5. Electrostatic conditions for minimizing the deleterious influence of surface states have been analyzed with the help of energy band diagrams. Recombination losses of photogenerated carriers may be reduced by inverting the semiconductor surface. For n-type GaAs, inversion may be achieved by choosing a redox couple such that its equilibrium potential lies more positive than 0.59V on the NHE scale. Similar considerations are presented for PEC systems in general, based on n- and p-type semiconductors.

6. A wider range of redox potentials satisfying the above conditions for inversion layer formation would be available with nonaqueous electrolytes such as $AlCl_3$-BPC molten salts because of (2) above.

ABSTRACT

A scanning cw argon laser has been used to epitaxially recrystallize silicon films deposited over exposed regions of single crystal silicon substrates and cause the lateral extension of these epitaxial regions into the portions of the silicon film deposited over oxide-covered regions of the substrate. Planar and cross-sectional transmission electron microscopy were used to investigate the microstructure, which is consistent with melting and liquid-phase regrowth.

In a recent report, Tamura *et al.* (1) have demonstrated the possibility of "bridging epitaxy" in which a single crystal silicon substrate is used as a seed for the laser recrystallization of a silicon film over silicon dioxide. The regrowth of the deposited film starts where the film contacts the substrate and extends laterally into the portion of the silicon film on top of the insulating oxide layer. Such a single crystal film would find many applications in integrated circuit technology.

In their experiments, Tamura *et al.* used a Q-switched ruby laser to melt the silicon layer deposited on the single crystal silicon wafer which was partially covered with oxide stripes. Using planar transmission electron microscopy, they observed the vertical epitaxial growth of the deposited silicon as it solidified over the exposed silicon substrate and some lateral extension of the single crystal material over the oxide-coated areas.

A pulsed laser, however, melts a large region of material which then solidifies in a manner primarily determined by heat transfer away from the molten areas. In this manner, Tamura *et al.* proposed that the regions over the exposed single crystal substrate crystallized before the silicon over the oxide because the low thermal conductivity of the oxide layer kept the film in these regions above the melting point for a longer time.

The use of a scanning cw laser would appear to be an attractive alternative to the pulsed laser for this application. The epitaxial regrowth process could start over the exposed silicon substrate, and then the molten zone could be moved into the film over the oxide-covered regions in a more controlled manner.

In this report we describe the use of a cw argon laser to epitaxially recrystallize silicon films over exposed regions of a single crystal silicon substrate and the lateral extension of these epitaxial regions into the deposited silicon film over oxide-covered regions of the substrate. Planar and cross-sectional transmission electron microscopy were used to reveal the structure both in the plane of the film and perpendicular to it.

Sample Preparation

Silicon wafers with (100) orientation were oxidized at 1000°C in a TCE/O_2 atmosphere to form a 1000Å thick oxide layer. The oxide was then patterned using a mask containing rectangles of varying sizes from 50×50 μm to 150×300 μm, and the oxide was removed from the orthogonal, 12 μm-wide grid lines separating the oxide rectangles. Silicon films were then deposited in a low pressure, chemical vapor deposition reactor onto both exposed substrate and the oxide-covered regions. (The wafers were cleaned with dilute HF no longer than 5 min before insertion into the LPCVD reactor.) Two different deposition temperatures were used: 550° and 625°C. Films deposited at 625°C have been shown to have a columnar, polycrystalline structure, while those deposited at 550°C are initially amorphous (2). Both types of film were deposited to a thickness of approximately 2000Å. For comparison with the regrown structure to be discussed below, Fig. 1 shows a cross-sectional TEM of an unrecrystallized area of 625°C polysilicon from one of the same wafers as the laser-recrystallized samples. The expected columnar, (110)-oriented grains are apparent (2, 3).

In an attempt to make the deposited layer and the surface region of the underlying single crystal substrate amorphous and facilitate regrowth, some of the structures were then implanted with a dose of 3×10^{15} cm^{-2} silicon ions while the substrate was held on a liquid-nitrogen-cooled support. The implant energy of 135 keV placed the peak of the implant close to the substrate-film interface.

After implantation, the deposited films were recrystallized with a cw argon laser at Stanford (4). The laser beam was moved by galvanometer-controlled mirrors. A 135 mm focal length lens was used, and the spot size on the wafer surface was 40 μm. The retrace was blanked so that the trace of the laser beam on the wafer surface was always in one direction. The scan speed was 12 cm/sec, and a power of 9.5W was used. With the given scan speed and spot size, this power appears to be optimum. At significantly lower powers, the

Key words: laser recrystallization, silicon film, epitaxial growth.

large-grained regions do not overlap, especially over the single crystal silicon with its high thermal conductivity. At much higher laser powers, the silicon over the oxide tends to agglomerate, and the substrate may be damaged. Other satisfactory combinations of laser parameters are, of course, possible.

After completion of the recrystallization, the wafers were returned to Hewlett-Packard for analysis. Suitable control wafers were thermally annealed for comparison with laser-recrystallized samples. These wafers were inserted into a standard diffusion furnace at 550°C and annealed for 5 hr before the temperature was ramped to 650°C for 2 hr and then to 950°C for 1 hr.

After preliminary observation with optical and scanning electron microscopes, planar and cross-sectional samples were prepared (5) from the various wafers and examined in a Siemens Model 101 transmission electron microscope. Some samples were also chemically etched using Secco etch to reveal grain boundaries.

Results and Discussion

Optical microscopy and SEM analysis of the regrown material showed regions of varying thickness over the oxide-covered areas of the substrate (deduced from interference colors) and also surface ripples, especially over the exposed substrate, probably due to optical interference effects, as has been described previously (6). The silicon film extending into the oxide-covered regions in the direction of the laser scan appeared to be especially smooth. Etching to delineate grain boundaries revealed fewer boundaries near the oxide step than farther onto the oxide-coated rectangles. These preliminary observations support the more detailed TEM analysis, although they cannot be considered definitive. A scanning electron micrograph of an unetched sample is shown in Fig. 2 to place the transmission electron micrographs to be discussed next in context. The laser scanned the sample from left to right. Thickness nonuniformities perpendicular to the scan direction are seen at the trailing edge (left side of oxide cut).

Cross-sectional TEM's of one sample are shown in Fig. 3. This sample contained a deposited layer of initially polycrystalline silicon and was implanted with silicon to disrupt any barrier to recrystallization at the film-substrate interface. The scan direction was again from left to right. Figure 3c shows the deposited film directly over the exposed single crystal substrate, and

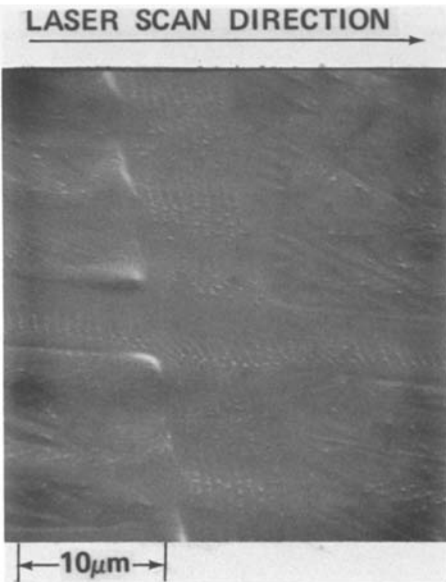

Fig. 2. Scanning electron micrograph of laser-recrystallized silicon film deposited over exposed silicon lines and oxide-covered rectangles. The laser beam scanned the sample from left to right.

the other portions of the figure show the silicon film extending over the oxide steps. (The speckled region above the deposited film is the epoxy used in preparing the cross-sectional TEM's). Figure 3 and detailed comparison of the relevant electron diffraction patterns confirm that the film directly over the single crystal substrate has recrystallized epitaxially; the crystal orientation is the same in the film as in the substrate, and the film contains few defects. The planar TEM of Fig. 3d reveals that the defects at the substrate-film interface seen in Fig. 3d are an orthogonal array of misfit dislocations propagating from the oxide step. These misfit dislocations were not observed in all regions, suggesting that they can be avoided by proper processing conditions. Occasionally, twins and inclined dislocations were seen extending from the substrate-film interface, as schematically indicated in Fig. 3f.

Figure 3e shows the silicon film extending onto the oxide layer. Detailed examination in the TEM reveals that the crystal orientation of the film is the same as that of the substrate, although variation of the thickness of the cross section makes comparison of the orientations directly from the photomicrographs difficult. Although some defects are seen in the film, no grain boundaries are visible within the portion of the film seen in the micrograph. Since this is the leading edge of the laser scan, where the laser moves from the part of the film over the substrate onto that over the oxide, the scanning beam is expected to extend the single crystal region of the film significantly in the lateral direction. Optical microscopy after grain boundary etching does, indeed, suggest that the single crystal region extends farther on this side of the oxide cut than on the other side, although the asymmetry is not clearly revealed by the cross-sectional TEM's, which sample only one isolated area. This observation suggests that two different mechanisms may dominate on the two sides of the oxide cut.

These cross-sectional TEM's reveal several other important features. Most obvious is the mass transport caused by the laser recrystallization. Since the deposited film initially has a uniform thickness of approximately 2000Å, a 1000Å-high step should appear at the top of the deposited film, replicating the oxide step. This step is not seen in Fig. 3e. On the thermally annealed samples, which remained solid during the recrystallization, the expected step of 1000Å was observed.

The opposite side of the oxide cut is seen in Fig. 3a and b. As on the right side, the crystal extends continuously over the oxide step. In this case the grain is seen to terminate at the left approximately 0.5 μm from the edge of the oxide step. Because the laser beam approaches this region from the area which contains a buried oxide layer, rather than from the region with the exposed substrate, the recrystallization mechanism may be quite different than on the opposite side. On the trailing edge there should be no marked tendency of the laser beam to "drag" a single crystal region away from the oxide edge. The controlling mechanism on this side could be similar to that described in experiments with the pulsed laser (1) where the low thermal conductivity of the oxide causes the silicon above it to remain molten longer than that over the exposed substrate. If the major heat loss is by lateral heat transfer toward the oxide cut, the solid silicon would propagate from the oxide edge, and lateral single crystal growth is possible. Although a step is seen at the top of the silicon film where it crosses the edge of the oxide, the step is much less abrupt and of less height than the oxide step. For comparison, the shape seen on the thermally annealed sample is shown by the dashed line superimposed on Fig. 3a. The silicon film on top of the oxide is also seen to be much thinner than that directly over the substrate, indicating significant mass transport, as is shown by the SEM of Fig. 2.

Near both edges of the oxide cut, defects are seen in the substrate. One might speculate that these defects

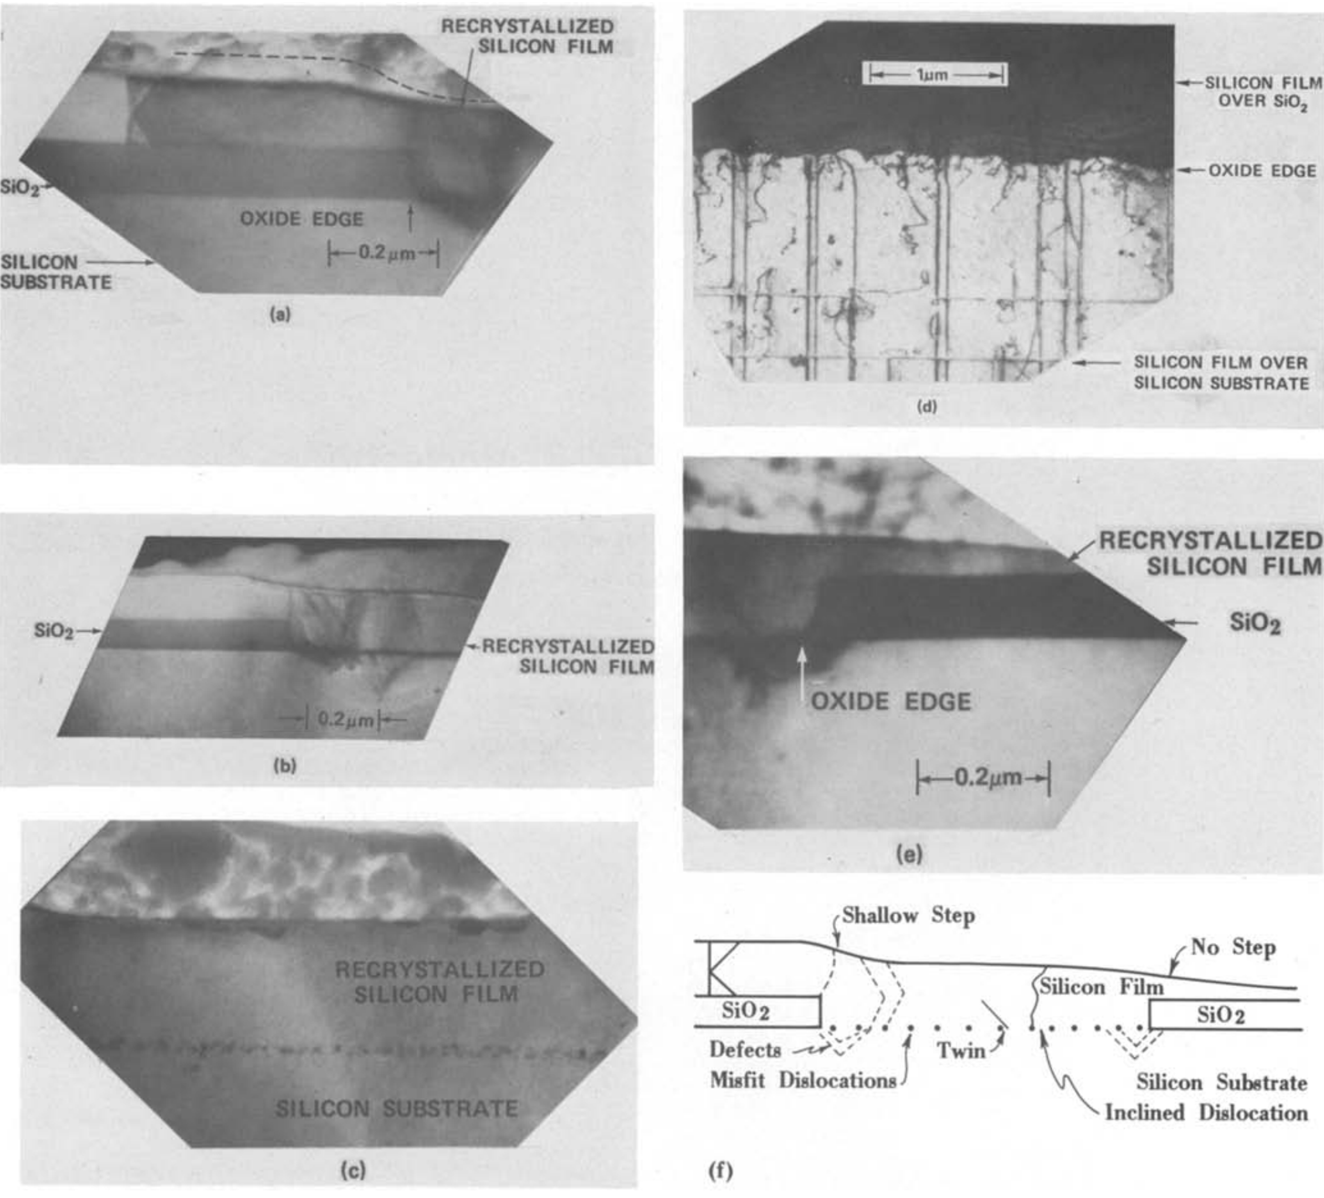

Fig. 3. Cross-sectional and planar TEM's of laser recrystallized silicon film: (a) and (b) over oxide steps at left of oxide cut (b is a dark-field micrograph); (c) over exposed single-crystal substrate; (d) planar section, primarily over exposed substrate; (e) over oxide step at right. (f) Schematic representation of features observed. The scan direction was from left to right in all except (d).

arise from relaxation of stress discontinuities caused by the different thermal expansion coefficients of silicon and silicon dioxide (3×10^{-6} compared to 0.5×10^{-6}/°C), as well as by temperature differences over silicon- and oxide-covered regions. Not only are defects observed extending into the substrate, but slip dislocations parallel to the wafer surface have also been seen several microns beneath the surface of the substrate. These have been observed both under the oxide and under the oxide cuts. These deep-lying dislocations are probably caused by thermal stresses associated with scanned beam recrystallization.

The regrowth of the initially amorphous films was similar to that of polycrystalline films in the regions which were melted. Surrounding the melted regions, of course, were regions where the initially amorphous film was converted to polycrystalline silicon, probably by solid-phase crystallization.

Observation of laser-recrystallized samples with and without the silicon implant showed little difference, with epitaxial regrowth over the single crystal substrate and defects at the interface. This suggests that the implantation is not needed in the case of liquid-phase recrystallization. The lack of epitaxial regrowth in the case of the thermally annealed sample indicates that the implant dose was insufficient to disrupt the interfacial layer present because of the deposition conditions and to allow solid-phase regrowth, even though the dose was sufficient to amorphize the surface regions of the silicon substrate beneath the interface. We speculate that a dose of 10^{16} cm^{-2} might produce the necessary disruption of the interfacial layer to allow solid-phase regrowth.

The different behavior on the two sides of the oxide cut leads us to suggest the following modification of the experimental structure. If the polysilicon is etched from part of the oxide cut and the laser scanning direction is such that laser-assisted growth is started where the polysilicon contacts only the underlying single crystal and proceeds over a gradually beveled oxide step, superior results might be achieved, including the possibility of solid-phase regrowth.

Conclusion

A scanning cw argon laser has been used to epitaxially regrow deposited silicon films over exposed regions of a single crystal silicon substrate and cause the lateral extension of these epitaxial regions into the deposited silicon film over oxide-covered regions of the substrate.

This process occurred by melting and liquid-phase regrowth.

Donor Densities in TiO_2 Photoelectrodes

J. Schoonman,* K. Vos, and G. Blasse

Solid State Department, Physics Laboratory, State University, 3508 TA Utrecht, The Netherlands

ABSTRACT

Mechanical polishing and etching in acids or molten NaOH of TiO_2 electrodes frequently lead to nonlinear Mott-Schottky plots. These surface treatments are discussed in relation to surface roughness effects and the occurrence of nonuniform donor distributions. Modified Mott-Schottky equations are presented and discussed. They account quantitatively for surface roughness and nonuniform donor distributions, which can be induced not only by etching, but also by anodical aging, surface doping, reoxidation effects, and cathodical loading with hydrogen.

Semiconducting TiO_2 (rutile) has attracted widespread attention as photoanode for the photoelectrolysis of water. Its surface properties are of paramount importance and their determination has received considerable effort. Usually, key parameters such as flatband potential V_{FB}, and donor density N_D, are obtained from capacitance measurements, when the semiconductor in contact with an aqueous electrolyte is in the depletion mode. The space-charge capacitance C_{sc} then varies with the potential drop ϕ_{sc} over the depletion layer according to the Mott-Schottky equation (1, 2)

$$C_{sc}^{-2} = \frac{2}{\epsilon\epsilon_0 e N_D A^2}\left(\phi_{sc} - \frac{kT}{e}\right) \qquad [1]$$

where ϵ is the relative dielectric constant, ϵ_0 the permittivity of free space, e the electronic charge, N_D the donor density, and A the interfacial surface area. The potential drop ϕ_{sc} can be expressed as $\phi_{sc} = V - V_{FB}$, V being the electrode potential, provided that the potential drop ϕ_H over the Helmholtz layer at the semiconductor/electrolyte interface is constant. The flatband potential and donor density are then obtained from a linear Mott-Schottky plot, C_{sc}^{-2} *vs.* V.

Nonlinear Mott-Schottky plots for TiO_2/electrolyte junctions have been reported frequently (3-10). Nonlinearity can be attributed to nonhomogeneous donor distributions in the depletion layer, or to surface roughness effects. Surface states on a TiO_2 surface can change the potential of the Helmholtz layer, thereby leading to nonlinearity. The latter model has been described quantitatively by Tomkiewicz (6).

It has become quite apparent that surface preparations are of crucial importance in the determination of V_{FB} and N_D (7, 8, 10). It is the purpose of the present paper to discuss some effects which lead to nonlinear Mott-Schottky plots in relation to surface preparations.

Key words: etching, doping, photoelectrodes.

Polishing and Etching

The plane parallel capacitance approach for the depletion layer leads with Eq. [1] to

$$L_D = \left(\frac{2\epsilon\epsilon_0}{eN_D}\right)^{1/2}\left(\phi_{sc} - \frac{kT}{e}\right)^{1/2} \qquad [2]$$

With donor densities of the order of $10^{18}/cm^3$, and ϵ(//-c axis) = 173, the width L_D of the depletion layer varies between 0.1 to 0.2 μm for potentials ranging from 0.5 to 2.0V. Larger donor densities will further decrease L_D.

Vos and Krusemeijer (4, 5) reported a deformation layer of 0.5 μm thickness for a TiO_2 electrode with a donor density of about $10^{18}/cm^3$ polished to 0.3 μm finish. The recent data of Wilson *et al.* (7) are very well in line with this observation. Although mirror-like surfaces are obtained using 1-0.3 μm grade diamond pastes (4, 10), the deformation layer may extend far beyond the depletion layer into the bulk of the electrode. As reduction procedures induce larger donor densities in the deformation layer (4, 5, 7), differential capacitance measurements need to be performed up to potentials of about 30V, *i.e.*, much larger than usually employed in order to establish not only the thickness of the deformation layer, but also the difference between the donor density in the bulk and in the deformation layer. In addition, L_D values of 0.1-0.2 μm compare unfavorably with 1-0.3 μm grade polishing pastes. Hence, surface roughness needs to be taken into consideration in order to obtain the true donor density in the deformation layer from Mott-Schottky plots. This will be further dealt with in detail in the next section.

It is common practice to remove the deformation layer by etching polished nonconducting TiO_2 crystals in molten NaOH at about 500°C (4-6, 9, 11, 12), in 1:1 mixtures of ammonium sulfate and sulfuric acid at 240°C (7), or in concentrated sulfuric acid at 250°-260°C (10). The amphoteric character of TiO_2 is illus-

trated by these etchants, which lead to the formation of Na_2TiO_3 and $TiOSO_4$, respectively (13). However, these etchants do not always lead to smooth surfaces (7, 9), and do not necessarily lead to linear Mott-Schottky plots (6-10). Nonlinearity for potentials up to 3V has been ascribed to a change in the potential of the Helmholtz-layer due to surface states on the TiO_2 crystal (6), or to different donor densities in individual areas of the surface region (9), or to donor densities which vary with depth (7, 8, 10). Side reactions during the etching process in molten NaOH may provide a rationale for varying donor densities. Usually, employed etching times are 1 hr. Cardon (14) has observed that under these circumstances a layer of 50 μm is removed. For TiO_2 surfaces polished to a 0.25 μm finish, etching periods of 2-5 min are sufficient. In our experience, etching for periods longer than 5 min sometimes results in the formation of a white porous layer on parts of the crystal's surface. This layer can be removed in boiling HCl, in which it does not dissolve. However, the surface in contact with the layer reveals severe pitting after etching. The formation of the layer is ascribed to a reaction between TiO_2 and sodium peroxide (15), inherently present in sodium hydroxide melts

$$4TiO_2 + 2Na_2O_2 \rightarrow 2Na_2Ti_2O_5 + O_2 \quad [3]$$

This reaction may also account for the white layer of colloidal titanates formed during etching as reported by Barber and Farabough (16), and may have other implications for the surface region. Commercial Verneuil-grown crystals contain as residual impurities, among others, Al, Fe, and Sb (Me_2O_3). In addition, residual hydrogen is present in Verneuil-grown crystals (17-19). This hydrogen has been found to compensate for the residual impurities Me_2O_3 (17). Following the defect notation of Kröger (20), and taking into account that OH stretch vibrations have been recorded (19) we can write for such extrinsic crystals

$$Me_2O_3 + H_2 \rightarrow 2Me_{Ti}' + V_0{}^x + O_0{}^x + 2\,OH_0{}^{\cdot} \quad [4]$$

These crystals can loose hydrogen when heated in O_2 at about 600°C (17, 19). If, in addition to etching, reaction [3] occurs the following interfacial reaction would produce charged oxide ion vacancies

$$1/2\,O_2 + 2\,OH_0{}^{\cdot} + V_0{}^x \rightarrow H_2O + 2\,O_0{}^x + V_0{}^{\cdot\cdot} \quad [5]$$

The $OH_0{}^{\cdot}$ centers can dissociate throughout the crystal, thereby producing regular lattice oxide ions $O_0{}^x$ and protons. As protons are more mobile than oxide ion vacancies the density of these vacancies will increase towards the surface. A subsequent hydrogen reduction will introduce titanium interstitials as multiple donors (21), the reaction being

$$2H_2 + 2\,O_0{}^x + Ti_{Ti}{}^x \rightarrow Ti_i{}^{n\cdot} + ne' + 2H_2O \quad [6]$$

where n is found to be 3 (22). Usually donor densities range from 10^{18} to $10^{20}/cm^3$ in reduced TiO_2 electrodes. Residual impurity contents (Me_2O_3) can be as high as $\sim 3 \times 10^{18}/cm^3$ ($\sim$100 ppm) (17) in commercial crystals. The reduced crystals exhibit the characteristic blue-black color, while the crystals with Me_2O_3, even for concentrations greater than 100 ppm, remain light yellow. This indicates that the neutral vacancy $V_0{}^x$ as present in proton compensated crystals does not act as a donor. Von Hippel *et al.* (18) already indicated that charged oxide ion vacancies will readily trap two electrons. Hence, a surface layer with a lower conductivity may be present after surface treatments in the sequence NaOH etching-reduction. In view of reaction [3], reversing the sequence can lead to reoxidation effects

$$Ti_i{}^{3\cdot} + 3e' + O_2 \rightarrow Ti_{Ti}{}^x + 2\,O_0{}^x \quad [7]$$

Extensive reoxidation has been observed by Wilson *et al.* (7) and by Dare-Edwards and Hamnett (10). In fact, reoxidation also takes place when the reduced crystal is stored in air at ambient temperature. Again a low-conductive layer will result.

The acidic etchants (7, 10) are preferential for several crystallographic planes (23-25). Dislocation densities and etch pits have been studied. The nonshiny faceted surfaces as reported by Wilson *et al.* (7) after etching in mixtures of ammonium sulfate and sulfuric acid generate nonlinear Mott-Schottky plots. However, their shape does not indicate surface roughness to be the cause, as will be shown in the next section. Instead, donor densities seem to decrease towards the surface. This would be consistent with proposed reoxidation effects in acidic etchants (10). Moreover, when anodically aged under illumination, TiO_2 electrodes show nonlinear Mott-Schottky plots which closely resemble in shape the plots obtained with acid-etched surfaces (7, 8). Butler (26) has established indeed that donor densities strongly decrease upon anodical aging, due to electromigration of the donors in the depletion layer. Besides the nonlinearity, an important difference is to be noted. The measured capacitances are much smaller for the aged electrodes, while acid treatments lead to capacitances that are larger than the initial capacitances (6, 8). It should be mentioned in passing that the initial capacitances also lead to nonlinear Mott-Schottky plots, which indicate decreasing donor densities towards the surface (8). These initial capacitances were measured on NaOH-etched surfaces (8), of which defect chemical aspects have been discussed above. It has been proposed that during acid treatments of NaOH-etched and subsequently H_2-reduced TiO_2 electrodes protons cross the interface as hydrogen atoms. Once inside the crystal they donate their electron to the conduction band (8). As electrons in the conduction band at the surface are assumed to cause some reduction of the protons in the electrolyte, the net effect is the introduction of protons on interstitial sites in the crystal, leaving the net n-type semiconductivity unaltered (8). This in fact violates the condition for electroneutrality for both the crystal and the electrolyte solution. It is known that the flatband potential of oxidic semiconductors varies with about 60 mV/pH unit. This variation is to be related with chemically bonded OH-groups on the surface of the semiconductor in contact with an aqueous electrolyte. The dissociation of these surface hydroxyl groups is pH dependent (6). This also indicates that the mechanism underlying the capacitance increase upon acid treatment could be more complicated than proton injection from the electrolyte. Irrespective of the mechanism, acid treatment does not restore the linearity to the Mott-Schottky plots in the studies reported by Harris and co-workers (7, 8), while it does in the study reported by Tomkiewicz (6). This author ascribes the nonlinearity to a change in the potential of the Helmholtz layer due to the presence of surface states on a matte, NaOH-etched TiO_2 surface. The smaller slope of the linear Mott-Schottky plot, and consequently the larger capacitances after acid treatment, were ascribed to a different roughness factor due to mild etching effects. This approach suggests a relation between the density of the surface states, and the surface roughness, but this has not been explored in the reported study (6). Recently, Ullman (27) has shown that the surface-state model needs some revision. Instead, a plausible alternative would be a thin surface layer with a smaller donor density, thus bringing about a general concordance between the results reported by Wilson *et al.* (7) and Tomkiewicz (6).

Modified Mott-Schottky Equations

From the preceding section it is apparent that rough surfaces and nonuniform donor densities may be inherently related with chemical etching and mechanical polishing procedures. Even smooth TiO_2 surfaces appeared matte after hydrogen reduction due to thermal etching (28).

Rough electrodes have actual interfacial areas ($A = A_0 + \Delta A$) which are greater than the geometrically determined surface areas (A_0). The edge of the depletion layer inside the crystal follows the surface roughness for small values of the electrode potential. For large values the edge of the depletion layer will approach A_0. Following Goodman (29) it can be shown that under these circumstances the following Mott-Schottky equation holds

$$C_{sc}^{-2} = \frac{2(1 - 2\Delta A/A_0)\left(\phi_{sc} - \frac{kT}{e}\right)}{\epsilon\epsilon_0 e N_D A_0^2} + \frac{4\alpha\left(\phi_{sc} - \frac{kT}{e}\right)^2}{\epsilon\epsilon_0 e N_D A_0^3} \quad [8]$$

where α represents $[dA/d(\phi_{sc} - kT/e)]_{V=V_{FB}+kT/e}$.

The Mott-Schottky plot will be concave upward. However, for small ($\phi_{sc} - kT/e$) values the plot will be linear, and may be used to determine V_{FB}. A reliable value for N_D will be hard to obtain. Tomkiewicz (9) reported a practically linear Mott-Schottky plot for a TiO_2 electrode polished to 0.3 μm finish for potentials up to 3V. With Eq. [1] he obtained the value $5.9 \times 10^{19}/cm^3$ for N_D. In this situation $L_D << 0.3$ μm. Consequently, the surface roughness is considerable. A small value for α, and $d\Delta A/d(\phi_{cs} - kT/e) \simeq 0$ are reasonable assumptions. The Mott-Schottky plot will be virtually linear indeed with a slope $2(1 - 2\Delta A/A_0)/\epsilon\epsilon_0 e N_D A_0^2$. The donor density as calculated with Eq. [1] need then be multiplied by a factor $(1 - 2\Delta A/A_0)$ in order to obtain a correct though smaller donor density. This may, as stated before, not be the electrode's bulk donor density as reduction induces a greater donor density in the deformation layer (4, 5, 7) Concave curves have also been reported (9).

The aging experiments reported by Butler (26) reveal a rather sharp edge to exist between the surface layer with smaller donor density and the bulk of the electrode. Figure 1 shows a schematic representation of the nonuniform donor distribution in aged TiO_2 (26). Here $N_{D,s}$ is the donor density in a surface layer with thickness δ_1, while $N_{D,l}$ is the donor density for $x > \delta_1$. If a deformation layer with depth δ_2 ($>\delta_1$) is present, $N_{D,l}$ will not be equal to the bulk donor density $N_{D,b}$, *i.e.*, $N_{D,l} > N_{D,b}$. For small potentials $L_D < \delta_1$. Equation [1] can then be used to calculate $N_{D,s}$. For $\delta_1 < L_D < \delta_2$ the following modified Mott-Schottky equation holds, where the surface at $x = 0$ is assumed to be flat (30)

$$C_{sc}^{-2} = \frac{2}{\epsilon\epsilon_0 e N_{D,l} A^2}\left(\phi_{sc} - \frac{kT}{e}\right) - \frac{N_{D,s} - N_{D,l}}{N_{D,l}}\left(\frac{\delta_1}{\epsilon\epsilon_0 A}\right)^2 \quad [9]$$

For still larger potentials the situation $L_D > \delta_2$ may occur. The Mott-Schottky equation is then given by (30)

$$C_{sc}^{-2} = \frac{2}{\epsilon\epsilon_0 e N_{D,b} A^2}\left(\phi_{sc} - \frac{kT}{e}\right) - \frac{N_{D,s} - N_{D,l}}{N_{D,b}}\left(\frac{\delta_1}{\epsilon\epsilon_0 A}\right)^2 - \frac{N_{D,l} - N_{D,b}}{N_{D,b}}\left(\frac{\delta_2}{\epsilon\epsilon_0 A}\right)^2 \quad [10]$$

The relations hold provided that Helmholtz layer, and Gouy-layer effects, and the capacitance of the counter-electrode need not be taken into consideration.

In Fig. 2 we have plotted calculated Mott-Schottky plots using $N_{D,s} = 5 \times 10^{18}/cm^3$, $N_{D,l} = 2 \times 10^{19}/cm^3$, $N_{D,b} = 8 \times 10^{18}/cm^3$, $\epsilon = 173$, $\epsilon_0 = 8.8542 \times 10^{-14}$ F/cm, $\delta_1 = 48$ nm, and $\delta_2 = 70$ nm. The lower linear curve in Fig. 2 has been calculated using Eq. [1], and

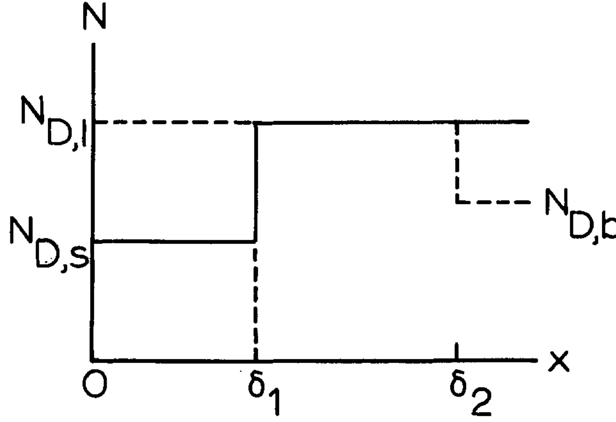

Fig. 1. Schematic nonuniform donor density in aged TiO_2. See text.

$N_D = N_{D,l}$ and represents the uniform doping level situation. The nonlinear curve in Fig. 2 (solid line) has been calculated using Eq. [1] with $N_D = N_{D,s}$ for $L_D \leq \delta_1$ and Eq. [9] for $L_D \geq \delta_1$. If the situation as depicted also in Fig. 1 were to occur, *i.e.*, $N_{D,s} < N_{D,l}$ and $N_{D,s} < N_{D,b} < N_{D,l}$ we find three linear portions in the curve, for which the slopes are governed with increasing potential by $N_{D,s}$, $N_{D,l}$, and $N_{D,b}$, respectively. In this case ($L_D \geq \delta_2$); Eq. [10] was used to calculate the (dotted) line in Fig. 2.

Taking into account Ullman's (27) discussion on the low C_{sc} values reported by Tomkiewicz (6), the solid lines in Fig. 2 represent the TiO_2 data before and after

Fig. 2. Mott-Schottky plot for uniform doping level ($N_{D,l}$), and for nonuniform doping level ($N_{D,l} > N_{D,s}$; $N_{D,s} < N_{D,b} < N_{D,l}$). See text.

treatment with a mild etchant (6). Upon using $N_D = 3.8 \times 10^{19}/cm^3$ (6) and Eq. [2] we arrive at the removal of a surface layer of only 22 nm in order to account for the observed data (6) on the basis of the present nonuniform donor-density model. This model provides a reasonable alternative for the nonlinearity as being due to surface states, and linearity after acid treatment as being caused by different roughness factors (6). In fact, Eq. [8] reveals that the surface roughness would have increased after the acid treatment in order to account for the larger C_{sc} values, and this is not to be expected when TiO_2 is washed with a mild acid etchant.

Harris and co-workers (7, 8) obtained nonlinear Mott-Schottky plots as given by the solid line in Fig. 2 only after prolonged etching in $(NH_4)_2SO_4:H_2SO_4$ mixtures at 240°C, or after anodical aging, while other nonlinear Mott-Schottky plots [Fig. 7 in Ref. (7)] indicate a situation $N_{D,s} > N_{D,b}$ and $N_{D,l} < N_{D,b}$. This latter situation leads to nonlinearity which is also observed in the C_{sc} data reported by Tomkiewicz (9) for a smooth NaOH-etched TiO_2 electrode [Fig. 9 in Ref. (9)], whereby it must be noted that side reactions during etching in molten NaOH as discussed in the preceding section do account for the opposite situation, *i.e.*, $N_{D,s} < N_{D,l}$. Nonlinearity which would be concordant with a situation $N_{D,s} > N_{D,b}$ and $N_{D,l} < N_{D,b}$ can also be accounted for by assuming nonuniform surface potentials as already indicated by Vos and Krusemeijer (4,5). This will be dealt with in more detail in a forthcoming paper (30).

Nonlinearity indicating $N_{D,s} < N_{D,l}, N_{D,b}$ is frequently encountered. Although several of the discussed defect chemical aspects may provide a rationale for having these nonuniform donor densities it must be noted that, in general, experimenting with TiO_2 photoanodes will cause electromigration of the donors (26), thereby contributing to the situation $N_{D,s} < N_{D,l}, N_{D,b}$. Equations [9] and [10] cannot only be used in clarifying anodical aging experiments quantitatively, they can also contribute to our insights into deformation layers having donor densities different from the bulk, reoxidation influences, cathodical loading of TiO_2 electrodes with hydrogen (4, 5, 8, 19), or TiO_2 electrodes modified by surface dopants (31).

Technical Notes

Luminescence of Silica Glasses Containing Copper

J. M. Brownlow and I. F. Chang*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

This note reports the conditions under which monovalent copper imparts photoluminescence to silica glass. A strong permanent luminescence is produced by Cu paired with Al. Cu paired with OH imparts a moderate activity which fades with time of heating at 1200°C. The activity with Cu and Ga together is weak but permanent. No activity was found when each of 20 other potentially active dopants was paired with Cu.

* Electrochemical Society Active Member.

Key words: copper, photoluminescence, dopants.

Samples for a composition survey of the Cu-Al-Si oxide system were made by mixing silicic acid with Cu and Al nitrates in water, drying, and reacting at 1200°C in wet nitrogen gas for 15 min. The compositions with the greatest activity were near 0.5 mole percent (m/o) Cu_2O and bridged a range of Al_2O_3 content from 1 to 10 m/o. Heating beyond 1 hr at 1200°C did not cause intensity loss. The light output of the brightest compositions in this ternary was enhanced by a factor of 2 by the addition of 10% B_2O_3.

The intensity of the emitted light under 254 nm excitation was comparable to that of commercial P15 (ZnO) phosphor. The emission spectrum is given in Fig. 1. This curve is similar to the results of Claffy and Schulman (1) who added Cu, Na, and Ca oxides to several alumina-silica mixtures. They suggested that crystalline phases may be the seat of the luminescence. This was not supported by experiments in which the bright luminescence of 1200°C reaction products was found to be preserved when they were melted to a clear glass in an oxy-propane flame. This glass has a broad absorption band at 250 nm.

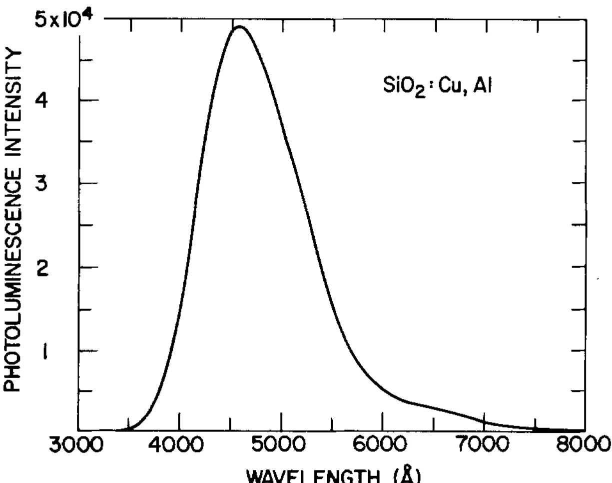

Fig. 1. Photoluminescence intensity (arbitrary units) vs. wavelength (Å) for SiO_2 glass containing 0.5 m/o Cu_2O, 10% Al_2O_3.

The conjecture that monovalent copper is part of the active center was supported by two findings. First, reactions carried out under neutral or slightly reducing conditions (wet N_2 or wet N_2 with 1-2% H_2) which minimize divalent copper produced brighter samples than reactions carried out in air. Second, a bright phosphor was produced when some of the Na^{+1} in Vycor[1] brand glass (96% SiO_2) was replaced by Cu^{+1} by electrolysis at 730°C.

The cooperative effect of bound water with Cu^{+1} was the focus of the following trials. Products of the initial reaction between silicic acid and cuprous oxide were moderately luminescent. However, this activity and that of Cu-doped Vycor nearly vanished after holding one or two days at 1200°C. Silica glass laboratory ware made from natural quartz exhibits a similarly fugitive weak blue luminescence which could be imitated in glasses synthesized from silicic acid with about 50 ppm Cu_2O. Anhydrous silica and cuprous oxide did not produce active products with or without addition of B_2O_3.

It remains to be explained why Al, Ga, or OH ions must be present to enable Cu^{+1} to impart luminescence to silica glass.

Manuscript received Oct. 17, 1980.

A Method for Rapidly Screening Polymers as Electron Beam Resists

Robert G. Brault* and Leroy J. Miller*

Hughes Research Laboratories, Malibu, California 90265

The search for new, improved electron resists could be greatly facilitated by having methods available for rapidly determining sensitivity (Q) and contrast (γ). Improved sensitivity is necessary to obtain desirable throughput, and good contrast is a necessary (although not a sufficient) condition for achieving high resolution (1). Such a rapid test would be useful not only for screening candidate resists, but also for accelerating subsequent process development, such as the optimization of developer composition, development time, and bake conditions. To evaluate Q and γ accurately, it would be desirable to have a large number of areas exposed at different doses, as many as 50 per decade, in the dose range of interest. The exposed areas should be as small as practical to minimize exposure time. Finally, a rapid, accurate method for measuring the thickness of each area on the developed wafer is needed. This paper describes a test method in which writing the test pattern takes about 30 min and making the required thickness measurements takes about another 30 min.

Test Method

The test pattern consists of a 10 × 10 matrix of squares each 25 μm on a side (see Fig. 1) and separated from other squares by 50 μm. The dosage received by each square is varied systematically by increasing the dwell time linearly along one axis of the matrix and increasing the point spacing linearly along the other. The squares are large enough to eliminate the proximity effect as a variable if the thickness measurement is made at the center, where the losses due to electron scattering are compensated for by scattering contributions from the surrounding area. Each matrix covers a range of dosages extending over more than two orders of magnitude. By writing two, three, or four such matrices at different beam cur-

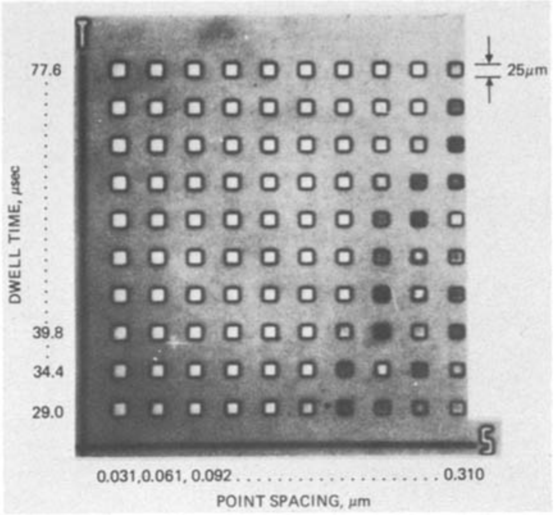

Fig. 1. Image of the test matrix in resist. At 3×10^{-11}A, the exposures range from 2.42×10^{-4} C/cm^2 at upper left to 9.05×10^{-7} C/cm^2 at lower right.

rents, an extremely wide range of exposures can be obtained with very small dose increments. When different processing procedures are to be tested, several such sets of matrices can be exposed on a single wafer with a single pump-down to achieve further time savings.

After the exposed image has been developed, the sensitivity can be estimated by examining the matrix under a microscope. With positive resists, the squares that are developed out cleanly can easily be identified, and the sensitivity is estimated as the minimum dose required to produce a cleaned-out square. In the case of negative resists, a distinct value for the sensitivity cannot be determined by simple visual examination, since the sensitivity is generally taken as the dose required to produce an image with a thickness that is some specific fraction of the thickness of the undeveloped resist.

A plot of the normalized thickness (t_N) *vs.* the log of the exposure (log E) is a more convenient and accurate method for determining both sensitivity and contrast of both positive and negative resists. This plot requires knowing the thickness of the residual resist in underexposed squares. But since the squares are too small to allow the thickness to be measured easily by a mechanical stylus technique, we investigated using a Nanospec AFT microarea film thickness gauge for this purpose.[1] This instrument measures thickness by recording the spectrum of visible light reflected from the coated silicon wafer and comparing it with standard data previously recorded for similar films and stored in memory. Its unique advantage is that it can measure the thickness of extremely small areas, the minimum spot size being 3.5 μm in diameter. For our purposes, a spot diameter of 9 μm was most suitable.

Among the programs currently available with the Nanospec are some for measuring the thickness of resist on both oxidized and unoxidized silicon surfaces. Since these programs had been prepared for positive photoresists, the validity of applying them to the measurement of other polymeric coatings was open to question. Therefore, 17 silicon wafers coated with poly(methyl methacrylate) (PMMA) in thicknesses ranging from 150 to 19,500Å were prepared and measured using the mechanical stylus technique with a Sloan Dektak surface profile measuring system as well as with the Nanospec photoresist-on-silicon program. As shown in Fig. 2, the Nanospec values are linear with the Dektak thicknesses. The linear-regression plot has

[1] Available from Nanometrics, Incorporated, Sunnyvale, California.

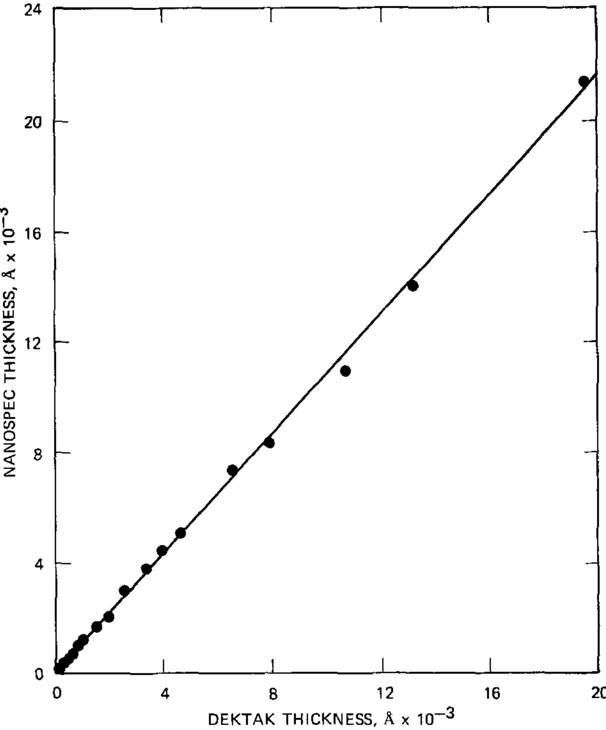

Fig. 2. Correlation of PMMA thickness measurements using the Sloan Dektak and the Nanospec AFT with the program for photoresist on silicon. The anticipated error in Dektak measurements is about ±2.5%.

a slope of 1.078 and a y intercept of 83.4Å. We are interested primarily in the normalized thickness t_N, which can be determined accurately from the formula $t_N = (t - b)/(t_o - b)$, where t and t_o are the thicknesses obtained with the Nanospec program for the exposed and unexposed resist, respectively, and b is the reading obtained in an area of the same wafer with no resist.

To obtain the data reported in this paper for positive resists, we routinely determined t_o as the average value for the unexposed areas at the four corners of the developed image of the matrix. Consequently, whenever there was any thinning of the unexposed resist during development, t_N was based on the thinned resist. Values for b were the averages of about four individual measurements on squares that received substantially different, but obviously excessive, doses and that clearly were developed completely and cleanly. For negative resists, we used a t_o value obtained before the image was developed, and the values for b were the average of several readings on cleaned areas of the developed wafer.

The surface of underexposed and partially developed resist coatings is often quite nonuniform, being uneven in thickness or having a bubbly appearance. In spite of this, the Nanospec generally yields internally consistent data that can be plotted to form smooth curves. Occasionally there are some exceptions, however, where the Nanospec measurement is obviously faulty. The overall quality is illustrated by the plot of t_N as a function of log E for poly(*tert*-butyl methacrylate) (PtBMA) shown in Fig. 3. In most cases, it is a simple matter to ignore the results that are clearly erroneous. Frequently, other areas that received approximately the same exposure to radiation are satisfactory for Nanospec measurements.

Screening Results

These methods were used to determine the electron beam sensitivity and contrast for 10 polymethacrylate positive resists and 14 negative resists, half of which were polystyrene derivatives. Many of the development conditions used in this study were previously re-

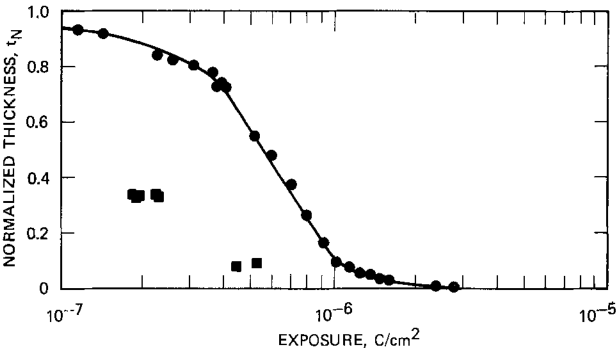

Fig. 3. Typical plot of normalized thickness as a function of the log of the exposure to 20 keV electrons. Resist is poly(*tert*-butyl methacrylate), 0.5 μm thick on silicon, baked 4 hr at 147°C *in vacuo*, and developed with 33% methyl ethyl ketone: 67% acetonitrile for 30 sec.

ported in the literature. In the case of positive resists, conditions were chosen to produce a limited amount of thinning of the unexposed resist (about 5%, but up to about 20% in one case). No attempt was made to optimize the development procedure. Tables I and II provide pertinent data on the polymethacrylates, the methods of development, and the results. Usually, the sigmoidal curves that were obtained from the t_N *vs.* log E plots were similar to those of PMMA and PtBMA shown in Fig. 4. No effort was made to eliminate the "toe" at the higher doses just short of those resulting in clean development. Additional rinses with weak solvents, particularly spray rinses, are sometimes useful in minimizing the size of the toe. The sensitivity (Q) determined by simple inspection of the matrix corresponded to the end of the toe. A second value for the sensitivity (Q_{ext}) could be obtained by extrapolating the approximately linear, descending portion of the sigmoidal curve to the baseline. Q_{ext} may be assumed to be the limiting value for the sensitivity if one is completely successful in removing the toe with appropriate rinses or a light plasma etch. The size of the toe varied with the resist and the development method.

[c]SENSITIVITY Q WAS OBTAINED BY INSPECTION OF THE MATRIX WITH THE OPTICAL MICROSCOPE; Q_{EXT} WAS OBTAINED BY EXTRAPOLATION OF THE LINEAR PORTION OF THE t_N VERSUS LOG E CURVE TO THE BASELINE WHERE t_N = 0.

This is also illustrated in Fig. 4 with the curves for poly(*iso*-propyl methacrylate) and poly(*sec*-butyl methacrylate). The particularly prominent toe in the curve for the latter resist was due to a discontinuous coating of polymer droplets that remained on the incompletely developed surface. The tendency to leave this type of residue was responsible for the large but poorly defined value for the contrast γ.

Values for γ were generally obtained as the absolute value of the slope of a least squares plot of "acceptable" data points. The subjective selection of the points that were acceptable was made from an examination of the graph, and it excluded the obviously erroneous readings previously discussed as well as those points clearly belonging to the regions in which the plot curves away from the straight-line, descending portion of the plot. Usually, the acceptable points were for t_N values ranging from 0.1 at the lower end to 0.4-0.8 at the upper end, depending on how quickly the curve deviated from a straight line at decreasing exposures.

Data for four of the resists included in Table II were derived from coatings on oxidized silicon wafers. The Nanospec measurements on these wafers were made using a program designed for photoresist on SiO_2-coated silicon, where the thickness of the SiO_2 was determined separately on a clean wafer and entered as a constant into the memory. The procedure used and

the results obtained were otherwise normal in all respects.

One resist, poly(n-butyl methacrylate), was so uneven after development that we could not obtain enough acceptable points to prepare a plot of t_N *vs.* log E. This was true for tests on both oxidized and unoxidized silicon wafers.

The results from screening a series of negative resists are presented in Tables III and IV. Some of the data in these tables were previously reported for comparative purposes (2). In the case of negative resists, we report Q_{50}, the dose required to give a film thickness of 50% of t_o, as the sensitivity. Although other values have also been used to represent sensitivity, this value seems reasonable to us for comparing experimental resists since the contrast curve of some resists starts to turn over soon after that value. The contrast is the maximum slope of the ascending portion of the curve and is usually the same as the tangent to the curve at $t_{0.5}$. It is sometimes impossible to obtain as many closely spaced points at the low dose end of negative resist plots as one would desire, because these squares do not adhere and frequently are removed during development.

The test method described is a quick and convenient method for screening polymers as resist materials. It can also be used in the preliminary stages of process development to help establish reproducible conditions for such processing variables as baking time and temperature, developer composition, and development time. We have found that the reproducibility in measuring the thicknesses of individual squares with the Nanospec AFT is about 5-20Å. The measurements of four different matrix sets of PMMA made over a period of a week gave sensitivity measurements that range from 1.84 to 1.91 $\times$ 10^{-4} C/cm², and γ values from 7.01 to 7.59.

Acknowledgments

We thank Mr. Vincent Coates and Mr. Russell Lewis of Nanometrics, Incorporated for their assistance and hospitality in permitting us to use the Nanospec AFT microarea film thickness gauge in their facility. We also wish to acknowledge the help of Mr. Philip Coane and Ms. Judi Thompson for making the electron beam exposures, the consultation of Dr. Edward Wolf and Dr. Faik Ozdemir, and the technical assistance of Mrs. Camille Van Ast and Mr. Willis Smith.

Anodic Dissolution Technique for Preparing Large Area GaAs Samples for Transmission Electron Microscopy

Jack P. Salerno,* John C. C. Fan, and Ronald P. Gale****

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173

This paper describes a novel technique that uses anodic dissolution for thinning relatively large, selected areas of single crystal or polycrystalline GaAs to prepare self-supporting, uniformly thin foils for transmission electron microscopy (TEM). Samples containing low-angle grain boundaries have been prepared by this technique from poly-GaAs grown by the horizontal Bridgman method. By TEM examination of these samples we have obtained the first electron micrographs showing the structure of grain boundaries in bulk GaAs.

Development of the new technique was motivated by our investigation of GaAs photovoltaic solar cells. Although we have achieved conversion efficiencies exceeding 20% (AM1) for single crystal GaAs cells (1), these devices will be too costly for large-scale applications unless much less expensive fabrication techniques are developed. Lower fabrication costs should be possible for cells utilizing polycrystalline GaAs thin films deposited on low cost substrates, but the efficiencies so far obtained for such cells are too low to permit their practical use. Consequently, there is considerable interest in achieving a detailed understanding of the role played by grain boundaries in reducing photovoltaic efficiency, with the objective of developing passivation techniques for minimizing their adverse effects on cell performance. While the electronic properties of grain boundaries in GaAs have been investigated in some detail (2), there has been little study of grain boundary microstructure, although this structure should have an important influence on the electronic properties (3). Furthermore, our investigations of electroluminescence and cathodoluminescence in poly-GaAs have shown variations in radiative recombination emission from different grain boundaries and, in some cases, along a particular boundary. Similar effects have been reported for polycrystalline Ge (4) and Si (5).

For these reasons it is desirable to study the structure of selected grain boundaries in conjunction with an analysis of their electronic properties. The new preparation technique was developed to facilitate this type of investigation by permitting TEM observation of preselected areas containing the boundary regions of interest. Since foils produced by this technique appear to be of uniform thickness over areas significantly greater than the boundary regions, they should also be suitable for direct analysis of compositional variations among grain boundaries by high spatial resolution (~50Å) x-ray and electron-energy-loss spectroscopy (6).

Before giving a detailed description of the foil preparation procedure, we will review the more conventional thinning techniques, chemical etching and ion-beam milling. Chemical (or electrochemical) etching, which is usually preformed by a jet process (7-9), is very rapid, generally taking only a few minutes. However, this technique yields a perforated foil with a tapered thickness profile. Usually only the region very close to the perforation is transparent to the electron beam, and control of the lateral position of this region is very difficult. This combination of small sample area and poor lateral positioning makes chemical etching unsatisfactory for the types of grain boundary studies described above. Chemical etching in conjunction with mechanical processing has produced small area foils at preselected locations in single crystal Si (10) but has not been applied to polycrystalline samples of brittle compound semiconductors.

Ion milling (11) is generally performed at very slow rates to avoid sample heating and thermal dissociation. The systems generally available produce a small foil area in an uncontrolled location. These problems were encountered in preparing TEM samples of GaAsP (12). It might be possible to produce large area foils by ion milling, but this would require elaborate equipment.

In contrast to chemical etching and ion milling, the anodic dissolution technique is moderately fast, readily controlled, and capable of producing uniformly thin foils over large preselected areas. The method is simple to use with both single crystal and polycrystalline samples.

To use the anodic dissolution technique, a GaAs wafer is first lapped with 2 μm grit, mechanochemically polished in Clorox to a thickness of 80-100 μm, and diamond sawed into square samples 2.5 mm on a side. The wafers used in this investigation were doped with Zn at concentrations of $\sim 10^{18}$ cm^{-3}. A sample selected for thinning is electroplated on one face (except for the region to be examined) with a layer of Au about 5 μm thick, then heated to 300°C for 1 sec to form an ohmic contact (1). A Pt wire is attached to the Au contact with conductive adhesive, and the sample is mounted contact-side-down on a glass slide with transparent wax. The area to be thinned is defined by covering the exposed surface with wax except for a circle, typically about 0.5 mm in diameter, opposite the region not plated with Au. The sample configuration is shown schematically in Fig. 1. Dissolution proceeds from the exposed surface toward the contact surface.

Key words: anodic dissolution, grain boundaries, photovoltaics.

The sample forms the anode of an electrochemical cell with a large area Pt-mesh cathode. The electrolyte is the disodium salt of 0.1M 4-5-dihydroxy-m-benzene-disulfonic acid, which is very similar in composition to the Tiron solution used by Faktor and Stevenson (13) for characterization of GaAs by anodic dissolution but is preferred because of its lower cost and better availability. Measured polarization curves for the two solutions are virtually identical. Dissolution is performed at a constant current density of 15 mA/cm^2 with an etch rate of approximately 0.3 $\mu m/min$, so that 4-5 hr is usually required to achieve the desired sample thickness. It was observed that lower currents delineate crystal defects while higher currents tend to result in nonuniform etching unrelated to such defects.

The transmission of a low power (2 mW) He-Ne (6328Å) laser through the foil is monitored to determine when the dissolution process should be terminated. To reduce background noise the laser beam is chopped mechanically at 400 Hz, and the transmitted radiation is detected by using a lock-in amplifier to measure the output of an Si photodiode across a 1Ω load resistor. The circuit of the electrochemical cell is interrupted as soon as transmission is detected, which occurs when the foil is about 2000Å thick. The measurements are made intermittently, and the laser is shuttered between measurements, since the dissolution rate is increased by light so that continuous laser exposure would therefore result in nonuniform thinning.

During the dissolution process the GaAs surface becomes coated with a brown-black film, which has been shown by Auger analysis to be composed of As and O without detectable Ga. Unlike films formed by anodic oxidation of GaAs, this coating is not soluble in HCl. To remove the coating, after dissolution is complete the GaAs surface is anodically oxidized in a tartaric acid/propylene glycol solution (1, 14) and the oxide formed is dissolved in dilute HCl. The sample is then removed from the glass slide by dissolving the wax and cleaned in successive acetone and methanol baths.

Self-supporting thin foils of both single crystal and polycrystalline GaAs have been prepared by the procedure described. The single crystal samples usually can be thinned uniformly without perforation. Figure 2 is an optical transmission micrograph of such an unperforated sample with a thin region approximately 0.2 mm^2 in area and 2000Å thick. Although the transmitted intensity varies strongly within this region, TEM examination shows that the foil is essentially uniform in thickness, and Nomarski contrast microscopy of the etched surface reveals the same features as the optical transmission micrograph. Therefore, we attribute the observed variation in transmitted light intensity to scattering resulting from the roughness of the foil surface. Samples given a better polish before anodic dissolution do not exhibit such scattering.

While foils prepared by anodic dissolution of polycrystalline GaAs are frequently perforated, they contain relatively large, uniformly thin areas. Micrographs of two grain boundaries in GaAs foils examined by TEM are shown in Fig. 3 and 4. The micrographs were taken using a two-beam condition and an accelerating potential of 125 kV. The structure of the grain boundary shown in Fig. 3, with dislocations separated by approximately 325Å, is indicative of a low-angle boundary with a misorientation angle of 0.7° for a Burgers vector of **a**/2 <110>. This structure is similar to that of grain boundaries observed in cast Si (15). A grain boundary with a smaller misorientation angle (<0.2°) is shown in Fig. 4. In this case the individual dislocations are separated by approximately 1470Å in a continuous matrix. This type of defect structure has been observed in heteroepitaxial GaAs/ GaAlAs films where there is a lattice mismatch between substrate and epilayer (16). While grain boundaries observed in the present study were formed during melt growth of bulk GaAs, they should be similar in structure to grain boundaries in GaAs epitaxial layers grown on polycrystalline GaAs substrates, a class of materials with potential application in high efficiency/low cost photovoltaics. Polycrystalline GaAs solar cells fabricated from such layers have achieved efficiencies of 13% (AM1) (17).

In summary, an anodic dissolution technique has been developed for the preparation of relatively large area, uniformly thin foils of single crystal or polycrystalline bulk GaAs. Use of this technique has made

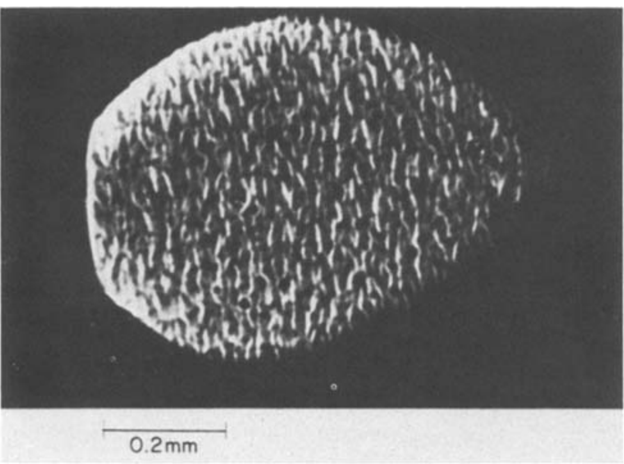

Fig. 2. Transmission optical micrograph of single crystal GaAs foil.

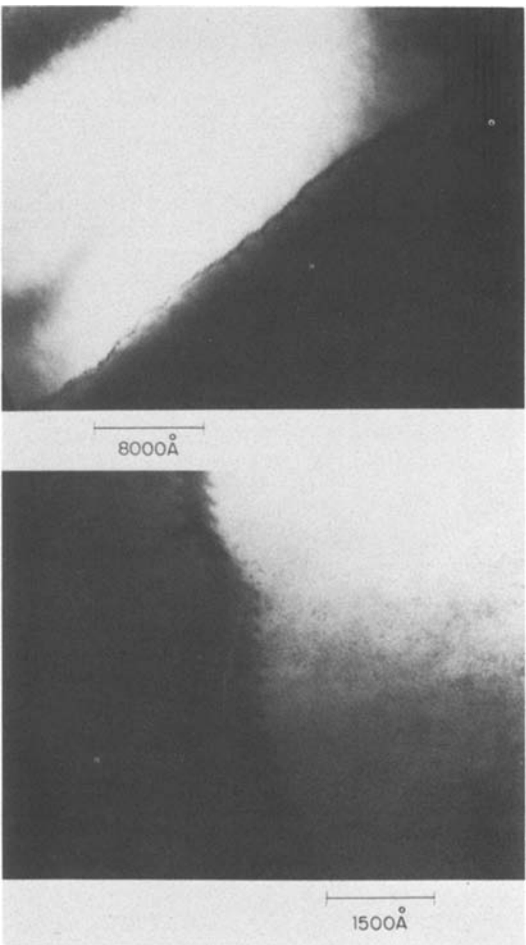

Fig. 3. TEM micrographs (two beam condition) of GaAs grain boundary with misorientation angle of 0.7°. Discrete dislocations composing the boundary are evident in the lower micrograph, which was taken at higher magnification.

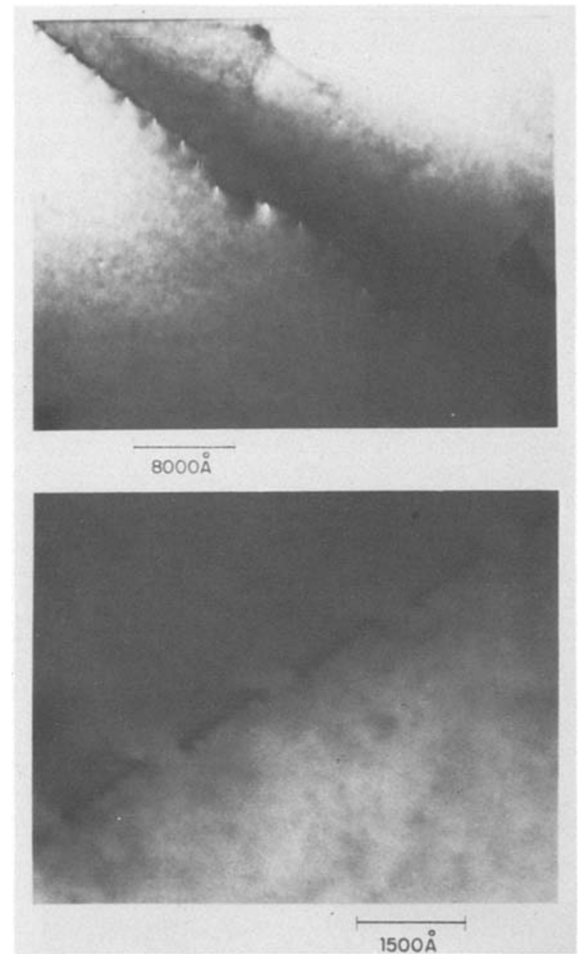

Fig. 4. TEM micrographs (two beam condition) of GaAs grain boundary with misorientation angle of $<0.2°$.

it possible to carry out the first TEM observations of grain boundaries in GaAs. With appropriate modifications, the technique should be applicable to other semiconductors. Development of this technique is significant in that it permits TEM examination of selected grain boundaries, facilitating the investigation of relationships between the structural, compositional, and electronic properties of grain boundaries in photovoltaic materials.

Anodization and Sulfation of Tetrabasicleadsulfate in Sulfuric Acid: *In Situ* Monitoring of Electrode Surface Phases by Laser Raman Scattering

R. Varma,* G. Cook,* and N. P. Yao*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

The morphology of lead-dioxide prismatic crystallites in freshly "formed" positive plates of lead-acid batteries has been reported[1] to evolve to a coralloid state and subsequently degrade during continued charge-discharge cycling. Since tetrabasicleadsulfate, $4PbO \cdot PbSO_4$, (TBLS) had been observed[2] to crystallize as large elongated prisms and undergo anodic conversion to a mechanically strong PbO_2 microstructure, which maintains a crystallite form similar to the original, the suggestion was made[3] that the use of TBLS as the active material on positive plates may help increase the cycle life of lead-acid batteries.

During electrolytic formation of TBLS-pasted lead plates in H_2SO_4, concomitant chemical sulfation reactions are anticipated, since TBLS has been shown[4] to react readily with sulfuric acid. Therefore, the morphology of "formed" active material in such electrodes will depend directly on the continuously changing phase compositions of the sulfate active material as well as the kinetics of anodization reactions of the various single phase components If rapid chemical sulfation reactions result in the formation of leadsulfate, $PbSO_4$, as a major component when the TBLS-pasted electrode is put in the electrolyte, the advantage of TBLS as a precursor of mechanically strong PbO_2 microstructure might be lost. A few experimental results identifying intermediates and products of the sulfation as well as anodic oxidation reaction are described in this communication.

The surface-layer composition was monitored continuously in-situ[5] by laser Raman scattering during anodization and open circuit stand of tetrabasicleadsulfate electrodes in 0.1N H_2SO_4 in a 3-compartment spectroelectrochemical cell, shown in Figure 1. In order to suppress the interfering spectra due to H_2SO_4 and HSO_4^- specie 0.1N sulfuric acid was used as the electrolyte Raman spectral transitions were observed ex-situ for $4PbO \cdot PbSO_4$ and a 1:1 mixture of $3PbO \cdot PbSO_4 \cdot H_2O$ and $PbO \cdot PbSO_4$. These results and the published[5] data for $PbSO_4$ are given in Table 1 for use as references in the interpretation of the experimental in-situ spectral data. The spectra in all cases were reproduced in duplicate runs. Analysis of electrode surface layers by ex-situ techniques, such as scanning electron microscopy and X-ray diffraction, provided additional supporting evidence for characterizing the phase compositions.

*The freqency recorded is average of observed frequencies extending over a range of ± 2 cm^{-1}

The spectrometer parameters such as the intensity of exciting laser light, scattering angle, scan rate, slit width, etc., were maintained at approximately the same level during each experimental run. In spite of these efforts the relative intensity of the Raman bands could not be used to estimate quantitatively the relative abundance of various phases in the surface layers. More sophisticated equipment would be required to obtain these estimates.

In-situ Raman spectra recorded at different time intervals during the anodization of TBLS-pasted lead electrode in 0.1N H_2SO_4 at 1.5 V vs. a Hg/Hg_2SO_4 reference are shown in Figure 2. Tetrabasicleadsulfate, characterized by Raman bands at 132, 142, 435, 444, 461, and 969 cms^{-1} (see Table 1), was observed to be converted partially, through the sulfation reaction into $PbSO_4$, as shown by the appearance of a shoulder at 977 cm^{-1} on the 969 cm^{-1} band in the spectra obtained at 18 and 130 minutes (see Figure 2).

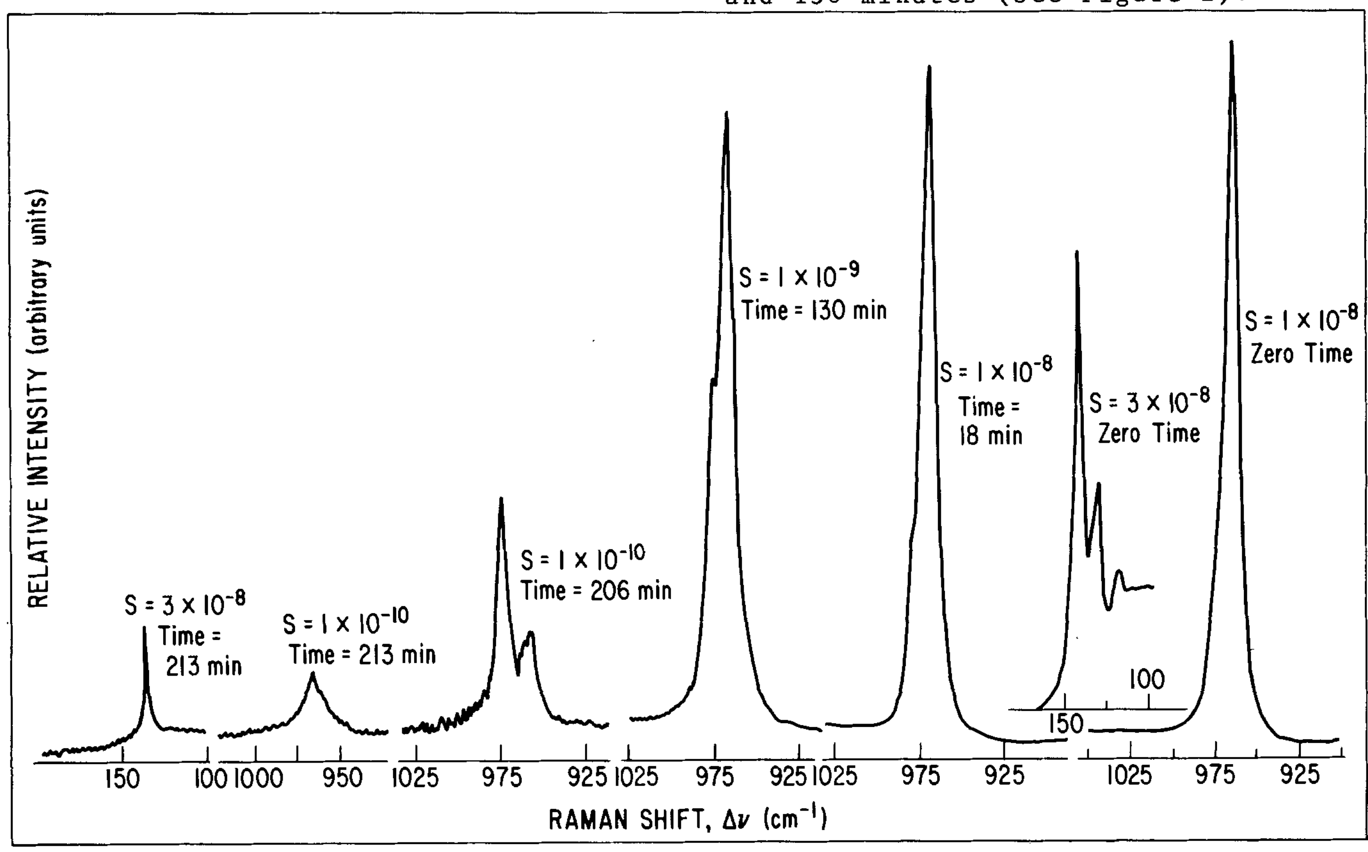

Figure 2. Laser Raman Scattering; In-Situ Spectra Observed on Tetrabasicleadsulfate Electrode During Anodization in 0.1N H_2SO_4 at 1.5 V vs. Hg/Hg_2SO_4

When compared with assigned spectra for $PbO \cdot PbSO_4$ and $3PbO \cdot PbSO_4 \cdot H_2O$ (see Table 1), the Raman Bands observed at 142, 960, and 973 cm^{-1} at end of 206 minutes strongly suggest the presence of these compounds in the surface layers of the PbO_2 which was formed as a blackened mass. The entire electrode active material was observed to turn black by the end of 213 minutes. In-situ Raman spectra recorded at this time showed very weak bands at 142 cm^{-1} and 958 cm^{-1} suggesting the presence of $PbO \cdot PbSO_4$ No $PbSO_4$ band was observed. The black mass was found to be primarily β-PbO_2 by ex-situ X-ray analysis In addition to providing an unambiguous identification of sulfate phases in the presence of β-PbO_2, these investigations also provided an indication of changes in composition of surface layers during anodization The observed production of β-PbO_2 during "formation" in 0.1N H_2SO_4 (specific gravity = 1.002) contrasts with the previous observation that[6] α-PbO_2, was the major product from formation in 0.2N H_2SO_4.

Tribasicleadsulfate, $3PbO \cdot PbSO_4 \cdot H_2O$, monobasicleadsulfate, $PbO \cdot PbSO_4$ and leadsulfate, $PbSO_4$, were observed in electrode surface layers during anodizations. Leadsulfate was observed to be the major product while $3PbO \cdot PbSO_4 \cdot H_2O$ and $PbO \cdot PbSO_4$ were minor constituents Close examination of the spectral data also suggests that the various leadsulfates are oxidized at different rates, at least for the particular experimental conditions a tentative ranking being TBLS>$PbO \cdot PbSO_4$>$PbSO_4$.

Any pre-soak proceeding the "formation" process must invariably involve the chemical sulfation process. Therefore, Raman bands were continuously observed for 20 hours, during the open circuit acid-soaking of a tetrabasicleadsulfate electrode. The continous generation of $PbSO_4$ in the electrode surface layers, was observed as shown (see Figure 3) by the growth of Raman bands in the region of 975-977 cm^{-1} as well as at 436 and 444 cm^{-1} Since the height of the TBLS band at the end of 20 hours is still ~50% of the original height a significant proportion of tetrabasicleadsulfate apparently remains unreacted Spectral representation of the dynamic sulfation process showing changes in composition over a period of time is shown in Figure 3. The spectrum recorded after 2 hours and 20 hours, showed definite shoulders, at ~960 cm^{-1} on the 975-977 cm^{-1} band and at ~420 cm^{-1} on the unresolved band in the region of 430-460 cm^{-1}. It is likely that $PbO \cdot PbSO_4$ phase is present along with TBLS. The presence of this compound was confirmed by ex-situ X-ray diffraction analysis. It is possible that tribasicleadsulfate, $3PbO \cdot PbSO_4 \cdot H_2O$, may be generated in the surface layers during the sulfation process. However, the spectral evidence for this intermediate is merely suggestive.

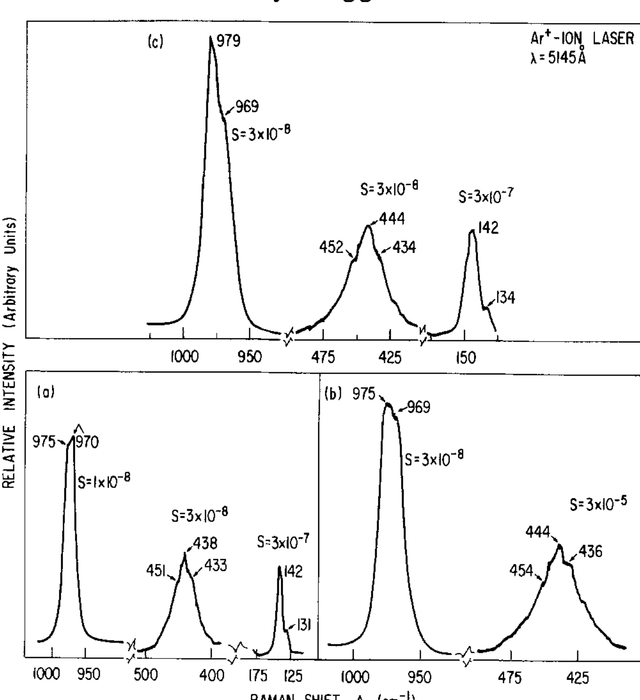

Figure 3. Laser Raman Scattering; In-Situ Spectra, Observed on Tetrabasicleadsulfate Electrode Immersed in 0.1N H_2SO_4; After (a) 1 hour, (b) 2 hours, and (c) 20 hours

We have shown that tetrabasicleadsulfate is partially transformed

through chemical sulfation reactions in 0.1N H_2SO_4 into a mixture of $PbSO_4$ and $PbO \cdot PbSO_4$, in the surface layers. This sulfation process seems to stop within 2-3 hours. The generation of $PbO \cdot PbSO_4$ as a reaction intermediate during electrolytic "formation", at 1.5 V vs. Hg/Hg_2SO_4, of tetrabasicleadsulfate in 0.1N H_2SO_4 (specific gravity 1.002) is clearly established. The essential features of the spectra were found to be reproducible in replicate experiments.

The observance of $PbO \cdot PbSO_4$ and $3PbO \cdot PbSO_4 \cdot H_2O$ reaction intermediates in the surface layers during chemical sulfation and potentiostatic anodization is consistent with the Pourbaix diagram[7] reported in literature only for conditions of high PH (PH > 8.0). Therefore, these conditions must prevail in the underlayers at the electrode and are due to electrolyte starvation. These results also show the multiphasic structure of the surface layer. This structure must be considered when studying the kinetics of "formation" and the microstructure of PbO_2 active materials. The mechanisms of the conversion of the several sulfates into a PbO_2 matrix during plate "formation" should be understood to achieve durability for the positive plate active material during cycling, since it is likely that the PbO_2 microstructure depends upon the starting material. Further studies required to accomplish this work, are in progress.

ACKNOWLEDGEMENT

Financial support by the Division of Electrochemical Systems, Department of Energy, is hereby acknowledged. The authors extend their thanks and appreciation to the Chemistry Division at Argonne for allowing the use of their Raman spectrometer. Donation of samples of tetrabasicleadsulfate by C&D Battery Company is gratefully acknowledged. We acknowledge contributions made to this work by John Englert of Northwestern University as an undergraduate research participant.

Initiation of Single Corrosion Pits by Focused Laser Illumination

Richard K. Ulrich* and Richard C. Alkire**

Materials Research Laboratory and Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

An experimental method has been developed for selective depassivation of small regions on an otherwise passive metal surface with use of focused laser radiation. Techniques for generating bare metal surfaces on passive metals have, to date, included scraping, straining, abrading, shearing, and fracturing (1). Each of these involves uncertainties in the initial active condition of the surface and/or gross mechanical disturbances. With the laser method, these uncertainities still exist but are confined to regions of time and/or distance which are orders of magnitude smaller than other methods.

Because the laser depassivation method allows generation of fresh metal surfaces under controlled and reproducible conditions, it should prove useful in fundamental studies on metal repassivation and localized corrosion. Preliminary results on pitting for example, are presented below.

While the corrosion behavior of laser modified surfaces has received some attention (2), no reports are known which use focused lasers for localized depassivation, although similar applications have been made previously to promote rates of maskless pattern electroplating (3).

APPARATUS

A tunable dye laser (Molectron DL-II, Exiton dye type BBQ, 390nm) was pumped by a pulsed nitrogen laser (Molectron UV-24) and provided a beam which was focused with an ordinary compound microscope lens (Bausch & Lomb) fitted with a 32 mm objective lens. The working distance between lens and (immersed) specimen was about 4 cm.

The metal specimen was held under conditions of controlled potential vs. SCE (Princeton Applied Research, 173-175-176 system). Flow of current after laser illumination was recorded either on a storage oscilloscope (Tektronix, 5103) or an X-Y recorder (Houston, 2000), depending upon the speed of the transient behavior under study.

*Electrochemical Society Student Member.
**Electrochemical Society Active Member.

The electrolytic cell was fabricated from Plexiglas in a manner which avoided crevice corrosion at the edges (4). The only materials in contact with the electrolyte were the specimen and the Plexiglas cell.

Post-electrolysis examinations were made with a scanning electron microscope (JEOL JSM-35C).

PROCEDURE

Iron specimens were cut from 2.54 cm stock (99.99%, Leico), polished with alumina down to 0.3 μm powder, and rinsed with acetone. Electrodes were passivated in 0.1 M $Na_2B_4O_7$ at 500 mV vs. SCE for one hour, whereupon the potential was changed to a value in the passive region (-300 to +860 mV vs. SCE) and sodium chloride solution was added to make $[Cl^-] = 0.01$ M. Under these conditions of potential and chloride concentration, the surface would remain passive for long periods (hours) unless otherwise disturbed.

Pulsed laser radiation (15 ns duration, 30 μJ energy, 20 hz repetition rate) was focused to about 5 μm diameter. Usually, a single pulse was sufficient to initiate a single pit.

Pit growth could be arrested by interrupting the power supply. After a short time, the surface would repassivate, and a fresh pit could be initiated at a new site on the specimen.

Post-electrolysis examination of pits with an SEM included measurement of pit shape and volume. Pit depth was determined as a function of radial position by measurement of parallax movement of features inside the pit based on photomicrographs taken at 0° and 30° tilt.

RESULTS AND DISCUSSION

The diameter ascribed to a focused laser beam cannot be precisely defined, and depends on the gaussian energy profile across the beam (5). Also some pulse energy may be lost in focusing optics, by reflection from the metal surface, and from the plasma cloud which

develops. Based on a 5 μm beam diameter, this system produced 10^{10} W/cm^2 for 15 ns, or 150 J/cm^2.

Preliminary laser-pulse experiments were carried out with a specimen immersed in chloride-free borate solution, and held at potentials where corrosion did not occur. SEM photomicrographs indicated that the damaged area was a smooth crater of 5 to 10 μm diameter, and 1 to 2 μm depth. These observations are in reasonable agreement with others (6) who studied laser damage of iron in air.

Focused laser illumination causes locally chaotic events which include heating, melting, evaporation, and cavitation; these events may interfere with corrosion processes within microenvirons of time and space during repassivation. Also, the microscope lens eventually requires replacement owing to damage to the coating.

In the pitting results reported below, the pit volumes were appreciably larger than the original cavity created by the laser pulse. For example, within two seconds after pulsing, the pit volume had increased by more than 100 times the original laser cavity volume.

By comparing measurements of pit volume with the coulombs which passed during pit growth, it was found that the current efficiency during the pitting was 130±10% based on n=2.

Figure 1 illustrates typical results for a series of six experiments repeated under identical conditions. The results indicate that data were reproducible to within a bandwidth of 5% of the average value. By using the least-squares method, these data were found to obey the empirical equation

$$I = 18\ t^{0.53}$$

with an r^2=0.998, where I is the measured current (μA) and t is the time since initiation (s). As seen in Fig. 1, the above relation was obtained over the range of 20 to 400 seconds after pit initiation.

CONCLUSIONS

Focused laser illumination can trigger localized depassivation and subsequent pitting at pre-selected sites on an otherwise passive surface. The method creates damage in the vicinity of the beam impaction region, and creates chaotic events which briefly influence local events on a micro-scale. For corrosion processes which occur over large scales of time and distance in comparison with these initial events, the method gives highly reproducible results.

The depassivated region has a well defined area which is orders of magnitude smaller than that produced by other depassivating techniques (1). The ohmic resistance associated with flow of current to the damaged region can be calculated accurately based on knowledge of the radius of the damaged region. The specimen remains immersed throughout an experiment, and there is ample working room in the vicinity of the specimen to place additional hardware nearby.

Investigations based on this method are in progress on metal repassivation and localized corrosion, and will be reported in future publications.

A Modified Approach to Isothermal Growth of Ultrahigh Quality HgCdTe for Infrared Applications

P. Becla,* J. Lagowski,* H. C. Gatos,* and H. Ruda*

Department of Materials Science and Engineering,
Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Epitaxial layers of $Hg_{1-x}Cd_xTe$ on CdTe substrate were isothermally obtained with mirror-like surface morphology, high radial compositional uniformity, and outstanding electronic characteristics (e.g., electron mobility of the value of 500,000 cm^2/V-sec for x in the vicinity of 0.15). The novel feature of the growth process was the utilization of Te-rich HgCdTe as a source material rather than HgTe (or stoichiometric $Hg_{1-x}Cd_xTe$) previously employed. Desired values of x were obtained by varying the composition of the source material and the growth temperature. Temperature high precision control and minimization of convection in the liquid (source) and vapor phases were achieved by employing a heat pipe.

. . . . .

HgCdTe is ideally suited for infrared detection and imaging, particularly in monolithic systems, such as charge coupled devices. Because of its broad phase diagram this material cannot be obtained by the standard growth techniques with a compositional uniformity and electronic properties required for high performance devices. This problem has to a great extent been resolved by the isothermal crystal growth method (1) also referred to as the "isothermal evaporation-condensation-diffusion" method. In this method CdTe is used as substrate and HgTe (or $Hg_{1-x}Cd_xTe$) as the source. Both substrate and source, in a closed ampul, are brought to an elevated temperature (but below the melting point of the source). Isothermal growth occurs because the equilibrium vapor pressure of Hg and Te over the source is higher than over the substrate (1-8).

As discussed in a recent publication (9), upon stringent control of temperature and Hg pressure in the processing ampul, HgCdTe of a very good quality suitable for IR applications has been obtained by the standard isothermal growth method. In this communication a modified approach to isothermal growth is reported in which (through the utilization of tellurium-rich solution as a source material) the control of the growth process and thus that of the composition, the morphology and electronic properties of the grown layers is enhanced.

Single crystal CdTe substrates of (111) orientation were polished and etched using standard procedures (5,6). Growth was carried out utilizing a spectral purity graphite boat with a rectangular well; the source material was placed at the bottom of the well on a sapphire plate, and the CdTe substrate on the top, closing the well. In this way, a confined space with the desired volume (typically a few cm^3) is defined for the growth system and free volume is minimized. The assembled graphite boat was placed in a quartz ampul which was then evacuated (below 10^{-5} torr) and sealed off. The ampul was positioned inside a heat pipe, which was placed in the constant temperature zone of a gold reflection-coated, resistance-heated furnace. The heat pipe maintained the temperature constant to within 0.02°C and the temperature gradients to within 10^{-2}°C/cm in the growth system.

The source material utilized in the present study contained excess tellurium and varying amounts of Hg and Cd; thus, its composition can be expressed by $(Hg_{1-z}Cd_z)_{1-y}Te_y$ where z and y vary between 0 and 1. It should be noted that the source material utilized in previous studies (1-8) was characterized by y = 0.5.

The source material of the desired composition was prepared by carefully weighing the components and placing in a quartz ampul, which was evacuated to 10^{-5} torr, sealed, and heated to a temperature 20°C above the melting point of the selected composition; after homogenization at this temperature the solution was quenched rapidly to room temperature. The compositions employed were $0<z<0.2$ and $0.5<y<0.6$, which correspond to an energy gap of the grown layer in the vicinity of 0.1 eV, most desirable for IR applications (~10 μm).

*Electrochemical Society Active Member.

Isothermal growth on CdTe substrates was carried out at two temperatures, 530°C and 575°C, for a period ranging between 20 and 48 hours. Typically the thickness of the grown layers ranged from 50 to 250 μm (the highest value corresponding to 48 hours' growth at 575°C). The layers were characterized with respect to crystallographic orientation, composition, compositional homogeneity, surface morphology, free carrier concentration, and mobility.

It was found that the surface composition of the layers grown at a given temperature was determined by the composition of the source material. However, in contrast to earlier findings (1-4), the surface composition of the grown layer was not identical to that of the source. The surface composition of the $Hg_{1-x}Cd_x$ Te layers grown with $(Hg_{1-z}Cd_z)_{1-y}Te_y$ sources is shown in Fig. 1a. Growth was performed at 575°C for 48 hours. The composition of the layers was determined with an Electron Microprobe and Energy Dispersive X-ray Analyzer.

Compositional profiles were determined on cross sections of the layers employing an electron microprobe; the results are shown in Fig. 1b. Consistent with the growth mechanism involving solid state diffusion, the grown layers exhibit composition gradients in the growth direction; however, no detectable compositional variations were found parallel to the surface.

Growth from a Te-rich source resulted in monocrystalline epitaxial layers with the same orientation as the substrate. On precisely oriented (111) substrates the layers exhibited high quality surfaces with a mirror-like appearance (Fig. 2). Deviations from (111) orientation affect adversely surface quality. Some of the macro- and microscopic defects in the substrate (grain boundaries, inclusions) usually propagate into the grown layer, although the surface quality of the grown layer is invariably superior to that of the substrate. The reasons for the superior surface morphology of the layers grown with a source containing excess tellurium are not clearly understood at present. It should be noted, however, that excess tellurium leads to noticeably slower growth rates than stoichiometric sources. Apparently, this change in growth kinetics has a highly beneficial effect on surface morphology. As seen from the Hall mobility data of Fig. 3, the as-grown layers with x values between 0.15 and 0.3 were intrinsic at room temperature; however, they became p-type at lower temperatures. Their corresponding hole concentration (N_A-N_D) was between $10^{17}cm^{-3}$ and $10^{16}cm^{-3}$, and the hole mobility between 215 and 600 cm^2/V-s at 77 K.

In as-grown layers p-type conductivity is due to Hg vacancies which act as acceptor centers; their presence is unavoidable at growth temperatures exceeding 500°C. Standard annealing in an Hg atmosphere at temperatures blow 300°C reduces vacancy concentration (N_A-N_D) and leads to n-type conduction. Typical carrier concentrations (N_D-N_A) at 77 K are as low as $10^{15}cm^{-3}$ in annealed layers. The high quality of these annealed layers is manifested by their high electron mobility which was found to be routinely as high as 500,000 V/cm^2s at 77 K for x = 0.15; the temperature dependence of the Hall mobility for annealed layers of different compositions is shown in Fig. 3. It should be noted that HgCdTe layers grown by liquid phase epitaxy, now extensively employed, exhibit carrier mobilities about an order of magnitude smaller (10-12) than the isothermally grown layers with similar values of x.

Advanced IR applications (e.g., detector arrays) require HgCdTe layers of uniform surface composition and with as large surface dimensions as possible. The heat pipe employed ensures a perfectly constant temperature over a distance of about 2 inches, which in principle makes possible isothermal growth of the layers exceeding 2 square inches. A practical limitation encountered in the present study was the unavailability of large area CdTe substrates. The available melt-grown CdTe substrates contain large amounts of twins. The largest single crystal twin-free substrates available for this study were 1 inch x 0.5 inch; these dimensions defined the largest dimension of isothermally grown HgCdTe layers.

Hydrogen Generation from Glucose Depolarized Water Electrolysis

Michael R. St. John,* Alan J. Furgala, and Anthony F. Sammells*

Institute of Gas Technology, Chicago, Illinois 60616

With presently available technology, the only non-fossil fuel method of hydrogen generation is water electrolysis. Hydrogen produced by water electrolysis is restricted to specific application where variable high-quality hydrogen is required because its cost is typically several times more expensive than hydrogen obtained using fossil fuels. As is well known, the high cost of the electrolytic hydrogen is largely a consequence of the electrical power requirements which provides an obvious incentive to reduce the electrolysis cell voltage. Approaches for cell voltage reduction have been directed at either enhancing electrode kinetics resulting in reduced overpotential losses, particularly at the oxygen electrode, or by "depolarizing" the oxygen evolution reaction. The latter approach involves substitution of a reaction with a more cathodic reversible potential than that for oxygen.

Recent attempts exploring suitable depolarizing reactions have concentrated on the oxidation of fuel-like substances such as coal (1-4), SO_2 (5-7), and methanol (6). All such reactions can be represented by the general reaction -

$$F + xH_2O \rightarrow FO_x + (2x)H^+ + (2x)e^- \qquad [1]$$

where F is a fuel-like molecule which becomes oxidized to FO_x with the generation of hydrogen ions and electrons. The oxidation of a fuel-like molecule insures favorable thermodynamics in the form of a reversible potential more negative than oxygen evolution.

It is the purpose of this communication to suggest that materials derivable from biomass possess attractive properties as the depolarizer F in Equation 1 and to present cyclic voltammetric data on the biomass derivable material, glucose, which indicate its potential as a depolarizer. Possible advantages that biomass derived materials have are renewability and in many instances availability as waste products.

*Electrochemical Society Active Member

Key Words: Hydrogen, Glucose, Oxidation Depolarizer

In the course of a program to survey biomass materials for their depolarizing ability, glucose was chosen because of its abundance in the biosphere.

Cyclic voltammograms obtained in 12 w/o H_2SO_4 with and without 0.51 molal glucose are compared in Figure 1 over the potential range available to the electrolyte, at 23°C. A platinized platinum working electrode was used with a sweep rate of 5 mV/s to approximate steady-state reaction conditions. In the absence of glucose, the 12 w/o H_2SO_4 electrolyte exhibits the well-documented surface reactions occurring on a platinum electrode upon cycling between these voltage limits (8). When the 12 w/o H_2SO_4 is made 0.51 molal in glucose, new anodic peaks were observed in the cyclic voltammograms as designated by the solid line in Figure 1. At ambient temperature the principal oxidation peaks observed in the anodic sweep are a sharp peak at +50 mV and large shoulder peak at around +510 mV, all potentials being measured versus Hg/Hg_2SO_4 in 12 w/o H_2SO_4 (+670 mV versus the reversible hydrogen electrode for comparison). These features are essentially the same as those reported for the oxidation of glucose on platinum foil in 1M H_2SO_4 (9). Not observed on the platinum foil was the broad anodic peak found upon sweeping cathodically, centered at -200 mV versus the Hg/Hg_2SO_4 reference.

Substantial changes in the cyclic voltammogram occur both qualitatively and quantitatively upon increasing the electrolyte temperature. Figure 2 compares the cyclic voltammograms under the same conditions as Figure 1, but at 92°C. The most striking qualitative change observed is transformation of the relatively sharp anodic peak at +50 mV found at 22°C, into a broad band spanning the potential range -50 mV to +200 mV at the higher temperature. In addition, the oxidation observed in the cathodic sweep has effectively coalesced with this band. The shoulder at +510 mV versus Hg/Hg_2SO_4 remains much the same at the higher temperature.

The anodic peak or band near +50 mV versus Hg/Hg_2SO_4 would, of course, be the most attractive for lowering the overall cell voltage for depolarized water electrolysis. Under ambient

conditions peak current densities of 15 mA/cm^2 were found, whereas at 92°C peak current densities increased to 140 mA/cm^2. Correspondingly the shoulder at +510 mV versus Hg/Hg_2SO_4 increased from 20 mA/cm^2 to 215 mA/cm^2 over this temperature range.

Continued oxidation of glucose past the well known gluconic acid state (10-12) would be desirable for anode depolarization. To investigate this property, cyclic voltammetry on the anticipated oxidation products, gluconic and glucaric acids, was performed. Figure 3 compares the cyclic voltammograms of glucose and gluconic acid in H_2SO_4 at 60°C. The intensity of the anodic bands centered around 0 mV versus Hg/Hg_2SO_4 and are very similar, but the shoulder current +510 mV is substantially reduced suggesting that it arises from oxidation of glucose to gluconic acid.

Cyclic voltammograms of glucaric acid and the H_2SO_4 electrolyte at 56°C are compared in Figure 4. Although there still remains an oxidation centered around +50 mV versus Hg/Hg_2SO_4, it is substantially reduced in intensity from either glucose or gluconic acid. These cyclic voltammograms of gluconic and glucaric acids indicate that continued electrochemical degradation of glucose occurs at potentials negative of the oxygen potential. The actual oxidation products formed are not known, and the possibility of the formation of useful organic compounds at the anode exists. In this event, the depolarizing scheme presented would become even more attractive.

In conclusion, it has been demonstrated that glucose and some of its oxidation products are possible candidates for depolarizing the water electrolysis reaction capable of affecting a large reduction in cell voltage. Compared to coal, water soluble biomass is logistically more convenient to introduce into an electrochemical cell. Equally significant is the short term renewable nature of biomass. Successful development of this approach could provide hydrogen at costs below those available with existing electrolytic technologies.

The Physics and Chemistry of the Lithographic Process

Murrae J. Bowden

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The object of the lithographic process is to delineate a pattern in a resist by means of some form of exposing radiation and to subsequently transfer that pattern to the underlying substrate. The faithful replication of the pattern originally described by the device designer is limited by the physical and chemical processes involved in both stages of pattern transfer. In this review discussion is confined to the first stage of the lithographic process, *viz.*, pattern delineation in the resist and in particular to the fundamental physical and chemical limitations of each of the exposure technologies as they relate to sensitivity and resolution.

RN

At the heart of the ongoing revolution in the field of microelectronics is the silicon integrated circuit. This tiny modular silicon chip contains all the active elements of an electronic circuit such as transistors, capacitors etc., inseparably associated and connected to each other by metallic interconnects on the surface of the chip. The packing density and complexity of circuit components has increased enormously with the number of components per circuit approximately doubling every year since 1959. This exponential growth of complexity has been provided by increased chip size, decreased feature size, and improved device design (1).

Circuit fabrication requires the selective diffusion of tiny amounts of impurities into specific regions of the silicon to produce the desired electrical characteristics of the circuit (2). These regions are defined by lithographic processes in which the desired pattern is defined in a resist layer (usually a polymeric film which is spin-coated onto a substrate) and then transferred via processes such as etching to the underlying substrate. Currently photolithography is used to delineate patterns in the resist but future device designs will demand resolution beyond the capability of conventional photolithography.

There are a number of potentially high resolution technologies being pursued, *viz.*, deep u.v. photolithography, electron beam lithography, x-ray lithography, and ion beam lithography. Each of these technologies involves the common feature of causing chemical changes in the resist system which enable the exposed regions to be differentiated from the unexposed regions either by solubility differences or by differences in plasma etch rate. The ultimate objective of these technologies is the economic production of submicron devices. Hence it is important to understand the implication of physics and chemistry to resist sensitivity and resolution for each of these processes coupled with their engineering limitations in order to make an objective assessment of each technology.

The lithographic process falls into two distinct areas: (*i*) definition of the pattern in the resist layer and (*ii*) transfer of this pattern to the underlying substrate. In this paper we will confine our discussion of the lithographic process to the former and concern ourselves with the fundamental physical and chemical limitations on pattern definition for each of the exposure technologies. It is important to distinguish between the fundamental limit of resolution of an exposure tool and its practical or achievable limit in fabricating devices in a manufacturing environment. The latter takes into account the variations in feature size due to errors in the system. Factors such as alignment tolerances and resist characteristics usually result in practical minimum feature sizes somewhat larger than theoretically expected.

Key words: lithography, x-ray, E-beam.

Physical Limitations

Photolithography.—There are a variety of methods for producing photoresist patterns on semiconductor wafers. These include contact and proximity printing, both of which are shadow printing techniques and projection printing which can be performed on a 1:1 scale or with varying scales of reduction such as 5:1 or 10:1. With shadow printing, only 1:1 replications are possible.

Historically, shadow printing techniques have been the mainstay of device lithography. The primary factor limiting resolution is diffraction of light as it passes through the clear areas of the mask. Figure 1 shows a typical distribution of the u.v. light intensity incident on the photoresist surface for light passing through a mask consisting of a periodic grid of opaque and transparent spaces with equal linewidths b. The period of the grid is $2b$ and $\frac{1}{2}b$ is its fundamental spatial frequency ν. If a gap of width s is maintained between the mask and the photoresist surface, then from diffraction theory and experimental evaluations, the practical minimum period $2b_{min}$ of the grid which can be replicated by shadow printing using collimated light for exposure is found to be (3)

$$2b_{min} = 3\sqrt{\lambda(s + d/2)} \quad [1]$$

where λ is the wavelength and d the photoresist thickness. Conventional photoresists operate in the 0.4 μm wavelength region for which the practical minimum linewidth obtainable in the contact printing mode ($s = 0$) is around 0.7 μm for a 1 μm thick organic resist film.

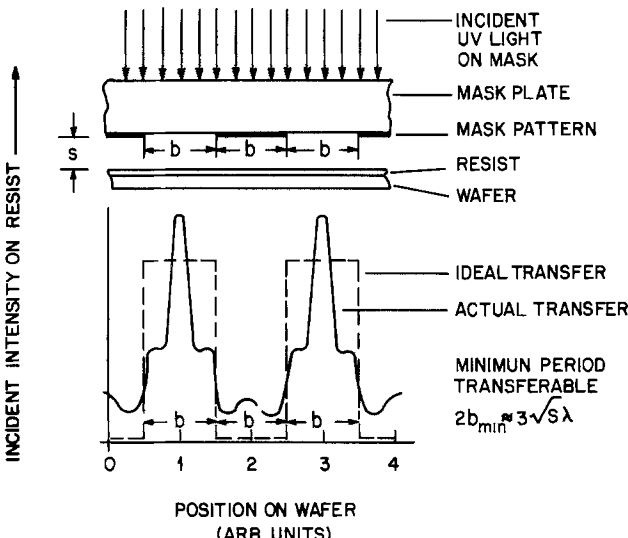

Fig. 1. Schematic representation of pattern transfer by projection printing [from D. Widmann and K. U. Stein, Solid State Circuits, Proc. 2nd Eur. Solid State Circuits Conf., 1976 pp. 29-47 (pub. 1977)].

The principal drawback to these shadow printing techniques stems from practical considerations. Contact between mask and wafer transfers debris from the wafer to the mask resulting in damage to both. A decrease in resolution in contact printing can also arise from lack of intimate contact between the mask and wafer due to such effects as process-induced wafer deformation, mask bowing, contamination, etc. These problems are reduced in the proximity printing mode but only at the expense of resolution. A small constant spacing requires flatness of both mask and wafer to a combined tolerance which is less than the gap in order to avoid contact. Proximity printers generally operate with a gap width of $\sim$ 10 μm and are most useful in the 2-4 μm resolution range. Resolution at a fixed gap width can be improved by reducing the wavelength since resolution is proportional to $\lambda^{1/2}$ (cf. Eq. [1]). Using light in the spectral range 2000-2600Å, Lin (4) has obtained 0.5 μm Y-I bars separated by 0.25 μm gaps in 1.78 μm of photoresist.

The major development thrust in exposure hardware technology has been in the area of projection printing. Modern projection printers employ optics which are essentially diffraction limited. This implies that the design and fabrication of the optical elements are perfect enough that their imaging characteristics are dominated by diffraction effects associated with fine apertures in the condenser and projection optics rather than by aberrations.

The concept of a modulation transfer function (MTF) has been applied successfully to describe and predict the resolution capability of projection aligners. Consider the same mask pattern as before consisting of a periodic grid of opaque lines and transparent spaces with equal linewidths b. Due to diffraction considerations, the light pattern projected onto the photoresist surface exhibits gradual transitions of the light intensity (illustrated schematically in Fig. 2) instead of abrupt transitions from bright to dark regions. Even in the center of the dark lines there is a considerable amount of light when the width of b approaches 1 μm. If we denote the light intensity in the center of the dark line as I_{min} and in the center of the bright line as I_{max}, then we define modulation M of the image as

$$M = \frac{I_{max} - I_{min}}{I_{max} + I_{min}} \quad [2]$$

The MTF is the ratio of the modulation in the image plane to that in the object plane of an exposure sys-

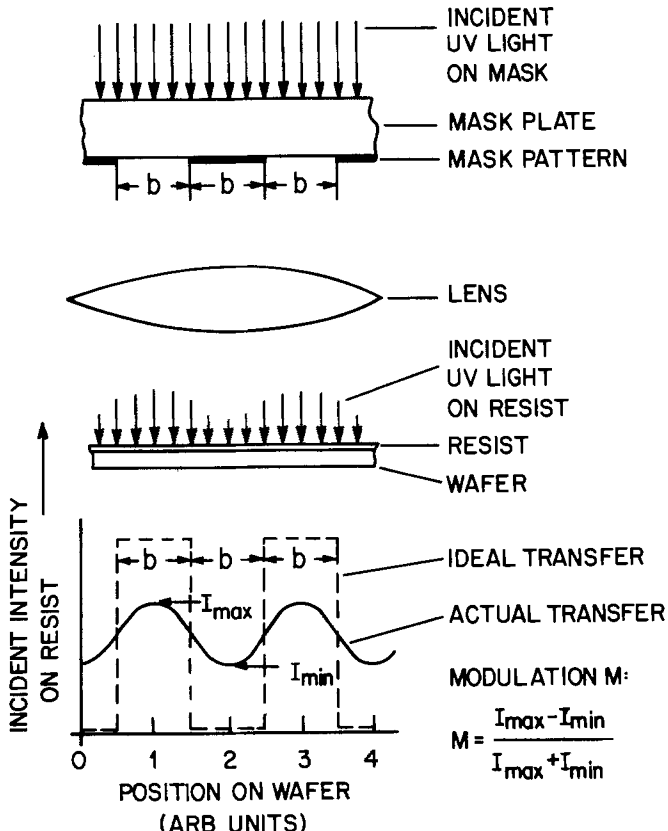

Fig. 2. Schematic representation of pattern transfer by 1:1 projection printing [from D. Widmann and K. U. Stein, Solid State Circuits, Proc. 2nd Eur. Solid State Circuits Conf., 1976, pp. 29-47 (pub. 1977)].

tem. It is a function of the frequency of the object to be imaged as well as the numerical aperture (NA) of the optical system. The NA is given by $n \sin \alpha$ where n is the refractive index in image space and 2α is the maximum cone angle of rays reaching an image point on the optic axis of the projection system. Thus the frequency dependence of the MTF characterizes the exposure system under given conditions of illumination, focus, and wavelength of the exposing radiation and is a quality criterion for projection systems.

The shape of the MTF *vs.* frequency curve depends on the spatial coherency of the illuminating system (5). Spatial coherency refers to the effective size of the source relative to the aperture of an optical system. In a projection system, Köhler-type illumination is used which means that the exposure source is imaged through a condenser in the entrance pupil of the projection lens. This source image is the effective size source. The degree of coherency can be quantified by the ratio $s = (NA)_c/(NA)_o$ where $(NA)_c$ and $(NA)_o$ are the numerical apertures of the condenser and objective, respectively. This parameter describes the degree of filling of the entrance pupil of the lens by the source and specifically is the ratio of the diameter of the imaged source at the pupil to the pupil diameter. An incoherent source is rigorously a source of infinite extent ($s = \infty$) whereas a coherent source ($s = 0$) is a point source. The fully incoherent case is only of academic interest because all light collected from the finite source is always deliberately imaged within the entrance pupil and hence $s \leq 1$. We refer to this case as partial coherence.

An appreciation of how the degree of illumination coherence will affect the MTF curve can be gained from Fig. 3. The solid lines show a plane wave front ($s \rightarrow 0$) incident normally on a mask (object) which contains a grating pattern of frequency ν equal to $1/2b$. The undiffracted or (d-c) component of light emerg-

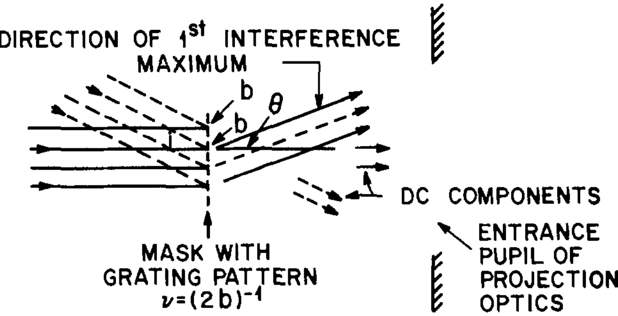

Fig. 3. Diffraction of coherent and incoherent light by a grating pattern [from J. D. Cuthbert, *Solid State Technol.*, **20**, 59 (1977)].

ing from the mask contains no information about ν. This information is contained only in the diffracted light. The direction of the first diffraction peak is given by the grating formula

$$n_0(2b)\sin\theta = N\lambda \quad (N = 1) \qquad [3]$$

so that

$$\nu = n_0\sin\theta/\lambda \qquad [4]$$

Clearly if the light diffracted into direction θ is to reach the image plane, then θ must be $\leqq \alpha_0$ where α_0 is defined by $NA_0 = n_0 \sin\alpha_0$, the numerical aperture of the projection optics. Therefore the highest grating frequency which can be imaged by an optical system with coherent illumination is

$$\nu_{max} = n_0\sin\alpha_0/\lambda = NA/\lambda \qquad [5]$$

For incoherent illumination (shown by dotted lines in Fig. 2) incident at a general angle ϕ, the direction of the first maxima is given by

$$n_0(2b)(\sin\phi + \sin\theta) = \lambda$$

In order for both the d-c beam and the first diffraction peak to reach the image plane, both ϕ and θ must be $\leqq \alpha_0$, *i.e.*

$$\nu_{max} = 2NA/\lambda \qquad [6]$$

The MTF curve can be described mathematically in terms of these variables. For example, the MTF ($H(\nu)$) of a lens system employing incoherent illumination and a circular exit pupil is given by (6)

$$H(\nu) = \frac{2}{\pi}\left[\cos^{-1}(\nu/\nu_{max}) - \nu/\nu_{max}\sqrt{1 - (\nu/\nu_{max})^2}\right] \qquad [7]$$

where ν_{max} is $2NA/\lambda$ (*cf.* Eq. [6]).

