of the cycling. Shedding of active material became a problem late in the cycle life and may have contributed to the final drop in capacity.

Several differences were evident between the structures in discharged positive plates and the structures in negative plates that had been discharged at the same current densities (1). The $PbSO_4$ size tended to increase when negative plates were cycled, in contrast to the decrease in size for positive plates. The $PbSO_4$ concentration was only a little larger near the surfaces of negative plates than in the interior after discharges at 2000 A/m², while strong differences were found in positive plates. Negative plates also differed in showing an increase in the amount of discharged active material remaining at the end of charges. The positive and negative plates were similar in having approximately the same ranges for sizes of $PbSO_4$, and having increasing amounts of charged active material remaining at the end of discharges as the electrodes were cycled.

Structure of charged plates.—Charged plates that were given an equal number of cycles generally resembled each other when examined by the SEM re-

gardless of which discharge rate was used. Charged active material consisted of clumps of PbO_2 containing small PbO_2 crystals about 0.1-0.3 μm in size. A few of the PbO_2 clumps contained small $PbSO_4$ crystals. Typical clump size was 1-4 μm after cycle 6 charge, decreased between cycle 6 and 16, and then remained approximately constant. Clump size was smallest in electrodes that had been discharged at 18 A/m^2.

When cross sections of charged positive plates were viewed by optical microscopy very little $PbSO_4$ was found. The charged plates that had always been discharged at 18 A/m^2 had a uniform structure throughout the active material with PbO_2 present as small particles. Charged plates given repeated cycles with discharges at 125 A/m^2 gradually developed larger PbO_2 clumps in the interior of the plates while the PbO_2 near the surface remained small. The PbO_2 clumps were randomly distributed at cycle 6 when using 125 A/m^2 but were mainly in the center of a cross section at cycle 16 and later.

The centers of charged plates that had been discharged at 500 or 2000 A/m^2 always had large clumps of PbO_2 which resembled the PbO_2 present at the end of the forming charge. The small change from the appearance after the forming charge probably resulted from the PbO_2 in the plate interior undergoing only a slight reduction during the discharges, followed by oxidation during charges. Charged electrodes given 26 or more cycles using 2000 A/m^2 as the discharge rate had smaller particles in the interior near the grid than elsewhere in the interior, but these particles near the grid were still larger than the PbO_2 in the outer layers.

Particles in the outer layers of a charged electrode always discharged at 500 A/m^2 resembled the small particles found when using 18 or 125 A/m^2. In charged plates always discharged at 2000 A/m^2, particles in the outer layers were much larger than those formed at the lower rates at cycle 6. The $PbSO_4$ developed during a discharge at 2000 A/m^2 was on the surface of large PbO_2 clumps. The centers of the original PbO_2 clumps were not reduced in the early cycles, but in later cycles increasing amounts of small PbO_2 clumps were present in the outer layers of plates always discharged at 2000 A/m^2.

Active material consistency.—The consistency of the active material was strongly affected by cycling conditions. For the cycle 1 discharges the active material was much harder at 18 A/m^2 than at higher current densities. Charged active material was always a little softer than discharged active material at the same cycle. Although the active material was fastened firmly to the grids initially, it gradually softened with cycling and became quite fragile by the time that over 50% of the original capacity had been lost. The grids became increasingly brittle with cycling.

These changes can be correlated with structural changes observed in the active material. The unusually large $PbSO_4$ crystals that develop during cycle 1 discharge at 18 A/m^2 (Table I) give the active material a hardness never found under other conditions. Smaller $PbSO_4$ crystals present more opportunity for movement when a force is applied, and result in softer active material. In addition, PbO_2 particles are much smaller than $PbSO_4$ and give the active material less strength. The increasing amounts of the PbO_2 that became inactive with cycling perhaps resulted from loss of physical contact with the conducting grids. If so, this lack of contact would contribute to the loss of strength that was observed.

Surface area.—It has been shown that the surface area of formed positive plates increased as the proportion of β-PbO_2 to α-PbO_2 increased (5, 9, 10). For formed plates with high β-PbO_2 content, the BET specific surface area decreased as acid concentration decreased, from 7.5 m^2/g in 3.5M H_2SO_4 to 5.2 m^2/g in 1.5M H_2SO_4 (5). Capacity was not proportional to the surface area of formed plates (5). Formed positive plates in the present work averaged 5 m^2/g, which is reasonable for a mixture of α- and β-PbO_2.

Current density had a strong effect on the specific surface area of discharged electrodes (Fig. 8). The values reported in the present work for cycles 1-27 were averages of surface areas measured from two or three electrodes that were cycled independently. A sample consisted of 14 pellets of active material. Surface areas from the individual electrodes had an average variation of 0.43 m^2/g from the values reported here. Repetition of a measurement usually gave less than 1% variation when surface area was 5 m^2/g or greater. Accuracy decreased when surface area was low, with repeated measurements differing by 1-4% for 1-3 m^2/g. These variations were smaller than structural variations within the samples.

The values in Fig. 8 can be compared to results of Voss and Freundlich (5) where β-PbO_2 plates would be expected to give BET specific surface areas of about 2.0, 3.0, and 5.2 m^2/g after discharges at 18, 125, and 350 A/m^2, respectively. Cycle number was not specified. Wiesener and Reinhardt reported surface area of about 3 m^2/g in the early cycles for cells discharged at what was apparently the 2 hr rate, with surface areas slowly rising to about 4.5 m^2/g at cycle 70 (10).

The large $PbSO_4$ crystals that were produced at a low current density (Fig. 4) cause a low surface area for electrodes discharged slowly. Discharged electrodes had larger surface areas when higher current densities were used because the average size of the $PbSO_4$ crystals was smaller and also because less $PbSO_4$ formed before the discharge ended, which resulted in larger amounts of PbO_2 remaining.

Charged active material always had a higher surface area than discharged active material (compare Fig. 8 with Fig. 9); an expected result because PbO_2 particles are much smaller than $PbSO_4$ crystals. One might expect all of the charged electrodes to give the same surface area, since all used the same charge currently density. However, the structures produced during discharge were not entirely destroyed during charge. Consequently, electrodes with the lowest surface area after a discharge tended to have the lowest area after being recharged. The differences in surface area of the charged active material were not nearly as great as the differences in the discharged active material. As cycling progressed the values for charged and discharged surface areas tended to approach each other. This was caused by increasing amounts of $PbSO_4$ remaining in the charged electrode and increasing amounts of PbO_2 remaining in the discharged electrode as the capacity slowly decreased with cycling.

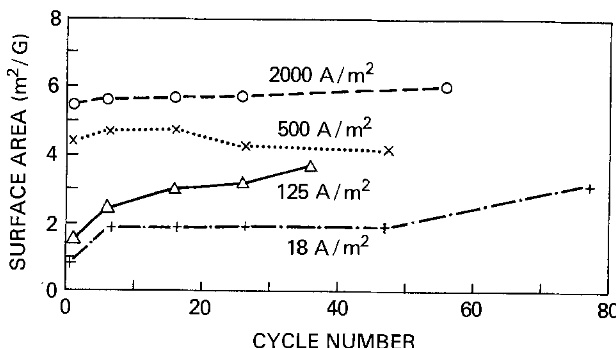

Fig. 8. BET specific surface areas of positive active material at the end of capacity discharges.

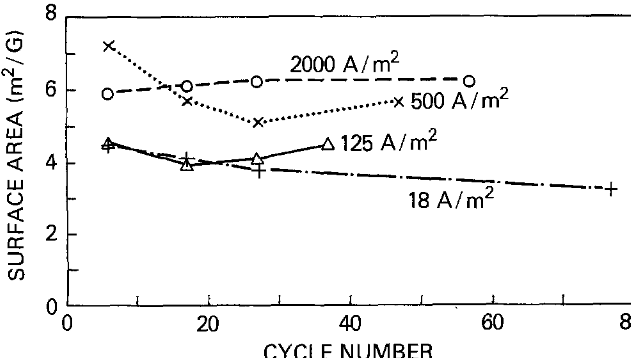

Fig. 9. BET specific surface areas after charges at 31.25 A/m^2. These positive electrodes were always discharged at the current densities given on this figure.

The specific surface area of unformed positive active material was 0.7 m^2/g, probably not significantly different from the 0.8 m^2/g for unformed negative active material (1). At the end of the forming charge the specific surface area of the positive active material had increased to about 5 m^2/g while the negative active material had decreased to only 0.2 m^2/g. Throughout the cycling the charged negative active material had only 3-4% of the surface areas given in Fig. 9 and discharged negative plates had only 4-6% of the values given in Fig. 8. This difference was caused by the high surface area of the PbO_2 particles always present in positive plates and the low surface area of the Pb particles in negative plates. It is surprising that discharged plates had such a great difference in surface area, since the sizes of $PbSO_4$ in positive and negative plates were comparable. Obviously the PbO_2 and Pb that remained in the discharged plates had a strong effect on specific surface area.

Summary and Conclusions

Positive plate capacity decreased with cycling because of PbO_2 failing to be reduced during discharge, instead of $PbSO_4$ not being oxidized during charge. An increasing proportion of the active material became inactive as the electrodes were cycled. The rates of capacity loss were 0.9, 1.2, 1.7, and 0.3%, respectively, for discharges at 2000, 500, 125, and 18 A/m^2. There were indications that the reaction at 18 A/m^2 was limited by a different mechanism than the diffusion processes which limit discharges at the higher rates.

The $PbSO_4$ crystal size varied inversely with current density and gradually decreased with cycling, particularly in the early cycles. The $PbSO_4$ crystals often contained PbO_2 that was not evident until the $PbSO_4$ crystals were cut open. In addition, as the cycling continued increasingly large areas of PbO_2 remained in discharged electrodes. The amount of void space in discharged electrodes increased with cycling and when discharge current density increased.

The active material consistency was strongly affected by cycling conditions. The hardest active material was obtained after the initial discharge at 18 A/m^2, and was caused by the unusually large $PbSO_4$ crystals that developed. At all discharge current densities the active material gradually softened with cycling as smaller crystals developed. The active material became quite fragile by the time that half of the original capacity was lost, and the grids became increasingly brittle.

Further work should be done to determine the reasons for the apparent change in mechanism when low discharge rates are used. Work should also be done to determine why part of the PbO_2 becomes inactive with repeated cycling. The inactivity may result partly from a change in the PbO_2 structure, and partly from loss of electrical contact.

Corrosion of Plated Nickel in Formamide-Water Mixtures

Lal Bahadur, V. B. Singh, and P. K. Tikoo

Department of Chemistry, Banaras Hindu University, Varanasi-221005, India

ABSTRACT

Corrosion behavior of plated nickel in formamide-water mixtures has been studied at 25°C galvanostatically covering the whole range of solvent composition. It has been observed that solvent composition has a pronounced effect on the corrosion behavior of nickel and it has been found that nickel is anodically active in water-rich solvent composition region while it becomes passive in formamide-rich region.

Corrosion studies of metals and alloys in nonaqueous media have been the center of interest during recent years (1-7) because of the wide use of organic solvents in different industries, chemical laboratories, and development of new energy sources. Corrosion in such cases affects the quality of chemical product, leads to failure of chemical units, and reduces the life of batteries, etc. From this view point the corrosion studies in nonaqueous media have attracted the attention of researchers in this field. However, while using nonaqueous solvents, the presence of water is hardly avoidable in many cases. So, studies on the effect of water on the corrosion of metals and alloys in organic solvents are quite essential to prevent corrosion in such media. Although some results have been reported in literature (8-20) on such work, the content of water has been kept very low in these investigations. Therefore it was of interest to make a systematic study on electrochemical behavior of metals in aqueous binary mixtures of organic solvents covering the whole range of solvent composition. Also, such work is of importance in view of growing interest in aqueous binary mixtures of organic solvents in many fields; simply by changing the composition of mixed solvent various physicochemical properties like viscosity, dielectric constant, solvent structure, percentage content of protic and aprotic constituents, etc. can be easily varied. Such variation will certainly affect the solvation ability of the solvent mixture and electrical conductivity of the solution which in turn will influence the structure and consequently the nature of electrical double layer formed at metal/solution interphase which governs the behavior of metals in contact with such solutions.

While choosing a class of aqueous binary mixtures for such work, previous work on amide-water mixtures was kept in view. Studies of different physicochemical properties of aqueous binary mixtures of amide(s) have shown (21) that nonsubstituted amide (*e.g.*, formamide)-water mixtures behave in a quite different manner as compared to mono- and di-substituted amides (*e.g.*, N-methylformamide and N,N-dimethylformamide)-water mixtures. But the main stimulus for the present work was given by our previous work on conductance of various electrolytes in different amide(s)-water mixtures. Very pronounced effect of dehydration of ions by the cosolvent (amide) [*i.e.*, the detachment of some of the water molecules associated with an ion in pure water as a result of the addition of the cosolvent due to stronger solvent-solvent (water-cosolvent) interaction than ion-solvent (water) interaction] was observed in DMF-water mixtures (22) in a water-rich solvent composition region, while the same effect was observed in an amide-rich region in formamide-water mixtures (23). In view of the above, it has been planned to make a systematic investigation of the electrochemical behavior of various metals in different amide(s)-water mixtures. As a first step in this direction, it was decided to choose formamide-water mixtures for the present work covering the whole range of solvent composition. Further, due to wide use of nickel for protective and decorative purposes, this metal has been chosen for the present investigation.

This paper contains studies on corrosion behavior of plated nickel in formamide-water mixtures at 25°C.

Key words: corrosion, passivity, formamide-water mixtures, galvanostatic, infrared, x-ray, scanning electron microscope.

Experimental

Formamide (L.R., B.D.H.) was purified as suggested by Dawson *et al.* (24). Formamide-water mixtures of compositions 2, 15, 25, 40, 50, 60, 75, and 98 mol percent (m/o) formamide were prepared by weight using doubly distilled water.

The galvanostatic method was used for the polarization studies. Constant current was drawn from a power supply ranging between 5 μA and 100 mA. Nickel was electroplated on a scratch-free mechanically polished copper electrode using Watts' bath (25). The working nickel-plated electrodes had areas of 2 cm^2 with a 4 cm long tag for electrical connection. The thickness of the nickel coating was sufficient ($\sim$ 0.1 mm) to avoid any interference of base metal (copper) in the corrosion study. The experiments were carried out with 100 ml test solvent mixtures in a Pyrex glass cell and an electronically controlled air thermostat was used to maintain the temperature at 25° $\pm$ 0.5°C. The potential measurements were made by a precision potentiometer (Pye, Catalogue No. 7569 P) with reference to a saturated calomel electrode. The null point was detected with the help of a multiflex galvanometer (Type MG-4). To minimize the IR drop in solution a Luggin capillary was used with a calomel electrode. The tip of the capillary was kept very close ($\sim$ 0.5 mm) to the surface of the test electrode. For each composition of the solvent mixture, the variation of open-circuit potential with time was measured. It was observed that a practically constant potential was attained after 1 hr in almost all the cases. Current-potential measurements were made after the test electrode attained a constant potential in the test solution. Measurements were made in solvent mixtures of different compositions mentioned earlier. Cathodic polarizations were determined first, the open-circuit potential was then re-established, and anodic polarizations were determined.

Results and Discussion

The anodic and cathodic polarization behavior of the plated nickel in galvanostatic mode in different compositions of formamide-water mixtures are shown in Fig. 1 covering the whole range of solvent composition. For clear depiction, the cathodic curves for all the solvent compositions are not shown in the figure because the cathodic pattern in solvent mixtures other

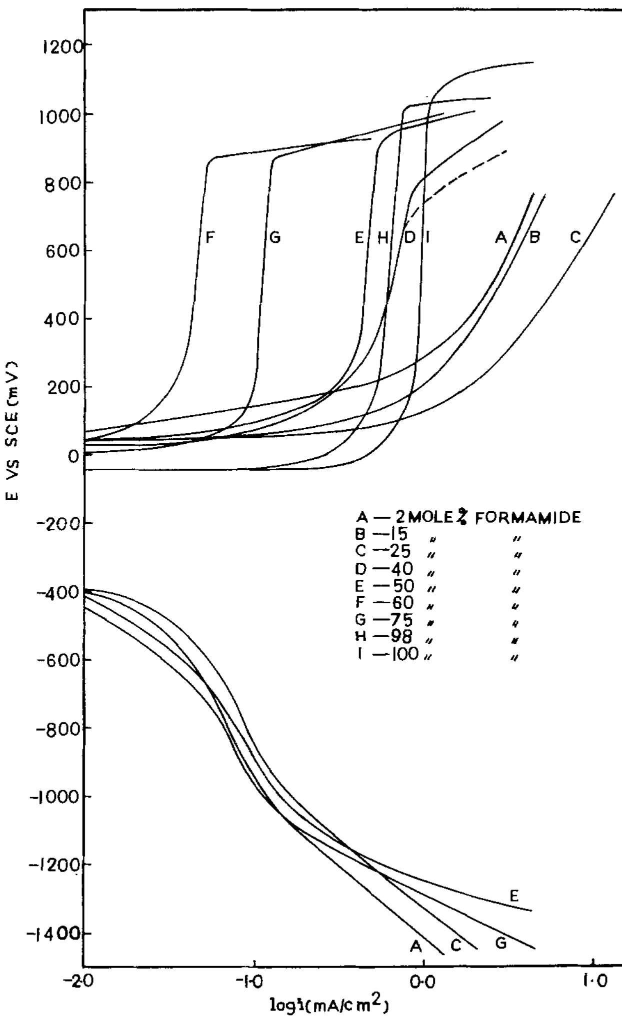

Fig. 1. Polarization behavior of plated nickel in different compositions of formamide-water mixture.

than shown in the figure is almost the same and some of them overlap with each other. As it is clear from the figure, nickel is cathodically more polarized than anodically in each case. However, the change in the solvent composition does not appreciably change the cathodic behavior of the metal indicating similar cathodic reaction irrespective of the solvent composition. But a change in solvent composition has a very pronounced effect on the behavior of anodic dissolution of the metal. As can be seen from the figure, in water-rich (2-25 m/o formamide) and in formamide-rich (60-100 m/o formamide) solvent composition regions, anodic curves shift toward higher current density with the increase of formamide content in the solvent mixture while a reverse trend was observed in intermediate solvent compositions (25-60 m/o formamide). In addition to this, it was interesting to observe the formation of a greenish-white sluggish material in water-rich solvent mixtures (up to 40 m/o formamide). It was formed in the vicinity of the test electrode and settled down in the cell; while in formamide-rich solvent mixtures (beyond 60 m/o formamide) a light green coloration of the test solution was observed which deepened with the increase of formamide content in the solvent mixture.

In order to discuss the role of solvent composition on the behavior of anodic dissolution of nickel, it is preferable to start with an extreme case, say pure water, and to proceed with the effect of addition of formamide in water. As is known and observed in the present investigation also, nickel is almost passive in pure water. It can be seen from Fig. 1 that addition of even small amounts of formamide (*e.g.*, 2 m/o) activated the surface and started the dissolution of the metal. Further addition of formamide led to a shift of the curve (Fig 1, curves B and C) more and more toward higher current density indicating that metal dissolution is increasingly facilitated in these solvent mixtures. This trend persists up to 25 m/o formamide solvent composition. It can also be seen from the figure (curves A, B, and C) that no clear passivity was observed in these cases. However, beyond 25 m/o formamide content in solvent mixture the reverse trend was observed up to 60 m/o formamide solvent composition. It is interesting to note that in the solvent mixture containing 40 m/o formamide the electrode surface tends toward passivation though clear passivity was not observed. This shows that this particular solvent composition is the transition composition from clear dissolution toward the tendency for passivation. In this particular case beyond a certain current density ($\sim$1 mA/cm^2) fluctuations in the potential during measurements were observed (shown by dotted line in Fig. 1, curve D). It appears from this observation that the film initially formed at the surface either does not adhere properly to the surface or is porous and/or loses its protectiveness. The fluctuations in potential appeared to be associated with rapid passivation and then activation of the electrode possibly caused by spalling. Such spalling has been observed by other researchers (7, 12, 13) also in the case of zinc, cadmium, and beryllium. As formamide content is further increased in the solution mixture, clear passivity was observed and the passive region shifted toward the lower current density region (Fig. 1, curves E and F). The earliest passivity (*i.e.*, at lowest current density) was observed in the solvent mixture containing 60 m/o formamide. Further addition of formamide (*i.e.*, formamide $>$ 60 m/o) resulted in a shift of the passive region again toward the higher current density and this trend persisted right up to the pure formamide. The present results are similar to those of Demo (10) who reported that a low water content in organic solvents led to passivation but in the presence of a high water content the film lost its protectiveness and corrosion was enhanced.

The results obtained in the present investigation can be explained in the light of the following probable phenomena which may be governing factors for the observed active-passive behavior. First, the electrochemical dissolution of nickel; second, its (nickel ion) preferential solvation with formamide and third, the reaction of this solvated ion with water forming some insoluble anodic product in the water-rich region. The diffusion of nickel ions from the phase boundary to the bulk of the solution is also an additional governing factor. In the water-rich region (up to 25 m/o formamide solvent composition) it seems that nickel complex with formamide is not stabilized and the third phenomenon mentioned above is favored giving insoluble sluggish compound. As formamide is further increased in the solvent mixture, the third phenomenon is expected to be less favored due to a decrease in the water content and at the same time an increase in formamide increases appreciably the kinematic viscosity of the solvent mixtures which hinders the diffusion of nickel ions into the bulk of the solvent. Probably for this reason nickel ions are accumulated at the surface and passivity is observed. Thus an increase in formamide content from 40 to 60 m/o leads to an early passivation. In solvent mixtures sufficiently rich in formamide ($>$60 m/o) formation of nickel complex is probably favored. In this region, it can be likely that the high dielectric constant ($\sim$110) plays an important role in stabilizing the nickel complex with formamide. Hence, with an increase in formamide

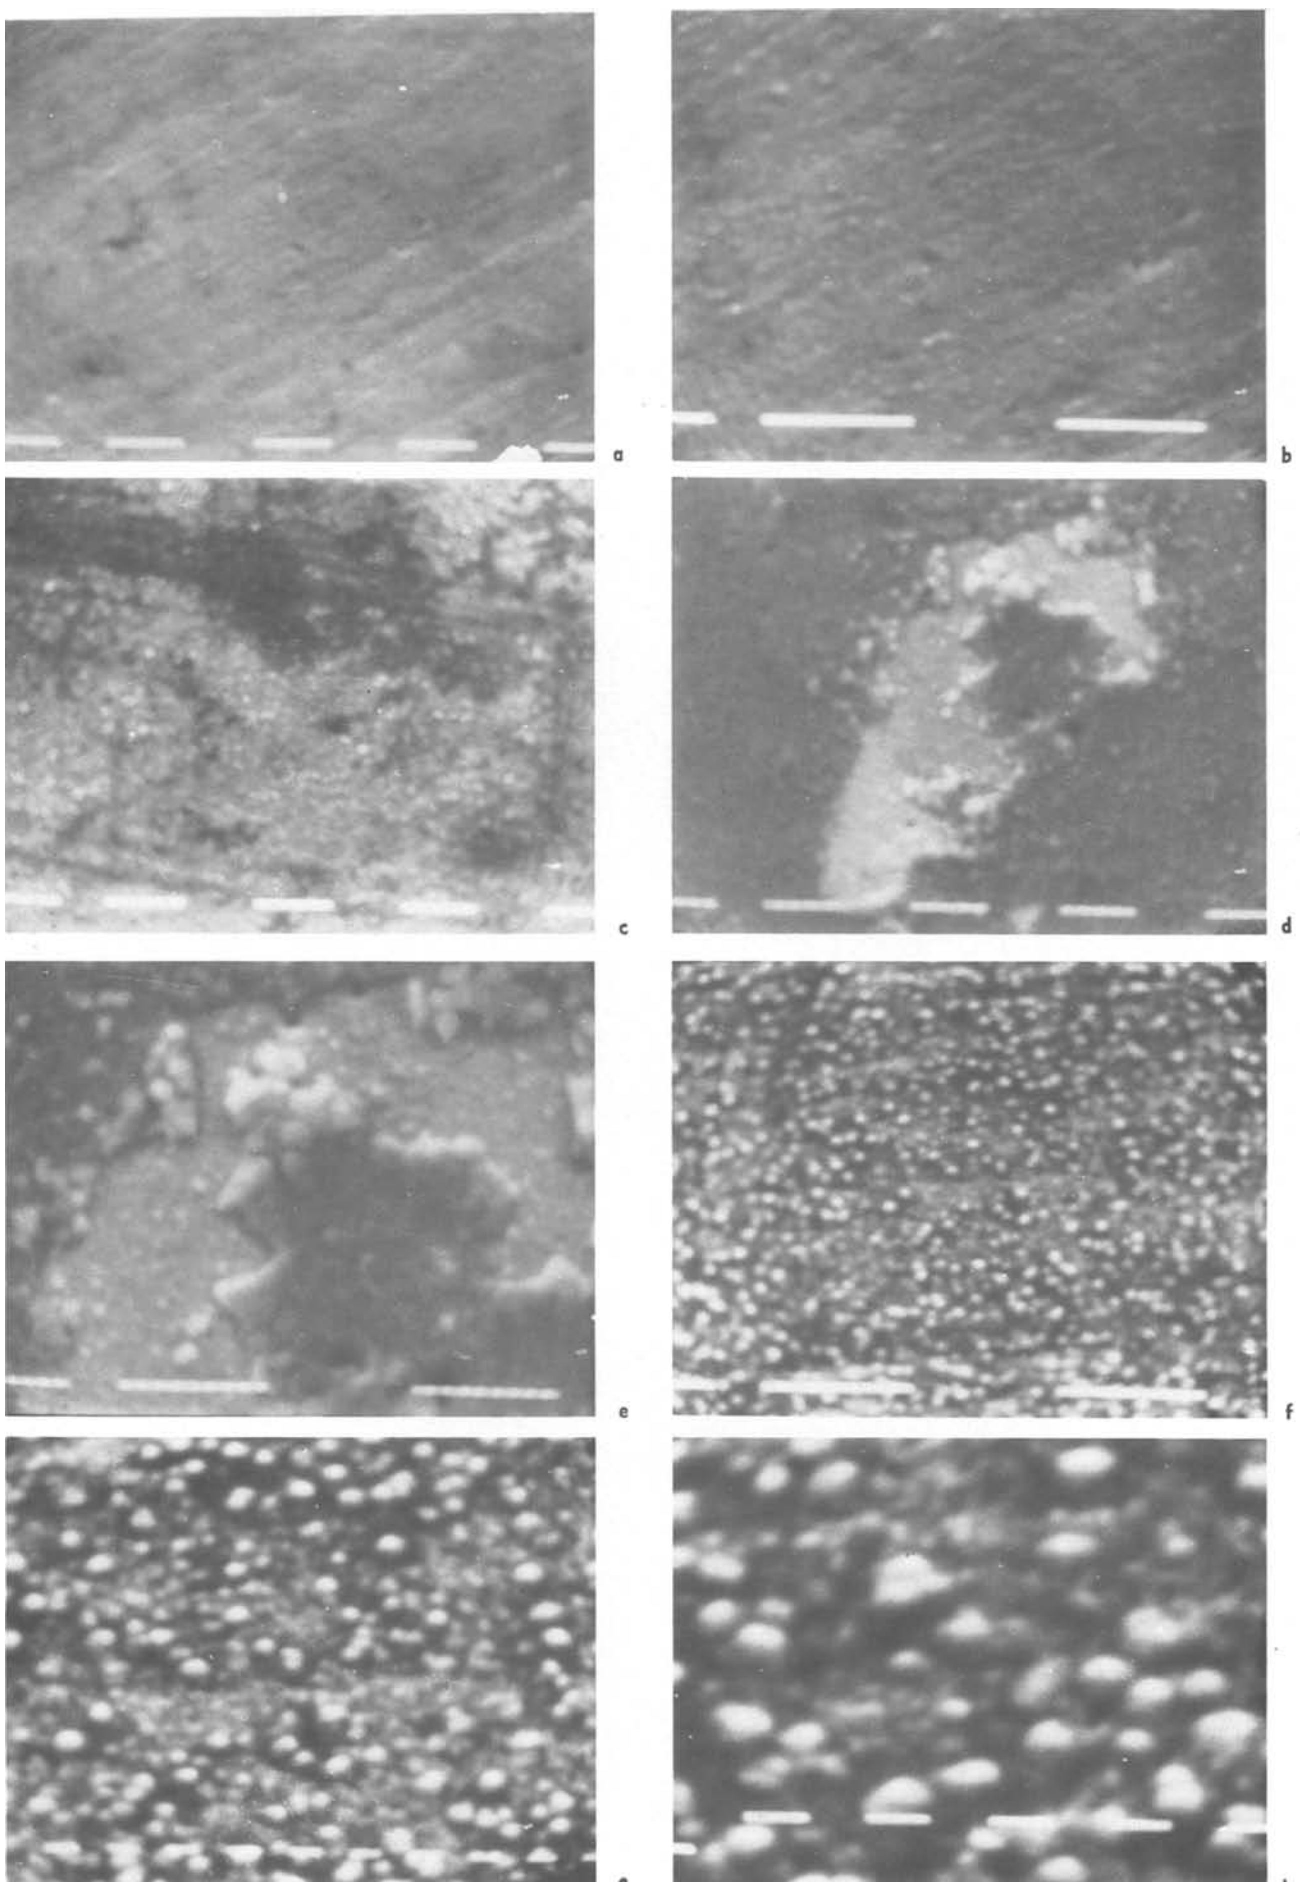

Fig. 2. Scanning electron micrograph of the working electrode after the polarization studies. In 15 m/o F: a, 1250×; b, 2500×. In 40 m/o F: c, 1250×; d, 1250×; e, 2500×. In 60 m/o F: f, 2500×; g, 5000×; h, 10,000×.

content, more and more nickel ions are taken away from the phase boundary because they can be stabilized in the bulk, resulting in the shift of passive region toward the higher current density. This is also evident from an increasingly deeper color of the solution with the increase of formamide content.

As is clear from the above discussion, the effect of water content on the anodic dissolution behavior of metal in nonaqueous medium is very complex, particularly if the whole range of solvent composition is covered. Its net effect depends on the competitive effect of other constituents of the solution. So it seems difficult to assign any particular effect of water, whether it enhances the dissolution or passivation. Such complexity has been realized by others also (10, 17). Farina and co-worker (17) observed that in the presence of an increasing quantity of water the stability of the oxide film becomes greater in case of iron in methanol while the addition of water increases the dissolution rate of iron in DMF. So it requires extensive investigation before coming to any definite conclusion regarding the role of water in corrosion behavior of metals.

The sluggish anodic products obtained in different solvent mixtures rich in water (2, 15, 25, 40 m/o F), were decanted, washed with acetone, and dried in a vacuum desiccator. They were subjected to infrared and x-ray analyses and were found to be the same. The infrared spectrum shows a broad band at 3400 cm^{-1} due to ν(OH) and a band at 300 cm^{-1} showing nickel-oxygen bonding. This indicates the presence of nickel hydroxide/nickel-oxide. The x-ray powder pattern of the material, subsequently, showed the presence of nickel oxide (NiO) and nickel hydroxide. However, a few additional lines also appeared in the pattern but were not sharp enough to help in the identification of the definite constituent. Formation of such metal hydroxide contaminated with respective metal has been reported by earlier investigators (14-16) for zinc, cadmium, and magnesium during anodic dissolution.

The surface of each working electrode was examined by scanning electron microscope after subjecting these to the electrochemical studies. An inspection of these photomicrographs reveals that they can be classified into three categories depending on the composition of the solvent mixture, viz: (*i*) 2-25 m/o formamide, (*ii*) in the vicinity of 40 m/o formamide, (*iii*) from 50 m/o up to pure formamide. It is remarkable to note that the galvanostatic studies lead to the same conclusion also (Fig. 1). The representative photomicrographs from each group are shown in (Fig. 2a-h). The photomicrographs a and b show no film formation on the surface and the metal surface was in the process of continuous dissolution in the first case. An uneven film formation is observed in the second case (Fig. 2c-e) which appears to be an oxide layer. The spalling of the surface becomes more apparent as different zones of the same surface are scanned (Fig. 2c, d). A uniform compact layer (probably oxide layer) is clearly realized in the third case where complete passivity was observed by polarization studies (Fig. 2f, g, h).

Conclusions

It can be concluded here that for nickel in formamide-water mixtures, a solvent mixture containing 25 m/o formamide is most corrosive while in 60 m/o formamide solvent composition, the earliest passivation is observed.

The explanations given above for the observed anodic dissolution behavior of nickel in solvent mixtures taken for the present work are not too conclusive or sufficient to propose a general mechanism; it requires further investigations of the same and other similar systems covering other parameters also. The work along these lines is in progress and will follow this communication.

Two-Layer Formation of Passivating Films on Cobalt in Neutral Solution

Toshiaki Ohtsuka and Norio Sato*

Electrochemistry Laboratory, Corrosion Research Group, Faculty of Engineering, Hokkaido University, Sapporo 060, Japan

ABSTRACT

Layer structure and thickness of passivation oxide films on cobalt have been investigated at stationary and transient states in solution of 0.30 mol dm^{-3} boric acid-0.075 mol dm^{-3} sodium borate mixture of *p*H 8.4 by means of chemical analysis and *in situ* ellipsometry combined with electrochemical measurements. A two-layer structure composed of an inner CoO and an outer $Co_{3-\Delta}O_4$ is found in a potential range more positive than 0.75V (*vs.* the hydrogen electrode at the same solution). The nonstoichiometry changes from $\Delta = 0$ to 0.33 with increasing anodic potential. The outer $Co_{3-\Delta}O_4$ layer thickness increases linearly with potential, whereas the inner layer thickness is not a simple function of potential, but depends on the film formation procedure. A step-wise potential increase gives an initial rapid growth of the outer $Co_{3-\Delta}O_4$ layer followed by a gradual thickening of the inner CoO layer. The transient film growth behavior is interpreted in terms of a field-assisted ion diffusion mechanism, and the self-diffusion coefficient in the inner CoO layer is estimated to be D/cm $sec^{-1} = 6.5 \times 10^{-21} \sim 2.6 \times 10^{-20}$.

The previous papers (1-4) have shown that the passive oxide film on cobalt is potential dependent in neutral boric acid-sodium borate solution of *p*H 8.4. At potentials more negative than 0.86V, referred to the hydrogen electrode in the same solution (HESS), a slightly soluble oxide film of CoO 2 ~ 3 nm thick is formed under stationary potentiostatic conditions (2-3). At more positive potentials a two-layered film is formed, consisting of an inner CoO and an outer $Co_{3-\Delta}O_4$ layer (2-3). The nonstoichiometry Δ of the outer layer depends on the anodic potential, changing from $\Delta = 0$ at 1.15V to $\Delta = 0.33$ at 1.4V. The outer layer thickness increases linearly with the potential, whereas the inner layer thickness is not a simple function of potential. In the present paper the kinetics and mechanism of electrochemical formation of two-layered oxide films on cobalt were studied by using a potential step technique associated with the ellipsometric measurements.

Experimental

The specimens were prepared from cobalt rods of 99.99% purity (Johnson-Matthey Limited) into polycrystalline sheets 0.8 mm thick with the surface area of 5 or 10 cm^2. The specimen pretreatment was the same as that described in the previous papers (1-4). The electrolytes were prepared from doubly distilled water and analytical grade reagents. Anodic formation of the passive films on cobalt was performed in a mixture of 0.30 mol dm^{-3} boric acid and 0.075 mol dm^{-3} sodium borate solutions at *p*H 8.4. Cathodic reduction of the passive films was conducted in a mixture of boric acid and sodium borate solutions at *p*H 6.5. A boric acid solution at *p*H 5.3 and a mixture of 0.5 mol dm^{-3} NH_4Cl and 0.5 mol dm^{-3} NH_4OH at *p*H 9.6 were also used for spontaneous dissolution of the passive films. Furthermore, a solution of boric acid-sodium borate mixture at *p*H 8.4 containing Co(II) ions at concentration of 1.03 mg dm^{-3} was used for anodic deposition of a Co(III) oxide film from Co(II) ions on a Pt electrode with the surface area of 10 cm^2. All the solutions were deaerated by bubbling purified nitrogen gas for more than 24 hr.

The ellipsometer used was of horizontal type with a quarter-wave plate placed on the side of incident beam. The fast axis of the plate was fixed at a 45° orientation. Measurements were made by the standard null method at a wavelength of λ/nm = 546 and at an incidence angle of $\Phi_1 = 73.303°$ (3, 5).

All measurements were made at 20.0° ± 0.2°C. The potential of cobalt electrodes was measured in reference to a saturated calomel electrode (SCE) and converted to a scale of the hydrogen electrode in the same solution (HESS).

The amount of cobalt ion dissolved into solutions was analyzed by a colorimetric nitroso-R-salt method.

Result

Two-layer structure of passivation films.—Figure 1 illustrates the results of ellipsometric measurements (Fig. 1a), the amount of dissolved Co(II) ion from the passive film, W_d, and the decay of potential, Φ, (Fig. 1b) during a galvanostatic cathodic reduction of a passive film on cobalt. The passive film was formed by 1 hr oxidation at a constant potential in the solution of *p*H 8.4 and the reduction was performed at a constant current in the solution of *p*H 6.5. The loci of polarizer azimuth P and analyzer azimuth A are directly plotted in Fig. 1a, where P_o and A_o correspond to the oxide-free reference surface of cobalt; P_o = 28.68° and A_o = 4.43° determine the complex refractive index of metallic cobalt, $\hat{n}_{Co}$ = 2.83-3.86i (2, 3). The loci δP *vs.* δA exhibit two breaks at the points marked on Q_c^o and Q_c^M, which appear to correspond to two breaks observed in W_d *vs.* Q_c and Φ *vs.* Q_c curves. In view of the previous results (3, 4), it is found that Q_c^o is the cathodic charge required for the nonstoichiometry Δ of the outer $Co_{3-\Delta}O_4$ layer to decreases to $\Delta = 0$, and that Q_c^M is the charge required for the outer layer to be completely reduced to Co^{2+} ions. Thus, the reaction for Q_c^o and the reaction for $Q_c^M - Q_c^o$ are respectively represented by reactions [A] and [B]

$$Co_{3-\Delta}O_4 + \frac{8\Delta}{3}H^+ + \frac{8\Delta}{3}e \rightarrow \left(1 - \frac{\Delta}{3}\right)Co_3O_4 + \frac{4\Delta}{3}H_2O \quad [A]$$

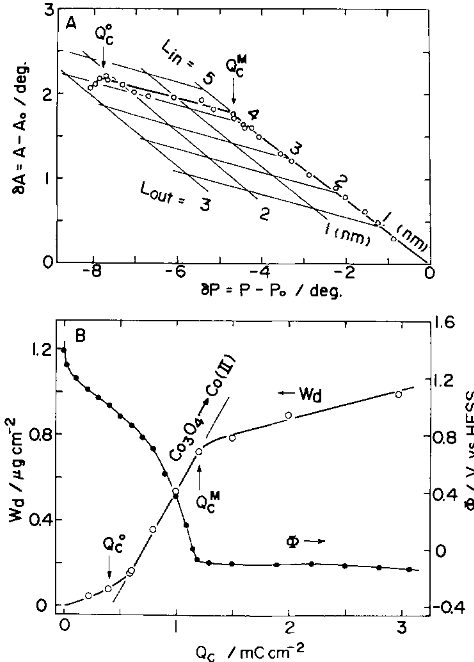

Fig. 1. Cathodic reduction of a passive film at constant C.D., $i_c = 5\ \mu A\ cm^{-2}$ in borate solution of pH 6.5. The film was formed at constant potential, $\Phi = 1.34V$, for 1 hr in borate solution of pH 8.4. (a) Change of ellipsometric parameters P and A during the reduction. (b) Amount of dissolved Co(II) from the film W_d and potential decay Φ as a function of cathodic charge Q_c passed during the reduction.

$$Co_3O_4 + 8H^+ + 2e \rightarrow Co^{2+} + 4H_2O \quad [B]$$

The third stage of film reduction after Q_c^M is the reduction of the inner CoO layer.

To determine the complex refractive indexes of the layers, the best fit approach was made between the theoretical δA *vs.* δP loci for different complex refractive indexes and the experimental ones by taking into account the approximate film thickness estimated from the film charge in anodic oxidation and in cathodic reduction. The complex refractive indexes thus determined for the outer layer are $\hat{n}_{Co_2O_3} = 3.2\text{-}0.95i$ and $\hat{n}_{Co_3O_4} = 3.2\text{-}0.5i$, and for the inner layer $\hat{n}_{CoO} = 2.3\text{-}0.1i$ (2, 3). In Fig. 1 the theoretical lines are also drawn for various thicknesses of the outer and the inner layers.

Figure 2 shows the δA *vs.* δP loci during the spontaneous dissolution of the passive film in two different solutions of 0.5 mol dm^{-3} NH_4OH-0.5 mol dm^{-3} NH_4Cl mixture at pH 9.6 and of 0.30 mol dm^{-3} boric acid at pH 5.3, where no composition change of the film appears to occur during the dissolution because of the absence of applied cathodic current. The δA *vs.* δP curves in Fig. 1 and 2 are almost the same.

Transient behavior.—To elucidate the layer growth, ellipsometric transient measurements of the film were carried out in two-step oxidation, in which, after renewal of the solution containing no dissolved cobalt ion, a potential step was applied to a preoxidized cobalt electrode. Figure 3 shows a δA-δP curve observed after a potential step from 1.04 to 1.24V is applied to a passivated cobalt that has been oxidized at Φ = 1.04V (V) for 1 hr. The filled circle in Fig. 3 indicates the values of δP and δA observed after direct 1 hr oxidation at 1.24V starting from the oxide-free cobalt surface. It is noted that more than 6 hr of oxidation is required for the δP-δA value of two-step oxidation to reach that of direct one-step oxidation for 1 hr.

By superimposing on the results of Fig. 3 the theoretical δP-δA loci calculated for two-layered films

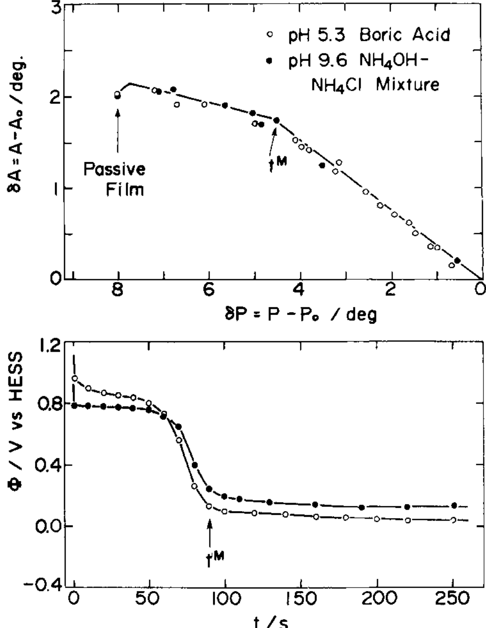

Fig. 2. Change of ellipsometric parameters P and A and potential decay during spontaneous dissolution of a passivation film in solutions of 0.5 mol dm^{-3} NH_4OH-0.5 mol dm^{-3} NH_4Cl mixture (△) and of 0.3 mol dm^{-3} boric acid (○). The break marked by t^M in the δP-δA loci corresponds to a point where the potential decays from the first to the second wave.

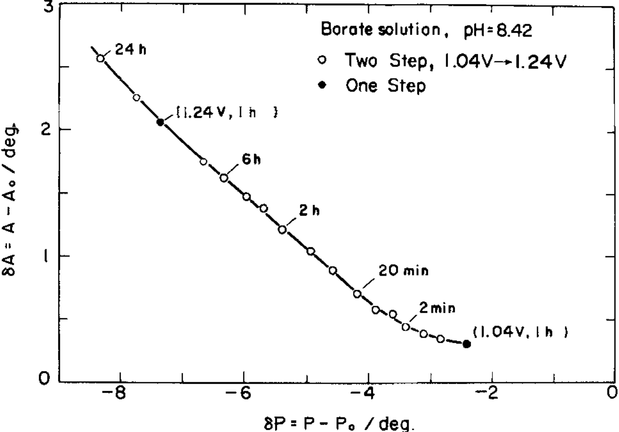

Fig. 3. Change in δA *vs.* δP loci with time during the second step at $\Phi = 1.24V$ in two-step oxidation in borate solution of pH 8.4. The electrode was first oxidized at $\Phi = 1.04V$ for 1 hr (1st step) and after renewal of the solution was oxidized further at $\Phi = 1.24V$ (2nd step).

with the complex refractive indexes, $\hat{n}_{CoO} = 2.3\text{-}0.1i$ and $\hat{n}_{Co_3O_4} = 3.2\text{-}0.5i$, as a function of layer thickness, the thickness of the both layers can be evaluated as a function of time during oxidation. In Fig. 4 and 5 the thickness change thus estimated is plotted together with the current density (C.D.) change. In Fig. 4 the thickness for 1.54V oxidation at which gaseous oxygen evolves on the electrode was estimated using the complex refractive index of $\hat{n}_{out} = 3.2\text{-}0.95i$ for the outer Co_2O_3 layer. It is seen that initially the outer layer increases accompanying no appreciable growth of the inner layer and that the inner layer begins to thicken after the outer layer grows to a certain thickness comparable to the thickness formed by direct one-step oxidation. It is noted that the inner layer formed by two-step oxidation is thinner than that formed by direct one-step oxidation. This is due to the anodic deposition of a Co(III) film from Co(II)

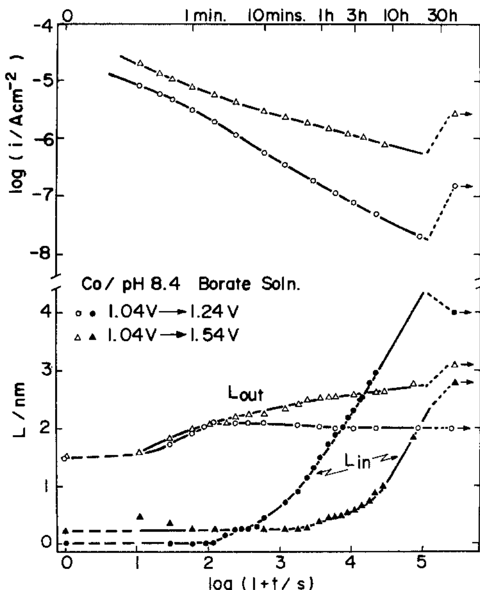

Fig. 4. Anodic C.D. *i* and thicknesses of two layers L_{in} and L_{out} as a function of time during the second step at Φ = 1.24V and 1.54V in two-step oxidation in borate solution of *p*H 8.4. The electrode was first oxidized at Φ = 1.04V for 1 hr. The arrows on the right side indicate C.D.'s and thicknesses in direct one-step oxidation for 1 hr.

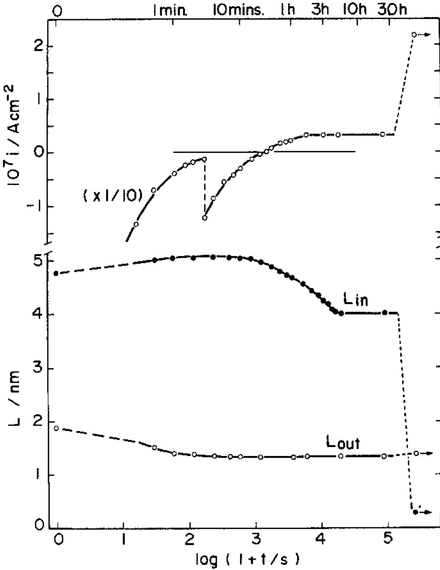

Fig. 5. Anodic C.D. and thicknesses of the two layers as a function of time during the second step at Φ = 1.04V in two-step oxidation in borate solution of *p*H 8.4. The electrode was first oxidized at Φ = 1.24V for 1 hr. The arrows on the right side indicate C.D. and thicknesses in direct one-step oxidation.

ions in aqueous solution produced prior to the film formation, as is shown later.

When the potential is stepped down (Fig. 5), an initial cathodic current causes a decrease of the outer layer thickness, producing a slight increase of the inner layer thickness, and then a definite decrease of the inner layer thickness occurs toward a steady-state value of 4.0 mn without yielding any change in the outer layer thickness after the C.D. turns to be anodic.

The preferential growth of the outer layer, which occurs in an initial period of potential step oxidation (Fig. 4), also takes place during galvanostatic oxidation, as shown in Fig. 6. In this case the anodic C.D. of 1 μA cm^{-2} was applied to a passivated cobalt electrode that has been oxidized at 1.03V for 1 hr. Before

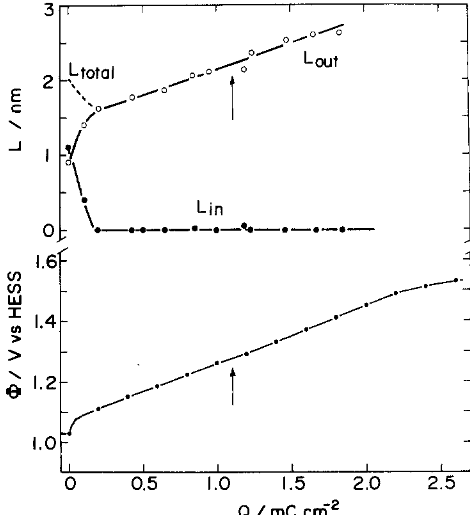

Fig. 6. Change in thickness and potential during galvanostatic oxidation at *i* = 1 μA-cm^{-2} of a film-covered cobalt electrode (L_{in} = 1.1 nm and L_{out} = 0.9 nm) which has been oxidized at Φ = 1.03V in borate solution of *p*H 8.4. The arrow in the figure indicates the amount of charge passed at which the complex refractive index of $Co_{3-\Delta}O_4$ layer begins to change.

the galvanostatic oxidation, the film has consisted of the inner layer of 1.1 nm and the outer layer of 0.9 nm. Application of a small anodic current first causes a rapid increase of the outer layer with a decrease of the inner layer and then the film of a single Co_3O_4 layer ($\hat{n}$ = 3.2-0.5i) with a linear rise of potential. Finally, the film transforms to Co_2O_3 ($\hat{n}$ = 3.2-0.95i) without producing any increase of the inner layer.

In Fig. 7 the change in the δA *vs.* δP loci is illustrated for the second step of oxidation at different potentials in the range of two-layer formation, starting from a passivated cobalt electrode that has been oxidized at 1.04V for 1 hr. The δP-δA value corresponding to the film formed by direct one-step oxidation for 1 hr lies on the extrapolated growth line of two-step oxidation. At potentials more positive than 1.34V the locus of the second step oxidation even after 22 hr (●) does not reach the value of the passivated electrode directly oxidized in one step for 1 hr (○). The second step oxidation at 1.54V gives rise to transformation of Co_3O_4 to Co_2O_3 in an initial

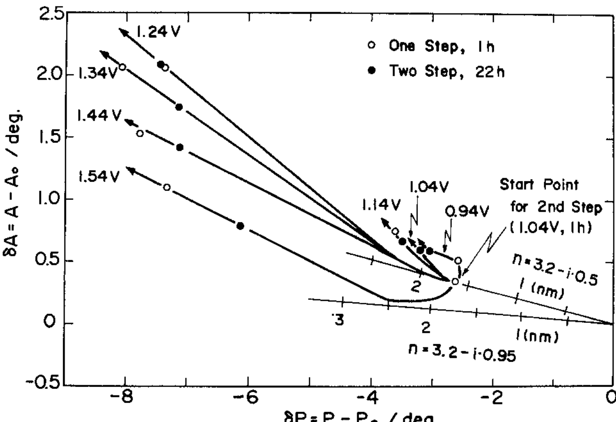

Fig. 7. Change in δA *vs.* δP loci during the second step at different potentials in two-step oxidation in borate solution of *p*H 8.4. The electrode was first oxidized at Φ = 1.04V for 1 hr. The filled circles indicate the values of δP and δA after 22 hr of the second step in two-step oxidation and the open circles the values after 1 hr in direct oxidation.

period, as suggested by a change in the complex refractive index from $\hat{n} = 3.2\text{-}0.5i$ to $3.2\text{-}0.95i$.

Comparisons of the thickness and the final C.D. are made in Fig. 8 between direct 1 hr oxidation and two-step 22 hr oxidation. In this figure the thickness and the C.D. in the potential region where the film of a single CoO layer is formed is also plotted. In the potential region for a two-layer film formation the final anodic C.D. in two-step oxidation is one-tenth times as small as that in direct one-step oxidation. Difference in C.D. between the potential regions of Co_3O_4 and Co_2O_3 formation can be seen in two-step oxidation, but becomes indistinct in direct one-step oxidation. The thickness of the outer layer does not depend on whether the film is formed by one-step or two-step oxidation and increases nearly linearly with potential except for the film formed above 1.4V. The inner layer thickness, however, differs in different oxidation procedures. It appears that the inner layer thickness of two-step oxidation is larger at potentials below 1.2V and smaller at potentials above 1.3V than that of direct one-step oxidation. From the above results it follows that the thickness of the outer layer is determined only by the oxidation potential, whereas the thickness of the inner layer is dependent on the oxidation procedure.

Anodic deposition of Co(II) ion in solution.—The previous work (1) has shown that the amount of Co(II) ion dissolved in solution was 0.5 $\mu g\ cm^{-2}$ in 5 sec oxidation and 0.03 $\mu g\ cm^{-2}$ in 1 hr oxidation at constant potential 1.34V starting from the film-free surface. This means that the Co(II) ion dissolved in solution in the initial period of anodic passivation is anodically deposited on the passivated cobalt. Another evidence on the anodic deposition is given from an experiment in which Pt electrode is potentiostatically oxidized for 1 hr in the boric acid-sodium borate solution of pH 8.4 containing Co(II) ion of concentration 1.03 mg dm^{-3}. Figure 9 shows the amount of Co(II) ion anodically deposited from the solution to form a cobalt oxide film on Pt, which was estimated from the decrease of Co(II) ion concentration in the solution after potentiostatic 1 hr oxidation at constant potential. The amount of Co(II) deposited was also evaluated from the amount of Co(II) ion dissolved from the film on Pt by galvanostatic reduction at 10 $\mu A\ cm^{-2}$ in the boric acid-sodium borate solution of pH 6.5. The anodic oxidation of Co(II) ion in the solution to form the film takes place at potentials more positive than 1.2V, which is in agreement with the potential at which an abrupt increase of the inner layer thickness as well as the outer layer nonstoichiometry Δ commences.

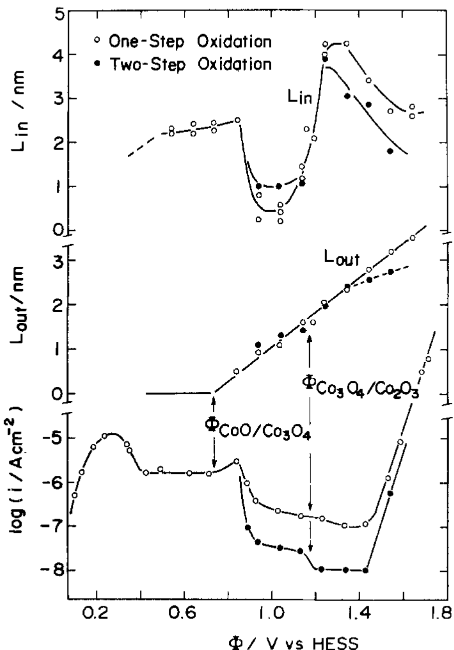

Fig. 8. Comparison of film thickness and anodic C.D. between one-step and two-step oxidations in borate solution of pH 8.4. The film thickness and anodic C.D. were measured after 1 hr for one-step oxidation and after 22 hr for two-step oxidation.

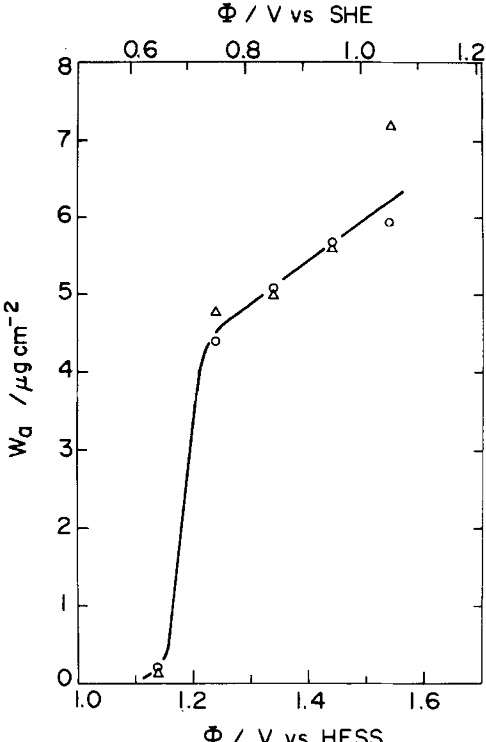

Fig. 9. Amount of cobalt ion anodically deposited on Pt electrode from borate solution containing Co(II) ions. The amount of cobalt ion deposited was estimated from the decrease of Co(II) ion in solution during potentiostatic oxidation (△) and the cathodic Co(II) ion dissolution from the film into solution of pH 6.5 during subsequent galvanostatic reduction at $i = 10\ \mu A\text{-}cm^{-2}$ (○).

Discussion

Potential distribution in the passivation film.—We consider the two-layered structure of an inner CoO and an outer $Co_{3-\Delta}O_4$ shown in Fig. 10 and the potential distribution in the film shown in Fig. 11. If the reactions between the phases are in equilibrium at all the interphases, the irreversible potential differences in CoO (II phase) and in $Co_{3-\Delta}O_4$ (III phase) are given by

$$\Delta\Phi_{II} = \Phi_{CoO/Co_3O_4} - \Phi_{Co/CoO} \quad [1]$$

$$\Delta\Phi_{III} = \Phi_{CoO/Co_{3-\Delta}O_4} - \Phi_{CoO/Co_3O_4} \quad [2]$$

where $\Phi_{Co/CoO}$, Φ_{CoO/Co_3O_4}, and $\Phi_{CoO/Co_{3-\Delta}O_4}$ are the potentials of electrode systems consisting of Co/CoO, Co/CoO/Co_3O_4, and Co/CoO/$Co_{3-\Delta}O_4$, respectively. If we assume the potential of $\Phi_{Co/CoO}$ to be 0.14 ± 0.04V *vs.* HESS, thermodynamically estimated by Göhr (6), and the potential of Φ_{CoO/Co_3O_4} to be 0.75V, experimentally established by the authors (1, 4, 7), the irreversible potential difference in the CoO phase is

$$\Delta\Phi_{II}/V = 0.61 \pm 0.06 \quad [3]$$

It is this potential difference which creates the driving force for growth of the CoO layer. It follows from Eq. [2] that the irreversible potential difference in the outer $Co_{3-\Delta}O_4$ phase can not be defined as a con-

stant value, but varies depending on the nonstoichiometry Δ.

Thermodynamically, we can describe the outer layer composition as a function of electrode potential. The layer structure may also be thermodynamically described, but a number of kinetic parameters are required for the determination of the composition profile in depth.

A kinetic model for two-layer formation.—There have been only a few theoretical studies on the two-layer growth on metals. Yurek, Hirth, and Rapp (8) and Shaw and Rolls (9) have derived kinetic equations of two-layer growth for relatively thick oxide scales on metals. We propose here a kinetic mechanism of two-layer growth in anodic oxide films, which explains the observed transient behavior of anodic oxide film on cobalt. For simplification we assume that the diffusing ion through the film toward the solution is Co(II) ion and that the inner and the outer layers are CoO and Co_3O_4, respectively. Further, we assume the reaction scheme shown in Table I, where subscripts I, IIa, IIb, IIIa, IIIb, and IV indicate respectively the locations in the electrode system illustrated in Fig. 10. The reaction rate is expressed in terms of mol flux of cobalt(II) ion $k_{x(x=a,b,\ldots)}$/mol-Co(II) ion sec^{-1} cm^{-2}.

From the mass balance of transferring ions, the following relationship can be obtained among the reaction rates

$$k_a = k_b \quad [4]$$

$$k_b = k_c + k_d \quad [5]$$

$$k_c = k_e \quad [6]$$

and

$$k_e = k_f + k_g \quad [7]$$

We now introduce the following quantities for the reaction rates

$$i_{II}/\text{A-cm}^{-2} = 2\mathbf{F}k_b \quad [8]$$

$$i_{III}/\text{A-cm}^{-2} = 2\mathbf{F}k_e \quad [9]$$

$$i_{diss}/\text{A-cm}^{-2} = 2\mathbf{F}k_f \quad [10]$$

$$i_{depos}/\text{A-cm}^{-2} = 2\mathbf{F}k_h \quad [11]$$

where i_{II} and i_{III} correspond respectively to the ionic C.D. of diffusing Co(II) ion through the inner CoO and the outer Co_3O_4 layers, and i_{diss} and i_{depos} to the dissolution C.D. and the deposition C.D. These ionic C.D.'s can be used to describe the three experimentally measurable quantities, i_a, L_{in}, and L_{out} by taking the mass balance given by Eq. [4], [5], [6], and [7] into account. From reactions [a], [b], [g], and [h], the anodic C.D. that can be measured is given by

$$i_a = \mathbf{F}\left(2k_a - 2k_d + \frac{2}{3}k_g + \frac{2}{3}k_h\right)$$

$$= \frac{4}{3}i_{III} - \frac{1}{3}i_{diss} + \frac{1}{3}i_{depos} \quad [12]$$

Table I. Reaction scheme for growth of CoO/Co_3O_4 two-layered film on Co

Reaction	Rate (mol-Co ion sec^{-1} cm^{-2})
[a] $_{I}Co \rightarrow {}_{IIa}Co^{2+} + 2_{I}\ e^-$	k_a
[b] $_{IIa}Co^{2+} \rightarrow {}_{IIb}Co^{2+}$	k_b
[c] $_{IIb}Co^{2+} \rightarrow {}_{IIIa}Co^{2+}$	k_c
[d] $_{IIb}Co^{2+} + {}_{IIIa}Co_3O_4 + 2_{I}\ e \rightarrow 4_{IIb}CoO$	k_d
[e] $_{IIIa}Co^{2+} \rightarrow {}_{IIIb}Co^{2+}$	k_e
[f] $_{IIIb}Co^{2+} \rightarrow {}_{IV}Co^{2+}$	k_f
[g] $_{IIIb}Co^{2+} + 4/3_{IV}\ H_2O \rightarrow 1/3_{IIIb}\ Co_3O_4 + 8/3_{IV}\ H^+ + 2/3_{I}\ e$	k_g
[h] $_{VI}Co^{2+} + 4/3_{IV}\ H_2O \rightarrow 1/3_{IIIb}\ Co_3O_4 + 8/3_{IV}\ H^+ + 2/3_{I}\ e$	k_h

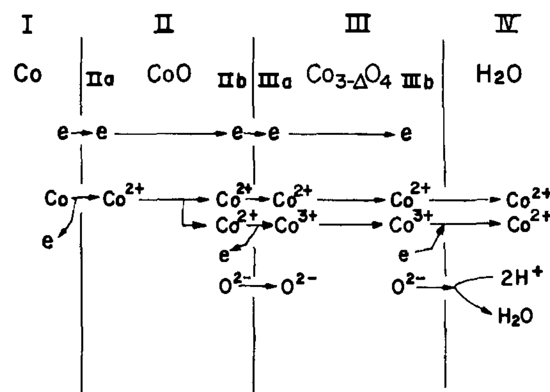

Fig. 10. Illustration of phase arrangement and reactions in two-layered passive films on cobalt.

Since the inner layer increases in thickness by reaction [d], the growth rate can be described from Eq. [6] and [7] in terms of i_{II} and i_{III}

$$\frac{dL_{in}}{dt} = 8\mathbf{F}k_d\tilde{L}_{CoO}$$

$$= 4(i_{II} - i_{III})\tilde{L}_{CoO} \quad [13]$$

where $\tilde{L}_{CoO}$/nm cm^2 C^{-1} is the thickness of CoO equivalent to 1 C cm^{-2} of Co(II) ion. The outer layer grows by reactions [g] and [h], and its thickness decreases by reaction [d]

$$\frac{dL_{out}}{dt} = 2\mathbf{F}(k_g + k_h - 3k_d)\tilde{L}_{Co_3O_4}$$

$$= \{i_{III} - i_{diss} + i_{depos} - 3(i_{II} - i_{III})\}\tilde{L}_{Co_3O_4} \quad [14]$$

where $\tilde{L}_{Co_3O_4}$/nm cm^2 C^{-1} is the thickness of Co_3O_4 equivalent to 1 C cm^{-2} of Co(II) ion. Values of $\tilde{L}_{CoO}$ and $\tilde{L}_{Co_3O_4}$ were experimentally obtained; $\tilde{L}_{CoO}$/nm cm^2 $C^{-1} = 9.1 \times 10^2$ and $\tilde{L}_{Co_3O_4}$/nm cm^2 $C^{-1} = 7.7 \times 10^2$ (2, 3). From Eq. [13] and [14] it is evident that the growth of one layer is strongly dependent on the ionic C.D. of the diffusing Co(II) ion in the other layer.

It is assumed that the ionic flux through the layer is a function of electric field strength $E = \Delta\Phi/L$ following the Cabrera-Mott theory (10, 11).

$$i_{II} = i_{II,0}\exp(B_{II}\,\Delta\Phi_{II}/L_{in}) \quad [15]$$

$$i_{III} = i_{III,0}\exp(B_{III}\,\Delta\Phi_{III}/L_{out}) \quad [16]$$

where $i_{II,0}$ and $i_{III,0}$ indicate the ionic self-diffusion C.D. at zero field, and B_{II} and B_{III} are constants given

below

$$B_{II} = Z_{II}a_{II}\mathbf{F}/RT \quad [17]$$

$$B_{III} = Z_{III}a_{III}\mathbf{F}/RT \quad [18]$$

in which Z_{II} or Z_{III} is the ionic valency of migrating ion, and a_{II} or a_{III} the jumping distance for ion migration.

Equations [12]-[16], which represent the increasing or decreasing thickness of the layers, can be used to understand qualitatively the observed transient behavior and may predict the thickness in some cases.

Film thickness at steady states.—At the stationary state, where $(dL_{in}/dt) = 0$, $(dL_{out}/dt) = 0$, and $(di_a/dt) = 0$, the ionic transfer across every interphase is equal to the ionic diffusion through every layer

$$i_{ss} = i_{II} = i_{III} = i_{diss} \quad [19]$$

where i_{ss} represents the anodic C.D. at the stationary state. Correspondingly, the thicknesses are determined by Eq. [15] and [16]. As $\Delta\Phi_{II}$ remains equal to the irreversible potential difference given by Eq. [1] or [3] irrespective of the anodic potential, the thickness of the inner layer, L_{in}, is determined by the dissolution rate, i_{diss}, of the outer layer. It follows therefore that the inner layer, even if it is soluble, will grow to a certain thickness in the presence of the protective outer layer. Since the outer layer sustains an increasing potential difference $\Delta\Phi_{III}$ with anodic potential $\Delta\Phi_T$, its thickness will increase with anodic potential at the stationary state

$$\Delta\Phi_{III} = \Delta\Phi_T - \Delta\Phi_{II} \quad [20]$$

In our experimental results the thickness of the outer layer satisfies the above prediction for both one-step and two-step oxidation films, as shown in Fig. 8, whereas the thickness of the inner layer behaves differently depending on the formation procedure. It is thus suggested that the outer layer can approach the stationary thickness more quickly than the inner layer.

Anodic deposition of Co(II) in solution.—The difference in the inner layer thickness between one-step oxidation film and two-step oxidation film is caused by the anodic deposition reaction [h] in Table I, which occurs only in the one-step oxidation. As shown in Fig. 8 and 9, the potential at which the anodic deposition from Co(II) ion commences is in agreement with the potential at which an abrupt change of the inner layer thickness is observed. A question is now raised why the inner CoO layer does become thick, when Co(II) ions in the solution are deposited to form the outer layer of higher valence oxide. As the outer layer thickness increases by anodic deposition from Co ion, the rate of Co(II) ion diffusion in the outer layer decreases because of a decreasing electric field intensity in the layer according to Eq. [16] and eventually becomes negligible compared with the ionic diffusion rate in the inner layer

$$i_{II} >> i_{III} = 0 \quad [21]$$

From Eq. [13] therefore the inner layer growth rate is

$$\frac{dL_{in}}{dt} = 4i_{II}\tilde{L}_{CoO} \quad [22]$$

which means that almost all Co(II) ions flowing through the inner layer to the CoO/Co_3O_4 interphase go into reaction [d] to form a new CoO layer at the expense of the outer Co_3O_4 layer. In this case the inner CoO layer may thicken without any diffusion of Co(II) ion through outer $Co_{3-\Delta}O_4$ layer which is a barrier against ion flow. By two-step oxidation, because of the absence of dissolved Co(II) ions in the solution, the film growth requires the diffusion of Co(II) through both the layers and hence the film growth rate is small compared with that in one-step oxidation where the anodic deposition is involved.

Inner layer growth.—As shown in Fig. 4, when an anodic potential step was applied to a passivated cobalt, the outer layer was observed to grow first in an initial period of time until its thickness reached a steady value, where $dL_{out}/dt = 0$. The initial growth of the outer layer was followed by a gradual increase of the inner layer thickness in the later period of time while the outer layer thickness remained constant. Therefore, for the later stage of film growth, we obtain by substituting $dL_{out}/dt = 0$ and $i_{depos} = 0$ into Eq. [13] and Eq. [14] the following equations

$$\frac{dL_{in}}{dt} = (i_{II} - i_{diss})\tilde{L}_{CoO} \quad [23]$$

$$i_a = i_{II} \quad [24]$$

Equation [23] means that the dissolution rate of the outer layer plays a large role in determining whether the inner layer increases or decreases after the outer layer reaches the stationary thickness. From Eq. [18] and the result shown in Fig. 4 and 5, it follows that the potential step from 1.04 to 1.24V causes the inner layer to grow because $i_{II} > i_{diss}$ and that the reverse potential step brings about a decrease of the inner layer because $i_{II} < i_{diss}$.

The growth rate of the inner layer can be described from the results of Fig. 4 and from Eq. [24] by assuming the Cabrera-Mott relation of Eq. [15]. Figure 12 shows the relationship between the logarithm of anodic C.D. i_{II} and the inverse of the inner layer thickness during the second step oxidation at 1.24V after the outer layer reaches the stationary thickness. From the slope and intersect of the curve, $B_{II}\,\Delta\Phi_{II}/\text{cm} = 4.3 \cdot 10^{-7}$ and $i_{II,0}/\text{A-cm}^{-2} = 1.2 \cdot 10^{-8}$. If we assume $\Delta\Phi_{II} = 0.61(\text{V})$ from Eq. [3], $B_{II}/\text{cm V}^{-1} = 7.1 \times 10^{-7}$. From the value of B_{II} Eq. [17] gives $a_{II}/\text{cm} = 1.8 \times 10^{-8}$ at $Z_{II} = 2$, and $a_{II}/\text{cm} = 3.6 \times 10^{-8}$ at $Z = 1$. By comparing the estimated a_{II} values with the distance between the neighboring Co ions in CoO, calculated to be 0.30 nm from the lattice constant of 0.426 nm, it is likely that the migrating species is monovalent cobalt vacancy. The ionic conductivity κ at low fields may be written as

$$\kappa = \left| \frac{\partial I_{II}}{\partial(\Delta\Phi_{II}/L_{in})} \right|_{(\Delta\Phi_{II}/L_{in})\to 0} = i_{II,0}B_{II} \quad [25]$$

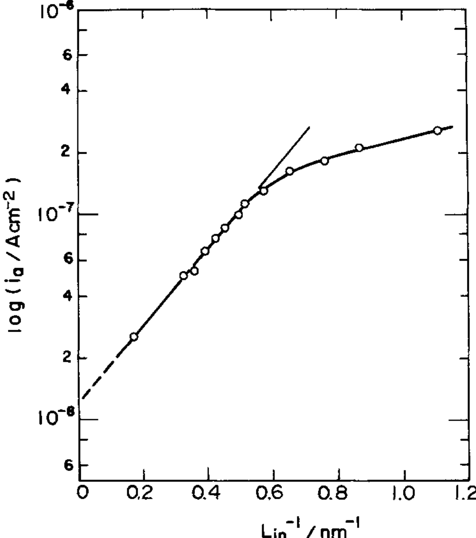

Fig. 12. Relation between inverse of the inner layer thickness and the anodic C.D. in logarithmic scale. Data correspond to the results of $\Phi = 1.24$V oxidation in Fig. 4.

and is estimated to be $\kappa/\text{S cm}^{-1} = 8.5 \times 10^{15}$. Furthermore, the self-diffusion constant D of moving species in the inner layer may be estimated using Einstein-Nerst relation (12), as follows

$$D = \frac{i_{II,0} B_{II} RT}{z^2 F^2} \cdot \frac{1}{C_{Co}} \qquad [26]$$

where $C_{Co}/\text{mol cm}^{-3}$ is the number of mol of CoO in unit volume and is calculated to be $C_{Co}/\text{mol cm}^{-3} = 0.086$ from the lattice constant. We estimate that $D/\text{cm}^2 \text{ sec}^{-1} = 6.5 \times 10^{-21}$ for $Z = 2$ and $D/\text{cm}^2 \text{ sec}^{-1} = 2.6 \times 10^{-20}$ for $Z = 1$. No comparable self-diffusion constant can be found in the literature and the estimated values in this work are 10^{10} times as large as the value extrapolated from the diffusion data for CoO obtained at high temperature above 1200 K by Richardson *et al.* (13) and by Chen *et al.* (14). The discrepancy may be attributed to a large concentration of lattice defects in the anodic oxide film.

Conclusion

The following conclusions may be drawn;

1. Cobalt is covered with a two-layered oxide film consisting of an inner CoO and an outer Co_3O_4 or Co_2O_3 in the passive potential region more positive than Φ/V *vs.* HESS = 0.75 in neutral boric acid-sodium borate solution at pH 8.4.

2. A growth model is presented for electrochemical two-layer formation, which explains the observed dependence of film thickness on the potential and on the time of oxidation.

3. The outer layer reaches within 1 hr the stationary thickness which increases nearly linearly with the electrode potential, and the inner CoO layer requires much longer oxidation time before the stationary thickness is reached. The inner layer thickness that grows in a few hours' oxidation depends not only on the potential but also on the oxidation procedure. It is revealed that the growth of the inner CoO layer is influenced by the ionic diffusion in the outer layer.

4. Anodic deposition of a $Co_{3-\Delta}O_4$ layer ($0 \leq \Delta \leq 0.33$) from Co(II) ion in solution of pH 8.4 can take place at Co(II) ion concentrations as small as 1.03 mg dm^{-3} in the potential region more positive than 1.2V. Therefore, the anodic oxide film on cobalt becomes thick in the presence of Co(II) ion in solution.

5. The ion migration in the anodic oxide film is likely to be assisted by high electric field and represented by the rate equation $i = i_o \exp(B\Delta\Phi/L)$ for each individual layer.

6. The self-diffusion coefficient in the inner CoO layer is estimated to be $D/\text{cm}^2 \text{ sec}^{-1} = 6.5 \times 10^{-21} \sim 2.6 \times 10^{-20}$.

Transistor Action Using ZrO_2 Electrochemical Cells

Robert E. Hetrick* and W. C. Vassell

Ford Motor Company, Research Staff, Dearborn, Michigan 48121

ABSTRACT

Transistor action is reported at elevated temperatures in a ceramic structure composed of two ZrO_2 electrochemical cells separated by an enclosed volume. The "emitter" cell pumps O_2 from an ambient atmosphere into the volume (base region) where it is returned to the ambient by the "collector" cell. Electrical operation, analogous to that of semiconductor transistors, can be understood in terms of the limiting currents caused by the Pt cathode of the collector cell. Small-signal voltage and current gain are illustrated in common transistor external circuit arrangements. The results for each arrangement also serve to illustrate various electrochemical aspects of ZrO_2 cells. A simple model is described which accounts for the main steady-state characteristics. The frequency response of the device is determined primarily by the double-layer capacity of the Pt/ZrO_2 interface. This approach to transistor action should be applicable to other electrochemical systems.

In a previous paper (1) it was shown that transistor action could be observed in an electrochemical ceramic structure composed of two ZrO_2 oxygen-concentration cells separated by an enclosed volume. Complementary to a concept by Letaw and Bardeen (2) using liquid electrolytes, the present approach to transistor action is general and should be applicable to a number of electrochemical systems. The purpose of this paper is to elaborate on the operation of the device. In particular, operation is illustrated in a number of common transistor configurations (common base, common emitter, common collector). A simple analytical model is put forward which accounts for the main steady-state characteristics. Those properties of the electrolyte, electrode, or electrode/electrolyte combination which determine or limit the device operation are discussed. In some cases the device proves to be a convenient structure for studying cell properties such as cathodic polarization phenomena.

For the present electrochemical system, the high operating temperature and low frequency response which attend oxygen ion conducting solid electrolytes would undoubtedly limit device usefulness to special applications. One such application is that of O_2 sensing in the automotive exhaust where the O_2 concentration provides a convenient, real-time measure (3) of engine intake air-to-fuel ratio (A/F). The latter quantity is a key parameter influencing many aspects of engine performance. High sensitivity O_2 sensors based on the properties of the present device structure could be useful for engine diagnostics or in the feedback control of A/F especially with regard to engines operating in the fuel-efficient lean A/F region.

Experimental

The device is shown in Fig. 1a. The active components are two electrochemical cells whose electrolytes are in the form of disks of ceramic ZrO_2 doped with 8 mol percent Y_2O_3. The disks have a typical diameter of 1.0 cm and a thickness of 0.1-0.2 cm. The material was obtained from the Ceramic Products Division of the Corning Glass Works. Because of the large concentration of oxygen vacancies introduced by the dopant, the material is a strong $O^=$ ionic conductor (4) and well suited for use as a solid electrolyte. Sputtered Pt films with thicknesses ranging from 0.5-1.0 μm were used as electrodes. As a result of sintering during high temperature firing (800°-1000°C), the films adopt a porous sponge-like structure (5). Pt paste was also used for electrodes, but sputtered films gave the most reproducible results. The cells are separated by an enclosed volume defined by a hollow ceramic spacer (0.1 cm in length) joined to each cell with ceramic glue (Aremco 552) or glass frit (General Electric RE-X). As discussed below, some types of operation require the volume to have a small leak to the ambient. This can be accomplished by making the seals somewhat leaky or by drilling a small hole into the spacer or cell face. Similar structures for O_2-sensing applications have been discussed (6).

The device is operated in a furnace at temperatures ranging from 600° to 1000°C. The ambient atmosphere is fixed by the use of calibrated gases containing O_2 at partial pressures ranging from 10^{-2} to 10 kPa in N_2. The total pressure is 100 kPa. The typical electrolyte resistance during operation was on the order of 50Ω.

Principles of Transistor Operation

Electrical operation is based on the electrochemical pumping of O_2 from the ambient into the enclosed volume (base region) by one cell (the emitter) while at the same time collecting and returning that O_2 to the ambient with the other cell (the collector). The use of ZrO_2 cells as very efficient O_2 pumps in this partial pressure region is well established (7-9). The overall electrochemical reaction step is given by Eq. [1]

$$O_2 \text{ (gas)} + 4e^- \text{ (electrode)} + 2V_o^{\cdot\cdot} \text{ (electrolyte)} \rightleftarrows 2\,O_o \text{ (electrolyte)} \quad [1]$$

where $V_o^{\cdot\cdot}$ represents an oxygen-ion vacancy and e is the electronic charge (5, 10-13). Numerous studies of ZrO_2 cells have brought out the complexity of the intermediate steps which combine to produce the overall reaction. When ionic current is drawn, one of these steps can become rate limiting leading to electrode polarization phenomena. For the O_2 partial pressures and electrodes used in this work, these studies indicate minimal polarization associated with the anodic release of oxygen, while under certain conditions, large cathodic polarization can occur on the uptake of oxygen. This polarization is related to the limited ability of the Pt electrodes to deliver O_2 to the electrode/electrolyte interface. The specific intermediate step responsible for this limitation, which plays an important role in the present device operation, has not yet been unambiguously identified. The actual electrochemical step does not appear to be rate limiting for $T > 700$°C, and an equilibrium exchange current density, $i_o \sim 1$ A/cm², has been determined

* Electrochemical Society Active Member.

Key words: transistor, solid electrolyte, ZrO_2, cathode polarization.

for porous Pt electrodes in this temperature range (14).

If an O_2 partial pressure difference exists at opposing sides of a ZrO_2 cell, an emf is developed whose magnitude is given at equilibrium by the Nernst equation (Eq. [2])

$$\text{emf} = (RT/4\mathbf{F}) \ln (P_1/P_2) \quad [2]$$

where R and $\mathbf{F}$ are the gas and Faraday constants while P_1 and P_2 represent the effective oxygen pressures or activities at the opposing electrode/electrolyte interfaces. In the analysis given below Eq. [2] is used to represent the cell emf's even though ionic current is drawn. The use of an equilibrium result to describe a nonequilibrium situation is justified when the current densities drawn are considerably less than i_o.

In the following, device operation is discussed primarily in the context of the common-base (CB) configuration. This will begin with a qualitative discussion of steady-state characteristics and the corresponding a-c amplification functions that can be realized because of these characteristics. Following this is a more detailed discussion of those cell parameters which define steady-state operation. Next a simple model describing steady-state behavior both in the CB and other configurations is put forth and compared with experiment. Small-signal parameters commonly used to compute transistor amplifier gain and impedance coefficients are derived from the steady-state model. With increasing frequency, the deviation in small-signal behavior from that predicted by the steady-state parameters is discussed in terms of several capacitive effects. The curves shown on subsequent figures are experimentally derived unless expressly indicated.

Steady-state operation.—Figure 1b shows the device wired in the CB configuration. In normal operation the emitter cell is "forward biased" by V_E to emit O_2 from the ambient into the base region. At the same time the collector cell is "reverse biased" by V_C through the load resistor R_L to collect the emitted O_2 and return it to the ambient. The emitter and collector currents are labeled by I_E and I_C, respectively. With the base electrodes of each cell connected, one has a three terminal device biased like an n-p-n semiconductor transistor. Because of the particular device structure, electrical operation is also similar. In fact, the device can be used to perform a number of common transistor functions including a-c or small-signal voltage, current, and power amplification.

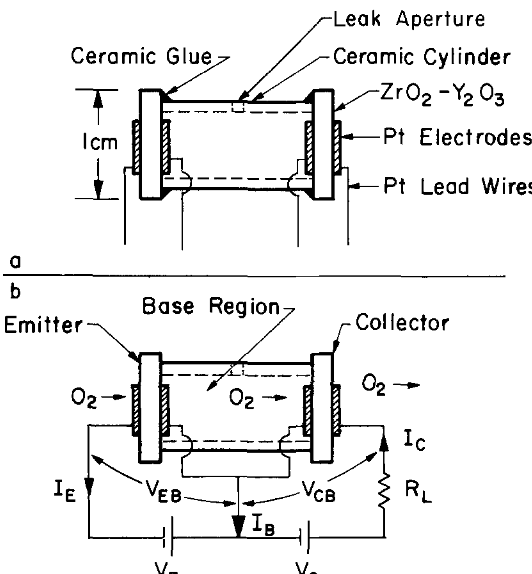

Fig. 1. a, Schematic view of the ZrO_2 transistor. b, Transistor wired in the CB configuration.

To understand device operation qualitatively, imagine that I_E has been fixed at a nominal value to pump O_2 into the enclosed volume. If the collector cell is open circuited, a steady state will occur when the flux ($i_E/4e$) of O_2 molecules entering the volume equals the flux leaving by means of a leak aperture. The steady state will be characterized by an O_2 partial pressure in the base, $P(B)$, as well as an absolute pressure, which are greater than their counterparts in the ambient. These pressure differences "drive" the leakage flux. If there were no leak, only a null emitter current would be possible in steady state (neglecting a number of small effects or processes such as electronic conductivity which would invariably result in a finite value of I_E). In this case V_E would generate a transient emitter current which builds a $P(B)$ value just large enough to produce a Nernst emf at the emitter cell which exactly offsets V_E. If a collector bias of proper polarity is now applied, O_2 molecules will be withdrawn from the base at a rate given by $I_C/4e$. As I_C is increased, $P(B)$ decreases with commensurate changes occurring in O_2 leakage. In particular, as $P(B)$ falls below $P(A)$ (the O_2 partial pressure in the ambient), the direction of leakage changes and O_2 is drawn into the volume. As discussed below, the principal leakage mechanism is one in which O_2 diffuses through its carrier gas (*e.g.*, N_2 or CO_2) in response to differences between $P(B)$ and $P(A)$. Because of the device structure, I_C must eventually saturate. The maximum saturation value would equal the fixed value of I_E plus a leakage contribution equivalent to the maximum flux of O_2 molecules that the leak aperture will pass [occurring for $P(B) << P(A)$]. In practice this maximum value is not achieved. As the steady-state value of $P(B)$ decreases, a point is reached where the collector cathode cannot deliver O_2 at a greater rate, and the cathode becomes completely polarized. As a consequence $P(B)$ saturates at some finite value and the maximum leakage current is not quite realized.

With an operating point established in the saturation region, the collector cell presents a high effective a-c impedance since small changes in collector bias, ΔV_C, serve primarily to modulate the degree of cathode polarization. By adjusting V_C, the total impedance of the collector circuit can be further increased by choosing an arbitrarily large value of R_L. At the same time, the impedance of the emitter circuit remains low, consisting primarily of the electrolyte resistance R_E. Accordingly, a modulation in emitter current, ΔI_E, can be achieved with a modest variation in emitter bias, ΔV_E. If ΔI_E is small, the collector-cell current will undergo a nearly identical modulation, ΔI_C, while still remaining in a saturated condition. However, the collector current is drawn through a much higher resistance resulting in a higher voltage modulation ($=\Delta I_C R_L$). As in the case of a semiconductor transistor, the a-c gain or ratio of collector circuit to emitter circuit voltage modulation is given within a certain range by R_L/R_E. Similar considerations hold for gain coefficients in other configurations. In many cases these coefficients or other device parameters serve to isolate various electrochemical aspects of ZrO_2 cells for study.

Results and Discussion

Figure 2 shows a plot of I_C *vs.* V_{CB} (the collector or output characteristic) for various values of I_E at $T = 800°C$ and $P(A) = 1.0$ kPa. Voltages are measured with respect to the common lead while currents are positive in the directions shown. As discussed, I_C shows saturation behavior with increasing collector bias. Higher saturation currents occur for larger I_E. Each curve in the family is labeled both with I_E, which

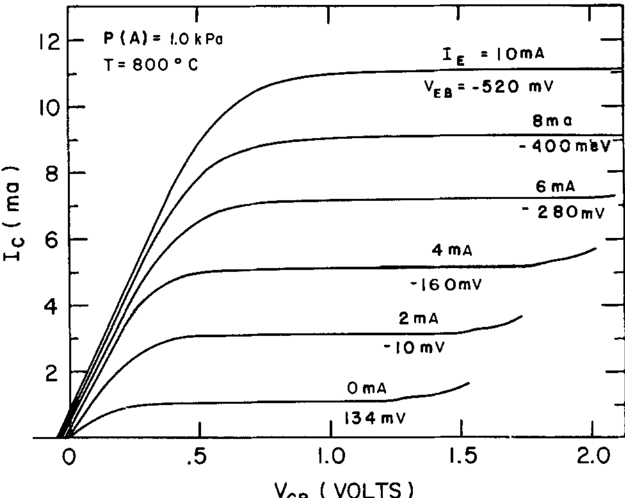

Fig. 2. Collector current vs. collector to base voltage (output characteristic) for the CB configuration.

is held constant, and with the emitter bias at saturation. Figure 3 shows the corresponding input or emitter characteristic in which I_E is plotted against V_{EB} at constant values of V_{CB}. The sign of V_{EB} has been changed in this figure to avoid the appearance of a negative input resistance. Inspection of both curves shows that the emitter resistance remains low ($\sim 60\Omega$) while the dynamic collector resistance is large ($\sim 2 \times 10^4\Omega$) at saturation. Referring to the collector characteristic, as V_C and accordingly V_{CB} are increased, saturation eventually terminates with a "breakdown" in which I_C begins to increase again. As is discussed more fully below, breakdown is accompanied by a large decrease in $P(B)$ which is reflected as a large increase in input resistance in the input characteristic (see the $V_{CB} = 1.5V$ curve in Fig. 3). In Fig. 2, O_2 leakage through leak apertures is evidenced by the fact that $I_C > I_E$. Gas leakage can be identified with the electrical current (leakage current), I_B, flowing in the base lead as expressed in Eq. [3]

$$I_B = I_C - I_E \qquad [3]$$

The main factor which determines the essential features of the collector characteristic is the O_2 transfer limitation of the collector cathode mentioned previously. This process, as well as that of leakage, can be, investigated by opening the emitter circuit and measuring the leakage curve ($I_E = 0$) of the characteristic while monitoring the emitter-base voltage V_{EB}. The open emitter cell acts as an O_2 pressure sensor allowing determination of $P(B)$ from the Nernst equation when $P(A)$ is fixed by the use of calibrated gases. Figure 4 shows a plot of I_C and V_{EB} vs. V_{CB} for this case with the same ambient conditions as Fig. 2. The important point is that V_{EB}, and hence $P(B)$, saturates (at the same value of V_{CB} that I_C saturates) indicating that I_C is limited by the polarization of the collector. For the case shown, the O_2 partial pressure at saturation is $P(BO) = 3 \times 10^{-3}$ kPa of (the extra label O identifying conditions where the only electrical current flowing in the base and collector circuits results from O_2 leakage). By varying $P(A)$ one finds that the saturated leakage current, I_{CO}, can be related to $P(BO)$ by Eq. [4]

$$I_{CO} = (1/R_{DC})P^n(BO) \qquad [4]$$

Here R_{DC} (on the order of 5.0 kPa-A^{-1} for 0.5 μm electrodes) represents the "resistance" the cathode presents to the delivery of O_2 while n is a constant having values ranging from $0.5 < n < 1.0$. The DC in the subscript suggests that the resistance is related to a diffusion process in the cathode.

As has been reported by other authors (5, 10, 12), the values of these parameters are strongly dependent on the method of electrode application, thickness, sintering temperature, and heavy current passage ($\sim$1 A/cm^2 in 100 kPa O_2). These factors determine the texture of the electrode which in turn governs the details of the cathodic polarization. When $n = 1$, a limiting process involving molecular O_2 (*e.g.*, pore diffusion) is likely and when $n = 0.5$, a process involving atomic O is limiting. A systematic study of these effects was not performed. In this work consistent and repeatable results were found using sputtered Pt electrodes.

We assume that Eq. [4] is the limiting form of a more general O_2 transfer expression for the cathode which can be approximated by Eq. [5]

$$I_C = (1/R_{DC})(P(B) - P(CB)^n \qquad [5]$$

where $P(CB)$ represents the effective O_2 partial pressure at the electrode/electrolyte interface of the cathode. As V_{CB} increases in the saturation region, a large effective O_2 partial pressure difference develops across the cathode ($P(CB) << P(B)$) and Eq. [5] approaches the limiting form of Eq. [4]. At low values of V_{CB}, Eq. [5] is the main relationship determining the curvature of the collector characteristic, as is discussed in the steady-state model developed later.

The dependence of leakage current on O_2 pressure can be characterized by a single parameter obtained

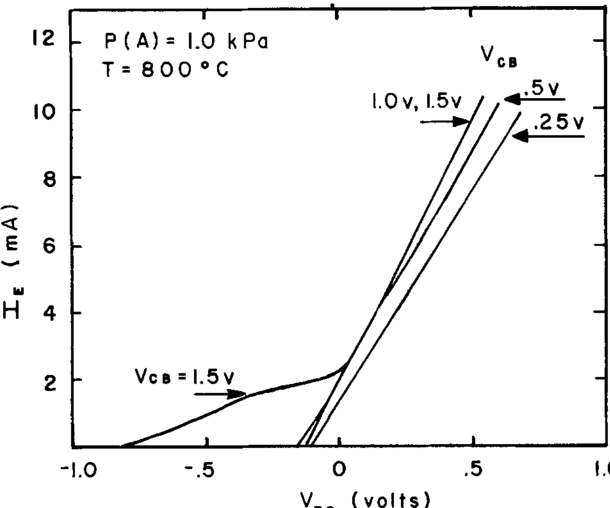

Fig. 3. Emitter current vs. emitter to base voltage (input characteristic) for the CB configuration.

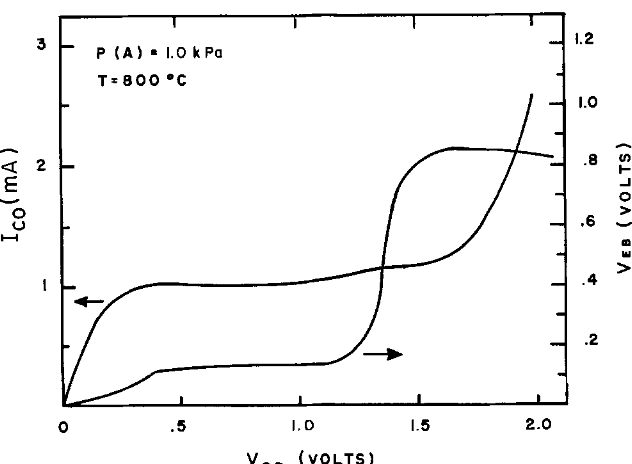

Fig. 4. Collector current and emitter to base voltage vs. collector to base voltage with the emitter cell open circuited.

from the data such as that of Fig. 4 in the presaturation region. The relation shown in Eq. [6] holds over a wide range of $P(B)$ values

$$I_B = (1/R_{DL})(P(A) - P(B)) \quad [6]$$

Similar to the constant in Eq. [4], R_{DL} represents the resistance of the leak to the flux of O_2. Figure 5 shows a typical plot of I_B *vs.* $P(B)$ from which the R_{DL} value is obtained.

Breakdown.—When the collector bias is increased, a breakdown region which is characterized by an increasing collector current eventually results, as in the case of semiconductor transistors. Although device operation is precluded in this region, a brief discussion of breakdown properties is useful for illustrating further how the present structure can be used to study interesting aspects of ZrO_2 cells in a variety of gaseous ambients.

The essential features of breakdown are illustrated in Fig. 4. For that case, the open emitter voltage starts to depart from its saturation value (0.134V) at V_{CB} 1.2V and rises sharply to approximately 0.85V, corresponding to $P(B) = 1.1 \times 10^{-14}$ kPa, where it peaks and eventually begins a slight decline. Simultaneously, I_{CO} starts to increase gradually from its saturation value. With increasing V_{CB}, I_{CO} rises more rapidly and for a range of collector voltages the slope of the curve may in some circumstances yield a dynamic resistance which approaches the bulk electrolyte resistance of the collector cell. Operation in this region is sluggish, being attended by long-term drifts in all electrical parameters not fixed by the external circuit. For example, as V_{CB} just reaches the point of breakdown, the drifts are in the direction of increasing values of V_{CB} while I_{CO} slowly decreases to a steady-state value. If V_{CB} is caused to increase beyond 3-4V, however, I_{CO} tends to increase continuously with time. These drifts are probably associated respectively with a reduction and finally decomposition of the collector electrolyte (7) consistent with the low values of $P(B)$ indicated by V_{EB}. The details of breakdown are systematically influenced by the composition of the ambient gas phase both in the amount of O_2 present and in the nature of the carrier gas employed. For example, the onset of breakdown occurs at smaller V_{CB} values as $P(A)$ decreases.

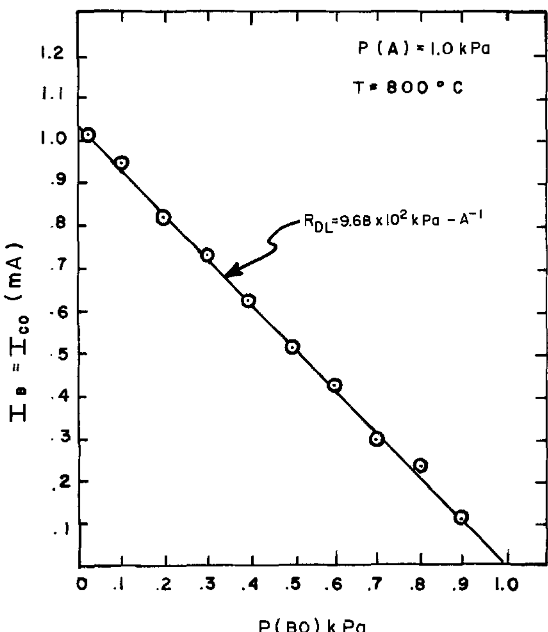

Fig. 5. Collector current *vs.* O_2 partial pressure in the base with the emitter open circuited.

Employing single ZrO_2 cells in the form of platelets or tubes, numerous authors (9, 15) have observed current breakdown subsequent to a saturation region. Yanagida *et al.* (10) suggested that with increasing applied voltage, the effective O_2 partial pressure at the Pt/electrolyte interface of the cathode, $P(CB)$, has been lowered sufficiently to reduce the electrolyte resulting in an enhanced degree of electronic conductivity. Initially present only at the cathode surface, this conductivity would eventually spread throughout the electrolyte as V_{CB} increases. Such a surface conductivity could render the entire electrolyte surface active for taking up the ambient O_2, thereby removing a portion of the electrode polarization and allowing additional O_2 to be pumped. We have observed that if V_C is initially applied so that V_{CB} lies in the breakdown region and is then removed, V_{EB} and the open-circuit value of V_{CB} remain at high values (~0.8V) for a period of time before each relaxes to 0.0V. The longer that V_C is applied, the longer it takes for the relaxation to occur. Recovery times are even longer if the O_2 content in the ambient is reduced .These observations are consistent with a cumulative reduction of the electrolyte. After V_C has been removed, the reduced ceramic continues to pump O_2 until it eventually equilibrates with $P(A)$. Lower $P(A)$ prolongs the relaxation.

Using open-ended tubular electrolytes, others (9) have found that the very low O_2 pressures (*e.g.*, 10^{-14} kPa) achieved with O_2 pumping are not due to the complete electrochemical removal of O_2, but are a consequence of the presence of CO_2, H_2O, or other oxygen-bearing species present as impurities in the feedgas. With sufficient pumping voltage, these species are electrolyzed producing CO or H_2 whose reaction with the remaining O_2 is catalyzed by the Pt electrodes. Since these oxidation reactions are strongly favored, very low O_2 pressures will result if the stoichiometric ratio for the unreacted species can be approached (*e.g.*, if $[P_{CO}(B)/P_{O_2}(B)] \geq 2$). For a given pump voltage this condition will be promoted if the feedgas contains larger CO_2 or H_2O pressures or lower O_2 pressures. Figure 6 shows plots of I_{CO} and V_{EB} *vs.* V_{CB} for the same device when the ambient gases are nominally 0.25% O_2 in CO_2 and 0.25% O_2 in N_2. The behavior is nearly identical until breakdown, which occurs much earlier for the ambient containing CO_2. For the present interpretation, the CO_2 result is explained by a substantial CO_2 electrolysis which quickly produces enough CO to eliminate the remaining O_2.

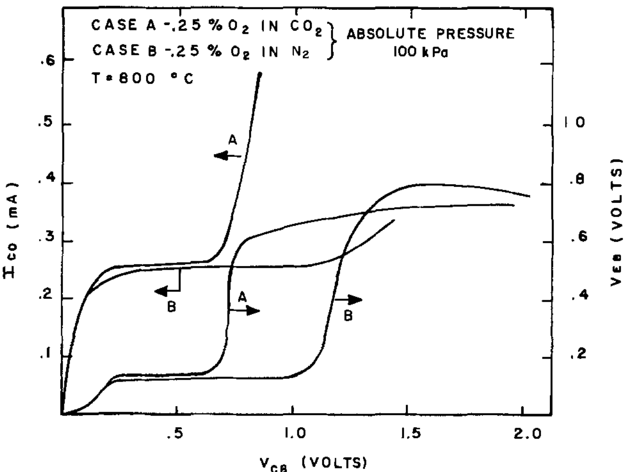

Fig. 6. Collector current and emitter to base voltage *vs.* collector to base voltage with the emitter open circuited for two different ambients; A, 0.25% O_2 in CO_2; and B, 0.25% O_2 in N_2; both at 100 kPa total pressure.

The data shown in Fig. 7 are also consistent with these results. When O_2 is injected into the base with a forward-biased emitter cell, the breakdown moves to higher V_{CB} voltages due to the increased value of $P(B)$ at saturation. Besides the progressive negative shift of the characteristic due primarily to the IR drop in the emitter, the main feature is the shift of the breakdown to higher V_{CB} with increasing I_E. This coupling between output (collector) and input (emitter) circuits is a form of internal voltage feedback which, although present in conventional semiconductor transistors, is much larger in the present device.

At low collector voltages, V_{EB} is negative for positive values of I_E. This is due to both the IR drop in the emitter electrolyte and the Nernst emf resulting from the "overpressuring" of the base $[P(B) > P(A)]$ when the injected O_2, instead of being electrochemically collected, is forced out the leak. This is also seen in Fig. 2 where, with increasing I_E, the $I_C = 0$ intercept shifts to negative V_{CB} values as the base is overpressured.

In summary, the main processes occurring at breakdown appear to be accountable in terms of phenomena previously observed with ZrO_2 cells. As was the case in the prior discussion of cathode polarization, the present device structure allows these processes to be manifested in a manner which is particularly convenient for study.

Steady-state model.—Using the values of R_{DC} and R_{DL} obtained from the leakage curve, the steady-state device behavior can be modeled by assuming that each cell represents a circuit element which shows an IR drop due to electrolyte resistance and a Nernst emf consistent with the O_2 partial pressures at each electrode. For an emitter circuit without an external series resistor, one has

$$V_E = I_E R_E - \frac{RT}{4F} \ln \frac{P(A)}{P(B)} \quad [7]$$

while for the collector circuit

$$V_C = I_C(R_L + R_C) + \frac{RT}{4F} \ln \frac{P(A)}{P(CB)} \quad [8]$$

and

$$V_{CB} = V_C - I_C R_L \quad [9]$$

Equations [3] and [5]-[8] allow computation of the input and output characteristics for any suitable independent variable.

A limiting case occurs when leakage is nonexistent ($R_{DL} = \infty$) and the O_2 transport limitation by the collector cathode is negligible ($R_{DC} = 0$). In that case

$$P(B) = P(A) \exp \left[\frac{-4F}{RT} (V_C - I_E(R_L + R_C)) \right]$$

$$I_B = 0, \quad P(CB) = P(B) \quad [10]$$

and

$$I_E = I_C = \frac{V_C + V_E}{(R_L + R_C + R_E)}$$

As is reasonable, the external current is determined by the series combination of applied voltages and ohmic resistances, the base electrodes acting as short circuits. The steady-state value of $P(B)$ is exponentially promoted by I_E which injects O_2 and diminished by V_C which withdraws O_2.

Using parameters appropriate for the data of Fig. 2 ($R_{DL} = 9.68 \times 10^2$ kPa-A^{-1}, $R_{DC} = 5.9$ kPa-A^{-1}, $R_E = 60\Omega$, $R_C = 56\Omega$, $P(A) = 1.0$ kPa, $T = 1073$ K), Fig. 8 shows the collector characteristic obtained from a solution of the above equations. There is reasonable agreement with Fig. 2 if the breakdown phenomenon which is not included in the model is ignored. At low values of V_{CB} the curvature of the measured output characteristic has as much as 30% lower current values than the computed data. This may in part reflect an oversimplified choice of n and R_{DC} to specify the cathode polarization. Although the model, and the latter aspect in particular, is not exact, it proves very useful for determining trends in device behavior with parameter variations.

The extent of the O_2 activity drop that develops across the cathode is shown by the model results of Fig. 9 where $P(B)$ and $P(CB)$ are plotted as a function of V_{CB} for $I_E = 0$ and 2 mA. At a given V_{CB} both $P(B)$ and $P(CB)$ increase with increasing emitter current.

Finally, unlike a semiconductor transistor, the present device has four external terminals if the base leads of the emitter and collector cells are not connected. This allows a degree of flexibility in biasing as shown by the three alternate arrangements of Fig. 10 which all result in nearly equivalent CB-type performance. The major effect of the different arrangements is to allow the polarity of the biasing for each cell to be varied. Further, for the arrangements of Fig. 10b and 10c, the low-frequency input and output signals will be in phase which is normal for CB mode, while for the arrangements of Fig. 10a and b the signals will be 180° out of phase which is a new feature.

Small-signal analysis.—As discussed previously, the device can be used as a small-signal amplifier in a manner analogous to that for npn transistors. In the CB mode V_C and V_E are adjusted to establish an operating point on the output characteristic. The slope of the load line is set by R_L. Inspection of Fig. 2 shows that even with a near vertical load line (low R_L), current gain, $G_I = \Delta I_C/\Delta I_E$ (where Δ signifies small-signal values), will never exceed unity as is typical for the CB mode. For a load line with a much smaller slope, voltage gain, $G_V = \Delta V_{CB}/\Delta V_{EB}$, can be realized. In fact voltage gains of 70 have been measured. Physically, gain results because the input modulation ΔV_{EB}, produces a small variation in P(B), which under saturation conditions and with a large R_L, produces a much larger percentage variation in P(CB). The latter variation, through the Nernst term in Eq. [8], provides the dominant modulation of the collector-cell voltage drop.

Characterization of amplification properties is most conveniently done using the standard small-signal parametrization of the steady-state input and output characteristics for a given mode. These parameters quantify the components of a small-signal equivalent circuit from which the low-frequency a-c response of the device can be computed. Hybrid parameters are used in the present work and their properties are discussed in Ref. (16). Choosing a typical operating point in the saturation region for the data under discussion, one finds (Fig. 2) that the current amplification factor $\alpha_{fb} = (\Delta I_C/\Delta I_E)_{V_{CB}} = 1.00$ indicating that all of the emitted current is collected. The conductance $h_{ob} = (\Delta I_C/\Delta V_{CB})_{I_E} = 2 \times 10^{-4}$ mhos shows the small slope of the saturated collector characteristic. The emitter input resistance $h_{ib} = (\Delta V_{EB}/\Delta I_E) = 60\Omega$ is accounted for by the emitter electrolyte resistance. This quantity is most easily obtained from Fig. 3. The reverse amplification factor $\mu_{rb} = (\Delta V_{EB}/\Delta V_{CB})_{I_C} = 10^{-2}$ and can most easily be obtained from Fig. 7. This parameter quantifies the internal feedback property discussed previously. In this case μ_{rb} is larger than for Si transistors ($\sim 10^{-4}$) and reflects the fact that P(B) is changing slightly in the region of collector saturation with the result that the Nernst component of V_{EB} is affected. Using these parameters, well-known formulas (16) exist for computing gain coefficients as well as input and output resistances in the various amplifier operating modes. Useful and instructive approximations to these coefficients can be obtained from the model equations. For example, although a variation ΔV_{EB} will produce a modulation ΔP(B), a reasonable approximation is that Δ ln $(P(B)/P(A))$ is small in Eq. [7] so that the input resistance R_{IN} is given by

$$R_{IN} = \frac{\Delta V_{EB}}{\Delta I_E} \sim R_E \qquad [11]$$

Further, in the region of saturation $P(CB) << P(B)$ and Eq. [3], [5], and [6] can be used to obtain a current gain G_I given by

$$G_I = \frac{\Delta I_C}{\Delta I_E} \sim \frac{R_{DL}}{R_{DL} + R_{DC}} \qquad [12]$$

Using R_{DL} and R_{DC} values for the sample of Fig. 2, $G_I \sim 0.994$ while the measured gain is essentially unity for low values of R_L (the effect of R_L on gains for the actual and model results in discussed more fully below). $G_I < 1.0$ because an increase in I_E produces a corresponding increase in P(B) which serves to reduce the leakage current I_B. Since the collector is drawing both the emitted and leakage currents, $(\Delta I_C/\Delta I_E) < 1$. Finally from Eq. [9] one finds that $\Delta V_{CB} = -\Delta I_C R_L$. Using Eq. [11] and [12] in this relation yields a voltage gain given by

$$G_V = \frac{\Delta V_{CB}}{\Delta V_{EB}} = \frac{R_{DL} R_L}{(R_{DL} + R_{DC}) R_E} = G_I \frac{R_L}{R_E} \sim \frac{R_L}{R_E} \qquad [13]$$

For low R_L ($< 10^4\Omega$) experimental results reasonably approximate this prediction.

The model can also be used to separately calculate all of the small-signal hybrid parameters. The results are only simple under saturation conditions where one finds $\mu_{rb} = h_{ob} = 0$, $h_{ib} = R_E$, and $\alpha_{fb} = R_{DL}/(R_{DL} + R_{DC})$. The null result for the first two parameters is consistent with the neglect of any breakdown processes in the model which results in "hard" saturation behavior. This model deficiency leads to errors when one attempts to calculate limiting amplification parameters [*e.g.*, maximum possible voltage or current gains, maximum (minimum) input (output) resistances]. For example, the model calculation shows voltage gain increasing indefinitely with R_L, whereas experimentally the gain saturates at high R_L. Perusal of the small-signal analyses shows that this saturation is expected due to the nonzero values of μ_{rb} and h_{ob}. Although the model is not accurate in these limiting calculations, it proves useful for identifying device parameters which should be modified to improve amplification features.

Common emitter (CE) and collector (CC) configurations.—As with semiconducting transistors, the present

device can be wired in the CE and CC configurations. Qualitatively all of the steady-state and a-c features normally associated with these configurations are manifested by the present device. These include both a-c current and voltage gain in the CE mode as well as current gain in the CC mode. As with the CB mode, model calculations provide a good qualitative description of steady-state characteristics. Low frequency gain parameters determined by R_{DL}, R_{DC}, and other external circuit parameters are in reasonable agreement with experiment. Since no new device parameters or cell characteristics are revealed by these modes, their detailed properties are not discussed.

Frequency response.—The small-signal frequency response of the device is determined by two capacitive aspects of the structure. The most important is the double layer capacity of the collector cathode which is prominent under conditions of collector saturation. The second is the pseudocapacity associated with changing the value of $P(B)$ within the base volume. Specifically, transient currents in excess or deficit of steady-state values must be drawn in the emitter circuit to modify $P(B)$ which in turn determines the amount of current drawn in the collector circuit. The magnitude of these transients, and correspondingly the pseudocapacity, will be proportional to the magnitude of the base volume. Electrically these effects are manifested by changes in the Nernst emf. In semiconducting transistors the analog is the so-called diffusion pseudocapacity in which the emitter must inject/withdraw an excess of minority carriers from the base in order to support a diffusion current of minority carriers across the base.

Which of the two capacitive effects limit the frequency response depends on the external ciricuit. R_L is the key parameter. As discussed below, the double layer capacity (C) is on the order of 0.1×10^{-3}**F** for the present device geometry and operating conditions. When in series with $R_L = 10^3\Omega$, one has a time constant $\tau = R_LC \sim 0.1$ sec. For the same conditions, the time constant, τ_P, associated with the pseudocapacity, C_P, is approximately 10^{-2} sec (see below). Hence double layer effects are limiting. Large values of R_L (with the attendant loss of frequency response) are appropriate to achieve voltage gain in the CB mode. In the CC and CE modes however, very low values of R_L are appropriate for realizing a-c current gain. Although double layer effects would then be greatly reduced, pseudocapacity emerges as the response limiting factor.

Because the double layer capacity at the Pt/ZrO_2 interface is so large, pseudocapacitive effects are usually of secondary importance and will not be discussed in detail. It is worth noting however that τ_P is not determined solely by the resistance, R_E, of the emitter circuit. This is because the leak and the saturated collector cell act as effective shunt resistances of C_P. This can be understood by considering that both act to moderate or offset the effect of the emitter cell in changing $P(B)$. In practice the effective shunt resistance of the collector is quite small ($\sim 1\Omega$) and fixes τ_P at approximately 10^{-2} sec for devices used in this work. More detail on this aspect will be given in a future publication (17) concerning use of the device as an O_2 sensor.

The double layer capacity of the Pt/ZrO_2 interface is well illustrated in the CB configuration. Figure 11 shows experimental results for the roll off in small-signal CB voltage gain, $G_V = \Delta V_{CB}/\Delta V_{EB}$, with increasing frequency for several values of R_L. Also shown is the phase angle by which the output lags the input. The drop in response occurs at lower frequencies for larger R_L values indicating that capacity in the collector circuit is the cause of the roll off.

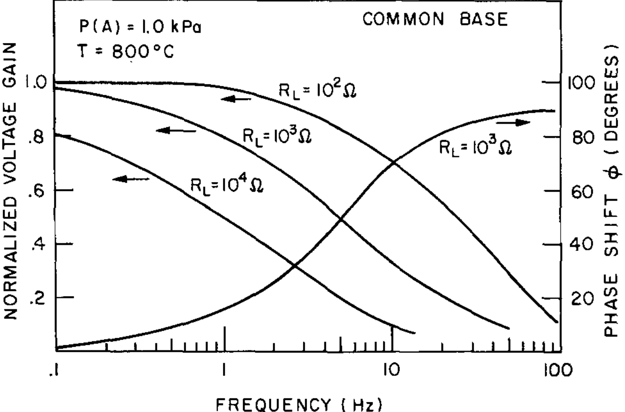

Fig. 11. Experimental results for a combined frequency plot of the normalized small-signal voltage gain and the phase shift of the collector voltage relative to the emitter voltage for various R_L values. The zero frequency gains in each case are G ($R_L = 10^4\Omega$) = 30, G ($R_L = 10^3\Omega$) = 12, G ($R_L = 10^2\Omega$) = 3.

Previous studies (18) have shown that the apparent double layer capacities at the Pt/ZrO_2 interface can be very high, on the order of several hundred μ**F**/cm². During operation in the saturation region, the modulation ΔV_{CB} is largely accomplished by changes in the polarization emf which must be supported by the charging/discharging of the cathode double layer capacity through R_L. This capacity was studied by biasing the collector to the saturation region and monitoring the transient response of I_C to superimposed voltage pulses of 0.1V. If no anode polarization is assumed, and since the cathode is blocking for any steady-state increase in current, the cathode is isolated for transient capacity studies. The time integral of the observed changing current, when divided by the voltage increment, yields a capacitance of approximately 250 μ**F**/cm² at 800°C. For a 0.35 cm² cathode area and $R_L = 10^3\Omega$, one finds $\tau = R_LC \sim 0.09$ sec and $(1/2\pi\tau) \sim 2$ Hz, a frequency in the range of most rapid gain decrease (Fig. 11). This capacity was found to be independent of bias voltage in the saturation region.

The capacity measured with the pulse technique increased with temperature as shown in Fig. 12, with an activation energy $\Delta E = 10.5$ kcal/mol. A similar temperature dependence was found by Chu and Seitz

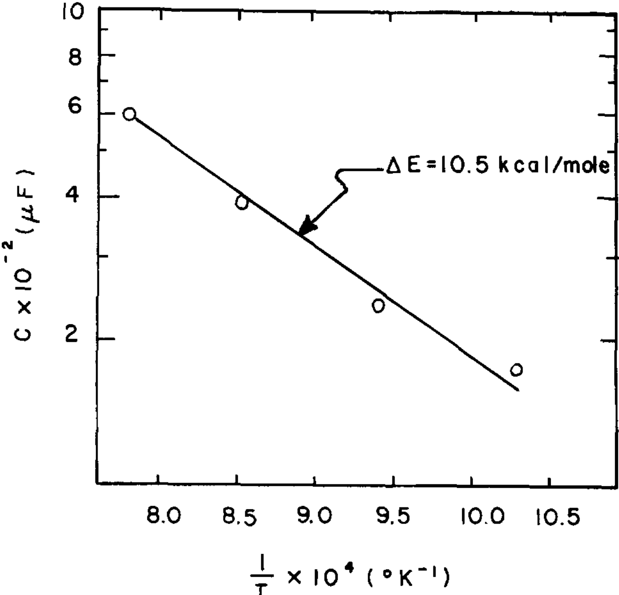

Fig. 12. Collector cathode double layer capacity vs. 1/T computed from experimental results.

(19). As far as the authors know, no adequate theory has been advanced to explain these capacitive properties. It seems reasonable to speculate that the large apparent capacities may in part be due to the partial reduction and oxidation of the electrolyte adjacent to the Pt cathode as it attempts to come to equilibrium with changing values of P(CB) during voltage applications. Such an effect would also be promoted by higher temperatures as is observed.

As R_L is reduced, the frequency response of the device improves until the pseudocapacitive effects discussed previously become limiting. As mentioned at the beginning, the low frequency response dictated by these effects coupled with a high operating temperature will undoubtedly limit the usefulness of the present device to special applications.

Summary

In summary, the present device illustrates an approach to transistor action in which a chemical species at a high ambient activity is emitted into a base region from which it is collected and returned to the ambient. Voltage, current, and power gain can be realized by the appropriate choice of external circuits and their parameters. As mentioned previously, this approach appears general and hence applicable to a variety of other electrochemical systems. For a given atomic species chosen as a charge carrier, a reasonable first choice of emitter and collector electrolyte would be dictated by the necessity of high ionic conductivity. The key technical problem would probably be the fabrication of a leak-tight or nearly leak-tight base structure or medium which would support a large variation in the activity of the species. The specialized circumstances attending the use of different electrochemical systems will probably result in equally specialized applications.

Reduction of Concentration Overpotential in Pulsed Current Electrolysis

A. A. Bedrossian[1] and H. Y. Cheh*

Department of Chemical Engineering and Applied Chemistry, Columbia University, New York, New York 10027

ABSTRACT

Pulsed current electrolysis reduces irreversibilities from mass transfer limitations. This results in an increase of the reacting species concentration in the diffusion layer and a reduction of the concentration overpotential. Consequently, high values of instantaneous currents have often been applied in practice. In this paper, theoretical calculations are presented for the reduction of concentration overpotential by pulsed current electrolysis. Experimental verification of the theoretical results is given.

Recently, the application of pulsed current to electrochemical systems has gained a great deal of attention. Cheh (1) and Ibl (2) have reported independently mass transfer studies of pulsed current electrolysis by using a Nernst diffusion model. Hale (3, 4) and Viswanathan *et al.* (5) have included convection as well as diffusion in mass transfer calculations. It has also been shown, that for short pulses under reasonable convective conditions, calculations based on the diffusion model yield adequate results (5). In this paper, calculations on the reduction of concentration overpotential by pulsed current electrolysis are reported. Experimental verification of these calculations is presented.

Key words: concentration overpotential, pulsed electrolysis.

Theoretical

Concentration overpotential is defined by

$$\eta_c = \frac{RT}{n\mathbf{F}} \ln \frac{c_i}{c_b} \quad [1]$$

where η_c is the concentration overpotential, c_i and c_b are the concentration of the reacting species at the electrode-solution interface and in the bulk solution, respectively, and R, T, n, and $\mathbf{F}$ have their usual meanings.

Under d-c electrolysis condition the concentration overpotential, $(\eta_{dc})_l$, is frequently expressed in terms of the limiting current density for the reaction by

$$(\eta_{dc})_l = \frac{RT}{n\mathbf{F}} \ln \left(1 - \frac{i_{dc}}{(i_{dc})_l}\right) \quad [2]$$

where

$$(i_{dc})_l = -n\mathbf{F}Dc_b/\delta \quad [3]$$

i_{dc} is the applied d-c current density, $(i_{dc})_l$ is the d-c limiting current density for the reaction, D is the diffusion coefficient of the reacting ion, and δ is the thickness of the diffusion layer under direct current conditions.

In accordance with the Nernst diffusion model, c_i under pulsed current and periodic state conditions (1) can be calculated along the lines given in (1):

During periods when the current is on

$$\frac{(c_i - c_b)n\mathbf{F}D}{i_p\delta} = 1 - \frac{8}{\Pi^2} \sum_{j=1}^{\infty} \frac{\exp[-(2j-1)^2 a\tau]}{(2j-1)^2} \cdot \frac{(\exp[(2j-1)^2 a\theta] - \exp[(2j-1)^2 a\theta_1])}{(\exp[(2j-1)^2 a\theta] - 1)} \quad [4]$$

During periods when the current is off

$$\frac{(c_i - c_b)n\mathbf{F}D}{i_p\delta} = \frac{8}{\Pi^2} \sum_{j=1}^{\infty} \frac{\exp[-(2j-1)^2 a\tau]}{(2j-1)^2} \cdot \frac{(\exp[(2j-1)^2 a\theta] - \exp[(2j-1)^2 a\theta_1])}{(\exp[(2j-1)^2 a\theta] - 1)} \quad [5]$$

where

$$a = \Pi^2 D/4\delta^2 \quad [6]$$

$$\tau = t - N\theta \quad [7]$$

i_p is the applied pulsed current density, θ is the cycle time of the pulse, θ_1 and θ_2 are the on and off period of the pulse, respectively, and N is the number of cycles already passed.

By combining Eq. [1] to [5] and by assuming that i_p is equal to i_{dc}, the reduction of concentration overpotential by pulsed current electrolysis when the system has reached a periodic state can be calculated by:

During periods when the current is on

$$\frac{(\eta_p)_c}{(\eta_{dc})_c} = \ln\left[1 - \frac{i_p}{(i_{dc})_l} \left(1 - \frac{8}{\Pi^2} \sum_{j=1}^{\infty} \frac{\exp[-(2j-1)^2 a\tau]}{(2j-1)^2} \cdot \frac{(\exp[(2j-1)^2 a\theta] - \exp[(2j-1)^2 a\theta_1])}{(\exp[(2j-1)^2 a\theta] - 1)}\right)\right] \Big/ \ln\left(1 - \frac{i_p}{(i_{dc})_l}\right) \quad [8]$$

During periods when the current is off

$$\frac{(\eta_p)_c}{(\eta_{dc})_c} = \ln\left[1 - \frac{i_p}{(i_{dc})_l} \frac{8}{\Pi^2} \sum_{j=1}^{\infty} \frac{\exp[-(2j-1)^2 a\tau]}{(2j-1)^2} \cdot \frac{(\exp[(2j-1)^2 a\theta] - \exp[(2j-1)^2 a\theta_1])}{(\exp[(2j-1)^2 a\theta] - 1)}\right] \Big/ \ln\left(1 - \frac{i_p}{(i_{dc})_l}\right) \quad [9]$$

where $(\eta_p)_c$ is the concentration overpotential under pulsed and periodic state conditions.

Since $(\eta_p)_c$ is a function of time in a given period, the average reduction for one complete cycle is given by

$$\left[\frac{(\eta_p)_c}{(\eta_{dc})_c}\right]_{avg} = \frac{1}{\theta_1 + \theta_2} \left[\int_0^{\theta_1} \left[\frac{(\eta_p)_c}{(\eta_{dc})_c}\right]_{Eq. [8]} d\tau + \int_{\theta_1}^{\theta_2} \left[\frac{(\eta_p)_c}{(\eta_{dc})_c}\right]_{Eq. [9]} d\tau\right] \quad [10]$$

Equations [8]-[10] provide a complete description of the reduction of concentration overpotential under pulsed conditions. Numerical evaluations of these equations are illustrated at various values of $i_p/(i_{dc})_l$ and $a\theta = 0.5$. Typical results from Eq. [8] and [9] at $\theta_1/\theta = 0.4$ are shown in Fig. 1. In this figure, the region, $0 < a\tau \leq 0.2$, represents the period when the current is on whereas the region, $0.2 < a\tau \leq 0.5$, is the period when the current is off. It is seen that the concentration overpotential increases during the on-period and the concentration overpotential decreases during the off-period. Results from Eq. [10] are presented in Fig. 2 which shows the average value of the concentration overpotential under pulsed conditions as a function of applied pulsed current density and duty cycle. At very low currents, the application of pulsed current has little effect on the mass transfer of the system. This fact is responsible for the result that as $i_p/(i_{dc})_l \to 0$, $(\eta_p)_c/(\eta_{dc})_c \to \theta_1/\theta$. On the other hand, when i_p increases, the value of $(\eta_p)_c/(\eta_{dc})_c$ decreases. This is because as the d-c limiting current density is approached, the value of $(\eta_{dc})_c$ also increases drastically.

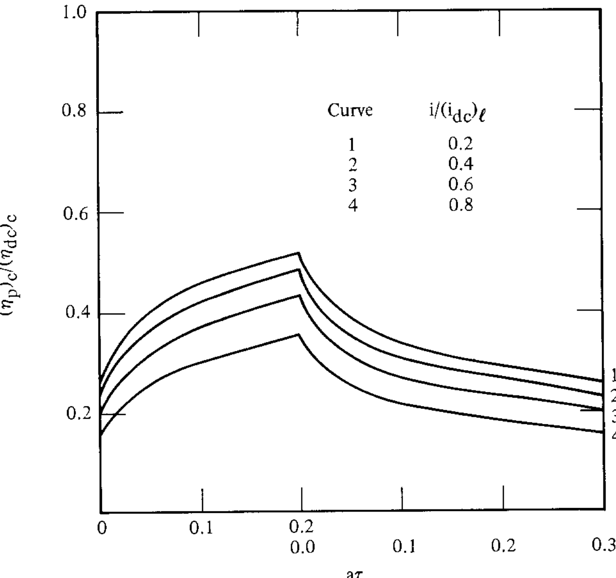

Fig. 1. Instantaneous values of $(\eta_p)_c/(\eta_{dc})_c$. Duty cycle = 0.4, $a\theta = 0.5$.

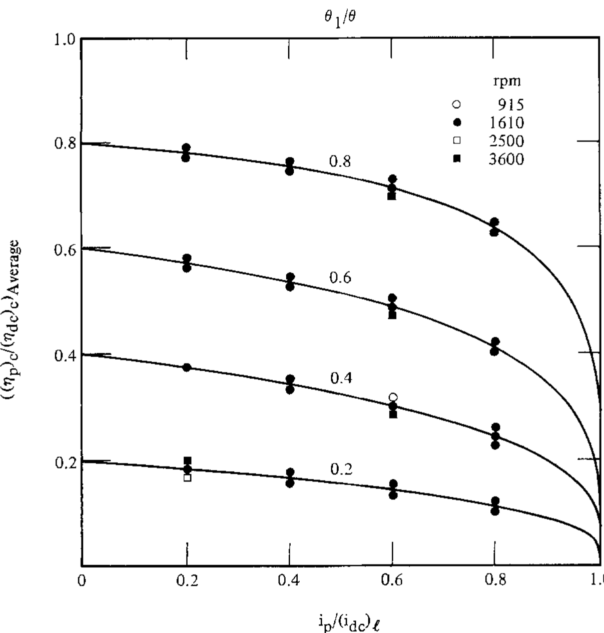

Fig. 2. Theoretical and experimental values of the average reduction of concentration overpotential. ($a\theta = 0.5$).

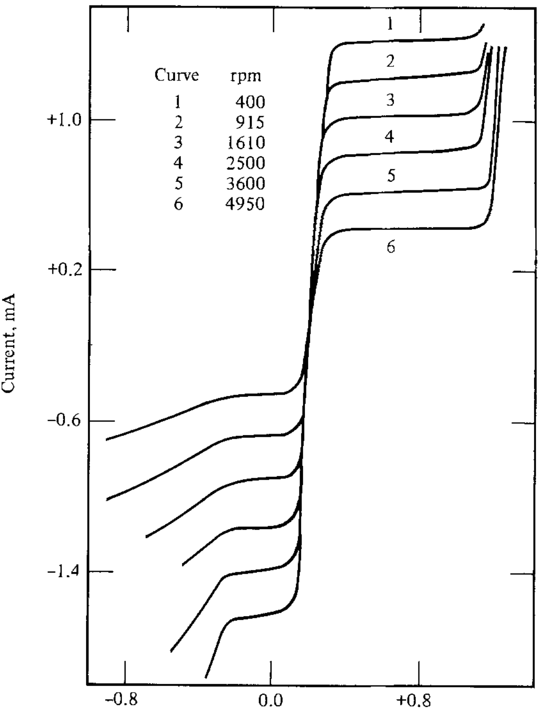

Fig. 3. Current-potential behavior for the ferri-ferrocyanide system.