The MTF *vs.* spatial frequency curves provide a convenient description of the variation of image quality since the higher the value of the MTF for a given frequency, the greater the contrast in the projected image. Figure 4 shows plots of MTF *vs.* spatial frequency for different degrees of coherency *s*. The figure shows that the MTF of a fully coherent optical system has a spatial frequency cutoff which is half that of an incoherent system (*cf.* Eq. [5] and [6]). With partially coherent illumination ($0 < s < \infty$) the MTF is higher for spatial frequencies $0 < \nu < \frac{1}{2}\nu_0$ and lower for $\frac{1}{2}\nu_0 < \nu < \nu_0$ where $\nu_0 = 2NA/\lambda$. This cross-over occurs at an MTF of ~ 0.4 for $s \approx 1$. From this we can conclude that partial coherence will be beneficial for recording media which require an MTF > 0.4 as is typical of most organic-based positive photoresists.

The best illumination for image reproduction is spatially partially coherent with $s \approx 0.7$ (5, 8). Although values of $s < 0.7$ result in even higher values of the MTF for a given frequency, other factors must be considered. For example increased coherence is achieved by narrowing the illumination slit and hence is obtained at the expense of longer exposure times.

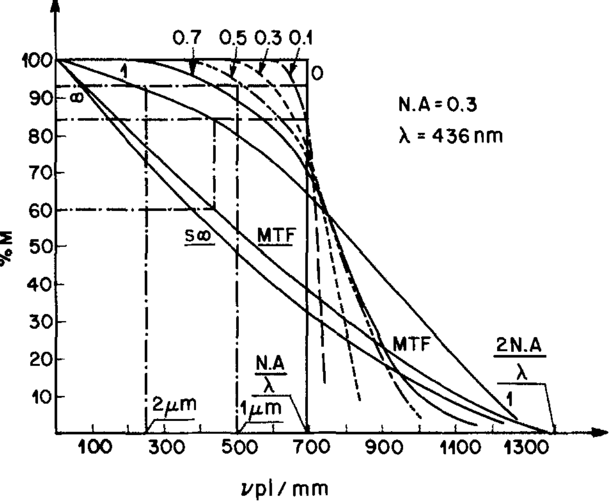

Fig. 4. Modulation *M* of the image intensity *vs.* spatial frequency ν of a sinusoidal amplitude transmission grating for different values of the coherency factor *s*. [from M. Lacombat, J. Massin, G. M. Dubroeucq, and M. Brevignon, *Solid State Technol.*, **23**, 115 (1980)].

The image characteristics of isolated edge features also degrade for values of *s* below 0.7 due to phenomena such as ringing (8) shown in the intensity distribution curve in Fig. 5. For degrees of coherency >0.7, it becomes difficult to maintain linewidth control in such features since the intensity of the low portion of the intensity distribution curve increases with increasing *s* (*cf.* Fig. 5). There is also decreased tolerance to focus error for $s > 0.7$ for focus errors $< 4\ \mu m$ (8). Thus a partial coherency of $s = 0.7$ represents an acceptable trade-off between these various factors.

Resolution can be improved by using lenses with higher numerical apertures or using shorter wavelengths. For example, Fig. 6 shows the MTF curves for 1X and 10X reduction lenses for exposure at 4360Å. It is seen that for a given spatial frequency, projection with the 10X reduction lens provides a larger modulation than 1:1 projection, the reason for this being the larger numerical aperture of the 10X reduction lens (0.33 for 10X *vs.* 0.125 for 1X). It will be noted however that the image field diameter of the 10X reduction lens is ten times smaller than that for the 1X reduction lens. This reflects an important constraint in

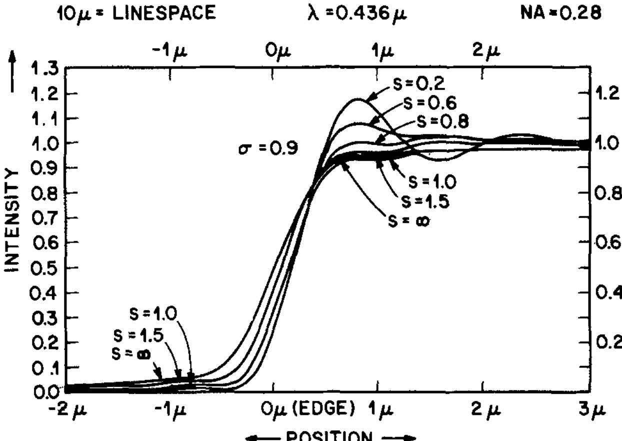

Fig. 5. Image intensity profile near the edge of a mask pattern consisting of 10 μm lines and spaces. The mask pattern was imaged at 4360Å with a lens of $NA = 0.28$ [from M. M. O'Toole and A. R. Neureuther, SPIE Developments in Semiconductor Microlithography IV, **174**, 22 (1979)].

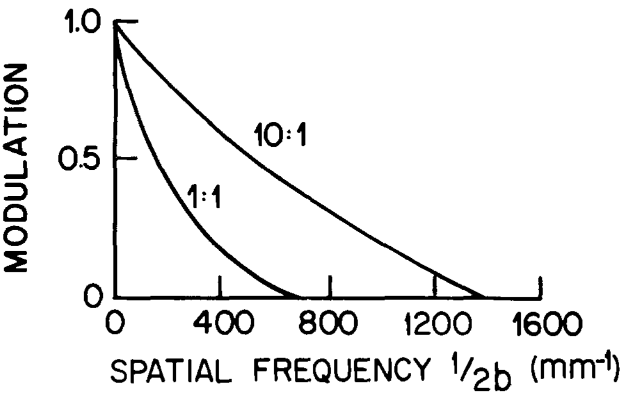

Fig. 6. Modulation transfer functions (MTF) for two different lenses. Lens 1: 1× reduction, NA—0.125, image field—75 mm diam; lens 2: 10× reduction, NA—0.33, image field—7.5 mm diam; the wavelength λ is 436 nm [from D. Widmann and K. U. Stein, Solid State Circuits, Proc., 2nd Eur. Solid State Circuits Conf., 1976, pp. 29-47 (pub. 1977)].

lens design, *viz.*, that higher resolution via higher NA is obtained at the expense of image field diameter. The current state-of-the-art in the design of refractive microcircuit lenses permits placement of ~ 10^8 resolved spots within the image field (9). With refractive lenses, this number depends little on field size or resolution. Thus for a given NA and λ, the limiting resolution ν_{max} will be obtained over a square field approximately given by $10^8/\nu_{max}^2$. For example, a lens system whose NA and λ enable resolution of 1 μm lines and spaces ($\nu_{max} = 1/2, \mu m^{-1}$), could only exhibit such resolution over a square field 4×10^8 μm^2, *i.e.*, 2 cm on the side. Higher resolution can only be obtained at the expense of field in a manner which keeps the total number of resolved elements within the field fixed. This relationship is shown in Fig. 7 as a line connecting points representing lenses of similar design and complexity. Such reduction in field size requires a step and repeat approach to pattern an entire wafer.

The other alternative for obtaining higher resolution for a fixed NA is to decrease λ. Usually monochromatic light is used in refractive projection systems in order to eliminate chromatic aberration effects. Such refractive lenses are designed to operate typically at $\lambda > 4000$Å. Shorter wavelengths are precluded by difficulties in lens design resulting from high absorption of optical glasses. On the other hand, resolution in an all reflecting optical system (10) can in principle be increased by reducing the wavelength provided that wave aberrations are suitably low at the reduced wavelength. For example, by using a modified optical design of the 1:1 Perkin-Elmer printer Bruning (7) demonstrated significant resolution improvement using 3100Å over 4000Å for the exposure.

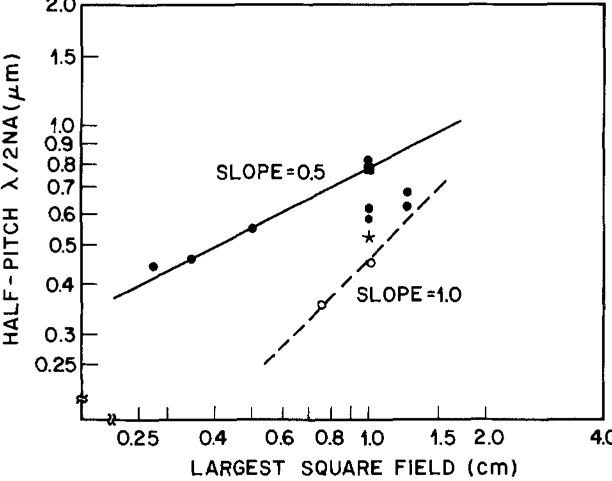

Fig. 7. Limiting resolution vs. field size for state-of-the-art refractive lenses for photolithography. Points indicated by closed circles are refractive designs which, for the same complexity have a constant number of resolution elements as field is traded for resolution. Open circles indicate scaling of a BTL reflective design which yields more resolution elements at smaller fields. Zeiss, 10× lens, 0.28 NA, CERCO Lippia 5× [from J. Bruning, *J. Vac. Sci. Technol.*, **17**, 1147 (1980)].

There are several other important physical limitations on image quality in projection systems. Clearly one would like as large a depth of focus δ as possible in order to compensate for aberrations, wafer distortions, and variable resist thickness due to topography. The depth of focus in an optical system is given by

$$\delta = \lambda/2NA^2 \quad [8]$$

Thus improvements in resolution resulting from an increase in NA or a decrease in λ provide for a smaller depth of focus or, put another way, less defocusing tolerance. For example, the Lippia 5X reduction lens of CERCO which achieves a 0.35 NA at 4047Å over a 1 cm square field provides a depth of focus of ~1.5 μm. Such a shallow depth of focus requires focusing at each chip during step and repeat operation in order to maintain linewidth control. We may note that since resolution is proportional to λ/NA, the fall-off in depth of focus will be less severe for resolution improvement gained by decreasing λ since there is only a first power dependence of both parameters on λ.

Step and repeat exposure systems use demagnifying optics to project the image of a reticle onto a wafer. Reduction ratios vary typically between 2X and 10X. The resolution capability of a lens depends only on its numerical aperture and not on its reduction ratio although a higher reduction ratio permits a higher NA (11). Considerations of the optimal reduction ratio appear to revolve around practical considerations such as defect densities associated with reticle size (9).

The other major factor which limits resolution and linewidth control is the standing wave phenomenon. When photoresist films are exposed using monochromatic radiation as in optical projection printing, standing waves are formed in the resist (5, 12). These are caused by coherent interference effects due to a reflecting substrate which result in periodic intensity distributions in the direction perpendicular to the plane of the resist with a period $\lambda_r/2$ (typically 1300Å) where λ_r is the exposure wavelength in the resist. This problem has been considered by several authors with the work of Dill *et al.* (12, 13) being especially comprehensive. Figure 8 shows the image intensity distribution as a function of depth in the resist determined from the model of Dill *et al.* using Fourier optical theory. It is noted that the average intensity decreases with increasing depth. This is due to the strong optical absorption of the resist which attenuates the light as it passes through the film. This intensity pattern changes in magnitude during exposure due to changes in absorption resulting from photo bleaching but the positions of the interference maxima and minima do not move.

Exposure of a positive photoresist under this condition destroys more inhibitor at the intensity maxima than at the minima. Thus the periodicity in the exposure profile as a function of depth into the film results in a similar variation in the rate of development of exposed regions of the resist and produces edge fringes or contours in the positive photoresist wall profile. Such fringes calculated by the Dill model which also takes development of the resist into ac-

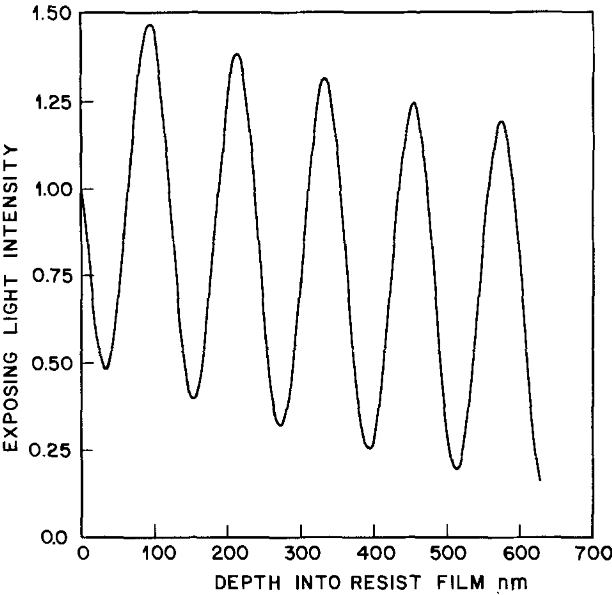

Fig. 8. Plot of intensity of exposing light within a 630 nm AZ1350 photoresist film on bare silicon at the beginning of exposure at a 4047Å wavelength [from F. H. Dill, *IEEE Trans. Electron Devices*, ed 22, 440 (1975)].

count are shown in Fig. 9 with experimental verifica- shown in Fig. 10. These fringes give rise to variations in linewidth that can obliterate lines or close up gaps at the 1 μm level.

A further disadvantage of standing wave effects is the linewidth variations over topography. Figure 11 shows the linewidth variation of an AZ1350H photoresist stripe running across a 0.5 μm vertical step. These linewidth variations stem from the fact that the resist thickness is not uniform across a step. Since reflectivity maximizes for even quarter wavelength multiples of resist thickness (lowering the energy coupled into the resist) and minimizes for odd quarter wavelength multiples (maximizing energy coupling), then the time to develop through a photoresist film becomes periodic with resist thickness for a fixed exposure flux (12). Thus the exposure variations resulting from variations in resist thickness in the vicinity of a step are manifested as linewidth variations.

Standing wave effects are more pronounced in systems employing monochromatic radiation than in those employing broad band illumination. The latter results in a smoothing of the distribution of light intensity within the resist layer. Correcting the projection optics for exposure at two wavelengths rather than a single wavelength appears to reduce the standing wave effect (16). This is seen in Fig. 12 which compares patterns in 1.2 μm thick HPR204 photoresist exposed using the CERCO 5X reduction lens designed for the Philips wafer stepper at 4050 and 4360Å (Fig. 12a and b) with

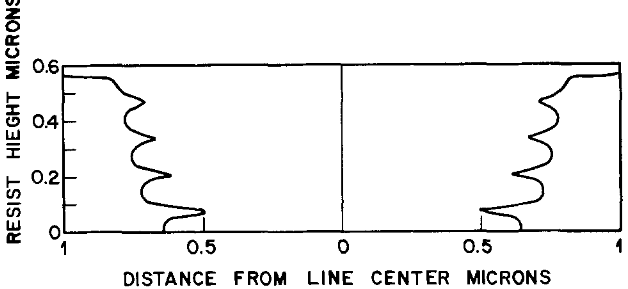

Fig. 9. Edge profile for a nominal 1 μm line in AZ1350 photoresist developed for 85 sec in 1:1 AZ developer:water [from F. H. Dill, A. R. Neureuther, J. A. Tuttle, and E. J. Walker, *IEEE Trans. Electron Devices*, ed 22, 456 (1975)].

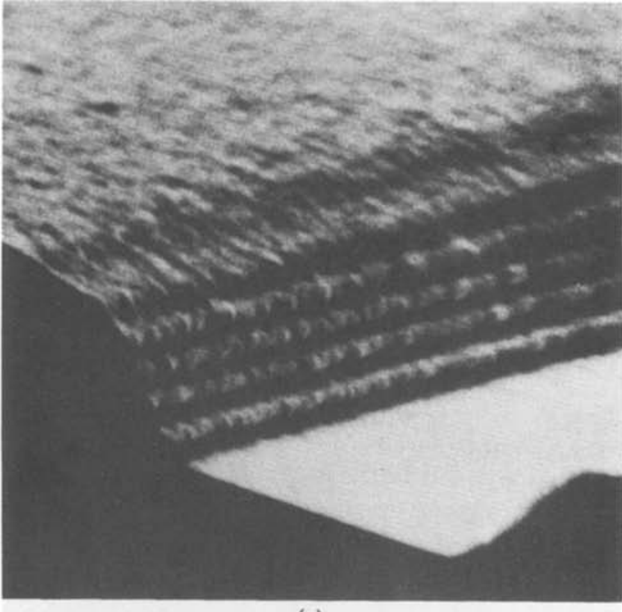

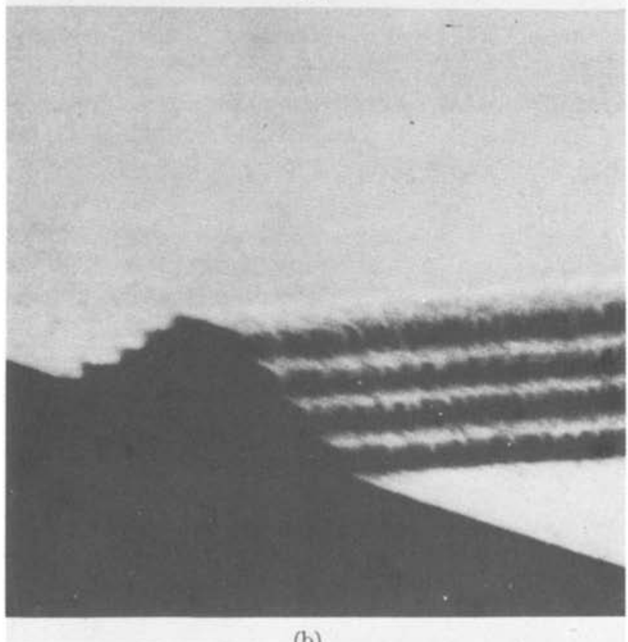

Fig. 10. Scanning electron micrograph of a 1.2 μm line AZ13505 photoresist exposed with a nominal 1 μm image [from F. H. Dill, A. R. Neureuther, J. A. Tuttle, and E. J. Walker, *IEEE Trans. Electron Devices*, ed 22, 456 (1975)].

patterns obtained by a single wavelength exposure at 4050Å (Fig. 12c and d).

Other approaches to reducing standing wave effects include optimizing resist and oxide thicknesses (5) as well as postexposure baking schedules (14) and using concentrated developers (13). It should be noted that the latter two approaches do not eliminate the sensitivity of the line size to the resist and dielectric layer thicknesses since the exposure is still monchromatic. Another approach utilizes a tri-level process (15) in which a planarizing polymeric layer is applied to the circuit at a thickness sufficient to smooth out all the topography (~1.5-2.5 μm). After a bake step at ~210°C to harden the film and render it opaque at the exposure wavelength, a layer of plasma-deposited SiO_2 ~1000Å thick is applied on top of the planarizing layer followed by a thin layer of the desired photoresist (3000-5000Å). This structure permits the image to be recorded in a thin resist on a planar, reflectionless sub-

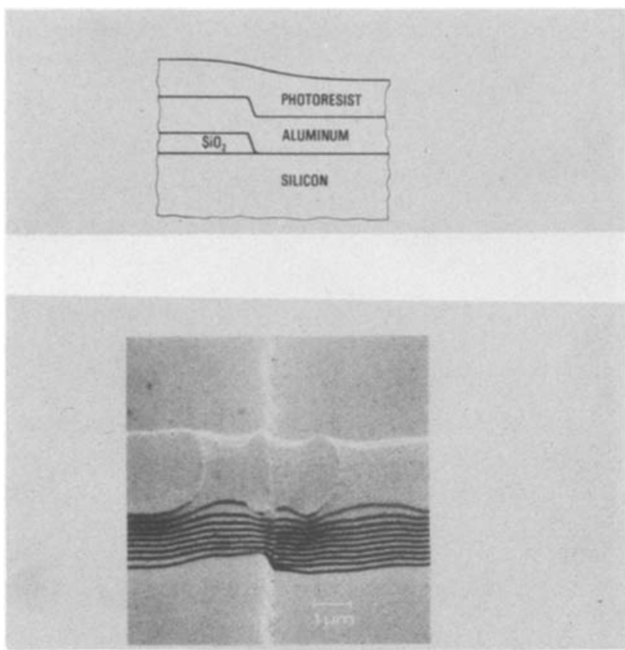

Fig. 11. Scanning electron micrograph of an AZ1350H photoresist stripe running across a 0.5 μm vertical step showing line width variation-across the step [from D. W. Widmann and H. Binder, *IEEE Trans. Electron Devices*, ed **22**, 467 (1975)].

strate. Following exposure and development, the SiO_2 layer is etched. The top photoresist layer thus only serves as an etch mask for the SiO_2 layer which in turn serves as an etch mask for reactive etching of the underlying thick polymer layer. It is the anisotropically patterned thick resist which serves as the "resist" layer for the underlying circuit. Since the primary lithographic patterning step is accomplished in thin resist with no reflection from the substrate excellent resolution and linewidth control can be maintained even over topography.

As was indicated earlier, the overall practical resolution is determined by a number of factors such as registration, alignment, and alignment control in addition to diffraction considerations and given the advances in lithographic technology and in design of photolithographic hardware, one is forced to speculate on the maximum practical resolution with some degree of uncertainty. Markle (17) has suggested that some combination of *NA*, short λ (summarized in Table I) combined with a high contrast resist may permit 0.5 μm resolution to be realizable. Bruning (9) also considers the end of the road for photolithography to lie somewhere between 0.4 and 0.8 μm depending on how fully deep u.v. and image partitioning are exploited.

Electron beam lithography.—The past 10 years have seen an enormous effort in developing electron beam lithography as a viable technology. Although electron projection (18, 19) and shadow printing methods (20) have been developed for full image exposure, these techniques have not gained major importance. The following considerations are therefore limited to electron beam scanning (21-23) in which an electron beam of defined shape is controllably deflected in order to

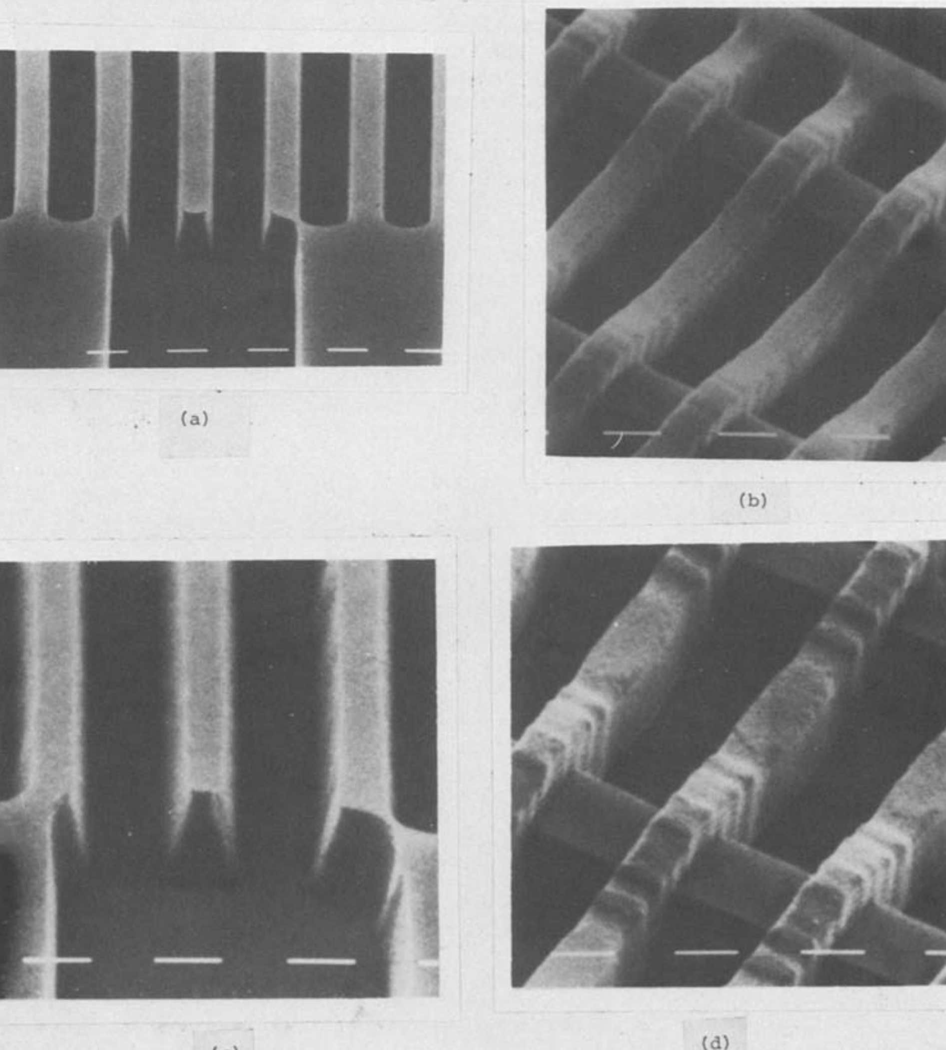

Fig. 12. Patterns in 1.2 μm thick photoresist (HPR 209) on silicon wafers. (a) and (b) exposed at 4050 and 4360Å; (c) and (d) exposed at 4050Å [from S. Wittekoek, *Solid State Technol.*, **23**, 80 (1980)].

Table I. Dependence of minimum feature size on *NA* and λ (17)

NA	λ(μm)	Minimum feature (μm)
0.164 (F3)	0.39	1.78
0.164	0.25	1.14
0.242 (F2)	0.25	0.775

expose the desired areas of the resist film. Since the wavelength of an electron is only on the order of a few tenths of an angstrom, the resolution limitation due to diffraction considerations is not important. However, although an electron beam can be focused to spot sizes of 1000Å or less, the minimum feature size may be considerably greater than the beam diameter because of electron scattering in the resist. When an electron beam enters a thin polymer film the electrons lose energy by elastic and inelastic collisional processes known collectively as electron scattering. This results in a transverse or lateral electron flux $J(z,y)$ normal to the incident beam direction (see Fig. 13). The magnitude of this flux which has scattering contributions from within the resist (forward and lateral) and from within the substrate (backscattering) depends upon the energy, current, and geometry of the beam, film thickness, and the atomic number of the polymer and substrate. The existence of this transverse flux of electrons results in energy dissipation at points remote from the point of entry of the beam and thus the developed contour of the exposed area in the resist is reflective of the energy dissipated in that region. In particular it may be considered that the developed contour represents a contour of constant absorbed energy density and measurement of exposure profiles can yield valuable information concerning energy dissipation profiles of electrons in the resist. Thus electron scattering provides the fundamental limitation to resolution in electron lithography.

In the past, the dose required to obtain a given relief structure in the resist has been determined experimentally. While an empirical approach permits one to write patterns and fabricate devices, it provides neither a basic understanding of the physical mechanism involved in polymer film exposure nor a means for predicting quantitatively how changing a given parameter will effect the polymer relief structure. As illustrated in Fig. 14, when a positive resist such as poly(methyl methacrylate) PMMA is exposed in a line by a scanned electron beam, developed in a solvent to remove the exposed regions, and viewed in cross section, undercut contours are observed whose dimensions

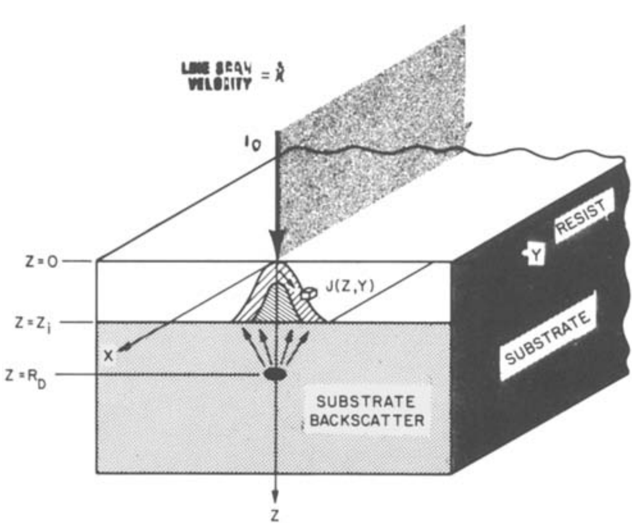

Fig. 13. Three dimensional electron scattering model for a polymer resist film on a substrate [from L. F. Thompson, *Solid State Technol.*, **17**, 27 (1974)].

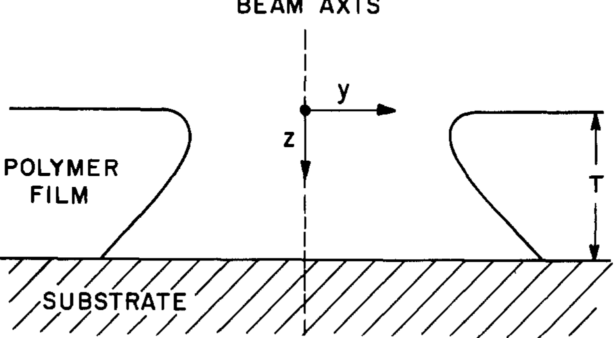

Fig. 14. Schematic diagram illustrating the undercut contours typically obtained in PMMA film of thickness *T* on top of a substrate after exposure by a scanned electron beam and developing [from R. J. Hawryluk, A. M. Hawryluk, and H. I. Smith, *J. Appl. Phys.*, **45**, 2551 (1974)].

depend on the line charge density. Similarly, if the beam is held at a fixed position and turned on for a time interval τ, a radially symmetric contour is obtained which is termed a dot exposure. These contours as already mentioned are identified as surfaces of equal energy dissipation per unit volume. Quantitatively, the contour $z(r)$ can be obtained from (24, 25)

$$qi\tau I(r,z) = D_{\text{crit}}(\text{erg/cm}^3) \quad [9]$$

where r is the radial distance from the beam axis, z is the depth in the polymer film, and D_{crit} is the energy dissipated per unit volume required to expose the polymer adequately for development. The azimuthally symmetric two-dimensional function $I(r,z)$ is the energy dissipated per unit volume per electron. The term preceding $I(r,z)$ is the product of the beam current i, the exposure time τ, and the number of electrons per coulomb q and is therefore the total number of electrons incident at the surface. Thus by determining the locus in the resist of the critical value of absorbed energy, we have in fact determined the contour of the developed line.

In similar fashion, the contour $z(y)$ of a line scan exposure obtained by scanning the beam along the x direction at a velocity $\dot{x}$ cm/sec (Fig. 15) can also be obtained. For adequate exposure the contour corresponds to the locus where the energy dissipated per unit volume equals D_{crit}

$$\int_{-\infty}^{\infty} qiI(r,z)\,dt = D_{\text{crit}} \quad [10]$$

The input line dose (linear charge density) $D^{\circ}_{x} = i/\dot{x}$. Transposing variables we thus obtain

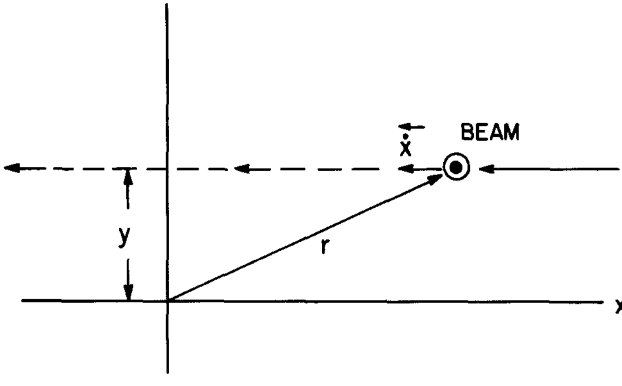

Fig. 15. Electron beam scanned past a point with velocity $\dot{x}$ at a lateral displacement y viewed normal to the sample surface [from R. J. Hawryluk, A. M. Hawryluk, and H. I. Smith, *J. Appl. Phys.*, **45**, 2551 (1974)].

$$\int_{-\infty}^{\infty} qI(r,z)dx \cdot D^{o}_{x} = D_{crit} \qquad [11]$$

which may be abbreviated to

$$E(y,z)D^{o}_{x} = D_{crit} \qquad [12]$$

where

$$E(y,z) = \int_{-\infty}^{\infty} qI(r,z)dx \quad \text{and} \quad r^2 = x^2 + y^2$$

$E(y,z)$ is the energy dissipated per unit volume per coulomb per centimeter. Thus from $E(y,z)$ and D_{crit}, one can calculate the linear charge density D^{o}_{x} required to obtain a given contour.

We should note that the proper exposure for an array of closely spaced lines is different than that for a single isolated line. This is because even a highly focused beam contributes to the exposure several micrometers away. This is referred to as the proximity effect (26) and will be discussed later. A careful evaluation of $E(y,z)$ for a single line permits one to calculate this cooperative exposure effect.

Both analytic (24, 27, 28) and Monte Carlo models (24, 29-31) have been used to calculate $I(r,z)$ and $E(y,z)$. The Monte Carlo method attempts to simulate via a digital computer the trajectories of the incident electrons within the resist/substrate system. This involves following the electron trajectory through a succession of distinct scattering events. Most approaches employ a single scattering model. The angular deflections suffered by the incident electrons are assumed to occur via elastic scattering with the target nuclei with the angle of scattering for each event being calculated in accordance with the differential scattering cross section for a nucleus in a screened atomic field. In between elastic scattering events, the incident electrons are assumed to travel in straight lines (given by the mean-free path) undergoing energy loss. This energy loss process is modeled via the continuous slowing down approximation in which the electron loses energy continuously along each free flight segment according to the Bethe energy loss formula (32)

$$\frac{dE}{dx} = \frac{-2\pi e^4 n_e}{E} \ln\left[\frac{E}{I}\left(\frac{e}{2}\right)^{1/2}\right] \qquad [13]$$

where n_e is the density of atomic electrons and I the mean excitation energy. Figure 16 shows 100 simulated trajectories projected onto the x-y plane for a 10 and 20 kV point source. This figure qualitatively shows the degree of forward and lateral scattering within the film as well as the degree and position of backscattering. We can also make a number of other qualitative deductions from the results of these simulated trajectories. Clearly the range of a 20 kV electron is greater than that of a 10 kV electron. But although scattering of 20 kV electrons occurs over a greater lateral distance, it is apparent that the absorbed energy density in regions transverse to the beam falls off more rapidly in this case than for 10 kV electrons suggesting that higher resolution can be obtained at 20 kV than at 10 kV. Of course for overexposure, the greater lateral spread at 20 kV will eventually result in broader lines. Heidenreich *et al.* (33) used Monte Carlo methods to calculate the effects of film thickness and operating voltage on the contour width. Their results are summarized in Fig. 17. This figure also shows the computed range of electrons in the resist calculated from the Bethe expression for energy loss as a function of electron energy. The data indicates two clear trends. For a given resist thickness, the linewidth, as expected, decreases with increasing incident electron energy up to some electron energy beyond which there is no further significant reduction. The decrease in linewidth continues over a wider range of incident electron energy for thick films. Hatzakis and Broers (34) generated experimental profiles in thick PMMA (Fig. 18) which confirm this conclusion. It would be difficult to make a quantitative comparison between theory and experiment here since the calculations of Heidenreich *et al.* include the effects of substrate backscattering while the data of Broers and Hatzakis do not. The second trend shown by the data indicates that for a given operating voltage, the linewidth decreases with decreasing resist thickness.

In order to determine spatial profiles, the distribution of electrons in the incident beam has to be taken into account. It is usually assumed that the beam has a Gaussian profile

$$J(r) = J_o \exp(-r^2/\bar{r}^2) \qquad [14]$$

where J_o is the current density at the spot center ($r = 0$) and $\bar{r}$ is the Gaussian radius. If the total current of the incident beam is i_o then

$$J(r) = \frac{i_o}{\pi \bar{r}^2} \exp(-r^2/\bar{r}^2) \qquad [15]$$

Thus for a given exposure dose, one can calculate equi-energy density contours. Figure 19 shows a comparison

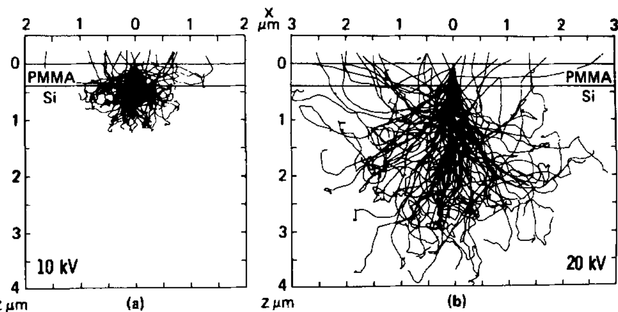

Fig. 16. Monte Carlo simulated trajectories of 100 electrons in PMMA resist on silicon [from D. Kyser and N. S. Viswanathan, *J. Vac. Sci. Technol.*, **12**, 1305 (1975)].

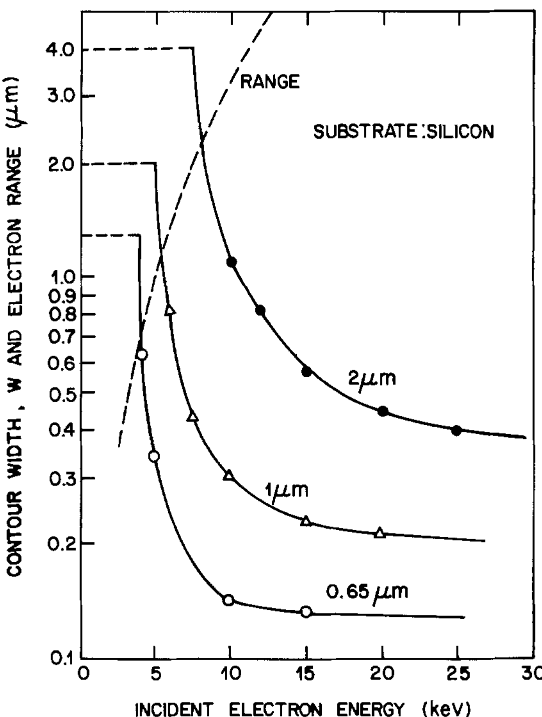

Fig. 17. Computed variation of contour width W as a function of incident electron energy for three resist thicknesses. The computed Bethe range of electrons in the resist material is also shown [from R. D. Heidenreich, J. P. Ballantyne, and L. F. Thompson, *J. Vac. Sci. Technol.*, **12**, 1284 (1975)].

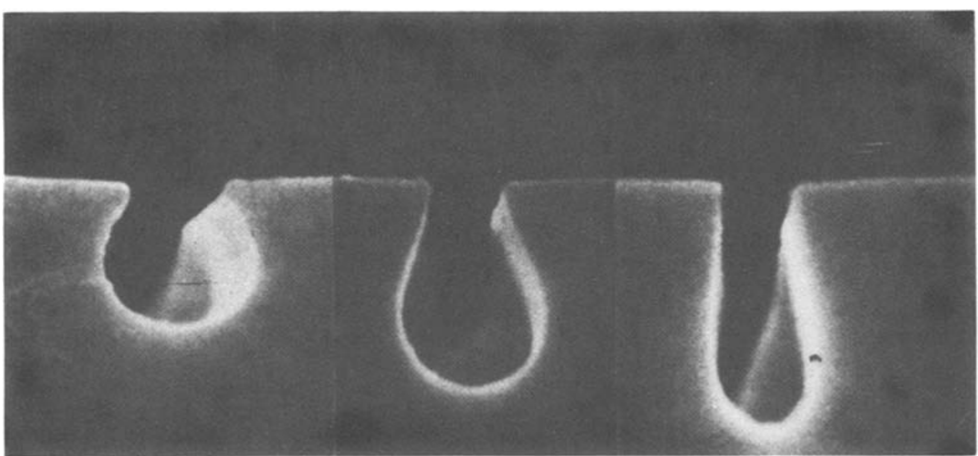

Fig. 18. Composite photomicrograph of the cross sections of three lines exposed at 10^{-4} C/cm^2 at varying beam voltages: left to right 10, 15, and 25 kV [from M. Matzakis, C. H. Ting, and N. Viswanathan, in "Electron and Ion Beam Science and Technology," R. Bakish, Editor, p. 542, The Electrochemical Society Softbound Proceedings Series, Princeton, N.J. (1974)].

of the Monte Carlo results obtained by Kyser and Murata (30) with the experimental results of Wolf *et al.* (35) for thick PMMA at 10 kV. The Monte Carlo calculations were arbitrarily matched to the experimental contour for $D^o{}_x = 0.3 \times 10^{-8}$ C/cm at $x = 0$, *i.e.*, on axis. This was achieved with a contour of $D_{crit} = 1.1 \times 10^{22}$ eV/cm^3 and this same contour value was then calculated for the remaining values of 0.7, 1.0, and 2.0 $D^o{}_x$. The agreement between theory and experiment shown in Fig. 19 is generally good in spite of the neglect in the theory of developer effects. The most obvious discrepancy occurs at the surface where the experiment shows a significant width for the contour and theory predicts a small width. This discrepancy may be due to (*i*) surface tension in the film after irradiation or (*ii*) finite etching rate of the polymer in regions where $D < D_{crit}$.

The major disadvantage of the Monte Carlo method is that it is necessary to calculate the trajectories of several thousand electrons in order to obtain meaningful results. This implies a great deal of computer time and expenditure. Thus for practical as well as heuristic reasons analytic models to predict the energy dissipation are useful.

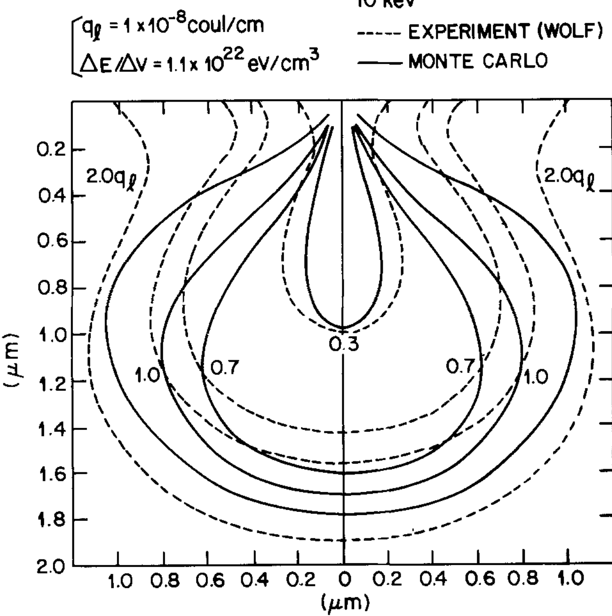

Fig. 19. Comparison of profiles calculated by Monte Carlo simulation with those determined by experiment for thick PMMA resist at 10 kV [from D. Kyser and K. Murata, in "Electron and Ion Beam Science and Technology," R. Bakish, Editor, p. 205, The Electrochemical Society Softbound Proceedings Series, Princeton, N.J. (1974).

In the analytical models, the energy dissipated by an electron beam is considered to be composed of three contributions, (*i*) small angle forward scattering of the incident beam in the polymer, (*ii*) large angle backscattering from the substrate, and (*iii*) large angle backscattering of the incident beam within the polymer.

We have seen that the cumulative effects of small angle scattering events determine the spatial distribution of electrons inside the resist film. By assuming those scattering events to be elastic and small angle, the spatial probability distribution of scattered electrons can be expressed as (28)

$$H(r, z) = \frac{3\lambda}{4\pi z^3} \exp\left(-\frac{3\lambda^2}{4z^3}\right) \qquad [16]$$

where r is the radial distance from the axis of the incoming electron, z is the vertical distance along the axis of electron penetration, and λ is the transport mean-free path which in the nonrelativistic approximation is given by

$$\lambda(\text{Å}) = \frac{5.12 \times 10^{-3} E^2 A}{\rho Z^2 \ln (0.725E^{1/2}/Z^{1/3})} \qquad [17]$$

where A = mass number, E = electron energy, ρ = film density, and Z = atomic number.

Equation [16] shows that the spatial distribution of electrons is Gaussian at any depth for an impulse input function. When the impinging electrons have a Gaussion distribution $J(r)$ defined by Eq. [15], then the resulting density distribution inside the solid will be given by the convolution of the integral of the input function $J(r)$ and the response function $H(r,z)$

$$J(r, z) = \int_0^{2\pi} \int_0^{\infty} H(r, z) J(r) r dr d\theta \qquad [18]$$

This integration cannot be carried out rigorously in closed analytical form and thus requires numerical integration. However, a very good approximation is obtained using the approximation that in a Gaussian distribution the value of $\bar{r}$ is the root-mean-square uncertainty in the radial position of an electron. If scattering now occurs, an additional uncertainty is introduced [in this case $(4z^3/3\lambda)^{1/2}$] and if the two uncertainties are random or independent they can be combined in quadrature to yield the minimum dispersion of the Gaussian. This dispersion $\bar{s}$ is the minimum uncertainty in electron radial position and is simply

$$\bar{s} = (\bar{r}^2 + 4z^3/3\lambda)^{1/2} \qquad [19]$$

for a spreading Gaussian profile. The Gaussian profile of the beam as it penetrates the resist is therefore given by

$$J(r) = \frac{i_0}{\pi \bar{s}^2} \exp\left[-\left(\frac{r^2}{\bar{s}^2}\right)\right] \quad [20]$$

The energy loss per cm³ per electron due to the forward scattered electrons can be calculated as

$$I(r, z)|_{FS} = \frac{dE}{dx} \times \frac{J(r)}{i_0} \quad [21]$$

The contributions of large angle backscattering from the substrate and polymer are obtained by following the approach of Everhart (36) which assumes that electrons undergo only one large-angle Rutherford scattering. The reflection coefficient is calculated on this basis and one parameter in the model is adjusted to obtain a good fit to experimental reflection coefficient data for atomic numbers $Z < 50$. Alternatively, the backscatter contribution may be calculated empirically. Heidenreich (37), for example, has developed an empirical backscatter model for thin resist films based on the direct observation of chemical change produced by backscattered electrons at different accelerating voltages on several substrates. The model is independent of scattering, trajectory, and energy dissipation calculations and is essentially a radial exponential decay of backscatter current density out to the backscatter radius determined by electron range.

The total electron flux per unit area at a given point is calculated as the sum of the individual components. One can then determine the total energy absorption from the integral over all space of the product of electron flux and the rate of energy loss. Figure 20 shows a comparison of developed profiles for line dose charges of 0.3×10^8 and 1.0×10^{-8} C/cm for PMMA on an aluminum substrate at different accelerating voltages. Comparison of the theoretical contours calculated from the model of Greeneich and Van Duzer (27) with the experimental contours of Wolf *et al* (35) also shows reasonable agreement except at 5 kV. Greeneich and Van Duzer attribute this to a lack of validity of the plural scattering theory for primary electrons at 5 kV.

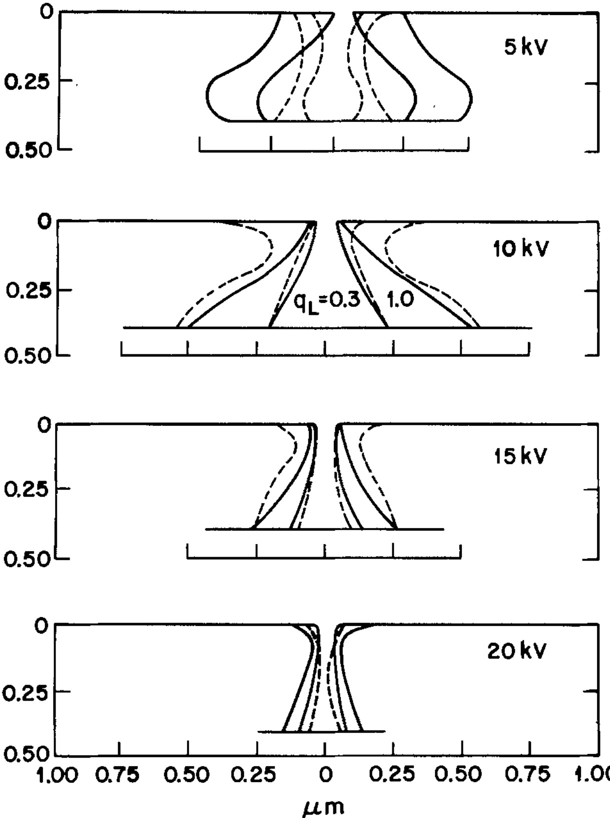

Fig. 20. Comparison of developed profiles for charges per unit length of 0.3×10^{-8} C/cm and 1.0×10^{-8} C/cm for PMMA on an aluminum substrate. The solid lines are from theory; the broken lines are the experimental contours of Wolf *et al.* [from J. S. Greeneich and T. Van Duzer, *IEEE Trans. Electron Devices*, ed 21, 286 (1974)].

Heidenreich *et al* (33, 38) developed an empirical or phenomenological model for determining gel energies and profiles in negative resists. For the case of a uniform large area exposure such as one encounters in the determination of the contrast curve, the incident electron energy dissipation density depends only on the depth z into the resist. The rate of energy deposition at penetration depth z is given by

$$\frac{dE}{dt} = \frac{J_0}{e} \frac{\partial V}{\partial z} \text{ eV/cm}^3\text{/sec} \quad [22]$$

where J_0 is the incident current density and $\partial V/\partial z$ the specific energy dissipation in eV/cm. The specific dissipation can be written as

$$\partial V/\partial z = \frac{V_a}{R_G} \Lambda(f) \text{ eV/cm} \quad [23]$$

for beam voltage V_a with R_G, the Grün range, given by

$$R_G = (0.046/\rho)\, V_a^{1.75}\, \mu\text{m} \quad [24]$$

and $\Lambda(f)$ the depth dose function in terms of normalized penetration ($f = z/R_G$). The density is ρ and is approximately unity for polymeric resists. From Eq. [22] it is seen that the minimum electron dose $D^0_g = J_0\tau$ for exposure time τ required to gel the resist at the substrate interface is related to the gel energy E^i_g by

$$E^i_g = \frac{D^i_g}{e} \left(\frac{\partial V}{\partial z}\right)_i \text{ eV/cm}^{-3} \quad [25]$$

The value of $(\partial V/\partial z)_i$ the energy dissipation at the interface, is obtained from Eq. [23] for a resist of initial thickness z_i. Heidenreich incorporated backscatter from the substrate by means of a backscattered coefficient η which is used to modify the forward scattered beam density as $J_0(1 + \eta)$.

The effects of backscatter are readily seen when we examine the lithographic response curves for negative resists supported on a variety of substrates. Figure 21 shows the response curves for ~6600Å COP on three different substrates. In this figure curves 1 and 2 are for a thin Si_3N_4 substrate (~1000Å thick) and the same Si_3N_4 film supported by a bulk silicon substrate, respectively. Curve 3 pertains to a substrate consisting of a layer of gold approximately 4000Å thick on top of a silicon wafer. The backscatter coefficient from Si_3N_4 is less than 3% so that the contrast curve for the thin Si_3N_4 substrate can be considered to be an acceptable approximation of that corresponding to an unsupported resist film. Such experiments provide a means of

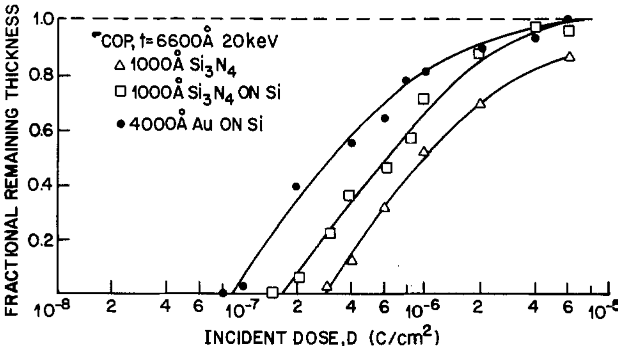

Fig. 21. Measured contrast curves for COP on three different substrates. Exposure conditions are as given in the figure [from M. C. Chung and K. L. Tai, in "Electron and Ion Beam Science and Technology," R. Bakish, Editor, p. 242, The Electrochemical Society Softbound Proceedings Series, Princeton, N.J. (1978)].

evaluating the backscattered coefficient (39). We consider $\partial V/\partial z$ to be the sum of two terms, *i.e.*

$$\partial V/\partial z = (\partial V/\partial z)_{FS} + (\partial V/\partial z)_{BS} \quad [26]$$

where $(\partial F/\partial z)_{FS}$ is the energy dissipation due to forward scattering and $(\partial V/\partial z)_{BS}$ is the energy dissipation due to electrons backscattered from the underlying substrate material. Equation [26] can be rewritten as

$$\partial V/\partial z = (\partial V/\partial z)_{FS}\{1 + (\partial V/\partial z)_{BS}/(\partial V/\partial z)_{FS}\} \quad [27]$$

$$= (\partial V/\partial z)_{FS}\{1 + \eta\} \quad [28]$$

where η is defined as the backscatter coefficient. For the case of the thin Si_3N_4 substrate, $\eta = 0$ so that from Eq. [25] we have

$$E^i_g = \frac{(D_g^i)_0}{e}\left(\frac{\partial V}{\partial z}\right)^i_{FS} \quad [29]$$

where $(D_g^i)_0$ is the incident interface gel dose for the zero backscatter contribution. For any other substrate

$$E^i_g = \frac{D^i_g}{e}\left\{\left(\frac{\partial V}{\partial z}\right)^i_{FS} + \left(\frac{\partial V}{\partial z}\right)^i_{BS}\right\} \quad [30]$$

Thus from Eq. [29] and [30] we obtain

$$(D_g^i)_0/D_g^i = 1 + \eta^i \quad [31]$$

where η^i is the effective backscattering coefficient evaluated at the interface.

The depth dose model thus allows the gel energy E^i_g of a resist to be calculated from an observed interface dose D^i_g and predicts a dependence of D^i_g on accelerating voltage going as $V_a^{(-0.75)}$ which agrees reasonably well with experiments.

The depth-dose model can also be used to determine energy profiles in the resist when convolved with the spreading Gaussian treatment of Nosker described earlier (28). Heidenreich *et al.* (33) simplified this even more by convolving the spreading Gaussian beam treatment with the experimentally determined relationship between resist thickness remaining after development and input electron dose (see Fig. 37). Backscattering was again included as $J_o(1 + \eta)$, *i.e.*, as a modification of the incident current. For a beam scanning along the x direction at line speed $\dot{x}$, the dose at distance y from the line center at penetration z is given by

$$D(y) = \frac{(1 + \eta)D^o_x}{\bar{s}\sqrt{\pi}} \exp(-y^2/\bar{s}^2) \text{ C/cm}^2 \quad [32]$$

where $D^o_x = i_o/\dot{x}$. The area input dose at the line center $y = 0$ is thus

$$D(0) = \frac{(1 + \eta)D^o_x}{\bar{s}\sqrt{\pi}} \text{ C/cm}^2 \quad [33]$$

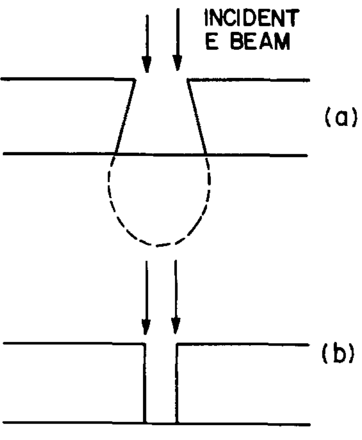
It should be noted that Eq. [32] is a quasi-monoenergetic approximation applying only for penetration z such that the loss in electron energy is about 0.1 V_a.

The significant amount of swelling that accompanies the removal of uncross-linked polymer during development of a negative resist renders the development process in these resists much more difficult to treat. In particular, the surface-limited etching hypothesis that has been found suitable for positive resists like PMMA (40) is completely inapplicable to negative polymer resists in general. Nevertheless, convolution of the input Gaussian with the resist response curve (Fig. 37) yields single line profiles which agree well with experimental profiles for widths down to about 0.18 μm below which interface distortion of the gel becomes dominant. Discrepancies can be attributed to the lack of mechanical integrity of the gel. Gel interactions can take place between neighboring features leading to distortion and errors in the experimentally developed profiles. Such results show the importance of good gel rigidity and high contrast for negative resists used in high resolution applications.

The simplified phenomenological model of Heidenreich was also used by Hatzakis *et al.* (41) to determine resist profiles in PMMA. These authors also took into account the effect of the developing process. The assumption that the developed profiles can be approximated by contours of equal absorbed energy density is a good approximation at high-exposure densities where development is time independent. As pointed out by Hatzakis *et al.* and Greeneich (42), such a model is not adequate for time-dependent developers. Using the phenomenological model, Hatzakis *et al.* obtained contour lines for equal absorbed energy in the resist and expressed it as an energy matrix $E(r, z)$ from the product of the electron intensity distribution and the energy dissipation function. Knowing the change in molecular weight for a given exposure level and the dependence of solubility rate on fragmented molecular weight, they were able to transform the two-dimensional energy density matrix into a solubility rate matrix. Greeneich (42) used a similar model based on a more rigorous analytical analysis of absorbed energy density. He used an empirically determined formula for solubility rate in the form

$$R = R_0 + \frac{\beta}{M_f^\alpha} \quad [34]$$

where R_0, β, and α are constants for a given developer. Hatzakis *et al.* concluded that the developed resist profiles are dominated by the developing process at low-exposure densities, but at high-exposure densities, the developed resist profiles are dominated by scattering inside the resist. Their results are summarized in Fig. 22. Experimental verification of these three profiles was presented by Hatzakis (43) using PMMA resist. The resulting resist profiles are shown in Fig. 23. By careful control of exposure conditions, Hatzakis was able to obtain a 2500Å wide line in 1 μm of resist



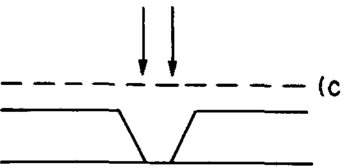


Fig. 22. Positive resist profiles for (a) high charge density (developed resist profile dominated by the electron penetration profile); (b) medium charge density (developed resist line shape results from combination of electron penetration profile and development process); (c) low charge density (developed resist line shape dominated by development process) [from M. Hatzakis, *J. Vac. Sci. Technol.*, **12**, 1276 (1975)].

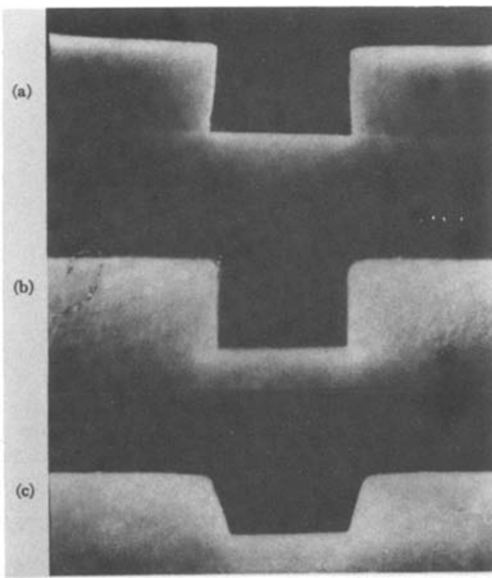

Fig. 23. Actual PMMA resist profiles at an incident charge density of (a) 10^{-4} C/cm^2, (b) 8×10^{-5} C/cm^2, and (c) 5×10^{-5} C/cm^2 [from M. Hatzakis, *J. Vac. Sci. Technol.*, **12**, 1276 (1975)].

with vertical walls using a 1000Å diam beam at 20 kV. Greeneich presented his results in terms of time evolution of developed contours. He also found the incident dose to be particularly important, as was the particular developer chosen. A typical time-developed profile observed for a low-incident dose is shown in Fig. 24. Overall, the results are qualitatively similar to those of Hatzakis *et al.*

In summary, both analytic and Monte Carlo methods calculate the spatial distribution of energy dissipation in a polymer film. Since the development of the image can be related to energy dissipation, such calculations provide a means of determining line profiles. In general the Monte Carlo model is more precise whereas the analytic models do show some discrepancies with experiment. Both methods have several disadvantages. The Monte Carlo approach involves a great deal of computer time and the results are difficult to adapt for various experimental conditions. The analytic models are mathematically complex, even with simplifying assumptions. The phenomenological model of Heidenreich is the simplest approach and has been used to determine profiles of both positive and negative resists.

Figure 25 represents an important result of the electron scattering effect. Although the incident charge density is the same for each of the five lines in Fig. 25, the outer two lines are underexposed because these two lines have only one neighboring line while each of

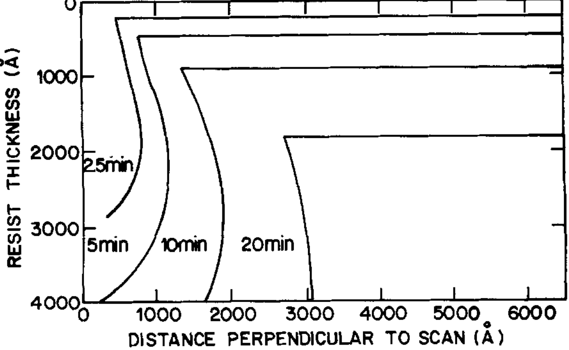

Fig. 24. Time evolution of developed contours in PMMA developed in MIBK at 22.8°C. $V = 10$ kV, $D = 5 \times 10^{-10}$ C/cm, and $M_n = 2 \times 10^5$ [from J. Greeneich, *J. Appl. Phys.*, **45**, 5264 (1974)].

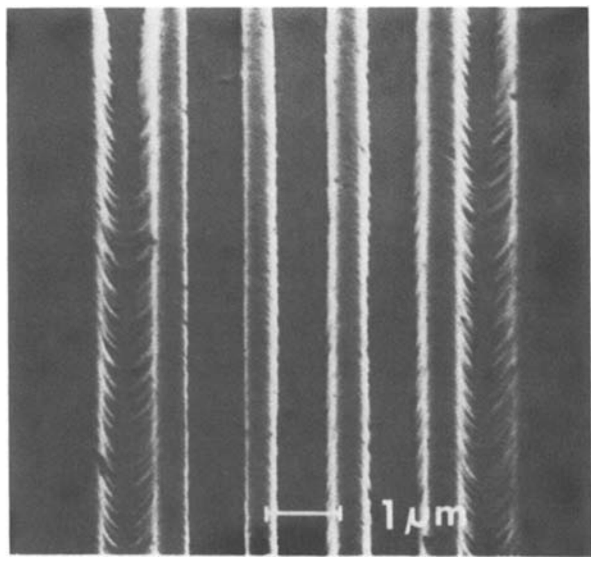

Fig. 25. Scanning electron micrograph of a line pattern in 0.8 μm PMMA on SiO_2. The incident charge density was 10^{-4} C/cm^2 for each of the five lines. The incomplete development of the outer two lines is due to the smaller number of electrons scattered during exposure of neighboring lines [from D. Widmann and K. U. Stein, Solid State Circuits, Proc., 2nd Eur. Solid State Circuits Conf., 1976, 29-47 (pub. 1977)].

the inner three lines has two neighboring lines from which electrons are scattered. This proximity effect which was alluded to earlier may be partially compensated by proper control of the beam scanning speed. However the lateral spread of the dissipated energy at the line edges remains and both the resist parameters and the development conditions must be carefully controlled in order to arrive at the desired linewidths.

If we define resolution as the smallest line-space pattern we can generate (as opposed to the width of an isolated line) we find that positive resists give much higher resolution than negative resists. Further, it is found that the calculated values of minimum grating spacing for a rigid negative resist are 2-5 times better than can be obtained experimentally (44). The gratings fail prematurely because the cross-linked lines swell and deform in the developer. The exact shape of a free standing line is determined also by the strength of the solvent used to develop it.

Thus the faithful production in the resist of a feature written by the electron beam does not depend exclusively on electron scattering and molecular parameters of the polymer but also on factors such as solvent-induced swelling, competitive wetting of the substrate by the solvent and the polymer, and gel rupture by forced-development (45). Solvent-induced swelling limits line space resolution in negative resists to about 1 μm for about 0.5 μm residual film thickness and a beam diameter of 0.5 μm. Somewhat higher resolution could be obtained for smaller residual film thickness (lower exposure dose). The developing process in certain positive resists such as PMMA is akin to a surface etching in which there is negligible swelling (46). Minimum line space resolution is therefore determined more directly by absorbed energy density and using the same 0.5 μm diam beam as above, one can easily resolve the beam address structure.

Another important physical limitation follows from the statistics of electron beam exposure (47). If we divide the electron resist surface to be exposed into a configuration of densely packed identical square elements of width a μm, then the average number of primary electrons per element $\bar{n}$ is given by

$$\bar{n} = \frac{a^2 D}{q 10^8} \quad [35]$$

where D is the exposure dose in C/cm² and q is the electronic charge. The actual number n of electrons per resolution element has a Poisson distribution and if we assume that a resolution element is exposed if it receives an exposure at or above a fraction r of the average dose $\bar{n}$, then a certain fraction $(1 - r)$ of the resolution elements will receive a dose which is below the exposure dose and hence will print as a defect. The statistics of the exposure can be treated mathematically and the results are summarized as a set of curves in Fig. 26. The figure shows as a function of resolution element size the exposure flux in C/cm² required to achieve a fixed average number of defective elements per cm². There are three pairs of curves. One pair pertains to situations in which an element is regarded as defective if it receives an exposure that is not within ±25% of the nominal level; the second pair applies if an exposure error is defined as a deviation of ±50% or more from the nominal level; the third pair considers exposure errors of exactly 100%, *i.e.*, elements which receive no electron hits at all. Within each pair, one curve pertains to a fixed average defective element rate of 1 defect/cm² and the other to a rate of 100 defective elements/cm². In Fig. 26 we see that by going from the upper to the lower curve of any pair, the defect rate increases by a factor of 100 with a flux decrease of only about 30%. Given that resist sensitivities are on the order of 10^{-6} C/cm², we are not yet in a regime where we are becoming statistically limited.

We have seen that the fundamental limit to resolution is due to electron scattering considerations. The extent of scattering is in turn determined by a variety of parameters discussed previously which determine the maximum resolution. The optimum resolution for a given resist thickness is best determined in those positive resists which do not swell during development, *e.g.*, PMMA, and whose profile is thus primarily determined by scattering considerations. The resolution can be obtained by exposing lines with a single beam spot of very small diameter and varying the exposure density. Figure 27 shows a plot of the ratio of beam spot size to developed linewidth in PMMA at the point of complete line development *vs.* the linear exposure charge density. The figure shows the results for resist thickness of 0.3, 0.5, and 1.0 μm, respectively, for a 1000Å diam beam. We can see that for thin films on the order of 0.3 μm, it is possible to obtain linewidth comparable to the beam diameter at linear charge densities of about 2×10^{-9} C/cm. Of course at higher charge densities the line starts to broaden considerably. Figure 28 is a scanning micrograph of one sample on the curve which exhibits an aspect ratio of 4. It shows a 2500Å wide line in 1 μm thickness resist with vertical walls and represents the optimum resolution that can be obtained in PMMA 1 μm thick exposed with a 1000Å wide beam (43).

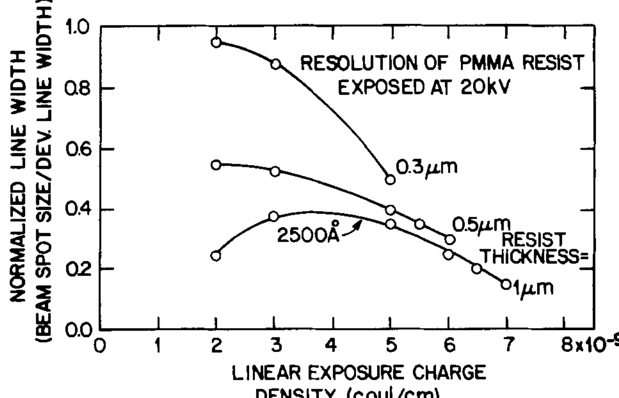

Fig. 27. Curves of normalized linewidth vs. linear exposure charge density for PMMA at 1.0, 0.5, and 0.3 μm [from M. Hatzakis, *J. Vac. Sci. Technol.*, **12**, 1276 (1975)].

In order to obtain even finer resolution, one has to resort to special techniques to minimize electron scattering effects. Two main approaches (48) have been used. Firstly the sample substrate is made so thin that electron backscattering is minimized. Secondly, the electron resist in which the pattern is initially formed is made so thin that forward scattering is also reduced. Broers *et al.* (49) for example have defined 250Å wide lines and spaces in 225Å thick films of $Pd_{40}Au_{60}$ using PMMA resist. The initial resist thickness was 1100Å and the resist was exposed in a high resolution scanning transmission electron microscope (STEM) at a charge density of 5×10^{-4} C/cm², a beam potential of 56 kV, and a beam diameter of 10Å. Thus 200-300Å would appear to be the range of the secondary electrons produced by passage through the resist of the primary electron. Using contamination techniques (a technique in which a line is built up by *in situ* poly-

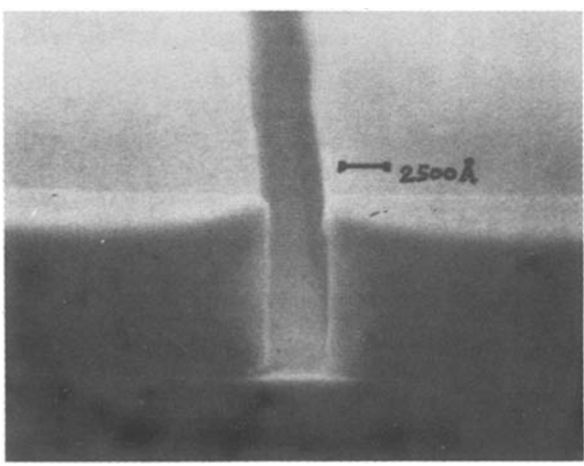

Fig. 28. Profile of a 2500Å wide line exposed and developed in 1 μm thick PMMA at 4×10^{-9} C/cm at 20 kV [from M. Hatzakis *J. Vac. Sci. Technol.*, **12**, 1276 (1975)].

merization of mobile monomers adsorbed on the substrate surface), Broers *et al.* (50) have fabricated 80Å wide and 100Å thick $Pd_{40}Au_{60}$ lines. In this case resolution was not limited by electron scattering but by the grain size of the metal films.

X-ray lithography.—X-ray lithography was established as a viable fabrication technique by Spears and Smith in 1972 (51). The essential ingredients of this process include: (*i*) a mask consisting of a device pattern made of x-ray absorbing material on a thin membrane of x-ray transmitting material, (*ii*) an x-ray source of sufficient brightness in the soft x-ray region to expose the resist through the mask, and (*iii*) an x-ray resist.

For all practical purposes, x-rays travel in straight lines through matter with resolution being primarily determined by the effective range δ of the photoelectrons produced in the resist following absorption of an x-ray photon (52). Energy absorption follows an exponential dependence on μ_m the mass absorption coefficient, on ρ the density, and on z the thickness of the absorbing film according to

$$I = I_0 e^{-\mu_m \rho z} \quad [36]$$

where I_0 and I are the intensities of x-rays before and after passage through the absorbing film. Photo-electrons lose energy by the same elastic and inelastic collisional processes discussed earlier producing secondary electrons which are responsible for nearly all changes in the resist. Each location of an absorption event is therefore surrounded by a small volume of dimension δ where the resist has been modified. The energy of photo-electrons ejected during absorption of 4Å x-rays for example is on the order of 3 keV for which the range is on the order of 0.3 μm. The range will be smaller [$\sim$50Å for C_K x-rays (λ = 44.8Å)] and hence potential resolution will be higher for longer wavelength x-rays.

Resolution is further limited by two types of geometrical distortion (Fig. 29). The opaque parts of the mask cast shadows onto the wafer below. The edge of the shadow is not absolutely sharp because of the finite extent of the x-ray source (diameter of focal spot of electrons on the anode) at distance D from the mask. If the gap between mask and wafer is g, this effect which is referred to as penumbral blur σ_p, limits resolution to

$$\sigma_p = g(d_s/D) \quad [37]$$

The angle of incidence of the x-rays on the wafer varies from 90° at the center of the wafer to $\tan^{-1}(D/R)$ at the edge of a wafer of radius R. The shadows are slightly longer at the edge by an amount Δ which is given by

$$\Delta = g(R/D) \quad [38]$$

This small magnification is generally of no concern but for multilevel devices it must have the same value for each level or at least its variation must be within the registration tolerance. This implies stringent control of the gap g. These geometric distortions can be reduced by increasing the distance between mask and source but since the intensity is inversely dependent on the square of the distance, the exposure times become too long. One way out of this dilemma is to use synchrotron radiation (53, 54). Synchrotron radiation arises as the major loss mechanism from electrons in motion at relativistic energies. The radiation consists of an intense continuous spectral distribution from the infrared out to x-ray wavelengths. It is highly collimated and is confined near the orbital plane of the circulating electrons thereby requiring spreading in the vertical direction or moving the mask wafer combination with constant speed through the fan of synchrotron radiation to expose the entire wafer surface. The high power output offers the advantage of reasonable resist exposure times and the fact that the radiation is produced over a few milliradians divergence means that run-out error and penumbral distortion are significantly reduced.

A further factor which can degrade resolution is mask contrast. Figure 30 shows the linear absorption coefficient α of some of the most absorbing and some of the most transparent materials available. Except for discontinuities at absorption edges, the absorption increases with increasing wavelength. It should be noted that the most absorbing materials are only about a factor of 50 higher in their absorption coefficient than the most transparent materials. Thus mask substrates have to be relatively thin to have sufficient transmission and the absorber pattern has to be relatively thick

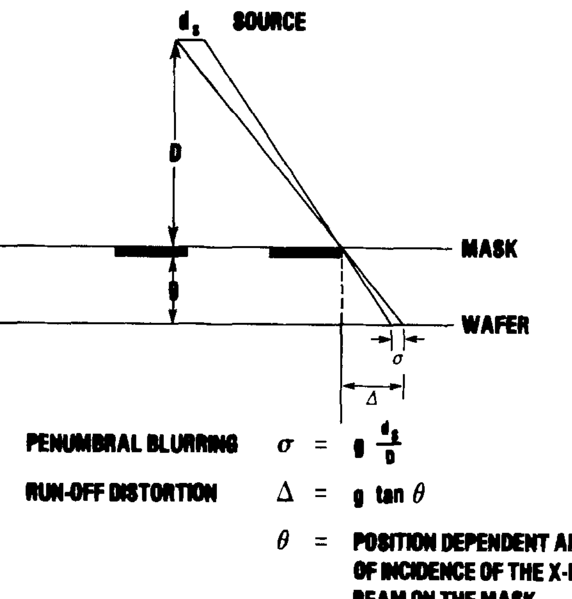

Fig. 29. Schematic diagam of an x-ray exposure system showing the types of geometric distortion encountered.

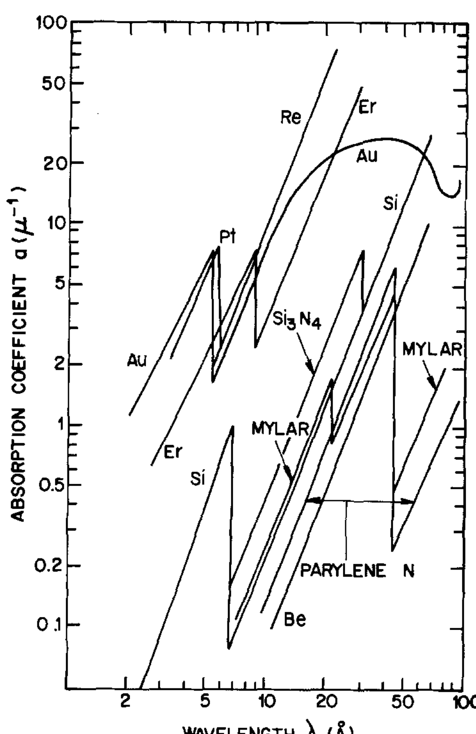

Fig. 30. Absorption coefficient of some of the most absorbing and most transparent materials for soft x-rays.

to attenuate x-rays sufficiently. Contrast is the ratio of the transmission of the "clear" area to the transmission of the "opaque" area. A low contrast mask will give rise to some additional spurious exposure of the resist (55) as shown in Fig. 31. The additional exposure is caused by (*i*) continuous x-rays, (*ii*) secondary electrons and Auger electrons ejected from the x-ray mask, and (*iii*) secondary electrons ejected from the resist substrate. As an example of the effect of continuous radiation, for an 8:1 contrast ratio in an x-ray resist exposed with a Pd x-ray source, 7000Å of gold is required for the absorber pattern on the mask. In comparison, if the exposure were done by 4.4Å characteristic radiation only, 4500Å of gold would give the same contrast ratio. Likewise the secondary electrons and Auger electrons contribute to the exposure of the resist in the regions underneath the gold layers and therefore decrease the resolution and contrast of the exposed pattern.

The fact that absorption coefficients for x-rays vary roughly as λ^3 between absorption edges favors the use of short wavelengths to penetrate the mask substrate and long wavelengths to be absorbed by the patterned areas. The selected wavelength is therefore a compromise between the desire to obtain as much transmission as possible and as much contrast as possible. For patterns with dimensions around 1 μm, the wavelength region between 4 and 50Å represents an acceptable compromise.

Mask contrast is also important in determining the shot noise limitation for the sensitivity of the resist (56). The shot noise in the absorption of photons defines a limitation for the sensitivity of any detector. Consider the average number $\bar{n}$ of x-ray photons absorbed in a small volume of resist (Fig. 32) to be given by

$$\bar{n} = \frac{E}{h\nu} A\delta^2 \quad [39]$$

where E is the incident exposure density, $h\nu$ is the energy of each x-ray photon, and A is the fraction of the incident energy which is absorbed in the resolution element of resist with lateral dimension δ and a thickness d. It is assumed that the resist is ideal, *i.e.*, there are no other limitations on its performance; the resist contrast is infinite. The absorption is given by

$$A = 1 - e^{-\alpha d} \quad [40]$$

$$A \approx \alpha d \quad \text{for} \quad \alpha << 1 \quad [41]$$

where α is the linear absorption coefficient. Since photons actually arrive at random, the actual number of photons absorbed in different resolution elements will deviate from the average value. These deviations

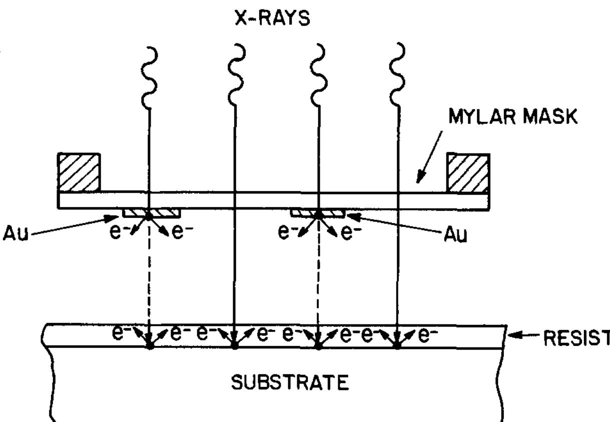

Fig. 31. Schematic representation of spurious exposure effects affecting the x-ray exposure [from J. R. Maldonado, G. A. Coquin, D. Maydan, and S. Somekh, *J. Vac. Sci. Technol.*, **12**, 1329 (1975)].

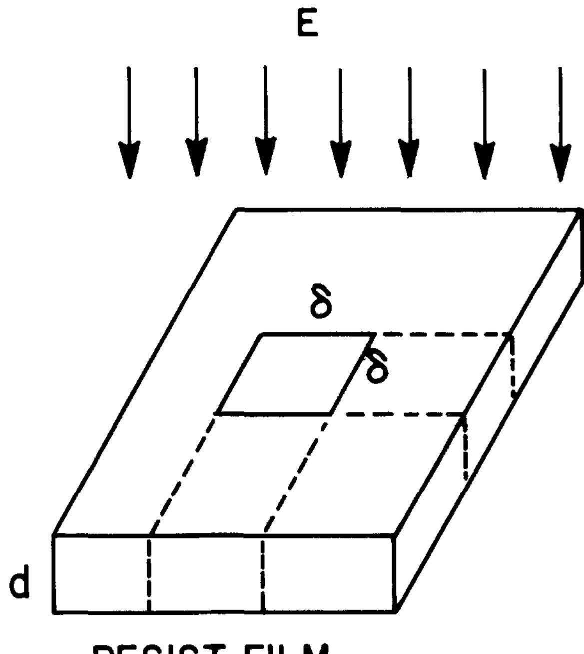

Fig. 32. Schematic resolution element in a resist film

from the average value are responsible for the performance limitations of an ideal resist. The probability of absorbing photons in one resolution element for which the average number of absorbed photons per resolution element is $\bar{n}$ is determined by the Poisson distribution

$$p(n, \bar{n}) = \frac{\bar{n}^n}{n!} e^{-\bar{n}} \quad [42]$$

Which for large $\bar{n}$ can be approximated by

$$p(n, \bar{n}) \approx \frac{1}{\sqrt{2\pi \bar{n}}} \exp\left[\frac{-(n - \bar{n})^2}{2\bar{n}}\right] \quad [43]$$

The Poisson distribution has a width defined by its standard deviation

$$\sigma = \sqrt{\bar{n}} \quad [44]$$

Let us now assume that the "clear" areas of the x-ray mask have a transmission of 1 and that the "opaque" areas have a transmission of T. The average exposure in the "opaque" area is then reduced to $\bar{n}_T = T\bar{n}$ as compared to the value $\bar{n}$ in the "clear" parts of the mask.

The probability $p(n)$ of observing n photons in a resolution element is plotted in Fig. 33 for areas under the clear and opaque parts of the mask for an exposure in which $\bar{n} = 15$ in the clear part and $\bar{n}_T = 7.5$ in the opaque part ($T = 0.5$). It can be seen from Fig. 33 that the two distributions overlap. Thus there is no way of knowing from the exposed resist copy whether the mask was transparent or opaque in a special area for observed photon absorptions which are in the overlap region. For an ideal resist we might define an optimum threshold value n_{opt} such that all elements which received $n \leq n_{opt}$ photons are developing as if not exposed and all resist areas with $n \geqq n_{opt}$ are recognized as exposed areas and then choose n_{opt} in such a way as to minimize the probability for an error. Whenever we observe $n \leq n_{opt}$ photons in the clear sections of the mask or $n > n_{opt}$ photons in the opaque sections, we have made an error and produced a defect. The probability P_{def} for such a defect is

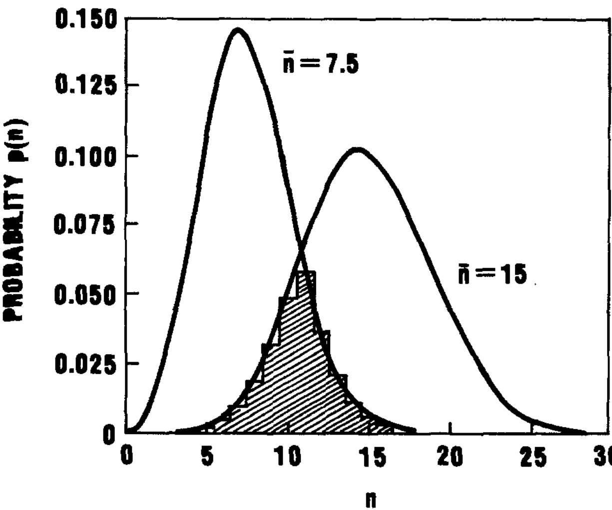

Fig. 33. Poisson distribution for an exposure $\bar{n} = 15$ in the clear and $\bar{n} = 7.5$ in the opaque areas of the mask ($T = 0.5$). The shaded area represents the probability for a defect which occurs when more than $n_{opt} = 11$ photons are observed in opaque areas or $n_{opt} = 11$ or less photons for the clear areas of the mask [from E. Spiller and R. Feder, Topics in Applied Physics, Vol. 22, "X-Ray Optics, Applications to Solids," Chap. 3, H. J. Queisser, Editor, Springer Verlag, Berlin (1977)].

$$P_{def} = \sum_{n=0}^{n_{opt}} p(n, \bar{n}) + \sum_{n=n_{opt}}^{\infty} p(n, T \cdot \bar{n}) \quad [45]$$

In Fig. 33, P_{def} is represented by the shaded area under the two Poisson distributions. The defect probability becomes smaller for a larger separation of the two Poisson distributions which can be achieved by increasing the exposure and/or by increasing the contrast of the mask.

Figure 34 is a plot of P_{def} as a function of exposure for various transmission values of the absorber pattern. For high contrast masks ($T < 0.02$) practically defect-free resist copies ($P_{def} < 10^{-6}$) can be obtained with exposures $\bar{n} > 30$. For masks of low contrast ($T \approx 1$) the exposure has to be increased drastically to obtain a similar performance. The 3σ criterion is a widely used measure for an acceptable low error probability. This requires that the overlap of the two Poisson distributions should only occur outside the 3σ limit of each distribution. The separation of the two distributions should be three times the standard deviation of each distribution

$$\bar{n} - T \cdot \bar{n} = 3\sigma_{clear} + 3\sigma_{opaque} \quad [46]$$

combining Eq. [44] and [46] we obtain for the required exposure

$$\bar{n} = 9/(1 - \sqrt{T})^2 \quad [47]$$

Thus, low contrast masks require higher exposures, *i.e.*, less sensitive resists, to obtain a predetermined defect density. The minimum value of $\bar{n}$ required to expose the resist is given by Eq. [39]. Equation [47] then gives the mask contrast required to meet the 3σ defect limit.

As mentioned already, the intrinsic resolution attainable with x-ray lithography is determined by the effective range of the primary photo-electrons and is as low as 50Å for a C_K x-ray ($\lambda = 44.7$Å). In order to test the resolution capability of x-ray lithography, one needs a mask. High-resolution test masks have been fabricated by electron beam lithography and have allowed replication of 0.1 μm geometries with x-ray lithography (52). The technique allows sharp vertical sidewalls and large aspect ratios to be obtained. Figure 35 shows a scanning electron micrograph of the cross section of a 1600Å linewidth grating pattern exposed in an 8500Å thick PMMA film on an SiO_2/Si substrate using Cu_L x-ray radiation at 13.3Å. The slight curvature of the grating lines are believed caused by overdevelopment which led to softening of the PMMA.

Ion beam lithography.—Resolution in ion beam lithography is determined by ion scattering and scattering of the resultant secondary electrons (57). The contribution of each to the overall transverse energy distribution is a function of the energy and atomic number Z of the ions. For ions of high Z and high energy for which the range may be considerably greater than the resist thickness, resolution is primarily determined by the range of the secondary electrons. For a large Z ion, *e.g.*, O^+ at 1.5 MeV, the velocity of the scattered electron is relatively small and so they have a relatively short range. In addition, the cross section for electron scattering from a heavy ion is greater so

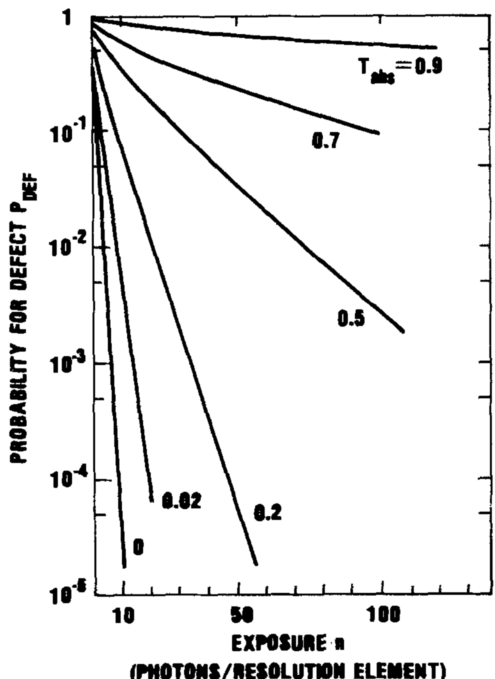

Fig. 34. Probability for a defect P_{def} as a function of exposure in the clear areas of a mask for an ideal resist for different transmission values in the opaque areas of the mask [from E. Spiller and R. Feder, Topics in Applied Physics, Vol. 22, "X-Ray Optics, Applications to Solids," Chap. 3, H. J. Queisser, Editor, Springer Verlag, Berlin (1977)].

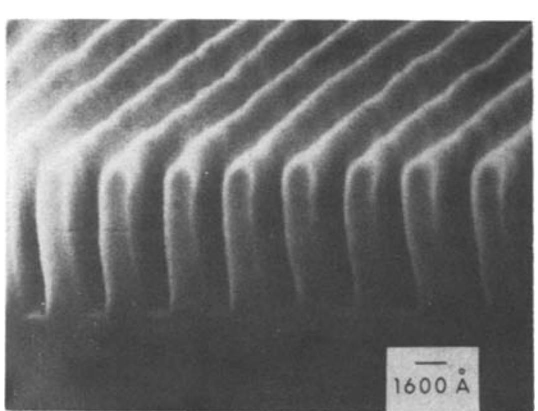

Fig. 35. Scanning electron micrograph of the cross section of a 1600Å linewidth grating pattern exposed in 8500Å thick PMMA on an Si/SiO_2 substrate using Cu_L x-rays at 13.3Å [from D. C. Flanders, H. I. Smith, H. W. Lehmansi, R. Widmer, and D. C. Shaver, *Appl. Phys. Lett.*, **32**, 112 (1978)].

the deposited energy density is high in the center of the particle track extending out to perhaps 100Å. For a lighter particle at the same energy, the secondaries have much higher velocities and hence a larger range. This situation is schematically represented in Fig. 36 which shows the radial distribution of deposited energy by secondary electrons for 1.5 MeV O^+, He^+, and H^+.

On the other hand, the range of secondary electrons for ions of low Z and energy, *e.g.*, 50 keV H^+ is very small ($\leqq$50Å) and resolution is primarily determined by ion scattering. Thus the practical resolution can be varied depending on choice and energy of the ion.

The amount of energy deposited by an ion per unit track length (dE/dx) as it passes through a resist is considerably greater than for electrons. The dissipation for 1.5 MeV O^+ is about 800 eV/nm, for 1.5 MeV He^+ is about 200 eV/nm, and for 1.5 MeV H^+ is about 20 eV/nm. The dissipation for 10 keV electrons is about 4 eV/nm and for 20 kV electrons is about 2 eV/nm. Thus the resist sensitivity in terms of incident dose (C/cm^2) is considerably greater [about one to two orders of magnitude (58)] for an ion beam exposure than for an electron beam exposure. One might expect that on the basis of absorbed energy, resists would have the same sensitivity. Preliminary results indicate however that the amount of deposited energy to achieve the same degree of exposure is not constant as one goes from electrons through light ions to heavy ions (57). Thus the resist chemistry is a function of the energy transfer function, *i.e.*, dose rate.

Chemical Limitations

We have seen that several factors contribute to inherent loss of resolution depending on the particular exposure technology. Diffraction of light, scattering of primary, secondary, and photo electrons, scattering of ions, and mask-related problems all contribute to energy deposition in areas remote from the point of entry of the impinging radiation. The scattered energy can cause chemical changes in the resist thereby leading to resolution loss. Thus an understanding of resist response, which has common elements for all exposure technologies, is important in determining the maximum resolution attainable with a given set of process conditions. The resist response function which primarily determines resolution is the contrast (γ). Contrast in the case of negative resist is related to the rate of cross-linked network (gel) formation and may be conveniently measured by exposing pads of known area to varying radiation doses. Gel is not formed until a certain dose, termed the interface gel dose ($D^i{}_g$), has been reached. Thereafter, the gel content increases with increasing dose; consequently the thickness remaining after development increases until, ultimately, the thickness of the developed pad is equal to the original film thickness (in practice it is slightly less due to volume contraction during cross-linking). This situation is shown schematicallly in Fig. 37a. Resist contrast (γ_n) is then defined as (59)

$$\gamma_n = 1/(\log D^0{}_g - \log D^i{}_g = \left[\log \frac{D^0{}_g}{D^i{}_g}\right] \quad [48]$$

where $D^0{}_g$ is the dose required to produce 100% initial film thickness and it is determined by extrapolating the linear portion of the thickness *vs.* dose plot to a value of 1.0 normalized film thickness. We may also note here that the sensitivity of a negative resist is usually taken as the dose ($D^{0.5}{}_g$) required to cross-link the film so that 50% of the initial film thickness

Fig. 36. Schematic representation of radial distribution of deposited energy by secondary electrons for O^+, He^+, and H^+ [from T. M. Hall, A. Wagner, and L. F. Thompson, *J. Vac. Sci. Technol.*, **16**, 1889 (1979)].

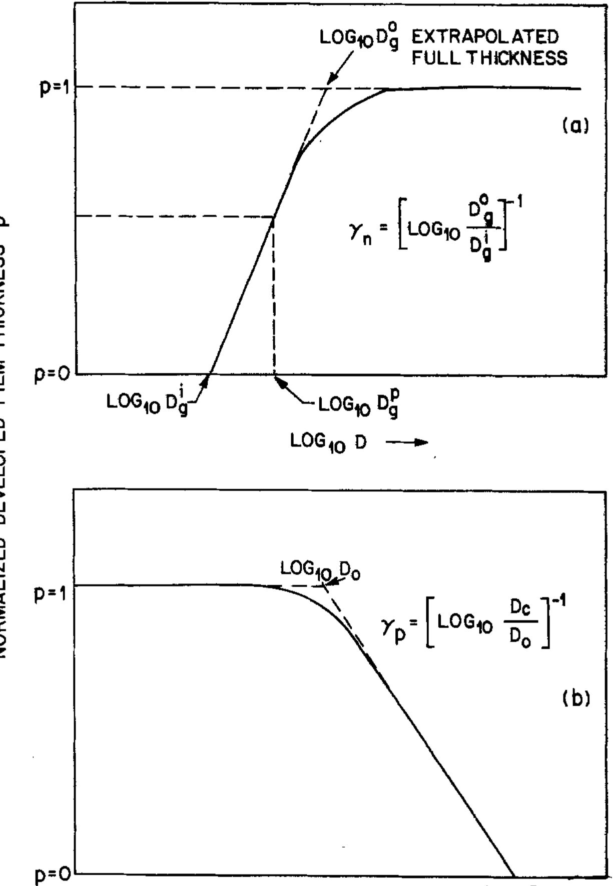

Fig. 37. Typical response or contrast curves for (a) negative resists and (b) positive resists.

remains after development. A residual film thickness 50% of the original film thickness is chosen somewhat arbitrarily as representing that thickness required for the resist to serve as a lithographically useful etch mask (60). Other considerations may dictate different thicknesses.

For a positive resist, the film thickness of the irradiated region remaining after development decreases, until eventually a dose D_c is reached, which results in complete removal of the film on development (Fig. 37b). This value also represents the sensitivity of a positive resist. Contrast (γ_p) is related to the rate of degradation of molecular weight and is defined as

$$\gamma_p = 1/(\log D_c - \log D_0) = \left[\log \frac{D_c}{D_0}\right] \quad [49]$$

where D_0 is the dose at which the developer begins to attack the irradiated film and is determined by extrapolating the linear portion of the film thickness remaining *vs.* dose plot to a value of 1.0 normalized initial film thickness.

Most negative resists operate on a cross-linking principle and most positive resists operate on a chain scission principle to achieve differential solubility. These mechanisms will be assumed for the purpose of the following discussion although it is recognized that other mechanisms like those operative in positive resists for photolithography at conventional wavelengths do exist. The reader is referred to the pertinent references for discussion of these mechanistic differences (61, 62).

Regardless of mechanism, it is the resist contrast which determines the response of the resist in regions remote from the point of entry of the exposing radiation. The contrast of positive resists such as PMMA or poly(butene-1 sulfone) PBS, is greater than 2 and is much higher than that of negative resists whose contrasts lie in the range between 0.5 exemplified by epoxidized polybutadiene to about 2 for monodisperse polystyrene. Positive resists accordingly show a higher resolution than negative resists although as we have already noted, resolution in negative resists is also determined by other factors such as swelling. Within negative resists, resolution is directly proportional to contrast.

Optical projection printing provides an excellent example of the importance of contrast. We saw earlier that the modulation transfer function provides a convenient measure of the range of exposure or light intensity levels achievable with a given pattern. Although the cut-off frequency of the MTF curve (*cf.* Fig. 4) indicates the resolution limit for the exposure tool, it is the resist contrast which determines the minimum MTF for acceptable imaging. For a given resist system, image development requires that the optically determined MTF exceeds some critical value related to the contrast characteristic of the resist material. This critical value has been defined as (63)

$$(\text{CMTF})_{\text{resist}} = \frac{I_{100} - I_0}{I_{100} + I_0} \quad [50]$$

where I_{100} is the minimum exposure energy for 100% exposure and I_0 is the maximum exposure energy for zero exposure (I_{100} is equivalent to D^0_g or D_c in Eq. [48] and [49]; likewise I_0 is equivalent to D^i_g or D_0). The contrast of the resist is related to the (CMTF) resist as shown in Fig. 38. The minimum sized printable feature using any combination of resist and lens is then determined by the condition $(\text{MTF})_{\text{optical}} \geqq (\text{CMTF})_{\text{resist}}$. The $(\text{CMTF})_{\text{resist}}$ for polymer resists is commonly quoted to be 0.6. Some newly developed negative inorganic resists exhibit contrasts three to four times greater than that of polymeric resists thereby facilitating imaging at higher frequencies than is possible with polymer-based resists (63).

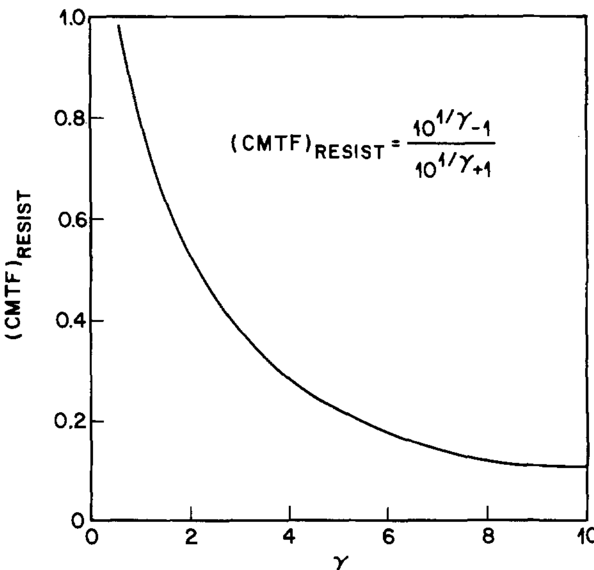

Fig. 38. $(\text{CMTF})_{\text{resist}}$ as a function of resist contrast [from K. L. Tai R. G. Vadimsky, C. T. Kemmerer, J. S. Wagner, V. E. Lamberti, and A. G. Timko, *J. Vac. Sci. Technol.*, **17**, 1169 (1980)].

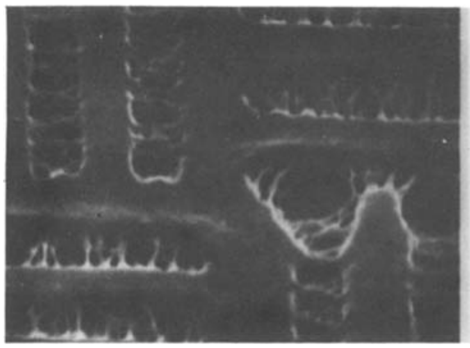
There is very little quantitative information on those factors which determine resist contrast. Attempts (64) have been made to describe the lithographic response curves in terms of physical-chemical processes particularly those accompanying cross-linking in sol-gel behavior in bulk samples. These processes include: (*i*) changes in molecular weight distribution; (*ii*) competition between cross-linking and degradation of polymer chains, and (*iii*) chemical amplification of the cross-linking process. In general though, theoretical arguments have only guided discussions of contrast (65).

The other major factor limiting resolution, particularly in negative resists, is swelling of the exposed areas during developing. Neighboring exposed areas swell during the development process and when those areas are close together, the swollen regions can fuse giving rise to "stringers" between exposed regions (Fig. 39). Swelling can also occur in positive resists such as poly(isobutylene) giving rise to poor resolution (61).

Nevertheless, in spite of the lack of a quantitative understanding of many of these factors, there is considerable body of information which can be applied to resist design in order to maximize sensitivity and contrast. Clearly, positive resists which operate on the chain scission principle should possess a high susceptibility to degradation (high *G*-value for scission) with negligible concurrent cross-linking (low *G*-value for cross-linking). [The *G*-value is a measure of radiation sensitivity and is the number of events (scission on cross-linking in this case) per 100 eV of energy absorbed]. Optimum sensitivity and contrast for a given system usually requires high molecular weight and narrow molecular weight distribution. Negative resists operating on the cross-linking principle should possess high *G* (cross-linking) and negligible *G* (scission), high initial molecular weight, and narrow molecular weight distribution. The implications of these design features to actual polymeric resist systems have been extensively reviewed (59, 61).

Polymers generally dissolve by first imbibing solvent to produce a swollen gel followed by disintegration of the gel into a true solution (54). In the case of negative resists, the swollen gel is insoluble and development involves leaching the soluble uncross-



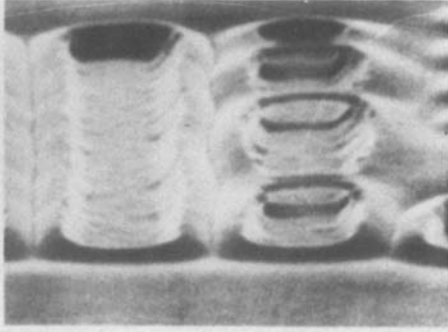


Fig. 39. Photomicrograph showing bridging between adjacent features caused by swelling during development [from D. W. Johnson, SPIE Vol. 174, Developments in Semiconductor Microlithography IV, 108 (1979)].

linked material from the gel. Positive resists form a swollen gel layer between the solvent and virgin polymer. Development involves dissolution of the gel portion as the solvent front moves through the polymer. The degree of swelling in both cases can be minimized by choice of developer (66, 67). Also, the glass transition temperature of the polymer should be greater than the dissolution temperature. PMMA appears unique among the positive resists (indeed among polymers in general) in that its dissolution mechanism effectively does not involve the formation of a swollen gel layer (54). By proper choice of solvent and temperature, swelling can be minimized in other positive resists such as PBS but unfortunately there is no clear cut understanding of just why PMMA exhibits this unique dissolution mode over the normal room temperature range.

Conclusions

For the near future, it appears that advanced optical lithography systems will be adequate to produce most of the next generation of microcircuits, but below 0.4-0.8 μm some alternative exposure technology will be required. Each of the other technologies is capable of submicron resolution with electron beam and x-ray systems being most advanced with respect to technological development. Electron beam lithography on thin substrates has opened up a new regime of dimensions below 100 nm that is of particular scientific rather than technological interest. The major driving force though in today's electronic industry is cost rather than performance so smaller and smaller dimensions are only desirable if they can be obtained without a large increase in cost. Thus, although the resolution capability of each technology is sufficient for the foreseeable future, the particular technology chosen will be on the basis of cost effectiveness.

Manuscript submitted Aug. 21, 1980; revised manuscript received Dec. 4, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by Bell Laboratories.

Structural Effect of Formic Acid in Electrolytic Solutions of Lithium Perchlorate in Tetrahydrofuran, at 298.15 K

E. T. de Almeida and A. A. Inocêncio*

Departamento de Química, Fundação Universidade de Brasília, 70910, Brasília, D.F., Brazil

ABSTRACT

The structural changes of electrolytic solutions of $LiClO_4$ in tetrahydrofuran (THF), caused by addition of HCOOH at 298.15 K, have been studied. The conductance data at different solvent composition showed the presence of ion pairs, triple ions, and quadrupoles in the solution. The measured viscosity, dielectric constant, electric conductance, and density values were used to calculate the equivalent conductivity at infinite dilution for simple ions Λ^{∞}, the association constant for the ion pairs, K_a, and the formation constant for the triple ions, K_t.

Interest in studying the physical properties of organic electrolytic solutions arises mainly from the likely application of the results to the improvement of lithium batteries in organic solvents. The knowledge of the physical parameters such as Λ, ϵ, η, ρ, and the constants of ionic association K_a, K_t, and K_q, becomes particularly important in connection to lithium batteries in organic solvents that use liquid catholytes such as H_2O, HCOOH, CH_3OH, etc., owing to the structural effect of those cathodic reactants in the organic electrolytic solution itself, *e.g.*, a solution of $LiClO_4$ in tetrahydrofuran or propylene carbonate (1-3). The results obtained in the present work may help the lithium cell manufacturers to choose optimum composition of the electrolyte in order to get minimum internal ohmic drop, using a minimum amount of the rather expensive electrolyte ($LiClO_4$), and maximum energetic capacity of the cell. This paper deals with the results obtained for HCOOH in an electrolytic solution of $LiClO_4$ in THF.

Experimental

A Leeds and Northrup bridge (Cat. No. 4866-60), and a Beckman pipette-type conductivity cell were used in all the conductance measurements. The cell constant L was obtained according to Jones and Bradshaw (4), with 0.01D solutions of KCl. A mean value of $L = 1.013 \pm 0.003$ cm^{-1} was found for 5 measurements. A Sargent oscillometer Model V, calibrated with standards of known dielectric constant, was used. The expression, $\epsilon = 2.107 + 2.646\ 10^{-4}S$, obtained by the least squares method, relates the dielectric constant ϵ, with the scale reading of the instrument S. Two Ostwald viscosimeters were used, calibrated with conductivity water $\eta_{H_2O} = 0.8903$ cp (5) and THF, $\eta_{THF} = 0.4583$ cp (6), as standards and utilizing the Jones and Stauffer equation (7), $\eta = A\rho t\text{-}B\ (\rho/t)$. All calibrations and measurements were carried out at 298.15 (± 0.02) K. The chemicals used were: tetrahydrofuran (THF), Merck p.a., density at 298.15 K, $\rho_{THF} = 0.8820$ (± 0.001) g cm^{-3}, measured with a 25 cm^{-3} picnometer and a Metler balance Model H20-T, compares well with the values found in the literature: 0.880 and 0.883 (8, 9). The measured dielectric constant $\epsilon_{THF} = 7.39$ also agreed with the values found in the literature (8, 9). Critchfield (10), by measuring the dielectric constant of THF as a function of water concentration, reported a value $\epsilon_{THF} = 7.39$ for 100% THF. The NMR and infrared spectra did not show the presence of water and consequently, it was used without any further purification. Anhydrous lithium perchlorate ($LiClO_4$) used was FLUKA, A.G., pure grade. The product showed no weight loss in an oven test after being heated at 463.15 K for 2-3 days. The reagent was carefully stored in a desiccator over $CaCl_2$. While preparing the solutions the bottle was left opened for the shortest possible time. In this way, the water content was always maintained below the limit of sensibility of the physical constants to be measured (Λ, η, ϵ, ρ), and therefore its influence in the experimental results cannot be significant. Formic acid (HCOOH), Merck p.a., was used without further purification. Potassium chlorite (KCl), Merck p.a., was dried at 443.15 K and low pressure in an oil bath to constant weight and stored in a desiccator over $CaCl_2$. Conductivity water was prepared according to Morita (11) using a borosilicate glass condenser. The mixtures of THF and HCOOH and the solutions of $LiClO_4$ in these mixtures, were prepared separately by weighing, and were used within 4 hr after being prepared.

Results and Discussion

Table I shows some physical properties of the THF + HCOOH mixtures. The density of 6-8 solutions of $LiClO_4$ in this mixture, at constant composition, was measured and the results fit a quadratic equation, of the type $\rho = a + bm + cm^2$. A plot of this equation was employed to get the density of any other solution

Key words: formic acid, electrolytic solutions, organic solvents, tetrahydrofuran, lithium perchlorate.

Table I. Physical properties of the solvent (THF + HCOOH)

Mass percent HCOOH	ρ/kg dm^{-3}	ϵ/D	η/cp	k/S cm^{-1}
0.0	0.8820	7.39	0.4583	—
1.5	0.8885	7.60	0.4696	4.6×10^{-10}
3.0	0.8907	7.80	0.4906	2.9×10^{-9}
5.0	0.8970	8.00	0.4857	1.1×10^{-8}
10.0	0.9046	8.90	0.5270	7.1×10^{-8}
15.0	0.9196	9.75	0.5526	2.1×10^{-7}

of the same solvent composition, Table II. In the equation above m is the molality, a, b, and c are constants.

The viscosity of the solutions becomes greater as the concentration of the HCOOH increases, because $\eta_{HCOOH} = 1.61$ cp (5) is greater than $\eta_{THF} = 0.4583$ cp (6). For each solvent composition the viscosity becomes greater too, as the concentration of $LiClO_4$ increases. The relative viscosity, η/η_o, η and η_o being the viscosity of the solution and of the solvent, respectively, fit a curve, whose analytical expression was found to be $\eta/\eta_o = 1 - 0.5776\sqrt{c} + 1.590c$.

It was also found that the logarithm of the electrical specific conductivity for solvent mixtures of THF and HCOOH log k, is a linear function of the logarithm of the mass percent of HCOOH, log $(100w)$, according to the equation $\log k = 2.65 \log (100w) - 9.80$; this expression was used to extrapolate the values of k for low values of the mass percent of HCOOH, when k went out of the scale of the conductance bridge. Figure 1 shows plots of log Λ *vs.* the logarithm of the concentration of the electrolyte ($LiClO_4$) in the solvent mixture, log c. The electrical conductance of the solutions increases with the percentage of the HCOOH (w/w) in the solvent mixture, Table III. This can be explained, partly, by the increase of the dielectric constant. With the increase in dielectric constant the ionic interactions become weaker and the ionic dissociation easier.

Equivalent conductivity at infinite dilution (Λ^∞).—The equivalent conductivity at infinite dilution Λ^∞ cannot be obtained by extrapolating the curves $\Lambda =$

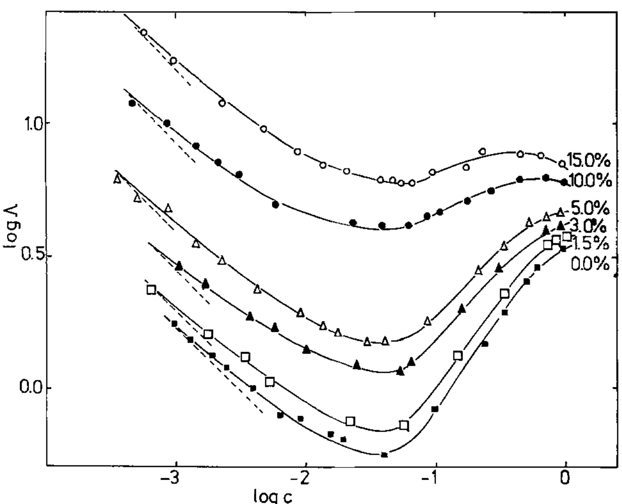

Fig. 1. Logarithm of the equivalent conductivity of $LiClO_4$ in THF + HCOOH (log Λ), vs. logarithm of the concentration of $LiClO_4$ (log c) at 298.15 K and different solvent composition (mass percent HCOOH).

$\Lambda(\sqrt{c})$, by Onsager's method (12), because Onsager's equation is not obeyed at the low concentrations at which the measurements were carried out. The plots of F/Λ against $c\Lambda\gamma^2_{\pm}/F$, which are straight lines with intercept $1/\Lambda^\infty$ and slope $1/K_a\ \Lambda^{\infty 2}$ for concentrations less than $3 \cdot 10^{-7}\ \epsilon^3$, cannot be used either, because the concentrations here were much higher (12, 14). The expression

$$K_a = 4\Lambda^{\infty 2}/(c\Lambda^2)_{\text{min.}} \qquad [1]$$

obtained from the condition for a minimum of $\Lambda = \Lambda(\sqrt{c})$ (15), cannot be used either because the mass action constant K_d, for the equilibrium

$$A^+ + B^- \underset{k_1}{\overset{k_{-1}}{\rightleftarrows}} AB \qquad [2]$$

is unknown. Therefore, the Walden's rule $\Lambda^\infty \cdot \eta_o$ = const., must be tried, where η_o is the viscosity of the solvent. If the dielectric constant ϵ does not vary much and one of the components of the binary mixture is predominant, this rule is accurate enough as to be applied. In the present work, the concentration of HCOOH in the THF did not exceed 15%, and the value of the dielectric constant laid between 7.39 and 9.75. The ionic equivalent conductivity for Li^+ and ClO_4^- are known from the literature: $\lambda^\infty_{Li^+} = 36.6$ S cm² eq⁻¹ (17) and $\lambda^\infty_{ClO_4^-} = 119.5$ S cm² eq⁻¹ (18), giving $\Lambda^\infty_{LiClO_4} = 156.1$ S cm² eq⁻¹, in THF (6). The results in Table IV were obtained with this value for $\Lambda^\infty_{LiClO_4}$. Out of this value λ_+^∞ and λ_-^∞, were calculated assuming that the transport number at infinite dilution does not vary too much with the concentration of formic acid.

Ionic association.—The shape of the plots log Λ *vs.* log c (Fig. 1) shows the existence of different types of ionic association in the electrolytic solution. At low concentration of $LiClO_4$, the slope of the curves, *d* log Λ/d log c ≃ − ½, with small $K_a^{-1} = k_1/k_{-1}$, is characteristic for ion association in strong electrolytes (17-19). As log c increases, the slope *d* log Λ/*d* log c tends to zero, taking this value at the minimum of the curves. This minimum shows the existence of triple ions, which are electrically charged and therefore contribute to the electrical conduction. At some distance after the minimum *d* log Λ/*d* log c diminish and the curves tend to a maximum. This shows the existence of quadrupoles, that being electrically neutral, cause the decrease of the electrical conductance. As the concentration of the HCOOH in the solution increases, a shift of the maximum of the curves toward lower values of log c is noted. For concentrations of HCOOH higher than 10%, the maximum of the curves is found at concentrations of the electrolyte lower than 1 eq dm⁻³. The electrolyte concentration at the minimum of the curves obeys the empirical rule of Walden, $\epsilon^3/c_{\text{min.}}$ = constant, wherein ϵ is the dielectric constant of the solvent (Table V). The main source of error in calculating the constant is perhaps the difficulty in localizing the minimum of the curve.

Ion pair association.—The plot of F/Λ against $c\Lambda\gamma^2_{\pm}/F$, $\gamma_{\pm}$ being the mean ionic activity coefficient and *F* a continued fraction, gives, according to Fuoss and Kraus, good straight lines at low concentrations (Fig. 2), but the values of Λ^∞ obtained from the intercept $(1/\Lambda^\infty)$ are too low (5-7 S cm² mol⁻¹). This shows the influence of ion associations of higher order, as it is expected at concentrations larger than 3.2 $10^{-7}\ \epsilon^3$ at 298.15 K (14). The presence of triple ions rather than the slope of a Fuoss-Kraus plot seems to affect the intercept and therefore the determination of Λ^∞ (6). With the values of Λ^∞ obtained by using Walden's rule, the association constant K_a can be obtained from the slope (Table VIA). Only the first value in this table can be compared with those values known from the literature. It is rather low when compared with K_a = 4.84 10⁷ mol⁻¹ dm³ found by Jagodzinski and Petrucci (6), with K_a = 3.60 10⁻⁷ mol⁻¹ dm³ given by Nicolas and Reich at 293.15 K (20) and with K_a = 1.56 10⁻⁷ mol⁻¹ dm³, obtained here using Eq. [1] (Table VIB). Consequently, it may be postulated that the K_a values in column B of Table VI are more reliable than those in column A, at least up to a concentration of 5% HCOOH in the solvent mixture, since the first value (mass percent HCOOH = 0) compares well with the one reported in Ref. (6) and (20). After a concentration of 5% HCOOH the error in localizing the minimum of the curves in Fig. 1 becomes greater. In both cases the K_a values decrease with increasing HCOOH concentration or with the permittivity of the medium, which is quite reasonable.

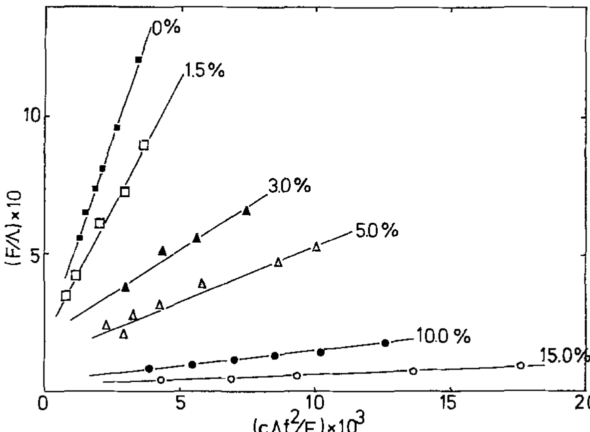

Fig. 2. Ion pair analysis, according to Fuoss and Kraus

Triple ion analysis.—The minimum of the curves in Fig. 1 shows the presence of triple ions in the electrolytic solution. The shape of the same curves at higher electrolytic concentrations shows the presence of quadrupoles too. If the influence of these quadrupoles could be neglected, a plot of $\Lambda \sqrt{c}\, g(c)$ against $(1 - \Lambda/\Lambda^{\infty})c$ should give a straight line. Except for low concentrations (Fig. 3a and b) this is not so and this may be due to the influence of the quadrupoles. Using Λ^{∞} from Table IV and taking $\Lambda_t/\Lambda^{\infty} = 1/3$ (15, 21), K_a and K_t can be calculated from the plots of Fig. 3b (Table VIC). The K_a value of this table from 0.0% HCOOH, is now of the same order of magnitude as those known from the literature and of that obtained here using Eq. [1]. It can be assumed that the K_a values for the concentrations 1.5, 3.0, 5.0, 10.0, and 15% HCOOH have also the correct order of magnitude and they are perhaps more reliable than those of Table VIB considering the concentration at which the minimum appears. This is especially so at higher concentration because of the difficulty in localizing the minimum of the curves in Fig. 1. Although these K_a values were obtained using a mathematical analysis for the case where aggregates up to the third order existed while the experimental results showed the presence of aggregates of higher order, this fact does not invalidate them at all, because they were calculated taking only the electrolyte concentrations where the influence of quadrupoles is not decisive.

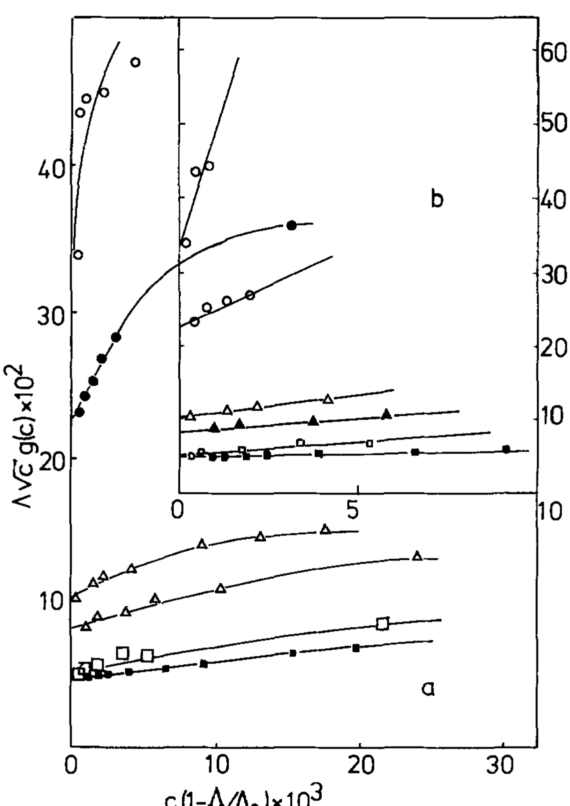

Fig. 3. (a) Triple ion analysis, according to Fuoss and Kraus. b) Amplification of (a) at low concentrations.

The change of the K_t values with increasing percentage of HCOOH, that in our opinion cannot be attributed to the error from applying Walden's rule, is rather surprising. As a matter of fact, an increase of dielectric constant would hinder the triple ion formation, but the experimental results showed that the contrary was true: The constant for the triple ion formation K_t had a value of 73 $dm^3\ mol^{-1}$ for $LiClO_4$ in THF + 0% HCOOH, and reaches 1,450 $dm^3\ mol^{-1}$ in THF + 15% HCOOH. This fact leads to the assumption that the formic acid shares the triple ion formation. It seems that the dissociation of the formic acid is favored by the presence of ionic species in the solution. The H^+ and HCOO ions seem to associate with the perchlorate ion pairs to give rise to triple ions. The apparent equivalent conductivity at infinite dilution $(\Lambda^{\infty}_{LiClO_4})_{app}$, would be the sum of the actual equivalent conductivity at infinite dilution $(\Lambda^{\infty}_{LiClO_4})_{act}$ plus the equivalent conductivity of the triple ions Λ_t: $(\Lambda^{\infty}_{LiClO_4})_{app} = (\Lambda^{\infty}_{LiClO_4})_{act} + \Lambda_t$.

Conclusion

The experimental results discussed above showed that the addition of HCOOH to the electrolytic solution of $LiClO_4$ in THF changes their physical properties and microscopic structure as well. The increase of the HCOOH concentration is not favorable to the ion pair formation (the K_a values decrease) but is favorable to the triple ion formation (K_t increases). The quadrupole association becomes important at lower $LiClO_4$ concentrations as the HCOOH concentration in the solvent mixture increases.

Thermodynamic Study of the Lithium-Tin System

C. John Wen*,[1] and R. A. Huggins*

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

A thermodynamic study of the lithium-tin system was made using galvanic cells of the type

Al, "LiAl"/LiCl-KCl (eut.)/Li-Sn

over the temperature range from 360° to 590°C. The composition of the alloy was varied from pure tin to 86 a/o Li using the coulometric titration technique. Coulometric titration curves showed that six intermediate phases exist, with nominal stoichiometric compositions LiSn, Li_7Sn_3, Li_5Sn_2, $Li_{13}Sn_5$, Li_7Sn_2, and $Li_{22}Sn_5$. At low lithium concentrations, the activity of lithium in molten lithium-tin alloys follows Henry's law behavior. The partial and integral molar thermodynamic properties of the lithium-tin system were evaluated as a function of composition from emf measurements at 415°C. The temperature dependence of the standard Gibbs free energies of formation for the six intermediate phases was also determined. The experimental results were used to map out parts of the phase diagram of the lithium-tin system. The homogeneity ranges of the six solid phases are all quite narrow. The phase LiSn congruently melts at about 488°C and the phase Li_7Sn_3 peritectically decomposes at 500°C. These two phases form an eutectic mixture of 57 a/o Li at 470°C. The liquidus line on the tin-rich side of the binary phase diagram was found to agree with data reported in literature.

Solid lithium-aluminum (1, 2) and lithium-silicon (3-5) alloys are currently being utilized instead of pure lithium as anode materials in high performance rechargeable lithium batteries being developed for use as power sources for electric vehicles and as energy storage devices for electric utility load leveling. As they are solid at the operating temperatures (400°-500°C), the retaining problems encountered with molten Li are avoided. Also, since they have lower Li activities, the solubility of Li in the molten salt electrolytes, which causes self-discharge due to increased electronic conduction and diffusion of Li to the other electrode, is significantly reduced. Furthermore, corrosion problems associated with molten lithium are avoided, resulting in less difficult materials selection and cell design problems.

The development of other new lithium battery systems should be aided by the investigation of other solid lithium alloys which might perform better than the lithium-aluminum and lithium-silicon alloys presently used as anode materials. In order to evaluate the suitability of other alloys as active materials for use in negative electrodes, the compositional variations of the lithium activity and the chemical diffusion coefficient within them is required. The former parameter determines both the potential and the capacity of an alloy anode, and thus influences the specific energy when coupled with an appropriate cathode. The electrode potential range must also lie within the stability window of the electrolyte in order to avoid interface reactions. The power is related to the rate processes involved in the electrode reaction. The charge transfer reaction at the electrode-electrolyte interface is generally very rapid in elevated temperature molten salt cells, and is seldom rate limiting. On the other hand, mass transport of the electroactive species within solid electrode phases by chemical diffusion is often quite important.

The properties of lithium-tin alloys relating to their possible use as anode materials have been examined. The results of the thermodynamic studies are reported here. Information about kinetic properties will be reported in a separate publication.

The lithium-tin system was first investigated by Masing and Tammann (6) using thermal and microscopic analysis, and the existence of the compounds Li_4Sn, Li_3Sn_2, and Li_2Sn_5 was claimed. Later, careful thermoresistometric and thermal analysis experiments on 58 alloys by Grube and Meyer (7) revealed a rather more complicated phase diagram. In 1964, structural work (8) showed that the phase originally thought to be Li_4Sn is actually $Li_{22}Sn_5$. Later structural investigations by Hansen and Chang (9) showed that the most tin-rich phase is Li_2Sn_5. Recently, the existence of the phases LiSn (10), Li_5Sn_2 (11), and Li_7Sn_2 (12), which also appear in Hansen's diagram, was confirmed by x-ray diffraction studies. In addition, new phases with nominal compositions of Li_7Sn_3 (13) and $Li_{13}Sn_5$ (14) have also been reported.

The thermodynamic properties of liquid lithium-tin alloys were measured by several investigators at elevated temperatures (15-17). Foster, Crouthamel, and Wood (15) carried out emf measurements on cells of the type

$$Bi,Li_3Bi/LiCl\text{-}LiF\ (30\ m/o)/Li\text{-}Sn \quad (1)$$

* Electrochemical Society Active Member.
[1] Present address: Shell Development Company, Houston, Texas 77001.

Key words: alloy, cell, phases, current.

where the alloy composition varied from 10 atomic percent (a/o) Li to tin saturated with the phase Li_5Sn_2. The temperature range was 800-1050 K. The standard Gibbs free energies of formation for solid Li_5Sn_2 at 800, 850, 900, 950, and 1000 K were determined to be −61.4, −59.8, −57.9, −55.3, and −52.4 kcal/mole, respectively, with an estimated error of 1 kcal/mole. EMF measurements were also made on cells of the type

Li (l)/LiCl-LiF/Li-Sn (l)

at 550°C by Morachevskii and co-workers (17), who calculated the partial and integral molar Gibbs free energies from 4 to 50 a/o Li. Liquid-vapor equilibrium data for the molten lithium-tin system were obtained from vapor pressure measurements using the transpiration technique by Fischer and Johnson (16).

The thermodynamic properties of the liquid lithium-tin alloys show negative deviations from ideal behavior. However, there is no information about the thermodynamic properties of the other phases in the lithium-tin system. Since this type of information is necessary to evaluate the potential use of materials in this system as electrode reactants, experiments were undertaken using techniques developed earlier for such purposes (18-22).

Experimental Details

Coulometric titrations and emf measurements were made using galvanic cells of the type

Al, "LiAl"/LiCl-KCl (eut.)/Li-Sn

where LiCl-KCl (eut.) represents the liquid electrolyte, which was the eutectic mixture of LiCl [58.8 mole percent (m/o)] and KCl (41.2 m/o) with a melting point of 352°C. The above cell was in a three-electrode configuration and it was set up in a controlled atmosphere glove box filled with high purity helium gas. Both counter and reference electrodes were made of two-phase mixtures of the α and β phases, Li-saturated Al and "LiAl," with an overall composition of 40 a/o Li. Pure tin (99.9% Baker Reagent Grade) was used as the starting material for coulometric titration and was placed in a small molybdenum bucket because it is molten at the experimental temperatures (from 360° to 590°C). Alumina crucibles were used to contain the molten salt electrolyte. Molybdenum was earlier shown to be suitable as an electrical lead material at all lithium activities (18-22). Furthermore, the solubility of lithium in molybdenum is negligibly small in the temperature range used in these experiments (23).

The LiCl-KCl eutectic salts were purchased from Lithcoa (Lithium Corporation of America). They were heated in an alumina crucible at 420°C in the glove box for 12 hr before use. Without further purification, these molten salts were clear and colorless.

The reference electrodes were made of cold-pressed pellets of two-phase lithium-aluminum alloy powder (40 a/o) and were held in molybdenum holders. They were prepared by melting preweighed lithium ribbons (99.9% Foote Mineral) and aluminum wires (99.9999% Cominco) together in a molybdenum cup with a cover at 750°C. The temperature was then slowly reduced to about 500°C and maintained there for 12 hr. The resultant solid alloys were crushed and ground to fine powder in a porcelain mortar and pestle. The powder was then cold-pressed into pellets of 3/8 in. diam at a pressure about 8×10^4 psi under a helium atmosphere. The emf of these two-phase reference electrodes relative to pure lithium may be expressed as a function of temperature as (1, 4, 20, 24)

$$E_{Al, \text{"LiAl"}} = 451 - 0.220\, T\ (K)\ mV$$

The counterelectrodes were prepared either by casting into molybdenum buckets under the conditions described above or by an electrochemical method. In the latter case, lithium was titrated into pure aluminum wires up to a composition of 40 a/o Li using molten lithium as the anode and the same eutectic molten salt as an electrolyte.

The use of these two-phase lithium-aluminum alloys as both reference and counterelectrodes offers several advantages over molten lithium. Because they have a lower lithium activity than pure lithium, the solubility of lithium (whose magnitude is not quantitatively known) in the LiCl-KCl eutectic salt is significantly reduced, thus decreasing the electronic leakage current through the electrolyte (25). The displacement reaction to produce potassium vapor (26) is also reduced.

In addition to the many (over 150) compositions produced by the coulometric titration technique, measurements were also made on 31 individually prepared lithium-tin alloys. These alloys were synthesized by use of the fusion technique in the glove box. EMF measurements were made after the synthetic alloys had been equilibrated in cells for at least 24 hr.

The electrochemical measurements were made using a PAR potentiostat/galvanostat (Model 173) with a plug-in digital coulometer (Model 179). The cell temperature was determined by means of two Chromel-Alumel thermocouples sheathed with 304 stainless steel.

Results and Discussion

Figure 1 shows the measured coulometric titration curve for the lithium-tin system at 415°C. The data are depicted by a solid line, as the resolution in such a figure is not sufficient to show the actual points from the more than 150 individual measurements. The emf measurements made on the 31 alloys of various compositions that were individually prepared are also included, as shown by the data points in Fig. 1, for comparison. It is seen that the results for compositions prepared in these two ways show excellent agreement. At that temperature, the solubility of lithium in liquid tin is 36.4 a/o Li, and on the lithium-rich side of this composition there are six intermediate phases within which the voltage varies with composition, and seven two-phase voltage plateaus at which the emf is independent of composition. The homogeneity ranges of the intermediate phases are all quite narrow, and their nominal compositions are LiSn, Li_7Sn_3, Li_5Sn_2, $Li_{13}Sn_5$, Li_7Sn_2, and $Li_{22}Sn_5$. The ranges of stoichiometry and data on the (very high) chemical diffusion coefficients within these six phases will be presented in a separate publication (27). Due to the high chemical diffusion coefficients in these phases, equilibrium could be reached easily in minutes to a few hours for

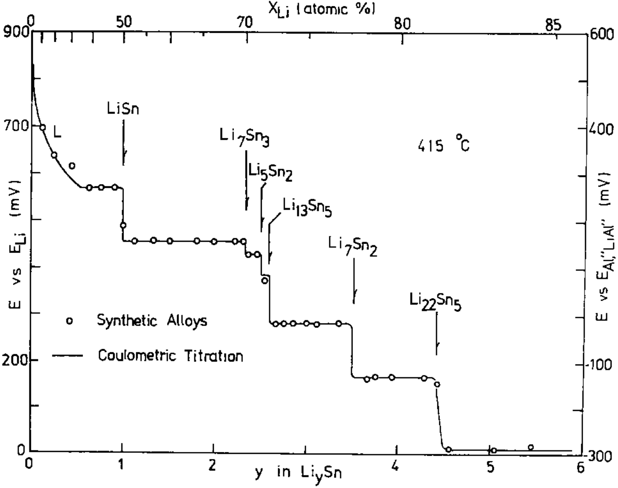

Fig. 1. Coulometric titration curve for the lithium-tin system at 415°C.

all compositions. Data taken by both adding and deleting lithium gave consistent results.

It was found that the activity of lithium, a_{Li}, in the liquid lithium-tin alloy obeyed Henry's law, so that the emf can be expressed by

$$E = -\left(\frac{RT}{\mathbf{F}}\right)\ln a_{Li} = -\left(\frac{RT}{\mathbf{F}}\right)\ln \gamma_{Li}X_{Li} \quad [1]$$

where the activity coefficient of lithium γ_{Li} is constant at a specific temperature. X_{Li} is the mole fraction Li. The experimental results at 415°C are shown in Fig. 2. It is seen that E varies linearly with the logarithm of X_{Li} to a composition of about 10 a/o Li. The slope, expressed as $dE/d\ln X_{Li}$, is 5.92×10^{-2}V, which is equal to the numerical value of $(RT/\mathbf{F})$ at 415°C. The activity coefficient of lithium, γ_{Li}, in this range is 6.44×10^{-5}. The liquid alloys of lithium-cadmium (28), lithium-gallium (29), lithium-indium (30), lithium-lead (31), and lithium-bismuth (32) all exhibit Henry's law behavior at low lithium compositions, and experimental results for these systems are summarized in Table I. In all cases, the activity coefficients of lithium in these liquid alloys are very low, showing negative deviations from Raoult's law.

Although the activity coefficient of lithium in the liquid alloys is independent of composition at low lithium concentrations at a constant temperature, it varies with temperature at a fixed composition. The emf at a constant composition varies approximately linearly with temperature. At the composition of 0.9 a/o Li, the activity coefficient of lithium was found to increase from 3.23×10^{-5} at 372°C to 4.70×10^{-4} at 589°C.

Figures 3 and 4 present typical emf measurements as a function of temperature at a number of compositions. The compositions were fixed by coulometric titration. Over the temperature range of 360°-590°C the measured emf was a linear function of temperature as long as no phase transitions occurred. For those compositions where phase transformations took place as the temperature was varied, the emf curves have changes in slope.

Figure 5 shows the derivative of the emf across the lithium-tin system with respect to temperature. The partial molar entropy of lithium, $\Delta\overline{S}_{Li}$, is also shown in the same plot, but with a different scale, since

$$\Delta\overline{S}_{Li} = \mathbf{F}\left(\frac{\partial E}{\partial T}\right) \quad [2]$$

The partial molar entropy of lithium is seen to vary with composition in the single-phase regions and to be independent of composition in two-phase regions.

Both the relationship between the emf and the temperature in the two-phase regions of the lithium-tin

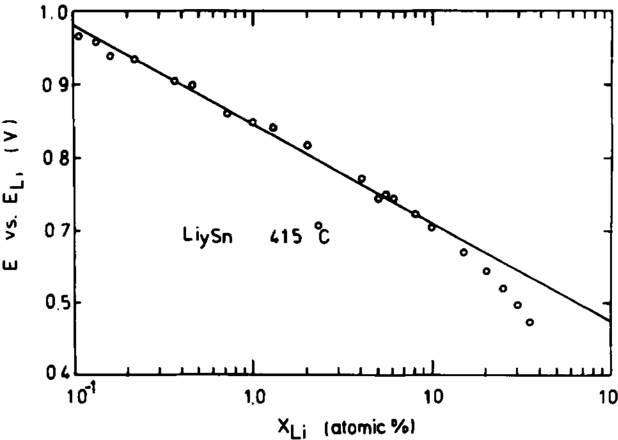

Fig. 2. Semi-logarithmic plot of the emf *vs.* mole fraction of lithium at 415°C.

Table I. Activity coefficients of lithium in various liquid lithium alloys

System	T (K)	γ_{Li}	Composition	Ref.
Li-Cd	688	6.85×10^{-4}	$X_{Li} \leq 0.077$	(27)
Li-Ga	688	4.49×10^{-4}	$X_{Li} \leq 0.083$	(28)
Li-In	688	7.12×10^{-4}	$X_{Li} \leq 0.071$	(29)
Li-Sn	688	6.44×10^{-5}	$X_{Li} \leq 0.100$	This work
Li-Pb	800	7.80×10^{-4}	$X_{Li} \leq 0.117$	(31)
Li-Bi	800	3.20×10^{-5}	$X_{Li} \leq 0.144$	(32)

system and the related values of the partial molar entropy of lithium are presented in Table II.

The partial molar enthalpies of lithium, $\Delta\overline{H}_{Li}$, in the lithium-tin alloys relative to pure lithium were calculated from the expression

$$\Delta\overline{H}_{Li} = \mathbf{F}\left[-E + T\left(\frac{\partial E}{\partial T}\right)\right] \quad [3]$$

The compositional variation of the partial molar enthalpy of lithium in the lithium-tin system at 415°C is shown in Fig. 6. Up to the composition 85.7 a/o Li, the partial molar enthalpy of lithium is negative. This is no longer true for the two-phase mixture of the most lithium-rich phase $Li_{22}Sn_5$ and the liquid alloy of lithium saturated with tin. The partial molar enthalpy of lithium in the single-phase lithium-tin liquid alloys was found to be essentially composition-independent. Values of the partial molar enthalpy of lithium in the two-phase regions at 415°C are presented in Table III.

The activity, a_{Sn}, and the chemical potential or the partial molar Gibbs free energy, $\Delta\overline{G}_{Sn}$, of tin were calculated as a function of composition for the lithium-tin system according to the relation (20)

$$\Delta\overline{G}_{Sn} = RT\ln a_{Sn} = \mathbf{F}\left(yE - \int_0^y E\,dy\right) \quad [4]$$

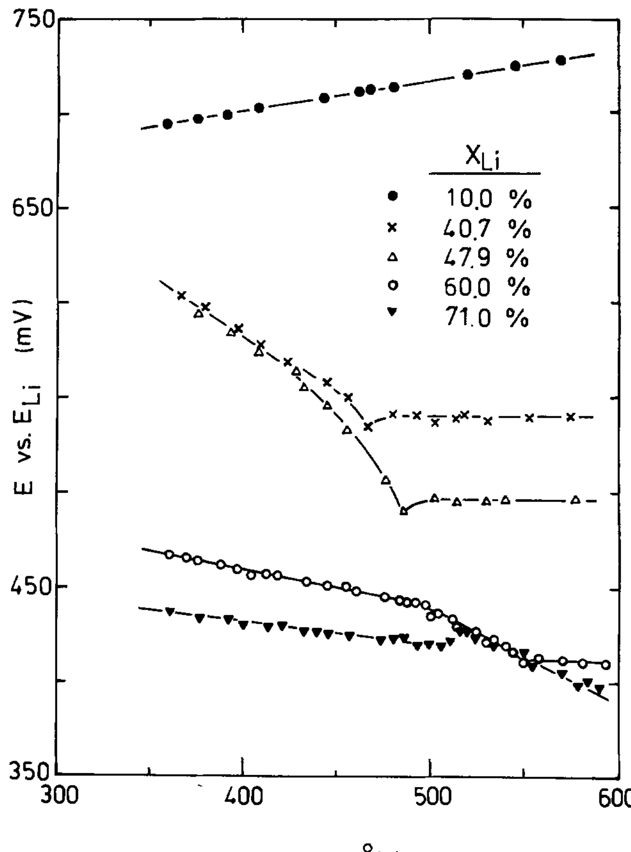

Fig. 3. Temperature variation of the emf at various compositions

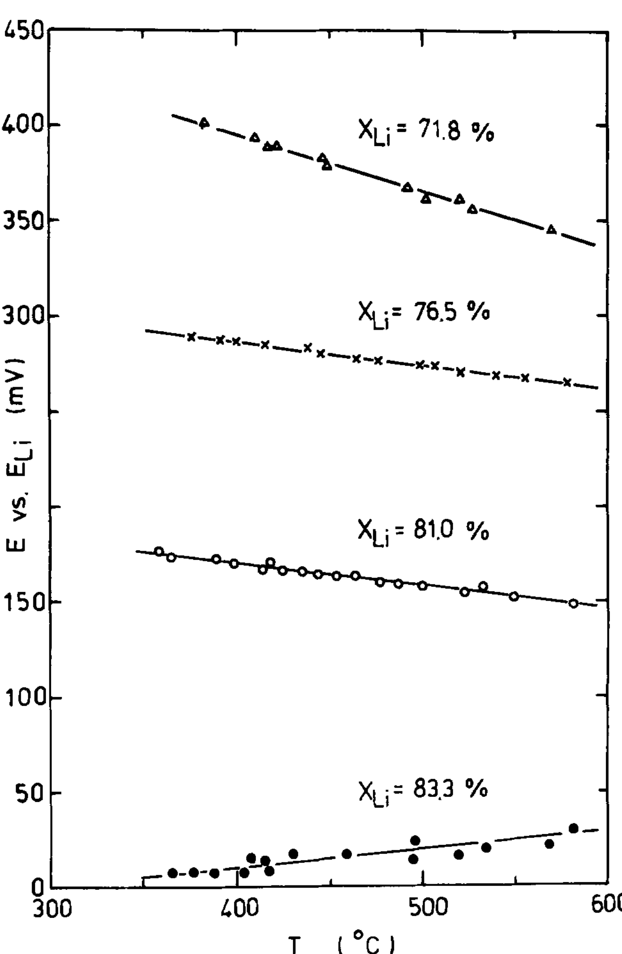

Fig. 4. Temperature variation of the emf at various compositions

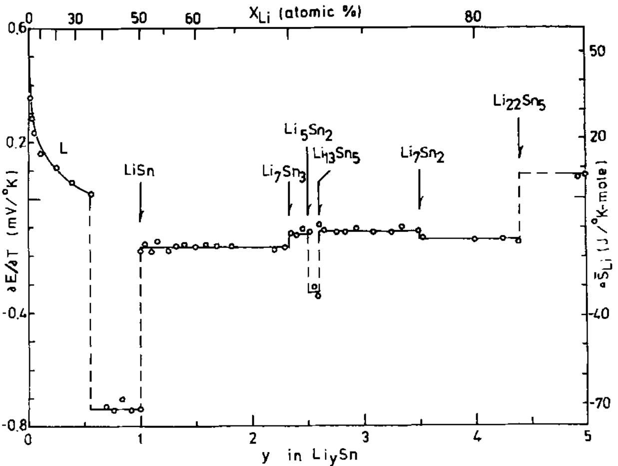

Fig. 5. Temperature derivative of the emf or the partial molar entropy of lithium at various compositions.

where y is the composition parameter in Li_ySn. The results at 415°C are shown in Fig. 7. It is seen that the

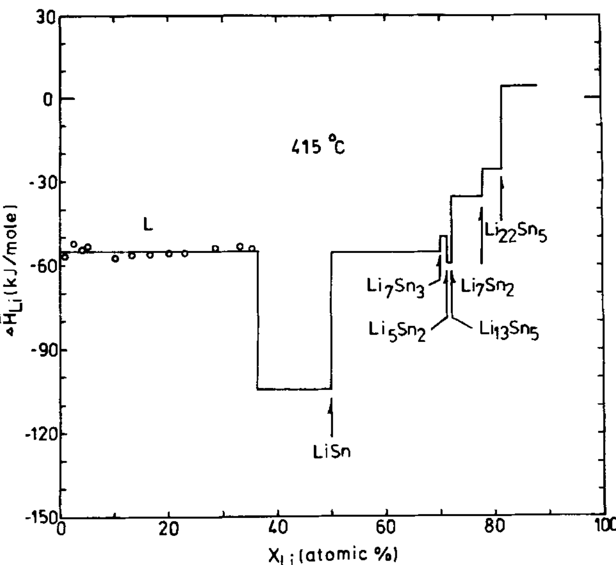

Fig. 6. Compositional variation of the partial molar enthalpy of lithium at 415°C.

activity of tin in the lithium-tin alloy system initially follows Raoult's law, *i.e.*, $a_{Sn} = X_{Sn}$ or $(1 - X_{Li})$, and then has a negative deviation as more lithium is added. The values of the activity of tin in the two-phase regions at 415°C are included in Table III.

The partial molar entropies of tin, $\Delta\bar{S}_{Sn}$, were evaluated from the expression

$$\Delta\bar{S}_{Sn} = -y\mathbf{F}\left(\frac{\partial E}{\partial T}\right) + \mathbf{F}\int_0^y \left(\frac{\partial E}{\partial T}\right) dy \qquad [5]$$

The partial molar entropy of tin is positive and slowly increases to a value of 5.6 J/deg mole with increasing lithium concentration in the tin-rich terminal liquid phase. The values of $\Delta\bar{S}_{Sn}$ in the two-phase regions are included in Table II.

The partial molar enthalpies of tin, $\Delta\bar{H}_{Sn}$, were calculated from the definitional expression

$$\Delta\bar{H}_{Sn} = \Delta\bar{G}_{Sn} + T\,\Delta\bar{S}_{Sn} \qquad [6]$$

It was found that $\Delta\bar{H}_{Sn}$ is essentially zero in tin-rich molten lithium-tin alloys. The values of $\Delta\bar{H}_{Sn}$ in the two-phase regions at 415°C are included in Table III.

The integral molar Gibbs free energy of mixing, ΔG_m, was determined by graphically evaluating the area under the coulometric titration curve using the equation (20)

$$\Delta G_m = -\frac{\mathbf{F}}{1+y}\int_0^y E dy \qquad [7]$$

The results at 415°C are shown in Fig. 8. It is seen that the values are negative over the entire range of composition, with a minimum (−35.7 kJ/mole) at approximately the nominal composition of the phase $Li_{13}Sn_5$. In the two-phase regions, ΔG_m is, of course, a linear function of the mole fraction of lithium, as expected.

Table II. Temperature dependence of the emf and the partial molar entropy of lithium and tin in two-phase lithium-tin alloys

Phases present	Temperature dependence of the emf (mV)	Partial molar entropy of Li (J/deg mole)	Partial molar entropy of Sn (J/deg mole)	Temperature range (°C)
Liq. + LiSn	$E = 1078 - 0.740\,T$ (K)	−71.4	+45.6	360-480
LiSn + Li_7Sn_3	$E = 573 - 0.170\,T$ (K)	−16.4	−9.4	360-480
Li_7Sn_3 + Li_5Sn_2	$E = 517 - 0.120\,T$ (K)	−11.6	−19.5	360-500
Li_5Sn_2 + $Li_{13}Sn_5$	$E = 616 - 0.330\,T$ (K)	−31.8	+29.9	360-590
$Li_{13}Sn_5$ + Li_7Sn_2	$E = 365 - 0.1100\,T$ (K)	−10.6	−23.4	360-590
Li_7Sn_2 + $Li_{22}Sn_5$	$E = 268 - 0.145\,T$ (K)	−14.0	−14.1	360-590
$Li_{22}Sn_5$ + Liq.	$E = -46 + 0.085\,T$ (K)	+8.2	−112.0	360-590

Table III. Thermodynamic data for two-phase equilibria in the lithium-tin system at 415°C

Phases present	EMF *vs.* Li (mV)	Activity of Li	Partial molar enthalpy of Li (kJ/mole)	Activity of Sn	Partial molar enthalpy of Sn (kJ/mole)
Liq. + LiSn	569	6.79×10^{-5}	−104.0	4.67×10^{-1}	+27.0
LiSn + Li_7Sn_3	456	4.57×10^{-4}	−55.3	6.94×10^{-2}	−21.7
Li_7Sn_3 + Li_5Sn_2	430	7.08×10^{-4}	−49.8	2.49×10^{-2}	−34.5
Li_5Sn_2 + $Li_{13}Sn_5$	390	1.39×10^{-3}	−59.3	4.06×10^{-3}	−10.9
$Li_{13}Sn_5$ + Li_7Sn_2	284	8.31×10^{-3}	−35.4	4.85×10^{-5}	−72.9
Li_7Sn_2 + $Li_{22}Sn_5$	170	5.88×10^{-2}	−25.8	4.57×10^{-8}	−106.0
$Li_{22}Sn_5$ + Liq.	10	8.40×10^{-1}	+4.4	4.61×10^{-18}	−239.0

The integral molar entropy of mixing, ΔS_m, was calculated from the relation (20)

$$\Delta S_m = \frac{F}{1+y}\int_0^y \frac{\partial E}{\partial T}\,dy \qquad [8]$$

The results given in Fig. 9 were obtained by graphical integration. ΔS_m is positive at low lithium compositions and becomes negative for lithium concentrations greater than 39 a/o Li, and thus for all the intermediate phases, in the temperature range investigated. It has a maximum value (4.2 J/deg mole) near the composition of 36 a/o Li and a minimum (−14.7 J/deg mole) at the composition of 72.2 a/o Li.

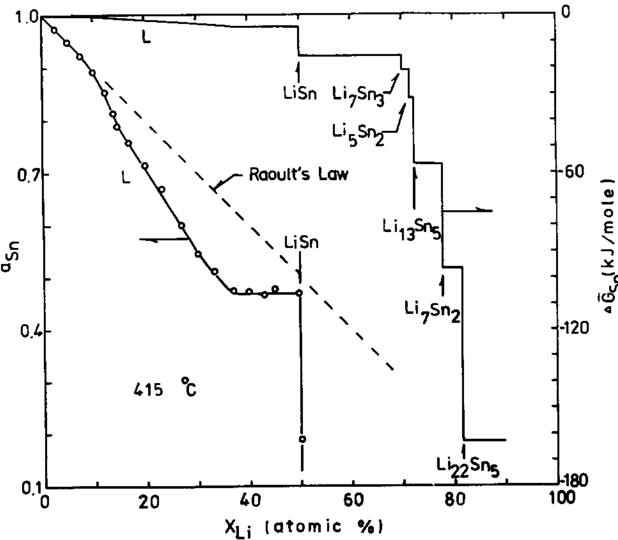

Fig. 7. Compositional variation of the activity and partial molar Gibbs free energy of tin at 415°C.

The integral molar enthalpy of mixing, ΔH_m was calculated from the expression

$$\Delta H_m = \Delta G_m + T\,\Delta S_m \qquad [9]$$

and the experimental results at 415°C are shown in Fig. 10. Like ΔG_m, ΔH_m is negative over the whole composition range studied and it has a maximum negative value (−45.8 kJ/mole) near the stoichiometric composition of the phase $Li_{13}Sn_5$.

The standard molar Gibbs free energy of formation, $\Delta G_f°$ (Li_ySn), for the intermediate phases per mole of tin were obtained from the relation (20)

$$\Delta G_f° (Li_ySn) = -F\int_0^y E\,dy \qquad [10]$$

and the results are shown as functions of temperature in Fig. 11. For all phases, $\Delta G_f°$ (Li_ySn) shows a linear dependence upon temperature. The standard entropies of formation, $\Delta S_f°$ (Li_ySn), were obtained from the slopes of best-fit straight lines, and the values are tabulated in Table IV.

The corresponding standard enthalpies of formation, $\Delta H_f°$ (Li_ySn), were evaluated from the extrapolated intercepts at $T = 0$. Those values are also included in Table IV.

Two types of emf measurements were undertaken to provide an independent check on portions of the binary phase diagram of the lithium-tin system reported by Grube and Meyer (7). The first kind was carried out at fixed alloy compositions, varying the temperature. Representative results were shown in Fig. 3. The temperatures at which phase transitions occur are evidenced by changes of slopes in the emf *vs.* temperature plots. The second set of measurements was made at constant temperatures, with the composition varied by use of the coulometric titration technique. Since the lithium activity is independent of composition in two-phase regions and varies with com-

position in single-phase regions, coulometric titration curves such as that in Fig. 1 can be used to locate phase boundaries.

On the basis of these results, a partly revised phase diagram has been deduced for the lithium-tin system. The results are shown in Fig. 12. The liquidus line is in good agreement with that determined by Grube and Meyer (7). The eutectic composition and temperature were found to be 57 a/o Li and 470°C, respectively. The phase LiSn melts congruently at about 488°C, close to the value reported by Grube and Meyer (485°C). In the present work, however, it was found that the phase Li_7Sn_3, rather than Li_2Sn, peritectically decomposes at about 500°C.

The new phase $Li_{13}Sn_5$, first discovered by Frank and Muller (14), was confirmed in this work by use of the coulometric titration technique as well as x-ray diffraction analysis. The equilibrium conditions for the existence of the phase $Li_{13}Sn_5$ have been recently examined by Bailey, Skelton, and Smith (33) using thermal analysis and metallography. They reported that the peritectic melting of Li_5Sn_2 at 716°, or 720°C as reported by Grube and Mayer (7), is in fact the peritectic melting of $Li_{13}Sn_5$, and that Li_5Sn_2 melts peritectically at a temperature about 18 degrees lower, *i.e.*, 698°C. That the most lithium-rich phase is $Li_{22}Sn_5$, instead of Li_4Sn, was also substantiated in the current investigation.

A Point Defect Model for Anodic Passive Films

I. Film Growth Kinetics

C. Y. Chao,* L. F. Lin, and D. D. Macdonald***

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

A model based on the movement of point defects in an electrostatic field is proposed to interpret the growth behavior of a passive film on a metal surface. This model results in a logarithmic growth law. The theoretical equations derived from the model readily account for experimental data for the growth of a passive film on iron. It is found that the field strength of the film is 1.11×10^6 V/cm. The dependence of film/solution interface potential difference on the applied potential (α) was found to be 0.743, and is independent of the identity of the anion in solution. However, the dependence of the potential difference across the film/solution interface on the solution pH (β) is strongly dependent on the identity of the solution anion.

It is generally believed that passivity is due to the formation of a three-dimensional film (usually an oxide film) on a metal surface. Experimentally, it is found that the film growth kinetics may follow one of the two following laws

$$L = A + B \ln t \text{ (logarithmic law)} \quad [1]$$

$$1/L = C - D \ln t \text{ (inverse logarithmic law)} \quad [2]$$

where L is the film thickness and t is time. A, B, C, and D are constants. However, many cases are known where the experimental data may fit both laws equally well (1-3). This dual behavior is not unexpected, since the logarithmic law and inverse-logarithmic law are almost mathematically equivalent when the change in thickness is small, as illustrated by Lukac *et al.* (2).

Over the last forty years, several models have been proposed to explain the form of either Eq. [1] or Eq. [2] (see the next section). However, as shown in the following section, none of the existing models are completely satisfactory from a physical viewpoint, nor are they in complete agreement with the experimental data. Accordingly, it is necessary to develop an alternative model that can account for all of the ex-

Key words: metals, passivity, films, growth.

perimental observations. The purpose of the present paper is to develop such a model and to demonstrate that the model is in substantial agreement with the data that are currently available.

Review of the Existing Models

Mott-Cabrera model.—One of the earliest models for the growth kinetics of passive films was proposed by Mott (4) in 1947 and was later extended by Cabrera and Mott (5) in 1948. This model assumes: (*i*) Film growth is due to the transport of metal cations across the oxide film to the film/solution interface where they react with the electrolyte; (*ii*) the penetration of cations through film is assisted by the high electric field strength which is assumed to exist within the oxide (field strength, $\epsilon = -d\phi/dx$, where ϕ is the electrical potential and x is the distance); (*iii*) the field strength is constant throughout the film, *i.e.*, $\epsilon = -d\phi/dx = \phi_f/L$, where ϕ_f is the total potential drop across the film of thickness L; (*iv*) ϕ_f is a constant and hence is independent of film thickness; (*v*) the rate-limiting step for film growth is the emission of metal cations from metal into film at the metal/film interface.

These assumptions lead to the following rate law for film growth

$$dL/dt = N\Omega\upsilon \exp\left[\left(-W + \frac{qa\phi_f}{2L}\right) \Big/ kT\right] \quad [3]$$

where N is the number of mobile ions per unit surface area, Ω is the molecular volume per cation, υ is the vibrational frequency, W is the activation energy for the rate-controlling step, q is the charge that the cation carries, a is the jump distance, and kT is the thermal energy.

An approximate solution to Eq. [3] can be obtained by integrating by parts and neglecting higher terms in $2LkT/qa\phi_f$. This approximation yields an inverse logarithmic rate law

$$1/L = C - D \ln t \quad [4]$$

where

$$C = \frac{2}{qa\phi_f}\left\{ W - kT \ln\left[\frac{2(W - 39kT)^2 N\Omega\nu}{\phi_f aqkT}\right]\right\} \quad [5]$$

and

$$D = 2kT/qa\phi_f \quad [6]$$

Sato and Cohen's model.—From their study of iron in pH 8.4 borate buffer solution, Sato and Cohen (6) found that the relationship between external current, i, the applied potential, V_{app}, and the accumulated charge in the oxide film, Q_T, can be expressed by the following empirical equation

$$i = k' \exp(mV_{app} - Q_T/n) \quad [7]$$

where k', m, and n are parameters.

The authors then used the so-called "place-exchange" mechanism to explain their results. According to this model, a layer of oxygen is adsorbed onto the surface which then exchanges places (possibly by rotation) with underlying metal atoms. A second layer of oxygen is then adsorbed and the two M—O pairs rotate simultaneously. This process is repeated and results in oxide film thickening. A schematic representation of this mechanism is given in Fig. 1.

From the "place-exchange" mechanism model, Sato and Cohen obtained analytical expressions for the parameters in Eq. [7]

$$k' = \frac{2\mathbf{F}kT}{h}\sqrt{N_s^{q/\nu}\,({}_0N_{Fe})^{2/\nu}} \exp\left[\frac{qE_o\mathbf{F}}{2\nu RT} - \frac{W_M - W_o + 0.5\,qW_s}{\upsilon RT}\right] \quad [8]$$

$$m = \frac{q\mathbf{F}}{2\nu RT} \quad [9]$$

(1)	(2)	(3)	(4)	(5)
			OOOOO	MMMMM
	OOOOO	MMMMM	MMMMM	OOOOO
MMMMM	MMMMM	OOOOO	OOOOO	MMMMM
MMMMM	MMMMM	MMMMM	MMMMM	OOOOO

Fig. 1. Oxide film growth by the "place-exchange" mechanism. M and O represent metal and oxygen atoms, respectively. The dashed line is the solid-electrolyte interface. (1) A film-free metal; (2) oxygen adsorption on the metal surface; (3) "place-exchange" between oxygen and metal; (4) second oxygen layer is adsorbed; (5) "place-exchange" between two M-O pairs simultaneously.

$$n^{-1} = l^2 W_o/4qRT \quad [10]$$

where $\mathbf{F}$ is Faraday's constant, h is Planck's constant, υ is defined as the number of times that a rate-controlling step occurs when the overall reaction occurs once, N_s is the total number of adsorption sites, and ${}_0N_{Fe}$ is the number of iron ions per unit area of oxide at the metal surface, and E_o is a constant. W_M is the chemical activation energy for the formation of the first layer of oxide, W_o is the chemical activation energy of subsequent layers, and W_s is the chemical activation energy for the incorporation of adsorbed oxygen into the growing film. R, T, and q have their usual meanings.

Later, Sato and Notoya (7) pointed out that under potentiostatic conditions, the integration of Eq. [7] results in the logarithmic law

$$L = A + B \ln(t + t_o) \quad [11]$$

with

$$A = \frac{l\nu RT}{W_o}\left[\ln\frac{W_o\beta T}{l\nu RT} + \frac{\sigma}{T}\right] + \frac{l\nu \mathbf{F} V_{app}}{2W_o} \quad [12]$$

and

$$B = \frac{l\nu RT}{W_o} \quad [13]$$

Fehlner and Mott's model.—As early as 1960, Eley and Wilkinson (8) pointed out that the logarithmic growth law could be obtained by assuming any mechanism whose activation energy increased linearly with film thickness. Based on this argument, they preferred the "place-exchange" model, since it is the only model that gives a linear dependence of the activation energy on film thickness. The theory was fully developed by Sato and Cohen four years later (see "Sato and Cohen's model" above).

However, the "place-exchange" mechanism does not provide a very convincing description of the growth of a film whose thickness is more than one or two monolayers. Thus, in 1970, Fehlner and Mott (9), modified the earlier Mott-Cabrera model to provide an alternative to the "place-exchange" mechanism. The modifications involve the following assumptions: (*i*) Anion diffusion is responsible for film growth; (*ii*) the rate-limiting step (rls) is the emission of an anion from the environment into the film at the film/environment interface; (*iii*) the field strength in the film is independent of thickness, *i.e.*, $\epsilon = \phi_f/L =$ constant; (*iv*) the activation energy, W, of the rls increases linearly with thickness by, as the authors stated, "whatever the mechanism is." (Fehlner and Mott did not provide details of how this might occur.) Accordingly

$$W = W^o + \mu L \quad [14]$$

where W^o and μ are constants.

Based on these new assumptions, Eq. [3] becomes

$$\frac{dL}{dt} = N\Omega\upsilon \exp\left[\left(-W^o - \mu L + \frac{qa\epsilon}{2}\right) \Big/ kT\right] \quad [15]$$

This yields another logarithmic law

$$L = A' + B' \ln(t + t_o) \quad [16]$$

with

$$A' = \frac{kT}{\mu}\left[\ln\frac{\mu}{kT} + \ln N\Omega v - \frac{W^{\circ}}{kT} + \frac{qa\epsilon}{2kT}\right] \quad [17]$$

and

$$B' = kT/\mu \quad [18]$$

Several comments regarding existing growth models. —Over the past four decades, the growth models reviewed above have been used to interpret experimental data with only minor challenges [*e.g.*, see Ref. (10-12)]. Recently, Lukac *et al.* (2) used ellipsometry to systematically investigate the growth kinetics of the passive film on iron in pH 8.6 borate buffer solution over a range of temperatures and potentials. Their data largely dispute some of the predictions of the existing models. Thus, the authors concluded "none of the existing models for film growth were found to be completely consistent with the temperature and potential dependence of the growth constants." Macdonald and Roberts (13) also found that none of the existing models are able to account for the potentiostatic transients observed during the growth of anodic films on iron in sodium hydroxide solution.

Further, there are a number of fundamental arguments that tend to discredit the existing models. (*i*) The inverse logarithmic growth law has been observed for solutions of low pH (14-17), where passive film dissolution is significant. The Mott-Cabrera model, however, does not take this phenomenon into consideration. (*ii*) Recent studies at the Chalk River Nuclear Laboratories (18-21) have used radioactive markers to identify mobile species in anodic films. These studies showed that, for all the metals investigated (Al, Nb, Ta, W, Zr, Hf, U, Si), anion transportation is largely, if not exclusively, responsible for film growth. This observation tends to discredit the Mott-Cabrera model, which assumes that metal cation diffusion is responsible for film growth. (*iii*) Transient phenomena resulting from sudden changes of the applied potential or the *p*H of the solution have been investigated (14, 15). The results showed that at the film/solution interface, the following equilibrium is established rapidly

$$O_{(oxide)} + 2H^{+}_{(aq)} + 2e^{-} = H_2O \quad [19]$$

This observation contradicts the Fehlner-Mott model which assumes that the rate-limiting step is located at the film/solution interface.

A New Model for the Growth of Passive Films under Anodic Polarization

In this section, a new model is presented to account for the growth kinetics of a passive film on a metal surface. Initially, the assumptions involved are clearly stated and the growth law is derived. Subsequently, it is demonstrated that the new model is in substantial agreement with many experimental observations that have been reported in the literature.

Basic features of the model.—This model is based on the following assumptions: (*i*) Whenever the external potential, V_{ext}, is more noble than the Flade potential, a continuous passive film will form on the surface of a metal. For the present purpose, the film is assumed to be an oxide of composition $MO_{\chi/2}$. However, the model developed below is perfectly general and can be applied to other (oxide and nonoxide) films as well. (*ii*) It is assumed that the passive film contains a high concentration of point defects. High temperature studies indicate that the major point defects that exist in an oxide film are $V_M^{\chi'}$, $V_O^{\cdot\cdot}$, e', and $h^{\cdot}$.[1] The same species are expected to be present in a passive film. (*iii*) It is well known that passive films are characterized by high electrical fields ($\sim 10^6$ V/cm) and we assume that the field strength is of the same order as that required for dielectric breakdown.[2] Accordingly, the passive film behaves as an "incipient semiconductor" because it exists on the verge of dielectric breakdown. Consequently, the field strength is a function of the chemical and electrical characteristics of the film and therefore is independent of thickness even for potentiostatic conditions. (*iv*) Since passive films are regarded to be "incipient semiconductors," it is assumed that electrons (e') and electron holes ($h^{\cdot}$) in the film matrix are in their equilibrium states, and that the electrochemical reactions involving electrons (or electron holes) are rate controlled at either the metal/film (m/f) or the film/solution (f/s) interfaces. On the other hand, the rate-controlling step for those processes which involve metal vacancies ($V_M^{\chi'}$) and oxide vacancies ($V_O^{\cdot\cdot}$), (*i.e.*, film growth) is assumed to be the transport of the vacancies across the film. This assumption implies that metal and oxide vacancies are in their equilibrium states at the m/f and the f/s interfaces.

Additional assumptions will be given later, as necessary.

Kinetic growth law.—Figure 2 shows schematically the relationship between the working electrode and reference electrode in an electrochemical cell, and the corresponding potential-position relationships. The parameters $\phi_{m/f}$, $\phi_{f/s}$, and ϕ_R represent the potential drops at the metal/film, film/solution, and solution/reference electrode interfaces, respectively. ϕ_f is the potential drop across the film and V_{ext} is the external position. The potential drops in the solution as well as that in the external circuit are neglected in the present treatment. From Fig. 2 we obtain

$$V_{ext} + \phi_R = \phi_{m/f} + \phi_f + \phi_{f/s} \quad [20]$$

Two reactions occur at the metal/film (m/f) interface

$$m \rightleftarrows M_M + \chi/2\, V_O^{\cdot\cdot} + \chi e' \quad [21]$$

and

$$m + V_M^{\chi'} \rightleftarrows M_M + \chi e' \quad [22]$$

where m represents the metal atom in the metal, and M_M is metal cation in the film. Since equilibrium is established at the m/f interface, then

$$\mu_m = \mu_{M_M} + \frac{\chi}{2}\mu_{V_O^{\cdot\cdot}} + \chi \mathbf{F}\phi_f' + \chi\mu_{e'} - \chi\mathbf{F}\phi_m \quad [23]$$

where ϕ_f' and ϕ_m are the flatband potentials for the film and metal at the m/f interface, respectively, and μ_i is the chemical potential of species i. Furthermore, the standard Gibbs energy of reaction [21], ΔG_{21}°, is defined as

$$\Delta G_{21}^{\circ} = \mu_{M_M}^{\circ} + \frac{\chi}{2}\mu_{V_O^{\cdot\cdot}}^{\circ} + \chi\mu_{e'}^{\circ} - \mu_m^{\circ} \quad [24]$$

By selecting appropriate standard states[3]

$$\mu_m = \mu_m^{\circ},\ \mu_{M_M} = \mu_{M_M}^{\circ},\ \mu_{e'} = \mu_{e'}^{\circ},\ \phi_m - \phi_f = \phi_{m/f} \quad [25]$$

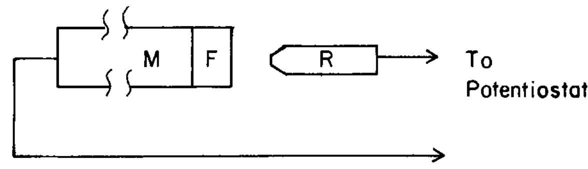
and

$$\mu_{V_O^{\cdot\cdot}} = \mu_{V_O^{\cdot\cdot}}^{\circ} + RT\ln a_{V_O^{\cdot\cdot}\,(m/f)} \quad [26]$$

[1] The Kroger-Vink notation is adopted here for designating point defect species. According to the notation, X_Y means that a species X occupies a Y lattice site (*e.g.*, V_M means a vacancy occupies a metal site in the oxide, *i.e.*, a metal vacancy); *e* and *h* are electrons and holes. The superscript gives the number and the sign of the charge. Thus, "··" means two positive charges. "χ'" means χ negative charges (*e.g.* $V_M^{\chi'}$ means a metal vacancy which carries χ negative charge).

[2] Very little dielectric breakdown data for oxides have been reported. Furthermore, wide variations exist in these values which have been reported. For impure sintered Al_2O_3 plates (25), breakdown has been reported to occur at 50 kV/cm. For higher purity Al_2O_3, breakdown was reported at 200 kV/cm. It seems reasonble to expect that the "intrinsic" breakdown for pure Al_2O_3 is of the order of 10^6 V/cm. Recently, a value of 1.1×10^7 V/cm has been reported for SiO_2 (26).

[3] The standard state for each species is defined as follows: m = a metal which is in equilibrium with the metal oxide; M_M = metal cation which occupies a normal cation site in the oxide lattice which is in equilibrium with the metal: e' = electron in the metal; and $V_O^{\cdot\cdot}$ = hypothetical "pure" $V_O^{\cdot\cdot}$ which possesses the same properties as if they were the species that are present in the metal oxide that is in equilibrium with metal.



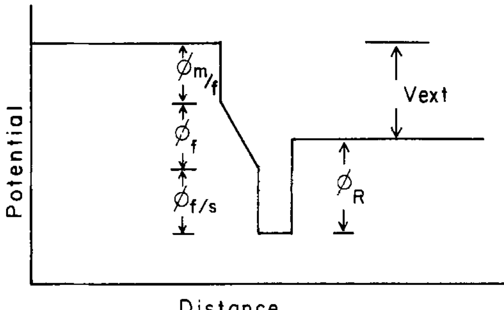


Fig. 2. Schematic of the working and reference electrodes in a typical electrochemical cell (upper figure), and the corresponding potential-distance relationships (lower figure). M represents metal, F represents film, and R represents reference electrode.

where $a_{V_O^{\cdot\cdot}\,(m/f)}$ represents the activity of $V_O^{\cdot\cdot}$ at the m/f interface.

Combining Eq. [23] and [24] yields

$$a_{V_O^{\cdot\cdot}\,(m/f)} = \exp\left(\frac{2\mathbf{F}\phi_{m/f} - (2/x)\Delta G_{21}^\circ}{RT}\right) \quad [27]$$

Similar treatment for Eq. [22] will result in

$$a_{V_M^{x'}\,(m/f)} = \exp\left(\frac{\Delta G_{22}^\circ - x\mathbf{F}\phi_{m/f}}{RT}\right) \quad [28]$$

where ΔG_{22}° is the standard Gibbs energy of reaction [22].

At this time, it is necessary to assume that the interaction between point defects is negligible, *i.e.,* the point defects behave as an ideal solution. Accordingly, the activity coefficient is unity and we estimate the number of $V_O^{\cdot\cdot}$ and $V_M^{x'}$ at the m/f interface as

$$C_{V_O^{\cdot\cdot}\,(m/f)} = \frac{N_v}{\Omega} a_{V_O^{\cdot\cdot}} = \frac{N_v}{\Omega}\exp\left(\frac{2\mathbf{F}\phi_{m/f} - (2/x)\Delta G_{21}^\circ}{RT}\right) \quad [29]$$

$$C_{V_M^{x'}\,(m/f)} = \frac{N_v}{\Omega}\exp\left(\frac{\Delta G_{22}^\circ - x\mathbf{F}\phi_{m/f}}{RT}\right) \quad [30]$$

where N_v is Avogadro's number and Ω is the molecular volume of oxide. C_i is the concentration of species i in units of No. of species/cm^3. At the film/solution (f/s) interface, two other reactions occur

$$V_O^{\cdot\cdot} + H_2O \rightleftarrows 2H^+(aq) + O_O \quad [31]$$

and

$$M_M \rightleftarrows V_M^{x'} + M^{x+}(aq) \quad [32]$$

where $M^{x+}(aq)$ is the hydrated metal cation in the electrolyte solution. Because of local equilibrium at the f/s interface, the number of oxide vacancies at this interface, $C_{V_O^{\cdot\cdot}}(f/s)$, can be calculated easily by equating the electrochemical potentials on both sides of Eq. [31]

$$\mu_{V_O^{\cdot\cdot}} + 2\mathbf{F}\phi_f'' + \mu_{H_2O} = 2\mu_{H^+} + 2\mathbf{F}\phi_S + \mu_{O_O} \quad [33]$$

where ϕ_f'' and ϕ_S are flatband potentials for the film and solution at the f/s interface, respectively. Furthermore, the change in standard Gibb's energy for reaction [31] is given by

$$\Delta G_{31}^\circ = 2\mu_{H^+}^\circ + \mu_{O_O}^\circ - \mu_{V_O^{\cdot\cdot}}^\circ - \mu_{H_2O}^\circ \quad [34]$$

where

$$\mu_{H_2O} = \mu_{H_2O}^\circ,\ \mu_{O_O} = \mu_{O_O}^\circ,\ \phi_f'' - \phi_S = \phi_{f/s} \quad [35]$$

$$\mu_{V_O^{\cdot\cdot}} = \mu_{V_O^{\cdot\cdot}}^\circ + RT\ln a_{V_O^{\cdot\cdot}\,(f/s)} \quad [36]$$

$$\mu_{H^+} = \mu_{H^+}^\circ - 2.303\,RT \times pH \quad [37]$$

These relationships lead to

$$C_{V_O^{\cdot\cdot}\,(f/s)} = \frac{N_v}{\Omega}\exp\left[\left(\frac{\Delta G_{31}^\circ - 2\mathbf{F}\phi_{f/s}}{RT}\right) - 4.606\,pH\right] \quad [38]$$

The number of $V_M^{x'}$ at the f/s interface, $C_{V_M^{x'}}$ (f/s), can be calculated from the Schottky-pair reaction

$$\text{Null} \rightleftarrows V_M^{x'} + \frac{x}{2}V_O^{\cdot\cdot} \quad [39]$$

Therefore

$$C_{V_M^{x'}} \cdot [C_{V_O^{\cdot\cdot}}]^{x/2} = \left[\frac{N_V}{\Omega}\right]^{1+x/2}\exp\left(-\frac{\Delta G_s^\circ}{RT}\right) \quad [40]$$

where ΔG_s° is the standard Gibbs energy change for the Schottky-pair reaction and the multiplier on the right-hand side arises because of the use of concentrations rather than activities. From Eq. [38] and [40], it is possible to obtain $C_{V_M^{x'}\,(f/s)}$

$$C_{V_M^{x'}\,(f/s)} = \frac{N_v}{\Omega}\exp\left[\frac{x\mathbf{F}\phi_{f/s} - \Delta G_s^\circ - x/2\Delta G_{31}^\circ}{RT} + 2.303\,x\,pH\right] \quad [41]$$

It is apparent (see Eq. [21] and [31]), that oxide ion vacancies are produced at the m/f interface but are consumed at the f/s interface. As a result, oxide ion vacancies diffuse from the m/f to the f/s interfaces. Similar arguments show that $V_M^{x'}$ diffuses from the f/s to the m/f interfaces or equivalently, metal cations diffuse from the m/f to the f/s interfaces. The net result of $V_O^{\cdot\cdot}$ migration can be seen by combining reactions [21] and [31] to yield

$$\frac{2}{x}m + H_2O \rightleftarrows 2/xM_M + O_O + 2H^+(aq) + 2e' \quad [42]$$

Similarly, combining Eq. [22] and [32] shows that the net result of $V_M^{x'}$ migration can be expressed as

$$m \rightleftarrows M^{x+}{}_{(aq)} + xe' \quad [43]$$

It is clear that the diffusion of $V_O^{\cdot\cdot}$ (or equivalently, oxygen anion) results in oxide growth, whereas the diffusion of $V_M^{x'}$ (or equivalently, metal cation) results in metal dissolution only. This conclusion is opposed to the assumption of accepted theories that cation diffusion is responsible for oxide growth (4, 5, 22, 23). However, this conclusion is subject to experimental verification (18-21).

Since $V_O^{\cdot\cdot}$ diffusion results in film growth, the problem of calculating film growth kinetics is equivalent to calculating the $V_O^{\cdot\cdot}$ diffusional rate. Thus

$$\frac{dL}{dt} = \frac{\Omega}{N_v}J_{V_O^{\cdot\cdot}} \quad [44]$$

where dL/dt is the film growth rate, Ω is the molar volume per cation, and $J_{V_O^{\cdot\cdot}}$ is the flux of $V_O^{\cdot\cdot}$ per unit area per unit time. In the Appendix, we show that it is possible to calculate the diffusional rate of a charged species in the presence of both concentration and potential gradients. The result is given by

$$J_{V_O^{\cdot\cdot}} = 2KD_{V_O^{\cdot\cdot}}{}^*\,\frac{C_{V_O^{\cdot\cdot}(m/f)}\exp(2KL) - C_{V_O^{\cdot\cdot}(f/s)}}{\exp(2KL) - 1} \quad [45]$$

where K, as defined in Appendix, is equal to $\mathbf{F}\epsilon/RT$.

Now, it is necessary to introduce an additional assumption that the potential drop at the film/solution interface, $\phi_{f/s}$, is a function of applied potential and solution pH, but is independent of anodic film thickness. Accordingly, we may express $\phi_{f/s}$ in the form

$$\phi_{f/s} = \alpha V_{ext} + \beta pH + \phi_{f/s}^{\circ} \quad [46]$$

The assumption that $\phi_{f/s}$ is independent of thickness seems reasonable, because the film growth results from a reaction at the m/f interface (*i.e.*, oxygen anions diffuse to the m/f interface and react with metal). The potential- and pH-dependent assumptions for $\phi_{f/s}$ also seem justified, since the f/s interface is polarizable.

From Eq. [20] and [46], it is possible to derive an expression for $\phi_{m/f}$

$$\phi_{m/f} = (1-\alpha)V_{ext} - \beta pH - \phi_{f/s}^{\circ} + \phi_R - \phi_f \quad [47]$$

According to the assumption [4], $\phi_f = \epsilon L$, so that

$$\phi_{m/f} = (1-\alpha)V_{ext} - \beta pH - \phi_{f/s}^{\circ} + \phi_R - \epsilon L \quad [48]$$

where ϕ_R is treated as a constant because the reference electrode is nonpolarizable. Substituting Eq. [29], [38], [45], [46], and [48] into Eq. [44] yields

$$\frac{dL}{dt} = \frac{A(B-1)}{\exp(2KL)-1} \quad [49]$$

where

$$A = 2KD_{V_O^{\cdot\cdot}}{}^{*} \exp\left[-\frac{2F}{RT}(\alpha V_{ext} + \beta pH + \phi_{f/s}^{\circ}) + \frac{\Delta G_{31}^{\circ}}{RT} - 4.606\,pH\right] \quad [50]$$

and

$$B = \exp\left[\frac{2F}{RT}(V_{ext} + \phi_R) - \frac{2\Delta G_{21}^{\circ}}{xRT} - \frac{\Delta G_{31}^{\circ}}{RT} + 4.606\,pH\right] \quad [51]$$

Note that A and B are functions of external potential, V_{ext}. When experiments are conducted potentiostatically, V_{ext} is equal to the applied potential (V_{app}) and is independent of the film thickness (L). Thus Eq. [49] can be integrated directly since

$$\int_0^L [\exp(2KL) - 1]\, d(2KL) = \int_0^t 2KA(B-1)\, dt \quad [52]$$

which therefore yields

$$\exp(2KL) - 2KL - 1 = 2KA(B-1)t \quad [53]$$

For most anodic films, the field strength (ϵ) is of the order of 10^6 V/cm (or 10^{-2} V/Å) at room temperature. Thus, $2KL = 2F\epsilon/RT\ L \approx 0.76L$. This means that whenever $L \geqq 5$Å, $\exp(2KL) >> 2KL >> 1$ and Eq. [53] can be simplified to

$$\exp 2KL = 2KA(B-1)t \quad [54]$$

or

$$L = \frac{1}{2K}[\ln 2KA(B-1) + \ln t] \quad [55]$$

Equation [55] has the form of the logarithmic growth law. Furthermore since current, i, is equal to $2F\frac{N_v}{\Omega}\frac{dL}{dt}$, Eq. [55] gives

$$i = \frac{FN_v}{K\Omega} t^{-1} \quad [56]$$

On the other hand, when the film thickness is small, Eq. [53] can be expanded using

$$\exp(2KL) = 1 + 2KL + 2K^2L^2 + \frac{4}{3}K^3L^3 + \ldots \quad [57]$$

to yield

$$2K^2L^2 + \frac{4}{3}K^3L^3 + \ldots = 2KA(B-1)t \quad [58]$$

For very small values for L (designated by subscript "s") the third and higher order terms may be neglected so that Eq. [53] reduces to

$$L_s = \left[\frac{A(B-1)}{K} t\right]^{1/2} \quad [59]$$

This gives a current transient of

$$i_s \propto \frac{dL_s}{dt} = \frac{1}{2}\left[\frac{A(B-1)}{K}\right]^{1/2} t^{-1/2} \quad [60]$$

where L_s and i_s represent the film thickness and current, respectively, for extremely thin films.

Under galvanostatic conditions, $i = 2F\frac{N_v}{\Omega}\frac{dL}{dt} =$ constant, and Eq. [49] becomes

$$i\frac{\Omega}{2FN_v}[\exp(2KL) - 1] = A(B-1) \quad [61]$$

Whenever $L \geqq 5$Å and hence $\exp(2KL) >> 1$ Eq. [61] becomes

$$i\frac{\Omega}{2FN_v}\exp(2KL) = A(B-1) \quad [62]$$

Justification of the new model.—The newly developed model contains four unknown parameters: α (the potential dependence of $\phi_{f/s}$), β (the pH dependence of $\phi_{f/s}$), $\phi_{f/s}^{\circ}$ (an intrinsic constant), and ϵ (the field strength). The best way to verify the model would be to determine (by some independent means) these parameters, and then to substitute the values into Eq. [55], [59], [60], and [62] for direct comparison with experiment. Unfortunately, it does not seem possible to determine values for these parameters by completely independent means. Accordingly, we will attempt to justify the model in a reverse manner, *i.e.*, by determining numerical values of these parameters from experimental data and demonstrating that the values obtained are physically reasonable. This analysis will be performed using experimental data for iron.

Before doing this, it is important to note that Eq. [49], [54], and [55] and Eq. [59], [60], and [62] involve a "$(B-1)$" term. The equations should become much simpler if one can prove that B is much larger than 1 so that $B - 1 \approx B$. Since

$$B = \exp\left[\frac{2F}{RT}(V_{ext} + \phi_R) - \frac{2\Delta G_{21}^{\circ}}{xRT} - \frac{\Delta G_{31}^{\circ}}{RT} + 4.606\,pH\right] \quad [63]$$

the criterion for $B >> 1$ is that

$$\frac{2F}{RT}(V_{ext} + \phi_R) - \frac{2\Delta G_{21}^{\circ}}{xRT} - \frac{\Delta G_{31}^{\circ}}{RT} + 4.606\,pH > 4 \quad [64]$$

Further, $2/x\ \Delta G_{21}^{\circ} + \Delta G_{31}^{\circ}$ is equal to the standard Gibbs energy for reaction [42], which is -2.33 kcal for $Fe/\gamma - Fe_2O_3$. Thus, whenever $V_{ext} > -0.06\ pH - \phi_R$, B is much larger than 1. Unfortunately, we do not know the exact value for ϕ_R, so that it is not possible to specify the V_{ext} value which will ensure that $B >> 1$. Nevertheless, we may conclude that at not-too-negative potentials, $B - 1 \approx B$. In the following treatments, it is always assumed that $B >> 1$ unless otherwise specified. Thus, under potentiostatic condition

$$\frac{dL}{dt} = \frac{C}{\exp(2KL) - 1} \quad [65]$$

$$\exp(2KL) - 2KL - 1 = 2KCt \quad [66]$$

$$L = \frac{1}{2K}[\ln 2KC + \ln t] \quad [67]$$

$$L_s = \left(\frac{C}{K}\right)^{1/2} t^{1/2} \quad [68]$$

$$i_s = \frac{1}{2}\left(\frac{C}{K}\right)^{1/2} t^{-1/2} \quad [69]$$

under galvanostatic condition

$$i\frac{\Omega}{2FN_v}\exp(2KL) = C \quad [70]$$

where

$$C = 2KD_{V_O^{\cdot\cdot}}{}^* \exp\left\{\frac{2F}{RT}[(1-\alpha)V_{ext} - \beta pH - \phi_{f/s}{}^\circ + \phi_R] - \frac{2\Delta G_{21}{}^\circ}{xRT}\right\} \quad [71]$$

Calculation of α and ϵ.—Equation [67] shows that in a given solution (*i.e.*, fixed pH and $\phi_{f/s}{}^\circ$) the film thickness is proportional to V_{ext} and $\ln t$. Therefore

$$\left.\frac{dL}{dV_{ext}}\right)_{t,\, pH,\, \phi_{f/s}{}^\circ} = \frac{1-\alpha}{\epsilon} \quad [72]$$

and

$$\left.\frac{dL}{d\ln t}\right)_{V_{ext},\, pH,\, \phi_{f/s}{}^\circ} = \frac{RT}{2F\epsilon} \quad [73]$$

Goswami and Staehle (1) have determined the growth kinetics of the passive film on iron in pH 8.4 borate buffer solution over a wide range of potential ($0.05V_{she} \leq V_{ext} \leq 1.05V_{she}$). They found that their data could be fitted to both logarithmic and inverse-logarithmic functions equally well. Disregarding this dual nature, G-S's data yield

$$\left.\frac{dL}{d\ln t}\right)_{V_{ext},\, pH,\, \phi_{f/s}{}^\circ} = 1.16\ (\text{Å}) \quad [74]$$

and

$$\left.\frac{dL}{dV_{ext}}\right)_{t,\, pH,\, \phi_{f/s}{}^\circ} = 28.1\ (\text{Å/V}) \quad [75]$$

Substitution of these experimental values into Eq. [72] and [73] yields $\epsilon = 1.11 \times 10^{-2}$ V/Å (or, equivalently, 1.11×10^6 V/cm) and $\alpha = 0.69$. The calculated value for ϵ is of the correct order.

Lukac, Lumsden, Smialowska, and Staehle (2) conducted a systematic investigation of the effects of temperature and potential on the growth kinetics of the passive film on iron in borate buffer solution (pH 8.6 at room temperature). The calculated α and ϵ values[4] at various temperatures are shown in Table I. It can be seen that the field strength, ϵ, and α decrease and increase, respectively, with increasing temperature.

Calculation of β and of the effect of anion type on α and β.—Sato, Noda, and Kudo (24) studied the formation of anodic films on iron in borate and phosphate solutions over a range of pH. Their data provide an excellent opportunity to evaluate β and/or the anion effect on α and β (assuming ϵ is independent of solution pH).

S-N-K's results are reproduced in Fig. 3 and 4. Figure 3 shows the film thickness after 1 hr of polarization in borate solution as a function of applied potential and pH. Figure 4 shows the film thickness for iron after polarization for 1 hr in phosphate solution.

From Fig. 3 and Eq. [72], one finds that for borate buffer solution

$$\left.\frac{dL}{dV_{ext}}\right)_{t,\, pH,\, \phi_{f/s}{}^\circ} = \frac{1-\alpha}{\epsilon} = 23.33\ (\text{Å/V}) \quad [76]$$

[4] The small pH changes due to the variation in temperature were not taken into consideration in the calculation.

Table I. Calculated α and ϵ values at various temperatures using L-L-S-S's data (2) for the growth of passive films on iron in borate solution

Temperature (°C)	Calculated α	Calculated ϵ (V/Å)
0	0.747	1.12×10^{-2}
20	0.728	1.10×10^{-2}
35	0.812	9.37×10^{-3}
50	0.841	8.10×10^{-3}
80	0.853	7.57×10^{-3}

for all pH values. If one assumes that ϵ is independent of pH, and is equal to 1.11×10^{-2} V/Å, then α is equal to 0.743 for all pH values. This value for α agrees with G-S's result within experimental error.

From Fig. 4, it is found that for the high pH range (pH $\geq$ 6.15), $1 - \alpha/\epsilon$ is also equal to 23.33 for iron in phosphate solutions. These data suggest that α is independent of pH and identity of anion. Figure 4 also shows that when pH $\leq$ 3.02, $1 - \alpha/\epsilon$ deviates from 23.33. However, at such low pH's, it is very possible that phosphate anions are incorporated into the passive film (the well-known Parker Process utilizes this fact to produce a conversion coating). Accordingly, the calculated α values no longer refer to a pure oxide film.

S-N-K's result can also be used to calculate a value for β. From Eq. [67], one obtains

$$\left.\frac{dL}{d\,pH}\right)_{V_{ext},\, t,\, \phi_{f/s}{}^\circ} = -\beta/\epsilon \quad [77]$$

The data plotted in Fig. 3 demonstrate that $(dL/d\,pH) = 0$ for all potentials. This indicates that β is equal to zero in borate buffer solution. On the other hand, Fig. 4 also shows that, whenever pH $\geq$ 6.15, $(dL/d\,pH) = 1.3$ at constant V_{ext}. This indicates that $\beta = -(1.3 \times \epsilon) = -1.44 \times 10^{-2}$ and suggests that β depends on the identity of the anion in the solution.

Current-voltage characteristics under galvanostatic conditions.—Equation [70] shows that, under galvanostatic conditions

$$i = k' \exp\left\{2K\left[\frac{1-\alpha}{\epsilon}V_{ext} - L\right]\right\} \quad [78]$$

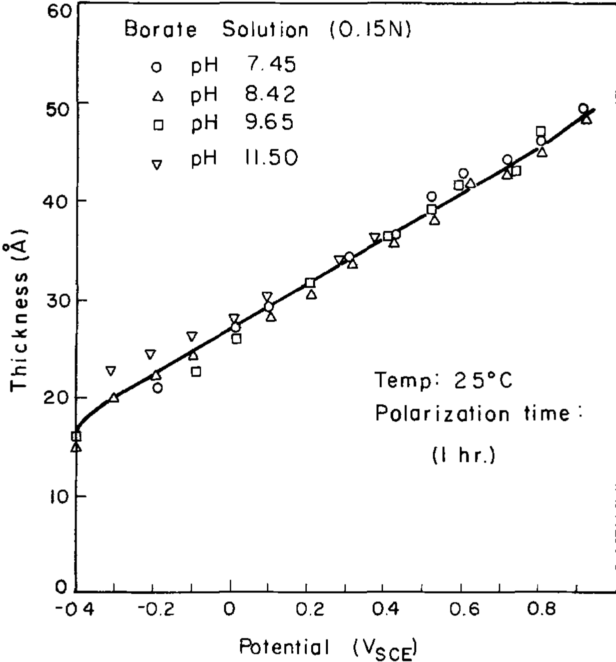

Fig. 3. Film thickness as a function of potential for iron that was polarized at passive potentials for 1 hr in borate solutions. [Figure 2 of Ref. (24)].

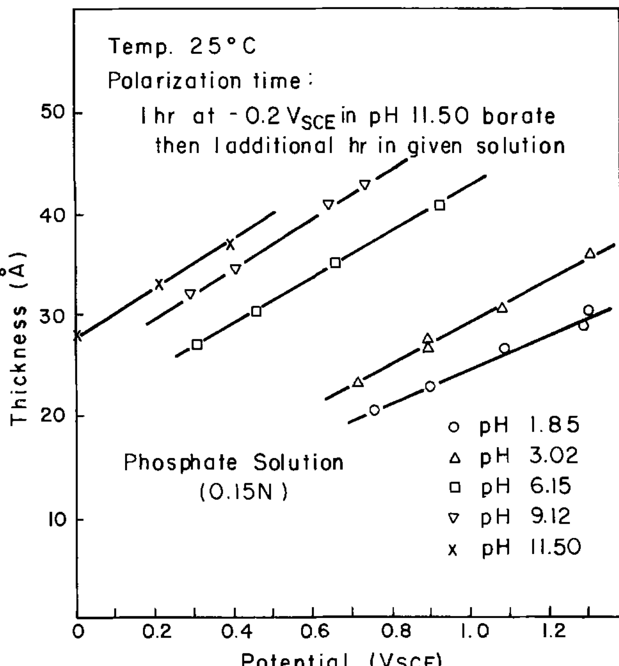

Fig. 4. Film thicknesses as a function of potential for iron that was polarized at passive potentials for 1 hr in phosphate solutions. [Figure 4 of Ref. (24).]

According to the previous calculation $\alpha = 0.743$ and $\epsilon = 1.11 \times 10^{-2}$ V/Å. Substitution of these values into Eq. [78] yields

$$i = k' \exp [19.97\, V_{ext} - 0.86\, L] \quad [79]$$

Sato and Cohen (6) have shown that, at constant anodic currents ranging from 0.3 to 23 μA/cm², $i \propto \exp \{\beta V_{ext}\}$ at any given thickness. Furthermore, they found that $\beta = 19.19$ which is in excellent agreement with the value ($\beta = 19.97$) predicted by the model developed in this paper.

Current-time transients for extremely thin film.—Equation [69] shows that for extremely thin films

$$i_s = \left(\frac{D_{V_O^{\cdot\cdot}}{}^*}{2}\right)^{1/2} \exp \left\{ \frac{F}{RT} [(1-\alpha) V_{ext} - \beta pH - \phi_{f/s}{}^\circ + \phi_R] - \frac{\Delta G_{21}{}^\circ}{xRT} \right\} t^{-1/2} \quad [80]$$

or

$$i_s = k'' \exp \left\{ \frac{F}{RT} (1-\alpha) V_{ext} \right\} t^{-1/2} \quad [81]$$

Since $\alpha = 0.743$, as determined previously

$$i_s = k'' \exp \left\{ \frac{0.257 F V_{ext}}{RT} \right\} t^{-1/2} \quad [82]$$

Usually, an extremely thin film is formed during the first few tenths of a second (*i.e.*, the transient period) during a potential jump between cathodic and passive potentials. Recently, Macdonald and Roberts (13) published a study of the potentiostatic transient behavior of carbon steel in 1M NaOH solution. They demonstrated that the transient current-time relationships follow an empirical equation of the form

$$i = k''' \exp \left\{ m \frac{F V_{ext}}{RT} \right\} t^{-n} \quad [83]$$

where n and m depend on the initial and the final potentials of the jump. Their data at high anodic potentials, where γ-Fe_2O_3 is expected to form (note that α refers to this oxide), indicate that $n = 0.5$ and m is equal to 0.21-0.23; this latter value is close to the value of 0.257 predicted by the new growth model. The success of the present model in interpreting the transient period growth kinetics should not be overemphasized, however, because the thickness of the "film" formed during this period is frequently smaller than the lattice parameter of film lattice. Therefore, attempts to model the film as a compact, continuous medium appears should be treated with caution.

Film growth due to reprecipitation of the cations from solution.—We have assumed that metal cations at the film/solution interface are in their equilibrium state. That is, the metal cations in the solution are in equilibrium with the metal cations in the highly defected film. Since the defected film has a more positive free energy of formation than a perfectly crystalline film, the concentration of metal cations in solution is greater than that for the perfectly crystalline oxide (or even hydroxide). Accordingly, metal cations will tend to reprecipitate back onto the surface to form a highly crystalline oxide (or hydroxide) upper layer. It should be pointed out that this deposit, or "secondary" layer, may not readily form because of the difficulties associated with the nucleation of a highly crystalline (low defect) phase. However, once it is formed, its thickness should be potential independent, as observed by Sato (27), provided that no change in oxidation state occurs during the deposition process and its structure may be porous. Finally, the formation of a secondary layer explains why radioactive marker experiments (18-21) indicate that the transport number of oxygen in a growing anodic passive film is less than one.

Conclusions

A point defect model has been developed to account for the kinetics of growth of passive films on metal surfaces. The model leads to a number of important generalizations concerning the kinetics of film growth.

1. The migration of oxygen anions or oxide ion vacancies ($V_O^{\cdot\cdot}$) is essential for passive film growth. On the other hand, the diffusion of metal cations or cation vacancies ($V_M^{\chi'}$) results only in metal dissolution.

2. The integrated rate law for film growth is of the form

$$\exp(2KL) - 2KL - 1 = 2KA(B-1)t$$

For thick films, this expression reduces to a logarithmic expression and yields a current transient which varies inversely with time. For very thin films, a current transient which varies inversely with the square root of time is indicated.

3. The validity of the model has been demonstrated by use of experimental data from the literature for the growth of anodic films on iron.

4. It is found that for the formation of $\gamma - Fe_2O_3$ on iron, the dependence of the potential difference across the film-solution interface on the applied potential (α) is equal to 0.743 and is independent of the identity of the anion in solution. On the other hand, the dependence of this potential difference on the pH of the solution (β) is a strong function of the identity of the anionic species in solution.

APPENDIX

Calculation of the Diffusional Rate of a Charged Species

The rate of diffusion of a charged species i under the influence of concentration and potential gradients can be calculated from the generalized Fick's first law

$$J_i = -D_i^* \frac{\partial C_i}{\partial x} - D_i^* \frac{C_i}{RT} q_i \mathbf{F} \frac{\partial \phi}{\partial x} \quad \text{[A-1]}$$

where $\partial C_i/\partial x$ is the concentration gradient, $\partial \phi/\partial x$ is the potential gradient, D_i^* is the electrochemical diffusivity of i, q_i is the charge of the species under consideration, and $\mathbf{F}$ is Faraday's constant.

According to assumption [4] in the text, the field strength, ϵ, is independent of distance so that

$$\epsilon = \frac{\phi_f}{L} = -\frac{\partial \phi}{\partial x} - \epsilon_{in} \quad \text{[A-2]}$$

where ϵ_{in} is the induced electrical field due to the presence of space charge. Since ϵ is of the order of 10^6 V/cm, we may assume that $\epsilon >> \epsilon_{in}$ and thus $\epsilon = \phi_f/L = -\partial\phi/\partial x$.

Substituting this result into Eq. [A-1] yields

$$\frac{dC_i}{dx} = -\frac{J_i}{D_i^*} + \frac{C_i}{RT} q_i \mathbf{F}\epsilon = -\frac{J_i}{D_i^*} + q_i K C_i$$

where K is defined as $\mathbf{F}\epsilon/RT$. Therefore

$$\int_{C_{i(m/f)}}^{C_{i(f/s)}} \frac{dC_i}{q_i K C_i - J_i/D_i^*} = \int_0^L dx \quad \text{[A-3]}$$

Here $C_{i(f/s)}$ and $C_{i(m/f)}$ are the concentrations of i at the f/s and m/f interfaces, respectively.

Under steady-state conditions, J_i is a constant throughout the film. The integration of Eq. [A-3] then becomes

$$J_i = q_i K D_i^* \frac{C_{i(m/f)} \exp(q_i KL) - C_{i(f/s)}}{\exp(q_i KL) - 1} \quad \text{[A-4]}$$

A Point Defect Model for Anodic Passive Films

II. Chemical Breakdown and Pit Initiation

L. F. Lin,* C. Y. Chao,* and D. D. Macdonald**

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

The point defect model that was previously developed (1) to explain the growth kinetics of a passive film has been extended to account for chemical breakdown. This model provides quantitative explanations of the dependence of breakdown potential on halide concentration, and of the incubation time-breakdown overpotential relationships that have been observed for iron and nickel in aqueous solutions. Limitations of the model are identified and discussed.

It is generally recognized that passivity is due to the formation of a thin film on the metal surface. Four basic questions arise as to the nature of the film: (*i*) What is the composition of the film? (*ii*) How fast does it grow? (*iii*) Why do some specific anions (*e.g.*, Cl^-, Br^-, etc) result in local breakdown and hence in the initiation of pitting? (*iv*) What is the ionic and electronic structure of the film? Any reasonable model for the film should provide satisfactory answers to these four questions.

Recently, Chao, Lin, and Macdonald (1) proposed a point defect model for the growth of a passive film. This model readily provides answers to the first two questions: (*i*) The passive film is a crystalline compound (*e.g.*, an oxide) which contains a high concentration of point defects (note that in an extreme case, where the concentration of point defects is large enough, the passive film may be regarded as amor-

Key words: metals, passivity, corrosion, films.

phous in structure), and (ii) the kinetics of film growth can be described by a linear logarithmic law of the form

$$\exp(2KL) - 2KL - 1 = 2KA(B - 1)t$$

where L is the film thickness and t is time. The other parameters are defined in Ref. (1).

The present paper provides an answer to the third question. A clear-cut explanation of the film breakdown phenomenon not only makes the model more acceptable, but also unifies two important processes in corrosion science—passivation and localized corrosion.

Experimental Observations and Existing Models

Due to extensive studies over the last five decades, a great deal of experimental data now exists concerning film breakdown and subsequent corrosion (*e.g.*, pitting). Although not all of the experimental data are in agreement, it is generally recognized that:

1. Film breakdown occurs only above some critical potential, V_c (the critical breakdown potential).
2. For a given material, V_c is a function of halide activity (*e.g.*, Cl^- or some other halide) of the form

$$V_c = A - B \log a_{X^-} \quad [1]$$

where A, B are constants and a_{X^-} is the activity of the halogen anion.

3. Breakdown occurs at highly localized sites.
4. There exists an incubation time between the addition of halide and the appearance of pits on the surface. This incubation time is potential dependent.
5. Ellipsometric work by Kruger *et al.* (3) reveals that during the incubation period the ellipsometric readings for the passive film undergo a sudden change which might be attributed to the incorporation of Cl^- anion into the oxide film.

Several models have been proposed to account for the breakdown of the passive film. The more popular models are briefly discussed below.

Competitive ion adsorption theory.—Uhlig (4) and Kolotyrkin (5) proposed that both $O^=$ and Cl^- anions can be adsorbed onto metal surfaces. When $O^=$ is adsorbed, the metal passivates whereas adsorption of chloride does not produce a passive surface. Thus, above a critical potential, where Cl^- adsorption is favored over $O^=$ adsorption, breakdown of passivity occurs.

Complex ion formation theory.—Hoar and Jacob (6) assumed that a small number of Cl^- ions jointly adsorb around a cation in the film surface to form a high energy complex. Once formed, this complex will readily dissolve into the solution. The film is thus made thinner locally. The stronger anodic field at this site will rapidly transfer another cation to the surface where it will meet more Cl^-, complex with them, and thereby enter the solution. This process will result in "autoaccelerated" breakdown.

Ion penetration theory.—This theory suggests that Cl^- incorporates into and migrates through the passive film, and, upon reaching the metal/film interface, results in film breakdown. This theory has strong support from the ellipsometric work of Kruger *et al.* (3). However, theoretical calculations (7) reveal that the time required for Cl^- to penetrate through a film is much longer than the induction time measured experimentally.

Chemico-mechanical theory.—Hoar (8) postulated that the adsorption of Cl^- onto the film/solution interface results in "peptization" due to the mutual repulsion of the adsorbed charged species. When the repulsive forces are sufficiently high, the film cracks. Later, Sato (9) suggested that thin films always contain a "film pressure"

$$P = P_o + \frac{\delta(\delta - 1)\epsilon^2}{8\pi} - \gamma/L \quad [2]$$

where P is the film pressure, P_o is the atmospheric pressure, δ is the film dielectric constant, ϵ is the electric field, γ is the surface tension, and L is the film thickness. Sato proposed that adsorption of chloride ion greatly reduces the surface tension γ which in turn, increases P. When P exceeds some critical value, the film breaks down.

Although, these models can account for most of the experimental data qualitatively, no quantitative treatment has been developed so far. A quantitative model for film breakdown is presented below.

Mechanism for the Breakdown of a Passive Film

This section is divided into two parts. The first part describes the basic concepts behind the model and the second part presents a mathematical treatment which yields analytical expression for the critical breakdown potential and the incubation time.

Basic concepts.—In a previous study (1), the authors proposed a model for the growth of a passive film which involves transport of both anions (oxygen ion) and cations (metal ion) or their respective vacancies. Furthermore, the model concludes that anions diffuse from the film/solution (f/s) interface to the metal/film (m/f) interface and subsequently result in film thickening. On the other hand, cation diffusion, while not excluded, results only in dissolution and not in the growth of the primary passive film. This model has successfully accounted for a number of previously unexplained experimental observations (1).

One consequence of the diffusion of metal cations from the m/f to the f/s interfaces is that metal vacancies (or "metal holes")[1] are created at the metal/film interface. These metal "holes" will tend to submerge into the bulk of the metal and hence to "disappear." However, when the cation diffusion rate (i.e., the metal hole production rate) is higher than the rate of "metal hole" submergence into the bulk, the metal holes will start piling up and hence will form a void at the metal/film interface (this is the process of pit incubation). When the void grows to a certain critical size, the passive film suffers local collapse which then marks the end of pit incubation period. Subsequently, the collapsed site dissolves much faster than any other place on the surface thereby leading to pit growth. According to this argument, the criterion for pit initiation can be expressed as follows

$$(J_{ca} - J_m) \times (t - \tau) \geqq \xi \quad [3]$$

where J_{ca} is the cation diffusion rate in the film, J_m is the rate of submergence of the metal holes into the bulk metal, t is the time required for metal holes to accumulate to a critical amount, ξ, (*i.e.*, t is the incubation time), and τ is a constant whose meaning will become clear in the following discussion.

Up to this point, we have described a process for film breakdown without incorporating a specific role for halide ion in the breakdown phenomenon. In the next part of this section, we will demonstrate that the presence of halide ions will greatly enhance J_{ca} and hence will accelerate film breakdown.

Mathematical expression for the critical breakdown potential and incubation time.—In the Appendix of Ref. (1), it was demonstrated that J_{ca} is given by

$$J_{ca} = \chi K D_{V_M{}^{\chi'}}{}^* \left[\frac{C_{V_M{}^{\chi'}}(\text{m/f}) \exp(-\chi KL) - C_{V_M{}^{\chi'}}(\text{f/s})}{\exp(-\chi KL) - 1} \right]$$

where, as defined in Ref. [1], χ is the charge on a

[1] The metal vacancy that is referred to here is a vacancy that is in the metal. In order to distinguish this from the metal vacancy that is in the film, we shall designate the former vacancy as a "metal hole."

cation, K is equal to $\mathbf{F}\epsilon/RT$, ϵ is the field strength in the film, $D_{V_M{}^{\chi'}}{}^*$ is the diffusivity of the cation vacancy, L is the film thickness, and $C_{V_M{}^{\chi'}}$ (m/f) and $C_{V_M{}^{\chi'}}$ (f/s) are the concentrations of cation vacancies at the metal/film and film/solution interfaces, respectively. Cation vacancies in the film are produced at the f/s interface but are consumed at the m/f interface so that one should expect $C_{V_M{}^{\chi'}}$ (f/s) > $C_{V_M{}^{\chi'}}$ (m/f). Moreover, since the passive films on many metals and alloys are of the order of 10 ~ 40Å thick, then exp $(-\chi KL) << 1$, and the above equation can be simplified to

$$J_{ca} = \chi K D_{V_M{}^{\chi'}}{}^* C_{V_M{}^{\chi'}}(\text{f/s}) \quad [4]$$

If the f/s interface achieves local equilibrium, consideration of the Schottky-pair reaction leads to the following relationship

$$[C_{V_O{}^{\cdot\cdot}}(\text{f/s})]^{\chi/2}[C_{V_M{}^{\chi'}}(\text{f/s})] = \left[\frac{N_v}{\Omega}\right]^{1+\chi/2} \exp\left(-\frac{\Delta G_s{}^\circ}{RT}\right) \quad [5]$$

where N_v is Avogadro's number, Ω is the molecular volume per cation, and $\Delta G_s{}^\circ$ is the change in Gibbs energy for the Schottky-pair reaction. Combining Eq. [4] and [5], one obtains

$$J_{ca} = J^\circ[C_{V_O{}^{\cdot\cdot}}(\text{f/s})]^{-\chi/2} \quad [6]$$

where $J^\circ = \chi K D_{V_M{}^{\chi'}}{}^* [N_v/\Omega]^{1+\chi/2} \exp(-\Delta G_s{}^\circ/RT)$

Equation [6] shows that J_{ca} can be enhanced by decreasing $C_{V_O{}^{\cdot\cdot}}$(f/s). Kruger *et al.* (3) have shown that Cl^- ions are capable of being incorporated into passive films. It is reasonable to assume that this is due to the occupation by Cl^- ions of oxygen vacancies,[2] that is

$$V_O{}^{\cdot\cdot} + Cl^-{}_{(aq)} = Cl_O{}^{\cdot} \quad [7]$$

where $V_O{}^{\cdot\cdot}$ is an oxygen vacancy in the film, and $Cl_O{}^{\cdot}$ is a chloride anion occupying an oxygen lattice site. Thus, as the concentration of chloride is increased, the number of vacancies that are occupied also increases. This gives rise to a concomitant decrease in the $V_O{}^{\cdot\cdot}$ concentration at the f/s interface. Quantitatively, Eq. [7] leads to the following expression (see derivation in the Appendix)

$$C_{V_O{}^{\cdot\cdot}(f/s)} \times a_{Cl^-} = u \exp\left(-\frac{\mathbf{F}\alpha V_{app}}{RT}\right) \quad [8]$$

Substitution of Eq. [6] and [8] into Eq. [3] yields the criterion for pit initiation as

$$\left[J^\circ u^{-\chi/2} \exp\left(\frac{\chi\mathbf{F}\alpha V_{app}}{2RT}\right)(a_{Cl^-})^{\chi/2} - J_m\right] \times (t - \tau) \geq \xi \quad [9]$$

Equation [9] shows that pit initiation will not occur if

$$J^\circ u^{-\chi/2} \exp\left(\frac{\chi\mathbf{F}\alpha V_{app}}{2RT}\right)(a_{Cl^-})^{\chi/2} < J_m$$

and that the critical pitting potential, V_c, is given by the equality

$$J^\circ u^{-\chi/2} \exp\left(\frac{\chi\mathbf{F}\alpha V_c}{2RT}\right)(a_{Cl^-})^{\chi/2} = J_m \quad [10]$$

Equation [10] is easily rearranged to yield

$$V_c = \frac{4.606RT}{\chi\mathbf{F}\alpha}\log\frac{J_m}{J^\circ u^{-\chi/2}} - \frac{2.303RT}{\alpha\mathbf{F}}\log a_{Cl^-} \quad [11]$$

The form of Eq. [11] coincides with experimental observation[3] (Eq. [1]) with

$$A = \frac{4.606RT}{\chi\mathbf{F}\alpha}\log\frac{J_m}{J^\circ u^{-\chi/2}}$$

and

$$B = 2.303RT/\alpha\mathbf{F}$$

In Ref. (1), we have demonstrated that α is equal to 0.743 for iron and Ref. (10) reveals that $\alpha = 0.878$ for Ni at 25°C. These data enable us to calculate the theoretical value for constant B in Eq. [1], *i.e.*, $B = 2.303RT/\alpha\mathbf{F} = 0.080$ (V) for iron, and $B = 0.067$ (V) for nickel. The calculation for constant A in Eq. [1] is not possible at the present time because it involves a number of unknown parameters.

Table I lists the experimental values for B as compiled by Galvele (11). It can be seen that the experimental value for Ni (0.071V) agrees very well with the theoretical value (0.067V) computed above. The experimental data for iron are badly scattered, indicating that the experimental determination of B is anything but easy. Nevertheless, the experimental data scatter around the theoretical value of 0.080V. Thus, it is concluded that the theoretical values are physically reasonable.

Although Eq. [11] was derived for Cl^--containing solutions, the same arguments can be extended to Br^-- and I^--containing systems. For brevity, the derivation is omitted. Interested readers can do it themselves by following the same steps from Eq. [7] to Eq. [11]. The extended treatment leads to two conclusions: (*i*) The constant B is independent of the identity of the anion which is present in the system and (*ii*) constant A increases with the energy of incorporation of an anion into an oxygen vacancy. Accordingly, values for A are expected to lie in the order $I^- > Br^- > Cl^-$.

Figure 1 shows the experimental result of Janik-Czachor (14) for the critical pitting potential for iron in iodide, bromide, and chloride-containing solutions. It can be seen that the experimental data are in excellent agreement with the theoretical predictions.

The analysis presented above also yields an analytical function for another important parameter in pitting corrosion—the incubation time. Substitution of Eq. [10] into Eq. [9] therefore gives

$$J^\circ u^{-\chi/2}(a_{Cl^-})^{\chi/2}\left[\exp\left(\frac{\chi\mathbf{F}\alpha V_{app}}{2RT}\right) - \exp\left(\frac{\chi\mathbf{F}\alpha V_c}{2RT}\right)\right](t-\tau) \geq \xi \quad [12]$$

or

$$J^\circ u^{-\chi/2}(a_{Cl^-})^{\chi/2}\exp\left(\frac{\chi\mathbf{F}\alpha V_c}{2RT}\right)\left[\exp\left(\frac{\chi\mathbf{F}\alpha\Delta V}{2RT}\right) - 1\right](t-\tau) \geq \xi \quad [13]$$

where $\Delta V = V_{app} - V_c$ is the breakdown overpotential.

Equation [13] shows that when the chloride concentration in the solution is fixed (*i.e.*, a_{Cl^-} and V_c are constants), the incubation time, t, is a function of the

Table I. Values for constant B in Eq. [1] for iron and nickel [Reproduced from Ref. (11)]

Metal	Buffer	Value of B (V)	Ref.
Fe	None (pH 10)	0.058	(12)
Fe	Borate (pH 8)	0.13	(13)
Fe	Phthalate (pH 5)	0.08	(13)
Fe	Borate (pH 8.4)	0.10	(14)
Fe	Borate (pH 8.4)	0.15-0.20	(15)
Fe	Various	0.03-0.08	(2)
		Mean 0.10 ± 0.05	
Ni	None	0.071	(16)

[2] Kruger has proposed a slightly different reaction from reaction [7].

[3] J_m is the rate of submergence of metal holes into the metal. Accordingly, it can be related to the bulk diffusion rate for holes in the metal and is independent of applied potential.

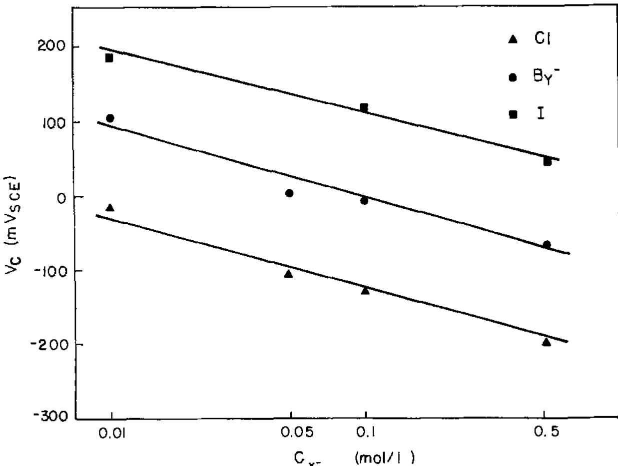

Fig. 1. Critical pitting potential V_c, vs. halide concentration (14).

breakdown overpotential. Mathematically, this can be expressed as

$$t = \xi' \left[\exp\left(\frac{x\mathbf{F}\alpha\Delta V}{2RT}\right) - 1 \right]^{-1} + \tau \qquad [14]$$

where

$$\xi' = \xi / J^{\circ} u^{-x/2} (a_{Cl^-})^{x/2} \exp\left(\frac{x\mathbf{F}\alpha V_c}{2RT}\right) \qquad [15]$$

Furthermore, when $\Delta V \geqq 0.05V$, $\exp(x\mathbf{F}\alpha\Delta V/2RT) >> 1$, so that Eq. [14] can be simplified to yield

$$t = \xi' \left[\exp\left(-\frac{x\mathbf{F}\alpha\Delta V}{2RT}\right) \right] + \tau \qquad [16]$$

At this point it is necessary to digress somewhat to discuss the significance of τ. Equations [9] and [12] were obtained by substituting Eq. [4] into Eq. [3]. However, Eq. [4] is valid only for steady-state diffusion, so that diffusion that takes place during the initial transient period is not properly included. The parameter τ is therefore introduced to account for diffusion during the transient period and it is a measure of the time over which transient diffusion is significant compared with steady-state diffusion.

Equation [16] shows that for very large values for ΔV, the incubation time, t, is dominated by the transient time, τ. On the other hand, for small values for ΔV (but that are still larger than 0.05V), t is proportional to $\exp(-x\mathbf{F}\alpha\Delta V/2RT)$. It is interesting to note that Heusler and Fischer (2) obtained an empirical equation for the relationship between t and ΔV of the form

$$\log t/t_o = V_o/\Delta V \qquad [17]$$

where t_o and V_o are constants.

Figure 2 shows the experimental data of Heusler and Fischer plotted in accordance with Eq. [17]. Replotting of the same data as log t *vs.* ΔV (Fig. 3), however, shows that Eq. [16] is also valid. Thus, for large values for ΔV, t approaches the value for the constant (τ), which is apparently of the order of a few seconds. However, for small values for ΔV, log t is inversely proportional to ΔV with a slope of -18.5. This value is in excellent agreement with the theoretical value of

$$\text{gradient} = -\frac{x\mathbf{F}\alpha}{4.606RT} = -18.8V^{-1}$$

which is obtained from Eq. [16] with $x = 3$ and $\alpha = 0.743$ for iron [see Ref. (1)].

Discussion

The analyses presented above demonstrate that the model developed in this paper for halide (in particular chloride) induced breakdown of passive films is in

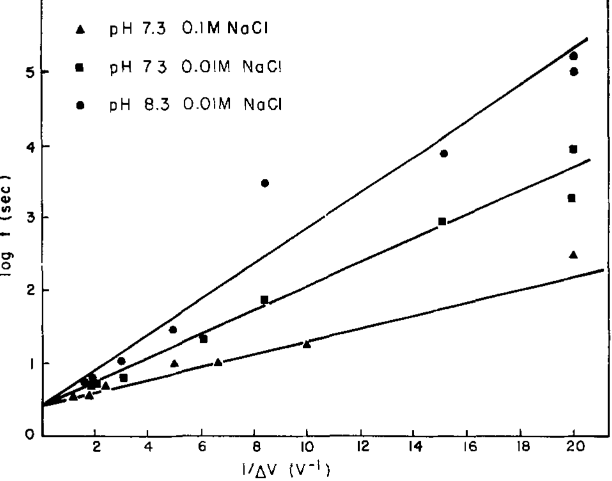

Fig. 2. Times t_i incubation for pitting of passive iron in borate buffer solution, 25°C, as a function of the reciprocal value of the potential difference, $\Delta V = V - V_c$ vs. the critical pitting potential, V_c. ▲: pH 7.3, 0.1M NaCl; ■: pH 7.3, 0.01M NaCl; ●: pH 8.3, 0.01M NaCl (17).

quantitative agreement with experimental data for the pitting of iron and nickel in halide-containing aqueous solutions. To our knowledge, no other model has demonstrated the same level of precision—in terms of both the functional and analytical dependencies of the critical pitting potential on halide concentration, and of the incubation time on breakdown overpotentials.

A limitation of the model in its present stage of development is that no surface "structure" (*e.g.*, inclusions, grain boundaries, etc.) is specifically taken into account, although we believe that the model is readily extended to the heterogeneous case. For example, because heterogeneities in the passive film are also likely to be sites of high defect concentration, the model presented here provides a qualitative explanation for the tendency for pits to nucleate at inclusions, grain boundaries, and other macroscopic defects. Also, the model may not be directly applicable to those cases in which the anion in solution forms strong soluble cation complexes, rather than incorporating into the outer layer(s) of the film. Finally, to our knowledge no direct observations of void formation have been made, although it is possible that this is due to a lack of incentive in the past to examine in detail the nature of the metal/film interface prior to formation of a pit.

APPENDIX

The reaction that is proposed to occur at the film/solution interface is

$$V_O^{\cdot\cdot} + Cl^-_{(aq)} = Cl_O^{\cdot} \qquad [A\text{-}1]$$

Since local equilibrium is established at this interface, the sum of the electrochemical potentials of the reactants should be equal to the electrochemical potential of the product. Therefore

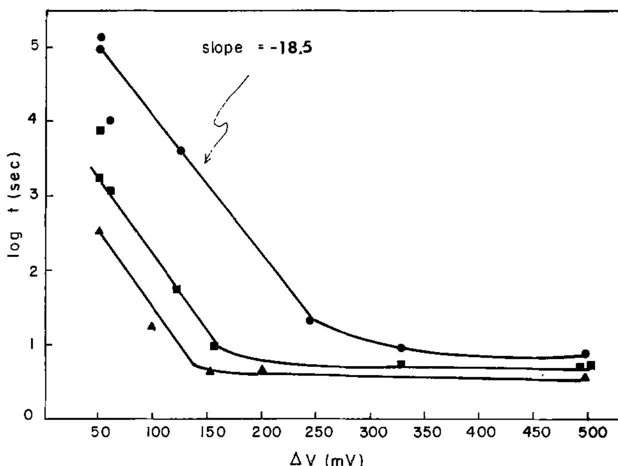

Fig. 3. Plot of log t vs. ΔV in accordance with Eq. [16]. Data taken from Fig. 2.

$$\mu_{Cl^-} - F\phi_s + \mu_{V_O^{\cdot\cdot}} + 2F\phi_f = \mu_{Cl_O^{\cdot}} + F\phi_f \quad \text{[A-2]}$$

where μ is the chemical potential, ϕ_s and ϕ_f are the flatband potentials of the solution and film, respectively. Furthermore

$$\phi_f - \phi_s = \phi_{f/s}$$

and Eq. [A-2] becomes

$$\mu_{Cl^-} + \mu_{V_O^{\cdot\cdot}} - \mu_{Cl_O^{\cdot}} + F\phi_{f/s} = 0 \quad \text{[A-2']}$$

The standard Gibbs energy of reaction [A-1] is

$$\mu_{Cl_O^{\cdot}}^{\circ} - \mu_{Cl^-}^{\circ} - \mu_{V_O^{\cdot\cdot}}^{\circ} = \Delta G_{A-1}^{\circ} \quad \text{[A-3]}$$

where $\mu_{Cl_O^{\cdot}}^{\circ}$ is the standard chemical potential of $Cl_O^{\cdot}$ and ΔG_{A-1}° is the standard Gibbs energy of reaction [A-1]. Since

$$\mu_{Cl^-} = \mu_{Cl^-}^{\circ} + RT \ln a_{Cl^-}$$

$$\mu_{Cl_O^{\cdot}} = \mu_{Cl_O^{\cdot}}^{\circ} + RT \ln a_{Cl_O^{\cdot}}$$

and

$$\mu_{V_O^{\cdot\cdot}} = \mu_{V_O^{\cdot\cdot}}^{\circ} + RT \ln a_{V_O^{\cdot\cdot}}$$

then combining Eq. [A-2'] and [A-3] results in

$$\frac{a_{V_O^{\cdot\cdot}}\, a_{Cl^-}}{a_{Cl_O^{\cdot}}} = \exp\left[\frac{\Delta G_{A-1}^{\circ} - F\phi_{f/s}}{RT}\right] \quad \text{[A-4]}$$

Now, in most of metal-oxygen-chloride ternary systems, the mutual dissolution of MO-MCl is very small, so that once a "$Cl_O^{\cdot}$" species is formed, it can be regarded as a precipitate of MCl in the MO matrix. Accordingly $a_{Cl_O^{\cdot}} = 1$ in all cases and Eq. [A-4] becomes

$$a_{V_O^{\cdot\cdot}} a_{Cl^-} = \frac{\Omega}{N_v} C_{V_O^{\cdot\cdot}} a_{Cl^-} = \exp\left[\frac{\Delta G_{A-1}^{\circ} - F\phi_{f/s}}{RT}\right] \quad \text{[A-5]}$$

In Ref. (1), the authors have demonstrated that

$$\phi_{f/s} = \alpha V_{app} + \beta pH + \phi_{f/s}^{\circ}$$

Thus, for a given solution, Eq. [A-5] becomes

$$C_{V_O^{\cdot\cdot}(f/s)} \times a_{Cl^-} = u \exp\left(-\frac{F\alpha V_{app}}{RT}\right) \quad \text{[A-6]}$$

where

$$u = \frac{N_V}{\Omega} \exp\left(\frac{\Delta G_{A-1}^{\circ} - F\beta pH - F\phi_{f/s}^{\circ}}{RT}\right)$$

Measurement of pH and Redox Potential in Boric Acid/Lithium Hydroxide Buffer Solutions at Elevated Temperatures

T. Tsuruta and D. D. Macdonald*

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

A palladium-hydride electrode (Pd black on Pt) was used for the measurement of pH in high temperature aqueous systems (25°-275°C). The electrode potential was calibrated against boric acid/lithium hydroxide buffer solutions, whose pH_T *vs.* temperature profiles have been calculated (1) using known dissociation constants for the components. The plateau potential for the $\alpha + \beta$ phase was observed up to 150°C, but was not observed above 200°C. The potential measured above 200°C was identified to be the redox potential and to correspond to the hydrogen electrode potential in the case of a hydrogenated system. The redox potential measured in hydrogenated systems were found to exhibit linear Nernstian responses to temperatures up to 275°C, but deviations of the measured potentials from equilibrium values were detected at temperatures above 200°C. The deviations are most probably due to uncertainties in the thermal and isothermal liquid junction potentials associated with the external reference electrode, and to uncertainties in the thermodynamic properties of high temperature aqueous solutions.