Experimental

The experimental system consisted of a Pine Instrument rotating Pt disk electrode (area = 0.46 cm^2), a Pt counterelectrode, a saturated calomel reference electrode with a Luggin capillary and an electrolyte containing 3 mM $K_4Fe(CN)_6$ and 3 mM $K_3Fe(CN)_6$ in 1M KCl. A Tacussel function generator (Model G STP-3C) and a Kepco power supply (Model BOP36-1.5M) were used as current sources for d-c and pulsed current electrolysis. The potential between the rotating disk electrode and the reference electrode was measured and recorded on a Tektronix oscilloscope (Model 5103N). In the present system, it was found that the location of the reference electrode had a negligible effect on the overpotential measurements.

In order to compare experimental results with those predicted by Eq. [8] and [9], overpotentials under both d-c and pulsed conditions were measured. It was also found that the activation overpotential contributed a significant portion of the total overpotential. In the presence of an excess supporting electrolyte, the concentration overpotential is represented by the difference between the total and the activation overpotential (6). Direct current-potential relationship was measured at six rotation speeds in order to determine the d-c limiting current densities, transport properties, kinetic parameters, activation and concentration overpotentials. Experimental current-potential curves are given in Fig. 3 and detailed analyses of the results are presented in the Appendix. Based on the measured values of transport properties, the cycle times for pulses were chosen for different rotating speeds such that $a\theta$ was always 0.5. The applied pulse current densities were 0.2, 0.4, 0.6, and 0.8 of $(i_{dc})_l$. Experimental pulsed current-potential qualitatively similar to those in Fig. 1 were recorded on an oscilloscope at duty cycles of 0.2, 0.4, 0.6, and 0.8. The average potential over an entire cycle was then integrated graphically. After subtracting the activation overpotential from the total overpotential, the experimental concentration overpotential results are included in Fig. 2. There is good agreement between the theoretical and experimental results.

Conclusions

The reduction of concentration overpotential by pulsed current electrolysis was calculated by using a Nernst diffusion model. The results were compared with experimental measurements which were made in a ferri-ferrocyanide system with an excess of supporting electrolyte. Good agreements were obtained between the theoretical and experimental results.

APPENDIX

Evaluation of Diffusion Coefficients of $[Fe(CN)_6]^{-3}$ and $[Fe(CN)]^{-4}$

The d-c limiting current densities for both cathodic and anodic reactions were measured from current-potential curves at six rotation speeds. The kinematic viscosity for the electrolyte was measured by an Ostwald viscometer and was found to be 0.01 cm^2/sec. The diffusion coefficient was then calculated by the following equation which was first derived by Newman (7)

$$(i_{dc})_1 = \frac{0.62048 n F \nu Sc^{-2/3} \nu^{1/2} \omega^{1/2} c_b}{1 + 0.298 Sc^{-1/3} + 0.14514 Sc^{-2/3}} \quad \text{[A-1]}$$

where ν is the kinematic viscosity of the electrolyte, ω is the rotation speed, and Sc is the Schmidt number which is ν/D. The diffusion coefficients which fitted best results from the six rotation speeds were found to be 6.9×10^{-6} cm^2/sec for $[Fe(CN)_6]^{-3}$ and 8.4×10^{-6} cm^2/sec for $[Fe(CN)_6]^{-4}$ at 22° ± 1°C. Once the diffusion coefficients are known, the thickness of the Nernst diffusion layer can be calculated readily by Eq. [3].

Evaluation of the Kinetic Parameters

We begin with the Butler-Volmer equation to represent the ferri-ferrocyanide system

$$i = i_o \left[\left(\frac{i_{l,a} - i}{i_{l,a}} \right) \exp\left[\frac{\alpha n \mathbf{F}}{RT} \eta \right] - \left(\frac{i_{l,c} - i}{i_{l,c}} \right) \exp\left[\frac{-(1-\alpha) n \mathbf{F}}{RT} \eta \right] \right] \quad [A\text{-}2]$$

where i_o is the exchange current density, α is the transfer coefficient, and $i_{l,a}$ and $i_{l,c}$ are the anodic and cathodic limiting current densities. By differentiating i w.r.t.η and evaluating the result at $\eta = 0$, we obtain

$$i_o = \frac{\left(\frac{di}{d\eta} \right)_{\eta=0}}{\frac{n\mathbf{F}}{RT} + \left(\frac{1}{i_{l,c}} - \frac{1}{i_{l,a}} \right) \left(\frac{di}{d\eta} \right)_{\eta=0}} \quad [A\text{-}3]$$

This equation allows one to evaluate i_o from experimental data at each rotating speed. The average value of i_o over the six rotation speeds was found to be 5.73 mA/cm^2. The transfer coefficient α can then be evaluated by applying Eq. [A-1] to the experimental data. The value of α was estimated to be 0.16.

For a system with an excess supporting electrolyte, η is the sum of η_c and η_a where η_a is the activation overpotential which can be determined by

$$i = i_o \left[\exp\left(\frac{\alpha n \mathbf{F}}{RT} \eta_a \right) - \exp\left(\frac{-(1-\alpha) n \mathbf{F}}{RT} \eta_a \right) \right] \quad [A\text{-}4]$$

η_c can now be determined by subtracting η_a from η which has been determined experimentally.

LIST OF SYMBOLS

- a — a constant defined in Eq. [6]
- c_b, c_i — concentration of reacting ion at the electrode surface and in the bulk solution, respectively
- D — diffusion coefficient of reacting ion
- $\mathbf{F}$ — Faraday's constant
- i — current density
- i_{dc}, i_p — d-c current density, and pulsed current density, respectively
- $(i_{dc})_l$ — d-c limiting current density
- $i_{l,a}$, $i_{l,c}$ — anodic limiting current density and cathodic limiting current density, respectively
- i_o — exchange current density
- n — number of electrons transferred in reaction
- N — number of cycles in a pulse train
- R — universal gas constant
- Sc — Schmidt number
- T — temperature
- t — time
- α — transfer coefficient
- δ — thickness of the Nernst diffusion layer
- η — overpotential
- η_a, η_c — activation overpotential and pulse concentration, respectively
- $(\eta_{dc})_c$, $(\eta_p)_c$ — d-c concentration overpotential and pulse concentration overpotential, respectively
- θ_1, θ_2, θ — on-time, off-time, and cycle time of a pulse, respectively
- ν — kinematic viscosity of the electrolyte
- τ — time defined in Eq. [7]
- ω — rotation speed

Investigation of Laser-Enhanced Electroplating Mechanisms

J. Cl. Puippe,*,[1] R. E. Acosta,* and R. J. von Gutfeld

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The mechanism responsible for the very high plating rates at electrodes illuminated by a laser beam was investigated. Absorption of the laser energy by the electrode results in a localized increase in temperature at the metal-solution interface. This leads to: (*i*) a shift in the rest potential, (*ii*) an increase in the charge transfer rate, and (*iii*) strong microstirring of the solution due to thermal gradients and, at high laser power densities, to strong local boiling. Verification of the first two effects was achieved by measuring the enhancement in plating rates as a function of overpotential, laser power, and substrate thickness and by comparing these results with measurements using solutions at various bulk temperatures. Observation of the cathode through a video monitor, as well as detection of bubble formation using a miniature microphone, verified that a correlation exists between the ejection of bubbles from the cathode and sharp increases in the current. Application of laser-enhanced electroplating for maskless generation of patterns is also briefly discussed.

A large local increase of current density at the point of incidence of a laser beam on a cathode was first reported by von Gutfeld *et al.* (1-3). Plating rates enhanced by as much as a factor of 1000 were reported for nickel, copper, and gold deposition. It has been shown (2-4) that electroless plating and electroetching rates can also be substantially increased by absorption of laser light.

In this paper a study of the enhancement mechanism is presented. The aim was to investigate whether the laser enhancement is due only to strong microstirring of the solution or whether it is due to a significant increase in the charge transfer rate. In other words, if the reaction were not mass transport limited, would the reaction rate be influenced significantly by the

Key words: battery, boiling, masking, mass transport.

laser light absorption? In order to answer this question the laser-enhanced plating rates were measured as a function of overpotential.

Previous experiments showed that back illumination of a thin cathode led to the same enhancement as that for front illumination (1). Hence a significant contribution of a photocatalytic effect is excluded. We therefore postulate that the phenomena involved are related to a local increase of temperature at the metal-solution interface as a result of laser light absorption. The findings reported in this paper permit us to elaborate on a thermal model for the explanation of the observed plating current enhancements. The influence of the laser power and the substrate thickness (which influences the radial heat flow in the cathode) on the deposition rate and on the plated spot diameter were also investigated.

Fundamental Studies

Experimental conditions.—Experiments were conducted under potentiostatic control in a Pyrex glass cell containing vertical electrodes approximately 1 cm on a side, Fig. 1. The laser light was directed normally onto the cathode through a small hole in the anode. The anode consisted of a copper plate, the cathode of a thin film of gold or copper. Thin films were used to reduce heat dissipation in the cathode. In some experiments a small, well-defined, active area was required. The cathode was then covered by a photoresist layer a few microns thick, except for a hole of the same diameter as the laser beam, measured to ~1/e of its maximum intensity. The details of this structure are given in Fig. 2. The laser beam diameter was adjusted by positioning a microscope objective lens (2.5×) at a distance from the sample so that 67% of the laser power was incident on the active area of the cathode. The laser wavelength was chosen so that the laser beam was essentially not absorbed in the electrolyte, but was at least partially absorbed at the cathode. The experimental conditions are summarized in Table I.

Enhanced plating rates as a function of overpotential.—Figure 3 shows the polarization curve for the system $Cu/CuSO_4$ without laser irradiation. In this curve one clearly distinguishes the overpotential region in which the current is mass transport limited from the region where charge transfer is the limiting step of the reaction. Figure 4 shows the polarization curve of the same system with periodic irradiation by the laser. Here the laser beam diameter was equal to that of the active cathode area (*i.e.*, 200 μm). Periodic pulsing of the laser was used to prevent excessive plating buildup that would result from continuous irradiation. This ensures a more accurate measurement of the plating enhancement, since the cathode is little changed during the short duration of the laser pulses. Figure 5 shows the same polarization curve as Fig. 4, but with a logarithmic current scale. The logarithmic current scale allows a more accurate reading of the current enhancement. The apparent slower current response is due to an artifact of the apparatus. The different overvoltage regions of the comb-shaped curves (Fig. 4 and 5) are analyzed in more detail below.

The mass transport controlled region.—According to the limiting current plateau of the polarization curve of Fig. 3, the mass transport controlled deposition extends from an overpotential of −200 to −650 mV. In

this region the maximum enhancement[2] measured on an electrode of the same size as the laser beam is 400×, Fig. 5. A current density of more than 18 A/cm^2 is reached. This plating rate, which is extremely high for this dilute solution, corresponds to a deposit growth rate of more than 6 μm/sec. Other experiments in the mass transport controlled region, with the electrode not defined by a hole in the photoresist but rather on a plain wafer of 1 cm^2 area, resulted in enhanced plating rates of more than 1000×, like those reported earlier (1). The apparent discrepancy is due to a smaller limiting current density without laser for large area electrodes. A decrease in the electrode size to very small dimensions leads to diffusion which is no longer one dimensional but spherical, and thereby increases the value of the limiting current for these small area cathodes. The influence of the electrode diameter on the limiting current density is shown in Fig. 6. The enhancement ratio for an electrode with an area much larger than the cross section of the laser beam is determined taking into account the small area irradiated by the laser. However, the enhancement is referred to the limiting current density of the large electrode, thus such cathodes show enhancements three times larger than the values shown in Fig. 4 and 5.

We attribute the enhancement of the limiting current to stirring through local convection of the solution due to a strong thermal gradient near the cathode interface (1, 2). We have also found that for higher laser power densities local boiling of the solution produces strong additional stirring. Observation of the cathode through a video monitor showed that the bubbles were ejected into the solution normally from the vertical electrode. The effect of this additional stirring has been measured quantitatively by recording the limiting current density for the copper deposition while the cathode was illuminated by pulsed laser light, the intensity of which produced boiling of the solution at the cathode. The bubble formation generated an acoustic wave which was detected with a miniature microphone attached to the external wall of the cell. Figure 7 shows both the acoustic wave (trace A) and the limiting current (trace B) simultaneously recorded on a dual beam oscilloscope. Six milliseconds after the beginning of the light pulse, trace A showed a sharp increase in the acoustic signal due to boiling of the solution, and at the very same time the limiting current increased by a factor of 4. This increase in the limiting current is due to the stirring generated by the ejection of one or more bubbles in the solution.

[2] The enhancement is the ratio of the plating current obtained with and without laser illumination.

The charge transfer controlled region.—The comb-shaped curves of Fig. 4 and 5 also show significant increases in the current for overpotentials well below the region where the reaction is mass transport limited. The increase in the reaction rate is believed to be due to higher temperature produced in the region of laser light absorption. The influence of temperature on the reaction rate has been studied quantitatively in a separate experiment in which the entire volume of the electrolyte was heated. The results are shown in Fig. 8. At a potential of −20 mV an increase of temperature from 25° to 85°C speeds up the reaction by a factor of more than 50.

It is seen from the curves of Fig. 8 that a shift of rest potential toward more positive values occurs with increasing temperature. This shift in rest potential is shown in more detail in Fig. 9. A shift of the equilibrium potential with increasing temperature is expected from thermodynamic considerations (5). The shift of the rest potential has been measured as a function of the laser power (Fig. 10) on an electrode of the same diameter as the laser beam. By comparing the results of Fig. 9 and 10 one obtains a relationship between the incident laser power density and the temperature at the interface, Fig. 11. The domain of extrapolation (B-C) gives approximate values for the interfacial temperature as a function of incident laser power density. A separate experiment showed that for laser power densities between B and C, strong boiling occurred with bubbles ejected normally from the cathode. This is consistent with the temperatures obtained by extrapolation.

Due to the positive shift of the rest potential at the hotter part of the cathode it is possible to plate locally on a large electrode with no background plating. This is achieved by maintaining the cathode at the potential value corresponding to the rest potential of the

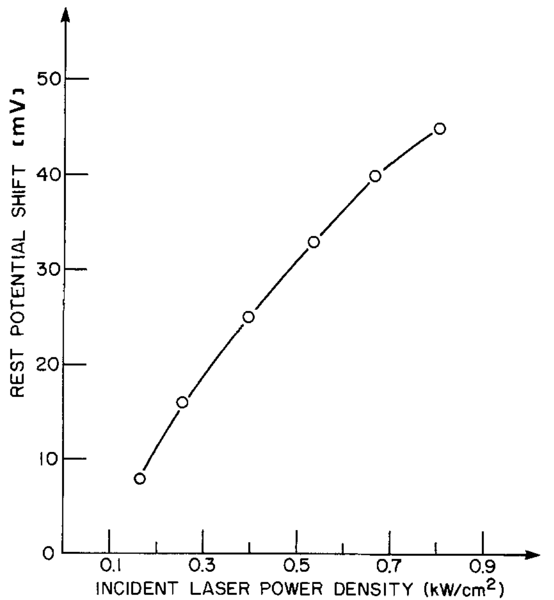

Fig. 10. Rest potential shift for the system $Cu/CuSO_4$ as a function of laser power density.

system Cu/Cu^{++} at room temperature. Since the illuminated part then has a more positive rest potential than the potential imposed on the rest of the electrode, plating occurs there and only there. According to the definition of enhancement previously given, the enhancement approaches infinity; however the absolute current increase is found to be one order of magnitude lower than under mass transport controlled conditions. Figure 12 shows the current densities obtained at different overpotentials as a function of the laser power density. The curve at $\eta = 0$ corresponds to the conditions for no background plating; the curve at $\eta = -50$ mV is in the charge transfer controlled region, and the one at $\eta = -600$ mV is in the mass transport controlled region.

The shift of the rest potential has other implications. The situation in which two regions of different rest potentials are electrically connected constitutes a battery. Thus, laser light focused onto a copper electrode immersed in an electrolyte will result in simul-

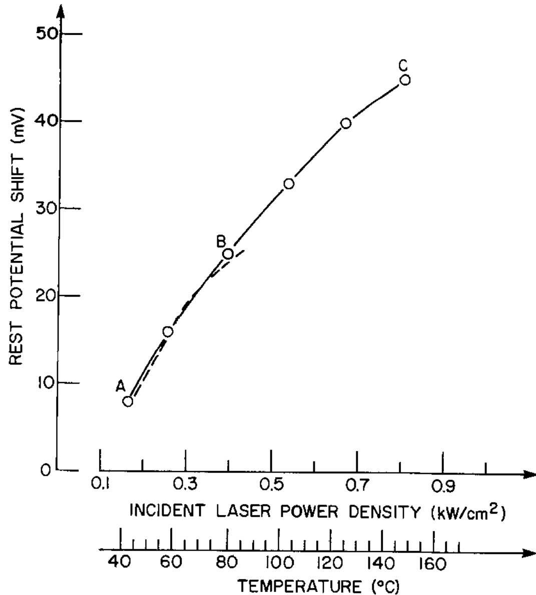

Fig. 11. Rest potential shift as a function of laser power density, indicated by ———, and of temperature indicated by - - - -. The figure is a superposition of Fig. 9 and 10. A, B, and C are referred to in the text.

taneous plating and etching without the use of an electrical circuit. For the solution in Table I, plating occurs in the region of higher temperature, *i.e.*, the region of laser light absorption, while simultaneous etching occurs in the colder adjacent regions. For a circular beam, this will result in a plated central circular spot surrounded by an etched annulus, Fig. 13. The necessary condition for plating in the hotter region is a positive shift of the rest potential with increasing temperature, which is not a universal behavior for electrochemical systems. The temperature coefficient for the potential shift is determined by the negative of the entropy change for the cell reaction (5). Reference (5) gives the temperature coefficient of the equilibrium potential for several systems, both positive and negative shifts are tabulated. The system nickel/nickel citrate has been studied in our laboratory (6). It has a negative rest potential shift with increasing temperature. According to this, we expect dissolution to occur at the hotter region and plating on the adjacent colder annulus. This is shown in Fig. 14

for a nickel cathode immersed in nickel citrate solution in conjunction with a focused laser beam.

Laser-enhanced plating mechanism: thermal model. —From the considerations above we postulate that in the presence of laser light the enhancement of the reaction rate is due to an increase of temperature at the metal-solution interface, which has three separate effects: (*i*) strong microstirring of the solution due to thermal gradients, with additional stirring at high laser power densities due to strong local boiling of the solution; (*ii*) an increase in the charge transfer rate with increasing temperature. This effect is more dependent on the nature of the system metal/electrolyte than the microstirring of the solution. For aqueous plating solutions the stirring will not vary substantially from one system to another, but the variation of the reaction rate with temperature at the interface is strongly dependent on the system; and (*iii*) a shift in the rest potential. The direction and magnitude of the shift depends on the system used.

Since the temperature change at the interface is responsible for the enhancement of the reaction, several experiments were undertaken in which the temperature at the interface could be varied. This was achieved by changing either the thickness of the metallic layer of the cathode or the incident laser power density. For these experiments the electrode was maintained at the rest potential and the resulting plating in the illuminated region occurred well below the limiting current. The total charge, Q, for each deposit was equal to 5×10^{-4}C. The laser was applied for sufficiently long time intervals to insure steady-state thermal conditions at the interface. The laser beam diameter was approximately 200 μm; the thickness of the metallic film of the cathode (on a glass substrate) was varied between 500 and 10,000Å. The main effect of increasing the metallic layer thickness is a decrease in the maximum temperature attained by the cathode interface due to the increased radial heat flow. The radial heat dissipation occurs mainly in the metallic layer because of its much higher heat conductivity compared to that of the supporting glass substrate. For thick metallic layers we expect a larger plated spot diameter. This trend is observed in Fig. 15. The increase of spot diameter for substrate thicknesses ranging from 500 to 10,000Å varies by a factor of 2. The temperature along the radial direction decreases rapidly with increasing distance from the center for values greater than the beam radius, so that plating does not extend much beyond the beam circumference even with the thickest layers investigated here. Figure 15 also shows that an increase of the metallic film thickness decreases the laser enhanced current. We attribute this directly to the lower interfacial temperature.

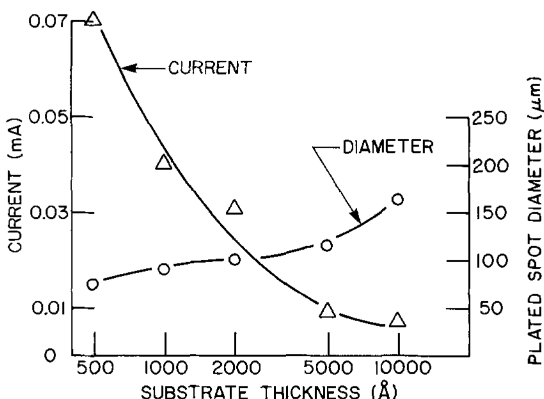

Fig. 15. Influence of the metallic film thickness on deposition rate and resulting deposited spot diameter. $Q = 5 \cdot 10^{-4}$C for each deposit; incident laser power, 100 mW.

With increasing laser power (maintaining fixed beam diameter) we observed the expected trends for the enhanced current and plated spot diameter, Fig. 16. For an incident laser power ranging from 100 to 300 mW the laser enhanced current increases by a factor of 13, whereas for the same power range the plated spot diameter increases by a factor of 2. This can again be explained by the strongly nonlinear radial temperature profile in conjunction with a sublinear plating enhancement that occurs for small temperature increases above ambient (2).

Applications

Copper lines in microcircuits have been connected or bridged using the laser-enhanced electroplating method, Fig. 17. The bridges were made by manual translation of a horizontal cathode under a focused laser beam. A lens with a magnification factor of 20 was used. The bridging work was done at low overpotential conditions which resulted in almost no background plating. The electrical resistance of these laser plated bridges is low. The solution used for this circuit repair experiment was $CuSO_4$, 0.5M/H_2SO_4, 0.01M.

Improvements in the optics used to focus the beam made it possible to reduce the width of the plated line to 2 μm. Figure 18 shows a line plated on an electrode using a copper fluoborate solution under thermobattery conditions, *i.e.*, without an external power source. This width is consistent with the limitations expected from both diffraction theory and from the aberration produced by the electrolyte layer. However, we believe this width is not the lowest attainable size. One can expect a smaller width with the use of a more elaborate lens design and possibly by decreasing the dwell time of the laser on the cathode.

For practical applications we see at least two important reasons for plating in the low overpotential region: (*i*) the possibility of avoiding, or minimizing, background plating and (*ii*) a better quality of deposit than that obtained in the mass transport controlled region.

Besides offering a means for maskless pattern generation through the use of a scannable laser beam, this technique can also result in a major cost saving when precious metals are to be deposited selectively. Clearly the technique is most useful for localized, small area plating.

Ceramic-Coated Positive Current Collectors for Li-Al/LiCl-KCl/FeS_2 Batteries

G. Bandyopadhyay

Argonne National Laboratory, Materials Science Division, Argonne, Illinois 60439

ABSTRACT

Several electronically conducting ceramic and metallic coatings were investigated to determine their potential for use as current collectors in the positive electrodes of Li-Al/molten LiCl-KCl/FeS_2 battery cells. Static and in-cell corrosion tests in laboratory-scale cells were performed; the static tests were considerably more severe than the in-cell tests. Chemical vapor deposited (CVD) TiC and TiN coatings on inexpensive iron-based substrates showed significant promise in both tests. Analysis of the results led to the recommendation that the coating quality and thickness, the substrate type, the coating procedure, the design of the cell components, and the electrochemical conditions be optimized to achieve maximum coating stability in long-term operation of Li-Al/FeS_2 cells.

High performance Li-Al/iron sulfide secondary batteries are being developed by Argonne National Laboratory (ANL) (1) for electric vehicle propulsion and for energy storage in electric utility systems. In the cells of these batteries, negative electrodes of solid lithium-aluminum alloy and positive electrodes of iron sulfide (either FeS or FeS_2) are used. At an operating temperature of 400°-500°C, the electrolyte LiCl-KCl remains in a molten state (the eutectic melting point of the electrolyte is 352°C). The overall reaction that takes place in the Li-Al/FeS_x ($x = 1$ or 2) cell on discharge can be written as (2)

$$2x\text{Li-Al} + \text{FeS}_x \rightarrow x\text{Li}_2\text{S} + \text{Fe} + 2x\text{Al} \quad [1]$$

where the composition of the positive electrode at complete discharge of a stoichiometric cell would be Li_2S and Fe. The reverse of these reactions occurs on recharging the cell.

Since the presence of lithium, lithium-aluminum, and iron sulfides makes the cell environment very reactive at elevated temperatures, the selection of suitable materials for various cell components is extremely critical for successful performance and commercialization of these batteries. The development of one such key component, the positive current collector, is the subject of this study.

Although low carbon or stainless steel performs reasonably well as the negative current collectors in Li-Al/FeS_x cells, extensive static, electrochemical, and in-cell corrosion testing of several commonly available metals and metallic alloys indicated that the selection of a suitable corrosion-resistant, cost-effective positive current collector poses a much more difficult problem (2-5). This is particularly true for FeS_2-type electrodes, in which the sulfur activity is considerably higher than that in FeS-type electrodes. Since Li-Al/FeS_2-type cells must be developed in order to achieve the long-term commercialization goals, it is important to identify and/or develop suitable positive current-collector materials for such cells. The only metal or metallic alloy that is known to exhibit the required chemical stability in an FeS_2-type electrode environment is molybdenum. However, molybdenum is expensive and difficult to fabricate in the shapes required for current-collector applications. Efforts are therefore underway to identify alternative positive current-collector materials for FeS_2-type cells. Electrically conducting ceramic coatings on inexpensive metallic substrates are being considered for such current-collector applications. The selection of suitable ceramics for coatings and the investigation of the stability of these coatings in static and in-cell corrosion environments is the subject of this paper.

Key words: corrosion, chemical vapor deposition, titanium nitride and titanium carbide coatings.

Selection of Materials

The criteria for the selection of ceramic coating materials for current-collector application include (*i*) sufficient electronic conductivity of the ceramic for adequate current-collection efficiency, (*ii*) corrosion resistance in the FeS_2 and LiCl-KCl environment at 400°-500°C, (*iii*) resistance to spalling under mechanical and thermal stresses, and (*iv*) cost effectiveness. Several metal borides, carbides, nitrides, and doped oxides are known to be good electronic conductors (6-8), and the coating technology of many of these materials is well developed (7, 9). Kuora *et al.* (10, 11) and Claar *et al.* (12) have performed preliminary

thermodynamic stability calculations on the borides, carbides, and nitrides of iron, niobium, tantalum, titanium, and zirconium with respect to the formation of metal sulfides at ~400°-500°C in the presence of FeS_2. The calculations indicate that iron boride, TiB_2, TiN, TiC, TaC, and niobium carbides should be stable in an FeS_2 environment. The oxidation potentials of TiN, TiC, TaC, FeB, and Nb_2C in LiCl-KCl were calculated and measured by Kuora *et al.* (10, 11). These data indicated that the above-mentioned materials could be suitable for positive current-collector application in the Li-Al/FeS_2 battery cell if the charge voltage was limited to 2.2V. The density, melting point, electrical resistivity, thermal expansion coefficient (which is important for compatibility with the substrates), and oxidation potential of several of the candidate coating materials and Mo and Fe are listed in Table I.

Experimental Procedure

Test specimens.—Most of the coated specimens for static corrosion tests were coupons ~25.4 × 25.4 × 0.5 mm in size. Coated screens (60 mesh) were also tested for their stability, because similar screens may be needed in-cell to prevent movement of electrode particles from their respective positions. For in-cell tests, coated positive components (identified later) were used in laboratory-scale Li-Al/FeS_2 cells.

AISI 1008 steel and ANL-5-0[1] alloy substrates were used. ANL-5-0 alloy was selected because it has exhibited better corrosion resistance than low carbon steel in an FeS environment (14).

Chemical vapor deposition (CVD) and rf-sputtering techniques were used to coat the substrates. The Materials Technology Corporation of Dallas, Texas, prepared most of the CVD coatings (*e.g.*, TiC. TiN,[2] TiCN, TiB_2, and combinations of TiC and TiN), and rf-sputtered coatings (*e.g.*, Cr, Mo, MoS_2, $MoSi_2$, Cr + TiN, Mo + TiN, TiC + TiN, and TiN + TiC) were prepared by Hohman Plating Company, Dayton, Ohio. The CVD coating thicknesses were varied from 5 to 25 μm; the total coating thickness in all rf-sputtered samples was ~7 μm.

Static corrosion tests.—The test specimens were placed in a graphite crucible in an argon-filled glove box and were completely covered with one of the following powders or powder mixtures: (*i*) equal-volume mixtures of FeS_2 (−50 +150 size fractions[3]) and LiCl-KCl (−50 size fraction) which simulated the fully charged positive-electrode environment in a cell; (*ii*) FeS_2 (−50 +150) to study the effect of sulfide alone on the corrosion behavior; (*iii*) eutectic LiCl-KCl (−50) to study the corrosion due to salt; and (*iv*) equal-volume mixtures of iron sulfide (FeS_2 or FeS in −50 +150 size fractions) and LiCl-KCl containing Fe powder (−325) to study the effect of sulfur activity, which varied with S:Fe mol ratio in the corrosion bath, on the corrosion behavior.

The crucibles were then heated to 500°C and were maintained at that temperature for the duration of the static tests. After the tests, the specimens were cleaned in water and alcohol, weighed, and examined macroscopically and microscopically.

The static test conditions were considerably more severe than those in the in-cell tests. The coatings that exhibited superior performance in the static tests were subsequently tested for in-cell stability.

In-cell tests.—In-cell tests were performed in small-scale, unsealed prismatic Li-Al/FeS_2 cells, similar to those that had been used for separator testing (15, 16). A schematic representation of the small-scale cells (7.6 × 12.7 cm), which were described in detail elsewhere (15, 16), is shown in Fig. 1. The cells were assembled in the semicharged state. The positive and negative electrodes consisted of powder mixtures of FeS, Li_2S, and eutectic electrolyte (−50 +150 size fractions), and Li-Al (17.45 w/o Li), Al, and electrolyte (−50 +150 size fractions), respectively. The materials were mixed in suitable proportions and amounts[4] and then hot pressed at 450°C. The stability of coated positive components such as the particle retainer screen, the electrode frame, and the current-collector plate in a cell environment were examined in these tests.

Results and Discussion

Characterization of as-received coatings.—Optical and scanning-electron microscopy indicated that the as-received coatings on AISI 1008 steel and ANL-5-0 alloy were, in general, uniform and dense with good adherence to the substrate. Typical micrographs of CVD-TiN and -TiC coatings are shown in Fig. 2. However, the edges of the coupon specimens sometimes revealed the presence of cracks or spalled coatings, indicating the difficulty of coating sharp edges and corners of specimens. Rf-sputtered coatings appeared to adhere well to the substrate, with porosity often detected on the surface. The sputtered coat-

[1] ANL-5-0 is an in-house ANL alloy with the composition [weight percent (w/o)] 95.5Fe-4.5Mo.
[2] CVD-TiN coatings always included an ~1 μm underlayer of TiC for improved adherence.
[3] These size fractions are similar to those used in-cell for electrode fabrication.
[4] The proportions of various active materials determined the level of charge for the cell, whereas the amounts determined the theoretical capacity in (A-hr) of the cells.

ings on sharp edges sometimes showed cracking or local spalling, similar to that observed on CVD-coated samples.

As discussed below, CVD-TiN and -TiC coatings showed the most promise and were therefore examined in more detail. Auger spectroscopy of these coatings indicated the presence of adsorbed oxygen on the surface. The bulk of the coatings, also examined by Auger spectroscopy after removing the surface by sputtering, did not show evidence of any impurities. Residual stresses[5] (which could influence the coating stability significantly in a corrosion environment) on the CVD-TiN and -TiC coated AISI 1008 coupons (coating thickness ~10 μm) were determined by x-ray diffraction analysis. Data were obtained only on the square faces, as the edges were too narrow for effective measurements; the surface measurements were made in the x and y direction at several locations on the square faces. The elastic constants used for these calculations and the range of calculated surface residual stresses are shown in Table II. Although the elastic-constant data contain uncertainties that can introduce systematic proportional errors in the stress values, the presence of significant compressive but nearly uniform residual stresses on the coated surfaces is evident.

Static corrosion tests.—The first series of static corrosion tests was performed to identify the coatings that showed enough promise to warrant further investigation and development for future applications. The static test results from several coated AISI 1008 steel coupons and a few selected monolithic ceramics that were tested in equal-volume mixtures of LiCl-KCl and FeS_2 at 500°C are summarized in Table III. Note that hot-pressed TiN and TiC showed no evidence of corrosive attack, indicating the inherent stability of these materials in the environment, whereas TiB_2 showed ~4% weight loss during a 300 hr test.

[5] Residual stress measurements were done by Lamda Research, Incorporated, Cincinnati, Ohio.

Table II. Elastic constants* and calculated surface residual stresses on CVD-TiN and -TiC coated AISI 1008 steel

Coating	Elastic modulus (MPa)	Poisson's ratio†	Surface residual stress (MPa)‡
TiN	250.3×10^3	0.26	−1310 to −1448
TiC	310.3×10^3	0.18	−1379 to −1862

* From Ref. (6 and 17).
† Poisson's ratio for TiN is assumed here to be similar to that for SiN.
‡ Negative sign indicates compressive stresses.

The CVD-TiC, -TiN, and -TiCN coatings provided significant protection to the low carbon steel substrate, although some attack[6] was observed from the edges and corners of the specimens. In contrast, CVD-TiB_2 and all the rf-sputtered coatings and coating combinations (including the TiC and TiN coatings) exhibited severe or complete reaction in <300 hr, and therefore were not considered for further investigation.

In their present quality and form, the CVD-TiC and -TiN were still vulnerable to corrosion. Additional tests were therefore performed to identify the cause and location of coating failures in these specimens in the static experiments. Several variables were considered during these tests. Table IV gives results on the percent weight loss of AISI 1008 steel and ANL-5-0 alloy substrates, both uncoated and coated with

[6] The extent of attack is described later.

Table III. Summary of static corrosion test* results in FeS_2 + LiCl-KCl (1:1 volume) at 500°C

Materials	Performance
Hot pressed: TiN, TiC	No evidence of chemical attack
Hot pressed: TiB_2	Some attack after 300 hr of corrosion
CVD coatings: TiC, TiN (with underlayer of TiC), TiCN	
CVD coating: TiB_2	Severe attack or complete reaction in <300 hr
Rf-sputtered coating: Cr, Mo, MoS_2, $MoSi_2$, (Cr + TiN), (Mo + TiN), (TiC + TiN), (TiN + TiC)	

* Maximum test duration 1000 hr.

Table IV. Data from static corrosion tests performed at 500°C for 300 hr

Substrate	Coating: Composition	Coating: Thickness (μm)	Weight loss as percent of total weight of coated sample after corrosion in: FeS_2 + LiCl-KCl	LiCl-KCl	FeS_2
AISI 1008 steel	None	—	100.00	0.80	100.00
	TiN	10	22.30	2.50	0.22
		19	32.50	2.45	4.92

		10	100.0	1.18	1.41
		13	6.8	+0.03	0.04

various thicknesses of CVD-TiN and -TiC, in three different corrosion environments (FeS_2, LiCl-KCl, and equal volume mixtures of FeS_2 + LiCl-KCl). The data show several important features: (*i*) In general, the coatings provided protection to the substrate; the protection was greatest in an FeS_2 environment. (*ii*) The FeS_2 + LiCl-KCl environment was much more corrosive than either FeS_2 or LiCl-KCl alone. (*iii*) The corrosion resistance of the specimens was strongly dependent on the coating thickness. (*iv*) The substrates that were tested in this study did not appear to influence the stability or corrosion resistance of the coatings.

Extensive microstructural examinations were performed to determine the nature of the coating failures in these samples. In all corrosion-tested specimens, the attack appeared to have initiated at the edges and corners of the specimens. Typical examples of such attack in LiCl-KCl and FeS_2 environments are shown in Fig. 3. Although the weight loss of the coated specimens in these environments was $<5\%$ (Table IV), the vulnerability of the coating at sharp corners and edges is evident. The specimens tested in the FeS_2 + LiCl-KCl environment exhibited much more severe corrosion of the substrate in the areas exposed by spalling of the coating. Figure 4 shows an example of exaggerated substrate corrosion initiated from the edge of the sample. Although the LiCl-KCl eutectic did not react with the substrates to any significant degree (Table IV), its presence in the sulfide environment resulted in exaggerated corrosion, probably because the molten salt contributed to early failure of

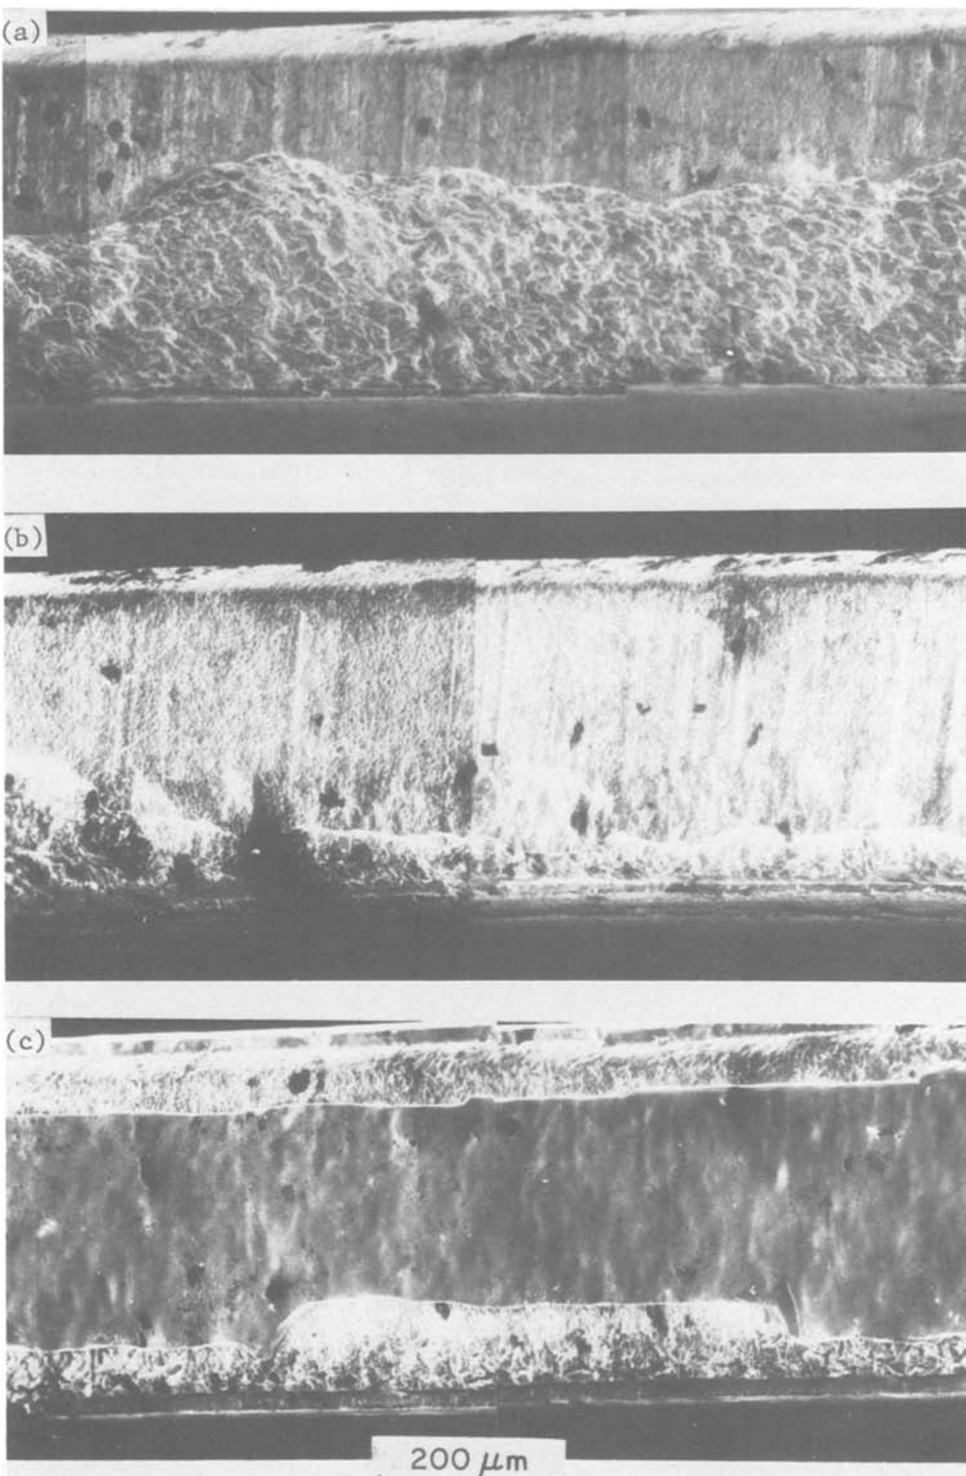

Fig. 3. Composite scanning electron micrographs of the edges of CVD-coated AISI 1008 steel specimens showing coating spalled after corrosion tests for 300 hr at 500°C. (a) 10 μm thick TiN in LiCl-KCl; (b) 10 μm thick TiN in FeS_2; (c) 10 μm thick TiC in FeS_2.

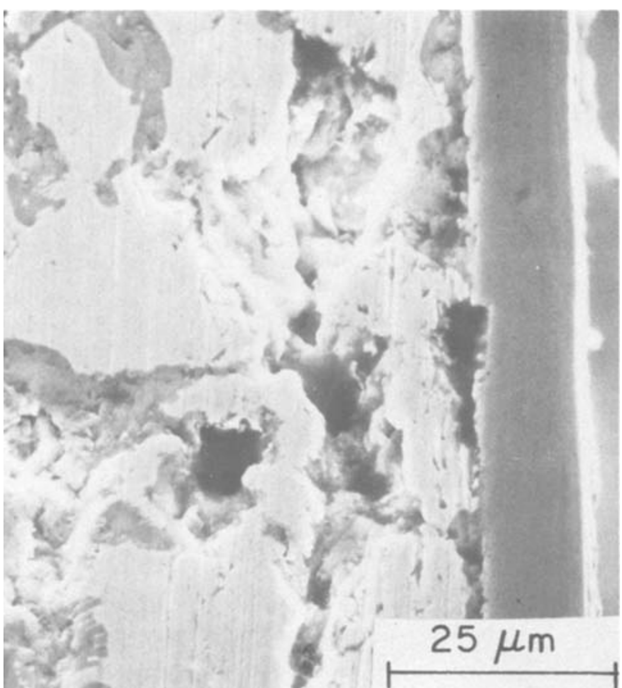

Fig. 4. Scanning electron micrograph of CVD-TiN coated AISI 1008 steel specimen tested in FeS_2 + LiCl-KCl (equal volume mixture) at 500°C for 300 hr, showing severe corrosion of the substrate adjacent to relatively unaffected coating. Initiation of attack on the substrate was due to coating failure at the edges.

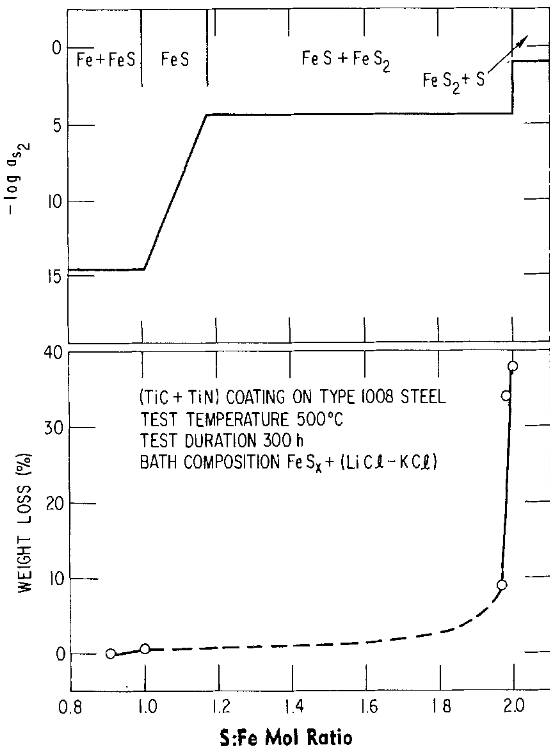

Fig. 5. (Top) sulfur activity and (bottom) corrosion of 5 μm TiC + 10 μm TiN-coated samples as a function of S:Fe mol ratio.

the coating and/or facilitated transport of sulfide ions to the reaction site.

The vulnerability of the coated samples at the corners and edges is probably related to the difficulty in coating these areas. We noted earlier that a substantial compressive stress exists on the coated surfaces of the sample. Although no information is available about the stresses at the edges and corners, one can speculate that large compressive stresses on the surfaces could generate significant shearing stresses at the corners. Such stresses would tend to spall the coating from these regions. The effect of the residual stresses should be even more significant in the presence of a corrosive environment such as salt or sulfide, which might lead to stress-corrosion cracking of the coatings at the sharp corners of the specimens.

The surface residual stresses in the coatings are expected to depend on the coating thickness, the substrate types, and the coating preparation procedure. A detailed study of these parameters and their relation to the coating stability and corrosion resistance of the specimens is beyond the scope of this investigation. However, the strong dependence of the sample performance on the coating thickness (Table IV) is probably related to the effect of coating thickness on surface residual stresses which, in turn, determines the tendency of the coatings to spall.

To determine the effect of sulfur activity on coatings, static tests were performed on TiN-coated AISI 1008 steel by varying the S:Fe mol ratio in the corrosion bath. In Fig. 5, the activity of sulfur at 500°C and percent sample lost after 300 hr corrosion tests are shown as a function of S:Fe mol ratio. A sharp drop in corrosion rate was observed as the composition shifted slightly to the iron-rich side of FeS_2. The drop in corrosion rate corresponds to the rapid drop of the sulfur activity. Note that the coating was vulnerable, although to a much smaller extent, even in an FeS + LiCl-KCl environment. This is probably because the coating failure was initiated by the high residual stresses and the corrosion environment. Subsequently, the sulfur activity essentially determined the corrosion rates of the substrate.

Several static tests in FeS_2 + LiCl-KCl at 500°C were performed on 60 mesh AISI 1008 screens coated with CVD-TiC and -TiN (coating thickness varied from 2 to 10 μm) to study the possibility of using such screens as positive particle retainers in the cell. The results showed that the coated screens were severely attacked by the corrosion environment in <300 hr, indicating that the coating stability can be strongly influenced by the geometry of the specimens.

The static corrosion test results as reported above indicate that the coatings will probably need further improvement to be stable in long-term applications. Since surface residual stresses are expected to play a key role in coating stability, it will be important to investigate the effect of the type, geometry, and physical and mechanical state of the substrate, the variables of the coating processes, and the coating thicknesses on the residual stress and its distribution, and on the corrosion resistance of the specimens. In addition to optimizing the quality and the thickness of the coating to minimize the residual stresses on the surfaces, one can recommend, based on the currently available static corrosion test data, the following modifications for improved in-cell performance of the coatings: (*i*) design the current collectors and frames without sharp corners and edges, and (*ii*) maintain slightly iron-rich FeS_2 in the positive electrodes to take advantage of the precipitous reduction of sulfur activity just below the fully charged state and thereby reduce corrosion on the positive components.

In-cell tests.—Despite the vulnerability of presently available TiN and TiC coatings in static corrosion tests, laboratory-scale in-cell tests were performed using TiN-coated positive components because the in-cell test conditions are considerably milder (lower temperature and lower sulfur activity, as compared to FeS_2, for a majority of the charge-discharge cycling times) than those of the static tests. No attempts were made to incorporate the above-mentioned recommendations in these preliminary in-cell tests.

Four laboratory-scale Li-Al/FeS_2 cells were assembled with 50 A-hr theoretical capacity using positive components made of monolithic TiN or CVD-TiN coated AISI 304 stainless steel. The cells were operated between charge and discharge cut-off potentials of 2.1 and 1.0V, respectively. Table V lists the cell numbers, the materials used for separators and positive components, the number of days and cycles of operation, the coulombic efficiency and utilization of the cells at a current density of 50 mA/cm^2, and the cause for termination of the tests. The cell cans, negative frames, and negative particle retainer screens in all these cells were made of AISI 304 stainless steel. The coulombic efficiency and utilization in these cells are comparable to those of similar laboratory-size Li-Al/FeS cells (15, 16).

Note from Table V that cell MS-5 was assembled using a monolithic hot-pressed TiN plate. The plate was placed between the two positive electrodes. Current collection from the positive side was achieved through the TiN plate and also through the positive frames that were in contact with the TiN plate. The current leadout was welded to the frame. During post-test examination, the TiN plate broke into several pieces. However, the thickness of the plate did not change during the cell operation, and no reaction product was detected. This is in agreement with the static corrosion test results, which indicated that TiN is stable in FeS_2/LiCl-KCl at 500°C.

Cell MS-6 was assembled using coated current-collector plates, frames, and screens. During disassembly of this cell, no attempt was made to identify the cause of the internal short that developed during operation; the primary purpose was to examine the positive components without damaging them during disassembly. The current-collector plate and the frames did not show any evidence of corrosion (Fig. 6). However, the screens were extensively corroded. The corrosion of coated screens is in agreement with the static test results.

Since the coated screens performed poorly in-cell, MS-8 was assembled without positive particle retainer screens. To prevent particle movement in this cell, sintered MgO separators (~55% theoretical density), which are characterized by extremely small pores (average diameter <1.0 μm) and a narrow pore size distribution (15), were used. Post-test examination of this cell showed no evidence of corrosion attack on the coated components (Fig. 7). Local coating loss was sometimes detected; however, the substrates did not show any evidence of corrosive attack, thus indicating that coating loss may have occurred during the cutting of the cell and sample preparation. Sintered MgO separators performed satisfactorily in this cell and did not exhibit any evidence of chemical reaction or active material in the separator (Fig. 8).

Cell MS-9 was assembled using coated positive current-collector plate, frames, BN fabric separators, and molybdenum screens for positive particle retention. Again, the post-test examination of this cell showed no evidence of corrosion attack of the coated components.

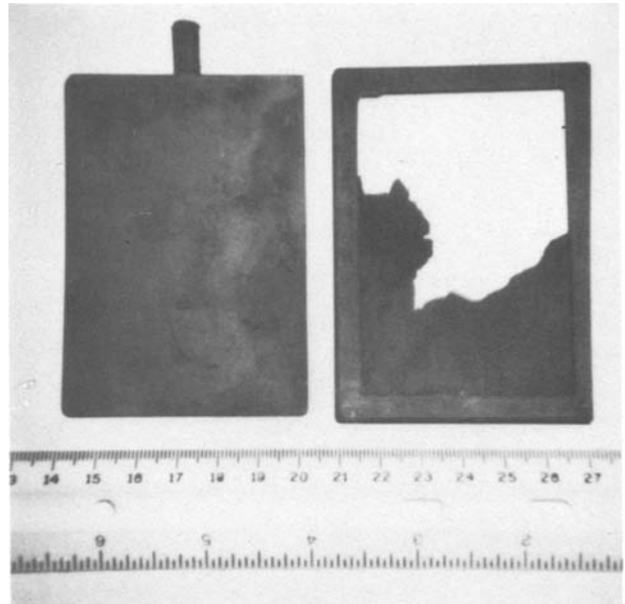

Fig. 6. Photographs of positive current-collector plate, frame, and screen after test in cell MS-6.

The in-cell test results, as presented above, indicate that monolithic TiN was chemically stable in the cell environment. Titanium nitride coated AISI 304 stainless steel current-collector plates and frames exhibited no evidence of corrosive attack, indicating that such coatings are indeed attractive candidates for use in an Li-Al/FeS_2 cell. Use of stainless steel instead of low carbon steel as the substrate may have contributed somewhat to the better stability of the in-cell positive components; stainless steel is known to be more corrosion resistant than low carbon steel in the positive-electrode environment (4). However, static tests of uncoated stainless steel in FeS_2/LiCl-KCl resulted in severe corrosion (4). Thus, the coating must have provided significant protection to the substrate. The coated particle retainer screens, however, were unstable in the cell environment; thus, the screens will have to be modified, or different materials used. Alternatively, screens may be eliminated from the cell assembly, as demonstrated in cell MS-8, by using sintered separators.

The stability of TiN-coated current collectors and frames in the laboratory-size Li-Al/FeS_2 cells in short-term tests is very encouraging. The results indicate that a moderate improvement in the coating quality, proper selection of the type and the condition of the substrate, some changes in the design of the current collectors and frames, and an optimized electrochemical condition for cell operations might lead to long-term stability of these coatings in the Li-Al/FeS_2 cell environment.

Table V. Li-Al/FeS_2 cells: component descriptions and performance data

Cell number	Separator	Positive components: Current-collector plate	Positive components: Frame	Positive components: Screens	Days of operation/number of cycles	Utilization (%)	Coulombic efficiency (%)	Cause of termination
MS-5	BN fabric	Hot-pressed TiN (1.9 mm thick)	Hastelloy B	Hastelloy B (200 mesh)	30/48	45.0	90.0	Voluntarily terminated
MS-6	BN fabric	10 μm TiN coating on Type 304 SS		10 μm TiN coating on 100 mesh Type 304 SS	20/15	61.0	100.0	Internal short
MS-8	Sintered MgO (~55% theoretical density)	↓		None	25/23	61.0	80.0	Break in the welded joint in the positive current-collector plate
MS-9	BN fabric	↓		100 mesh molybdenum	15/12	61.0	90.0	Internal short

Summary and Conclusions

Several electronically conducting ceramic and metallic candidate coatings and coating materials were investigated to determine their potential for use in positive components of Li-Al/FeS_2 battery cells. Chemical vapor deposited (CVD) and rf-sputtered coatings on inexpensive iron-based alloy substrates were considered. Static corrosion tests, which were considerably more severe than the in-cell tests, indicated that although none of the coatings tested in this investigation were completely satisfactory, CVD-TiC and -TiN coatings showed significant promise. The failure in the CVD-TiC and -TiN coatings in the static tests was initiated from the corners and edges

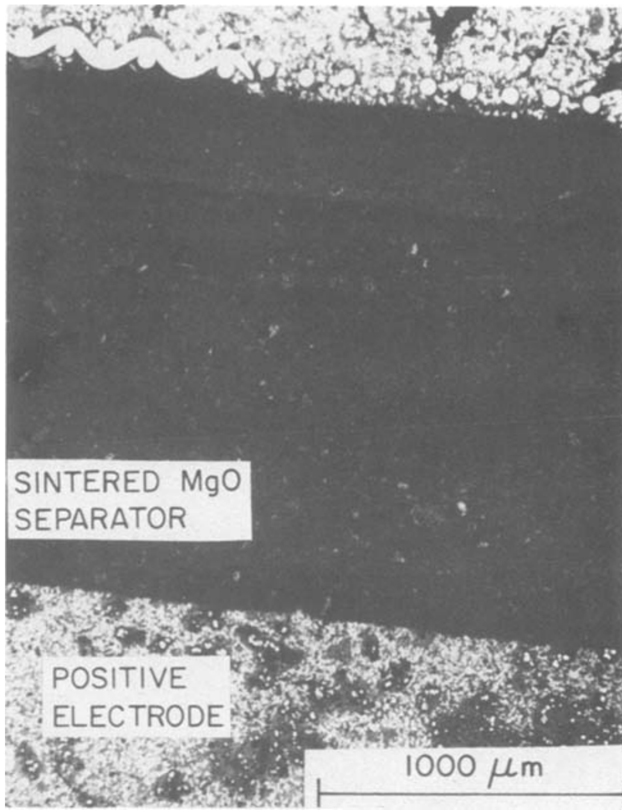

Fig. 8. Composite photograph of a polished section from cell MS-8 showing the sintered MgO separator.

of the specimens. The high compressive surface residual stresses, which were measured on the coated specimens by x-ray diffraction, and the corrosive media probably produced stress-corrosion cracking and spallation of the coatings. The coating stability was strongly dependent on the coating thickness and the geometry of the specimens.

The coatings performed significantly better in the in-cell tests because of the milder (lower temperature and lower sulfur activity) corrosion environment than that in the static tests. Monolithic TiN current-collector plate and TiN-coated AISI 304 stainless steel positive current-collector plates and frames were completely stable in Li-Al/FeS_2 cell after ~30 days of operation. The coated particle retainer screens, however, were unstable; therefore, alternate materials, modification, or elimination of the screens will be required.

Analysis of the static and in-cell test results led to several recommendations for application of the CVD-TiN and -TiC coatings in Li-Al/FeS_2 cells. Since surface residual stresses are expected to play a key role in the coating stability, they must be minimized through optimization of the coating quality and thickness, the substrate type, the coating procedure, and the design of the cell components. Designing positive cell components without sharp corners and edges should significantly improve the coating stability. In addition to optimizing coating quality and the component design, maintaining slightly iron-rich FeS_2 in the fully charged condition is recommended for improved coating performance. Optimized coating quality and electrochemical conditions for cell operation, and an improved cell design, should lead to long-term stability of these coatings in Li-Al/FeS_2 cells.

Behavior of Some Ions in Mixed Organic Electrolytes of High Energy Density Batteries

Yoshiharu Matsuda,* Hitoshi Nakashima, Masayuki Morita, and Yoshio Takasu

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube, Yamaguchi, Japan

ABSTRACT

Some physicochemical properties of the mixed solvents of propylene carbonate and 1,2-dimethoxyethane dissolving various salts have been measured at 30°C, in order to clarify the mixing effect of the organic electrolytes for high energy density batteries. The vapor pressure and laser Raman spectra of the mixed solvents provided significant information regarding the solvent-solvent interactions. Ionic conductivities under infinite dilution condition were determined by the measured molar conductivities of the salts and transport numbers of the ions; the Stokes' radii of the ions in the mixed solvents were also estimated. A specific solvation of cations with 1,2-dimethoxyethane in the mixed solvents seems to give captured cations like a crown ether does. These solvent-solvent and ion-solvent interactions mainly contribute to the excellent conductance of the electrolyte using the mixed solvents.

In the course of development of high energy density batteries with organic electrolytes, solutions containing mixed solvents have been used as the electrolyte solutions. For instance, mixed solvents of propylene carbonate (PC) with 1,2-dimethoxyethane (DME) (1, 2), γ-butyrolactone with tetrahydrofuran (3), and the like have been employed to obtain good cell performance. Among the properties of the solvents, low viscosity and high dielectric constant are important in obtaining a highly conductive electrolyte, because the former contributes to low resistance for ion transport in the solution and the latter serves to lower the ionic dissociation energy. The excellent mixing effect of the solvents on the conductivity has been reported in previous papers (4-8). Up to the present however, the reason for the improvement of the conductivity by mixing the solvents has not been appreciably clarified, in spite of the brief discussion connected with the data of dielectric constant and viscosity (7, 8).

In this work, the fundamental properties of the mixed solvents of PC and DME dissolving some salts were investigated in order to explain their synergistic effects. The examined characteristics are vapor pressure, viscosity, laser Raman spectrum, electric conductivity, and transport number of ion. From these data, some of the information concerning the solvent-solvent and ion-solvent interactions was obtainable, and the behavior of the ions in the mixed PC-DME system was discussed in detail.

Experimental

PC and DME were purified by the methods described previously (5, 9). Water contents were determined by

* Electrochemical Society Active Member.

Key words: mixed organic solvent, electric conductivity, Stokes' radius, specific solvation.

Karl Fisher titration and were below 80 mg · dm^{-3} in PC and 50 mg · dm^{-3} in DME. The $LiClO_4$ was an extra pure reagent by Kanto Kagaku Company Limited. $NaClO_4$, $KClO_4$, NH_4ClO_4, $(C_2H_5)_4NClO_4$, LiCl, and LiBr were of the same grade by Wako Pure Chemical Industries, Limited. $LiBF_4$ and $LiPF_6$ were obtained from Morita Chemical Industries, Limited. These reagents were used after drying under reduced pressure at the appropriate temperatures (80°-170°C) for 24 hr.

The vapor pressure of the solvents and solutions was measured by a static method (10). The viscosity, dielectric constant, and electrical conductivity were measured by the same methods as in the previous paper (8). The transport numbers of Li^+ and ClO_4^- ions were determined through measuring the electromotive force of the concentration cell with a liquid junction, Eq. [1], as used by Hoare and Wiese (11)

$$\text{Li} \mid \text{LiClO}_4\ (x\ \text{mol} \cdot \text{dm}^{-3}),\ \text{PC-DME} \mid \text{PC-DME},\ \text{LiClO}_4\ (0.001\ \text{mol} \cdot \text{dm}^{-3}) \mid \text{Li} \quad [1]$$

The transport number of ClO_4^- ion was calculated by using Eq. [2]

$$E = -\ (2RT\ t_{ClO_4^-}/\mathbf{F})\ \ln(x/0.001) \quad [2]$$

where E and $t_{ClO_4^-}$ are the electromotive force of the cell, Eq. [1], and the transport number of ClO_4^- ion, respectively, and other symbols have their usual meanings.

Molar conductivity and Stokes' radius of an ion were evaluated in the usual methods by using the experimental values of specific conductivity, transport number, and viscosity. All measurements were carried out at 30°C unless otherwise noted.

Results and Discussion

The vapor pressure of a mixed organic solvent is related to the fundamental properties of thermodynamics. Usually, the vapor pressure of real mixed organic solvent is given by Eq. [3]

$$P = P°_A x_A \gamma_A + P°_B x_B \gamma_B \quad [3]$$

where P, $P°_A$, and $P°_B$ are the vapor pressures of the mixed solvent and the pure solvents, A and B, respectively. x_A and x_B are the molar fractions of A and B in the mixed solvent, and γ_A and γ_B are the activity coefficients of A and B. If both γ_A and γ_B are unity, Eq. [3] is identical with Raoult's equation and the mixed solvent is an ideal liquid. The measured vapor pressure of the PC-DME system at various temperatures is shown in Fig. 1. Positive deviations from the straight lines in the figure indicate $\gamma > 1$ and a nonideal condition formed by mixing the two solvents. It is considered that a certain association of the PC molecules in the pure solvent is weakened by addition of DME, which is supported by the results of laser Raman spectra discussed in a later section of this paper. This interaction between PC and DME molecules would be one of the causes of the excellent conductance of PC-DME solutions of $LiClO_4$ and $NaClO_4$.

The mixing effect of the solvents on the electric conductance can be better understood under the infinite dilution condition. Table I shows the limiting molar conductivities, Λ^∞, of some salts consisting of univalent cations and anions in PC-DME mixed system. The values of Λ^∞ were determined by extrapolating the molar conductivities measured, Λ, to zero concentration in the Λ *vs.* $C^{1/2}$ plots (C represents the concentration of the salt, $10^{-3} \leqq C \leqq 10^{-2}$ mol · dm^{-3}) (7, 8). The Λ^∞ in the solutions composed of a higher percentage of DME (or 100% DME) was not determinable by the above procedure because of nonlinearity of the plots. This is also the case for 75% DME containing LiCl. The molar conductivities of the salts increase with increasing DME concentration in the solvent. It suggests that under such infinite dilution condition ion-ion interactions are fairly weak and then the molar conductivity mainly depends on the degree of facility in ion movement, or the ionic mobility. By Eq. [4], the limiting ionic mobility, u_i^∞, can be correlated to the limiting molar ionic conductivity, λ_i^∞, which is further calculated from the limiting molar conductivity and transport numbers, t_i^∞, by using Eq. [5]

$$u_i^\infty = \lambda_i^\infty/\mathbf{F} \quad [4]$$

$$\lambda_i^\infty = t_i^\infty\ \Lambda^\infty \quad [5]$$

where subscript i denotes the types of the ions.

In order to determine the λ_i^∞, the limiting transport numbers of Li^+ and ClO_4^- ions were measured in the PC-DME mixed system and the results are listed in Table II. The transport number of Li^+ ion increases with increasing DME concentration in the solvent. In Fig. 2 the limiting molar ionic conductivities or ionic mobilities of Li^+ and ClO_4^- are shown as a function of DME content in the solvent. The molar ionic conductivities increase with DME concentration because of lowering of the solvent viscosity. However, some differences are observed in the variations of molar ionic conductivities of these two kinds of ions, and it implies some different ion-solvent interactions depending on the kind of ions.

For other cations and anions, limiting molar ionic conductivities are shown in Table III, in which measured viscosity of the solvent is included. The values of λ_i^∞ were calculated by substituting the data of the limiting molar conductivities of the salts, Λ^∞, into Eq. [6]

$$\lambda_{M^+}{}^\infty = \Lambda_{MClO_4}{}^\infty - \lambda_{ClO_4^-}{}^\infty \quad [6\text{-a}]$$

$$\lambda_{X^-}{}^\infty = \Lambda_{LiX}{}^\infty - \lambda_{Li^+}{}^\infty \quad [6\text{-b}]$$

where M^+ and X^- represent the cation and the anion,

respectively. It is obvious from Table III that the molar conductivities of all ions tend to increase with increasing DME content in the solvent similarly to those of Li^+ and ClO_4^- ions. Thus, the low viscosity of DME would mainly contribute to the high conductivity of the solution.

Generally, ionic mobility depends on both viscosity of the solvent and size of ion. From the data presented above, Stokes' radius of the ion, R_s, which corresponds to the size of ion in solution, is evaluated by Stokes' equation, Eq. [7]

$$R_s = Z_i F^2/6\pi\eta_0 \lambda_i^\infty N_A \qquad [7]$$

where Z_i, $\mathbf{F}$, η_0, and N_A are number of ionic charge, Faraday constant, viscosity of the solvent, and Avogadro constant, respectively. The Stokes' radii of the ions were calibrated by the method using a series of tetraalkylammonium ions (12), and the resulting radii are shown in Table IV. Every anion tends to have increasing Stokes' radius with an increase in DME content. This seems to be due to the replacement of solvating PC molecules by DME added. On the other hand, the radii of the cations, especially Li^+ and Na^+ ions, are almost constant in the solutions containing 25-75% DME. In Fig. 3, R_s of the ions in 100% PC solvent and 50% PC-50% DME mixed solvent are plotted against the crystallographic radii of the ions, R_c, cited from the literature (13). R_s of the anions decreases with increasing R_c both in 100% PC solvent and in 50% PC-50% DME mixed solvent, which is the general phenomenon observed in hydration. The cations in 100% PC solvent behave almost in the same manner. However, R_s of the cations in the mixed solvent are scarcely different from one another. Such unique characteristics with respect to the Stokes' radii of cations may be explicable from the viewpoint of a specific (or selective) solvation.

Another information on the ion-solvent interaction is obtainable from some spectroscopic data. Figure 4 shows typical laser Raman spectra of the PC-DME-$LiClO_4$ system in the C=O region. With $LiClO_4$ dissolved in PC, the wave number of the C=O stretching band of PC (1782 cm^{-1}) is shifted to a higher value and the intensity decreases to a certain extent. This means the solvation of Li^+ ion with PC molecules through a coordinated bond such as $Li^+ \cdots O{=}C\langle$. On the other hand, the shifts of the wave number toward higher values with the addition of DME to PC are due to the weakening of C=O bond by added DME. This suggests that the degree of the intermolecule association of PC is reduced by the addition of DME. Such a phenomenon suggesting a solvent-solvent interaction would relate to the experimental results of vapor pressure of the mixed solvent shown in Fig. 1, and the excellent conductance of PC-DME containing perchlorates. In the case of PC-DME mixed system containing $LiClO_4$, the influence of $LiClO_4$ addition on the shift of wave number is rather small in the high DME content region; it might be because of the decreasing solvation of Li^+ ion with PC in the mixed solvents. Since the variation of the C—O—C stretching band of DME was not remarkable either, the interaction between Li^+ ion and DME molecules was not discussed from this viewpoint.

As a measure of the ion-solvent interaction, the solvation number of the ion, N_s, was estimated by Eq. [8]

$$N_s = \frac{4}{3}\pi(R_s^3 - R_c^3)/v_s \qquad [8]$$

where v_s is the molecular volume of the solvent, being considered to be 0.142 nm^3 for PC and 0.174 nm^3 for DME based on molecular weight and density. It was assumed in the calculation that the cations are solvated preferentially with DME in the mixed solvents owing to the reason explained later, while the anions are solvated with PC and DME in the same ratio as the bulk composition of the solvent. The data of R_s shown in Table IV represent the validity of this assumption. The resulting solvation numbers of the ions are summarized in Table V. The slight increase in N_s of the anions with the DME content may be associated with the decrease in the dielectric constant of the solvent (8). Among the cations, Li^+ and Na^+ ions seem to be highly subject to the specific solvation with DME in the mixed solvents. Their solvation numbers greatly

decrease with mixing DME into PC, and those in the mixed solvents are almost constant in the range of 25-75% DME. The specific solvation of the cations with larger R_c (K^+ and NH_4^+) is relatively weak. These phenomena would be caused by not only an electrostatic circumstance but also a spatial relation between the ion and the solvent molecule.

It may not be so general for ions to be solvated selectively with such molecules having lower dielectric constant as DME in the PC-DME mixed solvents (ϵ_r = 64.4 for PC, 7.2 for DME). However, the present case seems to be analogous to that in the specific solvation of Li^+ ion with THF (14, 15). A scheme presented in Fig. 5 is proposed as a model for the specific solvation with DME, suggesting the stability of alkali metal cations captured by crown ethers in PC solvent (16). The specific solvation with DME would result from the strong coordinate bond by two oxygen atoms whose configuration is spatially significant. In the present work, however, any definitive evidence by the spectroscopic method was not obtained concerning the direct interaction between the cation and the oxygen atoms of DME. According to the stereochemistry of DME, the number of the molecules solvating a cation must be less than two as shown in Table V. For the cations with larger ionic size, K^+ and NH_4^+, therefore, the coordination of DME becomes weak to give a poorer specific solvation. Consequently, the specific solvation of cations with DME, decreasing their Stokes' radii, contributes to the improvement in the conductivity of the PC-DME mixed solutions of $LiClO_4$ and $NaClO_4$. That is, the ionic mobility, or the ionic conductivity, of Li^+ and Na^+ in the PC-DME mixed solvent is increased because of the relatively small radius of the solvated ion, as well as owing to the suitable viscosity and dielectric constant of the solvent.

Electrochemical Nitration of Aromatic Hydrocarbons in Aprotic Media

J. M. Achord and C. L. Hussey*

Department of Chemistry, The University of Mississippi, University, Mississippi 38677

ABSTRACT

The electrochemical nitration of anthracene, naphthalene, 1-nitronaphthalene, and toluene was examined in aprotic solvents. Controlled potential electrolysis of anthracene in acetonitrile containing tetra-*n*-butylammonium nitrite resulted in low yields of 9-nitroanthracene. Oxidation of naphthalene in acetonitrile containing N_2O_4 at potentials insufficient to oxidize N_2O_4 resulted in high yields of 1-nitronaphthalene, while electrolysis of naphthalene at potentials sufficient to oxidize N_2O_4 resulted in moderate yields of dinitronaphthalenes. Similar experiments involving cooxidation of N_2O_4 and toluene gave moderate yields of 2- and 4-nitrotoluene in both acetonitrile and nitromethane. Nitronium ion was electrogenerated and used to effect nitration of toluene and 1-nitronaphthalene in acetonitrile. The nitrotoluene isomer distributions obtained were similar to those observed during nitration of toluene with nitronium salts. The results obtained during coelectrolysis of either 1-nitronaphthalene or toluene with N_2O_4 were interpreted in terms of electrophilic attack by nitronium ion solvated via electrolytically generated acid. Coelectrolysis of tetra-*n*-butylammonium nitrate and toluene in acetonitrile and nitromethane did not produce nitrated products. However, electrolysis of solutions of $LiNO_3$ and toluene in nitromethane gave low yields of mononitrotoluenes. Rotating disk measurements of the oxidation half-wave potentials of several nitroaromatic hydrocarbons are presented.

Several investigators have demonstrated that it is possible to electrochemically induce the nitration of aromatic hydrocarbons in aprotic media (1-5). Electrochemical nitration experiments have resulted in products which suggest direct nitration of the aromatic ring (1-5) and nitration of the alkyl side chain on alkyl substituted aromatic hydrocarbons (2). A variety of solvents, supporting electrolytes, and nitrating agents have been employed for these studies. However, the general approach used in most electrochemical nitration experiments was similar. The aromatic hydrocarbon to be nitrated was oxidized anodically in aprotic solvents that contained either dissolved nitrite or nitrate salts, or dinitrogen tetroxide.

A number of aromatic hydrocarbons have been successfully nitrated by means of these electrochemical nitration procedures. Oxidation of anthracene at a platinum anode in molten tetra-*n*-butylammonium nitrate resulted in the formation of 9-nitroanthracene, 1,10-dinitroanthracene, and 9,10-dinitroanthracene (1). Electrolytic oxidation of mesitylene at a platinum electrode in nitromethane containing tetra-*n*-butylammonium nitrate gave 2-nitromesitylene and 3,5-dimethylbenzyl nitrate (2). Electrolysis of naphthalene at a carbon anode in this same solvent and supporting electrolyte resulted in small amounts of 1-nitronaphthalene (2). Electrochemical oxidation of anthracene, anisole, *N*,*N*-dimethylaniline, naphthalene, trimethoxybenzene, and several dimethoxybenzenes in acetonitrile containing $AgNO_2$ yielded mononitro ring substituted products (3). Both 1- and 2-nitronaphthalene, the latter in small quantities, were obtained when naphthalene was oxidized at platinum electrodes in acetonitrile containing N_2O_4 (4, 5).

Two different mechanisms have been suggested to account for the nitrated products obtained during electrochemical nitration experiments involving oxidation of aromatic hydrocarbons in solutions containing NO_2^- and N_2O_4. These mechanisms include reaction of the electrogenerated aromatic hydrocarbon radical cation with NO_2 radical (3, 4) and homogeneous acid catalyzed nitration of the aromatic hydrocarbon by anodically generated acid (5). Nitrated products arising from experiments involving NO_3^- ion in aprotic solvents have been attributed to electrophilic attack by electrogenerated NO_2^+ ion or reactions involving $NO_3\cdot$ radical (2).

The electrochemically induced nitration of several aromatic hydrocarbons was studied in acetonitrile and nitromethane containing either NO_2^-, $NO_2(N_2O_4)$, or NO_3^-. This study was undertaken in order to gain additional insight into the mechanistic aspects and

synthetic utility of electrochemical nitration procedures. The results of this investigation are reported in this paper.

Experimental

Chemicals.—Anthracene and naphthalene (Fisher ACS Certified Reagents) were recrystallized before use. 1-Nitronaphthalene (Aldrich) and toluene (Fisher ACS Certified Reagent) were used without further treatment. Spectrophotometric grade acetonitrile, MeCN, (Burdick and Jackson) was stored over 3A molecular sieve (Linde) and passed through a column containing fresh molecular sieve and activated alumina directly into the electrolysis cell. Further attempts to purify this solvent resulted in degradation of its quality. Spectrophotometric grade nitromethane, $MeNO_2$, (Aldrich, Gold Label) was stored over molecular sieve prior to use. The supporting electrolyte, tetra-*n*-butylammonium hexafluorophosphate, TBAFP, was synthesized and purified according to standard procedures. Dinitrogen tetroxide, N_2O_4, (Matheson 99.5%) was contaminated with N_2O_3 as received. The green N_2O_3 contaminant was eliminated by passing dry oxygen gas through the chilled, liquified N_2O_4 until a golden brown color was obtained. Appropriate amounts of N_2O_4 were introduced volumetrically into the electrolysis cell. For simplicity the amount of N_2O_4 used in each experiment is denoted by the NO_2 formal concentration. Lithium nitrate, $LiNO_3$, (J. T. Baker, reagent), tetra-*n*-butylammonium nitrate, $TBANO_3$, (Fluka, purum), and tetra-*n*-butylammonium nitrite, $TBANO_2$, (Fluka, purum) were dried at 70°C under vacuum for 24 hr.

Instrumentation.—Voltammetric oxidation half-wave potential measurements were made using an AMEL Model 552 potentiostat programmed by means of an AMEL Model 566 function generator. Current potential curves were recorded on a Houston Model 100 X-Y recorder. Controlled electrode rotation was provided by means of a Pine Instruments Model ASR electrode rotator. The cell and electrodes used for these measurements were very similar to those detailed in a previous publication (6), except that the glassy carbon working electrode was provided with a longer shaft. Potentials are reported with respect to an Ag/Ag^+ (0.01M) reference electrode isolated from the bulk solution via a Vycor plug. The cell was thermostated to 25.0° ± 0.2°C in a water bath.

Controlled potential electrolysis experiments were coulometrically monitored by coupling the potentiostat to an AMEL Model 731 digital integrator. A three-electrode sealed cell of conventional design with a working volume of approximately 60 ml was used during these experiments. The working electrode was a platinum gauze basket and the counterelectrode was a platinum wire spiral separated from the working electrode compartment via a fine porosity fritted disk. Solutions were prepared and the cell was filled and sealed in a nitrogen atmosphere in a KSE dry box equipped with a 3 CFM inert gas purifier.

Product identification and analysis.—Products arising from electrochemical nitration experiments were analyzed using gas-liquid chromatography (GLC). Gas chromatographic analyses were performed using a Hewlett-Packard Model 5710A gas chromatograph equipped with a flame ionization detector. The chromatograph was furnished with 1m × ¼ in. copper columns packed with 8% OV-3 on Gas Chrom-Z. It was operated over a temperature range of 80°-280°C with helium carrier gas. Products resulting from experiments involving naphthalene were analyzed also using a Waters Associates liquid chromatograph equipped with a u.v. detector operated at 254 nm. The liquid chromatograph contained a Whatman Partisil PXS column and employed a mobile phase of 92% cyclohexane-8% ethyl acetate (v/v). The identity of all reported products was confirmed by comparison of their mass spectra and chromatographic retention properties with those of authentic samples. A Hewlett-Packard Model 5985 gas chromatograph/mass spectrometer system was used to obtain mass spectra.

Results

Electrolysis of anthracene and $TBANO_2$ in MeCN.—Solutions of anthracene (0.05*M*) and $TBANO_2$ (0.1*M*) in MeCN containing 0.1*M* TBAFP were electrolyzed at 1.2V *vs.* Ag/Ag^+ following the procedure of Laurent *et al.* (3). The applied potential was sufficient to oxidize both anthracene and $TBANO_2$ (Table I). Large bubbles of brown NO_2 gas were produced at the cell anode and high currents were observed. The former observation is consistent with data which indicate that NO_2 is a product of the oxidation of NO_2^- in aprotic solvents (10, 11). Controlled potential electrolysis was continued until approximately 1.0**F** of charge per mole of anthracene was passed. The resulting solution was yellow and GLC analysis revealed that some anthracene had been converted to 9-nitroanthracene in low yield, *ca.* 1.2%. The overall results obtained using anthracene and $TBANO_2$ were very similar to those reported by Laurent *et al.* (3) for controlled potential electrolysis of anthracene and $AgNO_2$ in MeCN. The copious quantities of NO_2 gas formed at the anode frequently interrupted electrical contact between the working electrode and the counterelectrode during electrolysis. As a result, this nitration procedure was found difficult to control and was not further investigated.

Electrolysis of naphthalene and N_2O_4 in MeCN.—Controlled potential electrolysis experiments were performed on solutions of naphthalene and N_2O_4 (0.1*M*) in MeCN containing 0.1*M* TBAFP. These experiments were conducted as a function of naphthalene concentration, applied potential, and charge passed. The results that were obtained during these studies are most conveniently described in terms of the applied potential employed, since the distribution and composition of products obtained were markedly dependent on the applied potential.

Potentials below approximately 1.75V resulted in the formation of 1-nitronapthalene in comparatively high yields (Table II). Small amounts of 2-nitronaphthalene could also be detected. The ratio of 1-nitro- to 2-nitronaphthalene was approximately 17 ± 3. The potential used for these experiments, 1.50V, was sufficient to oxidize naphthalene (Table I), but insufficient to oxidize N_2O_4. Figure 1 shows a plot of the percent yield based on the current of 1-nitronaphthalene prod-

[a] Experiments were conducted in MeCN containing 0.2*M* NO_2 and 0.1*M* TBAFP.
[b] 100% of the charge passed is equivalent to 1.0 F/mol of starting material.
[c] Based on the amount of starting material.

uct obtained *vs.* the charge passed, where 100% of the charge is equivalent to 1.0**F** of charge per mol of naphthalene. Data with which to construct this plot were obtained by periodically analyzing small samples of solution by GLC taken from the working electrode compartment of the cell during the course of several electrolysis experiments.

Figure 1 indicates that the production of 1-nitronapthalene under the conditions employed outruns the percentage of charge passed through the cell, *i.e.*, the formation of 1-nitronaphthalene from naphthalene is essentially complete after only a small fraction of the charge necessary to effect the one-electron oxidation of naphthalene has been provided. The role of adventitious water added to the electrolysis cell was also examined. It is significant from a practical synthetic viewpoint that the quantity of water introduced into the MeCN used in these experiments is not deleterious to the formation of 1-nitronaphthalene, at least within the concentration range studied (Fig. 1).

Formation of dinitronaphthalenes.—Controlled potential electrolysis of solutions of naphthalene and N_2O_4 in MeCN at potentials equal to or exceeding 1.75V resulted in the formation of 1-nitronaphthalene, 1,5-dinitronaphthalene, and 1,8-dinitronaphthalene (Table II). Small amounts of 2,3-dinitronaphthalene were also detected, but the yield of this material was always less than 2%. A significant amount of intractable, tarry material could also be isolated during these experiments. However, attempts to identify or further characterize this material were unsuccessful. The yield of dinitronaphthalene products obtained after passage of 1.0**F** of charge per mol of naphthalene appears optimum when the naphthalene concentration is approximately 25% of the NO_2 formal concentration. Further electrolysis until 2.0**F** of charge per mol of naphthalene are provided somewhat improves the overall material yield of dinitronaphthalenes. The amount of dinitronaphthalene compounds formed at a fixed ratio of naphthalene to NO_2 increased with the applied potential. The distribution of dinitronaphthalene isomers obtained from the electrochemical nitration of naphthalene, *ca.* 52% 1,5- and 48% 1,8-, is distinctly different than that observed for most chemical nitrations, approximately 33% 1,5- and 67% 1,8- (12). The dinitronaphthalene isomer distribution observed did not change appreciably with the applied potential over the potential range investigated.

The data collected in Table I indicate that potentials equal to or greater than 1.75V are sufficient to oxidize both naphthalene and N_2O_4. Furthermore the dinitronaphthalene products obtained would appear to originate by a mechanism that is at least in part different than that which results in mononitronaphthalenes. Evidence to support a nitration mechanism that is different than the process which produces mononitronaphthalenes can be obtained from Fig. 2. This figure shows plots of the material yield of 1-nitronaphthalene and the combined material yields of 1,5- and 1,8-dinitronaphthalene *vs.* the percent charge passed during a controlled potential electrolysis experiment at 2.25V. Data with which to construct these plots were obtained in the same manner as was the data used to construct Fig. 1.

Examination of Fig. 2 reveals that 1-nitronaphthalene is rapidly formed from naphthalene in the same fashion as was described in the previous section. The formation of dinitronaphthalene products, which appear after approximately 75% of the charge has been passed based on 1.0**F** of charge per mol of naphthalene, appears closely associated with the cumulative

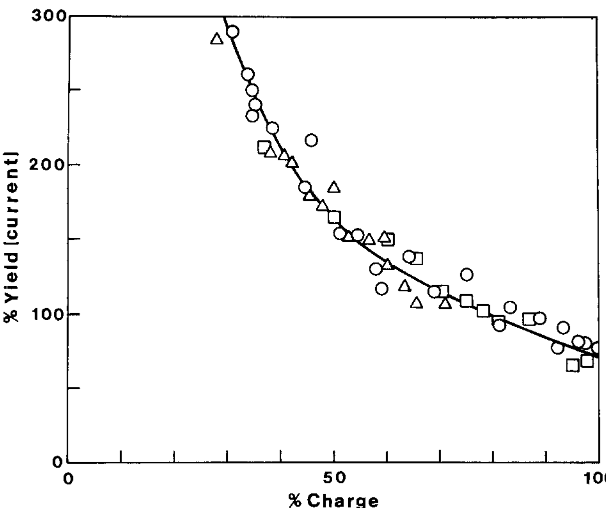

Fig. 1. Variation of the current yield of 1-nitronaphthalene with the charge passed during electrolysis of a solution of N_2O_4 (0.1*M*) and naphthalene (0.025*M*) in MeCN + 0.1*M* TBAFP at 1.50V *vs.* Ag/Ag^+ (0.01*M*). ○, MeCN containing *ca.* 6 × 10^{-3}*M* H_2O; □, MeCN containing *ca.* 2 × 10^{-2}*M* H_2O; △, MeCN containing less than 6 × 10^{-3}*M* H_2O.

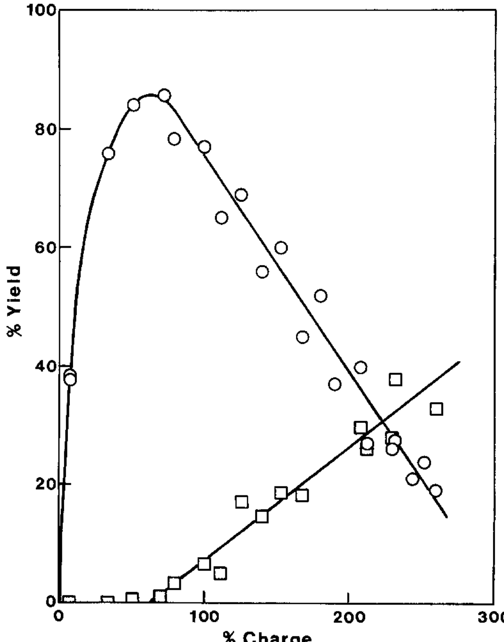

Fig. 2. Dependence of the material yield of 1-nitronaphthalene and dinitronaphthalenes on the charge passed during electrolysis of a solution of N_2O_4 (0.1*M*) and naphthalene (0.025*M*) in MeCN + 0.1*M* TBAFP at 2.25V *vs.* Ag/Ag^+ (0.01*M*). ○, 1-nitronaphthalene; □, dinitronaphthalenes.

electrolysis process. The plots shown in Fig. 2 suggest that the dinitration of naphthalene proceeds through rapid, intermediate formation of 1-nitronaphthalene in high yield. This step is followed by a slower nitration process, which results in the formation of dinitronaphthalenes concurrent with the disappearance of 1-nitronaphthalene. The absolute value of the slope of the descending portion of the plot for the oxidation of 1-nitronaphthalene at 2.25V, 0.33, indicates that a substantial portion of the charge passed involves the oxidation of solute species other than 1-nitronaphthalene, *e.g.*, N_2O_4. The ascending portion of the plot for formation of dinitronaphthalenes was slightly smaller, 0.20. If it is assumed that the oxidation of 1-nitronaphthalene is essential to the formation of dinitronaphthalenes, then the oxidation of 1-nitronaphthalene does not correspond to the formation of dinitronaphthalenes with 100% efficiency. A parasitic process, most likely oxidation of 1-nitronaphthalene to give high molecular weight materials (5, 13, 14) probably takes place. It was also possible to obtain a ratio and yield of 1,5- and 1,8-dinitronaphthalenes by controlled potential electrolysis of solutions of 1-nitronaphthalene and N_2O_4 in MeCN which were similar, within experimental error, to that obtained from electrolysis of solutions containing naphthalene and N_2O_4 (Table II).

Electrolysis of toluene and N_2O_4 in MeCN and $MeNO_2$.—Electrolysis experiments were conducted with solutions of toluene and N_2O_4 in MeCN and $MeNO_2$ to obtain additional information about electrochemical nitration processes utilizing N_2O_4. Controlled potential electrolysis experiments at potentials equal to or in excess of 1.75V resulted in the formation of 2- and 4-nitrotoluene (Table III) and small amounts of 3-nitrotoluene. The yield of the latter was less than 3%. The yield of 2- and 4-nitrotoluenes obtained varied with the applied potential (Table III). Controlled potential electrolysis experiments were conducted at 2.00V with solutions of toluene and N_2O_4 in MeCN to which a small amount of water had been added. The results obtained (Table III) indicate that water exerts a slight retarding effect on the formation of nitrotoluene products. An electrolysis experiment was conducted with toluene and N_2O_4 dissolved in $MeNO_2$ at an applied potential of 2.00V. The results of this experiment, shown in Table III, were generally the same as those obtained using MeCN as the solvent, but the combined yields of nitrotoluenes were less than observed with MeCN under the same conditions, *e.g.*, 39% for MeCN *vs.* 26% for $MeNO_2$. The isomer distribution for the nitrotoluenes produced during the electrolysis experiments reported in this section, *ca.* 60% 2- and 40% 4-nitrotoluene, was comparable to that reported for chemical nitration of toluene (15). It did not change within experimental error over the potential region investigated.

Applied potentials of 1.75V or greater were sufficient to oxidize both toluene and N_2O_4. Furthermore, the $E_{1/2}$ value for toluene oxidation is similar to that for oxidation of 1-nitronaphthalene (Table I). On this basis the electrolysis process by which nitrotoluenes are formed would be expected to be similar to that by which dinitronaphthalenes are produced from 1-nitronapthalene. Figure 3 shows a plot of the percent yield as a function of the charge passed during controlled potential electrolysis experiments at 2.00V. The formation of nitrotoluenes during these experiments, albeit somewhat inefficient, nevertheless closely follows the cumulative charge passed in a manner similar to that observed during electrolysis experiments in which dinitronaphthalenes are formed (Fig. 2). The slope of this plot, 0.30, was similar to that observed during formation of dinitronaphthalenes.

Electrogenerated NO_2^+ ion in MeCN.—Cauquis and Serve (16) report that NO_2 undergoes a one-electron oxidation to NO_2^+ ion in aprotic solvents. Solutions of NO_2^+ in dry MeCN are known to exhibit considerable stability (17). Controlled potential electrolysis at an applied potential of 2.00V was performed on solutions of N_2O_4 (0.1*M*) in MeCN that did not contain aromatic hydrocarbons to examine the possibility of effecting nitration with electrochemically generated NO_2^+ ion. Toluene and 1-nitronaphthalene were added to electrolyzed solutions of N_2O_4 in MeCN in separate experiments after the applied potential was discontinued. Dinitronaphthalenes and mononitrotoluenes formed in these solutions were monitored as a function of time using GLC. A plot of the combined yields of dinitronaphthalenes and mononitrotoluenes *vs.* elapsed time is shown in Fig. 4. Data used to construct this plot were obtained after passage of 1.0F of charge per mol of 1-nitronaphthalene or toluene added after cessation of the electrolysis. The reaction of both toluene and naphthalene with electrogenerated NO_2^+ ion appeared rapid during the first few minutes and then slowed

Table III. Results for electrochemical nitration of toluene

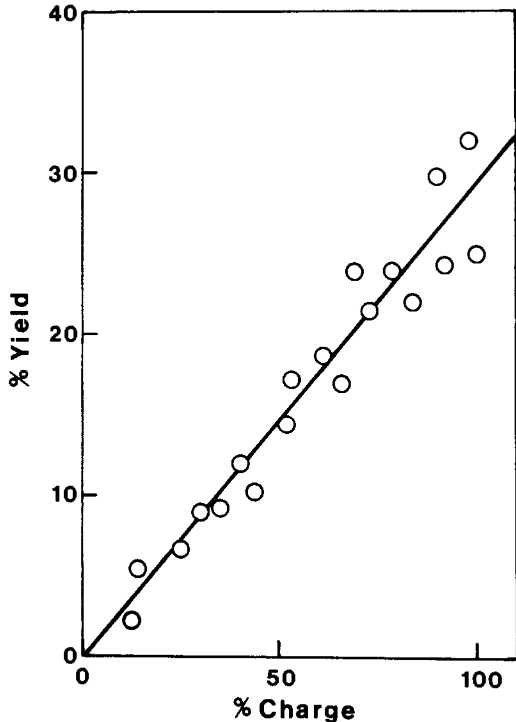

Fig. 3. Material yield of mononitrotoluenes as a function of charge passed during electrolysis of a solution of N_2O_4 (0.1*M*) and toluene (0.05*M*) in MeCN + 0.1*M* TBAFP at 2.00V vs. Ag/Ag^+ (0.01*M*).

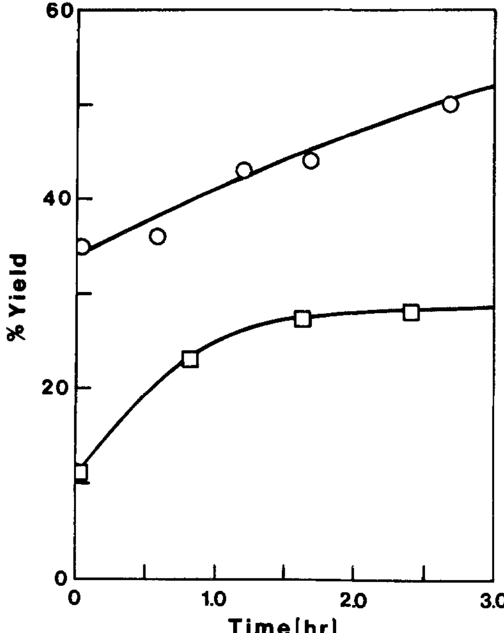

Fig. 4. Variation of the yield of nitrotoluenes and dinitronaphthalenes with time after the addition of toluene and 1-nitronaphthalene to solutions of N_2O_4 (0.1M) in MeCN + 0.1M TBAFP that were electrolyzed at 2.00V vs. Ag/Ag^+ (0.01M). ○, dinitronaphthalenes; □, nitrotoluenes.

considerably as time progressed. The nitrotoluene isomer distribution obtained from this experiment was 67% 2-nitrotoluene and 33% 4-nitrotoluene. It was in excellent agreement with values reported for nitronium salt nitrations of toluene (15). The quantity of 3-nitrotoluene formed during these experiments was not subjected to detailed examination. However the amount produced appeared to be very small. The nitration of 1-nitronaphthalene by the same procedure resulted in a dinitronaphthalene isomer distribution of approximately 39% 1,5- and 61% 1,8-dinitronaphthalene. Unfortunately there appears to be a paucity of literature data concerning the dinitronaphthalene isomer distribution resulting from nitronium salt nitrations of 1-nitronaphthalene with which to compare this data. The yield of dinitronaphthalene products obtained after 3 hr was slightly greater than observed during cooxidation of naphthalene with N_2O_4.

Electrolysis of toluene and NO_3^- in MeCN and $MeNO_2$.—The anodic oxidation of NO_3^- ion in aprotic solvents has been studied by several investigators (8, 18-20). Although there is some argument as to the actual mechanism by which NO_3^- ion is oxidized, most workers suggest that species like NO_2^+, $NO_3^\cdot$, or N_2O_5 may be formed during the oxidation process. Electrochemical nitration experiments were conducted on solutions of toluene and NO_3^- in both MeCN and $MeNO_2$ at applied potentials of 2.00V to examine the nitration capability of these solutions during oxidation of NO_3^-. The applied potential employed was sufficient to oxidize both NO_3^- and toluene (Table I).

The results of these experiments were highly dependent on the source of NO_3^- and the solvent chosen. For example, the use of $TBANO_3$ as the source of NO_3^- in electrolysis experiments conducted in both MeCN and $MeNO_2$ did not result in the formation of nitrotoluenes. When solutions of toluene in $MeNO_2$ were saturated with $LiNO_3$ and electrolyzed at 2.00V small amounts of 2- and 4-nitrotoluene could be detected (Table III). The isomer distribution of nitrotoluenes formed was 60% 2- and 40% 4-nitrotoluene. Mononitrotoluenes were not observed when similar solutions of toluene and $LiNO_3$ in MeCN were electrolyzed at 2.00V. The yield of nitrotoluenes obtained during these experiments was generally very inferior to that found during experiments with N_2O_4. Significant quantities of low boiling compounds were observed with GLC after coelectrolysis of NO_3^- ion and toluene in MeCN and $MeNO_2$. It is quite likely that the NO_3^- oxidation products attack the solvent or supporting electrolyte to produce these species. Similar effects have been reported during oxidation of NO_3^- in MeCN (8).

Discussion

Information obtained during the present study concerning the formation of 1-nitronaphthalene from naphthalene and N_2O_4 during electrolysis supports the acid catalyzed homogeneous nitration mechanism proposed by Eberson *et al.* (5). It is obvious that 1-nitronaphthalene is formed during electrolysis experiments by a rapid nitration reaction that is independent of the cumulative charge. A similar type of process is probably responsible for the formation of 9-nitroanthracene during the electrolysis of anthracene and $TBANO_2$ in MeCN, since the experimental conditions are fundamentally the same as those employed during oxidation of aromatic hydrocarbons in solutions containing NO_2. It is also quite likely that at least some of the products reported by Laurent *et al.* (3) arise through a similar mechanism.

The process or agent responsible for the production of dinitronaphthalenes and nitrotoluenes during electrolysis experiments involving cooxidation of the parent hydrocarbon and N_2O_4 appears different from that proposed by Eberson *et al.* (5). The formation of these products seems closely associated with the direct electrolytic production of the active nitrating species. If dinitronaphthalenes originated via the same route that produces 1-nitronaphthalene, then formation of dinitronaphthalenes in significant quantities would be expected concurrent with the production of 1-nitronaphthalene during experiments at 1.50V. However, applied potentials of 1.75V and above are requisite to effect nitration of aromatic hydrocarbons less reactive than naphthalene.

It is interesting to speculate about the process which results in the formation of dinitronaphthalenes and nitrotoluenes during coelectrolysis of the parent hydrocarbon and N_2O_4. It has been demonstrated that nitronium ion can be electrogenerated in MeCN containing N_2O_4 at potentials above 1.75V and used to nitrate toluene and 1-nitronaphthalene. The nitrotoluene isomer distribution obtained during this procedure was almost identical to that reported for nitration of toluene using NO_2PF_6 or NO_2BF_4 in sulfolane (Table IV). Nitronium salt nitration is thought to arise through electrophilic attack by NO_2^+ from an unsolvated ion pair, *e.g.*, $NO_2^+PF_6^-$ (15, 21). The dinitronaphthalene and nitrotoluene isomer distributions that result

Table IV. Isomer distribution for toluene nitration

[a] Toluene was added to a solution of electrogenerated NO_2^+.

from coelectrolysis experiments suggest less positional selectivity for the nitrating species than attack by unsolvated nitronium ion. This could result from steric effects. Although $NO_2^+PF_6^-$ ion pairs are anodically generated above 1.75V, the parent hydrocarbons are also oxidized. It is probable that hydrogen ion is also produced at the anode by one or more of the processes proposed by Eberson *et al.* (5). Under these conditions the NO_2^+ ion may be solvated in some way by anodically generated acid. This would lead to an increase in size or bulkiness for this nitrating agent and account for steric factors which could decrease the quantity of 2-nitrotoluene and 1,8-dinitronaphthalene obtained during coelectrolysis experiments compared to experiments involving unsolvated nitronium ion. A similar solvation effect is known to decrease the quantity of 2-nitrotoluene obtained during nitration of toluene by NO_2^+ ion solvated in sulfuric acid (15, 21).

Although a direct comparison cannot be made, the yields of nitrated compounds obtained via electrochemical nitration of aromatic hydrocarbons in organic solvents containing N_2O_4 appear comparable to those reported for conventional chemical nitration processes. This is especially true when the quantity of nitrating reagents expended in the latter procedures are considered. Nitration of aromatic hydrocarbons by means of electrogenerated NO_2^+ ion also has interesting possibilities and is the subject of further investigation in this laboratory. The yields obtained in the present study for electrochemical nitration experiments utilizing either NO_2^- or NO_3^- ion were inferior to those obtained using N_2O_4 or electrogenerated NO_2^+ ion. The low yields obtained during experiments with NO_3^- ion preclude definitive information concerning the agent by which nitration occurs during concurrent oxidation of NO_3^- ion and aromatic hydrocarbons. However, the isomer distribution of 2- and 4-nitrotoluene products was identical to that observed during similar experiments with N_2O_4.

Trapping of Anodically Generated Cations with Carbon Monoxide: The Anodic Koch Reaction

James P. Coleman*

Monsanto Company, Corporate Research and Development, St. Louis, Missouri 63166

ABSTRACT

Aliphatic carbenium ions, generated via anodic oxidation of saturated hydrocarbons in strongly acidic solutions, may be trapped efficiently with carbon monoxide, at atmospheric or elevated pressures, to yield carboxylic acids. Product distribution in the case of *n*-pentane oxidation may be explained in terms of kinetic *vs.* thermodynamic control in the carbonylation step.

Although a few investigations have been made (1-5), the use of carbon monoxide in organic electrosynthesis, an area which offers some interesting possibilities, has not been extensively investigated. I report here the results of some preliminary studies on the anodic oxidation of alkanes in strong acids in the presence of carbon monoxide at both atmospheric and elevated pressures.

The direct anodic oxidation of alkanes in anhydrous fluorosulfonic acid has been demonstrated (6), and,

* Electrochemical Society Active Member.
Key words: anodic Koch reaction, alkane carboxylation, carbon monoxide, fluorosulfonic acid.

although the exact details of the oxidation mechanism are still the subject of some discussion (6-10), it has been shown that the overall reaction involves two-electron oxidation to an intermediate carbenium ion which undergoes further reactions dependent on the nature of the acid medium

$$RH \xrightarrow[-H^+]{-2e,\ FSO_3H} \underset{(I)}{R^+} \begin{cases} \xrightarrow{\text{Low temp.}} ROSO_2F \\ \xrightarrow{R'CO_2H_2^+} \text{Ketones} \\ \xrightarrow{MOSO_2F} \text{Polymer} \end{cases}$$

The object of the present study was to trap the carbenium ion (I), formed under these conditions, with carbon monoxide and, thus, accomplish an anodically assisted Koch reaction (11) leading to a carboxylic acid

$$\underset{(I)}{R^+} \xrightarrow{CO} RCO^+ \xrightarrow{H_2O} RCO_2H$$

The carboxylation of saturated hydrocarbons has been reported previously.

Antimony pentafluoride in fluorosulfonic acid (12) or in liquid hydrogen fluoride (13) has been used to convert, respectively, methane to acetic acid and methylcyclopentane to cyclohexanecarboxylic acid. Saturated hydrocarbons with tertiary C—H bonds may be carboxylated in less acidic media by using protonated olefins as hydride-abstracting agents (14) in stoichiometric quantities.

Anodic oxidation would seem, however, to offer the possibility of a more attractive approach to carboxylation of saturated hydrocarbons without the use of additional reagents and generation of by-products.

Experimental

Reactions were carried out at constant current using a Lambda Model LP-412A-FM power supply. Preliminary voltammetry was carried out using a cell described previously (6), a Wenking 70HVI/90 potentiostat, an Exact Electronics Model 505 function generator, and a $Pd\text{-}H_2$ reference electrode (15).

Three different preparative cells were used during the course of this work. The first, cell [1], was a conventional glass H-cell, 40 ml volume, with sintered-glass divider, Pt gauze anode (4 cm^2), and with a sintered-glass gas sparger directly below the anode. The second cell, cell [2], was a similar H-cell without the built-in gas sparger. Instead, the anode was a disk (18 mm diam) of platinum gauze mounted on the bottom of a sintered-glass disk of the same diameter sealed to a tube through which gas was passed into the cell. Cell [3] was a modified pressure reactor, a Parr Model 4521, 1 liter Monel autoclave. The autoclave was equipped with a glass liner, a mechanical stirrer made of Teflon, and two platinum-foil electrodes (10 cm^2) mounted on a Teflon holder and situated 6 cm apart on either side of the agitator and close to the bottom of the reactor. Electrical connection was made with a commercially available "Conax" insulated power lead seal, and temperature was monitored with a glass-coated thermocouple (type J) immersed in the cell solution. Working volume was typically 100 ml.

Fluorosulfonic acid (Allied) and trifluoromethanesulfonic acid (3M Company) were distilled prior to use. Solutions of water in fluorosulfonic acid were prepared at −60°C and allowed to warm to room temperature.

Electrolysis at atmospheric pressure was carried out by sparging a hydrocarbon-saturated stream of carbon monoxide over the anode operating at constant current.

The pressure cell was operated remotely from outside a specially designed area, part of a larger high pressure reaction facility. Electrolyte and excess hydrocarbon were charged into the cell which was sealed and pressurized with carbon monoxide, typically to 1000 psig, and electrolysis at constant current was begun.

Products were isolated by carefully quenching the acidic solutions in icewater (vigorous hydrolysis of FSO_3H), extraction with methylene chloride, and back-extraction of carboxylic acid product into sodium carbonate solution. Acidification of the carboxylate solution allowed carboxylic acid and neutral products to be isolated separately.

Analysis of the products was carried out by GC, NMR, and mass spectrometry.

GC analysis utilized two columns—a 10-ft, 10% PEGA-1% H_3PO_4 on Chromosorb W, 55°C, or a 14-ft 5% FFAP on Chromosorb W 80°/12 min to 175° at 10°/min.

Samples were esterified with methanol-HCl prior to analysis. Authentic samples of cyclohexanecarboxylic acid, methylcyclopentanecarboxylic acid, *n*-hexanoic acid, 2-methylpentanoic acid, 2-ethylbutyric acid, and cyclopentanecarboxylic acid were employed as standards.

NMR spectroscopy was performed on a Varian T-60 spectrometer and mass spectra obtained on a Varian MAT CH7A mass spectrometer.

Cautionary note.—Fluorosulfonic acid is prepared by combining anhydrous HF and sulfur trioxide, has some of the safety hazards of both and, thus, should be treated with extreme caution. During the course of this investigation an unopened 5 pint bottle of fluorosulfonic acid exploded for no apparent reason, causing considerable damage but, fortunately, no injuries since the appropriate safety precautions were being taken. The value of such safety precautions in handling this material cannot be overemphasized.

Results

Studies at atmospheric pressure showed that carbon monoxide had no effect on the previously reported (6) voltammetry of cyclohexane in fluorosulfonic acid-potassium fluorosulfonate ($E_p = 1.12V$ *vs.* Pd/H_2). No competing oxidation of carbon monoxide was evident under these conditions. Preparative studies at 1 atm were, therefore, initiated while the high pressure reactor was being constructed.

Cyclohexane was selected as the substrate for initial study because of its relative ease of oxidation and predicted simplicity of product distribution.

Table I shows the results obtained by oxidizing cyclohexane at a platinum anode in fluorosulfonic acid solutions saturated with carbon monoxide at 1 atm.

With $KFSO_3$ as the electrolyte a modest 18% current efficiency for the formation of cyclohexanecarboxylic acid was observed.

The major product under these conditions was a mixture of hydrocarbon oligomers containing small amounts of the ketone (II) formed in a manner de-

(II)

scribed previously (6). By using water as the electrolyte ($H_3O^+FSO_3^-$), and trapping agent for acylium cations, current efficiency was increased to almost 60%

Table I. Anodic carboxylation of cyclohexane at atmospheric pressure in fluorosulfonic acid[a]

Electrolyte	Charge passed (C)	RCO_2H current efficiency[b] (%)	Ratio of carboxylic acid to neutral product[c]
FSO_3H-$KFSO_3$ (0.1M)	1260	18	0.23
FSO_3H-H_2O (0.5M)	1170	37	0.69
FSO_3H-H_2O (1.5M)	1170	57	2.1
FSO_3H-H_2O (3.0M)	1170	56	3.1
FSO_3H-H_2O (3.0M)	0	No products formed (18 hr)	

[a] Cell 1, 50 mA, 25°C, CO = 100 ml/min.

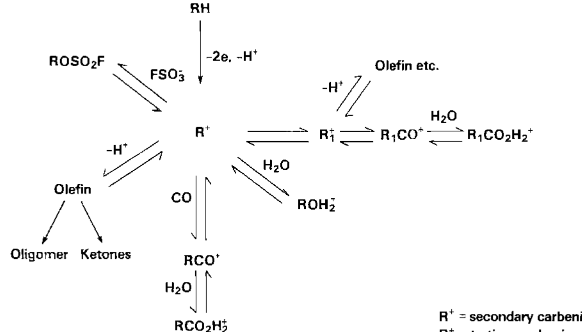
[b] Crude product >95% CO_2H.

[c] Oligomeric products, traces of C=O *cf.* earlier work.

with a concomitant decrease in the formation of neutral products. Increasing water concentration beyond 1.5M did not give any further increase in current efficiency.

It should be noted that the carboxylic acid formed from cyclohexane in this manner is almost exclusively the unrearranged material, cyclohexanecarboxylic acid. Only trace amounts of methylcyclopentanecarboxylic acid were observed.

n-Pentane was the next system studied, and results are shown in Table II. At ambient temperature current efficiency was lower than for the analogous reaction with cyclohexane and a mixture of three isomeric acids was obtained, the rearranged material predominating. Upon repeating this reaction at −25°C a cleaner, more efficient reaction was observed, yielding, almost exclusively, the rearranged product. In contrast, the first pressure reaction, at 1000 psig, yielded a mixture of products derived mainly from the unrearranged carbon skeleton. Further reactions in the high pressure electrolysis system are summarized in Table III. Cyclohexane was carboxylated more efficiently than at



Scheme I. Reaction pathways in anodic carboxylation of alkanes

atmospheric pressure, again with almost exclusive formation of unrearranged product. The limits of sustainable current density for this reaction were not pursued but increasing from 10 to 20 mA/cm^2 had no deleterious effect.

An alternative solvent system, the more expensive but more easily handleable trifluoromethanesulfonic acid, was studied briefly. As may be seen from Table III, respectable but slightly lower yields were obtained for the carboxylation of cyclohexane in trifluoromethanesulfonic acid.

Cyclopentane gave results similar to cyclohexane in fluorosulfonic acid, *n*-pentane was discussed previously and *n*-hexane gave an unresolved mixture of C_7 acids with 69% current efficiency.

Discussion

The direct, anodic oxidation of saturated hydrocarbons to give carbenium ion-derived products in strongly acidic solutions is well established (6-10). The present work has demonstrated that carbon monoxide will function efficiently as a nucleophile in such systems, giving carboxylic acid products without undergoing a competing oxidation process.

The results obtained may be understood by reference to Scheme (I). Electrolytic oxidation provides a simple method of converting the saturated hydrocarbon RH

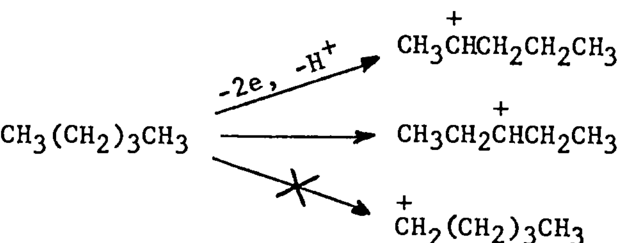
into the secondary carbenium ion R^+. Competition between the various reaction pathways shown then determines the distribution of products obtained.

The first observation made, regarding the beneficial effect of water in this system, may be explained in terms of acylium ion trapping. Carbonylation of the carbenium ion R^+ is reversible (16) and, at ambient temperature in the absence of a nucleophile such as water (H_3O^+) to trap the acylium ion, side reactions via deprotonation to form the olefin will be significant. Further, in the absence of an acylating agent, the products of such side reactions will be simply oligomeric hydrocarbons (6). The fluorosulfonate anion is not throught to play a significant role in stabilizing the secondary carbenium ion, R^+, at ambient temperatures although the formation of secondary fluorosulfonate esters at low temperature has been proposed (9), and methyl and ethyl fluorosulfonates have been generated anodically under similar conditions (17).

The principal factors influencing the product distribution obtained from a given carbenium ion appear to be temperature, CO pressure, and R^+ structure.

If we consider the results obtained with *n*-pentane *vs.* cyclohexane, it is apparent that in the latter case, under the conditions employed, kinetic control predominated at all times and the reaction path, as with cyclopentane, is simply the vertical line in Scheme (I). In the case of *n*-pentane we observe a mixture of kinetic and thermodynamic control, the balance of which may be changed by modifying conditions. In agreement with previous work (18) the initially formed carbenium ions are the secondary cations resulting from proton loss at the 2- and 3- positions. No primary products were observed.



With carbon monoxide at elevated pressure this mixture of carbenium ions is trapped efficiently to give a product mixture representative of the carbenium ions initially formed. However, at low temperature and low carbon monoxide pressure, the carbonylation reaction is much slower and almost complete rearrangement to the more stable tertiary carbenium ion occurs prior to carbonylation. At ambient temperature and low pressure, conditions are between the two previous extremes although still in favor of the thermodynamically controlled product.

n-Hexane gives a more complex product mixture and no attempt was made in this case to study its behavior in detail, although one would expect to observe phenomena similar to those observed with *n*-pentane.

No products of further oxidation of initially formed carboxylic acids were observed in these reactions as long as the hydrocarbon substrate was not depleted. This is to be expected since introduction of the electron-withdrawing $-CO_2H_2^+$ group has been shown to render the parent hydrocarbon less susceptible to further oxidation (19).

Further oxidation of carboxylic acids can occur at higher potentials, with products derived from oxidation of the hydrocarbon chain, rather than Kolbe-type products, being obtained (19, 20).

Summary and Conclusions

The trapping of anodically generated aliphatic carbenium ions with carbon monoxide has been demonstrated for the first time, allowing the efficient carboxylation of saturated hydrocarbons in strongly acidic solutions. In the present study, electrolytic oxidation has simply been used as a convenient means of generating the carbenium ion from the corresponding hydrocarbon without great attention being paid to the electrode reaction.

The results obtained may be readily interpreted in terms of numerous equilibria set up in such acidic solutions.

The possibility of using this approach for the carboxylation of other, more complex systems suggests itself and will be pursued.

Oxidation of Alkylbenzenes by Electrogenerated Hydroxyl Radical

Tomokazu Matsue, Masamichi Fujihira,* and Tetsuo Osa*

Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980, Japan

ABSTRACT

The oxidation of some alkylbenzenes by the hydroxyl radical, which is produced by the reaction of Fe^{2+} with H_2O_2 electrogenerated from O_2 in aqueous solution, was carried out. In the reaction, Fe^{3+}, generated by the above reaction, is also reduced to Fe^{2+} at the potential of reduction of O_2. The reaction products are hydroxylated products of the aromatic rings and side-chain oxidation products. In the oxidation of toluene at $[H^+] = 0.2M$, the yield of the former was higher than that of the latter, whereas the opposite was observed in the oxidations of ethylbenzene and cumene. From the results obtained at $[H^+] = 0.001M$, it appears that α-hydrogen abstraction from the side chains by the hydroxyl radical might make a certain contribution to the formation of side-chain oxidation products. The current efficiencies at low concentration of Fe^{2+} were very high, and the yields of the corresponding alcohols were very low, indicating that the carbonyl compounds were produced by the reaction between intermediate radicals and O_2 dissolved in the solution. The relatively high yield of the *meta*-isomer under O_2 saturated in solution can be explained by the fast addition of O_2 to hydroxycyclohexadienyl radical followed by elimination of $HO_2\cdot$ to yield phenolic products. Although the influence on the addition of α-cyclodextrin to the electrolyte solution on the regio-selectivity of phenol formation was small, it was observed that the *para*-isomer forms are slightly high.

The combination of hydrogen peroxide and a ferrous salt, "Fenton's reagent" (1), is an effective oxidant of various types of organic compounds. The actual oxidant of Fenton's reagent is the hydroxyl radical (2) generated by the reduction of hydrogen peroxide with ferrous ion

$$H_2O_2 + Fe^{2+} \rightarrow HO\cdot + HO^- + Fe^{3+} \qquad [1]$$

Oxidation of aromatics by the hydroxyl radical has been extensively investigated (3-19), and the products have usually been phenols and side-chain oxidation products. From radiation chemistry and spectroscopic results with u.v. and ESR, Walling *et al.* (4) concluded that the oxidation of substituted benzene derivatives by hydroxyl radical proceeded by the mechanism (5) illustrated in Scheme 1. The addition of the hydroxyl radical to an aromatic ring such as toluene is rapid compared with the hydrogen abstraction from the side chain (13, 16). However, in the hydroxyl radical oxidation of some aromatic compounds in which C-H bond energies of the side chain are relatively low, hydrogen abstraction may make a certain contribution to the reaction. This paper describes a study of the reaction of several alkylbenzenes with the hydroxyl radical generated by an electrochemical method which is apparently very different from the homogeneous conditions investigated by previous researchers. The presence of oxygen dissolved in electrolyte solution affected the product distribution. The effect of α-cyclodextrin (α-CD) on product distribution was also investigated. This molecule has the ability to include various compounds in its cavity in aqueous solution (20).

Experimental

All electrolyses were carried out using a Yanaco VE-8 controlled potential electrolyzer. The electrolysis cell was a divided H-type with a graphite cathode (30 × 20 × 2 mm) purchased from Tokai Carbon Company (G 2080), a Pt gauze anode, and a saturated calomel electrode (SCE) as the reference electrode inserted near the cathode. The catholyte consisted of 10 μl of substrate and $FeSO_4$ dissolved in 50 ml of aqueous H_2SO_4 solution and was stirred with a magnetic bar. Oxygen gas (1 atm) was bubbled through the catholyte so that a constant concentration of oxygen in solution was maintained. The electrode potential of the cathode at $[H^+] = 0.2M$ and at $[H^+] = 0.02M$ was set at −0.5V *vs.* SCE, and at $[H^+] = 0.001M$ was set at −0.6V *vs.* SCE.

After electrolysis, the catholyte was extracted with ether and this extract was concentrated under a reduced pressure for gas chromatography. Gas chromatographic analyses were carried out using Shimadzu GC-6A and GC-4CM chromatographs equipped with flame ionization detectors; oven temperatures were programmed from 80° to 200°C. Nitrogen was used as the carrier gas. The columns used in the analyses were 2m × 3 mmφ SUS packed with Carbowax 20M, DEGS, denatured lanolin, Silicon OV-1, and Silicon DC-560. Denatured lanolin was particularly suitable for separation of *meta(m)*- and *para(p)*-isomers of phenolic products. Current efficiencies were determined according to the mechanism proposed by Walling *et al.* (4), *i.e.*, one hydroxyl radical and one aromatic molecule produce the corresponding phenolic product or alcohol, and two hydroxyl radicals are consumed in forming the corresponding carbonyl compound. The current was maintained below 5 mA since the current efficiencies showed a tendency to decrease with higher values.

Cyclic voltammetric experiments were carried out using a conventional electrochemical instrument with a glassy carbon electrode in aqueous 0.1M H_2SO_4 solution. The potentials were referred to an SCE. The cell design used for cyclic voltammetry was similar to that previously described (21).

The dissociation constants of α-CD complexes were determined by spectrophotometric method (22).

Results

The electrochemical generation of hydroxyl radical was carried out by the reduction of oxygen in the presence of Fe^{2+} in aqueous solution. The cyclic voltammograms of oxygen (air saturated) and Fe^{3+} on a Tokai glassy carbon electrode in aqueous 0.1M H_2SO_4 solution are shown in Fig. 1. The peak potential of the reduction of Fe^{3+} was more positive than the onset potential of the reduction of oxygen. Therefore, Fe^{3+} generated by the reaction between Fe^{2+} and H_2O_2 was reduced to regenerate Fe^{2+} in the reduction of oxygen. From the results, the following mechanism

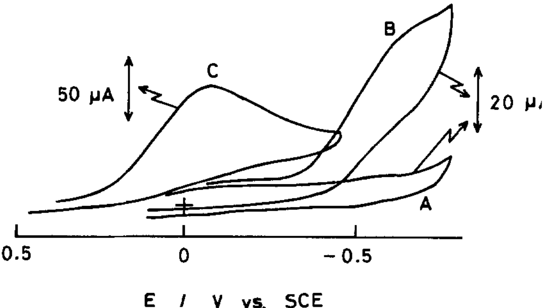

Fig. 1. Cyclic voltammograms at Tokai glassy carbon electrode in aqueous 0.1M H_2SO_4 solution: (A) under N_2 saturated; (B) under air saturated; (C) $1.0 \times 10^{-3}M$ $Fe_2(SO_4)_3$ under N_2 saturated.

was deduced for the generation of hydroxyl radical by the electrochemical method

$$O_2 + 2H^+ + 2e \rightarrow H_2O_2 \quad [2]$$

$$H_2O_2 + Fe^{2+} \rightarrow HO\cdot + HO^- + Fe^{3+} \quad [3]$$

$$Fe^{3+} + e \rightarrow Fe^{2+} \quad [4]$$

The reaction products in the oxidations of alkylbenzenes (toluene, ethylbenzene, and cumene) by electrogenerated hydroxyl radical were generally classified into hydroxylated products of aromatic rings and oxygenated ones of side chains. The electrolysis time was restricted to an hour to avoid further oxidations of the reaction products. The results are summarized in Tables I-III.

In the oxidation of toluene by electrogenerated hydroxyl radical at $[H^+] = 0.2M$, the hydroxylation of the aromatic ring predmoinated over the side-chain oxidation, whereas the opposite results were observed in the oxidations of ethylbenzene and cumene. Most of the side-chain oxidation products were carbonyl com-

pounds; benzaldehyde was obtained from toluene and acetophenone from ethylbenzene and cumene. Formation of the corresponding alcohols, which may be intermediates in the formation of carbonyl compounds, biphenyl derivatives, and bibenzyl derivatives was very low. In ethylbenzene oxidation, side-chain oxidation occurred only at the α-position. Products of β-position oxidation, such as β-phenethyl alcohol and phenylacetaldehyde, could not be detected. In cumene oxidation, phenol could not be detected although the auto-oxidation of cumene at high acidity results in the formation of phenol as the main product (23).

The *p*H of the reaction medium had a great influence on the product distribution. The yields of the corresponding phenolic products at $[H^+] = 0.001M$ were higher than those observed at $[H^+] = 0.2M$ since the low proton concentration lessens the conversion from the hydroxycyclohexadienyl radicals (adducts) to the cation radicals of the starting materials (15). The concentration of Fe^{2+} dissolved in the electrolyte solution also affected the yields of the phenolic products. At $[H^+] = 0.2M$, lowering the concentration of Fe^{2+} resulted in a decrease in the yields of phenolic products and an increase in the current efficiencies. Under such a condition ($[H^+] = 0.2M$, $[Fe^{2+}] = 0.005M$), high yields of side-chain oxidation products were also observed as well as high current efficiencies. The lower Fe^{2+} concentration minimizes the reduction of the intermediate cation radicals, formed in the oxidations, back to the starting materials (5). However, the yields of the phenolic products were almost independent of the acidity and of the concentration of Fe^{2+} when the proton concentration was less than 0.02M. The temperature during electrolysis had an influence on the reaction. The oxidation of toluene at low temperature (0°C), gave a higher yield of cresol (67%) than that observed at room temperature.

The results obtained for the oxidation of toluene in the present work by the electrochemical method when compared with those obtained for homogeneous oxidation by hydroxyl radical as carried out by Walling *et al.* (4) differed in the following ways: (*i*) The yield of cresol isomers was higher, (*ii*) the yield of benzyl alcohol was lower, and (*iii*) the yield of *m*-isomer of cresols was relatively high and that of *p*-isomer was low (*e.g.*, o:*m*:*p* isomer ratio of cresol at $[H^+] = 0.2M$ was 40:54:6). Similar results were observed in the oxidations of ethylbenzene and cumene.

The addition of α-CD to the electrolyte solution had little effect on the product distribution. In toluene oxidation, a slight increase in the yield of side-chain oxidation products was observed. The addition of α-CD for ethylbenzene oxidation resulted in a slight increase in the *p*-isomer ratio of ethylphenol, although it did not affect the overall yield of ethylphenol isomers. In cumene oxidation, a small enhancement of overall yield of *iso*-propylphenol, accompanying an increase of the *p*-isomer was observed. The current efficiencies were decreased by the addition of α-CD.

Discussion

The first reaction in the oxidation by Fenton's reagent is the generation of hydroxyl radical from hydrogen peroxide and Fe^{2+} in the reaction medium. Since the rate constant for this step [$2.2 \times 10^2\ M^{-1}\ sec^{-1}$ (24)] is very low in comparison with those for the subsequent reactions, the generation of hydroxyl radical is the rate-determining step in the oxidation of aromatics by Fenton's reagent. Further reduction by Fe^{2+} converts the initially formed hydroxyl radical to hydroxyl anion and this step acts as a major competitive reaction with the oxidation of aromatics by hydroxyl radical. Accordingly, in order to realize a high efficiency, it is necessary that the rate of reaction between a substrate and the radical be greater than that of the competitive reduction.

The reaction mode of aromatics with hydroxyl radical may be classified into two types. One is hydrogen abstraction from the side chain by hydroxyl radical, and the other is the addition reaction of the radical to the aromatic ring. In the oxidation of toluene by hydroxyl radical, the latter reaction takes precedence over the former (13, 16). However, the contribution of the former reaction to the oxidations of ethylbenzene and cumene becomes larger, since the α-hydrogen in these cases are more easily abstracted

rate constant ($M^{-1}\ sec^{-1}$)

$$H_2O_2 + Fe^{2+} \xrightarrow{k_1} HO\cdot + HO^- + Fe^{3+} \qquad k_1 = 2.2 \times 10^2 \qquad [5]$$

$$HO\cdot + Fe^{2+} \xrightarrow{k_2} HO^- + Fe^{3+} \qquad k_2 = 3 \times 10^8 \qquad [6]$$

$$HO\cdot + RH \xrightarrow{k_3} \begin{cases} \text{hydrogen abstraction} & k_{3\,\text{H abst.}} = 4 \times 10^8 \\ \text{addition} & k_{3\,\text{add.}} = 3 \times 10^9 \end{cases} \qquad [7]$$

RH = toluene

The *p*H of the reaction medium is one of the important factors determining efficiencies. The equilibrium in Eq. [8] must lie to the right at low proton concentration (3). $FeOOH^{2+}$ produced in this equilibrium decomposes and this is followed by further reaction as shown below

$$H_2O_2 + Fe^{3+} \rightleftarrows H^+ + FeOOH^{2+} \rightarrow FeO^{3+} + H_2O \qquad [8]$$

$$FeO^{3+} + H_2O_2 \rightarrow Fe^{3+} + H_2O + O_2 \qquad [9]$$

Consequently, the efficiency of the reaction may be low at low proton concentrations. Indeed, from our results, current efficiencies became low with decreasing acidity.