The importance of pH and redox potential measurements in high temperature aqueous systems, such as BWR and PWR (primary, secondary) nuclear systems, geothermal brines, chemical industries process waters, and for characterizing the solutions which have been used extensively in high temperature electrochemical studies, is widely recognized. A major obstacle to the measurement of pH at elevated temperatures is the lack of a reliable and generally applicable method for measuring the activity of hydrogen ion in these hostile environments. The precise pH measurements using concentration cells, which have been described by Mesmer *et al.* (2-5) and Macdonald and co-workers (6-8), and the use of single hydrogen electrodes, require the presence of molecular hydrogen in the system. Accordingly, these techniques are applicable only to those systems that are stable to reduction by molecular hydrogen. Many metal ions and anions are stable in hydrogenated systems and hydrogen electrodes have been shown to function at elevated temperatures. However, the problems involved with these electrodes are the precise determination of hydrogen fugacity and the difficulty of application for *in situ* pH measurements.

The potential decay of palladium-hydride electrodes has been used for the measurement of pH in high temperature aqueous systems by a number of workers (1, 9-12). The work of Dobson and co-workers (9-12) on this system has indicated that palladium-hydride electrodes exhibit Nernstian responses up to 195°C. However, their work was restricted to highly acidic or basic solutions, and no data were obtained for the technologically important pH range from 5 to 13. Recently, the palladium-hydride electrode has been used by Macdonald *et al.* (1) for the measurement of pH in various boric acid/lithium hydroxide buffer solutions ranging in pH (25°C) between 5 and 13 at temperatures to 275°C. Although linear potential *vs.* pH correlations were observed for all temperatures studied, the measured potentials deviated significantly from the equilibrium values calculated on the assumption that the potential determining reaction is $H^+ + e^- = H$ (Pd, $\alpha + \beta$). In this report, we discuss the applicability of the palladium-hydride electrode for pH measurements at temperatures above 200°C.

Experimental

The high temperature recirculating loop used for this study is shown in Fig. 1. Briefly, the aqueous solution was pumped from a reservoir through a heat exchanger and into the autoclave using a positive displacement diaphragm pump. The exiting solution was heat exchanged with the input solution and then discharged back to the reservoir via a back pressure regulator. The pressure in the circuit was maintained at 10 kg/cm^2 above the saturated vapor pressure in order to maintain a single liquid phase.

Schematic diagrams of the measurement cell and the external reference electrode are shown in Fig. 2 and 3, respectively. Details of the construction, operation, and calibration of the external reference electrode have been recently given by Macdonald, Scott, and Wentrcek (6).

Palladised platinum electrodes were employed. The Pd/Pt electrode was palladised cathodically in acidified

$PdCl_2$ solution (2 weight percent $PdCl_2$ in 1*N* HCl) at a current density of 160 mA/cm^2 for 2 min.

The solution in the reservoir was purged with prepurified argon or with hydrogen-nitrogen mixtures to remove oxygen and to maintain the desired concentration of hydrogen in the system. At all temperatures from 25° to 275°C, the Pd/Pt electrodes were cathodically charged at a current density of 12 mA/cm^2 for 6 min, prior to measurement of the potential decay.

Results and Discussion

Potential decay.—Typical potential decay curves for the Pd/Pt electrode in 0.01m LiOH at 25°C (*p*H 12.0) deaerated by argon or hydrogen are shown in Fig. 4. The $\alpha + \beta$ phase plateau potential (−659 mV *vs.* SHE) was observed in argon deaerated solution, and the *p*H was calculated as 12.01 using known data for $P_{H_2,\beta\alpha}$ (0.0194 atm) (1). Since the measured steady-state potential (−710 mV *vs.* SHE) in the hydrogen deaerated solution was 51 mV more negative than the $\alpha + \beta$ phase plateau potential, it was suspected that the Pd/Pt electrode was acting as a normal hydrogen electrode in this system (*i.e.*, one which involves equilibrium between H^+ and dissolved H_2 in the aqueous phase). This was confirmed by briefly anodizing the electrode as shown in Fig. 4. After brief anodization the potential decayed rapidly to the plateau at −659 mV, but then later decayed to the redox potential at −710 mV. It is apparent that anodization is necessary in order to observe the palladium-hydride plateau potential in highly hydrogenated systems, even at ambient temperature.

Potential decay curves for the Pd/Pt electrode in 0.01m LiOH over the temperature range 25°-275°C are shown in Fig. 5 and 6. The $\alpha + \beta$ phase plateau potentials were observed up to 150°C in argon deaerated solutions and those saturated with 5% H_2 in nitrogen, but not in the case of those systems purged with pure hydrogen. In this latter case, the stable potential was found to be several tens of millivolts more negative than the palladium-hydride plateau potentials and is attributed to equilibrium between H^+ and H_2, both in the aqueous phase (i.e., the normal hydrogen electrode reaction). At higher temperatures (>200°C) no palladium-hydride plateau potentials were observed even for argon deaerated systems. This behavior is attributed to the rapid decrease in plateau lifetime with temperature, a trend which is well illustrated by the data at lower temperatures ($\leqslant$150°C, Fig. 5). Since the thickness of the plated Pd layer on Pt employed in these measurements was thought to be insufficient to maintain the $\alpha + \beta$ phase for a significant time above 200°C, the potential decay measurements were repeated at 150° and 200°C using a thickly plated Pd/Pt electrode (160 mA/cm^2 × 30 min) and a palladium wire electrode (0.5 mm diam, bright and palladised conditions). However, an improvement of plateau lifetime was observed only at 150°C and no plateau potential was exhibited at 200°C with either electrode.

The phase diagram for the palladium hydrogen system has been extensively studied by many workers (9-16), and the average of their data is shown in Fig. 7 together with the diffusion coefficients for hydrogen in

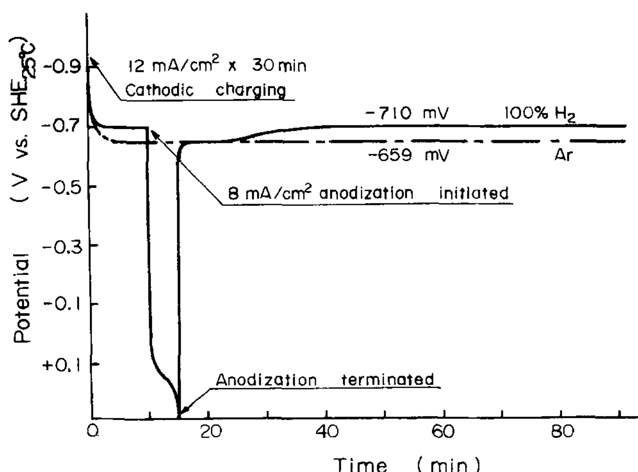

Fig. 4. Potential decay curves for a palladised platinum electrode in 0.01m LiOH deaerated by Ar or H_2 at 25°C.

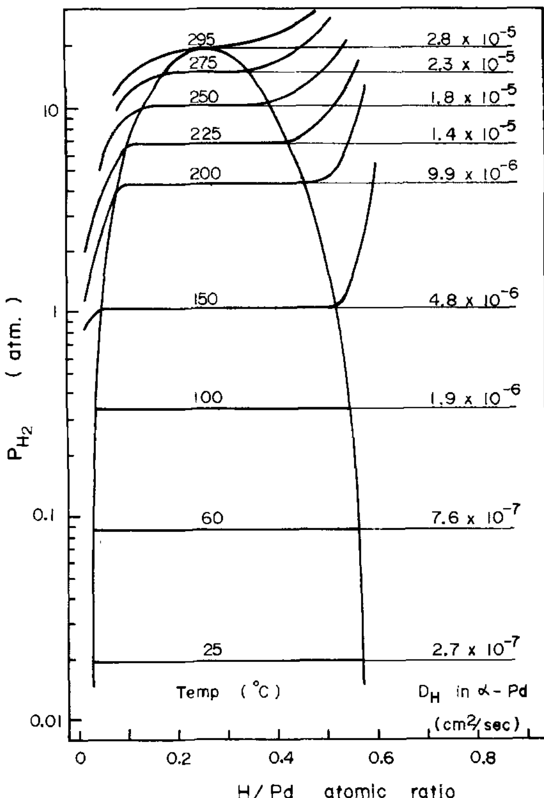

Fig. 7. Phase diagram for the palladium-hydrogen system

According to the data shown in Fig. 7, the width of the $\alpha + \beta$ phase region decreases moderately, but the diffusion coefficients for hydrogen in α-Pd increase rapidly, with increasing temperature. Therefore, it is apparent that the reason that no plateau is observed above 200°C is that hydrogen escapes so rapidly from the surface that the $\alpha + \beta$ phase cannot be maintained at the interface. A drastic decrease in plateau lifetime is also reported by Dobson and co-workers (12) who showed that unless the entry of hydrogen to Pd is restricted, the plateau lifetime observed during absorption of hydrogen from solution (*i.e.*, the reverse of the present case) is very short.

A second factor which must be considered in assessing the viability of the palladium-hydride electrode is the relative magnitude of the partial pressure of hydrogen in the aqueous phase and the dissociation pressure of palladium-hydride. For example, if the partial pressure of hydrogen in the aqueous phase is greater than the dissociation pressure of palladium-hydride, the potential will decay only as far as the normal hydrogen electrode potential and no plateau potential will be observed (unless anodization is employed, see Fig. 4). This is apparently the case at 25°C since the partial pressures of hydrogen for both the 5% and 100% H_2 systems are greater than the dissociation pressure of Pd_xH as indicated in Fig. 7. At higher temperatures (60°-150°C), however, the dissociation pressure of palladium-hydride is greater than the partial pressure of hydrogen for the argon deaerated and 5% H_2 spurged systems so that palladium-hydride plateau potentials are observed. It is not until a temperature of 150°C is attained that the dissociation pressure of palladium-hydride exceeds the partial pressure of hydrogen in the 100% H_2 spurged environment. In principle, therefore, plateau potentials should be observed in this system at high temperatures. However, the plateau lifetime decreases so rapidly with temperature that no distinct plateaus were observed in these experiments at 200°C and above.

Redox potential measurement.—It was argued from the data presented in Fig. 4-6 that the measured redox

potentials in hydrogenated systems correspond to the normal hydrogen electrode potentials. This view was confirmed by calculation, in that the redox potentials at elevated temperatures were found to correspond approximately to the hydrogen electrode potentials. Since the hydrogen electrode is an effective means for measuring the *p*H of the solution (at least under ambient conditions), the redox and plateau potentials were measured in various boric acid/lithium hydroxide buffer solutions, whose pH_T *vs.* temperature profiles have been computed by Macdonald and co-workers (1).

Corrections for the liquid junction potential and the partial pressure of hydrogen were made in order to compare the measured potentials with the theoretical values for the hydrogen electrode. Approximate values for the liquid junction potential between the internal KCl solution of the reference electrode and the $B(OH)_3/LiOH$ buffer systems at each composition and temperature have been given by Macdonald *et al.* (1) and are used in this analysis. The hypothetical partial pressure of hydrogen in the high temperature solution has been also calculated by Macdonald *et al.* (18) from the known concentration of hydrogen in the reservoir at 25°C and the Henry's law constants (19) up to 275°C. Briefly, the equivalent partial pressure of hydrogen at the operating temperature for x ppm H_2 in the reservoir at 25°C is

$$P_{H_2} = x/1000M_{H_2} \cdot B_{H_2,T} \quad [2]$$

where M_{H_2} is the molecular weight of hydrogen and $B_{H_2,T}$ is the Henry's law constant at temperature T.

The observed difference between the measured and calculated hydrogen electrode potentials (both the palladium-hydride and redox electrodes) in boric acid/lithium hydroxide buffer solutions are shown in Fig. 8 as a function of temperature. The measured normal hydrogen (redox) electrode potentials in 0.01m $B(OH)_3$/10^{-2}-10^{-4}m LiOH buffer solutions were in good agreement with the calculated values (within 5 mV up to 200°C and 15 mV at 275°C) and in all cases the deviations at elevated temperatures ($T > 200°C$) were positive.

The results of the hydrogen electrode potential measurements are summarized in Fig. 9 and 10 together with the theoretical Nernstian responses calculated using the estimated *p*H values (1) for boric acid/lithium hydroxide systems. Linear Nernstian responses were observed over the temperature range between 25° and 275°C. However, the positive deviations of the measured values from the calculated potentials above 200°C are again apparent.

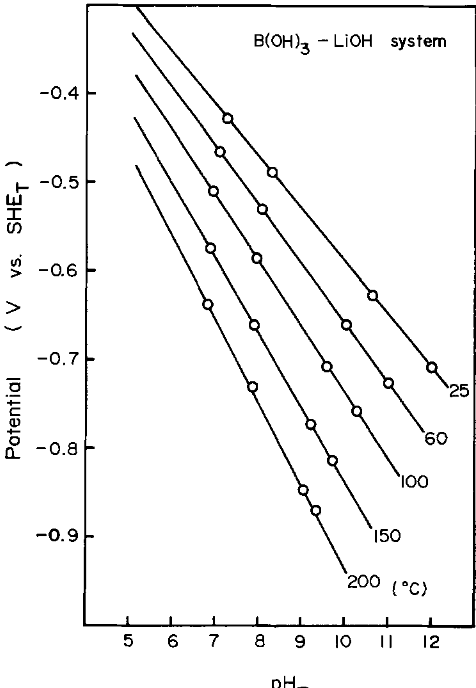

Fig. 9. Potential/*p*H correlations for the Pd/Pt hydrogen electrode. —— theoretical; ○ measured.

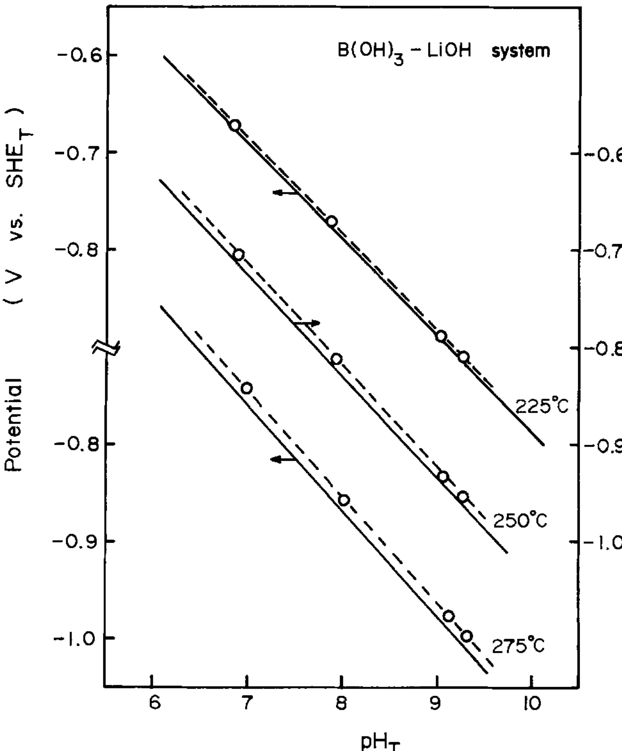

Fig. 10. Potential/*p*H correlations for the Pd/Pt hydrogen electrode. —— theoretical; --○-- measured.

The origin of this error has not been established unequivocally. Three sources are possible: (*i*) uncertainty in the isothermal liquid junction potential, (*ii*) error in the calculated *p*H values, and (*iii*) uncertainty in the calculated equilibrium potential for the H_2/H^+ couple. Because the error between the measured and calculated equilibrium potentials amounts to no more than 10-15 mV, it is difficult to assess which of the possible sources of error dominates. However, it should

be noted that the chemical potential of the hydrogen ion at elevated temperatures was computed using estimated entropy values (19) and that uncertainties from this source alone could easily account for the observed deviations.

Conclusions

1. A necessary condition for the appearance of a plateau in the cathodic potential decay for a palladium-hydride electrode in aqueous solution is that the partial pressure of hydrogen in the aqueous phase be less than the dissociation pressure of the hydride phase. If this condition is not satisfied, the stable potential corresponds to that for the normal hydrogen electrode. However, this limitation may be overcome by brief anodization immediately after cathodically depositing hydrogen into the metal phase.

2. The lifetime of the potential plateau for a palladium-hydride electrode was found to decrease sharply with increasing temperature, such that at 200°C and above no plateau could be discerned in the potential decay curves obtained in these studies even though the necessary condition stated in (1) above was satisfied.

3. Positive deviations of the measured hydrogen electrode potentials from the true equilibrium values were observed at temperatures above 200°C. The deviations are possibly due to uncertainties in the isothermal liquid junction potential, the calculated pH values for the buffer solution at elevated temperatures, and in the calculated equilibrium potential for the H_2/H^+ couple at elevated temperatures. This latter source arises because the chemical potential of the hydrogen ion at elevated temperatures is estimated using an entropy extrapolation technique.

Thin Platinum Films on Silicon

L. A. Harris and J. A. Hugo

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Smooth continuous films of platinum, as little as 20Å thick, may be sputter deposited on silicon that is sufficiently ion etched beforehand. The n-Si contact with Pt is ohmic, but on p-Si there is a small electronic barrier. The films display the electrochemical characteristics of platinum metal and are very stable under strongly oxidizing conditions.

Recent proposals for a new type of solar collector and electrolyzer have stimulated interest in the properties of silicon as an electrode in aqueous media (1). It is well known that silicon is unstable under these conditions owing to its tendency to form an insulating layer of SiO_2 on its surface (2, 3). Modification and protection of the Si surface by addition of a transparent, stable electrode material is necessary if the use of Si as the active light absorber within the electrochemical cell is to be retained.

Key words: catalyst, thin films, semiconductor metallization, oxygen electrodes, platinum.

While examining the properties of platinum coatings, chosen for the catalytic properties of this material, it was discovered that, if properly deposited, remarkably thin continuous layers of Pt on Si could be formed and that these films had interesting properties. The films were characterized by transmission electron microscopy and by electrochemical measurements, primarily by cyclic voltammetry and photoresponse. These measurements were useful in providing some information regarding the electrical nature of the interface between the platinum film and its silicon substrate. In this paper

we report and discuss some of the observations made in this study.

Experimental Procedures

The samples used were polished single-crystal, semiconductor grade wafers of silicon. Both n- and p-type wafers, having resistivities from 1 or 2 to about 50 Ω-cm, and with (100) or (111) faces exposed, were used. The wafers were degreased in acetone and methanol, then rinsed in distilled water, and finally cleaned in dilute HF to remove much of their native oxide coatings before they were mounted in a vacuum system for further treatment.

The crucial steps in preparation of the thin Pt films were ion cleaning of the Si substrate and sputter deposition of the Pt. In some initial work these steps were done in an rf sputtering system, but all later work reported here was done, with similar results, in a Veeco Microetch system[1] (4) owing to the lower base pressure and more reproducible conditions achievable in this system.

The vacuum system was pumped to about 2×10^{-6} Torr before argon gas was admitted to a pressure of about 8×10^{-5} Torr. At this pressure an argon plasma could be maintained in the ion-beam source and a beam of ions with a current density of about 0.95 mA/cm^2 at 500V acceleration was produced. The argon ion beam could be intercepted by a manually controlled shutter.

To ion etch (backsputter) the Si surface, the wafer was placed in the path of the beam under the closed shutter and then exposed to the beam for specific periods of time. The wafer was then immediately moved through a 90° arc so that it was no longer in the beam path, but was placed to receive Pt atoms sputtered from a diagonally mounted Pt target placed in the beam path. The shutter was then opened until the desired amount of Pt was deposited, as indicated by a quartz crystal thickness monitor mounted beside the sample holder.

The accuracy of the crystal thickness monitor was checked for indicated film thicknesses up to 1000A by means of electron-backscatter (Betascope) measurements[2] (5), x-ray absorption measurements, and by colorimetric analysis of platinum films dissolved in aqua regia. The Betascope measurements showed excellent proportionality with the thickness monitor readings, within a few percent, while the other methods agreed within about 20%. We have therefore assumed that the thickness monitor readings are reliable indications of the mass of Pt deposited. This assumption may not be entirely valid for the extremely thin films discussed here because of possible initial differences in sticking coefficients on the sample and monitor. These differences would tend to disappear as the coatings become thicker.

After removal from the vacuum system, the completed wafers were cut into pieces suitable for electrochemical tests or for examination of the films in a transmission electron microscope. Those pieces to be used electrochemically had ohmic contacts of a Ga-Ag paste applied to the back (uncoated) side after a local etch with a drop of HF to remove any SiO_2 (6).

The electrochemical tests were done in a specially constructed, three-compartment Pyrex cell shown in Fig. 1. The sample was pressed against a Viton gasketed opening in the central working compartment, opposite a flat window through which the sample could be illuminated. This arrangement defines the exposed area (⅛ cm^2) of the electrode and permits quick and easy replacement of test electrodes (6).

To provide for effective stirring of the electrolyte and to prevent bubble accumulation at the electrode

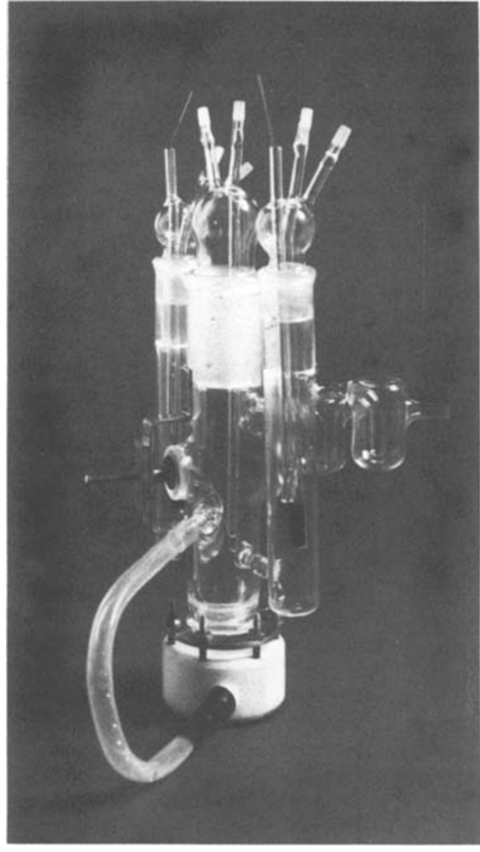

Fig. 1. The electrochemical test cell showing the pump at the bottom, the sample pressed against the black gasket by the screw clamp on the left, and the curved jet aimed at the sample recess.

surface a centrifugal pump, shown in Fig. 2, was incorporated at the base of the working compartment (7). This pump directed a stream of electrolyte through a glass jet aimed across the working electrode face. The pump consists of a Teflon polymer Star-Head™ stirrer[3] enclosed in a Teflon polymer housing and is driven by a conventional magnetic stirrer.

The remainder of the cell was of conventional design, with a Luggin capillary connecting the reference (hydrogen) electrode chamber to the electrolyte near the working electrode and a fine capillary diffusion barrier connecting the counterelectrode chamber to the working electrode chamber.

Most of the tests were done with 1*N* H_2SO_4 made from analytical reagent (J. T. Baker Chemical Com-

[3] Nalge Company.

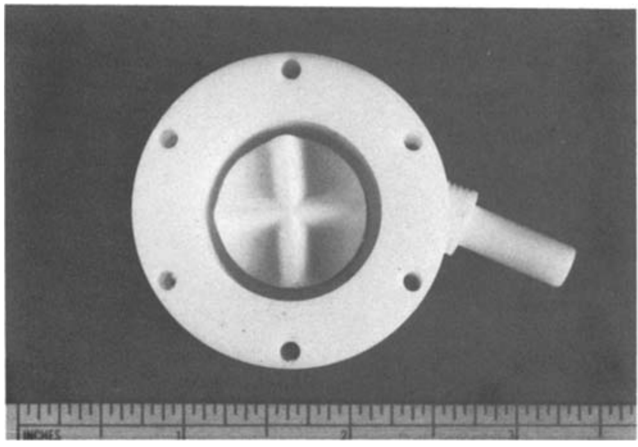

Fig. 2. Top view of the centrifugal pump. Stirrer is centered by a circumferential step on the bottom of the housing.

pany) diluted with quartz-distilled water. Purified H_2 or He could be bubbled through each chamber of the cell or maintained as an atmosphere over the electrolyte. Before each experiment the electrolyte was purged by bubbling H_2 gas in all three compartments of the cell, and then He was flowed over the electrolyte in the working and counterelectrode compartments, while H_2 continued to bubble over the reference electrode. Electrochemical characteristics were measured with a potentiostat (Pine Instrument Company RDE 3) and recorded with an X-Y recorder (Hewlett-Packard 7046A).

For electron microscopic examination, the films, in some cases coated with carbon and in others uncoated, were separated from the Si substrates by exposure to a mixture of HNO_3 and HF or to their vapors and then floated off on quadruple-distilled water. They were picked up on fine lacey carbon supporting films for insertion in the microscope.[4] The instrument used was a Siemens Elmiskop 101, operated at 120 kV.

Any particular experimental procedures associated with individual tests are given with the results in the next section.

Results

The tendency of Si to oxidize in aqueous electrolytes is clearly demonstrated in the voltammograms of Fig. 3. The curves represent a series of single sweeps. Each run, displayed below its predecessor, carried the Si electrode to an increasingly positive voltage before the negative excursion and the final return to the starting voltage. Results for n-type Si only are shown, but similar results differing only in detail were obtained with p-Si.

As little as 20Å of Pt on Si radically alters the electrochemical properties of the substrate. On n-Si with Pt, the hydrogen overvoltage is extremely low, characteristic of Pt, and quite insensitive to operation of the electrode at positive voltages. The cyclic voltammograms are also unaffected by illumination with photons having energy exceeding the bandgap of Si. Figure 4 shows stable cyclic voltammograms for the thin Pt film on n-Si and for Pt metal sheet tested under similar conditions. Although the similarity of these voltammograms is striking, there are some notable differences. The characteristic oxidation and reduction peaks are more prominent with the bulk Pt than with the thin-film specimen. On the thin-film voltammogram the platinum oxide reduction peak is shifted negatively by about 50 mV from that obtained on bulk Pt, and the oxygen evolution current at the maximum voltage (1.65V) is smaller in relation to the oxide reduction peak than it is for bulk Pt.

If the substrate is p-type Si the voltammograms, though stable toward oxidation, are quite different for the dark and illuminated cases, as Fig. 5 shows. Appreciable reduction currents are not obtained in the dark, but under illumination the Pt-like characteristics are again obtained, though shifted positively in voltage, and the cathodic current due to hydrogen evolution is limited by the light intensity. The extent of the positive shift is somewhat variable with different samples, but it is generally from 0.1 to 03.V in magnitude.

The stability of these thin films under strongly oxidizing conditions is shown in Fig. 6 which displays

cyclic voltammograms of a 20Å Pt film on n-Si taken before, during, and after operation at 1.75V. The changes evident in the first 24 hr of operation were complete after 48 hr, when the voltammogram (not shown) was identical to the final one shown.

Despite this stability to oxidation, the films do not retain their catalytic activity when subjected to repeated cycling. Earlier tests, similar to those of Fig. 6, showed the characteristic peaks of the voltammogram reduced to less than half of their original value after 2900 cycles between 50 and 1605 mV, though there was no evidence of increasing overvoltages like those shown for uncoated Si.

Transmission electron micrographs of films taken from wafers similar to the samples used for Fig. 4-6, and some others, are shown in Fig. 7. The large circular features in these pictures are due to the lacey carbon films on which the Pt films rest. The micrographs show that the 20Å films are continuous and virtually free of detectable pinholes, while the 10Å films have many pinholes, but nevertheless are continuous, conducting films.

Electron diffraction patterns from these films, not shown here, are characteristic of Pt with a very fine-grain polycrystalline structure. This structure is also revealed by the partial dark-field micrograph of Fig. 8, where only those crystallites of suitable orientation show up as bright spots in the image.

Figure 9 is a micrograph of a film, like that used for Fig. 6, after it had been repeatedly cycled to degrade its catalytic performance. It is evident that the apparently smooth continuous film indicated by Fig. 7 has been seriously affected by the electrochemical cycling, probably due to dissolution and rearrangement.

In order to assess the importance of the ion-etching step before Pt deposition, a series of 20Å films was deposited on n-Si substrates after differing exposures to the argon ion beam. Figure 10 shows the cyclic voltammograms obtained from these specimens. The Pt-like behavior is not well established until at least 10 sec of ion etching are used, though there is still further improvement if this time is increased to 20 sec or more. For comparison, the 25Å film used in Fig. 4 was sputter deposited on a silicon surface ion etched for 30 sec, while that used for Fig. 6 was 20Å with the same ion-etch time.

The electron micrographs of comparison pieces taken from the same wafers as those used for the tests of Fig. 10 are shown in Fig. 11. They show that with little or no ion etching the film growth is in the familiar island structure, and that film continuity increases with the duration of ion etching. Even with 10 sec of ion etching, the film is not entirely continuous as are the films of Fig. 7a and b which were deposited after 30 sec of ion etching.

It is also of interest to determine how thick the deposited film has to be to obtain the effective catalytic properties of the metal, assuming that sufficient ion etching has been used to prepare the substrate. A series of films of increasing thickness was deposited on n-Si substrates, after 20 sec of ion etching, by passing the ion beam through a rotating shutter. Exposure for each film was controlled by allowing the opening of the shutter (90°) to pass the ion beam different integral numbers of times.

Figure 12 shows a series of voltammograms obtained from some of the members of this series. They indicate that the transition occurs between 16 and 20Å of deposited material. Those substrates with thinner films display some instability toward oxidation and relatively large hydrogen and oxygen overvoltages, with few of the features characteristic of platinum. It is important to note that these last results are not entirely consistent with earlier good results obtained with films only 10Å thick, but deposited in one continuous exposure. Furthermore the electron micrographs of these films (not shown) indicated persistent island structures even in films more than 20Å thick. Indeed one film 21Å thick removed from its Si substrate, without a carbon coating, retained its integrity as a continuous film, but displayed an island structure of Pt particles on an unidentified continuous background film.

These results call for further investigation, but they show nevertheless that some critical thickness of Pt, perhaps determined by vacuum conditions and sputtering rates, is necessary to achieve the useful catalytic properties of this metal.

In these experiments one is led to consider the possible formation of platinum silicides, so it was considered desirable to observe the electrochemical behavior of such silicide films. The compound was deliberately formed by heating n-Si samples with approximately 15Å of deposited Pt in argon at 350°C for 15 min. Comparison samples from the same wafer, without heat-treatment, had been previously shown to give results comparable to those of the 25Å films shown in Fig. 4. Figure 13 shows the single-sweep voltammograms obtained from the Pt-Si surface in the manner described in connection with the tests of Fig. 3. The final (lowest) curve was essentially unchanged when swept cyclically and no effects of illumination could be observed.

Although these samples were quite stable to oxygen or hydrogen generation for periods of several minutes, they did not display any of the electrochemical characteristics of platinum metal.

Discussion

The electrochemical behavior of bare Si in the dark is explicable in terms of the large negative flatband voltage (high electron energy) of this material with respect to the H^+/H_2 potential in the electrolyte (3, 8). This condition implies that the energy bands of n-Si are bent up strongly near the electrolyte interface so that there is normally an appreciable energy barrier for the transfer of electrons into or out of the conduction band (9). The large hydrogen overvoltage results from the need to flatten the bands (by applying negative voltage to the Si) so that conduction band electrons can reach the surface where H^+ ions can be reduced.

This situation is unaffected by positive voltage excursions because oxidation of the electrolyte is prevented by the energy barrier. At very high positive voltages the bands are bent so strongly that electrons can tunnel from the electrolyte through the thinned barrier and allow the oxidation of water with the accompanying formation of SiO_2 (10). This thin insulating layer serves to increase the hydrogen overvoltage,

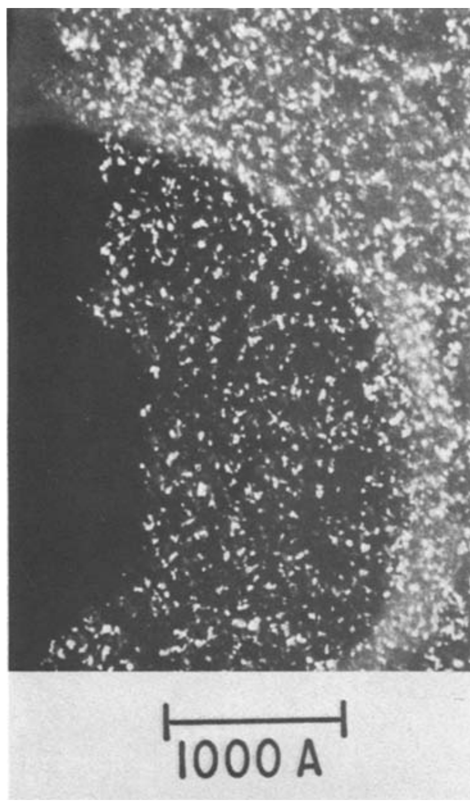

Fig. 8. Dark-field micrograph corresponding to Fig. 7c

an effect just visible in the lowest curves of the top part of Fig. 3.

When light shines upon the Si, oxidation is much more readily accomplished by the holes created in the valence band and moved toward the interface by the surface field (9). The resultant growth of a barrier layer (anodization) is clearly shown by the rapid suppression of positive oxidation current within a

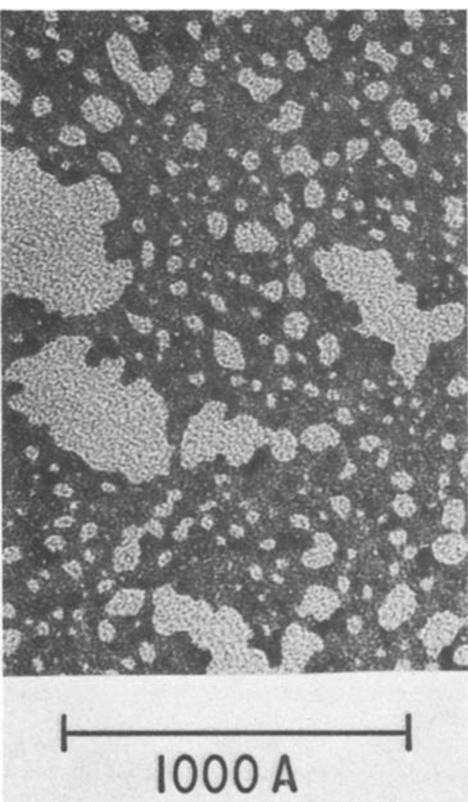

Fig. 9. Electron micrograph of film after prolonged cycling

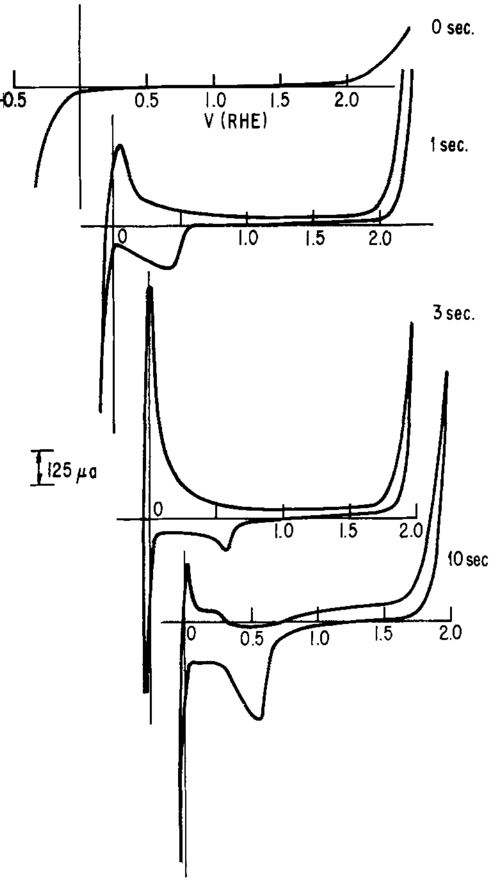

Fig. 10. Cyclic voltammograms from 20Å Pt films deposited on n-Si after varying degrees of ion etching. Sweep rate was 100 mV/sec.

single sweep and by the corresponding increase of hydrogen overvoltage to extremely high values.

The appropriate deposition of Pt on n-Si radically alters the situation described above. The voltage correspondence in the cyclic voltammograms for the test sample and the Pt sheet, shown in Fig. 4, indicates that the Pt film effectively makes an ohmic contact with its semiconducting substrate, a conclusion confirmed by the absence of any observed photoeffect. The more prominent characteristic features obtained on the bulk platinum, noted earlier, may fairly be attributed to its larger effective surface area (11), since the thin films are deposited on extremely smooth single crystal substrates. On the thin films the more negative potential of the platinum oxide reduction peak and the lower oxygen evolution current at maximum positive voltage, also noted earlier, suggest that oxygen atoms are bound more strongly to these films which must be thin enough to still show some effect of the substrate underlying the metallic platinum surface.

The photoeffects and voltage shift observed when Pt is deposited on p-type Si (Fig. 5) indicate the presence of an electronic barrier, shown schematically in Fig. 14. In this case, reduction of H^+ can occur only if electrons are promoted to the normally empty conduction band of p-Si by illumination with photons of sufficient energy. For this reason, the hydrogen reduction current is limited by light intensity.

The voltage shift with illumination allows H_2 to be generated at a voltage more positive than it would be on a bulk Pt electrode. Similar shifts have been observed on Si and other p-type semiconductors with electrodeposited metal layers (12). This undervoltage for reduction is accompanied by an overvoltage for all oxidation processes, though not necessarily of the same magnitude. When the p-Si is part of a photoexcited

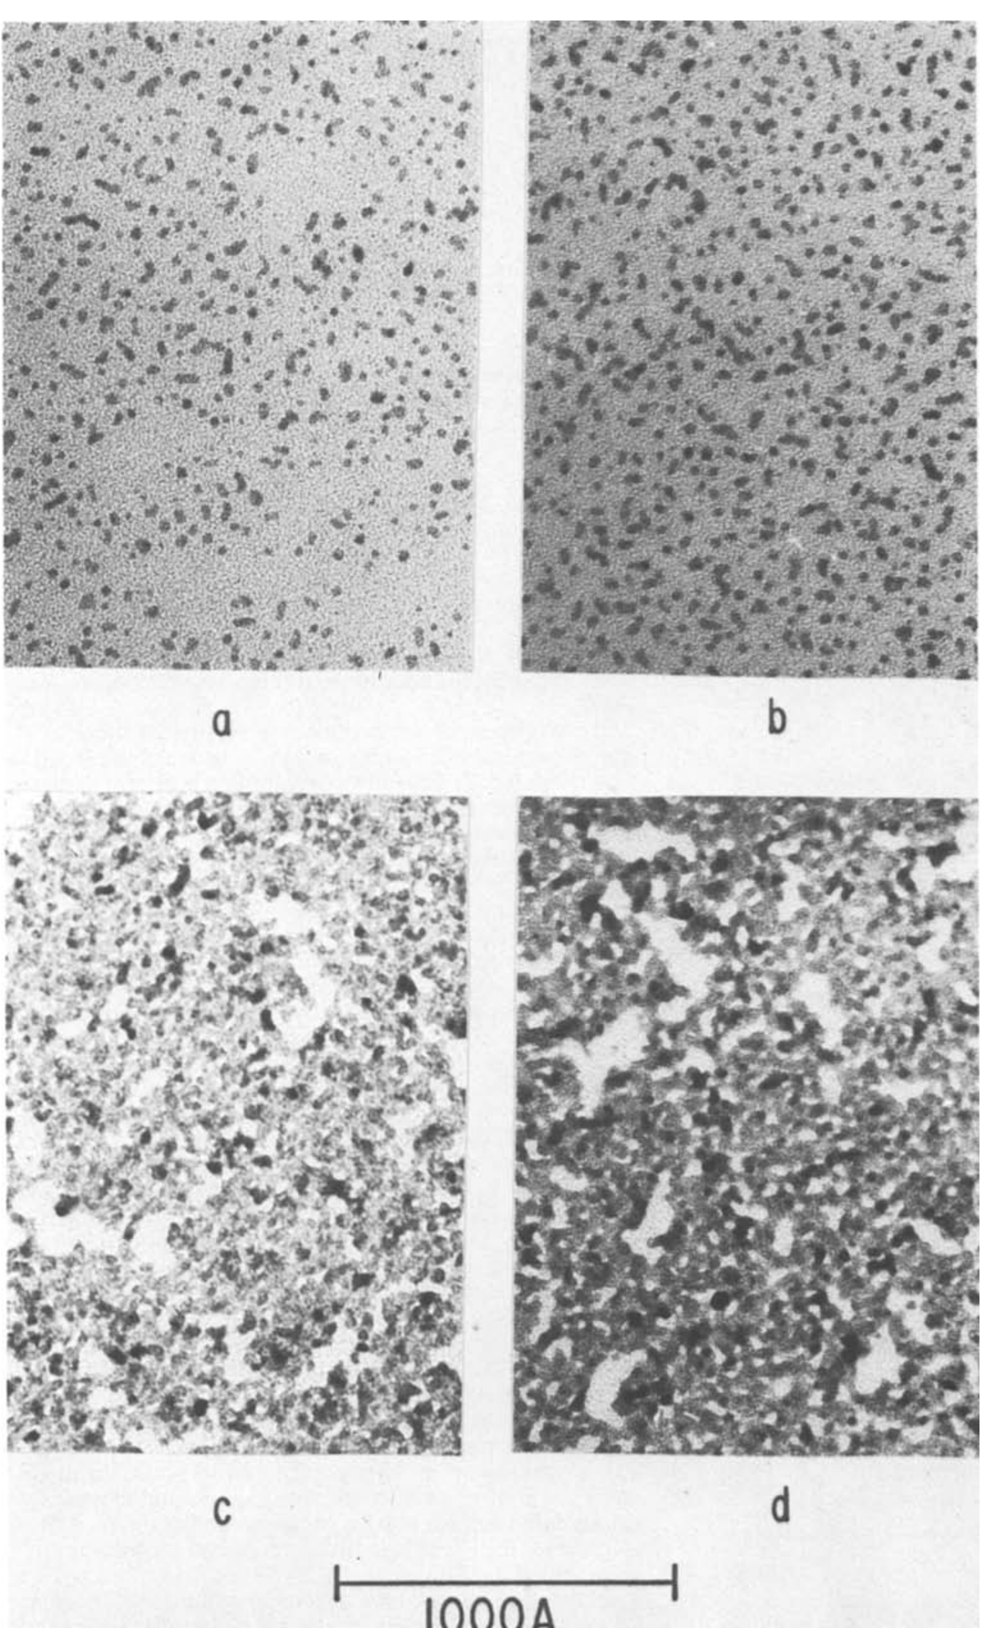

Fig. 11. Electron micrographs of the films of Fig. 10 untested electrochemically. a, No ion etching; b, 1 sec ion etching; c, 3 sec ion etching; d, 10 sec ion etching.

n-p junction device used to drive electrochemical reactions, it is the p-type surface at which oxidations should occur (1). The voltage shift due to the Schottky barrier can represent a significant loss of available electrochemical potential.

The importance of ion etching in obtaining the extremely thin metallic films is demonstrated by the effects shown in Fig. 10 and 11. Insufficient ion etching results in the island structure more usually observed with such thin films (13). The smoothness and uniformity of properly deposited Pt films may be attributed to the immobility of the first Pt atoms arriving at the chemically clean and active Si surface. Since Pt and Si interact to form distinct compounds (14, 15), the initial Pt atoms are likely to be chemisorbed with sufficient binding energy to prevent their subsequent migration over the surface.

In addition to removing any residual contaminants, some extra ion etching may be necessary to introduce sufficient disorder (16, 17), and even tighter binding

sites, in the Si surface. The rate at which SiO_2 is removed from the surface may be estimated from the ion current density, ion voltage, and sputtering rate of Si by argon ions, assuming the rate for SiO_2 approximates that for Si (18). The estimated rate is 5.35 Å/sec so 4 sec of ion etching should be sufficient to remove

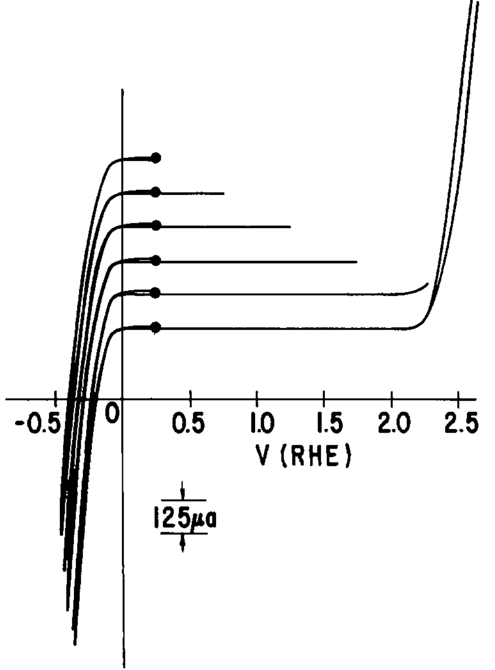

Fig. 13. Single-sweep voltammograms from approximately 15Å Pt on n-Si after heating in argon at 350°C for 15 min.

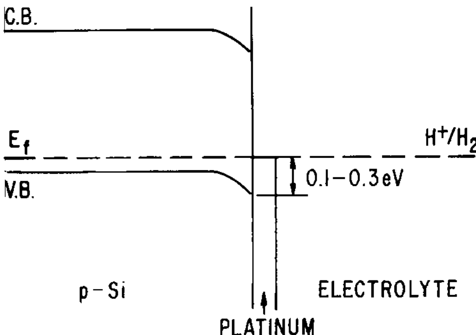

Fig. 14. Suggested energy diagram of p-Si coated with Pt in contact with acid electrolyte, showing Schottky barrier at Pt-Si interface.

an assumed 20Å of SiO_2. But in practice we find that about 20 sec of ion etching are required for good results. It is thus reasonable to assume that the surface disorder in the substrate is also an important factor in the adhesion and stability of the deposited films. This assumption is consistent with recent observations of the growth of thin Pt films on single crystal and on amorphous Si done under ultrahigh vacuum conditions (19).

If one thinks of applying these results to metallization of semiconductor devices, as in integrated circuits, this need for surface disorder, if it exists, would be a serious drawback. For electrochemical applications, however, where catalytic coatings with extremely light loading of the expensive catalyst is desired, considerations of surface disorder are not so serious. Of course, in these applications it is also unnecessary that the catalyst metal be disposed in a continuous film, but it must make intimate electrical contact with the substrate. It appears, however, that the conditions which promote this good contact also promote the continuity of the film.

The chemisorption view of Pt film deposition implies the formation of a layer of Pt-Si compound, perhaps only 1 or 2 monolayers thick followed by the addition of Pt metal. The results of Fig. 13 show that deliberately formed platinum silicide is a stable electrode, but has relatively poor catalytic properties. When insufficient Pt is deposited, as in the series of Fig. 12, most of the deposited material may have been consumed in formation of the compound interlayer, leaving little metallic platinum to function as a good catalyst. The continuous unidentified film on which islands of Pt were observed may indeed be evidence of this compound. Such considerations must play a part in determining the least amount of catalyst that can be used to obtain effective catalytic properties. The results of Fig. 12 show that such a minimum amount exists, but, as noted earlier, the quantitative aspects are presently in doubt because the results are influenced by rates of deposition and by vacuum conditions.

The instability of an initially active platinum film to repeated cycling is shown by Fig. 9 to be related to dramatic structural changes in the film. Aside from its relative smoothness, there would appear to be no reason why these thin films should not be subject to the same forces of dissolution that affect other catalytic deposits (20, 21). Although some of the Pt that dissolves in one part of the electrochemical cycle may be redeposited in another, the redeposited material may lose its intimate contact with the substrate and thus much of its catalytic activity.

The stability of the films toward oxidation must be due to the passivation of any exposed areas of Si by formation of SiO_2 which is chemically stable and prevents any undercutting of the intimate metal-semiconductor contact.

Conclusions

The work reported here is not intended to throw any new light on the processes of catalysis. It is well known that minute deposits of Pt on other substrates impart the catalytic properties of the metal to the combination (22). The electrochemical measurements reported here serve merely to characterize the nature of the Pt films on Si and the nature of the electrical contact at the Pt-Si interface.

The continuity of the metal films in such low thickness ranges is of unusual interest, however, as is the effective ohmic contact with the n-type substrate. It is hoped that these observations may contribute to the understanding of the nature of some substrate-deposit interactions.

The ultimate utility of deposits of this sort for electrocatalysis remains to be seen. In view of the excellent material utilization already reported with other methods, the motivation for using this more complex and costly process may depend on whether improved stability can be achieved with it. This, along with other aspects of the problem needs more study at present.

If our present ideas about the film formation are correct, it seems likely that there are many material variations on this theme. Silicon, because it reacts with so many different metals, should be a useful substrate for a variety of catalytic metals. The high purity, electronic grade, single crystal silicon used in these experiments should not be necessary; the cheaper technological grades of polycrystalline Si, provided it is n-type, should serve well as a conducting catalyst support.

Conversely, many of the noble metals might equally well be supported by other materials with which they form compounds and that form stable, chemically resistant oxides. Examples of such supports are the valve metals, Ti, Ta, Nb, and others. Indeed, preliminary experiments show that Pt can be deposited in 20Å amounts onto ion-etched Ti to impart its catalytic properties as it does on n-Si.

Volume Changes Induced by the Electrochromic Process in Sputtered Iridium Oxide Films

ABSTRACT

We report volume changes induced by the electrochromic process in sputtered iridium oxide films (SIROF's). We show that SIROF's expand on incorporation of water. The rate of water uptake is greatly increased by initial potential cycling, *i.e.*, coloring and bleaching. Hydration increases the kinetics of electrochromism by about an order of magnitude. We show also that electrochromic coloring and bleaching reversibly modulates the thickness of partially hydrated SIROF's. As-deposited SIROF's significantly contract upon initial cathodic bleaching which supports the anion mechanism of electrochromism in iridium oxide films.

Several recent papers have described the properties of electrochromic iridium oxide films (1-12). Initial studies were based on iridium oxide films anodically grown on a metallic iridium substrate (AIROF's). It has recently been reported (5) that electrochromic iridium oxide films can be prepared by sputtering from an iridium target in a reactive oxygen discharge. Such sputtered iridium oxide films (SIROF's) have the fast coloring and bleaching kinetics previously reported for AIROF's, and are considerably more resistant to degradation. Operation for more than 10^7 cycles in 0.5M H_2SO_4 leads to no detectable deterioration. Prototype seven-segment digit display cells with $\leq$100 msec response time have recently been demonstrated (12).

The mechanism of the electrochromic reaction has been extensively studied. Early speculations (13) were based on a proton extraction-insertion mechanism, as proposed for ruthenium oxide, and similar to the cation insertion-extraction process of tungstic oxide (14-16). There is evidence, however, that the electrochromism of iridium oxide films is fundamentally different (7-9) from that of WO_3. For iridium oxide an anion mechanism has been proposed which is supported by considerable experimental evidence (7-9).

The purpose of this paper is fourfold: (*i*) to demonstrate that SIROF's consist of a structure, which expands on incorporation of water; (*ii*) to show that the rate of incorporation of water into an as-deposited SIROF can be increased greatly by a few initial color/bleach cycles; (*iii*) to show that the uptake of water increases the kinetics of electrochromism by about an order of magnitude; and (*iv*) to show that, until fully hydrated, electrochemical coloring and bleaching reversibly modulates the film thickness. An as-prepared SIROF undergoes a contraction upon initial bleaching, which strongly supports the anion mechanism of electrochromism.

Experimental

To investigate the volume changes induced by the electrochromic process in SIROF's we have measured the thickness of the iridium oxide film on quartz substrates, (*i*) as deposited, (*ii*) after immersion in 0.5M H_2SO_4, (*iii*) after successive coloring and bleaching, and (*iv*) on further immersion after two color/bleach cycles.

A seven-segment digit of SIROF was deposited through a 2 μm thick photoresist mask. Dissolution of the photoresist in acetone removed the SIROF from surrounding areas leaving each segment with well-defined sharp edges along its length. The data reported are average segment thicknesses measured over many up and down steps. Thickness was measured *ex situ* using a stylus instrument, either an Alpha-step or a Talysurf. The electrode was rinsed in distilled water and blown dry with nitrogen before each measurement.

Both the colored and bleached states of SIROF's show significant electronic conductivity. Contact was made to a corner of a segment with silver paint, which was then covered with insulating varnish. Coloring or bleaching of each segment was accomplished by applying +1V or 0V, respectively (*vs.* SCE reference electrode) to the SIROF in the 0.5M H_2SO_4 electrolyte. The coloring or bleaching resulting from anodic or cathodic voltages was monitored by measuring the charge transferred. As previously demonstrated (10), the induced optical density change is essentially linear in the charge transferred.

SIROF's deposited on tantalum were used to measure the electrochromic response time, since in this case the rate of response is not limited by the low sheet conductivity of the iridium oxide film. Bleach/color cycles were performed by applying 1 sec pulses of 1V amplitude (*vs.* SCE), with compensation to the applied potential for *IR* drop in the electrolyte using a Princeton Applied Research potentiostat and programmer. The charge transferred was monitored by a digital coulometer, with the analog output recorded on a strip chart recorder or photographically from an oscilloscope.

Results and Discussion

We show in Fig. 1(a) the time dependence of the thickness of a SIROF having an initial thickness of 700Å upon immersion in 0.5M H_2SO_4. There is negligible change in thickness in 5 hr. On the other hand, if a film is first subjected to two color/bleach cycles, and subsequently kept immersed in the same electrolyte, it rapidly increases in thickness to a maximum of 950Å in 2 hr as shown in Fig. 1(b).

No change in coloration results from this increase in thickness, suggesting that the expansion is solely due to water uptake within the SIROF. It is surprising that two initial color/bleach cycles condition the SIROF to take up large amounts of water. Although we have not rigorously demonstrated the porous nature of SIROF's, a porous structure is probable since the electrochromic kinetics are similar to those of AIROF's, which are known to be porous films (11) with a high water content. Throughout this work "pores" is used in a generalized sense which includes microscopic channels. Preliminary thermogravimetric analysis (TGA) and evolved gas analysis (EGA) of SIROF's show (17) that these films, as prepared, contain some unbound (pore) water. In addition, it may be noted that the final thick-

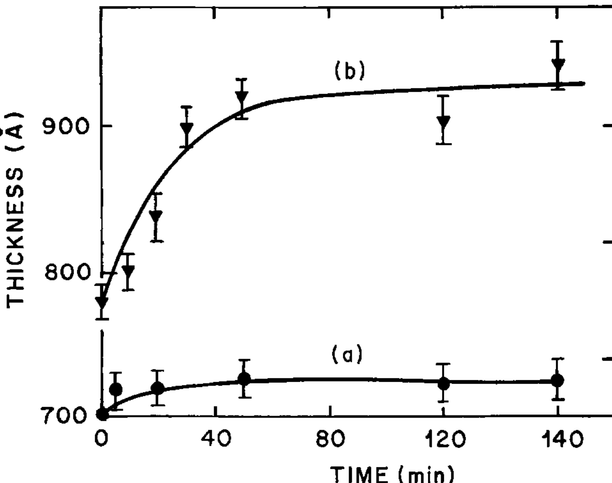

Fig. 1. Increase in thickness of a SIROF, initial thickness 700Å, (a) on immersion in 0.5M H_2SO_4, and (b) on immersion after two color/bleach cycles.

ness of a fully hydrated SIROF is approximately the same as that of an AIROF having the same charge density for the same potential step. For example, for a SIROF of final thickness 1800Å, coloration charge transfer (for 0-1V potential step *vs.* SCE) is ≈30 mC/cm², and that for an equal thickness AIROF is ≈27 mC/cm².

We have also investigated the electrochromic response time of SIROF's as a function of hydration. We show in Fig. 2 the electrochromic response of a SIROF for 1 sec voltage pulses stepping between 0 and 1V (vs. SCE) in an aqueous 0.5M H_2SO_4 electrolyte. The data in Fig. 2(a) and (b) were measured within the first 10 sec and after 40 min, respectively, of continuous cycling. Taken together, the data in Fig. 1 and 2 suggest that the film expands from the progressive incorporation of water into the film pores, and the speed of response increases due to the faster diffusion of ions along the pores. The total charge transferred during coloration and bleaching increases from 11.0 mC/cm² [Fig. 2(a)] to 12.6 mC/cm² [Fig. 2(b)] possibly due to a slight increase in the number of accessible iridium sites. The increase is not a kinetic effect; equilibrium values show the same charge increase.

For AIROF's which are known to be highly hydrated, a model of porous films with most of the oxide sites accessible to the electrolyte has been postulated (18) and experimentally verified (11). Such a model is in agreement with the observations reported here for SIROF's. The latter may thus be regarded as porous structures which can expand on water uptake. However, as shown in Fig. 1, expansion is only possible after the film has been subjected to a few color/bleach cycles. Apparently, as-prepared SIROF's have a "closed" structure, *i.e.*, impervious to water, which can be "opened" by potential cycling.

The effect of potential cycling on the structure of a SIROF is more clearly seen from the data in Fig. 3. We find that electrochemical coloring or bleaching produces a significant increase or decrease, respectively, in the film thickness. Data are shown for two different sets of SIROF samples deposited on quartz in an oxygen partial pressure of 20 μm. The data represented by squares refer to thick samples (≈1500Å as prepared); the circles refer to thinner samples (≈410Å as prepared). Full and open symbols designate completely colored and completely bleached SIROF's, respectively. The initial data (half-open symbols) represent measurements on as-deposited, partially colored samples before immersion in the 0.5M H_2SO_4 electrolyte.

It is evident from Fig. 3 that during the first few cycles the films contract upon bleaching and expand upon coloring. This effect has been observed not only for the two sets of samples reported in Fig. 3 but also for other samples of various thicknesses. Particularly significant is the contraction following the first cathodic (*i.e.*, bleaching) voltage pulse. Although not shown in Fig. 3, if the first applied pulse is anodic (*i.e.*, coloring), then the film expands. Since expansion of the film results also from immersion in the electrolyte [Fig. 1(b)], it is difficult to separate the effect of the voltage pulse from that of hydration. Nonetheless, the initial contraction observed upon bleaching clearly shows that the electrochromic effect *per se* causes a significant modulation in film thickness. Following the first few potential cycles in Fig. 3, the thickness modulation associated with coloring and bleaching diminishes. The SIROF's continue to expand until they reach their maximum thickness, approximately following the same behavior as shown in Fig. 1(b). Thus Fig. 3 shows that SIROF's can change their thickness because of two distinct effects: (*i*) a continuous uptake of water during immersion following a few color/bleach cycles [Fig. 1(b)], and (*ii*) a thickness modulation directly related to the electrochromic process, which decreases as the film hydration increases.

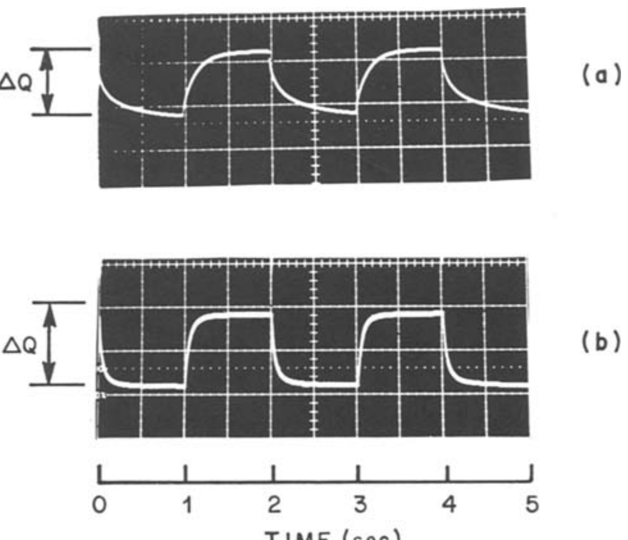

Fig. 2. SIROF electrochromic response (6.8 mC/cm²/div) for 1 sec voltage pulses stepping between 0 and 1V *vs.* SCE in an aqueous 0.5M H_2SO_4 electrolyte; (a) recorded within the first 10 sec, and (b) after 40 min of color/bleach cycling.

Conclusions

As previously noted, the porous nature of anodic iridium oxide films has been recognized for some time. The necessity of "pore" water within the structure for fast response times has also been postulated (1, 4). We

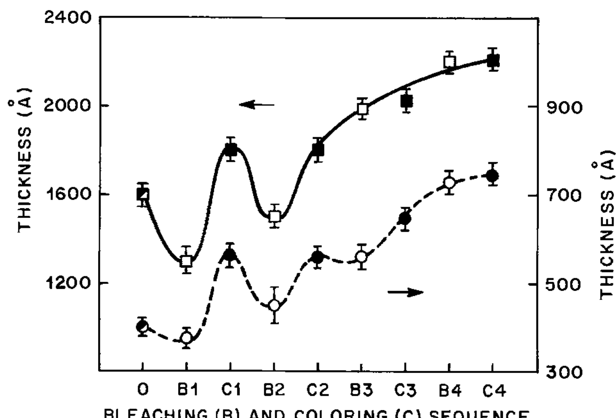

Fig. 3. Initial thickness (0) of SIROF films, and after successive bleaching (B) and coloring (C) for two films of different initial thicknesses.

have shown here that SIROF's have an expandable, porous structure and that water uptake expands the structure. More importantly we have also shown that, for as-deposited films, an expansion occurs upon coloring, and a contraction upon bleaching. The latter observation provides considerable insight into the nature of the mechanism of ion-insertion in electrochromic iridium oxide.

It is now accepted that the coloration reaction in iridium oxide films proceeds by anodic removal of electrons coupled with charge neutralization via ion transfer between the film and the electrolyte. For charge neutrality in aqueous electrolytes, models based on proton extraction or hydroxide ion injection have been postulated. Which of these models is operative is still controversial. Our results, however, suggest that a hydroxide ion mechanism is operative. Contraction of the film upon bleaching indicates removal of ions from the film, and thus precludes a model based on H^+ insertion.

Although the data in Fig. 3 provide convincing evidence that the ion exchange at the SIROF/bulk-electrolyte interface involves exchange of OH^-, in principle it is possible that the ion exchange at the iridium oxide grain/pore interface within the SIROF involves H^+ exchange. However, were H^+ to dominate the charge transport at the iridium oxide grain/pore interface, it is difficult to understand why OH^- would be inserted into the film from the bulk electrolyte in view of (*i*) the superior mobility of H^+ over OH^- in the pores, and (*ii*) the abundance of H^+ available from the acidic bulk electrolyte.

Exchange of OH^- at the iridium oxide grain/pore interface provides an explanation for the diminishing amplitude of the thickness modulation observed in Fig. 3 with increasing hydration. In an as-deposited dry film, coloring causes expansion by ion-insertion into the grains directly from the bulk electrolyte; this can only be in a direction normal to the substrate, otherwise loss of adhesion of the SIROF would occur. Once the film has become hydrated and swollen to a volume in excess of that of the colored state in the first coloration of the dry film, expansion of a grain on coloration is no longer constrained to be normal to the film but can also occur laterally by expansion from the pores. It should be noted that there is evidence (19) that AIROF's show a 10-15% thickness increase, measured by *in situ* ellipsometry, during electrochemical coloration in 0.5M H_2SO_4. The latter observation suggests that anion insertion is also responsible for the electrochromic properties of AIROF's. However, our observation that a thickness modulation no longer occurs in SIROF's after full hydration could explain the superior cycle lifetime of SIROF's relative to AIROF's, and be indicative of a different microstructure or H_2O distribution within the films.

In summary, we have measured volume changes in SIROF's and shown that these films: (*i*) have a sponge-like structure which expands by incorporating large amounts of water following electrochromic cycling; (*ii*) have electrochromic response times that decrease by an order of magnitude as more water is incorporated within their pores and their structure has expanded; and (*iii*) as-deposited, expand upon coloring and contract upon bleaching thus supporting the anion mechanism of electrochromism in iridium oxide.

The Influence of the Anion on Copper Electrocrystallization

G. Carneval and J. Bebczuk de Cusminsky

Laboratorio de Investigaciones de Metalurgia Física, Facultad de Ingeniería, Universidad Nacional de La Plata, 1900 La Plata, Argentina

ABSTRACT

Structural studies of copper electrodepositions from pyrophosphate, chloride, cyanide, and citrate solutions were carried out on highly polished (001) copper surfaces at a wide range of current densities under galvanostatic conditions. The study was performed by means of x-ray diffraction. The deposition morphology was observed with a scanning electron microscope. Correlation among internal structure, surface morphology, solution composition, and plating conditions were examined. The results were compared with previous studies from sulfate solutions. Epitaxial growth was observed in the early stage of deposition. The effect of the anion on the change from single crystalline to polycrystalline growth at further stage was analyzed. A specific adsorption of the different anions in relation to their ionic size was considered as a critical feature. As a comparative study the action of an addition agent was also considered.

Copper electrodeposition from sulfate solutions has been studied from different points of view and a considerable amount of data on its properties are now available. Electrodeposition of copper from other types of solutions, however, has been less extensively studied and the general picture of the anion effect on the growth mode is not clear. A knowledge of the magnitude of the influence of the anion on the different steps of the electrocrystallization process is desirable for the fundamental understanding of electrodeposition.

In studies on the mechanism and kinetics of copper deposition, Bockris and Enyo (1) assumed that one of the factors which influences growth is the blocking of deposition sites by adsorption of anions. Studies of the surface morphologies (2-3) and of the physical and mechanical properties of electrodeposited copper from different electrolytes were made by various workers (4-5).

Previous studies in this laboratory (6-9) dealt with the effect of the base metal characteristics of single crystalline surfaces on epitaxial growth of copper deposits from sulfate solutions. Most of the epitaxial growth features are explained in the literature (10-23). The change to nonepitaxial growth and a mechanism for the formation of polycrystalline deposits (7-9, 23) is less clearly understood and it is with this purpose that the present contribution was made. The work is a continuation of that mentioned in preceding studies, the structural aspects of deposition having been discussed with the aim of emphasizing how the growth is affected by the anion of the solution.

Experimental

Electrodeposition was carried out on as-grown OFHC (99.98%) copper single crystals of (001) orientation. Experimental details are given in previous communications (7-9); the preparation of the surfaces was considered as one of the very important factors. A 99.999% copper sheet was used as an anode. Depositions of copper were performed from copper solutions of the following anions: pyrophosphate, cyanide, chloride, and citrate, the chemicals being of "Analar" grade and the water triple distilled. Some depositions from sulfate solution, and others from amine-sulfate solution, were also made. The composition of the solutions is specified in Table I. A routine procedure for purifying the solutions (15) was used. Gentle stirring of the solutions was maintained by a glass-coated stirring magnet. In some cases stirring was made by slight bubbling with high purity nitrogen. Under these conditions the deposits under study usually had an optically smooth appearance and a good adherence to the substrate. The experiments were carried out galvanostatically between 5 and 90 mA/cm^2, while the potential was recorded continuously on a Honeywell X-t recorder. Each deposition was performed without any interruption to a predetermined thickness. The deposit thicknesses were calculated as detailed elsewhere (7). After a desired time of deposition, the cell was disassembled and the working electrode washed first with doubly distilled water and then with ethyl alcohol. After necessary studies the deposit was removed by mechanical polishing and electropolishing before plating again.

The structural studies were carried out with Philips x-ray equipment (P.W. 1140/00). Laue backreflection method with white chromium radiation was used in order to get a low penetration of the beam. Morphological observations were made, some by optical microscopy of low magnification (Reichart MeF Microscope), but most with a scanning electron microscope (JSM-U$_3$ JEOLCO Japan) because of a high resolution required.

Results and Discussion

Structural results by x-ray diffraction of the copper deposits from pyrophosphate, cyanide, chloride, and citrate solutions are plotted in Fig. 1, deposit thickness *vs.* current density, where each curve defines the initiation of the polycrystalline structure from the corresponding electrolyte. Previous results of copper deposits from sulfate copper solution on (001) OFHC copper surfaces (9) were also included. Details of the results from the citrate solution were plotted separately in Fig. 2. The characteristic surface morphologies are shown in Fig. 3-7 and are summarized in Table II.

It is observed in Fig. 1 that the structural results point to an essential difference in the action of the different copper solutions on the process of electrodeposition of copper. In the early stage of deposition, the structure from all the solutions used is single crystalline, that is, the copper deposits grew parallel to the substrate, but at further deposition, a polycrystalline structure was developed at a thickness depending on the type of the solution and the current density applied. Thus a critical thickness at which the breakdown of epitaxy occurs is different for the type of solution used.

It is known that during the process of electrodeposition of a metal, certain inevitable foreign species

Key words: copper electrodeposition, anion effect, x-ray study.

Table I. Composition of the deposition solutions

Sulfate solution		Chloride solution		Citrate solution	
$CuSO_4 \cdot 5H_2O$	0.5 mol	Cu_2Cl_2	0.5 mol	Copper citrate	0.5 mol
H_2SO_4	0.5 mol	HCl	0.5 mol	Citric acid	0.5 mol
Pyrophosphate solution		**Cyanide solution**		**Amine-sulfate solution**	
$CuSO_4 \cdot 5H_2O$	30 g/liter	CuCN	32 g/liter	$CuSO_4 \cdot 5H_2O$	0.5 mol
$Na_4P_2O_7 \cdot 10\,H_2O$	120 g/liter	NaCN	24 g/liter	$(NH_4)_2SO_4$	0.5 mol
$Na_2HPO_4 \cdot 12H_2O$	90 g/liter	Na_2CO_3	15 g/liter	Ethylenediamine	80 ml/liter
				NH_3 conc	4 ml/liter

generally present in an electrolyte as well as the anion may be codeposited or adsorbed at the cathode (1-5, 10-23). The growth during the process of electrodeposition can be seriously affected by these codeposited materials and may eventually influence the physical and mechanical properties of the deposits. On a relatively pure electrolyte, however, the anion must be considered as the main important component of the solution, owing to its large quantity. Codeposition of anions has been reported in the early studies of electrodeposition (24). Some workers (1) assumed that the specific adsorption of the anions may influence the electrochemical kinetic parameters.

If an adsorption mechanism of the anion is considered, all the evidence in the present experiments points to a possible correlation between the breakdown of the epitaxy of the deposits and some property of the anion, the size or spatial content of the anion being a relevant one. A remarkable relationship between the anion size and the deposit thickness at which the polycrystalline structure starts in each solution is stressed in Table III.

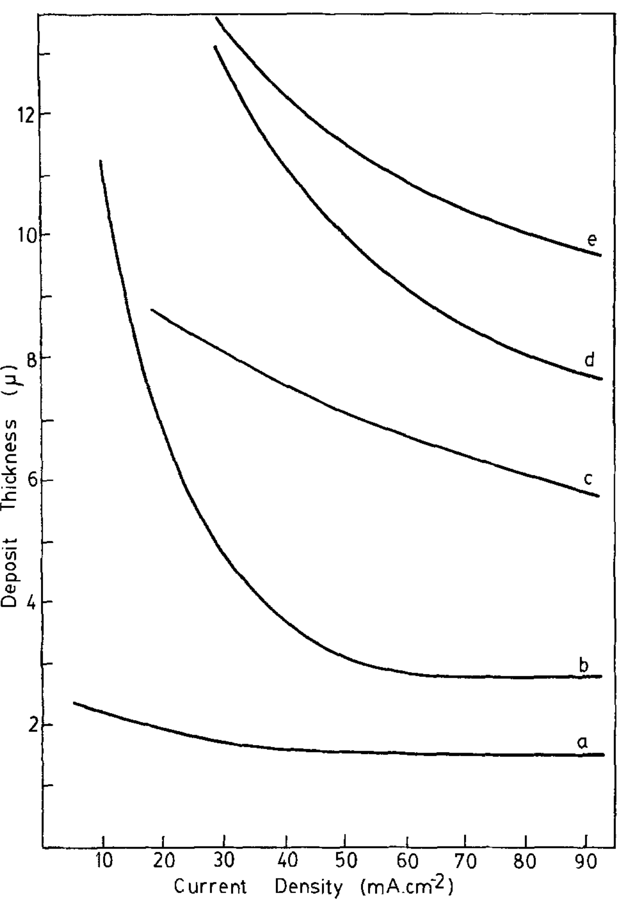

Fig. 1. Initial stage of polycrystalline structure of copper electrodeposit on single crystal substrate surfaces from: *a*, pyrophosphate solution; *b*, sulfate solution; *c*, cyanide solution; *d*, citrate solution; *e*, chloride solution. Plots of thickness of copper deposits *vs.* C.D. An x-ray diffraction study.

Table II. Morphological observations of copper deposits from different solutions

Sulfate: layers, square base pyramids (truncated or stepped), dendrites, cauliflower
Chloride: square base stepped pyramids, stepped boulders
Citrate: square base pyramids, balls, cauliflowers
Pyrophosphate: balls, cauliflowers, dendrites
Cyanide: small nuclei without any characteristic shape
Amine-sulfate (T = 25°C): spheres or balls, cauliflowers
Amine-sulfate (T = 55°C: approx. stepped pyramids

The size of the anions of the solutions is taken to be the values of the anion radius (interionic distances) (25), as well as the specific volumes of the anions. These last have been calculated from the molecular volumes (mol weight/ρ) found for copper salts by subtracting the space increment of the cation. The molecular volumes of the anions given by Hückel (26) were also listed. Although the figures represent approximate values only, they provide a clear comparative picture of the spatial relationship between the anions. The correlation observed between the spatial content of the anion and the deposit thickness is quite significant: the greater the size of the anion, the lower is the thickness of the deposit at which the change to polycrystalline structure occurs. This fact is observed at all current densities from approximately 10 mA/cm^2. At lower C.D.'s the number of anions and other particles adsorbed at the cathode is in a very small

amount and thus their influence in the structural results is less noticeable, as is observed in Fig. 1.

The values taken into account in Table III are at 50 mA/cm² C.D. An outstanding evidence of the effect of

the size of the anion on the results is the comparison of the values obtained from sulfate and chloride solutions. These solutions are the most representatives of the present experiments, where only copper, the respective anion, and the inevitable adventitious impurities are present. It is observed that the Cl^- ion volume is quite reasonably smaller than that of the $SO_4^=$ ion (Table III), and thus the electrodeposited copper from the Cl^- bath grows in epitaxial form until very high thicknesses (Fig. 1e) in relation to that from the $SO_4^=$ solution (Fig. 1b). Therefore the assumption that very small components may be buried into the deposit is implicit here.

The structural results of copper deposits from pyrophosphate and from cyanide solutions are also of interest to compare. In addition to their respective anion, both solutions have Na cations as the main extra components which may also codeposit (Table I). The differences in the results observed at all C.D.'s (Fig. 1) give evidence of the effect of the anion, the difference in size is quite prominent (Table III).

With the purpose of extending this study to deposits of copper from an organic solution, a copper citrate bath was used (Table I). The results are presented in Fig. 1 and detailed in Fig. 2 which show an epitaxial growth until very high thicknesses at all C.D.'s. As is seen in Fig. 1, the initiation of the polycrystalline structure occurs at deposit thicknesses very close to that from chloride solution. It seems that the anions from both solutions must have some characteristics in common that if adsorbed on the copper cathodes they produce similar effects on the surface structure. Both solutions are simple acidic solutions (Table I), but neither the anion size, nor the shape, solubilities of salts, etc. are similar. However, it is probable that the citric anion is decomposed before or during copper deposition, because of its carboxylic acid groups, giving radicals (C-H) of low radius, approximately 0.94-1.06Å (25). These values are in effect of the order of the Cl^- anion radius 0.99Å. Copper is able to form strain-free attachments with such small components due to the octahedral interstices of approximately 1.06Å in its lattice. On the other hand, a low effect of carboxyl groups was also observed, studying the cathode overpotential of copper deposits from solutions with additives having this kind of groups (27).

As a result it may be assumed that the basic action of an anion is similar to that of an addition agent which arises from the adsorption on the surface electrode (21, 27, 28) and affects somehow the elementary processes of electrocrystallization.

In order to observe the effect of an addition agent on the mode of growth, copper was deposited from an amine-sulfate solution. The solution contains together with the $SO_4^=$ anion (Table I), a more complex component (ethylendiamine) which may also be adsorbed. The experimental results were represented in Fig. 8. It is observed that the copper polycrystalline structure starts at lower thickness (Fig. 8b) than in copper deposits from the $CuSO_4$-H_2SO_4 solution (Fig. 8a). It seems that the amino groups play an important effect in the crystalline growth, in the sense that they "inhibit" the free mode of the single crystalline growth. A remarkable effect of these groups was observed also in copper deposition, from the electrochemical point of view by certain investigators (27).

However by heating the amine-sulfate solution at 55°C, the deposition of copper follows the single crystalline structure of the substrate up to higher thicknesses even than that from the $CuSO_4$-H_2SO_4 solution (Fig. 8c). Presumably ethylendiamine and the ammonium salt of the solution hydrolyze by heating, giving smaller components, some of which are evaporated or adsorbed and others may have the ability to make difficult the transport of the $SO_4^=$ ions to the cathode and thus allow the growth in single crystalline form. A *p*H effect could also be involved in the results. These changes observed in the structural aspect have certain similarities with the morphological observations. A square pyramidal growth was observed mostly at low C.D. in copper deposits from the $CuSO_4$-H_2SO_4 solution (Fig. 3), but if the solution contained also ethylendiamine and ammonium salt, no pyramids were observed, but rounded forms and cauliflowers (Fig. 9A and B). By heating the solution during deposition, nearly stepped pyramids appeared again (Fig. 9C).

Relating the habit of the crystal growth, the morphologies observed in the present experiments from the simple acidic copper solutions: sulfate, chloride, and citrate, are of a similar overall shape at low C.D.'s and under conditions which allow epitaxial growth to occur. They are mainly square pyramids or square blocks, with slight differences from one solution to the other, as observed in Fig. 3A, 4A, and 5A. As the size and geometry of the anions and most of the properties of their salts are different, these results confirm at first the strong influence of the atomic configuration of the substrate in copper deposits at low C.D. or low overpotential, as was observed in previous investigations from sulfate solutions (7-10, 15-19).

The differences of the surface topographies are more remarkable at increasing C.D.'s and thicknesses, *i.e.*, at 50 mA/cm^2 and under single crystallinity, the forms

Table III. Relation between the size of the anion and the thickness of the initial stage of polycrystalline structure of the electrodeposited copper

Anion	Radius of the anion (interionic distance) (Å) (approx. values)	Specific volume of the anion (cm^3/mol) Calculated	Specific volume of the anion (cm^3/mol) Given by Huckel (26)	Thickness to initiate polycrystalline structure† (μm)

observed from Cl^- anion solutions are boulders of certain geometrical shape, Fig. 4B. On the other hand, a cauliflower growth is observed from the sulfate and citrate solutions: Fig. 3B and 5B. A dendritic growth was observed also from the sulfate solution, but not from the other anion solutions. When the x-ray observation was polycrystalline, no defined forms were observed. Nevertheless, how the anion affects the surface morphology is difficult to elucidate due to the high sensitivity of the crystal habit with respect to very small amounts of adsorbed materials. Damjanovic, Paunovic, and Bockris (18) have found that amounts of certain organic substances in solution, as low as 10^{-12} mol/cm^2 produce visible changes in the morphology of the growing crystal. Taking into account that water molecules and adventitious impurities are always present and may also be adsorbed, the explanation of the different morphologies observed from one solution to the other is much more difficult than that of the crystallographic aspect where the x-ray observations involve a statistical result of the total geometrical area. So when deposition was carried out from more complex solutions, that is, pyrophosphate, cyanide, and aminosulfate, where together with the anion, the other components are present also in great quantity, pyramidal forms were not observed even at low C.D., but spheres or balls, cauliflowers, dendrites, and nuclei without any characteristic shape: Fig. 6 and 9, indicating a predominant influence of the adsorbed components.

Conclusions

1. The x-ray diffraction study of copper deposition shows a critical thickness of breakdown of epitaxy with C.D. This thickness is different for the type of the anion solution used.

2. A correlation between the anion size and deposit thickness at which the polycrystalline structure starts is observed: the greater the anion size, the lower is the thickness of breakdown of epitaxy.

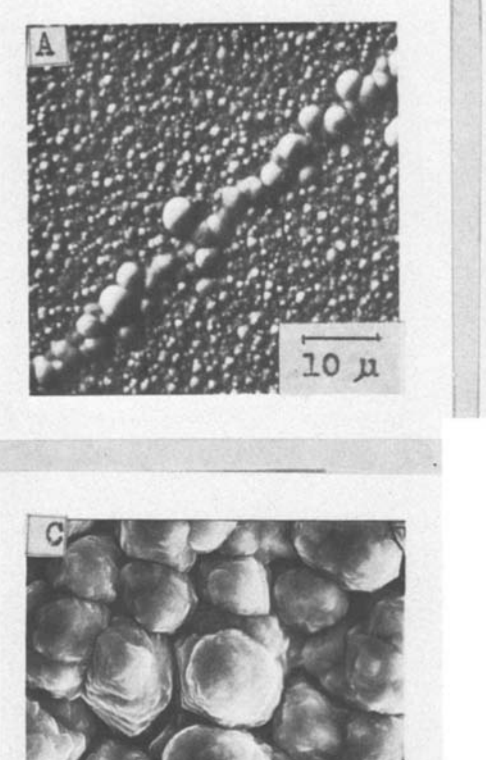

Fig. 9. SEM pictures of copper depositions from amine-sulfate solution; A and B at room temperature; C at 55°C. A, 10 mA/cm^2; 4 μm thickness; B, 20 mA/cm^2; 10 μm thickne[illegible] C, 20 mA/cm^2; 10 μm thickne[illegible]

3. The basic action of an anion is similar to that of an addition agent.
4. The morphologies from simple acidic copper solutions at low C.D. and thickness are of a similar overall shape, the differences are more remarkable at increasing C.D.'s and thicknesses and in deposits from complex solutions. No specific evidence of an anion effect is observed.

ABSTRACT

A blue thin film of amorphous silicon has been deposited on a nickel cathode by the electrolysis of a solution of tetraethylorthosilicate in acetic acid. The maximum thickness of the film obtained was about 0.5 μm. The deposit was confirmed to be amorphous silicon by *IR* reflection spectra, RHEED, and nondispersive x-ray analysis in the scanning electron microscope.

Amorphous silicon containing hydrogen, a-Si, is a promising material for the manufacture of low-cost large area solar cells with medium efficiency. Amorphous materials not containing hydrogen appear to have large concentrations of dangling bonds, producing levels in the forbidden gap which give the material a high resistance and make a change of the semiconducting properties by doping virtually impossible (1). In materials made in a glow discharge in silane, however, these bonds are saturated by hydrogen, the levels disappear, and doping to n- and p-type with appreciable conductivity becomes possible (2, 3). Conversion efficiencies as high as 6% have been measured in sunlight (4). The theoretical limit for the efficiency of a thin film a-Si solar cell is estimated to be around 15% (5).

Materials made in different ways have different properties. Amounts of H larger than required to saturate the dangling bonds lead to $(SiH)_n$ polymer formation with less favorable electrical properties. It is, therefore, important to regulate the hydrogen

* Electrochemical Society Active Member.

Key words: amorphous silicon, electrodeposition, tetraethylorthosilicate, nonaqueous electrolyte.

content of the material. Electrodeposition as a method of preparation is attractive for various reasons: It is easy to regulate the hydrogen content of a-Si; it does not involve vacuum equipment or furnaces and is therefore convenient; doped material can be made by adding compounds of the dopant to the electrolyte. It is therefore attractive to apply this method to amorphous silicon. However, the strong affinity of silicon for oxygen makes electrodeposition from aqueous electrolytes impossible. The use of organic solvents removes this difficulty.

Amorphous germanium (together with hydrogen) was plated from ethylene glycol (6). There are a few indications in the literature for a-Si electrodeposition. Warren reported electrodeposition of Si on Hg from a solution of SiF_4 in alcohol (7). Zyazev and Ezrielev described the cathodic deposition of Si on Pt (but not on Cu) from a solution of $SiCl_4$ or SiF_4 and KI in propylene glycol (8). Recently, Austin reported the electrodeposition of a-Si from SiX_4 (X: halogen) in various organic solvents (9).

In this study, cathodic deposition of a-Si from tetraethylorthosilicate ($Si(OC_2H_5)_4$) in acetic acid is presented.

Experimental

Commercial grade organic solvents and tetraethylorthosilicate (TEOS) were used without further purification.

The electrodeposition was carried out in an H-shaped vessel. The anode and cathode compartments were separated by a diaphragm of porous polytetrafluoroethylene. The solution of tetraethylorthosilicate in the organic solvents investigated in this study has a high resistance; reduction of the resistivity is achieved by adding tetramethylammonium chloride (TMAC) or tetraethylammonium chloride (TEAC), a usual additive for such purpose. TMAC and TEAC were dried under vacuum at 100°C. A cylindrical graphite rod was used as the anode and a nickel plate (99.99% pure) as the cathode. The effective area of the cathode was 2.3 cm^2. D-C current of 0.2 $mA/cm^2 \sim 20$ mA/cm^2 was supplied by a constant current power supply. In some cases, power was provided by a potentiostat, cathodic potential being measured relative to a silver-silver chloride electrode, which consisted of a mixture of silver powder and silver chloride powder in acetic acid with TMAC: Ag, $AgCl/CH_3COOH$, TMAC (0.12 mole/liter).

The electrode potential was 0.22V *vs.* SCE at 22°C. All experiments were carried out in flowing dry nitrogen. The deposits were investigated by reflection *IR* analysis, reflection high-energy electron diffraction (RHEED), and dispersive x-ray analysis in the scanning electron microscope.

Results and Discussion

Cathodic deposits were obtained on a nickel cathode from solutions of TEOS in acetic acid, propylene carbonate, and 1-chloropropane.

Table I shows typical experimental results of the electrodeposition from TEOS in acetic acid with TMAC at room temperature at a current density of 1 mA/cm^2. From this solution, bright blue deposits were obtained, which were tightly adhering to the nickel cathode. Acetone is effective to make the deposit homogeneous and also to decrease the resistivity of the solution. As shown in Table I, about a 20% increase in conductivity was observed by adding 2 cm^3 acetone to the solution of 60 cm^3 acetic acid, 4 cm^3 TEOS, and 2g TMAC. No deposit, however, was obtained from a solution with concentrations of acetone above 20 volume percent (v/o). A white precipitate became noticeable in the solution after passing a current for about 15 min. The formation of the precipitate was retarded by using distilled acetic acid. The white precipitate may be a product of hydrolysis of TEOS; *IR* spectra showed it to be a silica gel-like material. Table I indicates that the electrolysis from the solutions with higher concentration of TEOS gives lower weight gain (low current efficiency) (see 1st, 2nd, and 3rd lines). These solutions had the largest amounts of white precipitate, which adhered to the nickel cathode, preventing silicon deposition. The concentration of the supporting electrolyte affects the weight gain of the nickel cathode: There is an optimum concentration of TMAC to obtain the highest current efficiency (see 4th, 5th, and 6th lines). The highest current efficiency of about 60% calculated on the basis of a four-electron change was obtained from the solution consisting of 60 cm^3 acetic acid, 4 cm^3 TEOS, 2 cm^3 acetone, and 2g TMAC. The current efficiency decreases with increasing temperature; above 50°C no precipitate is formed in the solution and no deposit on the cathode is obtained; the evolution of hydrogen was observed.

Relations between the weight gain of the nickel cathode and coulombs passed at various current densities are shown in Fig. 1 for solutions containing 60 cm^3 acetic acid, 4 cm^3 TEOS, 2 cm^3 acetone, and 2g TMAC. As shown in this figure, the cathode increases its weight initially, but no change in weight is observed with further electrolysis. The weight gain and saturation by electrolysis were also observed on an n-type single crystal silicon cathode with relatively low resistivity. The saturation of the weight gain of nickel cathodes may be due to the low current efficiency on the pure silicon layer built on the nickel cathode. As can be seen from Fig. 1, the current efficiency decreases with increasing current density. Maximum weight gain of around 0.5 mg, which corresponds to 0.5 μm in thickness, is obtained at lower current density. No appreciable deposition was observed at current densities of 0.35 mA/cm^2 or less. Current *vs.* potential curves shown in Fig. 2 suggest that in this experimental condition hydrogen evolution begins to occur at 0.4 mA/cm^2. The potentials plotted were measured at the end of a 30 sec period of supplying the constant cathodic current. The electrode potential at 0.4 mA/cm^2 measured against the Ag/AgCl, acetic acid, TMAC reference electrode, was -0.85V *vs.* NHE. Therefore, hydrogen evolution on the cathode may play an important role for the cathodic deposition on nickel. Low current efficiencies at higher current densities may be due to the co-evolution of hydrogen.

Nondispersive x-ray analysis in the scanning electron microscope showed that the deposits contain larger concentration of silicon. The intensity ratio of

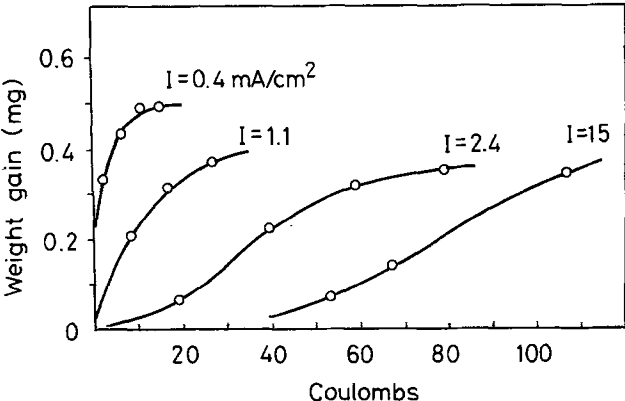

Fig. 1. The relation between the weight gain of the nickel cathode and coulombs passed for a solution containing 60 cm^3 acetic acid, 4 cm^3 $Si(OEt)_4$, 2 cm^3 acetone, and 2g $(CH_3)_4NCl$ at room temperature.

SiKα and NiKα, I_{Si}/I_{Ni}, of the nickel coated with silicon of about 0.5 μm thickness was 3.5. As shown in Fig. 3(A), *IR* reflection spectra of the deposits exhibit no absorption in the wave number range of 4000-600 cm^{-1}. X-ray diffraction patterns showed only those due to the nickel substrate. A RHEED investigation using Hitachi HU-12 A showed no reflection ring or spot from crystallization. It can be concluded from these results that the deposits consist of amorphous silicon.

As shown in Table I, the weight gain (current efficiency) on the cathode depends strongly on the concentration of TMAC in the solution. Attempts were made to plate silicon from a solution with a different supporting electrolyte, tetrabutylammonium chloride and tetrabutylammonium perchlorate. The results were similar to those obtained with TMAC. The conductivity of the solution of TEOS in acetic acid is markedly increased by the addition of pyridine. Pyridine reacts with acetic acid to produce a quaternary amine, which is effective as the supporting electrolyte. From the solution of TEOS, acetic acid, pyridine, and acetone, a whitish-gray deposit was obtained on the nickel cathode. A typical relation between the weight gain of the nickel cathode and coulombs passed at room temperature is shown in Fig. 4. The composition of the solution was 30 cm^3 acetic acid, 10 cm^3 acetone, 0.05 cm^3 pyridine, and 2 cm^3 TEOS, and the current density was about 4 mA/cm^2. In this case, the weight gain of the cathode increases approximately linearly with the number of coulombs passed. The current efficiency decreased with increasing current density; efficiencies of about 20 and 5% were obtained at 0.8 and 10 mA/cm^2, respectively.

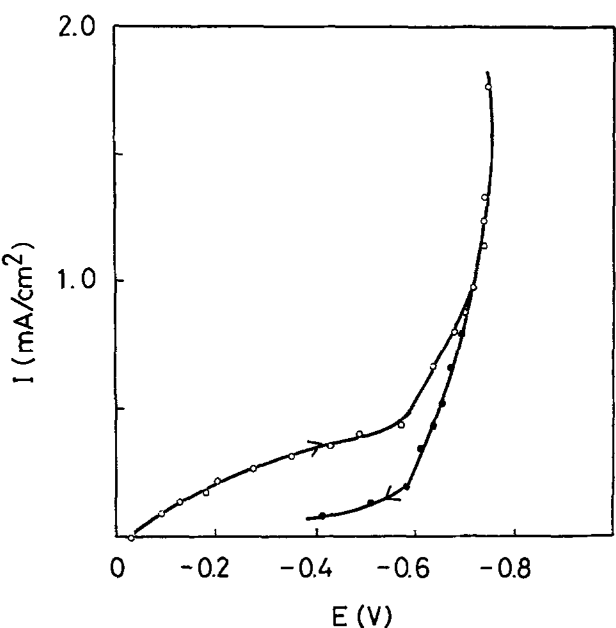

Fig. 2. Current density, *I*, vs. potential, *E*, (vs. Ag/AgCl, CH_3COOH, TMAC (0.12 mole/liter) curve for the solution containing 60 cm^3 acetic acid, 4 cm^3 $Si(OEt)_4$, 2 cm^3 acetone, and 2g $(CH_3)_4NCl$ at room temperature.

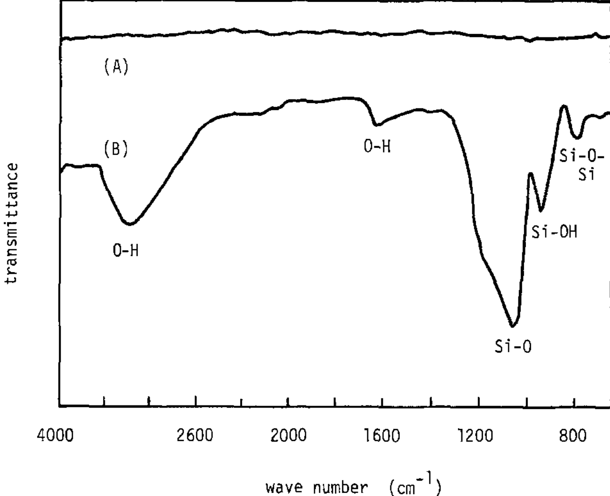

Fig. 3. *IR* reflection spectra. (A) Blue deposit obtained from the solution containing 4 cm^3 $Si(OEt)_4$, 60 cm^3 acetic acid, 2g TMAC, and 2 cm^3 acetone at a current density of 1 mA/cm^2. The thickness of the film is about 0.5 μm. (B) White deposit obtained from the solution containing 30 cm^3 acetic acid, 2 cm^3 $Si(OEt)_4$, 10 cm^3 acetone, and 0.05 cm^3 pyridine at a current density of 4 mA/cm^2. The thickness of the film is about 0.7 μm.

Nondispersive x-ray analysis showed the deposits to contain silicon. The ratio, I_{Si}/I_{Ni}, of the sample 0.5 μm in thickness was 0.8. *IR* reflection spectra of the deposits were similar to those of silica gel and of the white precipitate in the solution as shown in Fig. 3(B). A deposit of silica gel should lose its weight upon annealing in inert gas at 400°C. However, no weight change was observed after heating the sample at 400°C for 2 hr in flowing argon. These results suggest that the deposits from the solution with pyridine contain only a small amount of silica gel-like materials.

A white deposit was obtained on the nickel cathode from the solutions of TEOS in 1-chloropropane with TMAC as the supporting electrolyte. In a dry atmo-

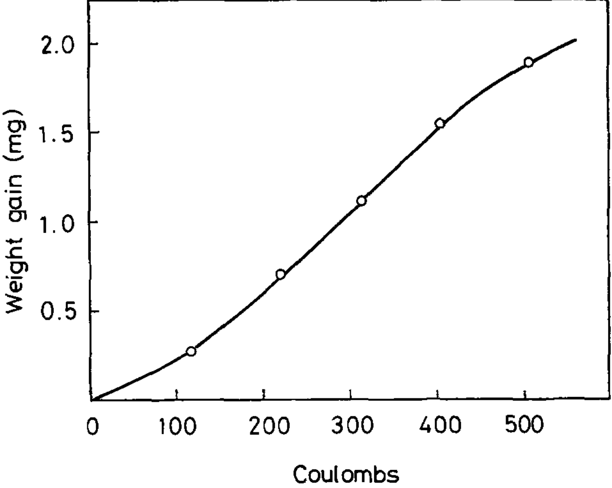

Fig. 4. The relation between the weight gain of the nickel cathode and coulombs passed for a solution containing 30 cm^3 acetic acid, 2 cm^3 $Si(OEt)_4$, 10 cm^3 acetone, and 0.05 cm^3 pyridine at room temperature.

sphere, no deposit was observed; in a wet atmosphere, a white precipitate was formed in the solution and a white deposit was obtained, with a maximum weight gain of about 0.5 mg. Nondispersive x-ray analysis showed that the deposit contained silicon, and I_{Si}/I_{Ni} of the sample 0.5 μm in thickness was 0.56. The *IR* reflection spectra exhibited peaks of Si-O modes; evidently, the white deposits contained silicon-oxygen compounds. Similar white deposits were obtained from a solution of TEOS in propylene carbonate.

In all cases of electrodeposition from solutions containing TEOS as a silicon source, the deposits were observed after the white precipitate of a silica gel-like material appeared in the solution. Yet the deposit on the cathode is only partly SiO_2. It is possible that hydrogen evolved on the cathode breaks Si—O bonds in the silica gel-like material and some ions containing silicon are reduced electrochemically on the nickel cathode. No deposit was obtained on copper, gold, and platinum used as cathodes. Clarification of the electrodeposition mechanism requires further study.

Summary

White, whitish-gray and blue deposits were obtained on the nickel cathode by the electrolysis of the solution of TEOS in organic solvents. Nondispersive x-ray analysis showed the deposits to contain silicon. However, it is doubtful whether the white and whitish-gray deposits are amorphous silicon or a silicon-oxygen compound, because *IR* spectra of these deposits were similar to those of silica gel, and the intensity ratios of SiKα to NiKα of these deposits were considerably lower than the ratio for the blue deposit. On the other hand, the blue deposits, which were obtained from the solution of TEOS in acetic acid, did not show the absorption due to Si—O and O—H modes, and had a high intensity ratio of SiKα to NiKα. The electrodeposition of thin films of amorphous silicon from the solution of TEOS in acetic acid seems promising, but problems such as the control of hydrogen content and the doping with donors or acceptors remain to be investigated before it can be put in practical use.

Photoactivation of CdSe Films for Photoelectrochemical Cells

Chin-hsin J. Liu, Judith Olsen, David R. Saunders, and Jui H. Wang*

Department of Chemistry, State University of New York, Buffalo, New York 14214

ABSTRACT

The efficiency of photoelectrochemical cells with thin-film CdSe electrodes can be enhanced by illuminating the semiconductor electrode in salt solution under closed-circuit condition. The photoactivation mechanism involves the photooxidation of CdSe to elemental selenium with concomitant release of cadmium ions into the salt solution and subsequent reductive dissolution of the resulting layer of elemental selenium. This method can be controlled more precisely than acid etching and hence is more suitable for large scale application.

The conversion of solar to electrical energy with moderate efficiency has been demonstrated by means of photoelectrochemical (PEC) cells with CdSe photoanodes (1-4). The performance of these semiconductor electrodes can often be greatly improved by limited acid etching. Heller *et al.* (2) showed an inverse correlation between the presence of surface states within the forbidden gap of the semiconductor and the efficiency of PEC cells. They suggested that acid etching of single crystals of CdSe removes the surface states which act as barrier traps and recombination centers.

A more easily controlled activation method particularly suitable for thin-film II-VI semiconductor electrodes is a photoactivation process developed in our work on PEC cells (5). In this process, the thin-film CdSe electrode was immersed together with a platinum counterelectrode in a salt solution (*e.g.*, NaCl) and illuminated under closed-circuit condition. When the photoactivated CdSe thin-film electrode was subsequently used as the photoanode in a photoelectrochemical cell with polysulfide solution, both the photocurrent and the fill factor were enhanced. Recently Hodes (6) reported a "photoetching" effect of 0.1M H_2SO_4 on $CdSe_{0.65}Te_{0.35}$ electrodes which could be of

similar nature. The present paper presents some results of our recent studies on the molecular mechanism of this photoactivation process.

Experimental

CdSe film was prepared by spray pyrolysis on titanium substrate (0.25 mm thick, Alfa Division, Ventron Corporation). The substrate was put on a hot-plate maintained at 235°C and a mixture of aqueous solutions of $CdCl_2$ (0.01M) and N,N-dimethylselenourea (0.01M), respectively, was sprayed onto the heated substrate through a chromatographic spray nozzle with a flow rate of 1-2 ml of the liquid mixture per minute at a constant excess air pressure of 5 psi. The spray apparatus was enclosed in a chamber and the spray nozzle was kept in reciprocating motion during the spraying to assure film uniformity. The CdSe film thus formed was subsequently annealed in the air at 400°-450°C for 20 min, and epoxy resin was applied to insulate the exposed titanium surface.

Photoactivation was conducted by immersing the CdSe electrode together with a platinized platinum counterelectrode in a neutral or weakly acidic salt solution and illuminating the CdSe electrode under closed-circuit condition for a few minutes with a projector light. The CdSe electrode was subsequently rinsed with deionized water and dried in a stream of nitrogen. In a few cases, the CdSe electrode and Pt counterelectrode were immersed in separate cell compartments connected by a salt bridge so that the pH of each cell compartment could be varied independently. The current passed through the system during photoactivation was measured with a Bausch and Lomb VOM-7 chart recorder.

The current-voltage characteristics of the resulting CdSe/polysulfide solution/Pt PEC cells were measured in the standard way. The composition of the polysulfide solution was 1M NaOH + 1M Na_2S + 1M S. A 12 cm^2 piece of platinized platinum was used as the counterelectrode in all the *I-V* measurements. The cell was made of Pyrex glass with a flat window. Light was admitted through this window and passed through a 1-2 mm layer of the polysulfide solution to reach the CdSe surface. A projector (Kodak Carousel 750 H) was used as the light source, and the intensity of light was measured with a YSI-Kettering Model 65A radiometer. The electrical measurements were made by means of an operational amplifier *I-V* plotter.

The photoactivated CdSe electrodes were analyzed by constant current cathodic reduction with a Pt wire as the anode and a saturated calomel electrode as the reference electrode. The current density was set at about 2 $mA \cdot cm^{-2}$, and the progress of cathodic reduction was monitored by recording the potential of the CdSe electrode as a function of time.

The concentration of Cd^{2+} ions released into the solution during photoactivation was determined by atomic absorption by means of a Perkin-Elmer 303 Atomic Absorption Spectrometer with an HGA-2100 graphite furnace.

Results and Discussion

The effect of photoactivation of CdSe electrode on the current-voltage characteristics of the resulting PEC cell is shown in Fig. 1. While the photoactivation process did not affect the open-circuit voltage (V_{oc}), it increased the short-circuit current density (J_{sc}) from 8.88 to 16.50 mA/cm^2 and the fill factor (*FF*) from 0.27 to 0.40, resulting in a substantial improvement in energy conversion efficiency. The CdSe surface turned from dark gray to blue as a result of photoactivation. But the blue color disappeared after the electrode was immersed in polysulfide solution, and the surface became darker and less reflective. Hodes (6) pointed out that the increase in J_{sc} he observed could not be fully accounted for by the lowering of reflectivity.

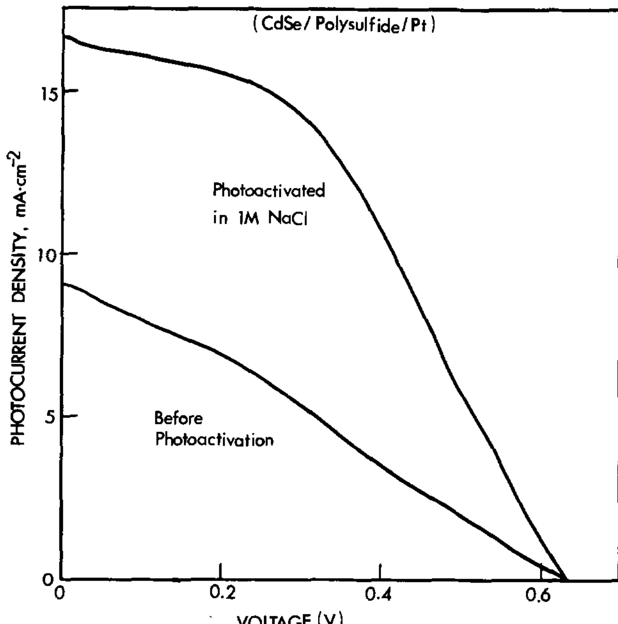

Fig. 1. Effect of photoactivation of the thin-film CdSe photoanode on the current-voltage characteristics of a CdSe/1M NaOH, 1M NaOH, 1M Na_2S, 1M S/Pt photoelectrochemical cell. The CdSe electrode was photoactivated in a 1M NaCl solution at *p*H 2.85. The light intensity for *I-V* measurements was 71 mW/cm^2.

Table I shows that photoactivation process is effective only when the CdSe electrode is illuminated under closed-circuit condition. These observations suggest that the CdSe electrode could be oxidized anodically during the photoactivation process. This possibility is also supported by the data in Fig. 2 which show that the observed enhancement in J_{sc} of the resulting PEC cell increases with the total amount of electricity passed through the CdSe electrode during photoactivation until saturation values are reached when the *p*H of the electrolyte solution was between 1.6 and 11.6. However at *p*H = 12.1, the CdSe electrode deteriorated as a result of the same treatment.

Figure 3 shows that the photoactivation process does not require specific anions in the electrolyte solution, and hence the observed increase in J_{sc} cannot be due to the adsorption or incorporation of those anions in the semiconductor. Figure 4 shows the dependence of photoactivation on electrolyte concentration. The observed higher J_{sc} values for CdSe electrodes photoactivated in more concentrated NaCl solutions are apparently due to ionic strength effect rather than due to the direct involvement of chloride ions.

In order to study the molecular mechanism of this photoactivation process, we measured the current during photoactivation under different experimental conditions instead of the characteristics of the finished PEC cells. Consistent with the data in finished PEC cells, Fig. 5 shows that between *p*H 1 and 10, the

† Measured in the PEC cell CdSe/1M NaOH, 1M Na_2S, 1M S/Pt under a projector light of intensity 71 mW/cm^2.

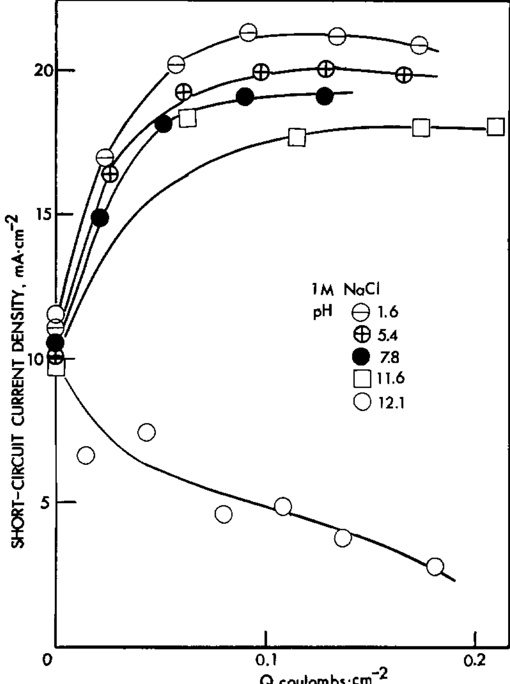

Fig. 2. Effect of pH and extent of electrode reaction during photoactivation on the short-circuit current of the resulting PEC cell CdSe/1M NaOH, 1M Na_2S, 1M S/Pt. Photoactivation was conducted in 1M NaCl solution. The J_{sc} measurements were made under white light intensity of 71 mW/cm^2.

photoactivation current increases with time to a steady-state value. But at pH 12, drops rapidly from an initial value to a much lower steady-state value.

In Fig. 6a, the observed steady-state activation current is plotted against the pH of the NaCl solution. Comparison with Fig. 2 shows that the photoactivation current and the J_{sc} of the finished PEC cell depend in the same way on the pH of the NaCl solution during the photoactivation process. In order to decide whether this observed pH dependence is due to that of the anodic reaction or cathodic reaction, the same photoactivation process was repeated with the CdSe photoanode and Pt cathode immersed in separate cell compartments connected by an agar salt bridge. Figure 6b

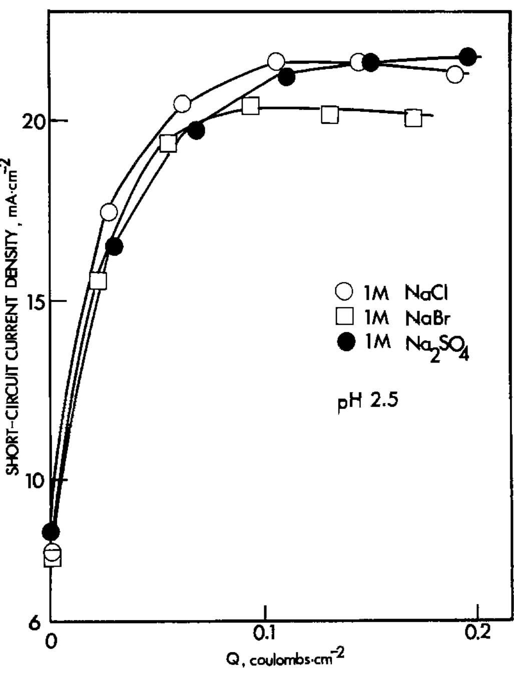

Fig. 3. Photoactivation in different electrolyte solutions

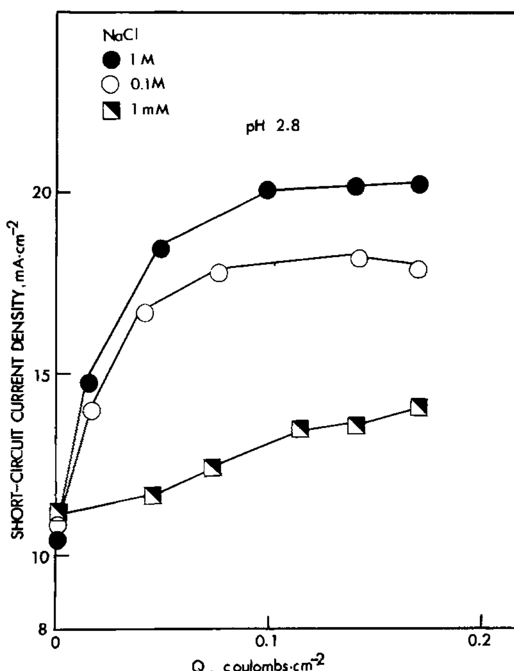

Fig. 4. Effect of NaCl concentration on photoactivation

shows the dependence of photoactivation current on the pH of anolyte (1M NaCl in the CdSe electrode compartment) when the catholyte (1M NaCl in the Pt-electrode compartment) was maintained at pH 2 with HCl. Figure 6c shows the dependence of the photoactivation current on the pH of the catholyte when the anolyte (1M NaCl) was maintained at pH 2. The similarity of pH dependence shown in Fig. 6a and 6b indicates that the rate-limiting step in the photoactivation process is the photooxidation at the CdSe electrode.

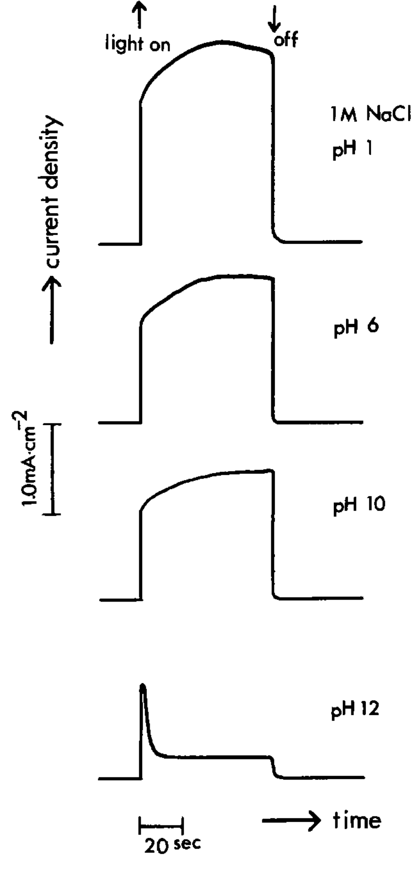

Fig. 5. Photoactivation current in a single-compartment cell containing 1M NaCl solution at different pH values.

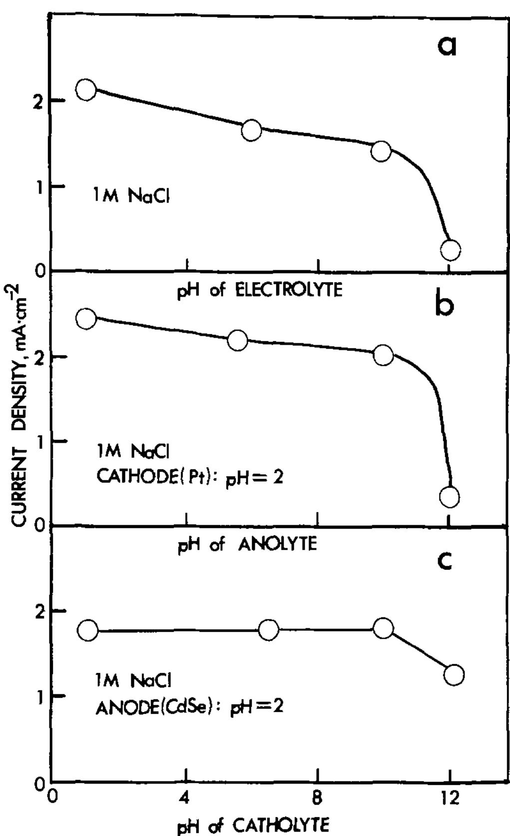

Fig. 6. (a) Photoactivation current as a function of pH in a one-compartment cell. (b) Photoactivation current as a function of pH of the anolyte in a two-compartment cell. (c) Photoactivation current as a function of pH of the catholyte in a two-compartment cell. The principal electrolyte in all three cases was 1M NaCl. These are all three separate series of experiments the slight differences in absolute photoactivation current densities between Fig. 6b and 6c are due to different illumination conditions employed.

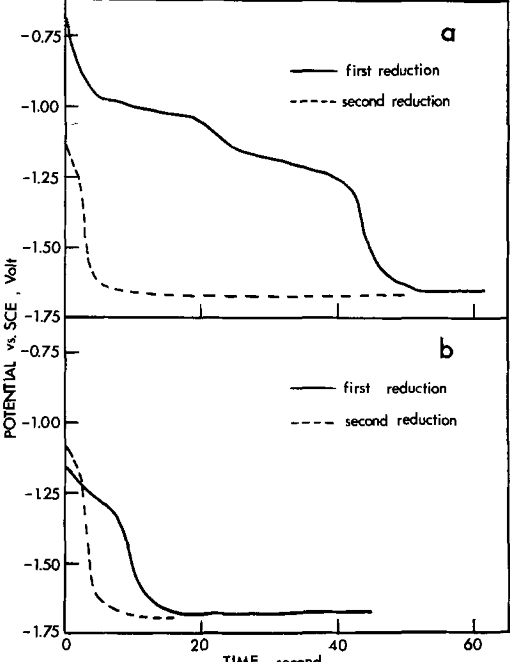

Fig. 7. Constant current cathodic reduction curves in the dark. (a) CdSe electrode was photoactivated in 1M NaCl solution at pH 6 and subsequently reduced electrolytically in the dark at constant current density. Solid curve, first reduction; broken curve, second reduction. (b) An identical photoactivated CdSe electrode was immersed in 1M NaOH + 1M Na_2S + 1M S solution for a few minutes and subsequently reduced electrolytically in the dark in 1M NaCl solution at pH 6. Solid curve, first reduction; broken curve, second reduction.

But what is oxidized at the photoanode—the electrolyte in solution or the semiconductor film? Figure 7a shows that after the CdSe electrode has been photoactivated in 1M NaCl solution at pH 6 and subsequently reduced electrolytically at constant current density of 1.9 mA/cm^2 in the dark, the following constant current reduction curves are obtained: (*i*) The first V-t curve at constant current, which showed electrode reaction(s) occurring at fairly low applied voltage, is the same whether the reduction is conducted in the solution used for photoactivation or a fresh solution of the same composition. (*ii*) Immediately after the first reduction, a second V-t scan at the same current density shows no reduction wave. These observations show that the product of photoactivation is a reducible substance on the semiconductor electrode, not in the electrolyte solution. The photoactivation reaction is probably

$$CdSe + 2h^+ \rightarrow Cd^{2+} + Se^o$$

where h^+ represents a photogenerated hole in the semiconductor. The release of Cd^{2+} ions into solution by this reaction is confirmed by the data in Table II which show that two electrons are extracted from the CdSe electrode for every Cd^{2+} ion released into solution by the photoactivation process.

The two plateau regions of the first electrolytic reduction curve in Fig. 7a at -0.98 and -1.16V, respectively, appear to have the same length on the time scale, an observation which suggests that the blue selenium layer may be formed by two one-electron oxidation steps during the photoactivation process.

When the photoactivated CdSe electrode was immersed in polysulfide solution, the blue color due to the thin layer of selenium disappeared. Figure 7b shows that subsequent electrolytic reduction of this treated CdSe electrode at constant current density in NaCl solution in the dark did not show a similar reduction wave.

These observations show that the photoactivation process takes place in two steps. In the first step, the photogenerated holes in the semiconductor oxidize CdSe to elementary Se with the concomitant release of Cd^{2+} ions into solution. The observed sharp drop in current density at the early stage of the photoactivation process as shown in Fig. 5 and Fig. 8a at high pH is probably due to the formation of an insoluble thin coating of cadmium hydroxide which retards further oxidation of Se^{2-} to Se^o with concomitant release of Cd^{2+} into solution. As expected, Fig. 8b shows that the addition of ammonia facilitates the release of Cd^{2+} at the same pH and consequently restores normal current density during photoactivation.

In the second step, immersion of the photoactivated electrode in Na_2S + Na_2S_2 + NaOH solution removes the selenium layer from the surface of the electrode

Table II. Correlation between quantities of electricity passed and the amounts of Cd^{2+} ions released into solution during photoactivation

and exposes a new surface of the semiconductor with higher electrochemical activity.

Since the above described photoactivation process can be precisely controlled, it can be safely applied to enhance the efficiency of sprayed thin-film CdSe photoanodes on a large scale. A detailed study of the photoactivation mechanism may help to improve further the photoelectrochemical properties of semiconductor thin-film electrodes and increase the efficiency of the resulting PEC cells.

On the Mechanism of Sodium Chlorate Formation

B. V. Tilak,* K. Viswanathan,* and C. G. Rader

Hooker Research Center, Grand Island, New York 14072

ABSTRACT

Sodium chlorate is formed from the chemical combination of HOCl and OCl^- ions. It is reported to be a third-order reaction involving 2 moles of HOCl and 1 mole of OCl^-. Contrasting literature data depict this reaction as bimolecular, involving 2 moles of HOCl only. Experimental results presented here clearly resolve the ClO_3^- formation reaction to be apparent third order. Dichromate, added in concentrations of 2-5 g/l during brine electrolysis to achieve high current efficiency, fulfills two key functions: (*i*) enhancement of buffer action in the pH region of 5-7; and (*ii*) prevention of adverse OCl^- and ClO_3^- electrochemical reduction reactions. Experimental evidence is presented elucidating the above observations.

In an electrolytic chlorate cell, the key chemical constituents are hypochlorous acid and hypochlorite ions. These species react chemically to form chlorate. However, the reactants and products involved in this reaction, namely HOCl, OCl^-, and ClO_3^-, are thermodynamically favored to react at the electrodes, resulting in inefficient operation of the cells. Nevertheless, industrial cells operate at high efficiencies (*e.g.*, >93%) by adept choice of operating variables and additives, *e.g.*, $Na_2Cr_2O_7$ (commonly called "chrome" in the industry).

The purpose of this communication is to elucidate the interaction of hypochlorous acid and hypochlorite ion, and to define the purpose of addition of "chrome" during electrolysis.

* Electrochemical Society Active Member.
Key words: chlorate, limiting currents, rotating disk electrodes.

A Brief Literature Survey

Two mechanisms are proposed in the literature to describe the formation of chlorate. The reaction sequence proposed by Foerster (1) and confirmed by many others (2-4) is a third-order reaction involving 2 moles of HOCl and 1 mole of OCl^- as

$$2HOCl + OCl^- \rightarrow ClO_3^- + 2HCl \quad [1]$$

However, according to Lister (5), who examined the decomposition kinetics of hypochlorite in alkaline solutions, chlorate formation follows a bimolecular sequence

$$2HOCl \rightarrow HCl + HClO_2 \quad \text{(Ionized)} \quad [2]$$

$$HOCl + ClO_2^- \rightarrow Cl^- + HClO_3 \quad \text{(Ionized)} \quad [3]$$

Eq. [2] being the slower of the above reactions.

Sodium dichromate is a conventional and multifunctional additive used routinely in the commercial production of sodium chlorate. Several roles are attributed to chrome which include: (*i*) suppressing the corrosion of the Fe cathode (6-9), (*ii*) buffering (2, 10) the electrolyte in the *p*H range of 5-7 where the chlorate formation rate is optimum, (*iii*) preventing the cathodic reduction of OCl^- and ClO_3^- ions by the "Cr_2O_3" film formed by chromate reduction (11, 12), and (*iv*) inhibiting the O_2 evolution reaction at the anode (13, 14). It is of interest to note that the fluoride ion (15) is believed to play a similar role as dichromate during chlorate electrolysis with PbO_2 anodes.

Experimental

All the solutions stated here were prepared from Analar grade chemicals and distilled water. The required hypochlorite concentration was achieved by passing chlorine through the solution (maintained alkaline) and bringing the *p*H to the desired value.

Titrations were performed with an accuracy of ± 0.01 cm^3—the *p*H being measured using a Corning *p*H meter at an accuracy of ± 0.05 units. Hypochlorite and chlorate concentrations were analyzed by standard analytical procedures (16) involving sodium arsenite and iodine. Experiments were conducted by maintaining *p*H within ± 0.02 units by dropwise addition of 10*N* NaOH.

Polarization studies were carried out using conventional (17) potentiostatic (Wenking ST72 potentiostat) and galvanostatic techniques. The rotating Pt disk electrode assembly by Pine Instruments Company was also used in this investigation.

Kinetic studies were performed in a batch reactor at about 25°C in 4*M* NaCl solutions at various *p*H values. Care was taken to exclude interaction of light during the course of the reaction. Electrochemical studies were conducted in solutions containing 450 g/l $NaClO_3$ and 150 g/l NaCl unless otherwise stated.

Results and Discussion

In a typical chlorate cell, the principal electrochemical reactions are as follows

$$6Cl^- \rightarrow 3Cl_2\ (aq) + 6e \quad \text{(at the anode)} \quad [4]$$

$$6H_2O + 6e \rightarrow 3H_2 + 6\,OH^- \quad \text{(at the cathode)} \quad [5]$$

In the bulk the following reactions take place, resulting in the formation of chlorate either by pathways described earlier by Eq. [1] or alternately by Eq. [2]

$$3Cl_2\ (aq) + 3H_2O \rightleftharpoons 3HCl + 3HOCl \quad [6]$$

$$HOCl \rightleftharpoons H^+ + OCl^- \quad [7]$$

However, the species involved in chlorate formation and the product formed, *i.e.*, ClO_3^-, may get reduced at the cathode as described by reactions [8]-[10]

$$HOCl + H^+ + 2e \rightarrow Cl^- + H_2O \quad [8]$$

$$OCl^- + 2H^+ + 2e \rightarrow Cl^- + H_2O \quad [9]$$

$$ClO_3^- + 6H^+ + 6e \rightarrow Cl^- + 3H_2O \quad [10]$$

Current efficiency losses result from any or all of the above reduction reactions. In this section, experimental results relating to the mechanism of chlorate formation and to the role of dichromate in suppressing the rates of reactions [8]-[10] are stated and discussed.

Mechanism of Chlorate Formation

Two reaction pathways are described in the literature for the chemical formation of chlorate: one proposed by Foerster (reaction [1]) and the other by Lister (reaction [2]). If the kinetics are controlled by reaction [1], then the integrated form of the rate expression may be shown to be

$$\frac{1}{C_o^2(t)} - \frac{1}{C_o^2(O)} = 6k_1t \times (1 + x)^{-3} \quad [11]$$

whereas the corresponding expression for reaction [2] would be

$$\frac{1}{C_o(t)} - \frac{1}{C_o(O)} = 3k_2t(1 + x)^{-2} \quad [12]$$

In the above equations k_1 and k_2 refer to third order and second order rate constants for reactions [1] and [2], respectively, the units for k_1 being $liter^2 \cdot mol^{-2}$ sec^{-1}, and k_2 being $liter \cdot mol^{-1}\ sec^{-1}$. $C_o(t)$ refers to the total hypo concentration (*i.e.*, concentration of HOCl + OCl^-) at time, *t*, expressed in g·mol/liter. $C_o(O)$ refers to the initial hypo concentration, *x* to the ratio of $K/10^{-pH}$ (*i.e.*, ratio of the concentration of OCl^- to HOCl) and *K* to the "conditional" equilibrium constant for reaction [7].

Thus, the diagnostic criterion for distinguishing between the reaction pathways 1 and 2 would be the constancy of k_1 and k_2 with *p*H. Values of k_1 and k_2 can be obtained from the slopes of the linear plots (see Fig. 1 and 2) of $1/C_o^2(t)$ and $1/C_o(t)$ *vs.* *t* using a *K* value of $10^{-7.18}$. This value of *K* for reaction [7] was determined in 4*M* NaCl solutions at ~25°C. Under these conditions H^+ ions are generated only by reaction [7] and not by the chlorate formation reaction—be it Eq. [1] or Eq. [2]. It must be stressed here that the *K* values published in the literature (18) for reaction [7], especially those obtained at high temperature (>40°C) and at high OCl^- concentrations, are not precise because of neglect of the H^+ contribution from Eq. [1] or Eq. [2].

Values of reaction rate constants presented in Table I show that while k_1 is constant over a wide range of *p*H values, k_2 varies significantly with *p*H. This confirms that the chlorate formation reaction is apparent third order involving 2 moles of HOCl and 1 mole of OCl^-—the third order rate constant being 0.025 $liter^2 \cdot mol^{-2} \cdot sec^{-1}$ at 25°C in 4*M* NaCl solutions. This conclusion is supported by the results of Taniguchi and Sekine (2) in which an alternate third order reaction mechanism, involving 2 moles of OCl^- and 1 mole of HOCl, was shown to be of negligible importance.

The present results raise questions regarding Lister's mechanism, as opposed to Foerster's mechanism, which was accepted by several investigators. The discrepancy

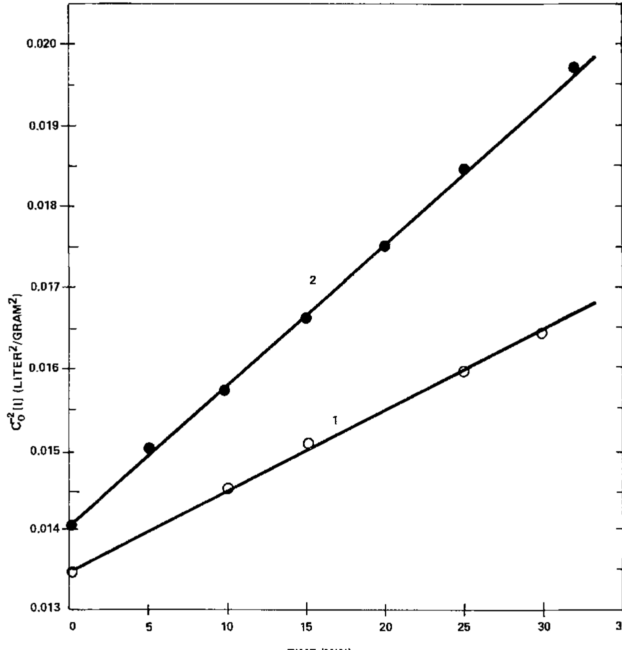

Fig. 1. Plot of $C_o^{-2}(t)$ with time. Curve 1: *p*H = 6; temp: 24°C; k_1 = 0.0275 liter²/g·mole²·sec. Curve 2: *p*H = 6.5; temp: 23°C; k_1 = 0.0230 liter²/g·mole²·sec.

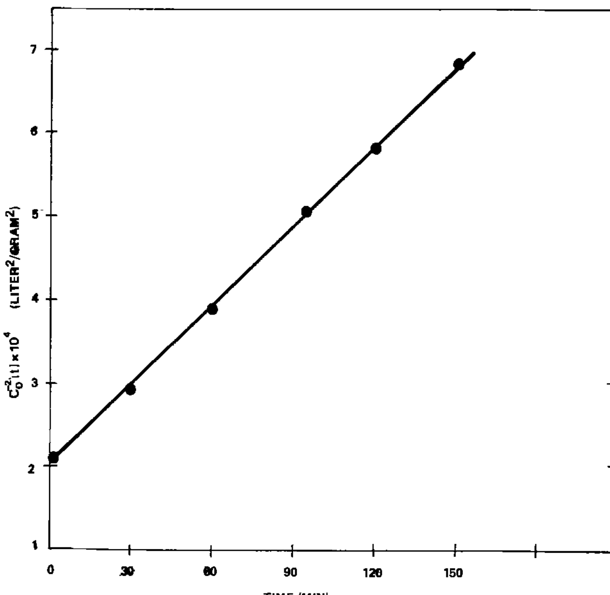

Fig. 2. Plot of $C_0^{-2}(t)$ with time ($pH = 8.5$); temp: 25°C; $k_1 =$ 0.0244 liter²/g·mole²·sec).

may be traced to the method of determination of HOCl concentration described by Lister (5), which was subsequently used in the estimation of the rate constant. The concentration of HOCl was determined by solving the material balance equation

$$[HOCl] + [HCO_3^-] = \text{acid} + \text{unneutralized NaOH} \quad [13]$$

This relationship is valid only for short periods when the H^+ generated from chemical chlorate formation is insignificant. However, Lister applied the above method to experiments wherein the chemical chlorate formation was significant and where the appropriate material balance equation is represented as follows

$$[HOCl] + [HCO_3^-] = \text{acid} + \text{unneutralized NaOH} + \text{acid generated due to hypo decay to chlorate} \quad [14]$$

Thus Lister's method of calculating the hypochlorous acid concentration, and hence the mechanism of chlorate formation, seems to be in error. From the present work it is evident that the rate of chlorate formation is proportional to the product of the square of the hypochlorous acid concentration and the hypochlorite concentration, and attains a maximum at a pH equal to (pK-log 2). This result has been experimentally verified by Jaksic (19). It may be noted that if Lister's mechanism were to hold, one would not anticipate a maximum rate in the pH range of 5-7. The reader is referred to Ref. (3) for a discussion of other possible mechanisms of chlorate formation of overall third order character.

Role of Dichromate during Chlorate Electrolysis

The functions attributed to dichromate that is added during chlorate electrolysis were noted earlier, and the relative importance of these roles are critically discussed and evaluated in this section.

Inhibition of corrosion of steel cathode.—Cathodes made of steel are generally used in electrolytic chlorate cells—the electrolyte under operating conditions analyzing 450 g/l $NaClO_3$, 150 g/l NaCl, 4-7 g/l OCl^-, and 2-6 g/l $Na_2Cr_2O_7$ at 70°C ($pH \sim$ 5-6). If the role of dichromate is indeed one of suppressing the corrosion of steel under open-circuit conditions, then the open-circuit potential (E_{ocp}) should show significant differences in the presence and absence of dichromate. However, experimental measurements in the above solutions show the E_{ocp} to be -0.30 to -0.32V *vs.* SCE in the presence and absence of dichromate, suggesting that the major role of $Cr_2O_7^{--}$ is not one of offering protection to steel from corrosion.

Enhancement of buffer capacity.—It was mentioned earlier that the preferred pH range of operation of a typical chlorate cell is in the range of 5.75-6.75 to achieve optimal conversion of hypochlorite to chlorate. The system has a natural buffer capacity in this range due to $HOCl/OCl^-$ equilibrium represented by Eq. [7]. Taniguchi and Sekine (2) mentioned that chrome addition enhances the buffer capacity in this critical pH range due to the equilibrium reaction

$$Cr_2O_7^{--} + 2\,OH^- \rightleftharpoons 2CrO_4^{--} + H_2O \quad [15]$$

Figure 3 shows the pH titration data obtained in the presence of dichromate in solutions containing 150 g/l NaCl and 450 g/l $NaClO_3$ at 70°C in the absence of hypo. It is obvious from these results that dichromate indeed buffers in the pH range of 5.75-6.75. During chlorate electrolysis, OCl^- and $Cr_2O_7^{--}$ are present in the electrolyte. Hence pH titrations were carried out in mixtures containing varying amounts of hypochlorite and dichromate. The results indicate that the buffer capacity is directly proportional to the concentration of OCl^- and $Cr_2O_7^{--}$ and that the buffer capacity of solutions containing OCl^- and $Cr_2O_7^{--}$ is a sum of the individual contributions from OCl^- and $Cr_2O_7^{--}$. Thus, it is definitively established that dichromate enhances the buffer capacity in the pH region of 5-7. However, the exact buffer requirements of a chlorate system are yet to be quantified especially for cases where chlorate formation is attempted by reacting Cl_2 and NaOH in the pH range of 5-7.

Suppression of parasitic cathodic reactions.—In an electrolytic chlorate cell, there are two parasitic cathodic reactions (Eq. [9] and [10]) arising from the cathodic reduction of negatively charged ions—OCl^- and ClO_3^-. If these negatively charged ions are to be reduced cathodically, they have to approach the cathode by diffusion and convection against an adverse

potential gradient. If the solution contains a large excess of supporting electrolyte, the adverse potential gradient is small and the transport of anions is affected only slightly. However, if an inert porous diaphragm is formed on the cathode that greatly counteracts the effect of convection, the approximate material balance equation for the species may be written as (20)

$$N_i = -Z_iU_iFC_i \nabla\phi - D_i \nabla C_i \quad [16]$$

where N_i refers to the flux of species i, Z_i to the valence of the species, U_i to mobility, C_i to concentration, $\nabla\phi$ to the potential gradient, and D_i to the diffusivity of species i.

The first term on the right-hand side of Eq. [16] accounts for transport by migration (away from the cathode surface for anions) and the second term to the contribution from diffusion. If the potential gradient term is increased by increasing the local current density, then the transport of anions to a cathode can be completely suppressed. This may be achieved by forming an inert film with low porosity on the cathode. These facts were clearly expounded in an excellent paper by Wagner (12).

Dichromate is known to be cathodically reduced to form a "Cr_2O_3" film on the cathode surface, which creates an adverse potential gradient that prevents the reduction of OCl^- and ClO_3^- ions. Polarization studies were performed in the presence and absence of dichromate to examine the influence on the electrochemical behavior of a steel cathode and the results are presented in Fig. 4. In the absence of dichromate, H_2 evolution was not observed even at a current density at 200 mA/cm^2 in solutions containing 450 g/l $NaClO_3$, 150 g/l NaCl, and ~2 g/l NaOCl. In addition, the surface was covered by a tenacious brown film (Fe_2O_3??). This is suggestive of chlorate reduction as such high currents cannot be sustained by either O_2 or OCl^- reduction. In the absence of hypochlorite and dichromate, the cathode assumed high potential values and H_2 evolution was moderate on a "patchy" brown film on the cathode surface. However in the presence of dichromate, the film disengaged followed by vigorous H_2 evolution.

To contest Wagner's hypothesis, further studies were carried out using 100 g/l $NaClO_3$ solution as electrolyte and steel cathodes coated with Kalgard[1] and Cr_2O_3 films. If ClO_3^- is indeed reduced according to Eq. [17]

$$ClO_3^- + 6H^+ + 6e \rightarrow Cl^- + 3H_2O \quad [17]$$

then the product of the reaction would be Cl^- ions. The chlorate and chloride concentrations were determined using standard volumetric procedures and the results are presented in Table II. It is clear from this data that the inert film on the steel cathode almost completely suppressed the chlorate reduction reaction.

The results presented above have important implications for the chlorate industry as they would provide a potential means of eliminating "chrome" from the

[1] Kalgard is a Teflon-based polymer composite obtained from Heany Industry.

product liquor stream which is primarily used as a raw material for ClO_2 generation.

HCC patent application (21) describes the "permanent film" concept described above. Studies on the optimization of the thickness and porosity of the film required for minimizing ohmic drops across the film are in progress.

According to Wagner (12), cathodic reduction of anions is suppressed by the adverse potential gradient generated by the surface film, whereas the cathodic reduction of cations is unhindered under the same conditions. These predictions were verified by limiting current measurements using the ferro-ferricyanide system (0.1*N* of each) in 1M KCl using a platinum rotating disk electrode. Results in Fig. 5 show that addition of as little as 0.1 g/l of $Na_2Cr_2O_7$ lowers the limiting current values to an insignificant level. This result further strengthens the "film concept" which effectively serves to repel the anion away from the cathode. Figure 6 shows similar experiments conducted in 1M KCl containing 0.1*N* $FeCl_2$ and 0.1*N* $FeCl_3$. It is seen that chromate has little effect on the limiting current for Fe^{3+} reduction which is in accordance with Wagner's theory (12).

These results conclusively demonstrate that the primary role of dichromate is in the suppression of the cathodic reduction of OCl^- and ClO_3^-. Further studies are required to characterize the compositional and structural features of the dynamically formed "Cr_2O_3" film.

Inhibition of oxygen evolution.—One of the parasitic anodic reactions during chlorate electrolysis is oxygen evolution from either the discharge of H_2O molecules (Eq. [18]) or oxidation of OCl^- to ClO_3^- (Eq. [19])

$$2H_2O \rightarrow O_2 + 4H^+ + 4e \quad [18]$$

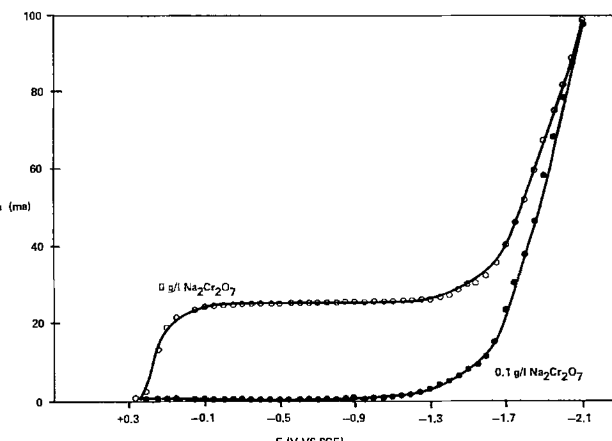

Fig. 5. Influence of $Na_2Cr_2O_7$ on the polarization data on platinum rotating disk electrode in 1M KCl + 0.1M $K_4Fe(CN)_6$ + 0.1M $K_3Fe(CN)_6$ at 20°C (electrode area: 0.46 cm²; rpm: 1600).

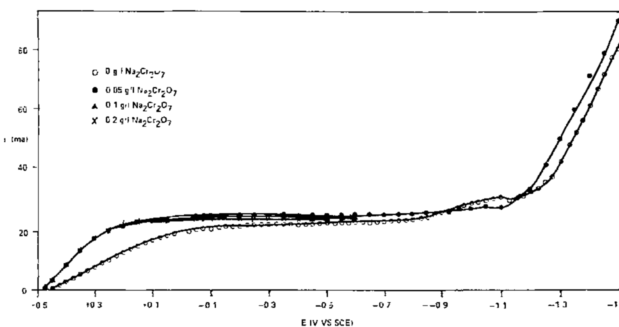

Fig. 6. Influence of $Na_2Cr_2O_7$ on the polarization data on platinum rotating disk electrode in 1M KCl + 0.1M $FeCl_2$ + 0.1M $FeCl_3$ at 20°C (electrode area: 0.46 cm²; rpm: 1600).

$$6\,OCl^- + 3H_2O \rightarrow 2ClO_3^- + 6H^+ + 4Cl^- + 3/2\,O_2 + 6e \quad [19]$$

It is stated in the literature (13, 14) that $Cr_2O_7^{--}$ suppresses the amount of oxygen generated during chlorate electrolysis. While one may rationalize this observation in terms of blocking of sites for oxygen evolution by dichromate and/or complexation of hypochlorite-decomposing catalysts (e.g., Fe, Co, Ni) by $Cr_2O_7^{--}$ (and/or CrO_4^{--}) further investigations are needed to understand the mechanistic aspects involved in this phenomenon.

Conclusions

1. Sodium chlorate formation is an apparent third order reaction involving 2 moles of HOCl and one mole of OCl^-. The "second order" mechanism proposed by Lister appears to be incorrect because of errors involved in his method of determining the HOCl concentration.

2. The primary function of dichromate added during chlorate electrolysis is the formation of an inert film which suppresses the ClO_3^- and OCl^- reduction reactions via the establishment of an adverse potential gradient. Wagner's film theory is further substantiated using steel cathodes coated with Kalgard and Cr_2O_3 films in chlorate solutions, and by rotating disk electrode studies wherein $Fe(CN)_6^{3-}$ reduction was hindered by 0.1 g/l $Cr_2O_7^{--}$, while Fe^{3+} reduction was unaffected. Secondary functions which chrome performs include enhanced buffer capacity in the critical pH range of 5.75 and 6.75 and suppression of the undesirable oxygen evolution reaction.

The Electrochemical Activity Determination of Trypsin-Like Enzymes

V. A Comparative Study of the Electrochemical Oxidation of the Marker, p-aminodiphenylamine, and of Electrogenic Substrates in Human Plasma, Whole Blood, and Aqueous Solutions

M. Daraio de Peuriot, J. M. Nigretto,* and M. Jozefowicz

Department of Chemistry, Université Paris-Nord, 93430 Villetaneuse, France

ABSTRACT

Easily oxidizable aromatic amines can be conveniently used as electrogenic markers for the evaluation of enzymatic activities in whole blood and human plasma dilution. The analytical procedure is based on the cyclic voltammetric detection of the amine released by thrombin (the tested blood coagulation factor) through an amidolytic cleavage from specific substrates. The relevance of parameters susceptible of interfering with the electrochemical signal have been reviewed using carbon paste and smooth platinum disk electrodes. Results obtained in blood and plasma dilutions are compared with aqueous solutions of the enzyme.

Since the early seventies, the use of chromogenic substrates started a rapid development in the field of the assay of trypsin-like enzymes and of their natural inhibitors. Several enzymes of this type are involved along the overall blood coagulation process. The final step in the blood clotting cascade is the conversion of fibrinogen to fibrin, which leads to the formation of the thrombus. The latter catalytic decomposition is mediated by a protease, thrombin. While thrombin induces the thrombosis, it is normally only present in the precursor form, prothrombin. Beside the clotting enzymes, plasma carries components fated to inhibit their action; thus, the most potent antiprotease associated with thrombin is antithrombin III, which has been definitely shown to play a role in the body's defence against thrombosis.

Therefore the quantitative evaluation of antiprotease levels in physiological media is determinant for clinical purposes. From that point of view, the availability of chromogenic substrates provides an access to thrombin and antithrombin activity assay. The principle of the photometric procedure lies in the following: the enzyme is added to a mixture containing the synthetic substrate. Since its chemical structure more or less mimics the C-terminal part of the fibrinopeptide A at the sequence preceding the fibrinogen bond cleaved, thrombin catalyzes the splitting of the chromogenic moiety. The activity of thrombin, or remaining thrombin when antithrombin III levels are assayed, is then proportional to a photometric variable (1).

Most substrates commercially available are designed to release p-nitroaniline (pNA) through amidolytic digestion, which is conveniently monitored photometrically in the visible spectrum region at 405 nm. However, severe limitations restrict the scope of the procedure to colorless, diluted, and homogeneous solutions. Human plasma dilutions fulfill these requirements, but not whole blood; accordingly, antithrombic assays need to be achieved following a centrifugation procedure.

In order to avoid such a more or less traumatic handling of the samples, an electrochemical technique has been recently proposed, so as to permit the assay of trypsin-like enzymes (*e.g.*, trypsin, factors IXa, Xa, kallikrein, thrombin, plasmin, and their inhibitors) in human whole blood. This technique involves the electroanalytical detection of electroactive markers in place of the chromogenic pNA. Several substrates of various specificity have been tested (Fig. 2). D,L benzoylarginyl p-aminodiphenylamide (D,L BAPADA) has been conceived for the assay of trypsin, S-2421, and S-2497 for thrombin and, accordingly, antithrombin III. Each of these substrates bears an easily oxidizable amine, p-aminodiphenylamine (pADA) (2-5).

While the electroanalytical detection of pADA in physiological media can be speculatively thought to be perturbed with respect to aqueous solutions, the aim of this paper is to investigate the influence of parameters which may mediate the electrochemical redox signal in the conditions for an actual assay. Therefore, the results obtained in whole blood and plasma are compared with those of aqueous solutions exempted from physiological fluids. The following variables of potential relevance are examined in the light of the shape and the position of the cyclic voltammogram of the amine: electroactivity of the substrates that have been tested, redox character of the enzymes, *p*H, and the effect of plasma and blood levels.

Experimental

Instrumentation, cells, and electrodes.—The instrument used for the electroanalytical studies was a standard amplifier-based potentiostat/galvanostat PAR Model 173 (Princeton Applied Research) provided with a three electrode configuration. Current-voltage and current-time curves were monitored with a Sefram TGM X-Y recorder and generated with a function generator PAR Model 175. For electroanalytical experiments, a one-compartment cell containing a carbon paste electrode (CPE), platinum wire auxiliary, and aqueous SCE reference was employed. Before each individual run, the carbon paste surface was renewed. The working electrode circuitry was buffered with a high impedance electrometer PAR Model 178. The smooth platinum disk electrode was embedded in Teflon (area: 0.0314 cm^2). Its pretreatment is detailed in the next section. Coulometric n values were obtained with a PAR Model 179 digital coulometer. The vessel consisted of a two-compartment cell in which the

* Electrochemical Society Active Member.

Key words: electrochemistry, trypsin-like enzymes, thrombin, blood, plasma.

platinum wire auxiliary electrode was in one compartment and the platinum gauze working electrode and aqueous SCE reference were in the other; the two were separated by a porous glass frit. Experiments were conducted in 0.2-7*N* H_2SO_4 aqueous solutions, in the presence of 5% added methanol or in buffered solutions. These conditions proved to facilitate the dissolution of the reactants. The analytical concentration range for pADA was in all cases 0.1-0.4 mmol.

Solvents and reagents.—Aqueous solutions were prepared from doubly distilled water and reagent grade H_2SO_4 or standard buffer reagents. The p-aminodiphenylamine (pADA) was a commercial product from Fluka (Switzerland), puriss. p.a., which was purified by successive recrystallizations from water/ethanol mixtures. The amine was stored under vacuum in the dark and was no longer used after one week storage. All other materials were reagent grade and were used without further purification.

Enzymes, plasma, and blood sampling.—Lyophilized thrombin (51 NIH-U/mg, Lot No. A 3133) was purchased from Hoffman-LaRoche, Basel, Switzerland, and stored in the freezer. Its activity was measured either with chromogenic substrates or with the clotting time method. Before use, aliquots of thrombin were dissolved in tris/NaCl buffer *p*H 7.45 to a concentration of about 50 NIH-U/ml and preincubated for 30 min in an ice bath. Stock solutions were no longer utilized after 60 min following dissolution. Pipettes and syringes were saturated with the thrombin solution before use. Whole blood was taken from a donor under usual conditions at the Centre National de Transfusion Sanguine (Paris, France): 92 ml blood and 25 ml of a citric acid/monosodium phosphate/glucose solution (3.27g citric acid monohydrate, 2.63g trisodium citrate dihydrate, 1.93g anhydrous monosodium phosphate, and 2.32g anhydrous glucose in 100 ml). The haematocrit was 0.48. Human plasma was prepared by centrifugation at 2000g for 20 min at 4°C and kept frozen at −20°C before use.

Results and Discussion

The electrochemical behavior of pADA in aqueous solutions and in dilutions of plasma and whole blood has been investigated with two kinds of electrodes. Mechanistic information has been collected using the carbon paste electrode for the range of potentials attainable with it is fairly extended anodically. It also provides almost zero residual currents. For optimizing the practical purposes, the use of smooth platinum electrodes was studied.

Aqueous Solutions (Results Obtained with the Carbon Paste Electrode)

Influence of pH.—In the moderate *p*H range, from 2 to 10, the cyclic voltammogram shows a marked *p*H dependence. The variation of the peak potential is is given by the relation

$$E_p{}^a = 0.06\ pH + 0.53V\ vs.\ \mathrm{SCE\ at\ 20°C}$$

which holds up to *p*H 7.5. The slope accounts for the global transfer of an equal number of electrons and protons. The voltammetric analysis of the signal shows the pADA molecule yields the parabenzoquinonediimine form (6). Whereas it is practically constant below *p*H 7.5, the anodic-to-cathodic peak separation increases as a result of increasing irreversibility (Fig. 1). In coincidence, the current ratio $i_p{}^c/i_p{}^a$ decreases. It must be noted that the break occurring in the potential/*p*H relationship does not arise at the *p*K for acid-base dissociation of pADA (*ca.* 5), but two units above, instead. This indicates that the nature of the diffusing species (the protonated pADA) differs from those undergoing the electrochemical oxidation at the electrode surface (the neutral amine). The apparent *p*K

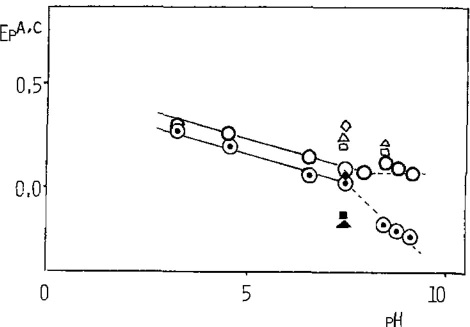

Fig. 1. Anodic and cathodic peak-pH relationship of the pADA redox couple at the carbon paste electrode. (Scan rate = 0.2 V/sec.)

△	▲	1/10 whole blood dilutions
◇	◆	Undiluted whole blood

involved would be that of the adsorbed form. Since the irreversibility more markedly affects the cathodic run than the anodic half-cycle, as shown on Fig. 1, it is suggested that the oxidant anodically formed undergoes a chemical conversion becoming preponderant above *p*H 7.5. The hydrolysis of the diimine may reasonably account for this trend (7).

The increasing irreversibility of the electrochemical signal, however, does not prevent utilizing it as a marker for enzymatic activity determinations; this was checked with amperometric titrations of the amine in solutions covering the *p*H range mentioned above. As a result, the endpoint procedure can be applied, for example, after blocking the enzymatic kinetic with the addition of acid (5).

Influence of the sweep rate.—Simplest voltammetric curves were obtained when scanning rates of 0.2 V/sec were used. At this scanning rate, the peak current (i_p) was found to be a linear function of p-aminodiphenylamine concentration with an accuracy of ±5% between 10^{-6} and 10^{-3}M. At lower scanning rates, faradaic and adsorption oxidation peaks of decomposition products of the radicals formed in the first electron uptake (6) were observed at potentials more positive than the oxidation peak of the parent compound.

Influence of the substrate.—Adequate substrates for electrochemical determinations should not be electroactive, at least in the potential span where the marker itself is detected. Three peptides were tested: D,L benzoylarginyl p-aminodiphenylamide, S-2497, and S-2421. The benzoylarginyl-p-aminodiphenylamide and S-2497 yielded p-aminodiphenylamine and S-2421 yielded 4-methoxy-2-naphtylamine (Fig. 2). The first peptide differed from S-2497 and S-2421 by bearing a benzoylarginyl group instead of the phenylalanyl-pipecolylarginyl group of the latter two.

The results of the electrochemical behavior of these substrates are presented in Fig. 3 and Table I. The study was performed in tris/NaCl buffered solutions at *p*H 7.45. The cyclic voltammograms of the three substrates are similar; they show two anodic peaks for the 10^{-6}M level, which gradually merge into one unique symmetrical peak above the 10^{-5}M range of concentrations. The associated cathodic peaks are not present in each case. Otherwise, the anodic peak current amplitudes are not linearly related to the concentrations of the depolarizer in the studied range. Rough calculation of the apparent diffusion coefficients leads to values above five times larger than that of the released amine. As concerns a relative insight, the data suggest that the ratio $I_p{}^a/C$ for the three sub-

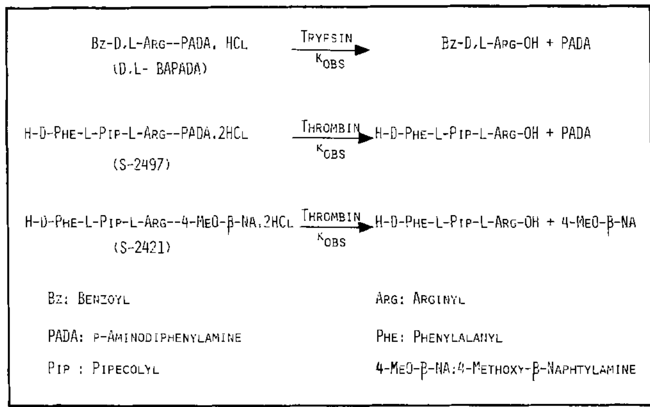

Fig. 2. Reaction schemes for the amidolytic decomposition of the specific substrates by proteases.

strates vary in the order of increasing molecular weight and/or adsorption ability, inasmuch as naphtyl groups are more capable of adsorbing than p-diphenylamine groups (8).

These observations indicate that preponderant adsorption controlled processes accompany the irreversible charge transfer reaction, in such a way that the whole peak only reflects a minor contribution of the faradaic component. This is best shown at low concentrations where the second peak ascribed to the faradaic reaction is gradually overlapped in favor of the preceding adsorption peak, in proportion the concentration is increased.

The potentials of the faradaic peaks were compared to those of the respective amines, in solutions of identical composition. The results are reported in Table I. The constant differences which are obtained provide the indication that the loss of the electrons is in each case promoted by the amine linked up with the peptide chain. It may be concluded that the electron withdrawing ability of the latter is essentially equivalent for the three substrates, whichever group substitutes the arginyl radical.

Due to the final levels at which the substrate is required to allow a pseudo first order kinetic to proceed (at least 10^{-4}M), adsorption affects the electrochemical signal of the amine when the potential exploration is pursed past the oxidation peak. This holds especially when consecutive sweeps are effectuated with the same electrode surface. In the case of the carbon paste electrode, however, the surface is renewed before each run. Therefore, although wide potential spans are attainable with this kind of electrodes, many determinations are excluded within the duration of the kinetic. Actually, this technique is essentially restricted to endpoint procedures. From this point of view, solid electrodes such as platinum electrodes provide a more suitable tool for continuous determinations. This point is examined below.

Influence of dimethylsulfoxide and of glycine.—DMSO has to be incorporated with the solutions to ensure a sufficient dissolution of the substrates, even at the 10^{-4}M level. Glycine, which is known to stabilize protein solutions, was also used at the 0.05M concentration. The effects of these compounds are described in light of the features of the amine oxidation signal: $E_p^a - E_p^a$ (1/2), the peak to half-peak potential difference, E_p^a, the peak potential, and the i_p^a/C ratio (Table II).

Table I. Observed oxidation peak potentials of various electrogenic substrates compared to those of the corresponding free amines in aqueous solutions (tris/NaCl *p*H 7.45 buffer). Concentrations fall in the 0.1 mm range. Mean deviation ±5 mV.

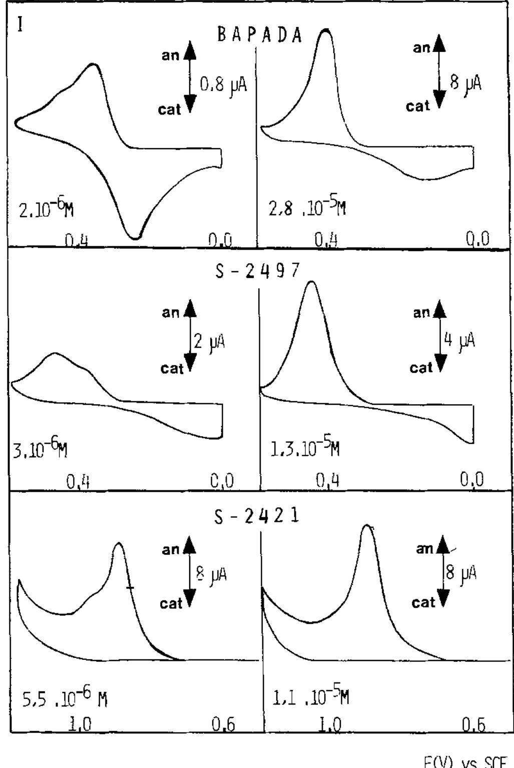

Fig. 3. Cyclic voltammograms of the substrates at the carbon paste electrode (scan rate: 0.2 V/sec; in tris/NaCl/Gly/DMSO solutions at *p*H 7.45).

The addition of DMSO markedly reduces the i_p^a/C ratio and hinders the reversibility of the charge transfer, as illustrated by increasing $E_p^a - E_p^a$ (1/2) values. As the increase in the viscosity of the solutions cannot itself explain the importance of the observed effect, it is envisaged that DMSO combines to dissolve superficially the paraffin used to elaborate the electrode material. Thus, the increasing irreversibility would account for an etching phenomenon of the electrode surface by diminishing its catalytic properties rather than for an electrokinetic effect occurring in the double layer.

Per se, glycine does not inhibit the reversibility of the voltammetric peak since the $E_p^a - E_p^a$ (1/2) variation remains the same as for acidic solutions; the observed 40 mV correspond to a number of exchanged electrons intermediate between one and two, which is compatible with the mechanism described elsewhere for the actual sweep rate (6). Although glycine shows no significant effect on the reversibility of the electronic transfer, it nevertheless affects the position of the peak potential, rendering it more anodic. Increasing the amount of DMSO acts likewise. In the case of glycine instead, it is probable that the amino acid modifies the structure of the solvent-electrode interface, presumably through local adsorption. Hence, the transfer of the electrons likely occurs under different local *p*H conditions which would be responsible for the anodic shift. On the other hand, adsorption of glycine molecules might also restrict the effectiveness of the electrode surface. It is thus not surprising to note a correlative decrease in the i_p^a/C values.

From these partial results, it can be concluded that accurate determinations of peak heights require precise experimental conditions. The potential shift is unimportant with regard to amperometric procedures unless a fixed potential detection is used. The current

function i_p^a/C, however, reflects the additive influences of the DMSO and glycine content. A calibration curve must therefore be assessed prior to the titration. In the following, the results will be referred to 5% v/v DMSO and 0.05M glycine solutions.

Influence of thrombin.—Similarly, the influence of the thrombin content is studied through the modification of the anodic half-cycle of pADA oxidation. Results are presented in Table III for pH 7.45 and 8.47.

Proteins, especially thrombin (9) and albumin, are known to readily adsorb on synthetic surfaces. The anodic shift shown by the peaks in proportion to the added amount of protein probably accounts for that phenomenon, in the same way as glycine does. In the activity range in which the electrochemical assay is monitored, *ca.* 0.1 NIH unit, the disturbance caused by thrombin can be neglected. The electrochemical characteristics of the voltammograms are not drastically modified by the adsorption of proteins, provided that the concentrations fall below a given limit (Table III). For example, the reversibility of the charge transfer rate depicted by the $E_p^a - E_p^a$ (1/2) values is maintained in aqueous solutions along the range for the activity determination of thrombin. Although the i_p^c/i_p^a ratio offers no analytical exploitation, it can be remarked that it does not vary past a given amount of thrombin. This should be relevant for a protein coverage of the electrode surface reaching saturation. After its occurrence, it will likely slow down the chemical reversibility of the cycle, without affecting the electrochemical kinetic.

Human Plasma and Whole Blood Dilutions

Study with the carbon paste electrode.—Results are presented in Fig. 4 and 5 and Table III.

The comparison with voltammogram a of Fig. 4 traced at the reference pH 7.45 (the enzymatic assays are actually conducted at the latter pH) leads to the following remarks:

The dependence of the peak potentials with the pH of the solution is illustrated by voltammograms f, e, and a in Fig. 4, traced in H_2SO_4 0.7*N*, pH 3.29 and 7.45, respectively. The cathodic shift with increasing pH is relevant to the thermodynamics.

The background voltammograms of blood solutions up to 50% dilutions show no evolution electrochemically detectable up to at least 30 min. At the latter concentration, the anodic width of potential reaches 0.4V *vs.* SCE. This indicates that the protein content remains electrochemically inactive at the carbon paste electrode, at least with respect to charge transfer reactions.

It is worthy to note that as much as a 10% plasma or blood content reduces the peak current function i_p^a/C by less than 10%, see Table III and voltammograms b, c, and d in Fig. 4. This result is of great interest, keeping in mind that the antithrombin III (or thrombin) content usually estimated this way is included in few microliters of pure sample; therefore, there is no need to set up accurate calibration curves with respect to the final amount of proteins, prior to the assay.

Lowering the dilution of blood or plasma still maintains linear relationships in the amperometric determination of pADA. Figure 5 gives the i_p^a/C values as a function of the plasma or blood dilution. Once the data are corrected by taking into account the viscosity changes, there is no significant difference between these biological fluids. In particular, the presence of a heterogeneous phase brought by the figurative elements of blood (the haematocrit is about 45%) does not affect the applicability of the method. When undiluted blood or plasma samples are tested, it is just necessary to adjust the calibration curve to the conditions for the actual assay. This feature definitely marks the advantage of the electrochemical assay over the photometric one for trypsin-like enzymes in heterogeneous

fluids such as blood, without turning to preliminary centrifugation.

In concentrated fluids and immediately following the mixing, the peak amplitude for pADA oxidation decreases up to *ca.* 50% of the original amplitude. Because the decrease is in relation to the dilution of the fluid and not to the analytical concentration of pADA, this trend cannot be attributable to macrophagic activity. It more probably concerns a modification of the electrode surface. This point will be discussed further, in light of the results obtained wtih the platinum electrode. The data presented here account for voltammograms traced passed this transient evolution.

Study with the smooth platinum disk electrode.—For practical purposes, it is obvious that solid electrodes potentially provide a very useful tool, easily applicable to automated or semi-automated analytical titrations, provided that several requisites are fulfilled:

1. The active surface of the electrode shall be sensitive enough and show evidence for reproducible peak currents, including constant background currents.

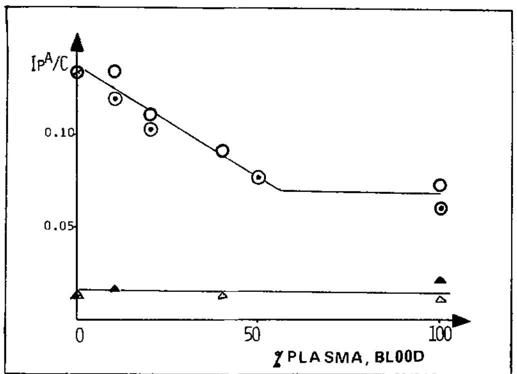

Fig. 5. Peak amplitudes vs. blood or plasma dilution relationships (with viscosity correction; scan rate 0.2 V/sec).

	Aqueous	Plasma	Blood
Carbon paste electrode	⊘	○	⊙
Smooth platinum electrode	◬	△	▲

2. To attain this purpose, it may be essential to elaborate a precise protocol of pretreatment.

3. The amperometric titration shall be effectuated as frequently as possible during the course of the amidolytic hydrolysis of the substrate. Thus, the same electrode surface shall operate several times while the potential is multicycled, without showing hysteresis, *i.e.*, the weakening of its catalytic properties and without restriction of its effective area (with respect to adsorbed species, for example).

The following results have been obtained in aqueous tris/NaCl/glycine/DMSO solutions buffered at *p*H 7.45. Blood and plasma dilutions were prepared just by mixing the biological fluids with the aqueous buffer.

Pretreatment procedure.—The background trace of metallic electrodes in aqueous solutions is quite sensitive to the chemical state of the surface and to adsorbed oxides. Therefore, the electrodes are often subjected to rather cumbersome prepolarizations, destined to obtain reproducible background voltammograms of the solvent. Inasmuch as the potential region of the amine undergoing oxidation is restricted to few hundred millivolts, it would be suitable to apply a pretreatment procedure inside of this span. Results show that an interrupted triangular sweep of potential between −0.1 and +0.4V promotes the rise of a steady-state background cycle, whatever solvent is used, aqueous or biological. In the latter case, the duration of the pretreatment is even shortened. The integrated currents of the limiting voltammogram is always smaller than the initial trace. It is assumed that the gradual charging of the double layer is responsible for the decrease. After the application of the described prepolarization, the background currents superpose quite reproducibly, within a 10^{-2} μA dispersion. In particular, no current increase or decrease develops on prolonged cycling over a period of time of at least 30 min. Here, the narrowness of the explored potentials and the gradual abrasion of the oxide peaks avoid some time-dependent effects related to the presence of proteins in the solution (9).

Refinements for the detection of pADA.—The optimum anodic and cathodic limits for the triangular sweep were analyzed in the light of the shape of the resulting anodic half-cycle. Results showed the relative unimportance of the potential bounds provided that the pretreatment procedure is applied before and provided that the limits coincide with those of the precycling. Of some importance instead is the rest time separating two consecutive runs, for the adsorbed material formed during the electrochemical conversion somewhat reduces the amplitude of the consecutive voltammograms. The optimum rest time could not be less than 45 sec.

Electrocatalytically speaking toward aromatic hydrocarbons or amines, platinum surfaces are known to behave poorly, in any event less than the carbon paste material. It is therefore not surprising that the pADA voltammograms show irreversible profiles. Although the criteria for electrochemical reversibility are far from being met, the amperometric detection gives nevertheless straight and proportional i_p^a/C · pADA relationships, in any point comparable to those obtained using the carbon paste electrode. The amplitudes are in correspondence with the respective geometrical areas (Fig. 5).

Calibration of the platinum electrode in plasma and blood dilutions.—As was observed with the carbon paste electrode, the peak amplitudes recorded with the platinum electrode show little weakening in blood and plasma dilutions (voltammograms b and c, Fig. 6) up to 10%, if compared against a voltammogram on the reference (voltammogram a) in aqueous medium. It is also typical to note that the peak separation $E_p^a - E_p^c$

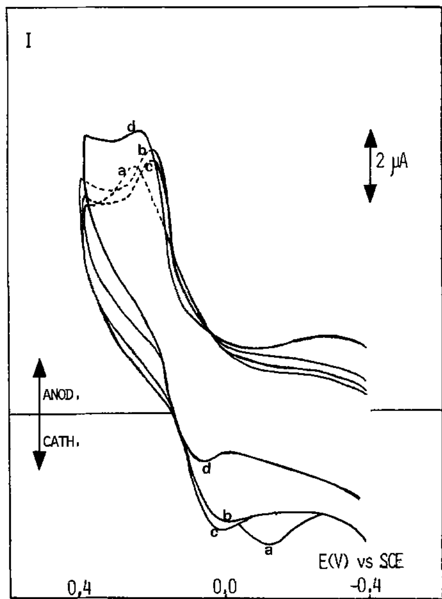

Fig. 6. Cyclic voltammograms of pADA at the pretreated smooth platinum electrode. (Scan rate 0.2 V/sec; tris/NaCl/Gly/DMSO pH 7.45). a, Aqueous solution; b, 1/10 diluted whole blood; c, 1/10 diluted plasma; d, undiluted whole blood.

decreases with the biological mixtures. Probably, the occurrence of the coated proteins favors the chemical reversibility of the redox couple by slowing down the propensity to migrate away (as might occur with more effective adsorption in the presence of coated proteins), although without interfering with the diffusion rate toward the electrode surface.

The more interesting result concerns the peak height for pADA oxidation which fairly well compares in aqueous buffers with even pure blood (voltammogram d in Fig. 6). These findings give rise to the data plotted in Fig. 5 for the platinum electrode in correspondence with those referring to the carbon paste electrode. The comparison is quite attractive inasmuch as it shows the neglectable influence of the blood or plasma content of the solution onto the calibration. In turn, these results indicate that the transient decrease of the peaks traced with the carbon paste electrode are to be related to surface effects, but not to the consumption of the depolarizer by the biological fluids.

It is obvious that the insensitivity to the biological environment confers to the pretreated platinum electrode a definite advantage over the other electrode systems. It also affords a substantial relief in the practical procedure preceding the enzymatic assay.

On the other hand, calibration curves proving that the measured signal is a linear function of concentration have been published in other papers of this series (3); the function is essentially identical for aqueous solutions, human plasma, and whole blood dilutions.

Conclusion

An electroanalytical method for the study of enzymatic kinetics is proposed. The use of modified electrode surfaces through the adsorption of proteins affords a new insight into the behavior of clotting enzymes in the presence of insoluble materials or into whole blood dilutions.

The Electrochemical Activity Determination of Trypsin-Like Enzymes

VI. The Electrochemical Oxidation of the Marker, p-aminodiphenylamine in Aqueous Solutions

Jean-Maxime Nigretto*

Department of Chemistry, E.R.A. 607, Université Paris-Nord, 93430 Villetaneuse, France

ABSTRACT

The electrochemical oxidation of p-aminodiphenylamine was investigated in the 0.1 mmol concentration range and in H_2SO_4 aqueous solutions. Cyclic voltammetry with slow scan rates at the carbon paste electrode and controlled potential step electrolysis were the techniques followed. Results suggest that the initial oxidation stage produces p-quinodiimine via an ECE process. This two-electron oxidation product further undergoes addition reactions involving the depolarizer. The hydrolysis of the adduct is assumed to yield a quinoidal derivative, aniline and ammonia, as deduced from step coulometry and visible spectroscopy experiments. The sequence of the decomposition which is proposed integrates most of the results available elsewhere. No polymerization of the starting material occurs in the used working conditions.

p-Aminodiphenylamine (pADA) appears to be a convenient marker for the electrochemical determination of enzymatic activities. The electroanalytical procedure is based on the periodical detection of the amine concentration level in the assay solution using its oxidation signal. The amine is released through a hydrolytic cleavage from a specific substrate by the enzyme (1-4).

This paper is aimed at gathering some mechanistic information on the electrochemical behavior of the marker. The electroanalytical data available in the literature are more concerned with the pADA as an intermediate in the general oxidation pattern of aniline and its related derivatives than per se. In the proposed reaction pathways, pADA is generated from the head-to-tail coupling of aniline with the anilinium radical after it has been formed at the electrode surface. Strong acid solutions favor this reaction scheme, whereas weaker acidities favor the alternate formation of tail-to-tail products, the benzidines (5, 6). The pADA oxidation was described as producing N-phenyl p-benzoquinonediimine, via the transfer of two electrons. Compounds of this series are known to undergo readily a hydrolytic decomposition reaction leading to p-quinone formation with aniline as side product. The intermediate for the proposed pathways, N-phenyl p-quinoneimine has, however, never been characterized, neither in the solution following macroscale electrolysis nor voltammetrically at the electrode surface (7).

Product isolation work in aqueous solution met only with mixed success. Leedy and Adams (8) have isolated and fully identified p-benzoquinone as the ultimate product of the decomposition stages. Hand and Nelson (6) have terminated the preparative electrolysis of pADA at 1.0V with n values of 6. Cyclic voltammetry runs on the solution showed that essentially all the parent material had been consumed. The I-E curves were identical with those obtained from a solution of hydroquinone. No other peak was observed. In other studies, various coupling derivatives, such as Willstätter blue and Willstätter red imines as the intermediates, have been evidenced electrochemically. On the other hand, the final product of the oxidation of aniline in aqueous solutions was depicted, nearly a century ago, as being an oligomer of aniline, called aniline black, usually supposed in the form of a linear octamer named emeraldine. Isolation experiments indicated that at least a major constituent of this precipitate is a quinone-hydroquinone mixture, although the full composition thereof has not been completely elucidated. Results show that it is actually composed of many adducts of unspecified structure, depending on the electrolysis parameters: parent to intermediate ratio, concentration range, current density, etc.

The aim of this work is to provide additional insights into the mechanism of the pADA oxidation in solutions initially exempted from the parent aniline molecule and in the tenth millimolar concentration range. In order to detect the possible intermediates issued from the decomposition reactions, slow scan cyclic voltammetry and step coulometry experiments have been used. The results reported herein show that additional features ought to be taken into account to describe the electrochemical behavior of pADA. Also some new indications are given with respect to the redox content of the solution following partial electrolysis.

Experimental

Instrumentation, cells, and electrodes.—The instrument used for the electroanalytical studies was a standard amplifier-based potentiostat/galvanostat PAR Model 173 (Princeton Applied Research) provided with a three electrode configuration. Current-voltage and current-time curves were monitored with a Sefram TGM X-Y recorder and generated with a function generator PAR Model 175. For electroanalytical experiments, a one-compartment cell containing a carbon paste electrode (CPE), platinum wire auxiliary, and aqueous SCE reference was employed. Before each run, the carbon paste surface was renewed. The working electrode circuitry was buffered with a high impedance electrometer PAR Model 178.

Coulometric n values were obtained with a PAR Model 175 coulometer. The vessel consisted of a two-compartment cell in which the platinum wire auxiliary electrode was in one compartment and the platinum gauze working electrode and aqueous SCE reference were in the other; the two were separated by a glass frit. In aqueous H_2SO_4 solutions, experiments were conducted in the presence of 5% added methanol; these conditions proved to facilitate the dissolution of the reactants. The analytical concentration range for pADA was in all cases 0.1-0.4 mmol.

* Electrochemical Society Active Member.
Key words: p-aminodiphenylamine, aromatic amines.

Solvents and reagents.—Aqueous solutions were prepared from doubly distilled water and reagent grade H_2SO_4 or standard buffer reagents. The pADA was a commercial product from Fluka (Switzerland), puriss. p.a., which was purified by successive recrystallizations from water/ethanol mixtures. The amine was stored in the dark and was not used after one week storage. All other materials were reagent grade and were used without further purification.

Results

The electrochemistry of this compound in aqueous H_2SO_4 solutions can be broadly characterized as involving an initial reversible charge transfer followed by a series of hydrolysis reactions including the parent material. A typical cyclic voltammogram is represented in Fig. 1. At low scan rates, a maximum number of three anodic peaks and four major cathodic peaks can be detected. In order to avoid confusion, since some couples behave irreversibly (when the cathodic counterpart of the half-cycle is missing or shifted), the half-cycles are numbered separately. Anodically, they will conveniently be labeled in the order of appearance from the right to the left: $i_p^{a_1}$, $i_p^{a_2}$, and $i_p^{a_3}$; with respect to the cathodic peaks, $i_p^{c_1}$ is assigned to the reversible redox couple and associated to $i_p^{a_1}$. The others are referenced as indicated in the figures. In the following, the label i_p indifferently refers to the nature of the couple or to the peak height. The decomposition sequence can be revealed by cyclic voltammetry by applying different pH and sweep rate conditions for the kinetics are pH dependent.

Thermodynamic Features

In buffered aqueous solutions from pH 8 to H_2SO_4 5.6*N*, the cyclic voltammogram of pADA, restricted to the first system, exhibits a reversible redox couple, $i_p^{a_1} - i_p^{c_1}$ (Fig. 1), followed by other irreversible systems. The features of this couple are markedly dependent on the acidity level and on the scan rate.

The position of the first anodic peak lies in pH dependence according to the relation (1)

$$E_p^{a_1} = -0.06\,\text{pH} + 0.53\text{V}\ vs.\ \text{SCE} \qquad [1]$$

At 0.2 V/sec sweep rate, the anodic-to-cathodic peak separation is close to 60 mV up to *ca.* pH 7.5, whereupon the peaks separate and the system behaves irreversibly. Variations in absolute $i_p^{a_1}$ values result in increases in the viscosity of the solutions as the H_2SO_4 content is increased. Except for strong acid solutions for which the pH definition is meaningless, no break occurs in coincidence with the acid-base constant for pADA dissociation (pK_a'(pADA, H^+/pADA) = 5). With respect to the Nernst equation, that slope predicts that an equal number of electrons and protons are globally lost by the species undergoing the electrochemical oxidation.

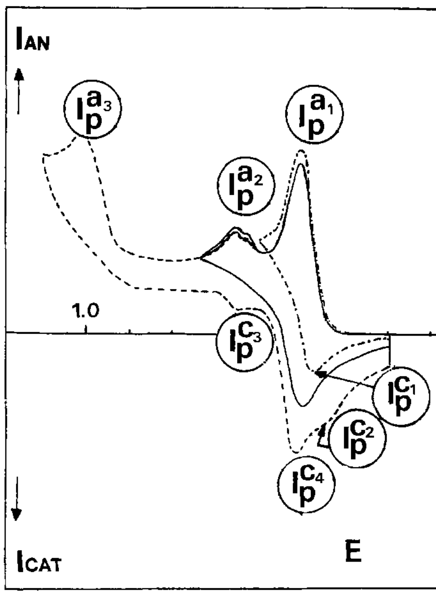

Fig. 1. CPE cyclic voltammograms of pADA in aqueous H_2SO_4 2.64*N* solutions. pADA 0.24 mmol; ν 0.075 V/sec.

Electroanalytical Features

The reversible $i_p^{a_1}/i_p^{c_1}$ couple.—The electrochemical behavior of the first couple is described by the data reported in Table I. The extent to which filming effects affect the electroanalytical data is unknown; however, the data presented are reproducible within the 5% dispersion normally attributed to the reproducibility of the CPE. It is found that $E_p^{a_1}$ values are constant with slow sweep rates. A slight trend to shift anodically becomes apparent with increasing scan rates, the magnitude thereof being globally inferior to 20 mV with a tenfold increase in the rate of the potential sweep. On the other hand, the anodic peak-to-half-peak potential differences show that the slowing down of the potential sweep favors a reversible two-electron transfer, as indicated by values close to the theoretically predicted 28 mV. With slow scan rates, the S-shaped cathodic cycle and the limiting value attained by the $i_p^{c_1}/i_p^{a_1}$ ratio at a given acidity level show evidence for a reversible conversion. That limiting value cannot be lowered by using scan rates slower than 0.050 V/sec in strong acid solutions. It remains likewise constant by varying the switching potential E_λ up to the foot of peak $i_p^{a_3}$ at 0.9V. The reversibility of the follow-up reaction is also corroborated by applying multiple potential scans at 0.010 V/sec scan rate to the first peak, *i.e.*, from 0.0V up to 80 mV past the peak maximum: the cathodic amplitude $i_p^{c_1}$ remains unchanged whereas the anodic one decreases slightly, but tends to a steady-state profile after few runs; it is probably originated from minor side-reactions and cannot be ascribed to filming effects since in that case the global amplitudes are expected to decrease gradually and significantly. Increasing the sweep rate ν, the system apparently evolves to show a monoelectronic charge transfer as indicated by larger $E_p^{a_1} - E_p^{a_1}(1/2)$ potential separations. Increasing the acidity of the solution acts likewise. These data are corroborated by the plot of the function (2) for increasing scan rates and acidities ranging from H_2SO_4 5.6*N* to pH 8

$$i_p^{a_1}/C \cdot \nu^{1/2} = f(\nu^{1/2}) \qquad [2]$$

where *C* and ν are the analytical concentration of the depolarizer and the sweep rate, respectively. Results show decreasing slopes in a manner similar to that described by Nicholson and Shain for a follow-up reaction after the primary electron transfer (9). This suggests a classic ECE mechanism, in which the species formed after the initial oxidation step undergo a chemical reaction and lead to more oxidizable species.

The test for chemical reversibility is best demonstrated by the current ratio $i_p^{c_1}/i_p^{a_1}$ (Table I). Results show the faster the sweep rate and the lower the proton availability (below pH 8), the best the reversibility is achieved. In contrast, more anodic switching potentials reinforce this trend. Thus, $i_p^{c_1}/i_p^{a_1}$ ratios vary from 0.52 to 0.97 with ν ranging from 0.01 to 1.0 V/sec in H_2SO_4 5.6*N* solutions and from 0.52 to 0.94 if the acidity decreases from H_2SO_4 5.6*N* to pH 3.17 at a constant 0.010 V/sec sweep rate. On the other hand, with a given H_2SO_4 2.64*N* level and slow sweep rates, the $i_p^{c_1}/i_p^{a_1}$ ratio remains constant at 0.52 when E_λ keeps inferior to 0.9V; beyond the potential of $i_p^{a_3}$ at 1.0V, $i_p^{c_1}/i_p^{a_1}$ increases significantly.

The irreversible $i_p^{a_2}$ redox peaks.—The ill-defined peaks $i_p^{a_2}$ can only be detected voltammetrically with

slow sweep rates if the acid content of the solution exceeds 2*N*. In these conditions, the amplitude remains inferior to 15% if compared to i_p^{a1}. i_p^{a2} should actually be considered as a complex system since it is composed of two bumps.

The irreversible i_p^{a3} redox peak.—The corresponding voltammetric data are compiled in Table II. At potentials *ca.* 0.5V more anodic than the first i_p^{a1}/i_p^{c1}, the anodic run gives a second major redox peak i_p^{a3} which has apparently not been taken into account in the literature so far. Slow sweep rates and strong acid levels contribute to increasing the peak height i_p^{a3} (it is hardly detected above 0.1 V/sec; compare for example Fig. 1 and 2). An indicative plot of i_p^{a3} as a function of the *p*H variation gives an S-shaped trend, the larger variation being centered around *p*H 0.3. Thus, the i_p^{a3} peak amplitudes are no longer affected by acidity changes above H_2SO_4 1M, at constant ν. Results also show that the peak

height i_p^{a3} increases linearly with the analytical pADA level. The function intersects the axis origin whereby the faradaic nature of the peak can be assessed. Otherwise, in given solution conditions, i_p^{a3} is also linearly related to the time gate measured past peak i_p^{a1} as shown by the straight function intersecting the origin of the *i*/*t* axis. This holds with time gates shorter than *ca.* 30 sec, thereafter a saturation profile takes place.

Cathodic peaks.—The cathodic features are related to the position of the switching potential E_λ. When E_λ precedes peaks i_p^{a2}, one unique cathodic peak i_p^{c1} rises up, the characteristics of which are compared to those of the associated i_p^{a1} in Table I. As soon as E_λ is reversed past i_p^{a2}, the cathodic half-cycle is displaced anodically by about 30 mV and the resulting peak i_p^{c4} is significantly increased if compared to the previous i_p^{c1} (Fig. 1). Finally, the effect of setting the E_λ potential back at 1.2V, *i.e.*, after i_p^{a3}, is to promote new cathodic peaks of minor importance, on each side of i_p^{c4}, i_p^{c3} at 0.65V, and the shouldered-peak i_p^{c2} at 0.43V, the latter bearing some importance as is mentioned later on in the step coulometry studies. It must be noticed that in the same conditions authentic aniline samples oxidized voltammetrically at 1.0V exhibit three cathodic peaks located at 0.65, 0.51, and 0.43V, matching up in position and amplitude with i_p^{c3}, i_p^{c4}, and i_p^{c2}, respectively. It may be concluded that these additional systems are, at least partially, promoted by the species issued from the i_p^{a3} oxidation peak.

Step Coulometry Experiments with the Platinum Anode

The pADA oxidation mechanism was investigated using step coulometry at the 0.8V controlled potential

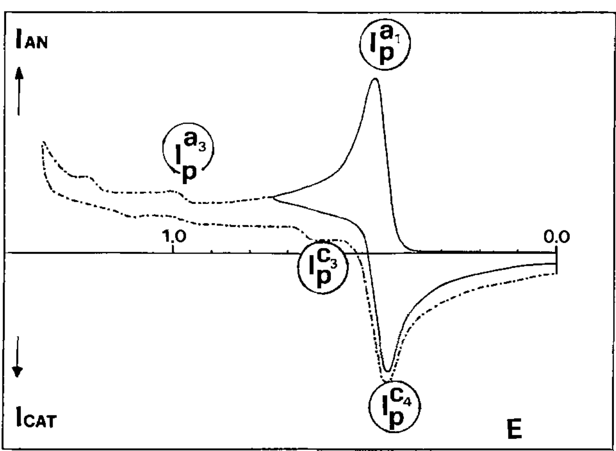

Fig. 2. CPE cyclic voltammograms of pADA in H_2SO_4 0.67*N* aqueous solutions. pADA 0.39 mmol; ν 0.100 V/sec.

in order to avoid interference with the $i_p^{a_3}$ system. Our results thus complete the data published previously in the literature and concerned with the exhaustive electrolysis of pADA at 1.0V for which $n = 6$ values have been collected. The data are reported on the diagram in Fig. 4; the voltammetric curves accounting for partially electrolyzed solutions up to one electron per pADA molecule are represented in Fig. 3; those for beyond that amount in Fig. 5.

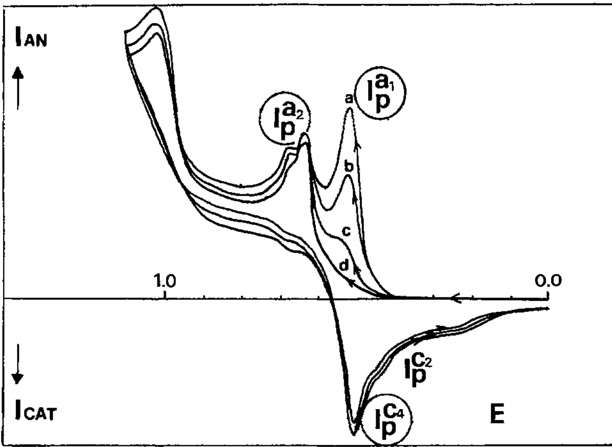

Fig. 3. CPE cyclic voltammograms of pADA in H_2SO_4 2.64*N* aqueous solutions partially electrolyzed at 0.8V. pADA 0.4 mmol; ν 0.010 V/sec. a, 0.25; b, 0.54; c, 0.85; d, 1.0 Cb/pADA.

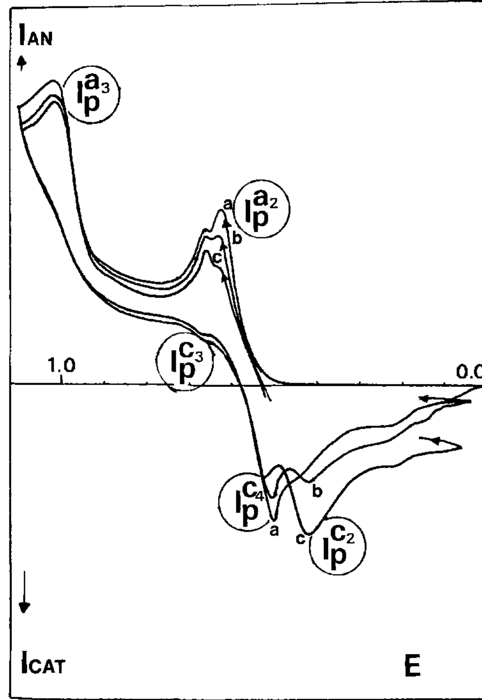

Fig. 5. CPE cyclic voltammograms of pADA in H_2SO_4 2.64*N* aqueous solutions partially electrolyzed at 0.8V. pADA 0.4 mmol; ν = 0.010 V/sec. a, 1.0; b, 1.15; c, 1.50 Cb/pADA.

One electron step coulometric oxidation.—A break in the charge/time curve indicates first a fast transfer of 1.00 ± 0.05 electron per depolarizer molecule. A transient deep-blue coloration results before the solution turns gradually deep-green. Voltammograms traced while the electrolysis is performed show a correlative decrease of peak $i_p^{a_1}$. This peak vanishes when the faradaic equivalency is attained, whereas the associated cathodic trace remains unaltered (if compared to the unelectrolyzed solution) if E_λ is reversed past $i_p^{a_2}$. When E_λ is reversed just after $i_p^{a_1}$, the decrease of $i_p^{c_1}$ parallels that of $i_p^{a_1}$. The limitation of the anodic exploration to past the first peak $i_p^{a_1}$ also results in constant $i_p^{c_1}/i_p^{a_1}$ values. As shown in Fig. 3 and 4, $i_p^{a_2}$ increases while $i_p^{c_4}$ remains constant with increasing electrolysis. This suggests that $i_p^{a_2}$ is relevant for the oxidation of relatively stable products being formed during the initial step of the electrochemical oxidation, while $i_p^{c_4}$ is promoted by the reduction of products generated via $i_p^{a_1}$ and $i_p^{a_2}$.

Over one-electron step coulometry oxidation.—At this time, the voltammograms have to be started from the rest potential of the solution located in the region of the disappeared first peak. After the transfer of the first electron, two additional charges are necessary to ensure the consummation of peaks $i_p^{a_2}$; meanwhile, a gradual lightening of the deep-green coloration can be observed in the solution. At the end of the experiment, the only remaining anodic feature is represented by the peak $i_p^{a_3}$, not concerned with the electrolysis conducted at 0.8V; when the used scan rates are slow, the peak amplitude remains constant and reflects the sum of the bulk and electrode concentrations of the species undergoing oxidation at 1.0V.

The major change in the cathodic features rises up with the extension of peak $i_p^{c_2}$ at 0.43V, which gradually overlaps $i_p^{c_4}$ (Fig. 5). It must be noted that peak $i_p^{c_2}$ originally exists as a shoulder promoted by the precursor oxidation at $i_p^{a_1}$ (Fig. 1) or by the use of insufficiently purified (atmospherically oxidized) pADA samples. The decrease of peak $i_p^{c_4}$ ($i_p^{c_4}$ merges with $i_p^{c_2}$ on the cathodic back runs traced from 1.2V) occurs in proportion to the increase of peak $i_p^{c_2}$ (Fig. 4.).

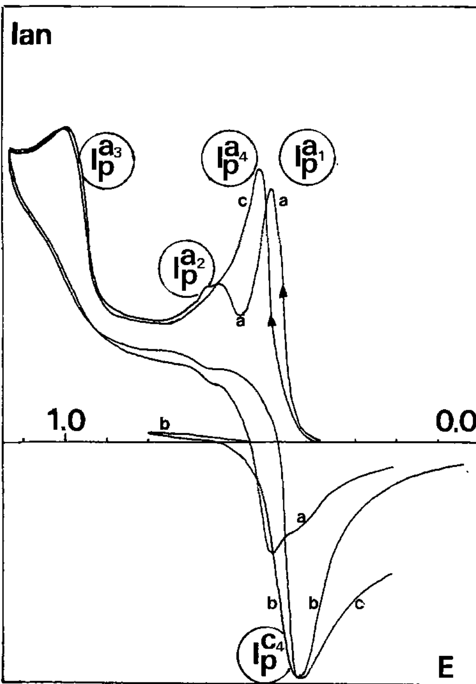

Fig. 6. CPE cyclic voltammograms of pADA in H_2SO_4 2.64*N* aqueous solutions partially electrolyzed. pADA 0.30 mmol; ν = 0.010 V/sec. a, Initial solution; b, following 3 Cb/pADA electrolysis at 0.8V; c, after the 2 Cb/pADA electrolysis at 0.0V following b.

These observed changes operate within the two-electron coulometric transfer in proportion to the charge balance exceeding one equivalent; thereafter, the solution is no longer oxidizable at 0.8V and the cathodic peak heights remain constant.

Reverse step coulometry at 0.0V following that conducted at 0.8V.—After the exhaustive three-electron electrolysis carried out at 0.8V, the controlled potential was set at 0.0V in order to integrate the oxidative capacity of the resulting solution. The Q/time function indicates the rapid proceeding of a two-electron reduction per original pADA molecule. The final voltammogram consists in an anodic peak $i_p^{a_4}$ (Fig. 6) at $E_p^{a_4}$ = 0.53V (slightly more anodic than the disappeared $i_p^{a_1}$ peak), exempted from the $i_p^{a_2}$ peaks characteristic of the pADA basic system and preceding the still remaining and unchanged $i_p^{a_3}$ peak. Thus, the reverse electrolysis conducted alternatively at 0.8 and 0.0V apparently operates the irreversible change from the original pADA reducer to a mixture composed of two electroactive reducers able to undergo two oxidations, at 0.53V (reversible) and at 1.0V (totally irreversible), respectively.

Visible Spectroscopy

Visible spectral curves recorded for partially electrolyzed solutions of pADA in 2.64*N* H_2SO_4 are shown in Fig. 7 a-b. Whereas the initial curve and the final curve following the exhaustive 3 Cb/pADA electrolysis are characteristically weak and ill-defined, intermediate solutions exhibit one intense and transient absorption band in the pADA region around 750 nm (6) and a weak band at 420 nm, in the quinone absorption region; another transient absorption band, not attributed, occurs at 500 nm. The increase of the major absorption band, related to the number of transferring coulombs, reaches a maximum value for one equivalent, thereafter it decreases gradually as shown in Fig. 7b.

Discussion

Electroanalytical Results

Since no apparent break produces on the $E_p^{a_1}$ *vs.* *p*H plots and since the $i_p^{a_1}$ values are mediated by viscosity changes rather than by changes in the diffusion coefficients, it can be postulated that in the studied *p*H range the same reacting species undergo oxidation at the electrode surface. It follows that fast deprotonation reaction(s) ought to precede the electron transfer, with rates unable to compete with the potential sweeps that have been used. Such a conclusion is in agreement with comparative chronopotentiometric (10) and voltammetric (11) studies performed with numerous aromatic amines in aqueous H_2SO_4 solutions. For example, as opposed to N,N-dimethyl p-phenylenediamine and p-phenylenediamine, the oxidation pathway of pADA and of diphenylamine were found to behave quite differently. In particular, no region of kinetic control occurred in the studied *p*H range. Likewise, the mechanism for the electrochemical oxidation of anilinium solutions involved a fast precursor deprotonation step following adsorption onto the electrode (12). It will therefore be postulated that the oxidation peak $i_p^{a_1}$ involves the same form, whatever acidity level condition prevails. This form is supposed to be the uncharged depolarizer molecule, for another assumption would less easily explain the ease of the oxidative attack and the stability of the multicharged species that would result from the oxidation as well. Above *p*H 7.5-8, the anodic-to-cathodic peak separation splits, as a result of a hydrolysis reaction affecting the oxidized species under mild alkaline conditions (13a).

To keep constancy with the coulometric results, it is necessary to envisage that two neutral molecules of the depolarizer participate globally in the oxidation step, thus transferring an equal number of electrons. These two charge transfers are separated by a chemical conversion, as indicated by the slope of the $i_p^{a_1}/C \cdot \nu^{1/2} = f(\nu^{1/2})$ function. Slow scan rates allow the reaction to proceed without interfering with the second charge transfer. Accordingly, with reference to the $E_p^{a_1} - E_p^{c_1}$ and $E_p^{a_1} - E_p^{a_1}$ (1/2) values, two electrons are kinetically exchanged successively. Conversely, applications of faster scan rates show only the transfer of one electron, owing to the competitive chemical reaction. Hence, just one parent molecule loses apparently one electron, the second species merely serves as a neutralizing organic base, all the more effectively as it would exist under the uncharged form.

In the framework of the aforementioned assumptions, it is obvious that the cation radical I is formed after the primary electron transfer (scheme 3)

$E_p^{a_1}$, $-e^-$ (I) $E_p^{a_1}$, $-e^-$ (II)

The involvement of radicals in the follow-up reaction was indirectly assessed. Hydroquinone is normally oxidized at 0.65V using the same solution conditions.

Since it is known to form stable radicals in acid solutions, mixtures with pADA solutions were prepared. The cyclic voltammograms resulted in the enhancement of the first peak in proportion to the added amount of hydroquinone. Otherwise, another evidence is brought by the involvement of free radical steps in the oxidation mechanism of related compounds with peroxidase (14).

The fate of the cation radical will depend both on the acidity conditions close to the electrode surface and on the scan rate. Since low acidities prove to facilitate the proton loss in favor of another parent molecule, the transient formation of the neutral semiquinone radical must be postulated. The latter species is presumably much more oxidizable than the original reducer or than its protonated form. This would explain the occurrence of the second electron transfer at the same working potential, accounting for an ECE-type sequence.

In fact, the stability of the semiquinone radical cation I is mediated by the disproportionation reaction (4), which is pH-dependent

2 (I) ⇌ (II) + pADA·H⁺

Spectrophotometric determinations conducted on p-phenylenediamine confirm the involvement of this charged radical in the solution on mixing solutions of the amine with chemical oxidants, such as bromine (15) or ferricyanide (13b). In acid solutions at $pH < 4$, the equilibrium is almost completely displaced to the left, as was shown in the bulk.

Turning back to the pADA system, it is clear that an analogous qualitative conclusion, ruling out the thermodynamics of these species, may be drawn out. Although pADA shows a less symmetrical structure, its resonance ability will expectably be enhanced due to the presence of the additional aromatic ring. At the electrode surface, however, where deprotonation conditions are locally operating, the stability of this charged radical would be hindered and its existence mediated by an acid-base conversion involving, as deduced above, the deprotonated pADA acting as a strong base. Therefore, the alternate mechanism setting into play the disproportionation reaction of the radical cation as the follow-up reaction will not be preferred. As a result, two monoprotonated species are kinetically assumed to form at the electrode surface, in two limit oxidation levels, the acid pADA form, on the one hand, and the charged p-quinonediimine II (pQDI), on the other.

Follow-up Reactions

It has been previously deduced from chemical oxidation experiments conducted with similar compounds that the diimine forms offer a weak resistance to irreversible changes when exposed to solvents such as water (16) or acetic acid (15). However, the reactions are not known for certain to be hydrolyses in any case. The results presented herein show that a fast electroanalytical technique, such as cyclic voltammetry combined with step coulometry at controlled potential, will give some insight into the preliminary stages of the hydrolysis.

There is no question as to the possible occurrence of 1,4 addition reactions in the oxidation of aromatic amines, as outlined in Feiser's study (17). The 1,4 addition (Michael) reaction of a nucleophile with quinoidal systems is well established and is assumed to play a predominate role in the follow-up reactions. The rates of these reactions are pH dependent, since they involve reactions of the free base forms of the attacking nucleophile on the partially positively charged 2 position of the quinoid. Results presented elsewhere (13c,d) have shown that the chemical oxidation of p-phenylenediamine, a model compound for pADA, gives Bandrowski bases as major product under mild pH conditions. The mechanism accounting for the formation involves the 2,5 coupling of two protonated diimine molecules to the unoxidized amine, followed by the oxidation of the resulting trimer in the 2,5 p-diimine p-phenylenediamine form. Although the proposed kinetic scheme could not be extended to acid solutions, it was nevertheless clearly indicated that the addition products require monoprotonated reacting species to be formed, even in the used mild pH conditions. Keeping in mind that the oxidative coupling of p-anisidine has been similarly realized in hydrochloric solutions (14), the viability of such coupling reactions in acidic media cannot be disregarded, irrespective of the charge status of the reacting species. From that point of view, the partial positive charge at the 2 site should be more facilitated in the p-quinone form than in pQDI, and in the protonated diimine form than in the neutral pQDI (18).

Another mechanism has been proposed to account for the oxidation of aniline in acidic solutions, based on the linear coupling (dimerization) of one pQDI and one pADA molecule to form an adduct called Willstätter blue imine (WBI). Through several oxidation steps combined with further additions of the parent molecule, the sequences are assumed to explain the formation of the octamer, emeraldine. Willstätter red imine (WRI), the oxidized counterpart of WBI, has been intermediately postulated. Under mild pH conditions, additions of the initial material in the 2,5 position on the pQDI have also been envisaged and characterized using thin layer chromatography analysis at the preparative scale (19).

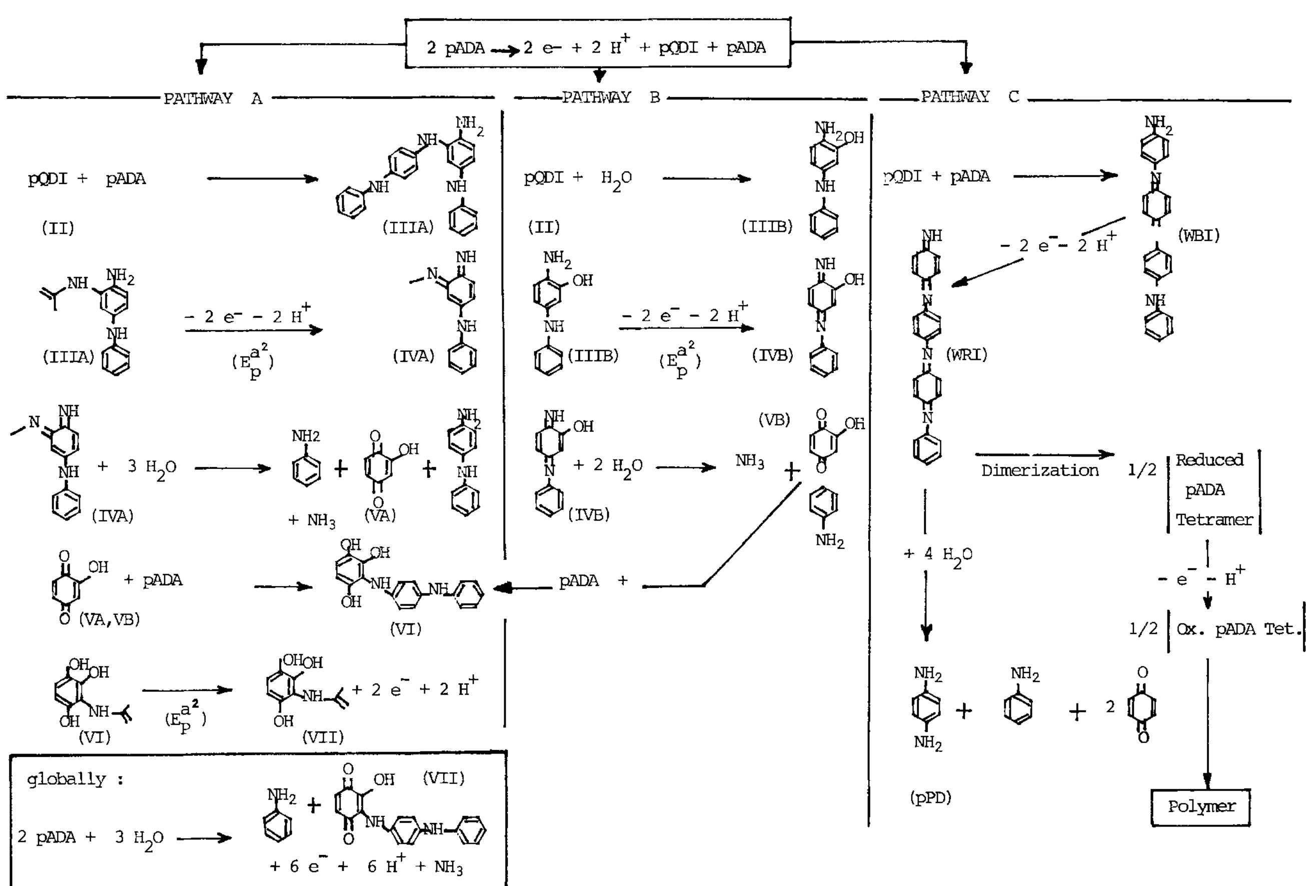
First redox couple.—Our results outline the relative chemical resistance of the first redox couple, as shown by the constancy of the i_p^{c1}/i_p^{a1} ratio, regardless of the number of consecutive cycles when they are strictly applied to the first oxidation peak. Upon step electrol-

ysis, the wave height i_p^{a1} is always proportional to the analytical amount of the depolarizer still remaining in the solution and the reverse half-cycle corresponds only to the reducible pQDI diffusing in the vicinity of the electrode. Thus, within the potential span ruling out the first redox couple, no material consuming irreversible conversion of significant importance can be electrochemically detected. This suggests that in turn the oxidized pQDI product, originated by the partial electrolysis and escaped in the bulk, is irreversibly involved in a follow-up reaction, yielding species that undergo a further oxidation at the i_p^{a2} potential.

Second redox couples i_p^{a2}.—The potential controlled electrolysis cannot be circumscribed about the first peak for i_p^{a1} is only separated by few tenths of a volt from i_p^{a2}. Therefore, the voltammetric features following the partial electrolysis of the solution at 0.8V actually integrate the reactions occurring at peak i_p^{a2} too. With respect to the magnitude of the peak heights, i_p^{a2} appears rather as a side-system if compared to the amplitudes of the major redox couples i_p^{a1} and i_p^{a3}. As indicated previously, the kinetic requires strong acid conditions and develops irreversibly for being solely detectable with scan rates slower than 0.05 V/sec. For these reasons, the voltammetric contribution of this system remains minor. In contrast, this system becomes preponderant in the electrolysis balance, *i.e.*, under long term conditions. In a similar manner, when the potential is multicycled over the span including i_p^{a2}, the cyclic voltammograms show an increase of peak i_p^{a2}. In the cathodic part, the global content of reducible material remains constant when the potential is switched beyond peak i_p^{a2}. This can be interpreted in the following manner: the reduction of the material produced in the i_p^{a2} steps occurs irreversibly at 0.51V (i_p^{c4}), close before the true reduction peak of the pQDI produced at the electrode surface at $E_p^{c1} = 0.48$V; as a result, the loss of reducible pQDI is gradually and fully compensated by the increase of new reducible species, the sum of the cathodic peaks remaining constant.

The occurrence of the peaks i_p^{a2} marks the existence of new species present at the electrode surface in an intermediate level of oxidation, obviously comprised between those of pADA and pQDI, since both are no longer oxidizable at this potential. This may suggest that the charged pQDI and pADA molecules, being actually present simultaneously at the electrode surface, interact to form an oxidizable adduct, in proportion of increasing i_p^{a2} values. Of interest in these experiments are the colors of the solutions. In the case of the dimethylaniline system (11), the solutions containing only the diimine form are green, whereas the solutions of the diimine plus the amine appeared pale blue. This observation has been attributed to addition compounds of the amine with oxidation products.

Inasmuch as an addition reaction is envisaged between the pQDI and the pADA species with the support of the aforementioned features, several mechanisms can be tentatively formulated to describe the fate of the adduct. Among those proposed in the literature so far, the following ones are retained for they integrate the coulometric results obtained in this study. The data reported in Fig. 4 indicate that two electrons per molecule are further transferred. These exchanges follow the precursor reaction producing pQDI and the chemical conversion of the latter. The mechanisms differ from each other in the nature of that irreversible reaction (scheme 5)



Pathway A: the addition of one pQDI onto one pADA molecule in the ortho position leads to a dimeric Bandrowski-type reduced base (IIIA).

Pathway B: the bulk hydrolysis of pQDI produces the o-hydroxy pADA form (IIIB).

In each case, the resulting product being easily oxidized would release electrons at the potential ascribed to i_p^{a2}.

Third anodic redox system.—In studying the acid hydrolysis of the Bandrowski bases, ammonia, aniline, and the original amine have been identified, aside from a quinoidal derivative, the structure of which is related to that of the starting amine (13c). The extension of that behavior to either possible pathway A or B would yield the same compound, the 2 hydroxy p-quinone (VA = VB), as depicted in scheme 5. The fit with the coulometric data implies that two depolarizer molecules react within the global kinetic sequence. Thereby, the typical 1,4 addition reaction can be postulated again involving the resulting p-quinone with aromatic amines, *i.e.*, the starting material. The products of these reactions are now substituted hydroxyquinones, which are also oxidizable below 0.8V, species VI.

The following arguments have supported the proposed mechanisms:

1. Since the 1,4 addition involves the nucleophilic nature of the attacking molecule, substitution reactions of nucleophilic groups by the hydroxyl moiety will not be assumed to occur, especially under mild electrolysis and *p*H conditions.

2. All the mechanisms, even those suggested elsewhere, result in the formation of aniline, in a ½ theoretical ratio with the pADA concentration. This leads us to discuss the nature of the third major redox peak i_p^{a3} detected at 1.0V. The oxidation of species existing in the solution, in initial thermodynamic equilibrium with the depolarizer, can be disregarded for in that case the redox couple would not be observable at all after the coulometric consummation of the first. Accordingly, the irreversible system i_p^{a3} must account for the oxidation of stable (the corresponding wave appears after the electrolysis and on the voltammogram traced at 0.01 V/sec with the same intensity) species issued from the first stages. The hypothesis that peak i_p^{a3} results from the oxidation of new species issued from irreversible conversions is supported by the following observation: the amplitude of peak i_p^{a3} is proportionally related to the peak height i_p^{a1} and only depends on the time gate (or on the scan rate); this holds for a given acidity level. There is no doubt that the position and the shape of peak i_p^{a3} match those of aniline in the same working conditions. This was shown on the cyclic voltammogram on mixing authentic samples. If this compound is supposed to form upon a proton-catalyzed decomposition of the adducts, it follows that the cathodic half-cycle initiated once the aniline oxidation has been achieved should integrate the behavior of both the oxidized aniline and the remaining pADA. Inspection of the data for the i_p^{c1}/i_p^{a1} ratio as a function of E_λ indicates an increase in the amount of reducible material at the electrode with increasing E_λ (Table I). This is due to an accumulation of reducible pQDI provoked by direct pADA oxidation at the working potential and indirectly after the head-to-tail coupling of the aniline oxidation products. Moreover, the peak i_p^{c3} also matches in position with that of oxidized benzidine, the alternate tail-to-tail coupling product of the aniline cation radicals (6). This is confirmed by the appearance of peak i_p^{c3} solely when the potential is reversed after the aniline oxidation peak (Fig. 2). On this basis, the estimation of the decomposition rate in aniline leads to the value $k_1 = 0.0027 \text{ sec}^{-1}$ in H_2SO_4 0.1*N* in agreement with values evaluated for model compounds (8). Thus, postulating the hydrolytic generation of aniline and quinones supports the fact that no significant decrease in magnitude affects peak i_p^{c4}, although i_p^{a3} reaches in optimal conditions up to 50% of peak i_p^{a1}. As a result it seems that the appearance of i_p^{a3} is neither determined by the charge status of the species [as observed in acidic acetonitrile solutions (20)], nor by the oxidation levels. The amplitude of peak i_p^{a3} reflects the full extent of the decomposition reaction in the solution or, with slow scan rates, at the electrode surface, instead; in the latter case, the measurement of the final aniline concentration level gives in any case a ½ estimate in good agreement with what might be expected from the pathways proposed. The conversion of i_p^{a3}/i_p^{a1} values in terms of concentrations was effectuated with the aid of aniline calibration curves.

3. pADA possesses a more pronounced nucleophilic character than aniline. Therefore, the chemical addition of pADA to the hypothetical quinone will always be preferred to that of aniline. This assumption is actually supported experimentally by the constancy of peak i_p^{a3} ascribed to the amount of aniline (not affected in that experiment) issued from the preceding decomposition reactions.

4. The addition of two pQDI molecules on the initial parent molecule instead of one as is figured in pathway A would disagree with the coulometric data.

5. In accordance with these data instead, three electrons are globally exchanged in pathways A and B, if the third irreversible stage is limited to the addition of one parent molecule onto the quinone (this may reasonably be envisaged with respect to the saturation of the quinone).

6. According to the hypothesis of a linear dimer formation involving the head-to-tail dimerization of pADA with pQDI, the net effect of the hydrolysis reaction would, after the oxidation of the products, generate p-phenylenediamine (pPD) (see pathway C in scheme 5). However, the multicycling of the potential does not show evidence for the superimposition of a new depolarizer system on the initial pADA system. On the other hand, the coupling reaction followed by oxidation would form another imine form able to couple again with the starting material. This was the basis of the proposed mechanism accounting for the formation of emeraldine (19). As a result, the number of exchanged electrons would probably be odd and not reproducible experimentally speaking, as might be expected from an oligomerization reaction producing insoluble products, which ought to depose on the electrode. We actually did not observe such an electrochemical behavior nor the occurrence of red color formation during the electrolysis experiment which would be due to WRI formation. The divergence in the experimental observations may account for the differences in the analytical concentrations used. This effect shall be determinant in the product distribution; low levels inhibiting the polymerization pathway. Therefore, the latter pathway C will not be preferred. In fact, insoluble green polymers have been observed in more concentrated depolarizer solutions.

The assignment of the pathways A and B for the possible mechanism would be fully supported by the identification of the substituted 2 hydroxy 3 pADA p-quinone. However, the voltammetric behavior in the cathodic part does not allow drawing unambiguous conclusions with respect to this point. Indeed, the cathodic behavior of quinones appears to be severely modified when the reduction is carried out in the presence of oxidized amines. For example, with mixtures of authentic aniline and p-quinone, the potential of the p-quinone reduction peak is shifted *ca.* 0.15V anodically when it is preceded by the oxidation of aniline. The apparent increase in the reversibility of the electrochemical transfer would be induced by the formation of amine radicals during the cathodic half-cycle. Therefore, quinones in mixture with oxidized amines cannot be voltammetrically identified on the simple basis of the matching of the peak potentials. This observation indicates that the electrochemical behavior of quinones and of quinoneimines exhibits some resemblance, especially in the presence of unoxidized amine, thus justifying *a posteriori* the viability of the quinone/amine and pQDI/amine coupling reaction.

However, an experimental indication evidencing these pathways is brought by the result of reverse electrolysis. The experiment was conducted discontinuously in two steps: first at 0.8V until three electrons have transferred, then back at 0.0V. The voltammograms indicated the gradual increase of an oxidation peak i_p^{a4} associated with the decrease of the reduction peak produced upon the three electron oxidation, i_p^{c4} (Fig. 4). The found balance of two additional electrons per pADA molecule is compatible with the reduction of the last reducible product remaining in the solution after the exhaustive electrolysis at 0.8V, the hypothetical 2 hydroxy 3 pADA p-quinone, according to the following reaction scheme

(VII) $\xrightarrow[(E_p^{c4})]{2e^-,\ 2H^+}$

$\longrightarrow H_2O\ +$

$\xrightarrow{2e^-,\ 2H^+}$ (VIII)

The first two-electron reduction would produce the 3 substituted 2 hydroxyhydroquinone, which in turn is known to undergo a second reduction step following the abstraction of one water molecule (7). At this time, the voltammogram indicates that the intermediate chemical reaction operates the removal of water rather than pADA as shown by the unaffected i_p^{a3} peak height, which would increase instead, in proportion to the reductive electrolysis. This illustrates again the nucleophilic character of the addition reaction, neutral pADA being a base much weaker than the hydroxyl anion.

Qualitatively, the effect of the reverse electrolysis is to denature the chemical nature of the initial reducer, pADA, since the final and unique reduction half-cycle only reflects the presence of one species, probably the 2 hydoxy 3 pADA p-quinone and the remaining aniline. In particular, peaks i_p^{a3} no longer appear on the resulting voltammograms (Fig. 6). Thus, the free pADA, abstracted from the solution through the electrolysis, ought to substitute one species, for example the quinoidal VII or VIII. As a result of the three-electron electrolysis conducted at 0.8V, the final redox couple ought to involve a substituted quinone/hydroquinone system, aside from aniline, and not an unsubstituted one, not compatible with the two-electron reoxidation data.

Visible spectroscopy experiments were performed during the step electrolysis to furnish some support for discriminating between the proposed mechanisms. Results showed that unsubstituted p-quinone samples absorb negligibly and that aniline does not absorb at all in the used conditions. However, the large increase affecting the broad band for pADA absorption (around 780 nm) following the first one-electron transfer and the residual maximum at the same position after the extensive three-electron electrolysis may testify for the strong resonating species IIIA and IVA and for the existence of the pADA radical substituting the quinone VII, respectively, rather than for the detection of species IIIB and IVB, of much less resonating ability. The development of the latter absorption band is clearly related to the blue coloration affecting partially electrolyzed pADA solutions. By analogy with studies concerned with model compounds (11), it may account for the formation of disproportionation products (IIIA or IVA), derived from the pQDI/pADA coupling. It must be emphasized that the reconstituted aniline and p-quinone mixtures are pale yellow, as also are the pADA solutions fully electrolyzed at 0.8V upon standing overnight; while the solutions freshly oxidized electrochemically are pale green. This shows, at least qualitatively, that the product distribution resulting from short-term experiments differs somewhat from that obtained with other duration conditions or with atmospheric oxygen as the oxidant. Another fact may account for pathway A. During the one-electron step electrolysis experiment, the position of the peak maximum i_p^{a2}, if projected onto the ordinates, remains constant whereas the global peak height increases. When it reaches its maximum value, i_p^{a2} is about half i_p^{a1} (Fig. 3). Inasmuch as peak amplitudes are correlated to concentrations, this observation might indicate, through the changes of the diffusion coefficients, the oligomeric structure of the diffusing species, *i.e.*, IIIA rather than IIIB. Unaffected two-electron peak amplitudes in the cathodic half-cycle would also corroborate the aforementioned assumptions.

Conclusion

The proposed mechanism A for the pADA first stages of oxidation has been distilled from the electroanalytical and spectroscopic data discussed in the preceding section. It must however be emphasized that mutual exclusion cannot be claimed in the proposed pathways. For example, free radical formation with sufficient lifetime should indeed be possible in the solution. As suggested by slow scan cyclic voltammetry and step coulometry experiments, the electrolysis at 0.8V appears to convert the pADA system into a mixture of aniline and of the proposed quinoidal derivative, via the hydrolysis of the intermediate species. Under the employed working conditions, any loss of the global redox content of the initial material has not been observed in the solution phase, indicating thus that the formation of insoluble (nonelectroactive) heavy molecular weight compounds would not be favored, at

least in the low concentration range and in the earlier stages of the oxidation. Thereby, the electroanalytical behavior of pADA appears to differ from that being described in more concentrated solutions (as in the preparative scale, for example), in which insoluble products result.

The two techniques employed do not support pathway A unequivocally. In particular, the coulometric data just furnish a global balance of the charges transferred, regardless of the structure of the species being formed. Thus, species VII, aside from aniline as the possible product, conveniently translates the redox content of the solution under a unique and concise form, although several other tautomeric forms can be formulated.

This depicted mechanism lacks from more convincing evidence as might be provided by direct product identification. However, the complexity of the system, with the involvement of the original species and the difficulty of characterizing products in the 0.1 mmol concentration range, prevents the somewhat speculative arguments presented in the discussion. From this point of view, however, it is typical to notice that the aforegoing attempts described in the literature failed to isolate the possible intermediates and even to detect them in the electrolyzed solutions. The results presented in this work yet give an indicative new insight in the nature of the hydrolytic sequence.

Spectroelectrochemistry of N-Retinylidene-n-butylamine

Kenneth J. Stutts, Linda A. Powell, and R. Mark Wightman

Department of Chemistry, Indiana University, Bloomington, Indiana 47405

ABSTRACT

The electroreduction of N-retinylidene-n-butylamine (NRBA) has been examined in acetonitrile and dimethylformamide solvents with tetra-n-butylammonium perchlorate as the supporting electrolyte. In dimethylformamide with small amounts of water and in acetonitrile, NRBA is reduced in a two-electron process to form the enamine of 5,6-dihydro-NRBA. In dimethylformamide dried with alumina, the radical anion ($\lambda_{max} = 615$ nm) and dianion ($\lambda_{max} = 550$ nm) of NRBA can be observed in an optically transparent thin layer electrochemical cell. The protonated form of NRBA is reduced in acetonitrile at a potential 1080 mV positive of NRBA in a one-electron process. Radical intermediates have not been spectrally observed in this reduction, since the electrogenerated products dimerize rapidly.

N-retinylidene-n-butylamine (NRBA) has been widely employed as a model for the chromophore of rhodopsin (1-11). In the protein, the aldehyde of vitamin A is thought to form a protonated Schiff's base linkage with lysine (12, 13) and is responsible for the first stage of the visual transduction process. The initial photochemical excitation of rhodopsin has been extensively studied and several theories including photoreduction (2, 7, 14-20) have been considered to explain the observed spectroscopic changes. However, the reductive electrochemistry of NRBA has not been previously reported although an ESR active species has been observed following uncontrolled potential electrolysis (2).

Electrochemical studies of retinal, the aldehyde of vitamin A, have been numerous (20-23). Recently, we showed that an optically transparent thin layer electrochemical cell is an ideal tool for examining the spectra of the reduction intermediates of retinal and for determining the reaction pathways of the retinal radical anion (23). In this paper we report a spectroelectrochemical study of the reduction intermediates and products of NRBA in its neutral and protonated form.

Key words: vision, aprotic solvents, radicals.