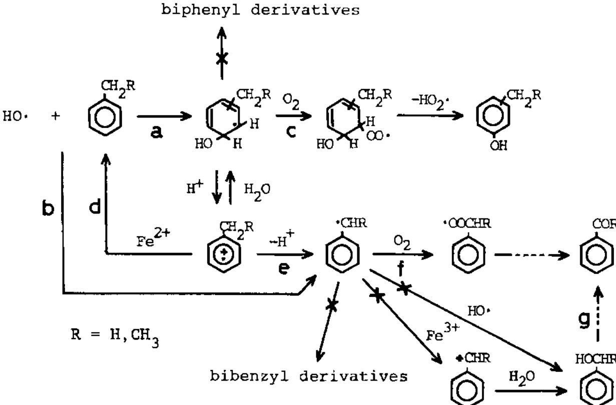
Next, we consider the characteristics of the oxidation by electrogenerated hydroxyl radical in the present work. The half-life of hydrogen peroxide formed by the reduction of oxygen at electrode surface is 6.3×10^{-2} sec under the pseudo-first-order condition; $[Fe^{2+}] = 0.05M$ ($[Fe^{2+}] >> [H_2O_2]$). According to the Einstein-Smolchowski equation (25), average distance of H_2O_2 transport by diffusion from the electrode surface during 6.3×10^{-2} sec is 1.3×10^{-3} cm, assuming a diffusion coefficient of H_2O_2 of $1.35 \times 10^{-5}\ cm^2\ sec^{-1}$ (26). The thickness of the reaction layer may extend about 10^{-3} cm from the electrode surface. Most of the oxidation therefore should proceed in the diffusion layer. On the other hand, the concentration of the substrate may be higher due to adsorption than that of the bulk solution. Accordingly, the oxidation by the electrochemical method was expected to be influenced partly by the electrode surface and the solution near the electrode. The results, however, did not differ greatly from the results observed in the

homogeneous oxidation except for the effect of oxygen which is described later.

A reasonable mechanism for the oxidation of toluene and ethylbenzene by electrogenerated hydroxyl radical is illustrated in Scheme 2 and may be compared with the one proposed by Walling *et al.* (4). In the present reactions, the role of oxygen as the oxidant in phenol formation must be large since the relatively high yields of the *m*-isomers and low yields of the *p*-isomers differed from those in the previous work where Fe^{3+} and/or Cu^{2+} was used as oxidant (4, 5). These results are in agreement with the report (4) that the yield of the *p*-isomer was low in the homogeneous oxidation of toluene by hydroxyl radical in the presence of excess oxygen. The isomer distribution of the phenolic products can be regulated by the reactivity of oxidant with adducts and by the equilibrium between the adducts and cation radicals formed by their dehydration. The following path c can be proposed in order to explain the relatively high yield of the *m*-isomer and low yield of the *p*-isomer, observed in solutions saturated with oxygen. The addition of oxygen to the adducts is considered to be very fast as suggested by Dorfman *et al.* (17), and the resulting hydroxycyclohexadienylperoxy radicals are converted easily to yield phenols. The fast reaction of oxygen with the adducts seems to contribute to the relatively high yield of the *m*-isomer, whereas using Fe^{3+} as the oxidant for step c the isomer distribution must be determined by the equilibrium and NIH-type shift as suggested by Walling *et al.* (4). Their results suggest that the rate of the oxidation by Fe^{3+} may be much smaller than that of oxygen addition to the adducts.[1] The fast addition of oxygen also causes the low yield of biphenyl derivatives. However, the exact mechanism for step c is still unclear.

The current efficiency and product distribution were greatly affected by Fe^{2+} concentration because of the reduction of the intermediate cation radical back to the starting material as shown in, Scheme 2, path d. Direct electron transfer from the substrate to hydroxyl radical is prevented (4). The intermediate cation radical undergoes deprotonation and forms the radical (path e) which yields the side-chain oxidation products. According to the mechanism proposed by Snook and Hamilton (6), the alcoholic compounds, formed by the oxidation of the above radical, react again with hydroxyl radical to produce the carbonyl compounds, path g. However, it is deemed that another pathway, *i.e.*, reaction of the above radical with oxygen in solution (path f) to form the carbonyl compounds without the formation of alcohols (29), may make a large contribution. This conclusion is derived from the following observation: (*i*) The yields of alcoholic compounds and bibenzyl derivatives were very low compared with those observed in the homogeneous oxidations in the absence of oxygen (4). (*ii*) The current efficiencies at low Fe^{2+} and high proton concentration, where relatively high yields of the carbonyl compounds were observed, were very high compared with those at other conditions; these results indicate that one hydroxyl radical was consumed in the formation of one molecule of the carbonyl compounds. Oxygen addition to the radical is considered to be extremely fast and is probably diffusion controlled in many instances (28), so that the yields of bibenzyl derivatives may be low. In cumene oxidation, the methyl group is probably lost in carbonyl formation from the peroxy radical.

[1] The addition rate of oxygen to alkyl radicals is considered to be almost diffusion controlled (28) whereas the oxidation rate of the radical by metal ion seems to be lower (27). Judging from the ratio of the yields of the phenolic products to those of the side-chain oxidation products in toluene oxidation in the presence of Fe^{3+} (4), the rate constant for the adduct oxidation by Fe^{3+} should be $\leq 5 \times 10^{7}$ M^{-1} sec^{-1}.



Scheme 2. The schematic mechanism for oxidations of toluene and ethylbenzene by electrogenerated hydroxyl radical in this work.

Next, we must consider the contribution made by hydrogen abstraction by hydroxyl radical, path b. The acid-catalyzed conversion of the adduct to the intermediate cation radical can occur to a lesser extent when the proton concentration is less than 0.02M, because the yields of the phenolic products were almost independent of proton and Fe^{2+} concentrations under such conditions. In such circumstances, the phenols are formed via addition, path a, and a great deal of the side-chain oxidation products are formed via path b. In toluene oxidation by hydroxyl radical at $[H^+] = 0.001M$, most of the products were cresol isomers, which indicates that the addition of the radical to the aromatic ring occurs more easily than the hydrogen abstraction from the side chain by the radical. However, the yields of phenolic products in the oxidations of ethylbenzene and cumene were only 40-50% at $[H^+] = 0.001M$. Accordingly, hydrogen abstraction from the α-position may make a certain contribution to the reaction in the oxidations of these compounds.

Finally, the effect of α-CD added to the electrolyte solution must be discussed. By the addition of α-CD, slight increases in the *p*-isomers of the phenolic products were observed in ethylbenzene and cumene oxidations. This fact may be accounted for by the following argument. When these compounds are included in α-CD's cavity, *o*- and *m*-positions of the substrates are not subject to attack of the hydroxyl radical since these positions are blocked by the inner wall of α-CD (30-32). On the other hand, the *p*-position is open to the solution so that the *p*-isomer is formed preferentially (Fig. 2). However, in the case of toluene included in α-CD, the side chain seems to be open to the solution because the toluene oxidation by hydroxyl radical in the presence of α-CD yielded more side-chain oxidation products than phenolic products. Although the included substrate is rapidly replaced by free molecules in solution (22), 60-80% of substrate is included in α-CD at any instance under the present conditions as the dissociation constants of α-CD-alkylbenzene (toluene, ethylbenzene, and cumene) complexes are $2\text{-}5 \times 10^{-3}M$ (no remarkable difference in the values among the three complexes is observed). In spite of the fact that such relatively high inclusion complexes are attained, α-CD had only a small effect on the product distributions. The current efficiencies

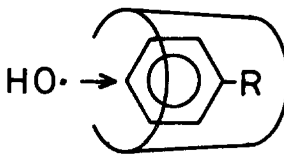


Fig. 2. Selective attack of hydroxyl radical to *p*-position of substrate included in α-CD.

in the presence of α-CD were very low for all cases. These results may be explained in the following two ways: (i) since the substrates can be included in the interior of the α-CD's cavity, the hydroxyl radical can scarcely attack the substrate in α-CD, but can attack free substrate; (ii) the hydroxyl radical reacts with added α-CD in a competitive reaction with the oxidation of substrate by the radical.

Anodic Evolution of Oxygen on Sputtered Iridium Oxide Films

S. Hackwood,* L. M. Schiavone,* W. C. Dautremont-Smith,* and G. Beni*

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

We report on the electrocatalytic properties of sputtered iridium oxide films (SIROF's) in acidic electrolytes. Long term stability (240 hr) is demonstrated. Typical steady-state currents are 75 mA/cm^2 at 1.85V (*vs.* RHE), which is 50% higher than previously reported. In addition, we introduce a new method of determining Tafel slopes based on the short-time decay of the oxygen evolution reaction (OER) current, corrected for the capacitative component. Tafel plots are presented for samples of different thickness and degree of hydration. The high current density and absence of corrosion demonstrate the superior catalytic properties of SIROF's *vs.* iridium over the entire voltage range investigated.

The production of hydrogen is an important commercial process, particularly as hydrogen can be used as a nonpolluting fuel (1). A simple and clean way of producing hydrogen is by electrolysis of water (2). The technology of electrolysis can be substantially improved and many research efforts have been aimed in this direction. At present, electrolysis has a low efficiency due to the high activation overvoltage for oxygen evolution. In addition, for most metals, electrolysis is accompanied by corrosion at high anodic potentials. Thus, much recent research has been focused on finding a better catalyst for the oxygen electrode.

* Electrochemical Society Active Member.

Key words: electrolytes, Tafel slopes, decay.

Commercial electrolyzers using alkaline electrolytes employ anodes such as nickel-plated iron and ferronickel alloys (3). More advanced electrolyzers, however, use acid electrolytes, as for example, the solid polymer electrolyte (SPE) electrolyzer developed by General Electric (4). For this acidic electrolyzer a number of anode materials have been proposed, *e.g.*, binary and ternary alloys of Pb, Ir, Ru, Ti, Ta, Nb, Zr, and W. In acidic electrolytes, it has been established that iridium shows the highest catalytic activity for the oxygen evolution reaction (OER).

These findings are based on a purely empirical approach. Few studies have been aimed at establishing the intrinsic factors affecting the OER so that we lack

the information necessary for a theoretical approach for finding better electrocatalysts. Semi-empirically (5), it has become accepted that a good OER catalyst must (*i*) have a relatively high electronic conductivity; (*ii*) be capable of existing in a number of valence states; and (iii) have a high affinity for adsorbed OH^- intermediates. Moreover, the electrode must not corrode; hence research has been restricted to the noble metals and their alloys.

Recent studies (6-9) have pointed out that a common factor among different electrodes known to be good electrocatalysts for OER (for example, Ir, Ru, Ni) is the presence of a relatively thick surface oxide film. These thick oxide films have a large ion insertion charge capacity. In many cases (10) reversible ion insertion, with concomitant oxidation reduction, is accompanied by changes in the optical and electrical properties of the films, *i.e.*, the films exhibit electrochromism. An example is the electrochromism of anodic iridium oxide films (AIROF's) (11). AIROF's show good electrocatalytic activity for the OER, producing a higher current density at a given overvoltage than bare iridium (8).

The electrochromic reaction in AIROF's takes place in the region of ~1V *vs.* reversible hydrogen electrode (RHE) in 0.5M H_2SO_4 and is thus a precursor of the OER which occurs with significant rate at ~1.5V (*vs.* RHE). Although the relationship between anodic electrochromism and OER catalysis is not yet understood, it is possible that high electronic conductivity in combination with the increased OH^- content in the colored state favors the OER.

Although AIROF's have higher OER rates than Ir, they dissolve at significant rates at low voltages (1.4-1.6V *vs.* RHE), and very rapidly at voltages above 1.6V (*vs.* RHE) in acidic solution (8). Therefore, they are of little use as practical catalysts. In a study of the electrochromic behavior of iridium oxide films, we produced films by reactive sputtering (12). These sputtered iridium oxide films (SIROF's) showed electrochromic behavior similar to that of AIROF's but with significantly higher stability in acidic electrolytes. We expected, therefore, that SIROF's might show superior stability to that of AIROF's under OER conditions. In the sputter deposition of a thin film, highly energetic species in the vapor phase impinge onto a cold substrate. This rapid quenching may produce metastable structures that are thermodynamically unstable at room temperature.

Cyclic voltammograms for sputtered iridium oxide films (SIROF's) are similar to those for AIROF's but differ in detail, *e.g.*, the potential at which the peak in the oxidation-reduction current occurs is ~0.80V (RHE) rather than ~0.95V (RHE). Both voltammograms at quasi-equilibrium rates are nearly symmetric about the voltage axis within the range $+0.25 \rightarrow +1.25$ (*vs.* RHE) resulting in excellent reversibility when operated within this range of potentials where electrochromism is observed. We have previously shown (13) that SIROF's exhibit a high OER electrocatalytic activity (similar to AIROF's) but, in contrast to AIROF's, are stable OER electrocatalysts.

In this paper we report a detailed characterization of the electrocatalytic activity of SIROF's. In the next section we describe the film preparation and describe the general parameters necessary to produce films with high catalytic activity. In the "Results" section we report the effects of hydration, and the long-term stability tests for oxygen evolution. We then report the catalytic activities of films prepared under different sputtering conditions. Finally, we analyze the intrinsic, as opposed to steady-state, activity of SIROF's. For this purpose, we introduce a new method of measuring the intrinsic catalytic activity, based on application of a pulsed voltage. In this way we have obtained Tafel plots over a wide voltage range. In the final section we summarize the main conclusions drawn from these measurements and discuss the general implications of this work for electrocatalysis research.

Experimental

Film preparation.—SIROF's were deposited on tantalum or on quartz substrates. For depositions on quartz, standard photoresist patterning and lift-off techniques were used to produce a sharp edge in the SIROF, at which a stylus instrument was used to measure film thickness (14). Electrocatalytic activity of SIROF's was investigated using tantalum substrates. The substrates were washed in detergent bath, rinsed in distilled water, ultrasonically cleaned in isopropyl alcohol, and vapor degreased in isopropyl alcohol. SIROF's were deposited from an iridium target in an O_2 plasma using a conventional diode rf sputtering system as described in Ref. (12). The pressure of oxygen in the sputtering chamber was 8 or 20 mTorr. Deposition times ranged between 20 min and 4 hr producing films of thickness 200-3200Å.

Electrochemical characterization.—The electrochemical properties of the SIROF's were examined in 0.5M H_2SO_4 electrolyte made up from spectroscopic grade sulfuric acid and deionized water. Using potentiostatic control, the current voltage characteristics of the SIROF's were examined in the potential range −0.25-+1.15V *vs.* a saturated calomel reference electrode. The cyclic voltammograms, for both AIROF's and SIROF's, recorded at a sweep rate of 100 mV/sec, are shown in Fig. 1.

SIROF's and AIROF's are ion-insertion materials, and the voltammograms in the range of 0-1V (*vs.* SCE) show almost complete reversibility.[1] A charge capacity, ΔQ, can be defined as the charge inserted when the potential is stepped between two arbitrarily chosen limits. ΔQ is related to the film thickness and the number of accessible iridium sites (10). For SIROF's over the potential step of 0-1V, the number of accessible sites is ~0.7 per Ir atom.

Electrocatalytic activity.—The electrocatalytic activity of SIROF's was examined by measuring the OER current in 0.5M H_2SO_4 in the voltage range 1.50-2.50V (*vs.* RHE). OER current characteristics were examined

[1] It is interesting that the hydrogen peaks are missing. This absence has been observed also for AIROF's grown on tin oxide [see J. L. Shay, G. Beni, and L. M. Schiavone, *Appl. Phys. Lett.*, **33**, 942 (1978)] and interpreted as due to the nonexposure of the substrate to the solution. On the other hand, the peak absence could be due to the presence of organic impurities in the deionized water. [See B. E. Conway, *Anal. Chem.*, **45**, 1331 (1973).]

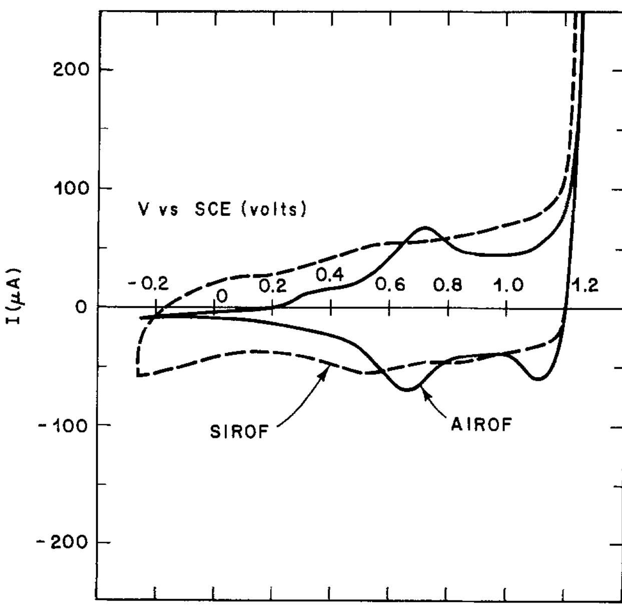

Fig. 1. Cyclic voltammograms for SIROF's and AIROF's recorded at a sweep rate of 100 mV sec^{-1}, in 0.5M H_2SO_4.

for SIROF's as a function of: (*i*) degree of hydration, (*ii*) time, and (*iii*) film thickness. The response of SIROF's to a square wave voltage between the OER voltage, and a lower, more cathodic voltage was also investigated to provide a measure of the intrinsic catalytic activity from which Tafel plots could be constructed. On completion of these experiments, the cyclic voltammogram and charge capacity of the SIROF were remeasured. In addition, the electrolyte was analyzed for iridium content by the stannous iodide method described in Ref. (15), and by atomic emission. The electrolyte solution was stirred throughout the experiments, and all of the data reported are corrected for *IR* losses in the electrolyte.

Results

In this section we report measurements of (*i*) the effect of hydration on the catalytic activity of SIROF's, (*ii*) steady-state oxygen evolution currents, and (*iii*) Tafel plots for various films.

Hydration.—Figure 2 shows the oxygen evolution current as a function of time at 1.95V (*vs.* RHE) for an as-deposited SIROF (3000Å thick) of total charge capacity $\Delta Q = 70$ mC cm^{-2}. The current increases by approximately 20% during the first few minutes of operation, but then decreases. A current decay similar to this occurs for most other materials used as OER anodes. The initial increase in the SIROF OER current is possibly due to an "opening" of the film structure by hydration. Volume changes induced by the electrochromic process in as-deposited SIROF's have been recently reported (14). It has been shown that SIROF's, after a few ion-insertion cycles, expand by incorporation of water, and hydration increases the rate of ion insertion by about an order of magnitude. Similarly, we see from Fig. 2 that hydration also increases the oxygen evolution current.

The effects of hydration are also evident in the cyclic voltammograms shown in Fig. 3. The solid line shows the voltammogram produced on initial cycling of an as-deposited SIROF between 0 and 1V (*vs.* SCE) in 0.5M H_2SO_4, and the dashed line is that of the same sample after 10 min of OER. The total charge transferred increases on hydration; in this case ΔQ increases from 51 to 57 mC cm^{-2}. This increase could be due to an increase in the number of sites exposed to the electrolyte, which is consistent with the picture of a more "opened" structure of the film. Figures 2 and 3 thus indicate that hydration of the deposited films is important for good OER catalytic activity.[2]

[2] An alternative explanation of the OER current maximum is adsorption of impurities from deionized water.

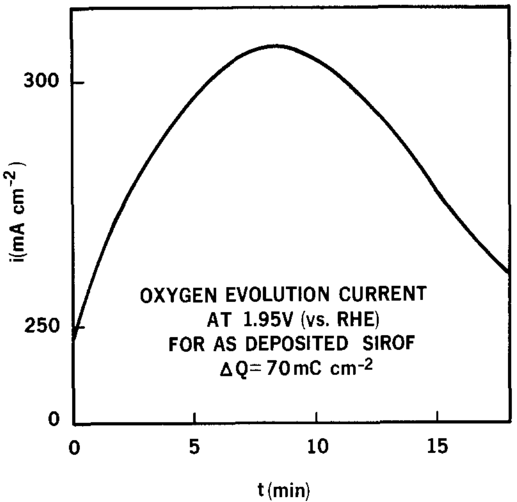

Fig. 2. Oxygen evolution current as a function of time at 1.95V (*vs.* RHE) for an as-deposited SIROF (3000Å thick) of total charge capacity $\Delta Q = 70$ mC cm^{-2}.

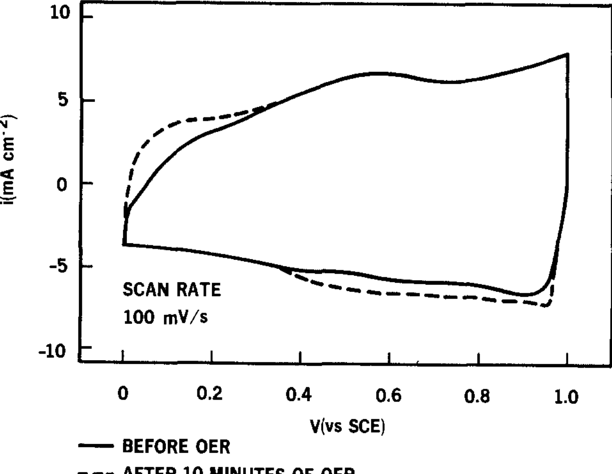

Fig. 3. The solid line shows the voltammogram produced on initial cycling of an as-deposited SIROF between 0 and 1V (*vs.* SCE) in 0.5M H_2SO_4 and the dashed line is that of the same sample after 10 min of OER.

Steady-state current.—Figure 4 shows the oxygen evolution current at 1.95V (*vs.* RHE) for a film of total charge capacity, (measured after hydration) $\Delta Q = 70$ mC cm^{-2} and film thickness as deposited of ~3200Å. The initially high current decreases with time and reaches a steady state after ~5 days. This steady-state current remains constant at ~75 mA cm^{-2} for over 18 days (the time limit of the experiment).

The SIROF did not corrode during OER, and no iridium was detected in the electrolyte. The voltammogram and total ΔQ recorded after 18 days of OER were unchanged from the initial values. In contrast, at 1.95V (RHE), pure iridium corrodes. In Ref. (16) the measured corrosion current is 58 $\mu C/cm^{-2}$ per cycle of potential sweep.[3] At this rate an amount of iridium metal equivalent to that contained in the sputtered film would be lost in approximately 20 min.

Figure 5 shows the OER current for SIROF's of three different thicknesses. Thickness (*d*) and charge capacity (ΔQ) of the SIROF's are shown in the inset in the upper right corner of the figure. The OER current density is seen to be dependent on film thickness, but not linearly as for thickness *vs.* charge density. There is a difference in the OER currents for the two thicker films of only 50%, whereas, the thicknesses of the two films differ by a factor of ~7. It has been postulated (8, 17) for AIROF's that the high catalytic activity is due to a highly porous structure. This, however, does not seem to be true for SIROF's. A highly porous structure implies a high surface to vol-

[3] Note that noble metals dissolve faster under alternating currents.

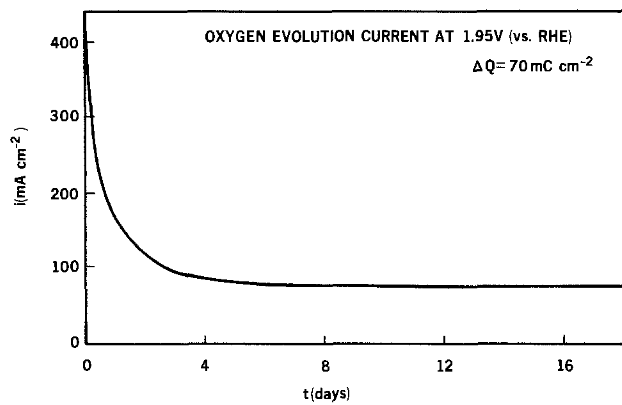

Fig. 4. Oxygen evolution current at 1.95V (*vs.* RHE) for a film of total charge capacity, (measured after hydration) $\Delta Q = 70$ mC cm^{-2} and film thickness (as deposited) of ~3200Å.

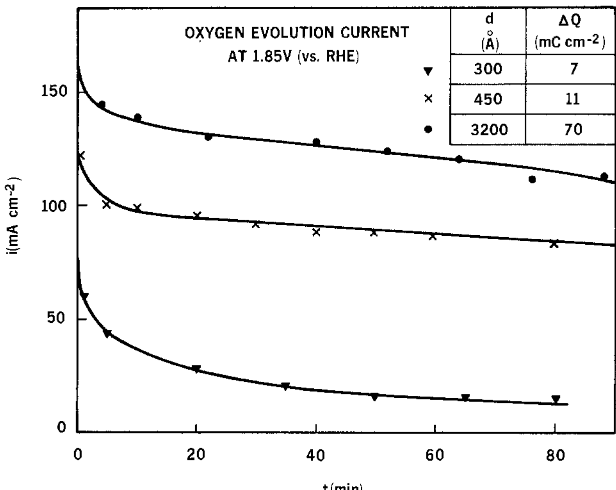

Fig. 5. OER current for SIROF's of three different thicknesses

ume ratio, independent of film thickness increases. If the catalytic activity were due to the number of active surface sites, activity and OER current would be linearly dependent on film thickness. The thinnest film shows substantially lower OER; this is, however, not due to an intrinsic factor, but to poor mechanical stability, as evidenced by loss of portions of the film. (It is possible that a critical thickness of the sputtered film must be reached before a mechanically stable layer is obtained.)

Tafel plots.—There has been uncertainty in how to measure the intrinsic catalytic activity of oxide films (18). The difficulty arises because the OER current decays at a variable rate from its initial value to the steady-state value which may not be achieved for a number of days. The catalytic activity is usually (8) measured by the value of the OER current after an arbitrarily specified time, (*e.g.*, 10 min following the onset of OER). This, however, leads to errors in the interpretation of the Tafel slopes because, in many cases, decay times vary with different voltages plots. A further difficulty with this type of measurement is that the initial value of the OER current is dependent on the history of the anode.

To overcome this problem, we have employed a pulse technique which gives a measure of intrinsic catalytic activity. In Fig. 6(a), we show the current response to an applied 0.5 Hz square wave voltage, pulsed between +1.95 and +0.05V (*vs.* RHE). The current corresponding to the anodic voltage is plotted as a solid line, whereas the cathodic current is shown as a dashed line. The sharp current spikes are due to the charging and discharging of the overall film capacitance (double layer and ion insertion). The OER current is measured by the slowly decaying current following the initial current spike. By extrapolating these current decays to intersect the current axis at $t = 0$, we obtain a measure of the OER current. Figure 6(b) shows the current obtained under voltage driving conditions identical to those of Fig. 6(a) but following 5 min polarization at +0.05V (*vs.* RHE). It can be seen that the OER currents are unchanged. This procedure of determining intrinsic catalytic activity is reproducible, and has been repeated on many samples under different conditions.

Using this method we have been able to construct Tafel plots for SIROF's and compare them with Tafel plots obtained for iridium. Figure 7 shows Tafel plots for iridium and an SIROF in the potential range 1.5-2.2V (*vs.* RHE). The figure shows that at low voltages the Tafel plots of iridium and SIROF differ substantially. At the lowest voltages the current for SIROF is approximately two orders of magnitude higher than that for iridium. At high voltages, the oxygen evolution currents are similar. The dashed line delineates the voltage region above which Ir corrodes (16) at a rate greater than 200 μA cm^{-2}.

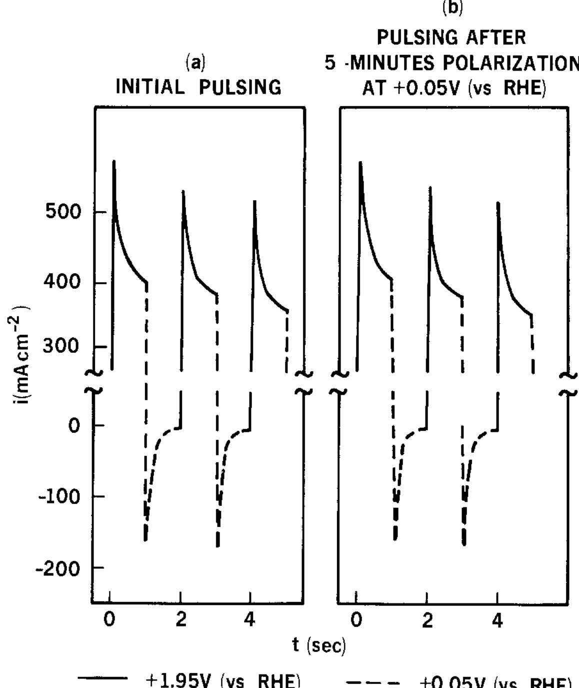

Fig. 6. Pulse technique to measure intrinsic catalytic activity. In (a), we show the current response to an applied 0.5 Hz square wave voltage, pulsed between +1.95 and +0.05V (vs.RHE). The current corresponding to the anodic voltage is plotted as a solid line, whereas the cathodic current is shown as a dashed line. In (b) is shown the current obtained under voltage driving conditions identical to those (a) but following 5 min polarization at +0.05V (vs. RHE). It can be seen that the OER currents are unchanged.

Finally, Figure 8 compares the Tafel plots of three different samples of SIROF's. The samples were deposited at oxygen pressures of either 20 or 8 mTorr with a total charge capacitance ΔQ of 70 and 35 mC cm^{-2}, respectively, as indicated in the upper left inset. From the figure, it can be seen that the intrinsic catalytic activity of these films is similar.

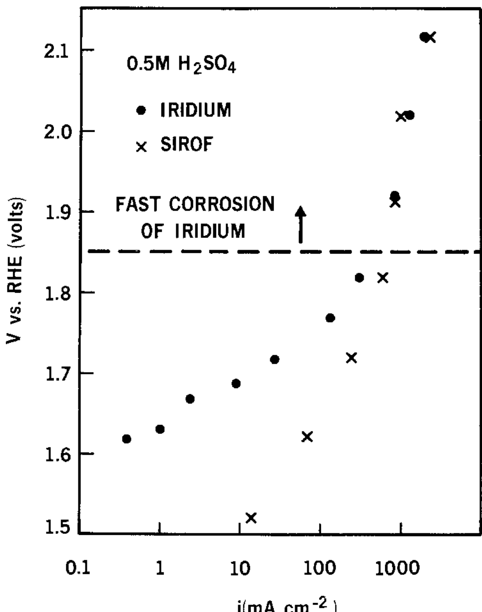

Fig. 7. Tafel plots for iridium and an SIROF in the potential range 1.5-2.2V (vs. RHE).

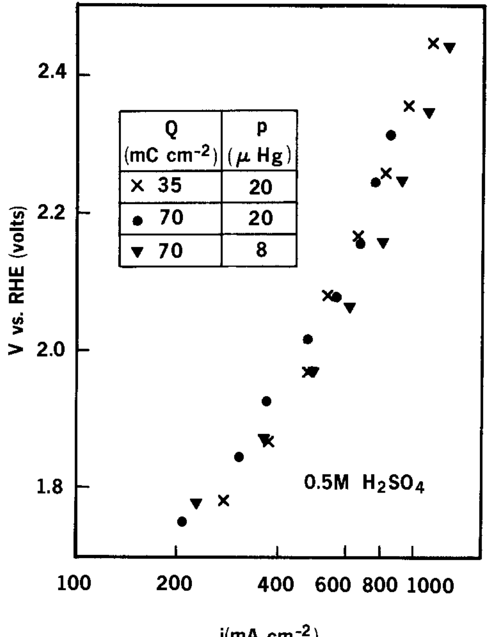

Fig. 8. Tafel plots of three different samples of SIROF's. The samples were deposited at oxygen pressures of either 20 or 8 mTorr with a total charge capacitance ΔQ of 70 and 35 mC cm^{-2}, respectively, as indicated in the upper left inset.

Conclusions

From these results, we can draw two main conclusions. Firstly, sputtered iridium oxide films show high OER catalytic activity. In the steady state the oxygen evolution reaction current is 75 mA cm^{-2} (geometric area) at 1.95V (*vs.* RHE), which is approximately equal to that for bare iridium. The intrinsic (*i.e.*, measured with the voltage pulsing technique) OER current shows that the catalytic activity of SIROF's is approximately two orders of magnitude larger than that of bare iridium at low overvoltages and approximately equal to bare iridium at high overvoltages.

Secondly, SIROF's show excellent corrosion resistance, even at high overvoltages. We observed no corrosion during 18 days of operation at 1.95V (*vs.* RHE) in 0.5M H_2SO_4. In addition, no corrosion was observed during the pulsed experiments.

Our results demonstrate, also, that the catalytic activity is not simply due to a large effective surface area because of a macroscopically porous structure. In fact, no significant change of catalytic activity was observed for films differing in thickness by almost an order of magnitude. Thus, the superior activity of iridium oxide is not due to a large number of iridium atoms exposed to the electrolyte, but is a property of the oxide itself.

It is conceivable that by reactively sputtering, we are not simply producing a large surface area catalyst, but a material which could not be formed under thermodynamic equilibrium. Indeed, the free energy of the SIROF is likely to be far higher than the free energy of iridium oxide. We may thus expect the structure to be amorphous or to contain a large number of oxygen vacancies. This structure may be regarded also as a "microscopically porous" structure. This hypothesis should be substantiated by detailed x-ray structure analysis of the films. Work in this direction is in progress (19, 20). A large number of vacancies favors the OER because hydroxyl anions have easy access (via the vacancies) to the bulk of the film. In this case the "oxide-path" of oxygen evolution (21) would be the rate-determining mechanism of the reaction.

Finally, we speculate that our interpretation of the high catalytic activity and high stability of SIROF's (if correct) is also applicable to other oxides, since the SIROF's catalytic properties are due to the particular structure formed during sputtering, and not to a high number of metal ions exposed to the electrolyte.

Moderate Temperature Na Cells

III. Electrochemical and Structural Studies of $Cr_{0.5}V_{0.5}S_2$ and Its Na Intercalates

K. M. Abraham* and L. Pitts

EIC Laboratories, Incorporated, Newton, Massachusetts 02158

ABSTRACT

Cathodic behavior of the layered mixed metal sulfide, $Cr_{0.5}V_{0.5}S_2$, has been studied in a rechargeable Na cell having the configuration

Liquid Na/β''-Al_2O_3/Na^+-containing electrolyte/$Cr_{0.5}V_{0.5}S_2$

The cell operates at 130°C and utilizes as electrolyte a 1M solution of NaI in 1,2-bis(2-methoxy-ethoxy)ethane, (triglyme). The first discharge of $Cr_{0.5}V_{0.5}S_2$ yielded a capacity of 0.95 $\bar{e}$/mole of the sulfide. However, the rechargeable capacity was limited to ~70% of the first discharge. The mechanism of discharge of $Cr_{0.5}V_{0.5}S_2$ involves Na intercalation. More than one crystallographically distinct phase has been identified in the compositional range, $0 < y \leq 1$ in $Na_yCr_{0.5}V_{0.5}S_2$.

The layered transition metal disulfides and diselenides have received widespread interest as rechargeable cathodes for electrochemical cells utilizing alkali metal anodes (1, 2). While most of the interest has been in rechargeable Li cells, some recent studies, particularly from this laboratory, have explored the usefulness of several dichalcogenide cathodes for secondary Na cells (3-6). Thus, we have evaluated the cathodic behavior of the disulfides (3), TiS_2, VS_2, and $Nb_{1.1}S_2$, and the diselenides (4), $TiSe_2$ and VSe_2 in a moderate temperature Na cell. This cell, which is a modification of the rechargeable Na/soluble S cell we described earlier (7, 8), utilizes a β''-Al_2O_3 solid electrolyte separator and an organic electrolyte comprising NaI in 1,2-bis(2-methoxy-ethoxy)ethane, (triglyme). Our x-ray structural studies (3, 4) of the electrochemically cycled cathodes showed that in all transition metal chalcogenides, the cathode reaction involved Na intercalation during discharge and deintercalation during recharge.

The topochemical reaction of the layered transition metal dichalcogenides with Na is often accompanied by structural changes of the host lattice so that in a given Na_yMX_2 ternary more than one crystallographically distinct phase appears with the degree of intercalation (2, 9-12). These crystallographic changes are often revealed in the electrochemical discharges which show potential plateaus closely correlating the structural changes (3, 4). In the case of the disulfides investigated, these structural changes affected cathode rechargeability. Thus with VS_2 and TiS_2 cathodes, only the Na associated with certain phase regions of the Na_yMS_2 ternary was rechargeable (3, 5).

The mixed metal disulfide, $Cr_{0.5}V_{0.5}S_2$ presents an interesting situation since the structural characteristics of the Na intercalates and consequently its electrochemical properties would be influenced by both Cr and V. In this paper we present our results on the structural and electrochemical properties of $Cr_{0.5}V_{0.5}S_2$ and $Na_yCr_{0.5}V_{0.5}S_2$.

Experimental

All the experiments were conducted in the absence of air and moisture under an argon atmosphere in a Vacuum Atmospheres dry box or by using standard procedures employed for the manipulation of air sensitive compounds (13). Elemental analyses were carried out by Galbraith Analytical Services, Knoxville, Tennessee.

Synthesis of the sulfides.—*$Cr_{0.5}V_{0.5}S_2$.*—The sulfide was synthesized via a two-step process combining the procedures of Van Laar (14) and Murphy (15). Initially $LiCr_{0.5}V_{0.5}S_2$ was synthesized by the reaction of H_2S with an intimate mixture of Li_2CO_3, V_2O_5, and Cr_2O_3 present in the mol ratio of 1:0.5:0.5 at 700°C for 16 hr.

The air sensitive $LiCr_{0.5}V_{0.5}S_2$ thus obtained was delithiated by the reaction of an I_2/CH_3CN solution at room temperature. The dark $Cr_{0.5}V_{0.5}S_2$ produced was washed several times with CH_3CN and dried *in vacuo* at ~150°C. The material was characterized by x-ray and elemental analyses. The Debye-Sherrer x-ray data, shown in Table I, is consistent with a layered 1T-CdI_2 type structure with a = 3.22Å and c = 5.71Å.

VS_2.—The compound was synthesized in the same manner as that of $Cr_{0.5}V_{0.5}S_2$ using Li_2CO_3 and V_2O_5 (3, 16). It exhibited a 1T-CdI_2 structure (16).

Sodium intercalates of $Cr_{0.5}V_{0.5}S_2$.—Sodium intercalates of various compositions were prepared by adding the disulfide to a requisite quantity of Na-naphthalide (0.3M in THF) and stirring the resulting mixture for 3 days at room temperature. In preparing the fully intercalated compounds, $Na_{1.0}MS_2$, a 30% excess of the naphthalide solution was initially used. The sodiated compound was separated by filtration and dried *in vacuo* initially at room temperature and then at ~70°C for 12 hr. The filtrate was analyzed for

unreacted Na-naphthalide by titrating an aqueous solution of the filtrate with a standard solution of HCl acid. The composition of the sodium intercalate thus obtained was further checked by elemental analysis and showed good agreement.

X-ray powder patterns of the samples were recorded using CuKα radiation and a Debye-Sherrer camera.

Electrochemical cell.—The electrochemical cell incorporating a β''-Al_2O_3 tube was of the same type described previously (3, 7). The sulfide cathodes were fabricated in the form of pressed electrodes from a cathode mix consisting of ~50 weight percent (w/o) sulfide, 40 w/o Shawinigan carbon (50% compressed), and 10 w/o Teflon (du Pont 7A), as described previously (3, 4). The electrolyte was a 1M solution of NaI in 1,2-bis(2-methoxy-ethoxy)ethane, triglyme (3). The assembled cell had the configuration

$$\text{Liquid Na}/\beta''\text{-}Al_2O_3/\text{triglyme-NaI}/Cr_{0.5}V_{0.5}S_2$$

The cells were cycled galvanostatically after thermostating at 130°C (3, 4, 7).

Results and Discussion

Structure of $Cr_{0.5}V_{0.5}S_2$.—The disulfide has a hexagonal layered 1T-CdI_2-type structure similar to that of TiS_2 or VS_2. The unit cell parameters a = 3.22Å and c = 5.71Å are comparable to those of VS_2, a = 3.22Å and c = 5.74Å, and TiS_2, a = 3.41Å and c = 5.69Å. VS_2 has only recently been characterized (16). The existence of the hexagonally layered mixed metal sulfides, $Cr_NV_{1-N}S_2$ and $Fe_NV_{1-N}S_2$ has been established in the recent studies of Murphy and co-workers (15). Their studies, however, emphasized $Cr_{0.75}V_{0.25}S_2$, focusing on their use as reversible cathodes in nonaqueous solvent Li cells. The structural data on $Cr_{0.5}V_{0.5}S_2$ are reported here for the first time.

Electrochemical behavior of $Cr_{0.5}V_{0.5}S_2$.—An electrochemical cell incorporating a $Cr_{0.5}V_{0.5}S_2$ cathode was discharged at a low rate, *i.e.*, at 0.5 mA/cm^2, to determine the capacity and the shape of the discharge curve. Typical discharge curves for two different cells are shown in Fig. 1 and 2. The first discharge corresponds to a capacity of 0.95 $\bar{e}$/mol of $Cr_{0.5}V_{0.5}S_2$.

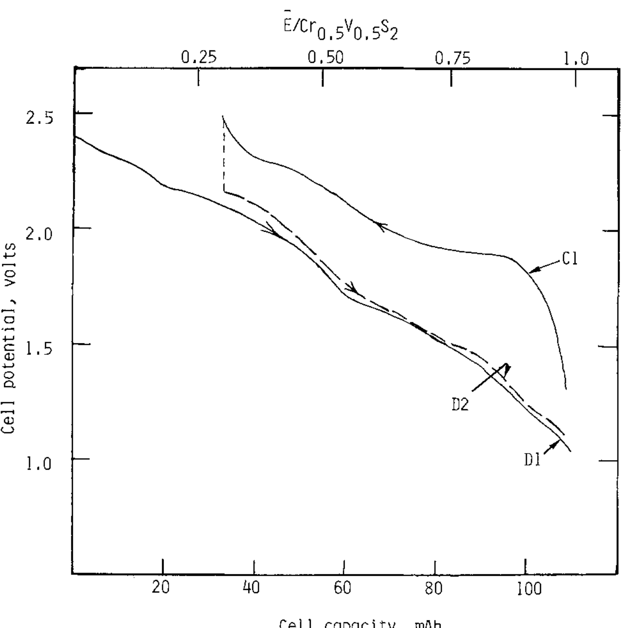

Fig. 1. Galvanostatic discharges and charges of the cell, liquid Na/β''-Al_2O_3/triglyme, NaI/$Cr_{0.5}V_{0.5}S_2$ at 130°C. Curves D1 and D2 are the first and second discharges. Curve C1 is the first charge. Current density = 0.5 mA/cm^2.

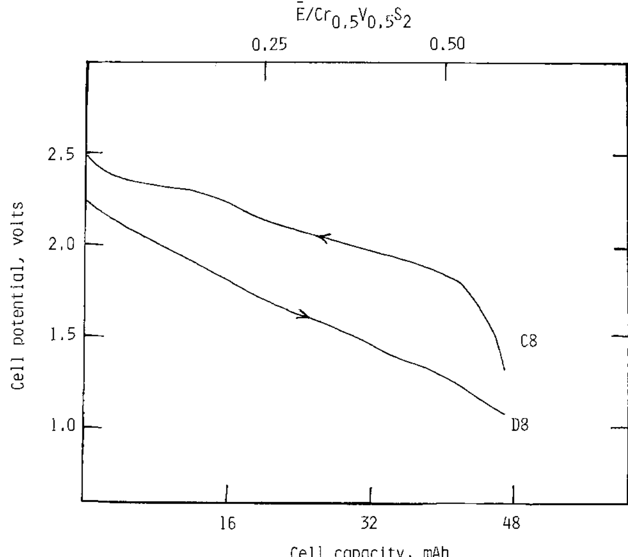

Fig. 2. The eighth cycle of a liquid Na/β''-Al_2O_3/triglyme, NaI/$Cr_{0.5}V_{0.5}S_2$ cell at 130°C. Current density = 0.5 mA/cm^2.

The discharge shows a somewhat gradual but definite end point to 1.1V. The first discharge is characterized by three potential regions spanning the Na compositional ranges (y) approximately at $0 < y < 0.17$, $0.17 < y \leq 0.55$, and $0.55 < y \leq 0.95$. In the first charge, only 70% of this capacity was recharged to 2.5V. The charge curve shows a definite end point at this stage. The capacity in the second discharge was 0.67 $\bar{e}$/$Cr_{0.5}V_{0.5}S_2$. Capacity losses with further cycling were minor and occurred in a gradual fashion, reflecting, as we found previously (3), electrode structural factors. However, the later cycles, illustrated in Fig. 2 by cycle 8 of a second cell, do not show the multistep characteristics seen in the early cycles; but rather the potential profiles of the later cycles are almost linear.

The Debye-Sherrer x-ray pattern of a $Cr_{0.5}V_{0.5}S_2$ cathode cycled nine times and terminated at the end of the discharge is tabulated in Table II. The pattern, on the basis of the structural data discussed below for $Na_yCr_{0.5}V_{0.5}S_2$ ternaries, can be assigned to two different crystallographic phases of the $Na_yCr_{0.5}V_{0.5}S_2$ ternary. Evidently Na discharge into and recharge from $Cr_{0.5}V_{0.5}S_2$ involves intercalation and deintercalation, respectively. The processes are, however, accompanied by crystallographic phase changes in the $Na_yCr_{0.5}V_{0.5}S_2$ ternaries.

Structural aspects of the $Na_yCr_{0.5}V_{0.5}S_2$ ternaries.—Sodium intercalates of $Cr_{0.5}V_{0.5}S_2$ and VS_2 were prepared by reaction of the respective sulfide with Na-naphthalide. The x-ray pattern for $Na_yCr_{0.5}V_{0.5}S_2$ where $y = 1$ is shown in Table III. The pattern can be satisfactorily indexed for a 3R rhombohedral structure with space group R$\bar{3}$M, isomorphic with $Na_{1.0}TiS_2$ (17) and $Na_{1.0}CrS_2$ (18). The lattice parameters are a = 3.52Å and c = 19.65Å. In this structure, which may be designated as the trigonal antiprismatic (TAP) form, sulfur forms a cubic close packing while the

transition metal atoms and Na occupy distorted octahedral interstices in alternate layers (14).

We have also prepared Na intercalates of nominal compositions $Na_{0.2}Cr_{0.5}V_{0.5}S_2$, $Na_{0.4}Cr_{0.5}V_{0.5}S_2$, $Na_{0.6}Cr_{0.5}V_{0.5}S_2$, and $Na_{0.8}Cr_{0.5}V_{0.5}S_2$. The compositions $Na_{0.2}Cr_{0.5}V_{0.5}S_2$ and $Na_{0.4}Cr_{0.5}V_{0.5}S_2$ appeared to be homogeneous phases whereas the other materials constituted a mixture of the TAP phase and of the phase corresponding to $Na_{0.4}Cr_{0.5}V_{0.5}S_2$. The x-ray pattern of the latter material is tabulated in Table IV. The ternary appears to have a phase isostructural with that of Na_yTiS_2 for $0.38 < y < 0.72$, discussed by Rouxel (17). This phase, which may be designated as the trigonal prismatic (TP) phase, (space group R3M) has a rhombohedral structure with Na occupying trigonal prismatic sites and the transition metal atoms octahedral sites. The lattice parameters of $Na_{0.4}Cr_{0.5}V_{0.5}S_2$ are a = 3.24Å and c = 21.24Å. An isostructural phase was identified also in the Na_yVS_2 ternaries for $0.3 \leq y \leq 1$ by Wiegers (11). It is to be noted that these Na_yVS_2 compositions of Wiegers were prepared by a high temperature route.

For $Na_{1.0}VS_2$, Wiegers identified two other phases, a TAP phase isostructural with $NaCrS_2$ and a hexagonal form isostructural with Li_yTiS_2 (19) or $LiVS_2$ (14). For comparison with the low temperature synthetic route employed in the present study for $Na_yCr_{0.5}V_{0.5}S_2$, we have prepared $Na_{0.8}VS_2$ and $Na_{1.0}VS_2$ by the Na-naphthalide reaction. The structural data for $Na_{1.0}VS_2$ are listed in Table V. The sample contains a mixture of the hexagonal form, a = 3.22Å, c = 7.3Å and the TAP form, a = 3.54Å and c = 19.74Å. The results are in agreement with those of Wiegers and support his suggestion that the TP form of $Na_{1.0}VS_2$ is a high temperature form. Our samples of $Na_{0.4}VS_2$ and $Na_{0.8}VS_2$ were homogeneous TP phases with c = 7.08Å and 6.94Å, respectively. A sample of $NaVS_2$ we obtained electrochemically (3) had the hexagonal structure.

It thus appears that the structural characteristics of $Na_{1.0}Cr_{0.5}V_{0.5}S_2$ more closely resemble that of $Na_{1.0}CrS_2$ in that only the TAP phase is present. Our samples of $Na_yCr_{0.5}V_{0.5}S_2$, $y = 0.6$ and 0.8, were heterogeneous mixtures with the components having lattice parameters identical to those of $Na_{0.4}Cr_{0.5}V_{0.5}S_2$ and $Na_1Cr_{0.5}V_{0.5}S_2$. Only a poorly defined pattern was obtained for $Na_{0.2}Cr_{0.5}V_{0.5}S_2$; but, from the magnitude of the d values apparently corresponding to the (ool) reflections, the phase appears to be a second stage compound, as found in the low Na content intercalates of TiS_2 and VS_2.

Cell chemistry in relation to phase changes.—The structural data presented above show that probably three crystallographically distinct phases are present in the $Na_yCr_{0.5}V_{0.5}S_2$ ternary for $0 < y \leq 1$. But, our x-ray data are insufficient to obtain the exact breakpoints in the phase-compositional relationships. However, we can attempt at a correlation from the discharge curve shown in Fig. 1. The two potential plateaus observed in the Na compositional (y) ranges, $y < 0.17$ and $0.17 < y \leq 0.55$ may correspond to a second stage phase and a first stage trigonal prismatic phase, respectively. The x-ray data presented in Table II for the cycled cathode, having the nominal composition $Na_{0.9}Cr_{0.5}V_{0.5}S_2$, show that it contains both TP and TAP phases. Then, the third potential region, spanning the range $0.55 < y \leq 0.95$, may encompass both a biphase region, comprising the TP and TAP phases and a single phase region, comprising the TAP phase. For a biphase region, one expects a corresponding plateau in the voltage-composition curve. However, our cell data are a result of both kinetic and thermodynamic factors and a true plateau region is not observed in the discharge curve at the compositional range $0.55 < y \leq 0.95$. For the same reasons, the biphase regions expected (20) at the beginning of the discharge and at the transition stage from the second stage compound to the first stage TP phase are not clearly seen in the discharge curve. It is to be noted that, previously, we found (3) correlations among the phase-compositional regions and the discharge profiles of TiS_2 and VS_2 cathodes. It is noteworthy that in the first discharge of $Cr_{0.5}V_{0.5}S_2$, Na intercalation is achieved for virtually all values of y, $0 < y \leq 1.0$. In this respect, $Cr_{0.5}V_{0.5}S_2$ resembles VS_2 (3). In TiS_2 on the other hand, the discharge was limited to 0.85 Na/mol of TiS_2.

The fractional rechargeability (*i.e.*, 70%) of the capacity in the first discharge of $Cr_{0.5}V_{0.5}S_2$, except for the specific capacity involved, resembles the behavior of the other sulfides we previously investigated, namely, TiS_2, VS_2, and $Nb_{1.1}S_2$. In all cases, a fraction of the capacity in the first discharge is not recharged in the following charge. In general, it appears that at low values of y in the Na_yMX_2 ternaries the crystallographic phase present is a second stage phase and that the Na involved in this phase is not rechargeable, at least at the rates employed in our studies.

Table VI. Specific energies of Na/MS_2 couples based on experimental capacities and voltages

Metal sulfide	Equivalents/ mol of MS_2	Mid-discharge voltage (V)	Specific energy (W-hr/kg)
$Cr_{0.5}V_{0.5}S_2$	0.70	1.9	273
VS_2*	0.70	1.8	258
TiS_2*	0.65	1.7	215
$Nb_{1.1}S_2$*	0.50	1.5	119

* Data from Ref. (3).

Our data indicate that the maximum rechargeable capacity of the $Cr_{0.5}V_{0.5}S_2$ cathode is 0.7 e/mol. With an average cell voltage of 1.9V, the theoretical specific energy of the cathode is 273 W-hr/kg. The specific energies of the Na/MS_2 couples tabulated in Table VI show that $Cr_{0.5}V_{0.5}S_2$ outperforms TiS_2, VS_2, or $Nb_{1.1}S_2$.

Solubility Products of Metal Oxides in Molten Salts by Coulometric Titration of Oxide Ion Through Zirconia Electrodes

M. L. Deanhardt*[,1] and K. H. Stern*

Naval Research Laboratory, Chemistry Division, Washington, D.C. 20375

ABSTRACT

Solubility products of nickel and cobalt oxides in molten NaCl (1100 K) and Na_2SO_4 (1200 K) have been measured by coulometric titration of the respective chlorides ($NiCl_2$, $CoCl_2$) and sulfates ($NiSO_4$, $CoSO_4$) with electrochemically generated oxide ion, using a stabilized zirconia electrode as an oxide pump. The metal oxide equilibria were complicated by competitive paths leading to Na_2O_2, $NaNiO_2$, and $NaCoO_2$ formation. Activity coefficients of soluble nickel and cobalt salts were also determined from a comparison of experimental data and thermodynamic calculations.

A knowledge of the behavior of metal oxides in molten salts is important in understanding corrosion processes in marine-operated gas turbines, molten salt fuel cells and batteries, salt processing baths, and solar energy storage by molten salts. Measurement of the solubility of metal oxides used as protective coatings in such systems is needed. This information should aid in the development of new materials and in the prevention of hot corrosion.

Recent studies (1, 2) have shown that stabilized zirconia (SZ), an oxide-conducting solid electrolyte, can function as an O^{2-} ion pump in molten NaCl at 1100 K and Na_2SO_4 at 1200 K. By applying a voltage to the cell

$$\tfrac{1}{2} O_2 + 2e^- \rightleftarrows O^{2-} \text{ (in melt)} \quad [2]$$

left or right. The O^{2-} activity in the melt is measured potentiometrically with another SZ electrode using the cell

$$\mathrm{Ag} \left| \begin{array}{c} \text{Melt} + \\ \text{AgCl or Ag}_2\text{SO}_4 \text{ (10 m/o)} \end{array} \right| \begin{array}{c} \text{Mullite} \\ (\text{Na}^+) \end{array} \left| \begin{array}{c} \text{Melt} + \\ \text{Na}_2\text{O} \end{array} \right| \text{SZ} \mid \text{O}_2 \text{ (Pt)} \quad [3]$$

The reaction and emf of cell [3] in molten NaCl are

$$2\text{Ag(s)} + \tfrac{1}{2} \text{O}_2\text{(g)} + 2\text{NaCl(l)} \rightleftarrows 2\text{AgCl(l)} + \text{Na}_2\text{O(l)} \quad [4]$$

$$E_{\text{cell}} = E^\circ - \frac{RT}{2\mathbf{F}} \ln \left(\frac{a_{\text{AgCl}}^2 a_{\text{Na}_2\text{O}}}{P_{\text{O}_2}^{1/2} a_{\text{NaCl}}^2} \right) \quad [5]$$

Similarly, the reaction and emf of cell [3] in molten Na_2SO_4 are

$$2\text{Ag(s)} + \tfrac{1}{2} \text{O}_2\text{(g)} + \text{Na}_2\text{SO}_4\text{(l)} = \text{Ag}_2\text{SO}_4\text{(l)} + \text{Na}_2\text{O(l)} \quad [6]$$

$$E_{\text{cell}} = E^\circ - \frac{RT}{2\mathbf{F}} \ln \left(\frac{a_{\text{Ag}_2\text{SO}_4} a_{\text{Na}_2\text{O}}}{P_{\text{O}_2}^{1/2} a_{\text{Na}_2\text{SO}_4}} \right) \quad [7]$$

The SZ electrode in cell [1] (referred to as the generating electrode) serves as an O^{2-} ion source, while the SZ electrode in cell [3] (referred to as the indicating electrode) serves as an O^{2-} ion monitor.

It is known (3-5) that in Na_2O-NaCl and Na_2O-Na_2SO_4 melts, oxide is partially converted to peroxide according to the following reaction

$$\text{Na}_2\text{O} + \tfrac{1}{2} \text{O}_2 \rightleftarrows \text{Na}_2\text{O}_2 \quad [8]$$

At constant O_2 pressure

$$[\text{Na}_2\text{O}_2]/[\text{Na}_2\text{O}] = K_{\text{e1}} P_{\text{O}_2}^{1/2} = K'_{\text{e1}} \quad [9]$$

where the brackets denote mol fractions. Cell [3] responds only to changes in the activity of Na_2O in the melt. The following relationships between the measured emf in Eq. [5] and [7] and equivalents of charge Q passed through cell [1] have been derived and verified (2):

1. Electrolysis of Na_2O into the melt

$$E_{\text{cell}} = E^{\circ\prime} - \frac{RT}{2\mathbf{F}} \ln \left([\text{Na}_2\text{O}]_\text{o} + \frac{Q}{2n(K'_{\text{e1}} + 1)} \right) \quad [10]$$

2. Electrolysis of Na_2O out of the melt

$$E_{\text{cell}} = E^{\circ\prime} - \frac{RT}{2\mathbf{F}} \ln \left[\left([\text{Na}_2\text{O}]_\text{a} - \frac{Q}{2n} \right) \Big/ (K'_{\text{e1}} + 1) \right] \quad [11]$$

where

$$E^{\circ\prime} = E^\circ - \frac{RT}{2\mathbf{F}} \ln \left(\frac{\gamma_{\text{Na}_2\text{O}}\, a_{\text{AgCl}}^2}{P_{\text{O}_2}^{1/2} a_{\text{NaCl}}^2} \right) \quad \text{for NaCl}$$

$$E^{\circ\prime} = E^\circ - \frac{RT}{2\mathbf{F}} \ln \left(\frac{\gamma_{\text{Na}_2\text{O}}\, a_{\text{Ag}_2\text{SO}_4}}{P_{\text{O}_2}^{1/2} a_{\text{Na}_2\text{SO}_4}} \right) \quad \text{for Na}_2\text{SO}_4$$

where n = total number of moles, γ_{Na_2O} = activity coefficient of Na_2O, $[Na_2O]_o$ = initial (impurity) concentration of Na_2O, and $[Na_2O]_a$ = added concentration of Na_2O. It is assumed that the electrolysis is slow enough that the oxide/peroxide equilibrium (Eq. [8]) is maintained at all times.

In the present work, this technique has been applied to the measurement of the solubility products of NiO and Co_3O_4 in NaCl at 1100 K, and NiO and CoO in Na_2SO_4 at 1200 K. Solubility products were determined from coulometric titration curves, obtained by measuring the charge passed through the generating SZ electrode as a function of the emf of the indicating cell [3]. Oxygen pressure above the melts was ~0.2 atm. Activity coefficients of sodium oxide in both NaCl and Na_2SO_4 were needed in order to define the solubility products in terms of mol fractions. Values of γ_{Na_2O} have been reported in an earlier work (6). It is also possible to calculate values of γ_{Na_2O} using the data of Ref. (2). These calculations, along with a comparison of the values of γ_{Na_2O} obtained from the two studies, are given in this work. Gupta and Rapp (7) recently measured the solubility of nickel and cobalt oxide in molten Na_2SO_4 as a function of salt basicity ($\log a_{Na_2O}$). Their results, as well as results of thermodynamic calculations, are compared with the results of this study. A preliminary report of this study (8) can be found elsewhere.

Experimental

Experiments were carried out in a helium-oxygen-filled (20% O_2) dry box (Vacuum/Atmospheres Corporation) with a recirculating dry train in which moisture and CO_2 were generally kept below 1 ppm. The electrodes, cell design, and experimental techniques have been described elsewhere (1, 2). High purity (99.8%) alumina crucibles were used in all experiments.

Reagents.—Reagent grade NaCl and Na_2SO_4 were vacuum-dried at 500°C before use. Anhydrous $NiCl_2$ and $CoCl_2$ (Alfa Products) were used without pretreatment. Anhydrous $NiSO_4$ and $CoSO_4$ were prepared from reagent-grade hydrate salts using a procedure described by Sanderson (9). The prepared salts were analyzed for purity by atomic absorption analysis of Ni and Co. All weighings and transfer operations were carried out in the dry box in which the experiments were done.

Procedures.—The emf of cell [3] was measured with a high impedance electrometer (Keithley Model 616). Cathodic potentials were applied to the generating SZ electrode using a PAR 173 potentiostat/galvanostat. The charge passed through cell [1] was measured with a PAR 179 digital coulometer. Since the coulometric titrations were generally run overnight, charge passed and emf's measured were recorded automatically on a Fluke 2200B data logger.

Least squares fits of the experimental data were calculated using a Hewlett Packard Model 9815S computer and its associated software. The titration curves were plotted with a Hewlett Packard Model 9865A digital plotter interfaced to the 9815S computer.

The melts were analyzed for their Co and Ni content before each titration. Samples were taken by dipping cold ceramic rods (high purity alumina) into the melt. The quenched-melt samples were analyzed using a Perkin Elmer Model 360 atomic absorption spectrophotometer.

Results

Solubility products of nickel and cobalt oxides.—The metal ion was added to the melt as $NiCl_2$ and $CoCl_2$, respectively, in NaCl, and as $NiSO_4$ and $CoSO_4$ in Na_2SO_4. As O^{2-} is coulometrically added to the melt, the insoluble metal oxide precipitates. A plot of emf *vs.* Q results in a titration curve. An example of such a plot is shown in Fig. 1 for the titration of $NiCl_2$ in molten NaCl. Similar titration curves were observed for $CoCl_2$ in a molten NaCl, and $NiSO_4$ and $CoSO_4$ in molten Na_2SO_4.

The reduction of oxygen to oxide could be carried out by either controlled potential electrolysis or controlled current electrolysis. In either case, care was taken not to exceed the electrolysis potential at which zirconia is reduced to substoichiometric ZrO_2 (2). A

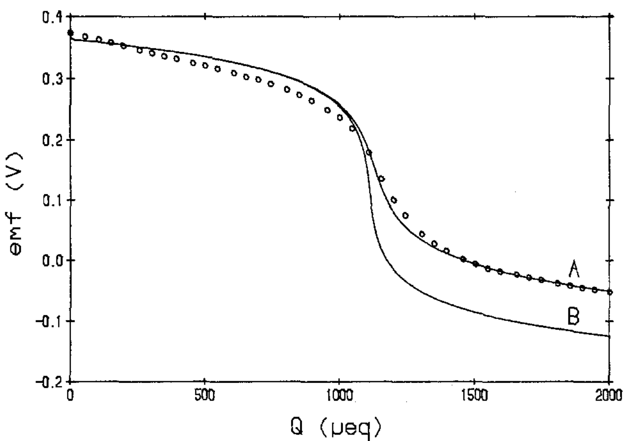

Fig. 1. Titration of $NiCl_2$ with Na_2O in molten NaCl. $[NiCl_2]_o = 3.18 \times 10^{-4}$; $T = 1100$ K; $P_{O_2} = 0.213$ atm; (○) experimental points: (——) least squares fit using Eq. [24]; A. $K_{sp} = 2.8 \times 10^{-12}$, $K_{e1} = 6$, $K_{e2} = 4.4 \times 10^{-4}$; B. $K_{sp} = 2.8 \times 10^{-12}$, $K_{e1} = K_{e2} = 0$.

typical titration took ~24 hr at an electrolysis current of ~2.5 mA and a total Q of ~2000 μequiv. The 24 hr period was ample time for the generated precipitate to equilibrate with the melt. This was substantiated by obtaining similar titration curves at longer time intervals and lower current densities. Close agreement between the calculated and observed end points of the titration curve also indicates precipitate-melt equilibration.

Two stable forms of nickel oxide exist in both molten NaCl and Na_2SO_4. In acidic melts (low oxide activity) the predominant form of nickel is NiO. Before the end point of each titration, the oxide activity remains low due to the following reactions

$$NiCl_2 + Na_2O \rightleftarrows NiO + 2NaCl \quad [12]$$

$$NiSO_4 + Na_2O \rightleftarrows NiO + Na_2SO_4 \quad [13]$$

After all of the nickel precipitates as NiO, the melt becomes basic (high oxide activity). In basic melts, NiO reacts with Na_2O and O_2 to form $NaNiO_2$ (7)

$$Na_2O + 2NiO + \tfrac{1}{2} O_2 \rightleftarrows 2NaNiO_2 \quad [14]$$

(The presence of Na_2NiO_2 in the melt is unlikely, especially in the presence of oxygen. Using thermodynamic data in Table I, the equilibrium constant for the reaction

$$Na_2NiO_2 + \tfrac{1}{4} O_2 \rightleftarrows NaNiO_2 + \tfrac{1}{2} Na_2O \quad [15]$$

is 4.4×10^2 at 1100 K and 1.6×10^2 at 1200 K. At the oxygen pressures and Na_2O activities encountered during the titrations, the activity ratio of $NaNiO_2$ to Na_2NiO_2 would be greater than 10^5.)

The form of cobalt oxide depends on the temperature and oxygen pressure according to the following equilibrium

$$3CoO + \tfrac{1}{2} O_2 \rightleftarrows Co_3O_4 \quad [16]$$

Using thermodynamic data in Table I, the equilibrium pressures of oxygen, P_{O_2}, at 1100 and 1200 K are 0.015 and 0.55 atm, respectively. At 1100 K and 0.2 atm O_2, the stable form of cobalt oxide, Co_3O_4, precipitates up to the end point

$$CoCl_2 + Na_2O + 1/6\, O_2 \rightleftarrows 1/3\, Co_3O_4 + 2NaCl \quad [17]$$

At 1200 K and 0.2 atm O_2, the stable form of cobalt oxide, CoO, precipitates

$$CoSO_4 + Na_2O \rightleftarrows CoO + Na_2SO_4 \quad [18]$$

In basic melts (past the end point), cobalt oxide reacts with Na_2O and O_2 to form sodium cobaltate, $NaCoO_2$, as indicated in the following equations

$$Na_2O + 2/3\, Co_3O_4 + 1/6\, O_2 \rightleftarrows 2NaCoO_2 \quad [19]$$

$$Na_2O + 2CoO + 1/2\, O_2 \rightleftarrows 2NaCoO_2 \quad [20]$$

As sodium oxide is added coulometrically to each melt, three equilibria are established. For example, in the case of nickel in molten NaCl the equilibria are represented by Eq. [8], [12], and [14]. Each titration curve can be derived theoretically by considering all three equilibria simultaneously. For brevity, theoretical calculations are discussed below only for the case of nickel in molten NaCl.

The K_{sp} is defined in terms of the equilibrium constant for reaction [12], *viz.*

$$K_{sp} = 1/K_{12} = [Na_2O]\,[NiCl_2] \quad [21]$$

and the equilibrium constant for reaction [14] is

$$K'_{e2} = K_{e2}P_{O_2}^{1/2} = [NaNiO_2]^2/[Na_2O] \quad [22]$$

The equilibrium constant for reaction [8] is defined in Eq. [9]. Letting Q equal the number of equivalents of charge passed through cell [1], the amount of oxide that reacts to form NiO, Na_2O_2, and $NaNiO_2$ at equilibrium is $Q/2n - [Na_2O]$. It is assumed that the initial Na_2O concentration in the melt is negligible. The amount of NiO formed is $[NiCl_2]_o - [NiCl_2]$, where $[NiCl_2]_o$ is the initial concentration of $NiCl_2$. Combining these two relationships results in the following equation

$$Q/2n - [Na_2O] = [NiCl_2]_o - [NiCl_2] + [Na_2O_2] + \tfrac{1}{2}[NaNiO_2] \quad [23]$$

Substitution of Eq. [9], [21], and [22] into Eq. [23] yields

$$Q/2n - [NiCl_2]_o - K_{sp}(1/[Na_2O]) + K'_{e1} + 1)([Na_2O]) + K'^{1/2}_{e2}([Na_2O]^{1/2}/2) \quad [24]$$

The relationship between $[Na_2O]$ and the emf of cell [3] can be calculated from Eq. [5]

$$[Na_2O] = \exp\left\{\frac{2F}{RT}(E^{\circ\prime} - E_{cell})\right\} \quad [25]$$

$E^{\circ\prime}$ can be calculated from the standard potential of cell [3] (10, 11), the activity coefficient of Na_2O (see Discussion section), and the activity coefficients of the binary salts used in the reference electrode (10, 12). For molten NaCl at 1100 K and 20% O_2, $E^{\circ\prime} = -0.520$V. For molten Na_2SO_4 at 1200 K and 20% O_2, $E^{\circ\prime} = -1.037$V. Substitution of Eq. [25] into Eq. [24] gives the $E_{cell} - Q$ relationship for the titration of $NiCl_2$ with Na_2O in molten NaCl

$$Q/2n - [NiCl_2]_o = -K_{sp}\left[\exp\left\{\frac{2F}{RT}(E^{\circ\prime} - E_{cell})\right\}\right]^{-1} + (K'_{e1} + 1)\left[\exp\left\{\frac{2F}{RT}(E^{\circ\prime} - E_{cell})\right\}\right] + K'^{1/2}_{e2}\left[\exp\left\{\frac{2F}{RT}(E^{\circ\prime} - E_{cell})\right\} \Big/ 2\right] \quad [26]$$

The three equilibrium constants in Eq. [26] were calculated for each titration by multiple regression analysis (13) which provided the minimum sum of squares of differences between the observed and calculated values of Q. Results are listed in Table II. Equilibrium constants in Eq. [26] are defined in terms of mol fractions. The numbers in parentheses indicate the range of the data for four titrations. Equilibrium constants calculated in this manner were used to plot the titration curve labeled A in Fig. 1. In addition, multiple regression analyses were used to determine K_{sp} values

Table I. Thermodynamic data

assuming no peroxide, nickelate, or cobaltate formation (*i.e.*, $K_{e1} = K_{e2} = 0$). The curve labeled B in Fig. 1 was calculated from these data. Due to a calculation error, the B-labeled curves in the preliminary report of this study (8) were plotted incorrectly.

Also included in Table II are equilibrium constants calculated from thermodynamic data in Table I. There are no data reported in the literature for $(\Delta G^\circ_f)_{NaCoO_2}$. In order to carry out the calculations, we have assumed that $(\Delta G^\circ_f)_{NaCoO_2} = (\Delta G^\circ_f)_{NaNiO_2}$.

Activity coefficients of soluble salts of nickel and cobalt.—The data in Table II were used to calculate the activity coefficients of the soluble salts of nickel and cobalt in the two melts. Each activity coefficient was calculated using the experimental equilibrium constant (defined in terms of mol fractions), the thermodynamic equilibrium constant (defined in terms of activities), and the activity coefficient of Na_2O. The calculated values along with literature values are given in Table III. The standard states for the salts are the pure solids (pure liquid for $CoCl_2$) and therefore the activity coefficients measure deviations from Raoult's law. The activity coefficient for $NaCoO_2$ in both NaCl and Na_2SO_4 is based on the assumption that $(\Delta G^\circ_f)_{NaCoO_2} = (\Delta G^\circ_f)_{NaNiO_2}$.

Discussion

The total number of mols of Na_2O added to a NaCl or Na_2SO_4 melt was determined by measuring the charge passed through the generating SZ electrode. The indicating SZ electrode, which monitors the unreacted oxide ion in the melt, responds only to the activity of sodium oxide. In order to measure the solubility products of nickel and cobalt oxides in terms of mol fractions, it is necessary to know the activity coefficient of Na_2O in these systems.

In a recent study, Stern (6) reported the activity coefficients of Na_2O in molten NaCl (1100 K) and Na_2SO_4 (1200 K) to be 1.07×10^{-4} and 3.6×10^{-4}, respectively. These data indicated large negative deviations from Raoult's law for the Na_2O-NaCl and Na_2O-Na_2SO_4 melts. The work was based on the cell reaction

$$\tfrac{1}{2}\,W(s) + Na_2O(s) + \tfrac{1}{2}\,O_2(g) = \tfrac{1}{2}\,WS_2(s) + Na_2O(l) \quad [27]$$

The activity of Na_2O in the melt was measured with an SZ electrode. The mol fraction of Na_2O was calculated from the added amount of Na_2O, the known equilibrium constant of Eq. [9], and the assumption that $\gamma_{Na_2O_2} = \gamma_{Na_2O}$.

In another recent work (2), we reported on the use of the SZ electrode to transport oxide ion into and out of molten salts. The cell reactions were the same as in this study (reactions [4] and [6]). Oxide ion was added electrochemically to molten NaCl and Na_2SO_4 via the SZ electrode, experimentally verifying the E_{cell}-log Q relationship of Eq. [10]. When $Q/2n(K'_{e1} + 1) >> [Na_2O]_o$, experimental plots of E_{cell} *vs.* log Q were linear with the expected $-2.303RT/2F$ slopes. The value of γ_{Na_2O} can be calculated from the intercept of the E_{cell} -log Q plot. The intercept is equal to $E^{\circ\prime} + 2.303RT/2F \log [2n(K'_{e1} + 1)]$, where γ_{Na_2O} is included in the $E^{\circ\prime}$ term. Again, if one assumes that $\gamma_{Na_2O_2} = \gamma_{Na_2O}$, the value of K'_{e1} can be calculated from the thermodynamic data in Table I. From these calculations, the average values of the activity coefficients of Na_2O in molten NaCl (1100 K) and Na_2SO_4 (1200 K) are 1.7×10^{-4} and 4.5×10^{-4}, respectively.

Activity coefficients from the two works are thus in reasonable agreement with one another, well within a factor of two. Since the cell reactions in this work and the work of Ref. (2) are the same, and the electrochemical addition of Na_2O is probably more accurate than the direct addition of Na_2O, we believe that the numbers, 1.7×10^{-4} and 4.5×10^{-4}, are the more reliable values of γ_{Na_2O} and are therefore used in this study.

The data in Table II indicate that the major reaction of Na_2O in the melts is formation of the insoluble metal

Table III. Activity coefficients of soluble salts of nickel and cobalt

Melt	Salt	γ (This work)*	γ (Literature)	Reference
NaCl (1100 K)	$NiCl_2$	$(2.2\text{-}5.8) \times 10^{-2}$	2.36×10^{-2}	(14)

		$Na_2O + 2CoO + 1/2\ O_2 \rightleftarrows 2NaCoO_2$	$(0.4\text{-}3.9) \times 10^{-2}$	1.54×10^{2}†

* Defined in terms of mol fractions.
** Defined in terms of activities.
† Assuming $(\Delta G^\circ_f)_{NaCoO_2} = (\Delta G^\circ_f)_{NaNiO_2}$.

oxides: NiO, Co_3O_4, and CoO. The competing equilibria (i.e., peroxide, nickelate, or cobaltate formation) are not significant before the end points of the titrations. This is borne out by curves A and B in Fig. 1. Curve A (competing equilibria assumed) and B (competing equilibria ignored) are identical up to the end point of a titration. This also explains the close agreement between the observed and calculated end points as shown in Table IV. The observed end point was determined by taking the second derivative of the titration curve; the calculated end point was based on the initial amount of metal added to the melt.

The titration curves strongly suggest that competing equilibria exist in these systems. The Na_2O activities after the end points are lower than one would expect based only on metal oxide formation. Formation of peroxide and nickelate or cobaltate would indeed lower the activity of Na_2O after the titration end point. Confirmation of Na_2O_2 in NaCl and Na_2SO_4, and $NaNiO_2$ in Na_2SO_4 has been reported in the literature (3, 4, 7).

The calculated activity coefficients for $NiCl_2$ and $CoCl_2$ in molten NaCl (Table III) agree very well with values reported by Hamby and Scott (14, 15). Comparable values of the activity coefficients of $NaNiO_2$ and $NaCoO_2$ in molten NaCl were not available in the literature. The calculated activity coefficients of soluble salts of nickel and cobalt in molten Na_2SO_4 were compared with data of Gupta and Rapp (7). In order to compare the activity coefficients for $NaNiO_2$ with the value obtained by Gupta and Rapp, their value of $\Delta G°_f$ was changed to that used in this work. Good agreement occurs for the activity coefficients of $NaNiO_2$ and $NaCoO_2$; however, our activity coefficients for $NiSO_4$ and $CoSO_4$ were at least a factor of ten lower than those reported by Gupta and Rapp.

Another way of expressing the data in Table II is to report the solubility of nickel and cobalt oxides as a function of salt basicity ($-\log a_{Na_2O}$). This type of information should assist in developing better materials to combat molten salt corrosion. Plots of solubility *vs.* salt basicity are given in Fig. 2 and 3. Solubilities are defined in terms of the soluble metal concentration. For example, in the case of NiO in molten NaCl, the solubility is equal to the sum of $[NiCl_2] + [NaNiO_2]$. Each of the concentrations can be calculated as a function of sodium oxide activity using the appropriate equilibrium constants reported in Table II. Solid lines in Fig. 2 and 3 indicate the actual range of sodium oxide activities encountered during the titrations; dashed lines are extrapolated values.

The solubility of NiO in molten Na_2SO_4 (curve A) is compared to the data of Gupta and Rapp (7) (curve C) in Fig. 3. The curves agree well in terms of the position of minimum solubility; however, the solubility of NiO determined in this study is about an order of magnitude higher than that reported by Gupta and Rapp. Their data were calculated at an oxygen pressure of 1 atm instead of the 0.2 atm used in this study, but this difference would only slightly shift the solubility at high sodium oxide activities, since $[NaNiO_2]$ is dependent on P_{O_2}.

Conclusions

The results of this study clearly show that the SZ electrode can be used to determine the solubility products of metal oxides in molten salts. Solubility products of NiO and CoO (Co_3O_4 in molten NaCl) have been determined in molten NaCl and Na_2SO_4 as have equilibrium constants of competing equilibria leading to the formation of Na_2O_2, $NaNiO_2$, and $NaCoO_2$. Activity coefficients of soluble salts of nickel and cobalt were also calculated and compared with literature values.

Table IV. Typical titration curve end points

Adsorption of Benzo-(f)-Quinoline on Gold and the Kinetics of the Quinone-Hydroquinone and the Iron(III)/Iron(II) Systems

G. M. Schmid* and T. A. Holmes[1]

Department of Chemistry, University of Florida, Gainesville, Florida 32611

ABSTRACT

The adsorption of benzo-(f)-quinoline on gold electrodes in 1.0M H_2SO_4 was estimated from differential capacity data. Between 0.0 and +0.7V adsorption is nearly independent of potential and can be fitted equally well to the Frumkin isotherm and to the isotherm with virial coefficients, $\Delta G^\circ_{ads} \simeq -35$ kJ mol^{-1}. Apparent standard rate constants for the quinone-hydroquinone system were obtained from low overpotential (±20 mV) and those for the Fe(III)-Fe(II) system from impedance (20-800 Hz) measurements. For the quinone-hydroquinone system the rate constant decreases exponentially with benzo-(f)-quinoline coverage from $k_a^\circ = 2.0 \times 10^{-3}$ cm sec^{-1} at $\theta = 0$ to $k_a^\circ = 3.2 \times 10^{-4}$ cm sec^{-1} at $\theta = 0.40$. For the Fe(III)-Fe(II) system the decrease is from $k_a^\circ = 1.3 \times 10^{-2}$ cm sec^{-1} at $\theta = 0$ to $k_a^\circ = 4.2 \times 10^{-3}$ cm sec^{-1} at $\theta = 0.20$, again exponential in θ. The decrease cannot be explained by changes in the outer Helmholtz plane, $\Delta\phi_2$, caused by benzo-(f)-quinoline, since $\Delta\phi_2$'s calculated for the quinone-hydroquinone system are 3 to 4 times larger than those obtained for Fe(III)-Fe(II). The decreases are ascribed to changes in free energy of activation due to interaction between the adsorbed layer and electroactive species.

The ability of organic and inorganic molecules and ions adsorbed at interfaces to control the rate of an electrochemical reaction has long been of interest. Such a substance may exert this control in several ways: (*i*) The substance may form a surface film which acts as a physical barrier to restrict the diffusion of ions or molecules to or from the electrode surface. (*ii*) The interaction of the substance with the surface metal atoms may prevent these metal atoms from participating in the electrochemical reaction. This simple blocking effect decreases the number of surface metal atoms at which reaction can occur, in proportion to the coverage at the electrode surface. (*iii*) If the electrode reaction involves the formation of adsorbed intermediates, the presence of adsorbed substances may interfere with the formation of these intermediates. Reaction may then proceed by alternate paths through other intermediates containing the adsorbed substances, thus affecting the activation energy of the reaction. (*iv*) Finally, the adsorption of substances on the electrode may change the structure of the electrical double layer at the electrode solution interface, which will affect the rates of the electrochemical processes (1).

Key words: electrochemical kinetics and adsorption, quinone-hydroquinone, Fe(III)-Fe(II), benzo-(f)-quinoline coverage, Au electrodes.

The substances in question frequently act as inhibitors. It is often not possible to assign a simple general mechanism of action to an inhibitor because the mechanism may change with experimental conditions such as inhibitor concentration, the pH of the solution, the nature of the anions in the solution, the nature of the metal, and the extent of reaction to form secondary inhibitors. One approach to a better understanding of the mechanism by which corrosion inhibitors operate is to simplify the electrochemical system. Thus, much work has been done in determining the effect of the adsorption on mercury and solid metals of organic inhibitors on the kinetics of simple charge transfer reactions (2-5).

Weber *et al.* (6) and Kuta and Smoler (7) as well as Müller and Lorenz (8) were among the first to suggest the equation

$$k_\theta = (1 - \theta)\, k_{\theta=0} + \theta k_{\theta=1} \quad [1]$$

for the standard rate constant, k_θ, of an electrochemical reaction at a given value of the fractional coverage, θ. Here $k_{\theta=0}$ and $k_{\theta=1}$ are the value of the standard rate constant for $\theta = 0$ and $\theta = 1$, respectively. For $k_{\theta=0} >> k_{\theta=1}$ and $\theta < 1$, Eq. [1] becomes the "blocking equation"

$$k_\theta \simeq (1 - \theta)\, k_{\theta=0} \quad [2]$$

Sathyanarayama (9) suggested the following relation to describe his experimental results

$$k_\theta = (1 - \theta)^b k_{\theta=0} \quad [3]$$

where b is a constant ($b > 1$) which accounts for lateral repulsive interaction between adsorbate molecules. Niki and Hackerman (10) have suggested that the electrochemical reaction will proceed only at those sites where at the same time b water molecules are present on the electrode surface and that the surface area occupied by such an aggregate will correspond to the cross section of the activated complex. The probability of finding b water molecules simultaneously in neighboring positions is $(1 - \theta)^b$, so that a relationship of the type of Eq. [3] may be expected. Lipkowski and Galus (11) obtained Eq. [3] by using the Flory-Huggins (12) isotherm in describing the adsorption of the activated complex.

Substantial deviations from these relations are observed (11, 13-16). To account for these deviations Parsons (17) proposed after Frumkin (18) that the change in the potential at the outer Helmholtz plane (OHP), due to surfactant adsorption, be taken into account when interpreting kinetic data. Damaskin and Afanas'ev (4) have suggested that the potential at the plane corresponding to the center of the activated complex may be useful in describing the electrochemical reaction rate as a function of fractional coverage. This potential can differ from that calculated by Parsons' method. Sathyanarayama (19) discusses an elementary electrostatic model where the dipole and its mirror image give rise to a potential at the site where the activated complex is located.

During surfactant adsorption on the electrode surface, one can expect a change in the interaction between the electroactive species and the surface layer as the solvent molecules are replaced by adsorbate molecules. A change in the free energy of activation of the electrochemical reaction following the change in the surface layer structure during adsorption can be taken into account in terms of the activity coefficient of the electroactive species in the transition state of the reaction. This idea has been formalized by Parsons (20), Danilov and Loshkarev (21), Avilova *et al.* (22), and Afanas'ev and Ternovskoi (23) to various degrees of complexity and usefulness.

The effect of the adsorption of benzo-(f)-quinoline on electrochemical reaction rates has been studied by several authors (24-29). However, a correlation between fractional coverage data and rate constants is still not available. The present work is an attempt at such a correlation on gold electrodes for the Fe(II)/Fe(III) and the quinone/hydroquinone system.

Experimental

A four electrode system was used consisting of test electrode, polarizing electrode, auxiliary electrode, and reference electrode.

The test electrode was a gold bead of 0.13 cm^2 geometric area made by heating a 7.9×10^{-3} cm diam wire of fine gold (Engelhard Industries) in a hydrogen-air flame. The electrode was inserted into a Teflon holder and the assembly slipped into a glass tube which could be mounted in the top of the cell. The electrode was cleaned with warm chromic-sulfuric acid solution and rinsed thoroughly with triply distilled water.

The polarizing electrode was a 1.0 mm diam platinum wire bent into a circle such that the test electrode was in the center and in the same horizontal plane as the polarizing electrode. The auxiliary electrode was a platinum cylindrical gauze (Engelhard Industries) of approximately 500 cm^2 apparent surface area. Both of these electrodes were plated with gold from a thiosulfate bath prepared according to Zak (30). The reference electrode was a saturated calomel electrode (SCE). All potentials are reported *vs.* the normal hydrogen electrode (NHE).

All solutions were prepared from water distilled from alkaline permanganate and twice more from a quartz still. The supporting electrolyte was 1.0M sulfuric acid made from Mallinckrodt ACS grade 98% sulfuric acid. It was purified by electrolyzing between gold electrodes for 12 hr at 10 mA. Ferric sulfate and ferrous sulfate stock solutions, 0.1M each, were prepared from Fisher Scientific Company certified reagent ferric sulfate and ferrous sulfate, respectively. The test solutions were prepared volumetrically from the standardized stock solutions using deaerated, electrolyzed 1.0M sulfuric acid for dilution. Quinone and hydroquinone test solutions were prepared gravimetrically just prior to each experiment from Fisher Scientific Company purified grade quinone and J. T. Baker purified grade hydroquinone. A 0.1M benzo-(f)-quinoline (R.S.A. Corporation) stock solution was prepared gravimetrically without further purification.

The electrochemical cell was cleaned daily with warm chromic-sulfuric acid and thoroughly rinsed with electrolyzed supporting electrolyte. Prior to making measurements, the electrochemical cell was purged of oxygen with a constant stream of helium (99.99%) for at least 30 min. During measurements helium was passed over the test solution. The test solution was replaced at least three times a day with fresh solution. This procedure produced reproducible results.

Prior to the kinetic measurements, the differential capacity was measured in supporting electrolyte alone or with benzo-(f)-quinoline at 17 different potentials between −0.05 and 1.65V. Polarization of the test electrode was accomplished using a Sensitive Research Instrument Corporation potentiometer/voltmeter. The test solution was potentiostated at −0.05V and deaerated for 30 min. Measurements were taken every 10 min (20 min for high concentrations of benzo-(f)-quinoline) at 100 mV intervals in quiescent solutions and were made in the anodic direction only. At the end of each run, the solution was replaced with fresh solution and the procedure repeated. At each potential, data were taken between 350 and 10,000 Hz (usually at five frequencies) using a General Radio 1608-A bridge with an external oscillator (General Radio 1310-A). The amplitude of the alternating current applied to the electrode was less than 5 mV rms and was monitored with a Hewlett-Packard Model 400 HR vacuum tube voltmeter. An external null detector (General Radio Model 1232-A) was used for bridge balance. The bridge was operated in the floating mode. A 10 Henry choke isolated the d-c from the a-c circuits. Potentials were measured *vs.* SCE using a Keithley 610 BR electrometer ($10^{14}\Omega$ input impedance). To achieve bridge balance, it was sometimes necessary to insert a decade resistor (General Radio 1432-J) in series with the internal resistor of the bridge.

The supporting electrolyte solution was then replaced by the electrochemically active test solution. The test solutions were stirred for 15 min prior to the taking of any measurements. The kinetics of the quinone-hydroquinone system were determined from steady-state low overpotential-current density data. Measurements were made over a range of 20 mV through the equilibrium potential in 2.5 mV steps using a Wenking 61 TRS potentiostat monitored by a Keithley 660 guarded differential voltmeter. Apparent effective exchange currents were obtained from the slopes of the potential-current curves. The Fe(II)/Fe(III) system was studied using the faradaic impedance technique. The total impedance of the cell was measured as a function of the frequency between 20 and 800 Hz. The solution resistance and the differential capacitance were subtracted (31) and the series resistive and capacitive components of the reaction impedance plotted *vs.* $\omega^{-1/2}$.

Results and Discussion

Adsorption of benzo-(f)-quinoline in 1M sulfuric acid solutions.—The base dissociation constant in aqueous solution for benzo-(f)-quinoline is 7.76×10^{-6} (32). Hence in acidic solutions this compound will be protonated to the quinoline cation.

Differential double layer capacitance *vs.* potential data in 1M H_2SO_4 with various concentrations of benzo-(f)-quinoline are shown in Fig. 1. The double layer capacity was obtained by extrapolation of the straight-line plots of capacity *vs.* $\omega^{-1/2}$ to infinite frequency. Frequency dispersion in the range measured was $< 10\%$. The 1M H_2SO_4 curve is characterized by an ever increasing capacitance up to +0.8V where a small maximum occurs followed by a slight decrease in capacitance up to +1.2V. At this point a rapid decrease in capacitance occurs indicating the adsorption of water.

Upon the addition of benzo-(f)-quinoline to the sulfuric acid solution, a substantial reduction in the differential capacitance is seen for each concentration until at 0.1M benzo-(f)-quinoline a virtually flat capacitance-potential curve is obtained between +0.4 and +1.4V. At concentrations of benzo-(f)-quinoline greater than 1.0×10^{-5}M it is seen that even at +1.6V the capacitance does not attain the same magnitude as that found in 1M H_2SO_4 indicating that the adsorption of water is hindered by the presence of the benzo-(f)-quinoline.

The fractional coverage for each concentration studied of benzo-(f)-quinoline between 0.0 and +1.2V was calculated according to (33)

$$C_\theta = (1 - \theta)\, C_{\theta=0} + \theta C_{\theta=1} \quad [4]$$

Where C_θ is the differential capacity at coverage θ, and $C_{\theta=0}$ and $C_{\theta=1}$ are the corresponding capacities at $\theta = 0$ and $\theta = 1$, respectively. The capacities measured in 0.1M benzo-(f)-quinoline were assumed to represent $C_{\theta=1}$. This is probably a very good assumption since the capacitance data for 0.01 and 0.1M benzo-(f)-quinoline did superimpose for the potentials between 0.8 and 1.2V and were very similar over the remainder of the potential region covered. The results are shown in Fig. 2. Each of the fractional coverage curves shows a small minimum centered at +0.3V. Only the 10^{-5}M benzo-(f)-quinoline curve shows a decreasing fractional coverage with increasing potential. The remaining three higher concentrations increase with increasing potential.

Curve A, 1.0M H_2SO_4; curve B, 1.0M H_2SO_4 plus 1.0×10^{-5}M benzo-(f)-quinoline; curve C, 1.0M H_2SO_4 plus 1.0×10^{-4}M benzo-(f)-quinoline; curve D, 1.0M H_2SO_4 plus 1.0×10^{-3}M benzo-(f)-quinoline; curve E, 1.0M H_2SO_4 plus 1.0×10^{-2}M benzo-(f)-quinoline; curve F, 1.0M H_2SO_4 plus 1.0×10^{-1}M benzo-(f)-quinoline.

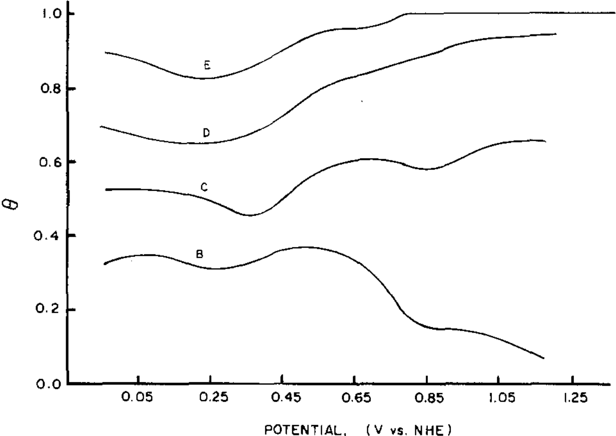

Fig. 2. Fractional coverage, θ vs. potential in 1.0M H_2SO_4 with various concentrations of benzo-(f)-quinoline. Curve B, 1.0M H_2SO_4 plus 1.0×10^{-5}M benzo-(f)-quinoline; curve C, 1.0M H_2SO_4 plus 1.0×10^{-4}M benzo-(f)-quinoline; curve D, 1.0M H_2SO_4 plus 1.0×10^{-3}M benzo-(f)-quinoline; curve E, 1.0M H_2SO_4 plus 1.0×10^{-2}M benzo-(f)-quinoline.

Between 0.0 and +0.7V the fractional coverage-concentration curves can be fitted equally well to the Frumkin isotherm (34) and to the isotherm with virial coefficients (35), two isotherms especially suited to the adsorption of organic molecules. The results are shown in Table I. Both isotherms have an arbitrary constant, a, which represents the two-dimensional interaction between the adsorbed particles. In all cases, the constant is less than zero, indicating a repulsion between adsorbed molecules. Both isotherms show similar variation in the parameters a and B with potential with a being smallest and B largest at +0.3V. This behavior might be expected from a large organic molecule close to the potential of zero charge. The latter has been reported in the vicinity by various authors (36). Adsorption is almost independent of potential as indicated by the almost constant free energy of adsorption, ΔG°_{ads}.

Electrochemical kinetics of the quinone-hydroquinone system.—Typical plots of the current density *vs.* overpotential are shown in Fig. 3. From the slopes of the least squares straight lines (correlation coefficient 0.9959) the apparent effective exchange current densities were calculated using the low overvoltage approximation (37), assuming a one-step, two-electron reaction. These results are shown in Table II along with the experimentally determined equilibrium potential, E_e.

The charge transfer coefficient, α, and the apparent standard rate constant, k_a°, were determined using the following expressions

Table I. Calculated values of a, B, and ΔG°_{ads} for the Frumkin isotherm and the isotherm with virial coefficients

	Frumkin isotherm*			Isotherm with virial coefficients**		
E (V)	a	B × 10^{-5} (l/mol)	ΔG°_{ads} (kJ/mol)	a	B × 10^{-6} (l/mol)	ΔG°_{ads} (kJ/mol)

* Frumkin isotherm: $Bc = \frac{\theta}{1 - \theta} \exp(-2a\theta)$.

** Isotherm with virial coefficients: $Bc = \theta \exp(-2a\theta)$.

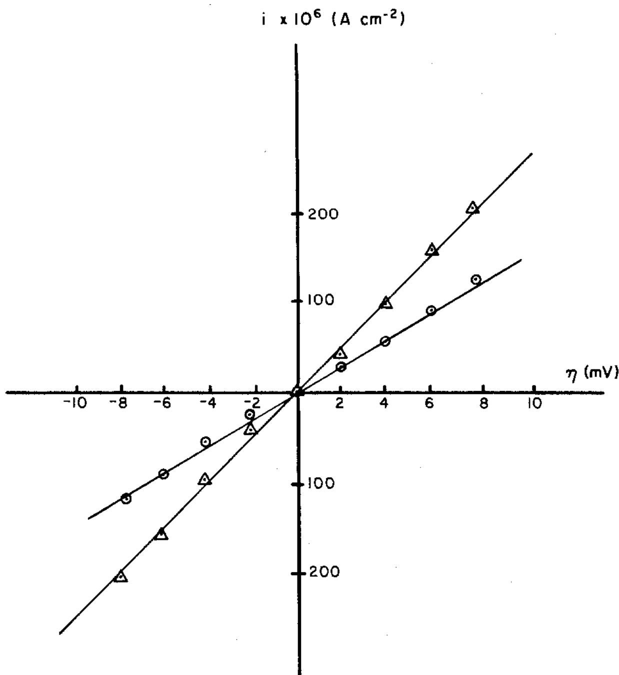

Fig. 3. Typical plots of current density vs. overpotential for the quinone-hydroquinone electrochemical system in 1.0M H_2SO_4. △ 7.47 × 10^{-4}M quinone plus 9.79 × 10^{-4}M hydroquinone; ⊙ 7.47 × 10^{-4}M quinone plus 2.40 × 10^{-4}M hydroquinone.

$$\ln (i_o/c_Q) = -\alpha n\mathbf{F}E_e/RT + \ln (n\mathbf{F}k_a^o) \quad [5]$$

$$\ln (i_o/c_{H_2Q}) = (1 - \alpha)\, n\mathbf{F}E_e/RT + \ln (n\mathbf{F}k_a^o) \quad [6]$$

The plot is shown in Fig. 4. The standard rate constant was found to be 1.98 × 10^{-3} cm sec^{-1} at a formal potential of 0.6879V. The cathodic charge transfer coefficient determined from the variation of the quinone concentration was 0.57, and from the variation of the hydroquinone concentration it was 0.38. This discrepancy may indicate that the reaction proceeds as two separate one-electron steps and not as a concerted two-electron transfer. This result is not unexpected and has been observed by other investigators (38-41). In this case, the measured effective exchange current represents $2i_{0,1}i_{0,2}/(i_{0,1} + i_{0,2})$, where $i_{0,1}$ and $i_{0,2}$ are the exchange currents of the two separate steps.

Electrochemical kinetics of the quinone-hydroquinone system in 1.0M H_2SO_4 with benzo-(f)-quinoline.—The results of the kinetic experiments in the presence of benzo-(f)-quinoline are presented in Table III together with the corresponding data for 1.0M H_2SO_4. It is seen that the charge transfer coefficient increases with increasing benzo-(f)-quinoline concentration, but then decreases again. It is felt that

Table II. Apparent exchange current densities, i_o^a, and equilibrium potentials at various quinone, Q, and hydroquinone, H_2Q, concentrations in 1.0M H_2SO_4

Solution	i_o^a × 10^6 (A cm^{-2})	E_e (V vs. NHE)
2.81 × 10^{-4}M Q	182	0.6759
5.18 × 10^{-4}M Q	222	0.6893
1.11 × 10^{-4}M Q	309	0.6935

2.01 × 10^{-3}M H_2Q	472	0.6767

Q concentration = constant = 7.47 × 10^{-4}M.

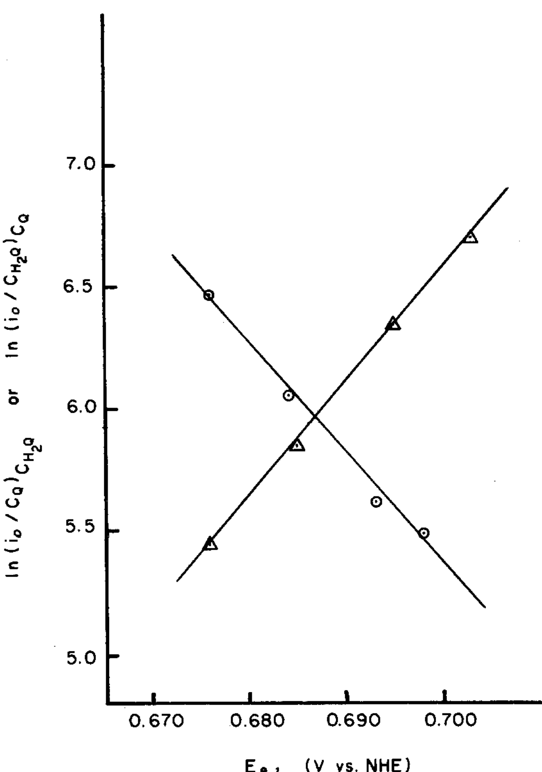

Fig. 4. Plot of ln (i_o/c_Q) and ln (i_o/c_{H_2Q}) vs. E_e for the variation of the concentration of quinone, ⊙, with constant hydroquinone concentration, and for the variation of the concentration of hydroquinone, △, with constant quinone concentration in 1.0M sulfuric acid.

this behavior does not represent a change in mechanism, but is the result of normal experimental error. The average value of the charge transfer coefficient for the variation of the quinone concentration was found to be 0.54 ± 0.09, and for the variation of the hydroquinone concentration 0.44 ± 0.05. The formal potential was found to be 0.6877 ± 0.0017V, independent of the concentration of benzo-(f)-quinoline. The dependence of the standard rate constant on coverage is logarithmic and this is shown in Fig. 5. In 1.0 × 10^{-2}M benzo-(f)-quinoline (θ = 0.75) and in 1.0 × 10^{-1}M benzo-(f)-quinoline (θ = 1.0), the experimentally determined values of the current density with applied overvoltage were those of background only and were not different from those determined in 1.0M H_2SO_4 with no electroactive species added.

Everett *et al.* (40) studied the quinone-hydroquinone system on rhodium in 1.0M $HClO_4$. The standard rate constant was determined at various coverages of

Table III. Charge transfer coefficient, standard rate constant, and $\Delta\phi_2$ for the quinone-hydroquinone system, in 1.0M H_2SO_4 with and without added benzo-(f)-quinoline

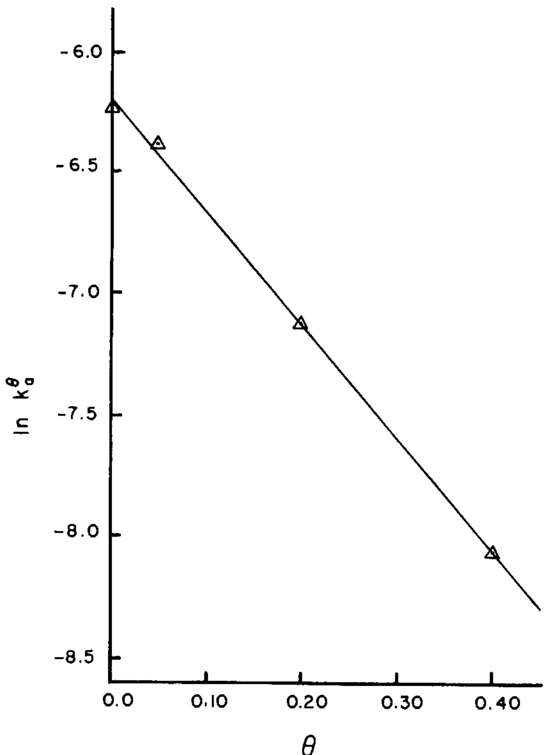

Fig. 5. Variation of the standard rate constant with fractional coverage for the quinone-hydroquinone system.

oxygen and was found to decrease linearly up to $\theta = 0.75$ and remain constant at higher coverages. This behavior was explained as being due to the geometric blocking model showing that the charge transfer reaction is much more rapid at free rhodium than at oxygen-covered rhodium. However, the model cannot explain the logarithmic dependence found here for benzo-(f)-quinoline.

Due to the adsorption of the benzo-(f)-quinoline, the potential at the OHP, ϕ_2, will change as the concentration is varied. In the absence of a geometric blocking effect, the change in this potential, $\Delta\phi_2$, can be calculated according to (17)

$$\frac{k_a^\theta}{k_a^\circ} = \exp\left\{-(Z + n\alpha)\frac{\mathbf{F}}{RT}\Delta\phi_2\right\} \quad [7]$$

where k_a^θ is the standard rate constant at some fractional coverage θ, and Z is the charge of the reduced species. The results of these calculations are included in Table III.

Changes in the surface layer structure resulting from interaction between electroactive species and the surface layer will alter the free energy of activation and this will result in the inhibition or acceleration of the electrochemical reaction. Afanas'ev and Ternovskoi (23) and Avilova *et al.* (22) have suggested that in the presence of adsorbed molecules, the concentration of the electroactive species within the surface layer is determined by an additional free energy term associated with the transfer of electroactive molecules from the bulk of the solution into the structured surface layer. They suggested the equation (23)

$$k_a^\theta = k_a^\circ \exp(-2a\gamma\theta)$$

where a is a constant characterizing the interaction between the adsorbate molecules and γ is a constant describing the degree to which the surface layer is disturbed when an electroactive molecule is incorporated into the surface layer. Thus a plot of ln (k_a^θ/k_a°) *vs.* θ should yield a straight line with a slope of $-2a\gamma$. This is indeed observed as is evident in Fig. 5. The least squares fit for the line is ln $(k_a^\theta/k_a^\circ) = -4.80\theta + 0.09$. The intercept of $+ 0.09$ is small and can be ascribed to experimental error.

Electrochemical kinetics of the Fe(II)/Fe(III) system.—A typical plot of the resistive and capacitive components of the faradaic impedance is shown in Fig. 6. The plots are linear and are nearly parallel. Thus, R_r is the sum of charge transfer and diffusion impedance and $1/\omega C_r$ is solely the diffusion impedance. The charge transfer resistance can then be determined by extrapolating the reaction resistance to infinite frequency, $1/\omega^{1/2} = 0$, since the diffusion impedance then goes to zero.

From the charge transfer resistance the apparent exchange current densities were calculated and are shown in Table IV, together with the observed equilibrium potentials. From these data the charge transfer coefficient was found to be 0.58 for the variation of the Fe(III) concentration at constant Fe(II) concentration and 0.51 for the variation of the Fe(II) concentration at constant Fe(III) concentration. The standard rate constant is 1.30×10^{-2} cm sec^{-1} at the formal potential of 0.6678V.

The Fe(II)/Fe(III) system is a well-studied reaction due to its simplicity (38). On platinum Gerischer (42) found the charge transfer coefficient to be 0.58 in 1.0M H_2SO_4 and the standard rate constant was 3×10^{-3} cm sec^{-1}. In 1.0M $HClO_4$ Randles and Somerton (43) found the standard rate constant to be 5×10^{-3} cm sec^{-1}. Anson (44) determined the standard rate constant for the iron system in 1.0M H_2SO_4, 1.0M $NaHSO_4$, and 1.0M $NaHSO_4$ plus 1.0M Na_2SO_4 and found that the rate constant was highest at 5.3×10^{-3} cm sec^{-1} in 1.0M H_2SO_4 solution and decreased to 2.7×10^{-3} cm sec^{-1} and 1.4×10^{-3} cm sec^{-1} for the 1.0M $NaHSO_4$ and 1.0M $NaHSO_4$ plus 1.0M Na_2SO_4 electrolytes, respectively. Angell and Dickinson (45) found 7×10^{-3} cm sec^{-1} in 0.5M H_2SO_4 and Samec and Weber (46) obtained 3.2×10^{-3} cm sec^{-1} in 0.5M H_2SO_4 and 8.0×10^{-3} cm sec^{-1} in 0.5M Na_2SO_4 of *p*H of 2.2. On rhodium in 1.0M $HClO_4$ the charge transfer coefficient is 0.59 and the standard rate constant 4.60 $\times 10^{-4}$ cm sec^{-1} (40). This rate constant is generally lower than usually found for the Fe(II)/Fe(III) system, but this is probably due to the electrode material used.

It is seen that the charge transfer coefficient determined in this work on gold is in agreement with those values determined by other investigators. The standard rate constant determined here, 1.30×10^{-2} cm sec^{-1}, is in good agreement with the value of 1.0 $\times 10^{-2}$ cm sec^{-1} found in 0.5M H_2SO_4 (45). Both are

Solution	Charge transfer resistance (Ω)	$i_0^a \times 10^3$ (A cm^{-2})	E_e (V vs. NHE)
1.25×10^{-3}M Fe(III)	58.6	3.37	0.6283
2.01×10^{-3}M Fe(III)	40.7	4.86	0.6427
3.57×10^{-3}M Fe(III)	33.0	5.98	0.6605
6.66×10^{-3}M Fe(III)	27.9	7.08	0.6749
1.29×10^{-2}M Fe(III)	24.3	8.15	0.6740
Fe(II) concentration = constant = 4.75×10^{-3}M			
1.19×10^{-3}M Fe(II)	69.5	2.84	0.6940
2.38×10^{-3}M Fe(II)	52.3	3.78	0.6785
4.75×10^{-3}M Fe(II)	33.0	5.98	0.6608
9.50×10^{-3}M Fe(II)	25.6	7.72	0.6443
1.90×10^{-2}M Fe(II)	20.6	9.58	0.6290
Fe(III) concentration = constant = 3.57×10^{-3}M			

higher by a factor of 10^2 than the one determined by Bockris *et al.* in 1M H_2SO_4 (47).

Electrochemical kinetics of the Fe(II)/Fe(III) system in 1.0M H_2SO_4 with benzo-(f)-quinoline.—The results of the kinetic experiments in the presence of benzo-(f)-quinoline are presented in Table V together with the corresponding data for 1.0M H_2SO_4. Experiments at 1.0×10^{-3}M benzo-(f)-quinoline ($\theta = 0.40$) were highly irreproducible and are omitted.

The standard rate constant found in 1.0M H_2SO_4, 1.30×10^{-2} cm sec^{-1}, decreased to 1.01×10^{-2} cm sec^{-1} in 1.0×10^{-5}M benzo-(f)-quinoline and to 4.21×10^{-3} cm sec^{-1} in 1.0×10^{-4}M benzo-(f)-quinoline. In 1.0×10^{-5}M benzo-(f)-quinoline, the charge transfer coefficient is 0.48, and 0.51 in 1.0×10^{-4}M benzo-(f)-quinoline. These two values are generally lower than those found in the literature, but agree well with the charge transfer coefficient found in 1.0M H_2SO_4 for the variation of Fe(II) concentration ($\alpha = 0.51$). In the presence of 1.0×10^{-5}M benzo-(f)-quinoline the formal potential was found to be 0.6704V, and for 1.0×10^{-4}M benzo-(f)-quinoline the formal potential was 0.6708V. These values are in good agreement with the formal potential calculated in 1.0M H_2SO_4 ($E°_F = 0.6678$V).

A comparison of the $\Delta\phi_2$ values calculated according to Eq. [7] with those obtained for the quinone-hydroquinone system (Tables III and V) shows the latter to be larger by a factor of 2-4. This would indicate that changes in the ϕ_2 potential are not the principal cause for the reduction in the standard rate constant, although the effective ϕ_2 potential may well be different for the two systems because of differences in the distance of closest approach. Still the decrease in the rate constant with coverage appears to be logarithmic, $\ln (k_a^\theta/k_a^o) = -5.68\theta + 0.01$. This may well indicate that both systems are inhibited by similar mechanisms. Again, the intercept, +0.01, is small and probably due to experimental error.

The explanation that the adsorption of benzo-(f)-quinoline increases the free energy of activation due to interaction between adsorbed layer and electroactive species is reasonable since the adsorbed layer is expected to increase the positive charge of the electrode surface by elimination of sulfate species during adsorption. This effectively increases the electrostatic repulsion between the more positively charged surface layer and the electroactive species, here positively charged also. Thus, electrostatic repulsion in the Fe(II)/Fe(III) system plays a role similar to the difficulty in penetration of the adsorbed layer in the quinone-hydroquinone system.

Table V. Charge transfer coefficient, standard rate constant, and $\Delta\phi_2$ for the Fe(II)/Fe(III) system in 1.0M H_2SO_4 with and without added benzo-(f)-quinoline

Concentration of benzo-(f)-quinoline	θ	α*	$k_a^o \times 10^3$ (cm sec^{-1})	$\Delta\phi_2$** (mV)
0	0.0	0.51	13.0	—
1.0×10^{-5}M	0.05	0.48	10.1	2.6
1.0×10^{-4}M	0.20	0.51	4.2	11.5

* Obtained from experiments at constant Fe(III) concentration.
** Calculated according to Eq. [7] with $Z = 2$.

Conclusions

The adsorption of benzo-(f)-quinoline on gold electrodes in 1.0M H_2SO_4 between 0.0 and +0.7V can be described by the Frumkin isotherm and the isotherm with virial coefficients. In this potential range, adsorption is almost independent of potential. The apparent standard rate constant for both the quinone-hydroquinone and the Fe(III)/Fe(II) system is an exponential function of coverage at $\theta \leq 0.40$ and $\theta \leq 0.20$, respectively. Such an exponential function would be expected if changes in the ϕ_2-potential caused by the adsorbed species are the principal cause for the decrease in rate constant. However, the changes calculated for the quinone-hydroquinone system are 2-4 times larger than those for the Fe(III)-Fe(II) system. Alternatively, an exponential decrease in rate constant can be caused by an increase in free energy of activation due to interaction between adsorbed layer and electroactive species.

Effect of Sinusoidal A.C. on the Kinetics of Cu/Cu^{2+} Reaction in Acidic Sulfate Solution

Srinivasan Venkatesh*[,1] and Der-Tau Chin*

Department of Chemical Engineering, Clarkson College of Technology, Potsdam, New York 13676

ABSTRACT

A study has been made of the effect of high amplitude a.c. on the kinetics of a copper rotating disk electrode in acidic copper sulfate solutions. It was found that the rest potential was shifted toward the negative direction, and the exchange current density and the Tafel slopes increased with the superimposition of a.c. A mathematical model which took into account the periodical change in the surface concentration, the double layer capacity, the surface and the ohmic overpotential, was proposed to explain the observed phenomena.

This work is concerned with the effect of a high amplitude alternating current (a.c.) on the kinetics of copper deposition and dissolution reactions in acidic copper sulfate solutions.

The kinetics of this system without any superimposed a.c. have been extensively investigated. Mattson and Bockris (1) performed galvanostatic measurements of copper electrodes. They concluded that the reaction was controlled by a redox process between cupric and cuprous ions and arrived at the following consecutive reaction steps

$$Cu^{2+} + e^- \rightleftarrows Cu^+ \quad \text{(rate-determining step)} \qquad [1]$$

$$Cu^+ + e^- \rightleftarrows Cu_{ads} \qquad [2]$$

$$Cu_{ads} \rightleftarrows Cu \qquad [3]$$

Hurlen (2) found that the rate of this reaction was independent of *p*H in the *p*H range 0-5. Bockris and Kita (3) performed experiments on different types of copper electrode surfaces, such as electrodeposited copper and He-quenched copper. They found that the kinetic parameters changed with the nature of the copper surfaces. Several other investigators (4-19) confirmed that the Cu/Cu^{2+} electrode reaction in aqueous sulfate and perchlorate solutions involved two consecutive charge transfer steps with Cu^+ as the intermediate. Hurlen *et al.* (20) studied experimentally the kinetics of the Cu^+/Cu charge transfer step. Their results conformed with the earlier morphological data on the spiral and pyramidal growth of Cu electrodeposits (21).

Sheshadri (22) has studied the growth of single crystals of Cu on nickel from acidic $CuSO_4$ solutions and has shown that superimposed a.c. brought about morphological changes in Cu deposits. He observed a gradual truncation of pyramids to smooth and flat deposits in the presence of a.c. The effect of a.c. on the corrosion of copper concentric neutral wires in underground environments has been investigated by Kruger *et al.* (23). They found that a.c. caused accelerated attack with pit formation and that the oxygen availability and the presence of chloride ions in solution favored the attack on the wires.

In the present work, a sinusoidal a-c modulation method has been used to study the kinetics of the copper electrode in sulfuric acid with the rotating disk electrode. In this method, a constant alternating current is passed through the electrode-electrolyte interface, and the resulting time-averaged (or d-c) electrode potential is measured as a function of d-c density at the electrode (24-26). A mathematical model taking into account the double layer capacity, the ohmic drop, and the change in the electrode surface concentration is proposed to predict the effect of a.c.

Experimental

A copper rotating disk was used as the working electrode. The details of the experimental setup are given in Ref. (27) and are only briefly described here. A Pyrex cell was used to accommodate the working electrode, the counterelectrode, a Luggin capillary, a thermometer, and a gas bubbler. The copper working electrode was modified from a Pine Instrument DT ring electrode, as described by Chin (28). It consisted of a Teflon support rod and a replaceable copper disk electrode of 0.794 cm in diameter. The rotation of the electrode was provided by a Pine Instrument PIR high speed rotator. The counterelectrode was a platinum screen. A saturated calomel electrode was used as the reference electrode and was placed in a separate reference compartment. Both the reference and the working electrode compartments were filled with the same electrolyte under study. The Luggin capillary was placed along the axis of rotation about 2 mm from the electrode surface. The electrolyte was 0.025-0.15M $CuSO_4$ in 0.5M H_2SO_4 and was deaerated by bubbling N_2 for 2-3 hr prior to the start of experiment. All the measurements were carried out at 22° ± 1°C.

The electrical circuit for a-c modulation is shown in Fig. 1. The current was controlled by connecting a known resistor across the reference and the working electrode terminals of a Wenking LT73 potentiostat and by controlling the voltage drop across them. The sinusoidal signal input to the potentiostat was adjusted by an audio oscillator and power amplifier (General Radio Type 1308-A). The d-c potential developed across the reference and the working electrodes, ϕ_{DC}, was measured with a d-c electrometer (Keithley 602 Solid State). The alternating potential, ϕ_{AC}, was measured with a true rms voltmeter (Hewlett Packard 3466) after filtering the d-c potential through a differential amplifier/filter (Tektronix AM502). The alternating potential waves were observed on an oscilloscope (Tektronix SC503).

The chemical composition[2] of the copper-disk electrode was determined by a spectrographic analysis. The electrode was initially polished with 400 and 600 grit emery paper and then electropolished in chromic acid. The electrode was further cleaned in 20% nitric acid, rinsed with distilled water, 5% H_2SO_4, again with distilled water, and transferred to the cell.

A sinusoidal a.c. of known magnitude and frequency was applied to the cell, and the new rest potential of the copper electrode was measured by letting d.c. equal zero. The difference between the new rest potential and the equilibrium electrode potential without a.c. was computed as a shift in the rest potential, ϕ_{sh}. Subsequently, by varying the d.c. across the cell, the resultant d-c potential and the alternating potentials were measured to obtain the cathodic and the anodic

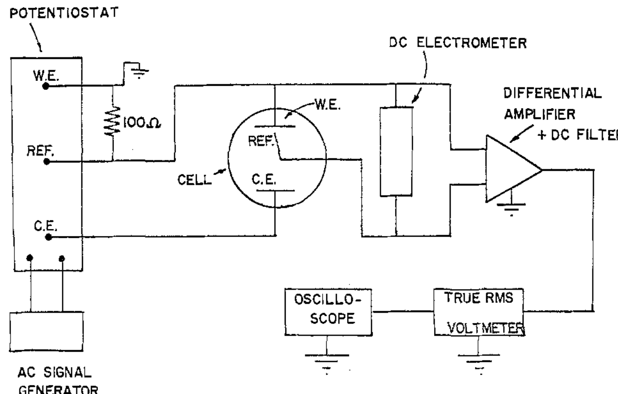

Fig. 1. A-C modulation electrical circuit

polarization curves. The exchange current densities and the Tafel slopes were obtained by the Tafel extrapolation method. The waveforms of the alternating potentials were observed with the oscilloscope and the oscillograms were taken at various applied a-c and d-c values.

A set of faradaic efficiency tests was performed. The electrodes were rinsed with distilled water, dried, and weighed before the start of each experiment. The electrodes were then pretreated by the procedure mentioned earlier and transferred to the cell. The experiments were performed at various d-c values superimposed with 25 mA/cm^2 rms a.c. After each run, the electrode was rinsed with distilled water, dried, and weighed again to determine the weight loss or gain of the electrode. Assuming a two-electron transfer reaction, the faradaic efficiency was determined. After the faradaic efficiency test, the electrode surface was coated with a thin layer of gold using a gold sputterer (International Scientific Company PS2 coating unit), and was examined under a scanning electron microscope (International Scientific Company Super Mini-SEM).

Results

Polarization curves.—Figure 2 shows a set of polarization curves for the copper rotating disk electrode in 0.05M $CuSO_4$ + 0.5M H_2SO_4 when 60 Hz sinusoidal a.c. was superimposed across the cell. The values of a-c varied from 0 to 150 mA/cm^2 rms. The data were obtained at a rotational speed of 2500 rpm; at this speed no appreciable concentration polarization was observed. The polarization curves were plotted after compensating for the ohmic drop. The anodic and the cathodic Tafel slopes for the polarization curve without a.c. were 41.5 and −142.2 mV, respectively, in good agreement with the values of 42 and −128 mV reported by Bockris and Kita (3). It can be seen that there was a shift in the rest potential toward the negative direction until a critical value was reached. Thereafter, the rest potentials were shifted back in the noble direction. The anodic and the cathodic Tafel slopes and the exchange current density were changed by a.c. The change is of an apparent property of a-c rectification, and the values with superimposed a.c. could be regarded as the apparent Tafel slopes and the apparent exchange current density. Furthermore, with superimposed a.c. the anodic and the cathodic Tafel lines no longer intersected at the rest potential; hence, an apparent anodic exchange current density i_{oa}, and an apparent cathodic exchange current density i_{oc} were calculated.

Evaluation of kinetic parameters.—Figures 3 and 4 show the apparent exchange current densities and the Tafel slopes as a function of superimposed a.c. The apparent cathodic exchange current density and the magnitude of the apparent cathodic Tafel slope increased consistently with increasing a.c. At high values of a.c., the apparent cathodic Tafel slopes ($-\beta_c$) were close to infinity. The i_{oa} curve initially increased with a.c., reached a maximum around 50 mA/cm^2 rms a.c., and then decreased with further increase in a-c densities. The apparent anodic Tafel slope, β_a, also exhibited the same behavior, but it peaked somewhere between 25 and 50 mA/cm^2 rms a.c. Figure 5 shows the rest potential shift, ϕ_{sh}, which exhibited a minimum around 50 mA/cm^2 rms a.c. The apparent exchange current densities, the apparent Tafel slopes, and the shift in the rest potentials are tabulated in Table I.

A-C potentials of the copper electrode.—In Fig. 6, the resulting root mean square of the alternating voltage (AV) component of the copper electrode potential due to the passage of a.c. is plotted against the d-c potentials. It is seen that as the d-c potential increased in the noble direction from the rest potential, the resulting AV decreased. This indicates that the impedance to

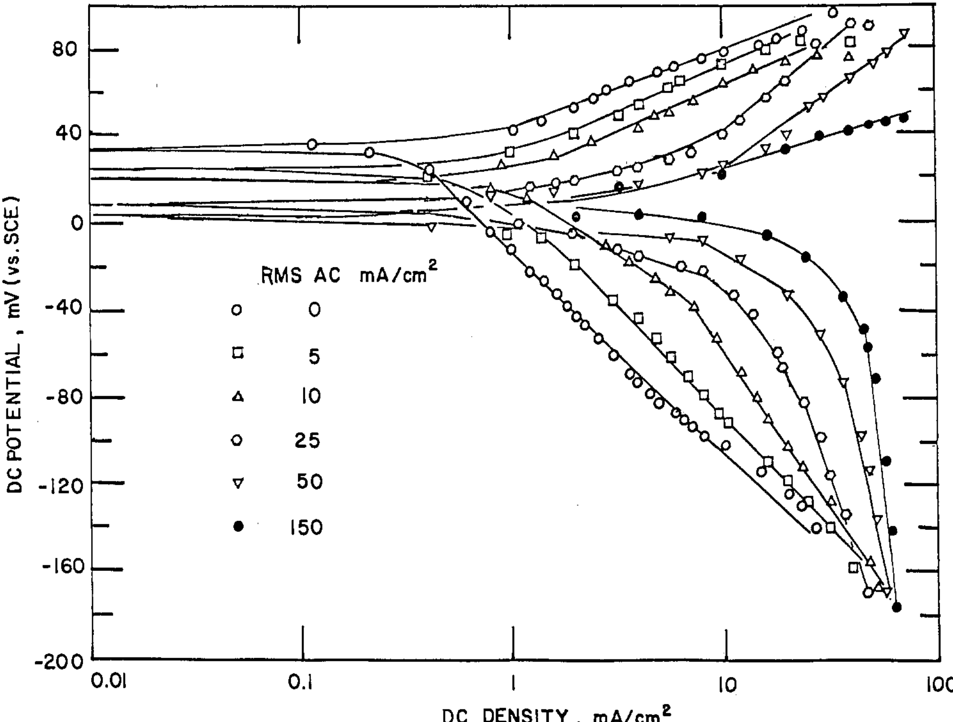

Fig. 2. Polarization curves for Cu in 0.05M $CuSO_4$ + 0.5M H_2SO_4 for various superimposed a.c. (60 Hz) at a rotational speed of 2500 rpm.

a.c. decreases when the d-c potential was shifted away from the rest potential. Increasing the d-c potential in the active direction (from the rest potential) decreased the resulting AV, until the superimposed a.c. reached 50 mA/cm² rms. Thereafter at higher AV values, the AV decreased with increasing d-c potential in the active direction. The oscillograms of the resultant AV at various a-c and d-c densities were re-

corded on a storage oscilloscope. It was found that the AV waveforms were slightly distorted from the sinusoidal shape.

Results of the faradaic efficiency tests.—The results obtained from the faradaic efficiency tests are summarized in Table II. The experiments were performed for both anodic and cathodic reactions. At 25 mA/cm^2 rms a.c., the efficiency tests were done at three different d-c values; one in the anodic, and two in the cathodic region. The faradaic efficiencies determined in all the tests were close to 100%, assuming that two electrons were transferred in the overall electrode reaction. Assuming the efficiency to be 100%, the number of electrons transferred was found to be two, as shown in the last column of Table III. It can be concluded from these results that the number of electrons transferred did not change during the application of a.c.

At the end of the faradaic efficiency test, the electrode surface was examined under an SEM. Figure 7 shows the effect of 25 mA/cm^2 rms of a.c. on the morphology of copper deposits obtained with 10C of charge at a cathodic d-c density of 4 mA/cm^2. It is seen that a.c. greatly increased the grain size of the copper deposits. In the anodic dissolution region, a.c. was found to increase the size of pits. The results were similar to the application of a.c. on the zinc electrode in zinc chloride solutions (29).

Effect of $CuSO_4$ concentration of kinetic parameters.—The a-c modulation experiments were also performed at different concentrations of $CuSO_4$. The Cu/Cu^{2+} reaction was found to be of a first order without the presence of a.c. When a.c. was superimposed, the apparent Tafel slopes (and hence the apparent transfer coefficients) changed with increasing concentrations of $CuSO_4$. Since the transfer coefficients have to be constant to determine the reaction order, the reaction order when a.c. was superimposed was not determined. However, the kinetic parameters derived from the polarization curves at different concentrations of $CuSO_4$ are reported in Table III.

Effect of a-c frequencies.—Figure 8 shows the effect of a-c frequency on the polarization curves at 25 mA/cm^2 rms a.c. It is seen that the shift in the rest potential decreased with increasing a-c frequency. The a-c frequency seemed to affect the cathodic Tafel region near the rest potential. Otherwise, there was no significant effect on the cathodic Tafel region. On the anodic portion, higher a-c frequencies shifted the polarization curves toward the zero a-c curve.

Discussion

The behavior of the polarization curves obtained by the a-c modulation can be attributed to the faradaic rectification process as explained in Ref. (24). There are other possibilities by which a.c. could influence the kinetics of the Cu-electrode reaction. These include: (*i*) the effect of a.c. on the rate-determining step and the number of electrons transferred in the overall electrode reaction; (*ii*) the formation of a copper-sulfate complex under the influence of a.c.; and

(*iii*) change in the surface characteristics of the copper electrode. The results of the faradaic efficiency test clearly ruled out the first possibility, for the number of electrons transferred in the Cu/Cu^{2+} reaction was two, with and without the application of a.c. To examine the second possibility, an a-c modulation experiment was also carried out using a Cu rotating disk electrode in 0.05M $Cu(ClO_4)_2$ and 0.5M $HClO_4$. This was done to compare the behavior of Cu in H_2SO_4 to that in $HClO_4$ electrolyte with superimposed a.c. The polarization curves obtained in $HClO_4$ solution at zero a.c. and 25 mA/cm^2 rms superimposed a.c. are shown in Fig. 9 after compensating for the ohmic drop in the electrolyte. Perchlorate ion is known to be a noncomplexing agent. Due to the similarity in the behavior of the polarization curves in $HClO_4$ and H_2SO_4, it can be concluded that there was no complex formation of Cu with the sulfate ions in H_2SO_4 electrolyte. On the other hand, the SEM photomicrographs exemplify the changes in the surface morphology with a.c. Hence, the observed behavior can be interpreted as a surface phenomenon and the a-c rectification.

The effect of a-c rectification on the behavior of the polarization curves can be explained by a mathematical model of a rotating disk electrode, taking into account the surface concentration change, the double layer capacity, the ohmic resistance, and the concentration overpotential.