Experimental

Chemicals.—All-trans retinal (Eastman) was used as received and was stored in the dark in a desiccator under nitrogen at 5°C. N-butylamine (Matheson Coleman and Bell) was distilled immediately prior to use. Acetonitrile (Burdick and Jackson) was dried over 4Å molecular sieves (Fisher) beneath a nitrogen atmosphere. N,N-dimethylformamide (DMF, Matheson Coleman and Bell) was vacuum distilled onto 4Å molecular sieves. Subsequent drying was accomplished by passing this solvent through a column containing neutral aluminum oxide (Woelm, activity grade 1) which had been dried at 450°C for at least 10 hr (24, 25). Tetra-n-butylammonium perchlorate (TBAP, G. F. Smith) and tetraethylammonium perchlorate (TEAP, G. F. Smith) were dried at 60°C in a vacuum oven for several hours. Rhodamine 6G (Matheson Coleman and Bell) and anthraquinone (Eastman) were recrystallized from ethanol. Perchloric acid (70%, Mallinckrodt) and acetic acid (Mallinckrodt) were used as received, and stock solutions of the acids were prepared in the appropriate solvents. The perchloric acid stock solution was standardized *vs.* 0.2*N* sodium hydroxide (Certified, Fisher). Phenol (Liquified, Fisher) was vacuum pumped to dryness and then fractionally distilled. (The liquified form was utilized as it contains no H_3PO_2 preservative.) A stock solution in acetonitrile was then made by the appropriate dilution and stored over 4Å molecular sieves at 5°C in darkness. Diethyl malonate (DEM, Fisher) was distilled prior to use. Deoxygenation of all solutions was accomplished with a nitrogen or argon purge.

Synthesis.—All-trans-NRBA was synthesized by a method similar to that of Nakanishi *et al.* (26). Approximately 0.5g of retinal was dissolved in 20 ml n-butylamine (containing 4Å molecular sieves) which had been cooled to −41°C in an acetonitrile slush bath. The reaction was allowed to proceed for approximately 2 hr after which the mixture was filtered and the excess n-butylamine removed via vacuum. The pale yellow crystals were three times dissolved in hexane and pumped to dryness. The product absorbed at 358 nm in acetonitrile (364 nm in ethanol) with a molar absorptivity of 57,600 ± 1,200 liter $mol^{-1}cm^{-1}$. The melting point of 61°C was slightly lower than that previously reported for NRBA (3). IR, NMR, and mass spectra of the product were consistent with the structure of NRBA. Due to the extreme sensitivity of this and similar compounds to CO_2 (1), O_2 (27), light, and H_2O (11, 28b) the above synthesis was carried out in a glove bag containing N_2 in semi-darkness. NRBA was stored under N_2 in the dark at −20°C.

Polarography and cyclic voltammetry.—Polarography was carried out with a polarographic analyzer (Model 174A, Princeton Applied Research Corporation) using a drop timer. A locally constructed three-electrode potentiostat and a Universal Programmer (Model 175, Princeton Applied Research Corporation) were utilized in conjunction with either a hanging mercury drop electrode (HMDE, Metrohm) (geometric area = 0.0136 cm^2) or a gold-disk electrode (geometric area = 0.0208 cm^2) for cyclic voltammetric experiments. The gold-disk electrode was fabricated by polishing the end of a flush-cut, 14-gauge gold wire with emery cloth and then with 5.0, 0.3, and 0.05 micron polishing aluminas (Buehler) in succession. Heat shrinkable Teflon (Small Parts, Incorporated, Miami, Florida) encased the wire and extended approximately 1 mm past the end of the disk to decrease convective effects. Convection was further minimized by supporting the electrochemical cell on a platform suspended from rubber tubing.

The electrochemical cell (~20 ml in volume) contained a coiled Pt wire auxiliary electrode concentric to the working electrode. A ground-glass joint was sealed to the top of the cell to accommodate the HMDE or the gold-wire electrode. An aqueous SCE reference electrode (saturated with NaCl rather than KCl) probed through a Luggin capillary and all potentials herein are reported *vs.* this electrode. The SCE was immersed in solution separated from the working electrode compartment by a fine frit to minimize water contamination.

Acetonitrile and DMF solutions were 0.1M or 0.5M in supporting electrolyte. *IR* compensation was used to decrease the effects of ohmic drop in the cell. During detailed studies of E_p as a function of sweep rate further correction for *i-R* effects was made using anthraquinone as a standard reversible compound (29, 30). A 30 sec pre-electrolysis at the base of the electrochemical wave was performed while bubbling the solution with N_2 to minimize adsorptive effects.

Large-scale electrolysis.—Large-scale electrolyses employed a mercury pool cathode (area ~3 cm^2) polarized at a potential 300 mV negative of the half-wave potential using the polarographic analyzer as the potentiostat. An SCE reference electrode was separated from the solution by a fine frit and the Pt auxiliary was isolated in similar fashion. Magnetic stirring and bubbling with N_2 accompanied the electrolysis. Polarographic monitoring of the electrolysis was performed at a DME in quiescent solution under N_2.

Approximately 35 ml of acetonitrile containing 0.1M TBAP was pre-electrolyzed at the potential at which the NRBA electrolysis was to be performed. DEM (100-500 μmol) was added before pre-electrolysis when a moderately weak proton donor was desired. Typically 50 μmol NRBA would then be added to the solution and electrolyzed.

Thin layer spectroelectrochemistry.—Two of the optically transparent thin layer electrochemical cells (OTTLE's) employed were of similar design to that described previously (23). One of the OTTLE's was 0.0109 cm thick with an electroactive volume of 3.34 μl and the other possessed corresponding dimensions of 0.00475 cm and 2.52 μl. A third OTTLE was modified especially for application at low temperatures. The sandwiched quartz plates forming the walls of the thin layer cavity were milled out with a diamond-tipped bit so that a cavity 0.25 cm wide extended to within 0.05 cm of the nearest edge of the gold foil. This modification of the previous design improves current distribution to the working electrode; however potential gradients across the working electrode are still apparent with the 0.5M TBAP/DMF solvent system employed in this work. A ground-glass top with inlet and outlet ports for argon bubbling was incorporated in the auxiliary compartment of the OTTLE. The cell was immersed in an acetonitrile-slush bath (−41°C) which was contained in a T-shaped, insulated, copper shell designed to fit into a Cary 14 spectrophotometer. Onto this shell were attached two quartz windows allowing spectral observation through the narrow (approximately 1 in.) arm of the acetonitrile bath encompassing the minigrid portion of the OTTLE. No serious absorptive, dispersive, or reflective problems occurred with this mode of observation. Frosting of the outer quartz windows was prevented with a gaseous nitrogen jet. The optical pathlength of this OTTLE was 0.00493 cm and its electroactive volume 1.95 μl.

Pathlengths of all OTTLE's were determined by the ratio of the absorption of solutions of rhodamine 6G in the OTTLE to that in a 1 cm cell. The one-electron reduction of a known concentration of anthraquinone to the radical anion was used to determine the electroactive volume of the cells. Other experimental procedures are as previously described (23).

Results

Polarography and cyclic voltammetry.—The polarography of NRBA at a DME in acetonitrile containing 0.1M TBAP exhibits a reduction wave at −1.68V. The height of the diffusion-limited current is 1.81 ± 0.19 times that of the first wave of retinal, a known one-electron reduction (21, 23). A second wave of variable

height is seen at −2.6V, near the breakdown of supporting electrolyte. Addition of a 1:1 stoichiometry of $HClO_4$ results in a new polarographic wave at −0.60V which is one-half the height of the wave produced by NRBA alone. A second wave (of equal height to the first) and a third wave (of variable height) are observed at potentials equal to the first and second half-wave potentials of unprotonated NRBA. A change in the absorption maximum from 358 to 445 nm (ϵ = 43,200 ± 3,600 liter $mol^{-1}cm^{-1}$) through an isosbestic point evidences the protonation of NRBA upon the addition of $HClO_4$. Addition of a 2:1M excess of $HClO_4$ reveals the sustained existence of the monoprotonated species although other workers (8) have noted the decomposition of NRBA upon addition of excess acid.

Cyclic voltammetry of NRBA at an HMDE at 0.1 $Vsec^{-1}$ in acetonitrile solution containing 0.5M TBAP also reveals two reduction waves (1 and 2, Fig. 1). An oxidation wave at −0.95V (wave 3) is observed following scan reversal after the first wave. This wave is associated with a small reductive wave ($E_p = -1.01V$) which is only apparent during the second scan (not shown). At 1.00 $Vsec^{-1}$ a new oxidation wave appears with a peak potential approximately 100 mV positive of that for the primary reduction (wave 1). The ratio of i_{pa}/i_{pc} for this couple increases at higher sweep rates while the relative size of the oxidation wave at −0.95V decreases. Addition of small amounts of water to the solution causes only minor changes in the observed electrochemistry—the reduction wave moves to slightly more positive potentials (*vide infra*) and the two oxidation waves diminish in height. In the presence of weak acids (water or DEM) a small prewave (<5% of the diffusion-limited current of NRBA) at approximately −1.4V is occasionally observed and is believed to be retinal formed by hydrolysis. Spectral evidence for hydrolysis was noted only at high (1000-fold molar excess) concentrations of water or DEM.

The reduction potential for 1:1 $HClO_4$ protonated Schiff's base under the above solution conditions and scan rate (0.1 $Vsec^{-1}$) is −0.60V (wave 4, Fig. 1). At 50 $Vsec^{-1}$ a very slight oxidation wave was noticed approximately 90 mV positive of the peak reduction potential. At 500 $Vsec^{-1}$ a significant oxidation wave was observed for the reduction product although the waves were badly skewed. Two additional irreversible reduction waves (not shown) are located at potentials equivalent to those of the first and second waves of NRBA, respectively. The first of these is equal in height to wave 4 (Fig. 1) while the second is approximately 2.8 times this height (indicating twice the number of electrons transferred).

Greater than stoichiometric amounts of phenol or acetic acid are required to completely protonate the Schiff's base. Spectral titration curves for NRBA in acetonitrile containing 0.1M TEAP with phenol or acetic acid are best interpreted by assuming that the titration product is a complex of NRBA and the acid rather than assuming proton transfer. For phenol the association constant with NRBA is 0.27 ± 0.05M^{-1}, and for acetic acid it is 16.8 ± 2.5M^{-1}. Reduction of NRBA in the presence of a tenfold molar excess of acetic acid or phenol results in a larger reduction current for protonated NRBA than expected from equilibrium considerations; apparently the greatly enhanced current results from the formation of additional protonated NRBA prior to reduction (a classical CE reaction). Protonation with large excesses of acetic acid or phenol results in cyclic voltammograms similar to those of NRBA protonated with $HClO_4$, but the background current obscures the second and third reduction waves.

In DMF containing 100 mM water and 0.1M TBAP, cyclic voltammetry at an HMDE at 0.1 $Vsec^{-1}$ gives qualitatively identical results to those observed in acetonitrile. The two-electron reduction wave corresponding to wave 1, Fig. 1, has a peak potential of −1.55V in DMF and the only oxidation wave observed corresponds to wave 3, Fig. 1. However, in dry DMF with 0.1M TBAP the two-electron cyclic voltammetric wave separates into two distinct waves both with gold (Fig. 2) and mercury electrodes. Scan reversal after the first wave ($E_p = -1.79V$) results in a spike-shaped oxidation wave at mercury electrodes. This oxidation wave ($E_p = -1.69V$) is well defined at gold electrodes, and the peak current ratio for this couple approaches unity (i_{pa}/i_{pc} = 0.8) at 0.1 $Vsec^{-1}$. The normalized current for the first wave increases as the scan rate is decreased with a concurrent diminution in the second wave. The apparent peak potential difference for these two waves also decreases with decreasing scan rate in dry DMF. A slight oxidation wave coupled with the second reduction wave is observed at 50 $Vsec^{-1}$ at a gold electrode. At slow scan rates, reduction past the second wave results in an increase in oxidation current at −1.06V.

The shift in the observed peak potential as a function of various parameters was investigated in an effort to elucidate viable reaction pathways. For NRBA in acetonitrile with 0.5M TBAP the observed $\delta E_p/\delta \log V$ is −19 mV/decade. A positive slope of 99 mV/decade is obtained for $\delta E_p/\delta \log [H_2O]$. In DMF with 0.5M TBAP and added water the corresponding values were −21 mV/decade and 58 mV/decade. A 0.1 $Vsec^{-1}$ scan rate was used in the water addition studies.

These cyclic voltammetric results are consistent with the following schemes for the initial reduction process of NRBA. In acetonitrile or moist DMF the first reduc-

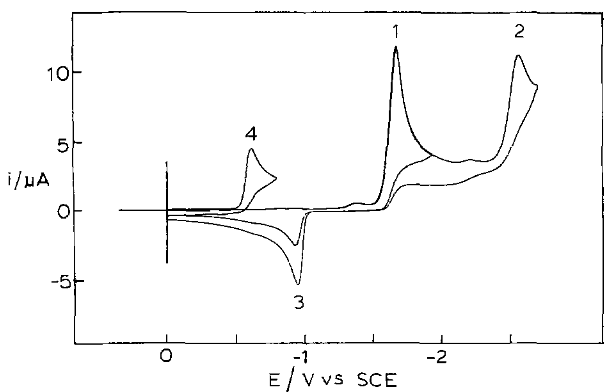

Fig. 1. Cyclic voltammograms of 2.18 mM NRBA in acetonitrile containing 0.1M TBAP at a hanging mercury drop electrode (wave 1, 2, and 3). Wave 4 is a cyclic of the same solution to which a 1:1 stoichiometry of $HClO_4$:NRBA has been added. The scan rate is 0.1 $Vsec^{-1}$.

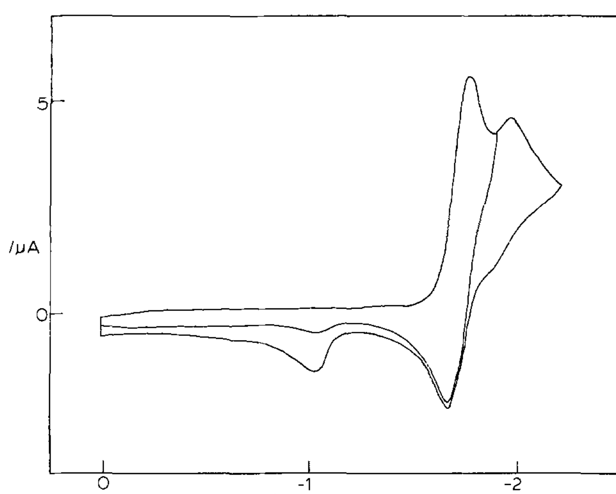

Fig. 2. Cyclic voltammogram of 1.66 mM NRBA in dry DMF containing 0.1M TBAP at a gold-disk electrode. The scan rate is 0.05 $Vsec^{-1}$.

tion wave generates a two-electron reduction product. The dependence of the peak potential on sweep rate indicates that either of two reduction-protonation mechanisms involving the radical anion (R^-) and a proton donor (HA) may be apparent following the initial electron transfer (28a and b)

$$2\dot{R}^- \xrightarrow{k} R + R^{-2}$$

$$R^{-2} + HA \rightarrow RH^- + A^-$$

[I]

or

$$\dot{R}^- + HA \rightarrow RH^{\cdot} + A^-$$

$$RH^{\cdot} + \dot{R}^- \xrightarrow{k} RH^- + R$$

[II]

where k indicates the rate-determining step and RH^- is the assumed product (*vide infra*). The dependence of the peak potential on water concentration indicates the importance of solvation (in the case of scheme [I]) or protonation (in the case of scheme [II]) on the overall rate of formation of the two-electron product. The appearance of two distinct waves in dry DMF, both of which are reversible at sufficiently high sweep rates, confirms that the radical anion is an intermediate in the reaction. The formation of dianion from radical anion is presumably the electrochemical process occurring during the second reduction as will be shown. However, the dependence of the cyclic voltammetric peak height (first reduction wave, Fig. 2) and potential on scan rate demonstrate that, even under dry conditions, subsequent reactions are occurring. To determine the products and mechanism of this reduction, we have employed large scale electrolysis and thin layer spectroelectrochemistry. We have also examined the reduction of the protonated Schiff's base with these techniques; however, as is apparent from the cyclic voltammetry, its reduction intermediates are far less stable.

Large scale electrolysis.—Large scale electrolysis of NRBA at a mercury pool electrode in acetonitrile solutions with 0.1M TBAP as supporting electrolyte consumes 1.97 ± 0.08 electrons/molecule. In polarograms of the reduced solutions, the reduction wave at −2.6V is still present. Following two-electron electrolysis with DEM, a well-defined polarographic wave is observed for the oxidation of diethyl malonate anion at −0.36V. The height of this polarographic wave and titration with standard $HClO_4$ indicate that 1.93 ± 0.11 diethyl malonate anions are formed per NRBA molecule reduced. Attempts to isolate the product for further characterization have not been successful. The product rapidly decomposes when removed from the electrolysis cell to a mixture of products as determined by u.v.-visible spectroscopy and subsequent polarography. Notable, however, is that the products obtained from the reduction of NRBA in the presence or absence of DEM have absorption bands at 350 and 328 nm in the visible region while the main absorption occurs at wavelengths less than 300 nm.

Thin layer spectroelectrochemistry.—Reduction of NRBA (0.5M TBAP/acetonitrile) at −2.00V in an OTTLE produces an n-value of approximately 1.6. The low result arises because of inadequate potential control in an OTTLE (23). The slow electrode-solution polarization leads to a condition where the homogeneous coupling rate exceeds the rate of heterogeneous reduction to dianion. During electrolysis at this potential the 358 nm absorption band for NRBA decreases and the predominant product of the electrolysis absorbs at 352 nm (Fig. 3). Spectra taken during the electrolysis (dashed line) indicate the presence of an intermediate ($\lambda_{max} \approx 500$ nm) which decays with an increase of the final product. The product which absorbs at 352 nm is also formed via reduction in the presence of diethyl malonate with a concurrent increase in the strong absorbance (255 nm) of the anion of DEM.

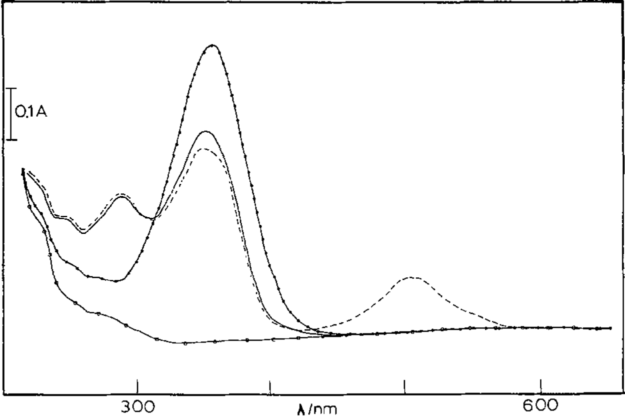

Fig. 3. Spectra of the reduction of 2.05 mM NRBA at −2.0V in acetonitrile containing 0.5M TBAP in an OTTLE. ●—●—●—● Prior to electrolysis; ------ during electrolysis (scan started at 650 nm concurrent with onset of reduction); ——— immediately following electrolysis (scan started at 650 nm approximately 250 sec after onset of reduction); ○—○—○ blank (0.5M TBAP/acetonitrile). Spectral scan rate was 2.5 nm sec^{-1}.

In dry DMF (0.5M TBAP) only one reduction wave ($E_p = -1.80V$) is observed for the reduction of NRBA at the 0.005 $Vsec^{-1}$ scan rate employed with the OTTLE. We attribute this to the decreased potential resolution of the OTTLE, as well as the chemical reactions outlined in schemes [I] and [II]. The reduction corresponds to 1.5-1.8 electrons/molecule of NRBA. (The low n-value can be explained as above.) There is no electrochemical evidence for stable reduction intermediates under these conditions. Electrolysis results in a relatively stable product absorbing at 498 nm with an absorbance 1.16 ± 0.08 times that of NRBA (Fig. 4). This species disappears slowly (minutes) with a simultaneous increase in the 350 nm region either with the applied potential 300 mV past the peak potential for the reduction of NRBA, or when the working electrode is disconnected, indicating a purely chemical decay mechanism. The 498 nm absorption band decays rapidly following a step positive of the −1.0V oxidation wave and the oxidation product absorbs at approximately 290 nm. The charge on oxidation is 0.48 ± 0.07 times that obtained during reduction.

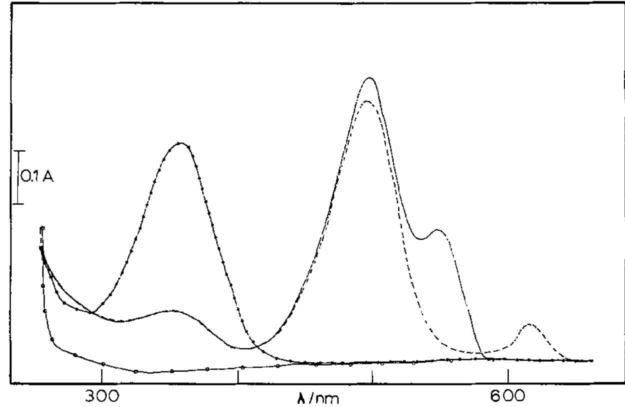

Fig. 4. Spectra of the reduction of 1.53 mM NRBA at −2.0V in dry DMF containing 0.5M TBAP in an OTTLE. ●—●—●—● Prior to electrolysis; ——— during electrolysis (scan started at 600 nm concurrent with onset of reduction); ------ during electrolysis (scan started at 650 nm concurrent with onset of reduction); ○—○—○ blank (0.5M TBAP/DMF). Spectral scan rate was 2.5 nm sec^{-1}.

Two transient absorption bands (615 and 550 nm) were first noted when wavelength scanning began at the same time as the potential step (dashed and solid lines, Fig. 4). By utilizing the temperature controlled OTTLE described in the experimental section and monitoring individual wavelengths during the potential step, absorbance *vs.* time curves such as those shown in Fig. 5 were obtained. During a reductive potential step at ambient temperature (~25°C) neither the rate of growth nor the rate of decay of the 550 nm band is significantly different from the corresponding rates of the 615 nm band when the 0.9 sec/full-scale time constant of the Cary 14 is considered (traces C and D, Fig. 5, upper half). However, when the working electrode is disconnected after production of these intermediates, it is found that the 550 nm moiety is less stable and the 615 nm species more stable than when the potential is left on.

At −41°C (traces C and D, Fig. 5, lower half), the 550 nm species rate of growth is 1.45 times slower than that of the 615 nm species and the absorbance at 550 nm is greatly increased with respect to that at 615 nm. The increase in absorbance at 498 nm (trace A) correlates in time with the decay of the 550 nm transient and follows first-order kinetics. The half-life of the 550 nm transient is 1.75 times longer than that of the 615 nm species with the potential on. Disconnecting the working electrode after production of these species at −41°C again decreases the half-life of the 550 nm intermediate and increases that of the 615 nm intermediate. A potential dependence is also noted when the voltage is stepped further negative. Under these conditions, the 550 nm species has a longer half-life and greater amounts are produced. The 615 nm intermediate's half-life decreases only slightly with increasing overpotential with no noticeable changes in the amount formed.

Thin layer reduction of 1:1 $HClO_4$ protonated Schiff's base (0.5M TBAP/acetonitrile) consumes 0.91 electrons/molecule following a potential step over the first irreversible wave. The initial absorbance at 445 nm decreases rapidly with a concomitant increase in the absorbance in the 270 nm region. No intermediates are apparent even at low temperatures. A potential step over both waves yields significantly less 270 nm absorbance with the main absorption band occurring at 352 nm.

Discussion of Results

Reduction products.—Both polarographic and coulometric results indicate that NRBA is reduced with two electrons in CH_3CN containing 0.5M TBAP as is typical of imines (28b). Large-scale electrolysis and thin layer spectroelectrochemical results where DEM is present demonstrate that two protons per NRBA molecule are consumed in the reduction. From these results we denote the final product RH_2. The fact that we have not been able to isolate RH_2 is not surprising—the instability of the reduced forms of NRBA as well as the molecule itself is well documented (1, 11, 27, 28b, 31). However, the spectra of several of these reduced forms have been reported (4, 31-34) and those pertinent to this work are summarized in Fig. 6. Of the previously reported compounds, our spectral data best agree with the reduction of the 5,6-double bond (structure B). In all-trans-NRBA the ring is out of the plane of the remainder of the conjugated system (4, 35) and thus its contribution to the absorbance maximum location is minimized. However, if 5,6-dihydro-NRBA was the product, remaining an imine, we would expect it to be reduced at approximately −2.0V. Instead the observed product is reduced at much more negative potentials (−2.6V). The most likely candidate for RH_2 is the enamine of 5,6-dihydro-NRBA (structure C). While HMO calculations of the π-electron density predict that the first electron should reduce either the 13-14 double bond or the imine bond (8), apparently the electron

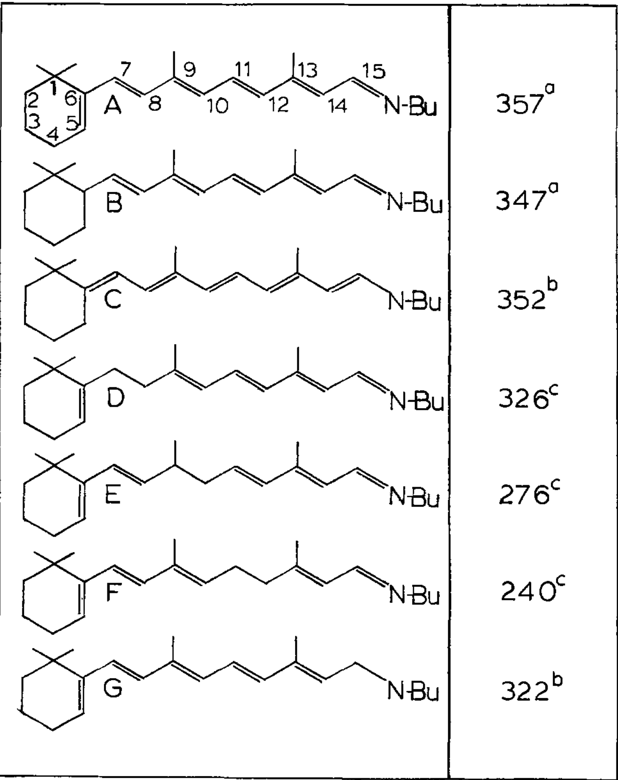

Fig. 6. Absorption maxima of various dihydroretinals and the corresponding n-butyl Schiff's bases obtained from: (a) Ref (4); (b) Ref. (32); (c) Ref. (33). Spectra were recorded in methanol or ethanol with the exception of C which was obtained in acetonitrile. Although maxima are tabulated for various geometric isomers (trans, 11 cis, and 9 cis) the differences in λ_{max} between these have been shown to be small (34) with respect to those between different dihydroretinals.

density of the radical anion (or protonated radical anion) formed electrochemically favors the second electron reduction in the ring under our solution conditions.

The one-electron reduction of the protonated Schiff's base leads to a mixture of dimeric products as observed spectroscopically. The expected shift in the reduction product distribution from the dimeric form to the direduced form (29) is found upon reduction past the second wave.

Reduction intermediates.—The spectroelectrochemical observation of a 500 nm transient during the reduction of NRBA in CH_3CN which chemically decays to produce the final product, RH_2, indicates that this intermediate is RH^-. The enhanced stabilization of the anion in DMF reflects that water is a much poorer proton donor in this medium (28b) and that DMF is a weaker acid than acetonitrile. The observation of decreased anodic current for the oxidation of this species and the decreased absorbance at 500 nm in the presence of the weak acid DEM or H_2O and at higher scan rates is further confirmation of this hypothesis. The one-electron oxidation of RH^- leads to an increase in absorbance at 270 nm and implies that a dimerization of the electrogenerated free radical species ($RH^\cdot$) occurs. This species has not been observed spectrally though there is some electrochemical evidence for its existence: Sweep reversal after oxidation of RH^- produces a small reduction wave separated 60 mV from the anodic counterpart at scan rates as slow at 0.1 $Vsec^{-1}$ in acetonitrile.

The 615 nm transient seen for NRBA reduction in DMF is the initial reduction product as shown by absorbance *vs.* time studies. Since a reversible couple is observed in cyclic voltammetry under these conditions we assign this intermediate as the radical anion ($\dot{R}^-$). The increased half-life at −41°C is in agreement with the measurements of Lang *et al.* (2) who have observed an ESR signal for this species in tetrahydrofuran. Since only one two-electron wave is present in the OTTLE, the observation of $\dot{R}^-$ is fortuitous; it can undergo protonation and homogeneous electron transfer (disproportionation) as well as obtaining a second electron from the gold-minigrid. The radical anion can be observed as a transient because of the imperfect characteristics of the OTTLE. Both the finite thickness, allowing R^- to diffuse away from the electrode before being reduced, and the nonuniform potential-gradient across the face of the OTTLE contribute to this anomaly. The increased half-life of this transient when the working electrode is disconnected is most plausibly explained by the elimination of one of the "decay" mechanisms, specifically that of heterogeneous electron transfer from the electrode.

The 550 nm moiety observed in dry DMF is tentatively assigned to the dianion of NRBA rather than the protonated radical anion. Although one would predict R^{-2} to be very unstable with respect to protonation (only in very fast cyclic voltammetry experiments have we evidence for an oxidation wave for this species) there are several facts which lead to this designation. The decay of the 550 nm intermediate coincides with the growth of RH^- which could be true for both R^{-2} and $RH^\cdot$. However, the half-lives of the 615 and 550 nm species are distinctly different and therefore obviate the possibility of scheme [II]. The first-order decay of the 550 nm species at low temperatures is indicative of the protonation of the dianion. The transient is longer lived at more reducing potentials, which is in agreement with the assignment of dianion since $RH^\cdot$ should be easily reduced. The dianion appears to be more stable with the working electrode at reducing potentials than when disconnected because in the former case its consumption by protonation is accompanied by its formation at the electrode. Furthermore, this species exhibits no ESR signal (2). All of this evidence supports scheme [I] as the primary reductive pathway for NRBA. (For dry conditions the rate-determining step is the protonation of dianion.)

Table I. Spectroelectrochemical comparison of results for retinal, NRBA, and protonated-NRBA (p-NRBA). p-NRBA results are in 0.5M TBAP/ acetonitrile. All other results are in 0.5M TBAP/DMF. $E_{1/2}$ values for RH^- are for oxidation.

	Retinal		NRBA		p-NRBA

RH_2	—	—	—	352	—	352

Comparison of the spectroelectrochemistry of retinal and NRBA.—Our results demonstrate that the protonated form of NRBA is much more easily reduced than retinal or NRBA. In fact, protonated NRBA is reduced at a potential similar to that of quinones, compounds known to be involved in biological redox processes. Therefore, protonated NRBA is a better model for the visual chromophore than retinal or NRBA when theories concerning photoinduced reduction are considered. However, we have not been able to determine the spectrum of the key intermediate for the photoreduction-visual transduction theory—the protonated radical anion.

The spectroelectrochemical data obtained during the reduction of NRBA are compared to results from retinal in Table I. The two-electron reduction product of retinal has only been observed as the anion, while RH^- for NRBA is more readily protonated to form the neutral RH_2. However, for both retinal and NRBA, the two-electron reduction product in acetonitrile/TBAP solutions is not the corresponding alcohol or amine. Electrolysis in the presence of weak proton donors results in dimer formation in the case of retinal, and a two-electron reduction for NRBA. While this presumably reflects differences in the equilibrium constants for disproportionation of these two compounds, a measurement of these constants is not possible since the dianion of both of these compounds is a very strong base and exhibits a short lifetime. For retinal reduction, we have demonstrated that the addition of weak oxygen acids results in a solvated or hydrogen bonded radical anion which subsequently dimerizes (36). Here, we have demonstrated that the oxygen acid, water, promotes disproportionation of the radical anion of NRBA through a solvated (rather than protonated) intermediate since the dianion is a distinct intermediate under conditions of very low water concentration. The dimeric products found after electroreduction of NRBA in the presence of strong proton donors exhibit u.v. spectroscopic features that are similar to those found following dimerization of retinal induced by oxygen acids. Since the reduction of protonated Schiff's base results in a neutral radical which dimerizes very quickly, disproportionation is disfavored. These results support the proposal of Savéant (28b)—the general features of imine reduction in aprotic solvents parallel those of carbonyl compounds.

ABSTRACT

The electrooxidation of sulfur in molten $AlCl_3$-NaCl (63-37 mole percent) has been investigated by means of u.v.-visible and electron spin resonance spectroelectrochemistry in the temperature range 132°-250°C. The electrode reaction sequence for the oxidation of S_8 to SCl_3^+ that was proposed previously based solely on electrochemical results has been modified to include several other intermediates, such as S_{19}^{2+}, S_5^+, S_4^{2+}, and S(II).

Tetravalent sulfur is a promising positive electrode in a secondary molten salt battery using chloroaluminates (mixtures of $AlCl_3$ and alkali halides) as solvents (1-3). The electrochemistry of sulfur in $AlCl_3$-NaCl melts has been studied by this group (4-7) as well as by others (8). In acidic [>50 mol percent (m/o) $AlCl_3$] chloroaluminate melts, it has been shown (7) that elemental sulfur can be electrochemically oxidized in three steps. Coulometric (7) and spectroelectrochemical (9) studies indicate that at least two species are formed during the first oxidation step, and a preliminary mechanism involving the formation of S_{16}^{2+} and S_8^{2+} was proposed (7, 9). The second and third oxidation steps yield S(I) and S(IV), respectively, as products.

Fehrmann *et al.* (10) and Bjerrum (11) have performed constant current oxidation of sulfur in $AlCl_3$-NaCl (63-37 m/o), followed by spectral measurements. A number of absorption bands due to oxidized sulfur species were observed in the 200-2000 nm spectral region. Evidence for the existence of S_{16}^{2+}, S_8^{2+}, S_4^{2+}, S(II), and S(IV) at various stages of the electrolysis was presented by these authors.

Preliminary ESR experiments with melts containing either chemically or electrochemically oxidized sulfur (12) indicated that free radicals are present both in the molten and frozen solutions. Sulfur radical cations

Key words: electrooxidation, spectroelectrochemistry, oxidation.

have previously been studied in several inorganic media (13-15), but the presence of such species in molten chloroaluminates has not been reported.

In order to obtain a better understanding of the nature of these sulfur species and the reactions by which they are formed, we chose to employ the technique of spectroelectrochemistry using an optically transparent electrode (OTE). This technique has been successfully coupled to several spectroscopic techniques in both aqueous and nonaqueous solvents (16). We have recently reported the use of OTE's in molten chloroaluminates (9). In this paper, an extensive study of sulfur spectroelectrochemistry in $AlCl_3$-NaCl (63-37 m/o) is reported for the temperature range 132°-250°C.

Experimental

The melt preparation and related experimental procedures have been published (17, 18). Elemental sulfur (Alfa Inorganics, t5N5 grade) was used without further purification. Sulfur monochloride (Pfaltz and Bauer, Incorporated) was purified by repeated vacuum distillations in the presence of sulfur and activated charcoal (19). Sulfur dichloride (Pfaltz and Bauer, Incorporated) was purified by repeated vacuum distillations in the presence of PCl_5 (20). The purities of the distilled SCl_2 and S_2Cl_2 were checked by Raman spectroscopy. SCl_2 or S_2Cl_2 was added to the spectroscopic cell by vacuum distillation. SCl_3AlCl_4 was prepared as previously described (21).

U.V.-visible absorption spectroelectrochemical experiments were carried out at Oak Ridge National Laboratory with a Tektronix Model J20 silicon-based vidicon rapid-scanning spectrometer interfaced to a PDP-8/I computer. The noise level for these measurements is in the range 0.003-0.005 absorbance units. The accuracy of the wavelength axis is ± 4 nm. Details of the spectrometer operation and the computer interface have been published (22). An ORNL Model Q-2943B controlled-potential and controlled-current cyclic voltammeter (23) was also interfaced to the system enabling electrochemical experiments to be synchronized with the acquisition of spectral data. A xenon arc lamp or a deuterium lamp served as u.v. light sources, and a tungsten lamp was used for the visible region. Some u.v.-visible measurements were made using a Cary 17 spectrophotometer.

The cell and furnace designs used for u.v.-visible spectroelectrochemistry have been previously described (9). Optically transparent working electrodes were prepared either from 80 mesh platinum screen or from 80 or 100 pore per inch reticulated vitreous carbon (RVC-4, The Fluorocarbon Company, Anaheim, California) (24) which was cut into thin slices (1-2 mm thick) of appropriate dimensions. The RVC was precleaned by soaking in 6M HCl, then rinsed and dried before use. Electrical contact to the RVC was made by pressing a cleaned 0.5 mm diam tungsten wire into the RVC to a depth of about 1 cm after the RVC had been inserted into the optical cell.

ESR spectroelectrochemical experiments were carried out at the University of Tennessee with a Varian E-Line Model E-109 spectrometer equipped with a Model E-257 Variable Temperature Accessory. The cell design is similar to that used for u.v.-visible spectroelectrochemistry. A platinum screen OTE was used inside a quartz ESR cell with a pathlength of approximately 1 mm. An auxiliary furnace consisting of a Pyrex tube wrapped with heating tape was used above the ESR cavity to maintain the solution molten and to prevent $AlCl_3$ condensation in the top of the cell. The electrode potential was controlled by a Princeton Applied Research, Model 173/179 potentiostat/coulometer.

The magnetic field was calibrated by using a sample of 2,2-diphenyl-1-picrylhydrazyl (DPPH, g = 2.0036) inside the microwave cavity but outside the electrochemical cell. A modulation amplitude of 4G and a modulation frequency of 100 kHz were employed. The microwave frequency was approximately 9.12 GHz and the microwave power was 3.5 mW. The scan speed was 200 G min^{-1}.

The melt used was $AlCl_3$-NaCl (63-37 m/o ≡ 63/37) in all cases, and potentials are reported *vs.* the Al(III)/Al reference electrode in this melt.

Results

ESR spectroelectrochemistry.—In preliminary experiments (12), sulfur was dissolved in the 63/37 chloroaluminate melt and then oxidized to formal oxidation states ranging from +1/8 to +1 either electrochemically or chemically using stoichiometric amounts of SCl_3AlCl_4. Most of these solutions produced ESR spectra consisting of two, and sometimes three, signals, both in the molten and in the frozen state. The strongest line in most cases had a g-value of ~ 2.0275, and weaker lines were observed at g ~ 2.016, g ~ 2.013-2.014, and g ~ 2.0075. These spectra were obtained at 132°-136°C.

ESR spectra were also obtained for pure S_8, S_2Cl_2, SCl_2, and SCl_3AlCl_4 dissolved in the melt at 132°C. These represent sulfur with formal oxidation states of 0, +1, +2, and +4, respectively. The latter two solutions produced no signal. S_2Cl_2 produced a weak signal at g = 2.0277 and stronger signals at g = 2.0155 and g = 2.013. Sulfur dissolved in the melt produced only a weak signal at g = 2.0155.

In order to study these radicals as a function of potential, a solution of 8.20×10^{-3}m sulfur was oxidized at a platinum OTE at potentials ranging from 1.3 to 1.9V. Figure 1 summarizes the resulting spectra at 132°C. Four lines are observed, labeled A, B, C, and D; the g-values and linewidths are summarized in Table I. Signal D was shown to be due to the quartz ESR cell.

A plot of relative signal intensity *vs.* potential for lines A, B, and C (Fig. 2) shows that signal A is observed at potentials less positive than signal C and that it reaches a maximum around 1.60V, whereas C reaches a maximum at 1.70-1.75V. It is reasonable to conclude from these results that radical A is due to a sulfur species in a lower formal oxidation state than radical C. The intensities shown in Fig. 2 were calculated from the first derivative spectra by correcting for the signal linewidths. Since line B is very narrow compared to A or C, its intensity is low. These corrected

intensities should be directly proportional to the concentrations of the respective radicals in the melt, however, the actual concentrations cannot be calculated since the values of the parameters involved in the proportionality constants are unknown.

An increase in temperature to 150° produced a loss in intensity for all the lines, but the intensity *vs.* potential curves remained unchanged. When the temperature was increased to 225°C, the intensities of all signals decreased considerably. Lines A and C became broader, and A was only barely detectable due to overlap with B. The linewidth of B remained the same at the higher temperature.

The behavior of species B differs from that of A and C in several ways. The fact that it is present over the entire potential range is unexpected assuming that it is due to a species containing sulfur in a formal oxidation state between 0 and 4. In fact, it is present at the open-circuit potential (~1.3V) where only S(O) should be present. Furthermore, the same signal was observed when elemental sulfur was dissolved in the melt. The line width of B is small and remains unchanged with temperature, whereas lines A and C are broadened at higher temperatures. A lineshape analysis of signals A, B, and C indicates that signals A and C approximate the Lorentzian function, but B is closer to the Gaussian function.

An experiment was carried out using ^{33}S enriched elemental sulfur as the solute in an attempt to obtain hyperfine splitting of the radical lines. We were unable to observe the hyperfine splitting; thus, the nature of these radicals can only be inferred by comparison with sulfur radicals previously studied in other media (13-15) and by correlation with the u.v.-visible spectroelectrochemical data which are discussed below.

U.V.-visible spectroelectrochemistry.—The various sulfur cations have several absorption bands in the 250-1100 nm region which are useful for determining which species are present in solution. In a previous paper (9) we reported some preliminary results concerning the oxidation of sulfur at OTE's, covering the potential range from 1.3 to 1.85V and the 250-1100 nm spectral region. In order to obtain a better understanding of the effects of temperature, potential, and concentration on the sulfur species produced in the melt, a more comprehensive investigation has been conducted.

The first oxidation step for sulfur has not been completely characterized, primarily because the oxidation involves a small number of electrons resulting in a broad cyclic voltammetric oxidation wave (7). This step covers the potential region from 1.3 to ~ 1.7V. Figure 3 illustrates spectra acquired at an RVC-OTE for four potentials at temperatures of 150° and 250°C. As previously reported (9), three absorption bands appear at ~ 600, ~ 730, and ~ 960 nm for potentials between 1.5 and 1.7V. In addition, a shoulder is observed around 450 nm. Although not shown in this figure, a shoulder is also seen in the ~ 330-350 nm region. The 600 nm band has previously been attributed to S_8^{2+} and the latter two bands to S_{16}^{2+} (9-11). The absorbance *vs.* potential behavior for these bands, shown in Fig. 4, supports the assignment of the 600 nm band to the species of a higher formal oxidation state.

Similar absorption bands have been observed when sulfur was oxidized in HSO_3F and oleum (13). After the completion of the present work, a paper by Burns, Gillespie, and Sawyer (15) appeared describing the oxidation of sulfur by AsF_5 in SO_2. Visible spectra similar to those described above were obtained, and a band at 585 nm was attributed to S_5^+ species. The two longer wavelength bands were assigned to an unknown sulfur radical cation which was previously identified as S_8^+ (13). A somewhat different interpretation of these absorption bands is given in the Discussion section.

The 730 and 960 nm bands have approximately equal absorbances, in agreement with other published spectra (11, 15), however, at potentials greater than ~1.55V,

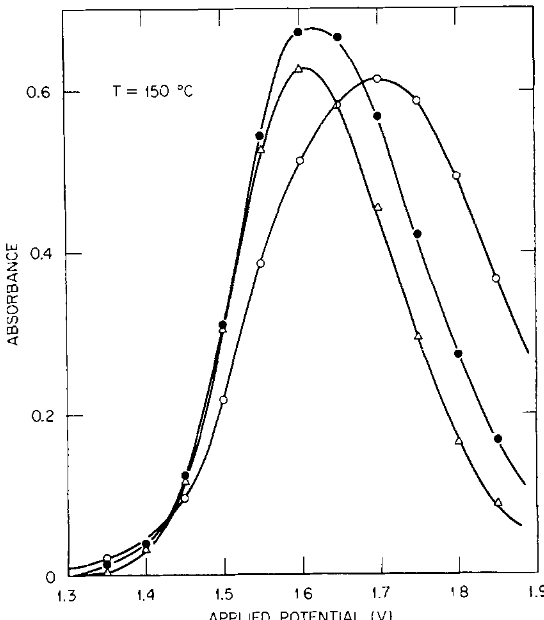

Fig. 4. Potential dependence plot for the absorption bands shown in Fig. 3 at 150°C. ○, 600 nm; ●, 730 nm; △, 960 nm.

the absorbance at 730 nm becomes greater than that at 960 nm. The cause apparently lies in the overlap of the 600 and 730 nm bands, such that, as the 600 nm band begins to increase, it contributes to the observed absorbance at 730 nm. This effect is also evident in the spectra of Gillespie and co-workers (15). The 960 nm band is sufficiently separated from the other bands to avoid this problem.

The temperature dependence of these bands, as shown in Fig. 3, indicates that the higher oxidation state species is favored at higher temperatures. This temperature effect is also evident in bulk coulometric results (7) and is further supported by the thin-layer coulometric experiments summarized in Table II. These data were obtained by integrating the current-time curve produced by exhaustively electrolyzing a sulfur solution at a platinum OTE. The increasing n_{app} value at higher temperatures indicates a shift in the equilibrium ratio favoring the higher oxidation state.

Absorbance *vs.* time profiles for the three absorption bands were obtained by stepping the potential of an OTE from 1.3V (rest potential) to various potentials on the current-limited region of the first oxidation wave. Figure 5 illustrates the results for the 600 and 730 nm bands at potentials of 1.60V (middle of current-limited plateau) and 1.70V (near the beginning of second oxidation wave) at 150°C. The higher potential results in a greater rate of increase in absorbance *vs.* time for both wavelengths, and a greater absorbance plateau value for the 600 nm band. The maximum and subsequent decrease in the absorbance at 730 nm at 1.70V is expected based on the absorbance *vs.* potential relationships shown in Fig. 4.

In the spectroelectrochemical experiments described thus far the sulfur concentration ranged from 1.3 to 1.5

Table II. Thin-layer coulometric n_{app} obtained at a platinum OTE for the first sulfur oxidation step. Potential was stepped from 1.30 to 1.65V.

t (°C)	n_{app}*
150	0.157 ± 0.004
200	0.167 ± 0.002
250	0.181 ± 0.006

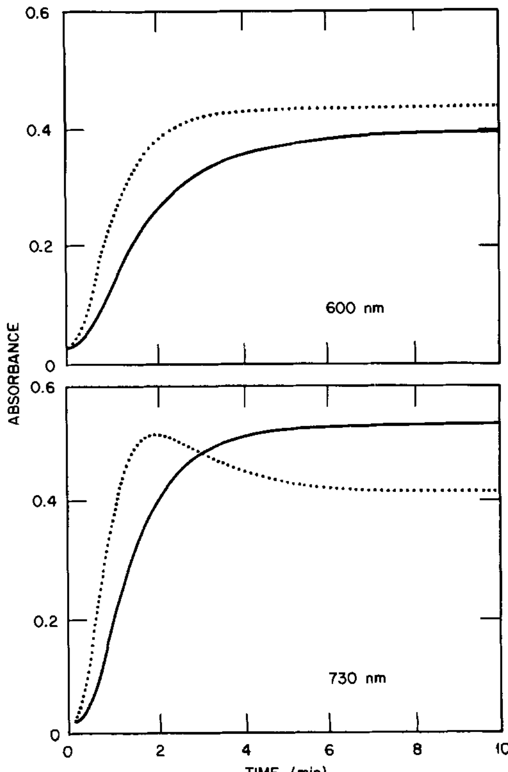

Fig. 5. Absorbance-time profiles for the 600 and 730 nm absorption bands following potential steps from 1.30 to 1.60V (———) and 1.70V (····). Sulfur concentration: 1.50×10^{-2}m.

$\times 10^{-2}$m (as monomeric sulfur). To study the effect of sulfur concentration, a 1.75×10^{-1}m sulfur solution was examined at a platinum OTE. Temperatures ≧200°C were necessary to avoid precipitation of molten sulfur from the melt, therefore, these spectra were acquired at 250°C.

The absorbance *vs.* potential relationships for the 600 and 730 nm bands for the higher sulfur concentration show a substantial increase in the concentration of the lower oxidation state species relative to the higher oxidation state species. The absorbance value at 730 nm now is greater than that at 600 nm for potentials as positive as 1.70V. This may be contrasted with the lower concentration case where the 600 nm absorbance predominates at 1.70V even at 150°C (Fig. 4), and to an even greater extent at 250°C. Attempts to analyze thin-layer coulometric data for this solution were unsuccessful due to the ill-defined nature of the charge *vs.* time curves. This is due to the large continuous faradaic current resulting from diffusion of sulfur from the bulk solution to the OTE contact region.

The potential region of interest for the second sulfur oxidation step extends from about 1.70 to 1.85V. This oxidation step was also studied spectroelectrochemically using a 1.35×10^{-2}m sulfur solution. As shown by previous coulometric results (7), the product of this oxidation is S(I). A spectrum of S(I) was obtained by dissolving S_2Cl_2 in the 63/37 melt. The resulting spectrum shows a strong band at 263 nm and two weak shoulders around 320-330 nm and 375-380 nm. Figure 6 illustrates spectra obtained at a platinum OTE for several potentials in this region. The correlation between the final spectrum (at 1.85V) and that obtained for S_2Cl_2 is good. Fehrmann *et al.* (10) have published a "calculated" spectrum for S(I) (as S_2^{2+}), indicating bands at 262 and 376 nm. There is also some indication of a shoulder near 320 nm, but this is more predominant in the calculated spectrum for the S_4^{2+} species, and it appears that this band is more properly

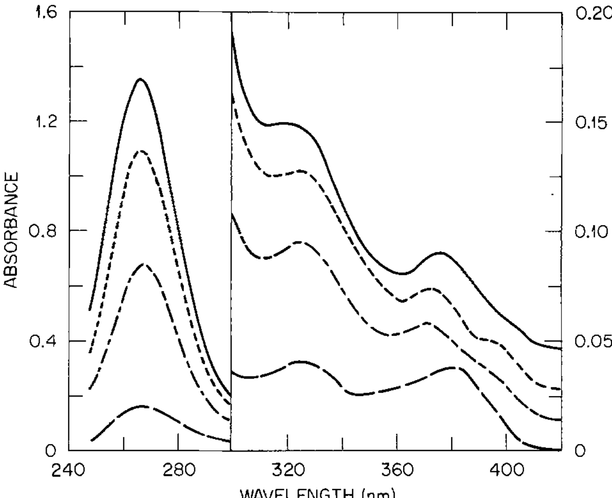

Fig. 6. Absorption spectra of the products of the second sulfur oxidation step at 250°C. Applied potentials: 1.70V (— — —), 1.775V (— - — -), 1.825V (- - - - - -), 1.85V (———). Sulfur concentration: 1.35 × 10^{-2}m.

assigned to S_4^{2+}. The position of the major band in the spectroelectrochemical experiment was approximately 265 nm, and the molar absorptivity was calculated to be ~3200. Fehrmann's calculated spectrum for S(I) has a molar absorptivity of ~3700 at the 262 nm band maximum.

An increase of the potential of the OTE past 1.85-1.95V results in the eventual disappearance of all absorption bands at wavelengths longer thon ~260 nm. There is an indication of a strong absorption at wavelengths less than 260 nm, but this was beyond the dynamic range of our instrumentation. At potentials between 1.85 and 1.90V, there is evidence that the band at ~325 nm disappears at a faster rate than the band at ~377 nm. This would require the presence of at least two species in this potential region. Since S(I) is known to be a product of the second oxidation step, S(II) might be expected to exist upon oxidation at potentials between the second and third oxidation steps. Fehrmann *et al.* (10) have proposed the existence of S(II) in the melt and have calculated an absorption spectrum showing a single band at 380 nm. The observation that the bands at ~325 and ~377 nm are seen at 1.85V, and only the ~377 nm band is seen at 1.90V supports the existence of an oxidation state between S(I) and S(IV), and S(II) is reasonable.

Discussion

The spectroelectrochemical results support the complexity of the first oxidation step indicated by the electrochemical results previously reported (7). These data also suggest a more complex oxidation path than previously proposed for the second and third oxidation steps. In the following discussion these three steps will be discussed separately.

First oxidation step (1.30-1.70V).—A reaction sequence was previously proposed (7) for the first oxidation step based on electrochemical results and some preliminary spectroscopic data. This is summarized by reactions [1a]-[2b]

$$S_8 = S_8^+ + e \quad [1a]$$

$$2S_8^+ \rightleftarrows S_{16}^{2+} \quad [1b]$$

$$S_8^+ = S_8^{2+} + e \quad [1c]$$

and

$$S_8 = S_8^{2+} + 2e \quad [2a]$$

$$S_8^{2+} + S_8 = S_{16}^{2+} \quad [2b]$$

Reactions [1] and [2] assume that both S_8^+ and S_8^{2+} are formed at approximately the same potentials. This reaction sequence, however, is not adequate to account for the presence of at least one other species which has been observed by us in this potential region.

Sulfur radical cations have been studied in HSO_3F, oleum, and SO_2 by several investigators (13-15), and, in most cases, two radical species, R_1 and R_2, were observed with g-values of approximately 2.013 and 2.027, respectively. Gillespie and co-workers (15) have observed an additional sulfur radical, R_3, with a g-value of 2.008. The radicals R_2 and R_1 appear to correspond to radicals A and C, respectively, in the present work. The linewidths of the ESR signals for these radicals in chloroaluminate melts (see Table I) are about a factor of two greater than those observed by Gillespie and co-workers (15), but this may be attributed to the difference in solvents and the higher temperatures of the chloroaluminate studies. Volkov *et al.* (25) have reported radicals giving similar ESR signals in $AlCl_3$-S_2Cl_2, however, their interpretation of the nature of species in these media is highly questionable.

The radical denoted as R_3 by Gillespie *et al.* was not observed when sulfur was oxidized in chloroaluminate melts at the OTE; however, its g-value of 2.008 is in good agreement with the signal at g = 2.0075 which was observed in preliminary nonelectrochemical experiments (12). In most cases, this signal was observed in solutions initially containing only elemental sulfur or very slightly oxidized sulfur. Also, whenever this signal was present, radical A was present. The relative intensity of signal A with respect to the signal at g = 2.0075 was approximately constant and equal to ~9. Gillespie and co-workers (15) also note a relationship between this radical (R_3) and radical R_2, although the ratio of the intensities appears to be greater than 9 in their case. It seems likely that this radical contains sulfur in a very low oxidation state since it is seen predominantly in weakly oxidized solutions. This observation is in agreement with Gillespie and co-workers (15) who propose the possibility of S_{12}^+ for this species. It is not clear as to why this radical was not observed at the OTE. Further studies will be required to characterize this species as well as radical B; therefore, they will not be considered in the proposed reaction sequence.

Radicals R_1 (C) and R_2 (A) were earlier believed to be S_4^+ and S_8^+, respectively (13), and monomer-dimer equilibria were introduced to account for their presence as shown below

$$2S_8^+ \rightleftarrows S_{16}^{2+} \quad [1b]$$

$$2S_4^+ \rightleftarrows S_8^{2+} \quad [3]$$

The existence of S_8^{2+} was confirmed by x-ray diffraction (13), however, no such data were available for S_{16}^{2+}. The stoichiometries of the radical cations were not proved, but rather proposed on the basis of above equilibria.

Gillespie and co-workers (15) have recently obtained x-ray diffraction data for a salt thought to contain S_{16}^{2+}; the cation S_{19}^{2+} was found instead. The structure of this species was shown to consist of two different seven-membered rings linked by a five-membered bridge. Earlier Low and Beaudet (14) determined that radical R_1, which was thought to be S_4^+, is S_5^+ based on analysis of hyperfine splitting data. The nature of radical R_2 has not been definitely established. Clearly it is important to consider this information along with the spectroelectrochemical data in order to arrive at a reasonable reaction sequence for the oxidation of sulfur in chloroaluminate melts.

A comparison of the spectroelectrochemical data shown in Fig. 2 and 4 suggests a relationship between

the radical species A and C and species producing the absorption bands at 600, 730, and 960 nm. Both the 730 and 960 nm absorbances and signal A reach their maximum values around 1.60V; this is also true for the 600 nm band and signal C around 1.70-1.75V. The temperature dependence data yield further information on this relationship. An examination of the absorption bands in Fig. 3 for a potential of 1.60V shows that the 600 nm band increases at higher temperature, whereas the 730 and 960 nm bands decrease. For the same potential and a temperature increase from 132° to 225°, the ESR signals A and C both decrease considerably. The relative differences in the amount of change in the absorption bands as compared to the ESR signals indicate that the absorption bands are due, at least primarily, to diamagnetic species which are probably in equilibrium with the radical cation species. Contributions to the absorption bands by the radicals cannot be ruled out completely based on the data available.

The 600 nm absorption band may be attributed to S_8^{2+} (9, 11, 13), which is related to radical C through one or more chemical reactions. Radical C is probably S_5^+ based on the study by Low and Beaudet (14). The formation of S_8^+ by a one-electron oxidation of S_8 (reaction [1a]) is supported by electrochemical data (7) and reasonably accounts for radical A. It also provides a simple pathway to the formation of S_8^{2+} by an additional one-electron step. The originally proposed reaction [1b] appears to best explain the presence of the diamagnetic species in equilibrium with this radical. Bjerrum (11) has presented potentiometric evidence for the existence of S_{16}^{2+} in chloroaluminate melts, and the 730 and 960 nm absorption bands have previously been attributed to this species (9, 11). The existence of S_{19}^{2+} in these melts has not been previously considered, however, the spectroelectrochemical data show a shoulder in the region ~330-350 nm for the early stages of sulfur oxidation. This may be attributed to S_{19}^{2+} on the basis of the assignment by Gillespie and co-workers (15). It was not possible to study this shoulder quantitatively by spectroelectrochemistry due to overlapping absorption bands attributed to higher oxidation state sulfur species (see below).

One set of reactions which may account for the relationships between these various species is shown below

$$2S_8^+ \rightleftarrows S_{16}^{2+} \quad [1b]$$

$$S_8^+ + S_{16}^{2+} \rightleftarrows S_5^+ + S_{19}^{2+} \quad [4]$$

$$4S_8^{2+} + S_8 \rightleftarrows 8S_5^+ \quad [5]$$

$$S_8^{2+} + S_8 \rightleftarrows S_{16}^{2+} \quad [2b]$$

Reactions [1b] and [4] provide a pathway for the formation of S_5^+ and S_{19}^{2+} using S_8^+ as the starting material. Reaction [5] is based on a similar reaction proposed by Low and Beaudet (14), but modified to take into account the presence of S_8 as the likely form of elemental sulfur in chloroaluminate melts (26). These reactions can also be used to explain the dominance of the lower oxidation state species (*i.e.*, formal sulfur oxidation state $\leq$0.20) at higher sulfur concentration as observed from the absorption spectra. This effect was also reflected in bulk coulometric measurements (7). It should be noted that these equations only attempt to represent the reaction sequence and should not be construed to be actual mechanisms.

Additional information concerning the electrochemical reactions involved in the first sulfur oxidation step can be obtained from the absorbance-time plots shown in Fig. 5. These data indicate that the initial rate of formation of the lower oxidation state species (*i.e.*, S_{16}^{2+} formed through reaction [1b]) is faster than that for the higher oxidation state species (*i.e.*, S_8^{2+}). This result favors an electron transfer sequence yielding S_8^+ initially, which is oxidized further to S_8^{2+}. Thus the originally proposed reaction [2a] is considered less likely.

Bulk coulometry data (7) as well as thin-layer coulometry (Table II) and spectroelectrochemical measurements indicate that the higher oxidation state of sulfur is favored at higher temperatures. This effect has been observed for other systems in chloroaluminate melts (27) and is probably caused by the increase in chloride ion activity as the temperature is increased (28), which, in turn, favors the higher oxidation state (29).

An overall reaction sequence for the first sulfur oxidation step under the experimental conditions studied (*e.g.*, highly acidic chloroaluminate melts) can be summarized as follows

$$S_8 = S_8^+ + e \quad [1a]$$

$$2S_8^+ \rightleftarrows S_{16}^{2+} \quad [1b]$$

$$S_8^+ = S_8^{2+} + e \quad [1c]$$

$$S_8^{2+} + S_8 \rightleftarrows S_{16}^{2+} \quad [2b]$$

$$S_{16}^{2+} + S_8^+ \rightleftarrows S_5^+ + S_{19}^{2+} \quad [4]$$

$$4S_8^{2+} + S_8 \rightleftarrows 8S_5^+ \quad [5]$$

Second oxidation step (1.70-1.85V).—The spectrum of the oxidation product of the second oxidation step agrees well with that expected for S(I) based on the spectrum of chemically prepared S_2Cl_2 dissolved in the melt. By assuming that the oxidation was complete at 1.85V and that no oxidation to S(I) had proceeded at 1.65V, the concentrations of the reduced form, [R], and the oxidized form, [O], were calculated from the absorbance spectra at each applied potential. This was possible by using the known bulk sulfur concentration. There oxidation reactions have been considered for this step

$$2S_5^+ \rightarrow 5S_2^{2+} + 8e \quad [6]$$

$$S_8^{2+} \rightarrow 4S_2^{2+} + 6e \quad [7]$$

$$S_8^+ \rightarrow 4S_2^{2+} + 7e \quad [8]$$

Nernst plots for these reactions are shown in Fig. 7; essentially straight lines are observed in both cases. The line for reaction [6] has a slope of 14.1 mV, giving an n-value of 7.36. Reactions [7] and [8] have a single Nernst plot, and it yields a slope of 18.6 mV and an n-value of 5.58. This n-value is closer to that expected for reaction [7] than for reaction [8] suggesting that reaction [7] is more likely. The n-values calculated from these slopes suggest that, under the experimental conditions, most of the sulfur in the R form is present as $S^{+1/4}$ or $S^{+1/5}$ rather than $S^{+1/8}$. Since these mea-

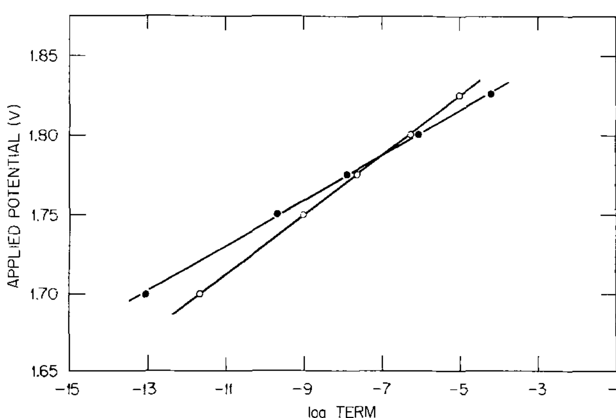

Fig. 7. Nernst plots for reactions [6]-[8] based on the spectroelectrochemical data shown in Fig. 6. Log term. ●, $[O]^5/[R]^2$; ○, $[O]^4/[R]$.

surements were carried out at 250°, this result is in agreement with spectroelectrochemical data indicating a shift in the A(600 nm)/A(730 nm) ratio to larger values with increasing temperature. Since the spectroelectrochemical data indicate that both S_8^{2+} and S_5^+ are present at 1.65V, reactions [7] and [6] may be occurring simultaneously.

Fehrmann *et al.* (10) have postulated the existence of S_4^{2+} in the melt. Gillespie and Passmore and others (13) have studied this species in oleum and superacid solvents. Some correspondence with bands attributed to S_4^{2+} by Fehrmann *et al.* has been observed at OTE's in the 1.70-1.85V potential range, but some of the proposed bands overlap bands attributed to S(I) and a proposed S(II) species (see below) making a clear assignment of S_4^{2+} difficult. If S_4^{2+} does exist, it is likely that it is formed as an intermediate product between $S^{+1/4}$ and S(I).

The second oxidation step is clearly more complex than originally proposed based solely on electrochemical data. These earlier measurements did not indicate the presence of S_4^{2+}, so it was not considered in the mechanism. Two sets of proposed reactions may now be formulated for this oxidation depending on whether S_4^{2+} is included in the sequence. If it is not included, reactions [7] and [6] are possible. A more complex reaction sequence involving an S_4^{2+} intermediate product is given below

$$S_8^{2+} \rightarrow 2S_4^{2+} + 2e \quad [9]$$

$$4S_5^+ \rightarrow 5S_4^{2+} + 6e \quad [10]$$

$$S_4^{2+} \rightarrow 2S_2^{2+} + 2e \quad [11]$$

Third oxidation step (1.85-2.0V).—The final product of this oxidation has been shown (7) to be S(IV), present as SCl_3^+. Assuming that S_2^{2+} is the major product of the second oxidation, the most likely possible intermediate product in the oxidation to S(IV) would be S(II). Fehrmann *et al.* (10) have proposed the existence of S(II) in chloroaluminate melts with a single absorption band around 380 nm. Spectroelectrochemical results indicate the presence of more than one species in the potential region between 1.85 and 1.90V, based on absorbance bands at ~325 and ~377 nm. Since S(IV) is known to have no bands in this spectral region, then S(II) is a possible candidate for the unknown species. This, however, is in disagreement with spectrum of pure SCl_2 dissolved in the melt, which does not possess any absorption bands at wavelengths longer than 300 nm and has a sharply increasing absorbance at wavelengths shorter than 300 nm. A Raman spectrum of this solution showed the presence of SCl_3^+, indicating disproportionation of S(II) to S(IV) and some unidentified lower oxidation state. Further study is required to address this problem, therefore we can only tentatively assign S(II) as an intermediate product in the oxidation to S(IV). The originally proposed reaction [7], then, can be modified to

$$S_2^{2+} \xrightarrow{-2e} 2S(II) \xrightarrow{-4e} 2S(IV) \quad [12]$$

Conclusions

The oxidation of sulfur in chloroaluminate melts is clearly very complex, more so than originally thought based solely on electrochemical measurements. It is convenient to picture this oxidation in terms of a decreasing number of S-S bonds and increasing Cl^- complexation as the formal sulfur oxidation state increases. Each sulfur oxidation wave, then, probably consists of a series of closely spaced sequential oxidation steps rather than single multi-electron steps.

At this point we cannot propose a detailed overall mechanism, but we have demonstrated the value of spectroelectrochemical techniques in enabling us to better understand the sulfur oxidation in these melts.

Acknowledgments

We would like to acknowledge the collaboration of R. Livingston, H. Zeldes, M. Conradi, Chemistry Division, ORNL and J. P. Wiaux, University of Tennessee, in obtaining preliminary electron spin resonance spectra of sulfur radicals, as well as useful discussions with R. Marassi throughout this work. We would also like to thank Professor J. Q. Chambers for the use of his ESR spectrometer. Photoelectrochemistry of Layer-Type Zirconium Disulfide

Helmut Tributsch

Laboratoire d'Electrochimie Interfaciale du C.N.R.S., 1, Place A. Briand, 92190 Meudon-Bellevue, France

ABSTRACT

Semiconducting zirconium compounds have never before been considered for solar energy applications, although Zr is more abundant than most commercially interesting metals and, as opposed to Cd, nontoxic. Reasonably high photocurrent densities (mA/cm^2) which were observed in ZrS_2 ($E_g = 1.68$ eV) suggest that it could possibly be developed as a material for solid-state solar cells. Its photoelectrochemical behavior is especially interesting from theoretical points of view. Although ZrS_2 has a layer-type structure very similar to that of MoS_2 or WS_2, its anodic photoproducts are very different. Sulfur and not sulfate is formed and there is no specific photoinduced surface interaction with iodide. Since photoreactive holes are generated on an energy band derived from sulfur p-orbitals (as in CdS) and not from d-orbitals (like MoS_2), the results are considered as further evidence for the advantage of d-bands for the photoreaction of water with visible light. Possible molecular reasons are discussed and a model is proposed which emphasizes the importance of kinetic factors for photoelectrochemical stability of electrodes and their reactivity with water. ZrS_2 does not seem to provide any advantage as a photoelectrode in regenerative redox solar cells, but some of its peculiar properties such as its high ability to form energy storing intercalation compounds still have to be evaluated.

ZrS_2 is a semiconductor with a layer structure of the cadmium iodide type. It consists of stacked composite layers comprising single sheets of metal cations sandwiched on either side by sheets of anions (Fig. 1). Since primary valency is limited within each multiple sandwich, adjacent layers are held together only by relatively weak van der Waals forces. The resulting structure is markedly anisotropic, exhibiting pronounced cleavage perpendicular to the c-axis of the octahedrally coordinated crystals. Crystal-chemical, optical, and electrical properties of ZrS_2 have been studied (1-5) and reviewed (6). Optical measurements (3-5), photoemission studies (7), and band structure calculations (8, 9) have shown that the lowest d-band of ZrS_2 (and HfS_2) is empty and separated from a bonding p-like valence band by about 2 eV. The theoretical values for the bandgap, 1.74 and 1.84 eV (8), are in good agreement with the experimental result (1.68 eV) (1). The electronic transition was found to be indirect. Calculations with the empirical tight binding (ETP) method (8, 10) indicate that the d-band which is acting as the conduction band is between 1.74 eV (3) and 2.25 eV (8) wide and might be viewed as an antibonding band, formed by the t_{2g} triplet of d-bands. The band configuration indicates considerable ionic character in the bonding. The fractional ionic bond character of ZrS_2 has been estimated to be 0.26, as compared with 0.12 in $2H-MoS_2$. When the applied electric field is perpendicular to the c-axis, the effective charge for a polar lattice vibration in ZrS_2 is found to be $e_T^*/e = 4.6$ (e: electric charge) as compared to $e_T^*/e = 0.78$ in $2H-MoS_2$. The force constants within the layers for MoS_2 is, on the other hand, considerably bigger ($c_w = 1.7\ 10^5$ dyne cm^{-1}) than that for ZrS_2 ($c_w = 0.36 \cdot 10^5$ dyne cm^{-1}) (11). When ZrS_2 is grown by iodine vapor transport from a charge in which the ratio S:Zr = 2:1, a crystal composition $ZrS_{1.98\pm0.03}$ results. When the charge composition is varied between the limits Zr:S = 1:3 to 3:1, the di-

Key words: photoelectrochemistry, oxygen evolution, photocorrosion.

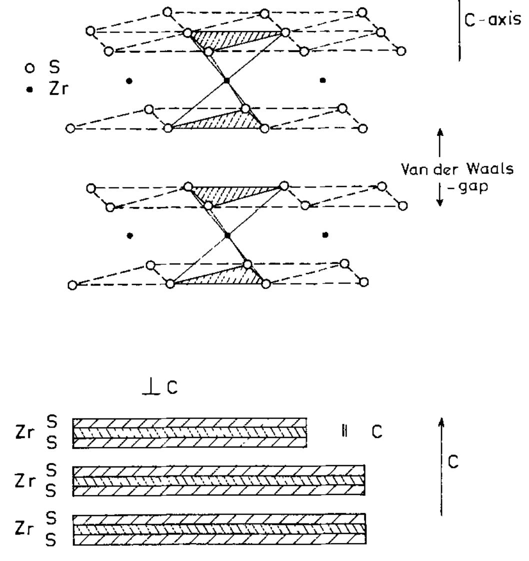

Fig. 1. Crystal structure and schematic arrangement of layers in ZrS_2.

sulfide phase is found to shift within a narrow homogeneity range between $ZrS_{1.98\pm0.02}$ to $ZrS_{1.94\pm0.03}$ (12). Zirconium is thus always present in excess. It can easily be taken up into vacant sites in the van der Waals gap. Nonintentionally doped ZrS_2 will therefore always show n-type character.

Since only weak van der Waals forces act between layers of ZrS_2, it is possible to intercalate a wide variety of atoms and molecules. The resulting ZrM_yS_2 ($0 < y \leq 1$) intercalation compounds exhibit markedly altered solid-state properties. Interestingly, they seem to remain semiconducting when the intercalated species are Cu or Fe with $0 < y \leq 0.22$ (13). Since intercalation compounds of ZrS_2 can readily be formed electrochemically (14, 15), a certain knowledge of their properties (16, 19) will be essential for understanding electrochemical and photoelectrochemical mechanisms.

There were three reasons which motivated us to start an investigation of the photoelectrochemical properties of ZrS_2, which has not yet been considered as a possible solar energy material. These are:

1. Zirconium is the eleventh most abundant element on earth, more abundant than Zn, Cu, or Pb. In addition it is, which is most important, practically nontoxic (20). Since zirconium has turned out to be a very valuable structural material for nuclear reactors, its technology is rapidly developing and it is becoming commercially interesting for other applications.

2. ZrS_2 is a layer-type transition metal compound with a crystal lattice almost identical with that of MoS_2. The only difference is that the cations have an octahedral arrangement (Fig. 1) and not a trigonal prismatic one. The MoS_2 structure can be obtained from that of ZrS_2 by just replacing the dashed octahedrons by prisms in Fig. 1. This close similarity of the crystal structures in combination with a similar chemical behavior of Zr and Mo is especially interesting with respect to a pronounced difference of the electronic structure found in MoS_2 as compared to ZrS_2 (Fig. 2). The trigonal prismatic symmetry in MoS_2 causes the t_{2g} triplet of d-bands found in layer compounds of octahedral symmetry (ZrS_2) to split into a lower d_{z^2} band and a higher d_{xy}, $d_{x^2-y^2}$ energy band. The consequence is that the valence band of ZrS_2 is an energy band derived from sulfur 3p orbitals and the "valence band" of MoS_2, which is a group VI transition metal compound, is the lower d_{z^2} energy band. Light absorbed in ZrS_2 will therefore produce holes in a sulfur 3p energy band as in CdS while light absorbed in MoS_2 will generate holes in the d_{z^2} energy band. Since layer-type molybdenum- and tungsten-dichalcogenides which permit photoreactions over d-bands have been shown to provide reasonably stable photoelectrodes for regenerative electrochemical solar cells and are able to photoreact with water (21, 22), comparison of ZrS_2 and MoS_2 will allow interesting conclusions with respect to the influence of the electronic state of a reactive hole on the quality of photoelectrochemical reactions. Figure 2 represents the approximate relative energetic position of these two compounds (see later) which also shows that the reactive holes have comparable energies. It should, however, also be pointed out that the energy scheme in Fig. 2 contains some degree of arbitrariness. For ZrS_2 the experimentally determined indirect gap of 1.68 eV (1) is, as already mentioned, well in agreement with theoretical results. The theoretical values for the indirect energy gap of MoS_2, however, scatter between 0.25 and 1.23 eV according to the theoretical model used (10). A weak transition corresponding to $\Delta E = 0.2$ eV has also been attributed to the d-d gap (3). The main optical transitions start to occur at 1.75 eV. Photopotentials as high as 420 mV, which were found when MoS_2 was in contact with an iodide solution, suggest a photoelectrochemically effective energy gap of at least 1 eV. Experimental values for the indirect energy gap of MoS_2 vary from 1.13 eV [optical measurements (23)] to 1.6 eV [conductivity measurements (24)]. As long as the actual value of the indirect energy gap in MoS_2 and its significance for photoelectrochemistry is not established we prefer to use the largest experimental value for the indirect ($E_g = 1.6$ eV) transition. The actually effective gap might be somewhat smaller, placing the "valence band" edge of MoS_2 to somewhat more negative potentials.

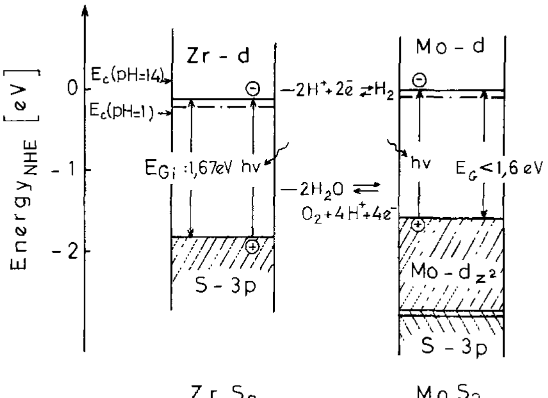

Fig. 2. Energy schemes and approximate relative energetic positions of ZrS_2 and MoS_2.

3. A third reason for us to start an investigation of the photoelectrochemical properties of ZrS_2 was the possible utilization of layer-type dichalcogenides of group IV.B as electrodes for energy storing batteries (25). Energy densities of up to 480 W-hr/kg and excellent reversibility were obtained with the Li-TiS_2 battery system. Semiconductors of group IV.B such as ZrS_2, $ZrSe_2$, HfS_2, and $HrSe_2$ offer the potentiality of cathodic photoreactions suitable for a combined conversion and storage of solar energy. A detailed analysis of this possibility has been provided in a separate publication (26).

Experimental and Materials

Single crystals of ZrS_2 with dimensions between a few mm^2 and 50 mm^2 were available for the investigation.[1] Their appearance was violet and metallic. As very thin sheets and viewed against the light they were reddish and transparent. Electrical contacts were made with copper wires attached to the semiconducting crystals ($\parallel$ c) by means of platinum paint (Emetron, Hanau). The crystals were embedded into a Teflon mounting exposing a van der Waals surface ($\perp$ c) to the electrolyte. The renewal of the interface was achieved by removing an attached adhesive tape. Microscopic analysis of the cleaved surface regularly showed a considerable concentration of step sites ($\parallel$ c) and crystalline imperfections. Electrochemical experiments were performed in a standard glass cell containing the semiconductor electrode, a Pt counter-electrode, and a saturated calomel electrode. A potentiostatic circuit and a wave generator for dynamic recordings were used. The light source was a 150W XBO xenon lamp, the monochromator a Jobin Yvon HRS 2 model. For phase sensitive (lock-in) measurements a PAR 121 lock-in amplifier and a PAR 125 A chopper were employed.

Experimental Results

When undoped ZrS_2 is used as an electrode in an electrochemical cell it behaves like an n-type material exhibiting rectifying behavior and photoeffects in the anodic potential region. Figure 3 shows the anodic photo- and dark-currents of ZrS_2 for two different pH values (1 and 13). It can be seen that the limiting current behavior of the material in the dark is not very

[1] We would like to thank Professor Nietsche, Freiburg, for the samples.

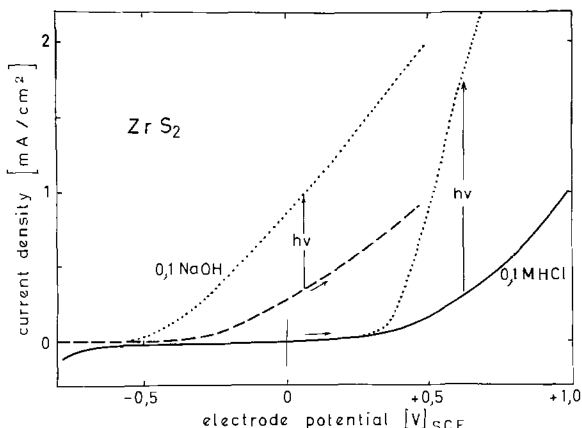

Fig. 3. Electrode photocurrent and dark current of ZrS_2 at two different pH values (pH 1 and 13).

pronounced. The magnitude of dark currents depends on the crystalline quality of the ZrS_2 interface and, like in layer-type transition metal dichalcogenides of group VI (Mo, W) (27), appears to depend on the fraction of surface areas || c. It increases after anodic polarization of the electrode (corrosion of the surface) or addition of reducing agents (*e.g.*, I^-). In the visible spectral region, the main contribution to the photocurrent comes from photons with wavelengths between 400 and 600 nm. The photocurrent spectrum is in reasonable agreement with the absorption spectrum of the material (Fig. 4). It appears that the $M_1^- \rightarrow M_1^+$ transition near $\Delta E = 2.73$ eV, which is theoretically (8) and experimentally (1, 4) well established, can be distinguished. When photocurrents are separated from dark currents by means of a lock-in technique, their characteristic voltage dependence and limiting current behavior can be recognized (Fig. 5). Limiting photocurrent densities of several mA/cm^2 have been observed (150W xenon, $400 \leq \lambda < 600$ nm). Their dependence on the light intensity is linear, but reaches a saturation value at high photon densities (Fig. 6). Cyclic current voltage dependencies of ZrS_2 in absence and during illumination are reproduced in Fig. 7 (sweep rate 40 mV/sec). It can be observed that a higher anodic photooxidation is followed by an enhanced cathodic reduction.

ZrS_2 shows considerable electrochemical reactivity both anodically and cathodically. As a consequence of an anodic (photo) current flow, the ZrS_2 electrode loses its metallic brightness and a layer of molecular sulfur is formed on its surface. The principal mechanism of the anodic photoreaction has been determined by our experiments to be

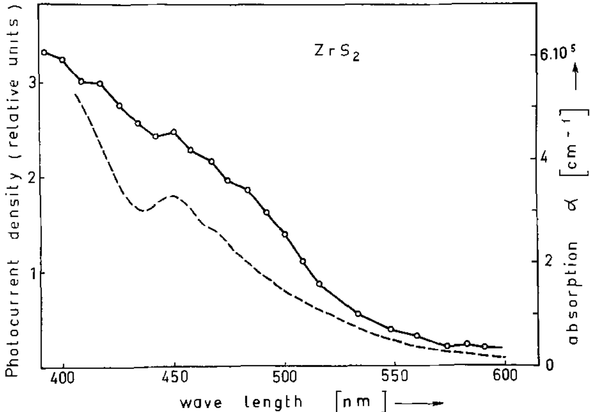

Fig. 4. Spectral dependence of electrode photocurrents and light absorption (dashed line) in ZrS_2 (electrode potential 0.85V, electrolyte 1M HCl).

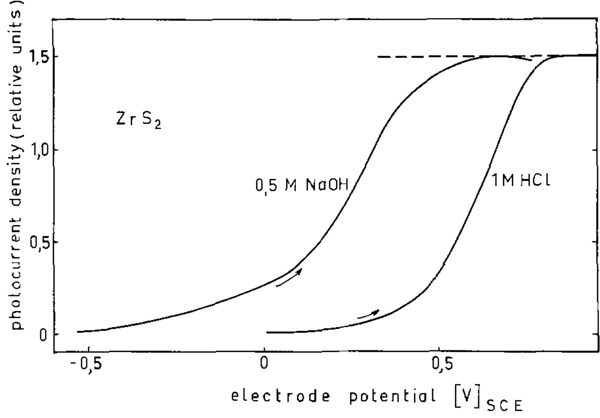

Fig. 5. Voltage dependence and limiting behavior of anodic photocurrents of ZrS_2 for two electrolytes with different pH values (dashed line: normalized limiting value).

$$ZrS_2 + 4p(h\nu) \xrightarrow{4h\nu} Zr(IV) + 2S \quad [1]$$

In absence of light the same reaction products are formed at a lower rate. In this case, holes are generated by a still undetermined potential dependent surface reaction in the dark. As a consequence of the formation of a sulfur layer on the ZrS_2 surface, the anodic photocurrents are unstable and, depending on the light intensity, decrease more or less rapidly with time. Cathodically, three electrode mechanisms are possible: intercalation of positive ions (*e.g.*, H^+), at somewhat more negative potentials their deposition (*e.g.*, evolution of H_2), and reduction of ZrS_2 leading to lower valent zirconium and H_2S. These electrode reactions cause profound changes of the electrode ma-

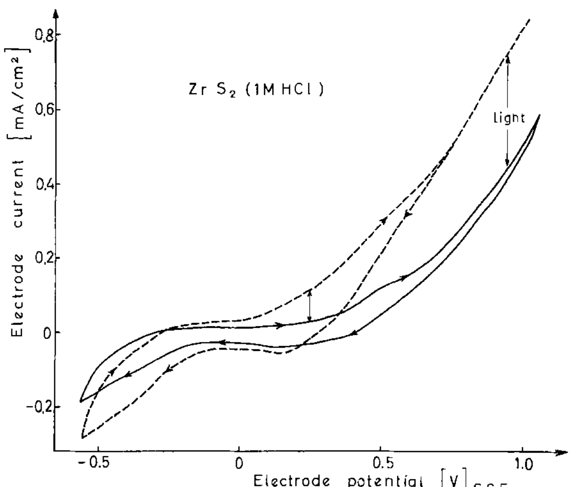

Fig. 7. Cyclic current-voltage curves for ZrS_2 in the absence of, and during, illumination (sweep 40 mV/sec; 1M HCl).

terial. Polarization of ZrS_2 at $-2V$ in 1M HCl for 30 sec leads, for example, to the formation of a gold-yellow surface dotted with many tiny crystal scales, which no longer shows an anodic photoeffect. Cathodic polarization in the presence of $NH_4Fe(SO_4)_2$, pyridinium ions (in ethanol), Cu^{2+}, or Li^+ (in acetonitrile) similarly affects the electrode material in a way characteristic for intercalation reactions (changes of optical properties, volume changes, alteration of the crystalline macrostructure—small crystal fragments appear on the surface).

The different anodic (photo) behavior of ZrS_2 as compared to MoS_2 which reacts with water to form molybdenum sulfate is also evident from its electrochemical behavior in contact with acetonitrile. While the anodic dark and photocurrents of MoS_2 are drastically reduced in the presence of acetonitrile as compared to an aqueous electrolyte and are dependent on traces of water or other oxidizable species, those of ZrS_2 retain a comparable order of magnitude. In this respect the behavior of ZrS_2 is more similar to that of CdS than that of MoS_2 or WS_2. In order to detect further differences between the photoelectrochemistry of ZrS_2 and MoS_2 we studied the effect of reducing agents on the voltage dependence of the photocurrent across the layer-type interface. As reported in some detail in preceding publications (21c, d, e) the presence of reducing agents (*e.g.*, I^-, Br^-, Fe^{2+}, hydroquinone) in the electrolyte considerably shifts the photocurrent across molybdenum and tungsten dichalcogenides in the negative direction. The largest shift was observed in the presence of I^-. It amounts to approximately 0.6V in the case of MoS_2 (Fig. 8). This very pronounced effect of I^-, which is essential for the operation of reasonably stable regenerative solar cells based on Mo- and W-dichalcogenides, is absent with ZrS_2 in spite of the very similar crystal structure and chemistry of layer compounds of group IV.B and VI.B transition metals (Fig. 8). Shifts of the current voltage characteristic were not observed, but only changes in the magnitude of the currents.

We made some efforts to understand the photocurrent characteristic of ZrS_2. Figure 4 shows that between 400 and 600 nm the absorption coefficient of ZrS_2 changes by a factor of approximately 30. Since the depth of the space charge layer, in which holes are collected and drawn toward the electrode surface, depends on the applied electrode potential, the voltage dependence of photocurrents should therefore change characteristically with the wavelength of the incident light. The photocurrent under reverse bias in a semiconductor electrolyte junction has been calculated to be (28)

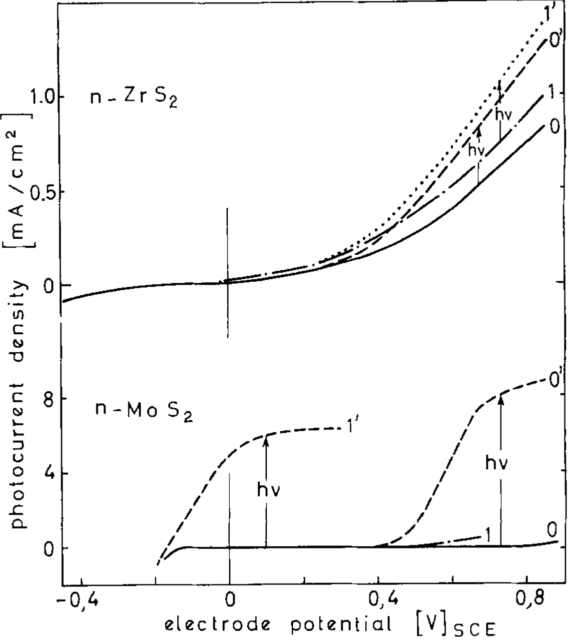

Fig. 8. Effect of addition of I^- (1M) to an aqueous electrolyte in contact with n-ZrS_2 and n-MoS_2 [0, 1 and 0', 1' dark currents and photocurrents, respectively, in the absence (0) and the presence (1) of I^-].

$$I_{ph} = eAI_L\left\{1 - \frac{e^{-\alpha W}}{1 + \alpha L_p}\right\} \quad [2]$$

where e = electronic charge, A = constant factor, I_L = light intensity, α = absorption coefficient, L_p = diffusion length, and W = the depth of the space charge, which depends on the electrode potential according to

$$W = \left(\frac{\epsilon \Delta V}{2\pi e N}\right)^{1/2} = B(\Delta V)^{1/2} \quad [3]$$

where ϵ = dielectric constant, N = density of donors, $\Delta V = V - V_{FB}$ = potential drop in the electrode surface (V_{FB} = flatband potential). At the beginning it seemed to be reasonable to assume that the diffusion length L_p of holes perpendicular to the electrode surface (| | c) is small since their transport across the layers will depend on some hopping mechanism. (A mobility for electrons of only 4.3 cm^2/Vsec has been reported for ZrS_2 parallel to the layers (2) where the carrier mobility should be 2-3 orders of magnitude higher than perpendicular to the layers.)

Assuming that $\alpha L_p << 1$, which should be expected for smaller values of α, and $\alpha W \gtrsim \alpha L_p$, relation [2] can be simplified and the exponential term expanded. With $e A I_L = I_{ph\text{-}lim}$ (= limiting photocurrent) and considering [3] it can be rewritten as

$$(I_{ph}/I_{ph\text{-}lim})^2 = B^2\alpha^2\Delta V \quad [4]$$

If we plot the square of the normalized photocurrent as a function of the electrode potential we should (at least in certain potential regions) expect straight lines with inclinations proportional to α^2, the absorption coefficient for the incident light. The results of such plots obtained with light of wavelengths between 400 and 600 nm (corresponding to a change of α by a factor of 30) are shown in Fig. 9 for two different pH values of the electrolyte. Although their inclination would be expected to vary by a large factor, all curves are actually found to be quite similar. Suspicions that the observed limiting currents are masked by concurring anodic electrode reactions have been discarded due to reasonable agreement between the spectral dependence of limiting photocurrents and absorption in ZrS_2 (Fig. 4). In order to understand the ob-

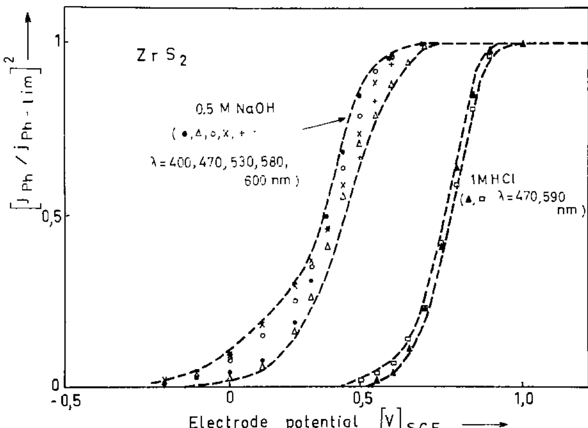

Fig. 9. Square of the normalized photocurrent of ZrS_2 at various wavelengths and two different pH values of the electrolyte plotted as a function of the electrode potential.

served contradiction we have to conclude that the diffusion length of holes L_p in ZrS_2 is much bigger than the depth of the space charge layer W.

In this situation a relation of the type

$$\frac{eAI_L}{I_{ph}} = \frac{1}{\alpha L_p} + 1 \quad [5]$$

should be expected, which seems to be approximately satisfied. More work will be needed to understand the surprisingly high diffusion length of holes in ZrS_2 and to exclude possible contributions by other energy transfer mechanisms (*e.g.*, exciton migration).

Capacity measurements have been attempted with ZrS_2, but simple and interpretable Mott-Schottky plots have not been obtained, possibly because of complications arising from intercalation. A preliminary estimation of the flatband potential has therefore been made by examining the potential region of the photocurrent onset. Experimental evidence indicates that (in the absence of redox systems), the flatband potential determined by capacity measurements in layer compounds (MoS_2, $MoSe_2$, WS_2, WSe_2) is usually situated a few hundred millivolts more negative than the photocurrent onset [compare also data in Ref. (28)]. We have accordingly shifted the flatband position of ZrS_2 into the negative direction so as to be able to explain complementary data on electron transfer reactions (Fig. 2).

Discussion

Experimental differences between ZrS_2 and MoS_2.—The most important result of our investigation of ZrS_2 is that its photoelectrochemical reaction behavior is entirely different from that of MoS_2 (or WS_2) in spite of a very similar chemical reactivity of its constituents and a largely identical crystal structure. Illuminated and anodically polarized ZrS_2 shows neither the ability to photoreact with water nor the property of specifically interacting with electron donors (*e.g.*, I^-) in the electrolyte. Since bandgaps of ZrS_2 and MoS_2 and the position of energy bands are comparable (Fig. 2) there is little doubt that the reason for the different photoelectrochemical behavior originates from the different electronic nature of photogenerated holes. When comparing the anodic light-induced liberation of molecular sulfur which occurs at ZrS_2 with the light-induced formation of sulfate or molecular oxygen, which was found with MoS_2 (30) we must conclude that the latter reaction is energetically much more demanding. At the energetic position at which holes are available in MoS_2 for electrochemical reactions, the oxidation of water cannot be initiated by a one-electron transfer reaction. Such a reaction would produce a radical and needs an oxidation potential near 2.85V (NHE). The upper edge of the Mo-d_{z^2}-energy band, however, might even be more negative than depicted in Fig. 2 since the indirect energy gap of this compound, which is effective for photoelectrochemical reactions, could be smaller than the value assumed [an indirect gap of $\Delta E = 1.6$ eV has more recently been derived from high temperature conductivity in MoS_2 (24), one of $\Delta E = 1.13$ eV from optical measurements (25); earlier work places it between $\Delta E = 1.4$ eV (31) and 1.7 eV (32)]. A photoelectrochemical reaction with water can therefore only proceed if electron transfer is coupled with the formation of a suitable chemical bond to the electrode surface which avoids the formation of a radical. The problem of understanding the difference in the photoelectrochemical reaction behavior with water at MoS_2 and ZrS_2 is therefore reduced to the question why OH^- ions are able to form a bond suitable for electron transfer with a layer type semiconductor in the presence of a hole on a d_{z^2}-energy band, but not in the presence of a hole on a p-energy band. Remarkably, a surface hole on a Mo-d_{z^2} orbital of MoS_2 which is centered at Mo atoms protruding perpendicular to the monolayer of sulfur that forms the van der Waals surface but does not penetrate it, is less exposed to reactive species in the electrolyte than a hole on a sulfur p-band in the top-most sulfur monolayer of ZrS_2 (Fig. 10). A steric hindrance for the photoreaction of holes with OH^- or I^- on ZrS_2 electrodes can therefore not be made responsible for the different mechanism.

Considerations on energetic conditions for water oxidation.—In order to estimate what kind of chemical or electrochemical interaction on an electrode surface is sufficient for the electrochemical reaction of OH^- or water on semiconductor electrodes, we must extend our energetic considerations on the reactivity of these reactants. Since the thermodynamic redox potentials of water $E_{redox}(O_2/H_2O) = 1.23V$ in an acid electrolyte and that of OH^- ions $E_{redox}(O_2/OH^-) = 0.40V$ in a basic electrolyte are only defined for a simultaneous transfer of more than one electron, they do not de-

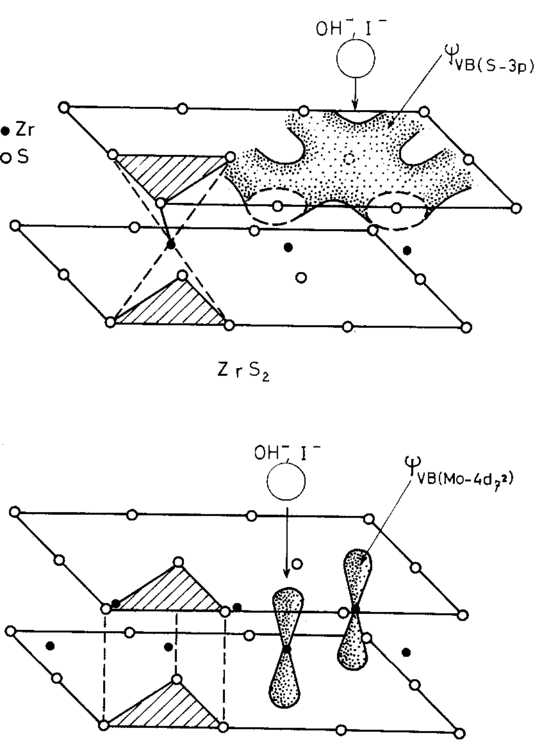

Fig. 10. Simplified schematic drawings characterizing the valence band orbitals responsible for photoelectrochemical reactivity in ZrS_2 (above) and MoS_2 (below).

scribe the actual energetic conditions which have to be met during the experiment. The distribution functions of the electronic states of OH^- and H_2O from which electrons have actually to be transferred to the electrode during the oxidation reaction are situated at much more positive energies (electrochemical energy scale). They center around 2.0V for the oxidation of OH^- to OH radicals (33) and around 2.85V (*vs.* NHE) for the oxidation of water to OH radicals (34). The most easily oxidizable species are therefore OH^- ions. When there is a chemical bonding interaction between OH^- in an electrolyte and an electrode surface, OH^- ions will adsorb and, as a consequence, their distribution function of electronic states will considerably change due to the interaction of the manifold electronic states of the solid and the electronic states of the adsorbate. It should be emphasized here that these adsorbed states of OH^- which form on the surface of oxides which are suitable for water photoelectrolysis (*e.g.*, TiO_2, $SrTiO_3$, Fe_2O_3, $KTaO_3$, SnO_2) would still largely be situated above the edge of the valence band of these large-gap semiconductors. If OH^- ions behaved like Br^- ions or other simple negative ions they could be readily oxidized. From water electrolysis on metallic electrodes we know, however, that water can be oxidized with electrode potentials which exceed its thermodynamic redox potential by only a few hundred millivolts (*e.g.*, RuO_2). This catalytically favorable behavior has been ascribed to the specific chemical interaction between OH^- ions and the electrode surface but few details are known about the molecular energetic conditions which have to be met.

On both photoconductors, ZrS_2 and MoS_2, OH^- ions can adsorb. This is evident from the fact that the current voltage curves are *p*H-dependent for each system and from the fact that a photoreaction with water actually occurs in the case of MoS_2. However, only in the case of MoS_2 is the interaction sufficiently strong or specific to provide electronic states at reasonably positive energy levels for electron transfer. Several questions arise. What is the difference between a kinetically favorable and an unfavorable chemisorption of OH^-, or its reaction product? What is the contribution of the electrical field in the electrode-electrolyte interface? Is there a minimum interaction energy needed to transform a merely adsorbed OH^- ion into a transition complex which can provide electrons at a considerably more negative redox potential?

Theoretical criteria for stability and reactivity.— Thermodynamic criteria for the stability or instability of photoelectrodes have been developed by Gerischer (35) and Bard (36). According to Gerischer, the energy positions of the redox Fermi levels for decomposition with respect to the position of the bandedges and the Fermi levels of competing redox reactions determine the susceptibility of a semiconductor for decomposition. The same author has already emphasized the possibility that kinetic parameters modify thermodynamic conclusions. The difference in the photoelectrochemical reactivity of ZrS_2 and MoS_2 can only be understood in terms of kinetic parameters. There is no thermodynamic reason why illuminated MoS_2 should react with water and ZrS_2 should not. Figure 2 shows that the valence bandedge of ZrS_2 is situated at more positive redox potentials than that of MoS_2. Such an energy position is also indicated by the experimental threshold for photoemission. It is bigger for ZrS_2 ($\approx$ 6 eV) than for MoS_2 ($\approx$ 5 eV) (37). More energy to extract electrons from water would therefore be available at illuminated ZrS_2. MoS_2 would be thermodynamically unstable against electrochemical decomposition but does not decompose into molybdenum ions and molecular sulfur. ZrS_2 would also be thermodynamically unstable, but is photooxidized to zirconium ions and molecular sulfur, although it has a similar layer structure as MoS_2 and even a higher molar enthalpy of formation ($\Delta H^\circ = -138$ kcal·mol^{-1}) than that of MoS_2 [$\Delta H^\circ = -65.8$ kcal·mol^{-1} (38)].

It seems that most semiconductors which absorb visible light are thermodynamically unstable and kinetic quantities will therefore finally decide on whether a material will be useful for regenerative or fuel producing solar cells. The understanding of their role appears therefore to be of fundamental importance for the further development of photoelectrode systems. The pronounced difference of photoelectrochemical behavior between layer-type ZrS_2 and MoS_2 could help us to find clues to the parameters which have to be considered.

Research on oxygen evolution on metal electrodes [see the summary in (39, 40)] is much older and much more developed than research on oxygen evolution on illuminated semiconductor electrodes (41). Interestingly, little attempt has been made to evaluate and transfer valuable information on kinetic and catalytic parameters involved in the discharge of OH^- ions or water molecules. It is, for example, well known that the nature of electrode material has a profound influence on the kinetics of oxygen evolution from water. The oxygen overvoltage of different metals can vary by as much as 1V depending on their chemical interaction with OH^- ions (39). If the chemical bonding is weak, a higher potential drop in the Helmholtz layer can make up for the difference. It generates an electric field (10^7 V/cm) which facilitates the discharge of OH^- ions. Now it has to be considered that the electrode potential applied to a metal electrode practically drops entirely in the Helmholtz layer where it can affect the energy factor of the electron transfer reaction. In contrast, there is little variation of the electric field strength in the Helmholtz layer of a semiconductor since the main potential drop will occur in the space charge layer. A potential applied to a semiconductor will therefore control the entropy factor of a reaction by controlling the concentration of electronic carriers rather than the energy factor. A high field will therefore not be present to assist the discharge of OH^- ions. The question arises to what extent other quantities can compensate for this disadvantage.

In order to get a qualitative understanding of those factors which are critical for the discharge of OH^- ions at illuminated semiconductor electrodes, we can start a calculation from a kinetic equation derived for metals, correct it for the smaller potential drop in the Helmholtz layer, and supplement it by considering the additional overpotential arising from the generation of reactive holes in the valence band. According to Rüetschi and Delahay (39), Frumkin, and others who treated the discharge of protons (42), the overvoltage for oxygen evolution on metals can be written in the form

$$\eta = \frac{RT}{\bar{\alpha}\mathbf{F}} \ln \xi + \frac{\Delta H^\ddagger}{\bar{\alpha} z \mathbf{F}} - \left(1 - \frac{1}{\bar{\alpha} z}\right) \psi_o \qquad [6]$$

In this relation $\bar{\alpha}$ is the transfer coefficient for the discharge process, z is the number of charges discharged during the rate-determining reaction, $\Delta H^\ddagger$ is the energy of activation for the discharge process, ψ_o the difference of potential across the diffuse part of the double layer, and ξ represents a group of terms, which includes the entropy of activation for the discharge process. The explicit form of ξ will not be needed here.

The overpotential η needed to drive the discharge of OH^- ions at metal electrodes (relation [6]) would now have to be substituted by a modified function in order to account for the situation at an illuminated semiconductor electrode. The first thing to be considered is that the electrical potential drop at the semiconductor-electrolyte interface (in the double layer)

Φ_{SE} is much smaller than the electrode potential which is applied. The second is that an additional source of a potential difference will arise at the interface due to the photogeneration of energetically favorable holes. As proposed by Gerischer (35) a reasonable function which describes their free energy would be their quasi Fermi level ($_pE_F{}^*$) rather than the position of the valence bandedge which would provide no measure of the entropy. The light-induced contribution to the overpotential, for which they are responsible, $\eta_{pE_F{}^*}$, should correspond to the difference between the quasi Fermi level for holes and the standard redox potential for the hydroxyl ion discharge.

$$\eta_{pE_F{}^*} = \frac{{}_pE_F{}^* - {}^\circ E_{Redox}}{zF} = \frac{{}_pE_F{}^* - E_F}{zF} + \frac{E_F - {}^\circ E_{Redox}}{zF} = -\frac{kT}{zF}\cdot \ln\left(1 + \frac{\Delta_p{}^*}{p_o}\right) + \frac{E_F - {}^\circ E_{Redox}}{zF} \quad [7]$$

In this relation $\Delta_p{}^*$ represents the change of the hole concentration when the semiconductor is illuminated and E_F is the Fermi level in the bulk. p_o, which is the equilibrium concentration of holes, can be expressed in terms of the bandgap of the semiconductor (n-type)

$$p_o = \frac{N_c N_v}{N_D}\cdot \exp^{-E_G/kT} \quad [8]$$

(N_c, N_v are the densities of states in the conduction and valence band, respectively, N_D is the donor concentration, and E_G the energy gap.)

For larger energy gaps ($E_G \gtrsim 1$ eV) which corresponds to a situation in which $\Delta_p{}^* >> p_o$, relation [7] can be rewritten with relation [8] to give

$$\eta_{pE_F{}^*} = -\frac{kT}{zF}\ln\frac{\Delta_p{}^* N_D}{N_c N_v} - \frac{E_G}{zF} + \frac{E_F - {}^\circ E_{Redox}}{zF} \quad [9]$$

In order to get a kinetic equation for the photoinduced discharge of hydroxyl ions on semiconductor electrodes, we substitute in Eq. [6] (e_o is an energy depending on the work function)

$$\eta = \Phi_{SE} + \frac{e_o}{F};\quad e_o \to e_o - F\eta_{pE_F{}^*}$$

We obtain the equation

$$\Phi_{SE} - \frac{\Delta H^\ddagger}{\bar{a}zF} + \frac{E_G}{zF} - \frac{E_F - {}^\circ E_{Redox}}{zF} - = \frac{RT}{\bar{a}F}\ln\xi - \left(1 - \frac{1}{\bar{a}z}\right)\psi_o - \frac{e_o}{F} - \frac{kT}{zF}\ln\frac{\Delta_p{}^* N_D}{N_c N_v} \quad [10]$$

We can simplify it by comparing electrodes with similar work functions (contained in e_o), similar densities of states, and similar donor concentrations, in which light produces a comparable concentration of holes which may initiate an equivalent photoelectrochemical reaction ($\bar{a}$ and z can be assumed to be 1). In this case the right side of Eq. [10] becomes a constant which is characteristic for a specific reaction (different for OH^- oxidation and photocorrosion) and a criterion for the photodischarge of hydroxyl ions or the onset of another photooxidation may be seen in the condition

$$F\Phi_{SE} - \Delta H^\ddagger + E_G - (E_F - {}^\circ E_{Redox}) > \text{Const} \quad [11]$$

with

$$\text{Const} = \frac{RT}{\bar{a}}\ln\xi - \left(1 - \frac{1}{\bar{a}z}\right)F\psi_o - e_o - \frac{kT}{z}\ln\frac{\Delta_p{}^* N_D}{N_c N_v}$$

It is interesting that this relates the potential dependent electrical energy which is provided at the interface $F\Phi_{SE}$, and the potential dependent difference between Fermi level and redox potential ($E_F - {}^\circ E_{Redox}$) with the energy of activation of an oxidation reaction ($\Delta H^\ddagger$) and the energy gap (E_G). It should therefore be possible to utilize it for the discussion of kinetic factors affecting an electrode's photoelectrochemical stability and reactivity with water. A comparison of magnitudes which are to be expected for the different quantities in relation [11] is instructive. The energy gap of photoelectrodes may vary between 4 and 1 eV. The difference between the Fermi level and the redox level is between ~1.5 eV (photoelectrolysis) and 0 eV (photoassisted electrolysis). The energy of activation for the discharge of OH^- ions or water molecules is more difficult to estimate. For platinum surfaces which show a relatively high overpotential, the activation energies obtained in acid solutions vary between 0.53 and 0.61 eV, in alkaline solutions between 0.36 and 1.1 eV (40). They are much lower for catalytically very active ruthenium-, osmium-, or iridium-electrodes. We estimate a practical variability of $\Delta H^\ddagger$ between 0.1 and 1.2 eV. The potential drop in the semiconductor-electrolyte interface Φ_{SE} in [11] may be expressed by the simplified relation (43)

$$\Phi_{SE} \approx \delta_H \frac{\epsilon}{\epsilon_H}\left(\frac{d\Phi}{dx}\right)_S - \chi_{dipole} \quad [12]$$

δ_H is the thickness of the Helmholtz double layer, ϵ and ϵ_H are the effective dielectric constants of the semiconductor and of the Helmholtz double layer, respectively; χ_{dipole} is the contribution of oriented dipoles in the Helmholtz layer and of the electric momentum in the surface of the semiconductor, and $(d\Phi/dx)_S$ is the field strength at the semiconductor surface. The latter can be written down in terms of the potential drop $\Delta\Phi$ in the space charge region and the Debye length L (n_o is the bulk concentration of electrons) (44)

$$\left(\frac{d\Phi}{dx}\right)_S = \frac{\Delta\Phi}{L} = \Delta\Phi\sqrt{\frac{4\pi e^2 n_o}{\epsilon kT}} \quad [13]$$

The electrical energy $F\Phi_{SE}$, which is available at the semiconductor electrolyte interface for the support of electrochemical reactions, is thus composed of a largely potential independent term due to the dipole orientation and a potential dependent one which is strongly affected by the Debye length and the dielectric constant of the semiconducting material. Between intrinsic semiconductors ($n_o \approx 10^{14}$ cm^{-3}) and metallic solids ($n_o \approx 10^{22}$ cm^{-3}) the Debye length varies from $L \approx 10^{-4}$ to $L \approx 10^{-8}$ cm. For moderately doped semiconductors ($n_o < 10^{+18}$ cm^{-3}), the electrical field (13) in the surface ($\Delta\Phi$ = 1V) will stay below 10^{+6} V/cm (43) but it could reach 10^7 V/cm in degenerate semiconductors ($n_o \approx 10^{20}$ cm^{-3}). At suitable photoelectrodes the contribution $F\Phi_{SE}$ may thus be systematically increased by controlling solid state parameters. Layer-type transition metal compounds which have very high absorption coefficients and apparently also high diffusion lengths for holes could, for example, be made highly conducting (provided surface recombination does not become a problem). If photodecomposition is kinetically inhibited (holes on d-energy bands) an electrical field could build up at the interface until water molecules can participate in the photoreaction. We estimate the possible contribution of $F\Phi_{SE}$ between 0 and 0.4 eV. If these values are inserted into relation [11]

$$(0 \text{ to } 0.4) - (0.1 \text{ to } 1.2) + (1 \text{ to } 4) - (0 \text{ to } 1.23) > \text{Const}$$

one immediately realizes the importance of the energy gap. If the gap is between 3 and 4 eV as in u.v.-

absorbing oxides used for photoelectrolysis of water (41), contributions from the electric energy in the interface and from the activation energy are of secondary importance. As long as the discharge of OH^- ions can efficiently compete with the photocorrosion there is no difficulty in obtaining oxygen evolution. If one, however, intends to utilize visible light ($E_G \lesssim 2$ eV) the first two terms become important. In order to accomplish an oxidation of water, one will have to choose systems which are especially catalytic, thus requiring a low activation energy $\Delta H^{\ddagger}$. If possible, a reasonably high electrical field should be created at the semiconductor surface. Simultaneously the activation energy for the photodecomposition of the semiconductor itself should be made as high as possible to suppress corrosion.

It seems to be possible to understand the different electrochemical behavior of MoS_2 and ZrS_2 in terms of relation (11). Since bandgaps and flatband potentials of these systems are comparable, the first two quantities become decisive for the path of the photoelectrochemical reaction. Since the generation of holes does not mean a disruption of chemical bonds in MoS_2, the activation energy for photocorrosion into molybdenum ions and sulfur is so high that an electrical field may build up at the electrode surface (a positive displacement of the photocurrent onset from the flatband potential could be an indication). A low activation energy for the discharge of hydroxyl ions may cooperate to accomplish a photoreaction with water. At ZrS_2 interfaces, where holes are equivalent to breaking essential bonds, a low activation energy for the photodecomposition into zirconium ions and molecular sulfur determines the overall reaction.