The total current density, i, is given by a d-c component, i_{DC}, and an a.c. component

$$i = i_{DC} + i_p \sin \omega t \qquad [4]$$

where i_p is the peak-to-peak value of a.c. and ω is the a-c frequency. The d-c portion aids the charge transfer reaction. A part of the a.c., i_{fAC}, also contributes to the charge transfer reaction. The other part, i_c, charges up the double layer and is the capacitance current. Hence, the total current density can be written as

$$i = i_{DC} + i_p \sin \omega t = i_{DC} + i_{fAC}(t) + i_c(t) \qquad [5]$$

The total faradaic current density is

$$i_f = i_{DC} + i_{fAC} \qquad [6]$$

For a metal/metal-ion system of the type

$$M^{n+} + ne^- \rightarrow M \qquad [7]$$

i_f may be given by the Butler-Volmer equation (30)

$$i_f = i_o \left(\frac{c_s}{c_\infty} \right)^\gamma \exp \left\{ \left(\frac{\alpha n \mathbf{F}}{RT} \eta_s \right) - \exp \left(- \frac{\beta n \mathbf{F}}{RT} \eta_s \right) \right\} \qquad [8]$$

where α and β are the anodic and the cathodic transfer coefficients, η_s is the surface overpotential, i_o is the ex-

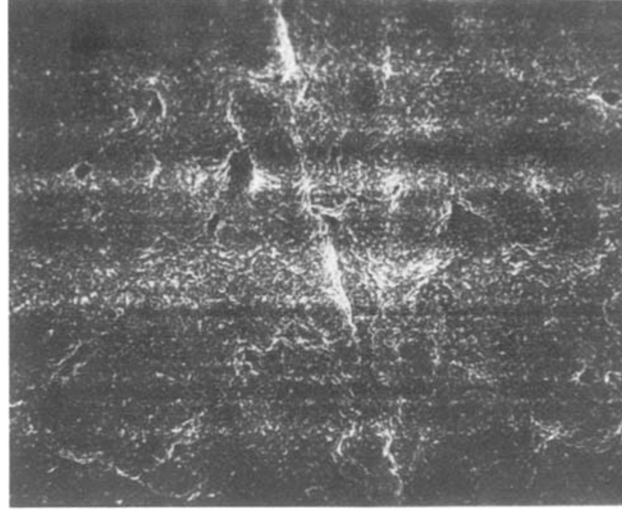

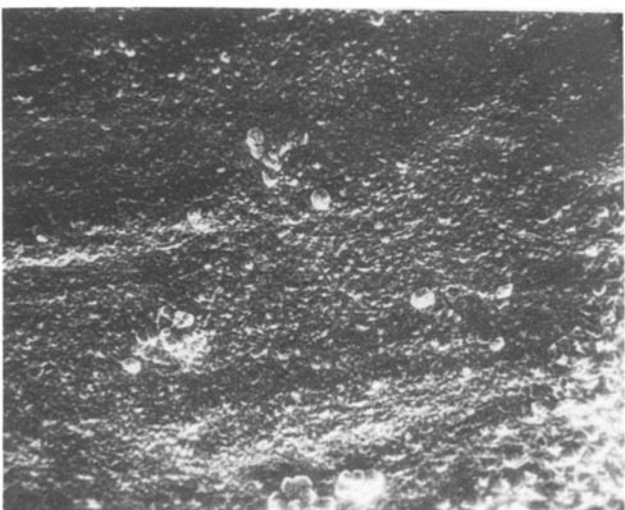

Fig. 7. Scanning electron micrographs of the Cu deposits after experiments at various cathodic d-c densities in 0.05M $CuSO_4$ + 0.5M H_2SO_4. The d-c and a-c densitiees (60 Hz) at which the experiments were performed are indicated on each picture. Magnification 280×.

change current density, and γ is a kinetic parameter. The capacitance current may be expressed as

$$i_c = \frac{d}{dt}(C_{dl}\eta_s) \quad [9]$$

where C_{dl} is the double layer capacity which is a function of η_s. Combining Eq. [8] and [9] and assuming that α, β, and γ do not change with the application of a.c., one has

$$i = i_{DC} + i_p \sin \omega t = i_o \left(\frac{c_s}{c_\infty}\right)^\gamma \left\{ \exp\left(\frac{\alpha n\mathbf{F}}{RT}\eta_s\right) - \exp\left(-\frac{\beta n\mathbf{F}}{RT}\eta_s\right) \right\} + \frac{d}{dt}(C_{dl}\eta_s) \quad [10]$$

at

$$t = 0, \quad \eta_s = \eta_{DC} \quad [11]$$

where η_{DC} is the d-c overpotential.

The total overpotential is equal to the sum of the surface overpotential, the concentration overpotential, and the ohmic overpotential

$$\eta = \eta_s + \eta_{conc} + \eta_{ohm} \quad [12]$$

$$\eta_{conc} = \frac{RT}{n\mathbf{F}} \ln \frac{c_s}{c_\infty} \quad [13]$$

$$\eta_{ohm} = i\rho l \quad [14]$$

where ρ is the specific resistance of the electrolyte and l is the distance between the reference capillary and the working electrode.

To determine the surface concentration, c_s, one needs the convective diffusion equation for the mass transport of ionic species

$$\frac{\partial c}{\partial t} + v_y \frac{\partial c}{\partial y} = D \frac{\partial^2 c}{\partial y^2} \quad [15]$$

The boundary conditions are

$$c(y, 0) = c_\infty$$
$$c(\infty, t) = c_\infty \quad [16]$$
$$-D \frac{\partial c}{\partial y}(0, t) = \frac{i_f(t)}{n\mathbf{F}}$$

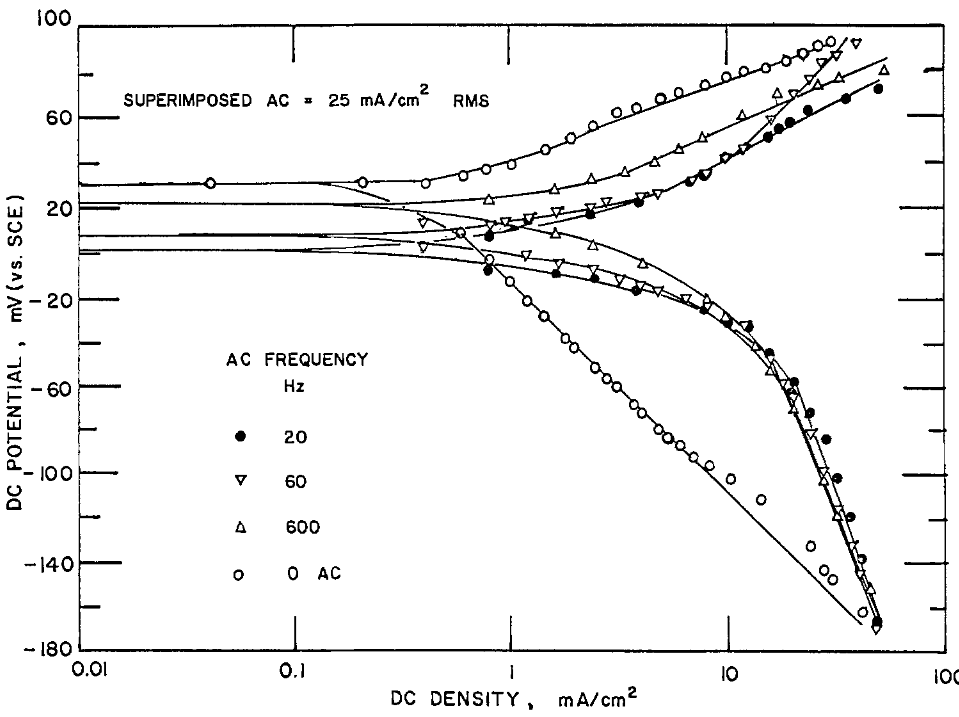

Fig. 8. Effect of a-c frequency on the polarization curves at 25 mA/cm^2 rms superimposed a.c. for Cu in 0.05M $CuSO_4$ + 0.5M H_2SO_4.

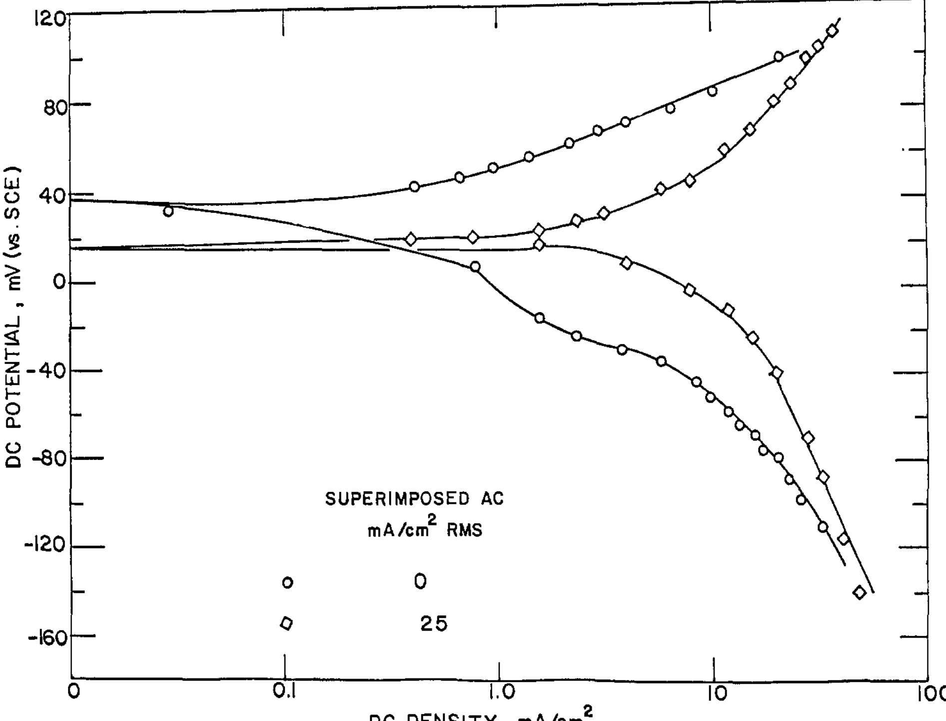

Fig. 9. Polarization curves for Cu in 0.05M copper perchlorate + 0.5M perchloric acid at 0 and 25 mA/cm² rms superimposed a.c. (60 Hz). Speed of rotation = 2500 rpm.

Here c is the concentration of the ionic species and c_∞ is the bulk concentration, y is the axial coordinate, D is the diffusion coefficient, v_y is the velocity components in the y direction, i_f is the faradaic current density, n is the number of electrons transferred, and **F** is the Faraday constant. The major assumptions involved are that there is an excess of supporting electrolyte and uniform current distribution on the electrode surface.

The foregoing model has been solved numerically with a digital computer. The details of the solution procedure are given in Ref. (27). The calculations were performed for the a-c modulation of a copper rotating disk electrode in 0.05M $CuSO_4$ and 0.5M H_2SO_4. The polarization curve, *i.e.*, d-c current density *vs.* the d-c potential, was evaluated by feeding the input parameters, i_o, α, and β obtained from the experimental polarization curve without a-c. A value of 0.4 was chosen for the kinetic parameter, γ, as suggested by Newman (30). An experimental value of the double layer capacity of 56 μF/cm² was used for the calculation. This value was obtained by Bockris and co-worker (8, 10) and was independent of the electrode potential for -200 mV $< \eta_s <$ 200 mV.

Figure 10 shows the polarization curves obtained from the theory at a superimposed a.c. of 25 mA/cm² rms (60 Hz). The curves were plotted after the compensation for the ohmic potential drop in the electrolyte. For comparison, the experimental values without any superimposed a.c. and at 25 mA/cm² rms a.c. are also shown in the figure. The theoretical curves clearly demonstrate that the a-c rectification is directly responsible for (*i*) the shift in rest potential toward the negative direction, (*ii*) an increase in the exchange current density, and (*iii*) an increase in both anodic and cathodic Tafel slopes. These results qualitatively agree with the observed phenomena. Since the mathematical model assumes that real kinetic parameters, such as i_o, β_a, β_c, and γ are not affected by the superimposition of a.c., the new exchange current density and the Tafel slopes can be regarded as an apparent property associated with the high amplitude a-c rectification.

Despite the similarities between the theoretical and the experimental polarization curves, there is a lack of quantitative agreement. The theory seems to overpredict the effect of a.c. The discrepancy can be at-

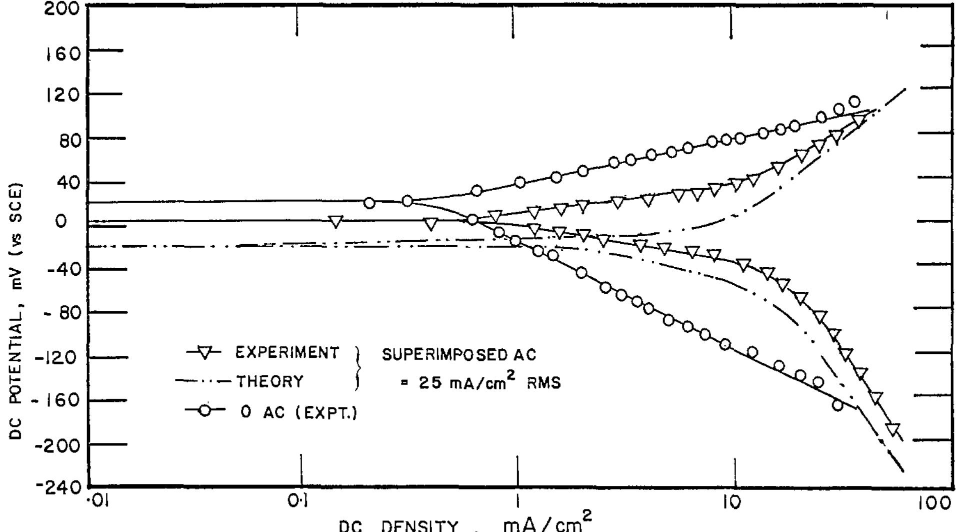

Fig. 10. Theoretical and experimental polarization curves for Cu RDE in 0.05M $CuSO_4$ + 0.5M H_2SO_4 at 25 mA/cm² rms superimposed a.c. at 60 Hz. The experimental curve obtained without a.c. is shown by the open circles, —○—.

tributed to various reasons, such as the roughening of the electrode surface during the experimental polarization measurements, the formation of an oxide layer during the anodic dissolution runs, and the nonuniform current distribution on the disk electrode. Further results obtained from the model will be published in a later report.

Conclusions

A study has been made of the effect of high amplitude sinusoidal a.c. on the kinetics of the copper electrode in acidic sulfate solutions using a rotating disk electrode. It was found that the anodic exchange current densities increased with increasing a-c densities until a critical value of 50 mA/cm^2 rms was reached; thereafter, the anodic exchange current density started decreasing with further increase in a-c densities. The cathodic exchange current densities increased with increasing a.c. The apparent values of the Tafel slopes increased with a-c superimposition. The rest potentials were shifted in the negative direction until the critical a-c density and further increase in a.c. shifted the rest potential back toward the noble direction. A mathematical model has been proposed to predict the phenomena of the high amplitude a-c rectification. The numerical results showed the characteristics similar to those observed in the experimental polarization measurements.

LIST OF SYMBOLS

- c — concentration of the ionic species, mol/m^3 (mol/cm^3)
- c_s — surface concentration of the ionic species, mol/m^3 (mol/cm^3)
- c_∞ — bulk concentration of the ionic species, mol/m^3 (mol/cm^3)
- C_{dl} — double layer capacitance, F/m^2 (F/cm^2)
- D — diffusion coefficient of the ionic species, m^2/sec (cm^2/sec)
- $\mathbf{F}$ — Faraday constant, 9.65×10^7 C/kg-equiv. (96500 C/g equiv.)
- i — current density, A/m^2 (A/cm^2)
- i_o — exchange current density, A/m^2 (A/cm^2)
- i_{oa} — anodic exchange current density, A/m^2 (A/cm^2)
- i_{oc} — cathodic exchange current density, A/m^2 (A/cm^2)
- i_{AC} — AC density, A/m^2 (A/cm^2)
- i_c — capacitance current density, A/m^2 (A/cm^2)
- i_{DC} — d-c density, A/m^2 (A/cm^2)
- i_f — total faradaic current density, A/m^2 (A/cm^2)
- i_{fAC} — faradaic portion of i_{AC}, A/m^2 (A/cm^2)
- i_p — amplitude of a-c density, A/m^2 (A/cm^2)
- l — distance between the working electrode and the reference capillary, m (cm)
- n — number of electrons transferred in the electrode reaction, kg equiv./mol (g equiv./mol)
- R — gas constant, 8.314 J/mol K (1.987 cal/mol K)
- t — time, sec
- T — absolute temperature, K
- y — axial coordinate, m (cm)

Greek symbols

- α — anodic transfer coefficient, dimensionless
- β — cathodic transfer coefficient, dimensionless
- β_a — anodic Tafel slope, V
- β_c — cathodic Tafel slope, V
- γ — kinetic parameter in Eq. [8], dimensionless
- η — overpotential, V
- η_{conc} — concentration overpotential, V
- η_{DC} — d-c overpotential, V
- η_{ohm} — ohmic overpotential, V
- η_s — surface overpotential, V
- ν — kinematic viscosity, m^2/sec (cm^2/sec)
- ρ — specific resistance of the electrolyte, $\Omega \cdot m$ ($\Omega \cdot cm$)
- ϕ_{AC} — a-c component of the electrode potential, V
- ϕ_{DC} — d-c component of the electrode potential, V
- $\phi_{equil.}$ — thermodynamical equilibrium electrode potential, V
- ϕ_{rest} — rest electrode potential when i_{DC} is zero, V
- ϕ_{sh} — shift in the rest electrode potential, V
- ω — a-c frequency, Hz (rad/sec)
- Ω — speed of rotation, rad/sec

Protection of Semiconductor Photoanodes with Photoelectrochemically Generated Polypyrrole Films

Rommel Noufi*,[1] Dennis Tench,* and Leslie F. Warren*

Rockwell International, Microelectronics Research and Development Center, Thousand Oaks, California 91360

ABSTRACT

Results are presented which show that photoelectrochemically generated polypyrrole films protect semiconductor photoanodes (*e.g.*, Cd chalcogenides, GaAs, and Si), from degradation while permitting electron exchange between the semiconductor and the electrolyte. The performance characteristics and stability of such film-covered photoelectrodes are discussed.

In an earlier brief communication (1), we described the electrochemical generation of conducting polypyrrole films on n-GaAs and the characteristics of the resulting photoanodes. It was demonstrated that such polymer films inhibit photodegradation of the semiconductor, presumably by impeding ion/solvent transport. Good photoanode performance characteristics, from an electrochemical solar cell standpoint, were also observed, as might be expected for films having high electronic conductivity. For polypyrrole electrodeposited on metallic electrodes, conductivities in the 10-100 Ω^{-1} cm^{-1} range have been reported (2).

In the present paper, details of our earlier work and results obtained for other semiconductor materials are presented. Emphasis is on the stabilization provided by polypyrrole films and their effect on the photoanode performance characteristics. The role of redox couples, both in the electrolyte and incorporated within the polymer matrix, is also discussed.

Experimental Details

Unless otherwise noted, polypyrrole films were electrodeposited from mechanically stirred acetonitrile solutions containing 0.5M pyrrole and 0.2M Et_4NBF_4 (supporting electrolyte). Based on a few experiments, comparable results were obtained for films deposited from analogous methylene chloride electrolytes, and from aqueous H_2SO_4 solutions (*p*H 1.5-1.9) containing 0.2-0.5M pyrrole. The counterelectrode was a 25 cm^2 Pt foil. Deposition on Pt electrodes was performed at a constant potential of +0.85V *vs.* SCE (saturated calomel electrode). Deposition on n-type semiconductors was performed under tungsten-halogen illumination (100 mW/cm^2) at constant potential (0.45V *vs.* SCE for n-GaAs, 0.2V for the Cd chalcogenides, and 0.4V for n-Si) such that the current, which remained practically constant except for an initial spike, was in the 2-3 mA/cm^2 range. Based on the charge passed (20 mC/cm^2), the film thickness used in the present work was 50-100 monolayers. All electrode potentials are reported *vs.* SCE and measurements were made with *IR* compensation. Illumination for photoresponse studies was also provided by a tungsten-halogen lamp. Additional experimental details are given elsewhere (1).

Semiconductors were single crystals (~0.2 cm^2) and were polished using aqueous alumina slurries to 1 μm particle size before mounting in RTV silicone rubber (M-Coat C, M-Line Accessories, Romulus, MI). Crystal orientations were perpendicular to the c-axis for CdS and CdSe, <111> for CdTe, and <111> or <110> (comparable results) for GaAs. Ohmic contacts were made by standard techniques. GaAs electrodes were etched in a 1:1 mixture of concentrated H_2SO_4 and 30% H_2O_2 for about 15 sec (until matte black finish was obtained) prior to use. Si electrodes were etched in 49% aqueous HF solution for 10 sec. CdSe, CdTe, and CdS electrodes were etched in 4M HNO_3, concentrated HNO_3, and 6M HCl, respectively. CdSe and CdTe were dipped in a polyselenide solution after etching.

Results and Discussion

Electrodeposited polypyrrole films were first prepared (on Pt electrodes) by Diaz *et al.* (2), who also investigated their electrical and electrochemical properties (2-4). They found that films deposited from acetonitrile/tetraethylammonium tetrafluoroborate electrolytes are adherent (on metal electrodes) and consist of polymerized pyrrole units plus BF_4^- anions, typically in the ratio of about 4:1 (2). The films are stable in air to at least 250°C (3) and as electrodes in both aqueous and nonaqueous electrolytes (2-4). Reversible electrochemical oxidation of the film is evident from cyclic voltammetry and is associated with a transition from insulating (reduced form) to highly conducting (oxidized form) behavior (4). This film redox process involves exchange of anions between the film and the electrolyte, as evidenced by the dependence of the redox potential on the nature of the electrolyte (4). Anodic of the transition potential (about −0.2V *vs.* SCE in both aqueous and acetonitrile solutions), polypyrrole films exhibit electrochemical behavior similar to that observed for Pt electrodes, *i.e.*, solution redox reactions occur reversibly. Data obtained in our laboratory are in general agreement with these results, except that the films appear to slowly decompose with potential cycling in aqueous solutions (containing ferro-ferricyanide) of *p*H > 13, long-term stability above *p*H 10 being questionable.

Electroactive species can also be incorporated in the film matrix. For example, polypyrrole films containing $Fe(CN)_6^{3-}$ are produced from acetonitrile electrolytes containing this anion instead of BF_4^-. Cyclic voltammograms for a polypyrrole-$Fe(CN)_6^{3-}$ film (on Pt) in an aqueous ferro-ferricyanide solution are shown in Fig. 1. Voltammetry peaks corresponding to the $Fe(CN)_6^{3-/4-}$ redox reaction are evident at about 0.2V. The linear dependence of the peak heights on sweep rate and the near coincidence of the anodic and cathodic peak potentials are characteristic of a surface-bound redox species. The voltammetric behavior depicted in Fig. 1 was unchanged after more than 50 cycles. Upon transfer of such electrodes to solutions not containing electroactive species, the peaks corresponding to the $Fe(CN)_6^{3-/4-}$ reaction gradually disappear as the redox species is lost to the solution. Likewise, the ferro-ferricyanide reaction on polypyrrole films deposited from solutions containing only BF_4^- anions initially exhibits the reversibility characteristic of Pt (some peak separation) but the anodic and cathodic peaks become more coincidental with potential cycling in the ferro-ferricyanide solution.

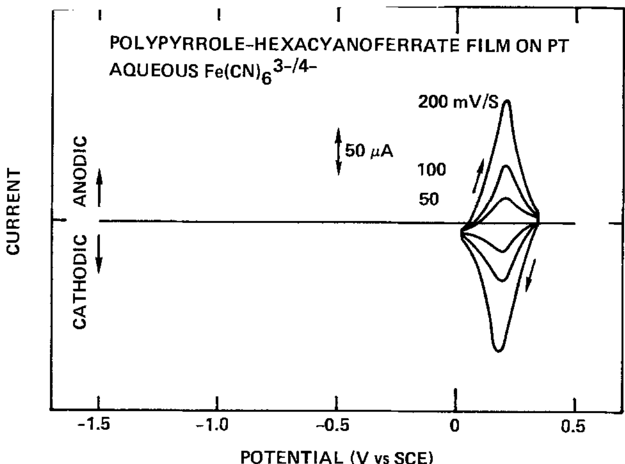

Fig. 1. Cyclic voltammograms at various sweep rates for a polypyrrole-$Fe(CN)_6^{3-}$ film on Pt (~0.1 cm^2) in aqueous 0.1M $Fe(CN)_6^{3-/4-}$ solution (pH ~10).

These results show that electroactive species can be incorporated within polypyrrole films and clearly demonstrate the mobility of anions in the polymer matrix.

Photoanode stabilization.—As discussed previously for n-GaAs (1), polypyrrole films stabilize semiconductor photoanodes against degradation while permitting electron exchange with the electrolyte. This is illustrated for n-GaAs in Fig. 2, n-CdSe in Fig. 3, and n-Si in Fig. 4. In all cases, the short-circuit photocurrent for the unprotected (bare) semiconductor decays rapidly (within a few minutes), presumably because of formation of an insoluble blocking surface layer of photodecomposition product, whereas that for the polypyrrole-coated photoanodes remains practically constant. Note that polypyrrole films also afford n-GaAs electrodes protection from dissolution in aqueous electrolytes, although in this case stabilization is less obvious since the photodecomposition products are typically soluble (5). At longer times, the film generally peels from the semiconductor surface *in toto* and the photocurrent decays. This is evident in Fig. 4 for coated n-Si after about 3 min. However, in some cases the film remains intact for several days (Fig. 2) and charge equivalent to more than the total weight of the crystal is passed without significant weight loss or degradation of the surface (inspected after film removal). Roughening the semiconductor surface by abrasion prior to film deposition appears to improve the film adhesion.

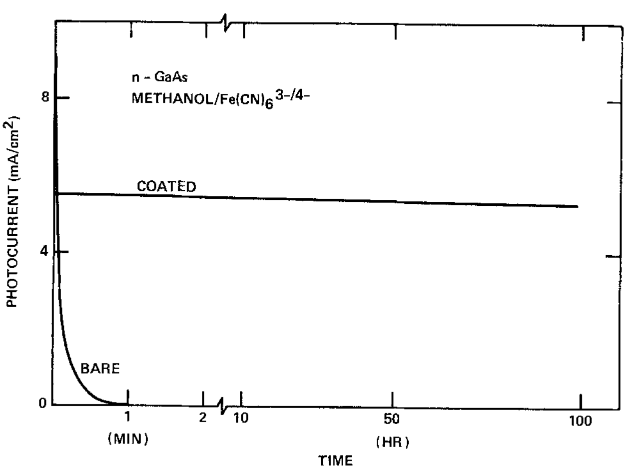

Fig. 2. Short-circuit photocurrent vs. time for bare and polypyrrole-coated n-GaAs electrodes in methanol/0.2M $Fe(CN)_6^{3-/4-}$/0.1M Et_4NBF_4 solution.

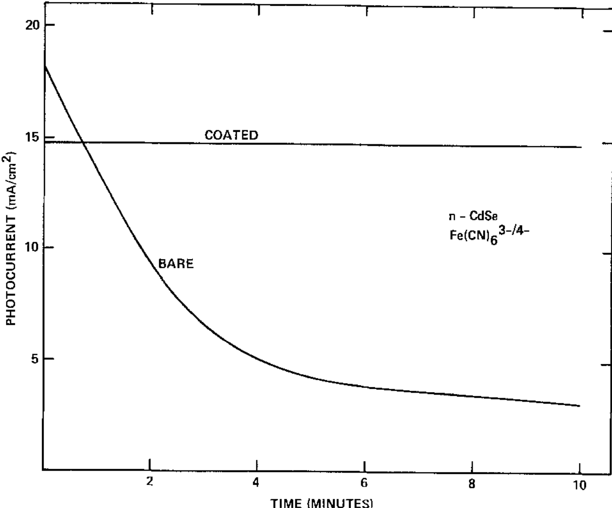

Fig. 3. Short-circuit photocurrent vs. time for bare and polypyrrole-coated n-CdSe electrodes in aqueous 0.2M $Fe(CN)_6^{4-}$/0.1M $Fe(CN)_6^{3-}$ solution (pH ~13).

Peeling problems may be associated with the permeability of polypyrrole films to solvent/solute species, since film stability appears to depend on the nature of the redox couple and/or pH of the electrolyte and in certain instances semiconductor decomposition underneath polypyrrole films is apparent. For example, polypyrrole-coated n-CdSe photoanodes are stabilized by $Fe(CN)_6^{3-/4-}$ electrolytes (pH = 10-13), but in $Fe^{3+/2+}$ perchlorate solutions (pH = 1), a red layer, presumably Se°, forms within a few minutes under the polymer film (which appears to be intact). These and related observations with a variety of semiconductor materials suggest that polypyrrole films are permeable to solvent/solute species, and that some photodecomposition may occur at the film-semiconductor interface, eventually causing the film to peel. The anion mobility discussed in the preceding section is in accord with this view. Insoluble decomposition products, *e.g.*, hydroxides, Se°, etc., may in some cases collect at the semiconductor-film interface and hinder or slow further degradation.

The apparent permeability of polypyrrole films to solvent/solute species poses a serious question regard-

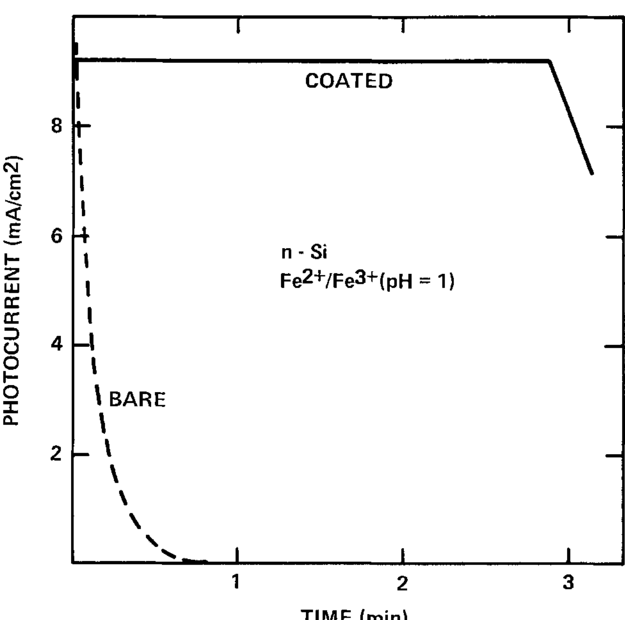

Fig. 4. Short-circuit photocurrent vs. time for bare and polypyrrole-coated n-Si in aqueous 0.2M $Fe(ClO_4)_2$/0.1M $Fe(ClO_4)_3$/0.1M $HClO_4$ solution.

ing the long-term stability of solar conversion devices employing such films. However, it may be possible to circumvent this problem. For example, sufficiently large immobile anions or redox species included in the film during electrodeposition would be expected to significantly reduce the film permeability. Encouragement for this approach is provided by the observed oxidation/reduction of the $Fe(CN)_6^{3-/4-}$ within the polypyrrole film matrix (see preceding section). Although the hexacyanoferrate species was found to be mobile in polypyrrole, there are many larger organic redox species for which this should not be the case. For example, we have deposited conducting polypyrrole films on Pt from acetonitrile/0.01M Cu(SPc)/0.1M pyrrole, where SPc is the tetrasulfophthalocyanin tetraanion. The photoelectrochemical properties of such films are currently under investigation. Other approaches are, of course, also possible, including the use of other conducting polymer films or a synergistic combination of film and electrolyte redox couple to provide long-term photoanode stability. Along these lines, we have deposited polyaniline films (6) on various semiconductors with results comparable to those obtained for polypyrrole.

Output characteristics of coated photoanodes.—Polypyrrole films apparently do not significantly affect the semiconductor energy levels important in photoelectrochemical processes. Thus, for film-coated electrodes, the flatband potential (V_{FB}) determined by a-c impedance or from the photocurrent onset, is practically unchanged, compared to the bare electrode, and remains dependent on the *p*H of the electrolyte. Also, except for the Cd chalcogenides and Si in acidic ferro-ferricyanide solutions, where appreciable cathodic dark currents are observed, the measured open-circuit photovoltages (V_{oc}) are generally close to the expected values ($V_R - V_{FB}$), where V_R is the electrolyte redox potential. This is illustrated by the data in Table I, for which V_{FB} values were determined from the photocurrent onset and may not correspond to those measured by a-c impedance in all cases. The V_R values, which were measured at a Pt electrode, correspond well with the standard handbook $E°$ values. Note that the V_{oc} values for polymer-coated n-GaAs and n-CdTe in ferro-ferricyanide solution containing excess CN^- are practically equivalent to the bandgap of the respective semiconductors. The increase in V_{oc} produced by excess CN^- can be accounted for by the observed negative shift in V_{FB}, but irreversible photooxidation of adsorbed CN^- (*e.g.*, to CNO^-) may also play a role. Since the cell voltage rapidly goes to zero when the electrode illumination is interrupted, the effect of the latter is probably small.

Table I. Measured and calculated open-circuit voltages (V_{oc}) for various polypyrrole-coated photoanodes in aqueous solutions

Semiconductor	Electrolyte*	V_{FB} (V *vs.* SCE)	Calculated V_{oc} ($V_R - V_{FB}$)	Measured V_{oc}
n-GaAs	A	−0.5	1.0	0.95
	B	−0.5	0.8	0.6
	C	−1.1	1.3	1.2
	D	−1.3	1.5	1.37
n-CdTe	A	−0.2	0.7	0.55
	B	−0.2	0.55	0.2
	C	−1.15	1.4	1.2

n-CdS	A	−0.4	0.9	0.65
	B	−0.4	0.75	0.3
	C	−0.8	1.0	0.9
	D	−1.3	1.5	1.25
n-Si	A	0.0	0.5	0.4

* Electrolyte A is 0.2M Fe^{2+}/0.1M Fe^{3+} perchlorates (*p*H = 1, V_R = 0.51V); electrolyte B is 0.2M $Fe(CN)_6^{4-}$/0.1M $Fe(CN)_6^{3-}$ (*p*H = 1, V_R = 0.35); electrolyte C is 0.2M $Fe(CN)_6^{4-}$/0.1M $Fe(CN)_6^{3-}$ (*p*H = 13, V_R = 0.22); and electrolyte D is 0.2M $Fe(CN)_6^{4-}$/0.1M $Fe(CN)_6^{3-}$/0.1M CN^- (*p*H = 13, V_R = 0.22V).

The effect of the polymer film on the photocurrent was difficult to ascertain since results for films produced under ostensibly the same conditions were variable, probably because of the difficulties associated with reproducing the substrate surface and film thickness. The latter was assumed to be directly proportional to the charge passed during deposition which may not be a valid assumption, especially since some semiconductor photodegradation undoubtedly occurs as deposition is initiated. In some cases, the photocurrents for the polymer-coated electrodes approached those for the bare semiconductor but the behavior depicted in Fig. 5 was more typical. In this case, the film is seen to reduce the photocurrent by about 30%. This reduction could be due to light absorption within the film or enhanced charge carrier recombination associated with interface states formed at the semiconductor-film interface. As mentioned previously, the reduction in open-circuit voltage (Fig. 5) is apparently due to cathodic dark current introduced by the film, which suggests that interface states may play a role. However, if such effects are not too pronounced, performance characteristics for polypyrrole-coated electrodes could approach those for the bare semiconductor for sufficiently thin films. Of course, a compromise would be required between photoanode stability and performance.

Summary and Conclusions

The results presented here show that electrodeposited polypyrrole films suppress photodegradation of semiconductor photoanodes while permitting efficient electron exchange with the electrolyte. Performance characteristics attainable with such film-coated photoanodes are typically comparable to those obtained for the bare electrode. Peeling is currently a problem which appears to be associated with permeability of the film to solvent/solute species. One promising approach for future work is to incorporate immobile redox species

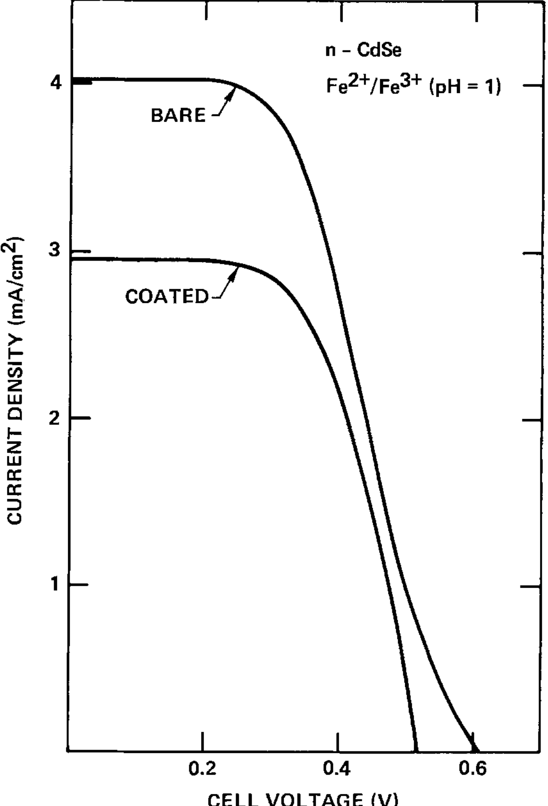

Fig. 5. Photocurrent-voltage curve for bare and polypyrrole-coated n-CdSe in aqueous 0.2M $Fe(ClO_4)_2$/0.05M $Fe(ClO_4)_3$/0.1M $HClO_4$ solution.

in the film to reduce permeability to electrolyte solvent/solute species.

Technical Notes

Properties of Borosilicate Glass Capillaries Used in Computer-Controlled Electrocapillary Measurements by the Maximum Bubble Pressure Method

Takashi Kakiuchi[1] and David M. Mohilner*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523

In our previous studies of organic electrosorption (1, 2) in which the electrocapillary curves were measured by a computer-controlled capillary electrometer (3, 4) the precision of the measurements was ± 0.1 mNm^{-1} and we were of the opinion that a single calibration of the maximum bubble pressure (MBP) capillary would remain valid over a period of many months. Recently, in preparation for a new study on the effect of temperature on organic electrosorption, because of the low temperature coefficient of interfacial tension, we improved the instrument (5) so that the 95% confidence limits of a triplicate measurement are now ± 0.02 mNm^{-1}. We decided it would be wise, with this greatly improved precision, to test whether, in fact, the presumption that a capillary calibration remains valid over an extended period of time really is justified. We therefore monitored two MBP capillaries, one over a period of 4½ months, the other over a period of 8½ months, with almost daily calibrations. The surprising result of this study was that, in fact, the radius of both capillaries increased approximately linearly with time and that this increase is significant for accurate electrocapillary measurements. The purposes of this note are to report the results of these measurements and also to give what we have found to be the best method of preparation of reliable MBP capillaries.

Preparation of MBP Capillaries

The method of preparing MBP capillaries which we report here has been developed empirically over a period of several years. It is the method which we have found yields the most reliable capillaries. The capillaries are drawn from 0.5 mm borosilicate capillary tubing. A 15 cm length of this capillary tubing is first but-sealed to a 15 cm length of ¼-in. OD borosilicate glass tubing. (¼ in. OD tubing is employed because we use Teflon Swagelok unions to connect the capillary to the mercury reservoir.) The glass is then soaked in ethanol saturated with KOH for 5 hr to remove any traces of greasy material. Then it is rinsed in distilled water and soaked for 5 hr in a mixture of concentrated sulfuric and nitric acids, rinsed with distilled water, and dried in the oven at 130°C. After this precleaning the glass is immersed in an aqueous solution of 5% HF and 30% HNO_3 for 5 min. This mixture is similar to the one recommended by Crawley (6) as a universal glass cleaning reagent. The HF etches a thin layer of glass from the capillary wall so that the new surface formed is less dependent on its history. The capillary is then rinsed thoroughly with triple distilled water and dried in the oven at 130°C. Then the capillary is drawn using a fairly cool gas-oxygen flame and examined with a Bausch and Lomb stereozoom microscope at 120× to see if its radius is approximately correct. A correct radius is approximately 7.0 μm. If the radius is correct the capillary is bent into a "U" shape. [For a photograph of an MBP capillary see Fig. 2, Ref. (3).] To be correct the narrowest portion of the capillary must be several millimeters long and be gently tapering. The capillary is then cut where narrowest with a silicon carbide knife and annealed at 550°C for 2 hr to remove strain around the bend.

The capillary bore is next dewetted. This is absolutely necessary because if solution penetrates between the glass wall and the mercury the effective radius will change with electrode potential due to the

Key words: capillaries, electrocapillarity, maximum bubble pressure.

interaction of the electrical double layers on the mercury and on the glass. The glass surface is always negatively charged (7) whereas the charge on the mercury varies from negative to positive. The interaction between the two double layers (8) can produce appreciable hydrostatic pressure when the mercury is negatively charged causing a decrease in the effective radius. Water vapor from a beaker of water at room temperature is first drawn through the capillary for 2 hr using an aspirator in order to ensure that the glass surface has a sufficient density of OH groups. The bore of the capillary is then dewetted with freshly distilled liquid trimethylchlorosilane and rinsed with chloroform. We had originally dewetted our MBP capillaries (1) with dimethyldichlorosilane which had been recommended by Payne (9), but careful checking with our improved capillary electrometer has shown that the radius of the capillaries dewetted with this compound exhibit a short-term instability which is probably due to the formation of polymethylsiloxane produced from the excess water which is always inside the capillary. Evidently pieces of this polymer can move to the capillary orifice causing the effective radius to become narrower. There is no possibility of polymer formation with trimethylchlorosilane and the hexamethylsiloxane which does form with the excess water is easily washed out with the chloroform.

After the capillary has been dewetted it is filled with mercury, placed in an electrolyte solution, and its potential adjusted to that of the electrocapillary maximum. Then it is pressurized to determine what pressure will push the mercury to the orifice. If the pressure is correct (about 80 cm mercury) the tip is recut removing only about 1 mm of glass, because the end of the capillary must be wet by the solution in order to get a correct MBP measurement.

MBP Capillary Calibration Over an Extended Period of Time

The calibrations of the MBP capillaries were all based on the sessile drop measurements of mercury in an aqueous 0.05M Na_2SO_4 solution at 25°C reported in 1961 by Smolders and Duyvis (10) which is the most accurate absolute determination of the interfacial tension of a mercury electrode available. Their reported value of the interfacial tension at the electrocapillary maximum is 426.2 ± 0.2 mNm^{-1}. The reference electrode employed when calibrating in this solution was a glass sodium ion electrode (Orion 94-11A). However we found (5) that actually this reference electrode is not stable enough for use with our new level of precision and the very stable two phase lead amalgam-lead sulfate electrode (11) is inconvenient to use in calibration. Therefore we have adopted a secondary standard, 0.1M NaCl, by calibrating a capillary with 0.05M Na_2SO_4 and determining the interfacial tension at the electrocapillary maximum at 25°C. The value of the interfacial tension at the electrocapillary maximum in 0.1M NaCl at 25°C is 425.78 ± 0.02 mNm^{-1}. The reference electrode used when calibrating in 0.1M NaCl is the Ag/AgCl electrode of the thermal electrolyte type (12).

Figures 1 and 2 are plots of the measured radius of the two capillaries (A and B, respectively) *vs.* the date of calibration. In the case of capillary A (Fig. 1), it was calibrated nearly daily *vs.* 0.05M Na_2SO_4 for a period of 3 months. Then the capillary was stored in triple distilled water for 5½ months. Finally it was calibrated five more times *vs.* 0.1M NaCl. Note that these last calibrations fall on the least squares straight line established for the calibration *vs.* 0.05M Na_2SO_4. Capillary B (Fig. 2) was calibrated only *vs.* 0.1M NaCl for a period of 4½ months.

The fact that the radius of capillary A continued to increase at a constant rate when it was stored in triple

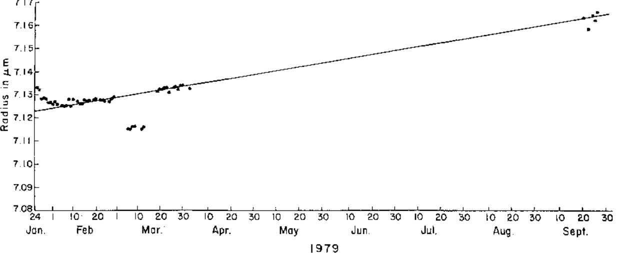

Fig. 1. Calibration of capillary A. Points to left were calibrated with 0.05M Na_2SO_4. Points to right were calibrated with 0.1M NaCl. During period between the two sets of points the capillary was immersed in triple distilled water.

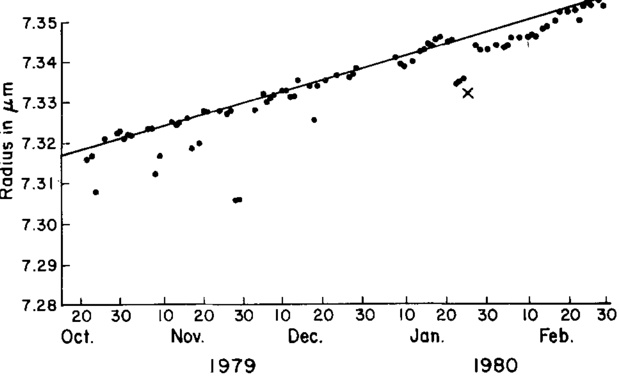

Fig. 2. Calibration of capillary B. Calibration was made using 0.1M NaCl. Points marked with X indicate when capillary was inadvertently dried for 15 min.

distilled water for 5½ months suggests that the glass is swelling by absorption of water molecules at the capillary tip. This phenomenon is similar to the swelling of a piece of macaroni on cooking, and therefore we have decided to refer to the phenomenon as the "macaroni effect."

The fact that the slopes of the least squares calibration lines for the two capillaries are different is probably due to the fact that the wall thicknesses of the two capillaries were different. For capillary A the rate of increase of radius was 0.0016 $\mu m\ day^{-1}$. For capillary B the rate was 0.0028 $\mu m\ day^{-1}$. For example, this means that for capillary A, if the true value of the interfacial tension is 425.78 mNm^{-1}, and if the initial radius was 7.13 µm, the apparent interfacial tension calculated on the assumption of an unchanged capillary radius would be −0.67 mNm^{-1} in error in one week. Since the experimental error in our measurements (5) is only ±0.02 mNm^{-1} this would constitute an unacceptable error. In the case of capillary B if the initial radius was 7.33 µm, the error in one week would be −1.1 mNm^{-1}. Thus one sees that assuming the capillary radius remains constant for only a week can result in errors in the interfacial tension which are 30 to 50 times larger than the 95% confidence limits of the measurement. Moreover occasionally for reasons which are not really clear, a calibration can exhibit an excursion which might be as large as the straight line produced in two months (*cf.* Fig. 2). (It is possible that these excursions might be due to movement of mercuric oxide, which is unavoidable, to the orifice.) The one large excursion in Fig. 2 marked X was due to the fact that the capillary was inadvertently dried for 15 min. Note, however, that after this drying the calibration did eventually return to the straight line. We take this phenomenon as further proof that what is happening is the swelling of the glass.

These measurements make it clear that the only safe procedure is to calibrate the MBP capillary daily. We have adopted daily calibration as our standard

procedure and we strongly recommend this. Actually a calibration only requires about 1½ hr including time for rinsing the cell and deaeration. We calibrate by measuring in triplicate the maximum bubble pressure at only 11 points in the vicinity of the electrocapillary maximum. We determine by digital computer the interfacial tension at the maximum by means of a least squares cubic fit to the average pressures.

Photovoltage Response to Temperature Change at Oxide Semiconductor Electrodes

Benjamin Reichman*[,1]

Christopher Newport College, Newport News, Virginia 23606

and Charles E. Byvik

NASA Langley Research Center, Hampton, Virginia 23665

One of the most important parameters in determining the energy conversion efficiency of a semiconductor photoelectrode used in a photoelectrochemical cell is its flatband potential (FBP). The more negative the flatband potential with respect to hydrogen for an n-type semiconductor used to photoelectrolyze water, the higher the energy conversion efficiency. The flatband potential of a highly doped n-type semiconductor electrode is determined by the electron affinity (EA) of the electrode material and the voltage drop across the Helmholtz layer (1, 2). The EA is a bulk parameter of the semiconductor material and can be changed only by modifying the bulk composition. The potential drop across the Helmholtz layer is dependent on the state of the electrode surface and on the solution used. The Helmholtz layer potential drop is determined by the point of zero zeta potential (pzzp) (1, 2) of the semiconductor surface. Measurements of the pzzp for some n-type semiconducting materials have been reported by Butler *et al.* (2). These measurements were made mainly on oxide semiconductor materials in powder form and correlation between the pzzp and the electronegativity was suggested. They also discuss the effect of temperature on the flatband potential of oxide electrodes (3).

We wish to report the results of a study of the effect of cell temperature on the onset potential of some n-type oxide semiconductor electrodes. We show that the change of the onset potential with temperature is due to the potential change across the Helmholtz layer. The amount of this change depends on the pzzp of the semiconductor electrode. The pzzp of some n-type semiconducting oxide electrodes was determined based on these temperature measurements, and was found to be in general agreement with the values given elsewhere (2). This technique can be used to determine the pzzp of semiconductor electrodes.

Experimental

Single crystals of TiO_2 (rutile), $SrTiO_3$, and α-Fe_2O_3 and polycrystalline WO_3 were used as electrodes. The first two single crystal electrodes were etched in hot 5% phosphoric acid, and the third was etched with 6M HCl. The polycrystalline WO_3 was formed by heating a tungsten disk to 500°C in air. Ohmic contacts to the single crystal electrodes were formed with In-Hg alloy and a wire was attached using silver paste. The wire was inserted through a glass tube, and the unexposed surface covered with epoxy. The onset potential, which is related to the flatband potential, was taken from the photocurrent-voltage recordings using a conventional three-electrode system. The light from a 150W xenon lamp was chopped and the photocurrent recorded using a lock-in amplifier. The cell was held inside a stirred and heated water bath. A reversible hydrogen electrode (RHE) was used as a reference electrode for most of the experiments. In some experiments conducted in basic solutions, an Hg/HgO electrode was used as a reference electrode for comparison. Solutions of NaOH (pH = 13) and H_2SO_4 (pH = 2) were used.

Results and Discussion

Several changes in the photocurrent-voltage curves were noted on increasing the temperature of a photoelectrochemical cell where TiO_2, $SrTiO_3$, Fe_2O_3, or WO_3 were used as photoanodes. These changes are demonstrated for the case of $SrTiO_3$ as an example in Fig. 1. Generally, with increasing cell temperature, (*i*) the onset potential for the photocurrent (which is related to the FBP) is shifted to more positive potentials, (*ii*) the initial slope of the current-voltage curve increases, and (*iii*) the saturation photocurrent increases. These effects, for $SrTiO_3$, give rise to an overall increase in the solar-to-chemical energy conversion efficiency up to cell temperatures of about 80°C; then efficiency decreases. These general trends exist up to 150°C and are discussed elsewhere (4). Here, the change in the onset potential with cell temperature is studied in more detail. In Fig. 2, the change in the onset potential of the photocurrent is shown for several n-type oxide semiconductor electrodes as a function of temperature. A linear change of the onset potential (with respect

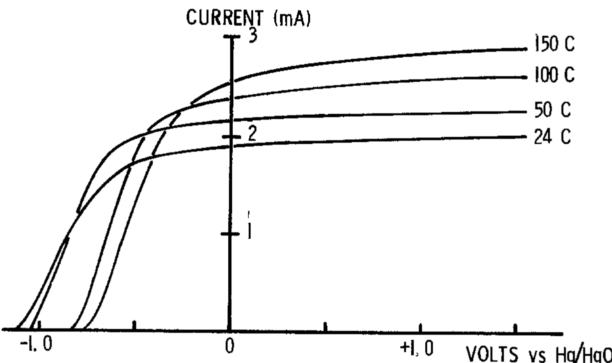

Fig. 1. Typical photocurrent-voltage curves for an $SrTiO_3$-based photoelectrolysis cell in 0.1M NaOH for temperatures ranging from room temperature to 150°C.

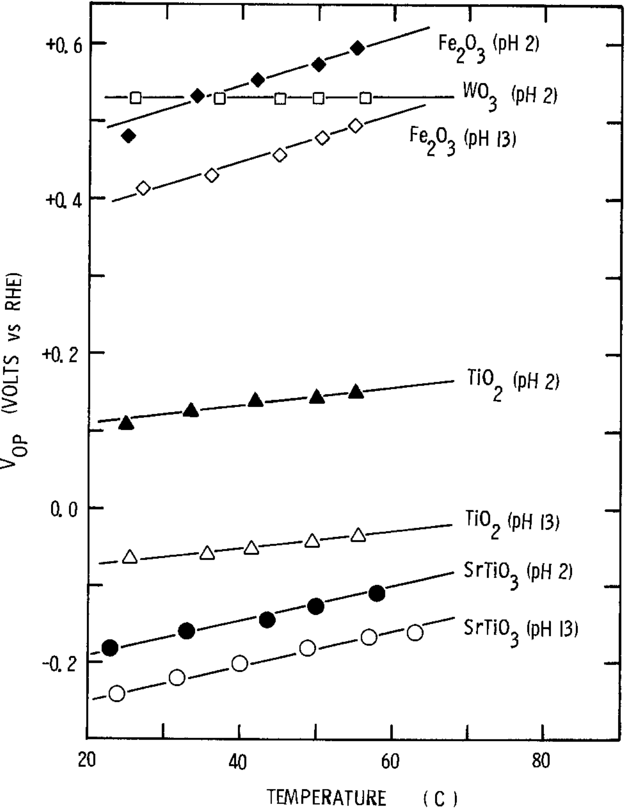

Fig. 2. Temperature dependence of the onset potential for TiO_2 WO_3, Fe_2O_3, and $SrTiO_3$.

to the reversible hydrogen electrode RHE) is observed in all the cases. The slope of the change is different from electrode to elctrode, the highest slopes observed for Fe_2O_3 and $SrTiO_3$, and the lowest for WO_3. These measurements were repeated with solutions of different pH, and in Fig. 2 it can be seen that the slope of the onset potential *vs.* temperature is about the same for each electrode with solutions of either $pH = 13$ or $pH = 2$.

The FBP of the semiconductor electrode with respect to a reference electrode can be described by Eq. [1]

$$V_{FB} = EA - \Delta_{FC} - \Delta_{pH} - E_o \qquad [1]$$

where EA is the electron affinity of the semiconductor (in volts), Δ_{FC} is the potential difference between the conduction bandedge and the Fermi level of the semiconductor, Δ_{pH} is the voltage drop across the Helmholtz layer, and E_o is the potential of the reference electrode with respect to vacuum. In principle, the temperature change can affect the FBP (V_{FB}) with respect to a reference electrode by changing Δ_{FC}, the Helmholtz layer (Δ_{pH}), and the potential of the reference electrode with respect to vacuum (E_o). The potential difference between the conduction band and the Fermi level for a nondegenerately doped n-type semiconductor is

$$\Delta_{FC} = \frac{RT}{\mathbf{F}} \ln \frac{n}{N_c} \qquad [2]$$

where n is the free carrier density, N_c is the density of states in the conduction band, and $\mathbf{F}$ is Faraday's constant.

The voltage drop across the Helmholtz layer at oxide semiconductor surfaces can be written as (2)

$$\Delta_{pH} = \frac{2.3RT}{\mathbf{F}} \log \frac{[H^+]}{[H^+]_{pzzp}} = \frac{2.3RT}{\mathbf{F}} (pH - pH_{pzzp}) \qquad [3]$$

where pH_{pzzp} is the pH of the solution at which the voltage drop across the Helmholtz layer is zero. When inserted into Eq. [1], one gets

$$V_{FB} = EA - \frac{RT}{\mathbf{F}} \ln \frac{n}{N_c} - \frac{2.3RT}{\mathbf{F}} (pH - pH_{pzzp}) - E_o \qquad [4]$$

Equation [4] shows the explicit dependence of the FBP on the potential drop in the Helmholtz layer as well as the well-known dependence of the FBP on the pH of the solution. The dependence of V_{FB} on the temperature is also expressed here. If a reference electrode which is reversible to hydrogen ions is chosen (*e.g.*, H_2/H^+ or Hg/HgO), the FBP with respect to this electrode will in principle be independent of the pH since

$$E_o = 4.5V - \frac{2.3RT}{\mathbf{F}} pH$$

Then

$$\frac{\delta V_{FB}}{\delta T} = \frac{2.3R}{\mathbf{F}} pH_{pzzp} - \frac{R}{\mathbf{F}} \ln \frac{n}{N_c} \qquad [5]$$

This resulting equation predicts that the FBP of an oxide semiconductor electrode will shift linearly with increasing temperature to a more positive potential with a slope which is independent of the pH of the solution and which is determined by the magnitude of the pH_{pzzp}. The more basic the electrode surface, the higher the pH_{pzzp}, resulting in a larger change in the FBP with cell temperature. The dependence of the onset potential with temperature for the electrodes studied is shown in Fig. 2. It should be noted that the dependence is linear and the slopes are positive as indicated by Eq. [5]. The pH_{pzzp} for each electrode was determined using Eq. [5] and the slopes of these curves for $pH = 2$ and $pH = 13$ solutions, and are given in Table I. Also given in Table I are the carrier concen-

Table I. Comparison of the pH_{pzzp} determined for two-solution pH values with values cited in the literature for the oxide semiconductor electrodes. The semiconductor parameters used in Eq. [5] are also listed. The carrier concentrations were determined from Mott-Schottky plots. The slopes are taken from Fig. 2

Electrode	pH (25°C)	V_{FB} *vs.* RHE (25°C)	Slope (mV/deg)	n (cm^{-3})	N_c (cm^{-3})	pH_{pzzp}	pH_{pzzp} (average)	pH_{pzzp} (literature)
Fe_2O_3	2	+0.5	2.9	5.1×10^{17}	2.4×10^{22}	9.8	9.3	8.6
	13	+0.4	2.7			8.8		
$SrTiO_3$	2	−0.18	2.25	3.2×10^{17}	6.8×10^{19}	8.9	9.3	8.6
	13	−0.24	2.4			9.7

trations and density of states for each of the semiconductor materials which were used to determine the magnitude of the second term on the right-hand side of Eq. [5]. The average value for the pH_{pzzp} of each electrode is shown in Fig. 3. It should be noted that the tungsten trioxide sample is degenerately doped and therefore the second term on the right-hand side of Eq. [5] is zero. Also shown in Table I and Fig. 3 are pH_{pzzp} values for these semiconductor materials taken from the literature. The curve drawn in Fig. 3 is taken from Ref. (2). Good agreement is observed between the values obtained in this work and the values taken from the literature. Since Eq. [5] properly describes the observed behavior of the onset potential of the oxide semiconductors reported here, the changes in the FBP with temperature are attributed to thermal effects on the potential across the Helmholtz layer. Thermal-induced changes in the pzzp [see Ref. (5)], EA, E_0, and Δ_{FC} [see Ref. (3)] for TiO_2 are of smaller significance than found in this study. The small difference in the pH_{pzzp} measured at different pH values (see Table I) may be due to the deviation from the ideal 59 mV/pH dependence at 298 K of the flatband potential.

It is interesting to note that in terms of the correlation suggested by Butler and Ginley (2) between the electronegativity of the semiconductor and the pH_{pzzp}, the pH_{pzzp} of Fe_2O_3 is expected to be more acidic than found. However, the value obtained by us for this material is closer to that of $SrTiO_3$ as is observed also by others from measurements with the powder materials. The trend in the slopes (hence the pH_{pzzp}) observed with the other materials are as predicted from the correlation of the pH_{pzzp} with the electronegativity (2) of the semiconductor: smallest for WO_3 and highest for $SrTiO_3$.

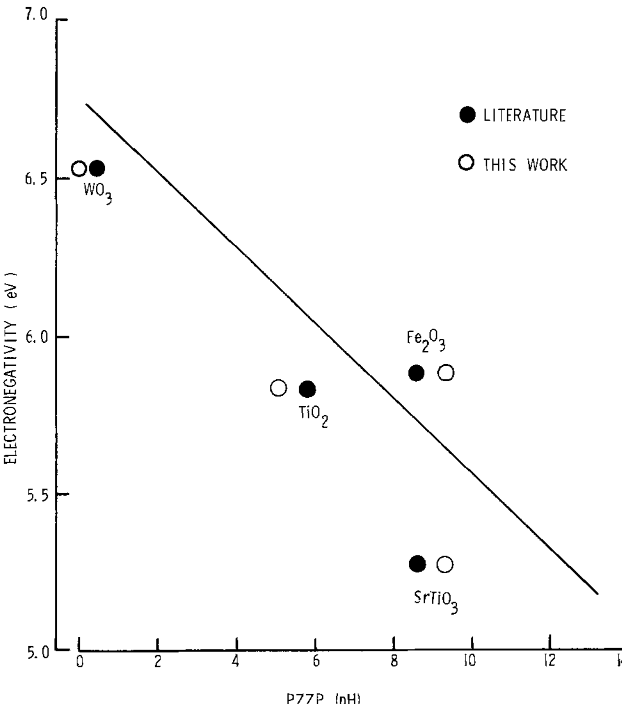

Fig. 3. Comparison of the literature values of the pH_{pzzp} with values determined in this work as a function of electronegativity. The line is taken from Ref. (2).

This conclusion leads to two important considerations for choosing semiconducting materials to be used as photoelectrodes in a photoelectrochemical cell. First, the FBP of the photoelectrode is dependent on the EA of the electrode material and on the potential across the Helmholtz layer. The FBP is more negative the smaller the EA and the more acidic the electrode surface (smaller pH_{pzzp}). While the EA of the electrode material cannot in principle be changed, the pH_{pzzp} can be changed (6). It was suggested (6) that by binding more acidic groups to the surface of TiO_2, for example, the FBP could be shifted to more negative values. The method we describe here can be used to evaluate in a relatively easy way any change in the acidity of the electrode surface following treatment. (The common methods of evaluating the pH_{pzzp} of the materials in the powder form will not be applicable here.)

Second, we discussed the possibility of increasing the solar-to-chemical energy conversion efficiency of a photoelectrochemical cell by increasing the cell temperature (4). For $SrTiO_3$ and TiO_2, the photocurrent increases by increasing the cell temperature and the overall efficiency begins to increase. At cell temperatures higher than about 80°C, the efficiency begins to decrease because the onset potential for these materials has shifted to more positive values.

Our study suggests that by decreasing the value of the pH_{pzzp} (*e.g.*, by binding acidic groups to the surface), the amount of the thermally induced shift in the onset potential of the photoelectrodes may be reduced, thus improving the efficiency of the photoelectrochemical cell by increasing the temperature.

Acknowledgment

We wish to acknowledge Mr. F. R. Parker for his able assistance in the performance of these experiments.

Manuscript submitted Dec. 4, 1980; revised manuscript received May 26, 1981. This was Paper 594 presented at the Hollywood, Florida, Meeting of the Society, Oct. 5-10, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 127, No. 12, December 1980, and Vol. 128, No. 1, 2, 3, and 4, January, February, March, and April 1981.

Electrochemical Aspects of the Cadmium Impregnation Process

T. Palanisamy, Y. K. Kao, D. Fritts, and J. T. Maloy
(pp. 2535-2544, Vol. 127, No. 12)

R. Barnard and F. L. Tye:[1] The authors are to be commenaed on a generally interesting and useful paper. However, their preference for oxidation of hydrogen adsorbed by nickel rather than discharge of nickel cadmium alloy as the more likely cause of the "stepped discharge" profile is surprising.

In an earlier paper Barnard *et al.*[2] checked whether hydrogen adsorption by the nickel sinter could account for the secondary step. The results showed clearly that hydrogen adsorption was far too small to account for the instances of large stepped-discharge profiles. Concerning the findings by Fritts *et al.* depicted in their Fig. 11, it is agreed that the increased hydrogen adsorption takes place as the cathodic potential is increased, but under equivalent conditions the contribution by Ni_5Cd_{21} is much greater. The region studied by Fritts *et al.* (−1.1 to −0.7V SCE) is always complicated by the overlap of hydrogen oxidation, nickel cadmium alloy oxidation, as well as nickel hydroxide formation. Studies concerning bulk γ-Ni_5Cd_{21} confirm the thin film behavior and indicate that the discharge involves the near stoichiometric formation of both $Ni(OH)_2$ and $Cd(OH)_2$. Hydrogen adsorption by this alloy also contributes a negligible discharge capacity.

T. Palanisamy,[3] Y. K. Kao,[4] D. Fritts,[5] and J. T. Maloy:[6] We appreciate the interest by Barnard and Tye in our paper.

Since our main interests were in the impregnation process and the quality of the cadmium electrodes prepared according to our new suggestions, we have not gone into the details of "stepped discharge" profile. But we have concentrated in bringing out the implications of our results and their relevance to the cadmium electrode in actual use.

The results in Fig. 11 of our paper, as agreed by Barnard *et al.*, translate into stepped discharge behavior in Ni-Cd batteries. We concede, as indicated in our original text, that other factors such as excessive carbonation of the electrolyte and the formation of alloys like Ni_5Cd_{21} can lead to similar discharge curves. However, conditions that promote one or more of the above contributions can be identified. One would expect Ni_5Cd_{21} alloy to be formed from rather reactive Ni metal produced by reduction of $Ni(OH)_2$ either formed by corrosion of the Ni sinter or by deliberate addition as in the reference of Barnard *et al.*[2] Higher depths of discharge of the negative electrode (compare the potentials for the reaction $M(OH)_2 + 2e \rightleftarrows M + 2\ OH^-$ where M = Ni, Cd) will tend to increase the amount of $Ni(OH)_2$ and thereby Ni_5Cd_{21} on subsequent charge/overcharge.

The contribution of the oxidation of absorbed hydrogen to the stepped discharge curve is expected to be predominant in situations favorable for the evolution of hydrogen. When the nickel substrate is not completely covered with active cadmium material (as in the microelectrode work shown in our figure), the accidental formation of Ni_5Cd_{21} is stoichiometrically limited by the available cadmium and hydrogen evolution on nickel would be the predominant reaction during overcharge. Thus, in those cases when the loading of active cadmium material per void volume is low, the contribution of the oxidation of absorbed hydrogen to the stepped discharge curve is expected to be high.

Clearly the stepped discharge behavior arises from a combination of factors as suggested in our paper and they are all important depending on the cycling regime, loading level, overcharge conditions, and depth of discharge, to mention a few.

Effect of Plating Parameters on Electrodeposition of NiFe

J. Horkans (pp. 45-49, Vol. 128, No. 1)

A. H. Du Rose:[7] In this paper and in the preceding 1979 paper [Ref. (8) in the paper under discussion], the author presents not only information on NiFe deposition but interesting data on hydrogen evolution.

The author evidently does not believe boric acid acts as a buffer in Ni or NiFe solutions so possibly the word "folklore" should have been used instead of "lore" (p. 45). Actually Table II shows two cases in which boric acid has prevented burned deposits at higher current density by preventing alkalization when i_l is approached. "As a guide," i_l values for hydrogen, determined from the 1979 paper, may be used; 2.8 mA cm^{-2} for solutions 1 and 2, 0.8 for 3 and 4, 28 for 5 and 6, and 8 mA cm^{-2} for solutions 7 and 8. Unfortunately the current densities for solutions at pH 2 in both papers were not carried to the limiting current density.

The author expects (p. 48) a buffer to decrease the efficiency and also lead to less anomalous deposition. However, the effect on efficiency would depend on the effective pK of the buffer and the current density or cathode film pH. Results in Table II are inconsistent and interpretation of the thickness data in the 1979 paper is difficult because of deposit distribution questions and the low current density used for the 1600 rpm rate of agitation.

Boric acid probably lowers the precipitation pH of a basic iron compound as it does for nickel. One might therefore expect more anomalism when boric acid is present at least for the pH 3 solutions. In this connection it would be of interest to know at what pH the basic iron compound forms, and how this corresponds with the Dahms and Croll mechanism at low current density or low pH. Is adsorbed FeOH a factor?

Interpretation of the results in this paper depends much on the interesting results given in the 1979 paper on H_2 evolution in sulfate and chloride solutions. It is surprising that this difference has not been noted

[7] Retired, Pinellas Park, Florida 33565.

before, although one would like more assurance that the Cl_2 and O_2 from the insoluble anode had no effect at the cathode.

Assuming the i_1 values to be correct, it would be of interest to try to rationalize the difference between chloride and sulfate solutions in accordance with some version of the Stokes and Robinson "hydration correction" [Ref. (9) in the paper under discussion]. NaCl will increase and Na_2SO_4 decrease the acidity of acid solutions including boric acid. So, *e.g.*, at *p*H 2, the sulfate solution contains more acid (by some interpretation) than the chloride solution. This may be due not only to different degrees of hydration of Na^+ but also of H^+.

Calculation will show that two of the citrate (*p*K 3.08, 4.75, 5.4) protons were involved in H_2 evolution in Fig. 6 of the 1979 paper (after correcting for H^+ diffusion and using $D = 6.65 \times 10^{-6}$ cm^2 sec^{-1} for citric acid). Possibly the cathode *p*H did not go high enough to use the last hydrogen. Therefore it would not be expected that boric acid (tetraborate or the trimer) would be effective where the *p*K in NaCl and Na_2SO_4 solutions are ~6.2 and 8, respectively [Table 4, Ref. (9) in the paper under discussion]. In a nickel solution the *p*K for boric acid is lower and it can act as a buffer at an advantageous *p*H.

As suggested by the author, the dissociation rate of the buffer is a factor to be considered. Also it should be noted that there is a wide disparity in experimentally determined cathode film *p*H values. There may not be a marked rise in *p*H until the H_2O discharge reaction is closely approached producing OH^-.

J. Horkans:[8] There is no question that boric acid plays an important role in the electrodeposition of Ni and NiFe. Du Rose argues that the effect of boric acid is due to its role as a buffer. The paper under discussion uses the definition that a buffer is a proton reservoir or sink which opposes a *p*H change. In the case of NiFe deposition, the buffer would provide protons to resist the surface alkalization due to H_2 evolution. Given this definition, neither this nor the earlier paper[9], also discussed, shows evidence of buffering by boric acid.

Table II does show instances where H_3BO_3 prevents burning of deposits, but this in itself is not evidence that buffering occurs. If H_3BO_3 is buffering according to the above definition, then the increased supply of protons at the electrode surface will result in a decrease in the current efficiency of the alloy plating. On the contrary, Table II shows that H_3BO_3 does not decrease the current efficiency. It is not valid to say that the effect on efficiency depends on the *p*K of the buffer and the *p*H at the interface; if the *p*K of the acid is too high, it is not serving as a buffer. Alternatively, if its dissociation rate is too low, it cannot buffer under the dynamic conditions occurring near the electrode during H_2 evolution. For this latter reason, the equilibrium *p*H measurements of Du Rose[10] may not be directly applicable to the nonequilibrium conditions during metal deposition.

There may be other mechanisms, such as adsorption, through which H_3BO_3 can influence NiFe deposition. Boric acid is shown to have the largest effect under conditions where iron hydroxide precipitation is most extensive. *i.e.*, near the hydrogen limiting current, at high *p*H, and in SO_4^{2-} solutions. Perhaps some influence of H_3BO_3 on $Fe(OH)_2$ precipitation is possible, as Du Rose suggests, but this is speculative as yet. There is no firm experimental evidence which could establish the validity of either of the above mechanisms.

[9] J. Horkans, *This Journal*, 125, 1861 (1979).
[10] A. H. Du Rose, *Plating*, 64, 52 (1977).

As Du Rose does not specify in what way he finds Table II to be inconsistent, a reply to this comment cannot be given. The fact that the current density in footnote 9 was not near the H_2 limiting current does not invalidate the conclusions concerning the effects of anion and H_3BO_3 on the efficiency of Ni deposition.

The remainder of the discussion contribution concerns footnote 9, not the present paper. The anion dependence of hydrogen limiting current cannot be explained by a "hydration correction," since these solutions are at constant *p*H and, by definition, have the same acidity. Such a model is also precluded by the fact that the addition of Na_2SO_4 to $NaClO_4$ solution did not increase the H_2 limiting current. It is also unlikely that reduction of gases evolved at the counterelectrode is contributing to the observed current. The low solubility of O_2 in solution implies that it could contribute only a small fraction of the observed current. Chlorine is more soluble in H_2O than O_2, yet the H_2 limiting currents in Cl^--containing solutions are lower than those in Cl^--free solutions. This shows that Cl_2 reduction currents are insignificant.

In calculating the number of protons which citric acid contributes to the hydrogen evolution current in a *p*H 3.0 solution 0.75M in NaCl and 0.1M in citric acid, one must consider the concentrations of the various citrate species. Only H_4Cit and H_3Cit^- are present at significant concentrations (0.054M and 0.045M, respectively, as calculated from the *p*K values). If only the first proton is available, the proton reservoir will have a concentration of 0.054M; if two protons are available, this value becomes 0.15M ($2 \times 0.054 + 0.045$); if three, 0.25M ($3 \times 0.054 + 2 \times 0.045$). The observed limiting current of Fig. 6 in footnote 9 lies between the values predicted from two and three contributed protons, assuming all species have a diffusion coefficient of 6.65×10^{-6} cm^2/sec. The diffusivities of the ions need not be the same as that of the undissociated acid, however, and thus it is difficult to say how many protons from citric acid participate in the electrode reaction. Whether a given proton does so depends, as stated above, on its *p*K, the interfacial *p*H, and the rate of dissociation.

Reaction Model for Iron Dissolution Studied by Electrode Impedance
I. Experimental Results and Reaction Model

M. Keddam, O. R. Mattos, and H. Takenouti
(pp. 257-266, Vol. 128, No. 2)

M. Cid and M. C. Petit:[11] M. Keddam, O. R. Mattos, and H. Takenouti have performed an impressive piece of experimental work on iron dissolution. We would like to raise two points.

1. In their paper the authors based to a large extent their interpretation on the assumption that the high frequency arc consists of only one time constant. This is in contradiction with the paper by H. Schweickert, W. J. Lorenz, and H. Friedburg,[12] according to which this arc must be interpreted by two overlapping time constants. Can the authors comment on the possibility of decomposition of an impedance loop in two or several poorly separated time constants?

2. In the model proposed, the frequency dependence of the impedance is accounted for by coverage relaxation effects. Can the authors give additional information on the delimitation between this approach and an alternative way as surface relaxation introduced by Schweickert *et al.*?[12]

[11] Laboratoire de Mécanique Physique, Université de Bordeaux I, 33405 Talence, Cedex, France.
[12] H. Schweickert, W. J. Lorenz, and H. Friedburg, *This Journal*, 127, 1693 (1980).

M. Keddam,[13] **O. R. Mattos,**[14] **and H. Takenouti:**[13] Both comments are very central to the discrepancy existing between our approach of the iron anodic dissolution and that adopted by W. J. Lorenz and coworkers. Most of our argumentation was emphasized in the Discussion[15] of their last paper.[16] Unfortunately it seems that our remarks and comments related to the present Discussion were not sufficiently answered.

1. A very large number of impedance data on solid electrodes is now available. With practically no exception, when performed over a wide range of frequencies their loci in the complex plane consist in an association of more or less depressed semi-circles. This holds not only for the high frequencies loop considered in footnote 16, but also for the loops exhibited at lower frequencies by electrodes submitted to dissolution or deposition. When modeling a-c behaviors it turns out that the very basic problem is to estimate whether each depressed semi-circle can be resolved in a few overlapping time constants or represented by a practicalily infinite number of time constants (transmission line) such as a Warburg impedance. In fact, this is known to be an extremely difficult task. The statement that a distorted impedance loop must be definitely resolved into two time constants rather than into a higher number can be advocated only by fitting high precision experimental data and by producing a complete set of statistical parameters showing that standard and systematic deviations are at their minimum. To our knowledge this was not done in the present case. Moreover, as we have shown,[17] pulse techniques (*e.g.*, galvanostatic double pulse[18]) are of no help since they absolutely require the *a priori* assumption that the impedance actually obeys a postulated equivalent circuit. Obviously such an assumption makes the problem under consideration meaningless.

2. This second point deals with the very origin of the time or frequency dependence of the metal/electrolyte interphase. In the present state of knowledge this problem is somewhat of a semantic nature. The so-called "surface relaxation" can be merely regarded as an aphorism since of course we are faced with relaxation phenomena taking place at the electrode surface. On its own, this terminology does not throw any light on what really relaxes. A crude assimilation of the surface to the geometric area (roughness effect) is completely irrelevant since relaxation associated with passivation, *e.g.*, Fig. 6, E_5 in the paper under discussion, should arise from a steadily decreasing electrode area. The observed relaxation processes including the d-c behavior of the electrode as their low frequency limit are most likely related to the ability of the surface to locally allow electron transfer. In that sense the term of "site" may be conveniently used, each time constant being induced by the variation of the surface density of distinct kinds of sites. Now the problem remains of the exact nature of these sites. It seems to us that this aspect can be clarified on the basis of an exhaustive experimental work focused on the influence of composition and structure of both phases on the interphase behavior. In our opinion, our paper brought serious evidence that, in the present case, these sites strongly depend on the electrolyte pH and must involve some kind of chemical bond between surface atoms and electrolyte species. Therefore, it is quite reasonable to propose a model with partial surface coverages for characterizing these sites. This is not at all harmful to the idea that these sites are also under the dependence of crystallographic or solid-state properties on the metal side but up to now this was not supported by convincing proofs. On the contrary, experiments performed with iron-base amorphous alloys hence free of crystallographic kinks or defects have shown a behavior nearly similar to crystalline iron.[19] This seems to further substantiate our interpretation.

Electron Transfer Reactions at Passive Tin Electrodes

S. Kapusta and N. Hackerman (pp. 327-332, Vol. 128, No. 2)

J. O'M. Bockris and S. U. M. Khan:[20] The theoretical interpretation made by the authors of their results in a study of redox reactions at passive tin electrodes evokes some comments because of the (partly admitted) lack of consistency between theory and experiment.

Experimentally, the authors well confirm that the linear Tafel relation is obtained both in the cathodic and anodic region for the redox reaction, $K_3Fe(CN)_6$/$K_4Fe(CN)_6$, they used. This result also supports the earlier reported Tafel linearity for similar redox reactions on passive iron by Olmedo *et al.*,[21] and on other metal electrodes by several authors.[22-24]

The basic model used by the authors (*cf.*, Eq. [20]) to represent current/overpotential relation involves thermal fluctuation as the origin of energy states in the ions in solution to and from which electrons exchange with the metal oxides. If the energy states in ions in solution arise by means of such fluctuations, however, the distribution is Gaussian (*cf.*, Eq. [20]), and hence, a nonlinear Tafel relation is always expected, in contrast to experimental observation. It is evident from the Gaussian distribution of energy state used in Eq. [20] that current/overpotential relation should show maximum at higher overpotential range ($|\eta| \leq 2V$), where a limiting region does not appear and if the proper value of reorganization energy, λ, is used. The value of λ, used by the authors, is that of Hale.[25] However, this value is erroneous because the image terms were neglected in the calculation.

The fluctuation concept was introduced by Levich[26] to provide a physical interpretation of the continuity of Tafel lines. The thought process is that the outer sphere solvent molecules, due to their vibrational motion, interacts with the redox ion, giving rise to fluctuation in the energy of the central redox ion sufficient for it to be activated. However, this view ends up with the Gaussian distribution of energy states and a nonlinear Tafel line.

We therefore suggest an alternative model. There are sufficient classical modes of motion (*e.g.*, translation) in the solvent to give the redox complex enough interaction to affect the activation of the ion solvent bond. There is spectroscopic evidence[27-29] of classical motion of solvent molecules in water. In such a model, the energy distribution is Maxwellian, and the quan-

tum statistics are similar to those considered in the theories of reactivity in gas and liquid phases.[30,31] Thus, one can have a current/overpotential relation of the following type: For cathodic current, i_c, we get

$$i_c = c \int \rho(E) f(E) P_T(E) D_{ox}(E) dE \quad [1]$$

where c is a constant, $\rho(E)$ is the density electron state in metal, $f(E)$ is the Fermi distribution of electron, $P_T(E)$ is the tunneling probability of electron, and $D_{ox}(E)$ is the distribution of electronic states of oxidized ions in solution, which is expressed in this model as:

Expressing $\rho(E)$, $f(E)$, and $D_{ox}(E)$ in Eq. [1], we get

$$i_c = c^1 \int E^{1/2} \frac{1}{[e^{(E-E_f)/kT} + 1]} P_T(E) \exp[-(E_o + \beta e_o \eta_c - E)/kT] dE \quad [2]$$

where c^1 is a constant, E_o is the ground electronic state energy of oxidized acceptor obtained from Born-Haber cycle for the process $M(e) + A^+ \rightarrow M\text{---}A$, β is the symmetry factor around 0.5, and η_c is the cathodic overpotential and negative. After integration, the expression [2] gives

$$i_c = i_o \exp(-\beta e_o \eta_c / kT) \quad [3]$$

where i_o is essentially independent of potential. Thus, one gets a linear Tafel relation from this model for which the distribution is Maxwellian (cf., Schmickler[32]).

S. Kapusta and N. Hackerman:[33] We appreciate Dr. Bockris' and Dr. Khan's comments since they raise important questions regarding the present state of understanding of charge transfer at semiconducting and metal electrodes.

Our Eq. [20] can be analytically solved with certain assumptions, *e.g.*, that charge transfer occurs mainly within 1 kT at the edge of the conduction band or, in the case of metals, the Fermi level. Taking bare metal electrodes as an example, we obtain for the cathodic current density

$$i_c = i_o \exp\left[\frac{\lambda}{4kT}\right] \exp\left[-\frac{(\lambda - e\eta)^2}{4kT\lambda}\right] \quad [1]$$

and an equivalent expression for the anodic current. Here i_o is the exchange current density, basically independent of potential, λ is the reorganization energy of the redox couple in solution, and η is the overpotential. Other symbols have their usual meaning.

As has been shown by Levich,[34] no exponential relation between current and potential can be expected from Eq. [1] which is in contradiction with experimental results. Only for the case $\lambda << \eta$ can Eq. [1] be approximated by

$$i_c = i_o \exp\left(\frac{e\eta}{kT}\right) \quad [2]$$

Theoretical and experimental evidence[35] indicates that λ values are about 1-2 eV for most redox couples, *i.e.*, within the experimentally accessible overpotential range. In particular, the value of $\lambda = 1.2$ eV for the Fe $(CN)_6^{4/3-}$ couple gives the best agreement with our experimental results. The same value was used by Heusler[36] on passive Nb electrodes. Lower values have also been reported: 0.65 eV,[34] 0.4 ± 0.2 eV,[37] and 0.75 eV.[38] It is likely that these discrepancies can be accounted for by uncertainties in the determination of other parameters used in solving Eq. [20], *e.g.*, flatband potential, donor energy, effective mass of the electron, etc.

The use of the "linear approximation," *i.e.*, Boltzmann distribution, to represent the energy levels in solution instead of our Eq. [1] and [2] (Gaussian) results in a solution of Eq. [20] having constant transfer coefficient, *i.e.*, linear Tafel slopes.[39-41] It seems, however, that the use of three-dimensional translational modes is inconsistent with the model used for the charge transfer reaction. An alternative explanation of the constancy of the transfer coefficient with potential can be found considering the effect of inner sphere vibration on outer sphere reactions, as proposed by Schmickler.[41] This results in an apparent linear distribution of energy levels in solution arising from the two (*i.e.*, inner and outer sphere) harmonic contributions.

Exothermic Reactions Among Components of Lithium-Sulfur Dioxide and Lithium-Thionyl Chloride Cells

S. Dallek, S. D. James, and W. P. Kilroy
(pp. 508-516, Vol. 128, No. 3)

M. A. Mueller and M. J. Domeniconi:[42] In this communication, the authors report the results of a very well-structured series of experiments designed to identify components of Li/soluble cathode cells which may react so vigorously to cause batteries to explode. With respect to the $Li/SOCl_2$ system, we have conducted a similar investigation, and in general our data agree with those reported by the authors. However, with respect to the reactivity of the initial components of the $Li/SOCl_2$-system, we wish to offer an alternative interpretation of the data.

On the basis of the data shown in Fig. 8(E) of the paper under discussion, the authors concluded that the initially present components of an undischarged battery are quite unreactive even after the lithium had melted. We had observed this same phenomenon, as shown in Fig. 1(B) below, and were initially puz-

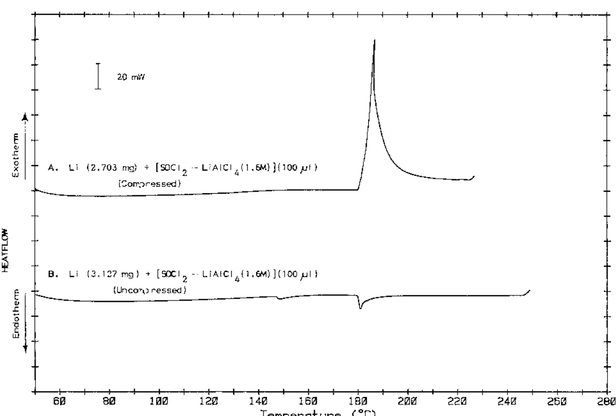

Fig. 1.

zled by the results. The stability of the system below 180°C can be explained by the protective LiCl film on the anode; above 180°C, we were surprised that this film apparently continued to prevent a direct reaction between Li and $SOCl_2$. On the assumption that these results were dependent on the experimental conditions, we prepared a sample in which the lithium was placed between two stainless steel plates and compressed to and maintained at a pressure representative of that found in Li/$SOCl_2$ batteries. The reactivity of the components under these conditions is considerably different above the melting point of Li, as shown in Fig. 1(A) above. In this case, a substantial exothermic reaction between the components is observed. It would appear, therefore, that above 180°C, the system is in only a metastable state, and that the thermodynamically favored reaction between molten lithium and thionyl chloride can proceed under conditions in which the LiCl loses its ability to act as a protective barrier. We believe such conditions generally prevail in complete Li/$SOCl_2$ cells, and are the principal reason for the phenomenon known as "thermal runaway."

We therefore conclude that the initial components of an undischarged Li/$SOCl_2$ battery must be considered very reactive after the lithium has melted, and that it is only under a limited set of conditions that the components may coexist without exothemic reaction.

S. Dallek, S. D. James, and W. P. Kilroy:[43] Mueller and Domeniconi suggest that our failure to observe a reaction between Li and $SOCl_2$-$LiAlCl_4$ at the melting point of Li is due to a significant departure of our DSC tests from battery conditions, *viz.*, to our lack of the Li compression that exists in most if not all Li batteries. In their very interesting experiment, Li compressed between stainless steel plates reacted violently as soon as the Li melted.

We may speculate that, in Mueller and Domeniconi's experiment, when Li melted (with its 20% volume increase) the spring pressure extruded a large, virgin, unpassivated Li surface which immediately reacted violently with the hot $SOCl_2$ giving their exotherm. However, we doubt that this situation holds in the jellyrolled C and D cells where most of the explosions have been reported. Here Li is contained on metal Exmet where on melting, Li flow could occur perpendicular to the plane of the Li without creating a substantial amount of fresh Li surface. The possibility should also be considered that the spring material acted as a catalytic surface (like C black) for the reduction of $SOCl_2$ and when Li melted, a shorted, high-rate cell was created. This situation also would not normally be present in a real battery. We reiterate that their experiment is very interesting; it certainly requires follow-up tests to elucidate its nature.

The Hydrogen Evolution Reaction on Electrodeposited Gold, Nickel, and Zinc Rotating Disk Electrodes

P. C. Andricacos and H. Y. Cheh (pp. 838-840, Vol. 128, No. 4)

Richard Haynes:[44] Several points should be questioned regarding this paper:

1. The validity of the kinetic constants derived from the data might be questioned regarding the lack of a: (*i*) definition of steady state and (*ii*) statistical treatment of data for such a limited range of potential, current, and rotational speed.

2. The contribution, if any, of deposition of hydrogen from H_2O is not considered especially regarding point (*i*).

3. Mechanism and rate-determining steps for the hydrogen evolution reaction are not uniquely determined by Tafel slopes and dependencies on proton concentration. These mechanisms and rate-determining steps have been shown to be a function of the metal, solution, and overpotential.[45] From the data presented here it is not possible to be so conclusive. A number of other possibilities could explain the observed data.

P. C. Andricacos and H. Y. Cheh:[46] 1. A careful analysis on the accuracy of our data was made during our work. For sake of brevity, we did not include our analysis in the paper. The statements made in our paper concerning our data are correct.

2. The limiting current density for hydrogen evolution is consistent with the Levich equation. We conclude that the deposition of hydrogen from H_2O cannot be a significant reaction in our study.

3. We have stated in our paper that our results are consistent with certain mechanisms. We have not claimed that mechanisms and rate-determining steps are uniquely determined by Tafel slopes and dependencies on proton concentration.

Lattice Defects in Semiconducting $Hg_{1-x}Cd_xTe$ Alloys

I. Defect Structure of Undoped and Copper Doped $Hg_{0.8}Cd_{0.2}Te$

H. R. Vydyanath*

Honeywell Electro-Optics Center, Lexington, Massachusetts 02173

ABSTRACT

Undoped $Hg_{0.8}Cd_{0.2}Te$ crystals were subjected to high temperature equilibration at temperatures ranging from 400° to 655°C in various Hg atmospheres. Hall effect and mobility measurements were carried out on the crystals quenched to room temperature subsequent to the high temperature equilibration. The variation of the hole concentration in the cooled crystals at 77 K as a function of the partial pressure of Hg at the equilibration temperatures, together with a comparison of the hole mobility in the undoped samples with that in the copper-doped samples, has yielded a defect model for the undoped $Hg_{0.8}Cd_{0.2}Te$ crystals, according to which, the undoped crystals are essentially intrinsic at the equilibration temperatures and the native acceptor defects are doubly ionized. Native donor defects appear to be negligible in concentration, implying that the p-to-n conversion in these alloys is mainly due to residual foreign donor impurities. The thermodynamic constants for the intrinsic excitation process as well as for the incorporation of the doubly ionized native acceptor defects in the undoped crystals have been arrived at. Copper appears to be incorporated on metal lattice sites acting as a single acceptor with little compensation. Results on the heavily copper-doped samples indicate that the quench from the equilibration temperatures was imperfect resulting in a large fraction of the copper precipitating during the quench. From results of experiments where the cooling rate from the equilibration temperatures was intentionally varied in the undoped samples, a qualitative correlation was established between the quenching efficiency and the presence of macroscopic defects such as voids and inclusions in the samples.

The importance of the pseudobinary semiconducting $Hg_{1-x}Cd_xTe$ alloys as a useful infrared detector material has long been recognized (1, 2). The bandgap of these alloys is variable depending on the proportions of HgTe and CdTe present in them; the variable bandgap makes these alloys suitable for infrared detector applications over a wide spectral range.

Considerable deviations from stoichiometry arise in these alloys prepared at elevated temperatures; these deviations result in electrically active point defects which in turn influence the carrier concentration and the lifetime in the material. Very little information exists on the systematic investigation of the nature of defects and the variation of the concentration of these defects in these alloys as a function of the physicochemical conditions of preparation. In fact, much disagreement prevails regarding the origin of p-type to n-type conversion in these alloys (2-5).

As part of a program aimed at investigating the defect structure of the undoped $Hg_{1-x}Cd_xTe$ alloys as well as the mode of incorporation of dopants, the present paper reports on the study of the undoped and copper-doped $Hg_{0.8}Cd_{0.2}Te$.

Based on the results of Hall effect and mobility measurements on the undoped and copper-doped crystals quenched to room temperature subsequent to high temperature equilibration, defect models for the undoped and copper-doped $Hg_{0.8}Cd_{0.2}Te$ have been arrived at. Thermodynamic constants for the intrinsic excitation constant and the incorporation of the native acceptor defects have been evaluated. These constants satisfactorily explain the electrical data in the undoped as well as the copper-doped crystals.

Experimental

Starting material.—The compositional uniformity of the $Hg_{1-x}Cd_xTe$ alloy samples used in the investigation was $x = 0.2 \pm 0.005$. Most of the experiments were carried out with starting material that was free of macroscopic defects such as precipitates, pores, and Hg or Te inclusions; in a few experiments where the intent was to establish the effect of macroscopic defects on the efficiency of quenching the high temperature equilibrium, material with a relatively high density of voids and inclusions was used. In order to assure ourselves that equilibrium was attained at temperatures as low as 400°-460°C within reasonable annealing periods (2-3 weeks), and also to increase the efficiency of quenching the high temperature equilibrium, the thickness of most of the $Hg_{0.8}Cd_{0.2}Te$ samples used in the present investigation was restricted to $\leq$ 0.04 cm. The residual donor or acceptor concentration in the starting undoped $Hg_{0.8}Cd_{0.2}Te$ material was $\leq 10^{16}$ cm^{-3}.

* Electrochemical Society Active Member.

Key words: lattice, defects, copper doping, $Hg_{1-x}Cd_xTe$, hole mobility, semiconductors.

Copper doping.—Doping to different concentrations of copper was obtained by evaporating various amounts of copper on to the surface of the undoped samples and subsequently diffusing in the copper in a known atmosphere of Hg. Copper concentration obtained in the doped samples was determined by atomic absorption analysis carried out by Photometrics, Incorporated, Lexington, Massachusetts.

It is to be noted that the samples used for copper diffusions at temperatures below 400°C had been previously annealed at 250°C for several months in order to reduce the native acceptor defect concentration to less than 10^{15} cm^{-3}. Since copper has a high diffusivity in $Hg_{1-x}Cd_xTe$ alloys (6-7), diffusion times of 6-8 weeks were found adequate for uniform doping of samples (0.04 cm thick) at temperatures below 400°C; uniform doping at these temperatures was confirmed by sequentially lapping away the material from both sides of the samples and making certain that the hole concentrations did not change.

High temperature annealing.—Prior to the anneals, crystals were cleaned in organic solvents followed by a Br-methanol etch and a final rinse in DI water. Annealing experiments in various partial pressures of Hg were carried out in evacuated quartz ampuls containing a small amount of Hg also, to obtain the desired Hg vapor pressure. In those experiments where the desired Hg pressure was high enough, an isothermal setup was used where the free Hg and the $Hg_{0.8}Cd_{0.2}Te$ samples were kept at the same temperature; the vapor pressure of Hg in such a setup depended on the amount of free Hg in the ampul and the volume of the ampul. In experiments where the desired Hg pressure was low a two-temperature zone setup was used; the $Hg_{0.8}Cd_{0.2}Te$ crystals were kept at the higher temperature end of the ampul and the free Hg at the lower temperature end; the vapor pressure of Hg obtained corresponded to the saturation pressure of Hg at the lower temperature and was independent of the amount of Hg in the ampul. The limits of Hg pressure, within which the solid is stable at a given temperature, were obtained from the partial pressure-temperature data for HgTe (8) and $Hg_{1-x}Cd_xTe$ alloys (9-10).

Equilibration periods ranging from 16 to 24 hr were used for annealing at temperatures of 500°C or greater and a two week equilibration was used for annealing temperatures of 460° and 400°C. Subsequent to the anneals, the samples were rapidly quenched in ice water, to freeze in as much of the high temperature equilibrium as possible; in a few cases the samples were air cooled from the equilibration temperatures.

Electrical measurements.—Hall effect and resistivity measurements were made using the van der Pauw method (11). Magnetic field strengths of 400 and 4000G were used for the measurement of the Hall coefficient.

Results

Only those Hall coefficient measurements where the Hall coefficient R_H did not vary with varying magnetic field strength, (400-4000G) were used in evaluating the hole concentrations in the crystals. This ensured that the samples did not show mixed conduction (12) and the carrier concentration was given by

$$\frac{1}{|R_H|q}$$

Figure 1 shows the variation of the Hall coefficient as a function of the temperature of measurement for the undoped samples equilibrated at different temperatures under known partial pressures of Hg and quenched to room temperature. It is evident from the figure that at temperatures exceeding 145 K the contribution from the intrinsic carriers becomes important, whereas at temperatures between 77 and 145 K the Hall coefficient is temperature independent indicating that the native

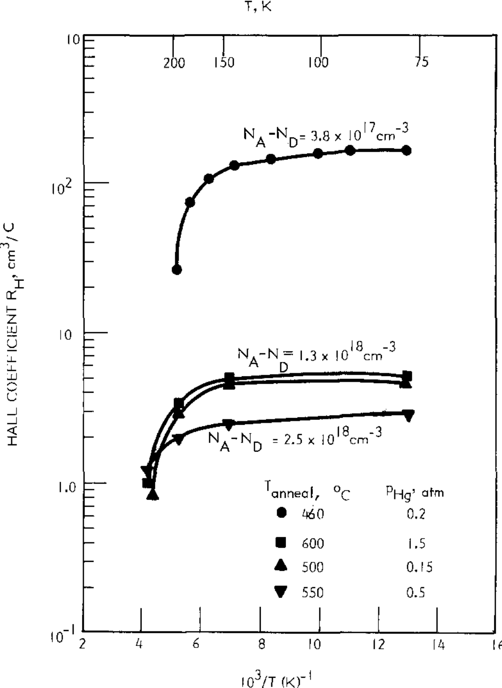

Fig. 1. Hall coefficient as a function of measurement temperature for undoped $Hg_{0.8}Cd_{0.2}$ samples equilibrated at the indicated temperatures and partial pressures of Hg and quenched to room temperature.

acceptors are completely ionized at 77 K for concentrations ranging from 10^{17} to 10^{18} cm^{-3}. Based on this inference, all the Hall effect measurements on the undoped samples were carried out at 77 K, and the resulting hole concentration was assumed to give a measure of the native acceptor defect concentration incorporated at the higher equilibration temperatures.

Figure 2 shows the hole concentrations at 77 K as a function of the partial pressure of Hg for the undoped crystals annealed at various temperatures and quenched to room temperature. The samples are invariably p-type for all partial pressures of Hg (throughout the existence region) at temperatures greater than 400°C and the hole concentration is roughly inversely proportional to the partial pressure of Hg, p_{Hg}. Phase boundary limits at each temperature are indicated by arrows in the figure. The solid lines

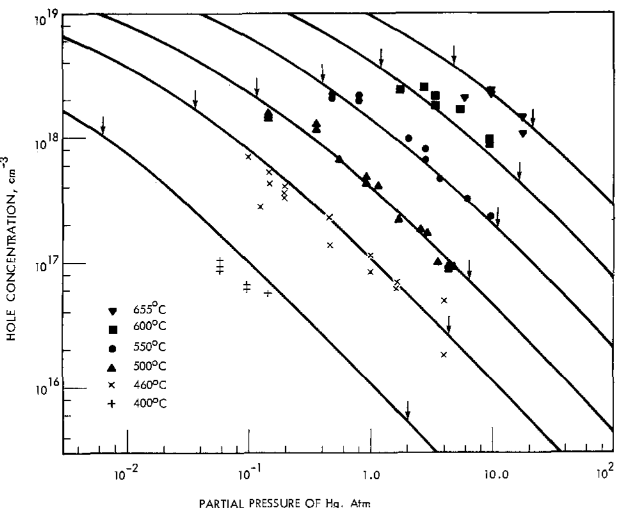

Fig. 2. Hole concentration at 77 K as a function of the partial pressure of Hg for undoped $Hg_{0.8}Cd_{0.2}$ crystals annealed at various equilibration temperatures and quenched to room temperature; solid lines correspond to the values calculated on the basis of the defect model discussed in the text.

shown in the figure correspond to the hole concentrations calculated on the basis of the defect model for the undoped crystals, to be discussed later.

Figure 3 shows the variation of the Hall coefficient as a function of the temperature of measurement for crystals doped with different copper concentrations. Just as with the undoped crystals, most of the copper present in the electrically active form appears to be completely ionized between 77 and 145 K, and at temperatures greater than 145 K the contribution from the intrinsic carriers becomes significant. The total amount of the electrically active copper concentration in the samples was inferred from the hole concentrations obtained at 145 K.

Figure 4 shows the hole mobility at 77 K for the undoped crystals as a function of the hole concentration. The data indicate that the hole mobility decreases with increase in hole concentration. Figure 5 shows the hole mobility at 77 K in various copper-doped samples. The temperatures at which the various copper diffusions were done are also indicated in the figure. It is apparent from Fig. 4 and 5 that the copper-doped samples

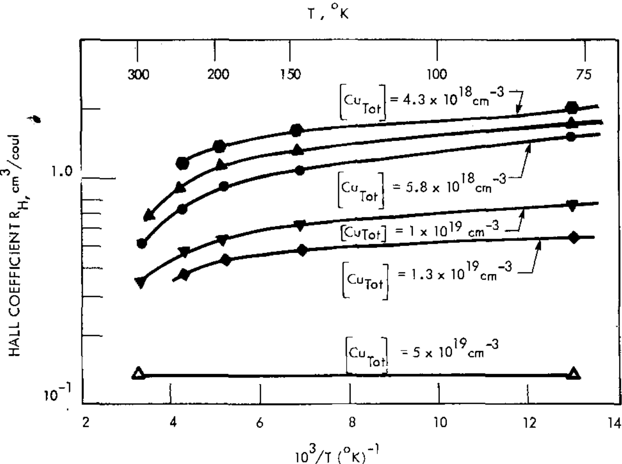

Fig. 3. Hall coefficient as a function of measurement temperature for copper-doped $Hg_{0.8}Cd_{0.2}$ crystals.

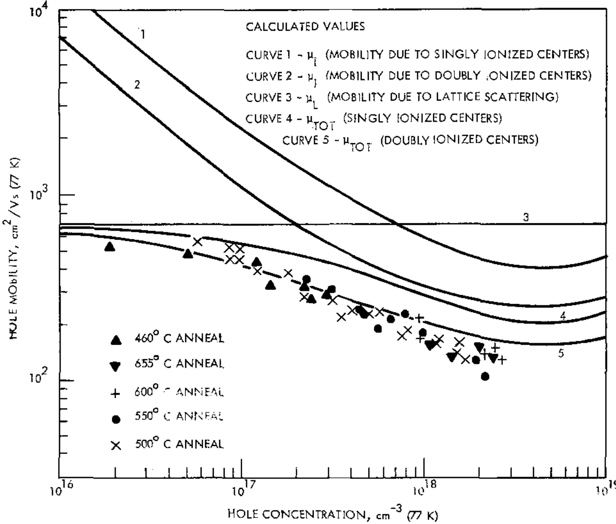

Fig. 4. Experimental and calculated hole mobility at 77 K as a function of the hole concentration for undoped $Hg_{0.8}Cd_{0.2}$ crystals; curves 1 and 2 show the calculated mobility due to impurity scattering (curve 1 for singly ionized centers and curve 2 for doubly ionized centers), line 3 shows the mobility due to lattice scattering, and curves 4 and 5 show the overall mobility calculated by reciprocally combining the impurity scattering mobility and the lattice scattering mobility (curve 4 for singly ionized centers and curve 5 for doubly ionized centers). See Appendix A for details of calculations.

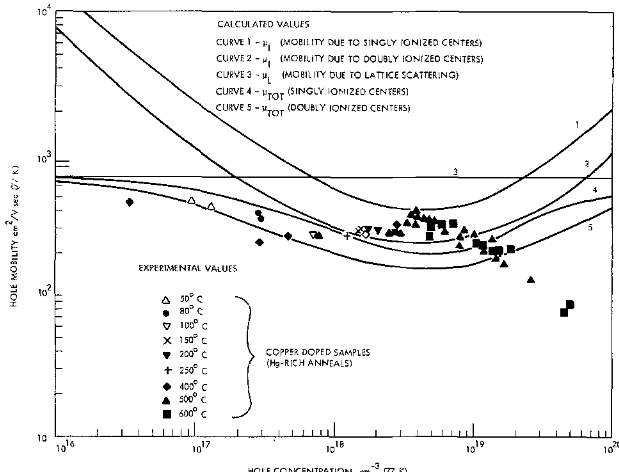

Fig. 5. Experimental and calculated hole mobility at 77 K as a function of the hole concentration for copper-doped $Hg_{0.8}Cd_{0.2}$ crystals; curves 1 and 2 show the calculated mobility due to impurity scattering (curve 1 for singly ionized centers and curve 2 for doubly ionized centers), line 3 shows the mobility due to lattice scattering, and curves 4 and 5 show the overall mobility calculated by reciprocally combining the impurity scattering mobility (curve 4 for singly ionized centers and curve 5 for doubly ionized centers). See Appendix A for details of calculations.

have higher hole mobilities than the undoped samples containing similar hole concentrations. The mobilities calculated on the basis of the combined ionized impurity and lattice scattering are also shown in the figures.

Figure 6 compares the electrical conductivity at 77 K obtained in the undoped crystals containing a relatively large concentration of voids and inclusions (~1000 per cm^2) with those containing a negligible concentration of these (≤ 20 per cm^2) subsequent to anneals at 500°C in different partial pressures of Hg and air cooled or quenched to room temperature; the voids and inclusions in the samples were approximately 10-30 μm in diameter, and depending on how the bulk crystals were grown, the inclusions were either Hg rich or Te rich. Figure 7 shows the electrical conductivity at 77 K, obtained in the undoped crystals containing a large concentration of voids and inclusions and which were air cooled to room temperature subsequent to anneals at 500°C in different partial pressures of Hg. Figures 6 and 7 clearly show that the electrical conductivity variations as a function of the partial pressure of Hg are similar for undoped crystals with and without voids and inclusions that were quenched to room tem-

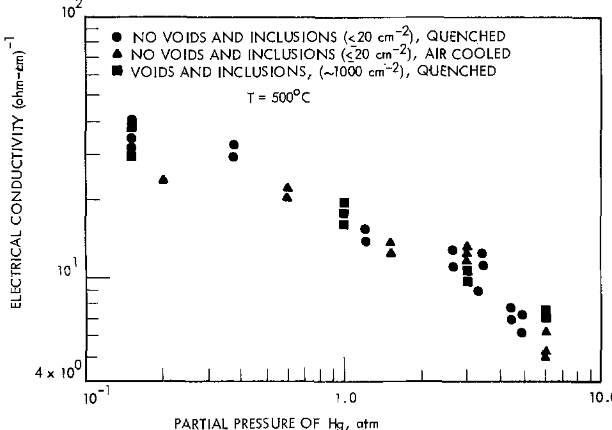

Fig. 6. Electrical conductivity at 77 K for various sets of undoped $Hg_{0.8}Cd_{0.2}Te$ crystals containing different concentrations of voids and inclusions, and quenched or air cooled subsequent to appeals in different Hg pressures at 500°C.

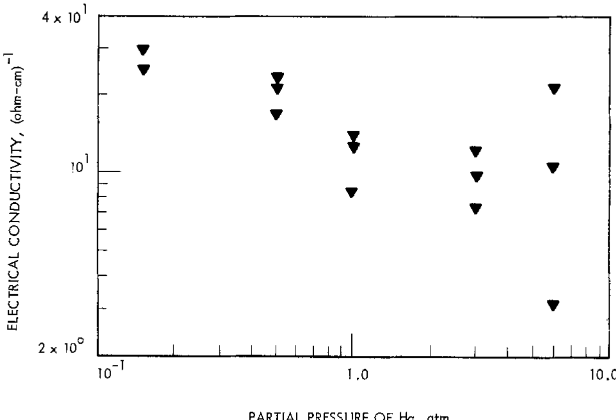

Fig. 7. Electrical conductivity at 77 K for undoped $Hg_{0.8}Cd_{0.2}Te$ crystals containing a large concentration of voids and inclusions and air cooled subsequent to anneals in different Hg pressures at 500°C.

perature subsequent to equilibration at 500°C; the results are also similar for the undoped crystals containing virtually no voids and inclusions and which were air cooled from 500°C. However, considerable scatter is obtained in the results for the undoped crystals containing a large concentration of voids and inclusions and which were air cooled from 500°C.

Discussion

Defect equilibria.—The way in which the concentrations of defects vary as a function of the physicochemical conditions of preparation (temperature, partial pressure of Hg or partial pressure of Te_2, and/or the dopant concentration) can be arrived at by utilizing the quasichemical approach developed by Kröger and Vink (13). The quasichemical approach has been used in many binary compounds to establish defect models (14). In such an approach, atomic and electronic defects are considered as chemical species and defect formation reactions along with the corresponding mass action relations are formulated. The concentrations of all the defect species comprising the electroneutrality condition and the dopant balance equation (for the doped crystals) are then expressed in terms of the relevant mass action constants and the concentration of one defect species. This results in equations containing the various mass action constants and the concentrations of one single defect species; numerical solution will then yield the concentration of this defect species for given values of the mass action constants. Once the concentration of one defect species is determined the concentrations of all the other defect species can be evaluated via the mass action relations.

Defect formation reactions and mass action relations for various defect species are listed in Table I. The defect notations are according to the scheme of Kröger and Vink (13), in which the major symbol indicates the defect, the subscript denotes the type of lattice site occupied, and the superscript indicates the charge. Superscripts prime (′) and dot (·) stand for effective negative and positive charges, respectively, while a cross (x) stands for a neutral charge. Thus V''_{Hg} indicates a doubly negatively ionized vacant lattice site of Hg. Square brackets indicate concentrations expressed as site fractions. The native acceptor defect species considered in this paper are the vacancies of Hg instead of the interstitials of Te. Electrical measurements cannot distinguish between the two species and hence the results will be the same if interstitials of Te are considered as the native acceptor defect species instead. Recent work on the defect structure of CdTe (15, 16) determined by Hall effect and tracer self-diffusion data indicates the presence of appreciable concentrations of Te interstitials in addition to the vacancies of Cd. Although the results of the present work showed no evidence of presence of any native donor defects such as Hg_i or V_{Te}, etc. in any appreciable concentration, Table I includes these defects also for purposes of later discussion in the paper.

Defect state in the cooled crystals.—Ideally, *in situ* high temperature physical property measurements and measurements on the crystals quenched from the equilibration temperatures should both be used to arrive at defect states prevailing at the high temperature as well as in the cooled crystals; much information regarding precipitation of atomic defects during quenching can be obtained by correlating the defect state in the cooled crystals with that obtained at the equilibration temperatures. CdTe (15-19) is only one of the few materials that has been studied extensively from such a viewpoint. In the present work, however, the defect state in the cooled crystal shall be used to derive information regarding the defect state prevailing at the equilibration temperatures.

While attempting to deduce the high temperature defect state of the crystals from measurements on the crystals quenched to room temperature from the high temperature physicochemical conditions, a few assumptions are made. The assumptions are (*i*) that the electrons and the holes recombine during cooling, (*ii*) that all the atomic defects at the high temperature are frozen in, and (*iii*) that the intrinsic carrier concentration $n_i = K_i^{1/2}$ at the measurement temperature $<<$ concentration of the electrically active atomic defects so that the Fermi level is pinned at the defect level and the carrier concentration in the cooled crystals gives the concentration of the atomic defects corresponding to the high temperature equilibrium. The first assumption is always satisfied and the third one is also satisfied as long as the carrier concentration measurement temperature is low enough for n_i to be low. The second assumption requires that the crystals be quenched fast enough that the precipitation of the atomic defects is not given rise to.

Approximation to the electroneutrality condition and dopant balance condition.—When the electroneutrality

Table I. List of the defect formation reactions, mass action constants, electroneutrality condition, and dopant balance equation

Reaction	Mass action relation
1. $O \rightarrow e' + h^{\cdot}; E_i$	$K_i = [e'][h^{\cdot}]$
2. $Hg^x_{Hg} \rightarrow V''_{Hg} + 2h^{\cdot} + Hg(g); H''_{VHg}$	$K''_{VHg} = [V''_{Hg}][h^{\cdot}]^2 p_{Hg}$
3. $V^x_{Hg} \rightarrow V'_{Hg} + h^{\cdot}; E_{a_1V}$	$K_{a_1V} = [V'_{Hg}][h^{\cdot}]/[V^x_{Hg}]$
4. $V'_{Hg} \rightarrow V''_{Hg} + h^{\cdot}; E_{a_2V}$	$K_{a_2V} = [V''_{Hg}][h^{\cdot}]/[V'_{Hg}]$
5. $(Hg_{0.8}Cd_{0.2})Te\ (S) \rightarrow 0.8\ (Hg(g) + 0.2\ Cd(g) + 1/2\ Te_2(g)$; $H_{Hg_{0.8}Cd_{0.2}Te}$	$K_{(Hg_{0.8}Cd_{0.2}Te)} = p_{Hg}^{0.8} p_{Cd}^{0.2} p_{Te_2}^{1/2}$

7. $Hg^x_{Hg} \rightarrow V''_{Hg} + Hg^{\cdot\cdot}_i; H''_F$	$K''_F = [V''_{Hg}][Hg^{\cdot\cdot}_i]$
8. $Hg(l) \rightarrow Hg(g); H_{Hg}$	$K_{Hg} = p_{Hg}/a_{Hg}$
9. $Te(l) \rightarrow 1/2\ Te_2(g); H_{Te}$	$K_{Te} = p_{Te_2}^{1/2}/a_{Te}$
10. Electroneutrality condition: $[e'] + [Cu'_{Hg}] + [V'_{Hg}] + 2[V''_{Hg}] = [h^{\cdot}] + [Cu^{\cdot}_i] + [Hg^{\cdot}_i] + 2[Hg^{\cdot\cdot}_i] + 2[V^{\cdot\cdot}_{Te}]$	
11. Copper balance equation: $[Cu'_{Hg}] + [Cu^{\cdot}_i] = [Cu_{tot}]$	

condition and the dopant balance equation (Table I) are approximated by only the dominant members (20), one can obtain the variation of the defect concentrations as a function of p_{Hg} and the total copper concentration (for copper-doped crystals) in the form

$$\text{Concentration} \quad \propto p_{Hg}{}^{r}\,[Cu_{tot}]^{s}$$

where r and s are small integers or fractions.

Table II lists the exponents of p_{Hg} and $[Cu_{tot}]$ for the variation of the concentrations of the different defects for various approximations to the electroneutrality condition.

Native acceptor defects.—The fact that the hole concentration in the undoped crystals is proportional to $p_{Hg}{}^{-1}$ (Fig. 2) indicates that the crystals are essentially intrinsic at the high temperature (Table II, electroneutrality approximation $[e'] = [h^{\cdot}]$); however, as can be noted from Table II, for a situation where the crystal is intrinsic, all the native acceptor defects vary as $p_{Hg}{}^{-1}$ irrespective of the charge state of the defects. In order to establish the charge state of the native acceptor defects dominant in the undoped crystals the electrical characteristics of the undoped and the acceptor doped crystals will be compared. Figure 4 shows that the hole mobilities in the undoped crystals at 77 K decrease with an increase in the hole concentration indicating that the contribution of ionized impurity scattering to the hole mobilities is substantial. If so, the fact that a majority of the copper-doped crystals shown in Fig. 5 have higher mobilities than the undoped crystals indicates that the ionized impurity scattering is less in the copper-doped crystals; the results can be explained if copper is a single acceptor occupying Hg lattice sites and the native acceptor defects in the undoped crystals are doubly ionized. Based on the theory of ionized impurity scattering (21) for comparable hole concentrations, the mobilities due to ionized impurity scattering in the copper-doped crystals containing x number of singly ionized copper centers can be expected to be twice that in the undoped crystals containing $x/2$ number of the doubly ionized native acceptor defect centers. Also, in those crystals where the electrically active copper concentration exceeds the intrinsic carrier concentration at the annealing temperatures, thus extrinsically doping them, the native acceptor defect concentration decreases with an increase in the copper concentration as a consequence of the mass action effect. As can be seen from Table II, as soon as the crystals become extrinsic with copper doping and the electroneutrality approximation becomes $[Cu'_{Hg}] = [h^{\cdot}]$, the doubly ionized native acceptor defects decrease in proportion to the square of the copper concentration in the crystals ($[V''_{Hg}] \propto [Cu_{tot}]^{-2}$). This is shown schematically in Fig. 8. Hence, in samples doped with copper to greater than the intrinsic carrier concentration, the concentration of the doubly ionized native acceptor defects is considerably depressed. If the native acceptor defects were singly ionized, their concentration would decrease in an inverse linear proportion to $[Cu_{tot}]$ as soon as the copper concentration exceeds the intrinsic carrier concentration (Table II and Fig. 8); however, the hole mobility of such samples should be no different from that of the undoped crystals for comparable hole concentrations. It may be argued that the larger hole mobility in the heavily copper-doped samples (Fig. 5) may result from shorting paths due to the high concentrations of copper; however, the fact that the hole mobility in the copper-doped samples decreases for hole concentrations in excess of 10^{19} cm^{-3} (Fig. 5) rules out this explanation. It should also be noted from Fig. 4 and 5 that the hole mobilities are essentially the same for both the copper-doped and the undoped samples when the hole concentration is less than 10^{17} cm^{-3}. This result indicates that ionized impurity scattering is probably less significant for hole concentrations less than 10^{17} cm^{-3}. Hole mobilities calculated by reciprocally combining the mobility due to lattice scattering and the mobility due to ionized impurity scattering (see Appendix A for details) are also shown in Fig. 4 and 5 for the cases of singly ionized and doubly ionized scattering centers; clearly, for the undoped crystals, the agreement between the experimental values and the calculations is better for the case of the doubly ionized scattering centers, whereas for the copper-doped crystals the agreement is better for the case of the singly ionized scattering centers. It should be noted that the

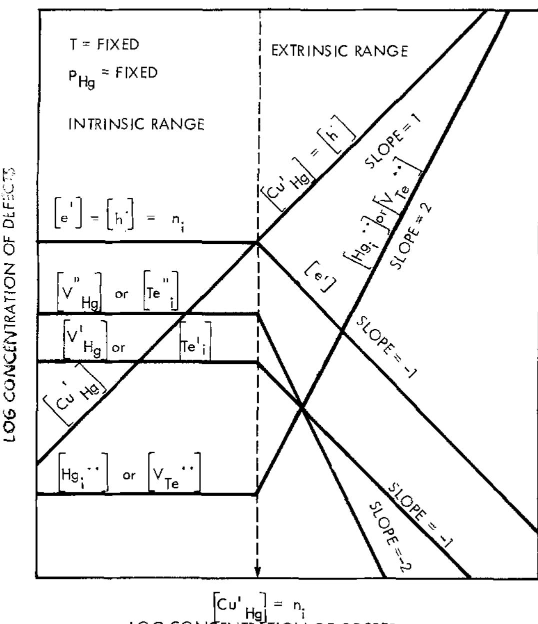

Fig. 8. Schematic variation of $[e']$, $[h^{\cdot}]$, $[Cu'_{Hg}]$, $[V''_{Hg}]$ (or $[Te''_i]$), $[V'_{Hg}]$ (or $[Te'_i]$), and $[Hg^{\cdot\cdot}_i]$ (or $[V^{\cdot\cdot}_{Te}]$) as a function of the electrically active copper concentration in $Hg_{0.8}Cd_{0.2}Te$ at a fixed temperature and partial pressure of Hg.

Brooks-Herring expression (21) used for calculating the mobility due to ionized impurity scattering is applicable only for nondegenerate semiconductors and hence the mobility calculations shown in Fig. 4 and 5 for hole concentrations in excess of 10^{19} cm^{-3} should not be deemed significant; for such large carrier concentrations impurity banding effects also become important.

Absence of compensation in the undoped and copper-doped crystals.—Absence of compensation in the undoped as well as the copper-doped crystals of $Hg_{0.8}Cd_{0.2}Te$ is evidenced by a few inferences. First, the hole mobilities in the undoped crystals are only dependent on the hole concentration and are independent of the temperature of anneal; if there was any compensation by native defects, the concentration of these defects would be expected to be exponentially dependent on temperature and the mobility dependence on the hole concentration would not have been nearly as linear as shown in Fig. 4. Second, if the undoped crystals had a considerable concentration of native donor defects compensating the native acceptor defects the concentration of these native donor defects would have considerably increased via the mass action effect as soon as the copper concentration exceeded the intrinsic carrier concentration and the crystal became extrinsic (Table II and Fig. 8). Since the copper-doped crystals, in fact, have higher mobilities than the undoped crystals for comparable hole concentrations, the undoped and the copper-doped crystals seem to be uncompensated and the native donor defect concentration in $Hg_{0.8}Cd_{0.2}Te$ seems to be negligible. Absence of compensation also has been established in $Hg_{0.6}Cd_{0.4}Te$ (22).

Origin of p-type to n-type conversion.—In the absence of any systematic defect studies in $Hg_{1-x}Cd_xTe$ various reasons for p-type to n-type conversion have been proposed (2-5, 23, 24). Reynolds *et al.* (23) observed that the $Hg_{0.8}Cd_{0.2}Te$ crystals annealed under Hg-saturated conditions converted to n-type below 360°C and the electron concentration was independent of temperature of anneal below 360°C. The temperature independence of the electron concentration under Hg-saturated conditions led them to conclude that the crystals were n-type due to residual donors in the crystals and not due to any native donor defects. Similar inferences and conclusions were reported recently by Bartlett *et al.* (24) for $Hg_{0.8}Cd_{0.2}Te$. Schmit and Stelzer (25) observed that their undoped $Hg_{0.6}Cd_{0.4}Te$ samples also turned n-type at temperatures below 350°-400°C under Hg-saturated conditions. Also the conversion temperatures were different for different samples. Although the temperature independence of the electron concentration in the undoped crystals of $Hg_{0.8}Cd_{0.2}Te$ (23, 24) and $Hg_{0.6}Cd_{0.4}Te$ (25) for Hg-saturated conditions does not, by itself, rule out the n-type conversion to be due to native donor defects (see Appendix B), the fact that the different samples in the experiments of Schmit and Stelzer (25) converted to n-type at different temperatures indicates that the conversion in these samples was due to residual foreign donors in the crystals, the samples with a higher residual foreign donor concentration being able to convert to n-type at a higher temperature. Also it was noticed in the present work that certain of the p-type samples (10^{15}-10^{16} cm^{-3}) did not convert to n-type even when annealed in Hg-saturated conditions at temperatures below 350°C. If the n-type conversion occurs due to native donor defects the inability to convert some of these samples is difficult to explain. In these samples the residual acceptor impurity concentration exceeded the residual donor impurity concentration and hence p-type to n-type conversion was not possible at any temperature. These arguments support our conclusion in the previous section that the native donor defects in $Hg_{0.8}Cd_{0.2}Te$ are negligible in concentration; (probably much less than 10^{15} cm^{-3} at 350°-400°C). The conversion to n-type in $Hg_{0.8}Cd_{0.2}Te$, as well as $Hg_{0.6}Cd_{0.4}Te$ does not appear to be due to native donor defects. The assumption that the p-type to n-type conversion in $Hg_{1-x}Cd_xTe$ alloys occurs due to native donor defects appears erroneous (2-5), and such a conversion only occurs due to residual donor impurities; also the conversion is only possible for samples with residual donor impurity concentration exceeding the residual acceptor impurity concentration in the crystals.

Correlation of the quenching efficiency with the presence of voids and inclusions.—Results of Fig. 6 and 7 indicate that the electrical conductivity variations in the cooled crystals at 77 K as a function of the partial pressure of Hg at the equilibration temperatures can be a sensitive function of the cooling rate, particularly for samples containing a large concentration of voids and inclusions ($\sim$ 1000 per cm^2). For samples containing a relatively small concentration of voids and inclusions ($\leq$ 20 per cm^2) the results are approximately the same except under very low Hg pressures where the air-cooled samples have smaller electrical conductivity than the quenched samples (Fig. 6). Electrical conductivity, rather than hole concentration, has been plotted in Fig. 6 and 7 for ease of comparison of the results of different anneals; for instance, some of the air-cooled samples showed mixed conductivity due to the formation of thin n-type inversion layers formed by a reduction in the hole concentration due to precipitation of native acceptor defects during cooling and/or partial type conversions of the samples. When such layers are thin, the overall conductivity is still dominated by holes ($p\mu_p > n\mu_n$) even if the Hall coefficient is negative ($n\mu^2_n > p\mu^2_p$), hence electrical conductivity for such samples was assumed to reflect the bulk crystal properties better than the Hall effect results. It can be inferred from Fig. 6 and 7 that the cooling rate obtained from air cooling the samples is not high enough to retain the high temperature equilibrium in the samples containing a large concentration of voids and inclusions, thus resulting in a reduction of the concentration of the native acceptor defects at 500°C. The diffusion distances for equilibration are lower in the presence of a large concentration of voids and inclusions, hence crystals containing a large concentration of these can come to equilibrium at an intermediate temperature between 500°C and room temperature during air cooling, whereas crystals containing fewer of them retain the high temperature equilibrium to a greater degree. It should also be noted from Fig. 7 that quenching in ice water is fast enough for crystals containing a large concentration of voids and inclusions to retain the 500°C equilibrium. Although experiments with varying cooling rates were not undertaken at higher temperatures it is reasonable to assume that the effect of the presence of voids and inclusions on the quenching efficiency is greater at temperatures higher than 500°C and lower at lower temperatures.

Analysis of the carrier concentration in the undoped crystals.—In the detailed analysis of the carrier concentration in the cooled crystals, the complete electroneutrality condition is considered. In order to distinguish the high temperature state of the crystal from the low temperature state of the crystal (cooled crystals) subscripts HT (high temperature) and LT (low temperature) are used.

For the undoped crystals, knowing that the native acceptor defects are doubly ionized and that the native donor defects are negligible in concentration and neglecting the influence of residual donors and acceptors, the complete electroneutrality condition becomes

$$[e']_{HT} + 2[V''_{Hg}]_{HT} = [h^{\cdot}]_{HT} \quad [1]$$

Expressing $[e']$ and $[V''_{Hg}]$ in terms of the mass action

constants defined in Table I, we obtain

$$(K_i|[h^\cdot])_{HT} + (2K''_{V_{Hg}}|[h^\cdot]^2 p_{Hg})_{HT} = [h^\cdot]_{HT} \quad [2]$$

or

$$[h^\cdot]_{HT}^3 - (K_i[h^\cdot])_{HT} = 2(K''_{V_{Hg}}|p_{Hg})_{HT}$$

The concentration of holes obtained in the cooled crystals is given by

$$[h^\cdot]_{LT} = 2[V''_{Hg}]_{HT} = (2K''_{V_{Hg}}|[h^\cdot]^2 p_{Hg})_{HT}$$

or

$$[h^\cdot]_{HT} = (2K''_{V_{Hg}}|p_{Hg})_{HT}^{1/2}|[h^\cdot]_{LT}^{1/2} \quad [3]$$

Combination of [2] and [3] with some simplification gives

$$[h^\cdot]_{LT}^{3/2} (2K''_{V_{Hg}}|p_{Hg})_{HT}^{1/2} + (K_i)_{HT} [h^\cdot]_{LT} = (2K''_{V_{Hg}}|p_{Hg})_{HT} \quad [4]$$

For given values of K_i and $K''_{V_{Hg}}$ at various temperatures, the solution of Eq. [4] gives the hole concentration in the cooled crystals as a function of p_{Hg}. By a procedure of trial and error, the values of K_i and $K''_{V_{Hg}}$ were optimized at each temperature to give the best fit between the experimentally observed hole concentrations and the calculated values. The calculated values are shown in Fig. 2 as solid lines. The agreement between the experimental values and the calculations appears to be within limits of experimental error.

Mass action constants K_i and $K''_{V_{Hg}}$ determined from the present investigation (valid for temperatures between 400° and 655°C) are given by

$$K_i = 5.77 \times 10^{-4} \exp(-0.57 \text{ eV/kT}) (\text{Site Fr})^2 \quad [5]$$

and

$$K''_{V_{Hg}} = 7.9 \times 10^2 \exp(-2.24 \text{ eV/kT}) (\text{Site Fr})^3 \text{ atm} \quad [6]$$

Noting that there are 1.26×10^{22} molecules/cm³ in $Hg_{0.8}Cd_{0.2}Te$, we get

$$K_i = 9.16 \times 10^{40} \exp(-0.57 \text{ eV/kT}) \text{ cm}^{-6} \quad [7]$$

and

$$K''_{V_{Hg}} = 1.58 \times 10^{69} \exp(-2.24 \text{ eV/kT}) \text{ cm}^{-9} \text{ atm} \quad [8]$$

Both K_i and $K''_{V_{Hg}}$ influence the absolute values of the carrier concentration obtained in the cooled crystals and the variation of the carrier concentration as a function of p_{Hg}. From Table II, it can be seen that the hole concentration in the cooled crystals (equal to twice the concentration of the doubly ionized native acceptor defects at the anneal temperature) is expected to be proportional to p_{Hg}^{-1} for crystals which are intrinsic, whereas it is expected to be proportional to $p_{Hg}^{-1/3}$ for crystals which are extrinsic with the situation $[h^\cdot] = 2[V''_{Hg}]$ at the high temperature. Thus, for a given value of $K''_{V_{Hg}}$, if the chosen K_i value was such that $[V''_{Hg}]$ was comparable in concentration to $[e']$ and $[h^\cdot]$, at the high temperature, the power dependence of the calculated hole concentration in the cooled crystals was between $-1/3$ and -1. On the other hand, if the chosen K_i values were high compared to the hole concentration in the cooled crystals, the calculated hole concentration varied strictly as p_{Hg}^{-1}. The absolute values of the calculated hole concentrations depended both on K' and $K''_{V_{Hg}}$. In order to show how sensitive the calculated hole concentrations are to the variation in the K_i values at the anneal temperatures, the hole concentrations in the cooled crystals were calculated as a function of p_{Hg} for K_i values 25% higher and 25% lower than given by expression [7] for K_i. The calculated hole concentrations in the cooled crystals for K_i values given by the expression as well as for K_i values ± 25% are shown for $T = 500°C$ in Fig. 9; the $K''_{V_{Hg}}$ value in the calculations was kept constant as given by expression [8]. It appears that ±25% variations in K_i do not affect the calculations adversely.

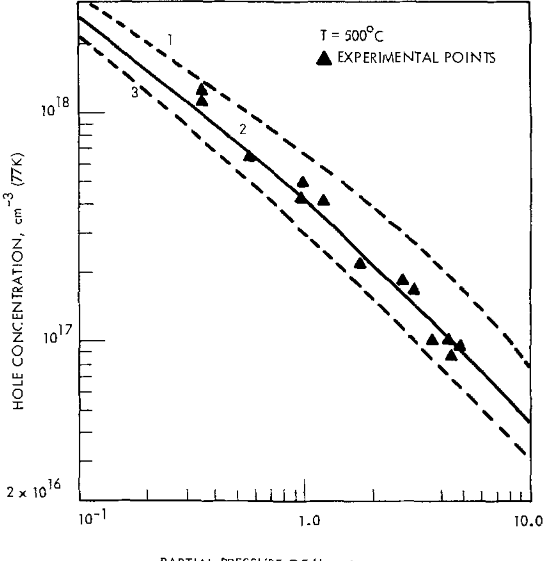

Fig. 9. Defect model calculations of the hole concentrations at 77 K for undoped $Hg_{0.8}Cd_{0.2}Te$ annealed at 500°C in various partial pressures of Hg and quenched to room temperature; solid line 2 represents calculations using K_i values given by expression [7] of the text, whereas the dashed lines 1 and 3 correspond to calculations using K_i values differing from those of expression [7] by ±25%; experimental points are also shown for comparison.

Assuming simple parabolic conduction and valence bands and nondegenerate semiconductor statistics the expression for K_i is written as

$$K_i = 2(m_e m_h)^{3/2} (\pi kT/h^2)^3 \exp(-E_g/kT) \text{ cm}^{-6} \quad [9]$$

where m_e and m_h are the effective masses of electrons and holes, respectively, and E_g is the energy gap. $E_g = E_g(0) + \alpha T$ where $E_g(0)$ corresponds to the energy gap at 0 K. A linear increase of the energy gap with increase in temperature has been verified by various researchers for temperatures up to 400 K (26-30). To the author's knowledge, no measurements on the energy gap or the intrinsic carrier concentration at temperatures much in excess of 400 K exist in the literature. If we assume the linear temperature dependence of the gap to hold good at temperatures greater than 400 K, with $E_g(0) \approx 0.1$ eV (3) and inclusion of the T^3 term in the exponent term (Eq. [9]), we get 0.32 eV for the enthalpy associated with K_i. This value is lower than the value of 0.57 eV found from the present investigation expressions [5] and [7]). The possible nonparabolicity of the bands at the higher temperatures and a nonnegligible temperature dependence of the effective masses of carriers may account for the higher enthalpy associated with K_i given by expression [7].

The dependence of the calculated hole concentrations in the cooled crystals on the value of $K''_{V_{Hg}}$ can be judged by the inspection of Eq. [4] which indicates that for crystals which are intrinsic at the annealing temperature, the second term on the left-hand side dominates, with the result that the hole concentration in the cooled crystals is proportional to the value of $K''_{V_{Hg}}/K_i$. As a result it is not hard to realize that for given values of K_i the hole concentrations in the cooled crystals depend on $K''_{V_{Hg}}$ in just the opposite way as they did with K_i for fixed $K''_{V_{Hg}}$ values. Thus, just as ±25% variations in K_i did not adversely affect the calculations (Fig. 9), we believe similar variations can be tolerated in the value of $K''_{V_{Hg}}$.

From the present work the enthalpy for the reaction

$$Hg_{Hg}^{x} \rightarrow V''_{Hg} + 2h^{\cdot} + Hg(g)$$

has been established to be 2.24 eV.

For comparison with CdTe, the enthalpy associated with the reaction

$$Cd_{Cd}^{x} \rightarrow V''_{Cd} + 2h^{\cdot} + Cd(g)$$

is evaluated to be 4.72 eV (15). The higher enthalpy associated with a similar defect reaction for CdTe is reasonable in view of the fact that CdTe has a larger melting point and bandgap than $Hg_{0.8}Cd_{0.2}Te$ and, hence, stronger bonding.

Table III summarizes the values of some of the mass action constants defined in Table I. Included in the table are the values of K_i and K''_{VHg} applicable for $T = 400°-655°C$ as well as the K_i value applicable for $T = 27°-400°C$.

The mass action constants K_i and K''_{VHg} established from the present work can explain the results on indium-doped (31). Iodine-doped (32) and phosphorus-doped $Hg_{0.8}Cd_{0.2}Te$ (33) satisfactorily.

Defect isotherms for undoped $Hg_{0.8}Cd_{0.2}Te$.—Once the values of K_i and K''_{VHg} are known, it is possible to calculate the concentrations of various defects as a function of p_{Hg} at any given temperature. Such a defect isotherm for $T = 500°C$ is shown in Fig. 10. As can be seen from the figure, the crystal is essentially intrinsic except at low Hg pressures at higher temperatures where native acceptor defects begin to become comparable in concentration to intrinsic carriers.

Hole concentration in undoped $Hg_{0.8}Cd_{0.2}Te$ under Hg-saturated and Te-saturated conditions.—The highest and the lowest Hg pressures in the experimental data indicated by arrows in Fig. 2, correspond to the Hg pressure under Hg-saturated conditions and the Hg pressure under Te-saturated conditions, respectively (8-10). Figure 11 shows the hole concentration variation in the cooled crystals as a function of temperature of equilibration for Hg-saturated and Te-saturated conditions. The temperature dependences of the hole concentration are given by

$$[h^{\cdot}] \text{ (Hg saturated)} = 1.54 \times 10^{24} \exp(-1.13 \text{ eV/kT}) \text{ cm}^{-3}$$

and

$$[h^{\cdot}] \text{ (Te saturated)} = 2.36 \times 10^{20} \exp(-0.314 \text{ eV/kT}) \text{ cm}^{-3}$$

Isohole concentration plot for $Hg_{0.8}Cd_{0.2}Te$.—Knowledge of K_i and K''_{VHg} permits us to calculate hole concentrations in the cooled crystals as a function of the physicochemical conditions of preparation, namely, p_{Hg} and T. Such a plot is shown in Fig. 12. As can be seen from Fig. 12, the undoped material is p-type throughout the existence region for all temperatures as long as the residual foreign acceptor concentration is greater than the residual foreign donor concentration in the crystals. This figure is different from the isocarrier concentration plot reported in Ref. (2, 4) where

Table III. Values of the parameters for the equilibrium constants $K = K_0 \exp(-H/kT)$ defined in Table I

	Equilibrium constant	K_0 (Site Fr, atm)	H (ev)	Source
1.	K_i	5.77×10^{-4}	0.57	This work
2.	K''_{VHg}	7.9×10^{2}	2.24	(400°-655°C)
3.	K_i	1.4×10^{-5}	0.354	(27°-400°C)
4.	$K_{Hg_{0.8}Cd_{0.2}Te}$	2.75×10^{9}	2.06	Ref. (10)
5.	K_{Hg}	7.84×10^{4}	0.62	Ref. (8)
6.	K_{Te}	1.82×10^{6}	1.27	

There are 1.26×10^{22} molecules/cm³ in $Hg_{0.8}Cd_{0.2}Te$.

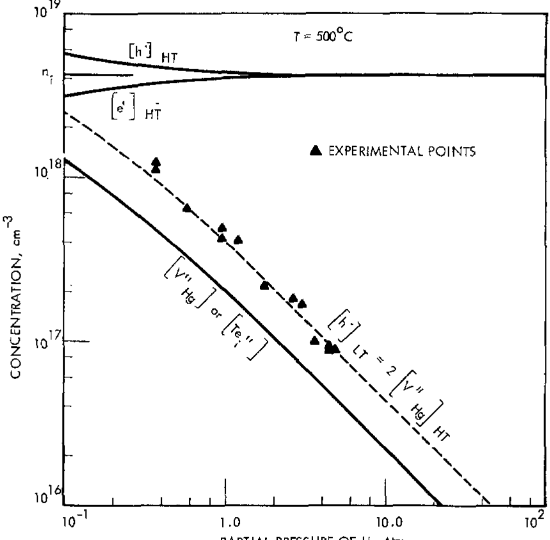

Fig. 10. Calculated defect concentrations as a function of the partial pressure of Hg at the equilibration temperature of 500°C; dashed line represents the calculated hole concentration in the cooled crystals at 77 K; experimental points are also shown for comparison.

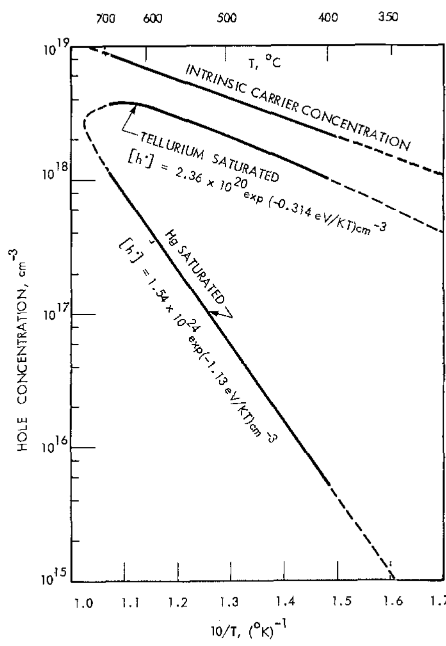

Fig. 11. Calculated hole concentration lines at 77 K as a function of temperature for undoped $Hg_{0.8}Cd_{0.2}Te$ equilibrated in Hg-saturated and Te-saturated conditions and quenched to room temperature. Calculations for temperature ranges outside the experimental work reported in this paper are shown dashed; intrinsic carrier concentration as a function of temperature is also shown.

p-type to n-type conversion was attributed to native donor defects. It can also be seen that the highest deviation from stoichiometry (or the highest hole concentration in the cooled crystals) attainable in undoped $Hg_{0.8}Cd_{0.2}Te$ is $< 3 \times 10^{18}$ cm^{-3}.

Defect isotherms for copper-doped $Hg_{0.8}Cd_{0.2}Te$.—With the assumption that all of the electrically active copper is present as Cu'_{Hg}, defect concentrations as a function of the electrically active copper concentration and p_{Hg} can be calculated. As before, we define high temperature and low temperature states of the crystal using subscripts HT and LT, respectively. The complete electroneutrality condition and the copper balance equation are

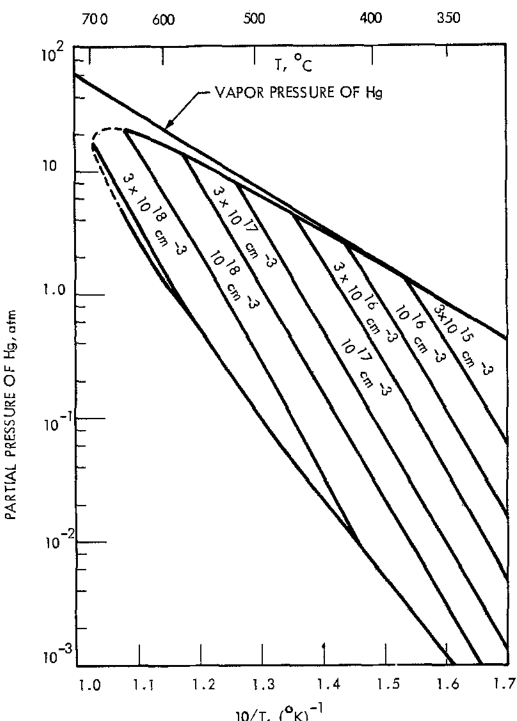

Fig. 12. Calculated isohole concentration lines at 77 K for $Hg_{0.8}Cd_{0.2}Te$ as a function of the partial pressure of Hg and temperature of equilibration.

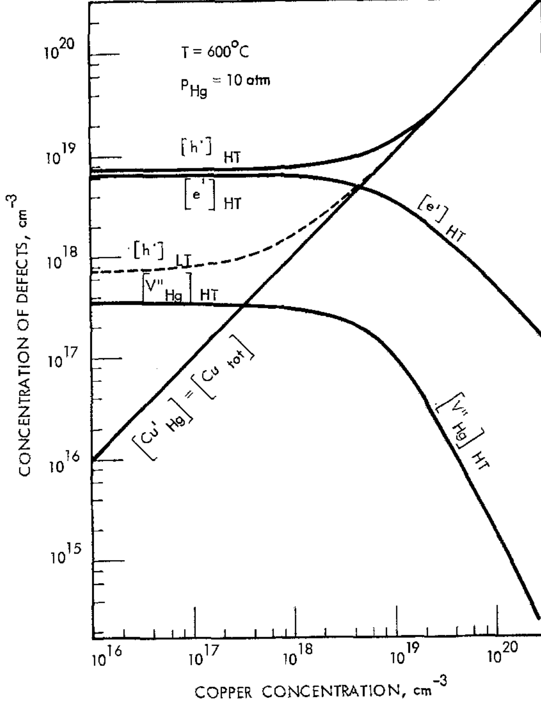

Fig. 13. Calculated defect concentrations as a function of the electrically active copper concentration in the crystals at the equilibration temperature of 500°C and $p_{Hg} = 3$ atm; dashed line corresponds to the calculated hole concentration in the cooled crystals at 77 K.

$$[e']_{HT} + 2[V''_{Hg}]_{HT} + [Cu'_{Hg}] = [h^{\cdot}]_{HT} \quad [10]$$

and

$$[Cu'_{Hg}]_{HT} = [Cu_{tot}]_{HT} \quad [11]$$

In terms of the mass action constants K_i and K''_{VHg}, the electroneutrality condition is rewritten as

$$(K_i/[h^{\cdot}])_{HT} + 2(K''_{VHg}/[h^{\cdot}]^2 p_{Hg})_{HT} + [Cu_{tot}] = [h^{\cdot}]_{HT} \quad [12]$$

or

$$[h^{\cdot}]_{HT}^3 - [h^{\cdot}]_{HT}^2 [Cu_{tot}] - K_i[h^{\cdot}]_{HT} = 2(K''_{VHg}/p_{Hg})_{HT} \quad [13]$$

In the cooled crystals, the hole concentration is given by

$$[h^{\cdot}]_{LT} = 2[V''_{Hg}]_{HT} + [Cu_{Hg}]_{HT} = 2[V''_{Hg}]_{HT} + [Cu_{tot}]_{HT} \quad [14]$$

or, expressing $[V''_{Hg}]$ in terms of K''_{VHg} and $[h^{\cdot}]$, we get

$$[h^{\cdot}]_{LT} = (2K''_{VHg}/[h^{\cdot}]^2 p_{Hg})_{HT} + [Cu_{tot}]_{HT} \quad [15]$$

With the knowledge of the mass action constants K_i and K''_{VHg} established for the undoped crystals, defect concentrations ($[V''_{Hg}]$, $[h^{\cdot}]_{HT}$, $[h^{\cdot}]_{LT}$, etc.) as a function of copper concentration for a fixed p_{Hg} or as a function of p_{Hg} for fixed copper concentration can be calculated from Eq. [13] and [15]. Figure 13 shows the defect isotherm for $T = 500°C$ and $p_{Hg} = 3$ atm as a function of the total copper concentration in the crystal. Similarity between Fig. 8 and 13 is to be noted. While Fig. 8 is drawn with approximation to the neutrality condition, Fig. 13 has been drawn with the consideration of the complete electroneutrality condition.

Imperfect quench for heavily copper-doped samples.—The electrically active copper concentration in various samples as inferred from the Hall effect measurements was found to be lower than the total copper concentration in the samples inferred from atomic absorption analysis (Table IV). From arguments in the previous sections, compensation by native donor defects or by copper interstitials (acting as donors) is ruled out as the explanation. On the other hand, precipitation of copper during quenching or the solubility limit of copper at the equilibration temperatures can explain the discrepancy. If the explanation is one of the solubility limit, it is hard to reason why samples having total copper concentration less than 10^{19} cm^{-3} also show electrically active copper less than the total amount of chemically inferred copper concentrations. Owing to the high diffusivity of Cu in $Hg_{1-x}Cd_xTe$ (6, 7), we are inclined to believe that precipitation of copper as CuTe or Cu_2Te during quenching results in the electrically active copper (as found by Hall effect measurements) to be less than that obtained by chemical analysis. The fact that the fraction of electrically active copper decreases for higher and higher copper concentrations (as determined by chemical analysis) also supports the view that precipitation occurs during quenching since the diffusion distance between copper atoms for precipitation to occur can be expected to decrease as $[Cu_{tot}]^{-3}$. Efforts to improve the quenching efficiency by breaking open the ampuls and quenching the samples directly in water did not result in any improvement. It appears that the high diffusivity of copper results in an imperfect quench from the equilibration temperature. If we believe that precipitation occurs during quenching, the solubility of electrically

Table IV. Comparison of the concentrations of electrically active copper and the total amount of copper (as determined from atomic absorption analysis) for samples doped with copper at 500° and 600°C

Temperature (°C)	Total copper concentration (cm^{-3}) (atomic absorption)	Electrically active copper concentration (cm^{-3}) (Hall effect)
500	3.4×10^{20}	10^{19}
500	1.6×10^{19}	5×10^{18}
500	8.7×10^{18}	4.3×10^{18}

active copper at $T = 500°-600°C$ appears to be in excess of 10^{20} cm^{-3}.

Conclusion

Lattice defect models for undoped and copper-doped $Hg_{0.8}Cd_{0.2}Te$ have been established via Hall effect and mobility measurements on crystals equilibrated under different partial pressures of Hg at high temperatures and quenched to room temperature. According to the models, native donor defects are negligible in concentration, native acceptor defects are doubly ionized, and copper acts as a single acceptor occupying Hg lattice sites. Equilibrium constants for the intrinsic excitation constant, as well as the incorporation of the doubly ionized native acceptor defects, have been established.

Acknowledgments

The author wishes to thank J. A. Carruthers of NASA for his interest in this work. Thanks are due to J. L. Schmit for making variable temperature Hall effect measurements for one of the undoped samples. Technical assistance by J. Donovan and P. Crickard with the experimental portion of the work is greatly appreciated. Thanks are also due to D. A. Nelson for many fruitful discussions on the calculations of hole mobility in these alloys. This work was supported by NASA under Contract NAS8-33245.

APPENDIX A

Calculations of Hole Mobility at 77 K in Undoped and Copper-Doped $Hg_{0.8}Cd_{0.2}Te$

The decrease of hole mobility at 77 K with an increase in the hole concentration in the undoped crystals (Fig. 4) indicates that the contribution of ionized impurity scattering to the mobility at 77 K is not negligible.

For a nondegenerate semiconductor with parabolic bands, the mobility due to ionized impurity scattering as given by the Brooks-Herring expression (21) is

$$\mu_I = 2^{7/2}\pi^{-3/2}(kT)^{3/2}(\epsilon_0\epsilon_S)^2(m_o)^{-1/2}(m^*/m_o)^{-1/2} \times N_I^{-1}\left\{\ln(1+b) - \frac{b}{1+b}\right\}^{-1} \quad \text{[A-1]}$$

where

$$b = \frac{24m_o(m^*/m_o)k^2(\epsilon_0\epsilon_S)}{e^2\hbar^2 p'} \quad \text{[A-2]}$$

and

$$p' = p + (N_A - N_D - p)(p + N_D)/N_A \quad \text{[A-3]}$$

In expressions [A-1], [A-2], and [A-3], k is the Boltzmann's constant, T is the temperature, ϵ_0 is the free space permittivity, ϵ_S is the static dielectric constant, m_o is the free electron mass, (m^*/m_o) is the effective mass ratio of holes, N_I is the number of scattering centers given by the total number of ionized donors and acceptors, e is the electronic charge, and $\hbar$ is Planck's constant. With $T = 77$ K, (m^*/m_o) (holes) $= 0.7$ (34). $\epsilon_S = 17.5$ (3) the expression for the mobility due to ionized impurity scattering becomes

$$\mu_I = 8 \times 10^{20} N_I^{-1}\left\{\ln(1+b) - \frac{b}{1+b}\right\}^{-1} \quad \text{[A-4]}$$

and

$$b = 9.42 \times 10^{18}/p' \quad \text{[A-5]}$$

In general

$$N_I = ([A'] + [D^{\cdot}]) + 4([A''] + [D^{\cdot\cdot}]) + 9([A'''] + [D^{\cdot\cdot\cdot}]) + \ldots \quad \text{[A-6]}$$

where $[A']$, $[A'']$, $[A''']$, etc. are the concentrations of the singly charged, doubly charged, and triply charged acceptors; a similar definition holds for the donor concentrations $[D^{\cdot}]$, $[D^{\cdot\cdot}]$, $[D^{\cdot\cdot\cdot}]$, etc. The multiplying factors of 4, 9, etc. in Eq. [A-6] arise because the centers are doubly ($z = 2$) and triply ($z = 3$) charged, etc. For the case where the undoped and the copper-doped crystals are not compensated (as discussed in the main text) we have

$$N_I = [A'] + 4[A''] + \ldots \quad \text{[A-7]}$$

Since the defects are completely ionized at 77 K in both the undoped and the copper-doped crystals (see main text for details), $p' = p$ (77 K) for the undoped as well as the copper-doped crystals. Using Eq. [A-4] and [A-5], μ_I was calculated as a function of p (77 K) for the case of (*i*) $N_I = [A'] = p$ (77 K) (dominance of singly charged centers) and (*ii*) $N_I = 4[A''] = 2p$ (77 K) (dominance of doubly charged centers).

The calculated mobilities due to ionized impurity scattering for the cases of the dominances of the singly charged centers and dominance of the doubly charged centers are shown as dashed lines in Fig. 4 and 5. Extrapolating the hole mobility due to lattice scattering to be 700 cm²/Vsec at 77 K the overall hole mobility as a function of the hole concentration at 77 K was calculated by reciprocally combining the mobility due to ionized impurity scattering and that due to lattice scattering

$$1/\mu_{TOT} = \frac{1}{\mu_{lattice}} + \frac{1}{\mu_{ionized}} = \frac{1}{700} + \frac{1}{\mu_{ionized}} \quad \text{[A-8]}$$

The calculated overall hole mobility as a function of the hole concentration is shown in Fig. 4 and 5 as solid lines.

APPENDIX B

Temperature Independence of the Native Donor Defect Concentration

Results of Reynolds *et al.* (23) on $Hg_{0.8}Cd_{0.2}Te$ and of Schmit and Stelzer (25) on $Hg_{0.6}Cd_{0.4}Te$ indicate that the crystals turn n-type below 300°-350°C under Hg-saturated conditions and the electron concentration under Hg-saturated conditions remains independent of the anneal temperature.

If the conversion is thought to be due to some sort of native donor defects, it remains to explain under what circumstances the temperature independence could arise. For an explanation of this we consider the following reactions

$$Hg(l) \rightarrow Hg(g);\ K_1 = p_{Hg} = (K_1)_0 \exp\frac{(-\Delta H_1)}{kT} \quad \text{[B-1]}$$

$$Hg(g) \rightarrow Hg^{\cdot\cdot}_i] + 2e';\ K_2 = \frac{[Hg^{\cdot\cdot}_i][e']^2}{p_{Hg}} = (K_2)_0 \exp(-\Delta H_2/kT) \quad \text{[B-2]}$$

$$O \rightarrow e' + h^{\cdot};\ K_3 = [e'][h^{\cdot}] = (K_3)_0 \exp(-\Delta H_3/kT) \quad \text{[B-3]}$$

Two electroneutrality approximations can be considered:

Case 1: $[e'] \approx [h^{\cdot}] = \sqrt{K_3}$.

Case 2: $[e'] \approx 2\,[Hg^{\cdot\cdot}_i]$.

Case 1: $[e'] = [h^{\cdot}]$. From Eq. [B-2], $[Hg^{\cdot\cdot}_i] = K_2 p_{Hg}/[e']^2$. Substituting $[e'] = [h^{\cdot}] = \sqrt{K_3}$ from [B-3] and for p_{Hg} from [B-1], we get

$$[Hg^{\cdot\cdot}_i] = \frac{K_1 K_2}{K_3} = \frac{(K_1)_0(K_2)_0}{(K_3)_0}\exp\left(\frac{-\Delta H_1 - \Delta H_2 + \Delta H_3}{kT}\right)$$

If $\Delta H_3 = \Delta H_1 + \Delta H_2$, $[Hg^{\cdot\cdot}_i]$ will be independent of temperature and the electron concentration under Hg-saturated conditions will be independent of temperature in the cooled crystals.

Case 2: $[e'] \approx 2\,[Hg^{\cdot\cdot}_i]$

From [B-2],

$$[Hg^{\cdot\cdot}_i] = K_2\, p_{Hg}/[e']^2 = K_2\, p_{Hg}/4\,[Hg^{\cdot\cdot}_i]^2$$

or

$$[Hg^{\cdot\cdot}_i] = (K_2\, p_{Hg}/4)^{1/3} = \left(\frac{(K_2)_0(K_1)_0}{4}\right)^{1/3} \exp\left(\frac{-\Delta H_1 - \Delta H_2}{3\,kT}\right)$$

Thus if $\Delta H_1 = -\Delta H_2$, $[Hg^{\cdot\cdot}_i]$ will be independent of temperature and the electron concentration in the cooled crystals under Hg-saturated conditions will also be independent of temperature.

It should be noted that while $Hg^{\cdot\cdot}_i$ are considered for the native donor defects here, the arguments are similar if $V^{\cdot\cdot}_{Te}$ are considered instead.

Lattice Defects in Semiconducting $Hg_{1-x}Cd_xTe$ Alloys

II. Defect Structure of Indium-Doped $Hg_{0.8}Cd_{0.2}Te$

H. R. Vydyanath*

Honeywell Electro-Optics Center, Lexington, Massachusetts 02173

ABSTRACT

Hall effect measurements were carried out on indium-doped $Hg_{0.8}Cd_{0.2}Te$ crystals quenched to room temperature subsequent to equilibration at 500° and 600°C under various partial pressures of Hg. All the indium-doped crystals were n-type under moderate to high partial pressures of Hg whereas they were p-type at very low Hg pressures. The concentration of electrons obtained in the cooled crystals was lower than the intrinsic carrier concentration at the equilibration temperatures. Also the electron concentration was much lower than the indium concentration in the crystals and was found to increase with increasing Hg pressures at the equilibration temperatures and with increase in the total indium present in the crystals. These inferences have led to a defect model according to which most of the indium is incorporated as In_2Te_3(S) dissolved in $Hg_{0.8}Cd_{0.2}Te$(S) with only a small fraction of indium acting as single donors occupying Hg lattice sites. Based on such a model, calculated electron concentrations in the cooled crystals as a function of indium concentration and partial pressure of Hg are in agreement with the experimentally observed values.

The role of indium as a donor and its influence on the native defect structure has been investigated in CdS (1-2) and CdTe (3-4). However, such a systematic investigation into the mode of incorporation of indium and its influence on the native defects has not so far been carried out for $Hg_{1-x}Cd_xTe$ alloys. The defect structure of undoped $Hg_{0.8}Cd_{0.2}Te$, the thermo-

dynamic constants for the incorporation of the native acceptor defects, and the intrinsic excitation constant in $Hg_{0.8}Cd_{0.2}Te$ have been established in the preceding paper (5) hereafter referred to as part I. The present work was undertaken to study the behavior of indium in $Hg_{0.8}Cd_{0.2}Te$ as a function of the physicochemical conditions of preparation (p_{Hg}, T, indium concentration, etc.) and to explain the properties of the indium-doped crystals with the knowledge of the defect structure of the undoped crystals (5).

Experimental

Indium was evaporated onto the surface of the undoped $Hg_{0.8}Cd_{0.2}Te$ crystals ($x = 0.2 \pm 0.005$) and the indium was diffused in at 600°C and $p_{Hg} = 10$ atm and at 500°C and $p_{Hg} = 3$ atm. Diffusion times of 24 hr at 600°C and 7 days at 500°C into samples of thickness $\leq$0.04 cm were found to be adequate for the homogeneous diffusion of indium. The concentration of indium in each sample was determined from atomic absorption analysis carried out by Photometrics, Incorporated, Lexington, Massachusetts. The residual impurity concentration in the starting undoped $Hg_{0.8}Cd_{0.2}Te$ was $\leq 10^{16}$ cm^{-3}. The thicknesses of the samples were minimized as much as possible in order to improve the quenching efficiency from the equilibration temperatures as well as to assure thermodynamic equilibrium within reasonable equilibration times. The equilibration procedure in various Hg atmospheres is similar to that described in part I. Subsequent to the equilibration, the samples were quenched to room temperature; in a few cases the samples were air cooled to room temperature from the equilibration temperatures. The samples were lapped, polished, and etched in Br-methanol solution. Hall effect and electrical resistivity measurements were made using the van der Pauw method (6). Magnetic field strengths of 400 and 4000G were used for the Hall effect measurements.

Results

As mentioned in part I, only those Hall effect results which did not vary with the magnetic field and thus showed no mixed-type conduction were used in evaluating the carrier concentrations in the samples using the expression

$$n = \frac{1}{R_H q}$$

The Hall effect data on all the samples doped to reasonable concentrations of indium and annealed at medium to high partial pressures of Hg showed n-type conductivity and the electron concentration in the samples at 77 and 300 K did not vary much, indicating that the indium was all ionized at 77 K. Figures 1 and 2 show the electron concentration in the cooled crystals as a function of the total indium present in the samples at $T = 500°$ and 600°C for various partial pressures of Hg. From the figures, it is apparent that the electron concentration in the samples increases with an increase in the total indium concentration in the samples and also increases as the partial pressure of Hg at the equilibration temperatures increases. It is to be noted that although the electron concentration is a function of the total indium present in the crystals, the electron concentration is much lower than the total amount of indium present in the crystals.

Figure 3 shows the electron mobility at 77 K in various indium-doped samples as a function of the electron concentration. These mobilities are lower than values reported for $Hg_{0.8}Cd_{0.2}Te$ samples containing low donor concentrations (7).

Figure 4 shows a comparison of the electron concentration obtained at 77 K as a function of the partial pressure of Hg at 500°C for crystals that were doped with various indium concentrations and were air

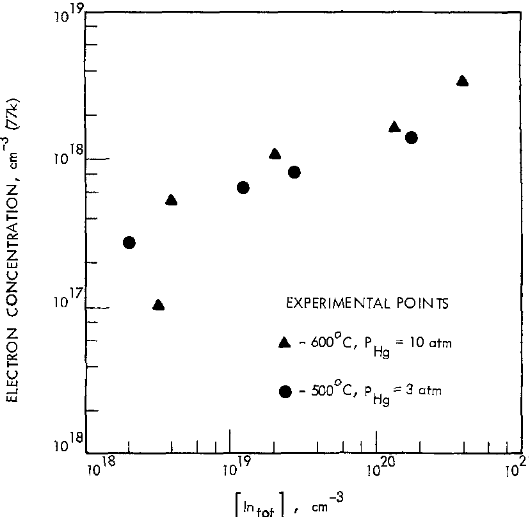

Fig. 1. Electron concentration at 77 K as a function of the total indium concentration for $Hg_{0.8}Cd_{0.2}Te$ crystals annealed at 500° and 600°C under the indicated partial pressures of Hg and quenched to room temperature.

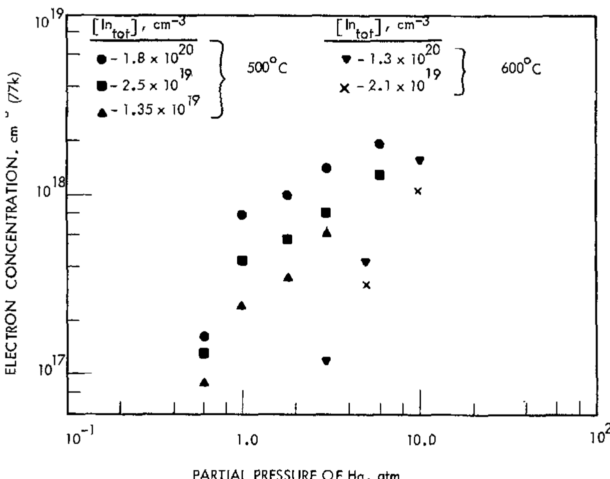

Fig. 2. Electron concentration at 77 K as a function of the partial pressure of Hg for $Hg_{0.8}Cd_{0.2}Te$ crystals doped with various amounts of indium and annealed at 500° and 600°C and quenched to room temperature.

cooled or quenched to room temperature. It appears from the results that higher electron concentrations are obtained in the air-cooled samples than in the quenched samples, the deviations between the two sets of samples being greater at lower Hg pressures.

Discussion

The approach utilized in arriving at a defect model for the indium-doped $Hg_{0.8}Cd_{0.2}Te$ is similar to that used for the undoped and copper-doped $Hg_{0.8}Cd_{0.2}Te$ in part I. Also any defect model that is established to explain the experimental results in the indium-doped crystals should be consistent with the observations in the undoped and the copper-doped crystals of part I.

Choice of a defect model.—Based on the value of the intrinsic excitation constant K_i arrived at for $Hg_{0.8}Cd_{0.2}Te$ (part I) for temperatures between 400°-655°C, data shown in Fig. 1 and 2 indicate that the electron concentration obtained in the cooled crystals is much less than the intrinsic carrier concentration at the equilibration temperatures.

Three different models can be considered to explain the electron concentration data shown in Fig. 1 and 2.

In the first model considered, a fraction of the indium is assumed to be present as singly positively

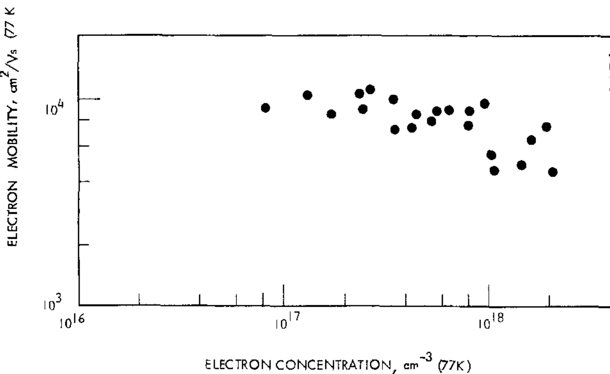

Fig. 3. Electron mobility at 77 K as a function of the electron concentration in indium-doped $Hg_{0.8}Cd_{0.2}Te$ crystals.

charged donors occupying Hg lattice sites while the rest of it is assumed to be present as negatively charged associates of singly positively charged indium on Hg lattice sites and doubly negatively charged native acceptor defects. Most of the indium is assumed to be self-compensated as given by the electroneutrality approximation

$$[In^{\cdot}_{Hg}] = [(In_{Hg}V_{Hg})'] = [In_{tot}]/2$$

For such a model the dependence of $[e']$ on $[In_{tot}]$ and p_{Hg} is inferred from the reaction

$$2e' + In^{\cdot}_{Hg} + Hg^x_{Hg} \rightarrow (In_{Hg}V_{Hg})' + Hg(g)$$

and the mass action constant

$$K_{(In_{Hg}V_{Hg})} = [(In_{Hg}V_{Hg})']p_{Hg}/[e']^2[In^{\cdot}_{Hg}] \quad [1]$$

with

$$[(In_{Hg}V_{Hg})'] = [In^{\cdot}_{Hg}] = [In_{tot}]/2$$

$$[e'] \propto [In_{tot}]^0 p_{Hg}^{1/2} \quad \text{from [1]}$$

Although this model qualitatively explains the weak donor activity of indium it predicts an independence of electron concentration as a function of the total indium present in the samples, contrary to the results shown in Fig. 1 and 2.

In the second model considered, most of the indium is assumed to be present as neutral triplets $(In_{Hg}V_{Hg}In_{Hg})^x$ formed by the association of two singly positively charged indium donor species on Hg lattice sites with a doubly negatively charged native acceptor defect; a small fraction of the indium is assumed to be present unassociated on Hg lattice sites acting as donors.

The reaction of interest is

$$2e' + 2In^{\cdot}_{Hg} + Hg^x_{Hg} \rightarrow (In_{Hg}V_{Hg}In_{Hg})^x + Hg(g)$$

and the mass action relation is given by

$$K_{(In_{Hg}V_{Hg}In_{Hg})^x} = [(In_{Hg}V_{Hg}In_{Hg})^x]p_{Hg}/[e']^2[In^{\cdot}_{Hg}]^2 \quad [2]$$

Since we know that the electron concentration obtained in the cooled crystals is less than the intrinsic carrier concentration at the equilibration temperatures, the electroneutrality condition at the equilibration temperatures can be approximated by

$$[e'] = [h^{\cdot}] = \sqrt{K_i}$$

and for $[(In_{Hg}V_{Hg}In_{Hg})^x] = [In_{tot}]/2$ as the approximation to the indium balance equation $[In^{\cdot}_{Hg}] \propto [In_{tot}]^{1/2}p_{Hg}^{1/2}$ at the equilibration temperatures. Although this model qualitatively explains the variation of electron concentration as a function of the indium in the crystals and the partial pressure of Hg at the equilibration temperatures, the calculated electron concentration in the cooled crystals considering the complete neutrality condition shows a much steeper dependence on p_{Hg} than observed experimentally. Also, the model predicts the crystals will turn p-type even at Hg pressures close to saturation pressures, contrary to the results of Fig. 2.

The third model considered is one where most of the indium is assumed to be present as In_2Te_3 dissolved in $Hg_{0.8}Cd_{0.2}Te$, with a small fraction of In on Hg lattice sites acting as donors. The dependence of the electron concentration on the indium in the crystals and p_{Hg} can be inferred from the reaction describing the incorporation of In_{Hg} from the $In_2Te_3(S)$ dissolved in $Hg_{0.2}Cd_{0.2}Te$.

The reaction of interest is

$$In_2Te_3(S) + Hg(g) \rightarrow Hg^x_{Hg} + 2In^{\cdot}_{Hg} + 2e' + 3Te^x_{Te}$$

The mass action relation is given by

$$K_{(In_2Te_3-In^{\cdot}_{Hg})} = [In^{\cdot}_{Hg}]^2[e']^2/a_{In_2Te_3}p_{Hg} \quad [3]$$

where $a_{In_2Te_3}$ is the activity of $In_2Te_3(S)$.

For

$$[e'] = [h^{\cdot}] = \sqrt{K_i} >> [In^{\cdot}_{Hg}]$$

from relation [3]

$$[In^{\cdot}_{Hg}] \propto a_{In_2Te_3}^{1/4}p_{Hg}^{1/4} \propto \gamma_{In_2Te_3}^{1/4}X_{In_2Te_3}^{1/4}p_{Hg}^{1/4} \quad [4]$$

where $\gamma_{In_2Te_3}$ and $X_{In_2Te_3}$ stand for the activity coefficient and the mol fraction of $In_2Te_3(S)$ dissolved in $(Hg_{0.8}Cd_{0.2})Te(S)$.

In the cooled crystals at 77 K

$$[e']_{77K} = [In^{\cdot}_{Hg}] - 2[V''_{Hg}] \propto X_{In_2Te_3}^{1/4}p_{Hg}^{1/4}$$

$$\propto [In_{tot}]^{1/4}p_{Hg}^{1/4} \quad [5]$$

Hence, the dependence of e' in the cooled crystals on the indium concentration in the samples and the partial pressure of Hg at the equilibration temperatures is explainable.

A defect situation where the crystal is saturated with the dopant has been observed for iodine-doped CdS (8) where $CdI_2(S)$ was present as a pure second phase; however, the concentration of the iodine donor species on sulfur lattice sites was independent of the activity of $CdI_2(S)$, a_{CdI_2} since a_{CdI_2} was taken to be unity for pure $CdI_2(S)$. In the present case, if the $In_2Te_3(S)$ does not dissolve in $Hg_{0.8}Cd_{0.2}Te(S)$ but re-

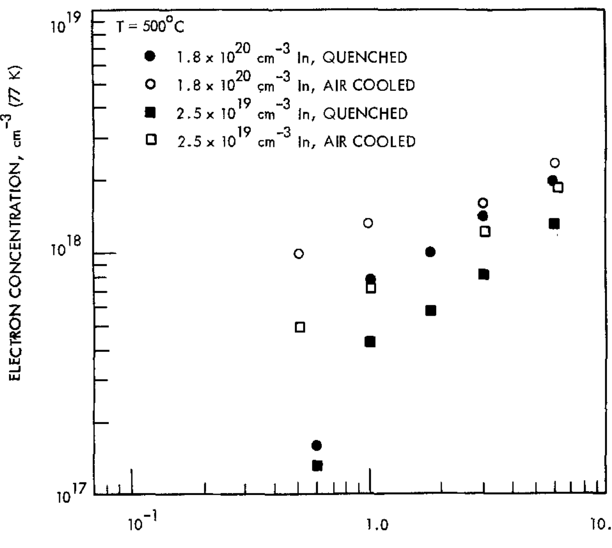

Fig. 4. Electron concentration at 77 K as a function of the partial pressure of Hg for crystals doped with different indium concentrations and quenched or air cooled subsequent to equilibration at 500°C.

mains as a pure second phase, the activity of $In_2Te_3(S)$ becomes unity and the electrically active fraction of indium $[In^{\cdot}_{Hg}]$ becomes independent of the activity of In_2Te_3 and in turn becomes independent of the amount of $In_2Te_3(S)$ or the total amount of indium present in the crystals (Eq. [3]-[5]) contrary to our experimental observations (Fig. 1 and 2). However, if $In_2Te_3(S)$ dissolves in $Hg_{0.8}Cd_{0.2}Te(S)$, the activity of $In_2Te_3(S)$, $a_{In_2Te_3}$, becomes a variable, increasing with increasing amount of the dissolved $In_2Te_3(S)$ and reaching a value of unity when the solubility limit is reached, and $In_2Te_3(S)$ becomes a pure second phase. For such a situation, the electrically active fraction of indium $[In^{\cdot}_{Hg}]$ becomes a function of the activity of $In_2Te_3(S)$ and thereby a function of the amount of $In_2Te_3(S)$ or the total amount of indium present in the crystals (Eq. [3]-[5]); the electron concentration in the cooled crystals which is directly proportional to the amount of the electrically active indium becomes a function of the total indium present in the crystals (Eq. [5]). Hence the dissolution of $In_2Te_3(S)$ in $Hg_{0.8}Cd_{0.2}Te(S)$ is an essential requirement in explaining the dependence of the electron concentration in the cooled crystals on the total indium present in the crystals. It should also be mentioned at this stage that if indium in interstitial sites is considered to be the donor species instead of indium on Hg lattice sites the incorporation reaction is written as

$$In_2Te_3(S) + 3Hg(g) \rightarrow 2In^{\cdot}_i + 2e' + 3Hg^x_{Hg} + 3Te^x_{Te}$$

and the mass action constant

$$K = [In^{\cdot}_i]^2[e']^2/a_{In_2Te_3}p_{Hg}^3$$

for an intrinsic crystal with $[e'] = [h^{\cdot}] = \sqrt{K_i}$

$$[In^{\cdot}_i] \propto p_{Hg}^{3/2}a_{In_2Te_3}^{1/2}$$

The electron concentration in the cooled crystals for such a situation can be expected to be dependent on p_{Hg} much more than experimentally observed. Also, such a model predicts that the crystals turn p-type at Hg pressures close to saturation pressures contrary to the experimental results (Fig. 1 and 2). Thus, in addition to the requirement that $In_2Te_3(S)$ be in solid solution of $Hg_{0.8}Cd_{0.2}Te(S)$ the requirement that the majority of the electrically active indium be present substitutionally on Hg lattice sites rather than in interstitial sites must also be satisfied in order to explain the experimental results.

The fact that the experimental results require that In_2Te_3 be in solution of $Hg_{0.8}Cd_{0.2}Te$ up to about 1-2 mol percent (m/o) is not unreasonable. HgTe, CdTe, and In_2Te_3 all have zinc blende structures with not too largely different lattice parameters (6.43Å for HgTe, 6.47Å for CdTe, and 6.15Å for In_2Te_3) and, in fact, it has been established by Woolley *et al.* (9) and Spencer (10) that amounts of up to 15 m/o In_2Te_3 dissolve in HgTe and the energy gap increases with increasing In_2Te_3 concentration somewhat significantly beyond about 5 m/o. We assume however, that in our experiments for In_2Te_3 concentration less than 1 m/o, the influence on the energy gap of $Hg_{0.8}Cd_{0.2}Te$ is negligible. The assumption appears justified since no drastic variation in the concentration of carriers is encountered with increasing indium concentration in the crystal. Pure In_2Te_3 is known to be p-type with an energy gap of 0.3 eV (10) and in fact one of the samples that was doped to 5×10^{21} atoms/cm^3 of indium showed excessive In_2Te_3 formation and the sample was p-type.

Preliminary x-ray and Auger analysis data also seem to support the model of indium being present as $In_2Te_3(S)$ dissolved in $Hg_{0.8}Cd_{0.2}Te(S)$. Auger analysis of the surface of a sample containing greater than 10^{21} cm^{-3} of indium indicated the surface to be rich in indium and tellurium and the composition corresponded to In_2Te_3. X-ray analyses indicated evidence of lattice parameter changes with an increase in the concentration of indium from 3×10^{19} cm^{-3} to 3×10^{20} cm^{-3} with no evidence of the presence of a second phase, whereas clear evidence of the presence of a second phase was obtained in samples containing greater than 10^{21} cm^{-3} of indium. Although not entirely conclusive, these data seem to support the idea that $In_2Te_3(S)$ is soluble in $Hg_{0.8}Cd_{0.2}Te$ from 1 to 5 m/o at 500°-600°C.

Analysis of the carrier concentration in the cooled crystals.—Denoting the high temperature defect state by subscript HT, the complete electroneutrality condition and the indium balance equation can be written as

$$[e']_{HT} + 2[V''_{Hg}]_{HT} = [In^{\cdot}_{Hg}]_{HT} + [h^{\cdot}]_{HT} \quad [6]$$

and

$$[In^{\cdot}_{Hg}]_{HT} + 2[In_2Te_3]_{HT} = [In_{tot}] \quad [7]$$

Expressing all the quantities in the electroneutrality condition [6] in terms of the mass action constants defined in part I, we get

$$[e']_{HT} + 2K''_{VHg}[e']_{HT}^2/K_i^2 p_{Hg} = [In^{\cdot}_{Hg}] + K_i/[e']_{HT}$$

or

$$2[e']^3_{HT}K''_{VHg}/K_i^2 p_{Hg} + [e']^2_{HT} - [In^{\cdot}_{Hg}][e']_{HT} - K_i = 0 \quad [8]$$

Owing to the narrow bandgap of $Hg_{0.8}Cd_{0.2}Te$, the correctness of the assumption of $K_i = [e'][h^{\cdot}] =$ constant for a fixed temperature for large donor or acceptor concentrations is arguable. Since all our experimental results have shown systematic variations of carrier concentrations as a function of the imposed physicochemical conditions in accordance with the mass action approach, we feel our assumption is a valid one.

In the crystals quenched to room temperature from the equilibration temperatures

$$[e']_{77\,K} = [In^{\cdot}_{Hg}]_{HT} - 2[V''_{Hg}]_{HT}$$

or

$$[e']_{77\,K} = [In^{\cdot}_{Hg}] - 2K''_{VHg}[e']_{HT}^2/K_i^2 p_{Hg} \quad [9]$$

values of the mass action constants K_i and K''_{VHg} are given by (part I)

$$K_i = 9.16 \times 10^{40} \exp(-0.57\,eV/KT)\ cm^{-6} \quad [10]$$

and

$$K''_{VHg} = 1.58 \times 10^{69} \exp(-2.24\,eV/KT)\ cm^{-9}\,atm \quad [11]$$

with the knowledge K''_{VHg} and K_i (Eq. [8]) gives $[e']_{HT}$ and $[V''_{Hg}]$ as a function of $[In^{\cdot}_{Hg}]$ for various partial pressures of Hg.

The product of the mass action constant defined by Eq. [3] and the activity of $In_2Te_3(S)$, $K_{(In_2Te_3-In^{\cdot}_{Hg})}a_{In_2Te_3}$ and $[e']_{77\,K}$ are also immediately obtained as a function of $[In^{\cdot}_{Hg}]$ from Eq. [3] and [9], respectively. Comparison of the calculated $[e']_{77\,K}$ as a function of $[In^{\cdot}_{Hg}]$ with the experimental values of Fig. 1 gives the concentration of the electrically active fraction of indium as a function of the total indium present in the crystals as shown in Fig. 5. Values of $K_{(In_2Te_3-In^{\cdot}_{Hg})}a_{In_2Te_3}$ calculated earlier as a function of $[In^{\cdot}_{Hg}]$ can then be related to the total indium concentration in the crystals and in turn to the amount of In_2Te_3 present in the crystals from the indium balance Eq. [6]. Figure 6 shows $K_{(In_2Te_3-Ig^{\cdot}_{Hg})}a_{In_2Te_3}$ as a function of $[In_2Te_3]$ present in the crystals. Since the slope of the curves on the log-log scale is different from unity, it appears that the activity coefficient of $In_2Te_3(S)$ dissolved in $Hg_{0.8}Cd_{0.2}Te(S)$ is not constant, but varies with the amount of $In_2Te_3(S)$. Once the values of $K_{(In_2Te_3-In^{\cdot}_{Hg})}a_{In_2Te_3}$ as a function of $In_2Te_3(S)$ are

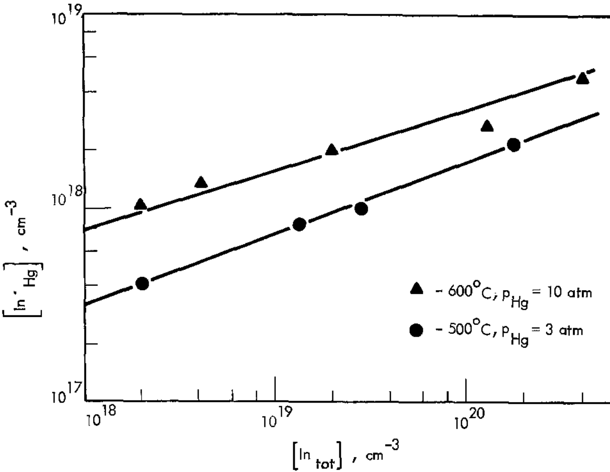

Fig. 5. Concentration of electrically active indium as a function of the total indium present in the crystals subsequent to equilibration at 500°C, p_{Hg} = 3 atm and at 600°C, p_{Hg} = 10 atm.

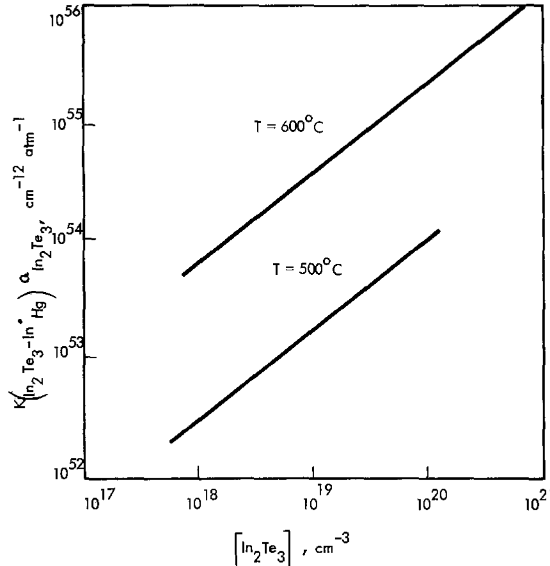

Fig. 6. Calculated value of the product of the mass action constant $K_{(In_2Te_3\text{-}In^{\cdot}_{Hg})}$ and the activity of In_2Te_3(S) in solution of $Hg_{0.8}Cd_{0.2}Te$(S) (=$[In^{\cdot}_{Hg}]^2[e']^2/p_{Hg}$; expression [3] in the text) as a function of the concentration of In_2Te_3 present in the indium-doped crystals subsequent to equilibration at 500° and 600°C.

known from Fig. 6, it is possible to calculate $[e']_{77\,K}$, $[e']_{HT}$, $[V''_{Hg}]_{HT}$, $[In^{\cdot}_{Hg}]$, and $[In_2Te_3]$ as a function of $[In_{tot}]$ and p_{Hg} from Eq. [3], [7], [8], and [9].

Figures 7 and 8 show the calculated defect concentrations at T = 500°C, p_{Hg} = 3 atm, and T = 600°C, p_{Hg} = 10 atm as a function of the indium concentration in the crystals. Calculated values of the carrier concentrations in the cooled crystals are also shown along with the experimental values. The agreement between the calculated values and the experimental ones appears satisfactory. The figures also predict that the crystal is essentially intrinsic with most of the indium being present as In_2Te_3 with only a small fraction present as single donors occupying Hg lattice sites. The concentration of the native acceptor defects is essentially constant in the figures since the partial pressure of Hg is kept constant and the crystals are essentially intrinsic.

Figure 9 shows the calculated defect concentrations at T = 500°C as a function of the partial pressure of Hg for a fixed indium concentration in the crystal. It can be noticed from the figure that although the total indium concentration is fixed in the crystal, the amount of the electrically active indium varies as a function of the partial pressure of Hg as predicted from the in-

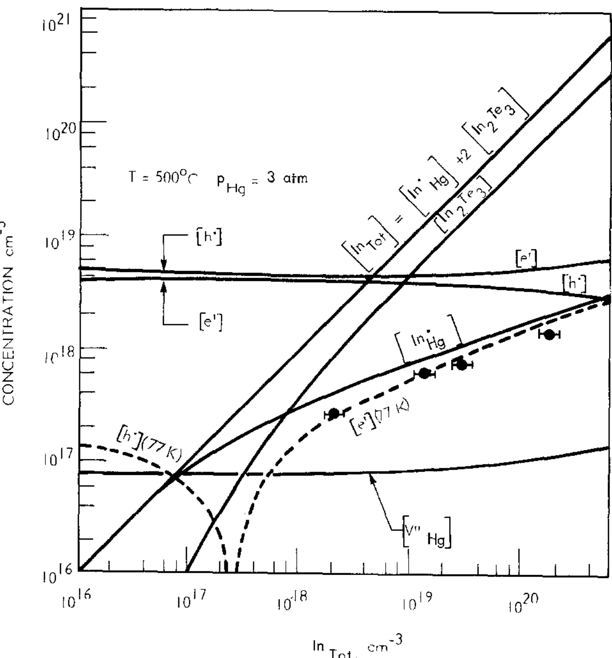

Fig. 7. Calculated defect concentrations ([e'], [h·], [V''Hg], [In·Hg], and [In₂Te₃]) as a function of the total indium present in the indium-doped $Hg_{0.8}Cd_{0.2}Te$ crystals subsequent to equilibration at 500°C and p_{Hg} = 3 atm; dashed lines show the calculated carrier concentrations obtained in the cooled crystals at 77 K; experimental points are also shown for comparison.

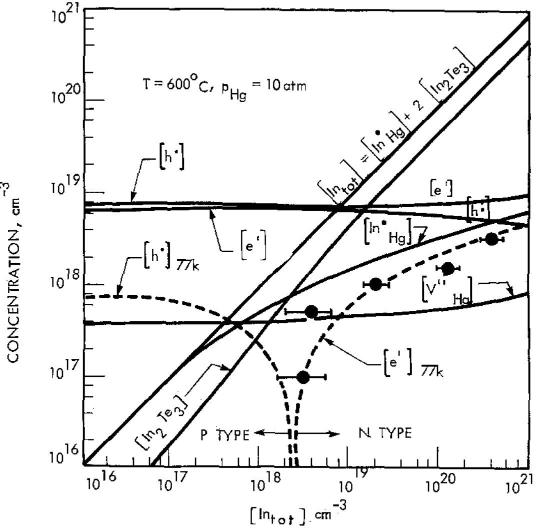

Fig. 8. Calculated defect concentrations ([e'], [h·], [V''Hg], [In·Hg], and [In₂Te₃]) as a function of the total indium present in the indium-doped $Hg_{0.8}Cd_{0.2}Te$ crystals subsequent to equilibration at 600°C and p_{Hg} = 10 atm; dashed lines show the calculated carrier concentrations obtained in the cooled crystals at 77 K; experimental points are also shown for comparison.

corporation reaction for In_{Hg} from In_2Te_3(S) (Eq. [3]). The concentration of the native acceptor defects ($[V''_{Hg}]$) also varies in Fig. 9 since the partial pressure of Hg is a variable. The calculated electron concentration values at 77 K as a function of p_{Hg} are in agreement with the experimental values shown in the figure. The p to n transition in the cooled crystals (Fig. 7 through 9) occurs when $[In^{\cdot}_{Hg}] = 2[V''_{Hg}]$.

Figures 10 and 11 show the calculated electron concentrations at 77 K for various indium concentrations in the crystals at T = 500° and 600°C as a function of p_{Hg}. Agreement between the calculated values and the experimental ones appears satisfactory.

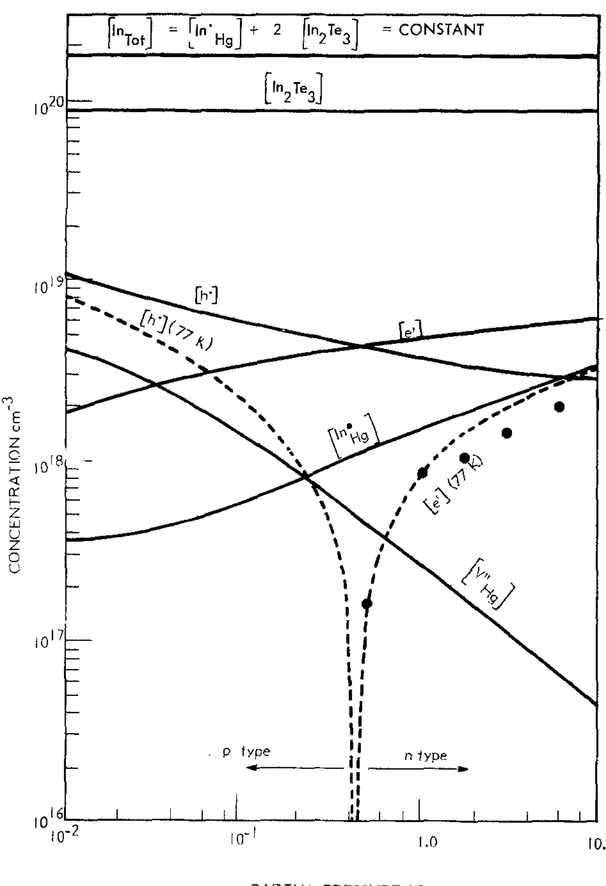

Fig. 9. Calculated defect concentrations ([e'], [h·], [V"$_{Hg}$], [In·$_{Hg}$], and [In_2Te_3]) as a function of the partial pressure of Hg at the equilibration temperature of 500°C for a fixed indium concentration of 1.8×10^{20} cm^{-3} in $Hg_{0.8}Cd_{0.2}Te$ crystals; dashed lines show the calculated carrier concentrations obtained in the cooled crystals at 77 K; experimental points are also shown for comparison.

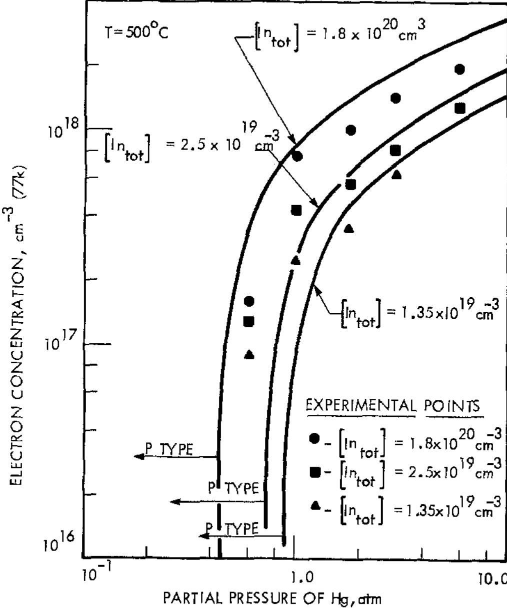

Fig. 10. Calculated electron concentration at 77 K in various indium-doped $Hg_{0.8}Cd_{0.2}Te$ crystals as a function of the partial pressure of Hg after the crystals are annealed at 500°C and quenched to room temperature; experimental points are also shown for comparison.

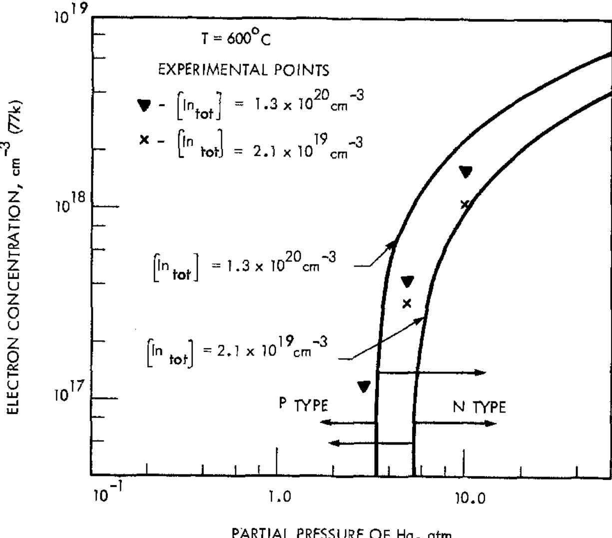

Fig. 11. Calculated electron concentration at 77 K in various indium-doped $Hg_{0.8}Cd_{0.2}Te$ crystals as a function of the partial pressure of Hg after the crystals are annealed at 600°C and quenched to room temperature; experimental points are also shown for comparison.

It is interesting to note from Fig. 8 through 11 that even for very high indium concentrations the crystals turn p-type under low Hg pressures thus demonstrating the complexity of dopant incorporation in defect semiconductors.

Effect of cooling rate on the electron concentration.—The results of Fig. 4 indicate that the electron concentration obtained in the indium-doped samples which are air cooled from 500°C is higher than in the ones quenched from 500°C, the deviation being greater at lower Hg pressures. This implies that the native acceptor defects frozen in the air-cooled samples is lower than in the quenched samples, thereby increasing the electron concentration in the samples air cooled from the equilibration temperatures. It is not presently clear why the native acceptor defects rather than the indium atoms tend to precipitate out during air cooling.

Electron mobility in the indium-doped samples.—As shown in Fig. 3, the electron mobility at 77 K in the indium-doped samples is on the order of 10^4 cm^2/Vsec, decreasing to lower values for electron concentrations exceeding 10^{18} cm^{-3}. These values are an order of magnitude lower than reported previously (7) for low donor concentrations ($<10^{15}$ cm^{-3}). The data shown in Fig. 3 correspond to various indium-doped samples containing indium concentrations varying from approximately 5×10^{18} cm^{-3} to greater than 10^{20} cm^{-3}; these samples also contain doubly ionized native acceptor defects varying from 10^{17} cm^{-3} to 5×10^{17} cm^{-3} in concentrations corresponding to the annealing temperature of 500°-600°C under various partial pressures of Hg. The large electrically active indium concentrations (10^{17}-10^{18} cm^{-3}) and the compensating doubly ionized native defect concentrations probably account for the much lower mobilities.

Conclusion

A defect model for indium-doped $Hg_{0.8}Cd_{0.2}Te$ has been established from Hall effect measurements on indium-doped crystals equilibrated under various partial pressures of Hg and temperatures and quenched to room temperature. According to the model, most of the indium is incorporated into the crystals as In_2Te_3(S) dissolved in $Hg_{0.8}Cd_{0.2}Te$(S) with only a small fraction being present as single donors occupying the Hg lattice.

Lattice Defects in Semiconducting $Hg_{1-x}Cd_xTe$ Alloys

III. Defect Structure of Undoped $Hg_{0.6}Cd_{0.4}Te$

ABSTRACT

Hall effect measurements were carried out on undoped $Hg_{0.6}Cd_{0.4}Te$ crystals quenched to room temperature subsequent to equilibration at temperatures varying from 450° to 720°C under various partial pressures of Hg. The variation of the hole concentration as a function of the partial pressure of Hg indicates that the native acceptor defects are doubly ionized. Native donor defects are found to be negligible in concentration and the p-type to n-type conversion is shown to be due to residual donors and not due to native donor defects. Thermodynamic constant for the incorporation of the doubly ionized native acceptor defect has been established.

Schmit and Stelzer (1) have reported electrical data on $Hg_{0.6}Cd_{0.4}Te$ crystals annealed at various temperatures under Hg-saturated and Te-saturated conditions. Brebrick and Schwartz (2) have recently analyzed these data on the basis of a defect model that assumes all the p-type crystals to be compensated by native donor defects and predicts the conversion of p-type to n-type in the crystals to be due to native donor defects. Conclusions of recent defect structure investigation in undoped $Hg_{0.8}Cd_{0.2}Te$ (3) are in contradiction to those of Brebrick and Schwartz (2). Since an exact power dependence of the hole concentration on the partial pressure of Hg at the annealing temperatures is not possible to evaluate from the experimental results of Schmit and Stelzer (2), which were done under Hg-saturated and Te-saturated conditions only, the present work was undertaken to obtain additional electrical data at various intermediate partial pressures of Hg in addition to those of Schmit and Seltzer (1). These data have enabled us to establish a more precise power dependence of the hole concentration on the partial pressure of Hg at the annealing temperatures; the hole concentration in the cooled crystals has been found to vary as $p_{Hg}^{-1/3}$ indicating that the dominant native acceptor defects at the annealing temperatures are doubly ionized. Just as for undoped $Hg_{0.8}Cd_{0.2}Te$ (3) the electrical data in $Hg_{0.6}Cd_{0.4}Te$ have been explained satisfactorily on the basis that the native acceptor defects are doubly ionized, that the native donor defects are negligible in concentration, and that the conversion to n-type in $Hg_{0.6}Cd_{0.4}Te$ crystals is due to residual foreign donors. The dependence of the hole concentration on the partial pressure of Hg and the temperature of equilibration has led to the establishment of the thermodynamic constant for the incorporation of the doubly ionized native acceptor defect.

Experimental

The composition of the crystals used in the present work corresponded to $x = 0.4 \pm 0.005$. The residual impurity concentration was $<10^{16}$ cm^{-3}. In order to improve the efficiency of quenching the high temperature equilibrium, the thickness of the samples was restricted to <0.04 cm. Equilibration periods ranged from 24 hr at temperatures >500°C up to 2-3 weeks at 450°C. The procedure of equilibrating the samples in various Hg pressures and quenching the samples subsequent to equilibration is identical to that of part I (3). It should be mentioned here that while Schmit and Stelzer (1) used Te powder along with the samples for equilibration under Te-saturated conditions, we have used equivalent Hg pressures (4-6). Subsequent to the equilibration, the samples were quenched to room temperature. The samples were lapped, polished, and etched in Br-methanol solution. Hall effect and electrical resistivity measurements were made using the van der Pauw method (7). Magnetic field strengths of 400 and 4000G were used for the Hall effect measurements.

Results

As mentioned in part I (3) only those Hall effect results which did not vary with the magnetic field and, thus, showed no mixed-type conduction, were

used in evaluating the hole concentrations in the samples using the expression

$$p = \frac{1}{R_H q}$$

Hall coefficient as a function of temperature of measurement is shown in Fig. 1 for undoped $(Hg_{0.6}Cd_{0.4})Te$ samples equilibrated at the indicated temperatures and partial pressures of Hg. It can be inferred from the figure that the ionization of the native acceptor defects appears to be complete around 190-200 K and at higher temperatures intrinsic carriers begin to become important. We have used hole concentration measurements at 192 K to infer the concentration of native acceptor defects present at the equilibration temperatures. Figures 2 and 3 show the hole concentration at 192 K as a function of the partial pressure of Hg for various equilibration temperatures ranging from 450° to 720°C. The hole concentration increases with decrease in the partial pressure of Hg, but more weakly than was found for $Hg_{0.8}Cd_{0.2}Te$ (part I) (3). In undoped $Hg_{0.8}Cd_{0.2}Te$ the hole concentration varied as p_{Hg}^{-1} (part I), whereas, results of Fig. 2 and 3 indicate that the hole concentration in undoped $Hg_{0.6}Cd_{0.4}Te$ varies as $p_{Hg}^{-1/3}$ and increases with increase in temperature.

Figures 4 and 5 show the mobility of holes at 77 and 192 K as a function of the hole concentration. The

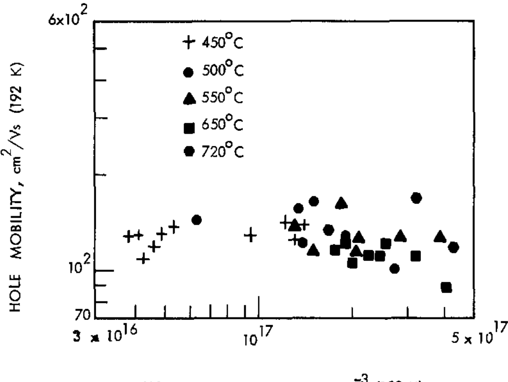

Fig. 5. Hole mobility at 192 K as a function of the hole concentration for undoped $Hg_{0.6}Cd_{0.4}Te$.

hole mobilities at 77 K are lower than those obtained for $Hg_{0.8}Cd_{0.2}Te$ (part I) (3).

Discussion

The quasichemical approach used to arrive at the defect model has already been described in part I (3) and, hence, is not detailed here.

Native acceptor defects.—The fact that the hole concentration in the crystals is proportional to $p_{Hg}^{-1/3}$ (Fig. 2 and 3) indicates that the native acceptor defects are doubly ionized. The formation and ionization of these defects can be described by the following reaction and mass action relation

$$Hg^x_{Hg} \rightarrow V''_{Hg} + 2h^{\cdot} + Hg(g); \quad H''_{VHg} \qquad [1]$$

$$K''_{VHg} = [V''_{Hg}]\,[h^{\cdot}]^2\, p_{Hg} \qquad [2]$$

If the electroneutrality condition is dominated by V''_{Hg} and $h^{\cdot}$ then we have

$$[h^{\cdot}] \approx 2[V''_{Hg}] > [e']$$

From expression [2] we get

$$[h^{\cdot}] = [2K''_{VHg}]^{1/3} p_{Hg}^{-1/3}$$

The dominance of V''_{Hg} at the equilibration temperatures implies that the undoped $(Hg_{0.6}Cd_{0.4})Te$ crystals are not intrinsic, unlike undoped $(Hg_{0.8}Cd_{0.2})Te$ crystals (part I), in $Hg_{0.6}Cd_{0.4}Te$, at the annealing temperatures

$$[h^{\cdot}] = 2[V''_{Hg}] > \sqrt{K_i} > [e']$$

whereas, in $Hg_{0.8}Cd_{0.2}Te$

$$2[V''_{Hg}] < [e'] = [h^{\cdot}]\sqrt{K_i} \quad \text{(part I)}$$

Thus, although the native acceptor aspects are doubly ionized in both $x = 0.2$ and $x = 0.4$ crystals, the dependence of the hole concentration on the partial pressure of Hg in the cooled crystals is different for the two compositions.

The fact that the intrinsic carrier concentration for the $x = 0.2$ material is higher than that for the $x = 0.4$ is a consequence of the lower bandgap for the $x = 0.2$ material.

Comparison of present experimental results with previous work.—Our experimental results differ from those of Schmit and Stelzer (1) at higher temperatures of equilibration as well as for Te-saturated conditions. We did not observe any decrease in the hole concentration at $T > 600°C$, as found by Schmit and Stelzer. Also, we obtain higher native acceptor defect concentrations (or higher hole concentrations) under Te-rich conditions than Schmit and Stelzer did. It is to be noted that the electrical data in Ref. (1) were obtained for crystals annealed in Hg vapor and Te_2 vapor, with Hg or Te being at the same temperature as $Hg_{0.6}Cd_{0.4}Te$. It is known that the saturation Hg pressure over $Hg_{0.6}Cd_{0.4}Te$ (4-6) is less than that of pure Hg itself, the difference being higher at temperatures greater than 500°C. Hence, by exposing the $Hg_{0.6}Cd_{0.4}Te$ crystals to saturated-Hg vapor at greater than 500°C, in the experiments of Schmit and Stelzer (1), compositional changes in the samples may have arisen. Also, similar arguments apply for anneals in saturated Te_2 vapor, reported in Ref. (1). In addition, it is also known (4-6) that the partial pressures of Te_2 over $Hg_{0.6}Cd_{0.4}Te$ under Te-saturated conditions are orders of magnitude lower than partial pressures of Hg under Te-saturated conditions. Hence, depending on the kinetics of the different equilibration processes and depending on the fact that during the heat-up of the samples and the tellurium source, the sample may not have stayed within the existence region, compositional changes for anneals under Te-saturated conditions may also have risen in the experiments of Ref. (1). In the present work, however, equilibrations under Te-saturated conditions were done in Hg vapor at equivalent partial pressures of Hg (4-6) rather than in Te_2 vapor. As discussed in part I, macroscopic defects such as voids, Hg or Te inclusions, etc. can affect the quenching efficiency of the crystals. Presence of these may also account for the lower hole concentrations obtained by Schmit and Stelzer (1).

p-type to n-type conversion in undoped $(Hg_{0.6}Cd_{0.4})Te$.—Schmit and Stelzer (1) found the undoped $(Hg_{0.6}Cd_{0.4})Te$ samples converted from p-type to n-type under Hg-saturated conditions at temperatures below about 350°C. The conversion temperatures for the two crystals that they experimented with were different and the electron concentration in both samples was independent of the equilibration temperature at temperatures below the conversion temperatures. If the p-type to n-type conversion is due to native donor defects, a temperature dependence of the electron concentration should be expected just as is observed for the hole concentration (1) unless the enthalpies associated with the vaporization of Hg(1), the intrinsic excitation constant, and the incorporation of the native donor defects are of such a sign and magnitude that the electron concentration in the cooled crystals is independent of the anneal temperature. For details see Appendix B of part I. However, if the conversion is due to native donor defects, the p-type to n-type conversion temperature should be the same for different samples as long as native donor defects are larger in concentration than the foreign donors. Thus, even if the temperature independence of electron concentration under Hg-saturated conditions can be explained on the basis of native donor defects, different conversion temperatures for different samples cannot be explained unless the conversion is due to foreign donor impurities present in the crystals. Hence, the concentration of native donor defects in undoped $(Hg_{0.6}Cd_{0.4})Te$ crystals appears to be negligible and, at least, less than 10^{15} cm^{-3} at 300°C.

Absence of compensation.—While attempting to explain the low experimental mobilities of holes in $(Hg_{0.6}Cd_{0.4})Te$, Scott *et al.* (8) assumed that all the undoped p-type samples were heavily compensated. This implied that the compensation mechanism in their crystals was probably a result of the dominance of either Schottky defects ($[V''_{Hg}] = [V^{\cdot\cdot}_{Te}]$) or Frenkel defects ($[V''_{Hg}] = [Hg^{\cdot\cdot}_i]$) (2). Evidence of any such compensation in our samples is lacking. Figure 4 indicates that the hole mobilities at 77 K vary (although only weakly) as a function of only the hole concentration in the crystals, irrespective of the partial pressure of Hg and the temperature of the anneal. If there was any compensation by native donor defects, the concentration of these defects can be expected to be exponentially dependent on temperature and the mobility dependence on the hole concentration would not have been as linear as shown in Fig. 4.

It should be pointed out that mobility results similar to those of Scott *et al.* (8) mentioned above, have been observed by others (9-14). For instance, electron and hole mobilities less than predicted by the Brooks-Herring expression for the ionized impurity scattering (9) have been reported by Reynolds *et al.* (10) for $(Hg_{0.8}Cd_{0.2})Te$. These authors explain the discrepancy to be due to the inadequacy of the Brooks-Herring formula for doping levels on the order of 10^{16} cm^{-3} in the n-type material and of 10^{18} cm^{-3} in the p-type material, and they choose not to invoke compensation as the reason. Ionized impurity mobility calculations at 77 K in degenerately doped n-type GaAs (11), n-type HgSe (12), and p-type Ge (13) at 77 K where the Brooks-Herring formula has considerably overestimated the mobilities due to ionized impurity scattering have also been reported. Recent calculations of Nishizawa *et al.* (14) for hole mobilities due to ionized impurity scattering in $(Hg_{0.82}Cd_{0.18})Te$ yielded values 4.5 times larger than the experimentally measured mobilities. According to these authors, the discrepancy between the theoretical and experimental mobilities of holes due to ionized impurity scattering is a common feature of many semiconductors. In view of these arguments it appears that more thorough calculations of hole mobilities in $Hg_{1-x}Cd_xTe$ alloys are needed.

Mass action constant K''_{VHg}.—Since the power dependence of the hole concentration on the partial pressure of Hg in the cooled crystals does not appear to be greater than 1/3, the only dominant species at the annealing temperatures appear to be the holes and

the native acceptor defects ($[e'] << [V''_{Hg}] = [h^\cdot]/2$). Assuming that $[h^\cdot] = 2[V''_{Hg}]$ at the high temperature as well as in the cooled crystals, from Eq. [2] we get

$$K''_{VHg} = ([h^\cdot]^3/2)p_{Hg} \quad [3]$$

Using a procedure of trial and error, an expression for K''_{VHg} in the form of $Ae^{-Q/kT}$ was arrived at, which best explained the experimental results of Fig. 2 and 3 at various temperatures. Greater emphasis was placed on the results at lower annealing temperatures with the assumption that results from the highest temperature anneals may suffer from a greater quenching inefficiency. The value of K''_{VHg} was evaluated to be

$$K''_{VHg} = 6.61 \times 10^{65} \exp(-2.29 \text{ eV/kT}) (\text{cm}^{-9} \text{ atm}) \quad [4]$$

or, in terms of site fractions, (there are 1.33×10^{22} molecules/cm^3 in $Hg_{0.6}Cd_{0.4}Te$)

$$K''_{VHg} = 0.279 \exp(-2.29 \text{ eV/kT}) \text{ site Fr}^3 \text{ atm} \quad [5]$$

The hole concentrations calculated based on this value of K''_{VHg} are shown in Fig. 2 and 3 as solid lines. The agreement between the experimental results and the calculated values appears satisfactory.

Since $Hg_{0.6}Cd_{0.4}Te$ melts at a higher temperature than $Hg_{0.8}Cd_{0.2}Te$ and has a greater bandgap, the enthalpy associated with the incorporation of the doubly ionized acceptor defect can be expected to be higher in $x = 0.4$ material than in $x = 0.2$ material. The enthalpy for $x = 0.4$ from Eq. [4] is 2.29 eV, whereas, that for $x = 0.2$ material established in part I is 2.24 eV.

Since the intrinsic carriers do not dominate the electroneutrality condition in $x = 0.4$ material for temperatures between 450°-720°C, evaluation of the intrinsic excitation constant $K_i = [e'][h^\cdot]$ was not possible. However, from the results of Fig. 2 and 3 it appears that the intrinsic carrier concentration is less than 3×10^{16} cm^{-3} at 450°C and less than 3×10^{17} cm^{-3} at 720°C. These upper limits of the intrinsic carrier concentrations are lower than those extrapolated from the empirical expressions for n_i for $x = 0.4$ in literature (15).

Hole concentrations for anneals under Hg-saturated and Te-saturated conditions.—With the knowledge of the partial pressures of Hg under Hg-saturated and Te-saturated conditions (4-6) and the value of K''_{VHg} (expressions [4] and [5]) established in the previous section, the hole concentrations in the crystals cooled to room temperature after anneals at different temperatures can be calculated from Eq. [3]. Figure 6 shows the calculated hole concentrations under Hg-saturated and Te-saturated conditions. It is to be noted that the calculations assume the concentrations of the residual donors and acceptors to be negligible in comparison with the native defect concentrations at the anneal temperatures. Figure 6 shows the experimental results of the present work, as well as those of Schmit and Stelzer (1). It is clear from the figure that quenching inefficiencies or the presence of voids and inclusions in the material (part I) can cause scatter in the data, particularly at higher temperatures. Also, the decrease of hole concentration with increase in temperature at $T > 600°$C for Hg-saturated conditions observed in Ref. (1) appears to arise from the quenching inefficiencies and is not a real effect since our results show a continuous increase in hole concentration with increase of temperature from 450° to 720°C. Residual impurity concentrations were neglected in the electroneutrality condition used to arrive at the hole concentration calculations detailed in the previous section. At lower temperatures of annealing the presence of residual donor concentrations can considerably affect the hole concentration in the sam-

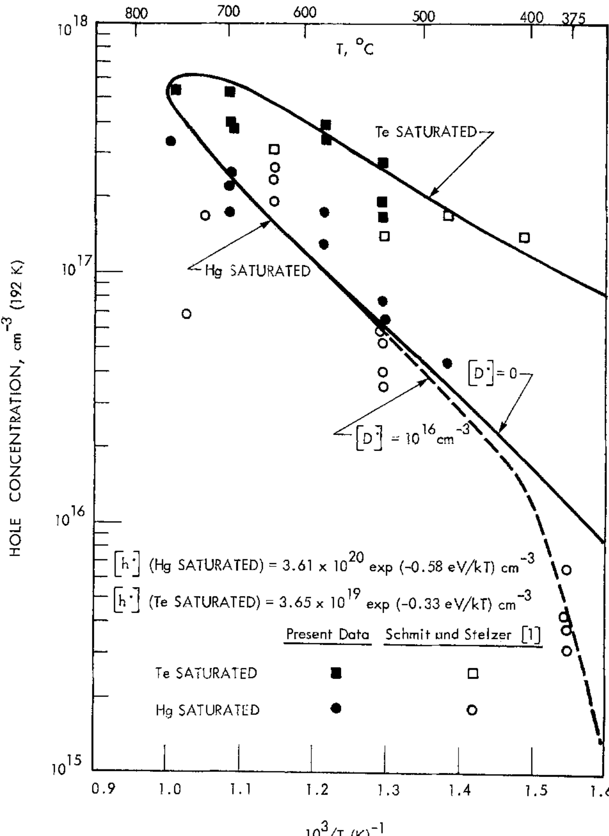

Fig. 6. Calculated hole concentration lines at 192 K as a function of annealing temperature for undoped $Hg_{0.6}Cd_{0.4}Te$ equilibrated in Hg- and Te-saturated conditions.

ples. The Appendix details the calculation of the hole concentration in the crystals in the presence of residual donors. Such a calculation assuming a residual donor concentration of 10^{16} cm^{-3} is shown as a dashed line in Fig. 6. It is clear from the figure that the results of Ref. (1) at 375°C under Hg-saturated conditions can be explained if the crystals are assumed to have approximately 10^{16} cm^{-3} residual donors.

The expressions for the hole concentrations in the cooled crystals as a function of temperature for Hg-saturated and Te-saturated conditions are given by

$$[h^\cdot] \text{ (Hg-saturated)} = 3.61 \times 10^{20} \exp(-0.58 \text{ eV/kT}) \text{ cm}^{-3} \quad [6]$$

and

$$[h^\cdot] \text{ (Te saturated)} = 3.65 \times 10^{19} \exp(-0.33 \text{ eV/kT}) \text{ cm}^{-3} \quad [7]$$

Isohole concentration plot.—Hole concentration calculations as a function of the anneal temperature and the partial pressure of Hg as detailed in the two previous sections enable us to draw lines of constant deviation from stoichiometry as a function of temperature and partial pressure of Hg. A plot of such lines of constant hole concentration is shown in Fig. 7. The upper and lower Hg pressures within which the solid is stable at each temperature were obtained from references (4-6). Comparison of this plot with a similar one for $Hg_{0.8}Cd_{0.2}Te$ (part I, Fig. 12) indicates that the concentration of native acceptor defects obtained in $x = 0.4$ material is lower than in $x = 0.2$ material. The temperature dependence of the hole concentration in the cooled crystals is also shallower for $x = 0.4$ than for $x = 0.2$ owing to the fact that the $x = 0.2$ crystals are intrinsic at the anneal temperatures, whereas the $x = 0.4$ crystals are not.

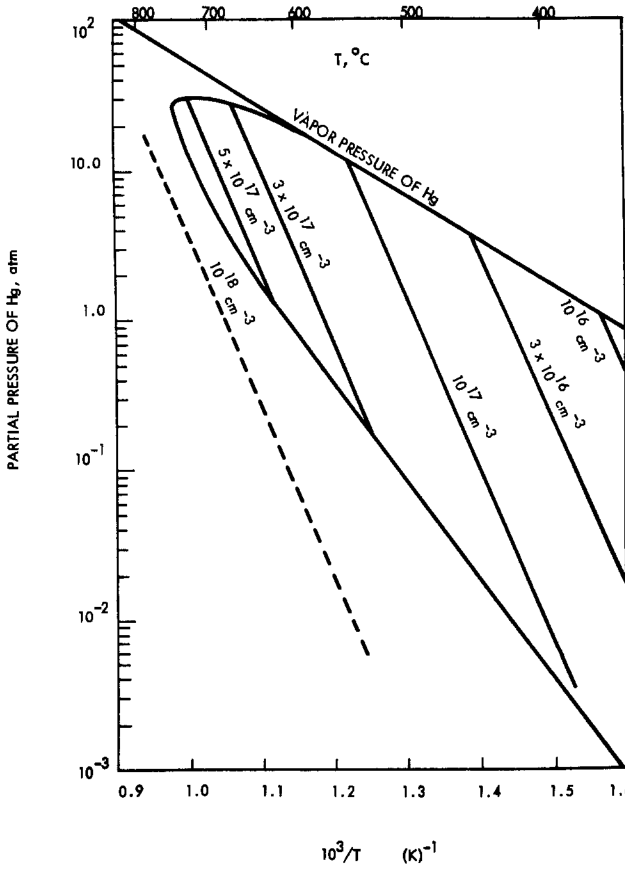

Fig. 7. Calculated isohole concentration lines at 192 K for $Hg_{0.6}Cd_{0.4}Te$ as a function of the partial pressure of Hg and temperature of annealing.

Hole mobility in $Hg_{0.6}Cd_{0.4}Te$.—Figures 4 and 5 show that the hole mobility at 77 K decreases with increase in hole concentration whereas it is relatively independent of the hole concentration at 192 K indicating that the hole mobility at 192 K is almost completely dominated by lattice scattering whereas ionized impurity scattering contributes to the mobility at 77 K. The absolute hole mobility at 77 K as well as its dependence on the hole concentration in $Hg_{0.6}Cd_{0.4}Te$ are less than in $Hg_{0.8}Cd_{0.2}Te$ (part I) (3).

Conclusion

Based on the variation of the hole concentration as a function of the partial pressure of Hg in crystals annealed at various temperatures and quenched to room temperature, the dominant native acceptor defects in undoped $Hg_{0.6}Cd_{0.4}Te$ have been established to be doubly ionized. The mass action constant describing the incorporation of the doubly ionized acceptor defect explains the experimental results satisfactorily.

APPENDIX

Hole Concentration Calculations in $Hg_{0.6}Cd_{0.4}Te$ Containing Residuals Donors

Electroneutrality condition:

High temperature

$$2[V''_{Hg}]_{HT} = [h^{\cdot}]_{HT} + [D^{\cdot}] \qquad [A\text{-}1]$$

Cooled crystals

$$[h^{\cdot}]_{LT} = 2\,[V''_{Hg}]_{HT} - [D^{\cdot}] \qquad [A\text{-}2]$$

Subscripts HT and LT in Eq. [A-1] and [A-2] refer to the high temperature and low temperature defect states, respectively; $[D^{\cdot}]$ refers to concentration of residual donors in the samples, assumed to be always ionized and independent of anneal temperature.

Expressing the species in Eq. [A-1] and [A-2] in terms of the mass action constant $K''_{V_{Hg}}$ (Eq. [2] of main text) we get

$$2\,K''_{V_{Hg}}/([h^{\cdot}]^2_{HT}p_{Hg}) = [h^{\cdot}]_{HT} + [D^{\cdot}]$$

or

$$[h^{\cdot}]^3_{HT} + [h^{\cdot}]^2_{HT}[D^{\cdot}] = 2K''_{V_{Hg}}/p_{Hg} \qquad [A\text{-}3]$$

In the cooled crystals

$$[h^{\cdot}]_{LT} = 2K''_{V_{Hg}}/([h^{\cdot}]^2_{HT}p_{Hg}) - [D^{\cdot}] \qquad [A\text{-}4]$$

with the knowledge of $K''_{V_{Hg}}$ (Eq. [2] of the main text) hole concentration in the cooled crystals can be calculated from Eq. [A-3] and [A-4] for various fixed residual donor concentrations in the crystals.

The Properties of LPCVD SiO_2 Film Deposited by SiH_2Cl_2 and N_2O Mixtures

K. Watanabe,[1] T. Tanigaki, and S. Wakayama

Sony Research Center, Fujitsuka-cho, Hodogaya, Yokohama, Japan

ABSTRACT

The distribution of Cl in LPCVD SiO_2 film deposited by SiH_2Cl_2 and N_2O was measured by IMMA. Cl was distributed broadly near the SiO_2-Si interface even in unannealed film. In thick LPCVD SiO_2 films on Si, surface roughness was observed after thermal oxidation. Cl was markedly piled up near the interface between the thermally grown oxide and the Si substrate. In thin films, surface roughness induced by oxidation was not observed. Cl distribution after oxidation was almost the same as that of unannealed film. The Cl pile-up is not caused by oxidation, but by the existence of the Si-SiO_2 interface. The cause of surface roughness is attributed to a smaller concentration of oxygen than Cl at the interface.

CVD (chemical vapor deposited) SiO_2 film, which is indispensable to Si planar technology, has been formed conventionally by the reaction of SiH_4 and O_2 at about 400°C at atmospheric pressure. LP (low pressure)-CVD SiO_2 film formed by the reaction of SiH_2Cl_2 and N_2O at about 900°C has been examined, because it is denser, its thickness is more uniform, and because samples are easier to produce compared with conventional CVD SiO_2 film (1). Oxidation treatment after deposition of the LPCVD SiO_2 film on Si, however, induces surface roughness. Many bumps on the SiO_2 surface and many etch pits on Si are observed.

Surface roughness may be caused by HCl or Cl_2 produced by the decomposition of SiH_2Cl_2, since similar phenomena have been observed in HCl oxidation (2-4). There may be a high concentration of Cl ions in the LPCVD SiO_2 film. In this paper the Cl distribution in the LPCVD SiO_2 film was investigated by ion microprobe mass analyzer (IMMA). Cl distribution, the relation between surface roughness and Cl distribution, and the mechanism of surface roughness were studied before and after oxidation and before and after N_2 anneal. To investigate the Cl distribution in the LPCVD SiO_2, whose growth mechanism is different from that of thermal SiO_2, we studied the effect of Cl on the SiO_2-Si interface. We are thus able to determine under which conditions useful LPCVD SiO_2 film could be produced.

Experimental

LPCVD SiO_2 films were formed on silicon wafers by the reaction of SiH_2Cl_2 and N_2O at 0.6 Torr at about 900°C. The two reactant gases, controlled by mass flowmeters, were mixed in the reactor. The evacuation system consisted of a mechanical booster pump and rotary pump. The flow rate of SiH_2Cl_2 was varied from 15 to 50 cm^3/min. The N_2O flow rate was fixed at 100 cm^3/min. The growth rate was from 55 to 70 Å/min. The films were deposited on 2 in. Si wafers set vertically on a quartz boat, perpendicular to the gas flow. Thickness of the film was measured by ellipsometry. The index of refraction of the film, n, was from 1.44 to 1.46. Infrared spectrum of the film showed the absorption at 9.4 μm caused by the Si—O bond. The absorption of Si—N bond was not observed at 12 μm.

To investigate the Cl redistribution of the film, the samples were oxidized in dry O_2 ambient or annealed in N_2 ambient. Since the samples were oxidized or annealed in the furnace different from that used in deposition, the possibilities of Cl in these ambients were eliminated.

Key words: CVD silicon dioxide low pressure, silicon dioxide chlorine distribution, Si-SiO_2 interface, thermal oxidation.

The different flow rates of SiH_2Cl_2 in our growth condition did not influence the chlorine concentration and distribution.

The depth profile was analyzed as follows. The surface of the sample was coated by Au evaporation to reduce charge accumulation and sputter-etched with a focused primary ion beam (~18.5 keV, O_2^+, 20 μm^{ϕ}). In order to get a uniform sputtering yield the beam was raster-scanned over a small area on the sample surface (400 × 320 μm). The electronic aperture system was used to eliminate the crater-wall effect. Integrated $^{35}Cl^+$ secondary ion intensity was measured during a 40 sec period. At the same time, $^{28}Si^+$ signals in the matrix were counted to normalize the Cl ion intensity. The depth of the crater was measured by Talystep with a mechanical stylus. The sputtering rates were approximately constant i.e., R_s = 4 Å/sec. Although previous researchers have experienced insulator sample charging problems which have caused the redistribution of mobile ions, we did not experience this phenomenon, and we were able to confirm that the Cl ions had not been redistributed by the as-implanted profile of Cl in SiO_2 film about 1000Å thick. The instrument used in this study was an Applied Research Laboratories ion microprobe mass analyzer.

Results

Characteristics of Cl distribution.—Figure 1a shows Cl distribution in an LPCVD SiO_2 film of 2400Å. Figure 1b shows the Cl distribution after the N_2 anneal at 1100°C for 1 hr. The two films were chemically pre-etched to prevent accumulation of an electrical charge on the film. We found that Cl ions are not uniformly distributed at all depths and the peak concentration is about 10^{19} ions/cm^3.

The maximum Cl ion intensity in the LPCVD SiO_2 film appeared to be at about 500Å from the SiO_2-Si interface. This is subjected to an error of about 100Å, however, because the interface cannot be precisely monitored by Si ion intensity. Si ion intensity gradually changes near the SiO_2-Si interface because of the difference of the sputtering rate and the yield of SiO_2 and Si.

To verify the IMMA measurement, we measured the Cl ion intensity of Cl ion-implanted SiO_2 (implantation conditions: 60 keV, 5 × 10^{15} ions/cm^2) film deposited by SiH_4 and O_2 at 420°C. The measuring conditions were the same as Fig. 1. Figure 2 shows the resulting Cl distribution. This profile agrees with the Gaussian profile which is based on the LSS theory. Maximum ion intensity is near the theoretically predicted depth of 515Å. This result confirms that the ion intensity of

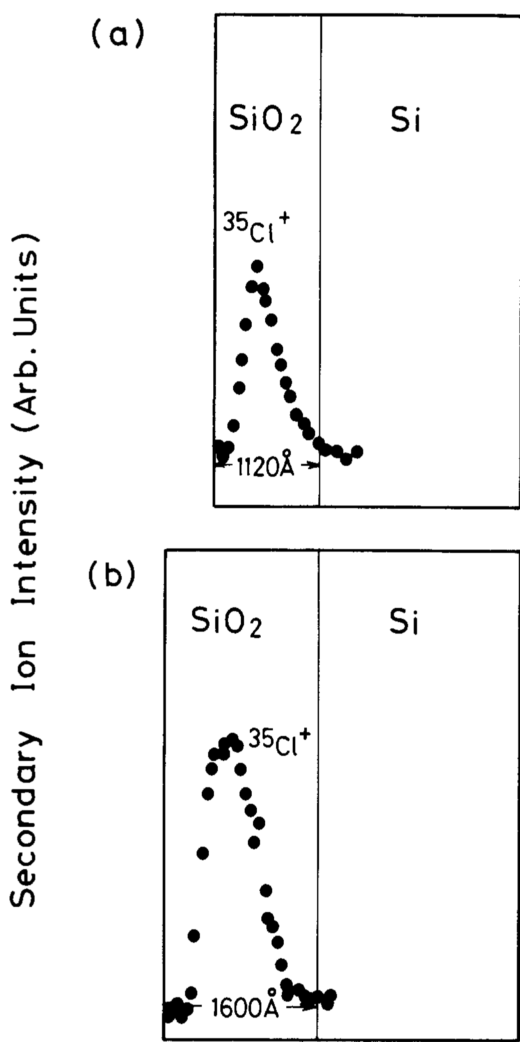

Fig. 1. Cl distribution of a chemically pre-etched LPCVD SiO_2 film (a) as deposited (b) after N_2 anneal at 1100°C for 1 hr.

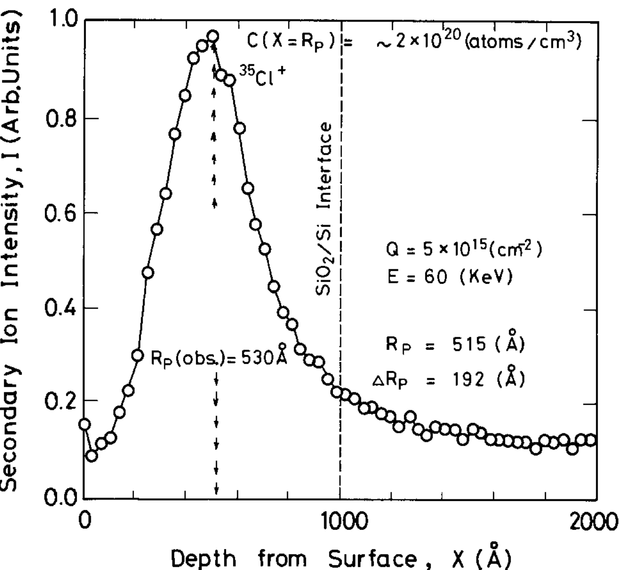

Fig. 2. Cl ion intensity of Cl ion-implanted CVD SiO_2 as deposited.

secondary ion $^{35}Cl^+$ has a linear relation to the Cl concentration.

To verify the accuracy of the Cl^{35} in-depth profile in thick SiO_2 film, eight points (Q21 to Q28) on the sample surface were analyzed at different depths. The results are shown in Fig. 3a. In this figure, N represents the number of sampling times. Figure 3b shows the in-depth profile of the same sample, but the areas analyzed were ion etched prior to depth-profile analysis to determine the influence of ion etching on these points. The resultant profile of Cl distribution is reproducible. Distribution in nonetched sample is the same as that in etched samples. The number of Cl ions escaping from the side walls of craters is negligible and the knock-on Cl ions or electrical fields induced by sputtering do not affect Cl distribution. Figures 3a and b show that Cl has a flat distribution near the SiO_2 surface and piles up near the interface.

The Cl distribution in samples of three different thickness, 1500, 2600, and 6000Å, before and after thermal oxidation is shown in Fig. 4. The characteristics of the Cl distribution are as follows: (*i*) Cl ions are distributed broadly near the interface as the film is deposited. Cl distribution is flat near the surface. (*ii*) Before annealing the magnitude and profile of Cl distribution near the interface are independent of the film thickness. (*iii*) Cl ions move toward the newly formed interface as the thermally oxidized layer grows. (*iv*) In the 6000Å film, Cl concentration near the interface increases and its profile becomes sharp after oxidation. The additional Cl ions come from outside the pile-up region. In the 1500 and 2600Å films, the Cl profile remains unchanged after oxidation, although, of course, distribution shifts to the new interface. (*v*) Cl distribution remains unchanged after the N_2 anneal at 1100°C for 1 hr.

Surface roughness is observed only in the 6000Å film. This can be attributed to the remarkable piling-up of Cl at the interface. The surface roughness induced by oxidation is accompanied by the redistribution of Cl. (In thin films surface roughness is not observed after a 1 hr oxidation.) Pancake shapes in thick LPCVD SiO_2 films, as shown in Fig. 5a, are observed after oxidation. Their diameter is from 5 to 10 μm, measured by Talystep. The center of the risen area is about 3000Å high. Many etch pits are observed on the silicon surface after removal of SiO_2 by diluted HF, as shown in Fig. 5b. The approximately 300Å deep pits are square or rectangular because of the anisotropic etching to the Si(100) wafer. A schematic drawing of a section of the SiO_2-Si structure is shown in Fig. 6. We can assume that SiO_2 thickness is constant over the convex and concave regions because the oxygen intensity in these regions, measured by EPMA, is constant.

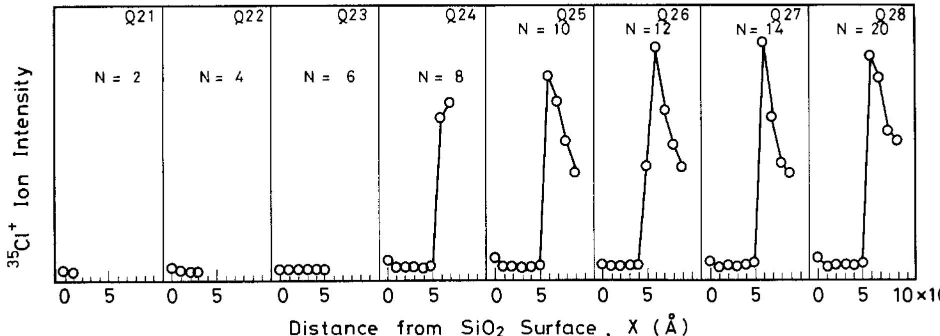

Fig. 3. (a) Cl ion distribution at eight different places (Q21-Q28) on LPCVD SiO_2 surface.

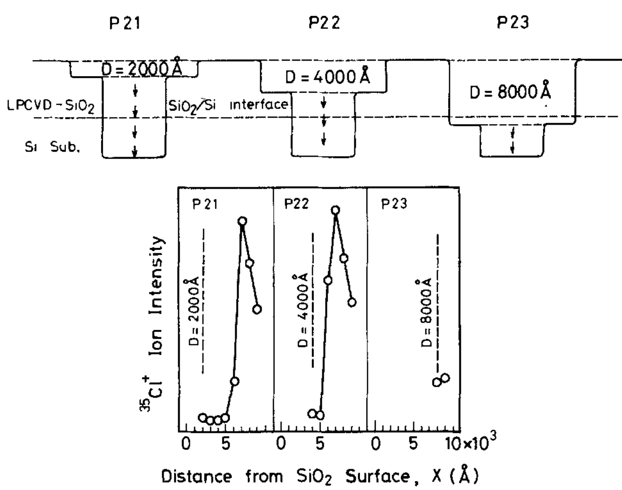

Fig. 3 (b) Cl distribution after ion etching of LPCVD SiO_2 to three different depths, DÅ.

After N_2 annealing of the film surface roughness is not observed. Oxidation following N_2 annealing, however, induces surface roughness. The fact that Cl distribution remains unchanged after N_2 annealing suggests that no surface roughness would be produced after the annealing, but that surface roughness would be induced after oxidation.

The influence of Cl distribution.—The influence of Cl ions in SiO_2 on the etching rate and on flatband voltage V_{FB} was investigated. The rate of etching to LPCVD SiO_2 and to conventional CVD SiO_2 is shown in Fig. 7. The rate of etching to CVD SiO_2 (deposited

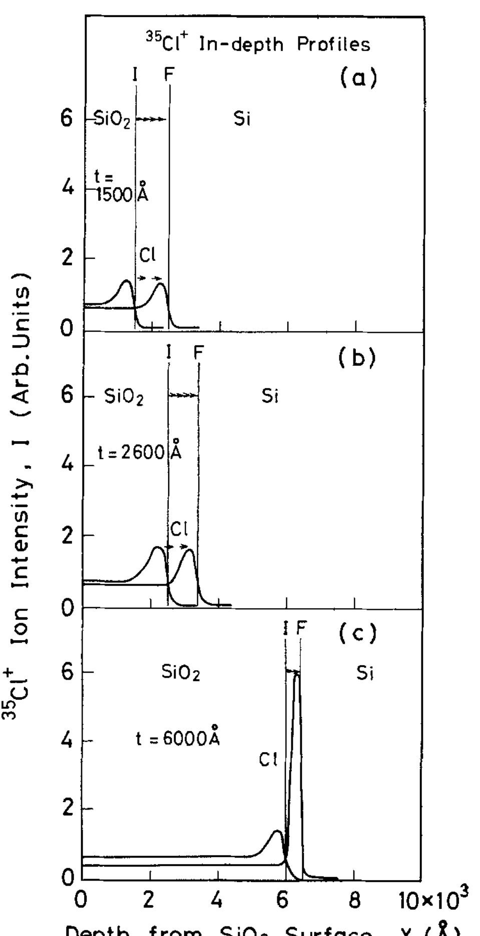

Fig. 4. Cl in-depth profile for three different thickness as deposited. I indicates the interface as deposited. F indicates the interface after oxidation at 1000°C for 1 hr.

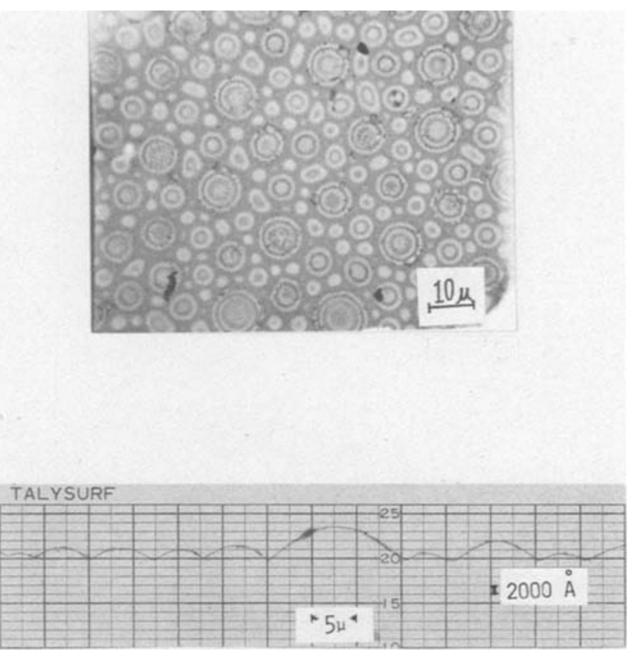

Fig. 5. (a) Surface of a thick LPCVD SiO_2 film after 1000°C anneal.

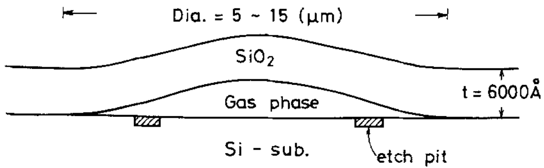

Fig. 6. Schematic illustration of the section of SiO_2-Si when surface roughness is observed.

by SiH_4 and O_2 at 420°C at atmospheric pressure) is constant, since this film does not include Cl ions. The rate of etching to LPCVD SiO_2 film decreases when the film becomes less than 1500Å thick. This tendency is also observed in another etchant, NH_4F:HF = 60:1.

Figure 8 shows the thickness dependence of V_{FB} on MOS structures [n-type (100) 2-3 Ω-cm Si] obtained

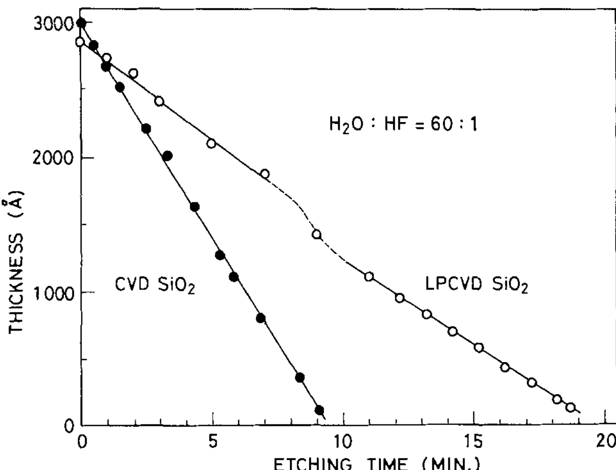

Fig. 7. Etching rates of LPCVD SiO_2 and atmospheric pressure CVD SiO_2.

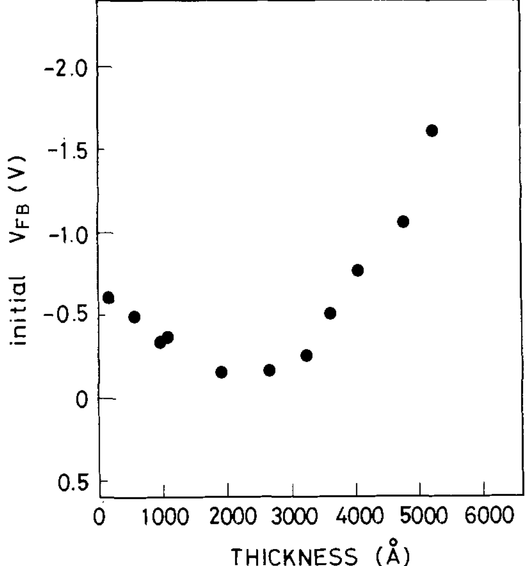

Fig. 8. Flatband voltage of Al-LPCVD SiO_2-Si structures obtained from step-etching of thick film about 6000Å thick.

from the step etching film about 6000Å thick. These data show that negative charges accumulate near the interface. To estimate the magnitude of these charges, we assumed that the charges were distributed as in Fig. 9. The negative charge density ρ is defined as

$$\rho = -b\rho_0 \quad (b > 0) \qquad [1]$$

where ρ_0 is the density of uniformly distributed positive charge and b is a constant. The flatband voltage shift, ΔV_{FB}, caused by fixed charges in SiO_2 is given

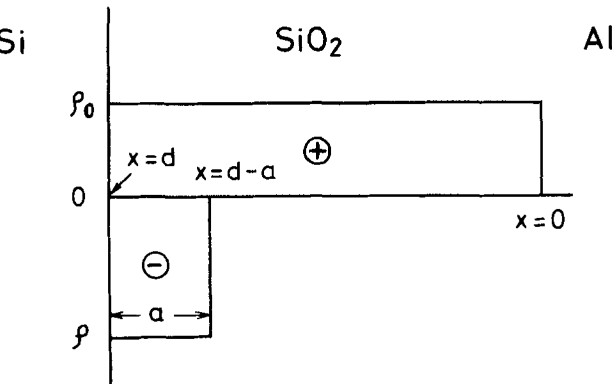

Fig. 9. Assumed charge distribution in LPCVD SiO_2 film

$$\Delta V_{FB} = -\frac{1}{C_0}\int_0^d \frac{x\rho(x)}{d}\,dx \qquad [2]$$

where C_0 is the oxide capacitance and d is the oxide thickness. ΔV_{FB} has a minimum value at $d = ab$. The difference of ΔV_{FB} between $d = 0$ and $d = ab$ is

$$\delta V_{FB} = \frac{\rho_0}{2\epsilon_0} b\,(1 - b)\,a^2 \qquad [3]$$

The results show that $\delta V_{FB} = -0.5V$ and $ab = 2500Å$. If $a = 1000Å$, then $b = 2.5$, $\rho = 1.4 \times 10^{16}$ qcm^{-3} and $\rho_0 = 0.56 \times 10^{16}$ qcm^{-3}. Since the order of magnitude of Cl concentration is 10^{19} cm^{-3}, the small portion of Cl has a negative charge.

Both the etching result and V_{FB} result do not bear directly on the profile of Cl distribution but do indicate that the film is not uniform.

Discussion

Cl ions are distributed broadly near the SiO_2-Si interface as the LPCVD SiO_2 film is deposited. It is well known that Cl ions distribute at the interface in HCl/O_2 oxidation. In thermal oxidation, SiO_2 films grow by the reaction of Si and O_2 and the growth rates depend on the film thickness. However, since the growth of SiO_2 at the interface by HCl/O_2 oxidation is simultaneous with the piling up of Cl, it is not clear in the case of thermally grown film whether the cause of the Cl pile-up is oxidation or the existence of the interface. On the contrary, CVD films grown by the chemical reaction of gases without consuming Si substrate and the growth rates are constant. The difference between the growth mechanism of thermally grown film and CVD film leads us to conclude that, in the case of CVD film, Cl distribution is determined not by the mechanism of Si oxidation but by the existence of the SiO_2-Si interface. If the cause of the Cl pile-up is existence of the interface, then it is clear that the profile of Cl concentration is independent of the thickness of unannealed LPCVD film. If the cause of Cl pile-up were the oxidation, Cl in LPCVD film would pile up at the SiO_2 surface or distribute uniformly because the oxidation of SiH_2Cl_2 in gas phase occurs at the surface.

The effect of the interface on Cl distribution can also be seen in the redistribution of Cl after the N_2 annealing of Cl-implanted SiO_2 film as is shown in Fig. 10. The distribution of Cl in conventional CVD films before annealing is shown in Fig. 2. Cl redistributes

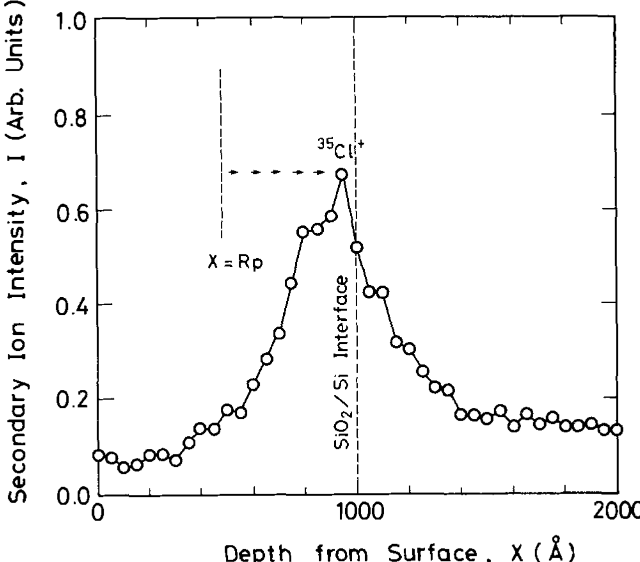

Fig. 10. Cl ion intensity of Cl ion implanted CVD SiO_2 after oxidation at 1000°C N_2 for 1 hr.

at the interface after N_2 annealing, although the extra implanted Cl ions are diffused out. The peak concentration of Cl after N_2 annealing of the Cl-implanted SiO_2 film is 10^{19} ions cm^{-3}. This value is equal to that of Cl in unannealed LPCVD SiO_2 film. Although we cannot explain the mechanism for Cl peak formation near the SiO_2-Si interface, we believe that Cl ions in SiO_2 are attracted to the interface by the existence of the interface.

Cl profile after heat-treatment.—Because thermal oxidation in some way causes the movement of the SiO_2-Si interface, Cl ions move toward the interface as the thermally oxidized layer grows. The velocity of Cl ions moving toward the interface is higher than the velocity of the interface movement caused by oxidation, as shown in Fig. 4. In this sense Cl ions are mobile in SiO_2 film.

Because the Cl profile is unchanged in thin films and the total number of Cl ions is preserved after oxidation and N_2 annealing, Cl ions do not diffuse out by thermal treatment. Cl ions are stably incorporated in SiO_2 film.

Cause of surface roughness.—After the oxidation of thick LPCVD SiO_2 film, the Cl profile near the interface changes remarkably. This behavior is explained as follows: In thermal oxidation oxygen diffuses through oxide and reacts on silicon. The concentration of diffused oxygen ions at the interface depends on the thickness of the film, but the concentration of Cl ions near the interface is independent of the thickness of unannealed film. Oxygen competes with Cl in reaction on Si. Since the oxygen concentration at the interface is sufficiently large in thin films, the reaction of Si-O is dominant and SiO_2 is formed even though Cl reacts on Si. In a thick film, because of the insufficient supply of oxygen to the interface, the Si-Cl formed by the reaction of Si and Cl cannot be completely transformed into SiO_2 and remains as a gas phase of Si-O-Cl. Pancake shapes are then formed. The gas of Si-O-Cl lifts the SiO_2 layer. Cl induces etch pits on the Si wafer. It is for this reason that surface roughness is observed only in thick films.

The following experiment shows clearly the thickness dependence of surface roughness. After the deposition of LPCVD SiO_2 film 2600Å thick, conventional CVD SiO_2 8000Å thick is deposited by the reaction of SiH_4 and O_2 at 420°C. The Cl distribution of LPCVD SiO_2 is unaffected by the low temperature deposition of CVD SiO_2. Wafers without the CVD SiO_2 deposition and wafers with the deposition were oxidized in dry O_2 for 1 hr at 1000°C. Though the integrated Cl concentrations are the same in both samples, the surface roughness is observed only in the film with addition of CVD SiO_2. Thus we can conclude that the surface roughness does not depend on the total amount of Cl, but does depend on the oxygen concentration at the interface.

Though we do not identify the gas at the SiO_2-Si interface, it seems to be the same as that produced by HCl/O_2 oxidation. Monkowski *et al.* (2) have suggested that the gas formed by HCl/O_2 oxidation is oxygen-rich chlorosiloxane. Lin (5) has discussed this oxygen-rich chlorosiloxane, $Si_nO_{2n-3}Cl_6$ (n = 2-11), which is formed in reduced oxygen pressure and appropriate chlorine atmosphere.

Surface roughness is not observed after N_2 annealing in spite of there being no O_2 concentration at the interface. This can be explained in the following manner: Silicon is etched by HCl

$$\text{Si (solid)} + \text{HCl (gas)} \leftrightarrows \text{SiCl}_4\text{ (gas), SiHCl}_3\text{ (gas)}$$

This reaction is reversible. Etching by Cl will not cause surface roughness. When oxygen is present, however, the formation of Si-O-Cl continues irreversibly.

Comparison between oxidation rate and etching rate.—Let us now consider the oxidation rate of Si under LPCVD SiO_2 film xÅ thick. Oxygen flow F_1 in SiO_2 can be expressed as

$$F_1 = D\frac{C_o - C_i}{x} \quad [4]$$

where D is the diffusion constant of oxygen, C_o and C_i are the oxygen concentrations at the oxide surface and at the SiO_2-Si interface, respectively. Oxygen flow at interface F_2 is

$$F_2 = K_sC_i \quad [5]$$

where K_s is the chemical surface-reaction rate constant for oxidation. In a steady state, that is where $F_1 = F_2$

$$C_i = \frac{DC_o}{K_sx + D} \quad [6]$$

The growth rate of SiO_2 is given by

$$\frac{dx}{dt} = \frac{B}{A + 2x} \quad [7]$$

where $A \equiv 2D/K_s$, $B \equiv 2DC_o/N_1$, and N_1 is the O_2 concentration in SiO_2. We can determine the values of A and B from oxidation. After dry O_2 oxidation for 1 hr at 1000°C of 2630Å thick LPCVD film, oxide thickness increased to 3370Å. Average oxidation rate and average thickness are 12.3 Å/min and 3000Å, respectively. The oxidation rates of films with three different initial thickness are plotted in Fig. 11. We can obtain A = 3000Å and B = 11.3 × 10^4 Å^2/min. In HCl/O_2 oxidation of (100) Si, using the data of Deal *et al.* (6, 7) A and B are given as follows: A = 2530Å, B = 2.6 × 10^4 Å^2/min at 1% HCl and A = 4300Å, B = 4.4 × 10^4 Å^2/min at 4.5% HCl. Linear rate of oxidation B/A = $(C_0/N_1)k_s$ is 10 Å/min in HCl oxidation both at 1% and 4.5%, whereas it is 37 Å/min in LPCVD SiO_2. If C_0 is the same in both these films, the values of k_s and D of LPCVD SiO_2 are large compared with those of HCl/O_2 oxidized SiO_2.

The rate of Si consumption, R_o, is derived from the oxidation rate

$$R_o = \frac{N_1B}{N(A + 2x)} = \frac{B}{2(A + 2x)} \quad [8]$$

where N is the density of Si, 5 × 10^{22} cm^{-3}.

We concluded that the Cl etching rate, R_e, was

$$R_e = 5 \text{ Å/min}$$

because Si was etched to a 300Å depth by Cl at 1000°C for 1 hr. From the above estimation, we can approxi-

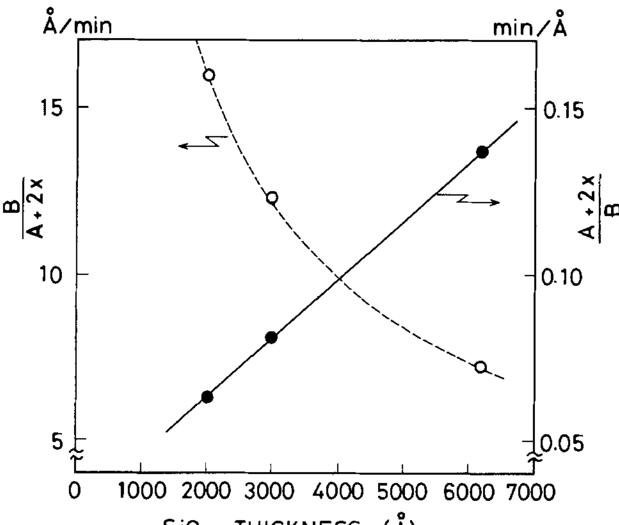

Fig. 11. Oxidation rate $B/A + 2x$ and its reciprocal rate of three different LPCVD SiO_2 thicknesses.

mate the point at which the film becomes too thick to be without surface roughness. The Cl etching rate is smaller than the oxidation rate

$$R_e < \frac{B}{2(A + 2x)} \quad [9]$$

By substituting the experimental values for A, B, and R_e

$$x < 4100\text{Å} \quad [10]$$

This value agrees with the experimental results. It is reasonable to assume that the existence of surface roughness depends on whether the Cl etching rate or the oxidation rate is higher.

By measuring surface state density, we confirmed that the microstructure of surface roughness does not appear after oxidation in thin LPCVD SiO_2 film on Si. Surface state density of the film as deposited and after N_2 annealing at 1100°C for 1 hr is comparable to that of thermally grown SiO_2.

Comparison of Cl profiles.—The Cl distribution in LPCVD SiO_2 film is broader than that in HCl/O_2 oxidized film. In HCl/O_2 oxidized film, Cl piles up within 200Å from the SiO_2-Si interface (6). In Cl_2/O_2 oxidized film, however, Cl ions distribute broadly within 1000Å (7). The difference between the Cl distribution in HCl/O_2 and Cl_2/O_2 oxidized films may be caused by H_2O produced by HCl/O_2 oxidation (8). In LPCVD SiO_2 films, judging from the reaction of SiH_2Cl_2 and N_2O and from the deposition pressure, H_2O is not produced. The Cl distribution in LPCVD SiO_2 is almost the same as that in Cl_2/O_2 oxidized film.

Summary

Cl distribution in LPCVD SiO_2 film deposited by SiH_2C_2 and N_2O was measured by IMMA. We found that Cl ions are distributed approximately 1000Å from the SiO_2-Si interface. The rate of etching to SiO_2 and the flatband voltage are affected by Cl distribution. The Cl distribution is independent of the thickness of unannealed film. After the oxidation Cl ions move toward the newly formed interface. In films thinner than 4000Å, the Cl profile remains unchanged after the oxidation, but in thick films Cl concentration near the interface is increased and surface roughness is observed. Cl distribution remains unchanged after N_2 annealing at 1100°C. From these results, it is apparent that the phenomenon of Cl pile-up is not caused by the mechanism of oxidation but by the existence of the interface itself. Surface roughness after oxidation depends on whether the Cl etching rate of the oxidation rate is higher. In a high oxygen concentration at the interface, the oxidation rate is larger than the Cl etching rate and surface roughness is not observed. In a low oxygen concentration, Si is etched by Cl and Si-O-Cl is formed. The surface of SiO_2 films is lifted by the gases and etching pits are observed. In this case Cl ions markedly pile up at the interface. When there is no O_2 (such as in N_2 annealing), even if Si is etched by Cl, Si-O-Cl is not formed and surface roughness is not observed.

Taking into account our estimation of the Cl etching rate and the oxidation rate, we can conclude that oxidation at 1000°C for 1 hr does not induce surface roughness when LPCVD film is less than 4000Å thick. We believe that LPCVD SiO_2 will be useful as the gate oxide of Si devices.

Au/Ni/SnNi/n-GaAs Interface: Ohmic Contact Formation

Atilla Aydinli[1]

Engineering Physics Department, University of Virginia, Charlottesville, Virginia 22901

and Robert J. Mattauch

Electrical Engineering Department University of Virginia, Charlottesville, Virginia 22901

ABSTRACT

The Au/Ni/SnNi/GaAs interface has been studied in order to understand ohmic contact formation. Depth profiling in conjunction with Auger electron spectroscopy has been used to determine impurity distribution in as-deposited and alloyed films and were correlated to electrical parameters. We find that ohmicity can be achieved without Sn due to Au-induced Ga vacancies and Ni-induced breakup of background Si covalent bonds. However, addition of Sn to the system lowers the specific contact resistances greatly.

Various studies have been conducted on metal-GaAs ohmic contact systems. Most of these are concerned with electrical and metallurgical properties of the contacts as well as their long-term reliability. The majority of the systems studied include Au-based metal contacts. Among them Ni/Au-Ge/GaAs is favored in many applications and have been exten-

[1] Present address: Department of Physics, Kansas State University, Manhattan, Kansas 66506.
Key words: interfaces, bonding, ohmicity.

sively studied (1-3). A similar system is Au/Ni/SnNi/n-GaAs, which is used quite successively in mm-wave Schottky barrier devices. We report here the results of a study on this system. Auger electron spectroscopy (AES) combined with *in situ* sputter etching was used to obtain chemical profiles which were correlated with electrical measurements. Attention was paid to the role played by each element of the system in the formation of the ohmic contact. This is particularly important since new information is becoming available on the interaction of different impurities with each other in GaAs (4).