Some words might be added to further explain the complete Eq. [10] from which the simplified relation [11] has been derived. Like Eq. [6] for metals it is a relation defining the overpotential needed for the discharge of OH^- ions at semiconductor electrodes and could also be used for the discharge of other species, including the oxidation of the surface itself. It can be seen that it depends on a larger number of quantities, including the entropy of activation, the transfer coefficient for the discharge process, the work function of the material, and its density of states. Most probably it could further be elaborated. The photoinduced discharge of OH^- ions (or photocorrosion) will proceed when the overpotential is trespassed, this is when condition [11] is met. In the general case the quantity taken as "Const" will vary from system to system, but could have a comparable value for the same reaction proceeding at different semiconductors with a similar density of states and work function. If one intends to learn about conditions which have to be met during light-induced oxygen evolution, such a relation could be an interesting subject for testing and improving.

Conclusions

The analysis of the photoelectrochemical behavior of ZrS_2 and its comparison with that of MoS_2 have emphasized the importance of considering kinetic quantities when searching for low-gap photoelectrodes which should be stable or react with water. Differences in the activation energies for electrochemical reactions can drastically change the reaction mechanism. In addition, the study suggests an energetic advantage of providing an electrical field at the semiconductor-electrolyte interface for the purpose of stimulating photoelectrochemical reactivity with water. At ZrS_2 interfaces there is, in contrast to MoS_2, neither a specific photoelectrochemical interaction between the crystalline solid and OH^- or I^- ions which decreases the activation energy for oxidation, nor is there a kinetic inhibition for the anodic release of metal ions which leads to the corrosion of the material. ZrS_2 behaves similarly to CdS and appears not to be an especially interesting material for conventional electrochemical solar cells. However, as discussed elsewhere (26), it might be possible to exploit its electrochemical property of forming energy storing intercalation compounds at low electrode potentials and to develop solar powered intercalation batteries. The comparison of ZrS_2 with MoS_2 has clearly underlined the peculiar nature of photoelectrochemical mechanisms involving holes on d-orbitals of transition metal compounds and their advantage in accomplishing energetically demanding oxidation reactions.

Relation [11] suggests two different strategies for achieving a photodecomposition of water with electrodes absorbing visible light. One is to make $\Delta H^{\ddagger}$ for the photocorrosion mechanism high (holes on d-bands, semiconductors containing insoluble cations), the other one is to make $\Delta H^{\ddagger}$ for the discharge of hydroxyl ions as low as possible (semiconductors containing catalytic metals such as Ru, Os, Ir). Any possibility for creating a supporting electric field at the site of OH^- discharge should be exploited. It might be more reasonable to accomplish photoelectrolysis with a small supporting electrical potential than to do it without externally supplied electrical energy at a much lower efficiency.

Current Limited by Transport Through the Space-Charge Region of a Semiconductor Electrode

David L. Ullman*

Littleton, Colorado 80161

ABSTRACT

Recently, work was published in *This Journal* on the observation of cathodic current saturation with respect to oxidant species concentration, on the wide-gap, low mobility, n-type semiconducting oxides TiO_2 and $SrTiO_3$. These results were interpreted in terms of a kinetic model involving electron transfer through surface states. In the present paper, an alternative explanation is put forward, as suggested by the title, and a detailed comparison made with the trapping kinetic model. The transport-limited model is quantitatively developed, using the simple depletion-region approximation, and to the extent the published data allow, comparison made with the experimental results. The relative strengths and weaknesses of the two competing theories are clearly shown. A quantitative test for distinguishing between the two mechanisms is suggested.

Recently, an experimental study was published in *This Journal* concerning the mechanism of faradaic reaction at semiconductor electrodes by Vandermolen *et al.* (1). These authors observed that, at constant *p*H and electrode potential, the cathodic current through TiO_2 and $SrTiO_3$ electrodes would initially rise with increasing concentration of solution oxidant species, and then reach a limiting value. From this, they inferred the presence of a discrete energy level in the bandgap on the surfaces, mediating charge transfer to solution species. This is a quite rational mechanism, and one yielding a solid fit to the experimental data. However, these results seem to be unique, in that such current saturation with respect to reactant solution species concentration has not, to our knowledge, been observed before.

There is considerable indication from experiments, both electrochemical (2, 3) and high vacuum (4), that surface states occur on semiconductors and may play a role in faradaic reaction. However, while discrete levels apparently can mediate current flow at "reverse biased" semiconductor-electrolyte Schottky barriers (5), Vandermolen's results are apparently the first indication that they might also govern "forward" faradaic currents.

For this and other reasons to be discussed below, it seems worthwhile to test this interpretation against an alternative hypothesis that seems able to explain the experimental results at least equally as well. This hypothesis is that the actual faradaic kinetics are simple first order (6), and current limitation is due to transport resistance in the space-charge region. This possibility seems all the more likely when we recall that TiO_2 and $SrTiO_3$ are characterized by quite low carrier mobilities, while nearly every other material so investigated has charge carriers with mobilities of at least 100 cm^2/Vsec, and no such saturation is observed. In fact, this possibility did occur independently to Vandermolen, and was also suggested by a reviewer

Key words: photoelectrochemical cells, semiconductor electrode, space-charge region, $SrTiO_3$, TiO_2.

when the paper was submitted for publication, but this interpretation was rejected for the reason to be described later (7). In the present paper, we provide an analytic technique for distinguishing between the two mechanisms, and provide a possible, testable solution to the objection that led originally to rejection of the transport-limited model.

The Models

The central result of Vandermolen's analysis is (1)

$$-j = e_o N_{ts} \frac{k_1 n_s c_{ox} - (k_{-1}k_{-2}/k_2) c_{red}}{(k_{-1} + k_1 n_s + k_{-2}c_{red})/k_2 + c_{ox}} \quad [1]$$

which may be restated as

$$j = j_{sat} c_{ox}/(A + c_{ox}) \quad [2]$$

where

$$-j_{sat} = e_o N_{ts} k_1 n_s = e_o N_{ts} k_1 N_D e^{-\phi} \quad [3]$$

$$A = [k_1(n_1 + n_s) + k_{-2}c_{red}]/k_2 \quad [4]$$

In Eq. [4], we have written n_1 for k_{-1}/k_1. For brevity, all terms are defined in the List of Symbols. We use the convention that cathodic current is negative.

It was also noted that experimentally, j_{sat} had the following potential dependence

$$\ln|j_{sat}| = \{\ln|j_{sat}|\}_{V=0} - \alpha \mathbf{F} V/RT \quad [5]$$

with α close to unity.

For the transport-limited model, we begin with a fairly general expression for simple first-order faradaic kinetics

$$-j = e_o(k_c c_{ox} n_s - k_a c_{red}) \quad [6]$$

Then, writing the equation for electron flux in a semiconductor, and using the simple depletion approximation for potential in the space-charge region, as suggested in MacDonald (8), we find the expression for net current at the interface, including transport resistance

$$-J = (e^{-\phi} - e^{-\phi_o})/(1/\sigma_t + \mathrm{Daw}(\sqrt{\phi})) \quad [7]$$

where, again, terms are defined in the List of Symbols. Details of the derivation and definition of the Daw function are given in the Appendix, where, for generality, dimensionless variables are used. Since it involves the depletion region approximation, we term this analysis depletion region transport theory, or DRTT.

Inspection of tabulated values of Dawson's integral shows that it may be well approximated by (9)

$$\mathrm{Daw}(\sqrt{\phi}) = (0.500 + 0.40/\phi)/\sqrt{\phi} \quad [8]$$

with an error of no more than 3% for $\phi \geqq 2.50$.

Equations [1] and [7] may be written in the same form, showing the rather strong mathematical similarity between these two physically very different models. Since they play no significant role, we neglect any terms involving c_{red} or anodic current

$$-j/e_o = \frac{k_1 N_{ts} N_D e^{-\phi} \cdot k_2 c_{ox}}{k_1(n_1 + N_D e^{-\phi}) + k_2 c_{ox}} \quad [9]$$

$$-j/e_o = \frac{(D_n N_D e^{-\phi}/\lambda\, \mathrm{Daw}(\sqrt{\phi})) \cdot k_c c_{ox}}{D_n/\lambda\, \mathrm{Daw}(\sqrt{\phi}) + k_c c_{ox}} \quad [10]$$

where we have written $N_D \exp(-\phi)$ for n_s and $k_1 n_1$ for k_{-1} in the trapping model, and used dimensional variables in the DRTT expression. Upon comparison of Eq. [10] with Eq. [2], we may write for the DRTT

$$-j_{sat} = (e_o D_n N_D/\lambda)(e^{-\phi}/\mathrm{Daw}(\sqrt{\phi})) \quad [11]$$

$$A = D_n/(k_c \lambda \mathrm{Daw}(\sqrt{\phi})) \quad [12]$$

It is seen that each model may be represented as two resistances in series, which may be approximately described as a conduction band-to-surface resistance, followed by a surface-to-solution resistance. In the models, the latter are practically identical; to distinguish the mechanisms, it is necessary to determine observable differences in predicted behavior of the former resistances.

We may use Eq. [11] to find α for this case, $= -d \ln|j_{sat}|/d\phi$

$$\alpha = \tfrac{1}{2}\sqrt{\phi}\mathrm{Daw}(\sqrt{\phi}) \quad [13]$$

We see that, at constant potential, the j *vs.* c_{ox} behavior predicted by both models is essentially identical and also that j_{sat} depends only on space-charge potential and not on the identity of the redox species, as was seen experimentally. That the trapping kinetic model predicts α equal to unity is seen immediately from Eq. [3]. Comparison of Eq. [8] and [13] shows that the DRTT yields values of α slightly less than unity for large ϕ. From Eq. [3] and [11] we see that there should be no dependence of j_{sat} on pH, other than through the variation of ϕ resulting from pH-induced changes in V_{FB}. Since the dependence of j_{sat} on ϕ is qualitatively quite similar for the models, the j_{sat} *vs.* pH behavior should be indistinguishable.

For nonadsorbed solution species, charge exchange must occur across the Helmholtz layer, so we expect pH-induced Helmholtz potential variations (manifesting as variation in V_{FB}) to influence the process, as Butler-Volmer type behavior on metallic electrodes is attributed to changes in Helmholtz potential. Then, using the same reasoning as is used to derive the Butler-Volmer equation (10), we find

$$k_c = k_c^o \exp(-(1 - \alpha_H)(\phi_H - \phi_H^o)) \quad [14]$$

Myamlin and Pleskov (11) arrive at a similar conclusion. An essentially identical expression may be written for k_2, which in the trapping kinetic model also describes electron transfer directly to solution species.

Comparing Eq. [4] and [12], we see that the dependence of A on k_c in the DRTT is identical to its dependence on k_2 in the trapping kinetic model. Thus, at least at constant space-charge potential (constant $V - V_{FB}$), the models predict identical dependence of A on pH; that is, plots of log A at constant ϕ against V_{FB} or pH should test the validity of Eq. [14], regardless of which mechanism is the actual one.

Contrasts Between the Models

In contrast to the trapping kinetic model, the DRTT yields an expression for j_{sat} having no adjustable parameters, and is thus fairly readily tested in this respect, provided that reasonably reliable values of the input can be measured independently. As we shall see below, this may be a problem with respect to V_{FB}.

If n_1 is not too large, the trapping kinetic model predicts that current saturatian with respect to n_s (like that observed with c_{ox}) should be observed at sufficiently negative electrode potentials. That such behavior was not reported suggests that the surface states must be taken as energetically rather close to the conduction band, that is, that $n_s << n_1$ at all investigated potentials. This is because if the ratio n_s/n_1 was at any given potential even a few percent, making the electrode only a fraction of a volt more negative would induce the condition $n_s >> n_1$, which, at low c_{ox}, would give current saturation.

This poses no problem for the DRTT, which predicts that no such saturation should be observed. But this makes the observed potential dependence of A rather difficult to account for by the trapping model, since we have ruled out as insignificant the only explicitly potential dependent term appearing in the expression for A, Eq. [4]. It is still conceivable, **admittedly,** that

the trapping parameters may change as a result of interaction with the charge carriers, whose concentration varies with potential.

On the other hand, the potential dependence of A is quite explicit in the DRTT expression Eq. [12], and readily lends itself to experimental test even in the face of uncertainty in V_{FB}, by the following rearrangement

$$[A\sqrt{\phi}\mathrm{Daw}(\sqrt{\phi})]^2 = (D_n/\lambda k_c)^2(e_o/kT)(V - V_{FB}) \quad [15]$$

This form is of interest to us because, as seen from Eq. [8], $\sqrt{\phi}\mathrm{Daw}(\sqrt{\phi})$ is rather insensitive to the value of ϕ for $\phi \gtrsim 10$. It is apparent that plots of lhs against V (at constant pH and constant identity of oxidant species) should yield a straight line, from whose slope and intercept we extract k_c and a new value of V_{FB}. This iterative process ultimately yields an optimum value of V_{FB}. Because of the rather weak dependence of lhs on V_{FB}, convergence should be fairly rapid. Depending on the accuracy warranted, approximation [8] or interpolations from tabulated values of Dawson's integral (9) may be used.

There are other implications of the DRTT interpretation that are of interest. One of these is the clear implication of first-order faradaic kinetics, which is demonstrated as follows. If we neglect the term in c_{red} of Eq. [6], and use this as the definition of k_c

$$k_c = -j/e_o c_{ox} n_s \quad [16]$$

then the mathematical development leading to Eq. [7] is just as valid, only now k_c is dependent on n_s and/or c_{ox} if the reaction is not simple first order. In particular, we see from Eq. [12] and [16]

$$A \propto n_s^{1-\alpha_n} c_{ox}^{1-\alpha_o} \quad [17]$$

where α_n and α_o are the true reaction orders. Thus, plots such as the authors' Fig. 4 (1) clearly demonstrate that $\alpha_o = 1$, since otherwise the slope could not be constant. Since n_s depends on j as well as on ϕ (Eq. [A-5]), the apparent value of A would have to change (as n_s changes) unless α_n also equals 1.

Such simple first-order reactions have been observed, as noted by the authors, on ZnO (12). We note here that the electron mobility of ZnO is about 180 cm^2/Vsec (13), about 30 times that for $SrTiO_3$, and at least 10^2 times that for TiO_2 (below), thus relegating transport resistance in this case to insignificance.

Another, and for us a more critical implication of the model, is that j_{sat} is actually a limiting current, corresponding to zero n_s (Eq. [A-5]) or infinite $k_c c_{ox}$ (Eq. [7]), and, being analogous to the Levich limiting current for a rotating disk electrode, cannot under any circumstances of fixed space-charge potential be exceeded, regardless of the assumed kinetic model. Thus, observed values of current greater than the computed j_{sat} must imply some error in the input data, or some violation of the assumptions under which the model is derived.

Comparison of DRTT Values of j_{sat} with Experiment

We find sufficient data in the article to allow at least approximate comparison between theoretical and experimental values of j_{sat}. We begin with the case for TiO_2 in Fig. 3 and 4 of Vandermolen *et al.*

V_{FB} at pH 0 is reported as −0.30V *vs.* SHE; this was probably extrapolated from a measurement at pH 2 at the rate of 60 mV/pH. Thus V_{FB} at pH 2 is probably close to −0.42V. We have shown, theoretically, that a rate of flatband potential variation with pH less than 59 mV/pH is more reasonable than otherwise (14); published data from the Gent laboratory (15) fairly clearly imply a rate of variation close to 50 mV/pH for hydrogen-doped TiO_2. Using this slope, we estimate a V_{FB} at pH 4.7 of −0.555V *vs.* SHE. With $V = 0.056$, $V_{sc} = 0.611$V and $\phi = 23.9$.

For the (001) of TiO_2, $\epsilon = 173$ (16). N_D is reported to lie in the range 10^{18}-10^{19} cm^{-3}. Wilson (3) quotes a value of μ_n for TiO_2 of about 1 cm^2/Vsec; a more recent measurement yields a Hall mobility of 0.24 cm^2/Vsec (17).

With this data, we may calculate maximum and minimum values for the limiting current, using Eq. [A-2], [A-3], [8], and [11]. We find 2.4×10^{-5} and 1.8×10^{-7} A/cm^2, corresponding to the high and low values of N_D and μ_n, respectively. These compare with the value in Fig. 3 of 2.0×10^{-5} A/cm^2 (1).

For $SrTiO_3$, V_{FB} at pH 0 was determined to be −0.60V *vs.* SHE, although considerable uncertainty in this value is admitted to. We infer a V_{FB} at pH 2 of about −0.72V. For $V = 0$, $V_{sc} = 0.72$ and $\phi = 28.1$.

Again N_D is in the range 10^{18}-10^{19} cm^{-3}; literature values for ϵ and μ_n are 307 (18) and 6 cm^2/Vsec (19), respectively. These inputs imply high and low values for j_{sat} of 1.7×10^{-6} and 5.2×10^{-8} A/cm^2, for which the common logarithms are −5.8 and −7.3, respectively. Comparing these with points 1 and 2 on curve b of the authors' Fig. 5, we see that even the high computation appears well over an order of magnitude below the curve. Recalling that current cannot exceed the DRTT value of j_{sat}, this result seems to corroborate the unreliability of the measured V_{FB}.

Acknowledging this uncertainty, we recalculate using a V_{FB} 0.20V more positive than the above, as recommended by the authors both in the article under discussion and in Ref. (18). We obtain values of log $|j_{sat}|$ between −2.5 and −4.0, and this time, the smaller value appears to lie quite close to curve b of Fig. 5.

While we cannot draw hard conclusions from these calculations, it is nonetheless interesting that the experimental values of j_{sat} lie within the range computed with DRTT. It is of course needless to point out the desirability of calculations using more accurate input, but we point out that it may be more consistent to use V_{FB} values found from Eq. [15].

The Weakness of the DRTT

The limiting-current concept brings us, finally, to a fundamental discrepancy between the DRTT and experiment, evident particularly in Vandermolen's Fig. 1, curve a. According to the DRTT, when the current is near j_{sat}, it must change with electrode potential at a rate close to 1 decade/60 mV, and this is presumably the rate in the high-current portion of the curve. However, the lower portion has a rate of change obviously much shallower than this.

It is stated that the curve was obtained in "sufficiently concentrated" oxidant, implying that the upper portion is in fact reasonably close to j_{sat}; but if the upper portion is extrapolated at 1 decade/60 mV to more positive potentials, it is immediately apparent that the experimental points are at least an order of magnitude above the extrapolation. As we pointed out, this is impossible for the case of transport limitation. But since these currents are observed, a logical inference is that all currents observed are below their transport-limited values, and it is another effect, trapping kinetics, that yields the observed saturation with respect to c_{ox}.

Because of the lack of data, and the hazard of extrapolation values of V_{FB} over several units of pH, any attempt to quantitative comparison seems rather futile. But the qualitative evidence seems sufficient to make the point. These curves were rather highly reproducible on several different samples (7), and, considering also the long experience of the Gent group in making these measurements, this would seem to rule out artifactual origins of the lower part of the curve.

Another explanation for the lower part of the curve suggested by the authors (1), besides surface states, was hole injection by the oxidant species. However, it

may be shown that the surface hole concentration in TiO_2 in equilibrium with an equimolar solution of each of these redox couples is quite small, and in the case of the $Fe(CN)_6^{3-/4-}$, vanishing. This would appear to rule out significant participation by holes.

However, an interesting possibility put forward by Tomkiewicz (20) involves a mechanism of flatband potential change due to a high concentration of surface states, which capture electrons as the electrode is made more negative, thus changing their charge. This causes a change in the Helmholtz potential, manifesting as a shift in V_{FB}.

We criticized Tomkiewicz's work on the basis of the fact that when this shift occurred, there were practically no electrons at the surface in his case (21). In the present case, the surface electron concentration is much more substantial. These states, of course, do not directly participate in faradaic reaction.

If such a shift does occur, it should be apparent in Mott-Schottky measurements. We see that Mott-Schottky plots reported by the Gent laboratory on TiO_2 (22) and $SrTiO_3$ (18) are shown only for potentials 1V or more positive of apparent V_{FB}; on the other hand, values of V_{sc} involved here in the computation of j_{sat} are less than 1V. It is possible that impedance measurements made at more negative potentials than previously would reveal such a shift.

Summary

In summary, we find four reasons that we feel merit the investigation of possible transport (as opposed to kinetic) limitation of the current on TiO_2 and $SrTiO_3$, as observed by Vandermolen *et al*: (*i*) Absence of similar observations on other, and in particular, high-mobility materials; (*ii*) absence of current saturation with respect to n_s; (*iii*) experimental values of j_{sat} that lie within the range estimated using the DRTT; and (*iv*) the dependence of A on potential. In short, with the exception of the lower portion of the j-V curves, the published data imply electrode behavior highly consistent with the predictions of the DRTT. We feel that a good fit of the data to Eq. [15], yielding values of V_{FB} reasonably close to those obtained by impedance measurements, would almost conclusively prove the transport-limited mechanism, since it would really be expecting too much of coincidence for a mysterious potential dependence of trap behavior to occur in such a manner that it mimics transport limitation.

Clearly, we welcome discussion and criticism from these workers, and hope they see fit to investigate our interpretation with a reasonably open mind. We are not insensitive to the amount of labor involved in measuring even a single value of A, but it was remarked that several of these had already been computed, and considering the novelty of these results, it may be worthwhile to expend the necessary effort to compute more, if needed.

Whichever theory proves correct, it is clear that these are extremely novel results with important implications for the theory of operation of semiconductor photoelectrochemical cells. Finally, we wish to remark that this episode should demonstrate the wisdom of entertaining all reasonable interpretations of experimental work when publishing, even if a particular one is favored over the others.

Acknowledgment

The study on which this work is based was done at the University of California, Berkeley, Dept. of Chemical Engineering, under a U.S. Dept. of Energy grant.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

APPENDIX

Current Flow Through a Space-Charge Region

From the simple depletion-region approximation (23), we find the potential profile in the space-charge region

$$\Phi = -y^2 e_o N_D / 2\epsilon\epsilon_o$$

where we choose $y = 0$ at the boundary between the space-charge region and the quasi-neutral bulk. In dimensionless form

$$\phi = -(y/\lambda)^2 = -x^2 \qquad \text{[A-1]}$$

$$\lambda^2 = 2\epsilon\epsilon_o kT/e_o^2 N_D \qquad \text{[A-2]}$$

The one-dimensional equation for electron current is

$$j/e_o = D_n dn/dy - \mu_n n d\Phi/dy$$

This may, with the aid of the Nernst-Einstein relationship

$$\mu_n = D_n e_o/kT \qquad \text{[A-3]}$$

also be written in dimensionless form

$$J = dN/dx - N d\phi/dx$$

Using the integrating factor $\exp(-\phi)$ for rhs, this becomes

$$J e^{-\phi} dx = d(N e^{-\phi}) \qquad \text{[A-4]}$$

Substituting [A-1] into [A-4], and integrating with the boundary conditions

$$N = 1, \quad \phi = 0 \quad \text{at} \quad x = 0$$

$$N = N_s, \quad \phi = -\phi_{sc} \quad \text{at} \quad x = \sqrt{\phi_{sc}}$$

and recalling that J is constant, we find, after rearrangement

$$J = (N_s - e^{-\phi_{sc}})/\text{Daw}(\sqrt{\phi_{sc}}) \qquad \text{[A-5]}$$

where Dawson's integral

$$\text{Daw}(x) = e^{-x^2} \int_0^x e^{t^2} dt$$

is tabulated in Ref. (9).

Equation [6] of the text may be restated as

$$-j = e_o k_c c_{ox} (n_s - n_{so})$$

and written in dimensionless form

$$-J = \sigma_t (N_s - e^{-\phi_o})$$

since clearly $N_{so} = e^{-\phi_o}$. We may use this to eliminate N_s in [A-5], and obtain Eq. [7] of the text. We have dropped the subscript on ϕ_{sc} for brevity.

Upon examining the mathematical properties of the Daw function, we uncover some rather interesting implications of the model. First, we note that the function has a maximum of about 0.54 occurring at about $\phi = 0.85$, and rather slowly, but monotonically, decreases from this point, approaching zero as ϕ approaches infinity. At rather large space charge potential, $\phi = 60$ ($V_{sc} \approx 1.5$V), Daw$(\sqrt{\phi}) = 0.065$. It is apparent, then, that the Daw function is rather slowly varying, much more so than $\exp(-\phi)$, which explains the result $\alpha \approx 1$ (Eq. [11] and [13]).

We see from Eq. [7] that three basic regimes are implied, namely, transport limited ($1/\sigma_t << $ Daw), kinetically limited ($1/\sigma_t >> $ Daw, by far the most common case), and intermediate, in which the terms are roughly equal.

We have tested Eq. [7] against exact numerical solution of the transport equations (24) and found, not surprisingly, that the largest errors occur for transport limitation. For $1/\sigma_t = 0$, Eq. [7] predicts J about 45% too large at $\phi = 4$, but this error decreases to 7% for $\phi = 9$, and decreases with increasing ϕ. Since we deal with j on a logarithmic basis, we shall rather arbitrarily take $\phi > 4$ ($V_{sc} > 0.10$V) as the condition for model validity. In this domain, Daw$(\sqrt{\phi})$ has a maximum of 0.30 at $\phi = 4$.

Because of this slow variation of the Daw function, it is apparent that, for the case of simple first-order kinetics, transition from one regime to another solely as a result of electrode potential variation is quite unlikely. In fact, if we take 0.15 as a representa-

tive value of the Daw function, we can compare $1/\sigma_t$ with this value to determine the approximate extent to which an electrode is transport limited.

If the kinetics are not simple first order, $1/\sigma_t$ must be evaluated as

$$1/\sigma_t = e_o D_n n_s / \lambda |j| \quad [A-6]$$

In most such cases, $|j| \propto n_s^{\alpha_n}$, with $0 < \alpha_n < 1$. This means that transport limitation is more likely at low current densities, and can undergo a transition to kinetic limitation at higher currents. This should manifest as a Tafel slope variation from about 60 mV/decade at low C.D.'s to some higher value at high C.D.'s.

It is apparent that it is chiefly the quantity $\mu_n n_s/|j|$ that determines whether a particular case will be transport limited or otherwise. Unfortunately, because of the difficulty of placing an upper limit on $|j|/n_s$, it is not possible to determine a value for μ_n, above which transport limitation cannot occur. However, it appears from experience that significant transport effects are at least unlikely for materials with carrier mobilities of at least 100 cm²/Vsec. For example, our examination of Morrison's (12) data for first-order cathodic reaction on ZnO ($\mu_n = 180$ cm²/Vsec) indicates that, even if the Daw function takes on its maximum value (= 0.54), the maximum error incurred by neglect of transport effects is 3%, for the case of smallest $1/\sigma_t$.

A similar investigation of transport in illuminated electrodes is under way.

LIST OF SYMBOLS

Terms not defined here or in the text have their usual meaning.

- A — empirical parameter appearing in j vs. c_{ox} plot; see Eq. [2], mol/liter
- c_{ox} — concentration of oxidizing species of redox couple, mol/liter
- c_{red} — concentration of reducing species of redox couple, mol/liter
- e_o — elementary charge, 1.602×10^{-19}C
- j — current density, negative when cathodic, A/cm²
- j_{sat} — limiting value that current reaches as c_{ox} increases indefinitely; see Eq. [2], A/cm²
- J — dimensionless current, $= \lambda j / e_o D_n N_D$
- kT/e_o — $= RT/F = 0.0256$V
- k_1 — electron capture rate constant for surface states, cm³/sec
- k_{-1} — rate of electron emission by traps, sec⁻¹
- k_2 — parameter for transfer of electrons from occupied surface states to solution oxidant species, 1/mol sec
- k_{-2} — parameter for oxidation of reduced solution species by vacant surface states, 1/mol sec
- k_a — anodic rate constant, 1/mol cm² sec
- k_c — cathodic rate constant, cm 1/mol sec
- n_1 — trap parameter, $= N_C \exp((E_t - E_C)/kT)$. In the present case, it equals k_{-1}/k_1. See Ref. (23), p. 129-134, cm⁻³
- n_{so} — surface equilibrium electron concentration at zero current flow, $= k_a c_{red}/k_c c_{ox}$, cm⁻³
- N — dimensionless electron concentration, $= n/N_D$
- N_{ts} — density of surface states, cm⁻²
- V_{sc} — space-charge potential, $= V - V_{FB}$, volts
- α — empirical parameter governing the experimental current-voltage behavior, Eq. [5], dimensionless
- α_H — Butler-Volmer coefficient, having a value between 0 and 1, governing variation of faradaic reaction kinetic parameters due to change in Helmholtz potential, dimensionless
- ϕ — dimensionless space-charge potential, $= e_o V_{sc}/kT$, text; dimensionless electrostatic potential in space-charge region, $= e_o \Phi/kT$, Appendix
- ϕ_o — dimensionless space-charge potential corresponding to zero current flow, $= \ln(n_{so}/N_D)$
- ϕ_H — dimensionless Helmholtz potential; $\phi_H - \phi_H^o = e_o(V_{FB} - V_{FB}^o)/kT$; the superscript o denotes arbitrary reference
- Φ — electrostatic potential in space-charge region, volts
- λ — space-charge region Debye length, Eq. [A-2], cm
- σ_t — dimensionless electron transfer coefficient, $= \lambda k_c c_{ox}/D_n$

Transient Natural Convection near a Plane Vertical Electrode Surface after Reversing the Electrolytic Current

Y. Fukunaka, T. Minegishi, N. Nishioka, and Y. Kondo*

Department of Metallurgy, Kyoto University, Sakyo-ku, Kyoto 606 Japan

ABSTRACT

Time variations of the concentration profile of $CuSO_4$ and of the velocity profile of laminar natural convective flow were measured near the electrode surface during the transient electrolysis after reversing the current. A symmetrical transient variation of natural convection was observed after anodic and cathodic current reversions. It was found that the concentration profile possesses an extreme value, and the inverted flow appears near the electrode surface. The effects of current density and vertical location on the natural convection were discussed. Based on the experimental results, the space-time structure of the transient natural convection was considered.

Among numerous works (1-3) in the past on the natural convective flow along the surface of a plane vertical electrode installed in unstirred electrolyte, only a few works concerned the transient natural convection encountered in the unsteady electrolysis. This is in spite of its importance in the practical operation of unsteady electrolysis, such as periodic current reversal in copper refining, as well as in the study of the nature of transient natural convective flow itself.

Tvarusko *et al.* (4, 5) studied the transient natural convection at the start of electrolysis by applying a technique of Mach-Zehnder interferometry and showed that both the concentration difference of $CuSO_4$ between bulk electrolyte and cathode surface and the thickness of the cathodic diffusion layer increase in proportion to the square root of time elapsed from the start. However, they were not successful in photographing the concentration profile of $CuSO_4$ in the diffusion layer which develops downstream. This is supposed to be due to the severe optical restriction in two-beam interferometry.

Only after the application of a technique of holographic interferometry, it became possible to precisely measure the concentration profile in the diffusion layer near the electrode surface, and the transient cathodic diffusion layer (6, 7) was studied by applying this technique. In addition, the corresponding transient velocity profile was measured by recording the motion of colophonium particles suspended in the cathodic hydrodynamic boundary layer (7, 8).

Following these studies, it is intended in the present work to study the transient natural convection after the direction of electrolytic current is reversed. Time variations of the concentration profile of $CuSO_4$ and of the velocity profile of natural convective flow are measured during the time period from reversing the current until the steady natural convection in reversed direction is established.

Experimental Procedures

The inner dimensions of the glass electrolytic cell were 0.6 cm (thickness), 7.5 cm (width), and 19.7 cm (height). Both tough pitch copper electrodes were 0.5 cm square and 26 cm long. They were insulated with PVC resin except for the working surface of 0.5×8.0 cm^2 between the vertical distance of 4 and 12 cm from the lower edge. Each electrode was vertically installed in the electrolytic cell at a distance of 4.8 cm. Analytical reagent grade $CuSO_4$ and deionized water were used to make up aqueous 0.6M $CuSO_4$ solution. The solution was poured into the electrolytic cell until its surface was positioned at a height of 16 cm from the lower edge of electrodes. With this configuration, equal vertical lengths of insulated surface of 4 cm were maintained on the lower and upper sides of each working electrode, respectively, and the effect of circulating flow of electrolyte was avoided during the measurement. The distance of the electrode surface traversed by the incident beam was 0.5 cm.

The electrolysis was carried out at $23° \pm 1°C$ at the current densities of 1.0, 2.0, and 4.0 mA/cm^2, respectively. The electrolytic current was supplied by a galvanostat. The applied current densities were far lower than the cathodic limiting current which was measured at about 45 mA/cm^2 from the current-potential curve. Thus the uniform distribution of current density along the electrode height was ensured (9). The measuring positions of concentration and velocity profiles at the working electrode surface were, respectively, 2, 4, and 6 cm from the lower edge.

After it was confirmed that the bulk electrolyte was at rest, the electrolysis was started and continued for 10 min to attain the steady state. Then the current was reversed to the same absolute value, and the measurements of concentration and velocity profiles were started. They were made at appropriate time intervals until the reverse steady state was attained.

A technique of holographic interferometry was used for measuring the concentration profile (3). The focal plane was set at the center of the electrode. When the cathodic current was reversed, the interference fringes started to shift upward as shown in Fig. 1, and an extreme value of concentration appeared adjacent to the electrode surface. The steady anodic concentration profile was gradually attained in which the interference fringes were deflected upward.

The horizontal interference fringes in the bulk electrolyte were extended to the electrode surface, and the number of intersecting points with the shifted fringes, N, was counted. The concentration was calculated by the following equations

$$(n^* - n)d = N\lambda \quad [1]$$

$$n = 1.3332 + 27.89c \qquad (0.19M < c < 0.72M \text{ at } 23°C) \quad [2]$$

The latter Eq. [2] is the regression of the refractive index upon $CuSO_4$ concentration in the above concentration region. The deflection of the incident beam in the boundary layer was corrected by the procedure

* Electrochemical Society Active Member.

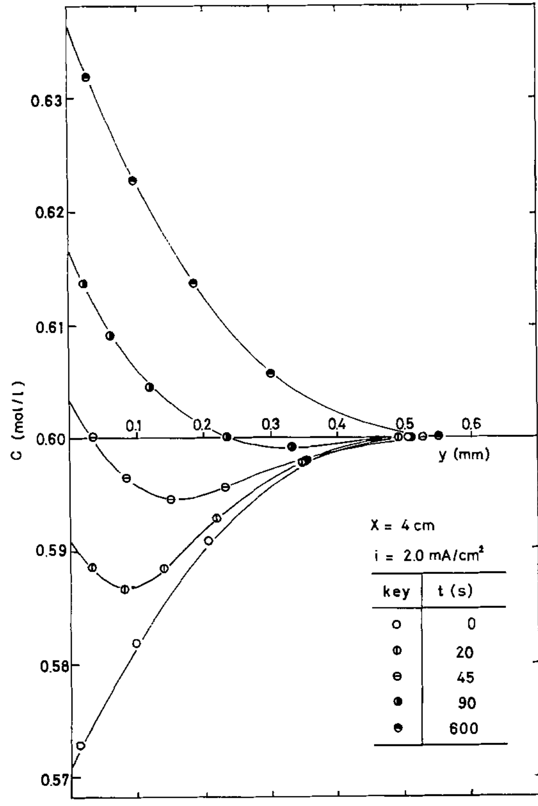

Fig. 2. Concentration profiles during the unsteady process after reversing the direction of current (cathodic to anodic).

mentioned before (10). The reproducibility in the measurement of concentration profile at the same height was excellent because of the same optical configuration. On the other hand, due to a slight difference in the configuration which was inevitable in the adjustment of electrode surface parallel to the incident beam, the reproducibility in the measurement at various heights was slightly lower. However, this error was less than about 8% to the total variation and was negligible as far as the transient behavior of the concentration profile was concerned.

The measurement of velocity profile was described in a previous paper (11). An aqueous suspension of colophonium particles of 5-10 μm size was prepared by sedimentation and poured into the electrolyte. Before recording the motion of colophonium particles dragged along with the natural convective flow, a thin nylon fiber was vertically hung along the center of the working electrode, on which the incident beam was focused. The electrode was adjusted to be parallel to the beam by rotating it around the vertical axis. The drift of colophonium particles on the cinefilm was measured by using a NAC DF-1613/MB film motion analyzer.

Results and Discussion

The transient concentration profile at $x = 4$ cm after reversing the cathodic current of 2 mA/cm^2 is shown in Fig. 2. As seen in this figure, an extreme value appeared adjacent to the anode surface after the current was reversed and moved toward the bulk electrolyte. The remaining cathodic diffusion layer almost disappeared at 90 sec from the current reversal, and the anodic concentration profile gradually grew to the steady profile.

Time variation of velocity profile of natural convective flow is shown in Fig. 3. The experimental conditions were the same as above. It is seen that the velocity of natural convection uniformly decreased in the whole region of hydrodynamic boundary layer during the initial 60 sec. A downward flow appeared in the vicinity of anode surface at 90 sec, while the remaining flow was still upward in the region apart from the surface. Along with further elapsed time, it gradually converged to the downward steady velocity profile.

In order to represent the time variation of concentration and velocity profiles, several parameters were used. They are as follows: the concentration difference between the electrode surface and bulk electrolyte, Δc_s; the thickness of concentration boundary layer, δ; the concentration difference between the extreme value and bulk electrolyte, Δc_ξ; the distance between the electrode surface and the position of the extreme value, ξ; the maximal velocity of natural convection, u_m; and the horizontal distance between the electrode surface and the position of u_m, τ.

They are schematically illustrated in Fig. 4. Dual u_m and τ values were observed in the so-called inverted flow which appeared at 90 sec from the current reversal as shown in Fig. 3.

In the first place, the transient natural convection after the cathodic current reversal was compared with that after the anodic current reversal. An excellent symmetry is seen in Fig. 5 between the time variations of Δc_s after the cathodic current reversal at $x = 6$ cm and after the current reversal in the opposite direction at $x = 2$ cm. Both vertical positions correspond to 2 cm from the leading edge of anodic and cathodic natural convective flow, respectively. Similar symmetry was also observed in the time variation of u_m. Based on this symmetrical nature of the natural convection, the following discussion is concentrated on the cathodic current reversal.

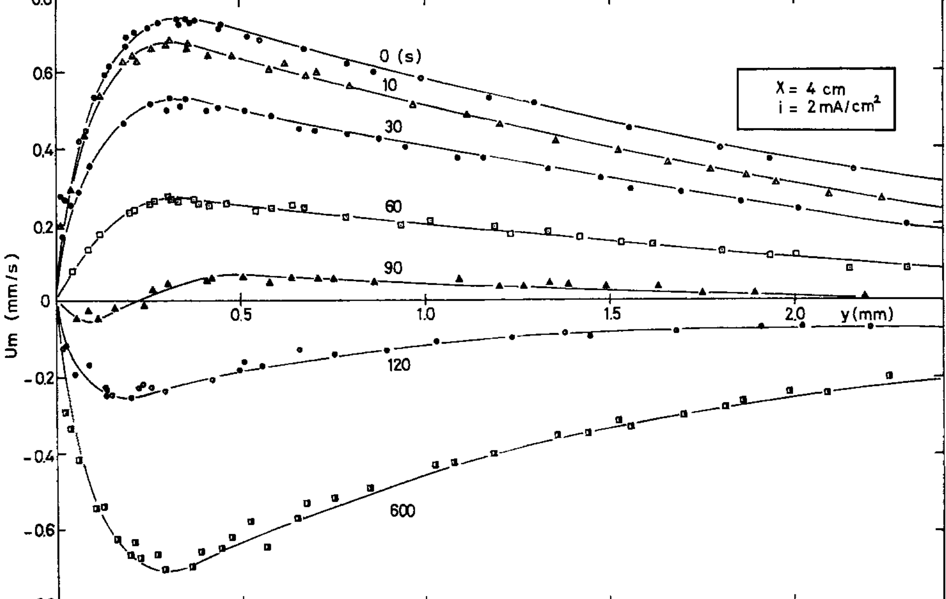

Fig. 3. Time variation of velocity profile (cathodic to anodic).

Time variation of concentration profile.—The time variation of Δc_s at different current densities is shown in Fig. 6. All measurements were made at $x = 4$ cm. It is seen that the rate of change of Δc_s is affected by the applied current density: the required time before Δc_s diminishes to zero is shorter at higher current densities, and Δc_s attains the steady value more rapidly at higher current densities. This is due to the combined effect of higher dissolution rate of Cu^{2+} ion on the anode surface and the broader range of concentration between initial and final steady Δc_s values.

In view of the decrease in velocity of natural convection after the current reversal shown in Fig. 3, it is supposed that the effect of convective mass transfer of Cu^{2+} ion is reduced. Presuming that the effect of convective mass transfer is minor (12), the following diffusional equations approximately hold

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial y^2} \qquad (0 \leq y < \infty) \qquad [3]$$

at

$$t = 0,\ c = f(y) \qquad \begin{cases} f(y) = c^* + (c^* - c^s)(1 - y/\delta)^\omega & (0 \leq y \leq \delta) \\ f(y) = c^* & (y > \delta) \end{cases} \qquad [4]$$

$$y = 0, \quad -D\frac{\partial c}{\partial y} = \frac{i(1 - t_1^*)}{z_1 F} \qquad [5]$$

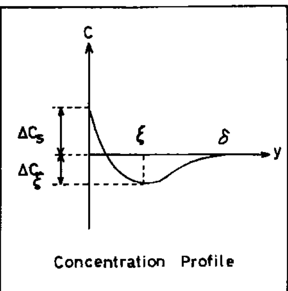
From these equations, we have

$$\Delta c_s = \frac{1}{\sqrt{\pi D t}}\left[\frac{2i(1 - t_1^*)}{z_1 F}t - \Theta\int_0^\delta \left(1 - \frac{\eta}{\delta}\right)^\omega e^{(-\eta^2/4Dt)}d\eta\right] \qquad [6]$$

where

$$\Theta = 1.49\frac{(1 - t_1^*)}{D z_1 F}\left\{\frac{z_1 F \nu D^2}{g\alpha(1 - t_1^*)}\right\}^{1/5} \cdot i^{4/5} \cdot x^{1/5} \qquad [7]$$

Equation [6] was used to calculate the required time from current reversal to a moment where the concentration at the anode surface becomes equal to bulk electrolyte ($\Delta c_s = 0$) and the time from current reversal to anodic steady state ($\Delta c_s = -\Theta$), respectively. The calculated time was compared with the measurement. As seen in Fig. 7(a) and (b), the variation of the calculated and measured times before attaining $\Delta c_s = 0$ and $\Delta c_s = -\Theta$ due to the applied current



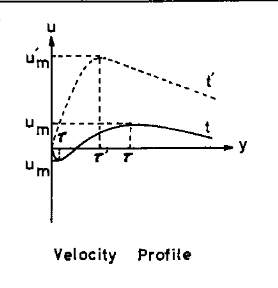


Fig. 4. Schematic illustration of concentration and velocity profiles.

density is very similar, though the calculated time is shorter than the measurement due to the assumption of neglecting convective mass transfer in Eq. [6]. It is also interesting to note that these current density dependences are roughly approximated to a power of -0.4 under the present experimental conditions.

The theory of transient natural convection was developed in the field of heat transfer where the rate of heat transfer on the surface of a vertical plate was studied (13, 14). Gebhart (14) obtained the result that the rise of a dimensionless temperature which is defined as the rise of the mean temperature along the height divided by the total rise of temperature up to the steady value is described by a function of the dimensionless time of

$$T = \alpha' t/\bar{\delta}^2 \qquad [8]$$

It is also clarified in a wide range of Prandtl number that the effect of transient natural convection can be neglected until almost 80% of the steady value is reached and the steady state is virtually realized at 0.4 of the dimensionless time.

From the analogy between heat and mass transfer, the required time before the steady natural convection is attained in the present unsteady electrolysis is given by

$$t = 0.4\,\bar{\delta}^2/D \qquad [9]$$

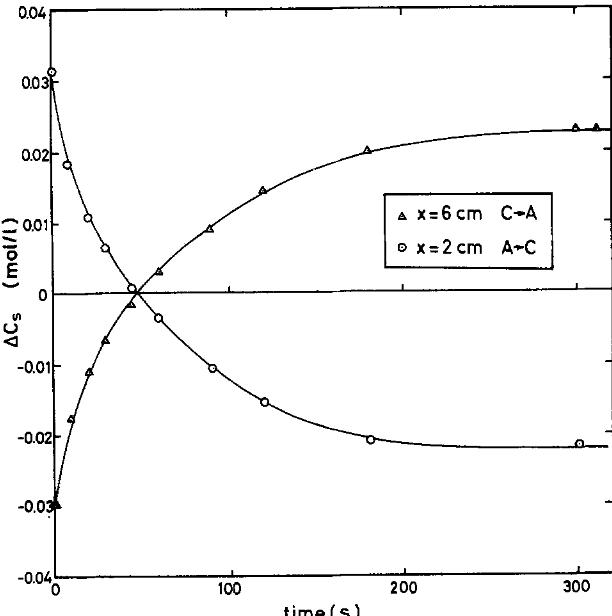

Fig. 5. Symmetrical transient variation of concentration difference at the electrode surface.

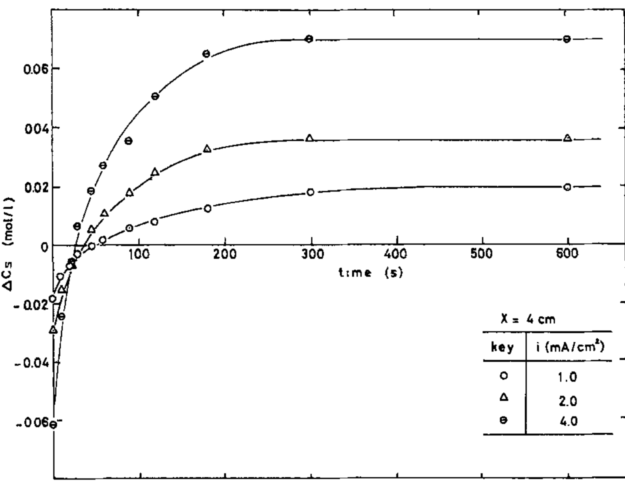

Fig. 6. Time variation of Δc_S along the elapsed time at x = 4 cm.

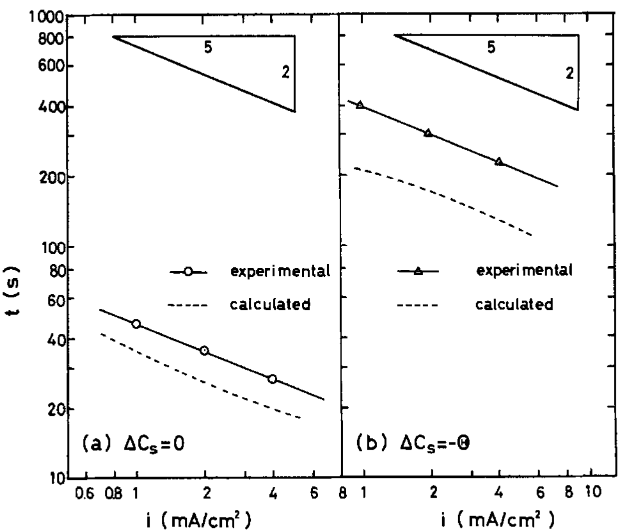

Fig. 7. Current density dependence of the time before Δc_S reaches zero value and $-\Theta$.

On the other hand, it is known that the thickness of the concentration boundary layer is proportional to $i^{-1/5}$ at the steady state (3). Then the relationship of

$$t \propto i^{-2/5} \quad [10]$$

is obtained, which was shown in Fig. 7.

It should also be noticed that Eq. [8] was derived from the consideration of a vertical plate which is placed in a stagnant fluid and is suddenly heated up with a uniform heat flux along the vertical plate and that the analysis was carried out by applying the similarity of velocity and temperature profiles in the vertical direction, respectively. Though these conditions are not directly applied to the present system of current reversal as seen in Fig. 2 and 3, the same dependence on the driving force was shown in both cases of heat and mass transfer. This may be related to the insensitiveness of the adopted profiles in the analysis using the integral method.

The natural convective flow develops downstream. The time variation of Δc_S at different vertical locations is shown in Fig. 8. When the initial and final Δc_S values at various vertical locations are compared, it is seen that they are the same at $x = 4$ cm and that the initial Δc_S value at $x = 2$ and 6 cm is equal to the final value at $x = 6$ and 2 cm, respectively. It is due to the symmetrical character of natural convection mentioned before.

No significant difference was found among the elapsed time before attaining the anodic steady state. The initial Δc_S value at lower vertical locations is smaller (3), and the anodic natural convection affects earlier because of the uniform dissolution rate of Cu^{2+} ion. On the other hand, the anodic natural convection develops downward from the upper edge, and the above-mentioned earlier effect of anodic natural convection is compensated.

This explanation is further supported by the time variation of ξ shown in Fig. 9. It is seen that ξ advances toward the bulk electrolyte and that no evident difference was found among the vertical locations during the initial 100 sec. The effect of natural convection is minor near the anode surface during the inversion of natural convective flow; diffusion and migration are the prevailing mechanisms of Cu^{2+} ion transfer. Due to the virtually uniform dissolution rate of Cu^{2+} ion in the vertical direction on the electrode surface, ξ has no significant dependence on vertical location.

Time variation of velocity profile.—The time variation of u_m at different current densities is shown in Fig. 10. After the current reversal, it linearly changes until the anodic steady value is attained. Corresponding to the time variation of Δc_S shown in Fig. 6, the

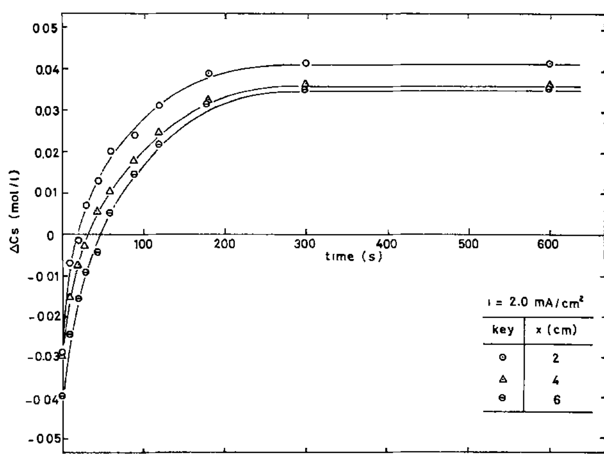

Fig. 8. Time variation of Δc_S along the elapsed time at a current density of 2 mA/cm^2.

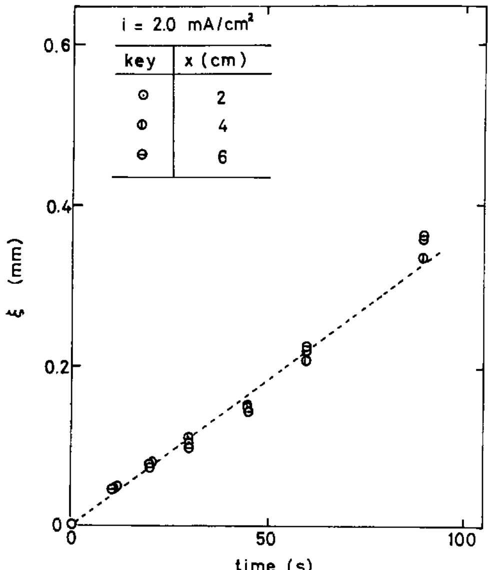

Fig. 9. Time variation of ξ at a current density of 2 mA/cm^2

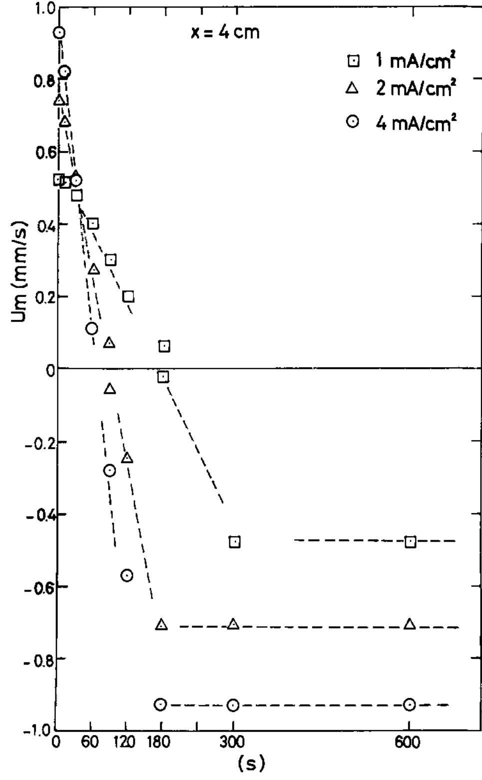

Fig. 10. Time variation of u_m at $x = 4$ cm

rate of change of u_m is higher at higher current densities.

Time variation of τ at different current densities is shown in Fig. 11. During the initial period immediately after the current reversal, τ is maintained at the initial value. After attaining the maximal value, it suddenly falls to the minimal value. Then it again increases to the anodic steady value. This apparently strange variation of τ is simply due to the appearance of inverted natural convective flow during the transition; the newly formed anodic natural convective flow starts to develop from the anode surface, while the remaining cathodic flow is pushed away to the bulk electrolyte where it disappears.

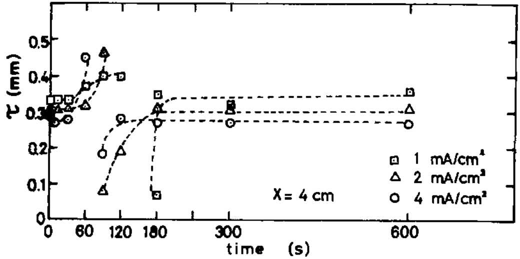

Fig. 11. Time variation of τ at $x = 4$ cm

Space-time structure of transient natural convective flow.—We have tried to visualize the transient variation of natural convection after the current reversal. First, the transient concentration profile near the lower edge of working electrode is shown in Fig. 12. Before the current is reversed, the cathodic diffusion layer is observed on the working cathode surface, while no concentration gradient is observed on the insulated surface below the lower edge. An extreme value appears at 10 sec after the current reversal, but no change is observed on the insulated surface: it is indicated that the direction of natural convection is still upward. After more than 30 sec are passed, a concentration gradient is clearly observed on the surfaces of the working anode and the insulated portion; it is shown that the anodic natural convection starts to flow downward.

Next, the transient concentration profile near the upper edge of the working electrode is shown in Fig. 13. Even before current reversal, a concentration gradient is observed on the upper insulated surface. It is due to the convective mass transfer of Cu^{2+} ion by the upward natural convective flow. After the current is reversed, an extreme value appears on both the sur-

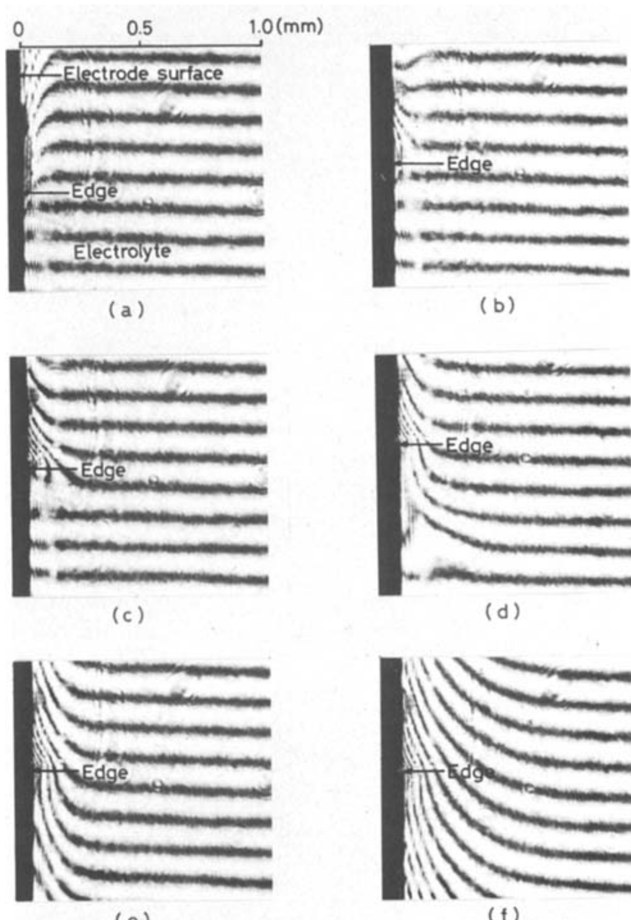

Fig. 12. Holographic interferograms (cathodic to anodic) (a) $t = 0$ sec, (b) $t = 10$ sec, (c) $t = 20$ sec, (d) $t = 30$ sec, (e) $t = 45$ sec, (f) $t = 600$ sec elapsed after reversing the electrolytic current (0.6M $CuSO_4$, $i = 2.0$ mA/cm^2, $x = 0$ cm).

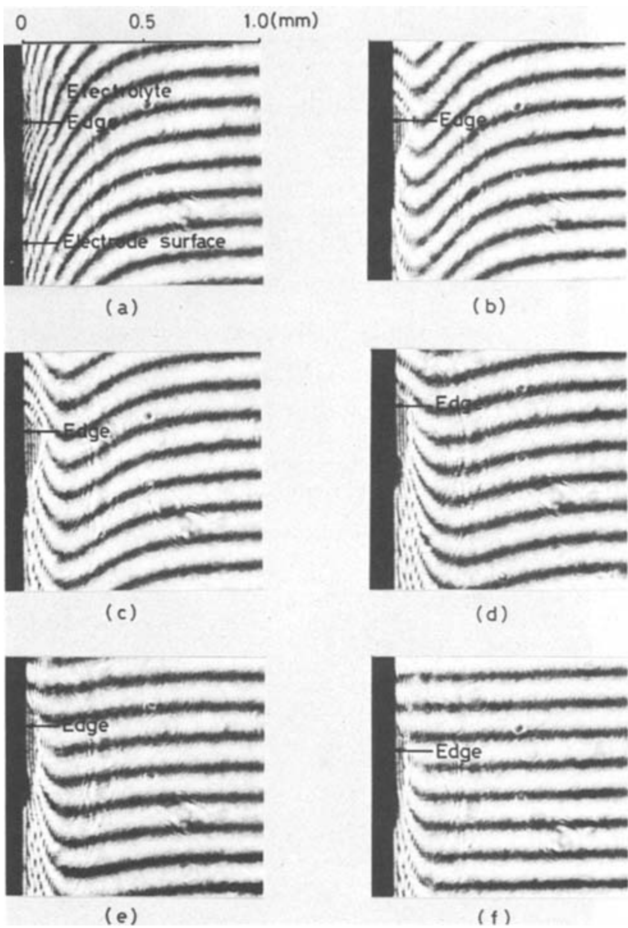

Fig. 13. Holographic interferograms (cathodic to anodic) (a) $t =$ 0 sec, (b) $t = 20$ sec, (c) $t = 45$ sec, (d) $t = 90$ sec, (e) $t =$ 120 sec, (f) $t = 600$ sec elapsed after reversing the electrolytic current (0.6M $CuSO_4$, $i = 2.0$ mA/cm^2, $x = 8$ cm).

faces of the working anode and the insulated portion. One may also note that the latter concentration profile has zero gradient at the surface. The extreme value moves toward the bulk electrolyte, and the anodic natural convection develops. At 600 sec the steady anodic convective flow is established. It is seen that the natural convection originates from the upper edge of the working anode, and no concentration gradient is observed on the insulated surface.

The foregoing observations and consideration lead to a presentation of the space-time structure of transient natural convective flow. It is shown in Fig. 14. In this diagram, the time variation of the velocity profile at different vertical locations is shown in the upper part, and the corresponding time variation of the concentration profile is illustrated in the lower part. The arrows shown in the diagram demonstrate the direction of cathodic natural convective flow.

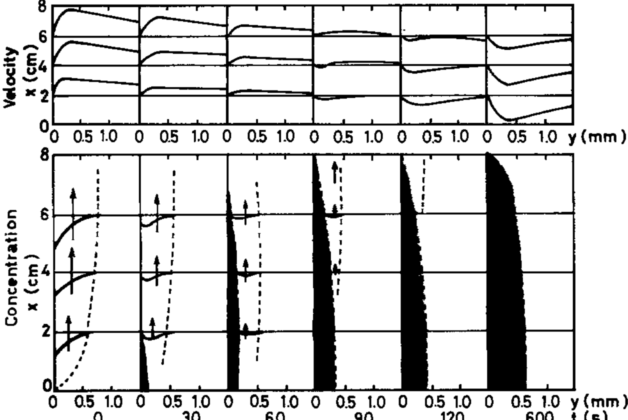

Fig. 14. Transient behavior of natural convection at various heights of electrode (cathodic to anodic).

After 30 sec are passed from the current reversal, an anodic diffusion layer has formed at the lower portion of anode. It continues to grow, though the direction of convective flow is still upward. At 60 sec, this anodic diffusion layer extends to a height of 6 cm from the lower edge, and the direction of natural convective flow starts to turn downward at a height of 2 cm. Along with further elapsed time, this downward natural convection covers the whole surface of the working anode and pushes the remaining upward convective flow away to the bulk electrolyte. At 120 sec, the whole natural convective flow is downward, and the anodic steady state is attained at 600 sec.

Summary

Transient natural convection after reversing the electrolytic current was studied by measuring the concentration and velocity profiles at various vertical locations on the electrode surface. The applied current density was also varied.

When the current is reversed, the concentration profile starts to shift from its original steady, approximately parabolic, shape: an extreme value appears, and it moves from the electrode surface to the bulk electrolyte. Thus the concentration profile evolves to the steady state. Momentum transfer is caused by the convective mass transfer of electrolyte, and thus the velocity of convective flow is decelerated. A new natural convective flow is formed in the reverse direction. It develops in the horizontal direction from the electrode surface toward the bulk electrolyte, until the steady velocity profile is established.

Symmetry between anodic and cathodic transient natural convection was observed. The rate of change of both the concentration at the electrode surface and the maximal velocity of natural convection are higher at higher current densities. The former effect was explained by a simplified mass balance calculation of Cu^{2+} ion near the electrode surface assuming that the convective mass transfer is neglected; while the inversion of natural convection is occurring, the convective mass transfer of Cu^{2+} ion is minor near the electrode surface, and diffusion and migration are the prevailing mechanism of Cu^{2+} ion transfer. It was shown that the required time before attaining the steady state is proportional to a power of -0.4 of the applied current density.

From these observations, a diagram of the space-time structure of transient natural convection was developed.

Electroactive Coatings of Tris(bipyridyl)- and Tris(o-phenanthroline)-Ruthenium(II) Attached to Electrodes via Hydrosilylation or Electropolymerization of Vinyl Derivatives

Pushpito K. Ghosh and Thomas G. Spiro*

Department of Chemistry, Princeton University, Princeton, New Jersey 08544

ABSTRACT

Synthetic methods are given for the introduction of a vinyl group into α,α-bipyridine (bipy) and o-phenanthroline (phen). These groups have been employed to attach $Ru(bipy)_3^{2+}$ and $Ru(phen)_3^{2+}$ to Pt electrodes by (*i*) hydrosilylation followed by polycondensation with the electrode, or (*ii*) cycling the electrode to negative potentials to induce anionic polymerization at the surface. The thickness of silanized films increased linearly with contact time, after an induction period, and also increased with increasing temperature. $Ru(bipy)_3^{2+}$ coatings prepared in this way showed reversible cyclic voltammograms up to about 20 layers. For thicker films the electrode kinetics became increasingly slow, and the amount of electroactive material actually decreased. Silanized $Ru(phen)_3^{2+}$ coatings showed sluggish behavior even at lower coverages. The films were stable upon anaerobic storage (exposure to air reduced stability), but showed electrochemical instabilities. Scanning to potentials sufficiently negative to reduce Ru^{2+} produced immediate loss of electroactivity. Holding the electrode at a potential sufficiently positive to produce Ru^{3+} led to a slow loss of electroactivity, while continuous scanning of the $Ru^{3+/2+}$ wave led to much faster losses (time scale of minutes), the rate increasing with scan rate. A still more rapid loss was observed after scanning the redox wave of ferrocene dissolved in the electrolyte, although the amplitude of the ferrocene wave was nearly undiminished with respect to that observed at an uncoated electrode. Thus the silanized film is permeable to counterions and solution redox species, but is also fragile, and susceptible to disruption by the ion fluxes. Electropolymerization gave a $Ru(phen)_3^{2+}$ coating which was much more stable, showing very little loss upon continuous cycling. However the cathodic peak, but not the anodic peak, gradually became less reversible. A slow conformation change resulting in inhibited counterion efflux from the film upon reduction is suggested. When electropolymerized at a TiO_2 electrode, the $Ru(phen)_3^{2+}$ film, in contact with an aqueous solution containing hydroquinone as mediator, supports a steady photocurrent which is stable for at least 15 hr.

We have previously shown (1) that attachment of $Ru(bipy)_3^{2+}$ (bipy = α,α-bipyridine) to SnO_2 electrodes can be accomplished via hydrosilylation of a vinyl group on one of the bipy rings. Contact with the SnO_2 electrode produces a water-stable coating that shows both electroactivity and photoelectroactivity, albeit with low quantum efficiency. In order to better define the characteristics of this attachment method, we have investigated the electrochemistry of coated platinum electrodes under a variety of conditions. (To avoid complications due to the H_2O oxidation and reduction waves, the measurements were carried out in acetonitrile.) The studies were extended to $Ru(phen)_3^{2+}$ (phen = o-phenanthroline) via a vinyl group attached to phen by a new synthetic route. Finally we have explored the use of electropolymerization, following the recent report by Murray and co-workers (2) that this method also produces stable coatings when applied to complexes with pendant vinyl groups.

Experiment

Synthesis.—The syntheses of 4,4′-dimethyl-2,2′-bipyridine(I) and 4-hydroxyethyl-4′methyl-2,2′bipyridine(II) as well as the synthesis of 4-vinyl-4′methyl-2,2′-bipyridine(III) from (I) via the alcohol (II) (Fig. 1A) have been described previously (1). The preparation of (III) employing the reaction sequence reported below for the synthesis of 4-vinyl-1,10-phenanthroline (Fig. 1B) was also tried, but gave a lower yield.

4-Formyl—1, 10-phenanthroline (IV)[1].—3.68g (3.31×10^{-2} mol) SeO_2 in 35 ml dioxane (4% H_2O) was placed in a 500 ml flask and the temperature gradually raised until all the SeO_2 dissolved (50°C). 4.5g (2.32×10^{-2} mol) of 4-methyl—1,10-phenanthroline (G. F. Smith Chemical Company) in 180 ml dioxane was slowly added to the SeO_2 solution while its temperature was steadily raised to reflux (25 min). Vigorous stirring was maintained during the reaction. After an additional 20 min of refluxing, the solution turned clear and the bottom of the flasks was coated with metallic selenium. The solution was filtered hot and on removal of solvent yielded a solid compound which was laced with colloidal selenium. By redissolving the solid in chloroform, centrifuging to remove the selenium, and subsequently stripping off the solvent (this procedure was repeated four times), all of the unwanted selenium was separated out.

Weight of product = 3.45g (yield 71%); 1R: 1710 cm^{-1} (carbonyl stretch); NMR (60 MHz, $CDCl_3$): 10.55δ (s, 1H, $-\underline{CH}O$), 9.55 — 7.45δ (7H, aromatic protons).

4-Vinyl—1,10-phenanthroline (V).—2g (9.6×10^{-3} mol) of (IV) in 450 ml dry tetrahydrofuran (THF)

* Electrochemical Society Active Member.
Key words: modified electrodes, surfaces, photosensitization.

[1] The use of selenium dioxide in the preparation of quinoline aldehydes has been previously reported (3).

Fig. 1. Synthetic schemes for the preparation of (A) 4-vinyl-4'-methyl-2,2'-bipyridine and (B) 4-vinyl-1,10-phenanthroline.

was placed in a predried 1000 ml three-neck flask equipped with a stirring bar. One neck was closed with a septum and the other two were used for flushing with nitrogen. 3.42g (9.6×10^{-3} mol) of dry (methyl) triphenyl phosphonium bromide (Aldrich) suspended in 10 ml of THF was placed in a separate airless flask and to this was added a solution of n-butyl lithium (9.6×10^{-3} mol). An orange solution resulted almost immediately and this was then syringed into the flask containing (IV). The solution slowly turned milky; after stirring for ~5 hr the reaction was quenched with 30 ml of cold water. The resulting transparent solution was extracted three times with a total of ~900 ml ether. The ether solution was washed once with 100 ml water and then extracted with 350 ml of 1M HCl. The aqueous layer was neutralized (pH 8-10) and extracted with ~750 ml ether. The ether layer was washed once with 100 ml water and dried with anhydrous sodium sulfate. The olefin was recovered from the ether layer.

Weight of product, 1.08g (yield 54%); NMR (60 MHz, $CDCl_3$): 9.1δ (m, 2H, aromatic), 8.2-7.35δ (5H, aromatic), 7.6-5.4δ (3H, vinylic, AMX spin system).

Ru(2,2'-bipy)₂ (4-vinyl—4'-methyl—2,2'-bipy)²⁺ (VI) was prepared as reported previously (1) from Ru(2,2'-bipy)$_2$Cl$_2$ · 2H$_2$O. *Ru(1,10-phen)$_2$Cl$_2$ · 2H$_2$O* (VII) was prepared by a procedure analogous to that for Ru(2,2'-bipy)$_2$Cl$_2$.

Ru(4-vinyl-1,10-phen)(1,10-phen)$_2^{2+}$(PF$_6^-$)$_2$ (VIII) was prepared by heating a solution of ethanol/water (1:1) containing (V) (6×10^{-4} mol) and (VII) (5×10^{-4} mol) for 8 hr at reflux under nitrogen. The hot solution was filtered and the complex was precipitated by the addition of a saturated solution of NH_4PF_6. The solid was collected, washed first with a total of 25 ml H_2O and then with 20 ml ether. Yield 80%. λ max ~450 nm; NMR indicative of both vinylic and aromatic protons.

Hydrosilylation of (VI) and (VIII) to give (IX) and (X), respectively.—A typical procedure is as follows: 1.12×10^{-4} mol of (VI) 1.12×10^{-4} mol of trichlorosilane ($HSiCl_3$), and 2.5×10^{-6} mol of triethylamine (Et_3N) were dissolved in a total of 3 ml acetonitrile (silylation grade, Pierce Chemicals) and was syringed into a flame dried Pyrex tube. The tube was sealed and then heated for 5 hr in an oil bath maintained at 155°-160°C. It was then stored in a refrigerator until ready for use.

Preparation of modified electrodes.—Electrode mounting.—Pt electrodes were prepared by spot-welding a foil of Pt onto one end of a short piece of Pt wire, the other end of which was sealed into a 6 mm OD soft glass tubing. The seal was covered with silicone rubber (Dow) to avoid thin-layer effects. Contact to the external circuit was made with the help of a mercury pool. TiO_2 electrodes[2] were mounted by attaching a Cu wire onto the back side of the electrode and passing the wire through Pyrex tubing. The contact was first fastened with a drop of epoxy cement and then all exposed metal was insulated with silicone rubber.

Pretreatment.—Pt electrodes were anodized in 0.5M H_2SO_4 by holding the potential at 1.9V *vs.* SCE for 5 min, cycling between 1.23 and −0.25V for 2 hr (100 mV/sec) and then letting the dark current decay to <1 μA/cm² at 1.1V. The electrodes were then rinsed successively with distilled water and methanol and finally dried under vacuum. The true surface area of Pt electrodes was estimated from the area under the hydrogen adsorption waves in the voltammetric scans. TiO_2 electrodes were etched for 30 sec in conc HCl and rinsed with distilled water before being dried under vacuum.

Silanization.—The electrodes were placed in air-tight tubes maintained under inert atmosphere and containing 2-3 ml of (IX) or (X) (10^{-2}M) in acetonitrile. The reaction temperature was maintained between 25° and 70°C and the reaction time varied from a few hours to a few days. The electrodes were then removed from solution, rinsed several times with dry acetonitrile, dried, and stored under vacuum.

Electrochemical polymerization.—Clean Pt foils and etched TiO_2 electrodes were cycled between 0 and −1.6V *vs.* SCE in an acetonitrile solution containing 5×10^{-4}M (VIII) and 0.1M tetrabutyl-ammonium perchlorate (TBAP, MC/B). After cycling for 30 min at 200 mV/sec, the electrode was removed, rinsed with acetonitrile, and dried under vacuum. Polymer deposition was evident from the yellowish-orange appearance of the electrodes.

Electrochemical and photoelectrochemical measurements were made in an air-tight cell constructed with O-ring joints. The reference electrode (saturated calomel) was placed in a side arm extending into a Luggin capillary. The working electrode and counterelectrode (Pt) were placed in a parallel configuration in the same solution. Two stopcocks allowed the cell to be flushed with nitrogen and light was focused onto the working electrode through an optical window glued onto one side of the cell. The volume of solution in the cell was ~50 ml.

All nonaqueous electrochemistry was carried out using 0.1M TBAP as electrolyte. Cyclic voltammetry was carried out with a PAR Model 175 Programmer, Model 173 Potentiostat, and Model 179 coulometer. Voltammograms were recorded on an X-Y recorder.

[2] The electrode, which was a TiO_2 coating on a titanium metal substrate, was a gift from Pacific Northwest Laboratories.

Photocurrents were generated with a chopped (PAR 125A) Ar^+ laser (Spectra Physics 166) and were measured with a lock-in amplifier (PAR 124).

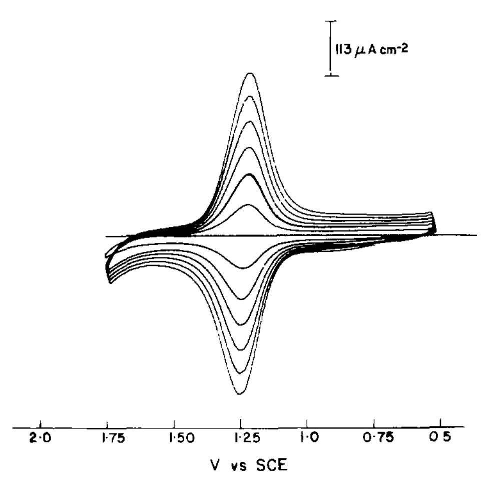
Results and Discussion

Vinyl groups on heterocyclic ligands.—A vinyl group attached to a heterocyclic ligand provides a convenient functionality for relatively stable attachment of transition metal complexes to electrode surfaces. We found previously (1) that hydrosilylation of vinyl-bipy bound to $Ru(bipy)_2^{2+}$, and subsequent condensation with an SnO_2 electrode, produced a water-stable coating, whereas ester or amide links to the electrode were rapidly hydrolyzed. Murray and co-workers (2) have recently shown that this complex, and others that contain vinyl heterocycles, can form stable coatings at electrodes which are simply scanned to potentials negative enough to induce anionic polymerization of the vinyl groups.

In our procedure the ethylene group was introduced (scheme A of Fig. 1) by lithiating 4,4'-dimethyl-bipy, condensing with formaldehyde, and dehydrating the resulting alcohol. The same procedure fails with o-phenanthroline, however, possibly because the Li^+ ions are chelated by the N atoms of phen more effectively than bipy. An alternative route (scheme B, Fig. 1) involving SeO_2 oxidation of 4-methyl-phen, followed by a Wittig reaction, was found to be effective. This procedure did not, however, work as well with bipy, for which scheme A remains the preferred synthetic route.

Hydrosilylation of coordinated vinyl-bipy or vinyl-phen proceeded smoothly to products which formed durable multilayer coatings on anodized Pt electrodes upon prolonged contact in dilute solution. The thickness of the coating could be controlled via the time and temperature of contact, and the results were reproducible, provided the electrodes were anodized by the same procedure. We also found that stable coatings with either species could be obtained by the electropolymerization method.

Silanized film characterization.—Figures 2 and 3 show cyclic voltammograms at the $Ru^{3+/2+}$ redox step for Pt electrodes coated with $Ru(bipy)_3^{2+}$ and $Ru(phen)_3^{2+}$, respectively, via the silanization procedure. The amount of electroactive material is given by the area under the voltammograms and corresponds to 21 and 16 equivalent layers for $Ru(bipy)_3^{2+}$ and $Ru(phen)_3^{2+}$, respectively, assuming that a monolayer contains 9×10^{-11} mol/cm^2, the maximum concentration estimated from space-filling models (4). The $Ru(bipy)_3^{2+}$ electrode behaved nearly ideally, with small peak-to-peak separations, 34 mV, and a linear response of the peak current to sweep rate (5). The $Ru(phen)_3^{2+}$ electrode gave significantly larger peak-to-peak separations and negative deviations from current linearity at higher sweep rates. Increased re-



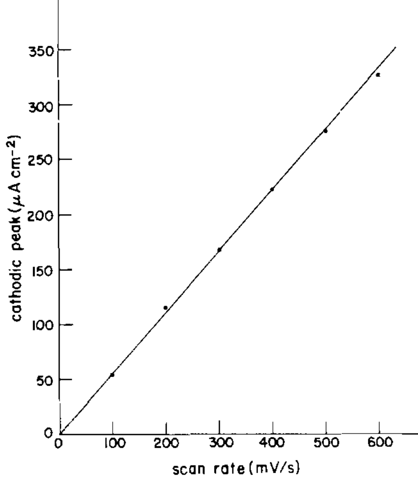


Fig. 2. Voltammograms for a platinum electrode silanized with $Ru(bipy)_3^{2+}$ and cycled at various scan rates (electroactive coverage is ~21 equivalent layers); also shown is the corresponding plot of peak current vs. scan rate. The electrolyte was 0.1M TBAP in acetonitrile.

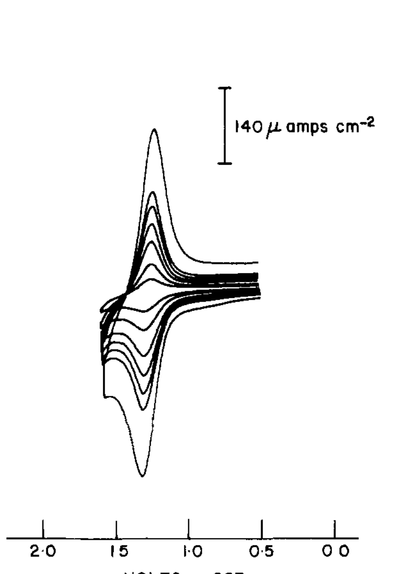

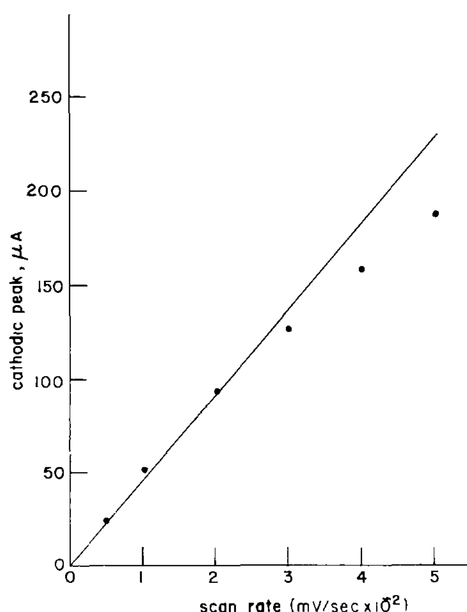

Fig. 3. Voltammograms for a platinum electrode silanized with $Ru(phen)_3^{2+}$ and cycled at various scan rates (electroactive coverage is ~16 equivalent layers); also shown is the corresponding plot of peak current vs. scan rate. The electrolyte was 0.1M TBAP in acetonitrile.

sistance to counterion movements (6) by the bulkier and more rigid $Ru(phen)_3^{2+}$ complexes might be a factor.

The $Ru(bipy)_3^{2+}$ film is quite porous, as evidenced by Fig. 4. The peak current density for the redox wave of ferrocene in solution is only 15% smaller for a coated than for an uncoated Pt electrode. $Ru(bipy)_3^{2+}$ cannot mediate electron transfer from ferrocene, since the redox waves do not overlap. Consequently ferrocene must find its way to the electrode surface to be oxidized. Either the coating, estimated in this experiment to be 14 equivalent layers thick, contains pinholes, or the molecular framework is flexible enough that diffusion of ferrocene to the electrode surface is unimpeded on the voltammetric time scale. This behavior is reminescent of that observed for polyvinyl ferrocene films on Pt electrodes (6, 7).

The thickness of the silanized $Ru(bipy)_3^{2+}$ film increases with the length of time the electrode is exposed to the silylated complex, and with increasing temperature, as illustrated by the data in Table I. At a given temperature the amount of electroactive material in the coating increases linearly with time, as shown in Fig. 5. There is, however, an induction period, of about 5 hr at 25°, indicating a preliminary reaction preceding the process. This might involve prereaction of the silylated complex, perhaps oligomerization, required for effective coating.

The linearity of Fig. 5 requires that all of the $Ru(bipy)_3^{2+}$ in the coating is electroactive, or, less plausibly, that the fraction of electroactive material is constant with increasing thickness. For films thicker than about 20 equivalent layers, the electroactivity

(measured at a given scan rate) begins to decrease, and indeed the absolute amount of electroactive material decreases at higher temperatures and longer contact times, as illustrated in the last three lines of Table I, although the films continue to thicken as evi-

denced qualitatively by the deepening color of the electrode surface. For these thick films the electrode kinetics are slow, as shown by the greatly increased peak separations (ΔE_p) and widths (δ). Presumably the movement of counterions across the increasingly thick films is slowed to the extent that the total number of electrons transferred at a given sweep rate actually decreases. This trend might account for the fact that the ~1000 layer thick coatings deposited on SnO_2 were found to show electroactivity corresponding only to a few layers (1). Since in that case the redox wave appeared to be reversible, this remnant electroactivity might have been due to film heterogeneity, allowing a few counterions rapid access to the electrode.

Table I also shows that the electrode kinetics actually improve somewhat with increasing coverage for the first ten or so equivalent layers (4) contrary to theoretical expectation (8). The electrode with about a monolayer showed significantly broader peaks, and larger peak-to-peak separation, suggesting some heterogeneity at this low coverage.

Film instabilities.—While the silanized films were stable indefinitely under anaerobic storage (exposure to air produced irregularities in the subsequent voltammograms), they were subject to electrochemically induced losses. Figure 6 shows that scanning cathodically past the $Ru(bipy)_3^{2+/1+}$ and $Ru(bipy)_3^{1+/0}$ waves of the silanized $Ru(bipy)_3^{2+}$ films leads to immediate loss of the $Ru(bipy)_3^{3+/2+}$ wave. Similar results were observed with $Ru(phen)_3^{2+}$ films. Evidently, the reduced forms of the complex are unstable. On the hypothesis that the resulting electrode surface might still contain bound but uncoordinated bipy, we tried reconstituting the film with $Ru(bipy)_2(DME)^{2+}$ (DME = dimethoxyethane) which reacts with bipy in solution to form $Ru(bipy)_3^{2+}$ (9). The film was not regenerated by this procedure, however. The source of the reductive instability is not presently understood.

For the silanized $Ru(bipy)_3^{2+}$ films, moderately rapid loss of electroactive material was also observed on repeated scans of the $Ru(bipy)^{3+/2+}$ wave, the rate increasing with the scan rate, as shown in Fig. 7. The curves are not first order, but show a continuous slowing of the loss rate with time. While reactive species might have been generated in the course of the scans, their effect should have been the same for a given exposure time, independent of the sweep rate. A plausible hypothesis to account for the dependence on sweep rate is that the film is disrupted by the movement of counterions accompanying the flow of current, the rate being proportional to the total counterion flux. The flux increases with scan rate, and the slopes of the curves in Fig. 7, at a given coverage, are roughly proportional to the scan rate. On this model the loss of the first 20% of the film electroactivity is accounted for by the disruption of one $Ru(bipy)_3^{2+}$ center per 145 counterion transits (round trip), while the corresponding number for the first 45% of loss is ~190. The slowing of the loss rate is expected if there is a distribution of $Ru(bipy)_3^{2+}$ attachment modes in the film, with varying susceptibility to disruption induced

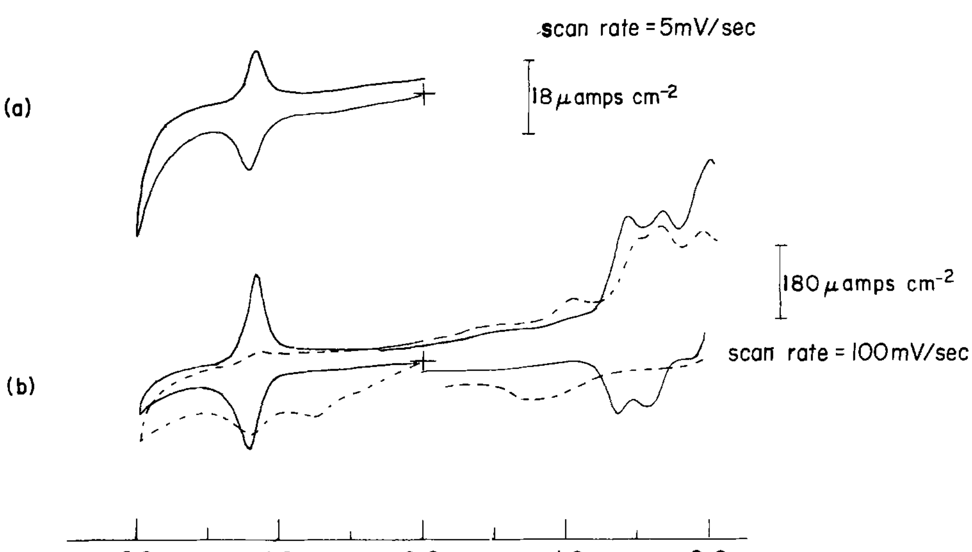

Fig. 6. (a) Single scan of the $Ru(bipy)_3^{3+/+}$ wave of a moderately thick silanized film on platinum. (b) Successive scans of the same electrode extended to the region of the $Ru(bipy)_3^{2+}$ reduction waves. (———) First scan (- - - - -) fourth scan.

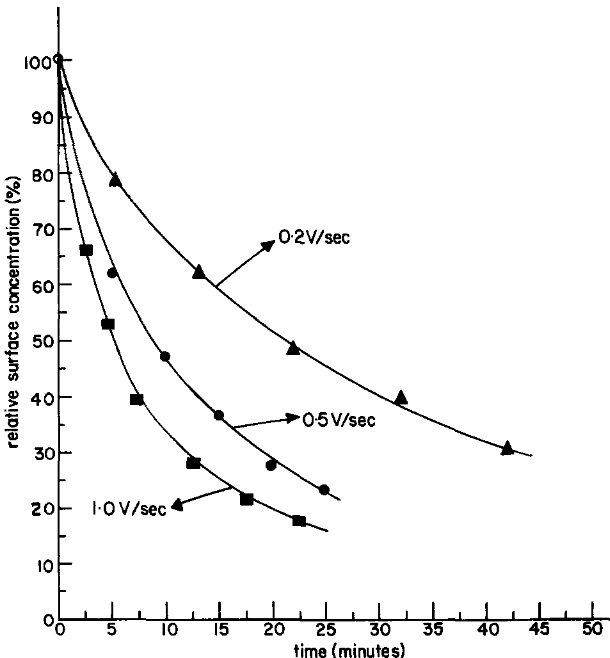

Fig. 7. Electroactive coverage, as percent of original electroactivity, vs. total cycling time, for different values of the scan rate. All three electrodes were identically prepared and had initial coverages of ~5 equivalent layers. They were continuously cycled between 0.5 and 1.75V.

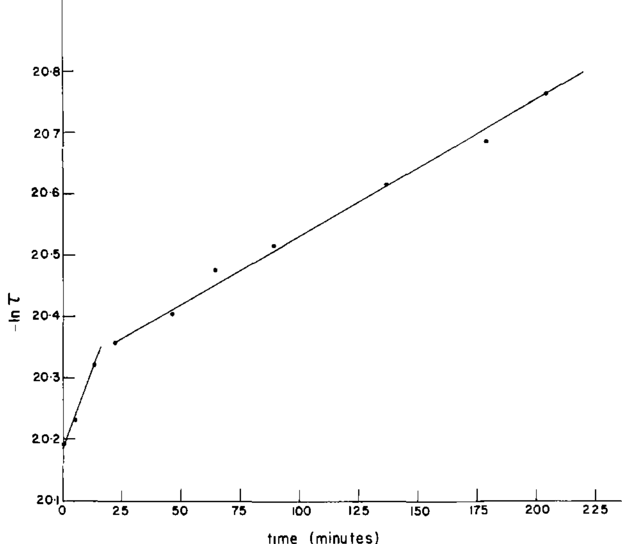

Fig. 8. First-order decay plots (decreasing electroactivity) for a platinum electrode silanized with $Ru(bipy)_3^{2+}$ (~15 equivalent layers) and potentiostated at +1.5V (except to obtain sample voltammograms at various times). (τ = mols/cm^2 of electroactive material.)

by the passage of ions. Space filling models suggest that the silyated $Ru(bipy)_3^{2+}$ (1×) cannot form highly cross-linked polysiloxane networks due to steric crowding. Weak interactions, susceptible to ion induced disruption may be involved in multilayer film formation.

An additional observation supporting this model is that when the electrode was placed in contact with a ferrocene (Fc) solution and cycled over the $Fc^{+/0}$ wave, a rapid loss of $Ru(bipy)_3^{3+/2+}$ activity was again noted (see Fig. 4), even though no electrons passed from $Ru(bipy)_3^{2+}$ during the cycling. While the film did not impede the diffusion of Fc to the electrode surface on the voltammetric time scale (see above), this diffusion, or more probably the outward diffusion of Fc^+, did damage the film. The disruption rate was one $Ru(bipy)_3^{2+}$ per ~20 $Fc^{+/0}$ transits over the first 10% of electroactivity loss.

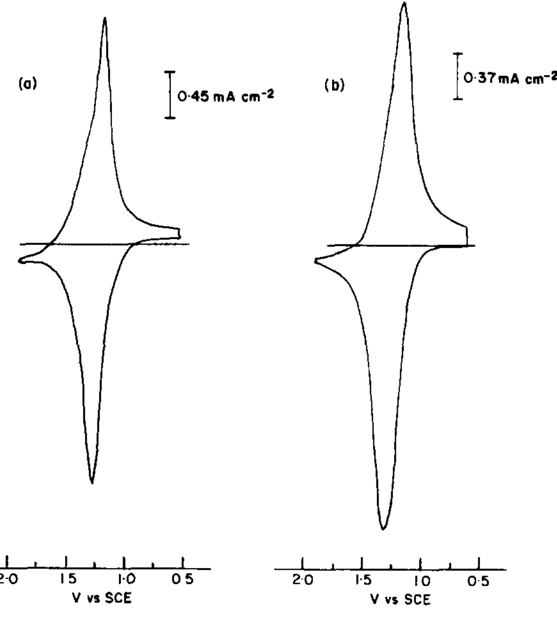
A slower loss of electroactivity was observed when the film was maintained in the Ru^{3+} state. Figure 8 shows that holding the coated electrode at +1.5V led to two successive first-order decay processes, as measured by the $Ru^{3+/2+}$ voltammetric peak area, sampled periodically. The fast process, with $t_{1/2}$ = 72 min corresponds to a 15% loss of electroactivity; the slower process has $t_{1/2}$ = 296 min. Similar decays have been seen for $Ru(bipy)_3^{2+}$ films by Murray and co-workers (4) and attributed to the chemical instability of $Ru(bipy)_3^{3+}$, which has been demonstrated in aqueous solution (10). In view of the present results, however, an alternate explanation is that the slow decay at +1.5V might be due to ion transport associated with the significant background currents observed at this potential. In line with this hypothesis, we observed that the loss of electroactivity is qualitatively higher when the electrode was held at +1.75V, where the oxidation state is still $Ru(bipy)_3^{3+}$ but the background current is higher than at +1.5V.

Electropolymerized $Ru(phen)_3^{2+}$ films.—Pursuant to the demonstration by Murray and co-workers (2) that stable electrode films could be prepared by electropolymerization of $Ru(bipy)_3^{2+}$ with attached vinyl groups, we were able to obtain similar results with $Ru(phen)_3^{2+}$. In our hands the method worked in acetonitrile, but not in dimethylsulfoxide (DMSO). Since vinyl pyridine is subject to anionic polymerization in DMSO (11) we presume that electropolymerization of vinyl-$Ru(phen)_3^{2+}$ may have taken place, but that the resulting polymer was soluble enough in DMSO not to adhere to the electrode. On the other hand, we found that the electropolymerized coating, once formed in acetonitrile, did not subsequently wash off in DMSO.

Like the silanized film, the electropolymerized coating was unstable when the voltage was scanned to sufficiently negative values to reduce the $Ru(phen)_3^{2+}$. Repeated cycling of the $Ru(phen)_3^{3+/2+}$ wave produced a small initial loss in electroactivity (10% during the first 20-30 scans), but very little loss thereafter, in contrast to the silanized films (Fig. 7). The repeated scanning did, however, produce a curious asymmetry in the voltammetric waves, as shown in Fig. 9. The cathodic peak gradually broadened and shifted to less negative potentials, although the anodic peak remained essentially unchanged. Thus there was a progressive slowing of electron transfer from the electrode to the Ru^{3+}, but not from the Ru^{2+} to the electrode. The likeliest explanation is that under the influence of repeated counterion movements the film underwent a slow change of molecular conformation, to a framework appropriate for $Ru(phen)_3^{3+}$. The mobility of anions out of, but not into, the film might thereby have been reduced. It is possible that a similar rearrangement took place in the silanized films, described above, but that the resulting molecular conformation strained the framework too much, producing the observed loss of electroactive material.

Films with >35 equivalent layers of electroactive material imparted a distinct yellow color to the electrodes, which decolorized when the voltage was stepped to values sufficient to oxidize $Ru(phen)_3^{2+}$ to $Ru(phen)_3^{3+}$ (which has much weaker visible absorption). Films of this character might find use in electrooptic devices.

Photostability.—We have previously shown (1) that the silanized $Ru(bipy)_3^{2+}$ coating on n-type SnO_2 supported a steady, albeit low efficiency, photoanodic current when illuminated in the $Ru(bipy)_3^{2+}$ visible absorption band. A gradual (~25% in 2 hr) decay in the photocurrent was observed with continuous illumi-



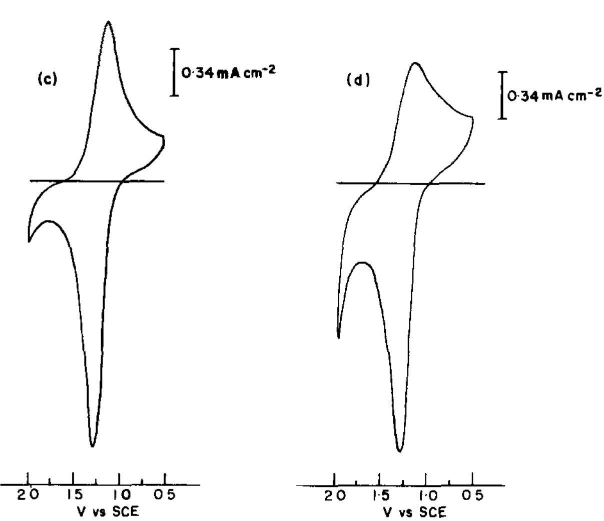


Fig. 9. Tiime evolution of the shapes of the anodic and cathodic voltammetric waves for electropolymerized $Ru(phen)_3^{2+}$ on platinum, cycled between 0.5 and 1.9V. The voltammograms were recorded at a scan rate of 200 mV/sec; initial electroactive coverage was ~80 equivalent layers.

nation. In view of the present results, a contributing factor might have been reductive quenching of $Ru(bipy)_3^{2+}$ via back electron transfer from the heavily doped SnO_2, to produce unstable $Ru(bipy)_3^{+}$ (1).

As shown in Fig. 10, a very stable photocurrent is observed for $Ru(phen)_3^{2+}$ electropolymerized at n-type TiO_2. In this case hydroquinone was added to the electrolyte to discharge the $Ru(bipy)_3^{3+}$ formed on photooxidation. The 476.5 nm Ar^+ laser wavelength is close to the $Ru(phen)_3^{2+}$ absorption maximum, 452 nm. As in the SnO_2 experiments, quantum efficiency was very low (calculated as ~1% if a monolayer was photoactive), but the photocurrent shows no decay during 15 hr of steady illumination. Thus the coating shows no intrinsic photoinstability.

Conclusion

A new synthetic approach to introducing a vinyl group into a heterocyclic ligand has been developed and applied to phen. Both $Ru(bipy)_3^{2+}$ and $Ru(phen)_3^{2+}$, with a pendant vinyl group, can be attached to anodized Pt or TiO_2 in films of controlled

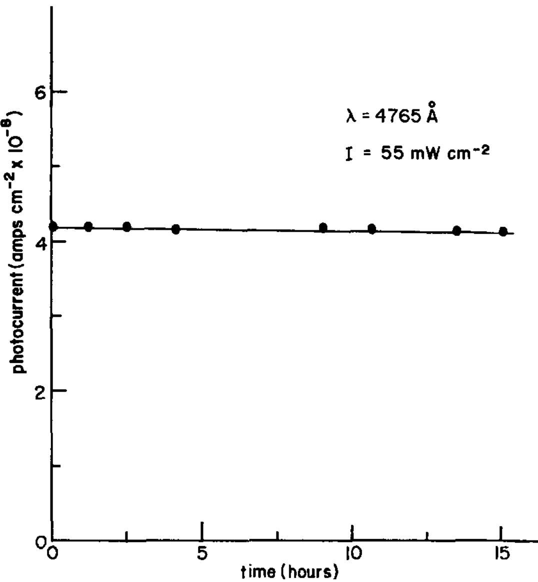

Fig. 10. Anodic photocurrent vs. time for a TiO_2 electrode coated with electropolymerized $Ru(phen)_3^{2+}$, in contact with 0.1M hydroquinone in 0.5M H_2SO_4.

thickness, via hydrosilylation or electropolymerization. The films are stable on storage or to illumination, and support steady, low level photoanodic currents on TiO_2. They show nearly reversible $Ru^{3+/2+}$ redox behavior, but decay slowly upon repeated cycling, and sometimes show evidence of slow conformation change. Immediate decay occurs upon reduction of Ru^{2+}. It can be concluded that while $Ru(bipy)_3^{2+}$ and $Ru(phen)_3^{2+}$ can be stably attached to electrodes, the films remain stable only if the ruthenium is maintained in the 2+ state, through rapid regeneration with solution redox agents.

Kinetics of Color Reversal in Lutetium Diphthalocyanine Oxidation Products Formed with Different Anions

F. A. Pizzarello and M. M. Nicholson*

Rockwell International, Anaheim, California 92803

Lanthanide diphthalocyanines are of increasing interest as multicolor electrochromic display materials (1). Recent work in this laboratory has shown that the anodic oxidation of a lutetium diphthalocyanine film in contact with an aqueous electrolyte occurs with fast migration of anions from the solution into the organic solid to compensate for the loss of electrons (2-4). Reaction I

$$\mathrm{LuH(Pc)_2} + y\mathrm{A}^{-z} \rightarrow \mathrm{LuH(Pc)_2}\cdot y\mathrm{A} + ne \quad (n = yz)$$

Green Red [I]

is accompanied by a color change of the film from green to red. Experimental n values of approximately 2 were found with chloride and sulfate electrolytes. Measurements on moving color boundaries in alumina-supported dye films led to the suggestion of predominant charge transport by the corresponding anions in the oxidation products (2). A radiotracer study then confirmed that stoichiometric quantities of chlorine and sulfur were incorporated in the red forms of the dye (3). Galvanostatic transients in lutetium diphthalocyanine films on tin oxide were interpreted with the same moving-boundary model, although the direction of current flow was then perpendicular, rather than parallel, to the surface of the film (4). The rate-controlling factor for the transients was a space charge in the red phase. Meanwhile, the anion reaction mechanism was proposed independently by Yamana to account for anodically induced color changes in erbium diphthalocyanine films (5).

Red colors persist in oxidized films of lutetium diphthalocyanine for minutes to days, depending on experimental conditions. It was observed in the tracer study that the chloride product on alumina gradually lost its red color and its chlorine content while in contact with ambient air (3). The sulfate film remained red, however, and lost no sulfur in a month. On a tin oxide substrate, the bright red is easily regenerated by application of anodic potentials, and electrical cycling between the red and green states has been repeated many thousands of times (1).

This paper reports a spectrophotometric investigation of the anodic oxidation products formed by lutetium diphthalocyanine films with seven different anions in aqueous solutions. These products differed chemically and spectroscopically from the oxidized diphthalocyanines $\mathrm{PcLnPc_{ox}}$ of lanthanide elements (Ln) isolated by Moskalev *et al.* at a platinum anode in a dimethylformamide-hydrazine hydrate solution (6).

Experimental

Green films of lutetium diphthalocyanine were vacuum-sublimed onto 1.25 × 6 cm strips of single crystal sapphire or Mylar plastic. Details of the specimen preparation were described previously (2). The electrolytes were air-saturated 1M solutions of NaOAc (sodium acetate), KF, KCl, NaBr, KI, $\mathrm{Na_2SO_4}$, and NaOOCΦ (sodium benzoate).

The dye films were converted to red forms by the boundary-propagation technique used earlier (2, 3). For the present study, however, the cell was mounted in a Perkin-Elmer Model 202 dual-beam spectrometer instead of a viewing device. The reference and counterelectrodes were silver foil anodized in samples of the cell electrolytes; lead foil was used in $\mathrm{Na_2SO_4}$. The first absorption spectrum was recorded on the green film with no liquid present. Electrolyte was then added to immerse the lower end of the film, and the red color was propagated upward from the meniscus by application of a constant anodic current through a gold contact at the top of the specimen. When the red area intercepted all of the incident light beam, the current was turned off, and spectra were recorded at intervals for about 24 hr. Since the red film extended only several millimeters above the liquid, it was in contact with moist air throughout the experiment.

Results and Discussion

Yamana noted spectral differences in anodic oxidation products of erbium diphthalocyanine films obtained with various anions on a glass substrate but did not report these differences in detail (5). We observed no significant differences in the initial absorption spectra from 350 to 750 nm for lutetium diphthalocyanine oxidation products containing different anions. The rates of spectral changes that occurred on standing in moist air were dependent on the anion, however, and so were the voltages required to propagate the red color. Three types of behavior that were distinguished are discussed below.

Low propagation voltage and relatively fast reversal from red to green.—These characteristics were observed with acetate and fluoride solutions. Representative absorption spectra for the acetate are shown in Fig. 1, where isosbestic points are clearly evident at 571 and 686 nm. Such common intersection points are a necessary, but not a sufficient, condition for a two-component absorption system (7).[1] As a first approach, it was appropriate to examine the results in terms of a first-order reaction with respect to the red dye species

$$\ln(C/C_0) = -kt \qquad [1]$$

In Eq. [1], C represents the concentration of the red species in the film at a time t, C_0 is its initial concentration, and k is the first-order rate constant for the red-to-green chemical reaction. The data were analyzed for reactant and product components from the film absorbances at 645 and 690 nm. It was assumed that Beer's law held; that the initial spectrum recorded after boundary propagation was that of the oxidation prod-

* Electrochemical Society Active Member.

Key words: diphthalocyanines, oxidation, anions, kinetics.

[1] Isosbestic points would occur, for example, with A → B, A → 2B, or A → B + C.

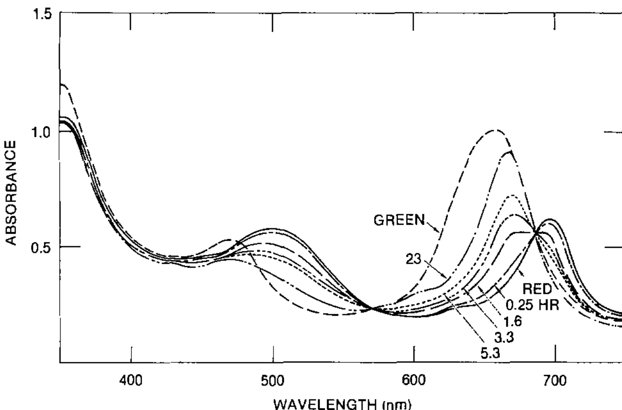

Fig. 1. Absorption spectra of lutetium diphthalocyanine film anodically oxidized in 1M NaOAc. Green denotes original dye film on sapphire; red denotes freshly oxidized film.

uct only; and that a completely reversed film would have the same spectrum as the initial green at the selected wavelengths. Figure 2 includes plots of $\log_{10}(C/C_o)$ *vs.* t for the acetate and fluoride films. The relationships are linear, in conformity with Eq. [I]. Rate constants evaluated from the slopes are given in Table I. The propagation of the red areas with acetate and fluoride solutions began at about 10V with applied currents of a few microamperes. The final voltage, at a propagation distance of approximately 1 cm, was some 60-70V. Thus, the propagating field was of the order of 50 V/cm.

Low to moderate propagation voltage and stable red film.—Propagation of the red color from chloride, bromide, and sulfate solutions also required fields below 100 V/cm. The oxidation products were much more stable than those containing acetate or fluoride ion, however. The absorption spectrum of the sulfate product in moist air was constant for 20 hr. The spectral changes of the chloride films were too small to determine a rate constant in the 24 hr spectrophotometric experiments, but a value of 0.0039 hr^{-1} was evaluated from the earlier tracer data for films in ambient air (3). With bromide ion, the absorption spectrum changed enough in 18 hr that a rate constant of 0.003 hr^{-1} could be estimated from a large-scale linear plot.

High applied voltage and insufficient color propagation.—With iodide and benzoate ions, the color boundary was again initiated at about 10V, but it required nearly 100V to travel 1 mm. Hence, the applied field was of the order of 1000 V/cm, and it was impractical to obtain absorption spectra of red areas propagated in contact with the gas phase. The very large size of the benzoate ion probably hindered the anodic color

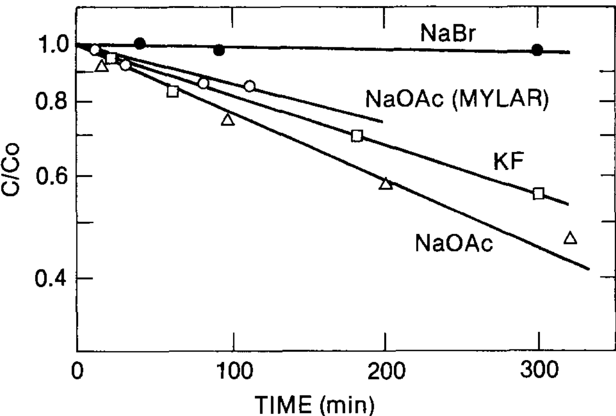

Fig. 2. Plots for determination of first-order rate constants for oxidized films containing different anions. Ordinate is on logarithmic scale.

Table I. Reaction rates of red films containing different anions[a]

Electrolyte[b]	A_{max} (initial)[c]	Current (μA)	k (hr^{-1})	Comments
NaOAc	1.01	2	0.16	
NaOAc	1.37	4	0.09	Mylar substrate
KF	0.86	5	0.12	
KCl	1.00	3	—	Red form stable >18 hr
KCl	1.00	1	0.0039	Propagated from 0.011M KCl; rate measured in ambient air with tracer (3)
NaBr	0.83	2	0.003	Estimated at 18 hr
KI	0.88	5	—	No propagation above liquid
Na_2SO_4	1.11	1-3	—	Red form stable >20 hr in this study; stable >30 days in ambient air (3)
NaOOCΦ	0.64	—	—	Slight propagation above liquid

[a] Dye film on sapphire unless noted.

propagation, and this may have occurred with iodide. It is of interest in this context that Moskalev and Kirina were able to extract iodine anodically from an aqueous iodide solution with a lutetium diphthalocyanine/tin oxide electrode (8). The current flow was then perpendicular to the dye film, however, and with a thickness of 3000Å a field of 1000 V/cm would have caused an overvoltage of only 0.03V.

From the spectral changes such as those in Fig. 1, it is inferred that the organic product of the color reversal was the original green dye or a closely related form such as a hydrate of that compound. Therefore, an oxidized species such as a halogen or oxygen also must have been produced. For the red film containing fluoride, the color change was relative fast, and formation of the elemental halogen may be ruled out thermodynamically. Slow oxidation of water by the organic cation is plausible, however

$$LuH(Pc)_2^{++} \cdot 2F^- + H_2O \rightarrow LuH(Pc)_2 + 2HF + 1/2\,O_2 \quad \text{[II]}$$

Corresponding reactions may be suggested to account for the red-to-green color changes that occurred in the cases of other anions on standing in moist air.

Factors that may determine the rate of color reversal include volatility of the acid formed, mobility of the anion in the organic solid, and the morphology of the film in the red and green states. Red films containing halide and acetate ions, which form volatile acids, were found to be less stable than those containing sulfate. However, the chloride film was more stable than the acetate, even though HCl is more volatile than HOAc. Although the mobility of the anion should depend on its size, the paths available for ionic or molecular transport within the organic solids are also influenced by water and oxygen. We have found, for example, that oxygen is required to propagate the red color from a sulfate solution but not from chloride, while ambient water vapor is needed in both cases (9). Further investigations of these systems are in progress.

An Improved Electrochromic Display Using An Asymmetrical Viologen

Gabriel G. Barna* and John G. Fish*

Texas Instruments Incorporated, Dallas, Texas 75265

During the past decade there has been a concentrated effort (1-7) to develop a passive electrochromic display (ECD) based upon the reversible reduction and oxidation of viologens. The basic structure of these 4,4'-dipyridinium salts is shown below

$$R_1-\overset{+}{N}\langle 0 \rangle-\langle 0 \rangle\overset{+}{N}-R_2 \quad 2X^-$$

where X^- is typically bromide or dihydrogen phosphate. While there has been an investigation of a variety of these compounds with symmetrical alkyl end groups, the majority of the development work has been with salts of 1,1'-diheptyl-4,4'-dipyridinium, that is, where $R_1 = R_2 = (n - C_7H_{15})$. The ability to deposit a uniform purple film onto a transparent electrode (SnO_2) by the one electron reduction of this dipositive cation, has been well established (6). However, it has been demonstrated (3, 7) that while this crystalline film is on open circuit, it reorients into a phase with a higher degree of ordering. This reorientation is postulated to be the cause of the ultimate failure of the display, which is the formation of a visible residue on the segments. The proposed mechanism of this failure mode is that the reoriented film does not completely erase, hence leaving a visible deposit after a certain number of cycles.

The driving force for this open-circuit reorientation of the deposited film has been postulated (7) to be the intermolecular interaction between adjacent viologen molecules. It was therefore assumed that by working with an asymmetrical viologen, with at least one bulky end group, the driving force for the intermolecular stacking would be decreased. This should thus decrease the open-circuit reorientation of the deposited film and hence improve the erase characteristics. While there have been other attempts to develop modified viologens (3), all these species were still symmetrical, *i.e.*, $R_1 = R_2$. This difference is not simply fortuitous; it is more difficult to synthesize an asymmetrical viologen molecule. This paper will describe the preparation of one such molecule, benzyl-heptyl-viologen (BHV), its electro-optical properties, and the improved device performance that it provides.