Experimental Procedure

In order to identify the role of each element in Au/Ni/SnNi/n-GaAs ohmic contact, we studied SnNi/GaAs, Ni/SnNi/GaAs, and Au/Ni/SnNi/GaAs systems. In each case the GaAs used consisted of a 3.3 μm thick epitaxial layer doped to 2.3×10^{17} cm^{-3} on a substrate doped with Si to 2.8×10^{18} cm^{-3}. All the metal layers were electroplated through conventionally defined 175 μm diam windows opened in the SiO_2 layer covering the GaAs epitaxial layers. Both SnNi and Ni were pulse plated from stannous-nickelous and nickelous chloride solutions, respectively, while Au was d-c plated from Autronex solution. The unmasked backsides of the wafers were ohmically contacted with the Au/Ni/SnNi process prior to anode metallization. After sample preparation, individual chips each bearing one anode, were cut with a high speed diamond wheel dicing saw in preparation for heat-treatments. Each chip was soldered at 130°C to a 0.79 mm diam Ni post and the anode was contacted with 50 μm diam Au wire for electrical measurements, which were carried out both before and after heat-treatment. Such treatment was carried out on a Ta strip in a chamber containing constantly replenished forming gas (95% N_2-5% H_2). For prolonged heat-treatments, a bore furnace was used.

Auger electron spectroscopy (AES) and argon ion sputtering were used for chemical analysis. The AES data were taken in derivative form and peak-to-peak amplitudes of Auger transitions were used to calculate the surface coverages in atomic percentages (5). Optical microscopy was used to determine surface uniformity before and after sputter etching. AES analysis was carried out on each chip with a 5 keV 25 μm diam electron beam having a current of approximately 1 μA. Depth profiling was done with a 1 keV Ar-ion beam at a pressure of 5.0×10^{-5} Torr. The depth profiles are presented in atomic percentages *vs.* sputter time. Relevant sputter etch rates are given in the text.

Device electrical measurements were taken with a Tektronix 576 curve tracer and a Boonton 75B-S8 capacitance bridge. Structure series resistance, R_s and ideality factor, η were calculated from *I-V* characteristics of the diodes in accordance with the method of Polhamus (6). Built-in voltage values were calculated from $(1/C^2)$ *vs.* *V* plots.

Results

SnNi/GaAs interface.—Samples analyzed after SnNi electroplating showed the metal film to be composed of 10% Sn and 90% Ni. Depth profiles indicated that these percentages were maintained throughout the 2800Å film thickness, as shown in Fig. 1. The metal/GaAs interface was found to be sharp. Although Ni is seen to extend further into GaAs than Sn, this effect is thought to be due to differential sputtering during the Auger profile analysis. The depth profile of an SnNi/n-GaAs interface after heat-treatment at 400°C for 20 min is shown in Fig. 2. The surface spectrum showed carbon and oxygen as well as Sn and Ni. Neither Ga nor As was observed on the surface. Figure 2 shows evidence of fast diffusion of Ni into GaAs. The relative stoichiometry of Ga and As in Ni rich region indicates a diffusion process rather than eutectic alloying. Unlike Au/GaAs, SnNi/GaAs junctions do not dissociate the semiconductor. The stationary behavior of Sn is due to an apparently larger diffusion coefficient of Ni

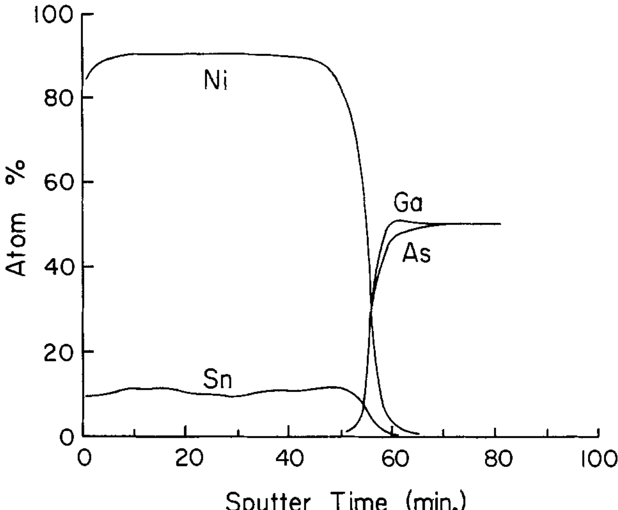

Fig. 1. Depth profile of as-plated SnNi/GaAs junction

than Sn in GaAs and the fact that Sn-Ni binary system has very few compounds (7, 8). *I-V* measurements of nonheat-treated structures exhibited diode behavior with ideality factors, η, ranging from 1.07 to 1.2. Plots of $(1/C^2)$ *vs.* *V* gave built-in potentials of 0.750-0.775V. Heat-treatment at 300° and 400°C did not change built-in potential values appreciably. The value of the ideality factors deteriorated slightly due to heat-treatment of 400°C for 20 min. More important, however, the series resistance of diodes increased threefold.

The behavior of SnNi/n-GaAs at high temperatures can be explained as follows: Ni is an acceptor in GaAs while Sn is a donor. At high temperature Ni diffuses farther into GaAs due to its higher diffusion coefficient, compensating the donor concentration and thereby raising the series resistance of the diode. It should be kept in mind that this process may lead to a p-n junction (9) and electrical data then would have to be viewed accordingly.

Ni/SnNi/GaAs interface.—Results similar to those for the SnNi/GaAs interface were obtained when a 3000Å thick layer of Ni was electroplated onto plated SnNi on GaAs. Results of the electrical measurements were the same as SnNi/GaAs. The chemical depth profile of these junctions after heat-treatment at 400°C for 10 min is shown in Fig. 3. Diode behavior with an increase in series resistance R_s as mentioned for the SnNi/GaAs system was observed. We also observe that Sn has remained stationary at the Ni/SnNi interface while Ni diffused into GaAs as in the case of

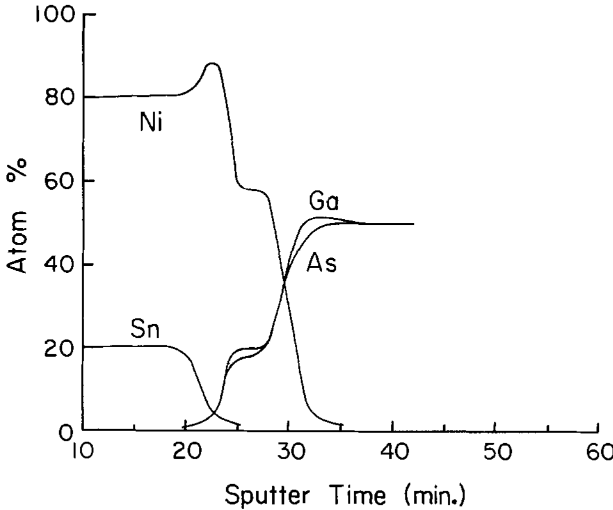

Fig. 2. Depth profile of SnNi/GaAs junction annealed at 400°C/20 min.

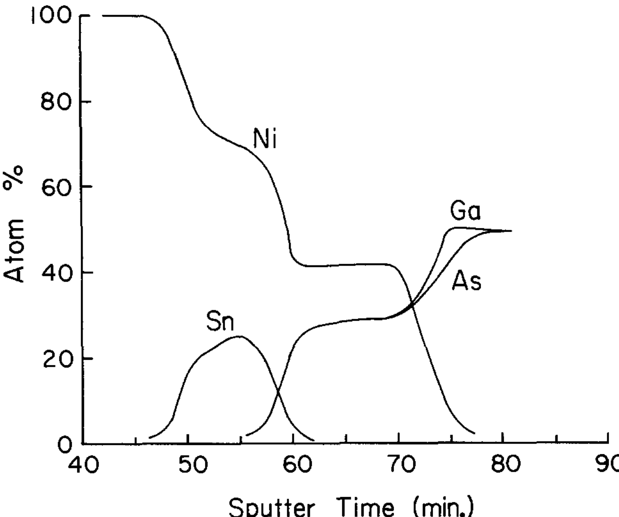

Fig. 3. Depth profile of Ni/SnNi/GaAs junction annealed at 400°C/10 min.

SnNi/GaAs. The difficulty of introducing Sn into GaAs in these systems is in contrast with Au/Ni/SnNi/GaAs system discussed next where a uniform distribution of Sn throughout the alloyed junction is observed.

Au/Ni/SnNi/GaAs interface.—The formation of an ohmic contact to n-type GaAs depends on greatly increasing the majority carrier concentration at the metal-semiconductor interface in order to cause increased tunneling current. In the case of Au/Ni/SnNi/n-GaAs samples both Au and Ni are acceptors in GaAs whereas Sn is a donor. As pointed out above in the cases of SnNi/GaAs and Ni/SnNi/GaAs, neither the concentration nor diffusion kinetics of Sn is suitable to achieve the needed excess carrier concentration to produce an ohmic contact. However, in Au/GaAs junctions both Ga and As are known to diffuse through Au metallizations even at room temperatures. At higher temperatures, Au tends to gather Ga, creating Ga vacancies in GaAs.

In Au/Ni/SnNi/GaAs junctions, Sn is expected to diffuse into Au-induced Ga vacancies thereby producing an excess electron concentration. Ni is expected to provide good wetting so that Sn does not "ball up" during the alloying process. The process is similar to that occurring for Au/Ni-Ge/GaAs contacts with Sn taking the place of Ge. A depth profile for a nonalloyed structure is shown in Fig. 4. As expected, such structures exhibited diode behavior of the nature mentioned above for the SnNi/GaAs samples. Heat-treatment of Au/Ni/SnNi/GaAs samples was carried out at 232°, 328°, and 420°C. Samples were held at their respective temperatures for 10 sec and the strip heater power supply was turned off to allow cooling. Heating rates were 700°, 560°, and 500°C/min, respectively. The samples alloyed at 232°C were uniform under microscopic observation. Surface analysis showed 18% Sn on Au, suggesting grain boundary diffusion of Sn through the Ni layer. Depth profiling of the samples did not indicate any diffusion of Au into Ni or of Ni or Sn into GaAs. However, samples alloyed at 328° and 420°C were ohmic but had visibly grainy surfaces. Surface analysis of these samples revealed measurable amounts of Au, Sn, Ni, and Ga but not As. Depth profiles of these samples however were not consistent due to lateral inhomogenity. Samples prepared in the same manner on large area wafers without any SiO_2 mask were homogenous upon alloying when observed by optical microscopy.

A depth profile of a fully alloyed (420°C for 10 sec) Au/Ni/SnNi/n-GaAs contact with Au overlayer plated after alloying is shown in Fig. 5. Region I consists of Au electroplated after the alloying process to ensure good solderability. Region II is Ga rich starting at the Au-alloyed junction interface. Arsenic is observed after sputter etching 5 more minutes. This is consistent with our previous observation of Ga but not of As on the surface of heat-treated Au/Ni/SnNi/GaAs junctions. A slight As richness is apparent in region III but not enough to account for the excess Ga in region II. We suspect that some As may have evaporated from region II during heat-treatment prior to region I Au deposition. Ni reaches its peak at the region II/III interface. It is obvious from region IV that Ni diffuses the furthest into GaAs. It is crucial to note that the Sn concentration throughout the alloyed junction is very low, although it may be high from an electrical doping standpoint. The average depth of the (163 min) ion sputtered region was 3 μm. We refrain from assigning specific thickness intervals due to the existence of a five element alloy. The changing composition of the alloy undoubtedly results in a varying etch rate.

Discussion and Conclusions

The specific contact resistances of various contacts were also measured. After establishing an ohmic contact on both sides of a wafer it was cut into 0.01 $\times$ 0.01 in. size chips with a dicing saw. The I-V measurement was taken by soldering the chip on two 0.015 in. diam nickel posts on each end and connecting a high input impedance voltmeter (Keithley 610) across the sample next to the chip ohmic contacts. The current was supplied with a precision current source (Keithley 227) to the ends of the nickel posts. The resulting I-V curve was linear. Contact resistance was obtained by sub-

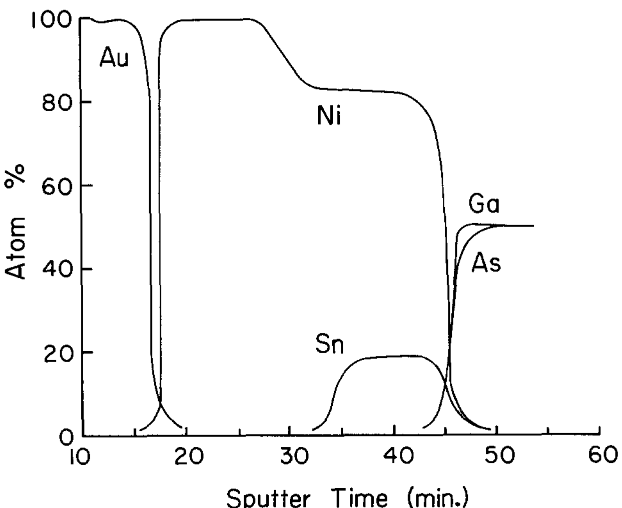

Fig. 4. Depth profie of as-plated Au/Ni/SnNi/GaAs junction

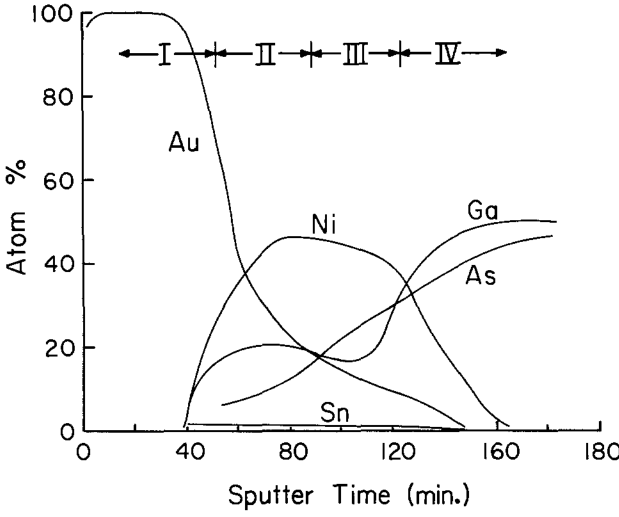

Fig. 5. Depth profile of fully alloyed Au/Ni/SnNi/GaAs ohmic contact (420°C/10 sec) with Au overlayer electroplated.

tracting material bulk resistance from measured resistance and dividing it by two. With this technique contact resistances of 5×10^{-5} Ω cm^2 or lower was routinely obtained, although low 10^{-4} Ω cm^2 was also measured. This data is consistent with published contact resistance of 3-7 $\times 10^{-5}$ Ω cm^{-2} of a similar alloy system (10). Thus the Au/Ni/Sn-Ni/GaAs contacting process has been found to give rise to specific contact resistances lower than achieved by the Au/Ni-Ge/GaAs process (1, 2). An investigation of the former contact indicates that while the consideration that the diffusion of Sn into Ga vacancies created by an Au/GaAs reaction as the sole mechanism of ohmic contact formation is interesting, it seems simplified at best. This is felt to be the case not only due to the very low concentration of Sn in alloyed junctions and the diffusion kinetics of Sn in GaAs being not favorable, but also due to the existence of large concentrations in Ni well into the GaAs. One may expect that such high concentrations of electrically active Ni would compensate Sn resulting in the formation of a p-n junction. Experiments prompted by this concern on Au/Ni/n-GaAs showed that contact ohmicity can be obtained without Sn. However in a comparative study, the specific contact resistance of the Au/Ni/SnNi/n-GaAs ohmic contact ($\sim$3.5 $\times 10^{-4}$ Ω cm^{-2}) was two orders of magnitude lower than that of the Au/Ni/n-GaAs ohmic contact ($\sim$4.4 10^{-2} Ω cm^{-2}). Since the existence of electrically inactive Si in boat-grown GaAs is known, the formation of an ohmic contact in the Au/Ni/n-GaAs system is attributed to either of two possible processes: (*i*) Ni diffusion into GaAs and subsequent breaking of inactive Si-Si bonds of background Si in GaAs thereby producing active Si impurities (4); or (*ii*) Au giving rise to the formation of Ga vacancies into which active Si diffuses. In either case the background concentration of Si in the epitaxial GaAs is relatively low, possibly resulting in high specific contact resistance ($\sim$4.4 $\times 10^{-2}$ Ω cm^2) of the tested Au/Ni/GaAs contacts. The addition of even low concentrations of electrically active Sn is sufficient to provide a greater concentration of donor impurities thus lowering the contact resistance.

We have refrained from detailed interpretation of the depth profiles since we do not have detailed understanding of ion-induced effects on alloyed junctions during sputter etching. The effects of differential sputtering and ion knock-in should be identified and taken into account before further analysis can be carried out.

We have investigated the Au/Ni/Sn-Ni/GaAs ohmic contact systems at various stages of contact formation by means of Auger analysis coupled with *in situ* sputter etching. As indicated above, our data indicate that despite introduction of high concentrations of p-type impurities it is possible to obtain an ohmic contact in Au/Ni/n-GaAs systems. The formation of an ohmic contact is attributed to activation of background n-type impurities by Ni and occupation by these impurities of Au-induced Ga vacancies. Addition of Sn to Au/Ni/n-GaAs system lowers the specific contact resistance by at least two orders of magnitude.

Packaging Improvement of a Liquid Cooled Silicon Chip

M. D. Reeber and R. G. Frieser*

IBM General Technology Division, East Fishkill, Hopewell Junction, New York 12533

ABSTRACT

Because of the increasing density of devices on a chip (to increase the effectiveness of computers) the amount of heat generated per unit area of chip increases as well. This must be removed efficiently to prevent failure of the device. In order to provide reliable nucleation sites for boiling on silicon surfaces, a number of techniques may be used, one of which is the combination of mechanical abrasion coupled with the removal of induced defects by liquid etchants. Consistent nucleation, which does not occur on polished silicon surfaces, is required to assure proper heat transfer of silicon circuit chips. Heat transfer data for treated and untreated surfaces are presented.

Heat generated in operating silicon semiconductor devices must be removed in order to prevent burnout or fatigue failure of the device. To increase the usefulness of computers using these devices, it is necessary to package the devices more densely and to increase their operating speed. Both of these considerations combine to increase the quantity of heat generated per unit volume of computer, and improving packaging efficiency requires the removal of this large heat load. One useful technique for removing this heat is to submerge the device in a bath of perfluorohexane which will be operated at its boiling point of 56°C. Perfluorohexane is an inert dielectric fluid that does not interact with any of the materials used in semiconductor packaging. Boiling is an efficient technique for transferring heat from a solid to a fluid.

Theory

When a heat generating solid is placed in a fluid, the fluid in the vicinity of the solid warms up as heat is transferred by conduction. Most fluids (including perfluorohexane) are poor conductors and the fluid heats up near the solid. Because of the thermal expansion of the fluid, the hot fluid has a lower density than the remaining cooler fluid, and consequently moves away from the heat generating surface. This gives rise to convection currents in the fluid and brings additional cool fluid into contact with the solid. As we increase the quantity of heat generated in the solid, both the convection rate and the fluid temperature increase.

The major impediment to heat flow at this point is the velocity profile of the fluid at the surface of the hot body. The fluid in actual contact with the solid is moving at zero velocity, and some short distance away it increases to its maximum velocity. The nonmoving layer at the surface of the solid is called the stagnant layer and heat must cross it by conduction. Since the fluid is a poor conductor, a large temperature gradient is developed across this layer even though it is quite thin. The solid becomes considerably hotter than the bulk of the fluid, eventually reaching or passing the boiling point of the fluid as we increase the heat flow.

Boiling will improve the efficiency of the heat transfer process by: (*i*) breaking up the stagnant layer and eliminating the temperature gradient between the bulk of the fluid and the solid and, (*ii*) contributing the latent heat of boiling to the heat transfer process. However, boiling cannot proceed until a bubble is established. This requires either sufficient excess energy to form the vapor-liquid interface, or a geometry that is particularly favorable for this purpose. Without this geometry, the excess energy is supplied by raising the temperature of the solid far above the boiling point of the fluid.

To assure proper heat transfer to the fluid, the surface of the semiconductor must contain a large number of sites at which bubbles of vapor can be consistently and easily nucleated. These sites are essentially nonexistent in a polished silicon surface and must be built into any surface that we wish to use for this purpose. Among the techniques that may be used to provide nucleation sites for boiling, we have found that a combination of sandblasting followed by a preferential etch provides a consistently high density of active sites. The study of heat transfer on a variety of surfaces, specially prepared, was performed on silicon wafers. Once a satisfactory technique had been obtained, this process was applied to a product chip. A more extensive discussion of techniques to provide nucleation sites is published elsewhere (1).

Experiment

Such a useful active surface is produced by first sandblasting with a water slurry of alumina at about 60 psi. This results in a highly stressed surface, roughened by the action of the oxide. The surface is then etched with a 5*N* aqueous solution of KOH mixed at 1:1 ratio with methyl alcohol (2). The etching takes place at 80°C for about 1-2 min in a typical example. The heat transfer efficiency of the surface is not particularly sensitive to the etch time. The surface is thoroughly rinsed with distilled water and air dried. The action of the etchant on silicon is anisotropic, accentuated by the presence of locally stressed regions. Thus, the etching further increases the irregularities beyond those generated in the surface by the original sandblasting.

This treatment results in a surface that is largely pitted, as can be seen in Fig. 1. These pits usually have irregular outlines, most edges are sharp, and undercutting is prevalent. Occasionally, long, narrow, very deep pitting can be seen. In Fig. 1, the cross is about 10 μm long, 1 μm wide, and 5 μm deep.

The thermal behavior of treated wafers was established and shown in Fig. 2, in the apparatus (3) designed specifically for this purpose. The silicon wafer, with the treated side in contact with the fluid is cemented to a phenolic mount (D). Heat is supplied by the heater disk (A) which is in thermal contact with the wafer. The heater disk contains a winding (C), and thermocouple (B).

Other thermocouples measure the temperature of the block and the fluid. The construction of the apparatus is such that over 95% of the heat generated in the sample holder by the heater block is transferred to the fluid through the silicon wafer with the treated surface

* Electrochemical Society Active Member.

Key words: nucleation sites, silicon surfaces, heat transfer.

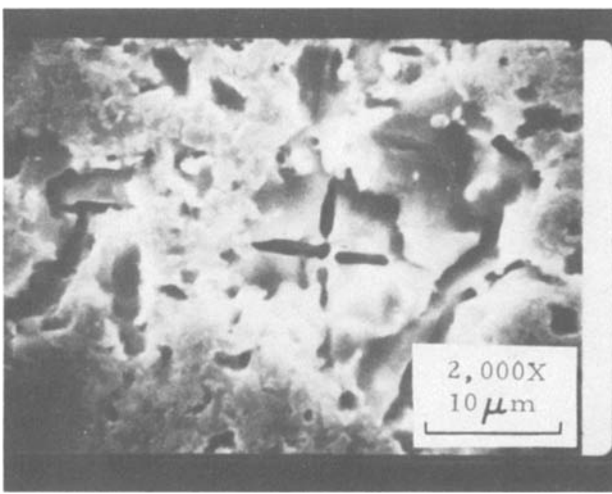

Fig. 1. Treated surface—SEM photograph, normal incidence

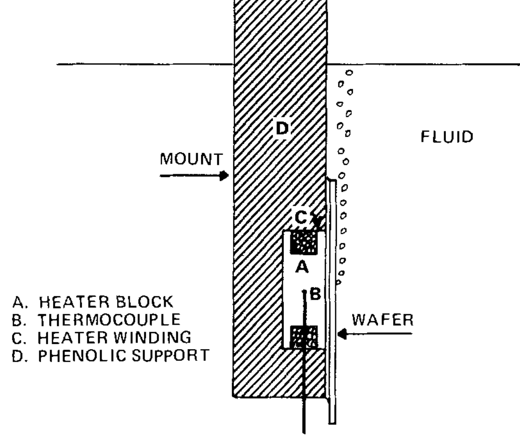

Fig. 2. Heat transfer apparatus

in contact with the fluid. The wafer is considerably larger than the heat source, so that edge effects, which would be disastrous in this investigation, are eliminated.

Results

The curves shown in Fig. 3 summarize the results of our investigation. Heat transfer is shown for three types of surfaces: (*i*) polished, (*ii*) sandblasted only, and (*iii*) sandblasted followed by chemical etching.

The polished silicon surface, a standard production wafer, shows no tendency to nucleate. Within the power limitations of the apparatus, approximately 2 W/cm², heat transfer from the untreated silicon surface remained in the convective region of the heat transfer curve. This is shown by the linear relation between power and temperature. When this material is used in a semiconductor device that is submerged in the dielectric fluid, boiling only occurs at the cut edges of the chip and is delayed until the chip temperature rises well above the boiling temperature of the fluid. In some cases, boiling does not occur at all and overheating of the chip results.

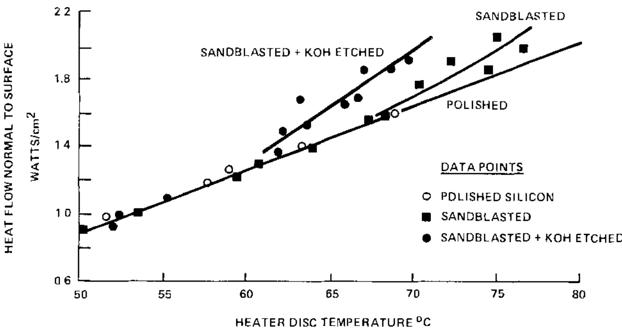

Fig. 3. Heat transfer to C_6F_{14} for base, sandblasted, and etched surfaces.

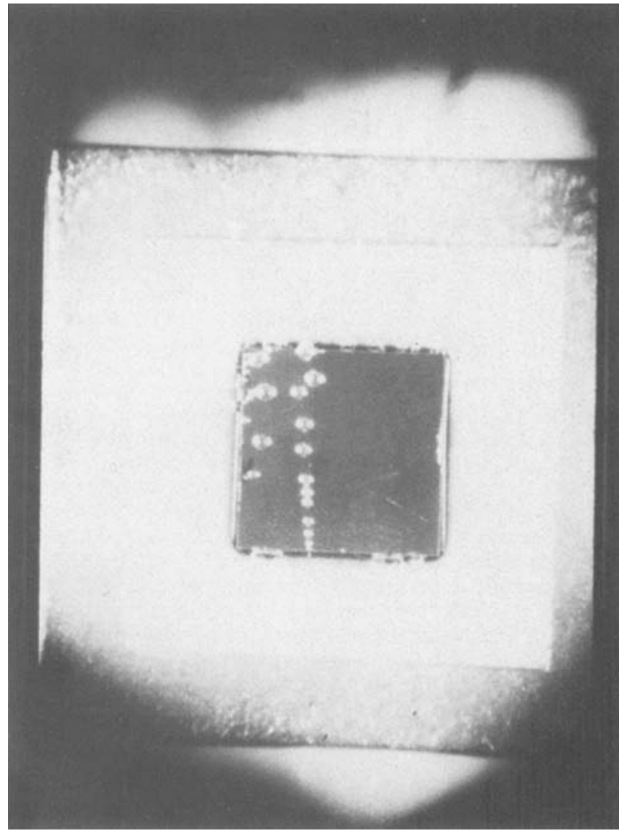

Fig. 4. Boiling from an untreated chip at 4.2W

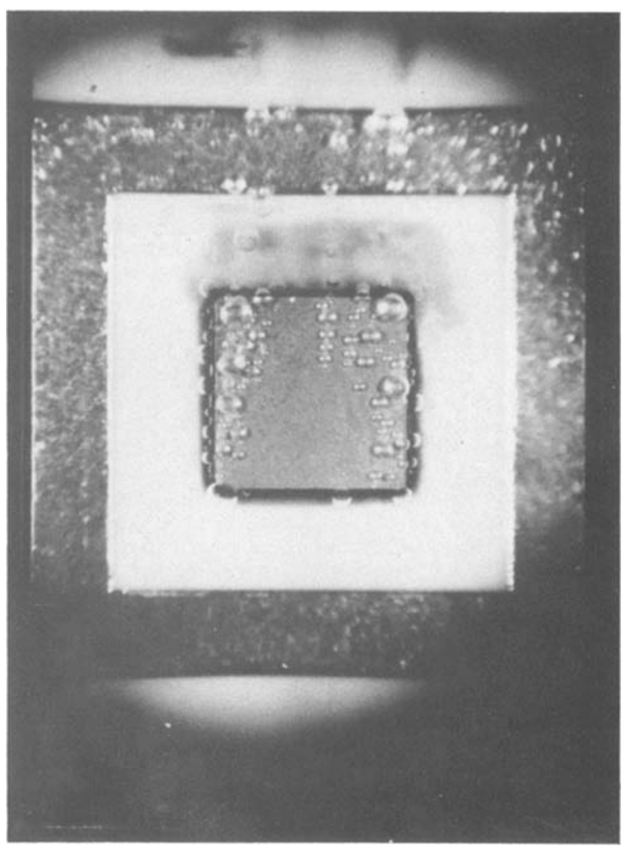

Fig. 5. Boiling from a treated chip at 4.2W

Sandblasting improves the situation somewhat, with boiling starting at about 1.6 W/cm^2, because only a limited number of nucleation sites have been provided. The sandblasted surface curve separates from the polished surface curve at 12°C above the boiling temperature. In other words, the surface is 12°C above the boiling temperature of the liquid before boiling will start on the sandblasted surface.

The best performing surface, sandblasted plus etched, initiated boiling at only 1.3 W/cm^2. The separation of the curve from the convection line occurs at only 4°C above the boiling temperature of the fluid.

The important question is: How does the real chip perform in the fluid environment? Figure 4 shows a typical silicon chip mounted on its substrate by means of an array of solder balls. The space between the chip and the substrate is sealed to prevent effects in that narrow space from interfering with our perception of back-side effects. A close look reveals that nucleation occurs at a few isolated locations at the edge of the chip. Nucleation sites can be identified by following the bubble trails back to their origin.

Figure 5 shows a treated chip in the same condition as before, the same power level, fluid temperature, chip size, and mounting. Here multiplicity of nucleation sites extends over the entire back surface of the chip.

Summary

We have demonstrated that untreated silicon is not suitable for heat transfer systems whose efficiency depends on boiling at the back of the chip. We have shown that proper treatment will reduce chip temperature and insure controlled chip temperatures in this kind of environment.

TEM Observations of Defects in Ge-Doped LPE GaAs and $Al_{0.4}Ga_{0.6}As$

Wilfried R. Wagner*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The formation of structural defects in degenerate Ge-doped LPE GaAs and $Al_{0.4}Ga_{0.6}As$ films was investigated. At growth initiation temperatures of 780°C, Ge doping does not result in structural defects even in films grown from solutions containing ~50 a/o Ge and even after heat-treatment at 720° and 820°C. On the other hand, films grown from heavily Ge-doped solutions below the decomposition temperature of GeAs (737°C) contained defects after a 15 hr heat-treatment at the growth temperature. These defects consisted of dislocation clusters and were only observed in films grown on substrates with elevated dislocation densities. It is concluded that the observed defects did not nucleate from the threading dislocations, but from GeAs or $GeAs_2$ particles decorating the dislocations.

In the past, the subject of structural defects in GaAs and $Al_xGa_{1-x}As$ has received considerable attention (1, 2), but now interest in this subject has shifted to other III-V compound semiconductor alloy systems such as In-Ga-As-P. Nevertheless, the significant quantities of AlGaAs-GaAs lasers and LED's being manufactured today still require that a major effort in this materials technology be directed toward improving device characteristics and yield. In this direction, attempts to improve device resistances by improving the conductivities of the heteroepitaxial layers comprising the device have been unsuccessful. The reason for this is indicated in the paper of Wolfe and Stillman (3). In GaAs it was found that for Si, Ge, Sn, Se, S, and Te donor doping, at $(N_a + N_d) = 10^{17}$ cm^3, N_d equals $3N_a$, while for $(N_a + N_d) = 10^{18}/\text{cm}^3$, N_a equals N_d. Essentially, self-compensation negates the conductivity benefits that should have been realized from the increased doping. The nature of the compensating centers is of considerable interest. In their paper (3) Wolfe and Stillman invoked impurity-vacancy complexes, but dopant-induced structural defects examined by transmission electron microscopy (TEM) have usually been found to be extrinsic, *i.e.*, interstitial in nature (4-7). There exists then a disagreement between the presumed nature of dopant-induced point defects in GaAs that could only be reconciled by complex point defect interactions (8). Further disagreement seems to be indicated by the effects of Sn and Ge in GaAs. Except for these two, the compensation effects described by Wolfe and Stillman (3) have been correlated with dopant-induced structural defects in GaAs (2, 4, 5, 7). Yet it is accepted that Sn and Ge doping of GaAs, however high, does not induce structural defects in epitaxial films, even subsequent to heat-treatment.

In our work on Te-induced defects in GaAs (4) and $Al_{0.4}Ga_{0.6}As$ (2), we proposed that the formation of the observed interstitial defects depends on the existence of nucleation sites consisting of second phase clusters whose principal constituent is the dopant species, *i.e.*, GaTe and Al_2Te_3. In this paper, we re-

examine this model for the case of Ge doping of GaAs and $Al_{0.4}Ga_{0.6}As$ films grown by LPE and subsequently heat-treated. Ge is the principal p-type dopant used in the LPE growth of GaAs and $Al_xGa_{1-x}As$ films in LED's and heterojunction lasers. Degenerate Ge-doped GaAs layers are frequently used as contact layers in such devices. Structural defects may not be generated in such layers or device reliability will be degraded.

Experimental

The epitaxial films for this study were grown by LPE on {100} GaAs substrates doped with Si or Te. The dislocation densities of one class of substrates used was $3000/cm^2$, another class contained $1\text{-}2 \times 10^4/cm^2$ dislocations as determined by the application of the A/B etch. All samples consisted of two-layer heterostructures, an $Al_{0.8}Ga_{0.2}As$ film was grown first as an etchant blocking layer, followed by the p^{++} GaAs or p^{++} $Al_{0.4}Ga_{0.6}As$ sample films, 2-4 μm thick. The growth solution of the sample film contained 20-55 atomic percent (a/o) Ge, but most samples were grown from solutions containing 40 a/o Ge. The growth initiation temperature of the sample films was 720° and 780°C with a temperautre gradient resulting in growth rates of 4 μm/hr. The Al composition of the $Al_{0.4}Ga_{0.6}As$ films was corrected for the decrease in the Al distribution coefficient arising from the high Ge doping (9) and was confirmed by measuring the lattice mismatch between the GaAs substrate and the sample film by x-ray diffractometry (10, 11).

The sample wafers were first polished to a 125 μm thickness, then diced into 3 mm disks. Samples were evacuated together with a large quantity of GaAs powder (1×10^{-6} Torr) in quartz ampuls then heat-treated at 720°C for 15 or 60 hr, and at 820°C for 15 hr. Self-supporting TEM samples were fabricated by etching a hole into the back-side of the disks using the PA etch. The high Al content of the buffer layer would stop the etching action, subsequently this layer was removed by warm conc. HCl. Final electron transparency was achieved using the 10:1:1, $H_2SO_4:H_2O:H_2O_2$ etchant. A JEOL-JEM 200 kV transmission electron microscope was used to evaluate the defect distribution occurring in the individual samples.

Results

Observations of As-grown samples.—In GaAs and $Al_{0.4}Ga_{0.6}As$ films grown from solutions containing 20-55 a/o Ge and at 720° or 780°C no contrast features were observed initially in the TEM that could be attributed to the high Ge doping. Neither dislocations nor precipitates were observed in films grown on low dislocation density substrates. Simple threading dislocations were observed in GaAs and $Al_{0.4}Ga_{0.6}As$ films grown on highly dislocated substrates (Fig. 1). Other diffraction contrast was not observed in such films (Table I). At a growth temperature of 780°C and a growth solution doping of 54.5 a/o Ge the GaAs-Ge phase boundary was crossed and Ge films resulted. The expected crossed grid of misfit dislocations was observed in such specimens at the substrate-epi interface.

Table I.

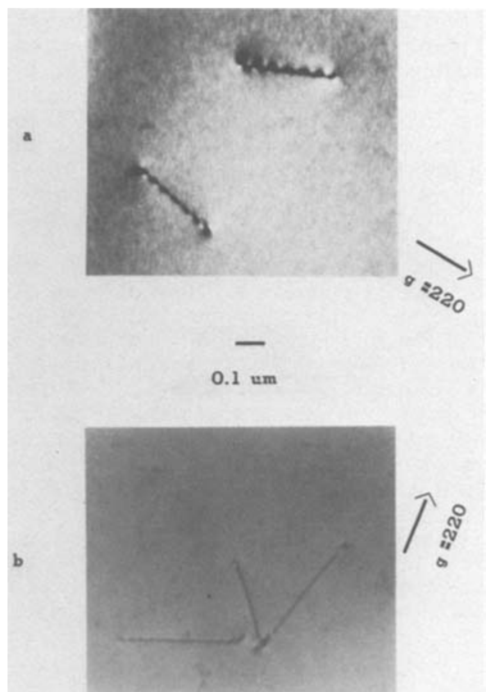

Fig. 1. Largest aggregate of threading dislocations observed in films grown on highly dislocated substrates. (a) Ge-doped GaAs; (b) Ge-doped $Al_{0.4}Ga_{0.6}As$.

The result of heat-treatments.—Dislocation multiplication and climb was observed to have taken place (Fig. 2) in GaAs and $Al_{0.4}Ga_{0.6}As$ films grown at 720°C on high dislocation-density substrates and from solutions containing 40 a/o Ge, after a 15 hr heat-treatment at 720°C. More extensive dislocation networks (Fig. 3) were observed in such films after a longer heat-treatment (60 hr at 720°C) or after a 15 hr heat-treatment at 820°C. Under quasi-kinematical diffraction conditions, contrast effects were observed in GaAs films that appeared to arise from small precipitates along the

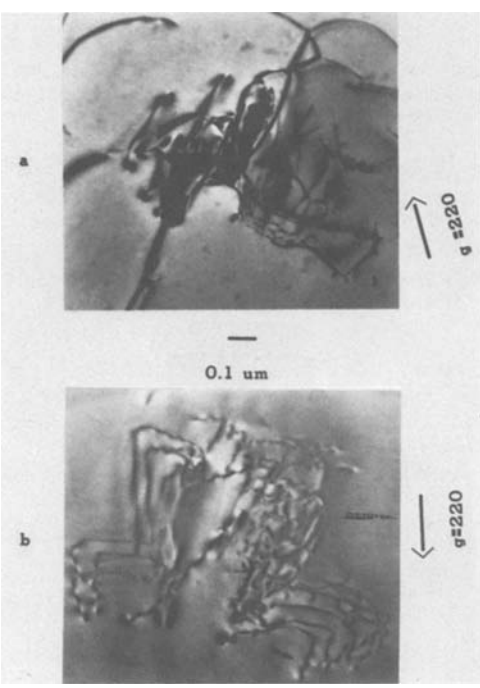

Fig. 3. Dislocation cluster observed in Ge-doped films heat-treated for 15 hr at 820°C. (a) GaAs; (b) $Al_{0.4}Ga_{0.6}As$.

dislocation line segments. Such contrast effects were not observed in $Al_{0.4}Ga_{0.6}As$ films. After a 15 hr heat-treatment at 720°C or at 820°C, structural defects were not observed in GaAs and $Al_{0.4}Ga_{0.6}$ films grown on substrates with low (<3000/cm^2) dislocation densities. These films were grown from solutions containing 20-55 a/o Ge and were grown at 720° and at 780°C. GaAs and $Al_{0.4}Ga_{0.6}As$ films grown at 780°C and from solutions of 40 a/o Ge on substrates with high dislocation densities (1-2 $\times$ 10^4/cm) contained only simple threading dislocations even after a 15 hr heat-treatment at 720° or at 820°C. These results are summarized in the table.

Discussion

In epitaxial films, one type of dopant-related structural defect may form during epitaxial growth and usually consists of dislocations or stacking faults originating at precipitates (4). Another class of defects may occur during the heat-treatment of doped films and usually consists of either vacancy or interstitial loops (2). Structural defects formed as a result of the massive Ge-doping of the LPE growth solutions were not expected to occur in the as-grown GaAs and $Al_{0.4}Ga_{0.6}As$ films. Substantial stress centers, such as second phase particles at least large enough to punch out generator dislocation loops (12) to the growth interface, have to exist in such films. Subsequently the dislocation loop is extended by the advancing growth interface forming a large defect. Such second phase particles could consist of Ge, GeAs, or $GeAs_2$, but the growth conditions used in this experiment locate our films well within the GaAs phase field (13), therefore such second phase particles are not expected. Also, for films grown from 780°C the absence of second phase particles is indicated *a priori* by the curves relating growth solution doping to resultant free carriers (2, 4, 14, 15). Prior studies found that growth solution doping within the limit of a constant distribution coefficient does not result in defects in the as-grown films (2, 4). A constant distribution coefficient for Ge in GaAs ($N_a - N_d < 1 \times 10^{20}$/cm^3) and $Al_{0.4}Ga_{0.6}As$ ($N_a - N_a < 2 \times 10^{18}$) has been reported (14, 15), indicating that defects do not occur.

The formation of defects such as dislocation loops during heat-treatment depends upon the presence of diffusing point defects as well as strain centers to nucleate the loops (12), while the diameter of such loops depends on the concentration of the nucleation centers, the concentration of the point defects, and the diffusivity of the point defects. It was observed for films grown a 720°C that in both the Ge-doped GaAs and the $Al_{0.4}Ga_{0.6}As$ films the presence of threading dislocations was a precondition for the occurrence of dislocation multiplication and climb during heat-treatment. This is quite evident in Fig. 2b where an existing threading dislocation (arrow) has bowed out into a helix. The threading dislocations, however, do not appear to be the actual nucleating centers for the observed defects. Assuming that the point defects which cause the observed line defects in films grown at 720°C are present also in Ge-doped films grown at 780°C and subsequently heat-treated at 720° or 820°C, then the absence of dislocation multiplication and climb in films grown from 780°C must lie in the absence of suitable nucleation sites. Suitable nucleation sites would not consist of ordinary threading dislocations; they should consist of jogged dislocations or dislocations decorated by precipitates. This was the reason the low growth temperature of 720°C was selected. Both GeAs and $GeAs_2$ (16) are stable below 730°C. At a growth temperature of 720°C, momentary deviations from equilibrium growth kinetics combined with the enhanced nucleation and the changed thermodynamic potential at the emergence points of the threading dislocations are thought to result in the decoration of the threading dislocations with GeAs or $GeAs_2$ clusters. This cannot take place above the decomposition temperature (736° and 732°C, respectively) of these phases, therefore the diffusing point defects in films grown at 780°C could not aggregate along the threading dislocations and induce dislocation multiplication and climb.

In experiments with Te-doped GaAs and $Al_{0.4}Ga_{0.6}As$ films it was possible to prevent the formation of defects by decomposing the nucleation sites during heat-treatment above the melting point of the second phase particle (2, 4). But once the generator loop existed, the extrinsic dislocation loops continued to grow larger even during heat-treatment above the decomposition temperature of the nucleation center. The continued defect formation during heat-treatment even above the melting point of the precipitate points out the likely interaction between the threading dislocation and the precipitate. A precipitate becoming attached to a dislocation at the growth interface very likely induces a jog or kink. This means that such particles need not be large enough to punch out generator loops and explains why they were not directly resolved. Heat-treatment above the melting point of the precipitate would decompose the particle, but not the generator loop, and the dislocation could still climb as a result of a point defect flux.

The presence of point defect complexes in heat-treated, Ge-doped $Al_{0.4}Ga_{0.6}As$ films is indicated by a recent photoluminescence study (15). An observed decrease in photoluminescence intensity after heat-treatment was attributed to high concentrations of nonradiative centers that formed during heat-treatment. The present observation of increased defect complexity as a function of heat-treatment time or increased heat-treatment temperature confirms the activity of point defect diffusion. It is likely that a diffusion process enhanced by the stress field of the threading dislocation (18) and assisted by pipe diffusion along the dislocation results in the occurrence of the observed line defects. The formation of these defects may be examined with a model based on a complex point defect consisting of a substitutional impurity associated with at least one vacancy (3, 17). In considering a different point defect, it must be noted that the observed decrease in the PL intensity of heat-treated

$Al_{0.4}Ga_{0.6}As$ (15) must be the result of point defect interactions resulting in nonradiative centers. While Ge interstitials are expected to be fast diffusing and could cause the observed dislocation climb by combining with vacancies at the threading dislocations, resulting in climb (18), this mechanism would result in improved PL efficiencies. In the same vein, an interstitial Ge-vacancy complex is not likely to form as Ge is known to be amphoteric. More substantial interstitial complexes certainly do not form. The Ge-doping of GaAs and $Al_{0.4}Ga_{0.6}As$ is known to result in only very small lattice dilation (19, 20) that appear to be exclusively due to electronic effects.

In this experiment we did not differentiate if the observed dislocation climb was of interstitial or vacancy origin, mechanisms similar to Hurle's (8) could be applied to explain either effect. Frenkel defects formed during heat-treatment supply Ga and As vacancies which are "strongly gettered" (8) by the substitutional Ge impurity thereby increasing the concentration of the point defect complexes. The resulting supersaturation of Ga and As interstitials can then combine at the threading dislocation to form Ga_IAs_I and incorporate as a step into the dislocation line. Alternatively, a simple decomposition reaction of the Ge-vacancy complex at the nucleation site or the existing defect will also result in a germanium decorated, climbing dislocation. Again, more of the diffusing defect complex could be formed during heat-treatment from the interaction of As vacancies and the substitutional impurity to maintain the equilibrium vacancy concentration. More extensive TEM studies, as well as precision lattice parameter measurements need to be utilized to identify the dislocation climb mode and to reveal the nature of the diffusing point defect.

Conclusions

The massive germanium doping of LPE GaAs and $Al_{0.4}Ga_{0.6}As$ films grown at 720°C results in the formation of high concentrations of point defects during heat-treatment at 720° and at 820°C. During heat-treatment at 720° and 820°C the point defects diffuse to nucleation sites and decompose, resulting in the formation of dislocation aggregates. The nucleation sites for the observed defects appear to consist of GeAs or $GeAs_2$ clusters that form during growth only near threading dislocations in the doped epitaxial films. For films grown above the melting point of the GeAs or $GeAs_2$ phases the nucleation sites do not exist near the threading dislocations and as a result the dislocation aggregates do not form.

High Temperature Flow Resistance of Micron Sized Images in AZ Resists

H. Hiraoka and J. Pacansky

IBM Research Laboratory, San Jose, California 95193

ABSTRACT

A simple u.v. curing process is described that renders micron sized images in AZ resists resistant to flow when heated to temperatures as high as 210°C. The u.v. treatment prevents the image flow problems usually encountered in reactive ion etching processes.

The implementation of reactive ion etching (RIE) in lithographic processes has created new demands on resists (1); one of the foremost is the resistance to flow at the high temperatures created by a plasma discharge. It is not uncommon for micron size images to flow when subjected to the temperatures that could be over 200°C in an RIE environment. The well-known and widely used class of lithographic materials labeled the AZ resists consists of a mixture of a diazo-oxide (I) and a phenolic resin (IV) (see Scheme I). Most members of the class of AZ resists, for example, have exhibited image flowing at high temperatures. This report describes a very simple u.v. curing process that renders images in any member of the AZ family of resists stable to flow at temperatures over 200°C.

Experimental

Resist patterns.—AZ-2400 (trademark of the Shipley Company, Newton, Massachusetts) was spin-coated onto silicon wafers, and subsequently prebaked at 83°C for 12 min. The wafers were exposed to a 20 keV electron beam using a vector scan type apparatus at a dose of 2×10^{-5} C/cm^2. The patterns were developed in (1:3) AZ-2401 developer.

A Hanonia SH(616A) medium pressure mercury lamp with a total u.v. output of 6.3W was used for the u.v. curing; the intensity at 2540A was 2×10^{-4} W/cm^2. The lamp was used either without filters or with a Corning No. 054 glass filter (0%T for $\lambda < 3000$). The imaged resists were exposed in air at a distance of 15 cm away from the lamp. Exposures were also conducted with the imaged resist under vacuum.

Heat treatment.—A hot plate or a vacuum oven was used for the heat-treatment. The procedure consistently followed was to set the hot plate or the oven at the specified value; the wafers with the resist patterns were then placed on the heated surfaces so that very rapid heating took place. The temperature was measured with a thermocouple that was firmly attached to the surface of the hot plate.

Procedure.—A direct comparison was made between patterns u.v. cured and not u.v. cured by breaking a resist line pattern into two pieces through the lines. When a comparison was made between the u.v. exposed and the unexposed samples both pieces of the pair were heated side by side at the same time for identical periods in order to avoid inconsistencies in the data. Afterwards, the wafers were coated with aluminum thin films for SEM inspection. The SEM micrographs were obtained with an ISI Super II SEM.

In order to test the effect of wavelength and the atmosphere on the process irradiations were performed with and without filters in the mercury lamp with the sample contained in a vacuum system or in air.

Key words: u.v. treatment, reactive ion etching, lithography.

Results

In Fig. 1(a) and (b) the effect is shown for a postbake at 95°C for 30 min in air. Figure 1(a) displays the resist without a postbake while Fig. 1(b) shows the patterns after a postbake. Clearly a thermal flow of the resist has occurred during the postbake. Figures 1(c) and (d), however, show that u.v. exposure prior to a postbake at 100°C completely eliminated thermal flow of the resist pattern. For example, in Fig. 1(d) the results are shown for patterns with no postbake that were exposed to u.v. light and then heated at 100°C for 30 min in air. For comparison, Fig. 1(c) contains an SEM of original patterns with no postbake.

In essence the results summarized in Fig. 1 demonstrate the detrimental effect of postbake before u.v. curing on flow resistance of resist images. Elimination of the postbake prior to u.v. curing is a paramount consideration for the process to be successful; this is amply demonstrated by the results that follow.

The exposure time required for the u.v. cure is a function of the temperature at which the resist patterns must not flow. In general, the exposure time increases as the temperature at which the resist is heated increases. Figures 2 and 3 demonstrate this for resist patterns heated at 155° and 210°C, respectively. Figure 2(a) contains an SEM micrograph of the resist pattern obtained after development; Fig. 2(b) shows the effect of u.v. exposure for 15 min followed by heating at 155°C for 30 min with no prebake; Fig. 2(c) shows the effect of heating without the u.v. cure. The contrast between Fig. 2(b) and (c) vividly demonstrates the beneficial effect of the u.v. cure, which under the conditions used in the present studies requires an exposure time of 15 min for flow resistance at $\approx$150°C. For flow resistance of the resist patterns at 210°C a longer exposure time is required. In Fig. 3(a) the re-

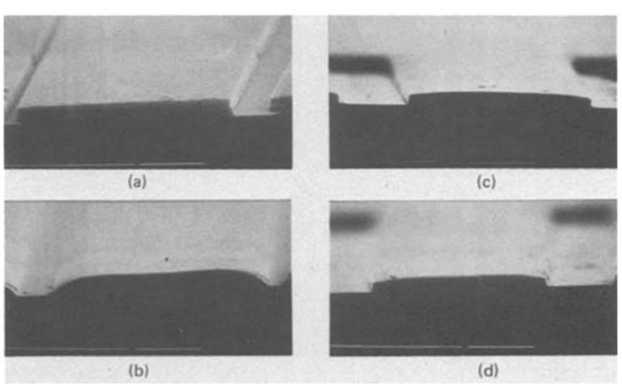

Fig. 1. The effect of postbake on the resist patterns in the AZ-2400; (a) the resist patterns without postbake; (b) the resist patterns after postbake at 95°C for 30 min in air; (c) the resist patterns without postbake; (d) the resist patterns exposed to the u.v. light, then subsequently heated at 100°C for 30 min in air.

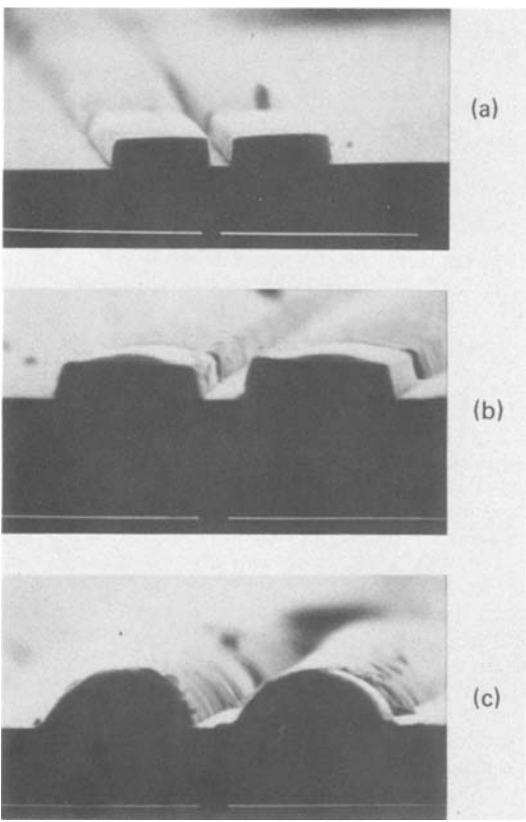

Fig. 2. The effect of a 15 min u.v. exposure on the resist patterns in AZ-2400; (a) the patterns with no postbake; (b) the resist patterns exposed to the u.v. light for 15 min in air, then subsequently heated at 155°C for 30 min; (c) the resist patterns heated at 155°C for 30 min without the u.v. exposures.

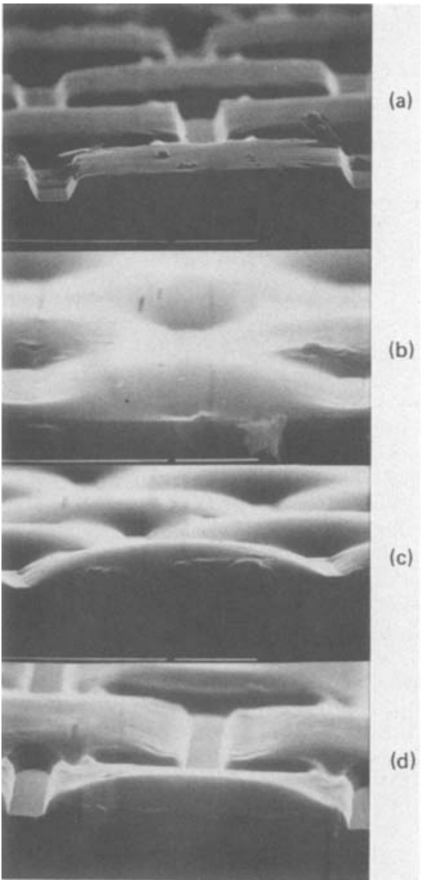

Fig. 3. The effect of increasing u.v. curing time; (a) original patterns; (b) no u.v. hardening but heated at 210°C for 25 min; (c) u.v. exposure for 15 min, then heated at 210°C for 25 min; (d) u.v. exposure for 30 min, then heated at 210°C for 25 min.

sist pattern is shown after development. Figure 3(b) contains an SEM showing the complete loss of the patterns after heating to 210°C for 25 min. Figure 3(c) shows that a 15 min u.v. exposure has dramatically retarded but has not stopped the image flowing at 210°C. Figure 3(d), however, clearly demonstrates that a 30 min exposure has prevented the catastrophic image flow at 210°C.

Discussion

Irradiation of an AZ type resist with u.v. light after images have been developed renders the material resistant to flow at high temperatures. The u.v. exposure, however, will only be effective when done without a postbake. This point must be stressed because it is a common practice to postbake resists in order to enhance the quality of the film.

Another important requirement for the u.v. cure is that longer exposure times are required for flow resistance at higher temperatures. For example, it was shown that an exposure time of about 30 min was needed for flow resistance at 210°C. This exposure time also suffices for temperatures somewhat higher than 210°C (the high temperature limit was not tested because temperatures around 210°C are believed to approximate those found under RIE conditions). The amount of time required for the u.v. cure seems rather excessive but the mercury lamp used in this study has a relatively low output of u.v. light in comparison to other high pressure mercury lamps (2). A conservative estimate that is easily obtained is that lamps are available with >200 times the u.v. output of the Hanonia lamp used in this study; consequently, exposure times of about 10-20 sec are possible. In this respect the implementation of the u.v. curing described in this report into a commercial process becomes quite attractive.

In general, the u.v. cure works for the AZ class of resists. On the basis of the known photochemical mechanism (3) operative in the AZ class of resists an explanation was sought for this phenomenon. The photoactive compound in the resist is a diazo-oxide (I) that is photochemically converted to a ketene (II) as shown in Scheme I. In the presence of moisture (II)

Scheme 1

forms the carboxylic acid (III), or, in the absence of moisture (*e.g.*, high vacuum) the ketene (II) reacts with the resin (IV) to form the ester (V). Under the conditions used in the experiments described in this

report the u.v. curing seems to be independent of whether the irradiations are performed in vacuum or in the atmosphere. Furthermore, infrared studies indicate that neither the carboxylic acid (III) or the ester (V) are photochemically produced; instead the salt of the carboxylic acid (VI) is produced. Studies have shown that the origin of the salt formation is due to residual developer (KOH) left in the resist after development. Since the ketene (II) or the acid (III) reacts vigorously with bases then salt formation easily proceeds. The production of the potassium indene carboxylate salt in this manner renders the resist more resistant to flow at high temperature.

Summary

A simple u.v. cure has been described whereby the high temperature flow resistance of the AZ class of resists is dramatically improved. The u.v. cure involves exposure of the imaged resist to light after development and appears to work under a variety of exposure conditions. The salient feature that makes the chemistry of the u.v. cure different from that normally found in the resist is that the potassium indene carboxylate salt is photochemically produced instead of the indene carboxylic acid.

High Pressure Plasma (HPP) Deposition of Polycrystalline Silicon Ribbons

K. R. Sarma* and M. J. Rice, Jr.*

Motorola Incorporated, Semiconductor Group, Solar Energy R&D Department, Phoenix, Arizona 85008

ABSTRACT

A high pressure plasma (HPP) deposition process has been characterized for its potential in producing polycrystalline silicon films (ribbons) at low cost. Gas chromatographic (GC) analysis of HPP deposition reactor effluent gases has been used for characterizing the deposition process. Silicon tetrachloride, trichlorosilane, dichlorosilane, and silane have been evaluated as possible silicon source gases for silicon deposition by HPP. Deposition efficiencies have been determined under various experimental conditions such as rf power of HPP, concentration and flow rate of reactant gases, and substrate temperature. These efficiencies were found to be higher than those obtained by a conventional chemical vapor deposition (CVD) process under all conditions of practical interest. The observed improvements in HPP silicon deposition may be explained using thermodynamics, operative kinetic processes, and deposition mechanisms. Economic potential of the HPP deposition process for producing silicon films appears favorable.

Chemical vapor deposition (CVD) of silicon by high temperature (1000°-1200°C) hydrogen reduction of a chlorosilane such as $SiHCl_3$ is a well-established process used extensively in the semiconductor industry. It is used for producing bulk polycrystalline silicon as well as thin films of silicon in polycrystalline or in single crystal form. In many of these processes, cold-wall deposition systems are used to prevent wall deposition. This CVD process, as it is used, is characterized by low chemical and energy utilization efficiency, low throughput rate, and high cost. Recently, devices for which silicon material cost is a major part of the total cost (*e.g.*, solar cells) have provided an impetus for development of advanced technologies capable of reducing the cost of depositing silicon. We have been investigating a high pressure plasma (HPP) deposition process as a means for depositing polycrystalline silicon ribbons (films) at low cost (1-4). Unlike many low pressure plasma processes used in the semiconductor industry that operate in the pressure range of few Torr, this HPP operates at a pressure near one atmosphere.

Key words: chromatography, thermodynamics, semiconductor, quenching, kinetics.

The HPP deposition system, which is schematically shown in Fig. 1, includes a 13.56 MHz rf generator, an impedance matching module, a plasma beam nozzle, and a hot-wall deposition reactor. Silicon films are deposited onto the substrates covering the deposition reactor walls by introducing hydrogen and chlorosilane directly into the rf circuit through a tubular output coil in the impedance matching module. The tubular output coil terminates in a nozzle containing a hollow tungsten electrode. Tuning the impedance matching module for resonance creates, at the tip of the electrode, a high voltage which results in an electrical discharge plasma. Due to macroscopic motion of the reactant gas stream through the electrode, the plasma extends into the space in front of the nozzle as a jet. Emission spectroscopic measurements have indicated localized temperatures in the vicinity of 4000°C in the plasma beam.

Previously, the feasibility of depositing semiconductor grade purity polycrystalline silicon films, at high chemical utilization efficiencies, using $SiCl_4$ and $SiHCl_3$ as silicon source gases has been shown (1, 2). In this paper, we will present the results of a more detailed characterization effort. The HPP deposition

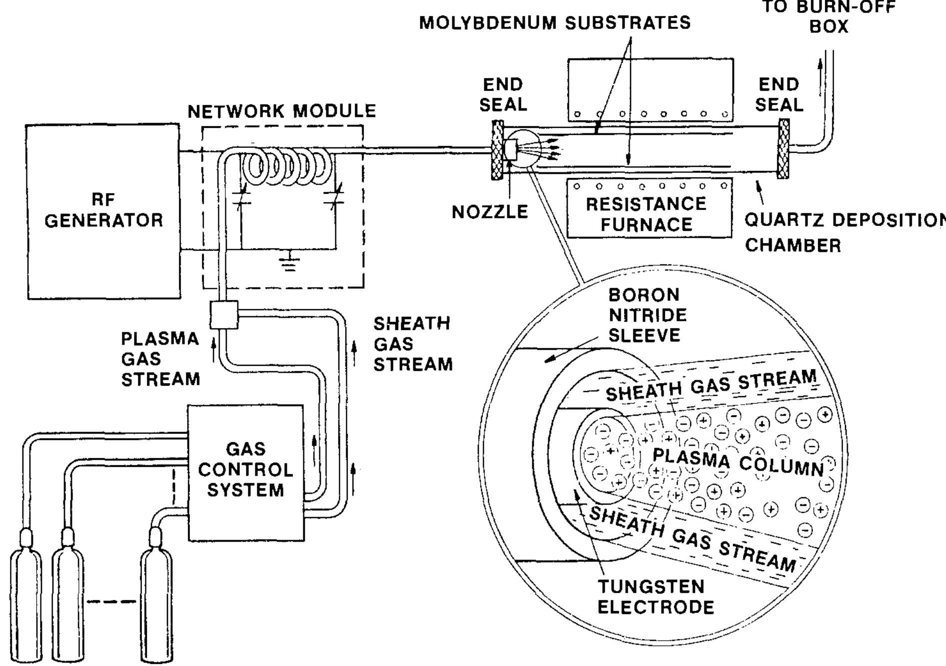

Fig. 1. Schematic of the high pressure plasma (HPP) deposition system.

process is thoroughly characterized by on-line gas chromatography (GC) as a function of various experimental parameters such as rf power of the HPP, concentrations and flow rates of input reactant gases, and substrate temperature. These results on HPP deposition are compared with results obtained under CVD conditions. The observed results are discussed in terms of thermodynamics and deposition mechanisms and kinetic and transport processes operative in HPP deposition.

Experimental

Experimental work consisted of determining silicon deposition efficiency using an on-line GC. The HPP deposition apparatus used in this investigation is shown schematically in Fig. 1. The fused silica deposition reactor was of 5×5 cm^2 cross section. The walls of this reactor were covered with 1 mm thick molybdenum substrates. The auxiliary resistance furnace employed had a hot zone length of 30 cm and served for controlling the substrate temperature. Molybdenum acts as a temporary substrate (5) for producing self-supporting silicon ribbons; *i.e.*, silicon films deposited on Mo substrates are separated from the substrate, by cooling from deposition temperature, due to differential thermal expansion coefficients of Mo and Si.

The effluent gas stream from the deposition reactor was split into two gas steams as shown in Fig. 2. The large gas stream was sent to a hydrogen and chlorosilane burn-off box and exhaust. The small gas stream was sent to a six port gas sampling valve of a Hewlett Packard 5840A Reporting Gas Chromatograph with a thermal conductivity detector. A 10 ft stainless steel column packed with Chromosorb-W and a 20% loading of SF-96 as the absorbant phase were used. The instrument was calibrated for retention time and detector response by sampling gas with known concentrations of HCl, SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$ in H_2, which was passed through the reactor and sampling system at room temperature. Calibrations were made with individual constituents and with mixtures. Column temperature was time programmed to shorten analysis time, starting at 35°C, increased at a rate of 30°C/min to 80°C, and remained at that temperature until the analysis was complete. Using 30 ml/min hydrogen carrier gas, retention times of 0.92, 1.75, 2.52, and 3.43 min were obtained for HCl, SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$, respectively, and the GC run was terminated at 4 min. The column cooled to 35°C in 3.5 min allowing a new sample to be taken every 7.5 min. Application of GC for characterization of silicon CVD processes has been described in the literature (6) and detailed theory and practice of GC analysis may be found in many of the standard textbooks, *e.g.*, Ref. (7). Since the sample gas to be analyzed is cooled to the column temperature this technique is not suitable for studying chemical equilibrium in the high temperature environment, but can be used to obtain reactant utilization efficiency.

Figure 3 shows a typical chromatograph. Using the composition of effluent gases from the deposition reactor determined by the GC analysis, the deposition efficiency (reactant utilization efficiency), η, is calculated as follows

$$\eta = \frac{(Si/Cl)_{in} - (Si/Cl)_{out}}{(Si/Cl)_{in}} \cdot 100\%$$

where $(Si/Cl)_{in}$ and $(Si/Cl)_{out}$ are the silicon to chlorine ratios in the input and effluent gas streams. For example, when using $SiCl_4$ as the silicon source gas, $(Si/Cl)_{in}$ will be 0.25. $(Si/Cl)_{out}$ is calculated as

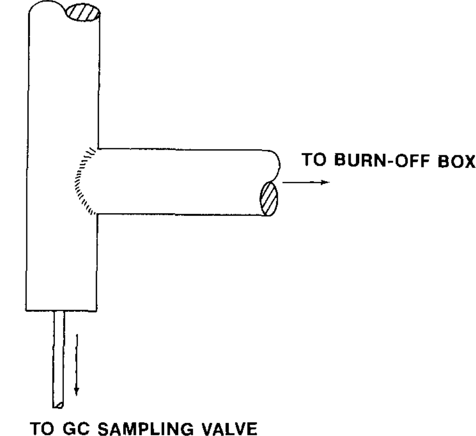

Fig. 2. Gas chromatographic (GC) gas sampling arrangement

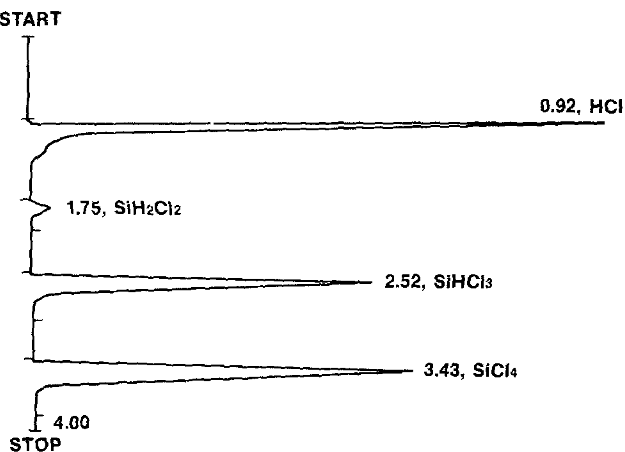

Fig. 3. Example of a typical chromatograph of the HPP reactor effluent gas stream.

follows

$$(\mathrm{Si/Cl})_{\mathrm{out}} = \frac{m_{\mathrm{Si}}}{m_{\mathrm{Cl}}} = \frac{100 - m_{\mathrm{HCl}}}{m_{\mathrm{Cl}}}$$

where

$$m_{\mathrm{Si}} = m_{\mathrm{SiH_2Cl_2}} + m_{\mathrm{SiHCl_3}} + m_{\mathrm{SiCl_4}} = 100 - m_{\mathrm{HCl}}$$

$$m_{\mathrm{Cl}} = m_{\mathrm{HCl}} + 2m_{\mathrm{SiH_2Cl_2}} + 3m_{\mathrm{SiHCl_3}} + 4m_{\mathrm{SiCl_4}}$$

and m_{HCl}, $m_{\mathrm{SiH_2Cl_2}}$, $m_{\mathrm{SiHCl_3}}$, and $m_{\mathrm{SiCl_4}}$ are mole percentages of HCl, SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$, respectively, in the effluent gas stream, as determined by GC analysis. Deposition efficiencies calculated from GC measurements were found to be repeatable to within $\pm 0.5\%$. Under certain conditions, gas phase nucleation in the deposition reactor was excessive and led to powder growth, instead of dense film growth. Also some of this powder was found to leave the reactor with the effluent gas stream, resulting in a difference between deposition efficiencies determined by GC analysis and weight gain measurements. (Silicon particles in the gas stream were filtered out before going into the GC column.) Deposition efficiencies were found to agree well with the values calculated from weight of silicon deposited when powder growth was absent. For comparative purposes, results were also obtained for the CVD mode of operation (*i.e.*, without HPP beam) under otherwise identical conditions.

Results

RF power required for a stable HPP beam was found to increase with increases in concentration and flow rate of the reactant gas stream. Once a stable HPP beam is established at a particular rf power, a further increase in rf power is not found to have any noticeable effect on silicon deposition efficiency. Hence in all the experiments rf power employed was kept close to the minimum required for a stable operation of the HPP beam.

Silicon tetrachloride.—Table I summarizes results obtained using $SiCl_4$ as the silicon source gas. Reactant concentration can be seen to have a major effect on deposition efficiency both for CVD and HPP modes of operation. In general, the effect of increased flow rate is to decrease the deposition efficiency as expected. One major exception to this is the case for 1100°C, Cl/H = 0.04 deposition, where increasing the flow rate increased the efficiency. For HPP, flow rate seems to have a similar but smaller effect. Substrate temperature, in the range of 1050°-1150°C, did not seem to have much effect on deposition efficiency either for CVD or HPP except for lower reactant concentrations (*e.g.*, Cl/H = 0.04). Deposition enhancement by HPP was found to occur for low reactant concentrations (Cl/H = 0.04). Effect of reactant concentration, Cl/H, is plotted in Fig. 4 both for CVD and HPP for a substrate temperature of 1100°C and reactant flow rate of 30 liters/min. Also, in Fig. 4, the thermodynamic equilibrium efficiency calculated (1, 3) for 1100°C deposition is shown. Both the CVD and HPP efficiencies can be seen to be higher than the equilibrium predictions, particularly at high concentrations. (See section on Transport processes for discussion of reasons for this.)

Table I. Summary of results obtained using $SiCl_4$ as silicon source gas

Trichlorosilane.—Results obtained with $SiHCl_3$ are summarized in Table II. Similar to the case with $SiCl_4$, reactant concentration seems to have a major effect for both CVD and HPP modes of operation. In the case of CVD, in general, the effect of increasing flow rate is to decrease deposition efficiency except for depositions with Cl/H = 0.4 and with substrate temperature in the range of 1100°-1200°C. In the case of HPP, changing the flow rate from 15 to 30 liters/min seemed to improve the deposition efficiency in many cases and in some cases substantially. The effect of substrate temperature is plotted in Fig. 5, for concentrations Cl/H = 0.08 and 0.1 and flow rate = 30 liters/min. A maxima in concentration can be seen at 1100°C both for CVD and HPP. The effect of reactant concentration is plotted in Fig. 6 for a substrate temperature of 1100°C and flow rate of 30 liters/min. For comparison, efficiencies calculated from thermodynamic equilibrium (1, 3) are also plotted. Deposition enhancement by HPP is highest for lower concentrations. Also, while CVD efficiencies are consistently lower than equilibrium efficiencies, HPP efficiencies are found to be higher than equilibrium values for Cl/H < 0.12.

Dichlorosilane.—Table III shows the results obtained with SiH_2Cl_2. It also shows the calculated equilibrium efficiencies for an 1100°C substrate temperature. The

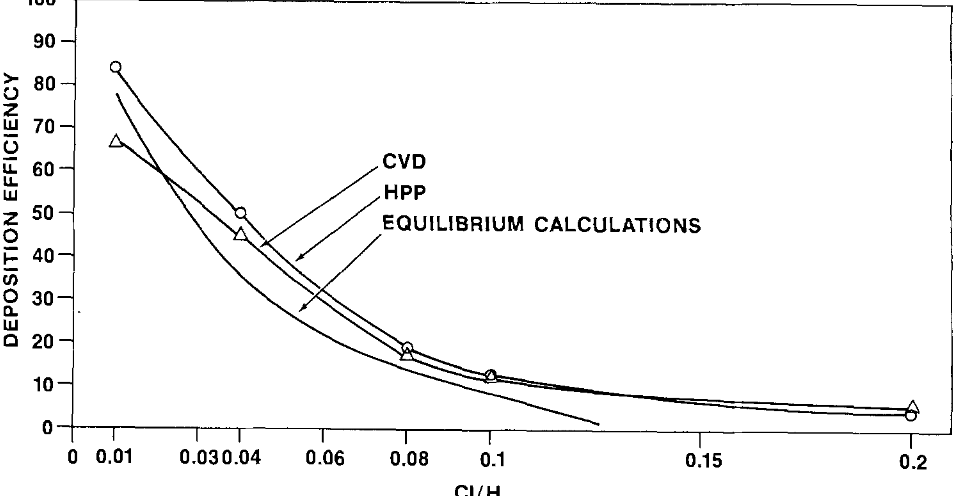

Fig. 4. Deposition efficiency with $SiCl_4$ source. (Total reactant flow rate = 30 liters/min, substrate temperature = 1100°C). Note that the concentration range in this figure extends beyond the one given in Table I.

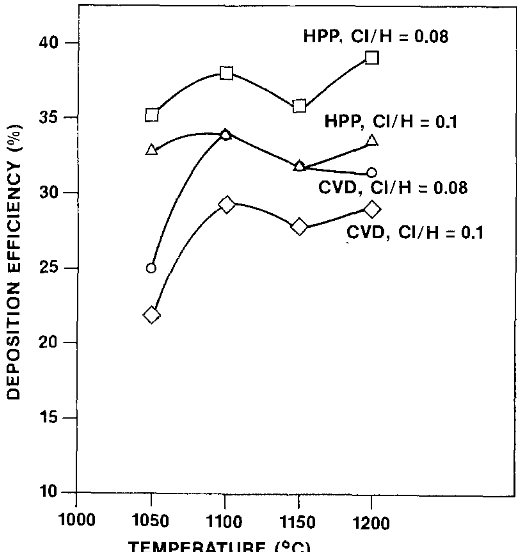

Fig. 5. Deposition efficiency vs. substrate temperature for $SiHCl_3$ source. (Total reactant flow rate = 30 liters/min).

HPP efficiencies, in general, are found to be higher than CVD values. Deposition enhancement by HPP appears to be higher (compared to CVD) for lower substrate temperatures and lower reactant concentrations. HPP efficiencies can be seen to be quite close to the calculated equilibrium efficiencies for an 1100°C substrate temperature. Gas phase nucleation leading to powder growth was found to be a problem when using SiH_2Cl_2 both with CVD and HPP modes of operation. This problem was found to become more severe with increases in flow rate, concentration, and substrate temperature.

Silane.—Silane was also investigated as a source gas for silicon deposition. However, powder growth was found to be a problem with both CVD and HPP under all conditions of practical interest that result in reasonable throughput rate. Hence work with SiH_4 was discontinued.

Throughput rate.—Apart from deposition efficiency, throughput rate (in which throughput rate is used as the amount of silicon deposited in unit time) is another important parameter affecting the cost of depositing silicon. Reactor throughput rate determines the number of reactors (capital) required for a given capacity, which in turn determines production floor space requirements. Throughput rate can be calculated knowing reactant concentration and flow rates and deposition efficiency. Figure 7 shows the calculated throughput rates for $SiCl_4$ and $SiHCl_3$ source gases under CVD and HPP modes of operation as functions of concentration for a substrate temperature of 1100°C and a total reactant flow rate of 30 liters/min. For $SiCl_4$, throughput rate shows a maximum both for CVD and HPP modes of operation. This is in agreement with equilibrium calculations. In the case of $SiHCl_3$, throughput rate can be seen to increase with increasing reactant concentration both for CVD and HPP modes of operation, which is again in agreement with equilibrium calculations. However, a practical limit on throughput rate will be set by deposit mor-

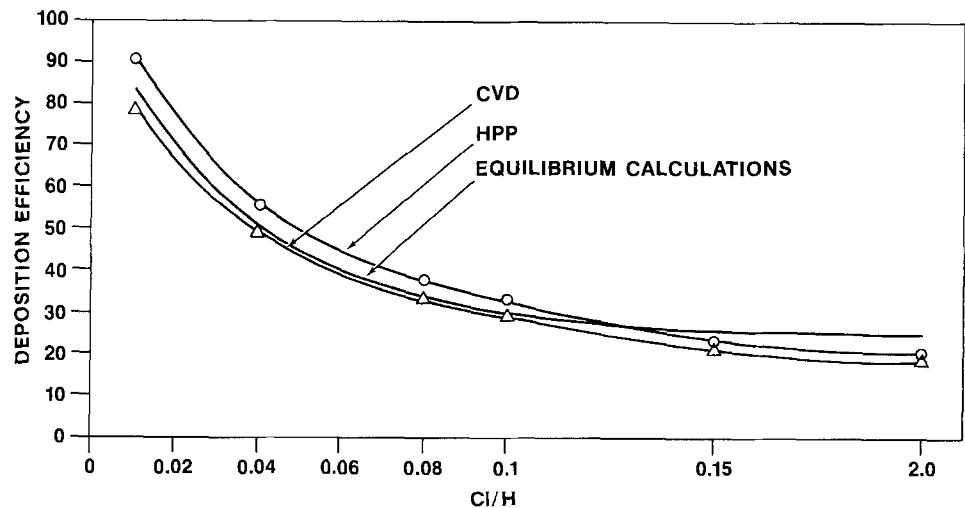

Fig. 6. Deposition efficiency with $SiHCl_3$ source. (Total reactant flow rate = 30 liters/min, substrate temperature = 1100°C.) Note that the concentration range in this figure extends beyond the one given in Table II.

phology considerations and the increasing severity of gas phase nucleation leading to powder growth. Increasing reactant concentrations are found to lead to nodule and whisker growth instead of smooth film growth. These problems are found to limit the maximum usable concentration to about Cl/H = 0.1, when using $SiHCl_3$. Thus the practical throughput rate obtainable from $SiHCl_3$ is about a factor of two higher than that from $SiCl_4$. Also, practical throughput rate can be seen to be higher with HPP compared to CVD when using $SiCl_4$ and $SiHCl_3$. For Cl/H = 0.1, throughput rate is over 15% higher with HPP compared to CVD when using $SiHCl_3$. Practical throughput rate obtainable from SiH_2Cl_2 is found to be similar to the one with $SiHCl_3$ in spite of the higher deposition efficiency. This is due to the lower limit on concentration necessary to avoid powder growth.

Discussion

For a low-cost process, both deposition efficiency and throughput rate (silicon production rate) have to be high. While the H_2 and chlorosilanes from the deposition reactor effluent can be separated and recovered from HCl and recycled through the deposition reactor for improved reactant utilization efficiency, there is a cost associated with the recovery process. Hence, the higher the deposition efficiency is, the lower the recovery costs and thus the lower the cost of deposition. From the experimental results, deposition efficiency can be seen to be higher for the HPP mode of operation than for CVD under cases of practical interest. Furthermore, under several cases of practical interest, HPP deposition efficiency is found to be higher than the equilibrium value calculated by assuming thermodynamic equilibrium in the reactor at the substrate temperature. In the following we discuss this and explain some of the observations using thermodynamic and kinetic considerations and the operative deposition mechanisms and transport processes.

Thermodynamic factors.—Classical thermodynamic discussions assume equilibrium conditions and practical silicon deposition reactors do not generally operate under equilibrium conditions. The authors note that the plasma system used here cannot be characterized as equilibrium with both severe gradients in temperature and compositional profiles. However, thermodynamics can be used as a qualitative tool to evaluate results and the reasonableness of experimental observations. Chemical thermodynamic equilibria of the system Si-H-Cl, relevant to HPP deposition involving temperatures of up to 5000 K have been calculated (1, 3) using Gordon and McBrides's computer program (8). This program is based on a free energy minimization technique. All possible species between Si, H, and Cl for which data existed in JANAF tables (9) were considered in these calculations, namely, Cl, Cl^+, Cl^-, Cl_2, e, H, H^+ H^-, HCl, H_2, Si(s), Si(l), Si(g), Si^+, SiCl, $SiCl_2$, $SiCl_3$, $SiCl_4$, SiH, SiH^+, SiH_4, SiH_2Cl_2, $SiHCl_3$, Si_2, and Si_3. Figure 8 is an example of the results of these calculations showing the relative concentrations of various species at equilibrium as a function of temperature, for a reactor pressure of 1 atm and a reactant input concentration, C/H = 0.1. It should be noted that SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$ have not been shown in the figure for reasons of clarity and that their mol fractions are less than 10^{-3} above 1700 K and decrease rapidly with increasing temperature. With this information the deposition efficiency can be calculated utilizing the input Si/Cl ratio and the equilibrium Si/Cl ratio. The

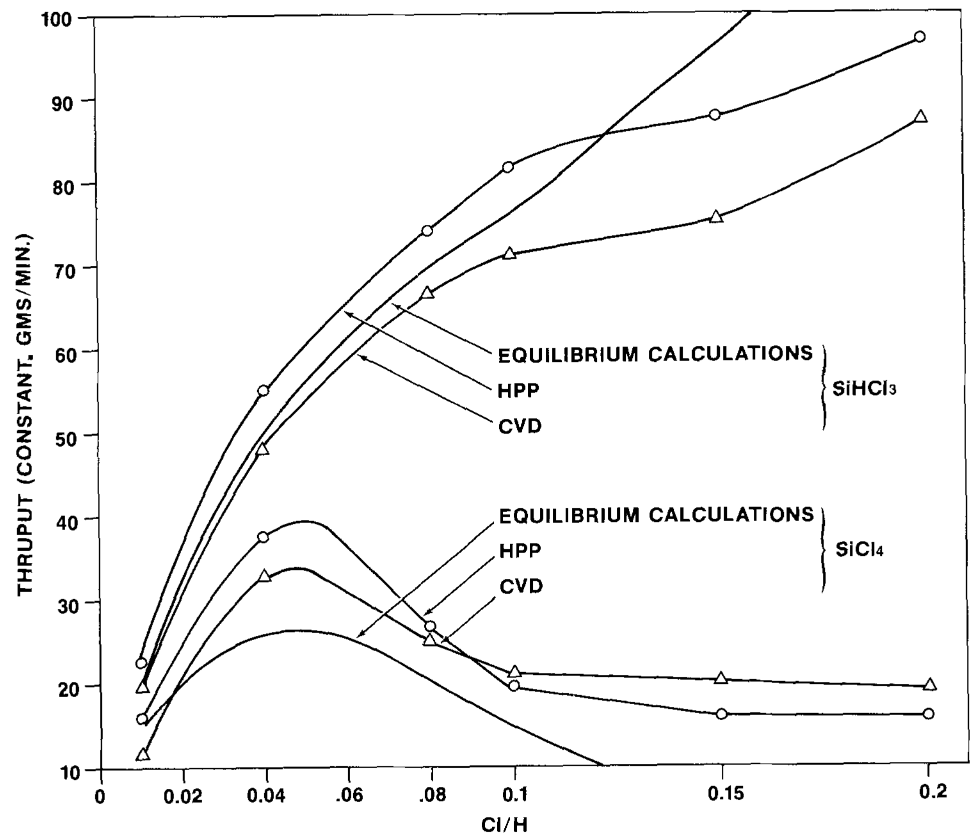

Fig. 7. Reactor throughput as a function of reactant concentration.

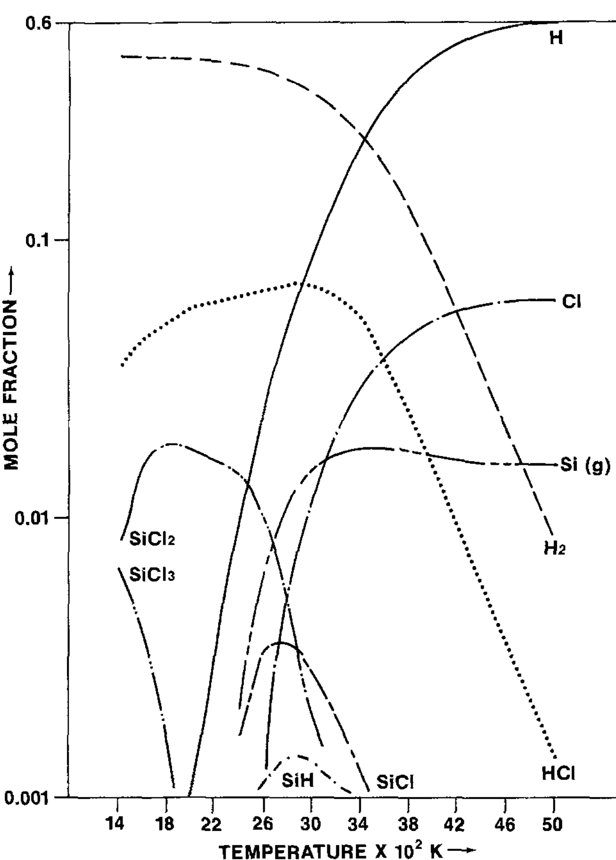

Fig. 8. Relative concentrations of various species in Si-H-Cl system as a function of temperature for $P = 1$ atm, and Cl/H = 0.1, obtained from chemical equilibrium calculations [Ref. (1, 3)].

calculated deposition efficiency as a function of temperature is shown in Fig. 9 for $SiHCl_3$ source, 1 atm reactor pressure and Cl/H = 0.1. It should be noted that in Fig. 9, for temperatures above the boiling point of silicon, 2950 K, efficiency should be considered as reaction efficiency rather than deposition efficiency. With increasing temperature from 1100°C, the efficiency can be seen initially to decrease slightly

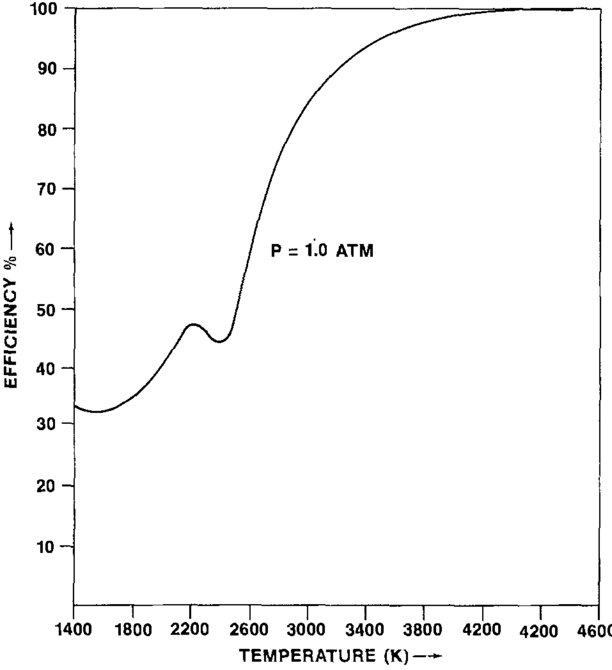

Fig. 9. Equilibrium deposition efficiency with $SiHCl_3$ as a function of temperature (1, 3).

then to increase gradually to around 45% at 1900°C, then to decrease somewhat, and finally increase rapidly and saturate around 4000°C at nearly 100%. The rationale for investigating HPP deposition is that by quenching the equilibrium mixture present at the very high plasma temperature where efficiencies are extremely high it should be possible to obtain higher efficiencies than from the equilibrium mixture present under lower temperature CVD conditions. From experimental results, it can be seen that although improvements in efficiencies are not as much as thought possible, useful improvements in efficiencies were obtained. As a practical matter, with the system geometry used here, the process is neither a pure plasma process nor a pure CVD process, but rather a plasma-enhanced CVD process. High efficiencies can be obtained from the plasma process by proper quenching; however, to form dense, smooth films of silicon the substrates were heated to 1000°C. It is probable that the process gases approach CVD conditions at some point in the reactor. We discuss factors that determine the efficiency improvements obtainable by HPP in the next sections.

The relative performance (deposition efficiency) of $SiCl_4$, $SiHCl_3$, and SiH_2Cl_2 is in agreement with thermodynamic predictions as can be seen from Fig. 10 (1, 3), which shows equilibrium efficiencies as a function of concentration. While equilibrium calculations predict etching (zero deposition) for a Cl/H of 0.125 at 1100°C for $SiCl_4$, it has not been observed, either for CVD or HPP even up to Cl/H of 0.2. In the case of CVD, this has been explained by Van der Putte *et al.* (10) by taking into account species dependent ordinary diffusion coefficients and thermal diffusion. We further discuss this under the section Transport processes.

Silicon deposition mechanisms.—In the case of conventional cold wall CVD reactors, the deposition mechanism generally involves transport of reactants to the substrate surface, chemical reaction on the surface producing silicon atoms, and incorporation of these atoms into the growing silicon film. However, a second deposition mode involves occurrence of chemical reactions in the gas phase producing free silicon atoms, condensation of these atoms into nuclei in the gas phase, transport of these nuclei to the substrate surface, and their incorporation into the growing silicon film. This latter mode of deposition becomes important in CVD reactors with the use of SiH_2Cl_2 and SiH_4 source gases, higher substrate temperatures, and hot wall deposition systems (11-13).

With HPP deposition, however, the gas phase nucleation and deposition mode is found to be important under all conditions regardless of the type of chlorosilane, its concentration, and the reactor (substrate) temperature employed. One of the consequences of gas phase nucleation can be powder growth; *i.e.*, silicon nuclei, instead of reaching the substrate surface and contributing to film growth, grow in the vapor phase to a larger size forming silicon powder. This powder either lands on the substrate surface or exits from the deposition reactor along with the effluent gas stream. Powder formation constitutes a loss process, and furthermore creates problems in the exhaust gas (chlorosilane and hydrogen) recovery system. While it has not been possible to estimate the relative contributions to film deposition rates of these two different mechanisms in the HPP deposition process, powder formation can be at an inconsequential level in operation of the system (2) under practical film growth conditions. The reasons for this are discussed in the section on Transport processes.

Kinetic factors.—Kinetic processes could play a dominant role in deposition processes, and they have

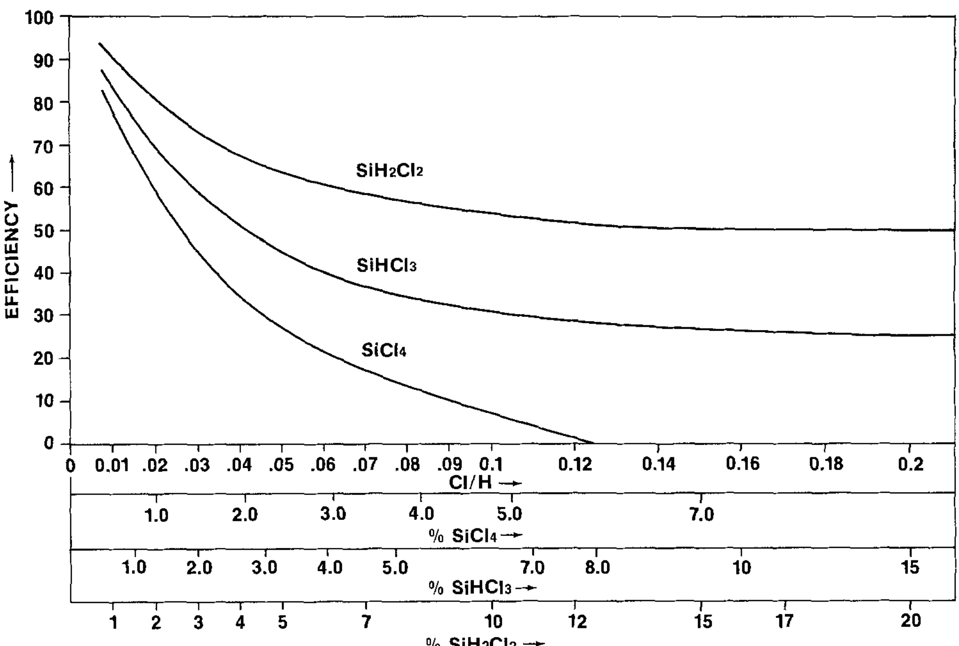

Fig. 10. Calculated equilibrium deposition efficiency a function of concentration with chlorosilanes $SiCl_4$, $SiHCl_3$, and SiH_2Cl_2 for $T = 1100°C$ and $P = 1$ atm (1, 3).

been studied extensively by various investigators of silicon CVD. In the following, we discuss the various kinetic processes that we believe could explain the observed results with HPP. In HPP deposition, reactant gases experience temperatures up to 4000°C in the plasma as they are introduced into the deposition reactor. Localized chemical equilibrium can be assumed in the atmospheric pressure plasma. At 4000°C, the predominant species are H, Cl, Si(g), H_2, and HCl (see Fig. 8). As this high temperature gas stream flows through the reactor and impinges on the reactor walls, it will be quenched. When the temperature lowers through the boiling point of silicon (2677°C), there will be a driving force for condensation of silicon vapor. Upon further cooling through the silicon melting temperature (~1410°C), there will be a driving force for solidification of silicon. At the same time, as the temperature is lowered, there is a tendency for formation of $SiCl_2$ and $SiCl_3$ species. However, silicon condensation could occur before the equilibrium concentrations of $SiCl_2$ and $SiCl_3$ species increase. When this happens, reaction between the condensed phase and HCl will be the rate-limiting step in the attainment of equilibrium as the gas mixture is quenched. This sequence of events can qualitatively explain the improvements in deposition efficiencies observed with the HPP deposition process.

Another kinetic factor of importance in HPP deposition is the incorporation of gas phase nucleated silicon into the silicon film growing on the substrate surface. Substrate temperature and gas flow behavior (laminar or turbulent) were found to have a major influence on this step. Higher substrate temperatures and turbulence in the gas stream enhance the incorporation of silicon nuclei into the growing silicon film. Substrate temperature in excess of 1000°C was found to be sufficient for a dense film growth. In the following section we discuss the operative transport processes in the HPP deposition reactor.

Transport processes.—Mass transport processes can profoundly influence a deposition process. There are several excellent papers [*e.g.*, Ref. (14)] dealing with this subject pertaining to CVD silicon using cold-wall reactors. Srivastava *et al.* (15) have modeled hot wall silicon deposition reactors and have given an excellent discussion of silicon particle transport properties and processes, in which they considered the agglomeration of gas phase nucleated particles in the absence of chemical reaction.

A complete understanding of the HPP deposition process requires consideration of the operative mass transport processes along with simultaneous chemical reactions. In the HPP reactor gaseous species as well as gas phase nucleated particles are present. Transport of these species to the substrate surface is due to both convective and diffusive processes. Two important regions of the HPP reactor can be identified to be: entry region, where the plasma beam is introduced into the deposition reactor which is schematically shown in Fig. 11, and the isothermal region where the substrate temperature is controlled at a desired level using the auxiliary furnace. Gas flow in the reactor was found to be in a turbulent regime for the conditions investigated, which is in agreement with Reynold's number calculations based on the reactor dimensions. We believe that, at the entry region, the HPP deposition model can be schematically illustrated as shown in Fig. 11. At the entry region of the reactor, the gas stream from the plasma beam disperses as it moves through the reactor and impinges on the reactor walls. Within a short distance after this region, a turbulent flow is well established through the rest of the deposition zone. There will be a stagnant region near the reactor walls (substrate surfaces) where the mass transport is by diffusion. The axial gas stream at a given position along the reactor length can be assumed to be of uniform composition due to mixing by turbulent eddies.

The driving force for diffusion is due to concentration gradients (Fick) as well as thermal gradients (Soret). While the Fick diffusion coefficient is positive for all species (*i.e.*, diffusion down to concentration gradient), the Soret diffusion coefficient will be negative for some species (*i.e.*, in a temperature gradient, lighter species tend to move toward high temperatures and heavier species toward low temperatures). Steep radial temperature gradients exist at the entry region of the reactor, where the plasma core gases are much hotter than the substrate temperature. In this region thermal diffusion is expected to be important. This situation is fortuitous, since the silicon particles nucleated in the gas phase due to their higher density compared to the gas stream, will be transported to the substrate surfaces by thermophoretic force (Soret effect) and become incorporated into the growing silicon film. While submicron sized particles deposit by a diffusion process, particles larger than about a micron will deposit by turbulence-induced inertial impaction (15).

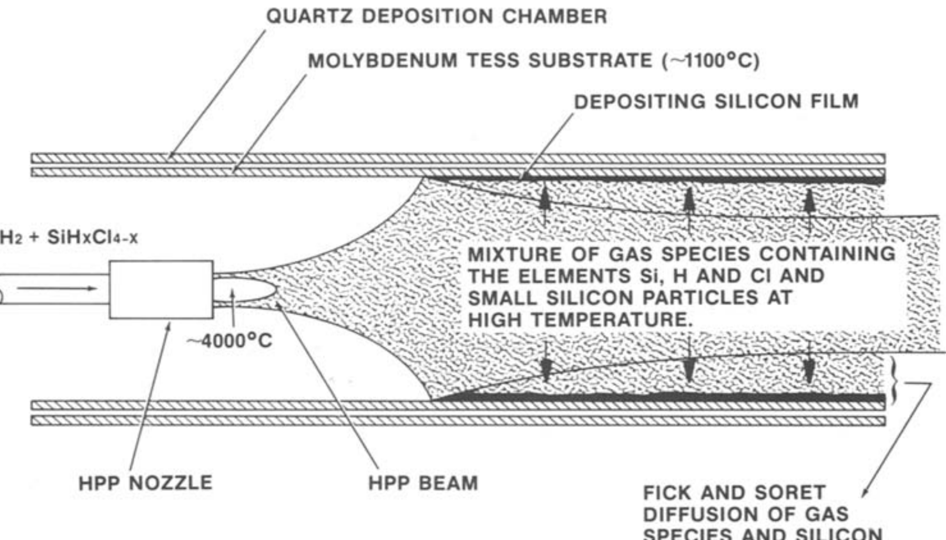

Fig. 11. Schematic illustration of the HPP deposition model.

In the isothermal region of the reactor, mass transport through the stagnant layer is due only to Fick diffusion. Diffusion coefficients of heavier molecules (*e.g.*, $SiCl_4$, $SiHCl_3$, etc.) are lower than lighter ones (*e.g.*, HCl). This leads to a condition where the concentration (Cl/H) near the substrate surface is lower than in the bulk ambient gas stream (which is related to reactor input concentration). As a result, experimental deposition efficiencies can be higher than the theoretical predictions since the effective Cl/H ratio at the substrate is lower than the input value. This is indeed observed in the case of $SiCl_4$ input, both for CVD and HPP, at high concentrations (see Fig. 5). A similar phenomenon is observed in the case of cold-wall CVD reactors also (10). At this time we cannot explain, with certainty, why the deposition enhancement by HPP is highest for lower concentrations, which is observed with all silicon sources. It may be due to a concentration-dependent gas phase nucleation phenomenon and/or transport properties.

Economic potential of HPP deposition.—Under conditions of high practical throughput rates, deposition efficiencies are higher for the HPP mode of operation compared to the CVD mode. With the reactor geometry used here an increase in efficiency of 4-5% was realized. This implies that the chlorosilane and hydrogen recovery system for the effluent gases would need a smaller capacity. Also, the amount of silicon deposited per unit time is about 15% higher for the HPP than the CVD mode, requiring fewer reactors for the same output. These savings should be considered along with the added expense for rf generators. Electrical energy requirements are believed to be approximately the same for HPP and CVD, since the energy input for HPP is found to go mostly toward reactant gas heating (1-4) with a corresponding reduction in electrical requirements for the resistance furnace. The type of silicon source could also influence the economics. When using SiH_2Cl_2, the HPP mode may not offer substantial advantages since the CVD mode has a high deposition efficiency also. Presently SiH_2Cl_2 is very expensive, compared to $SiHCl_3$ and $SiCl_4$, although this may change with new production methods currently being developed. Considering the increased deposition efficiencies and increased silicon deposited per unit time when using $SiCl_4$ and $SiHCl_3$ under high throughput conditions, the HPP mode offers economic advantages over CVD when the high effluent gas recovery costs are considered.

Conclusions

A high pressure plasma (HPP) deposition process, operating at a pressure of about 1 atm, has been characterized for its potential for producing polycrystalline silicon ribbons. Silicon tetrachloride, trichlorosilane, dichlorosilane, and silane have been examined as silicon source gases. Use of silane is found to be impractical due to excessive gas phase nucleation and powder growth. Improvements in deposition efficiencies were observed with HPP when using $SiCl_4$, $SiHCl_3$, or SiH_2Cl_2, compared to the CVD mode of operation. These improvements were found to be highest at lower reactant gas concentrations. In general, deposition efficiency dependence on reactant flow rate was found to be smaller for HPP compared to CVD. The observed results were discussed in terms of the thermodynamics of the Si-H-Cl system at plasma beam temperatures (~4000°C), operative deposition mechanisms, and the kinetic and transport processes in the reactor. Based on the observed results, it is believed that HPP deposition has economic advantages over CVD deposition for producing silicon ribbons from $SiCl_4$ and $SiHCl_3$ sources.

Chemical Characterization of Complex Oxide Products on Titanium-Enriched 310SS

A. S. Nagelberg* and R. W. Bradshaw*

Sandia National Laboratories, Exploratory Chemistry Division I, Livermore, California 94550

ABSTRACT

The phases present in the complex oxide scales formed on titanium-modified 310 stainless steel alloys after exposure to coal gasification atmospheres are described. The significant titanium concentrations in the inner Cr_2O_3 layer have been shown to arise from the substitution of titanium for chromium in the Cr_2O_3 due to the increased stability of Ti^{3+} at low oxygen partial pressures. In the absence of manganese, the external layer after a 100 hr exposure at 1255 K consists of TiO_2 and a cubic spinel phase. When manganese is present in the base alloy, $MnTiO_3$ is found instead of TiO_2. The absence of external sulfides on the surface of these alloys has been explained by the preferential formation of mixed oxides containing base metal elements.

The development of alloys that exhibit low corrosion rates is a critical problem in the reliability of coal gasifier internal components. The internal components are exposed to high pressure (0.7-1.0 MPa) and high temperature (1000-1300 K) environments. Typical gasifier atmospheres contain a mixture of hydrogen [15-50 mole percent (m/o)], water (15-40 m/o), carbon dioxide (4-20 m/o), carbon monoxide (5-15 m/o), methane (8-20 m/o), and hydrogen sulfide (0.03-1.0 m/o) (1). In these atmospheres at elevated temperatures, alloys tend to form rapidly growing oxide and sulfide scales.

The Ni-30Cr alloy group and 310 stainless steel alloys are representative of the nickel-base and iron-base alloys considered for use in coal gasifiers (2-4). Bradshaw and co-workers (5-7) have studied the effect of minor alloying additions on the corrosion resistance of these two alloys and have shown that titanium has a marked effect on improving corrosion resistance. Alloys without titanium additions were heavily sulfidized after a 100 hr exposure forming both external sulfides as well as internal sulfides at the scale-metal interface (Fig. 1). Titanium was found to preclude the formation of both external and internal sulfides in 100 hr exposures at 1255 K.

Titanium-containing alloys formed a complex scale after 100 hr (5, 7), as shown in Fig. 2, which contains only oxide phases. The 2-3 μm thick outer scale is titanium-rich and contains large amounts of manganese (when manganese is present in the base alloy). Below this outer scale is a 10-15 μm dense scale of Cr_2O_3 (Fig. 2) containing significant concentrations of titanium. Internal titanium oxides and silicon oxides (when silicon is present in the base alloy) are found within ~10 μm layer below the scale-metal interface.

* Electrochemical Society Active Member.

Key words: alloy, coal gasification, corrosion, oxidation.

At longer times (>300 hr), titanium sulfides appeared below the oxide scale and internal oxides.

In-depth investigations of the chemical composition of corrosion scales formed on the 310-base alloys with titanium additions are described in this paper. These investigations suggest possible explanations for the unexpectedly high titanium contents observed in the Cr_2O_3 scale and lack of sulfide formation at the gas-scale interface.

Experimental

Alloys examined in this study were developed by Bradshaw *et al.* (5, 7) for coal gasification applications. The alloys are based on 310 stainless steel (Fe-25Cr-20Ni) and a modified alloy that remains austenitic with the addition of 3 weight percent (w/o) titanium, (Fe-22Cr-23Ni-3Ti). Additions of titanium as well as the major impurities in 310 SS, manganese and silicon, were made to examine the effect of these constituents on corrosion behavior as previously discussed (7). The chemical composition of alloys used in this study is given in Table I. Subsequently, "modified alloy" refers to the composition Fe-22Cr-23Ni-3Ti, and any other additions are referred to in the text.

Alloy coupons were polished to 180 grit finish before exposure to the two different atmospheres given in Table II at 1255 K (1800°F) for up to 139 hr. The first atmosphere, high BTU, is representative of the gaseous species expected in a high BTU coal gasifier with the H_2S level at its expected upper extreme. The second atmosphere, simulated high BTU, reproduces the effective oxygen and sulfur partial pressures of the high BTU coal gasifier atmosphere at 1255 K without carbon-bearing species. Both atmospheres resulted in the formation of similar corrosion scales, and subsequently no distinction is made.

After exposure, oxidized sample surfaces were examined by x-ray diffraction analysis. Metallographic samples were first prepared by vapor depositing a flash of chromium or vanadium followed by gold before being plated with 1-2 mm of nickel. This coating procedure was required to avoid edge rounding and to retain the outer scale which was otherwise easily removed by metallographic polishing. After plating, the samples were sectioned and metallographically polished before examination by optical microscopy, scanning electron microscopy (SEM), and energy dispersive analysis (EDA). Several samples were further examined by electron microprobe analysis.

Temperature = 1255 K.
P_{O_2} and P_{S_2} represent values from equilibrium thermodynamic calculations at a total pressure of 1 atm.

Chromium oxide and titanium oxide powder mixtures were prepared for comparison with the diffraction patterns obtained from the scales formed on the alloys studied. Mixtures of powders containing TiO_2 to Cr_2O_3 mol ratios ranging from 0.075 to 7.0 were compacted in a ½ in. diam die and initially fired in air at 1625 K for 12 hr. A second firing was performed at 1300 K in an H_2/H_2O mixture of 1:1 for 30 days.

Results

X-ray diffraction results.—The presence of titanium in the alloys results in complicated x-ray diffraction spectra. The phases identified on the modified alloys are given in Table III. The scales on the modified alloy (Fe-22Cr-23Ni-3Ti) and the modified alloy containing silicon (Fe-22Cr-23Ni-0.5Si) were identified as consisting of Cr_2O_3, TiO_2 (rutile), a cubic spinel phase, and a mixed $Cr_2O_3 \cdot nTiO_2$ phase (8, 9). The lines observed for the $Cr_2O_3 \cdot nTiO_2$ phase after long exposures to the corrosion atmosphere are limited, but can be only identified with the shear structures reported by Anderson (8). X-ray diffraction patterns of mixtures of Cr_2O_3 and TiO_2 fired in the low P_{O_2} atmosphere exhibited similar diffraction patterns, indicating the presence of the $Cr_2O_3 \cdot nTiO_2$ phases where $n = 3, 4$, and 5.

X-ray diffraction patterns were significantly different for the alloys 1.5 w/o Mn (Fe-22Cr-23Ni-3Ti-1.5Mn and Fe-22Cr-23Ni-3Ti-1.5Mn-0.5Si). The manganese additions eliminated the diffraction lines associated with TiO_2 (rutile) and the $Cr_2O_3 \cdot nTiO_2$ phase, but lines identified with $MnTiO_3$ appeared. As observed in the other scales, Cr_2O_3 and a cubic spinel phase were identified.

Electron microprobe results.—Elemental profiles through the corrosion scales were determined by electron microprobe (EM) analysis and the results are shown in Fig. 3 and 4. The titanium content increases from 2 to 10 w/o as the metal-scale interface is approached. These titanium levels are greater than the reported solubilities in Cr_2O_3 ($\ll 1$ w/o) in established phase diagrams (8, 9).

An electron microprobe trace of the scale on a manganese-containing alloy, Fig. 4, indicated that the outer oxide scale was $MnTiO_3$ with the manganese and titanium weight proportions nearly equal (atomic weight of Cr = 52.0, Ti = 47.9). In addition, the concentration profiles showed that manganese tracked titanium exactly in the outer scale. The manganese content in the chromium-containing layer was less than the sensitivity of the microprobe for manganese, $\approx$0.01 w/o.

Discussion

The x-ray diffraction measurements showed that titanium enhanced the formation of complex oxides such as $MnTiO_3$ or the cubic spinels. A precise identification of the chemical constituents in the spinel phase is difficult due to the similarity of lattice parameters for mixed oxides of the metallic constit-

uents of the alloy (10). Both iron-chromium oxide ($FeCr_2O_4$) and iron-titanium oxide (Fe_2TiO_4) have spinel structures and the lattice parameters are similar, 8.377 and 8.535Å, respectively. The lattice parameters observed for the cubic spinel in the oxide scales on the modified alloys that do not contain manganese ranged from 8.45 to 8.49Å, suggesting the formation of a mixed iron-chromium-titanium oxide ($Fe_{1-x}Cr_{2(1+x)}Ti_xO_4$) with a spinel structure. When manganese was an alloy constituent, the intensities of the spinel diffraction peaks were enhanced. This very rapid diffusion of manganese through Cr_2O_3 scales has been previously observed (11). Manganese easily substitutes for iron forming the spinel structure compounds Mn_2TiO_4 and $MnCr_2O_4$ with lattice parameters of 8.679 and 8.437Å, respectively. Again, the spinel phase formed

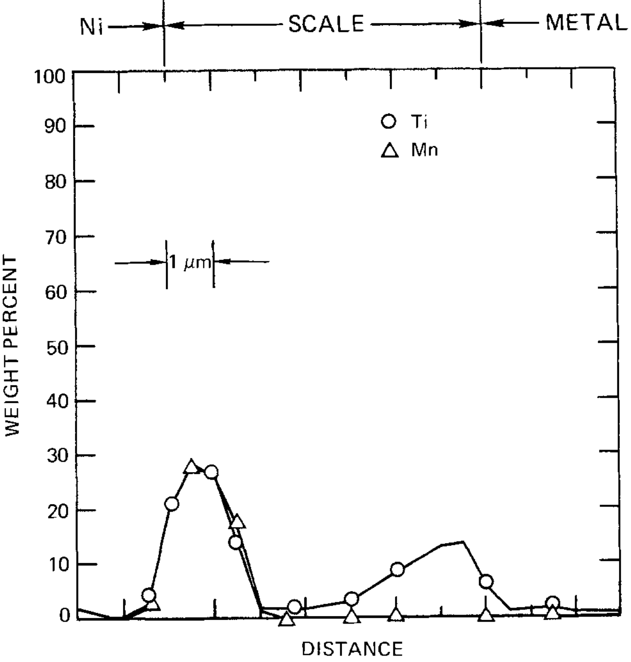

Fig. 4. Electron microprobe trace for titanium and manganese of Fe-22Cr-23Ni-3Ti-1.5Mn-0.5Si coupon exposed to high BTU atm for 100 hr at 1255 K.

can have a variable lattice parameter depending on Cr, Ti, Fe, and Mn contents, ($(Mn,Fe)_{1-x}Cr_{2(1+x)}Ti_xO_4$).

The solubility of titanium in Cr_2O_3 has been reported to be very low (8, 9), and such behavior is not unexpected since the substitution of a Ti^{4+} on a Cr^{3+} site requires the formation of one cationic vacancy for every three substituted titanium atoms. In the chromium oxide layers formed in this study, titanium concentrations as high as 10 w/o were observed. A possible explanation of the high titanium levels observed in this study is the formation of a mixed chromium-titanium oxide, $Cr_2O_3 \cdot TiO_2$. The composition of the chromium-rich mixed oxide phase at 1255 K is in dispute, being either $Cr_2O_3 \cdot 2TiO_2$ or $Cr_2O_3 \cdot 3TiO_2$ (8, 9). In any event, the titanium content for either phase is in excess of that observed, and if these phases were responsible for the high titanium levels observed, stronger x-ray diffraction peaks for those phases would be expected.

The reported phase diagrams were all generated at high oxygen partial pressures (8, 9), while the highest oxygen partial pressure experienced by the scale is $\sim 10^{-15}$ atm. It is in this oxygen pressure range between the gas atmosphere ($P_{O_2} \approx 10^{-15}$ atm) and the scale-metal interface ($P_{O_2} \approx 10^{-21}$ atm) at 1255 K that TiO_2 decomposes to Ti_3O_5 (12, 13) via a number of shear structures of the chemical formula Ti_nO_{2n-1} (14), as shown in Fig. 5. The shear structures are related to TiO_2 and form because additional titanium atoms can be accommodated in the TiO_2 lattice by a slight sliding of crystal planes. Further lowering of the P_{O_2} to $\sim 10^{-25}$ atm results in the formation of Ti_2O_3 at 1255 K. Both Ti_2O_3 and Cr_2O_3 have similar crystal structures. The similarity of the lattice parameters of Ti_2O_3 (a = 4.94Å, c = 13.659Å) and Cr_2O_3 (a = 4.954Å, c = 13.584Å) (13), and the size of Ti^{3+} (r = 0.76Å) and Cr^{3+} r = 0.63Å) ions (15), suggest the possibility that the high titanium level observed in the Cr_2O_3 scale is the result of an increased titanium solubility in Cr_2O_3 at low oxygen partial pressures. Obviously, an increase in the stability of Ti^{3+} would result at low P_{O_2}.

As a first approximation to estimate the titanium solubility, it was assumed that the substitution of titanium onto chromium sites in Cr_2O_3 is ideal. Applying Temkins rule (16), it is found that the activity of Ti_2O_3 is given by

$$a_{Ti_2O_3} = N_{Ti}^2 \quad [1]$$

where N_{Ti} is the fraction of cationic sites occupied by titanium atoms. A maximum value of $a_{Ti_2O_3}$ can be calculated as a function of P_{O_2} by considering the

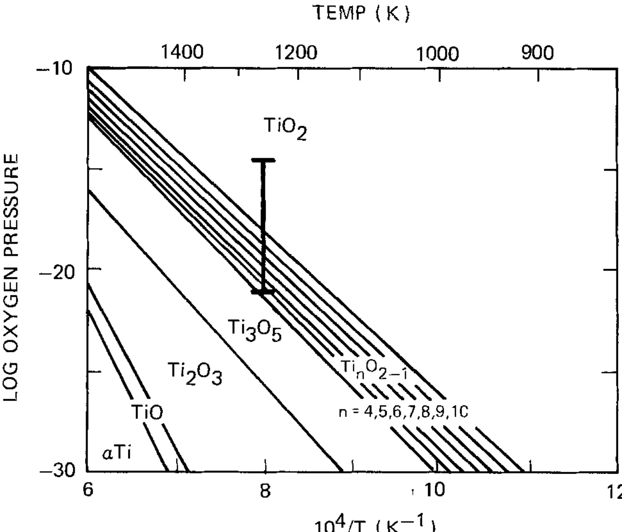

Fig. 5. Stability diagram for titanium oxides (12)

equilibrium

$$2Ti_nO_{2n-1} \rightleftharpoons nTi_2O_3 + \left(\frac{n}{2} - 1\right) O_2 \quad [2]$$

where n is determined by the stable phase at the selected P_{O_2} and temperature. For example, at 1225 K and $P_{O_2} = 10^{-20}$ atm, the stable titanium oxide is Ti_6O_{11} as can be seen in Fig. 5. At this oxygen pressure, Eq. [2] can be rewritten as

$$Ti_6O_{11} \rightleftharpoons 3Ti_2O_3 + O_2 \quad [3]$$

Obtaining the stabilities of the titanium oxides is a sequential process, since the stability of the oxygen-deficient oxide (Ti_nO_{2n-1}) is related to that of the oxygen-rich oxide ($Ti_{n+1}O_{2n+1}$). The stability (free energy of formation) of Ti_nO_{2n-1} was obtained by considering the P_{O_2} at which $Ti_{n+1}O_{2n+1}$ decomposes to Ti_nO_{2n-1} obtained from Fig. 5 and the known stability of TiO_2. The procedure produces stabilities for Ti_nO_{2n-1} in agreement with other sources (12, 13).

A value of the $a_{Ti_2O_3}$ in metastable equilibrium with Ti_6O_{11} at 1255 K and a P_{O_2} of 10^{-20} atm can be calculated using Eq. [4] and the calculated stability of Ti_6O_{11} (−4098 kJ/mol), where

$$\ln a_{Ti_2O_3} = \frac{\Delta G°_f(Ti_6O_{11}) - 3\Delta G°_f(Ti_2O_3)}{3RT} - \frac{1}{3} \ln P_{O_2} \quad [4]$$

A value of $\Delta G°_f(Ti_2O_3) = -1177$ kJ/mol was obtained from JANAF (17). This value of $a_{Ti_2O_3}$ at $P_{O_2} = 10^{-20}$ atm is 0.063. From Eq. [1] this is equivalent to a value of $N_{Ti} = 0.25$ in Cr_2O_3 saturated with titanium at $P_{O_2} = 10^{-20}$ atm or the chemical composition $Cr_{1.5}Ti_{0.5}O_3$. Values of N_{Ti} calculated by a similar procedure as a function of oxygen pressure are shown in Fig. 6.

An assumption about the spatial variation of oxygen chemical potential in the Cr_2O_3 scale must be made before a comparison of the calculated titanium contents with experimental results can be made. If it is assumed that a linear oxygen potential gradient exists within the Cr_2O_3 layer, the calculated curve of the Cr:Ti metal weight ratio shown in Fig. 7 can be compared to the experimental curve obtained from the EM concentration profiles. The use of the Cr:Ti weight ratio plot gives a sensitive technique to observe the oxide composition since the EM results are sensitive to surface irregularities in the cross-sectional polishing. The formalism of the Wagner theory for the oxidation of metals (18) requires that for a linear oxygen potential gradient to exist in the solid solution scale, the mobility of titanium and chromium must be equal. In addition, the requirement of a negligible oxygen partial pressure variation of chromium diffusivity in Cr_2O_3 has been shown (19). It is seen in Fig. 7 that the calculated and experimental curves exhibit similar curvatures and at no point does the experimental titanium concentration exceed the calculated saturation concentration. The close agreement makes it reasonable to assume that the high observed titanium levels are due to the substitution of Ti^{3+} for Cr^{3+} in the Cr_2O_3 lattice.

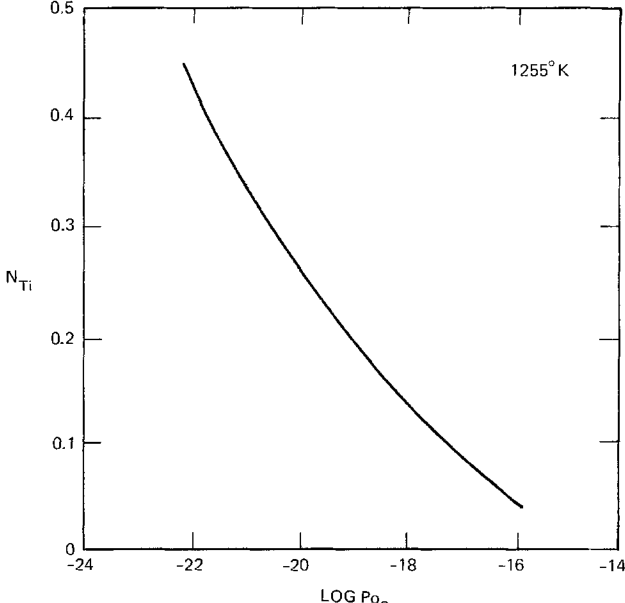

Fig. 6. Calculated variation of titanium cationic fraction (N_{Ti}) with oxygen partial pressure.

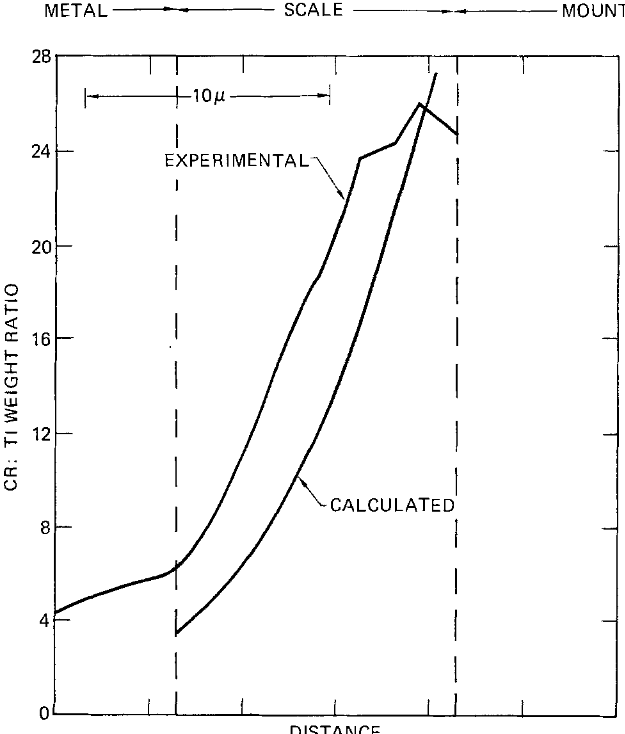

Fig. 7. Spatial variation of chromium to titanium weight ratio in Cr_2O_3 layer of Fe-22Cr-23Ni-3Ti-1.5Mn-0.5Si scale.

For chromium oxide forming alloys such as 310 type alloys, sulfide formation is supposed to occur by both the permeation of sulfur through the chromia layer to the base metal and migration of base metals to the external surface. Bradshaw (7) has discussed the possible causes for the apparent reduced permeation of sulfur through oxide scales on titanium-modified 310 alloys. A possible explanation of the role titanium plays in minimizing the formation of sulfides on the external surface is straightforward. The x-ray diffraction results indicated that the presence of titanium enhances the formation of complex oxides containing base metals that migrate to the external surface. The effect of the formation of a complex Fe-Ti oxide on the relative stability fields in an Ellingham diagram is shown in Fig. 8. Instead of the equilibrium of iron and its oxides being defined by the Fe-FeO equilibrium (solid line), it is defined by the Fe-$FeTiO_3$ equilibrium (11) (dashed line) in the presence of pure TiO_2. The transition moves the equilibrium oxygen partial pressure from 1×10^{-15} to 3×10^{-18} atm. The formation of an $FeTiO_3$ phase instead of FeO would also shift the line for oxide-sulfide equilibrium as shown by the dashed line in Fig. 8.

As seen in Fig. 8, the region containing the range of oxygen and sulfur partial pressures typical of the coal gasification process straddles the line represent-

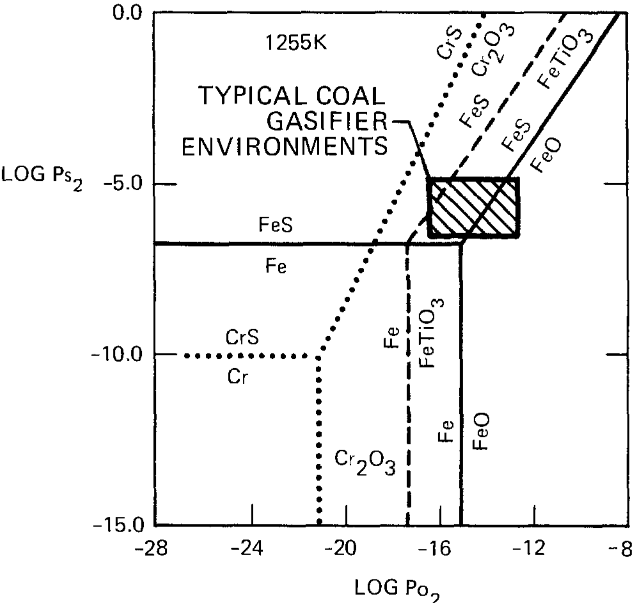

Fig. 8. Ellingham diagram for iron-sulfur-oxygen system at 1255 K. Dashed line indicates the changes that occur in the presence of TiO_2. The dotted lines represent the chromium-sulfur-oxygen system and are given for comparison.

ing the sulfide-oxide equilibrium when the formation of a complex oxide is not considered. However, all except the most severe atmospheres (log $P_{S_2} \gtrsim$ log P_{O_2} + 10.96) lie in the stability region for $FeTiO_3$. Thus any base metal that reaches the external surface is converted to a complex oxide instead of being converted to a molten sulfide. An exception is nickel which exists in 310 at an activity insufficient to form a pure nickel sulfide phase (20).

Summary

An explanation of the high titanium levels observed in the Cr_2O_3 scale formed on a titanium-modified 310 stainless steel by Bradshaw *et al.* (2) has been presented. Titanium in the form of Ti^{3+} is believed to substitute for chromium atoms in the Cr_2O_3 lattice. The observed increase in titanium solubility as the scale-metal interface is approached through the Cr_2O_3 layer has been shown to be caused by the incfeased Ti^{3+} stability as the oxygen partial pressure is decreased. The titanium levels and spatial variation can be explained by the formation of a solid solution of Ti_2O_3 in Cr_2O_3 at the reduced oxygen partial pressures present throughout the layer.

X-ray diffraction studies have indicated that the external layer formed on the titanium-modified alloys without manganese was a mixture of TiO_2 and a cubic spinel phase, $Fe_{1+x}Cr_{2(1-x)}Ti_xO_4$, with x being small. When manganese was present in the modified alloy, the external layer consisted of $MnTiO_3$ and a cubic spinel phase, probably $[(Mn,Fe)_{1+x}Cr_{2(1-x)}Ti_xO_4]$. The formation of complex oxides containing base metals which would otherwise tend to form sulfides in coal gasification atmospheres appears to be enhanced by the presence of titanium. The formation of complex oxides such as $MnTiO_3$ or $MnCr_2O_4$ effectively shifts the atmosphere, typical of the coal gasification process, from a region in the Fe-S-O Ellinghafn diagram that straddles the equilibrium between base metal sulfides and oxides to a region that solely allows the formation of oxides.

The Deposition of Silicon Films by Pyrolytic Decomposition of SiF_2 Gas

M. Janai, S. Aftergood, R. B. Weil, and B. Pratt
Department of Physics and Solid State Institute, Technion-Israel Institute of Technology, Haifa 32000, Israel

ABSTRACT

Production of silicon films by a silicon fluoride transport reaction is described here. The effect of various deposition parameters including temperature, partial pressure, and gas flow rate on the deposition kinetics was investigated. X-ray analysis, surface electron spectroscopy, optical absorbance and reflectance, and electrical measurements indicate that the films have properties similar to those of silicon films obtained by CVD from silane.

The silicon fluoride transport reaction has been suggested by Wolf *et al.* as a low cost purification process of metallurgical-grade silicon. Combined with a simultaneous on-line CVD process the method can be used for the production of silicon sheets for photovoltaic solar cell arrays (1, 2). The purification capability of this process has been further investigated by Ingle *et al.* (3). The process makes use of the cyclic reaction sequence

$$\mathrm{Si(solid)} + \mathrm{SiF_4(gas)} \xrightarrow{T_1} \mathrm{2SiF_2(gas)} \qquad [1a]$$

$$\mathrm{2SiF_2(gas)} \xrightarrow{T_2} \mathrm{Si(solid)} + \mathrm{SiF_4(gas)} \qquad [1b]$$

T_1 is a temperature above 1100°C and T_2 is in the range of 450°-850°C. In a complete cycle of the process the SiF_4 gas reacts with silicon at temperature T_1 to yield SiF_2, which in turn decomposes on a substrate held at temperature T_2, resulting in the deposition of a solid silicon film and the release of SiF_4 gas. The SiF_4 is circulated in the system in a closed loop. The purification potential of the process results from the preferential reaction of SiF_4 with the silicon rather than with its impurities at the temperature T_1, and from the higher condensation temperature of the metalfluoride impurities which may be formed in the high temperature zone (1-3).

We have studied the above transport reaction for its thin film deposition capability, with pure solid silicon as the starting material. This process may be useful in polysilicon deposition for microelectronics purposes since deposition takes place even at the relatively low temperature of 550°C and the films have high specular reflectance, which is desirable for photolithographic processing. Films deposited at 550°C, however, are amorphous and for some applications might have to be annealed at a higher temperature for a short period of time to increase the charge carrier mobility. A further advantage of the CVD process utilizing the silicon fluoride transport reaction is that oxygen leaking into the system may be easily adsorbed on an appropriate getter, as discussed below. In the silicon fluoride transport process the SiF_4 may be cycled again and again through the deposition in cost savings.

We have reported previously (5) on a deposition system where SiF_2 is transported from the high temperature zone to the substrate without going through an intermediate zone with a temperature lower than that of the substrate. In the present work we have studied a deposition system where the gas is quenched down to room temperature at the exit of the high temperature zone (T_1) and is transported at room temperature to the substrate, which is held at temperature T_2. The effect of various deposition parameters on the deposition kinetics and the properties of the resultant film are described below.

Key words: thin films, amorphous Si:F, polymerization, CVD kinetics.

System Description

The deposition system is schematically depicted in Fig. 1. About 200 silicon cubes 2.5 mm on edge each were cut from a Czochralski grown silicon single crystal. The cubes were held in a vertical quartz tube which was mounted in a resistively heated furnace. The temperature of the silicon (T_1) was monitored by an external thermocouple. The temperature of the silicon cubes was between 0° and 20°C higher than the reading of the external thermocouple, depending on the height level of the silicon in the column. The walls of the tube at the exit of the furnace were cooled, forming a temperature gradient of approximately 200°C/cm between 1000° and 100°C in the gas.

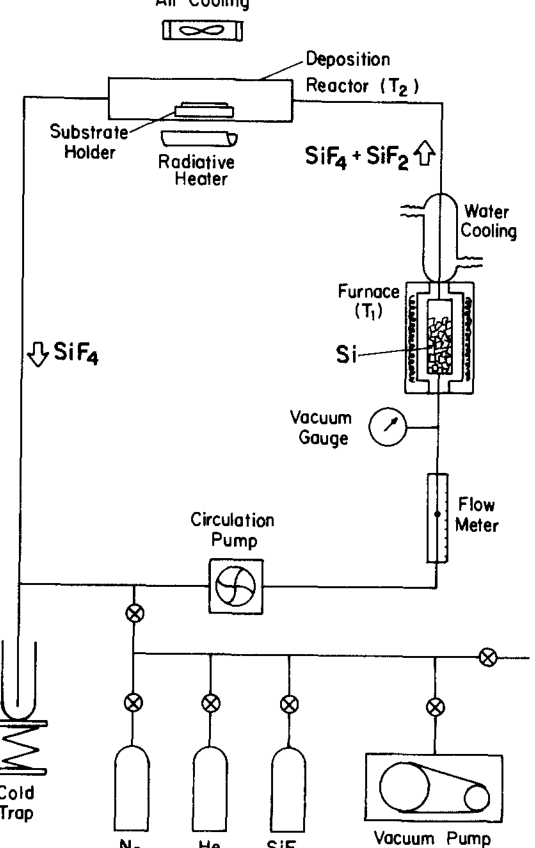

Fig. 1. Schematic illustration of the deposition system

The gas was transported from the high temperature zone to the deposition zone in a 70 cm long glass tube. The substrates in the deposition zone were supported on a radiatively heated graphite holder, placed in a horizontal quartz tube 45 mm in diameter. The walls of the deposition reactor were air-cooled. The temperature gradient over the deposition region was less than 1°C/cm. A Dia-Vac™ pump was used to circulate the gas in the system. A Matheson Model 603 ball type flowmeter monitored the gas flow rate. The total volume of the system was approximately 1.5 liters.

In a typical deposition cycle the silicon cubes were rinsed in HF acid to remove any oxide layer. The silicon cubes were placed in the quartz tube and the system was pumped, purged with nitrogen and helium, and again pumped down to a vacuum of 0.05 Torr. The pump was turned off and SiF_4 from an external tank was admitted into the system until the desired SiF_4 initial pressure was achieved. The SiF_4 was then solidified in a liquid-air trap inside the system. Once the SiF_4 completely solidified the heaters were turned on and the system was pumped again to remove any volatile species. Once the temperatures T_1 and T_2 had stabilized the vacuum pump was disconnected, the SiF_4 was re-evaporated into the system, and the circulation pump was turned on. The pressure in the hot system was usually 7% higher than the SiF_4 initial pressure of the room temperature system. In a typical deposition cycle (*e.g.*, sample E-14) we used the following deposition parameters: SiF_4 initial pressure = 80 Torr, T_1 = 1100°C, T_2 = 600°C, and flow rate 0.3 mol/hr. No carrier gas was used. Unless otherwise specified, each deposition run lasted 30 min. At the end of each deposition run the SiF_4 gas was returned to the storage tank by refreezing it. The SiF_4 pressure in the system and the silicon weight were determined before and after the deposition.

Fused silica substrates were used in most depositions. The gas source was Matheson 99.7% purity SiF_4 (6). As indicated above, the gas was further purified by freezing it to 77 K and pumping off the volatile species.

Effect of Deposition Parameters on Deposition Kinetics

Experimental.—The thickness of the films was routinely determined from their reflectance traces in an infrared spectrophotometer by the interference fringes method (7). For the calibration of these measurements we determined first the wavelength dependence of the refractive index, $n(\lambda)$, of one of our samples whose thickness was determined with an interference microscope. This refractive index was used in turn to calculate the thickness of all other samples according to

$$d = \frac{N \cdot \lambda_N}{2n(\lambda_N)} \qquad (N = 1,2,\ldots)$$

where d is the film thickness, N is the order of the reflectance minima, and λ_N is the wavelength of the minima of order N.

Thickness uniformity.—The uniformity of the film thickness was found to depend mostly on the method of cooling the walls of the deposition reactor, probably due to its effect on convection currents in the gas. Under usual deposition conditions the film thickness uniformity was better than 1%/cm perpendicular to the gas flow direction, and monotonically decreasing at about 4%/cm over an 8 cm long sample parallel to the gas flow direction. The latter effect was probably associated with the depletion of SiF_2 from the gas along the direction of flow. In the experiments reported below we used 1 cm² samples placed reproducibly on the substrate holder about 3 cm from its leading edge.

Time dependence of film thickness.—Figure 2 shows the dependence of the sample thickness on the deposition time for periods between 20 and 60 min. The linear curve which passes through the origin indicates that the deposition rate is constant with time. It implies that any time-dependent variables in the deposition system (such as the SiF_2 and SiF_4 partial pressures) either reach their steady-state values quickly relative to our deposition time scale, or their time-dependent effect on the variation of the deposition rate is negligible.

Reaction temperature (T_1).—The temperature T_1 was varied between 1060° and 1200°C. Figure 3 shows a semilog plot of the film thickness deposited in 30 min *vs.* the reciprocal of temperature T_1. For temperatures lower than 1060°C the deposited layer was too thin to be measured by our optical technique. We did not exceed 1200°C because of material limitations imposed by the quartz tube. As shown below, the deposition rate is proportional to the SiF_2 generation rate, so that Fig. 3 indicates a generation rate activation energy of 54 ± 4 kcal/mol (2.3 ± 0.2 eV).

Deposition temperature (T_2).—The temperature T_2 was varied between 475° and 675°C. Figure 4 shows a semilog plot of the 30 min deposition thickness *vs.* reciprocal substrate temperature. Below 550°C the deposition rate increased with temperature with an ac-

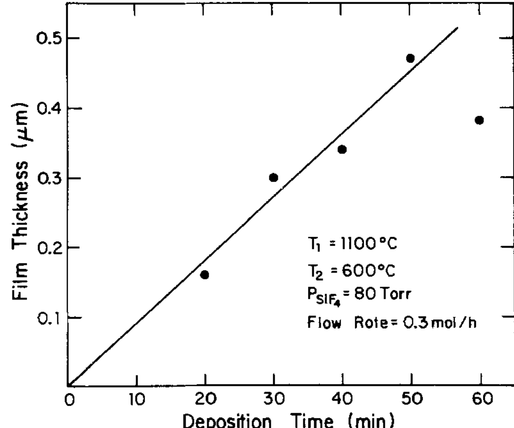

Fig. 2. Dependence of the deposited silicon film thickness on the deposition time.

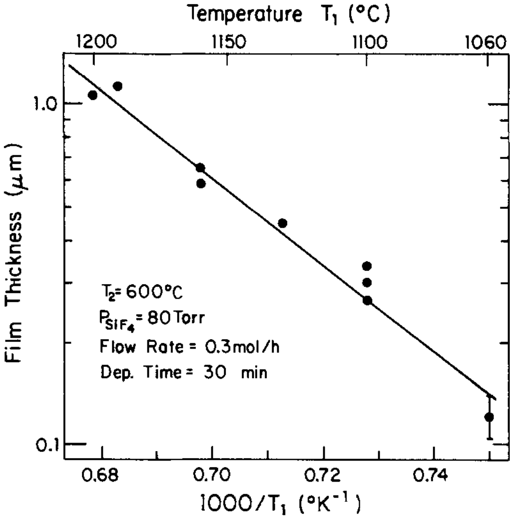

Fig. 3. Dependence of the deposition rate on the temperature of the reactor in which SiF_2 is formed.

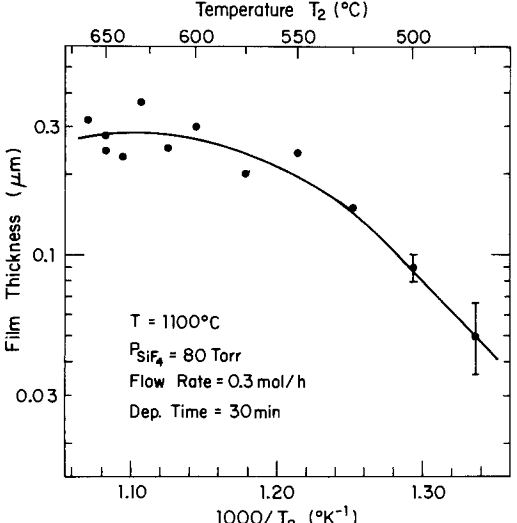

Fig. 4. Dependence of the deposition rate on the substrate temperature.

tivation energy of 29.0 ± 1.5 kcal/mol (1.26 eV). The maximum deposition rate was achieved around a substrate temperature of 620°C, and was almost constant over the temperature range 600°-675°C. Depositions made with a different setup (5) indicated that above 675°C the deposition rate decreases with temperature, and above 900°C no silicon deposition could be detected even after extended deposition periods.

Flow rate.—The gas flow rate (measured in units of moles per unit time) was determined from a calibration curve of the 603 flowmeter for SiF_4 under standard conditions (760 Torr, 21°C) by multiplying the standard flow rate by $(P/760)^{1/2}$ where P is the system pressure in Torr. As shown below, under most deposition conditions the molar fraction of SiF_2 in the system was small, particularly in the section of the system following the deposition reactor. Since the flowmeter was mounted after the deposition reactor the monitored flow was practically that of the SiF_4 alone. Figure 5 shows the dependence of the deposition rate on the gas flow rate for flow values between 0.18 and 0.63 mol/hr. As seen from the figure, in this range the deposition rate increases linearly with flow rate.

Pressure.—Since the molar fraction of SiF_2 in the system was relatively low the total pressure of the system was approximately the partial pressure of the SiF_4 gas. Depositions were made with SiF_4 initial pressures between 70 and 220 Torr. In these experiments we kept the setting of the ball of the flowmeter at a constant height for all pressures. Under these conditions (8)

$$\rho\nu^2 = \text{constant} \quad [2]$$

where ρ is the density of the gas in the system in units of mass per unit volume (or moles SiF_4 per unit volume) and ν is the gas flow velocity in units of volume per unit time. From Eq. [2] we obtain that

$$\nu = A \cdot \rho^{-1/2} \simeq A \cdot 135 \cdot P^{-1/2} \quad [3]$$

and

$$\text{flow rate} = \nu \cdot \rho \simeq A \cdot P^{1/2}/135 \quad [4]$$

where P is the initial pressure in Torr in the room temperature system, ρ,ν, and the flow rate are given in units of mol/liter, liters/hr, and mol/hr, respectively, and A is a system constant obtained experimentally by multiplying ν by $\rho^{1/2}$, and it depends on the setting of the flowmeter. The constant 135 is the square root of the standard pressure (760 Torr) times the specific volume of SiF_4 at room temperature at 760 Torr (24.08 liter/mol) (6). Under the condition of Eq. [2], we observed no difference in deposition rate for the various SiF_4 initial pressures. For $A^2 = 21$ mol · liter/hr^2, we obtained a deposition rate of 0.32 ± 0.03 μm per 30 min deposition or 1.8 ± 0.2 Å/sec (see Fig. 6, left scale).

During depositions, which all started with given initial SiF_4 pressures, a pressure drop varying between 5 and 40% was observed. This pressure drop was nearly linear with deposition rate with varying T_1. The pressure drop ΔP for experiments with various initial SiF_4 pressures, at constant T_1 and $\rho\nu^2$, is shown in Fig. 6 (right scale). From the slope in Fig. 6 and the deposition parameters given in the figure one gets a pressure drop $\Delta P/P = 12\%$. It can be seen that the absolute pressure drop was linear with the initial pressure, for a constant $\rho\nu^2$ value, while under the same conditions the deposited film thickness was independent of the pressure. (The scatter of the experimental results probably reflects the degree of control we had on the parameter $A^2 = \rho\nu^2$ and on the system temperatures in the various depositions.) From the above considerations we obtain the empirical relation

$$\Delta P/P = B(T) \cdot f(\rho\nu^2) \cdot \Delta t \quad [5]$$

where B is a constant depending on the system temperatures, Δt is the deposition time, and f is a function of the parameter $\rho\nu^2$, determined by the kinetics of the

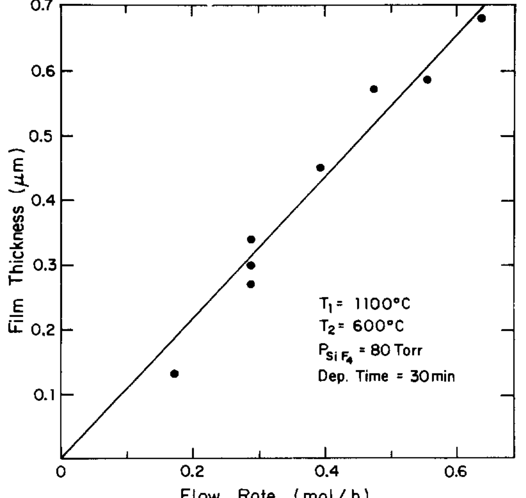

Fig. 5. Dependence of the deposition rate on the SiF_4 gas flow rate for a constant pressure of SiF_4 in the system.

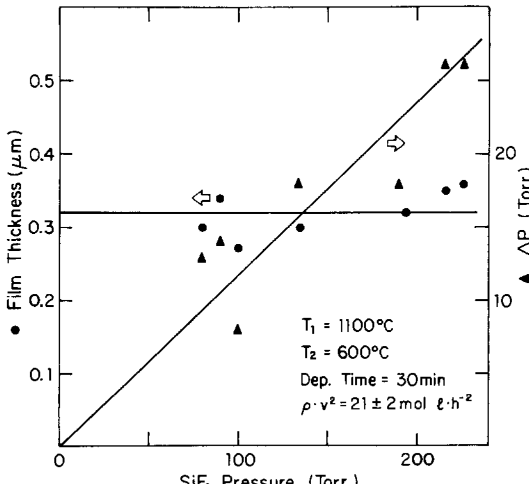

Fig. 6. Dependence of the deposition rate (●, left scale) and the pressure drop in the system during a 30 min deposition (▲, right scale) as a function of the initial pressure in the system.

mechanism causing the pressure drop. From measurements of ΔP under constant initial P and varying flow rates we obtained $\Delta P \propto \nu^{1.8\pm0.3}$ which suggests that in Eq. 5, $f(\rho\nu^2) = \rho\nu^2$. The probable reason for the pressure drop has been identified as condensation of SiF_2 molecules in the form of $(SiF_x)_n$ polymers on the water-cooled walls of the tube following the high temperature zone (9). In Table I the results of two similar deposition runs—one with, and one without water-cooled walls—are given. The original reason for water cooling the walls at the exit of the high temperature zone was to reduce the length of the tube section over which the wall temperature was between 450° and 900°C, thus limiting the back-reaction given by Eq. [1b] in the unwanted sections of the system. The results shown in Table I demonstrate, however, that with no water cooling, where the tube walls were heated to 100° ~300°C by the hot gas flow, polymerization was significantly reduced and the deposition rate was increased. As seen from the table, without water cooling the percentage pressure drop was reduced by a factor of 4, and the deposition rate was increased by a factor of 1.8. The pressure drop in depositions E-44 and E-45 implies a loss of 11×10^{-4} and 2.5×10^{-4} mol of SiF_4 from the gas, respectively. Assuming (9) that the majority of the polymerization is of the form $(SiF_2)_n$, this SiF_4 gas loss is equivalent to the removal of an equal number of mols of silicon transported from the high temperature zone, *i.e.*, 31 and 7.7 mg silicon, respectively. The loss of the transported silicon due to polymerization is significant in view of the fact that the total silicon weight deposited on the substrate and substrate holder in these two depositions was only 6.8 and 12.4 mg, respectively.

Other observations.—A direct correlation between the total silicon mass tranport, as measured by the loss of silicon weight in the high temperature reaction zone during a deposition, and the thickness of the deposited film was observed. The weight loss in a typical deposition run (*e.g.*, in deposition E-14) was 120 mg. However, only approximately 3% of the transported silicon coated the substrate and substrate holder in that deposition experiment. From the observed value of ΔP we know that 13% of the transported silicon was lost in condensation of $(SiF_2)_n$ polymers. The rest of the transported silicon appeared as deposits on the walls of the tube at the exit of the high temperature zone where the temperature was in the range of 450°-900°C. Silicon deposits were observed also on the walls of the deposition reactor. A thin silicon deposit was also observed on the hot wall at the entrance to the high temperature reactor, probably due to SiF_2 which did not decompose in the deposition zone and so completed a full cycle in the system. This happened particularly with low substrate temperature depositions. A full flow cycle in the system at F.R. = 0.3 mol/hr took 1.25 min, which sets a lower limit on the lifetime of the SiF_2 molecule in the gas.

The diffuse part of the reflectance of the films deposited below $T_2 = 700°C$ was equal to or lower than that of silicon films deposited from silane. During deposition, under intense illumination of the gas

white smoke could be observed, probably arising from $(SiF_2)_n$ long polymer chains swept along by the gas stream. This smoke was minimized by water cooling the tube between the high temperature reactor and the deposition reactor. However, the presence of this smoke did not affect the smoothness of the deposited silicon films. In fact, the smoothness of the films was so high that it was difficult to focus the beam of a scanning electron microscope on the sample surface because of lack of features.

After some depositions, a thin oxide layer could be observed on the silicon cubes at the bottom of the silicon column in the high temperature reactor. By weighing the silicon at the end of each deposition run before and after rinsing it in HF acid we estimate a a typical oxidation rate of 2 mg SiO_2 per deposition cycle, which is equivalent to an oxygen leak of 4.5×10^{-5} mol per deposition cycle. No other effects of this oxygen leak (or outgassing) could be observed in the system and in particular no oxygen was observed in the deposited films. In view of the fact that there was no outlet for this gas during the deposition we conclude that the lower section of the silicon column in the flow system acts as a getter to remove oxygen from the circulating gas.

Discussion of Deposition Kinetics Experimental Results

Our results for depositions at $T_2 > 550°C$ are consistent with the assumption that the rate-limiting process of the transport reaction is the conversion of SiF_4 into SiF_2 in the high temperature zone (2). In the high temperature reaction zone equilibrium conditions prevail and the reaction there can be written as

$$Si(s) + SiF_4(g) \rightleftarrows 2SiF_2(g)$$

$Kp(T)$, the pressure equilibrium constant of the reaction, is given by

$$Kp(T) = P_{SiF_2}{}^2/P_{SiF_4} \quad [6]$$

where P_{SiF_2} and P_{SiF_4} are the partial pressures of the SiF_2 and SiF_4 gases, respectively. Out of each mol of SiF_4 entering the high temperature reaction zone, a fraction α is converted into pairs of SiF_2 molecules. The partial pressures in the high temperature reactor can be written as

$$P_{SiF_4} = [(1-\alpha)/(1+\alpha)] \cdot P \quad [7a]$$

and

$$P_{SiF_2} = [2\alpha/(1+\alpha)] \cdot P \quad [7b]$$

where P is the sum of the partial pressures $P_{SiF_4} + P_{SiF_2}$. In terms of α, the pressure equilibrium constant can be written as

$$Kp(T) = 4\alpha^2 P/(1-\alpha^2) \quad [8]$$

which for small values of α gives

$$\alpha \cong (Kp(T)/4P)^{1/2} \quad [9]$$

The experimental value of α can be obtained by dividing the total number of transported silicon mols per deposition run by the total number of SiF_4 mols that flowed through the reactor. Equation [9] predicts that under equilibrium conditions in the high temperature reactor α will be proportional to the inverse square root of P, and will be temperature activated with half the activation energy of $Kp(T)$. Fitting the results of our weight-loss measurements to the functional dependence given by Eq. [9] we obtain

$$\alpha = [1.15 \times 10^8/P^{1/2}] \cdot \exp(-E/RT_1) \quad [10]$$

where $E = 54 \pm 4$ kcal/mol, $R = 1.987 \times 10^{-3}$ kcal/mol · K, T_1 is the temperature in K, and P is given in Torr. The highest value of α in our experimental regime, $\alpha \simeq 0.13$, was obtained for $T_1 = 1473$ K and

$P = 80$ Torr. In most of the depositions α was less than 0.1, which justifies the approximation $\alpha << 1$ made in Eq. [9], and the assumptions made above regarding the monitoring of the total pressure and the flow rate. We found the value of α to be independent of the flow rate, which justifies the assumption of equilibrium conditions at the high temperature reactor under our experimental conditions. Equilibrium at the high temperature reactor may be maintained as long as the flow velocity of the gas through the reactor is slow relative to the length of the silicon column divided by the reaction rate.

As indicated above, the rate-limiting process was found to be the reaction in the high temperature (T_1) zone. It is thus consistent to assume that the deposition rate is proportional to the number of SiF_2 molecules arriving at the deposition reactor per unit time, which is proportional to the value of α times the SiF_4 flow rate. Indeed, as can be seen from Fig. 5, it was found that the deposition rate is linear with the flow rate. In the experiments in which we varied the total pressure and kept the value of $\rho\nu^2$ constant, the flow rate was proportional to $P^{1/2}$ (Eq. [4]) and, since α is proportional to $P^{1/2}$ (Eq. [9)], the deposition rate is expected to be independent of P, as was observed (Fig. 6). From these results we also conclude that under a constant flow velocity (in units of volume per unit time) the deposition rate should increase with the square root of the SiF_4 pressure, and under constant flow rate (in mols per unit time) the deposition rate should vary as the inverse square root of the pressure.

As for the polymerization dynamics, it is recalled that under constant P and ν the temperature (T_1) dependence of $\Delta P/\Delta t$ scaled linearly with the deposition rate. This implies a linear dependence of $\Delta P/\Delta t$ on α, that is, on the partial pressure of SiF_2 in the system. This would be consistent with a monomolecular production mechanism for $(SiF_2)_n$ polymers. On the other hand, from measurements of the dependence of $\Delta P/\Delta t$ on the flow rate and on the total pressure, it was found that $\Delta P/\Delta t$ is proportional to $\rho\nu^2 \cdot P$, which in turn is proportional to $P^2 \cdot \nu^2$ (see Fig. 6 and Eq. [5]). This implies that $\Delta P/\Delta t$ is proportional to $P^{3/2} \cdot \nu^2$ after one takes out the monomolecular reaction dependence on αP. This higher order pressure dependence of $\Delta P/\Delta t$ may imply that the pressure of SiF_4 at the polymerization sites enhances the $(SiF_2)_n$ polymerization rate. The mechanism for the observed pressure and velocity dependence of the polymerization kinetics still remains to be explained.

Film Properties

The optical transmittance and reflectance of the films were measured with Beckman Models ACTA MVII and IR 4250 spectrophotometers. From these measurements the refractive index and the absorption coefficient were derived. Within experimental accuracy these results are identical to previously published results on CVD silicon deposited below 675°C from silane (10).

The optical properties of all films deposited below 675°C were identical. Debye-Scherrer x-ray diffraction analysis of films deposited in another reactor (5) indicated that films deposited between 700° and 900°C are polycrystalline, while below 700°C the films are amorphous, as indicated by the broad diffraction halos and indistinguishable second and third rings in the diffraction patterns. At deposition temperatures between 850° and 900°C a thin yellow powdery deposition was observed. No deposition could be observed above 900°C. The room temperature electrical resistivity of the films deposited below 700°C was 2×10^5 $\Omega \cdot$ cm. From photoconductivity measurements a carrier lifetime of the order of 10^{-10} sec is estimated, assuming a mobility of 1 cm^2/V sec. The results of the electrical, optical, and ESR measurements of these films were published elsewhere and they are characteristic of anneal-stable amorphous silicon films (5).

Impurities in the films have been studied by surface electron spectroscopy (Auger and XPS) with a PHI system Model 590A and 555. Depth profiling Auger spectroscopy under Ar^+ sputter etching showed 99.6 ± 4% purity silicon. Oxygen and carbon signals could not be observed within a detectability limit of 0.2 a/o XPS (x-ray photoelectron spectroscopy) confirmed these results regarding oxygen and carbon, but it showed about 0.6 a/o fluorine in the film. The fluorine in the film. The fluorine concentration in the film has been further studied by the nuclear reaction $^{19}F(P,\alpha)^{16}O^*$, as described previously (5). This technique was found to have a resolution of 50 ppm with our counting times. The results showed a concentration between 0.5 and 1.5 a/o fluorine, depending on the substrate temperature during deposition (5). The reason we were not able to detect this fluorine by Auger depth profiling and got smaller values in XPS than with the ion implantation system is probably because the fluorine in the samples is in the form of SiF_4 gaseous molecules which were trapped in the film during deposition. During depth profiling sputter etching these molecules are freed and pumped out of the electron spectrometer, so they could not be detected by the Auger technique which is sensitive only to the composition of the first two or three monolayers of the film. The XPS technique probes at a depth of approximately 20Å, while the nuclear reaction probed the fluorine concentration at a depth of 500Å below the surface, where the SiF_4 molecules can be found. This point has recently been supported by infrared spectroscopy associated with Auger spectroscopy measurements (11). These silicon fluoride molecules were found to be electronically inactive, and there is evidence that when the sample is anneal crystallized at 800°C they leave the film (3, 11).

In summary, we have demonstrated a new deposition method of silicon films from SiF_2 vapor. Deposition temperature can be as low as 550°C with acceptable deposition rates. The properties of the films were found to be similar to the properties of silicon films prepared in the same temperature range by CVD from silane. The transport reaction given by Eq. [1] was studied and the fractional conversion of SiF_4 into SiF_2 at equilibrium at temperatures above 1060°C was deduced. This transport reaction can also be used in conjunction with glow discharge deposition system of fluorinated amorphous silicon (a-Si:F) where the SiF_2 decomposition is assisted by an electric field. This approach is currently being investigated in our laboratory.

ABSTRACT

Surface photovoltage spectroscopy was successfully applied to silicon-on-sapphire and it enables simultaneous determination of band structure, trapping centers, deep levels, the refractive index, and the film thickness. Studies of "as-grown" and ion-implanted films revealed a noticeable degree of amorphization manifested by 1.45 eV energy gap structure clearly resolved in addition to standard 1.1 eV structure of bulk Si. Three deep levels were identified, *i.e.*, electron trap at $E_c - E_t = 0.25$ eV, hole trap at $E_t - E_v = 0.15$ eV, and deep centers at $E_c - E_t = 0.6$ eV. It has been found that the degree of amorphization and concentration of deep centers in the layers depends on the thermal history of the SOS film.

Rapidly growing need for high speed, radiation resistance CMOS memories and microprocessors with large capacity and high packing density puts new demands on SOS technology. One of the factors which can limit circuit performance is the presence of deep levels in the silicon-on-sapphire. Deep levels acting as traps can decrease speed, shift threshold voltage, and/or cause excessive junction leakage of transistors in the circuit. A nonuniform distribution of deep centers across a wafer can result in nonuniform yield and circuit performance on the wafer. These facts emphasize the importance of developing methods to experimentally assess the sources of deep centers in as-grown layers and processed silicon films.

Techniques for the characterization of heteroepitaxial silicon have been reviewed by Ham (1). Most of these methods rely on the measurement of test structures on processed wafers or on resistivity and capacitance measurements on as-grown films. Recently a u.v. reflectance method has been developed which allows quantitative characterization of the crystallinity in SOS films (2). These techniques have been designed as effective and practical tools for establishing screening criteria to inspect the quality of as-grown wafers used for fabrication of device structures. They do not provide direct information about deep levels in SOS films.

Previous studies of polycrystalline and amorphous silicon and of dislocation structures in elemental semiconductors have demonstrated the promising character of photoelectric measurements in assessing the electronic and optical properties of silicon, and in identifying the mechanisms of phenomena related to defects and disorder (3-5). The photovoltage spectroscopy technique selected for the present study is rather specific among photoelectric effects as it permits the measurement of bulk material as well as the conducting or high resistivity films on insulating or metallic substrates (6-8). Furthermore, this technique does not require ohmic contacts, and if necessary it can be utilized in a nondestructive, contactless, configuration employing capacitive coupling to the sample. Therefore, as-grown wafers and wafers after different processing steps can be analyzed without the fabrication of test structures. Also a light spot can be easily focused to a small area which permits the characterization of defect distribution on a microscale.

This investigation has been undertaken to assess the feasibility of using photovoltage measurements for characterization of defects in SOS. Information concerning the deep states (their energy levels and relaxation time) and the basic parameters of SOS layers (the band structure, the film thickness, and the refractive index) were obtained from the spectral, transient, and temperature dependence of the photovoltage. The measurements performed on layers after different stages of processing (as-grown, ion-implanted, and heat-treated) show that the photovoltage technique is able to detect a variety of defect structures in SOS films.

Experimental

In the present study the photovoltage generated by a monochromatic light (energy range 0.5-3.5 eV) was measured with respect to a semitransparent gold electrode separated from the SOS film by a 10 μm thick Myler foil (MIS configuration) or directly evaporated on SOS film (MS configuration).

* Electrochemical Society Active Member.
Key words: defects, amorphous, silicon-on-sapphire, surface photovoltage.

As shown schematically in Fig. 1, the measurements of chopped light a-c photovoltage were performed using lock-in detection, while the photovoltage transient was measured with a signal averager. The SOS wafers were placed on the cold finger of a variable temperature cryostat. This provides the capability to precisely adjust the sample temperature in a range from 10 to 300 K.

The illumination intensity was selected on a level sufficiently low that the generated photovoltage (of the magnitude between 10^{-7} and 5×10^{-3}V) satisfied "low signal" conditions (*i.e.*, $|\Delta V| << kT/q$).

In order to separate possible surface state effects, the photovoltage spectra were measured in various ambients (room atmosphere, $N_2 + H_2O$, vacuum 10^{-6} Torr). Furthermore, comparative studies were carried out on the same films utilizing both the MIS and MS configurations. It is concluded, on the basis of these studies, that the surface has a negligible effect on the photovoltage spectra up to the energy of about 2.5 eV. The surface sensitive effects for higher photon energy are most likely related to the enhanced role of surface recombination ($\alpha d > 1$ where α is the absorption coefficient and d is the film thickness).

A typical photovoltage spectrum of an SOS film is schematically represented in Fig. 2. In the subbandgap region ($h\nu < E_g$) the photovoltage is due to photoionization or photothermoionization transitions involving deep levels. Accordingly, it can be used to judge the effect of growth and processing parameters on deep level characteristics. For $h\nu > E_g$ (intrinsic excitation)

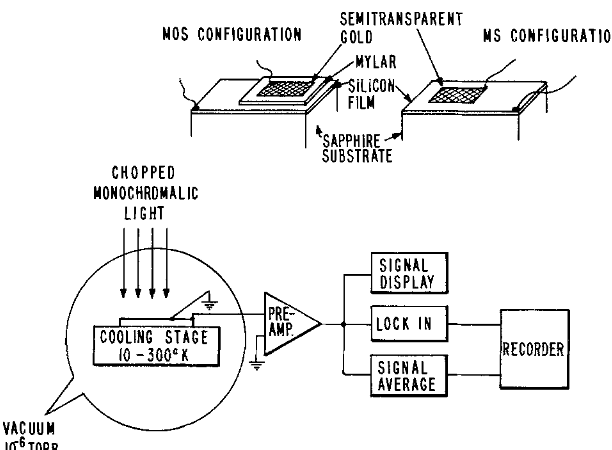

Fig. 1. Experimental arrangement for photovoltage measurement and sample configuration.

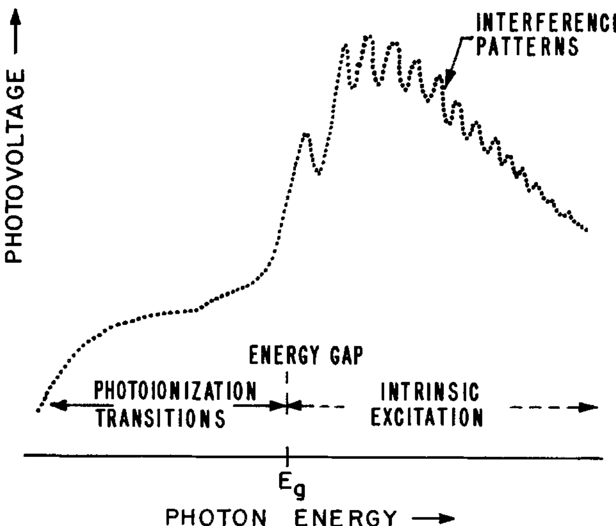

Fig. 2. Schematic representation of photovoltage spectra of silicon-on-sapphire films.

the photovoltage is due to photogenerated electron hole pairs. In comparison with bulk material, thin film photovoltage exhibits a specific feature, *i.e.*, a series of interference maxima occurring at wavelengths $\lambda_k = 2nd/k$; where $k = 1, 2, 3, \ldots$; n is the refractive index dependent on energy); and d is the film thickness.

Photovoltage transient measurements were also carried out in order to determine the lifetime of excess carriers and/or trapping characteristics. It has been found that the photovoltage transient of SOS films is dominated by trapping of excess carriers rather than by recombination transitions. This provides the possibility to determine the energy levels of trapping centers from the temperature dependence of photovoltage relaxation time.

The results discussed were obtained with SOS samples listed in Table I.

Results and Discussions

Band structure transitions.—The room temperature photovoltage spectra of silicon-on-sapphire films for photon energy corresponding to intrinsic excitation are presented in Fig. 3. The first and very pronounced increase of photovoltage occurs in the vicinity of the energy gap (E_g) of bulk Si. However, the second photovoltage increase for photon energy $h\nu \simeq 1.4$ eV is also clearly observed in all spectra. It should be noted that a rapid rise of photoresponse and of the absorption coefficient for photon energy 1.4-1.8 eV is a specific feature of amorphous silicon (4, 9) and it is attributed to the optical energy gap of a-Si, $E_g \simeq 1.45$-1.5 eV. The photovoltage increase observed for silicon-on-sapphire is significant, as it indicates the presence of partial amorphization of SOS films. It should also be noted that the magnitude of the increase in the photovoltage between 1.4 and 1.8 eV was noticeably different for different samples, which indicates that a degree of amorphization of SOS films depends on growth and processing parameters.

The analysis of interference minima and maxima (intentionally not included in spectra of Fig. 3, which represented average photovoltage) enables the determination of $d \cdot n$, and thus relative changes of the refractive index *vs.* energy. The results given in Fig. 4 indicate that the energy dependence of the refractive index of silicon-on-sapphire is practically identical with that of bulk Si (dotted line) (10) up to the energy of about 2.8 eV. For $h\nu > 2.8$ eV a slight discrepancy between the bulk Si and epitaxial film is observed, however in this region determination of the refractive index from interference patterns becomes less reliable due to a significant absorption and a rapid decrease of the amplitude of interference patterns. The observed similarity is not surprising since even a-Si films have refractive indexes close to values observed in single crystal Si (9). Accordingly, SOS films characterized by only a slight degree of amorphization should in principle exhibit refractive indexes identical with bulk Si.

Using the bulk Si value of n, the thickness of the measured films was determined as: $d_1 = 0.60$ μm, $d_2 = 0.63$ μm, $d_3 = 0.61$ μm, and $d_4 = 0.61$ μm, for samples S1 to S4, respectively. These values were identical to film thickness determined using commercially available thickness monitor.

Table I. Silicon-on-sapphire samples employed in the photovoltage studies

Sample	History	Annealing conditions
S.1	As grown	Not annealed
S.2	Boron implant 1×10^{11} cm^{-2}	Not annealed
S.3	Phosphor implant 4×10^{11} cm^{-2}	Not annealed
S.4	Phosphor implant 1×10^{11} cm^{-2}	1 hr, 900°C in dry oxygen

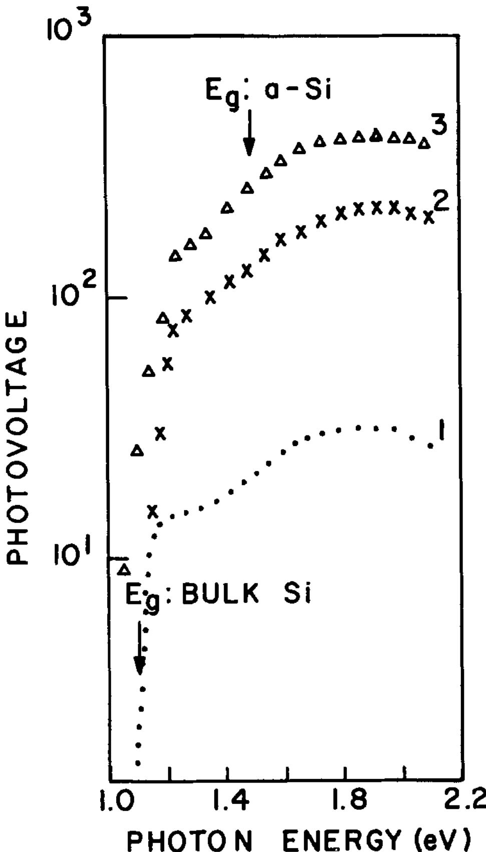

Fig. 3. 300 K photovoltage spectra of silicon-on-sapphire films in a region of intrinsic excitation. Each spectrum was averaged regarding the interference maxima-minima. The spectrum of sample 4 is not shown for clarity, since it was practically identical with sample 2.

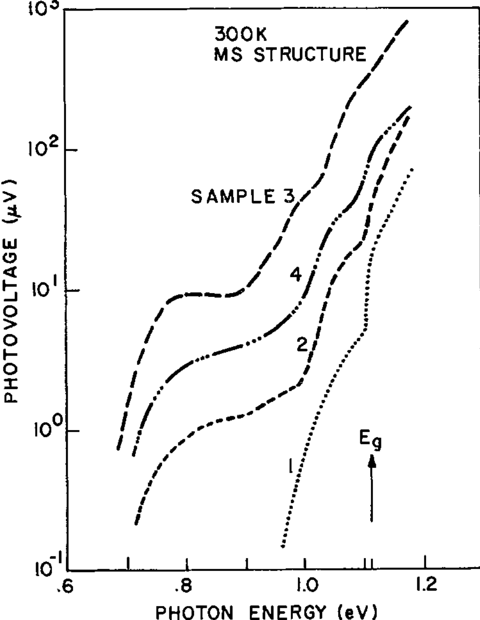

Fig. 5. Open-circuit photovoltage spectra of MS structures prepared on SOS films.

Vicinity of energy gap and deep level photoionization transitions.—Figure 5 presents room temperature "open-circuit" photovoltage spectra of SOS films measured using the MS structure. Drastic differences between "as-grown" films and ion-implanted films are clearly visible in the low energy region (deep level transitions) and in the vicinity of the energy gap. The sharp photovoltage increase in sample 1 for $h\nu \simeq E_g$ becomes much broader in samples 2 and 4, and it practically cannot be resolved for unannealed sample 3. The same features were found to be characteristics for photovoltage spectra measured in the MOS configuration, which indicates negligible contribution from photoionization of surface states (which in general can affect MOS measurements) and from photoinjection of excess carriers from the metal.

A typical low temperature (230 K) photovoltage spectrum measured in the MOS configuration is given in Fig. 6. The lack of a sharp increase in the photovoltage for sample 3 in the vicinity of $h\nu = E_g$ is also evident at this temperature.

Decreasing the temperature further (see Fig. 7) converts the broad spectrum of sample 3 into a clearly visible edge. Such behavior can be explained by assuming that ion implantation introduces a high density of levels located in the vicinity of valence and conduction bandedges. Transitions between these levels combined with thermal excitation (photothermoionization transitions) effectively mask the band-to-band excitation of free carriers at higher temperatures. At low temperatures photothermoionization transitions are negligible and band-to-band excitation of free carriers become dominant. Thus, a rapid photovoltage increase due to (bulk) band-to-band excitation ($h\nu \simeq$ 1.18 eV) becomes clearly visible.

As seen in Fig. 5 and 6, ion-implanted samples exhibit a pronounced increase in the photovoltage in the low photon energy range ($h\nu >$ 0.6 eV) apparently due

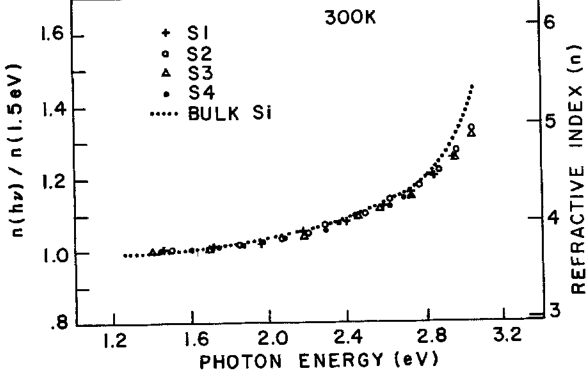

Fig. 4. Refractive index of SOS films vs. photon energy. Bulk Si refractive index was taken after Ref. (10).

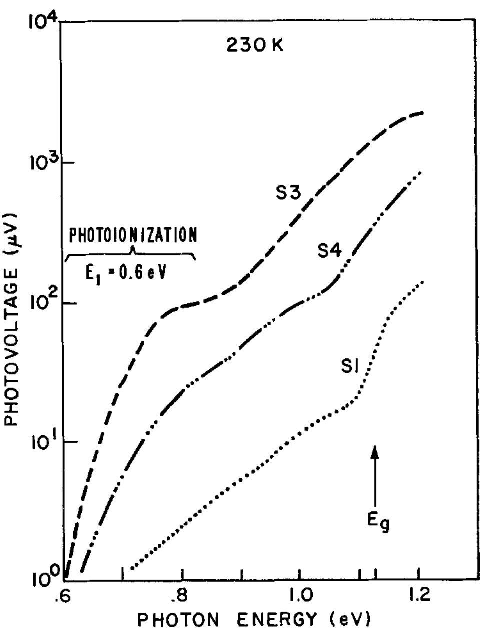

Fig. 6. 230 K photovoltage spectra of SOS films (MOS configuration).

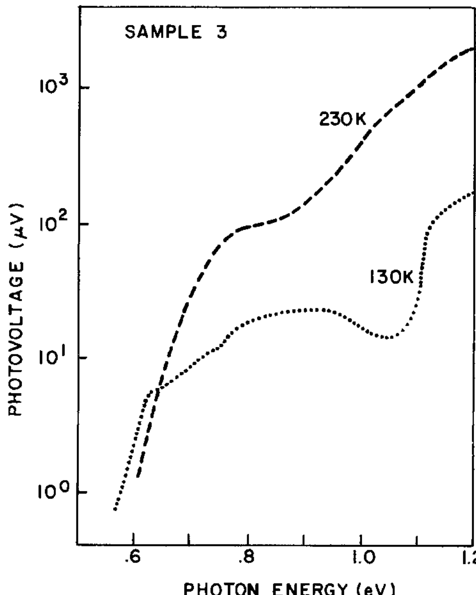

Fig. 7. Photovoltage (MOS configuration) spectra of sample 3 measured at 230 and 130 K, respectively. Note at 130 K the appearance of well-defined photovoltage edge in the vicinity of energy gap.

to photoionization of deep defect levels. Consistent with this interpretation, the low energy photovoltage threshold has been found to satisfy a power dependence on energy $\Delta V \sim |h\nu - E_t|^P$, with $E_t = 0.6$ eV (see Fig. 8).

It may be of interest to note that a similar low energy (about $h\nu \simeq 0.6$ eV) threshold is commonly observed in photoelectric response and absorption coefficient of polycrystalline and amorphous Si (4, 8) and also in plastically deformed bulk Si which contains high densities of intentionally introduced dislocations (11).

Temperature dependence of photovoltage.—A typical plot of the temperature dependence of the a-c photovoltage in SOS films is shown in Fig. 9. Two regions are clearly distinguished. In the higher temperature

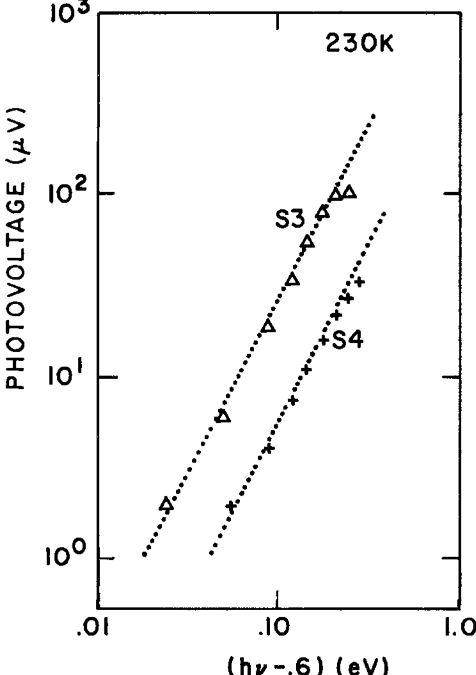

Fig. 8. The analysis of low energy photovoltage threshold (see text).

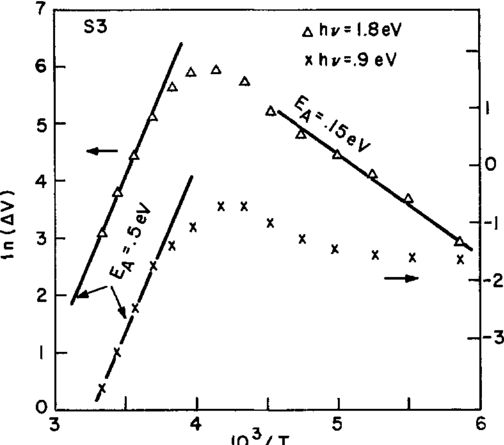

Fig. 9. Temperature dependence of photovoltage of sample S.3 (MOS configuration).

region (300-220 K) the subband and intrinsic photovoltage increases exponentially with $1/T$. A corresponding activation energy ($E_A \simeq 0.5$ eV) was found to be identical for all samples. Furthermore, the same activation energy governs the photovoltage increase for intrinsic ($h\nu > E_g$) and subbandgap ($h\nu < E_g$) excitation. A similar increase of photovoltage or photoconductivity was previously observed for polycrystalline Si (3) and for plastically deformed Si (12). A suggested interpretation of these findings involve thermal excitation of deep traps located about 0.5-0.6 eV below conduction band associated with defects or dangling bonds due to edge dislocations (3, 12).

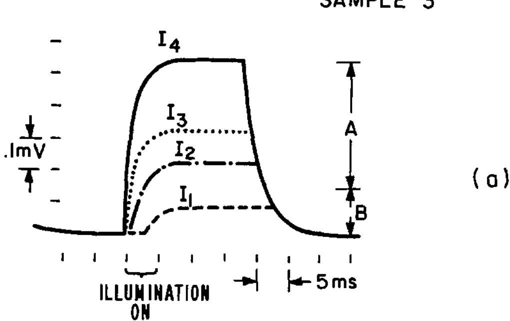
In the lower temperature region (T < 220 K) the measured photovoltage decreases due to an increase of the photovoltage relaxation time, τ. The amplitude of a-c photovoltage generated by the light chopped at angular frequency, ω, can be expressed as (7)

$$\Delta V \text{ measured} = \Delta V\ (1 + \omega^2\tau^2)^{-1/2} \quad [1]$$

Accordingly, at higher temperatures where the relaxation time is short enough to satisfy $\omega^2\tau^2 << 1$, $\Delta V_{measured}$ reflects the amplitude of the steady-state photovoltage ΔV. For lower temperatures the relaxation time becomes very long (see next section). Thus, $\omega^2\tau^2 >> 1$ and the measured photovoltage $\Delta V_{measured} = \Delta V \cdot 1/\omega\tau$. It was found (from direct transient measurements described in the next section) that in low temperature region ($T < 220$ K), ΔV is practically constant, and thus the decrease of photovoltage after passing through the maximum is caused by an increase in relaxation time.

It is also seen in Fig. 9 that the relaxation time increase at low temperatures is different for intrinsic excitations ($h\nu = 1.8$ eV) and subbandgap ($h\nu = 0.9$ eV) excitation. As discussed in the next section, these differences can be explained considering that under intrinsic excitation τ is determined by thermal excitation of minority carriers from trapping levels while for subbandgap illumination the relaxation time is determined by nonradiative recombination transitions to traps, which are weakly dependent on temperature.

Photovoltage transient and trapping of photogenerated carriers.—Typical transients of photovoltage in SOS films for intrinsic illumination are shown in Fig. 10a, b, for samples 3 and 4, respectively, at room temperature. These transients generated by intrinsic excitation were found to be identical for MOS and MS configurations. It is seen that an increase of the illumination intensity (*I*) results in the appearance of fast nonexponential decay, denoted as region "A." However, the slow exponential tail denoted as region "B" remains unaffected by illumination intensity. It is of interest to note that transients in Fig. 10 constitute almost a "textbook" illustration of the photoelectric



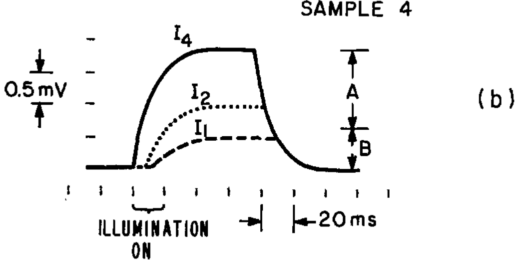


Fig. 10. Room temperature photovoltage transients of samples 3 and 4, respectively. The illumination intensity increases in the sequence $I_4 > I_3 > I_2 > I_1$. Transients measured for $h\nu = 1.8$ eV.

transient in the typical case of pronounced trapping (13). Thus, the exponential tail "B" can be considered as due to the thermal release of trapped minority carriers.

The corresponding exponential time constant is given as

$$\text{n-type; } \tau^{-1} = \sigma_p v_t N_v e^{-E_A/kT} \quad \text{where } E_A = E_t - E_v \quad [2a]$$

$$\text{p-type; } \tau^{-1} = \sigma_n v_t N_c e^{-E_A/kT} \quad \text{where } E_A = E_c - E_t \quad [2b]$$

where [2a] and [2b] describe the time constant of the thermal release of trapped holes and electrons, respectively.

According to [2a], [2b] the trapping relaxation time should increase exponentially with $1/T$, upon decreasing the temperature. As shown in Fig. 11, such behavior was indeed observed experimentally, for both p- and n-type samples (2 and 3, respectively). Determined energies of minority carrier trapping levels are: electron traps (p-type Si) 0.25 eV below the conduction band; and hole traps (n-type Si) 0.15 eV above the valence band. It is evident that the latter value agrees very well with an energy $E_A = 0.15$ determined in the previous section (see Fig. 9) from the temperature dependence of the amplitude of the a-c photovoltage. The estimated (from expressions [2]) values of the effective capture cross sections $K_p = \sigma_p \cdot v_T$ and $K_n = \sigma_n \cdot v_T$ are in order of 10^{-11} cm^3 sec^{-1} and 10^{-13} cm^3 sec^{-1} for hole and electron traps, respectively.

Transient analysis in terms of parameters of trapping centers could not be performed for "as-grown" sample 1, due to the very low magnitude of photovoltage signal caused by a high density of lifetime killing centers.

Summary

It has been shown that photovoltage measurements detect differences in defect density in SOS wafers in different stages of processing. The results obtained from subband and interband photovoltage measured in as-grown and processed SOS wafers can be summarized as follows.

1. Photovoltage measurements established the presence of deep levels located close to the center of the energy gap (0.6 eV) in all SOS films. The density of these levels is a function of processing: increases after ion implantation and is reduced by the heat-treatment.
2. The photoelectric response of SOS films is dominated by trapping phenomena which are very similar to those encountered in bulk Si containing a high density of dislocations or in polycrystalline Si. It has been established that the characteristics of the trapping process (*e.g.*, time constant, activation energy) depend on film processing. Hole trapping levels located 0.15 eV above the valence band and electron traps located about 0.25 eV below the conduction band have been found in ion-implanted films.
3. It has been found that ion implantation causes drastic changes in the density of states in the vicinity of bandedges. These changes have been reduced, but not totally eliminated, by annealing.
4. It has been found that all ion-implanted and "as-grown" films exhibit a slight degree of amorphization. Thus, the structure characteristic of amorphous silicon (energy gap at about 1.45 eV) was clearly resolved for SOS films, in addition to the standard energy gap structure (1.1 eV) bulk Si.
5. The refractive index (as a function of photon energy) of SOS films was found to be very similar to that of bulk Si.

A summarizing energy level diagram of silicon-on-sapphire is shown in Fig. 12 together with corresponding photoionization transitions (arrows) in n- and p-type material. We believe that the above results dem-

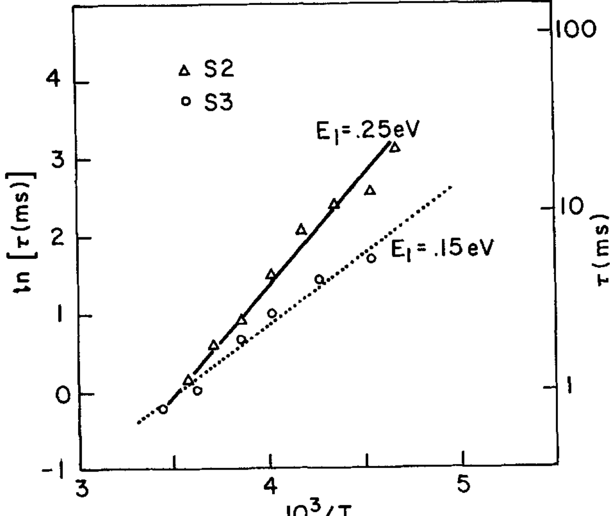

Fig. 11. Temperature dependence of trapping time, τ, for p-type sample S2 and n-type S3. Transients measured for $h\nu = 1.8$ eV.

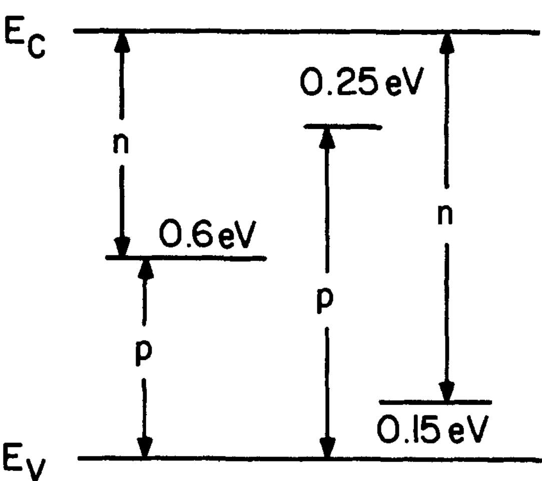

Fig. 12. Energy levels and transition diagrams in n- and p-type SOS films.

onstrate the potential of photovoltage as a unique technique to provide a reliable means for the characterization of deep centers in SOS wafers during different stages of processing. Furthermore, the large magnitude of the photovoltage signal in ion-implanted and annealed wafers confirms the possibility to extend this technique for the characterization of deep levels on a microscale.

The Solid Electrolyte System $RbCu_4Cl_3(I_{2-x}Cl_x)$, $0 \leq x \leq 0.40$

I. Stability

K. Nag[1] and S. Geller

Department of Electrical Engineering, University of Colorado, Boulder, Colorado 80309

ABSTRACT

The stoichiometric solid electrolyte, $RbCu_3Cl_3I_2$, can be converted, by cold-work, to a new low symmetry phase with the probable composition $RbCu_4Cl_3(I_{1.96}Cl_{0.04})$ (and very small amounts of CuI and probably, $Rb_2Cu_3Cl_5$). The new phase has a crystal structure which appears to be related to that of the cubic phase. It transforms rapidly to the cubic phase with formula $RbCu_4Cl_3(I_{1.96}Cl_{0.04})$ at temperatures above 75°C. The new phase is stable in a very narrow temperature range, almost surely not wider than 0°-35°C. It has a conductivity of $1.5 \times 10^{-4}\ \Omega^{-1}\ cm^{-1}$ at 298 K. Stoichiometric $RbCu_4Cl_3I_2$ is thermodynamically stable in the narrow temperature range 200° ± 15°C. The solid solution range $RbCu_4Cl_3(I_{2-x}Cl_x)$ $0.00 \leq x \leq 0.40 \pm 0.01$ has been confirmed. For $0.02 \leq x \leq 0.40$, the materials appear to be stable from at least 78 K to their preparation temperatures which depend on x. None of these can be made to convert to the new phase; that is to say, the only established route to the new phase is through cold-working of the stoichiometric phase.

In an earlier paper (1), it was reported briefly that there exists a solid solution range in $RbCu_4Cl_3(I_{2-x}Cl_x)$ with $0.00 \leq x \leq 0.40$. In the present work, we have studied the effects of substitution of chloride for iodide ions on the practical stability and on the conductivity. Because of the considerable detail involved in the description of the results, it has been decided to divide the presentation into two parts: part I will be devoted mainly to the stability and part II mainly to the conductivity studies of the materials.

With the passing of time, there are new developments with regard to the nature of the stoichiometric material. A pellet and some powdered material from the same prepared specimen that had been stored in a capped vial in a desiccator for several months were checked by x-ray powder diffraction. It was found that all the material in the pellet was a new phase related to the solid electrolyte; a slight amount of CuI was present, but no other phases were detected. In the case of the powder, the same new phase was present, but so was cubic solid electrolyte and apparently somewhat more CuI than for the pellet. The solid electrolyte, however, had a smaller lattice constant, indicating that it had the composition given by $RbCu_4Cl_3(I_{1.96}Cu_{0.04})$. After two years, no further change in either part of this specimen has been found. When the material from the powder or pellet was heated to 200°C, the cubic solid electrolyte was regenerated from the new phase, except that it had a lattice constant of 10.028Å, 0.004Å less than that of the

[1] On leave from Indian Association for the Cultivation of Science, Calcutta 700032 India.

Key words: solid electrolyte, cuprous ion conductor, rubidium cuprous chloroiodide, transformation, stability.

stoichiometric phase, indicating again a formula $RbCu_4Cl_3(I_{1.96}Cl_{0.04})$; CuI was also present. After two years, this material did not revert to the new phase.

Remarkably, no other specimen, regardless of composition, has changed on standing this way. Numerous experiments resulted in a method of forcing the change, namely, by cold-work, as will be described later. Although the new phase can be produced by this method, the material is strained as indicated by the appearance of the high angle region of the x-ray powder pattern. In the case of the stored specimen, the high angle lines in the x-ray powder photographs of the new phase are relatively sharp; at present, it is not known how the changes occurred in this specimen. The experiments carried out subsequently lead to the conclusion that they could not have resulted simply from the instability of the compound.

Only the stoichiometric material undergoes the transition by cold-work; even a very small substitution of Cl^- for I^- ions, *e.g.*, $x = 0.02$, inhibits it. A smaller lattice constant for the cubic phase, whether other phases present are detectable or not, means that some Cl^- ions are replacing iodide ions in the material.

The new phase is not isostructural with either β- or γ-$RbAg_4I_5$ (2). However, it does appear to have a structure related to that of α-$RbAg_4I_5$ (3) or $RbCu_4Cl_3I_2$ (1).

The materials with $x \neq 0$ appear to be stable over a much wider temperature range than the stoichiometric material. In all cases, care must be taken to prepare the materials in the temperature range appropriate to the particular composition.

Experimental

Materials preparation.—CuCl was prepared by the reduction of an aqueous solution of $CuCl_2$ (from $CuCl_2 \cdot 2H_2O$) with Na_2SO_3 in accordance with the method of Keller and Wycoff (4). The white crystalline material so obtained may be preserved indefinitely if stored dry. CuI was obtained by reacting $CuSO_4$ with KI and $Na_2S_2O_3$ in aqueous solution as described by Kauffman and Pinnell (5). The CuI that precipitates in microcrystalline form was separated from the solution with some difficulty. The product was thoroughly washed and then dried *in vacuo*. However, an x-ray powder photograph of this material indicated the presence of occluded $Na_2S_2O_3$.[2] Therefore, the material was dissolved in aqueous HI (Baker, 47-51%); undissolved material was separated by filtration with a sintered glass crucible (G-4). Water was added slowly to the filtrate while stirring until precipitation of the CuI was complete. The CuI settled readily and was separated by and washed on a glass frit. Washing with water was continued until the filtrate was acid-free. Finally three washings with dry acetone were made; the material was then dried in a vacuum oven at 100°C for 12 hr.

RbCl (Cerac 99.9%) was used after drying *in vacuo* at 100°C for 4 hr.

Sample preparation.—Appropriate amounts of RbCl, CuCl, and CuI (originally ground fine with agate mortar and pestle) to prepare about 3.5g of $RbCu_4Cl_3(I_{2-x}Cl_x)$ were weighed into a glass vial and thoroughly mixed by shaking. The mixture was then pelletized in a ½ in. tungsten carbide die at 1 kbar pressure with a Carver press. The pellet was then put into a Pyrex test tube which was evacuated, flushed with dry nitrogen, evacuated, and again flushed with dry nitrogen. The pressure was then reduced to ½ atm and the tube sealed off. The material was then melted in a furnace at about 320°C and held at this temperature for 10 min, with occasional stirring of the melt. The tube was then removed from the furnace and after cooling to room temperature, broken open inside a nitrogen-recirculating glove box. The pellet was pulverized and ground fine with an agate mortar and pestle. After repelletizing and sealing the material in a Pyrex tube as before, the material was annealed at the "desired" temperature[3] for 4 hr. Our experiments led to the conclusion that in all, four regrindings, repelletizings, and annealings of 4 hr, maximized the chance of obtaining a single phase material. X-ray powder diffraction photographs with both $CuK\alpha$ and $CrK\alpha$ radiation were taken with 114.6 mm diam Norelco cameras. The $CrK\alpha$ photographs were used for lattice constant measurement. The lattice constants and annealing temperatures for the various samples prepared are shown in Table I. Lattice constants are plotted *vs.* x in Fig. 1.

[2] Commercially obtained CuI, probably prepared by the same method (5), contains $Na_2S_2O_3$.

Results and Discussion

Lattice constants and composition.—Our studies have shown that phase-pure stoichiometric $RbCu_4Cl_3I_2$ is obtained when the annealing is done in the narrow range ± 5°C about 205°C. The lattice constant of this material is 10.032 ± 0.001Å. Although it is not possible to detect the presence of very small amounts of other phases in large excess of the solid electrolyte, the determination of the lattice constant is a powerful indicator as to whether impurity phases are present or not. When attempts were made to prepare the stoichiometric compound at temperatures outside the temperature range 200°-210°C, the materials obtained always had lattice constants lower than 10.032Å (see Table II and later discussion of stability of the materials).

The existence of a solid solution range $RbCu_4Cl_3(I_{2-x}Cl_x)$ has been established[4] prior to the present work, and the earlier reported range, $0.00 \leq x \leq 0.40$ has been confirmed to ±0.01. In the stoichiometric compound, only Cl^- ions surround the Rb^+ ions; new experiments corroborate the previous result (8) that small amounts of these Cl^- ions cannot be replaced by I^- ions, accounting for the formulation that we use, *i.e.*, $RbCu_4Cl_3(I_{2-x}Cl_x)$.

The lowest lattice constant in the series is 10.001 ± 0.001Å for $RbCu_4Cl_3(I_{1.6}Cl_{0.4})$. An attempt to prepare a specimen with formula $RbCu_4Cl_3(I_{1.55}Cl_{0.45})$ did not give single phase material. It contained the solid electrolyte $RbCu_4Cl_3(I_{1.6}Cl_{0.4})$, *i.e.*, with lattice constant 10.001Å (see Fig. 1). Other phases were difficult to detect in the powder photograph. The reaction is

$$RbCl + 2.45CuCl + 1.55CuI \rightarrow 0.968RbCu_4Cl_3(I_{1.6}Cl_{0.4}) + 0.0064Rb_2Cu_3Cl_5 + 0.0064Rb_3Cu_7Cl_{10} + 0.064CuCl^{5}$$

[3] It was found that the "desired" temperature was a function of x.
[4] References (6) and (7) notwithstanding.
[5] This CuCl is really unreacted material.

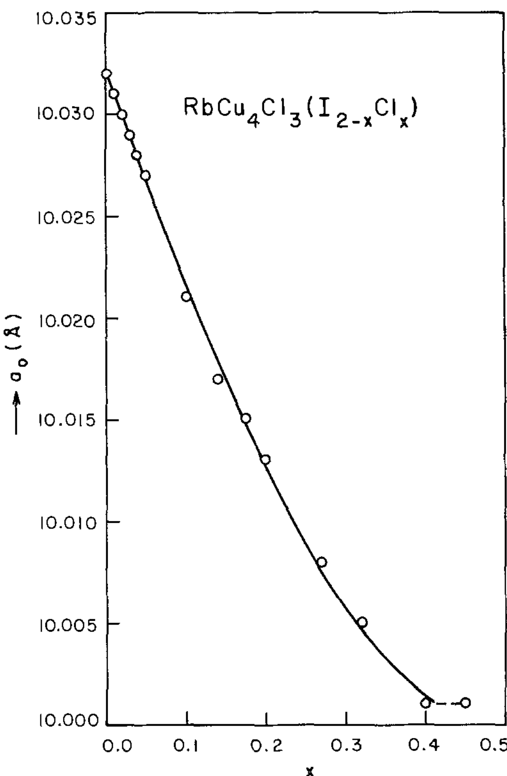

Fig. 1. Lattice constant vs. x in $RbCu_4Cl_3(I_{2-x}Cl_x)$

This reaction was verified by an attempted preparation of "$RbCu_4Cl_3(ICl)$," in which case the cubic solid electrolyte with a_o = 10.001Å, as before, as well as the three other phases were seen in the powder photograph.

The two compounds $Rb_2Cu_3Cl_5$ and $Rb_3Cu_7Cl_{10}$ have been mentioned in Ref. (9) [and $Rb_2Cu_3Cl_5$ in Ref. (10)]; we have confirmed their existence by preparation by solid-state reaction. (Appropriate mixtures of RbCl and CuCl were ground together in an agate mortar, pelletized, inserted in a tube, evacuated, flushed with dry nitrogen, finally sealed off with N_2 pressure of ½ atm, and heated at 140°C for 6 hr. Each was given two additional regrindings, pelletizings, etc., and annealings at 140°C for 6 hr.) The material reported in Ref. (10) as $RbCu_4Cl_5$ is a mixture of $Rb_2Cu_3Cl_5$, $Rb_3Cu_7Cl_{10}$, and CuCl in mol ratio 1:1:10.

In the preparation of a solid electrolyte with specific x, the required annealing temperature must be reduced as x increases (see Table I). For example, attempts to prepare $RbCu_4Cl_3(I_{1.6}Cl_{0.4})$ at temperatures above 180°C gave cubic materials with lattice constant greater than 10.001Å. This implies that these materials have $x < 0.40$, even though it was often difficult to discern the extra phases in the x-ray powder photographs (see later discussion).

The annealing temperatures given in Table I are those that were found to be optimum. A comparison of results on specimens with $0 \leq x \leq 0.10$ prepared at two different annealing temperatures, 205° ± 5°C and 180°C, is given in Table II. In this range of composition, there is no doubt that the higher temperature annealings are required. It is noteworthy that after the samples were prepared by annealings at 180°C, reannealing[6] at the higher temperature resulted in increased lattice constant. This implies homogenization either by further reaction of the solid electrolyte with incompletely reacted constituents or possibly

[6] This should be understood to mean additional cycles including regrinding, repelletizing, etc., as described under Sample preparation.

Table II. Lattice constants of specimens in system $RbCu_4Cl_3(I_{2-x}Cl_x)$ prepared at two different temperatures*

x	205° ± 5°C	180°C
0	10.032	10.030
0.01	10.031	10.028
0.02	10.030	10.027
0.03	10.029	10.026
0.05	10.027	10.025
0.10	10.021	10.020

Higher temperature results are the correct ones: see text.

the further reactions of a continuous mixture of solid solutions, in a narrow range, of course.

When an attempt was made to prepare $RbCu_4Cl_3I_2$ at 225°C, the lattice constant of the cubic phase was 10.030Å also (see Table II). This may mean that the following reaction occurred

$$RbCl + 2CuCl + 2CuI \rightarrow 0.9934RbCu_4Cl_3(I_{1.98}Cl_{0.02}) + 0.0066RbI + 0.027CuI$$

An attempt to prepare $RbCu_4Cl_3(I_{1.6}Cl_{0.4})$ at 225°C gave a cubic phase with lattice constant 10.013Å, and when tried at 205°C, gave 10.006Å. These results may be explained by reference to Fig. 1; a lattice constant of 10.013Å means x = 0.20, and of 10.006Å means x = 0.29. The reaction for the first case is very likely

$$RbCl + 2.40CuCl + 1.60CuI \rightarrow 0.890RbCu_4Cl_3(I_{1.8}Cl_{0.2}) + 0.022Rb_2Cu_3Cl_5 + 0.022Rb_3Cu_7Cl_{10} + 0.220CuCl$$

A similar reaction may readily be written for the second case.[7]

Stoichiometric $RbCu_4Cl_3I_2$.—X-ray powder diffraction photographs and diffractometer patterns were taken of a sample of the stoichiometric $RbCu_4Cl_3I_2$ that had been stored in a closed vial in a desiccator for several months. Part of the sample was still in pellet form and part was powder. Both were different from stoichiometric $RbCu_4Cl_3I_2$: The pellet contained a new low symmetry phase plus a very small amount of CuI; the powder contained the low symmetry phase, cubic solid electrolyte with a_o = 10.028Å (therefore having x = 0.04) and perhaps slightly more CuI. After two years, no further changes have taken place in the two parts of the specimen; therefore it is unlikely that the changes observed resulted from slow decomposition. It is not known why the two parts of the specimen behaved differently. No other specimen, regardless of composition, has converted in either of these ways over much longer periods of time than transpired for the initial observation.

Judging from the x-ray powder pattern, the structure of the new phase seems still to be related to the $RbAg_4I_5$ structure (3) (with which all members of the $RbCu_4Cl_3(I_{2-x}Cl_x)$ system are isostructural), but it is not isostructural with either β- or γ-$RbAg_4I_5$ (2). Table III lists powder diffraction data, taken with a diffractometer, for the new phase. For comparison, data are given also for the cubic $RbCu_4Cl_3(I_{1.96}Cl_{0.04})$ solid electrolyte phase.

Attempts were made to prepare the new phase directly. These included trying to introduce I^- vacancies and substitution of various types and amounts of other ions for Rb^+ and for Cu^+. These experiments were unsuccessful.

We sought to obtain the new phase in another way, namely, by pressurizing, depressurizing, grinding, and repeating. Applied pressure was 5000 kg cm^{-2} for

[7] In part of the following section, we show that the single phase $RbCu_4Cl_3(I_{1.6}Cl_{0.4})$ prepared at 180°C decomposes in the same way at higher temperatures.

* The data are arranged to show that the two structures are related. The relative intensities are given for the individual materials. The strongest line of the cubic phase has at least 2.3 times the intensity of the strongest line of the new phase.

½ hr. After seven such treatments, the material was found to be completely converted to the new phase. It was found that grinding continuously for 3 hr or alternately pressurizing and depressurizing alone did not result in conversion. As a consequence of this experiment, a device was built to perform the cold-work automatically. It consists essentially of a hardened steel base to which is attached a stainless steel cylinder with ⅜ in. ID. These parts rotate about a hardened steel piston with ¼ in. diam attached to a variable speed reciprocating motor. About 200 mg of the sample to be cold-worked are put into the cylinder. The motor and piston are adjusted over the specimen so that it is off the center of rotation and rather close to the cylinder wall. When the machine is turned on, the piston pounds the material against the hardened steel base. The powder spreads about inside the cylinder, and unless it clings to the wall receives almost continuous pounding. In effect, the particles are subjected to both normal and shear stresses. Unfortunately, some powder adheres strongly to the cylinder wall. This powder could be removed, the whole sample homogenized, pounding continued, and so on. However, we used this method mainly to determine whether different specimens could be made to transform to the new phase. There is no doubt that the method was useful in this respect. After 24 hr of pounding, a specimen of stoichiometric $RbCu_4Cl_3I_2$ was converted partially to the new phase; CuI was also detected. The unchanged cubic solid electrolyte still present had $a_o = 10.032$Å.

Nonstoichiometric specimens with compositions $0.02 \leq x \leq 0.40$ were also subjected to this treatment for longer periods, in some cases, as many as eight days. X-ray powder diffraction photographs indicated no change in any of these materials. It is therefore concluded that only the stoichiometric $RbCu_4Cl_3I_2$, within $x < 0.02$, undergoes this change.

Measurements of conductivity[8] *vs.* temperature were made on a sample of the completely transformed material prepared by pressurizing, depressurizing, grinding, and repeating (PDGR). The cell used was: $Ag|RbCu_4Cl_3I_2$, Ag|transformed material$|RbCu_4Cl_3I_2$, Ag|Ag. The plot of $\log_{10} (\sigma T)$ *vs.* $10^3/T$ is shown in Fig. 2. At 298 K, the material has a conductivity of $1.45 \times 10^{-4}\ \Omega^{-1}\ cm^{-1}$. The conductivity increases linearly to $2.87 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$ at 348 K. [For the linear portion of the curve between 298 and 348 K, the activation enthalpy of motion, h_m, is 0.43 eV, indicating that the material is not a good solid electrolyte (12).] Just at 348 K, the conductivity rises sharply; σT increases by two orders of magnitude in the range 348-365 K. At 378 K, the conductivity reached 0.24 $\Omega^{-1}\ cm^{-1}$, and at 440 K, 0.47 $\Omega^{-1}\ cm^{-1}$. An x-ray powder diffraction photograph taken of the material following the measurements shows the presence of cubic $RbCu_4Cl_3(I_{1.96}Cl_{0.04})$; strangely, no CuI or other phases were detected. However, when some new phase material was heated at 80°C, again the cubic phase with formula $RbCu_4Cl_3(I_{1.96}Cl_{0.04})$ was regenerated; in this case CuI was detected in the powder photograph.

[8] These results are included here because they elucidate the relation of the new phase to the cubic phase. For cell preparation and other details of conductivity measurement, see part II (11); it should be noted that the heating cycle was not included in the preparation of the cell.

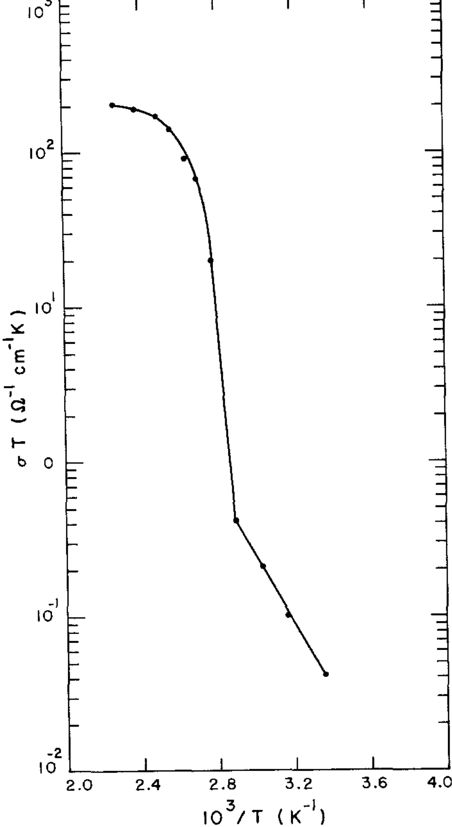

Fig. 2. Conductivity multiplied by temperature vs. reciprocal temperature for the new phase.

The results of the conductivity experiment prove that the new phase converts easily to the cubic solid electrolyte phase, *i.e.*, in a few minutes at the appropriate temperature. This implies that although it must be prepared by a route which must involve some decomposition of the stoichiometric material, it probably has the composition $RbCu_4Cl_3(I_{1.96}Cl_{0.04})$ or very close to it. It is also very clear that the transition is first order.

Much before the conductivity experiment on the transformed material, portions of it were heated at higher temperatures, 140° and 200°C. In all cases the lattice constant of the cubic solid electrolyte indicated a composition $RbCu_4Cl_3(I_{1.96}Cl_{0.04})$, within experimental error, $-0.01 \leq \Delta x \leq 0.00$. If the composition of the new phase is actually the same as that of the regenerated cubic phase, the decomposition could be written as follows

$$RbCu_4Cl_3I_2 \rightarrow 0.926RbCu_4Cl_3(I_{1.96}Cl_{0.04}) \quad \text{(new phase)} + 0.185CuI + 0.037Rb_2Cu_3Cl_5$$

The $Rb_2Cu_3Cl_5$ is not detected in either the powder photographs or diffractometer patterns of either the transformed material (*i.e.*, containing the new phase) or the reheated transformed material (*i.e.*, containing the regenerated cubic solid electrolyte phase), very likely because it is only 3 mol percent of the total and its strongest line is apparently much less intense than that of the strongest line of CuI. This conclusion is supported by the results of another experiment. Some of the transformed material, prepared by cold-work (PDGR), was heated at 60°C for 3 days, the new phase decomposed completely according to

$$RbCu_4Cl_3(I_{1.96}Cl_{0.04}) \text{ (nominal)} \rightarrow 0.173Rb_2Cu_3Cl_5 + 0.218Rb_3Cu_7Cl_{10} + 1.96CuI$$

Only a few of the low angle lines of the first two phases on the right of the equation were observed in the powder photographs taken with $CuK\alpha$ radiation.

There is the possibility that the new phase may have iodide vacancies and a deficiency of Cu^+ ions. The formula would then be $RbCu_{3.92}Cl_3(I_{1.92}V_{0.08})$, that is, if only CuI were exsolved. If the decomposition is as written in the last equation and the structure is ordered, the formula must be close to $Rb_{51}Cu_{200}Cl_{153}I_{98}$. This would be the minimum unit cell content. The volume of such a cell would be about 13 times larger than that of $RbCu_4Cl_3I_2$. This seems unlikely. We believe that the most likely possibility is that indicated earlier; namely, that the new phase has the composition $RbCu_4Cl_3(I_{1.96}Cl_{0.04})$ with some disorder among the iodide and small number of chloride ions in sites analogous to those in the crystal structure of the cubic phase. It may be difficult to ascertain the truth in this case, because it does not seem probable that single crystals can be produced; however, further work is planned in this direction.

It was stated above that the material that was prepared by cold-work (PDGR) decomposed completely after being held at 60°C for 3 days. The original transformed material from the pellet showed incomplete, but considerable, decomposition after 5 days at 50°C; also, another sample held at 40°C for 3 days showed substantial decomposition. While an experiment on this material was not done at 60°C, there is an indication that the cold-worked material decomposes more rapidly than the other. The greater rate of decomposition is consistent with the strain in the material indicated by the powder photographs. In any case the experiments indicate that the new phase is not thermodynamically stable at 40°C or higher.

Both materials, *i.e.*, the one prepared by cold-work (PDGR) and the original one from the pellet, decompose partially when kept at liquid nitrogen temperature for 16 hr. Again the rate of decomposition of the former is greater than that of the latter. Decomposition also takes place when the new phase is kept at −5°C for 12 days. Thus the new phase, if it is thermodynamically stable at all, is so in a very narrow temperature range, almost surely not greater than 0° to 35°C.

In the foregoing, we have distinguished between the new phase which was first found in the stored material and the same, but strained, new phase which was prepared by cold-work. It may appear that we mean to imply that the transformation that occurred in the stored material did so simply because of the instability of stoichiometric $RbCuCl_3I_2$. However, we must emphasize that this cannot be the case, because, as pointed out, no other specimen of the stoichiometric material has behaved in the same way. We must admit that we do not know how the original changes occurred, but it is probable that they occurred by cold-work. Unfortunately, there is no indication, in the record, that this is or is not the case and too much time has elapsed for the original preparer to recall just what had occurred.

Experiments on the stability of stoichiometric cubic $RbCu_4Cl_3I_2$ indicate that it is thermodynamically stable in only a narrow temperature range about 200°C, perhaps no greater than ±10°-15°C. At temperatures outside this range, it decomposes, but not always in the same way (see Table IV).

The stability relationships of the stoichiometric cubic phase, the cubic $RbCu_4Cl_3(I_{1.96}Cl_{0.04})$ phase and new phase with respect to each other are summarized in Fig. 3.

$RbCu_4Cl_3(I_{2-x}Cl_x)$, $0.00 < x \leq 0.40$ compositions.— Exhaustive experiments were not carried out, but those that have been done (Table V) indicate that one may expect that all compositions with $x \neq 0$ should be stable between their optimum preparation temperatures (Table I) and liquid N_2 temperature. This stability cannot be guaranteed to be thermodynamic over the whole temperature ranges.

It should be emphasized, that specimens with $x = 0.02$ and $x = 0.05$ could not be converted to the new phase by 3 days of continuous cold-work.

Table IV. $RbCu_4Cl_3I_2$ stability experiments

Experiment*	Observations†
40°C, 5 days	CuI + S.E.: $x > 0$, but lines too broad to measure a_o
60°C, 5 days	CuI + S.E.: $a_o = 10.028A \Rightarrow x = 0.04$
140°C, 3 days	CuI + S.E.: $a_o = 10.028A \Rightarrow x = 0.04$
175°C, 3 hr	CuI + S.E.: $a_o = 10.028A \Rightarrow x = 0.04$
225°C, 15 hr	No CuI detected, $a_o = 10.030A \Rightarrow x = 0.02$
−5°C, 2 months	CuI + S.E. (broad lines) + $Rb_2Cu_3Cl_5$ + $Rb_3Cu_7Cl_{10}$
−196°C, 15 hr	$a_o = 10.032A$, much CuI, decomposed stoichiometrically

* Experiments done at 185° < *T* < 215°C indicate no change in a_o or phase purity.
† S.E. = solid electrolyte.

Table V. $RbCu_4Cl_3(I_{2-x}Cl_x)$ stability experiments

Experiment		Observations
$x = 0.40$:	225°C, 16 hr	$a_o = 10.013A \Rightarrow x = 0.20$
	205°C, 16 hr	$a_o = 10.006A \Rightarrow x = 0.29$
	140°C, 16 hr	No change, *i.e.*, $a_o = 10.001A$

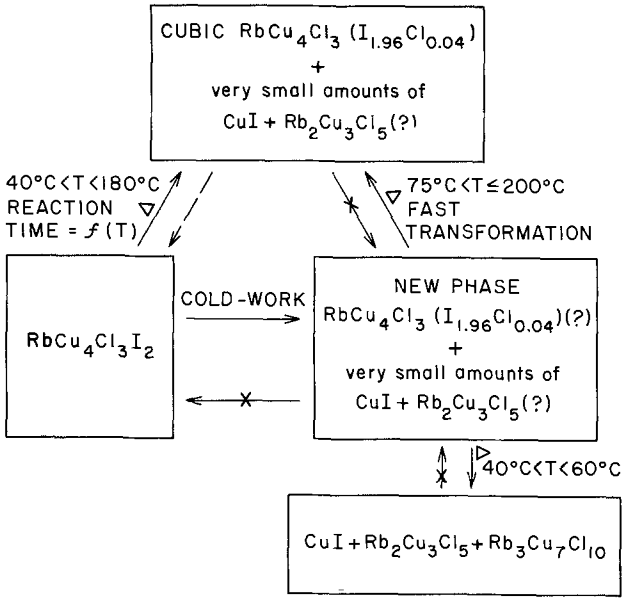

Fig. 3. Summary of stability relationships of stoichiometric $RbCu_4Cl_3I_2$, cubic $RbCu_4Cl_3(I_{1.96}Cl_{0.04})$, and the new phase.

Note added in proof:

It appears that the new phase produced by the cold-working of stoichiometric $RbCu_4Cl_3I_2$ is isostructural with a thermodynamically stable phase of $CsCu_4Cl_3I_2$ (to be published). The x-ray diffraction data given in Table III have been indexed on an orthorhombic cell with $a = 13.908$, $b = 24.752$, $c = 11.664$Å, probably good to ±0.005Å. (This indexing does not account for the very low intensity line with $d_{hkl} = 6.259$Å.) The possible space groups are *Cmca* (D_{2h}^{18}) and *C2ca* (C_{2v}^{17}).

The Solid Electrolyte System $RbCu_4Cl_3(I_{2-x}Cl_x)$, $0 \leq x \leq 0.40$

II. Electrical Conductivity

S. Geller, K. Nag,[1] and A. K. Ray

Department of Electrical Engineering, University of Colorado, Boulder, Colorado 80309

ABSTRACT

Electrical conductivity has been measured as a function of temperature and composition in the system $RbCu_4Cl_3(I_{2-x}Cl_x)$. Room temperature conductivities, uncorrected for deviation of bulk from x-ray densities, decrease very nearly linearly from 0.39 Ω^{-1} cm^{-1} for the stoichiometric composition to 0.28 Ω^{-1} cm^{-1} for $x = 0.40$. Corrections for density could increase these values by about 10%. The enthalpies of activation of motion for the Cu^+ ions range from 0.112 eV for $x = 0.00$ to 0.117 eV for $x = 0.40$, indicating that the decrease in conductivity with increasing x is caused by the disorder introduced by the replacement of iodide by chloride ions.

In this paper, we give the results of measurements of conductivity as a function of temperature and composition in the $RbCu_4Cl_3(I_{2-x}Cl_x)$ system. The conductivities decrease very nearly linearly with increasing x. This is attributed to a decrease in the mobility of the Cu^+ ions (which is very sensitive to h_m, the activation enthalpy of motion) caused by the disorder introduced by the substitution of Cl^- for I^- ions.

[1] On leave from the Indian Association for the Cultivation of Science, Calcutta 700032 India.

Key words: solid electrolyte, conductivity, solid solution, cuprous ion conductor, rubidium cuprous chloroiodide.

The conductivity results obtained on stoichiometric $RbCu_4Cl_3I_2$ in the present work cast doubt on the existence of low temperature transitions reported earlier (1). The "apparent transitions" are very likely caused by development of hairline cracks in the pills.

Experimental

Details on starting materials and on preparation of the solid electrolyte samples are given in part I (2). The preparation of the cells for the conductivity measurements was one of the formidable problems in this investigation. Unlike the case with the conductivity

measurements on $NH_4Cu_4Cl_3(I_{1.9}Cl_{0.1})$ (3), we could not find a way to use copper powder as electrode material either in pure form or mixed with various proportions of solid electrolyte.

The procedure which turned out to be best for obtaining 6.35 mm diam pellets of 3 mm length with 0.2 mm electrodes at the ends with densities of the solid electrolyte in the range 94-96% of theoretical is described here. We use a die made of 440-C hardened stainless steel of ¼ in. ID with a finely polished inner surface. At the bottom of the die is a small tungsten carbide piston of ¼ in. diam and ¼ in. long. 35 mg of an intimate mixture of the 1 μm Ag powder[2] and solid electrolyte (1:1 by weight) are placed in the die on the small piston. This material is smoothed with the help of a longer piston, being careful that no particles adhere to the wall of the die. The material is then subjected to a pressure of 600 kg cm^{-2} for about 1 min. Pressure and piston are removed and 400 mg of the solid electrolyte added. Again this material is compressed at the same pressure. Then 35 mg of electrode material are added, and again pressure is applied. Then another ¼ in. diam-¼ in. long tungsten carbide piece is inserted followed by a 2 in. long piston. A heating tape is wound about the die and a Chromel-Alumel thermocouple inserted between the tape and die. The die is heated slowly to a temperature of 50°C and a pressure of 3000 kg cm^{-2} applied. Temperature and pressure are held at these values for 10 min. Pressure is released and temperature slowly raised to 80°C over a period of 1 hr. Then the temperature is slowly decreased to room temperature over a period of 2 hr. The pill is then readily removed from the die, examined under the microscope for small cracks and for measurement of dimensions with an eyepiece micrometer.

Conductivities as a function of temperature were measured with essentially the same equipment as described elsewhere (1, 4). A thin layer of the 1 μm Ag powder is spread over the electrode surfaces of the pill to improve contact between the platinum electrodes (formerly silver) of the equipment [see Fig. 1 of Ref. (4)] and the electrode surfaces of the specimen. Dry nitrogen flows continuously around the specimen.

Measurements were also made on carbon resistors with accurately known resistances over the range of resistances of the specimens and over the range of frequencies used in the measurements of the solid electrolyte resistances. (Generally the frequencies were close to 5 kHz.) Appropriate corrections were made.

Checks on conductivity results obtained with the vector impedance measuring device were made with a General Radio 1650B impedance bridge used in conjunction with a GR 1310 oscillator and GR 1232A tuned null detector. Agreement was very good (within 1%) in all cases.

Results and Discussion

In Fig. 1, $\log_{10}(\sigma T)$ *vs.* $10^3/T$ is plotted for three runs on the same pellet of stoichiometric $RbCu_4Cl_3I_2$ between room temperature (295 K) and 450 K. A separate pellet was used to obtain the low temperature data shown in Fig. 1 and 2.

On the first heating from room temperature, ($10^3/T = 3.35$), there is a slight deviation from the straight line beginning at $10^3/T = 2.50$ ($T = 400$ K). [In Ref. (1) such a deviation was not observed; the measurements were made only to 385 K.] On cooling, the points obtained all fitted a straight line very well. The sample was removed from the apparatus and kept in a desiccator. On the following day, a second heating cycle was performed; the points obtained lie on a straight line (within experimental error) though not quite as well as for the two prior runs. The slopes for the first two give h_m (the enthalpy of activation of motion) equal to 0.112 eV; the slope of the third

gives 0.115 eV. (Note: all straight line fits to the data were performed by linear regression analysis.)

It is to be noted that no deviation from the straight lines occurred at high temperatures for any specimen with $x > 0$ (Fig. 3). Considering the observations that had been made on the stability of the stoichiometric material [see part I (2)], it was at first believed that the deviation from the straight line resulted from some decomposition of the solid electrolyte. (It should be mentioned that this deviation was observed on three separately investigated pellets.) An x-ray powder photograph of the tested material indicated that no decomposition had occurred. We can only speculate that the deviation perhaps resulted from an unfavorable reaction of the stoichiometric $RbCu_4Cl_3I_2$ with the silver in the electrode at the solid electrolyte-electrode interface. Some further reaction might have occurred during the overnight period, because the conductivities dropped slightly; the change of the room temperature conductivity between the two heating cycles was 0.04 Ω^{-1} cm^{-1}, *i.e.*, from 0.39 to 0.35 Ω^{-1} cm^{-1}.

It has been observed that the measured conductivity of a pellet decreases as the pellet ages. This is true for all x. Reaction with Ag is believed to be involved, but it is not yet known what it is. In any case, for best results the pellets for measurement should be freshly prepared as described earlier.

Shown also in Fig. 1 and 2 are the results of measurements made on a fresh pellet at subambient temperatures. Down to 250 K, the points obtained lie on the same straight line as the initial higher temperature data (to 400 K). A deviation from the straight line begins at 235 K and at 225 K looks as though a first order transition were occurring. Figure 2 shows a continuation of the data for $RbCu_4Cl_3I_2$ down to 156 K. Data were then taken on warming the same specimen through the region in which there appeared to be a transition during the cooling cycle. All these data lie on a straight line and therefore do not indicate a transition. The conductivity values were lower in the heating cycle. Also the slope is much steeper than the slope between 250 and 400 K (m = 840 *vs.* 565, see Table I).

After the measurements (to room temperature) the pellet was examined under a microscope; a hairline crack was detected. An x-ray powder pattern of the solid electrolyte showed that no decomposition had occurred. We therefore conclude that the cause of the results shown below room temperature in Fig. 1 and 2 is the hairline crack in the pellet that must have occurred at around 250 K.

Considering the close relationship of the crystal structures of $RbAg_4I_5$ and $RbCu_4Cl_3I_2$, the results of the earlier (1) conductivity measurements implied transitions in $RbCu_4Cl_3I_2$ similar to those in $RbAg_4I_5$ (5). However, the present results cast doubt on the existence of these transitions in the $RbCu_4Cl_3I_2$. This is a tentative conclusion awaiting further experiments with an improved low temperature device (now on order) for x-ray diffraction experiments and differential scanning calorimetric measurements by others (for which the required equipment is not directly available here).

In Fig. 3, $\log_{10}$ (σT) *vs.* $10^3/T$ is plotted for representative members of the $RbCu_4Cl_3(I_{2-x}Cl_x)$ system in the temperature range 295-425 K. The straight line fits were obtained by linear regression analysis of the data. Various results of the measurements made on all the specimens are given in Table I, including x-ray densities, bulk densities of the pellets, activation enthalpies of motion, h_m, the slopes and intercepts of the straight lines (in the form $\log_{10}$ $(\sigma T) = m(10^3/T) + b$), σ at 298 K, and 419 K (the solid electrolyte transition temperature of AgI).

The attainable densities of the pills listed in Table I are 94-96% of the x-ray densities. An experiment was performed to try to determine the effect on the conductivity of deviation of density from the x-ray density. A pellet of $RbCu_4Cl_3I_2$ with 91% of the x-ray density gave a conductivity of 0.37 Ω^{-1} cm^{-1};

† As obtained from straight line fit.

at 94% the conductivity is 0.39 Ω^{-1} cm^{-1} (Table I). Thus a difference of 3% in density gives a difference of 5% in conductivity. If the effect were linear one would expect $RbCu_4Cl_3I_2$ crystals to have a conductivity of 0.43 Ω^{-1} cm^{-1} at 298 K and 1.06 Ω^{-1} cm^{-1} at 419 K.

These results as well as those for h_m reported here for $RbCu_4Cl_3I_2$ differ from those reported earlier (1). The former results were 0.47 Ω^{-1} cm^{-1} at 298 K, a predicted 1.53 Ω^{-1} cm^{-1} at 419 K and $h_m = 0.15$ eV for the activation enthalpy of motion. The substantial differences in the second and third values from those given in Table I resulted from a systematic error (which should have been, but was not recognized at that time). Nevertheless, all the conductivities are quite high and it is correct to say that $RbCu_4Cl_3I_2$ has the highest room temperature ionic conductivity of all solid electrolytes. In fact, even the material $RbCu_4Cl_3(I_{1.6}Cl_{0.4})$ with the largest amount of Cl^- ion has a higher conductivity at 298 K than $RbAg_4I_5$. However at 419 K, α-AgI has the highest ionic conductivity.

In Fig. 4, the room temperature conductivities are plotted as a function of composition, x in $RbCu_4Cl_3(I_{2-x}Cl_x)$. (These conductivities are uncorrected for density, as are all results in Fig. 1-3.) It is seen that the conductivities decrease almost linearly with increasing x. The conductivity is given simply by $\sigma = nq\mu$, where n is the charge carrier concentration, q is the charge, and μ is the mobility. Because the lattice constant decreases with increasing x, the charge carrier concentration increases with decreasing x, but not very much, *i.e.*, from 1.585×10^{22} cm^{-3} for $x = 0.00$ to 1.600×10^{22} cm^{-3} for $x = 0.40$, a difference of +0.9%. This increase in n should cause a 0.9% increase in σ.

The reason for the decrease in conductivity with increasing x is very likely the decrease in mobility caused by the disorder resulting from substitution of the Cl^- for I^- ions. The mobility is very sensitive to the value of h_m. In Table I, the values of h_m are given to three decimal places. This is required to demonstrate the sensitivity of σ to h_m. If we calculate h_m from

$$h_m = kT \log [ne^2D_o/k\sigma T]$$

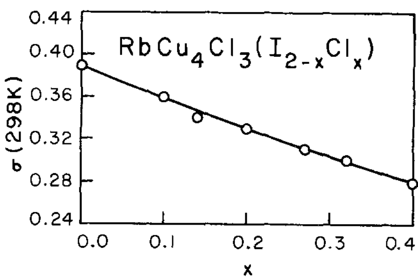

Fig. 4. Conductivity at 298 K vs. x in $RbCu_4Cl_3(I_{2-x}Cl_x)$

where D_o is the diffusion preexponential factor, k the Boltzmann constant, and e the charge of the proton, and take D_o equal to the value for stoichiometric $RbCu_4Cl_3I_2$ (*i.e.*, assuming $h_m = 0.112$ eV) constant for all x, the values of h_m obtained are those listed next to the experimental ones in Table I. The value of D_o for $x = 0.00$ is 3.1×10^{-4} cm^2 sec^{-1}. The values for σ are the experimental ones for 298 K and are listed in Table I. It is seen that the largest deviation from the experimental values is less than 4%. It is also seen that a change in h_m of 8% results in a change of 28% in the conductivity.

It is highly probable that the increase in h_m with decreasing x is real. The replacement of I^- by Cl^- ions might be expected to affect adversely the "windows" through which the charge carriers must move; that is to say, the barrier heights are increased on the average, as indicated by increase in h_m, and this in turn decreases the mobility.

Note added in proof:

As a result of continuing work on related materials, we no longer believe that electrode reaction is the cause of decreased conductivity once measurements have been made to high temperature (see left column, p. 2677). There is increasing evidence that the cause is mechanical (rather than chemical), namely increased grain boundary width in the pellet, drastic, as manifested by fine cracks, or, more subtle, localized recrystallization. Further discussion of this matter is included in a publication now in preparation.

On the Tetrachloroaluminate Dissociation in Aluminum Chloride-1-n Butylpyridinium Chloride Mixtures

J. P. Schoebrechts[1] and B. P. Gilbert

Laboratory of Analytical Chemistry and Radiochemistry, University of Liège, B-4000 Sart Tilman-Liège, Belgium

ABSTRACT

The dissociation of tetrachloroaluminate anions in room temperature $AlCl_3$-1-n butylpyridinium chloride mixtures has been investigated as far as both reproducibility and reliability are concerned. The determination of the dissociation constants is based on the aluminum electrode potential variation measured around the equimolar composition. Experimental conditions have been determined which avoid the reduction of the pyridinium cation by Al in slightly basic melts and where the potentials of the Al electrode are stable. The average values of the dissociation constants are, respectively, $(1.2 \pm 0.2)10^{-13}$, $(4.5 \pm 0.4)10^{-13}$, and $(7.5 \pm 0.8)10^{-13}$ at 40°, 49°, and 55°C and are systematically lower than previously published values. The corresponding average values of ΔH and ΔS are, respectively, equal to 20.3 kcal mol^{-1} and 6.5 eu. It has also been shown that the dissociation equilibrium of $AlCl_4^-$ into $Al_2Cl_7^-$ and Cl^- is the only one required even in very acidic melts (up to 66.6 m/o of $AlCl_3$), provided a correction is made for the junction potential.

For the past few years, several groups of scientists have been interested in aluminum chloride containing melts. Most of these investigations deal with $AlCl_3$-alkali halide mixtures because of their particular properties. In particular, the chloroacidity (pCl) can be varied to a large extent, especially about the equimolar composition range (1-4). It has also been shown that the acidic nature of such melts stabilizes low oxidation state ions and organic radical cations (5-12). However, as pointed out by Koch *et al.*, the use of aluminum chloride-inorganic chloride molten salts for organic reaction investigation is limited, essentially because of temperature problems (13).

Recently, a new molten salt, first reported by Hurley and Wier (14), namely a 67/33 mol percent (m/o) aluminum chloride-ethylpyridinium bromide mixture, has been proposed as solvent for organic studies (15). It is liquid at room temperature, apparently very acidic (in a chloroacidity sense), and exhibits a large electrochemical window. However, although it has been used successfully to investigate different organic or inorganic systems (13, 15, 16), no quantitative data exist, either about the acidic strength of such melt or about the dependence of the acidic properties with respect to the melt composition. The main reason is that the mixture ethylpyridinium bromide-$AlCl_3$ is liquid at room temperature only in a limited range of composition, close to 2:1 and no investigation has been made outside this range.

As a consequence, investigations have been directed to mixtures of $AlCl_3$ with other pyridinium salts, mainly n-methyl and n-butylpyridinium chlorides. The latter appears to be the most interesting; it is liquid at temperatures lower than 40°C across a large composition range (66-43 m/o of $AlCl_3$) whereas the former mixture is liquid at room temperature only in the range of 2:1 composition. Physical and spectroscopic properties of these melts (pure or mixed with benzene) have been investigated by Osteryoung *et al.* (19, 21, 24) and King *et al.* (18). Electrochemical studies of organic [mainly aromatic (20, 25)] and inorganic solutes [Fe(III)/Fe(II) (22), Cu(II,I) (17), Ni(II/0) (26)] as well as the reduction of the melt in acidic (27) or basic (31) mixtures have also been performed. One of the main conclusions of these studies is that a better knowledge (qualitative and quantitative) of the equilibria involved is needed (22).

Qualitative information has been obtained from Raman measurements. It was concluded that the same dissociation equilibrium [1] which characterizes the high temperature inorganic chloroaluminate melts, exists in the room temperature melt

$$2AlCl_4^- \rightleftarrows Cl^- + Al_2Cl_7^- \quad [1]$$

The spectrum of $AlCl_4^-$ and $Al_2Cl_7^-$ are well defined and exhibit much sharper lines than for conventional chloroaluminates (24). Furthermore, reaction [2] seems quantitative

$$\tfrac{1}{2} Al_2Cl_6 + AlCl_4^- \rightleftarrows Al_2Cl_7^- \quad [2]$$

and an exactly 2:1 mixture shows essentially the $Al_2Cl_7^-$ spectrum, contrary to the high melting mixtures.

Osteryoung and Gale have tentatively estimated by potentiometric titration the corresponding equilibrium constant (K_1) at various temperatures and the ΔG of reaction [1]. The proposed constant at 30°C is six orders of magnitude lower than for NaCl-$AlCl_3$ mixtures at 175°C (19). The results indicate, however, a lack of reproducibility in the basic side of the titration curve due to partial spontaneous reduction of the melt by the Al indicator electrode (31). Furthermore, no significant difference in the potential span with temperature was found, unlike the $AlCl_3$-NaCl system. The experimental equilibrium constant was then regarded as a maximum value. Titrations of the melt diluted with benzene led to similar conclusions (19, 27).

Another way of obtaining quantitative information about the equilibrium constant (K_1) is to investigate the potential variation of a pCl sensitive couple other than aluminum. Osteryoung *et al.* proposed a more precise value of K_1 based on the titration curve of Ni(II) followed by a nickel electrode. The assumptions were, however, that $NiCl_4^{2-}$ is the only complex formed on the basic side and that the equivalence point potential of the Ni(II) titration curve is the potential of the neutral point of the melt (26).

The purpose of this work was then to find out if improving experimental conditions could lead to more precise and reproducible equilibrium constant determinations.

[1] Chercheur à l'Institut Interuniversitaire des Sciences Nucleaires, Brussels, Belgium.

Key words: chloroaluminate melts, butylpyridinium, equilibrium constants, potentiometry.

Experimental

Melts were prepared by mixing sublimed $AlCl_3$ (Fluka, iron-free) and 1-n-butylpyridinium chloride (BPC) as described by Robinson and Osteryoung (20). Provided careful preparation of 1-n-butylpyridinium chloride (20) was carried out, colorless melts were obtained.

Potentiometric titrations have been performed by accurately weighed (± 0.1 mg) additions of $AlCl_3$ crystals to a basic melt rather than BPC addition to a slightly acidic melt. The latter procedure was indeed found less satisfactory because BPC dissolves slowly and, with stirring, sticks to the aluminum indicator electrode causing a local increase of basicity. As already mentioned (19, 31), highly basic melts react with aluminum by formation of radicals and the potential measurements become erratic.

The electrochemical cell was made of a Pyrex vessel provided with 5 ground joints. The electrode design is identical to the one described (12) except that the joints have been replaced by ground joints. The indicator electrodes were either an Al wire (Analar m3N) or a glassy carbon disk electrode (Tokai). The reference electrode is an Al wire in a 2:1 $AlCl_3$:BPC melt. The reference compartment is separated from the melt by a Pyrex soft glass junction as described by Moe (28).

The melt is thermostated (± 0.5°C) by a constant temperature bath (ethylene glycol) circulating in a jacket around the electrochemical cell and an external thermostat.

Potentiometric measurements were performed with an H.P. 3465A digital voltmeter. Before use, the aluminum electrodes (previously cleaned with an H_2SO_4, HNO_3, H_3PO_4 mixture and dried) are digested for 1 day in an acidic mixture; the electrode is then removed from the cleaning melt and wiped completely free of melt. Following this procedure, the potential measurements are stable within 1 mV for several hours, even in a 49% melt. In some cases, erratic measurements have been observed in basic melts, together with the appearance of a slightly blue color and the melt and the electrode are then discarded.

The electrochemical measurements other than potentiometry were performed with a Princeton Applied Research polarograph, Model 170.

All handling of the melts and electrochemical experiments were performed inside a dry box with water and oxygen content below 20 ppm.

Results and Discussion

As already mentioned there have been two different ways of evaluating the stability constant of equilibrium [1]: (*i*) A direct potentiometric titration which is apparently limited on the basic side by the Al reduction of the melt, even if diluted with benzene; and (*ii*) an indirect determination from a *p*Cl sensitive couple Ni(0)/Ni(II). This couple is, however, sensitive to *p*Cl essentially on the basic side because of an $NiCl_4^{2-}$ complex formation. Considering the assumptions made, an Ni(II) potentiometric titration allows one only to estimate the minimum *p*Cl variation in order to complex quantitatively the nickel, provided that the complex formation constant is known. From this minimum *p*Cl variation, it is then possible to estimate a maximum value of the constant K_1.

We have tentatively chosen to improve the determination of the equilibrium constant from direct potentiometric titration of the melt with Al electrodes based on the experimental finding that reduction of the melt occurs only at a certain point of basic compositions and an Al electrode could still be used in a narrow range. The extent of this range depends on the cleanliness of the melt and the physical state of the Al surface. With Al electrodes pretreated as described above, the experimental cathodic potential limits in the basic side are −1.15, −1.11, and −1.02V, respectively, at 40°, 49°, and 55°C. These limits correspond to the most cathodic potentials observed in basic melts where no "apparent" reduction of the melt can be observed, *i.e.*, the Al electrode potential is stable within 0.5 mV for a period of at least 2 hr under constant stirring, no color is developing around the electrode, and the background recorded by cyclic voltammetry at a glassy carbon electrode exhibits no wave in the whole useful electrochemical range. The aluminum reduction of the melt produces a monocation radical which can be either oxidized or reduced, respectively, at −0.56 and −0.96V *vs.* the potential of Al in a 2:1 $AlCl_3$-BPC melt (31).

By using melt compositions so that the potential does not exceed the limits and the experimental procedure described above, the titration curve (shown in Fig. 1) could be reproduced in any case.

In some cases, the limits above were exceeded with no apparent reduction of the melt (as defined above). An example of a titration curve obtained under these conditions is shown in Fig. 2. The most basic points are located 0.07V beyond the limiting potential. Despite the fact that for this particular experiment the potentials were very stable, it was found difficult to reproduce the same titration curve, starting with a new melt and a new Al electrode. The problem of reproducibility of very basic points indicates that the kinetics of melt reduction depends primarily, at a given melt composition, on the physical state of the Al electrode.

If the Al electrode exhibits a potential depending essentially on the Al/Al(III) couple, our results are apparently in contradiction with the recent work of Gale and Osteryoung (31). Assuming a very slow reduction of the pyridinium cation in our titration curves, their results indicate that the potential of an Al electrode in a 0.8/1 melt should be around −1.4V whereas Fig. 2 indicates for the same melt a potential of −1.2V. A possible explanation is that the pyridinium cation reduction is not as slow as we think (but it is then difficult to understand the stability of our potential measurements), or that the results of

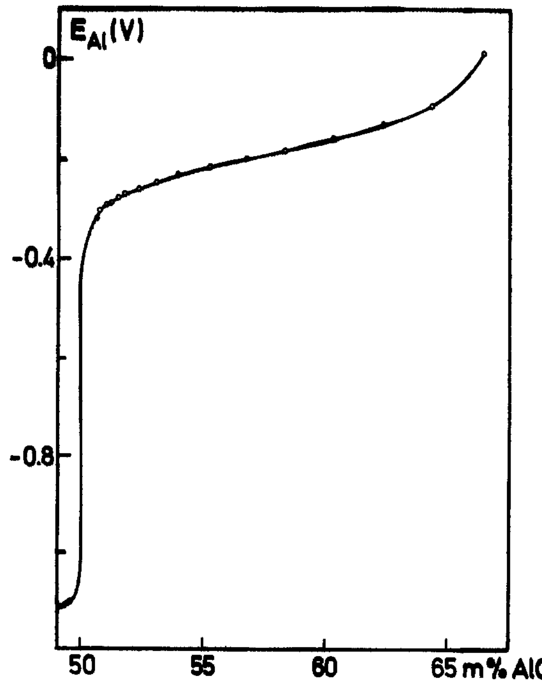

Fig. 1. Complete titration curve of a basic melt at 40°C. E_{Al}: the potential of an Al electrode in the melt *vs.* an Al electrode in 2:1 reference melt.

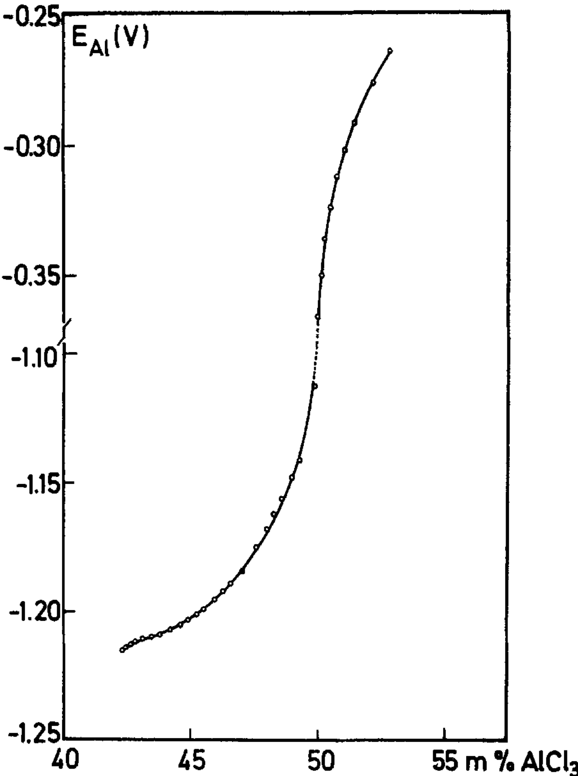

Fig. 2. Titration curve of a very basic melt at 40°C in the equimolar range.

Gale were obtained from dynamic methods on a glassy carbon electrode where a strong nucleation underpotential for the Al deposition may occur as it is the case in acidic mixtures (27).

Besides the problems of precise potentials measurements on the basic side, the determination of the stability constant by comparing the equivalence point and acidic point potentials of the titration curve is probably not very satisfactory because of the large experimental errors on the direct equivalence point potential measurement. The only quantity which can be determined with precision is the amount of $AlCl_3$ (or BPC) added to reach the equivalence point. Two different methods have then been used in order to evaluate the equilibrium constant without measuring directly the equivalence point potential.

Assuming a constant concentration of $AlCl_4^-$ in the vicinity of the equivalence point and a constant liquid junction potential (19), the simple treatment of Torsi and Mamantov was applied. By using successive potential differences between an acidic and a basic point, the cell voltage can be written as follows

$$E_A - E_B = \frac{4RT}{3\mathbf{F}} \ln \left((\gamma_{Al_2Cl_7^-})_A \cdot [Al_2Cl_7^-]_A (\gamma_{Cl^-})_B [Cl^-]_B \right) - \frac{4RT}{3\mathbf{F}} \ln \left(K_1 [AlCl_4^-]^2 (\gamma_{AlCl_4^-})^2 \right) \quad [3]$$

where E_A and E_B are the potentials measured, respectively, at an acidic composition A and a basic composition B, $(\gamma_{Al_2Cl_7^-})_A$, $(\gamma_{Cl^-})_B$, and $\gamma_{AlCl_4^-}$ are the respective activity coefficients, $[Al_2Cl_7^-]_A$, $[Cl^-]_B$, and $[AlCl_4^-]$ are the corresponding concentrations (expressed in $mol \cdot kg^{-1}$), and K_1 is the thermodynamic dissociation constant of equilibrium [1].

As previously discussed (32), the activity coefficients of $Al_2Cl_7^-$, Cl^-, and $AlCl_4^-$ are not known. However, as the concentrations of Cl^- in the basic region and $Al_2Cl_7^-$ in the acidic side do not vary to a great extent, it can be assumed that the corresponding $(\gamma_{Cl^-})_B$ and $(\gamma_{Al_2Cl_7^-})_A$ are constant (32). For the same reason, $\gamma_{AlCl_4^-}$ can also be considered as constant on both acidic and basic sides. The cell voltage can then be rewritten as

$$E_A - E_B = \frac{4RT}{3\mathbf{F}} \ln \left([Al_2Cl_7^-]_A [Cl^-]_B \right) - \frac{4RT}{3\mathbf{F}} \ln \overline{K_1} \quad [4]$$

where $\overline{K_1}$ is a conditional equilibrium constant equal to

$$\frac{K_1 [AlCl_4^-]^2 (\gamma_{AlCl_4^-})^2}{(\gamma_{Cl^-})_B \cdot (\gamma_{Al_2Cl_7^-})_A}$$

As will be seen below, the good agreement between the experimental titration curve and the theoretical curve calculated on the basis of concentration changes, indicates that the assumption made on the constancy of the activity coefficients is reasonable.

The $[Al_2Cl_7^-]_A$ and $[Cl^-]_B$ are calculated from the added amounts of $AlCl_3$. The procedure and the precise determination of the amount of $AlCl_3$ added at the equivalence point by a linearization method, are explained in Appendix A.

The second method involves the calculation of the standard potentials $E_B°$ and $E_A°$ corresponding to the respective reactions

$$AlCl_4^- + 3e \rightleftarrows Al + 4Cl^- \quad [5]$$

and

$$4Al_2Cl_7^- + 3e \rightleftarrows Al + 7AlCl_4^- \quad [6]$$

The equivalence point molar composition is adjusted for a minimum standard deviation on $E_B°$ and $E_A°$; the equilibrium constant is then simply calculated from

$$E_B° = E_A° + \frac{4RT}{3\mathbf{F}} \ln K_1 \quad [7]$$

A more detailed description of the procedure is given in Appendix B.

In Table I, we have summarized some of the results obtained at three different temperatures and the precision on each of the experimental constants. The results obtained from method 1 or 2 were found similar within experimental errors but method 2 is preferred because it involves less assumptions and allows the complete calculation of the titration curve, even in more acidic melts. It can be noticed that at 40°C, the measurements are reproducible within 25%. The temperature variation of the results corresponds to an average value of ΔH and ΔS equal, respectively, to 20,300 $cal \cdot mol^{-1}$ and 6.5 eu.

In Table II, we compare our results with the previously published values. Because it is possible that mixed potentials are involved in our titration curves (19, 31), the stability of potential measurements indicates that the kinetics of basic melt reduction must be particularly slow provided that the above-mentioned melt compositions are not exceeded. The resulting equilibrium constants were found systematically lower than the constants obtained by other workers below 120°C and are thus considered as

closer to the true value for which no Al reaction with basic melt would occur.

All previous equilibrium constant determinations were obtained from melts whose composition was in the vicinity of the equimolar BPC-$AlCl_3$ melt. Titration curves were also extended to more acidic mixtures, up to the 2:1 composition (see the acidic part of Fig. 1). Systematic deviations between experimental and calculated potentials, increasing with the melt acidity for melt compositions higher than 55 m/o were observed. Tentative interpretation of these deviations based on the introduction of a second equilibrium such as [8] were unsuccessful

$$AlCl_3 + AlCl_4^- \rightleftarrows Al_2Cl_7^- \quad [8]$$

The necessary equilibrium formation constant K_2 was found much too high (six order of magnitude) with respect to what is expected by extrapolation at room temperature of K_2 constants known for inorganic chloroaluminates (3).

Another explanation involves the fact that the exact formulation of the emf is given by (33)

$$-FE = \int_I^{II} \left(1/3\, d\mu_{AlCl_3} - \frac{t_{Al}}{3} d\mu_{AlCl_3} - t_{BP^+} d\mu_{BPC} \right) \quad [9]$$

In the preceding calculations, only the first term is taken into account.

For titration curves involving inorganic chloroaluminate, it has been generally accepted that either the last two terms are indeed negligible (2, 3) or can be calculated based on the assumption that the cation is the only current carrying species (4). In agreement with the work by King and Øye (33), for room temperature organic chloroaluminate melts, the organic cation cannot be considered with certainty as the only current carrying species because of its much larger size with respect to the inorganic cation. By measuring conductivities of various molten methylpyridinium halides, Newman *et al.* concluded that the principal charge carrier is the anion simply because chloride melts are better conductors than bromide melts. However, such a simple conclusion cannot be made when comparing the conductivities of several alkylpyridinium halides where both the alkyl chain and the halide were changed (29).

In the pyridinium chloroaluminates, it is reasonable to consider that the main current carrying species can be the pyridinium cation, the $AlCl_4^-$ and Cl^- anions (33), since the $Al_2Cl_7^-$ anions have a much lower mobility due to their size. The chloride anions may contribute to the current only on the basic side where their concentration is not negligible with respect to other ions. This can be taken into account by assuming that t_{Cl^-} is proportional to the Cl^- concentration (30).

By integrating the last two terms of Eq. [9] and introducing the equilibrium $AlCl_3 + Cl^- \rightleftarrows AlCl_4^-$, a correction ($E_j$) to the initial emf can be calculated

$$E_j = -\frac{RT}{F}\left(\ln\frac{[BP^+]}{[BP^+]_{ref}}\right)\cdot t_{BP^+} + \frac{RT}{F}\cdot t_{AlCl_4^-} \cdot \ln\frac{[AlCl_4^-]}{[AlCl_4^-]_{ref}} + \frac{RT}{F}\cdot k\cdot([Cl^-]_{ref} - [Cl^-]) \quad [10]$$

As already discussed by Von Barner *et al.* (30) the various transport numbers and k are not known but, considering that the mobilities of the ions are roughly inversely proportional to their ionic radii, an appropriate evaluation of the E_j correction term can be made. With this assumption, the maximum chloride ion contribution to E_j is of the order of one mV at 25°C and will therefore be neglected. The approximate t_{BP^+} and $t_{AlCl_4^-}$ are then, respectively, 0.6 and 0.4. By introducing these values to Eq. [10], the whole corrected theoretical titration curve can then be evaluated.

Two different experiments were performed. The first one involves the titration of a basic melt by successive $AlCl_3$ additions with a 66 m/o $AlCl_3$ reference; the second one involves the titration of a very acidic (66.6 m/o $AlCl_3$) by BPC additions with a 57 m/o $AlCl_3$ reference. Because of the problems encountered by BPC additions (see the experimental part), only the acidic part of the curve was recorded in this case. In both cases the agreement between the theoretical and experimental potentials was now remarkably good (Table III). The average deviations were, respectively, ±1.4 mV and ±2 mV, for the whole titration curve, *i.e.*, even for the very acidic points (66 m/o). We have also noticed that no agreement was found assuming only one current carrying species, either BP^+ or $AlCl_4^-$.

Finally, in the acidic part of the titration curve, the derivative of the potential *vs.* the total mol fraction of $AlCl_3$ exhibits a minimum near the 57 m/o $AlCl_3$ composition. In this region, the electrode potentials are less sensitive to pCl than in the 1:1 or 2:1 $AlCl_3$:BPC melts. A 57 m/o melt would then be the most appropriate in a reference compartment with an Al electrode.

From this study, it can be concluded that: (*i*) Some experimental conditions can be adjusted to give reproducible values of the equilibrium constant K_1. Because the titration curve involves mixed potentials, the values may not correspond to the exact K_1 value and are then considered as maximum values as in previous works (19). However, the stability of our potential measurements in the basic side, indicates that the melt reduction by Al is particularly slow and our results must be close to the true K_1 value. (*ii*) Only one equilibrium is necessary to fit the whole experimental titration curve, provided a complete formulation of the emf is taken into account.

Table III. Comparison in acidic medium of experimental potentials ($E_{Exp.}$) and theoretical potentials without ($E_{Th.1}$) and with ($E_{Th.2}$) corrections for the junction potentials (E_J). Reference: an Al electrode in 66.2 m/o $AlCl_3$

APPENDIX A

The titration involves successive additions of weighed amounts of $AlCl_3$ to a basic melt of initial weight W_O (in grams). The amount of added $AlCl_3$ is calculated so that only the 49-52 m/o composition range is investigated.

Let n be the total number of $AlCl_3$ mols added from the starting point. The subscript A, B, and Q will be used to describe, respectively, an acidic side, a basic side, or the equivalence point.

Assuming that the following reactions are quantitative

$$Cl^- + AlCl_3 \rightarrow AlCl_4^- \quad [A-1]$$

$$AlCl_3 + AlCl_4^- \rightarrow Al_2Cl_7^- \quad [A-2]$$

the concentrations $[Al_2Cl_7^-]_A$ and $[Cl^-]_B$ involved in Eq. [4] are easily calculated if n_Q is known

$$[Al_2Cl_7^-]_A = \frac{(n_A - n_Q)\ 10^3}{(W_O + n_A \times 133.33)} \quad [A-3]$$

$$[Cl^-]_B = \frac{(n_Q - n_B)\ 10^3}{(W_O + n_B \times 133.33)} \quad [A-4]$$

In order to evaluate precisely the experimental number of mols of $AlCl_3$ necessary to reach the equivalence point (n_Q), a linearization method similar to the one described by Gran (23) has been applied to the more precise points, *i.e.*, the acidic side points.

The potential of an Al electrode in an acidic melt is given by the Nernst equation

$$E_A = E_A{}^\circ + \frac{RT}{3\mathbf{F}} \ln \frac{[Al_2Cl_7^-]_A{}^4}{[AlCl_4^-]_A{}^7} + E_R + E_A{}^J \quad [A-5]$$

where E_R and $E_A{}^J$ are, respectively, the reference electrode potential (unknown but constant) and the junction potential.

Because the composition range investigated to calculate the equilibrium constant is very narrow, we will assume that the E^J and the $[AlCl_4^-]$ are constant. The relation [A-5] can then be rewritten as follows

$$E_A = E_A{}^{\circ\prime} + \frac{4RT}{3\mathbf{F}} \ln\ [Al_2Cl_7^-]_A \quad [A-6]$$

From [A-3], [A-6], and rearranging, one obtains

$$\exp\left(\frac{E_A \times 3\mathbf{F}}{4RT}\right)(W_O + n_A \times 133.3) = k(n_A - n_Q) \quad [A-7]$$

where $k = \dfrac{10^{+3}}{\exp\left(\dfrac{-3\mathbf{F} \times E_A{}^{\circ\prime}}{4RT}\right)}$

A plot of $\exp(3\mathbf{F} \times E_A/4RT)\ (W_O + n_A \times 133.33)$ *vs.* n_A gives a straight line allowing the evaluation of k and n_Q by a least-squares fitting computer program. An example of such a plot is given in Fig. 3. Knowing n_Q, the program computes $\bar{K}_1$ from every successive basic and acidic point and relation [4], then the equivalence point potential and the whole theoretical curve.

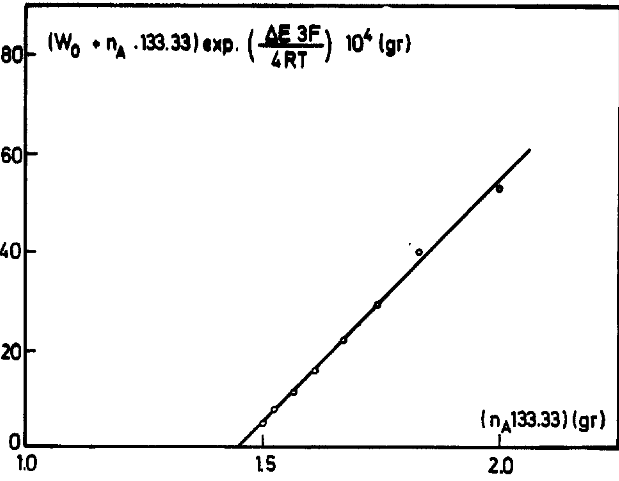

Fig. 3. Determination of the amount of $AlCl_3$ added to reach the equivalence point following the method of Gran (23).

APPENDIX B

In order to evaluate the equilibrium constant from the respective $[Al_2Cl_7^-]$, $[Cl^-]$, and $[AlCl_4^-]$, another method of evaluating precisely n_Q (as defined in Appendix A) is explained below.

1. A first approximate value of n_Q is given to the computer program. Assuming that the reactions [A-1] and [A-2] (see Appendix A) are quantitative, the necessary $[Al_2Cl_7^-]$, $[Cl^-]$, and $[AlCl_4^-]$ (which is not assumed as constant in this case) can then be evaluated for every point of the titration curve.

For example, in the acidic side, the number of $AlCl_4^-$ mols equals the number of $AlCl_4^-$ mols at the equivalence point less the number of added $AlCl_3$ mols in excess to the equivalence point. The $[AlCl_4^-]_A$ is then

$$\frac{(3.28\ 10^{-3}\ (W_O + n_Q \times 133.33) - (n_A - n_Q)) \times 10^3}{(W_O + n_A \times 133.33)} \quad [B-1]$$

where W_O, n_A, and n_Q have the same meaning as above. The $[Al_2Cl_7^-]_A$ is given by the same relation as in Appendix A (Eq. [A-3]).

2. From [A-5], [A-3], [B-1], and the experimentally measured potentials $(E_A - E_R)$, the $(E_A{}^\circ + E_A{}^J)$ can then be calculated for each acidic side point

$$E_A{}^\circ + E_A{}^J = E_A - E_R - \frac{RT}{3\mathbf{F}} \ln \frac{(n_A - n_Q)^4\ (W_O + n_A \times 133.33)^3}{(3.28\ 10^{-3}(W_O + n_Q \times 133.33) - n_A + n_Q)^7 \times 10^9} \quad [B-2]$$

From a similar development and the Nernst equation applied to reaction [5], the $(E_B{}^\circ + E_B{}^J)$ can also be evaluated for each point in basic melts

$$(E_B + E_B{}^J) = E_B - E_R - \frac{RT}{3\mathbf{F}} \ln \frac{(3.28\ 10^{-3}(W_O + n_Q \times 133.33) + n_B - n_Q)(W_O + n_B \times 133.33)^3}{(n_Q - n_B)^4 \times 10^9}$$

3. The respective standard deviation (σ) on all the $E_A{}^\circ + E_A{}^J$ and $E_B{}^\circ + E_B{}^J$ values is then calculated.

4. A new value of n_Q is chosen by the computer; the calculation process restarts from the beginning and leads to a new set of $E_A{}^\circ + E_A{}^J$, $E_B{}^\circ + E_B{}^J$, and σ values.

The final values of n_Q, $E_A{}^\circ + E_A{}^J$, and $E_B{}^\circ + E_B{}^J$ are obtained by successive modification of n_Q in order that the standard deviation (σ) is minimum.

Assuming a negligible junction potential between the acidic and basic points $(E_A{}^J - E_B{}^J \simeq 0)$, the equilibrium constant is then evaluated from relation [7] as explained in the text.

Technical Note

Semiconducting Zinc Oxide Films Prepared by Metal Organic Chemical Vapor Deposition from Diethyl Zinc

A. P. Roth and D. F. Williams

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R6

Zinc oxide exhibits large piezoelectric and optical coupling coefficients, and is often used in acousto-electric and acousto-optic devices (1). It is also an extrinsic n-type semiconductor with a room temperature bandgap of 3.3 eV and can be used as a transparent semiconducting electrode in opto-electronic devices such as solar cells. Indium tin oxide is generally used as the transparent electrode for many solar cells; it is typically an n-type semiconductor due to oxygen deficiencies. If relatively high conductivity in zinc oxide could also be achieved either by preparing nonstoichiometric films or by doping, this source material would be less expensive than indium tin oxide. Nonstoichiometric films would experimentally be the simplest and most economical to prepare, if a sufficiently high conductivity could be achieved. Zinc oxide films have been prepared by rf sputtering (2) and more recently by magnetron sputtering (3). Short reports have also been published of the metal organic chemical vapor deposition of zinc oxide (4, 5), but the aim of these authors was to prepare high resistivity stoichiometric films.

Key words: zinc oxide, chemical vapor deposition, diethyl zinc.

We have a particular interest in semiconducting zinc oxide and have recently studied the growth characteristics and related electrical properties of films prepared by the controlled oxidation of diethyl zinc (DEZ). Changes in the substrate temperature were found to significantly alter the film deposition rate and resistivity, two critical factors for any potential zinc oxide electrode applications.

The zinc oxide films were deposited on clean Pyrex glass substrates over an area of ~1.5 cm × 3 cm. The substrates were supported on a graphite susceptor which top surface had been cut at an angle of 15° from the horizontal axis of the reactor tube to provide a grazing incidence gas flow over the substrates. The susceptor/substrate combination was placed in the center of this horizontal square quartz reactor tube, 3.5 × 3.5 × 50 cm, and this central area then enclosed in a cylindrical aluminum reflector containing two 500W quartz halogen lamps. These lamps could heat the

substrate to temperatures of up to 900°C. A calibrated thermocouple encased in thin stainless steel monitored the substrate/susceptor temperature throughout the film preparation.

All fittings to the reactor tube were either quartz or stainless steel. Gas flow into the reactor tube was all passed through mass flow controllers. High purity argon (99.999%) was used as an inert gas and also as a carrier gas by bubbling through DEZ contained in a steel bottle in a temperature controlled bath. Homogeneous gas phase reactions between diethyl zinc and oxygen occur even at room temperature and thus, the DEZ was kept separated from the oxygen until it reached the reaction zone. This was achieved by attaching to the oxygen inlet a small diameter quartz tube which extended inside the reactor to ~2 cm in front of the substrate edge. Gas-phase homogeneous reactions which lower the film growth rate and damage film quality were further minimized by reducing the overall pressure of the system below atmospheric. A more extensive description of the apparatus and experiments will be given later in a full-length paper.

The experiments were all performed at a pressure of 76 Torr (10.13 kPa) with a constant argon flow (2 SLM) and partial pressures of DEZ and oxygen of 1.85×10^{-2} Torr (2.46 Pa) and 1.3×10^{-1} Torr (17.3 Pa), respectively. In the substrate temperature range investigated, 280°-480°C, clear homogeneous films of 2 cm^2 were grown with an average optical transmission of 85-90% for film thicknesses between 4000 and 8000Å. Room temperature electrical properties of these films were obtained by four probe conductivity and by Hall measurements. Film thickness was measured by a Sloan Dektak profilometer.

The variation of the film deposition rate and electrical properties are presented in Fig. 1 and 2, which show the importance of the substrate temperature on the film characteristics. In the low temperature range (below 370°C), the film growth rate is constant while the resistivity decreases drastically from 30 to 8×10^{-2} Ωcm. In this range, a white ZnO deposit appears on the reactor walls downstream of the reaction area, caused by the homogeneous reaction of O_2 with the metalorganic which is only partly decomposed at these temperatures. The decrease in the resistivity can be related to an improvement of the crystallization of the films as shown by the increase of the Hall mobility μ_H.

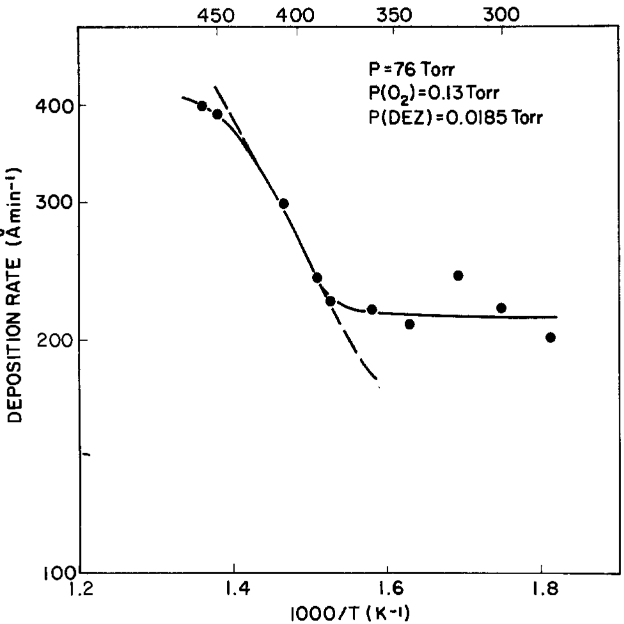

Fig. 1. Variation of the growth rate of zinc oxide films as a function of substrate temperature. Diethyl zinc, pp. 0.0185 Torr, and oxygen, pp. 0.13 Torr were used with argon carrier gas, overall pressure 76 Torr.

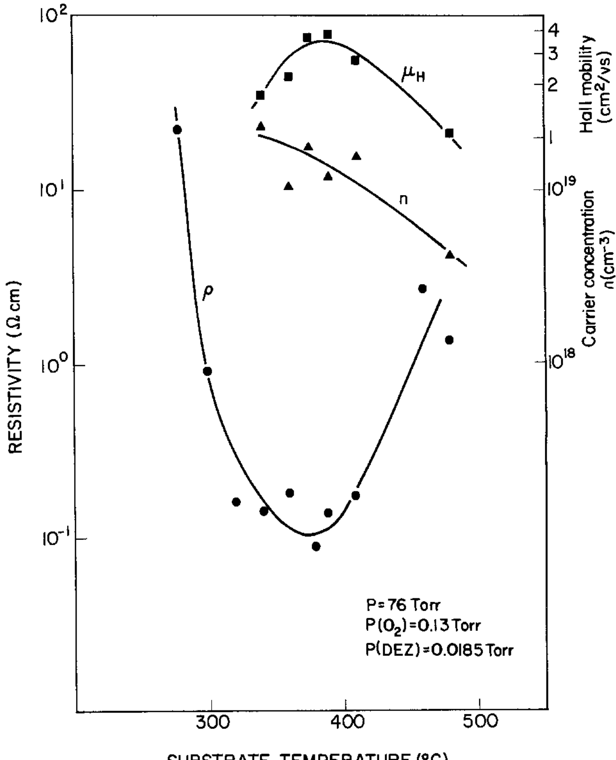

Fig. 2. Variation of the zinc oxide film resistivity, carrier concentration, and carrier mobility with substrate temperature. Deposition conditions were the same as for Fig. 1.

When the temperature of the substrate is further increased, the growth process becomes reaction-rate controlled (Fig. 1). The film growth rate (GR) in such a case can be represented by the relation (6)

$$GR = KT \exp(-E/RT)$$

where K depends on the order of the reaction and on the reacting gas flow rates, and R is the gas constant. The dashed line in Fig. 1 corresponds to an activation energy of 30 kJ/mol (0.31 eV/molecule) and $K = 85$ Å min^{-1} K^{-1}. A saturation in the deposition rate appears around 450°C indicating a mass transport limited regime. In this temperature range (above 370°C) the parasitic deposit on the reactor walls disappears almost completely and the amount of oxygen which is used in the direct film growth increases. Furthermore the ratio of zinc to oxygen included in the films also changes. This can be inferred from the decrease of the carrier concentration (Fig. 2), that is from the decrease of the film nonstoichiometry due to interstitial zinc or oxygen vacancies. The parallel variation of μ_H causes a net increase of the film resistivity.

The variation of the film resistivity with substrate temperature is therefore caused by the competition between crystallization and degree of nonstoichiometry of the films. It has been observed (5) that, in ZnO films deposited by MOCVD at atmospheric pressure on glass substrates using a much higher O_2/Zn mol ratio than in our own experiments, the degree of c-axis orientation of the crystallites increases with temperature up to 400°C and decreases above that temperature. A phenomenon such as this is very likely to have an effect on μ_H as observed.

In summary, thin transparent semiconducting films of zinc oxide can be grown relatively easily by the controlled oxidation of diethyl zinc. The temperatures needed to produce relatively low resistivity films are ~350°-400°C; film electrical properties are strongly dependent upon this decomposition temperature, other

temperatures giving film resistivity increases due to decreasing carrier concentration and decreasing carrier mobility.

Manuscript submitted Feb. 11, 1981; revised manuscript received May 26, 1981.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.

Some Problems in Plasma Etching of Al and Al-Si Alloy Films

Kado Hirobe,* Yoshinori Kureishi, and Takashi Tsuchimoto

Computer Development Laboratories, Limited, 1450, Kodaira-Shi, Tokyo 187, Japan

Generally, aluminum and aluminum-silicon alloy films are widely used as the electric interconnection metal in large scale integrated circuits (LSI). The technology by which fine patterns can be precisely defined in Al and Al-Si films has been indispensable to high density and high speed LSI. Among various kinds of etching methods for the films, the plasma etching in the parallel plate electrode reactor is considered one of the most useful methods to delineate high resolution patterns in the films.

This technology has been developed by several workers (1-4), and it has been well known that the etching method has excellent characteristics, such as anisotropy and less undercutting than the conventional plasma etching in a barrel type reactor and wet chemical etching in acid solutions.

However, there are some problems which were encountered when the technology was applied to the metallization processes. These problems come from the characteristics inherent in the etching technology.

One of the purposes of this work is to survey the problems which were introduced when the etching technology was applied to the metallization process of LSI devices.

Another purpose is to find the origins of these problems and to provide effective approaches to solve them.

In this work, plasma etching of Al and Al-Si alloy films was carried out in a parallel plate, anode coupling type of reactor. Wafers were placed on the susceptors which were placed on the lower Al electrode coated with an aluminum oxide film. This electrode was grounded and rotated at the rate of 4 rpm. RF power of 380 kHz was applied to the upper electrode. An optical emission spectrometer was attached to the chamber. The spectrometer was used to measure the intensity of spectra emitted from the plasma during etching. The 396.2 nm peak of Al atomic spectrum was used (5), as well as the AlCl 261.4 nm peak. CCl_4 was used as the etching gas. Etching experiments were carried out using two types of substrates. One of them was a flat substrate coated with Al or Al-Si alloy films of uniform thickness. The other was a substrate with steps about 1 μm in height. Both pure Al and Al-Si alloy films were deposited on the substrates by a planar magnetron sputter system.

* Electrochemical Society Active Member.

Key words: metallization, sputtering, surface oxide film, emission spectroscopy, plasma etching, Al alloy film.

In our early experiment, when the etching technology was applied to delineate patterns in the films, the following problems were observed: (*i*) Surface oxide film caused a delay in the initiation of the etching reaction of Al with CCl_4, and the delay time varied from several tens of seconds to several minutes, as shown in Fig. 1. (*ii*) The reproducibility of etch rate of the films was poor. The etch rate varied from about 80 to 170 nm/min under the same condition, and so it was difficult to determine the end of etching by time. (*iii*) Al residues were observed along the steps of the substrate and around the hillocks of annealed Al films. The residues of Al caused low current leakage and in the worst case, electric shorts occurred between the adjacent Al patterns. (*iv*) After Al-Si alloy film etching, Si remained as residue on the substrate. The residues also led to leakage of electric current between the adjacent Al patterns. (*v*) Furthermore, severe degradation of photoresist film patterns was found after etching, especially at relatively high rf current or rf power.

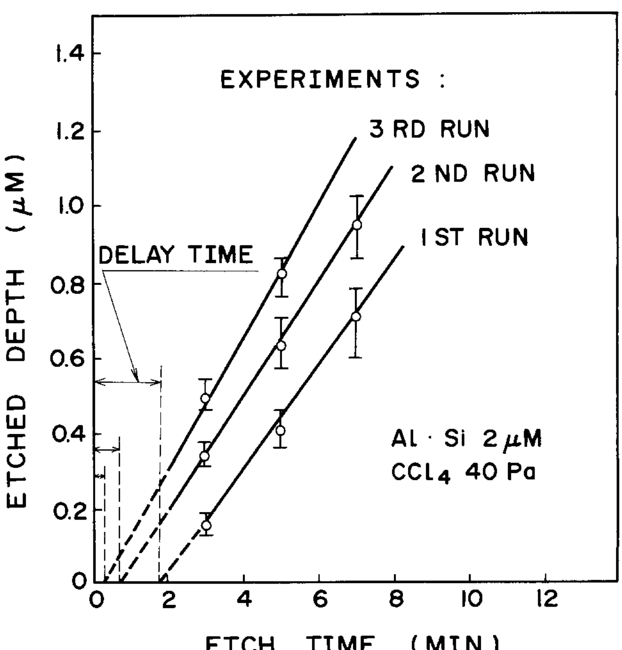

Fig. 1. Etched depth as a function of etch time

It was found that the delay time in etching was decreased with increasing rf current, as shown in Fig. 2. The delay time at higher rf currents was more reproducible than that at lower rf currents. Etching at high rf current for a long time, however, caused the degradation of photoresist films by substrate heating. Etching at high rf current for a short time, such as less than 2 or 3 min at 1A, caused no damage to the photoresist films. Therefore, one of the effective etching procedures was attained by using a two-step etching technique. This etching consisted of the 1st step etching at higher rf current for a short time and then the 2nd step etching at lower rf current to the etch end.

Figure 3 shows typical emission intensity during etching by the two-step technique. The Al etching was started at high rf current, in this case 1A or at rf power density of 0.46 W/cm^2. The initiation of etching was detected by the strong 396.2 nm peaks on the figure. RF current was decreased to 0.8A or to 0.31 W/cm^2 of power density after the occurrence of the strong emission peaks. As the end point was approached, the emission intensity leveled off. Thus, the end point could be detected precisely from batch to batch.

Another technique for removing the protective surface oxide easily and reproducibly, was to supply inert gases such as Xe and Kr to the etching gas. Figure 4 represents a dependence of the delay time on etching gas composition for CCl_4 and Xe. It was found that the appropriate addition of Xe to CCl_4 could greatly decrease the delay time even if the rf current was as low as 0.6A. Decrease of the delay time is considered to be due to removing the surface oxide with the aid of bombardment by energetic Xe^+.

Figure 5 shows typical residues of Al along the steps of the substrate after Al etching. It was found that the steeper the slope of the edge, the more Al remained. One of the reasons for the occurrence of the Al residues was considered to be due to the anisotropic etching of the parallel plate reactor. The etch rate of Al depends on the incidence angle of ions (6), and it is reduced around step edges with incidence angles of about 90 degrees. Another reason was that the Al film at the base of the edge was much thicker than that on the flat area of the substrate. Overetching or ex-

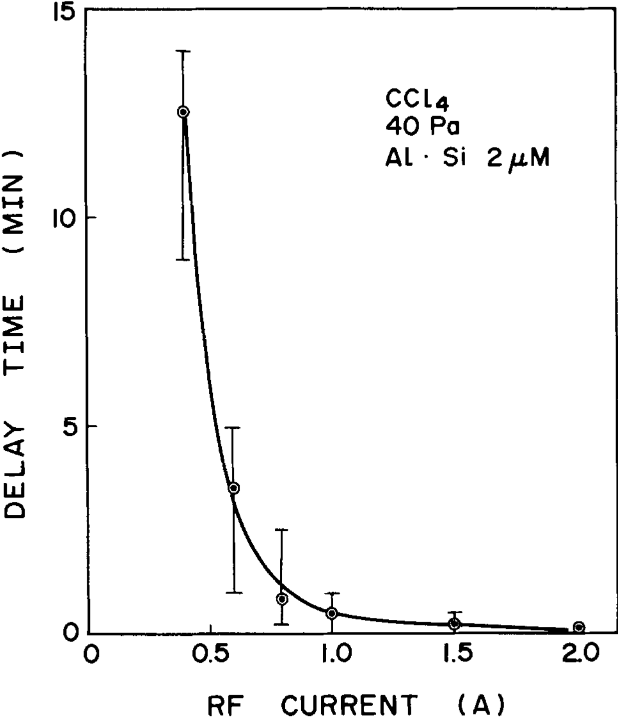

Fig. 2. Dependence of the delay time on the rf current

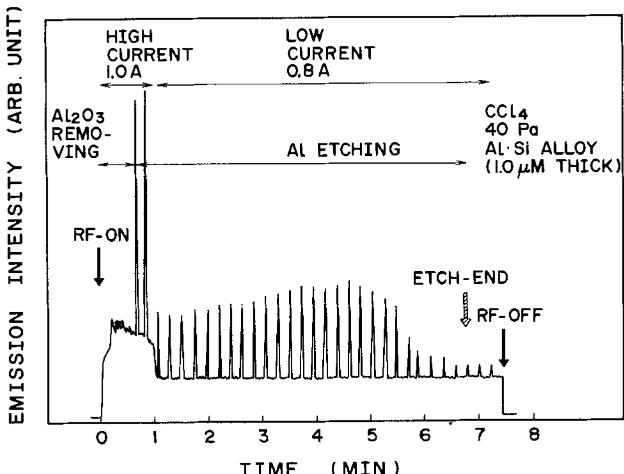

Fig. 3. Typical emission intensity during etching Al-Si alloy film by the two-step etching technique: RF current 1 and 0.8A correspond to 0.46 and 0.31 W/cm^2 of power density, respectively. Etching was monitored by the Al 396.2 nm line. The lower electrode was rotated at the rate of 4 rpm, and so emission peaks were observed 4 times per minute.

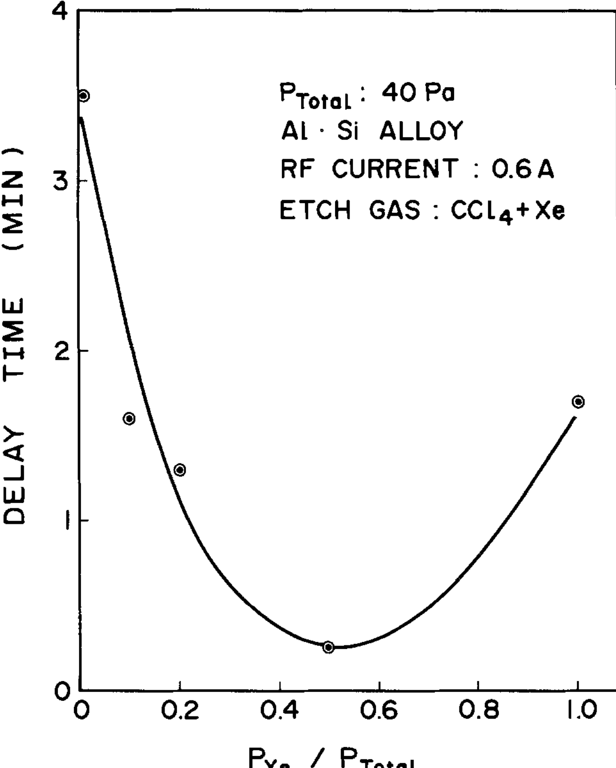

Fig. 4. Dependence of the delay time on the etching gas composition.

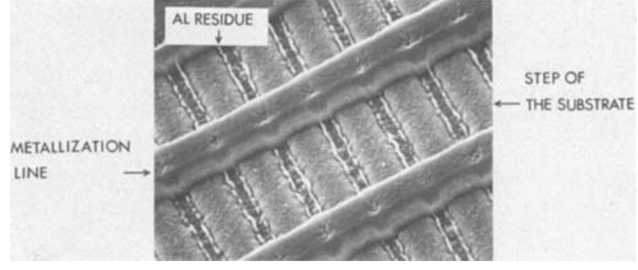

Fig. 5. SEM photograph of Al residues along the steps of the substrate.

cessive etching was one approach to solving the problem. However, a more basic and effective approach was to reduce the steepness of the steps, namely to achieve a smooth surface topography.

Si residues on the substrate after etching the Al-Si alloy film were effectively removed by CF_4 plasma etching.

In summary, some problems which were encountered in plasma etching of Al and Al-Si alloy films were investigated in this work. The protective oxide film caused a delay in the initiation of the etching reaction. The film was effectively and reproducibly removed by a relatively high rf current or by mixed CCl_4-Xe gas plasma at low rf current. A reproducible Al etching process was developed by using the two-step technique. Al residues along the steps of the substrate were found to be due to the surface topography of the substrate and the characteristics of the etching technology.

Polishing of CdTe Surfaces by Diamond Milling

J. A. Mroczkowski

Honeywell Electro-Optics Center, Lexington, Massachusetts 02173

The preparation of semiconductor wafers usually involves either mechanical polishing with a wet abrasive slurry, etching, or chemical mechanical polishing. A new dry technique for polishing zincblende structure componds is described in this article, based on cleaving the top layers of an oriented semiconductor with a single diamond edge. The technique, which is an adaptation of the diamond milling process commonly used for polishing aluminum surfaces to precision flatness for large area infrared optical scanning systems, has been found to be very useful for the preparation of CdTe substrates for LPE $Hg_{1-x}Cd_xTe$ film growth (1).

The principle of the diamond milling technique is illustrated in Fig. 1. Figure 2 shows the effect of different milling directions <h'k'l'> across low index (111)A, (110), and (100) CdTe surfaces.

For the (111)A surface only milling directions within a few degrees of the set of 3 [$2\bar{1}\bar{1}$] directions in the (111)A plane resulted in smooth polishing of the surface, while other directions resulted in rough surfaces. Figure 2 shows the sequence of good and poor polishing directions across 36 cleaved pieces from the same original (111)A surface which were reassembled with the pieces rotated relative to the first by increasing angles in the sequence 5, 15, 30, 45, 55, 60, 65, 75, 90, 105, 120, ... 355 degrees running from left to right and then down consecutive rows. It should be noted that piece 14 in the sequence was misplaced at the very end, and the seventh piece from the end was positioned at the incorrect angle. When these errors are recognized the contrasts in the polishing results clearly show a threefold symmetry of optimum milling directions across the (111)A surface.

The [$2\bar{1}\bar{1}$] polishing directions could be uniquely identified by using a 0.6328 micron helium neon laser beam at normal incidence on the initially rough pol-

Key words: semiconductor surfaces, stress/strain, aluminum.

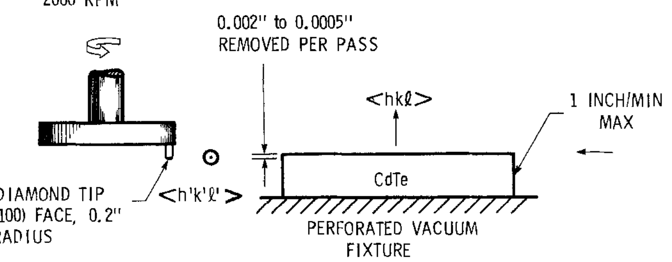

Fig. 1. Schematic of diamond milling process of CdTe (hkl) surfaces along [h'k'l'] directions in the (hkl) plane.

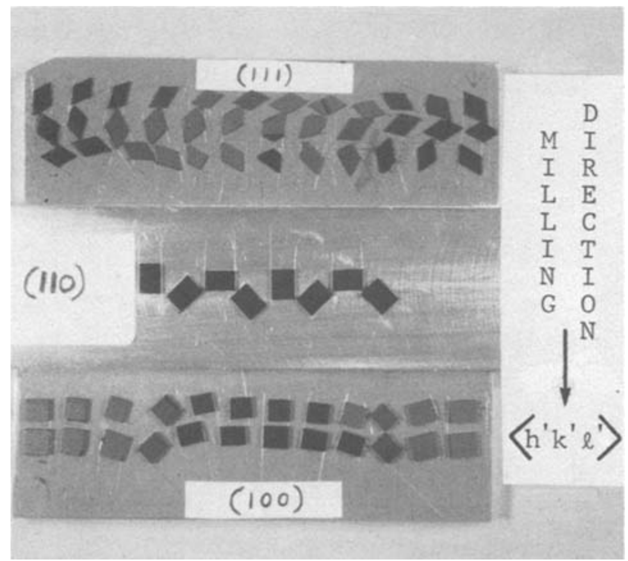

Fig. 2. Demonstration of the effect of different milling directions. After breaking up 3 initial single surfaces into small pieces the pieces were reassembled for milling at consecutively increasing angles.

ished CdTe (111)A surface, and observing the selective reflections from the 3 groups of {110} microfacets. By transmitting the beam through a small aperture in a screen placed in front of the CdTe, three reflected bright spots could be projected on the screen at twice the angle between either of the 3 {110} directions and the <111> direction, *i.e.*, 70.5°. The same identification and polishing procedures worked for the ($\bar{1}\bar{1}\bar{1}$)B surfaces with [$\bar{2}$11] milling directions.

For the (110) surface eight pieces from one initial single (110) surface were rotated in consecutively increasing steps of 45°. The results shown in Fig. 2 suggest that the milling direction is unimportant.

For the (100) surfaces with orthogonal {110} facets 24 pieces were reassembled with increasing angles relative to the first piece in the top left-hand corner in the sequence 5, 15, 45, 75, 85, 90, 95, 105, . . . 355. The results appeared to indicate only 2 permissible [110] milling directions.

The CdTe zincblende crystal structure shows that stereo-hindrance is possible between the 3 [2$\bar{1}\bar{1}$] directions resulting in smooth surfaces and the 3 [$\bar{2}$11] directions resuling in rough surfaces. The unimportance of the milling direction on (110) surfaces is not surprising in view of the fact that the (110) surfaces are the preferential cleavage surfaces. The results on the (100) surfaces exhibiting apparent twofold symmetry instead of the expected fourfold symmetry were surprising; they could only be explained on the basis that the (100) surfaces were insufficiently oriented in the cutting plane of the diamond.

Etching, x-ray, and Nomarski phase contrast analyses of the CdTe samples were used to estimate the extent of surface damage and smoothness. Figures 3a and b show two (111)A samples of CdTe, number 8 and 14 from that shown in Fig. 2, which had been milled across the surface in different directions. These samples had the right third area unetched after diamond milling, the middle third etched in Br methanol solution to a depth of about 5 microns, and the left third etched for about 20 microns. Figures 4a and b show the boundaries between the 5 micron etched and unetched surfaces. Significant surface gouging was detected in the samples which had not been polished in the optimum direction, while there was virtually no gouging on surfaces which had been polished in the optimum direction. In addition, very little difference was seen in the 5 micron etched and the unetched surfaces. At 20 microns of etching slight "orange peel" features were observed.

Double crystal x-ray spectroscpy using copper $K\alpha$ radiation and etched (111) germanium as the first crystal was used to assess polishing damage. X-ray rocking curves were obtained on both the diamond polished CdTe surfaces and also adjacent surfaces which had 5 microns etched off. An etched (111) silicon reference as the second crystal showed a diffracted x-ray half-width of about 40 sec.

For the (111)A samples 2θ was 23.8 degrees and the unetched surface of the sample polished with the optimum milling direction showed a half-width of 50 sec. No improvement was seen in the adjacent etched areas.

The (110) surfaces were examined using (220) reflections with a 2θ angle of 39.3 degrees. A reference cleaved surface showed a half-width of 60 sec. A milled unetched surface showed a half-width of 170

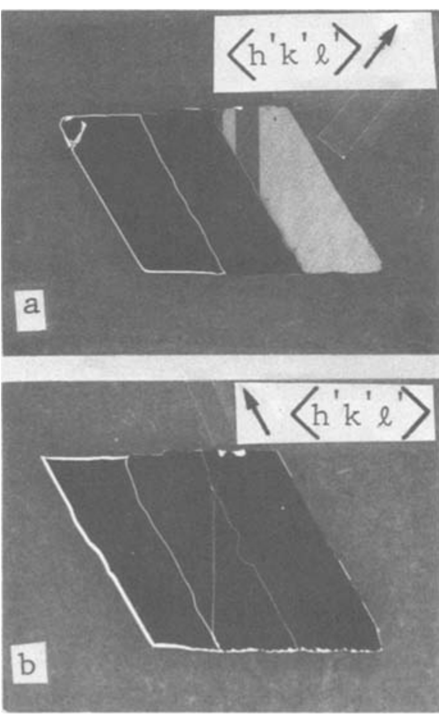

Fig. 3. a, b: Enlarged micrographs of (111)A pieces 8 and 14 shown in Fig. 2 milled at 65° and 0°, respectively, from the optimum direction. Left third and middle third areas had 20 and 5 microns etched off. Right-side areas are unetched. Note twins running through piece 8.

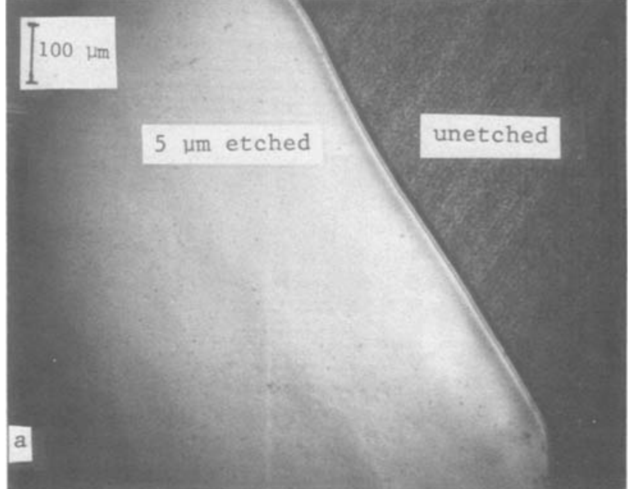

Fig. 4. a, b: Nomarski phase contrast of boundaries between the unetched and 5 micron etched (111)A surfaces shown in Fig. 3a and b. In Fig. 4a extensive surface pitting is revealed by the dark contrast areas on the as-milled unetched surface. In Fig. 4b the parallel regions of slightly varying contrast reveal very small differences in the surface topology due to the finite diamond edge radius and very small imperfections in the diamond edge.

sec, while an adjacent surface which had 5 microns removed by etching showed a half-width of 150 sec.

The (100) surfaces were examined using (400) reflections with a 2θ angle of 56.8 degrees. Half-widths of 100 and 110 sec were obtained on the etched and unetched surfaces, respectively.

The relation between the x-ray line width $\Delta\theta$ and a uniform depth-wise strain distribution $\Delta d/d$ is

$$\frac{\Delta d}{d} = \text{Cot}\ \theta\Delta\theta$$

From the values of $\Delta d/d$ obtained on the unetched surfaces it appeared that the strains in the (111)A and (100) surfaces were comparable, and much less than on the (110) surface. In addition the (110) surfaces showed a significant number of gouged pits left behind after diamond milling compared to almost none on the (111)A and (100) surfaces.

The half-width data on unetched and 5 micron etched surfaces suggest that most of the polishing damage was confined to within 5 microns of the surfaces. A more quantitative estimate of the upper limit to the damage depths on the unetched (111)A and (100) surfaces was then made by determining the depths x from within which most of the reflected x-rays were diffracted the same fraction, G_x. From Cullity (2)

$$G_x = 1 - \exp - (2\mu x/\sin \theta)$$

where $\mu = 1540\ \text{cm}^{-1}$ was also determined from (2), and θ is the angle of incidence. For the (111)A surface 95% of the diffracted energy came from within 2 microns of the surface, compared to 5 microns for the (100) surface. From these estimates we infer that the smallest damage depth was obtained on the (111)A surface.

To fulfill demands for polished CdTe substrates for LPE $Hg_{1-x}Cd_xTe$ crystal growth with preferred (111)A surfaces, only these surfaces were subsequently routinely polished. Figure 5 shows the mirror smooth quality of a reflection of an infrared CCD photomask from a $5 \times 4\ \text{cm}^2$ diamond polished CdTe substrate. Figures 6a and b show the flatness of a large area 1 mm thick unsupported substrate. The staightness of the fringe pattern is believed to be limited not by the technique, but only by the thinness of the substrate and possibly the intrinsic strain anisotropy of the A and B surfaces.

In summary, a technique of polishing CdTe with a single diamond edge has been described which involves the cleaving off of thin surface layers when the shearing forces produced by the diamond edge are directed along select crystallographic directions. Very smooth mirrorlike surfaces have been obtained with low work damage and no chemical contamination beyond surface interaction with the ambient atmosphere. The technique should be applicable to other semiconductors which have the same crystal structure and are not too hard.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 128, No. 1, 3, and 6, January, March, and June 1981.

Resolution Limits of PMMA Resist for Exposure with 50 kV Electrons

A. N. Broers (pp. 166-170, Vol. 128, No. 1)

G. Langner and W. Stickel:[1] In this paper, Dr. Broers compares light optical and electron beam lithography on the basis of the conventional image contrast defined by

$$C_{pp} = \frac{I_{max} - I_{min}}{I_{max} + I_{min}} \quad [1]$$

I denotes the intensity, C_{pp} indicates peak-to-peak contrast. This definition applies to continuous tone images with a linear transfer characteristic and is commonly used in the analysis of photographic and TV images. In lithography it is important that the boundaries between the areas of undissolved resist and dissolved resist are positioned with a minimum error and show steep walls (even undercut for lift-off process). This requires the exposure of patterns with a steep lateral intensity gradient. A contrast definition of merit in lithography should take into account the edge slope of the exposing spot profile. A suitable definition is the "edge contrast C_E" given by

$$C_E = \frac{2}{\pi} \tan^{-1} \frac{W}{E} C_{pp} \quad [2]$$

C_{pp} is defined by Eq. [1]. Both definitions are depicted in Fig. 1. Broers stated that E-beam lithography is superior to light-optical lithography on grounds of the contrast C_{pp} for linewidth below 0.8 μm. It can be shown[2] that the edge contrast of an E-beam lithography system as compared to a light optical system is higher already for linewidths below 1.4 μm for the system chosen by Broers.

A. N. Broers:[3] I agree with the point made by G. Langner and W. Stickel and believe it is an important point. I also discussed the difference in edge contrast for electron beam and optical exposure qualitatively when referring to Fig. 1. Langner and Stickel's C_E is a good measure of edge contrast and this is more important in determining the definition of resist patterns than the line/space contrast C_{pp}. In their comparison of optical and electron beam exposure, however, they have assumed that the optical system is incoherently illuminated. In practice partial coherence is usually employed because it improves contrast, particularly edge contrast.[4] Their conclusion about the turnover point between optics and electron beam may, therefore, be pessimistic with respect to optics.

Transmission Electron Observations of the Early Stage of Epitaxial Growth of Silicon on Sapphire

S. Hamar-Thibault and J. Trilhe (pp. 581-585, Vol. 128, No. 3)

H. F. Mataré:[5] The authors have carried out a thorough structural analysis of th first stages of nucleation of SOS-films. It is important that partially coherent growth has been proven in contradiction to the theory of complete elastic adaptation, *i.e.*, coherent layer growth.

It is also important that here an apparent discrepancy is resolved, when the authors state: (*i*) "The distortion of the silicon lattice decreases with growing time" (page 581) and (*ii*) "There is a progressive increase in the misfit between silicon- and sapphire lattices with increasing deposit time" (page 583).

As is well known, silicon films on sapphire improve in perfection (mobility, lifetime) as they become thicker. Beyond a μm, the interface dislocations and the influence of the interface charge states are much decreased. Distortion decreases away from the interface. However, the lattice parameters are closer near the interface. Here the silicon islands elastically adapt to the sapphire lattice, resulting in the stresses calculated at some 10^{10} dynes/cm^2. Similar values have been derived from the difference in expansion-coefficients.[6]

Also, the influence on the bandgap was indicated.[6] The regular appearance of the silicon nuclei in the initial growth stages[7] cannot hide the fact that the interface lattice misfit requires a certain number of atomic layers to relieve the strain and grow out from the highly defect (Al-doped) mating plane (as shown by TEM; see, *e.g.*, footnote 6, page 253) into a useful layer. An interface state density of some 10^{11} cm^{-2} and a dislocation density in this range[8] requires at least 1000 lattice parameters for a decrease by a factor of 1000, *i.e.*, to get into the range of 10^8 cm^{-2}.

It is conceivable that laser annealing[9] will reorder the SOS lattice but also redistribute the aluminum across the entire layer. The interface state density of 10^{11} e/cm^2 was confirmed recently on SOS layers.[10]

It appears that SOS is useful for fast recovery and radiation resistant devices (thicker layers) and less for

An Improved Model for Analyzing Hole Mobility and Resistivity in p-Type Silicon Doped wth Boron, Gallium, and Indium

L. C. Linares and S. S. Li (pp. 601-608, Vol. 128, No. 3)

F. L. Madarasz,[12] J. E. Lang,[13] and F. Szmulowicz:[14] In reading the paper by Linares and Li (LL) we have found several errors and misapplications of existing theories for mobility calculations in semiconductors.

Firstly, LL state they use the Barber[15] temperature dependent density of states (TDDOS) effective mass. The inadequacies of the Barber mass model are well known.[16,17] The model ignores the strong nonparabolicity of the heavy hole band in the <110> directions, and grossly oversimplifies the light hole band's nonparabolicity by a piecing together of two parabolic bands, which results in a discontinuous band.

As a consequence of using the Barber mass the carrier concentration is underestimated, especially the contribution from the heavy hole band. The net result is that any determination of the conductivity mobility from resistivity measurements and a carrier concentration obtained through the use of the Barber model will be overestimated. We therefore feel that any agreement between experimental and theoretical values of mobility, in Fig. 1 of the LL paper, is somewhat fortuitous.

Secondly, we want to show that given the strong nonparabolicity and anisotropy of the valence bands in silicon it is not possible to write the conductivity mobility, μ_i, for the ith band in terms of an energy averaged relaxation time $\langle\tau_i\rangle$ as LL did in their Eq. [1] which is

$$\mu_i = \frac{e\langle\tau_i\rangle}{m_{ci}^*} \qquad [1]$$

Here e is the electronic charge and $\langle\tau_i\rangle$ takes the form

$$\langle\tau_i\rangle = \frac{\int E^{3/2}\,\tau_i\,\partial f_o/\partial E\,dE}{\int E^{3/2}\,\partial f_o/\partial E\,dE} \qquad [2]$$

where f_o is the equilibrium Fermi-Dirac distribution function. m_{ci}^* is the conductivity effective mass which is canonically defined by the equation for the conductivity

$$\sigma = \frac{pe^2}{m_c^*}\langle\tau\rangle \qquad [3]$$

where p is the carrier concentration.

It is implicit in the definition of m_{ci}^*, Eq. [3], that τ must be isotropic and at most energy dependent, *i.e.*, $\tau = \tau(E)$. However, because of the nonspherical-nonparabolic nature of the light hole band (LL treat the heavy hole and split-off bands as parabolic) any intra- or interband transition including that band will yield a transition rate which depends on the magnitudes as well as the directions of the incident and scattered wave vectors of the charge carriers with respect to the axes of the Brillouin zone.[18,19] This results in an anisotropic relaxation rate which depends on the magnitude and direction of the incident wave vector, precluding the use of Eq. [3] to define m_{ci}^* for the light hole band, and the use of Eq. [1.]

Even if an isotropic relaxation time could be justified, an energy averaged relaxation time as given by Eq. [2] will not arise in the conductivity mobility if the band structure is nonspherical-nonparabolic. This conclusion follows from the fact that in the general Kane band model the relationship between wave vector $\vec{\mathbf{k}}$ and the band energy is given by

$$k^2 = \frac{2m_o}{\hbar^2}\gamma(E, \hat{\mathbf{k}}) \qquad [4]$$

where m_o is the rest mass of an electron and $\hbar$ is Planck's constant divided by 2π. The factor, $\gamma(E, \hat{\mathbf{k}})$, is a complicated function of energy and direction in **k**-space which, in general, is not separable into E and $\hat{\mathbf{k}}$ dependences. With Eq. [4], and the basic integral definitions of conductivity and carrier concentration (for cubic symmetry and in the nondegenerate limit), it can be shown that

$$\sigma = \frac{pe^2}{(2m_o)^2} \frac{\int_{E,\Omega}\left(\frac{\partial\Gamma(k,\hat{\mathbf{k}})}{\partial k}\right)^2 f_o\,\tau\gamma^{1/2}(E,\hat{\mathbf{k}})\,\frac{\partial\gamma(E,\hat{\mathbf{k}})}{\partial E}\,dE\,d\Omega}{\int_{E,\Omega}\gamma^{1/2}(E,\hat{\mathbf{k}})\,\frac{\partial\gamma(E,\hat{\mathbf{k}})}{\partial E}\,E\,f_o\,dE\,d\Omega} \qquad [5a]$$

$$\equiv \mu_c\,pe \qquad [5b]$$

Here, Ω is a solid angle in **k**-space and Γ is a result of the inversion of Eq. [4], *i.e.*

$$E = \frac{\hbar^2}{2m_o}\Gamma(k, \hat{\mathbf{k}}) \qquad [6]$$

For the general case of a nonspherical-nonparabolic band, the energy and angular dependences are not separable in the integrands of Eq. [5a]. The implication is that an energy averaged relaxation time, as that in Eq. [2], cannot be factored in Eq. [5a] and thus a conductivity effective mass as defined by Eq. [3] cannot be obtained. We therefore question LL's calculation of the conductivity effective mass for their light-hole band.

Thirdly, consider the expression given by Eq. [3] of the LL paper

$$\tau_i = \frac{1}{\delta}\left(1 + \frac{m_{Di}^*}{m_{Dj}^*}\,\frac{\tau_{jj}}{\tau_{ij}}\right)\tau_{ii} \qquad [7]$$

where

$$\delta = 1 - \frac{\tau_{11}\tau_{22}}{\tau_{12}\tau_{21}} \qquad [8]$$

and the $m_D^*(T)$ are the TDDOS effective masses associated with the ith and jth bands. From the original work, Bir *et al.*,[20] an expression like Eq. [6] may be extracted, but only with the restriction of spherical-parabolic bands, where m^* is a constant. Given this restriction the masses which occur in Eq. [7] are the m^*'s obtained from the curvature of each band.

LL claim that the procedure for going from a parabolic to a nonparabolic band is to simply substitute the TDDOS effective mass for m^*, and cite Radcliffe[21] and Barrie[22] as having shown this. Quite the contrary, both Radcliffe and Barrie attempt to generalize relaxa-

tion rates for different inband scattering processes when going from a spherical-parabolic band, in which $E = \hbar^2k^2/2m^*$, to a spherical-nonparabolic band, in which $E = f(|\vec{k}|)$. In their generalizations they showed that the substitution of $\hbar^2k(dE/dk)^{-1}$ for m^* tended to account for variations in the temperature dependences of mobilities, which the spherical-parabolic model could not account for.

Furthermore, LL cite Braggins[23] as having successfully used the substitution of the TDDOS effective mass for m^*. In fact what Braggins writes is $1/m^*(E) = \hbar^2k(dE/dk)^{-1}$, which is only a matter of notation. This "band effective mass" $m^*(E)$ is not directly related to the (temperature dependent) TDDOS effective mass nor is it the true DOS effective mass.[16,17]

The substitution of $\hbar^2k(dE/dk)^{-1}$ for m^* is not a prescription for the substitution of the TDDOS effective mass for m^* when treating nonparabolic bands. The TDDOS effective mass arises in only one place and that is in the calculation of the carrier concentration. If one starts out with a truly nonspherical-nonparabolic band structure like the valence bands of Si, and then derives a relaxation rate for the ith band from its definition

$$\frac{1}{\tau_i(\vec{k})} = - \left.\frac{\partial g_i(\vec{k})}{\partial t}\right|_{\text{coll}} \frac{1}{g_i(\vec{k})} \qquad [9]$$

where $g(\vec{k})$ is the deviation from f_0, one will at most find the rest mass, m_0, of the charge carrier in the resulting expressions. The rest mass appears only because of nomalization (see Eq. [4]). The reason the true DOS effective mass, which is energy dependent in the case of a (non)spherical-nonparabolic band, does not occur is that the collision integral includes the transition rate and $g(\vec{k})$. This means that the DOS never appears as a simple factor. And it is the DOS which is needed for the DOS effective mass.

Fourthly, although LL state at the beginning of their paper that they employ the nonspherical-nonparabolic silicon valence band structure through the use of the Barber model, later they go on to state, "The anisotropy of the energy spectrum is not considered in this model, because from the transport theory of parabolic bands it is known that anisotropy has no influence on the temperature dependence of mobility, but only on its absolute value." We agree with this conclusion for lattice limited mobility,[24] and would like to emphasize this point as well since Tiersten[19] has shown that the use of spherical energy surfaces can lead to an error in the lattice limited mobility of ~20%.

Lastly, we focus our attention on the empirical formula γ_{hh}^a which is used to correct acoustic phonon-hole scattering for the influence of hole-hole interactions. This formula as given by LL

$$\gamma_{hh}^a = 1.0004\text{-}4.013378 \times 10^{-19} N_A \qquad [10]$$

depends on the concentration of acceptors, N_A, rather rather than on the concentration of holes which in itself is quite puzzling. Furthermore, note that this formula produces a value comparable to that obtained from the theoretical expression for γ_{hh}, which they display in their Eq. [12], only at an impurity concentration of 3×10^{17}. Since data in Fig. 1 seem to cover a range greater than that for which the formula applies, some other correction must have been applied below 10^{15} and above 3×10^{17}. The form of this empirical correction is important because it helps to produce the proper shape of the curve in Fig. 1, enhancing the agreement with the data.

Not only have the authors varied τ_0 and W to fit the data, but they have also adjusted the constants in the empirical formula to produce the proper dependence on carrier concentration shown in Fig. 1. Because the empirical formula is without physical justification, it would seem that the fit shown in Fig. 1 is artificial.

In summary, we feel the oversimplified band model used by LL coupled with the use of an energy averaged relaxation time for nonspherical-nonparabolic bands, and the improper use of Eq. [7] in the text as well as the use of the empirical formula γ_{hh}^a, will seriously affect calculations of mobilities and carrier concentrations. Only a detailed consistent calculation involving an accurate band model and a full solution of the transport equations allowing for anisotropic scattering can provide a complete picture of electronic transport in silicon.

L. C. Linares:[25] The primary reason for the publication of this paper was apparently misunderstood by the authors of the discussion. The main intent of this work is to present a more complete and accurate representation of mobility and resistivity in p-type silicon that would be of practical engineering utility. In presenting a work of this type, one is always faced with a choice between extremely intricate and difficult theoretical details and some reasonably simple engineering models of the very complicated physical reality. Unfortunately, what one gains in tractability, one loses in completeness and mathematical sophistication. The usual assumptions made by most workers in the analysis of mobility are: (*i*) an energy averaged relaxation time, (*ii*) isotropic mobility, and (*iii*) spherical parabolic valence bands. While retaining the first two assumptions, we hoped to improve agreement between theoretical calculations and experimental measurements by modeling a temperature dependent effective mass based on Barber's[26] work, thus approximating the nonparabolic nature of the valence bands.

Barber's model provides, via simple calculations, values of effective mass that more accurately reflect the experimentally observable variability of effective mass with changes in temperature and dopant density. The model never presumed to be the final answer to everyone's questions concerning the band structure of silicon; however, within its limitations, it accomplishes its intended purpose, to improve the accuracy of mobility calculations by approximating the temperature dependence of the effective mass. It is curious that the authors of the discussion cite the work of Nakagawa and Zukotynski[27] as expressing the inadequacies of the Barber model, when Nakagawa and Zukotynski never even mention Barber or his work.

In mobility calculations, most authors have limited their analyses to only scattering by acoustical phonons, or optical phonons, or ionized impurities, or neutral impurities, or combinations of these. Our paper attempts to present a more complete picture by considering all of the above mechanisms as well as interband and hole-hole scattering. The use of a temperature dependent effective mass contributes significantly to the improvement between theoretical calculations and experimental values; but equally important is the more complete treatment of the scattering which includes corrections for hole-hole scattering. The empirical formula used to correct acoustic phonon-hole scattering for the influence of hole-hole interactions resulted from an attempt to neither underestimate nor overestimate the effect. The justifications and rationale behind this empirical expression are well stated in a previous work.[28] This empirical formula, derived in footnote 28, has been used in its original form both in our paper and by Thurber *et al.*,[29] where excellent agree-

ment was reported between theoretical calculations and experimental determinations of mobility in p-type silicon. The constants were not adjusted to fit our particular situation. On the other hand, the adjustment of the acoustic and optical deformation potential constants via τ_0 and W, respectively, has always been a perfectly acceptable procedure. Until a complete theoretical treatment of the true nature of the valence bands is undertaken, no one will know the true value of these constants.

In conclusion, we stress that, although limited by the simple model of the band structure, this work is of significant practical value as a reasonable engineering study of mobility and resistivity in p-type silicon. We agree that it will take a detailed, consistent calculation involving an exact band model and a full solution of the transport equations allowing for isotropic scattering, to provide a complete picture of electronic transport in silicon. We hope that our work will encourage others to develop such a picture and satisfy everyone's needs.

The Quenching of Y_2O_3:Eu Luminescence by Cerium

M. J. Fuller (pp. 1381-1383, Vol. 128, No. 6)

G. Blasse:[30] Fuller has nicely shown that the presence of cerium in Y_2O_3:Eu quenches the Eu^{3+} luminescence, because the absorption of the Ce^{4+} ion competes successfully with the charge-transfer absorption of the Eu^{3+} ion.

The cerium-codoped samples fired in air show an absorption band at <230-300 nm just extending into the visible. This was ascribed to Ce^{4+}. In view of the pale-yellow color of CeO_2[31] this seems to be correct. It is well known that this is a charge-transfer transition.[32] Reduced samples showed an absorption band in the visible region which was ascribed to Ce^{3+} (4f-5d transition). This assignment seems to be unlikely, because (*i*) Ce_2O_3 is white,[31] (*ii*) the 4f-5d transitions of the Ce^{3+} ion in oxides are usually situated in the ultraviolet.[33]

If the visible absorption band is neither due to Ce^{3+} nor to Ce^{4+}, the only alternative is a Ce^{3+}-Ce^{4+} intervalence charge-transfer transition. This would imply that the cerium ions occupy nearest neighbor lattice sites. Compositions in between CeO_2 and Ce_2O_3 are strongly colored due to transitions of this type.[31]

Fuller proposes that three substitutional Ce^{4+} ions introduce one cation vacancy. It seems more probable that two substitutional Ce^{4+} ions introduce one interstitial oxygen ion, because Y_2O_3 has a fluorite lattice with ordered anion vacancies. The latter will be filled up if tetravalent ions are introduced. If these defects form an associate $(2Ce_Y \cdot O_i)^x$ or even clusters (like in the fluorite lattice),[34] we have the possibility of Ce^{3+}-Ce^{4+} neighbors in the reduced samples. These may also be responsible for the photochromic properties. This alternative assignment seems to be worthwhile to investigate further using spectroscopical and electrical techniques.

M. J. Fuller:[35] Blasse's suggestion that the visible absorption of the thermally reduced Y_2O_3:Ce samples is due to Ce^{3+}-Ce^{4+} intervalence charge transfer is an interesting alternative to my assignation of it to 4f-5d transitions in Ce^{3+}. While the breadth of the absorption band certainly more resembles that for a charge transfer state than for 4f-5d transitions, I dismissed the former alternative on the basis that random cerium substitution at low concentrations would not produce the required nearest neighbor lattice sites. Although, as Blasse mentions, the 4f-5d transitions of Ce^{3+} in Y_2O_3 should be expected to lie in the ultraviolet range, there are examples of oxidic host lattices, and notably $Y_3Al_5O_{12}$ in which the 4f-5d absorptions of Ce^{3+} extend significantly into the visible region (*i.e.*, to $\geqq$ 500 nm).

However, if Blasse's suggestion that Ce^{4+} substitution is not random but occurs as associates is correct, then the possibility of intervalence charge transfer absorption becomes much more likely. In view of this, I agree that further investigations would be worthwhile in an attempt to resolve this matter.

A Technique for Profiling a Laser Beam and Its Application to the Recrystallization of Polysilicon Films

B. P. Von Herzen, T. I. Kamins,* and C. I. Drowley**

Hewlett-Packard Laboratories, Palo Alto, California 94304

Abstract: A rapid method of obtaining the intensity distribution of a cw laser beam used for the recrystallization of polysilicon has been demonstrated. Correlation of the structure of the recrystallized polysilicon with the spatial distribution of the laser light shows the importance of controlling the mode structure and, consequently, the intensity distribution of the laser beam.

Introduction: Melting and recrystallization of a fine-grain polysilicon film with a cw laser has been shown to improve its electrical properties so that MOSFETs can be fabricated with their active channels in the resulting layer of large-grain, recrystallized material (1,2). The structure of the polysilicon has been shown to depend on the local temperature and the temperature gradients during recrystallization (3). In particular, the entire thickness of the polysilicon must be melted to obtain the large-grain structure necessary for device fabrication (4). More complex applications, such as "lateral seeded annealing"(5,6), will depend more critically on the detailed power distribution in the laser beam.

In this note we will describe a method of mapping the intensity of the laser beam as a function of position and relate this distribution to the structure of the recrystallized polysilicon. The technique employs a photodiode to measure the light distribution at the position of the wafer surface which is to be recrystallized so that the effect of the optical elements in the light path, as well as the laser itself, can be considered.

Experimental Apparatus: The technique has been used with a Coherent Model 5000 laser annealing system, which includes an 18 W cw argon ion laser. In this system, the laser beam is scanned across the wafer surface by galvanometer-controlled mirrors. A variable-focus flat-field lens causes the light to strike the wafer surface at normal incidence for all positions on the wafer surface.

To measure the beam profile, a photodiode is inserted into the annealer in place of the wafer to be processed. The photodiode is attached to a silicon wafer for ease of handling in the system, and this assembly is held by the vacuum chuck which normally holds the wafer to be processed. A 2μm diameter pinhole is mounted in front of the photodiode to improve the spatial resolution. A filter is placed in the optical path to attenuate the laser beam by a factor of approximately 10,000 so that the photodiode is not damaged by the laser. The distance from the surface of the backing wafer to the pinhole is accurately known so that the optical system can be offset to measure the intensity distribution at the desired focal position.

A Hewlett-Packard 9845 desktop computer system is used to control the process (Fig. 1). A signal from the HP9845 is sent along an HP

interface bus (HP-IB) to control two A/D converters, which provide the signals to raster the galvanometer-controlled, beam-deflection mirrors across the pinhole. The beam is typically moved in 5μm steps at a rate of 20 Hz. With these typical parameters, the spatial resolution is approximately 7μm. The photodiode output current is sampled typically 10 ms after the mirrors are moved, which allows for their 1-10 ms settling time. Only a small voltage of about 50 mV appears across the 100 ohm load resistor in parallel with the photodiode. Thus, the photodiode operates essentially in the short-circuit mode, and the output varies nearly linearly with light intensity. The signal from the photodiode is sampled by an HP3455 voltmeter, and the digital output is sent over the HP-IB to the HP9845, which correlates the beam intensity with position and stores and displays the data.

The data may be displayed in a quasi-three-dimensional format or in two dimensions, with the intensity of the shading representing the intensity of the beam. A representative profile is shown in Fig. 2 in both formats. In this case it is seen that the beam is not Gaussian but shows a combination of modes. The mode structure can be changed by varying the input power to the laser or the elements of the optical system and is more Gaussian at lower input powers.

As an alternate beam-profiling technique, the pinhole can be omitted, and the signal observed as the laser moves across the edge of the photodiode can be differentiated to obtain the beam profile. This alternate technique, however, relies on numerical differentiation of experimental data and tends, therefore, to be noisy. Since smoothing of the data leads to loss of resolution, we prefer the first technique described.

Correlation With Structure of Polysilicon: The shape of the beam has been correlated with the structure of the recrystallized polysilicon. In these experiments a 0.55μm thick film of conventional LPCVD polysilicon was deposited at 625°C onto a 1.4μm thick layer of thermally grown silicon dioxide on a 3-inch diameter, (100)-oriented silicon wafer. The polysilicon was capped with a layer of LPCVD silicon nitride approximately 6 nm thick to prevent agglomeration of the polysilicon while it was molten (7). The substrate was heated to 500°C during recrystallization, and the laser was scanned across the wafer with a velocity of 25 cm/sec using the internal driving electronics in the annealer.

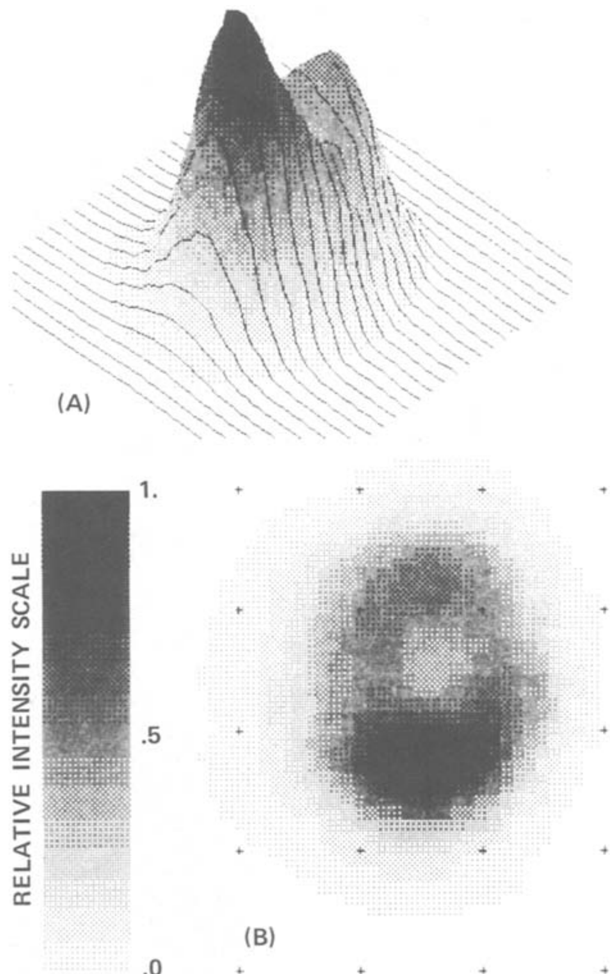

Fig. 2.
Laser beam profile: (a) Three-dimensional plot. (b) Two-dimensional plot with darker shading indicating the more-intense portions of the beam.

The width of the recrystallized region varies with laser power, increasing rapidly after the onset of melting, then varying slowly with further increases in laser power. The structure of the polysilicon depends on the distribution of the power in the laser beam. If enough energy is deposited into a region to melt the entire thickness of the polysilicon film, it recrystallizes into a large-grain structure with a relatively smooth surface. If only a portion of the thickness melts, the solidifying material is seeded by the underlying fine-grain polysilicon which did not melt, and a large-grain structure is not obtained.

The grain structure is, therefore, related to the power distribution within the laser beam. A rapid decrease in intensity with

position at the top and bottom edges of the melted region provides an abrupt transition between large-grain polysilicon and unmelted material. A gradual decrease in the intensity results in a wide region which melts only through a portion of its thickness, with the resulting intermediate grain size and rough surface.

Figure 3 shows such a correlation. At the bottom of the beam only a narrow region of partial melting with its roughened surface is seen between the large-grain and unaffected polysilicon (Figs. 3b and 3c). At the top of the beam, the intensity decreases more gradually from the primary peak, with a secondary peak occurring about 90μm away from the main peak. The transition between unaffected and large-grain polysilicon is much broader on this side.

When the spacing between adjacent scans is made less than the width of the large-grain region, the gradual decrease in the intensity will cause a portion of the previously recrystallized material to be partially remelted. This remelting, in turn, can leave a roughened surface, which will be more difficult to process, although it may not be degraded crystallographically.

At higher powers with the beam profile shown, the transition from the unmelted to the large-grain region occurs in the steepest parts of the profile, resulting in narrow transitions on both sides.

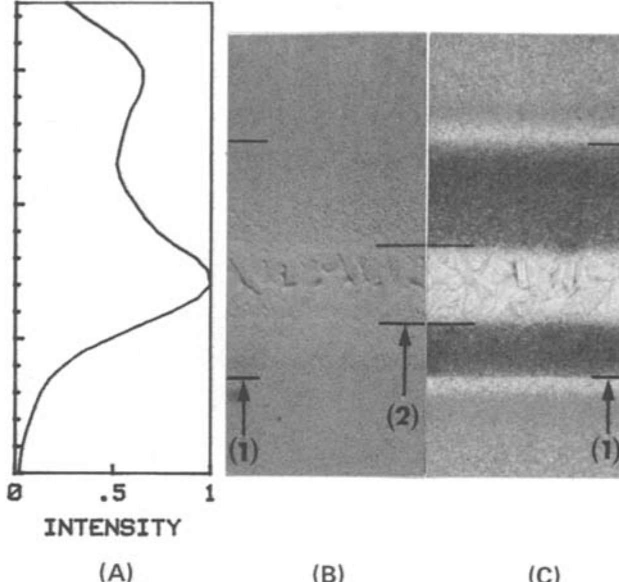

Fig. 3.
Effect of laser intensity distribution: (a) Peak intensity normal to the scanning direction; each mark on the vertical scale represents 10μm. (b) Structure of polysilicon after laser recrystallization (Nomarski phase contrast). (c) Structure after grain-boundary delineation by Sirtl etching: (1) Melted width; (2) large-grain region.

Summary: We have shown a relatively straightforward method of measuring the intensity distribution of the laser beam used to recrystallize polysilicon. Observation of the structure in the recrystallized material shows the importance of controlling the intensity distribution in the laser beam and, consequently, the modes present. Control is expected to become critical for more sophisticated applications, such as seeded recrystallization.

A Semipermeable Anode for Silicon Electrorefining

J. M. Olson and K. L. Carleton

Solar Energy Research Institute, Golden, Colorado 80401

The development of inexpensive silicon solar cells depends critically on the availability of a low cost, high purity silicon. Electrochemical methods offer the potential for producing (1,2) and purifying (3) silicon but these processes usually produce material with a low space-time yield (4) and limited purity. We have recently developed a semipermeable anode that enhances the effectiveness of the silicon electrorefining process and permits the low temperature fabrication of "silicon" anode plates, a prerequisite for the operation of an efficient, multiplate electrorefining process. The anode is solidified from a hypereutectic solution of copper and metallurgical grade silicon (mgSi) to form a two-phase system consisting of a primary silicon phase embedded in a Cu_3Si matrix. At the temperature of operation (750°C), the interdiffusion of Cu and Si in the Cu_3Si phase is fast (5), $D=2.5 \times 10^{-5} cm\ s^{-1}$. Hence, this silicide phase can be used under certain conditions as a filter for purifying silicon. When combined with an electrorefining process, this filtering action ostensibly improves the purity of the electrodeposited silicon as compared to previous work (3) by about two orders of magnitude.

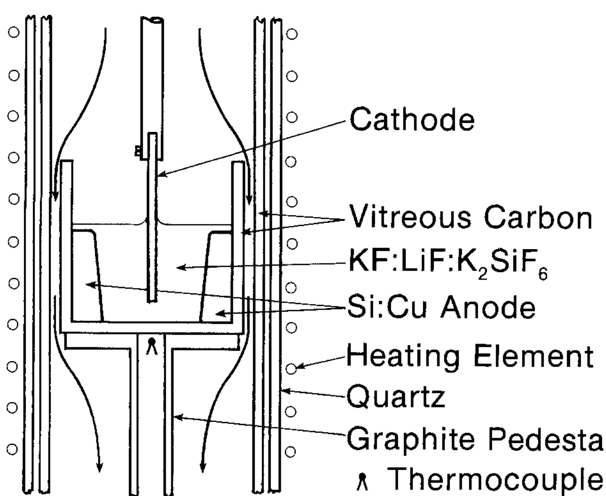

Figure 1. Schematic of electrorefinement cell

*Electrochemical Society Active Member
Keywords: Silicon, semipermeable anode, electro-refining, electrodeposition

A schematic of the electrorefinement set-up is shown in Figure 1. The melt composition is similar to that used in previous work (2), however, the K_2SiF_6 is synthesized in situ by reactively dissolving $SiF_{4(g)}$ in a KF rich melt. The electrolyte is purified by a pre-electrolysis step using a reverse bias of 2.0 volts. The cathode is typically a high density, high purity graphite. The silicon-copper anode (30 w/o mgSi) is fused and solidified in situ with the electrolyte serving as a flux.

In Table I, we compare the chemical purity (as measured by spark source mass spectrometry) of the starting material (mgSi in Cu/Si anode) with the purity of the refined, electrodeposited silicon.

From an electrorefining viewpoint, those elements which have an electronegativity

TABLE I. Typical metal impurity concentration in the mgSi used to form the anode and in the refined, electrodeposited silicon.

Mn	550.0	0.03
Mo	1.4	<0.03
Ni	39.0	<0.1
P	14.5	3
S	7.0	0.4
Ti	290.0	<0.1
V	250.0	<0.05
Zr	13.0	<0.03

greater than that of silicon will remain at the anode (e.g., Cu, B, P, etc). Elements with an electronegativity less than that of Si (e.g., Al, Cr, Ti, V, and Zr) normally would not be segregated in a closed, steady state electrorefining process. From Table I, we find, however, that with the Si:Cu_3Si anode, these impurities are efficiently segregated. The most probable mechanism responsible for this result is the diffusional trapping of these metals in the bulk of the anode. While the interdiffusion coefficient in Cu_3Si is fast, it is expected that other metallic impurities will have typical solid state diffusion coefficients in the Cu_3Si matrix. To be transferred to the cathode, these impurities must be present at the surface of the anode. After the surface has been depleted, the electrotransport of the impurities to the cathode will be limited by diffusion in the bulk of the anode, essentially trapping these impurities.

The final copper concentration illustrates the effectiveness of the electrochemical segregation mechanism for elements with an electronegativity less than that of silicon. The data for copper strongly suggests that the final concentrations of B and P are not intrinsic but may be an artifact of postdeposition contamination and, as such, are subject to further improvement. Efforts to reduce this contamination are in progress.

The interdiffusion coefficient of copper and silicon in Cu_3Si is a function of the intrinsic diffusion coefficients for the species D_{Si} and D_{Cu}. The ratio D_{Cu}/D_{Si} is unknown at this time. From marker experiments, Veer et al (5) claim that Cu is the diffusing species in Cu_3Si (i.e. $D_{Cu}/D_{Si}>>1$), but they did not consider the complicating effects of interface drag on the motion of the marker (6). Our preliminary experiments (7) indicate that Cu diffusion may dominate but that the diffusion of silicon is also significant.

Electrocrystallization of coherent, stable films of silicon is a natural result of the electrorefining process if the current density is less than a critical value. This critical current density is strongly affected by electrolyte composition, temperature, and hydrodynamic conditions in the melt. Current densities in excess of $100mA/cm^2$ have yielded dense, coherent, thick films on graphite substrates. For $i = 20\text{-}30mA/cm^2$, grain sizes of 200μm are typical. Deposits on vitreous carbon have similar characteristics.

Electrical characteristics of the refined polycrystalline silicon have been measured. The conductivity type is generally n-type. The resistivity is 0.3-0.7 ohm-cm. The Hall mobility is 90-110 cm^2/Vs with a carrier concentration of $\sim 4\times10^{17}$ cm^{-3}. The minority carrier lifetime as measured by the V_{oc} decay technique is 10-20μs. The interpretation of these data relative to previous work is the subject of another paper (7). In general, however, this material has a higher minority carrier diffusion length and lifetime than similar polycrystalline silicon produced by other techniques (8).

In summary, polycrystalline silicon can be electrodeposited from metallurgical grade silicon in a molten salt system. The use of a Si:Cu_3Si semipermeable anode as the silicon source enhances the purification process and facilitates the fabrication of anode plates.

Moderate Temperature Na Cells

IV. VS_2 and NbS_2Cl_2 as Rechargeable Cathodes in Molten $NaAlCl_4$

K. M. Abraham,* M. W. Rupich, and L. Pitts

EIC Laboratories, Inc., Newton, Massachusetts 02158

Recent work from this laboratory has shown (1-3) that the layered transition metal dichalcogenides which intercalate Na are useful as cathodes for a rechargeable moderate temperature Na cell which operates at 130°C and utilizes 1,2-Bis(2-methoxy-ethoxy)ethane/NaI(1M) as the electrolyte. However, practical uses of those cells are limited by factors such as limited thermal stability of the organic electrolyte, relatively low rate capabilities and fractional irreversibility of the chalcogenide cathodes due to crystallographic phase changes. To circumvent these problems, we have evaluated molten $NaAlCl_4$ as an alternative electrolyte. This study has led to the discovery of novel chemical and electrochemical reactions between molten $NaAlCl_4$ and the metal sulfide cathodes, for example VS_2. These reactions result in the in situ formation of novel, high energy density cathode materials showing high electrochemical reversibility. In this paper we present our preliminary results on the cycling of Na cells utilizing VS_2 or NbS_2Cl_2 as the cathode in molten $NaAlCl_4$.

VS_2 was synthesized as described previously (1). NbS_2Cl_2 was synthesized according to the procedure in ref. 4. The experimental cell, operating at 165°C, has the configuration,

Liquid Na | β"-Al_2O_3 | Molten $NaAlCl_4$, | VS_2 or NbS_2Cl_2

Cell setup and operation have already been described (1,5). Basic $NaAlCl_4$ was prepared by melting a mixture of NaCl and $AlCl_3$, slightly rich in NaCl, at 190°C and purified by preelectrolysis between two Al electrodes. Prior to adding to the cell, the electrolyte was mixed with a slight excess of NaCl to insure its basicity.

A cell with VS_2 as the cathode exhibits an open-circuit-voltage (OCV) of 3.05V at 165°C. The first discharge of the cell to 1.8V usually yields capacities between 0.90 and 0.70 electrons/vanadium (e^-/V) at current densities between 1 and 5 mA/cm^2. The discharge occurs at three voltage regions - a downward sloping region between 2.8 and 2.4V, with ~8% of the capacity, another downward sloping region between 2.4 and 2.2V, with ~25% of the capacity, and a plateau at 2.2V with the remaining capacity. The mid-discharge voltage is slightly above 2.2V. The first recharge to 3.5V usually corresponds to 100% of the discharge. The recharge occurs in three major voltage regions - an upward sloping region between 1.8V and 2.2V, with ~20% of the capacity, a second upward sloping region between 2.2 and 3.1V, with ~20% of the capacity, and a plateau at 3.2V, with the remaining capacity. The discharge and recharge curves exhibit considerable hysteresis (Cycle 1 in Fig. 1). Repeated cycling of the Na/VS_2 cell between 1.8V and 3.5V results in a gradual increase in cathode capacity with

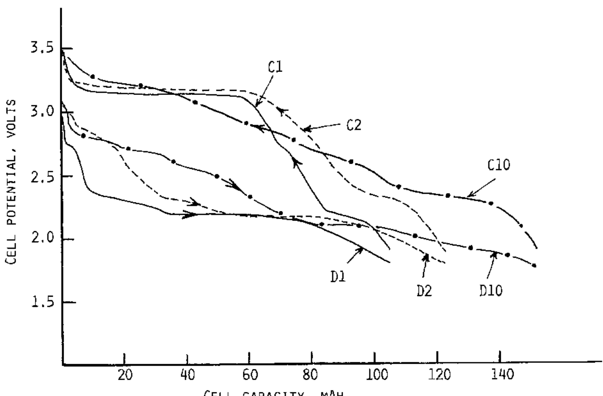

Fig. 1. Galvanostatic cycling curves for a liquid Na/β"-Al_2O_3/$NaAlCl_4$, VS_2 cell at 165°C. Voltage limits, 1.8 and 3.5V. Curves marked D's are discharges and those marked C's are charges. Current = 16 mA (2 mA/cm^2). The VS_2 cathode has a 120 mAh 1e- theoretical capacity.

Key Words: Transition Metal Chalcogenides, Cycling.

the mid-discharge voltage moving to higher values and the mid-charge voltage moving to lower values. The capacity increases to values between 1.2 and 1.3e$^-$/V in about 10 cycles. These characteristics are illustrated in the three cycles of the cell shown in Fig. 1.

It was found, however, that if after the first discharge to 1.8V the cell is allowed to stand on open circuit at 165°C, instead of being recharged immediately, the OCV increases from 1.9V to a constant value of 2.3V in a period of ~75 hr (Cycle 1 in Fig. 2). This indicates a reaction between the discharged cathode and $NaAlCl_4$. Moreover, the recharge capacity of the cell after this open circuit stand is about twice that of the previous discharge, i.e., 1.6e$^-$/V for the cell in Fig. 2. Most of the recharge occurs at a plateau at ~3.2V. During the next few cycles the discharge capacity to 1.8V increases to even higher values, with the respective recharges to 3.5V showing capacities higher than the discharges. The capacity then reaches a constant value of ~2.6 to 2.8e$^-$/V in 5 to 8 cycles. The cycling of the cell then becomes 100% coulombically efficient. The mid-discharge voltage is ~2.5V and the mid-charge voltage is ~2.8V. The discharge proceeds in four major voltage steps (Cycles 6 and 28 in Fig. 2). The cell exhibits excellent rechargeability. One cell has been cycled more than 100 times with very little capacity loss. The average current density was 4.5 mA/cm^2 of β''-Al_2O_3.

The same behavior is observed in cells which are initially constructed with $NaVS_2$ as the cathode. Thus, in a cell with $NaVS_2$ the initial OCV of 1.9V increased to 2.3V in ~16 hr at 165°C. The initial charge to 3.5V corresponded to 1.3e$^-$/V and the potential profiles of the charge were identical to those seen in Cycle 1 in Fig. 2. The cell capacity increased to 2.4e$^-$/V in the following discharge. The voltage profiles of this discharge and subsequent cycles were identical to those of Cycles 6 and 28 in Fig. 2.

Analysis of solid cathodes from several cycled cells, after removal of $NaAlCl_4$ by washing with CH_3CN, indicated that the higher capacities result from the cycling of an *in situ* synthesized compound of the apparent composition $VS_{2.7}Cl_{1.6}$. The latter compound appears to be related to NbS_2Cl_2, which has a pseudo-one-dimensional chain structure (4).

NbS_2Cl_2 was synthesized and its cycling behavior examined. The first discharge of NbS_2Cl_2 to 1.8V yields a capacity equivalent to 2e$^-$/NbS_2Cl_2. The following recharge to 3.6V is nearly 100% efficient. The second and subsequent discharges yield an average reversible capacity of 2.8e$^-$/NbS_2Cl_2. Typical cycles are shown in Fig. 3. The cycling characteristics of NbS_2Cl_2 are very similar to that of the *in situ* synthesized compound of the Na/VS_2 cell. This is depicted in Fig. 4.

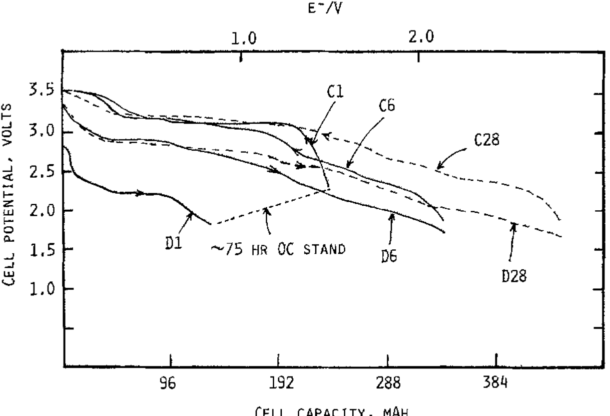

Fig. 2. Galvanostatic cycling curves for a liquid Na/β''-Al_2O_3/$NaAlCl_4$, VS_2 cell at 165°C prior to and after the open circuit (OC) stand. Curves marked D's are discharges and those marked C's are charges. Voltage limits, 1.8 and 3.5V. Current = 16 mA (2 mA/cm^2).

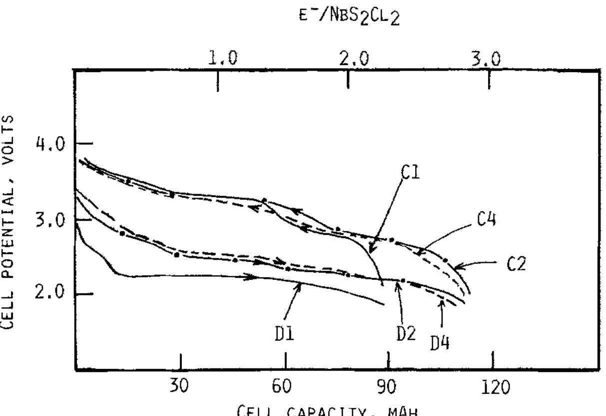

Fig. 3. Galvanostatic cycling curves for a liquid Na/β''-Al_2O_3/$NaAlCl_4$, NbS_2Cl_2 cell at 165°C. Curves marked D's are discharges and those marked C's are charges. Voltage limits, 1,8 and 3.6V. Current = 10 mA (1 mA/cm^2).

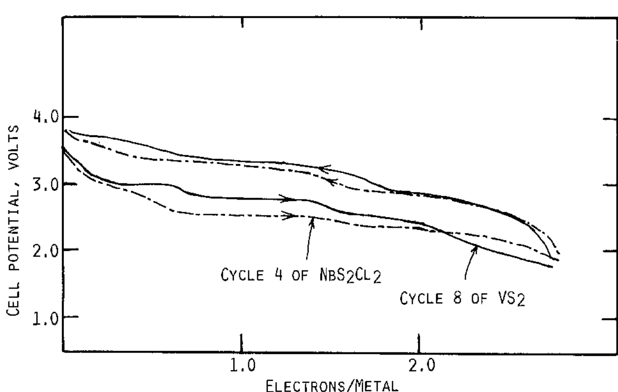

Fig. 4. A comparison of the cycling curves of Na/VS_2 and Na/NbS_2Cl_2 cells.

Cycling behavior similar to that of VS_2 in molten $NaAlCl_4$ is also exhibited by many other dichalcogenides, including VSe_2 (6). The cycling behavior of NbS_2Cl_2 and related compounds in basic $NaAlCl_4$ is considerably different from that of S in this melt (7) and the sulfur halides in the acidic $NaAlCl_4$ melt (8,9).

Our research on this novel chemistry is continuing. In future papers (10) we will discuss the mechanisms of cathode cycling, rate/capacity of the cathodes, and performance characteristics of practical cells.

Reference Electrode Development for Molten LiCl-KCl Eutectic Electrolyte

Laszlo Redey*

Chemical Engineering Faculty, Technical University of Budapest, Hungary

and Donald R. Vissers*

Argonne National Laboratory, Argonne, Illinois 60439

Molten LiCl-KCl binary salt electrolytes are often used in high-temperature electrochemical studies; the eutectic composition of this electrolyte is frequently used (1,2) because of its relatively low melting point (352°C) and high decomposition voltage (3.62 V). One major use of the LiCl-KCl system is as the electrolyte in lithium alloy/iron sulfide battery cells (3). This article describes the development, calibration, and evaluation of a reference electrode for these cells containing LiCl-KCl eutectic electrolyte.

A reference electrode must have a thermodynamically well-defined, reproducible potential and possess a suitable geometry with adequate mechanical strength. For battery testing, its electrochemical and mechanical stability must be measured in thousands of service hours. The choice of a reference electrode was based on an evaluation of our preliminary experiments (4) and of published findings with the following electrodes: Cl_2/Cl^- (5,6), $Ag/AgCl/Cl^-$ (7,8), Pt/Pt^{2+} (2), $Ni/NiS/S^{2-}$ (9), $Li\text{-}Al/Li^+$ (10-12). Two systems were selected for further development: (a) the $Ni/Ni_3S_2/S^{2-}$ electrode of the second kind, which was shown (4) to have excellent long-term stability, and (b) the $Li\text{-}Al/Li^+$ electrode of the first kind, which has excellent short-term stability and reproducibility making it suitable as an *in-situ* calibration standard for the $Ni/Ni_3S_2/S^{2-}$ electrode.

Development of the Ni/Ni_3S_2 Reference Electrode

The high lithium and sulfur activities present in the lithium-aluminum/iron sulfide cell system make strict demands on the reference electrode and thus sharply limit the choice of suitable materials. A schematic diagram indicating the electrode design and construction materials is shown in Fig. 1. Beryllia tubing (1/8 in. OD and 1/16 in. ID) has been shown to be an excellent electrode housing. The inner compartment of the electrode contains a substantial surplus of high-purity Li_2S powder, which maintains a stable, well-defined saturation concentration (748 ppm in LiCl-KCl eutectic at 425°C) for very long periods (∿1 year). The diffusion barrier, with a resistance of 10 to 20 kΩ is either constructed of Y_2O_3 fibers or a close fitting solid Al_2O_3 plug. The latter leaves open only a fine capillary pathway to the outer electrolyte. The electrodes are assembled "dry" in a high-purity helium-atmosphere glove box and are activated by letting molten electrolyte penetrate through the diffusion barrier; an anodic treatment (approx. 0.1-2 C charge with 5-20 $\mu A/cm^2$ on the Ni wire) is used to form the Ni_3S_2 layer on the metal wire.

Four identically prepared electrodes were immersed into a pool of Li_2S-saturated LiCl-KCl eutectic contained in a high-purity Al_2O_3 (McDaniel 998) beaker. During a 30-day test period after electrode activation, we found not more than ± 0.3 mV potential variation from the mean value, which was calculated from potential differences between electrode pairs measured four times a day. Slow (<1°C/min) temperature cycling from 400-460°C did not increase this variation. Fluctuation of the mean values was within 0.5 mV.

Development of the $Li\text{-}Al/Li^+$ Electrode as a Calibration Standard

Since aging and other effects might cause changes of the $Ni/Ni_3S_2/S^{2-}$ electrode potential, an *in-situ* calibration technique was developed.

Like the hydrogen electrode in protonic solvents, the Cl_2/Cl^- electrode, from a thermodynamic standpoint, is excellent for use in establishing a reference potential in the LiCl-KCl electrolyte. Use of this electrode, however, is hindered by severe experimental difficulties. The other natural choice, the Li/Li^+ electrode, is ill-defined because of the lack of real equilibrium as a consequence

*Electrochemical Society Active Member.

of the following reaction (13):

$$Li + KCl \rightleftarrows K + LiCl \quad [1]$$

A third (theoretically possible) electrode having a common element with the electrolyte, the K/K^+ electrode is thermodynamically unstable in the system, see equation [1], as it has too high a vapor pressure in the required temperature range.

When lithium is alloyed with aluminum, however, its activity is decreased and thus the quantity of potassium formed is small and the system approaches equilibrium. Furthermore, as long as the two-phase ($\alpha + \beta$) Li-Al alloy composition is present (~10-46 at. % Li), the potential is independent of the lithium content of the alloy (9-11). The $Li\text{-}Al/Li^+$ electrode, therefore, was selected as the calibration standard.

The construction of the Li-Al electrode is similar to that of the Ni/Ni_3S_2 electrode shown in Fig. 1, except that powdered Li-Al alloy is substituted for Li_2S. Another way to prepare the Li-Al electrode is to wind a short piece of aluminum wire around the nickel wire (Fig. 1) and cathodically produce the two-phase alloy.

However, we observed that Li-Al electrodes having only small quantities of the alloy (a few mg) are prone to instability with a potential shift in the positive direction and so the constant value may hold only for days or hours. To overcome the problem of this uncertainty, we have developed an intermittent charging technique to electrochemically generate the electrode *in-situ*. This technique allows us to measure the rest potential of the Li-Al electrode during cathodic treatment of the aluminum wire and observe from these measurements the establishment of an equilibrium condition. In Figure 2, the potential indicated by the apparent consecutive steady-state, open-circuit values reaches a constant level which corresponds to the two-phase ($\alpha + \beta$) equilibrium value. This simple technique is used to prepare the primary calibration standard.

Evaluation of the Ni/Ni_3S_2 Electrode

The calibration cell utilizes the couple:

$$\underset{T_1\ \ T_2}{Ni\text{-}Ni}/\ (\alpha+\beta)\ Li\text{-}Al/LiCl\text{-}KCl\ eut.,\ Li_2S(s)/Ni_3S_2/\underset{T_2\ \ T_1}{Ni\text{-}Ni} \quad [2]$$

where T_1 is the temperature of the glove-box and T_2 is the cell temperature. According to the primary-standard concept, the potential of the two-phase ($\alpha + \beta$) Li-al alloy is defined as zero at any temperature in order that this alloy serve as a thermodynamic reference state. Consequently, the emf of the cell described in Eq. 2 is the potential of the Ni/Ni_3S_2 electrode on this "standard" potential scale. Least-squares fitting of the E-T data defines the cell voltage (E in mV) according to the following relationship:

$$E = 1367.5 + 0.097(T-700) \quad [3]$$

where T is the cell temperature in K.

Thermal cycling betweeen 360 and 500°C causes no hysteresis and indicates excellent reproducibility. Other aspects of this measurement will be published elsewhere (14). The electrode potential obeys the Nernst equation, and is controlled by the activity of S^{2-} ions (15). X-ray diffraction analysis of material taken from the nickel sulfide electrode indicates that the anodically formed compound is Ni_3S_2. Studies indicate the Li-Al electrode potential is not measurably affected by the presence of Li_2S.

The cell described by Eq. 2 is almost free of liquid-liquid junction potential. Although the Ni_3S_2 may maintain a concentration step function,in the diffusion barrier region, its solubility is very low. Using the Ni/Ni^{2+} standard potential value (2), the calculated Ni^{2+}-ion activity is approximately 10^{-12} g ion/kg in Li_2S saturated eutectic at 700 K.

The Ni/Ni_3S_2 reference electrode described above possesses a well-defined potential of excellent stability. For example, these electrodes have undergone many thermal cycles from operating temperature to room temperature and back with no observable mechanical or electrochemical effects. Many of our electrodes performed well for longer than one year of continuous service in Li-Al/FeS cell testing, thus proving their chemical stability and compatability. Although only this example of use is given here, this reference electrode can be utilized successfully in other LiCl-KCl electrolyte systems as well.

Influence of Metal Ions on the O_2 Reduction of Noble Metals in Alkaline Solutions

R. Amadelli, J. Molla,* P. Bindra,** and E. Yeager**

Case Laboratories for Electrochemical Studies and Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106

Underpotential deposited layers of Pb (1) and Tl (2,3) have been found to produce substantial increments in the catalytic activity of Au for O_2 reduction in alkaline solutions. In the course of a systematic study of such effects we found these same species to enhance the activity of Pt for O_2 reduction, including high area Pt catalyst on carbon supports in alkaline solutions. The purpose of this note is to call attention to this effect which may be useful to electrochemists concerned with increasing the activity of high area Pt electrocatalysts for O_2 reduction.

EXPERIMENTAL

The O_2 reduction has been examined on smooth Pt, high area Pt on carbon supports and smooth Au with the rotating disk ring electrode in 1 M NaOH (Baker, low in carbonates) which was pre-electrolyzed as described elsewhere (4). For the dispersed supported catalyst the material has been applied to an ordinary pyrolytic graphite (OPG) electrode as a thin Teflon bonded layer similar to the technique of Tarasevich (5).

For the measurements without Tl or Pb present the smooth Au and Pt electrodes were treated in two ways. For one the electrodes were cycled between 0 and -0.70 V (all potentials are given vs. Hg/HgO) at 50 mV/s until steady state behavior was obtained and then the current potential curves (Figs. 3,4) was recorded either point by point or scanning towards more positive potentials. Almost negligible hystereis was observed with measurements made with increasing and decreasing potentials. The second procedure involved treating the electrode at -0.9 V for 30 s before recording each polarization curve, otherwise with the same treatment. In the runs with Pb or Tl present, the conditions of the electrode were the same except that the pre-treatment at -0.90 V was not used. The ring was of the same material as the disk and was maintained at +0.125 V for Au and +0.25 V for Pt.

RESULTS AND DISCUSSION

Cyclic voltammetry studies show that thallium forms a UPD layer on Au with a pronounced peak at ∿ -0.20 V (Fig. 1).

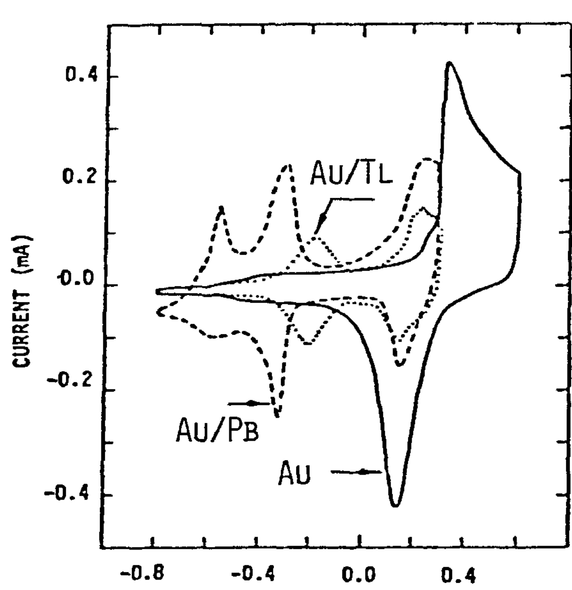

Fig. 1 Cyclic voltammetry curves for Au in N_2 saturated 1 M NaOH in the absence (solid line) and in the presence of 5.8×10^{-5} M Pb(II) (dashed line) and 2.6×10^{-6} M Tl(I) (dotted line). Scan rate: 50 mV/s. Electrode area: 3 cm^2. T = 25°C.

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.

Key words: catalysis, electrodeposition electrode.

This peak potential is independent of the scan rate but depends markedly on the pH, shifting in the anodic direction by 57 mV/pH unit. Decreasing the pH results in a considerable broadening of the peak. This phenomenon may be due to complexation of Tl (1) with OH^-. Kulba et al. (6) reported two possible complexes of Tl in alkaline solutions: inner and outer sphere complexes of the form $[Tl(OH)_n(H_2O)x]^{1-n}$. The relative amount of the two complexes depends on the pH. The anodic region of the Au voltammogram appears to be greatly modified by the presence of Tl. A similar phenomenon has been observed for Pb on Au (1,2). The Tl and Pb adsorption on Pt is considerably more complex (Fig. 2) than on Au due to anodic film formation at less positive potentials on Pt. It is possible that Tl and/or Pb adsorb on the anodic film covered Pt, for example in forms such as Pt-O-PbOH or Pt-O>Pb<O-Pt where the H of the PtOH has been replaced by Pb and water in the inner coordination sphere of Pb is not shown. Alternatively, Pb can underpotential deposit according to the following process:

$$OH(ads) + e^- \rightleftharpoons OH^-$$
$$HPbO_2^- + H_2O + 2e^- \rightleftharpoons Pb(ads) + 3\,OH^-$$
$$\overline{OH(ads) + HPbO_2^- + H_2O + 3e^- \rightleftharpoons Pb(ads) + 4OH^-}$$

This implies that the adsorption of the metal ion suppresses the anodic film formation. A similar effect may also occur on Au on which OH adsorption occurs already at $E \geq 0.45$ V RHE. Hydrogen adsorption is also inhibited when foreign metal ions adsorb or underpotential deposit on Pt.

Figs. 3 and 4 show the polarization curves for O_2 reduction in 1 M NaOH on Au and Pt (the latter both in low and high area form) with and without Tl(I) and Pb(II) added to the electrolyte.

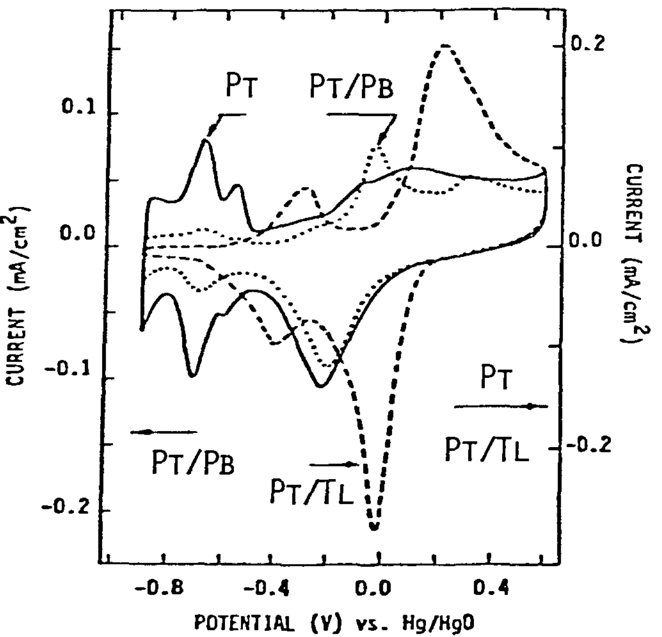

Fig. 2 Cyclic voltammetry curves for Pt in N_2 saturated 1 M NaOH in the absence (solid line) and in the presence of 2×10^{-5} M Pb(II) (dashed line) and 1×10^{-5} M Tl(I) (dotted line). Scan rate: 50 mV/s. Electrode area: 7.5 cm^2. T = 25°C.

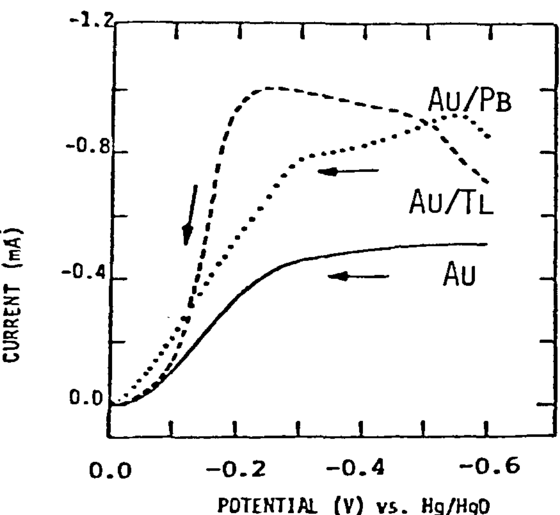

Fig. 3 Polarization curves for O_2 reduction on Au in 1 M NaOH in the absence (solid line) and in the presence of 1.4×10^{-4} M Pb(II) dotted line) and 6.6×10^{-6} M Tl(I) dashed line). Scan rate: 10 mV/s. Rotation rate: 3600 rpm. Electrode area: 0.196 cm^2. T = 25°C.

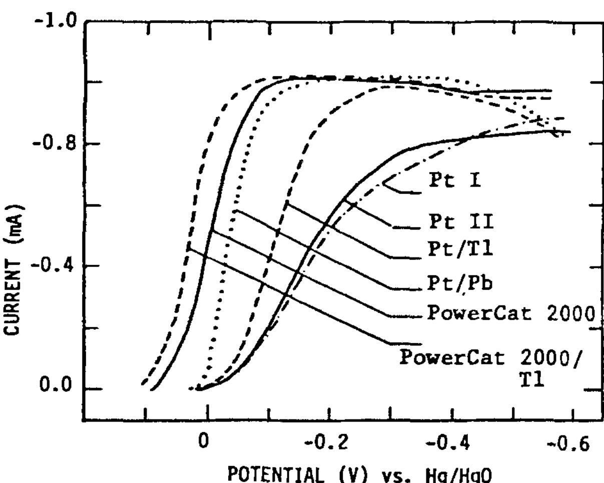

Fig. 4 Polarization curves for O_2 reduction on different substrates in 1 M NaOH. Tl(I) concentration: 6.6×10^{-6} M for Au, 3.2×10^{-6} M for Pt and 1.1×10^{-5} M for Powercat 2000. Pb(II) concentration: 2×10^{-6} M. Scan rate: 10 mV/s except for Powercat obtained point by point). Electrode area: 0.196 cm^2. Powercat 2000 supported as a thin coating on OPG. Pt I: no cathodic pretreatment, Pt II: cathodic pretreatment.

With Au in pure NaOH solutions, O_2 reduction proceeds by the series mechanism with the further reduction and decomposition of the HO_2^- very slow. This results in 2 e^- per O_2 reaching the electrode surface. With the addition of $\geq 10^{-5}$ M Tl to the electrolyte, the current on Au is very substantially increased although the half wave potential is not changed very markedly. Rotating disk-ring data, analyzed using the method of Wroblowa et al. (7), indicate that the process now proceeds by parallel mechanism with close to 4 e^- per O_2 reaching the electrode surface. For example, at 25°C in 1 M NaOH + 6.6×10^{-6} M Tl(I), $k_1/k_2 = 0.4$ (k_1, k_2 are the rate constants for the 4 and 2 e^- reductions to OH^-, respectively). While part of the current increase is due to k_1, a significant portion of the increase produced by the Tl addition also appears to be associable with an increase in the reduction and/or decomposition of the peroxide at the electrode surface. In contrast to the results with Tl, even in solutions containing up to 10^{-4} M Pb(II), the O_2 reduction on Au still proceeds through only the series mechanism although the peroxide elimination through reduction and/or decomposition is greatly increased.

With the addition of $\geq 10^{-6}$ M Pb or Tl to 1 M NaOH the O_2 reduction on Pt is very substantially increased and the half wave potentials are shifted to much more anodic values, particularly on smooth Pt. Rotating disk-ring studies indicate the O_2 reduction to proceed by the parallel mechanism both with and without Pb or Tl present but the ratio of k_1/k_2 is substantially increased as is also k_1.

The high area catalyst Powercat 2000 was obtained from Stonehart Associates (Madison, Connecticut) and consists of dispersed Pt on a carbon support with a Pt area of ∿ 100 m^2/g. Prior experiments with this catalyst in gas-fed O_2 cathodes in the authors' laboratory have indicated unusually high activity. Even so, the addition of 10^{-6} M Tl results in a substantial increment in the current density in the potential region where kinetic control is involved. Pb produces a similar effect although not quite as large.

The reduction and oxidation of HO_2^- on Au and Pt have also been examined in N_2 saturated 1 M NaOH containing Tl or Pb. The peroxide reduction current is increased by approximately 2 fold on both Pt and Au in the presence of 10^{-6} M Pb or Tl as potentials of 0.0 to -0.4 V. The authors believe that most of the increase in current observed with the Tl and Pb additives is caused by the destabilization of the anodic film on the Pt and Au by the adsorbed metal species. Adzic et al. (8) have reached the same conclusions as to the destabilization of the anodic films analogous to the observation of Bruckenstein et al. with Hg and Bi on Pt. With the Pb particularly the O_2 reduction proceeds at potentials which are quite anodic compared to those when the UPD peaks are observed (Fig. 1). It is unlikely that a simple UPD layer is found at such anodic potentials and it is more likely that a complex ion species containing Pb is the adsorbed species.

DECEMBER 1981

An Assessment of the Processes Leading to Pit Nucleation on Iron

M. Janik-Czachor[1]

Department of Chemistry, Northwestern University, Evanston, Illinois 60201

ABSTRACT

In this review the controversial issues of the processes leading to the chemical breakdown of passivity are discussed. The following problems are considered: (*i*) aggressive anion concentration buildup and the effect of potential; (*ii*) effect of defects and inhomogeneities within the metal phase and/or within the passivating film; (*iii*) the possibility of incorporation of aggressive ions into the film; (*iv*) effect of aggressive ions on film thickness and structure; (*v*) significance of the induction period, and (*vi*) relevance of the prevention of repassivation.

Pitting is one of the most dangerous forms of localized corrosion of passive metals in solutions containing aggressive ions X^- ($=Cl^-$, Br^-, I^-). The mechanism of processes leading to pit nucleation is still a subject of controversy (1-25).

Some authors distinguish between an initiation and a propagation step in pitting (1-3, 5, 7, 13, 14, 17). For them the crucial questions with the initiation step are: (*i*) how the aggressive ions change the protective ability of the passivating film locally, so that it no longer prevents high anodic currents from flowing, and (*ii*) what is the role of the potential of pit nucleation, E_{np}.[2] Others claim that there is no fundamental difference between the initiation and propagation steps (4, 8, 12), since direct contact between the bare metal and the electrolyte occurs instantaneously upon the immersion of the passive metal. Local weak spots or flaws always exist within the film; the aggressive electrolyte instantaneously penetrates the film at these flaws and reacts with the bare metal, resulting in rapid metal dissolution.

The experimental background for these two approaches has been reviewed by Janik-Czachor, Wood, and Thompson (6).

To decide which of the approaches is likely to be applicable for iron, the present state of understanding of passivity on iron must be taken into account (26-37).

In the stationary state, passive iron is covered by a film, several nanometers in thickness, having low ionic conductivity, and supporting electric fields of the order of 10^6 V/cm. Optical measurements suggest that it is an insulator with a principal energy gap above 5.5 eV (32, 33).

Although local defects always exist within the film, there is experimental evidence that no bare metal surface is exposed to the electrolyte (26, 27). Iron in the active state dissolves as Fe(II), whereas in the passive state the primary dissolution product is Fe(III). According to Vetter (26), in the passive state the reactions $Fe \rightarrow Fe^{+2} + 2e$ and $Fe^{+2} \rightarrow Fe^{+3} + e^-$ are excluded. So the primary products of iron dissolution in the active and in the passive state are basically different. Only after pitting commences, that is, the initiation step is essentially over, does Fe(II) appear as a corrosion product from the pits, whereas Fe(III) production continues from the remaining passive surface. It is reasonable to assume, therefore, that there is an initiation step for pitting of passive iron. In attempting to rationalize the information available, the following problems are discussed:

1. Aggressive ion concentration buildup and the effect of potential.
2. Effect of defects and inhomogeneities within the metal phase and/or within the passivating film.
3. The possibility of incorporation of aggressive ions into the film.
4. Effect of aggressive ions on film thickness and structure.
5. Significance of the induction period, τ.
6. Relevance of the prevention of repassivation.

The author's point of view is presented.

Aggressive Anion Concentration Buildup and the Effect of Potential

The important questions for initiation are: (*i*) how sufficient halide becomes available at the initiation sites to stop repassivation effectively; (*ii*) does this occur at specific sites as a result of local processes on the passive film surface or in the adjacent environment; and (*iii*) why breakdown of the film only occurs after a certain critical potential is exceeded. Many authors agree that E_{np} is a characteristic parameter for pitting. The existing data show that E_{np} decreases as the concentration of the aggressive ions C_{x^-} increases and depends on their nature (see Fig. 1). It is also influenced by the presence of inhibitors but does not depend on pH (1-3, 6, 7, 13, 14, 24, 25, 39, 41, 44-46). The following relationship is obeyed for E_{np}

$$E_{np} = a - b \ln C_{x^-}/C_{inh} \quad [1]$$

[1] On leave from the Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw, Poland.

Key words: metals, films, corrosion, passivity.

[2] The situation is more complex. There exists a critical pitting potential E_{cp} sometimes called "the protection potential" (3, 6, 17, 38-43). Usually $E_{cp} < E_{np}$. Below E_{cp} the pits once initiated can be stopped. The existing data infer however that when E_{np} is determined in a way that eliminates the time for breakdown, $E_{np} = E_{cp}$ (13, 14, 24, 42, 44).

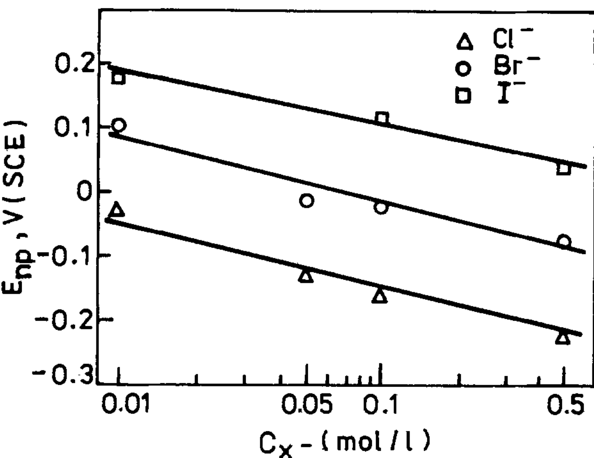

Fig. 1. Critical pitting potential *vs.* halide concentration (25). (Reprinted with permission of *Werkstoffe und Korrosion.*)

The relatively high values of the slope b ($\cong$100 mV/decade C_x-) suggests a strong halide effect (1, 3, 7, 13, 14, 24, 25). An increase in inhibitor concentration C_{inh}, shifts E_{np} to more positive values. Some authors (1, 13, 14, 16, 44, 45) have suggested, therefore, that the first step of pit nucleation is halide adsorption and that there is a competitive adsorption process between halide and inhibitors that results in the E_{np} shift.

Coverage with a halide and an inhibitor depends on the electrode potential and the concentration of these species in the bulk electrolyte. Strehblow (48) has considered this dependence in detail and concluded that in the absence of any inhibitor, coverage with X^- increases logarithmically with potential; he assumed that E_{np} corresponds to a critical coverage above which there are sufficient aggressive ions at the surface to break down the film. When an inhibitor is also present, the relations between the critical coverage and E_{np} is given by a formula similar to Eq. [1].

Why do halides tend to adsorb locally?

There are various inhomogeneities and defect sites within the metal phase and/or in the film. It is, therefore, reasonable to expect a preferential adsorption of halide at these sites. The important role of such defects and inhomogeneities in halide agglomeration is considered in more detail in the next section.

It is interesting to recall here the point made long ago by Kolotyrkin (1) that the passive metal surface never dissolves homogeneously. The halides migrate to the sites of accelerated dissolution. Therefore, the critical concentration of halide will first be attained at these sites. Indeed there is direct evidence that chlorides already agglomerate as islands on the passive surface at potentials less than E_{np} (49, 52). Heusler and Fischer (14, 50) considered island formation; they pointed out that the solubility of chloride in the oxide on iron is negligibly small. Under these conditions, chemisorption of chloride is said to yield preferentially chloride islands rather than a statistical distribution, even if the passivated surface were completely homogeneous.

Effect of Defects and Inhomogeneities Within the Metal Phase

Some authors rule out the role of surface inhomogeneities in pit nucleation (13, 14, 51) and assume that it is a stochastic process (54, 55). However these concepts are contrary to the common observation that pits form at grain boundaries (3, 15, 64), nonmetallic inclusions (3, 6, 10, 15, 17, 53-59, 61-63, 65-70), and at some dislocations (60).[3] These findings are not surprising, since in reality commercial metals and alloys, and indeed the surfaces of materials as pure as those prepared by zone refining, are not "ideal," homogeneous systems. Metals contain nonmetallic inclusions, second-phase particles, and usually some segregation of impurities; the boundaries of such phases with the matrix are likely regions of susceptibility to pit nucleation. The passivating film over these regions is certainly defective, and its structure and composition are different from that over the metal matrix. Studies with the aid of modern surface analytical techniques may provide more detailed information about the composition and the structure of these regions.

Even in the absence of aggressive ions, a somewhat accelerated dissolution of a passivated metal has been observed at certain inhomogeneities, like nonmetallic inclusions (10, 71). More rapid dissolution at these sites in the presence of aggressive ions should certainly lead to their local accumulation there. On the other hand, electron probe microanalysis has given evidence for the formation of chloride salt island at the boundary between sulfide inclusions and the metal matrix for iron and steels prepassivated electrochemically (72) or in air (59), when polarized in chloride solution, even at potentials less than E_{np}.

There is always a "spectrum" of the induction period for pit nucleation, τ, suggesting a "spectrum" of susceptibility for different sites on the surface (73). This behavior is characteristic for commercial alloys and for high purity metals. For the latter one can, therefore, expect that agglomeration of halides will occur at the most susceptible sites, *e.g.*, impurity segregates, certain dislocation configurations, etc. Summarizing the above discussion, it is suggested that various inhomogeneities within the metal phase and/or the surface film help aggressive ions to agglomerate on the passivated metal surface.

Adsorption alone cannot change the protective abilities of the passivating film. Other processes must be operative, simultaneously or subsequently. Two processes are usually discussed and will be considered here: (*i*) incorporation of halides into the passive film and (*ii*) film thinning and alteration of its structure due to halide action.

Incorporation of X^- into the Passivating Film

Various models of pit nucleation postulate migration of aggressive ions through the thermal or anodic passivating film lattice by ionic migration under an electric field or by field-independent anion exchange (2, 18, 20, 74-76), processes which are likely to be accompanied by a change in the film conductivity. The available evidence for aluminum is contradictory (6, 7, 12). For iron in a borate buffer solution, it has been found from electrochemical and ellipsometric measurements that the induction period for pit nucleation, τ, increases with an increase in the film thickness (74). It was concluded, therefore, that this resulted from the longer path chloride ions had to traverse to reach the metal surface when the film was thicker. This explanation seems unlikely, however, because no change in the ionic conductivity of the film has been found due to chloride action (14, 50). Furthermore, Auger electron spectroscopic (AES) measurements have not given any evidence for chloride entry into the film (Fig. 2) (6, 17, 77, 78).

Some valid reasons against the concept of migration of aggressive species through the film lattice have been advanced by Vetter and Strehblow (13, 79). Transport of metal ions and chloride ions through the passivating layer occurs under a high electric field 10^8 V/m. For an exchange of oxygen ions by chloride ions, the divalent O^{2-} ions must migrate against this high field, which is unlikely. It also seems unlikely that large ions, such as ClO_4^- and SO_4^{2-}, which can also

[3] In particular, the important effect of nonmetallic inclusions on pit nucleation has been studied in detail in our laboratory and is discussed elsewhere (57, 70).

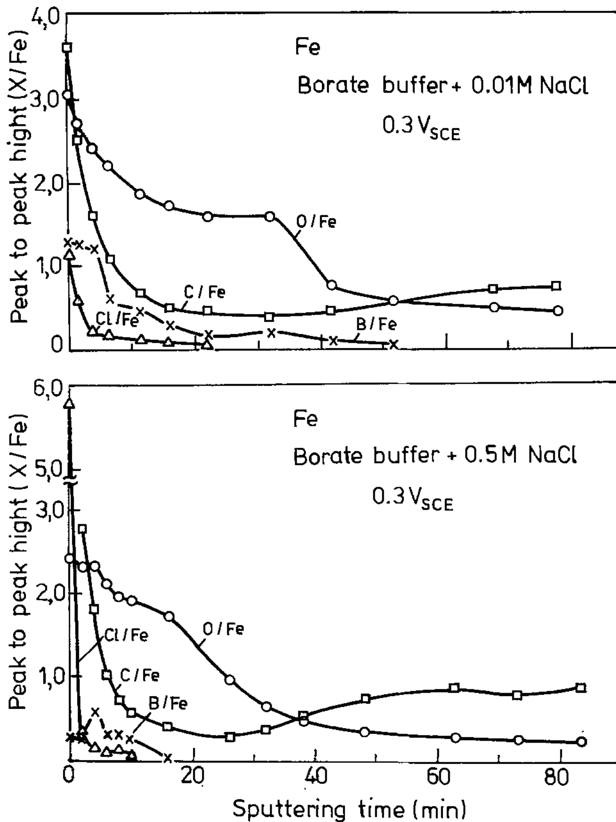

Fig. 2. Depth profiles of the passivating film on iron prepassivated in borate buffer solution and polarized at $E = 300\ mV_{SCE}$ in borate buffer solution containing (a) 0.01M NaCl, (b) 0.5M NaCl (77). (Reprinted with permission of *Werkstoffe und Korrosion*.)

provide pitting, should migrate through the passive film lattice.

Effect of Aggressive Ions on the Passivating Film Thickness

Existing data show no agreement on the effect of chloride ions on the thickness or structure of the passivating film on iron.

Ellipsometric measurements indicated that the film thickens due to chloride action (2, 74, 80). For example, McBee and Kruger (74) reported that chloride ions produce changes at all wavelengths in the visible spectrum of the film on iron, formed and held at $E < E_{np}$; they interpreted this to be caused by film thickening. On the other hand, at $E > E_{np}$, the visible spectrum is affected at only a few wavelengths when chloride is introduced into the borate buffer solution in which the film is formed. The authors claim, therefore, that subtle changes in the film due to chloride action are affected by the potential at which the film is exposed to chloride, and these changes are related to the tendency for the film to breakdown, when $E > E_{np}$. The manner in which ellipsometric data, which averages the behavior of the entire surface, are influenced by local action, such as halide island formation, breakdown and repair processes, film undermining, etc. has not been clarified.

As mentioned above, the use of AES with ion milling has enabled in-depth composition profiles of films to be determined (17, 77, 78, 81). It was concluded that the polarization of passive samples at $E > E_{np}$ and $t < \tau$ in chloride solution makes the film easier to sputter (77), (Fig. 2). However, it is not clear whether the observed effect is due to thinning of the film or to a change in the film structure.

Recent findings with the iron rotating disk ring electrode (14, 50, 51) may have brought valuable insight to the processes under consideration. The ring current, indicative of Fe(III) production, in borate or phthalate buffers grows linearly with the chloride concentration, but there is no effect on the total disk current density (Fig. 3). The authors assume that this ring current increase must be due to the dissolution of the passivating γ-Fe_2O_3 layer. They claim that the increase in oxide dissolution stops as soon as the new steady state is established, corresponding to a thinner oxide layer from which Fe(III) dissolves faster than in the absence of chloride. The chemisorbed halide may replace oxygen ions or hydroxyl ions on the passivating film. The authors assume that the decrease in film thickness is localized and occurs under chloride islands formed over the film. Local fluctuations in island life, location and development and in passivating film thickness occur and may result in complete local removal of the film at sufficiently high anodic potentials. This is accompanied by a steep increase of Fe(II) production, when pitting commences (Fig. 3). Problems with this concept include its lack of direct evidence that the salt deposits do thin the passivating film and the absence of a detailed theory of how they do it.

This discussion has shown why it is reasonable to expect accumulation of halides at heterogeneities in the passivating film. However, even at these weak spots the removal of the film evidently requires a certain period of time; Fe(II) production, indicative of film breakdown, is clearly detected not immediately, but only after a certain time has elapsed (Fig. 3).

Our coulometric measurements (77, 78) for the iron/borate buffer system have shown that the amount of charge necessary to reduce cathodically the passivating oxide film tends to diminish after the passivated metal has been exposed to chloride or bromide containing borate buffer at $E < E_{np}$. The effect increases with halide concentration, (Fig. 4). A similar effect of halide has been found for iron in phosphate-borate buffer (22). The suggestion has been made, therefore, that the passivating film on iron should be thinning before pitting commences. Our primary *in situ* measurements by Raman spectroscopy seem to confirm this suggestion. The Raman intensities of the bands corresponding to the passivating film formed on iron in borate buffer diminished after an exposure of the passivated metal to a chloride-containing solution, at $E < E_{np}$ (82). This infers that there is less of the original passivating oxide film on the metal surface after exposure to chloride. The conclusion is also supported by the re-

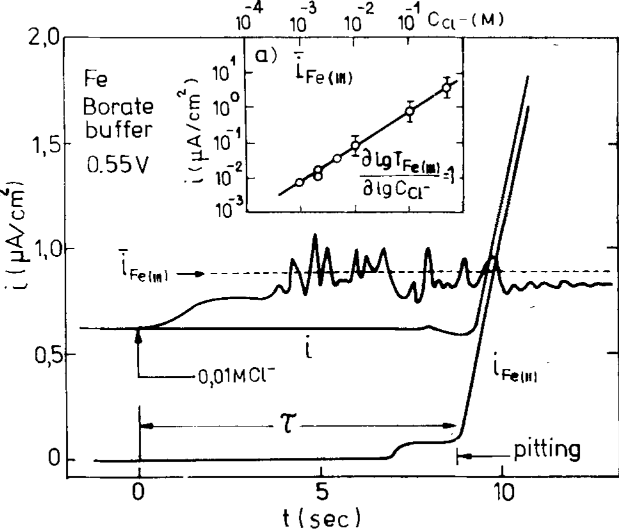

Fig. 3. Effect of time on total current *i*, and Fe(II) and Fe(III) dissolution of passive iron after addition of chloride into borate buffer solution. sults of Valverde and Wagner (91, 92). These authors argue that halide ions enhance release of cations from the surface of transition metal oxides, since these cations form complexes with halide ions. Their experimental results show an increase in the dissolution rate of some iron oxides with an increase in chloride or bromide concentration in acid solution. However a systematic investigation of the chemical characteristics of the relevant iron oxides is lacking, as is a knowledge of the morphology of the dissolving surface.

Significance of the Induction Period, τ

Many authors believe that τ represents a characteristic feature of the pit initiation stage (2, 3, 5, 6, 14, 17, 20, 21, 23, 25, 41, 44, 51, 64, 73, 83, 84). They consider that once conditions for pitting are established, the first pit appears after an induction period, and that within this period, conditions are established which are necessary for the breakdown of passivity.

The previous discussion suggested that the incorporation of X^- into the film is unlikely, and that the aggressive action leading to pitting takes place at the film/solution interface.

For the effect of halide concentration on τ the following relation is obeyed

$$1/\tau = \text{const.}\, C^n_{x^-} \qquad [2]$$

The constant n is 1 for iron in chloride solution (84), suggesting that the reaction leading to pit nucleation is 1st order with respect to chloride since $1/\tau$ is an estimate of the rate of the breakdown process. It is interesting to note that the mean rate of dissolution of the passivating film $\bar{i}$(Fe,III) increases linearly with chloride concentration, (Fig. 3), in agreement with n = 1. Careful kinetic measurements by Heusler and Fischer (14) and by Janik-Czachor (25) have shown that the effect of potential on τ is given by

$$\ln \tau/\tau_0 = E_0/\Delta E \qquad [3]$$

τ_0 is the minimum induction period, for $\Delta E = E - E_{np} \rightarrow \infty$. τ_0 does not depend on halide concentration (Fig. 5) but does depend on its kind and is an order of magnitude higher for I^- than for the other halides (Table I). The slope $E_0 = \partial \lg\tau/\partial\ (1/\Delta E)$ diminishes with halide concentration (Fig. 5) and strongly depends on the anion (Table I).

Equation [3] is analogous to the relation governing the mean time of formation of two-dimensional nuclei as a function of overvoltage. A suggestion has been made that pit nucleation starts with a formation of two-dimensional nuclei of the chloride salt layer (14), which leads to thinning of the film and eventually to its complete removal locally.

The validity of the model based on Eq. [3] has been confirmed only for iron and Fe-5% Cr alloy (14, 25, 51). There are indications that it may also be applicable to nickel (85), Fe-13% Cr alloy (86), and aluminum (87), but the data cover a too narrow range of τ to enable a decisive conclusion to be reached.

Further experiments are also necessary to test the validity of Eq. [3] for other systems. The effect of the kind of aggressive ions must also be clarified.

The other factor that should be investigated is the effect of bound water in the passivating film. Some authors argue that, *e.g.*, in stainless steels, the bound water may restrain pit formation, that is, increase τ significantly (21, 23). It is not clear how bound water influences halide island and salt formation or how important this effect is. On the other hand, there are

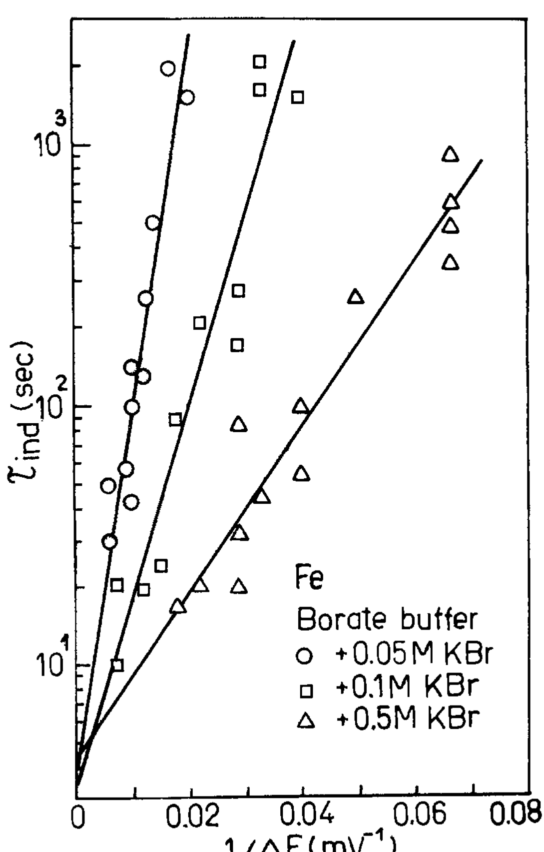

Fig. 5. Effect of potential on the induction period of pit nucleation on iron (25). (Reprinted with permission of *Werkstoffe und Korrosion.*)

Table I. The constants τ_0 and E_0 (Eq. [3] for iron in borate buffer solution containing various halogen ions

opinions that a high anodic electric field will expel water from the metal/film interface, producing an almost dehydrated film (31).

Relevance of the Prevention of Repassivation

There is a strong evidence that X^- not only promotes breakdown of passivity but also prevents repassivation of active sites. For example, at moderate concentrations of X^-, when the potential of the electrode is stepped from the active dissolution range into the pitting range only incomplete passivation occurs (44). Rapid metal dissolution continues at some sites, whereas the rest of the surface passivates. However, the electrode potential governs the aggressive action of X^-, because stepping the potential from the active into the passive range results in complete passivation (24, 38, 41, 44).

Some authors believe that the role of chloride ions in the breakdown of passivity is largely to prevent repair during a dynamic breakdown/repair process (4, 8, 12, 19, 21, 23). However, careful electrochemical measurements for iron did not give evidence that this process occurs in the stationary passive state (26-28, 88). One may argue that these breakdown/repassivation sites are so small that it is difficult to detect them with electrochemical methods. However, these events should lead to a distinct irreproducibility of the experimental data, which is not the case for iron in the absence of the aggressive ions. Modern techniques of noise analysis may provide an insight into this problem. On the other hand, in a nonstationary state, breakdown of the film occurs (88), and when a bare metal surface is thus exposed to the aggressive electrolyte, prevention of repassivation becomes a decisive factor.

With the aid of a ring disk electrode, Strehblow (88) has claimed to demonstrate that temporary breakdown of passivity occurs in the absence of X^-, when the nonstationary state is introduced by an abrupt potential change within the passive region. The ring disk electrode sensitively and rapidly detected temporary Fe(II) production, indicative of active metal dissolution, when stepping the potential from, *e.g.*, 1.3-0.7 V_H (Fig. 6). The bared metal surface underwent repassivation within a few seconds.[4] However, the presence of X^- prevented repassivation and produced pitting instantaneously at remarkably high nucleation rates (13, 88). There were certain similarities to findings of MacDougall (4, 89, 90).

When the active centers are generated, pit development may conveniently occur. This process has its own mechanism and rate-determining steps and strongly influences the pitting process (2, 7, 8, 11, 13, 16, 93-102).

Conclusions

Upon contact of passivated iron with a halide-containing solution at a potential higher than the pit nucleation potential, processes occur which, after an induction period, result in pitting.

The possible processes that occur either consecutively or simultaneously and lead to a concentration buildup of the aggressive ions are as follows:

[4] The result seems to be quite convincing. In general, however, analysis of the potential step ring disk electrode measurements should be done with caution, since the instrumental artifacts caused by the interaction of the potentiostat with the ring disk electrode system may occur (103).

1. Agglomeration of halide in solution near the surface, particularly near various inhomogeneities.
2. Preferential localized adsorption of halide at these inhomogeneities.

Coverage with halide increases with electrode potential. The defects and/or chemical inhomogeneities facilitate the localized agglomeration, so that a critical accumulation can be attained locally at sufficiently high anodic potential.

The way in which the adsorbed halides change the protective ability of the passivating film is most controversial. The present discussion has shown, however, that incorporation of halide into the film is unlikely. Moreover, for the passivating film under steady-state conditions the importance of breakdown/repassivation events has not yet been demonstrated. On the other hand, there exists evidence that the following processes leading to the breakdown of passivity are likely to occur:

1. Thinning of the film and formation of the halide islands, *i.e.*, pit prenuclei.
2. Local removal of the passivating film at sufficiently high anodic potentials and its replacement by halide salt film.

The specificity of the type of halide ion manifests itself in their relative aggressiveness. The potential of pit nucleation and the minimum induction period are higher for I^- than for Cl^- and Br^-. Presumably the catalytic effect of film thinning is weakest for iodide.

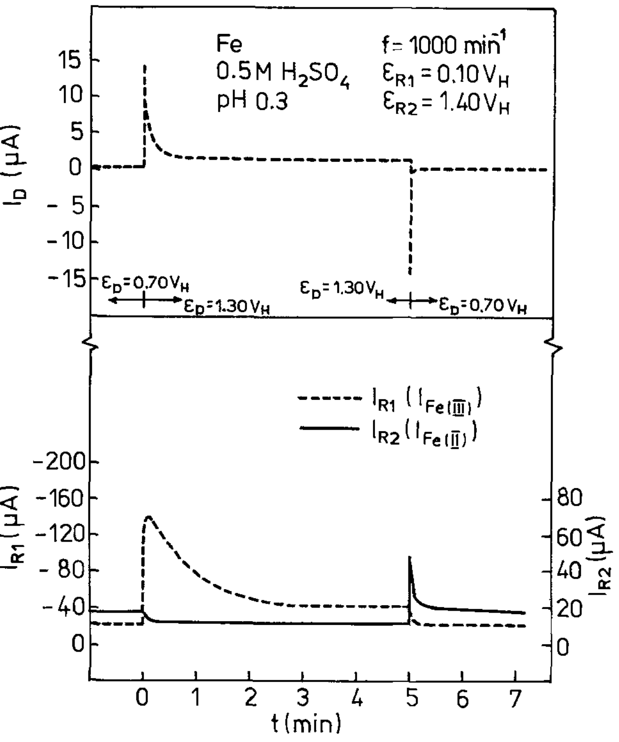

Fig. 6. Effect of time on the total current i_d and Fe(II) and Fe(III) dissolution i_{R1} and i_{R2}, respectively, after stepping potential from 1.3 V_h down to 0.7 V_h, 0.5M H_2SO_4, ring disk electrode measurements (88). (Reprinted with permission of *Werkstoffe und Korrosion*.)

More detailed information on the effect of various halides and electrode potential on film structure, film thickness, and film thickness fluctuations are necessary. The existence and properties of the breakdown/repassivation events should also be examined further.

Acknowledgment

The author expresses her gratitude to Professor Z. Smialowska for her interest in the pitting experiments. Helpful discussions with Professors J. Kruger, K. E. Heusler, G. C. Wood, and B. R. MacDougall are gratefully acknowledged. Thanks are also due to Professor M. B. Ives and Dr. W. Raczynski for their criticism of the manuscript.

Manuscript submitted June 5, 1981; revised manuscript received June 26, 1981. This was Paper 68 presented at the Minneapolis, Minnesota, Meeting of the Society, May 10-15, 1981.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.