Synthesis

An equimolar amount of 1-bromoheptane dissolved in acetonitrile (ACN) was added to a −10°C solution of 4,4'-dipyridyl. This mixture was refluxed at 85°C for 2 hr, then cooled to room temperature. The solvent was evaporated off, and the residue washed with cold xylenes. It was then dissolved in chloroform and the 1-heptyl-4, 4'-dipyridinium bromide was recrystallized by the addition of xylenes. The product was a pale yellow powder with a yield of 51%. This intermediate was redissolved in ACN, and was slowly combined with an equimolar amount of α-bromotolune, also dissolved in ACN. This solution was purged with N_2 then stirred over the weekend at room temperature. The bright yellow precipitate was filtered, washed with ACN and $CHCl_3$ (to eliminate any reactants), and dried in a vacuum dessicator. The purity of the product was established by the single peak seen in a liquid chromatogram. The yield for this second reaction was 79% providing an overall yield of 40% for the synthesis of the BHV.

The structure of the product was confirmed by both proton and C^{13} NMR, obtained on a JEOL FX60Q FTNMR, with the sample dissolved in D_2O. The peak positions are referenced to the 2.040 ppm H peak and the 206.00 ppm C^{13} peak of acetone. The peak positions are listed in Table I, with assignments made where possible. It should be noted that the 4.569 ppm proton peak is partially hidden under the H_2O (in the D_2O) peak. Its identification was made possible only by

selectively decoupling the protons while observing the carbon spectrum. The assignment of the carbon peaks to the benzene and pyridine rings was also achieved through selective decoupling of the protons on the benzene ring.

Experimental

The benzyl-heptyl-viologen bromide was ion exchanged with NaH_2PO_4, as previously described (6). A saturated solution of ~0.045M BHV phosphate/1M dihydrogenphosphate was then prepared under nitrogen.

Sealed cells were fabricated as before (7). Electrooptical tests were run in these patterned cells, in the potentiostatic mode, under crossed polarizers (7). A given electrode was first turned on by applying −1 VDC between it and the counterelectrode. This segment was then employed as the internal reference electrode for the subsequent experiments. The electrical and optical response of segments to potentiostatic cycling is shown in Fig. 1, where the mechanical offset between the two pens has been left unchanged. In addition to these photometric measurements, the films were also examined visually. This was done with the cell between 80° crossed polarizers. This configuration allowed enough light to leak through to be able to see the amorphous phase (as dark spots), while it was polarizing enough to resolve the crystalline phase (as bright areas).

Experiments to check the residue problem were performed both within the sealed cells as well as in a typical 3-necked flask inside an N_2 purged glove box. In the latter case, the working electrode was a cleaned and treated (6) piece of Nesatron 20 (PPG Industries), identical to the electrodes within the sealed cells; the counter and reference electrodes were a Pt-disk and a double junction Ag/AgCl (10% KNO_3 outer solution) electrode, respectively.

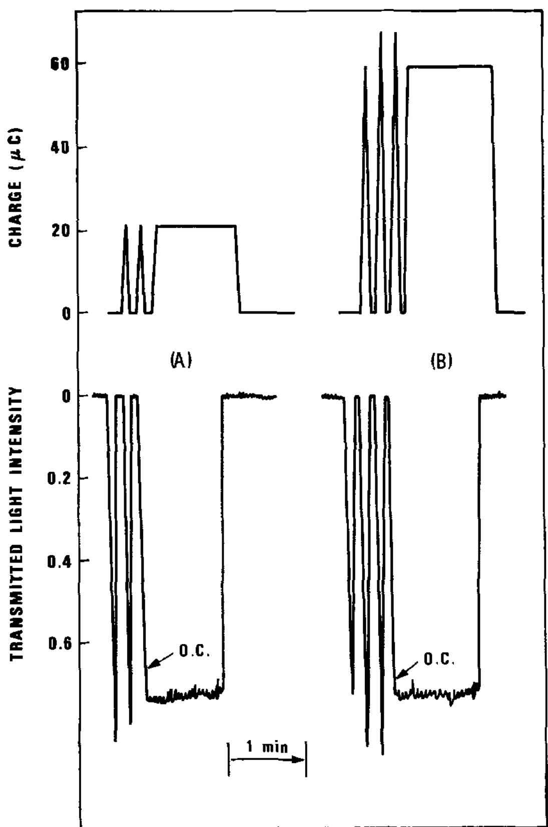

Fig. 1. Electro-optical response of a BHV film, under crossed polarizers, during cycling and open-circuit (O.C.) conditions: (A) −25/+400 mV and (B) −100/+400 mV pulsing at 0.1 Hz.

Results and Discussion

A cyclic voltammogram of the BHV solution shows the typical one electron reversible waves seen with all viologens. The open-circuit potential of the BHV solution is −50 mV from that of the diheptyl viologen (n-C_7) solution; the reduction and oxidation peaks are at $\eta = -45/+45$ mV, respectively, at a 5 mV/sec scan rate. The deposited film is violet.

Visual examination, under 80° crossed polarizers, of a film deposited at −50 mV, shows it to be significantly different from that of an n-C_7 film. While the n-C_7 film deposits in a birefringent, crystalline form, the BHV deposit is a mixture of amorphous and crystalline phases. When placed on open circuit, these is a brief period of ~3 sec (see next paragraph) when some of the amorphous form continues to reorient into the crystalline, optically anisotropic form. The "'particle" size of both forms is in the 5-10 μm range with an ~10:1 ratio between amounts of the amorphous and crystalline phases. Upon the application of a positive erase potential, both forms seem to erase at the same rate.

Photometric measurements, under 90° crossed polarizers, were also performed. The electrical and optical response of a single segment, to potentiostatic pulsing, is shown in Fig. 1. In contrast to the behavior of the n-C_7 film, the BHV film (i) increases in crystallinity for only ~3 sec after being put on open circuit, and (*ii*) after this time, there is no subsequent, continuous reorientation of the deposit into a more crystalline form, for films formed at any potential.

The effect of the stable morphology of the open-circuited film, on the subsequent erasure of this film, was tested both in sealed patterned cells as well as with unpatterned Nesatron 20 inside the glove box. In this latter configuration, a transparent electrode was cycled between $\eta = -75/+400$ mV, at 10 sec/cycle. After 41,500 cycles, there was absolutely no visible residue on the electrode. The electrode was then rinsed off and replaced in an identical setup containing the 0.1M diheptylviologen/1M dihydrogenphosphate solution. After less than 50 cycles, a portion of the deposit would not erase at all. This phenomenon was confirmed in the opposite sense also. A freshly cleaned and treated piece of Nesatron 20 was placed in the n-C_7 solution. After 1000 cycles, a large number of residual spots were formed on the electrode. This electrode was then cleaned ultrasonically in the phosphate buffer solution and placed into a solution of BHV. It was then cycled 6100 times, with no visible deposit formed.

Similar improvements were observed in sealed patterned cells. All segments of an "1888" display were driven, in a constant voltage driving mode, in a WRITE/HOLD/ERASE cycle at 5 cycles/min. The first visible residue was seen only after 11,400 cycles. An identical cell filled with the n-C_7 viologen solution, cycled in a similar fashion, gave rise to a greater amount of residue after only 375 cycles. In both cases, the buildup of the residue was at the edges of the segments, *i.e.*, where the current density is the greatest.

To summarize, several assumptions have been proven. First, looking at the viologen film reorientation problem from the viewpoint of intermolecular interaction is valid. The large majority of the asymmetrical BHV film is deposited in an amorphous phase, in contrast to the complete crystallinity of the symmetrical n-C_7 film. After a brief (3 sec) rearrangement on open circuit, neither the amorphous phase, nor the small amount in the crystalline phase, undergoes a subsequent continuing reorientation. This must be a consequence of the decreased intermolecular forces, *i.e.*, the greater steric hindrance caused by the bulky end group. Second, the data confirm what previously was only a hypothesis, that the open-circuit reorientation of the deposited film is a cause of the subsequent erasure problems, since the stable, nonreorientating BHV is much easier to erase. It is anticipated that further developments

along these lines might yield displays with even longer practical lifetimes.

Acknowledgment

The author wishes to thank P. G. Fields for the synthesis and analysis of the BHV, and Dr. R. A. Owens for the extensive NMR work.

Manuscript submitted Oct. 6, 1980; revised manuscript received Dec. 20, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by Texas Instruments Incorporated.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 127, No. 7, 8, 9, 10, 11, and 12, July, August, September, October, November, and December 1980.

Primary Li/SOCl₂ Cells XI. SOCl₂ Reduction Mechanism in Supporting Electrolyte

W. L. Bowden and A .N. Dey (pp. 1419-1426, Vol. 127, No. 7)

Clifton A. Young:[1] In this paper the authors have reported on the electrochemical reduction of thionyl chloride in the supporting organic solvents, N,N-dimethylformamide and dimethyl sulfoxide. This paper is one of a series of lithium-thionyl chloride batteries by Dey.[2] The work in N,N-dimethylformamide has been previously reported in *This Journal*[3] and elsewhere.[4] The studies in dimethyl sulfoxide have also been reported elsewhere.[5] It was reported that these and other results suggested a new approach to solving the explosion problem in lithium-thionyl chloride batteries.[6]

Thionyl chloride, along with phosgene and phosphorus oxychloride, reacts with N,N-dimethylformamide to form the Vilsmeier-Haack reagent which has been identified to be $[(CH_3)_2N{=}CHCl]^+Cl^-$.[7,8] Dimethyl sulfoxide reacts with thionyl chloride to form chloromethyl methyl sulfide.[9] This compound was isolated.[9] Dimethyl sulfoxide has been reported to decompose violently when in contact with thionyl chloride and acid chlorides.[10] The reaction of thionyl chloride with dimethyl sulfoxide has also been reported in the battery literature.[11]

In my opinion as a result of these reported reactions the electrochemical reduction of thionyl chloride in N,N-dimethylformamide and dimethyl sulfoxide cannot be used as a model of the electrochemical reduction of thionyl chloride at an electrode or in a lithium-thionyl chloride battery. Furtherfore, the reported results[12] may apply to the reaction products[7,9] instead of to thionyl chloride.

W. L. Bowden and A. N. Dey:[13] We have proposed a mechanism for reduction of thionyl chloride, $SOCl_2$, in dilute solution with a supporting electrolyte. Since numerous aspects of this mechanism mirror the behavior of $LiSOCl_2$ cells, we have extended this reduction mechanism to the discharge of $Li/SOCl_2$ cells.

During our investigations we were particularly concerned with the possibility of reactions between thionyl chloride and the supporting solvent. Accordingly we tried a wide variety of solvents of widely different characteristics, such as CH_2Cl_2, CH_3CN, $HCON(CH_3)_2$ (dimethylformamide, DMF), $SO(CH_3)_2$ (dimethylsulfoxide, DMSO). We found similar reduction behavior in these four solvents, of widely different structure and reactivity. The techniques we used, cyclic voltammetry and constant potential coulometry, are both techniques which operate on bulk of the sample and are thus insensitive to relatively small amounts of impurities so that a substantial amount of reaction must occur to have a noticeable effect on results. Both CH_3CN and CH_2Cl_2 are unreactive to $SOCl_2$.[14-16] Although both DMSO and DMF are known to react with $SOCl_2$, the reactions were run in refluxing solvent for substantial periods[14,15] and gave rather disparate products. While the results in DMF and DMSO are by no means central to our conclusions, the similarity to behavior in CH_2Cl_2 and CH_3CN demonstrates the validity of the results. As stated in our paper, we also took samples of partly discharged $SOCl_2$ electrolytes and examined them by cyclic voltammetry in dilute solution. These voltammograms were identical to voltammograms of partly reduced dilute $SOCl_2$ solutions, which also demonstrates that reaction of $SOCl_2$ with solvent was not a serious problem in this work.

Structure-Reactivity Relationships of Methylated Tetrahydrofurans with Lithium

J. L. Goldman, R. M. Mank, J. H. Young, and V. R. Koch (pp. 1461-1467, Vol. 127, No. 7)

M. H. Miles:[17] This paper shows that the position of the methyl group greatly affects the stability of methylated tetrahydrofurans toward corrosion reactions with lithium metal. Although tetrahydrofuran

(THF) and 3-methyl THF in contact with Li show observable corrosion within a few days at 71°C, it was found that 2-methyl THF was stable for over 10 months under similar conditions. The authors postulate a reduction mechanism involving an initial electron transfer from Li to the lowest unfilled molecular orbital centered on the oxygen atom of THF. They suggest that the location of an electron donating methyl group in the 2-position adjacent to the oxygen atom raises the activation energy by localizing additional electron density on that oxygen atom. An alternative explanation that should be considered involves the quantum mechanical tunnel effect for the transfer of the electron in this reaction. Tunneling through the barrier is generally much more probable than the overcoming of the activation energy barrier for such electron transfer reactions.[18,19] For the simplest assumption of a rectangular energy barrier, the probability of electron transfer

$$W \approx \exp\left[-4\pi a h^{-1}(2m(E_a - E_o))^{1/2}\right] \quad [1]$$

is more sensitive to changes in the tunneling distance (a) than to changes in the activation energy (E_a). Assuming $E_a = 20$ kcal/mol and $a = 5$Å, then a decrease in the tunneling probability by a factor of about 100 would require a fourfold increase in E_a while the tunneling distance would only need to increase by a factor of two to give the same effect. Electron tunneling from lithium metal cannot occur until the structure of the THF molecule is modified in such a way that the transfer of the electron leaves the total energy unchanged. The reaction rate will be determined by a compromise between the tunneling probability, W, and the free energy of rearrangement,[20,21] $\Delta G_r^{\neq}$, thus the rate constant, k_r, for the electron transfer step is given by

$$k_r = kTh^{-1} \cdot W \cdot e^{-\Delta G_r^{\neq}/RT}$$

$$= kTh^{-1} \cdot W \cdot e^{\Delta S_r^{\neq}/R} \cdot e^{-\Delta H_r^{\neq}/RT} \quad [2]$$

The experimental heat of activation measures only the rearrangement energy required for tunneling to occur, *i.e.*, $\Delta H_r^{\neq}$. In general, $\Delta H_r^{\neq}$ is considerably smaller than the actual height of the energy barrier (E_a) for reactions involving tunneling. It is therefore doubtful that the change in the activation energy produced by a methyl group adjacent to the oxygen atom is the major factor for the corrosion reaction of 2-methyl THF with lithium being much slower than the THF or 3-methyl THF reactions with this metal. The location of the methyl group in the 2-position, however, may significantly increase the tunneling distance between the adjacent oxygen atom and the electron in the lithium metal. Adsorption of the methylated THF molecule could be the key factor determining the rate of this corrosion reaction, and this adsorption at the lithium surface might be hindered by steric effects of the methyl group when it is adjacent to the oxygen atom. In accord with a corrosion model proposed elsewhere,[22,23] the polar oxygen atom end of the THF molecule would be attracted to the film/solution interface by excess positive ions present within the passivating film.

Regarding the mechanistic role of Li^+, the strong electric field of this ion exerts major effects on many reactions such as the electrode reduction of molten nitrates,[24,25] the decomposition of oxyhalides,[26] the degradation of pyrophosphate,[27] and the reduction of propylene carbonate by lithium.[28] The association of Li^+ with electronegative elements in a reacting molecule or ion facilitates electron transfer and bond breaking processes. For the THF molecule, however, the affinity of Li^+ for the sole electronegative oxygen atom is competitive with the attraction and adsorption of this molecule at the positively charged film. With propylene carbonate, lithium ions can interact with the two oxygen atoms in the ring in addition to the terminal oxygen atom that is the likely adsorption site. In fact, the ring oxygen atoms in propylene carbonate are apparently involved in the bond breaking process in the reaction with lithium judging from the reaction products of propylene gas and carbonate ions. In all of the reactions cited above that show strong Li^+ effects, there is more than one oxygen atom present in the reacting molecule or ion. Perhaps Li^+ effects are diminished in heterogeneous reactions involving adsorption when only one electronegative element is present in the molecule. Adsorption involving that lone electronegative element would likely result in a reduced affinity for lithium ions in the solution.

V. R. Koch:[29]We thank M. H. Miles for bringing the quantum mechanical tunneling argument to our attention. Without doubt, the energetics of heterogeneous electron transfer mechanisms include contributions from adsorption and tunneling phenomena in addition to the activation energy of the solvent molecule itself. Weighting these contributions in terms of relative importance is a difficult task given the reactivity and nonuniform character of the Li-electrolyte interface.

With regard to the possibility that methyl groups α to the oxygen atom of THF increase the tunneling distance between the lowest unfilled molecular orbital (LUMO) and Li, we report on the following recent stability experiments. A 50:50 mixture of *cis/trans* 2,5-dimethyltetrahydrofuran (2,5-di-Me-THF) (Aldrich) was fractionally distilled until two fractions enriched (80:20) in each isomer were obtained. When these solvents were stored with Li foil at 71°C, the *cis*-fraction manifested superior stability over the *trans*-fraction. Electrolytes of each fraction were prepared 1.5M in $LiAsF_6$. When subjected to our usual Li on Li cycling regime[30] at 1 mA/cm^2, the *cis*-enriched electrolyte afforded 56 "100%" cycles while the *trans*-enriched electrolyte gave 35 "100%" cycles. The 50:50 *cis-trans* mixture prepared under identical conditions gave 47 "100%" cycles.

Space filling models of the *cis* and *trans* isomers show that the oxygen atom of the *cis* isomer may more closely approach and thereby more readily interact with a solid surface. Were the electron tunneling argument operational, one would expect the *cis* isomer to react faster than the *trans* isomer. In the 2,5-di-Me-THF system, however, the reverse is observed.

That there is a difference in reactivity between two electronically equivalent LUMO's is of great interest. The results suggest that those molecules which interact strongly with Li^+ are more stable toward Li metal. Since we have shown from ^{13}C NMR measurements that 2-methyltetrahydrofuran and 2,5-di-Me-THF (*cis/trans* mixture) interact more strongly with Li^+

than THF,[30] Dr. Miles' speculation regarding a solvent's Li^+ affinity competing with adsorption is particularly noteworthy.

Impedance Measurements of the Anodic Iron Dissolution

H. Schweickert, W. J. Lorenz, and H. Friedburg
(pp. 1693-1701, Vol. 127, No. 8)

M. Keddam, O. R. Mattos, and H. Takenouti:[31] Schweickert *et al.* mentioned extensively our studies on the anodic dissolution of iron. Most of the author's criticisms are answered in our recent paper.[32] We note with satisfaction that, according to an opinion we have been claiming for the last ten years, a-c data are now recognized as more selective than d-c ones for elaborating and testing intricate kinetic models. As a very illustrative example, the interpretation of results on the basis of impedance measurements is in entire contradiction with previous and even parallel[33] papers by one of them (W.J.L.): The authors withdraw the two-step consecutive mechanism which has been considered for years as unquestionably proven by the 40 mV Tafel slope. As shown below, essentially because of a number of self-inconsistencies, experimental data excepted, it seems difficult to acquiesce is conclusions drawn in this paper. In particular, the meaning of surface relaxation is not clarified, and no original argument is brought in favor of a delimitation between kinetic and surface effects.

1. On p. 1695, it is stated that at steady state, a plateau is found in the transition range in contrast with a maximum in earlier findings under potentiodynamic conditions. This is not compatible with the negative real part of the impedance in the transition range mentioned [p. 1696 (*iii*) and Fig. 5] since as stressed by the authors themselves, the low frequency limit of the impedance is identical to the polarization resistance (the slope of the steady-state polarization curve about which the electrode impedance is measured). In solutions of $pH \geqq 5$, the reproducibility of results is declined even if it can be improved by the buffering effect of a large volume of electrolyte.[34] In fact, the difference between a plateau and a maximum is of poor significance.

2. The assumption $\nu_{0,3} << \nu_{0,4}\, E_4$ (Eq. [4]) is a violation of Table II, in which the step [3] is presented at equilibrium and the step [4] rate determining. Under the conditions of Eq. [4], the step [3] is no longer in pseudo-equilibrium.

3. On p. 1639, the authors claim, "A complete correspondence of all experimental results with the model proposed can be achieved for this set of parameters only." Not only is this correspondence far from being complete (see below), but also such a statement is, at least, nonsense. In fact, even if a fitting program (not mentioned for this particular purpose) were applied for nonlinear equation, a minimal distance between model and experiments cannot prove to be absolute but only local. In the present case, the set of parameters is the best one among those tested on a trial-and-error procedure, nothing more.[32]

4. According to the conclusion, "The impedance measurements show clearly that the impedance behavior is determined ... also by the influence of electrocrystallization step and surface relaxation phenomena." It seems to us that such a viewpoint is seriously misleading with respect to the very nature of the information provided by impedance or by any other experimental approach. Surface and kink sites contribution to the impedance is a theoretical possibility which cannot by any means be borne out from the looking of an impedance loci on its own. As a rule, the value of this interpretation should have been founded on its compatibility with commonly accepted physico-chemical laws (*e.g.*, a crystallographic balance for kink sites) and its ability to explain experimental findings. Contrary to the authors' statement on p. 1699, fitting parameters are not restricted to Eq. [19]-[26], but are needed also in the description of surface relaxation. In other words, the authors introduced a hypothesis of surface relaxation with a formal model in such a manner to show an inductive loop in low frequency range. No experimental proof was made in the paper under discussion and thus that remains a pure assumption.

5. All through this paper it is assumed that the high frequency capacitive loop contains two capacitive contributions: The double layer at higher frequencies and a faradaic pseudo-capacitance at lower frequencies. This assumption is very central to the paper since it leads to the value of the charge transfer resistance, crucial in the subsequent deductions, lower than the intercept of this loop on the real axis. Moreover, it brings up to five the number of time constants in the system. This interpretation is certainly supported by the seriously depressed shape of this semicircle with respect to the true one corresponding to a single *R-C* circuit. According to the paper, this view is also corroborated by a fitting of the experimental impedance to a fifth order broken-rational function. Unfortunately, Fig. 3 is erroneously mentioned, and no fitting data are provided to substantiate seriously this result of outstanding importance. Can the authors supply further information such as estimated standard deviation and statistic parameters showing the absence of systematic deviations, and proving that higher order function does not result in better fitting as usual with distributed impedance? *A-C* measurements being limited to 10 kHz, an accurate fitting in the high frequency domains is rather doubtful. In the authors' mind, additional argument is given by the GDP technique. We have recently established[35] that this technique cannot be used for resolving an apparently distributed impedance into overlapping *R-C* time constants except in those cases where the impedance is independently proved to obey such a circuit. This can be performed, for instance, by a fitting calculation, which provides the values of *R* and *C* components. The GDP is thus fully redundant. Even though not clearly understood, frequency distribution is a general feature of solid electrodes.[36] That holds for the whole frequency spectrum as clearly shown by experiments, but surprisingly, only the high frequency range is considered by the authors. Distribution of the surface properties at a microscale mentioned in the course of the paper is able to give rise to this effect. Is the theoretical meaning of step [1] (Table II) at equilibrium so strong as to require such an effort to find a lower R_t value? It can be remarked, futhermore, that the R_t value, calculated according to the model (see Fig. 10), is of the same order of magnitude as the size of the capacitive loop. Thus no electrochemical step seems to be at fast equilibrium.

6. Though the paper is apparently devoted to impedance, d-c arguments are of predominant value in the more critical mechanistic considerations, in particular for transition and prepassive ranges. Dynamic behaviors, in terms of $R_t I_s$ and b_t, based on the postulated processing of high frequency data (see 5 above) are favored compared to obvious and undoubtful low frequency results. Five time constants exist, in the

view of the authors, but only three of them are considered in the simulation, *i.e.*, a pseudo-capacitance at high frequency (from θ_1), an inductive loop about 100 Hz (from θ_{k1}), and finally, one more inductive loop about 160 mHz (from $\tau = 1$ sec). The latter is simulated by dropping a convenient value for representing the so-called surface relaxation (Eq. [43]). The simulation concerns only pH 0 solution, and the impedance diagram in Fig. 6 is disregarded since its explanation is completely beyond the possibility of the model: A capacitive loop is observed about 160 mHz in Fig. 6. The process leading to this loop is revealed by an inductive loop in the active range,[32] unfortunately, in spite of the formal parameters involved (α_ψ and τ can be varied at will) it cannot predict capacitive effects, *a fortiori* the change of inductive to capacitive behavior or vice versa. Intricate behaviors evidenced in pH 3-5[32] are also not explained by the model. Can the authors propose an interpretation of the diagram in Fig. 6?

7. Equations [33] and [39] are proposed as valid in the whole potential range. (Equation [39] is erroneous: read + instead of − at the numerator, and $\nu_{0,6}W_4$ instead of $\nu_{0,6}$ in the denominator.) Subsequently, these equations are simplified in Eq. [41] and [42] for the active range, and the same for Eq. [44]. With the set of parameters used [values of some of them by Ref. (31) of the paper under discussion], this procedure is not correct. Figure 1 shows the diagrams obtained when the simulations (Fig. 10) are repeated by using the complete impedance expression in θ_1, θ_2, θ_{k1}, θ_{k2}, and τ.

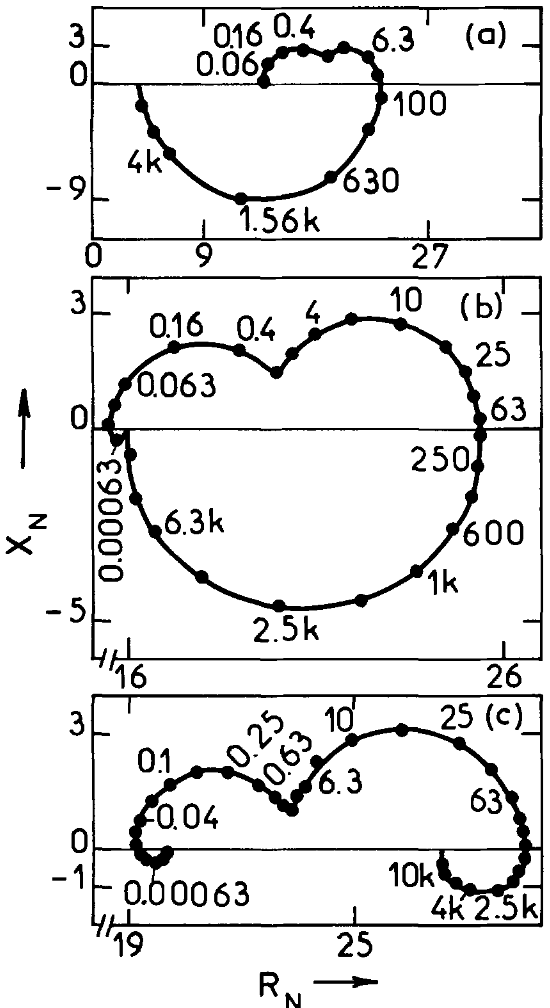

Fig. 1. Simulated transfer loci of the faradaic impedance with complete impedance expression: (a) $\eta = 0.33V$, (b) $\eta = 0.37V$, and (c) $\eta = 0.44V$. For details see Fig. 10 of the paper under discussion.

By comparison with Fig. 4 and 10 of the paper, it can be seen that in addition to the preceding remarks, the model is not satisfactory, since an additional time constant (from θ_{k2}) arising from the prepassive dissolution path, contributes to the impedance in the active range at the low frequency extremity of the diagrams. Inequality $\nu_{0,7a} > \nu_{0,7b}\, E_7$ assumed in the paper makes this contribution capacitive in contradiction with the inductance shown by experiments. Can the authors explain their interpretation of this inductance in terms of "cosorption?"

We limited our discussion to the basic aspects of their contribution, and tried to keep our questions precise. We hope the authors will reply to each item.

H. Schweickert,[37] W. J. Lorenz,[37] and H. Friedburg:[38] First of all, we agree with Keddam *et al.* that a-c impedance measurements represent a powerful tool for determining the kinetics and mechanisms of electrode reactions. However, this experience is much older than the work of Epelboin *et al.* during the last decade. It is entirely due to the important work of the French group that a-c impedance measurements down to very low frequencies have been introduced in this field. Many complicated electrochemical systems can be analyzed in more detail using this modern technique. This has been attempted in the paper under discussion as well as in the very recently published papers by the authors[39] concerning the iron dissolution mechanism. Most of the discussion remarks and questions of the authors deal with the interpretation of very similar experimental results in both papers. Therefore, the different basic concepts of interpretation should be considered first.

In both papers, the common idea is that the iron dissolution at the corrosion potential and in the active, transition, and prepassive polarization ranges occurs via different intermediates called $Fe(I)_{ad}$, $Fe^*(I)_{ad}$, $Fe(II)_{ad}$, and $Fe^*(II)_{ad}$, where Fe* stands for an adsorbed intermediate at an active surface site. However, different assumptions lead to different interpretations of the experimental data in terms of models.

In both papers, a basic assumption was made that iron dissolution can occur in consecutive and/or parallel paths including "catalyzed" charge transfer processes with a two-electron exchange. It is very interesting to note that the concept of such a catalyzed charge transfer of iron, which was originally established by Heusler,[40] has been rejected by the French group for a long period, in contrast to our previous interpretations.[41] Furthermore, in both papers it is proposed as a first approximation that the adsorbed intermediates follow Langmuir isotherms.

Only one additional assumption was made in the paper under discussion, namely that the surface concentration of active sites is strongly potential-dependent and leads to surface relaxation phenomena. This assumption seems to be justified by several investigations[42-48] even by the French group.[49]

On the other hand, the authors introduce the following *a priori* assumptions for the interpretation of a-c impedance results:

(*i*) The hydrogen evolution reaction on the iron electrode follows a Volmer-Heyrovski mechanism with the Heyrovski reaction as the rate-determining step.[50,51] The degree of coverage of adsorbed hydrogen is assumed to be nearly unity at the corrosion potential and is supposed to be responsible for an inductive loop in the a-c impedance diagram which can be observed at this potential as well as at low anodic polarization. This inductive loop is completely discarded in the mechanistic interpretation of iron dissolution.

This assumption seems to be in contradiction to hydrogen permeation experiments on iron electrodes (footnote 52 and previous papers cited therein) which show that the Volmer reaction is always rate determining and the degree of coverage of adsorbed hydrogen should be very small. This discrepancy is also very important for different interpretations of a-c impedance results at the corrosion potential in terms of corrosion rates.[53]

(*ii*) The steady-state behavior of the iron electrode in the active range is assumed to be strongly influenced by a slow adsorption-desorption process of hydrogen surface coverage. Only a "real" steady-state Tafel slope of +60 mV at $T = 298$ K is accepted in the model of the authors.

The steady-state Tafel slope of the active iron dissolution reaction is well known from many studies under different conditions and values either +40 or +30 mV have been measured independent of the polarization direction and of the rotation speed in disk experiments.

(*iii*) The deviation of the high frequency capacitive loop in complex a-c impedance diagrams from a true semicircle is assumed to be caused by frequency-dispersion of the system studied. The arguments of the authors[39] in order to exclude pseudo-faradaic parts in this high frequency capacitive loop are based on both a rough estimation of the adsorption capacitance and the constancy of the product of the so-called charge-transfer resistance (which should correspond to the intercept of the extrapolated capacitve loop with the real axis) and the steady-state current density.

It can easily be shown that the first argument does not hold for a decision on frequency-dispersion or pseudo-faradaic contributions. On the other hand, the constancy of the product $R_t \cdot i_s$ has not been observed in our experiments up to $i_s \approx 30$ mA · cm^{-2}.[54]

(*iv*) The authors accept electrochemical charge-transfer coefficients very close to zero or unity in order to explain the experimental results by their proposed model. Furthermore, nonelectrochemical steps are assumed to be potential dependent.

Although not in contradiction with quantum mechanical treatment, strong deviations from the usual value of 0.5 for the electrochemical charge-transfer coefficients have been measured only in few systems under extreme conditions.

Using these additional assumptions [(*i*)-(*iv*)], the authors were able to interpret the a-c impedance data measured over wide potential and *p*H ranges. This impressive work seems to be more complete and self-consistent than the paper under discussion which tried only to explain the d-c and a-c behavior in the active range and the d-c behavior in the transition and prepassive ranges but by using less crucial assumptions in comparison to the paper of the authors.[39]

Now we would like to answer with respect to the points of the authors as follows:

1. There is no contradiction between the results shown in Fig. 1 and 5 because of the extremely slow attainment of the steady state at the current density plateau.

2. As can be seen from Table II, step [4] becomes faster with increasing potential while step [3] is potential-independent. According to Eq. [40], it is assumed that step [3] will be rate determining in the active iron dissolution range studied instead of step [4]. However, the reaction scheme in Table II holds for lower anodic potentials or at the Fe/Fe^{2+}-equilibrium potential in strong acid solutions because $v_{0,3}/v_{0,4}$ has been calculated to be about 10^2 at $pH = 0$.[54]

3. The α_i values calculated from experimental data and using the proposed model seem to be quite reasonable (p. 1699).

4. Measurements on iron single crystal faces have been interpreted in terms of a physical model with a very similar analytic expression for the concentration dependence of kink sites.[42,44,45]

5. There is no physical background for assuming a frequency dispersion to such an extent as observed in the iron system. In the paper under discussion, only one additional time constant was sufficient to obtain a statistically significant fit of the distorted high frequency capacitive loop. Therefore, it seems to us more reasonable to include this behavior into the kinetic model of the system studied.

From the value of R_t, it cannot be concluded that step [1] must be irreversible because in the proposed model (Table II) this step is in parallel with the iron dissolution reaction steps [3], [4], and [5]. Under steady-state conditions it follows that $v_1 = 0$, *i.e.*, step [1] is in pseudo-equilibrium.

6. Figure 6 has only been analyzed with respect to the d-c behavior of the system studied because of the absence of an explicit surface relaxation model.

7. The simulation carried out by the authors does not allow any decision on the validity or nonvalidity of the proposed model, because the appearance of very small capacitative loops at extremely low frequencies are outside of experimental reproducibility.

We thank the authors for the indication of typing errors in Eq. [39] where + instead of − should read in the numerator, and $v_{0,6} \cdot W_4$ instead of $v_{0,6}$ in the denominator. Furthermore, in footnote 6 on p. 1699 it should read $a_{Fe^{2+}} \approx 10^{-4}$ instead of 10^{-7}.

Finally, at the present state of knowledge one should ask for sufficient experimental and theoretical criteria for or against the different assumptions made in the paper under discussion and in the papers of the authors.[39] It seems to be more reliable to study simpler systems than the complicated iron dissolution process in order to check the basic assumptions for the interpretation of a-c impedance measurements.

Ellipsometry and Auger Analysis of Chromium Surfaces Passivated in Acidic and Neutral Aqueous Solutions

M. Seo, R. Saito, and N. Sato (pp. 1909-1912, Vol. 127, No. 9)

G. Dubpernell:[55] This is a noteworthy communication on an important subject. The authors report their electrode potential measurements as "E_{HESS}" (referred to a hydrogen electrode in the same solution). It is indicated that they make their measurements with a saturated calomel electrode. Since several different methods of converting from one electrode potential scale to another have been used in the past, it would be helpful if they would give the exact method

used in calculating the electrode potentials at each of the four pH's studied.

M. Seo:[56] The electrode potential, E_{HESS}, referred to a hydrogen electrode in the same solution was converted from the electrode potential, E_{SCE}, actually measured with a saturated calomel electrode by using the following equation

$$E_{HESS}(\text{Volt}) = E_{SCE}(\text{Volt}) + 0.241 + 0.059\,pH \text{ (at } 25^{\circ}\text{C)}$$

The electrode potential scale expressed in terms of E_{HESS} is convenient in dealing with electrochemical behavior of metal electrodes covered with thin oxide films in different pH solutions, as the equilibrium electrode potential of metal/metal oxide systems changes by 0.059V for a unit pH change of solution.

Electrical Conductivity of the $LiI-H_2O-Al_2O_3$ System

S. Pack, B. Owens, and J. B. Wagner, Jr.
(pp. 2177-2179, Vol. 127, No. 10)

J. Bradley Phipps and D. H. Whitmore:[57] The general trends reported in the paper by Pack, Owens, and Wagner are in agreement with those observed by us in a recent study[58] of the $LiI-H_2O$ system; however, we do not agree with several of their conclusions. Those points made by the authors with which we take some issue are discussed below.

1. The authors of this paper suggested that the sudden increase in conductivity at 130°C was due to the formation of a highly conductive solid phase, possibly the half-hydrate, $LiI \cdot \frac{1}{2} H_2O$. We found that the sharp increase in conductivity at 130° was simply due to the formation of a liquid phase (arising from a eutectic reaction at that temperature) which, not surprisingly, has an ionic conductivity many orders of magnitude greater than the solid-state material that exists below 130°C. In addition, our LiI/H_2O phase diagram work suggests that the compound $LiI \cdot \frac{1}{2} H_2O$ does not actually exist.

2. Pack, Owens, and Wagner state that "(their) results suggest that the presence of a few mole percent of the hydrate-phase in the $LiI-Al_2O_3$ material increases the conductivity by one to two orders of magnitude." Our work on hydrated lithium iodide, in contrast, suggests that the presence of a few mole percent of the hydrated phase increases the conductivity by only a few percent. In fact, for overall water contents ranging between the compositions LiI and $LiI \cdot H_2O$, the observed conductivity was closely approximated by that predicted with the aid of the effective-medium theory (developed by Landauer),[59] if it was assumed that the microstructure consisted of randomly distributed grains of anhydrous lithium iodide and the monohydrate.

One might argue that the monohydrate phase, instead of existing as isolated grains, may actually form an interconnected network in $LiI(Al_2O_3)$ composites due to the influence of the alumina particles. For such a case, the monohydrate phase would act as a highly conductive, parallel path for ion transport and the overall conductivity, σ_c, would be given by

$$\sigma_c = X_m\sigma_m + X_a\sigma_a$$

where X_m and X_a represent the volume fractions of the monohydrate and anhydrous phases and σ_m and σ_a are the corresponding conductivities. However, even for this situation (which would optimize the composite conductivity) the presence of, say, 2 mole percent (m/o) of the monohydrate would only result in a composite conductivity about three times larger than the conductivity of an anhydrous $LiI(Al_2O_3)$ composite and not the one or two orders of magnitude increase suggested by Pack, Owens, and Wagner. It should be stressed that we do not disagree with the general conclusion of the authors of this paper that the presence of water in lithium iodide is an important consideration. However, we do disagree with their contention that a *small amount* of water, as may be present on the surface of alumina particles, can increase the ionic conductivity of the composite sample by two orders of magnitude.

3. Liang *et al.*[60] reported that the room temperature conductivity of lithium iodide containing about 50 m/o alumina particles was about 500 times larger than that found for lithium iodide alone. Liang also noted that the activation energy for lithium ion migration in the $LiI(Al_2O_3)$ composite was 0.4 eV which is equal to the activation energy for extrinsic conduction in lithium iodide. Pack and co-workers suggest that "it is possible that some moisture in (Liang *et al.*'s) samples affected their results." It is worthwhile in this connection to point out that Pack, Owens, and Wagner observed (as did we) that the activation energy increased substantially when water was present in $LiI(Al_2O_3)$ composites. We found that as water was added to anhydrous lithium iodide, the activation energy increased from the anhydrous value of 0.39 eV to 0.68 eV for the monohydrate. More specifically, we found that the presence of about 5 m/o of the monohydrate phase caused the activation energy to increase by 20%. Even if only a small amount of moisture was present in Liang's samples, the activation energy should have been greater than 0.4 eV.

In summary, we have suggested that a small amount of monohydrate phase, even if present as an interconnected network, cannot cause an increase of two to three orders of magnitude in the conductivity reported for some $LiI(Al_2O_3)$ composites. We also found that the presence of even a small amount of the monohydrate phase substantially increased the activation energy. In contrast, no increase in the activation energy was observed by Liang for $LiI(Al_2O_3)$ nor by us for $LiI(SiO_2)$ composites which suggests that the enhanced conductivity observed for these materials is not due to the presence of the monohydrate phase. We have evidence that fast ionic transport along microstructural imperfections, arising from the presence of the inert particles, may account for a substantial amount of the enhancement in conductivity observed for $LiI(Al_2O_3)$ and $LiI(SiO_2)$ electrolytes.[61]

S. Pack,[62] B. Owens,[63] and J. B. Wagner, Jr.:[62] We thank the discussors for their contribution and reply as follows. Point 1: Our paper stated (page 2178), ". . . that a highly conducting solid $LiI \cdot \frac{1}{2} H_2O$ phase is formed *or* a fusion process occurs. Further study of the phase diagram is needed." The phase diagram cited in footnote 58 was unavailable. We are pleased that the behavior has been shown to be a fusion process, *i.e.*, a eutectic, thus ruling out one of our two suggested possible mechanisms.

Point 2: We showed that the introduction of moisture increased the conductivity of initially anhydrous LiI regardless of whether the source of moisture was from a hydrate or from moisture sorbed on the Al_2O_3 par-

ticles. The work of Skarstad, Merritt, and Owens[64] on lithium halides containing dispersions of SiO_2 or Al_2O_3 show that although the monohydrate is more conductive than the anhydrous LiI by a factor of about 10^2, this alone does not account for the highest conductivities observed in the LiI-Al_2O_3-H_2O systems. The water contents corresponding to each conductivity are presented in that paper which also appeared after our earlier one. In other systems[65-67] such as AgI and HgI_2 in which hydrates do not form, the introduction of moist Al_2O_3 particles enhances the conductivity more than the introduction of predried Al_2O_3 particles of the same particle size and volume fraction.

The discussors' equation

$$\sigma_c = x_m\sigma_m + x_a\sigma_a$$

is apparently not applicable to the ternary systems containing the dispersion.

Point 3: We agree that the activation energies reported by Liang did not change and this is evidence against our suggestion that "some moisture in (Liang's *et al.*'s) samples affected their results." Our data show that the introduction of predried, 0.3 micron Al_2O_3 particles to anhydrous LiI did not enhance the conductivity (See Fig. 1 and 2 of Pack, Owens, and Wagner).

To their summary, we reply that our paper reported a one to two orders of magnitude increase not a two to three orders of magnitude change.

We appreciate the interest of the discussors and look forward to reading their work cited in footnotes 58 and 61.

Simultaneous Discharge of Two Reacting Species under Pulsed Current Conditions

K. Viswanathan, M. A. Farrell Epstein, and H. Y. Cheh (pp. 2383-2385, Vol. 127, No. 11)

Richard Haynes:[68] Several points should be mentioned regarding the paper under discussion and related works,[69,70] namely:

1. There is a need for a more quantitative description of both the thermodynamics and the electrode kinetics of the model, otherwise apparent contradictions may arise from the conditions imposed by the model for irreversible reactions, diffusion control, and the requirement that the total current is zero during the off time. It is difficult to conceive, without further quantitative limits, that the current would be zero during the off time for all values of δ, D, τ_1, i_o, E_o, β. A mixed potential may be reached, thus polarizing reaction [1] cathodically and reaction [2] anodically. The relaxation of the processes may not occur during the off time for all parameters. Therefore, this model may not allow the use of calculated values of $(i_p)l,1$ and $(i_{int})_{l,1}$ by Cheh[69] and Viswanathan *et al.*[70] since boundary condition for mass transport may not be met during the off time.

2. The efficiencies of the reactions under certain conditions are a function of the on and off times (see Haynes)[71] and are restricted by time constants for the processes. This concept should be incorporated in a complete model and its limits defined.

3. The calculations of Cheh[69] and Viswanathan *et al.*[70] have not incorporated influences of the pulse on diffusion layer thickness although increased limiting current densities[72-74] have been observed in magnitudes greater than predictable by the present authors (but see Haynes[75]).

A theory of pulse plating should be able to, when necessary, incorporate the effects of the products of the reaction (such as gas bubbles) on diffusion layer thickness. Such effects have been investigated in direct current electrolysis.[76] If such an enhancement of mass transport occurs during the pulse due to the field effects,[72-74] bubble formation,[76] etc., then the rates and quantity of metal deposited in pulse plating can be greater than in direct current plating. The relative effects of gas bubbling on diffusion layer thickness in the pulse and direct current cycles are important with respect to the relative rates. The quantity of the metal deposited is seen to be effected by this enhanced efficiency in the model of Haynes.[71] In this model the effect of gas bubbling is eliminated in the pulse cycle but not necessarily in the direct current cycle. If field effects in the pulse cycle enhance the mass transport rates more than gas bubbling in the d-c cycle than $E_p > E_{D\text{-}C}$ and $Q_p > Q_{D\text{-}C}$.

K. Viswanathan,[77] **M. A. Farrell Epstein,**[78] **and H. Y. Cheh:**[78] We agree with Haynes that there is a need for a more quantitative description for simultaneous reactions under pulsed current conditions. Our calculations are strictly valid under the assumption stated in our note. The situation is approached in practice when the exchange current density for reaction [2] is much smaller than that for reaction [1].

The statement that our work has not incorporated influences of the pulse on diffusion layer thickness is not valid. A quantitative analysis on this effect has been presented thoroughly in a paper by us.[79]

An Investigation of Electrode Materials for the Anodic Oxidation of Sulfur Dioxide in Concentrated Sulfuric Acid

P. W. T. Lu and R. L. Ammon (pp. 2610-2616, Vol. 127, No. 12)

Hassane Saab and Robert Spotnitz:[80] The authors claim that the reversible potential for the anodic oxidation of sulfur dioxide cannot be determined unambiguously because it is "highly uncertain whether the overall electrochemical reaction for SO_2 oxidation is represented by"

$$SO_2 + 2H_2O \rightarrow SO_4^{-2} + 4H^+ + 2e^- \quad [1]$$

or

$$SO_2 + 2H_2O \rightarrow HSO_4^- + 3H^+ + 2e^- \quad [2]$$

However, at the reversible potential, the following chemical equilibrium can be assumed to take place

$$HSO_4^- \rightleftarrows H^+ + SO_4^{-2}, \quad \Delta G_{rxn}^{equil} = 0.0 \quad [3]$$

Therefore calculation of the reversible potential using either reaction [1] or reaction [2] leads to the same value, although reactions [1] and [2] do lead to different values of the *standard state* potentials.

[80] Department of Chemical Engineering, University of Wisconsin, Madison, Wisconsin 53706.

The difficulty in determining the reversible potential stems, not from the ambiguity of the overall reaction, but rather from the lack of thermodynamic data for the system SO_2-H_2SO_4-H_2O. The authors reference the paper of Appleby and Pichon[81] in which it is stated that there was little possibility of extracting rate constants from linear potential sweep data because of the difficulties in defining the reversible potential, since analysis of linear potential sweep data requires knowledge of the standard state potential [*e.g.*, footnote 82]. Appleby and Pichon[81] did report an approximate exchange current density based on their steady-state potentiostatic data.

Surface Intermediates of an n-Type Gallium Phosphide Electrode as Related with the Shifts of the Surface Band Energy Induced by Oxidants in Solution

Yoshihiro Nakato, Akira Tsumura, and Hiroshi Tsubomura*

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560, Japan

ABSTRACT

The energy of the electronic band at the surface of an n-GaP electrode shifts downward, that is to say, to more negative, by the addition of oxidizing agents. Although the surface band energy of GaP for the (111)-face changes linearly with *p*H, it stays constant in an intermediate *p*H range in the presence of the $[Fe(CN)_6]^{4-}/[Fe(CN)_6]^{3-}$ couple. This result is explained by assuming a "surface-trapped hole" formed by oxidative interaction with the solute. It is also assumed that this surface-trapped hole is acting as an electronic surface state in electronic equilibrium with the redox couple in solution, its energy being estimated to lie about 0.5 eV above the valence bandedge. At higher *p*H, or in the case of the $(\bar{1}\bar{1}\bar{1})$-face, the surface band energy interacting with the redox couple increases with *p*H. The shift in this case is mainly attributed to the accumulation of oxide- or hydroxide-type surface intermediates. It is suggested that these surface intermediates effectively mediate the electron transfer from the conduction band to the oxidizing agents in solution.

It is well known that the energy of the semiconductor electronic band at the surface measured as the potential at minimum capacitance is changed by adsorption of ions in electrolyte solutions onto the electrode surface (1-5). It is also known that it changes sometimes with the electrode potential by the change in the chemical structures at the electrode surfaces, *e.g.*, from an oxidized structure to a reduced one (2).

We have reported in a previous paper (5) that the surface band energy of an n-GaP electrode is shifted by electrode illumination under anodic polarization. The shift was explained from the accumulated surface intermediates formed by photogenerated holes. Similar shifts are therefore expected to occur at dark when holes are injected by oxidizing agents in solutions. Several reports were published on the hole injection from redox couples into the GaP electrode (6-9). In the present paper we report and discuss the shift of the surface band energy caused by interaction with the redox couple.

Experimental

Single crystals of n-type GaP from Yamanaka Chemical Industries, Limited were used as electrodes. The (111)-face (Ga-face) and the $(\bar{1}\bar{1}\bar{1})$-face (P-face) were distinguishable by microscopic inspection of the etched surface (5). The current-potential curve was obtained by use of a Hokutodenko HA 101 potentiostat. The differential capacitance was measured with a Yokogawa-Hewlett-Packard Universal Bridge 4265B, together with a function generator. The solutions were deaerated by nitrogen bubbling and were stirred magnetically during the measurements. Further experimental details were described elsewhere (5). The concentration unit, mol/dm^3, is abbreviated as M in the present paper.

Results

Figure 1 shows current-potential (*i*-*U*) curves for the (111)-face of an n-GaP electrode at dark. It is seen that the onset potential of the cathodic current (U_c) is shifted largely to the positive by the addition of the $[Fe(CN)_6]^{4-}/[Fe(CN)_6]^{3-}$ couple. A similar result was obtained with heavily etched electrodes. This current-potential behavior is therefore independent of defects or dislocations at the surface produced by mechanical polishing. Similar shifts were reported by some authors for other semiconductor-redox systems (6, 10, 11).

Figure 2 shows examples of Mott-Schottky plots for the (111)-face of the n-GaP electrode in the presence of the $[Fe(CN)_6]^{4-}/[Fe(CN)_6]^{3-}$ couple. Very good straight lines are obtained, like those in the absence of the redox couple (5). In solutions of high *p*H, relatively high dark anodic currents, of the order of 1-10 $\mu A/cm^2$, were observed, increasing with *p*H and the redox concentration, in agreement with the results reported previously (6, 10). In spite of such currents, the capacitance measurements could be done independently. The U_s value was determined from the intercept of the Mott-Schottky plot with the abscissa. As de-

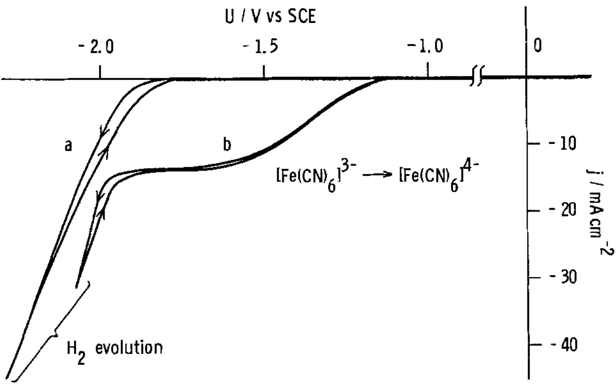

Fig. 1. Current-potential curves for the (111)-face of an n-GaP electrode in a 0.1N NaOH solution, in the absence (a) and the presence (b) of 0.05M $K_4[Fe(CN)_6]$ and 0.05M $K_3[Fe(CN)_6]$. The scan rate is 120 sec/V.

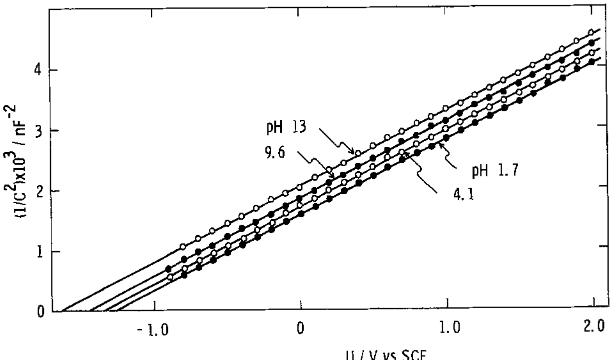

Fig. 2. Mott-Schottky plots for the (111)-face of an n-GaP electrode in solutions containing 0.05M $K_4[Fe(CN)_6]$ and 0.05M $K_3[Fe(CN)_6]$.

scribed previously (5), the U_s value is related to the lower energy limit of the conduction band at the surface, $E_c{}^s$, as shown below

$$E_c{}^s = -eU_s + \Delta \quad [1]$$

if $E_c{}^s$ and $-eU_s$ are measured with respect to the same reference electrode. Δ refers to a small energy difference between the Fermi level and the lower energy limit of the conduction band in the interior of the semiconductor.

The U_s values for the (111)-face of the n-GaP electrode thus obtained, together with those of U_c, which has been taken as a potential at which the dark cathodic current exceeds 4 $\mu A/cm^2$, are shown in Fig. 3, where U_s and U_c designate the values for solution lacking the redox couple (5) and U_s (redox) and U_c (redox) designate those in the presence of the $[Fe(CN)_6]^{4-}/[Fe(CN)_6]^{3-}$ couple. It is seen that the U_s (redox) is kept close to the U_s in the range of $pH \leqq 4$, but deviates more to the positive at $pH > 4$. It is also seen that the U_c (redox) changes with pH, nearly in parallel with U_s (redox). This indicates the validity of the U_s (redox) values obtained from the Mott-Schottky plots. It is to be noted that U_s (redox) is kept nearly constant, in parallel with the redox potential of the redox couple (ϵ_{redox}) in the range of pH 5-10, while it moves upward with pH in the range of $pH > 10$.

Figure 4 shows the pH dependence of U_s (redox) for the (111)-face at various concentrations of the redox couple. The concentrations of $[Fe(CN)_6]^{4-}$ and $[Fe(CN)_6]^{3-}$ were made equal so as to keep the redox potential unchanged. It is seen that the U_s (redox) value remains nearly constant at the intermediate pH region. The constancy of U_s (redox) was maintained in a wider pH range, as the redox concentration increases.

Figure 5 shows the effect of the redox concentration on U_s (redox) and U_c (redox) at pH 6.8 and 13. The

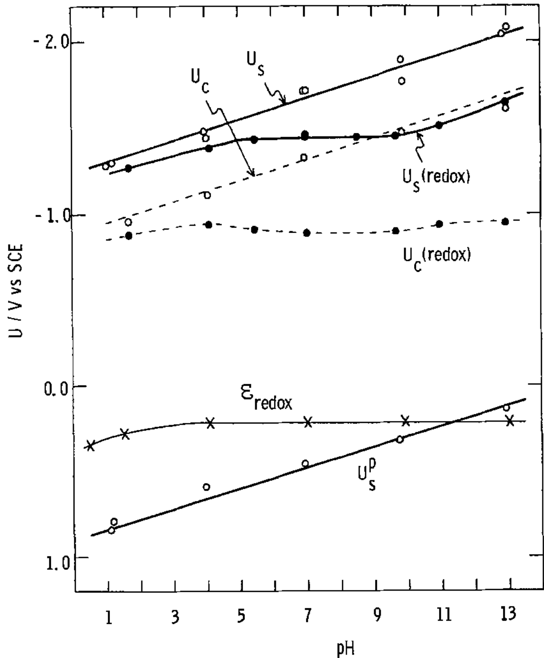

Fig. 3. U_s and U_c for the (111)-face of an n-GaP electrode, measured in the presence and the absence of 0.05M $K_4[Fe(CN)_6]$ and 0.05M $K_3[Fe(CN)_6]$. ϵ_{redox} is the redox potential of the redox couple determined by the cyclic voltammetry. $U_s{}^p$ is the U_s of a p-GaP electrode (5).

concentrations of $[Fe(CN)_6]^{4-}$ and $[Fe(CN)_6]^{3-}$ were kept equal also in this case. It is seen that the U_s (redox) and U_c (redox) curves are again parallel to each other. The U_s (redox) value for pH 6.8 remains nearly constant at least in the range of the redox concentration higher than 3×10^{-3} mol/dm^3, whereas U_s (redox) for pH 13 shifts to the positive with the concentration.

Figure 6 shows the U_s values for the $(\overline{111})$-face in the presence and absence of the $[Fe(CN)_6]^{4-}/[Fe(CN)_6]^{3-}$ couple. In contrast to the case of the (111)-face (Fig. 3), the U_s (redox) value for the $(\overline{111})$-face changed with pH throughout the pH range measured.

Similar experiments were made for other redox couples. As shown in Fig. 7, the shifts of U_s and U_c were observed by addition of an Fe^{2+}/Fe^{3+} couple and $[Cu(NH_3)_4]^{2+}$. In the latter case the reduced form, $[Cu(NH_3)_2]^+$, is unstable in solutions and was not added in the solutions. The redox potential for $[Cu(NH_3)_4]^{2+}$ was determined by cyclic voltammetry. By adding a V^{2+}/V^{3+} couple at $pH \leqq 3$, the U_s shifted very little and the U_c only slightly shifted. The redox potential for this couple is highly negative, about $-0.5V$ *vs.* SCE.

Discussion

The dark cathodic currents observed at the p-GaP electrode (Fig. 8) show that holes can be injected into the GaP electrode by the redox couples used in the present work, except V^{2+}/V^{3+}. The redox potentials of these redox couples are a little higher than the U_s of the p-GaP electrode ($U_s{}^p$), as is seen from Fig. 3 and 7. This means that the holes are injected by thermally activated oxidizing agents.

The shift of U_s of the n-GaP electrode caused by the addition of the redox couples is explained most probably by injected holes, similar to the interpretation given previously for the shifts in U_s by electrode illumination (5). The Mott-Schottky plots for solutions containing the redox couples show good straight lines in the potential range where the band bending is large (Fig. 2), indicating that U_s is kept nearly constant in this potential range. The electrode surface in contact with the redox solutions is thought to be in a stationary state in a range of potential where the band bending is large.

As mentioned before, the U_s for the (111)-face of the n-GaP electrode in the presence of the $[Fe(CN)_6]^{4-}$/$[Fe(CN)_6]^{3-}$ couple remains nearly constant in the intermediate pH range (pH 5 ~ 10), if the redox concentration is sufficiently high (Fig. 3, 4, and 5). In analogy to the Bardeen barrier in metal-semiconductor contacts (12, 13), these results suggest that the U_s value in such a pH range is determined by an electron transfer equilibrium between the redox couple in solution and electronic surface states at the electrode. We may assume that such surface states imply electron deficient surface Ga-P bonds. These species, which can be called a "surface-trapped hole," may be stabilized by the distortion of the surface Ga-P framework and also by the orientation of electric dipoles of solvent (water) molecules, their energy being a little above the valence bandedge at the surface ($E_v{}^s$). The nucleophilic attack of bases such as H_2O on these species leads to the electrode decomposition (5, 14). Such species can also accept electrons from reducing agents in solution, recovering to the normal Ga-P bonds. Hence, these species, together with the surface Ga-P bonds, can be regarded as making up a surface redox system, when the nucleophilic attack of H_2O is slow.

The above-mentioned constancy of U_s in the intermediate pH range can be explained as follows. The redox potential for the surface-trapped hole, ϵ_h, with respect to a certain reference electrode, can be described approximately in a form

$$\epsilon_h = \epsilon_h{}^\circ + (kT/e)\ln c_h + \psi + \text{const} \qquad [2]$$

where c_h means the density of the surface-trapped hole,

which is assumed to be much less than the density of the surface Ga-P bonds. ψ is the surface potential at the electrode. The electronic equilibrium between the surface redox system and the redox couple in solution is established at $\epsilon_h = \epsilon_{redox}$, ϵ_{redox} being the redox potential of the redox couple in solutions (Fig. 9).

It is to be noted that ϵ_h shifts with c_h through both the second and the third term on the right-hand side of Eq. [2], since the change in ψ arises from the electrical double layer due to the surface-trapped hole and therefore varies with c_h. The shift in ψ by the surface-trapped hole, $\Delta\psi$, can be expressed approximately as $\Delta\psi = ec_h/C$, where C is the capacitance for the electrical double layer at the interface. Accordingly, by differentiating the second and third term of Eq. [2] with respect to c_h, we can see that the third term changes with c_h much more steeply than the second in the range of $c_h > (CkT/e^2)$. Let us define $c_h^\circ = (CkT/e^2)$. It is calculated to be 5×10^{12} cm^{-2} when C is assumed to be of the order of 30 $\mu F/cm^2$, as generally done (15). This concentration corresponds to about one surface-trapped hole per two hundred outermost Ga-P bonds. The condition, $c_h > c_h^\circ$, can therefore be achieved rather easily.

With this condition, the energy difference between $-e\epsilon_h$ and the conduction or the valence bandedge at the surface ($E_c{}^s$ or $E_v{}^s$ in Fig. 9) is kept nearly constant, since $E_c{}^s$ and $E_v{}^s$ also change with ψ in the same manner as $(-e\epsilon_h)$. We can therefore see that, when $\epsilon_h = \epsilon_{redox}$, $E_c{}^s$ (or U_s) is determined solely by ϵ_{redox} in such a case, in agreement with the experimental results (Fig. 3 and 4).

The shift in ψ (or U_s) may also be caused partly by the hydroxide- or oxide-type surface intermediates (5) formed by the nucleophilic attack of H_2O on the surface-trapped hole. Even in such a case, the same conclusion as above can be derived as far as the electronic equilibrium ($\epsilon_h = \epsilon_{redox}$) is established under the condition of $c_h > c_h^\circ$.

Based on the above interpretation and the results of Fig. 3, the electronic equilibrium in the intermediate pH range is accomplished when U_s is about -1.45V *vs.* SCE, that is, about 1.65V above ϵ_{redox}. By estimating Δ in Eq. [1] to be *ca.* 0.1 eV and from the bandgap of GaP (2.26 eV), we can see that ϵ_h is about 0.5 eV above $E_v{}^s$, as is shown in Fig. 9. This value, called ΔE, reasonably corresponds to the stabilization energy for the surface-trapped hole due to the distortion of the surface Ga-P framework and the solvation, mentioned before.

It is to be pointed out here that an electroluminescence is observed when the n-GaP electrode is under a

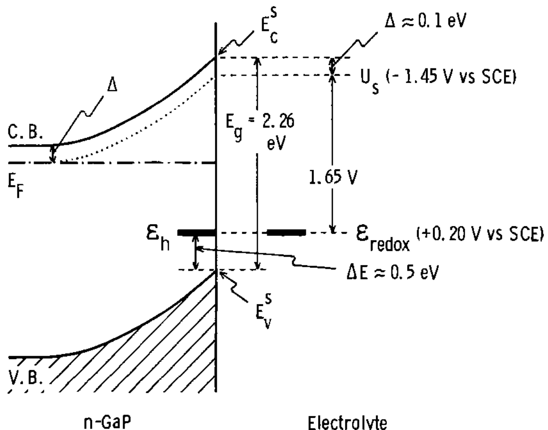

Fig. 9. A model of an electronic equilibrium at an n-GaP/electrolyte interface. For simplicity, the energy such as $E_c{}^s$, $E_v{}^s$, etc. and the potential such as U_s, ϵ_h, etc. are both used. These can be compared with each other by using a relation, (energy) = ($-e$) $\times$ (potential), if they are measured with respect to the same reference electrode.

slightly cathodic potential in solutions containing the $[Fe(CN)_6]^{4-}/[Fe(CN)_6]^{3-}$ couple (16). The luminescence spectrum ranges from 1.9 to 1.3 eV, with a peak at about 1.6 eV. The similar luminescence was reported in the literature (7, 9) and interpreted to be due to the hole injection by the oxidizing agents in solution. Since a sum of the energy of the luminescence peak and the ΔE value above is 2.1 eV, very close to the bandgap of GaP, it is highly probable that the electroluminescence is caused by a recombination between the surface-trapped hole and the electron in the conduction band.

In the discussion made so far, we assumed that the rate of the nucleophilic attack of H_2O on the surface-trapped hole (R_3) can be neglected as compared to the rates of the hole injection (R_1) and the reverse process (R_2). The very small R_3 value assumed here implies the presence of a fairly large activation energy for the nucleophilic attack of H_2O, which may be understood from three dimensionally bound surface Ga-P bonds of a high covalent character (17), since the attack of H_2O on one Ga-P bond must induce large steric strain in the surrounding Ga-P bonds.

Figures 3 and 4 show that a parallel relation between U_s (redox) and ϵ_{redox} is broken at pH higher than a certain value. The break point becomes higher, the higher the redox concentration. These results can be explained by assuming that the rate of the nucleophilic attack of H_2O, R_3, increases with pH and exceeds R_2 at a certain pH value. In that case, the electronic equilibrium is broken and ϵ_h is no longer equal to ϵ_{redox} at a high pH region. Figure 5 shows that the constancy of U_s (redox) at pH 6.8 is also broken when the redox concentration is too low. This can be explained by taking into account the low rate R_2 at a low redox concentration.

In both cases, namely, in the range of high pH and in the case of low redox concentration at $p\text{H} \gtrsim 5$, the electrode dissolution occurs predominantly by the hole injection ($R_1 \cong R_3 >> R_2$). The density of the surface-trapped hole (c_h) must be very small in such cases. The observed shift in U_s can then be attributed mainly to the accumulation of highly polar Ga-O or P-O bonds present in the oxide- or hydroxide-type surface intermediates mentioned before.

The U_s (redox) value for the $(\bar{1}\bar{1}\bar{1})$-face of the n-GaP electrode does not show any parallelism with ϵ_{redox} throughout the pH range measured (Fig. 6). This suggests that the surface-trapped hole at this face is less stable than that at the (111)-face.

It may be pointed out here that the difference between U_s (redox) and U_c (redox) is considerably larger than that between U_s and U_c in the absence of the redox couple (Fig. 3, 5, and 7). This can be explained by assuming that the capture of electrons in the conduction band by the surface intermediates is very efficient. It was reported previously (5) that a potential at which the photoanodic current deviates from the saturation value ($U_{sat}{}^a$) shifts largely from U_s under illumination [U_s (illum.)]. The shift was attributed, in the same way as above, to the effective capture of the electrons by photoanodically formed surface intermediates (5).

Manuscript received April 28, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

A Sensitive Novolac-Based Positive Electron Resist

M. J. Bowden, L. F. Thompson, S. R. Fahrenholtz, and E. M. Doerries

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A positive electron resist has been developed which appears to operate on a different mechanism from conventional positive electron resists. Resists in the latter category such as PBS or PMMA achieve differential solubility primarily as a result of scission of the main chain. In the case of the new resist, differential solubility appears to be achieved by the removal of a polymeric dissolution inhibitor. The resist is a composite system consisting of a novolac resin similar to that used in most positive photoresists in solid solution with poly(2-methyl-1-pentene sulfone) which functions as a dissolution inhibitor of the novolac resin in aqueous base. The process operates by spontaneous depolymerization of the polymeric dissolution inhibitor, a process which is initiated by electron irradiation. The sensitivity of this resist (called NPR) is 3 μC cm^{-2} at 20 kV and the contrast is 1.0. Submicron features have been delineated in 1.0 μm resist films. The resist withstands Al, poly-Si, SiO_2, doped SiO_2, and Si_xN_y plasma etching environments and has been used as a plasma etch mask to transfer submicron features into these film substrates.

Positive resists are characterized by increased solubility of the resist film after exposure to radiation. This increase in solubility is achieved by one of two mechanisms, viz., simple chain scission of individual bonds in the main chain (1, 2) or decomposition of a dissolution inhibitor (3, 4). Resists of the former type are high molecular weight polymers which undergo main chain scission under irradiation resulting in a decrease in molecular weight. This process leads to enhanced solubility of the irradiated region which may be developed by fractional solution. Resists which operate on the second principle consist of a mixture of a low molecular weight polymer, *e.g.*, a novolac resin, which is soluble in a given solvent (usually an aqueous base) and a material which inhibits the dissolution of the composite film in that solvent. The dissolution inhibitor is converted to an acidic species during irradiation and as a result of this chemical change, the composite becomes soluble in the aqueous base.

Most positive electron resists are of the first type (5). For example, poly(butene-1-sulfone) (2) and poly(methyl methacrylate) (6) are chain degrading polymers which are used primarily as resists for liquid etching. However, these polymers are thermally unstable and are also unstable to other forms of ionizing radiation; hence they are not very resistant to dry etching environments such as found in plasma etching, ion beam milling, and sputter etching.

The next generation of electron exposure machines will have high-throughput for direct exposure of VLSI silicon devices with submicron features. The high resolution requirement will almost certainly necessitate dry etching processes for pattern transfer. This requirement places an additional constraint on the resist other than the sensitivity and resolution requirements commensurate with machine design.

Clearly the etch resistance requirements would appear to preclude the positive electron resists which are currently available. Positive photoresists, on the other hand, exhibit excellent resolution and dry etch resistance particularly those positive photoresists based on novolac resins. These resists operate by the second mechanism alluded to earlier and a more detailed description of this mechanism will be helpful in understanding the new concept to be proposed in this paper.

Positive-acting photoresists are composed of three components: a resin, a photoactive compound (dissolution inhibitor), and a solvent system. All positive photoresists utilize the same basic photochemical mechanism, but they may be split into two families on the basis of the resin systems employed. The Shipley and Hunt resist formulations employ low molecular weight novolac resins (I) of this general formula

[Structure I: OH-substituted methylphenyl rings linked by CH_2 bridges, each ring bearing CH_3; repeating unit in brackets with subscript n]

$2 \le n \le 13$

I

A novolac resin (in connection with nomenclature, the

Key words: films, etching, radiation.

term novolak is sometimes used; following more popular usage and the recommendations of the "Encyclopedia of Polymer Science and Technology," (7) we use the term novolac) is an acid-catalyzed condensation product of a phenol and an aldehyde (usually formaldehyde). The resins have number average molecular weights in the range 600-2000 and are soluble in organic solvents and basic aqueous solutions. The properties of a novolac depend on the structure of the phenols and/or aldehydes used as well as the molecular weight and degree of branching (7, 8).

These resist formulations employ substituted naphthoquinone diazides (II) as the photosensitive dissolution inhibitor

II

the solvents are mixtures of cellosolve acetate, xylene, and n-butyl acetate (9).

The GAF positive resists (10) utilize a terpolymer of ethyl acrylate, styrene, and methacrylic acid in the approximate ratio 10:5:2 as the resin. Their photoactive component is also a substituted naphthoquinone diazide (III)

III

The photoactive component:resin ratio is approximately 1:1 and the solvent system is a mixture of xylene and methyl ethyl ketone (9). This particular system will not be discussed further since the dry etch resistance of these resins is inferior to that of novolac-type resins.

The positive working photoresist systems become soluble in aqueous alkaline developers after exposure to u.v. light. This change in solubility depends on the photochemical decomposition of the diazide followed by rearrangement and hydrolysis

There is a synergistic solubility effect between the decomposed diazide and the novolac since the solubility of an exposed resist is greater than that of the pure novolac (11). This is an important point of comparison to the new electron resist and is discussed later.

The resistance of these resists to dry etching processes is due to the excellent radiation and thermal stability of the novolac resin. The diazide dissolution inhibitor probably has no effect or even a detrimental effect on resistance to dry etching.

Electron Resist Considerations

It has been shown by several workers that positive photoresists can also be exposed by an electron beam (12, 13). The sensitivity is reported to be ~100 μC cm^{-2} at 20 kV. Resolution and processing characteristics are excellent. The sensitivity is low compared with other resists such as PBS and is attributed to the fact that the resist contains 20-30% of the low molecular weight quinone diazide dissolution inhibitor which must be largely decomposed in order to achieve complete differential solubility. The high percentage of functional groups necessitates a large number of photon (electron) interactions per unit volume.

The sensitivity of these systems is more than an order of magnitude too low for direct wafer exposure. In order to enhance the sensitivity, it would be necessary to incorporate some chemical amplification into the dissolution inhibitor decomposition. An alternative and somewhat novel approach would be to use a polymeric dissolution inhibitor which undergoes spontaneous depolymerization (unzipping) during irradiation (14). This can occur when a polymer exists above its ceiling temperature T_c, the latter being the highest temperature at which polymerization is possible for the prevailing conditions of monomer concentration and pressure. Above T_c the polymer is thermodynamically unstable but kinetically stable. Radiation-induced cleavage of a single bond in the main chain results in the production of propagating-type radicals with concomitant extensive depolymerization along the polymer chain. The volatile monomers produced by depolymerization evaporate from the film, a process we have called vapor development (15). A dissolution inhibitor of this type would thus be vaporized, *i.e.*, removed, resulting in an increase in solubility of the remaining film. The polymeric dissolution inhibitor should have the following properties: (*i*) phase compatibility with the novolac to allow uniform film formation, (*ii*) kinetic stability (as opposed to thermodynamic stability) at normal ambient conditions both in solution and in bulk, (*iii*) rapid rate of depolymerization during irradiation at room temperature resulting in adequate electron sensitivity (<10 μC cm^{-2} at 20 kV), and (*iv*) dissolution inhibition of novolacs with concentrations of less than 30 weight percent (w/o).

Certain poly(olefin sulfones) are known to meet the above requirements. Factors that affect the rate of depolymerization are dose rate, temperature, olefin structure, molecular weight, and molecular weight distribution with the best combination of properties being shown by poly(2-methyl-1-pentene sulfone) (IV). This material has been extensively studied by Bowden and Thompson (16-18). These polymers do not absorb above 2000Å and can be handled without special care

$$-\!\!\left(CH_2 - \underset{\underset{CH_2CH_2CH_3}{|}}{\overset{\overset{CH_3}{|}}{C}} - SO_2\right)_{\overline{n}}$$

IV

The use of a degrading polymer as a dissolution inhibitor represents a clear difference between this resist system and positive photoresist systems. The dissolution inhibitor in the photoresist is converted to a carboxylic acid whereas the polysulfone dissolution inhibitor in the resist described here is removed. There is no synergistic solubility effect with the polysulfone/novolac system.

The physical and chemical properties of the novolac are also important to resist performance. Not only must the solubility be within a certain range, but also the thermal and radiation stability and the adhesion must be optimum since the novolac will determine final resist performance. The desired properties are summarized as follows: (*i*) phase compatibility with the polysulfone to allow uniform film formation, (*ii*) solubility in aqueous alkaline solutions at *p*H 9-13, (*iii*) thermal and radiation stability sufficient for dry etching techniques and process bakes, and (*iv*) adhesion to film substrates used in device and mask fabrication.

Experimental

Novolac preparation.—An experimental novolac[1] (N64C) was evaluated as the base polymer. The polymer was prepared by an acid catalyzed condensation of substituted phenols with formaldehyde (7, 8).

PMPS preparation.—The dissolution inhibitor used in this work was poly(2-methyl-1-pentene sulfone) PMPS. This is an alternating copolymer of sulfur dioxide and 2-methyl-1-pentene and was prepared by free radical polymerization in excess SO_2 using *t*-butyl hydroperoxide as the initiator. The procedure has been reported elsewhere (15). The polymer is quite stable (up to ~130°C) (18) as the ends are "capped" (protected from degradation) by initiator fragments and/or fragments resulting from transfer reactions.

Resist preparation.—Resist solutions were prepared by dissolving the novolac with PMPS in a solution of methyl cellosolve acetate (80%) and cyclohexanone (20%). The solutions were then filtered several times through a 0.2 μm Teflon filter.

Spin coating.—Films were spin-coated using a Headway EC-101 spinner equipped with a 15 in. bowl. The novolac spun good uniform films from methyl cellosolve acetate. Difficulties were sometimes encountered, however, in spinning uniform films from resist solutions containing PMPS. First, phase separation tended to occur with some novolacs in films spun from pure methoxyethyl acetate. This problem was eliminated by the addition of 10-20% cyclohexanone to the resist solution. Second, the excess liquid which is spun off the substrate during spin coating had a tendency to form fibers (cotton candy) that deposited on the wafer resulting in poor quality films. This problem was reduced by covering the sample with a large beaker during the first 10-20 sec of spinning, then removing the beaker for the final 50 sec drying period. This problem could also have been eliminated by using a different exhaust configuration on the spinner.

[1] The novolac was prepared by Polychrome Corporation to Bell Laboratories specifications.

Baking.—The resist and novolac films were prebaked either in vacuum or a forced air oven in a conventional manner.

Developing.—The developer used in this study was Shipley AZ developer. This is an aqueous alkaline solution with a *p*H of 12.9. Temperature has a strong influence on dissolution rate and was controlled at 21° ± 0.1°C. Developing was carried out by immersion in a bath without agitation. Samples were removed after a given time, rinsed with deionized water, and dried. Developer strength was varied by dilution with distilled water, the proper strength being that which did not thin or attack the unirradiated film.

Exposure.—Electron beam exposure was carried out using either a modified Cambridge Mark II scanning electron microscope or EBES-I. Relevent exposure conditions are given in the discussion.

Plasma etching.—Films spun from a resist solution containing a weight ratio of PMPS to novolac of 1:10 (9% PMPS) were evaluated as plasma etching masks for SiO_2, polysilicon, and aluminum. The resist thickness removed during plasma etching was measured with a Dectack.

Image evaluation.—The quality of images in both resist patterns and etched patterns were evaluated with an ETEC Autoscan scanning electron microscope.

Results and Discussion

Solubility characteristics of the novolac resin.—Positive resist action depends on a differential solubility between exposed and unexposed regions. The electron resist principle described in this paper requires that the dissolution inhibitor be removed by irradiation; hence, solubility of the irradiated film cannot be greater than that of the pure novolac. Accordingly, it is important to determine the solubility rate of the pure novolac.

The rate of dissolution of a novolac resin in aqueous alkaline solution is dependent on molecular structure and molecular weight of the novolac, base strength (*p*H), dissolution temperature, and prebake temperature and conditions. Some representative dissolution curves for the particular novolac studied are shown in Fig. 1. Initially we chose a developing temperature of 21° ± 0.1°C and a prebake treatment consisting of 2 hr in an air oven at 120°C. It was observed, however, that the dissolution rate at constant *p*H decreased with increasing prebake time (Fig. 2) until ultimately the film became totally insoluble, even in organic solvents. The infrared spectrum of a film prior to baking is shown in Fig. 3 (spectrum a) together with the spectrum of the same film after 24 hr at 120°C in air (spectrum b). The infrared spectra of another film which had been baked at 120°C in vacuum for (a) 2.5 hr and (b) 24 hr are shown in Fig. 4. Whereas there is no difference between the spectra before and after heating in vacuum, there is a significant change in the case of the film heated in air. A carbonyl band appears at 1650 cm^{-1} whose intensity increases with time indicating oxidative degradation. This process appears to give rise to cross-linking so that eventually the film becomes insoluble. The absence of spectral changes for the film heated in vacuum suggests that the dissolution rate should be unaffected. Figure 5 shows that the dissolution rate for films baked 1 hr and 4 hr in vacuum is identical. The slight induction period for the sample prebaked for 4 hr may be due to a small amount of surface degradation resulting from trace oxygen, or removal of unreacted monomer from the film.

Solubility characteristics of novolac/PMPS films.—Not all novolacs appeared to spin uniform films with PMPS. Qualitative observations of the cosmetic ap-

pearance of spun films indicated that novolacs based on phenol-formaldehyde are incompatible with PMPS (Fig. 6A). Novolacs based on substituted phenols usually appear to be compatible with PMPS (Fig. 6C) although in some circumstances, depending on the particular substituent and spinning solvent, partial phase separation may be observed (Fig. 6B).

The novolac used in the present study gave uniform, single phase films with PMPS. The presence of PMPS in the novolac film greatly increased the pH required to affect the film. Unlike the films containing quinone diazide dissolution inhibitors which do dissolve at measurable rates in high pH solutions, novolac/polysulfone (NPS) films often do not dissolve uniformly, but rather become extremely pitted (Fig. 7). However, this type of surface attack only occurs at a pH greater than that required for development of the resist so that within the pH range of interest, PMPS does totally inhibit dissolution. The actual pH such films can withstand before pitting depends on the amount of PMPS in the film. Table I shows the maximum pH which the film will withstand for 5 min without pitting as a function of PMPS content.

Exposure characteristics of pure PMPS.—The exposure characteristics of pure PMPS films have been extensively studied (16, 17). A typical plot of the frac-

tion of film remaining against dose is shown in Fig. 8. The exposure was carried out at 20 kV. The film removal rate is an exponential function of dose. Clearly, if it were required to remove all the PMPS, *i.e.*, reduce the residual film thickness to zero, a very large dose would be required. It is also apparent from Fig. 8 that the contrast, as determined from the slope of the line, is extremely low, being only 0.3. One might be led to conclude, *a priori*, that the low contrast of the

vapor development process would result in poor resolution. However, the contrast of importance is that obtained on development of the resist and as we shall see, it is significantly higher. Also shown in Fig. 8 is the vapor development curve for a PMPS sample of lower molecular weight. As expected, the dose to remove a given fraction of the film is higher (lower sensitivity), but the contrast is unchanged.

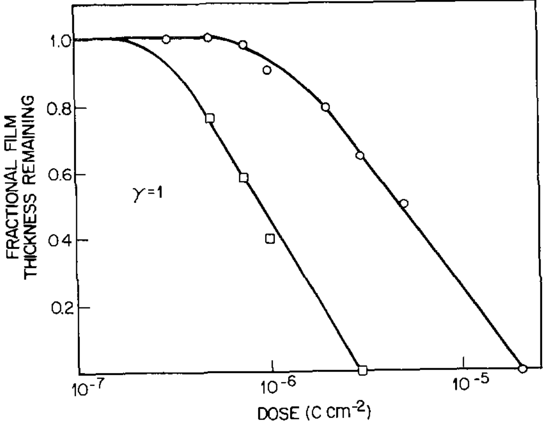

Fig. 9. Developed NPR resist film thickness as a function of electron dose at 20 kV. (○) NPR film as exposed. (□) NPR film exposed and baked at 120°C for 15 min prior to developing.

Exposure characteristics of NPR films.—The exposure characteristics of NPR films were determined by exposing known areas to varying electron doses at 20 kV followed by development in a standard develop-

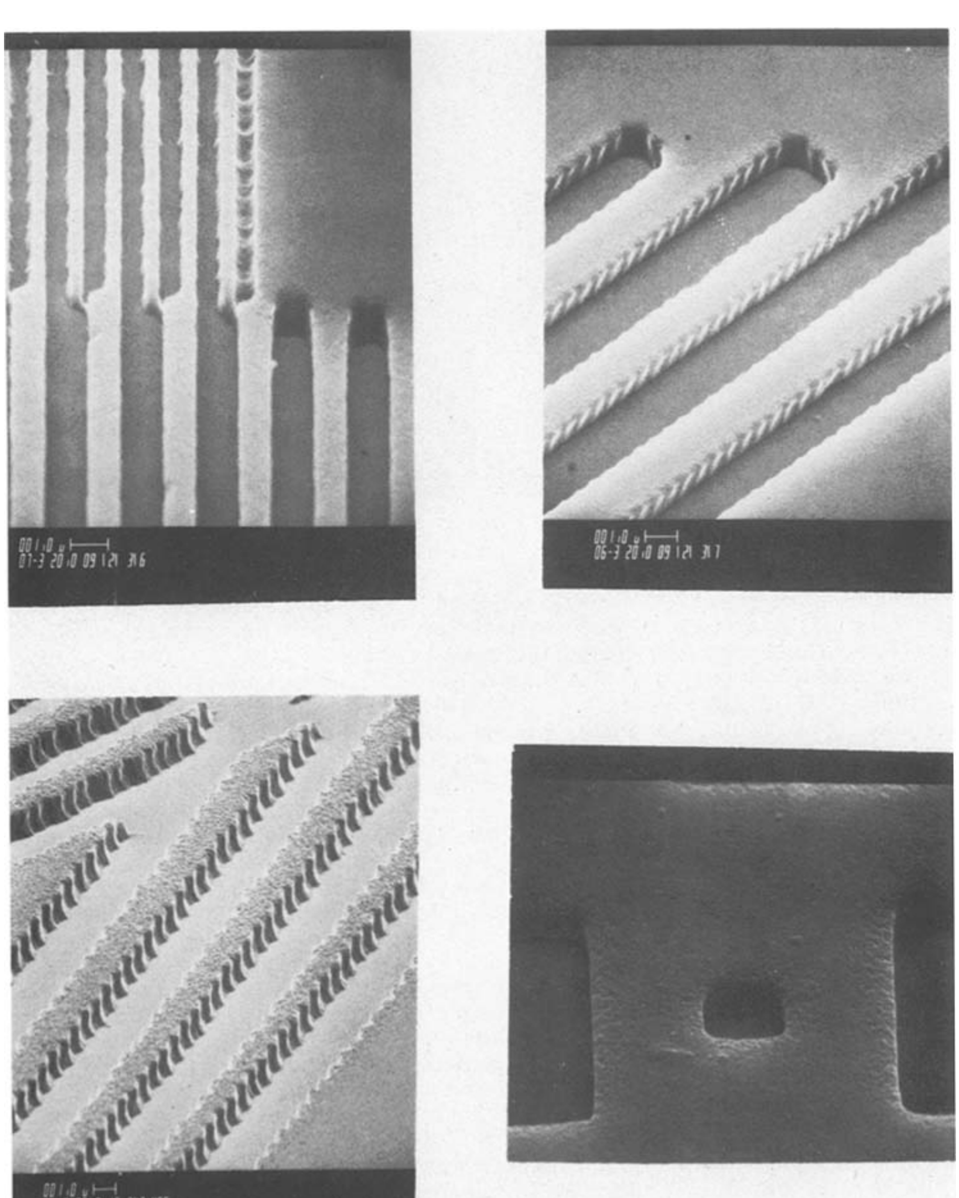

Fig. 10. SEM micrograph of developed pattern in NPR resist. Exposed at 10 kV on EBES I with a dose of 3 μC cm^{-2}.

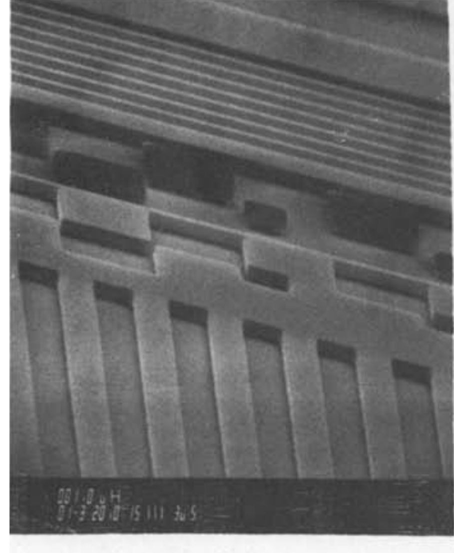
ing solution of sufficient strength to develop the pattern in a reasonable period of time (≤5 min). A typical contrast curve generated for the resist containing 9 w/o PMPS is shown in Fig. 9 from which a contrast of 1.0 is obtained. The sensitivity is 16 $\mu C\ cm^{-2}$ at 20 kV.

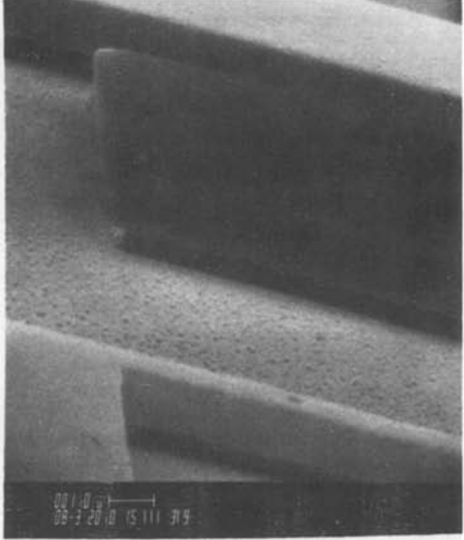
The sensitivity can be increased to 3 $\mu C\ cm^{-2}$ by subjecting the irradiated resist to a postexposure bake at 120°C for 15 min prior to development as shown in Fig. 9. We have attributed this result to additional depolymerization during postexposure baking. Under normal irradiation conditions at room temperature, active radicals becomes trapped thus halting depolymerization. By subjecting the sample to elevated temperatures following exposure, the radicals acquire sufficient energy to escape from the trap giving rise to additional depolymerization, *i.e.*, material loss. Studies on the nature of the trapped radicals are in progress.

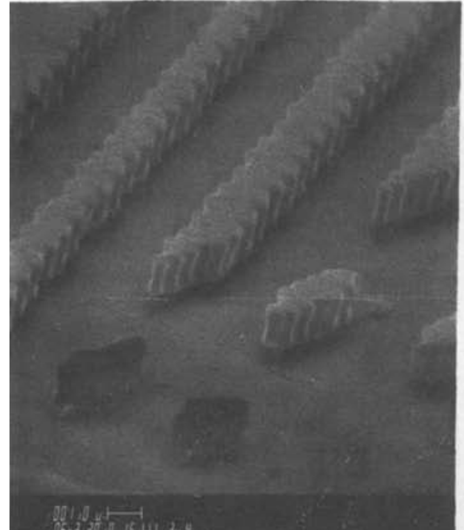
Infrared studies (19) have shown that the depolymerization kinetics of PMPS in solid solution with novolac are the same as in a film of pure PMPS. Thus the development dose of 3 $\mu m\ cm^{-2}$ at 20 kV reflects a loss of about 60% of the PMPS leaving about 3.6 w/o PMPS in the NPR film. This residue still has an inhibiting effect on the dissolution rate so that the developer strength required to develop the image is greater than would be necessary to dissolve the pure novolac in a comparable period of time.

The contrast for the resist system of 1.0 is improved by a factor of three over that of the vapor development process. This higher contrast presumably reflects the ability of the developer to distinguish small differences in the amount of PMPS remaining in the film.

We speculate that the increase in solubility results directly from the removal of the dissolution inhibitor. Admittedly the depolymerization process produces large amounts of gaseous by-product with subsequent void formation which in turn would enhance the solubility rate ratio between exposed and unexposed film (20, 21). We have noted however that postexposure baking above the glass transition temperature of the novolac results in an increase in sensitivity. Under these conditions one would expect the voids to collapse and this is indeed observed in practice as a surface relief caused by reduction in the film thickness in the exposed areas during postexposure baking. Since void collapse would, on the above premise, result in a decrease in sensitivity it seems reasonable then to attribute the increase in solubility solely to the removal







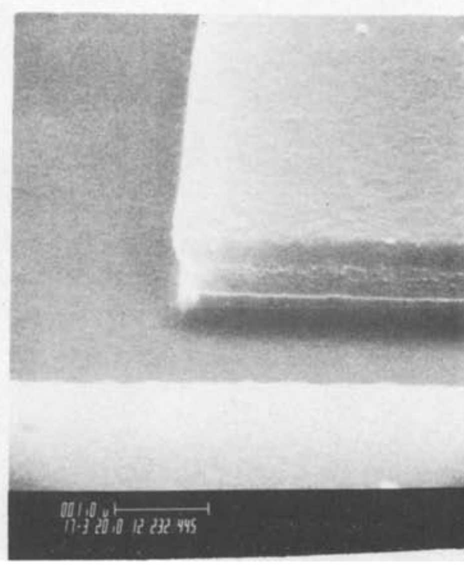


Fig. 12. SEM micrograph of plasma etched polysilicon (0.75 μm) patterns without the resist removed.

of the PMPS. Further evidence is needed to corroborate this point.

Image quality and resolution.—A number of factors such as material and processing parameters determine the reproducibility of image quality obtained. Not all of these are completely understood and further work is required to elucidate these effects. Nevertheless we have been able to obtain patterns with excellent image quality. There is no pattern distortion due to swelling. Line width control is, however, extremely susceptible to overdevelopment and/or overexposure and these difficulties are further compounded by poor adhesion. Nevertheless, with careful development, we have been able to develop 0.5 μm lines and spaces in 0.8 μm resist. The high resolution of this resist system is also reflected in the EBES address structure which is resolved on all oblique lines. Some micrographs showing the pattern quality and resolution are shown in Fig. 10.

Plasma etching resistance.—Test patterns were written on a variety of resist-coated substrates with EBES-I. The substrates and the various plasma etching conditions for those substrates are listed in Table II. The resist withstood all plasma environments, even the Al etch which is considered to be the most reactive of all. Photomicrographs of test patterns plasma etched in SiO_2, poly-Si, and Al are shown in Fig. 11, 12, and 13, respectively.

Conclusions

1. We have described a new resist system in which differential solubility appears due to the removal of a polymeric dissolution inhibitor.

2. The sensitivity of this resist system is approximately 3 $\mu C\ cm^{-2}$ at 20 kV with a contrast of 1.0.

3. Submicron features have been delineated in 1 μm thick resist films.

4. The resist system withstands Al, poly-Si, SiO_2, p-SiO_2, and Si_xN_y plasma etching environments and

Electrical Properties and Stability of Supersaturated Phosphorus-Doped Silicon Layers

M. Finetti, P. Negrini, S. Solmi, and D. Nobili

CNR-Istituto LAMEL, Via Castagnoli, 1, 40126 Bologna, Italy

ABSTRACT

Supersaturated solutions of phosphorus in silicon were obtained by ion implantation and pulsed ruby laser annealing. The dependence of electron mobility and electrical resistivity on carrier density was accurately determined by Hall effect and resistivity measurements. Maximum dopant concentration was 5×10^{21} atom/cm^3, corresponding to a resistivity of 110 $\mu\Omega \cdot$ cm and to an electron mobility of 11 cm^2/V $\cdot$ sec. The stability of these alloys was analyzed by isochronal and isothermal annealing. In the more heavily doped samples a remarkable deactivation of the dopant was verified also for thermal treatments of 1 hr at 300°C. TEM examinations showed a large amount of precipitates with density and size depending on supersaturation. Finally it was observed that the electron mobility depends only on the carrier density and is unaffected by the electrically inactive phosphorus, even when present at very high concentrations.

Many recent papers have indicated laser irradiation as an interesting technique for the recovery of radiation damage in implanted layers (1-8). It was also observed by some authors (6-8) that dopant concentrations in excess of the solid solubility values can be dissolved in silicon by these techniques. The possibility of obtaining higher conductivities, both in monocrystalline silicon slices and in polysilicon films, is of great importance in microelectronics in order to further reduce device geometries as required by the very large scale integration.

In this paper supersaturated silicon layers obtained by Q-switched ruby laser annealing after heavy phosphorus implantation were accurately characterized and the dependence of resistivity and electron mobility on carrier concentration was determined. In addition, the stability of these metastable alloys was studied by isochronal and isothermal annealing; these experiments provided information on the precipitation phenomena of excess dopant.

Experimental

For our experiment we used p-type, <100> oriented, CZ pulled, dislocation-free silicon slices of nominally 1 $\Omega \cdot$ cm resistivity. Wafers were about 300 μm thick and mirror finished on one side.

The crystals were phosphorus implanted in a random direction with an energy of 100 keV and at doses ranging between 2×10^{15} and 5×10^{16} atoms/cm^2.

Before annealing a thin silicon layer, about 400Å thick, was removed by anodic oxidation to eliminate the contamination of carbon atoms introduced by the implantation process.

Laser annealing was carried out by a 20 nsec single pulse delivered by a Q-switched ruby oscillator (λ = 0.69 μm) operating in multimode regime. An optical guide was used to yield a uniform 14 mm diam light spot with an energy density of 1.8 J/cm^2.

Key words: phosphorus implantation, laser annealing, electron mobility in silicon, stability of supersaturated layers, phosphorus precipitation.

For the determination of the electrical profile, the van der Pauw geometry was etched on the specimen's surface by a photolithographic process, or alternatively by using an ultrasonic drill. Sheet resistance and Hall effect measurements were performed after anodic oxidation in steps of 200Å and oxide stripping.

The stability of these metastable layers was analyzed by isothermal annealing at 450° and 550°C, from 15 min to 1500 hr, and by 1 hr isochronal heating in steps of 25° from 300° to 750°C. The processes were carried out in an open tube furnace in nitrogen atmosphere.

After each treatment resistivity and Hall effect measurements were performed to determine the total amount of carrier concentration and the average mobility.

The recovery of the radiation damage and the effects of the successive heat-treatments were checked by transmission electron microscopy (TEM) observations and Rutherford backscattering (RBS) analysis.

Results and Discussion

Electrical characterization of the supersaturated layers.—In Fig. 1 are reported the carrier concentration profiles obtained on samples implanted at 100 keV with doses of about 5, 0.8, and 0.3×10^{16} atoms/cm^2 and successively laser annealed. In any case the total amount of implanted phosphorus was electrically active. At the highest dose a carrier concentration of about 5×10^{21} cm^{-3} (corresponding to 10 atomic percent) was obtained, more than one order of magnitude higher than the maximum value of phosphorus solid solubility in silicon (9).

TEM and RBS examinations showed that the above-defined laser annealing completely restored the crystal lattice which was found free of observable defects. This behavior was confirmed also for the most heavily doped specimens.

The dopant was localized in an extremely shallow surface region and the typical high diffusivity tail associated with phosphorus profiles was not present

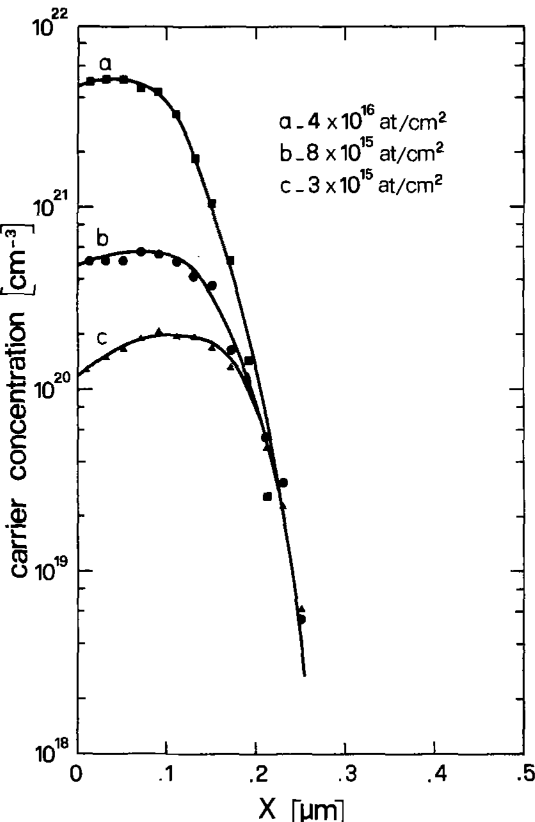

Fig. 1. Carrier concentration profiles of phosphorus-implanted laser annealed samples.

(9-10). The junction depth was lower than 0.3 μm and the corresponding sheet resistance was about 8 $\Omega/\square$. The quality factor ($q.f. = (\rho_s \cdot x_j)^{-1}$) of this layer is about 0.45 $\mu m^{-1} \cdot \Omega^{-1}$, higher by a factor of four than the one obtainable by the traditional furnace processing.

In Fig. 2 we report the electron mobility *vs.* carrier concentration as determined by resistivity and Hall effect measurements. The experimental points refer not only to the profiles reported in Fig. 1, but also to other implanted doses annealed in the same conditions. The dotted curve represents the behavior followed by thermally diffused samples (11). It stops at about 4×10^{20} cm^{-3}, corresponding to the highest concentration obtainable by the traditional techniques.

The curve of mobility in laser annealed samples joins to the Masetti-Solmi data (11) and decreases with increasing carrier concentration, down to values of 11 cm^2/V·sec corresponding to an electron concentration of 5×10^{21} cm^{-3}.

At carrier densities lower than 3×10^{20} cm^{-3} the laser annealed samples present mobility values about 10-20% lower than in diffused samples. This effect was attributed to a high concentration of electrically active point defects introduced in the crystal by the laser treatment (12-13). The influence of these defects on mobility is significant only at relatively high μ values (> 50 cm^2/V·sec) and becomes gradually negligible with decreasing mobility. It has been observed that after a thermal treatment at 700°C these defects are completely annealed (12). This behavior is confirmed by our results obtained on supersaturated samples thermally annealed at 850°C for 30 min (open circles in Fig. 2); in this case the mobility values fall on the Masetti-Solmi curve (11).

The data from laser annealed samples, reported in Fig. 3, allow the empirical resistivity *vs.* carrier density curve of n-type silicon to be extended to higher concentrations. By this technique it is possible to obtain resistivities as low as 110 $\mu\Omega$·cm, a factor of three lower than the minimum values presented by thermally predeposited samples and comparable to those characteristic of the transition metal (Mo, W, ...) silicides (14). In this figure we have also shown, for comparison, two experimental curves (dotted lines) of ρ *vs.* n already reported in the literature (9, 15). Irvin data have not been considered here because, as the author himself points out (16), for concentrations in excess of 2×10^{20} cm^{-3} they are not reliable due to the possible differences between dopant and electron concentrations.

Stability of the supersaturated layers.—These highly supersaturated solutions are far from the equilibrium conditions, therefore their thermal stability, a necessary condition for practical applications, depends on the kinetics of precipitation of the silicon phosphide phase.

The occurrence of precipitation was extensively studied in a companion paper (17). Here we report the results of the observations of the stability as a function of the implanted dose.

Isothermal annealing of four different compositions was performed at 450°C for 1500 hr and at 550°C for 1000 hr. The initial carrier concentration in the top of the profile was 5×10^{21}, 2×10^{21}, 5×10^{20}, and $2 \times$

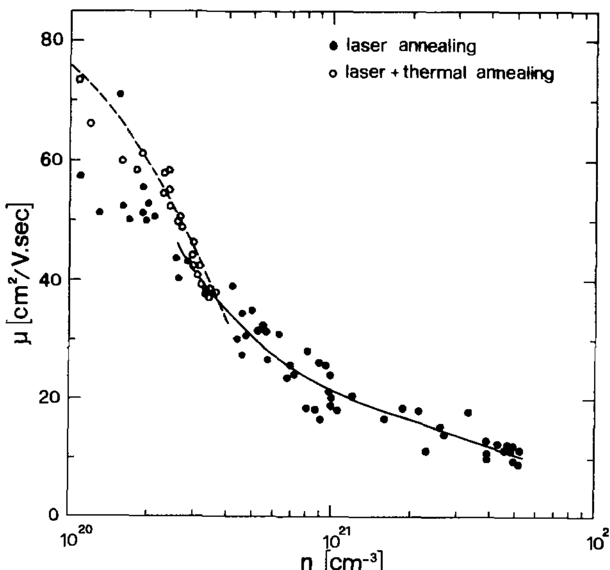

Fig. 2. Electron mobility *vs.* carrier concentration. The dotted curve represents the behavior of mobility in diffused samples (11).

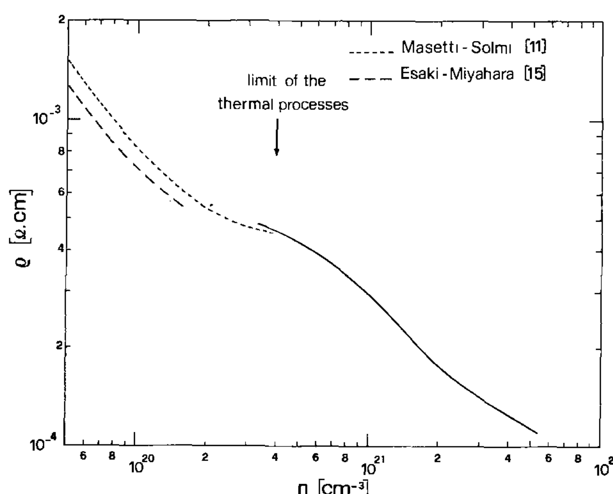

Fig. 3. Resistivity *vs.* carrier concentration in phosphorus-doped silicon.

10^{20} cm^{-3}, respectively. In Tables I and II we report, at increasing annealing times, the phosphorus precipitated fraction f, as defined by

$$f = [C_i - C(t)]/[C_i - C_e]$$

where C_i is the implanted dose, $C(t)$ the time dependent electrically active dose as determined by Hall measurements, and C_e the equilibrium dose.

The calculations of C_e were performed by using phosphorus solubilities of 2.2×10^{19} atoms · cm^{-3} at 450°C and 3.8×10^{19} atoms · cm^{-3} at 550°C. These data were determined by Ekstrom *et al.* (18) by analysis of the kinetics of P precipitation in $Si_{0.7}Ge_{0.3}$ thermoelectric alloys and are significant in our case as silicon and germanium form ideal solutions. Moreover, they are in very good agreement with the solubility values, that we will discuss in a subsequent paper, deduced by the concentration profiles at the end of our isothermal treatments.

Examination of these results puts in evidence the marked dependence of the extent of precipitation on the initial supersaturation; this behavior is foreseen by the models of the precipitation kinetics (18-20). For low concentrations (2×10^{20} cm^{-3}), comparable to the ones obtained by thermal processes, an appreciable precipitation is observed only after significant annealing times ($t > 100$ hr at 450°C and $t > 1$ hr at 550°C). The extent of the process increases rapidly with supersaturation and at 5×10^{20} cm^{-3} we obtained a significative precipitation just after 15 min.

TEM observations of the samples showed a very high density of precipitated particles, which is connected to a very high nucleation frequency. Precipitate size decreases with increasing concentration; this is in agreement with the classical model of nucleation (21)

$$I_n = A \exp - B/[RT(\ln i)]^2$$

where I_n is the nucleation frequency, A and B are constants at constant temperature, and i is the supersaturation defined as the ratio of the actual and the equilibrium solute concentration.

In Fig. 4 are reported two examples of TEM micrographs taken on specimens phosphorus implanted with dose of 2×10^{15} atoms/cm^2 (Fig. 4a) and 8×10^{15} atoms/cm^2 (Fig. 4b) after 1500 hr annealing at 450°C.

The less doped sample, which corresponds to an initial concentration of 2×10^{20} atoms/cm^2, presents precipitates of about 200Å in diameter with a density of about 10^{10} cm^{-2}. Conversely in the more doped specimen (initial concentration 5×10^{20} atoms/cm^3) the size of the precipitates is smaller (50-80Å in diameter), and their density is higher (10^{12} cm^{-2}). The micrographs were taken in the weak beam geometry in order to have image widths very close to the true particles size. From the density of precipitates (per unit volume), which was obtained by taking into account the geometrical effect of the overlapping (22), and from their average diameters we deduced that the amount of the silicon phosphide phase is consistent with that of the electrically inactive dopant.

Thermal stability as a function of temperature was investigated by isochronal annealing in the range 300°-750°C in steps of 25°C. Heating time per step was 1 hr. We report in Fig. 5 and 6, respectively, the electrically active dose C and the average mobility μ *vs.* temperature for three different implanted doses. As expected the stability decreases with increasing supersaturation, in particular a remarkable decrease in C is observed in the most heavily doped specimens where about 40% of the dopant is precipitated after 1 hr at 300°C. The less doped composition is fairly stable and shows a monotonic trend, while those more heavily doped present a minimum active concentration followed by redissolution. The temperature for reverse annealing decreases with increasing initial dopant concentration.

As we discussed in detail (17), this reverse annealing phenomenon is due to the Gibbs-Thomson effect (21). The solubility of the dopant increases with decreasing size of the precipitates; this enhancement is important only for precipitates of very small size. When temperature is raised enough, small particles redissolve and the process takes place at lower temperatures and higher dopant concentrations, the

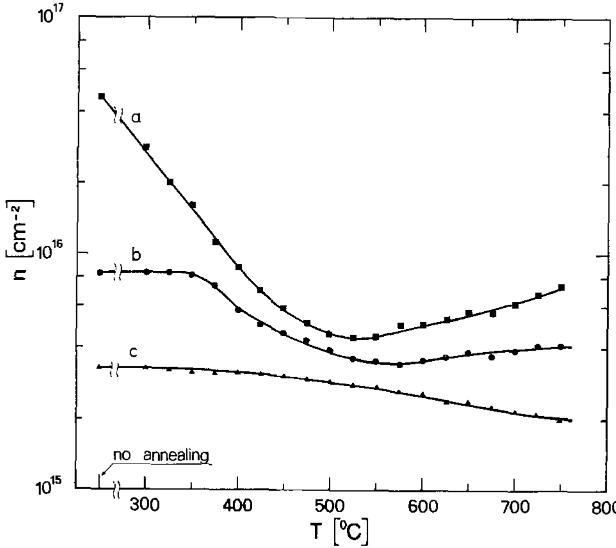

Fig. 5. Electrically active dose vs. 1 hr isochronal annealing temperature for three different implanted doses.

smaller the particle size. This is clearly shown in Fig. 5 where, as it was observed previously, the higher the initial supersaturation the smaller is the particle size.

Finally we point out that this large density of small particles does not influence the carrier mobility. In fact, the average mobility data (Fig. 6) show a behavior depending essentially on the electrically active concentration and lie on the same curve when plotted *vs.* C.

This phenomenon is demonstrated clearly by measurements performed on specimens implanted at doses of 4×10^{16} atoms/cm^2 (profile a in Fig. 1), laser annealed, and successively thermally treated at 850°C for 30 min. The mobility values (open circles in Fig. 2), in spite of the large amount of inactive phosphorus, fit very well with the experimental curve reported in the literature (11). This experiment excludes the formation of a significant amount of point defects which compensate or make the excess dopant electrically inactive (10, 23), since their presence would considerably affect carrier mobility.

Conclusions

The following conclusions can be drawn from this study:

1. Silicon n^+ layers with electron concentration up to 5×10^{21} cm^{-3} can be obtained by high dose phosphorus implantation and pulsed laser annealing.

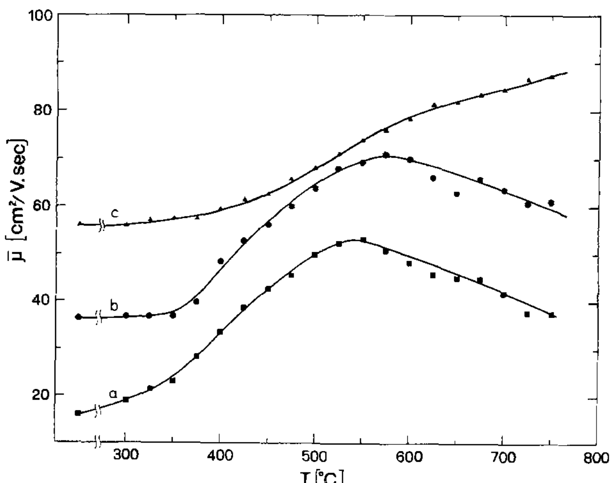

Fig. 6. Average electron mobility vs. 1 hr isochronal annealing temperature for three different implanted doses.

2. Electron mobility decreases monotonically with increasing dopant concentration from ~ 45 cm^2/V·sec at 3×10^{20} to ~ 11 cm^2/V·sec at 5×10^{21} atoms/cm^3. Silicon resistivities as low as 110 $\mu\Omega$·cm, comparable to those presented by the refractory metals silicides, can be obtained.

3. The thermal stability of these alloys, determined by isochronal and isothermal annealing, is strongly dependent on the supersaturation. Even short processes at low temperature, such as metal sintering or die bonding or packaging, can produce a marked precipitation of dopant in the more heavily doped samples.

4. The electrically inactive phosphorus is present in the form of small precipitates, with densities and mean diameter depending on supersaturation.

5. The electrically inactive phosphorus, even when present in concentration about 15 times higher than the carrier density, does not affect the electron mobility, which depends only on carrier concentration.

Anomalous Arsenic Diffusion in Silicon Dioxide

Yasuo Wada*,[1] **and Dimitri A. Antoniadis***

Department of Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The diffusion of ion-implanted arsenic in thermally grown silicon dioxide is examined as a function of temperature, arsenic concentration, and ambient. Diffusion coefficients are calculated from profiles obtained by secondary ion mass spectroscopy (SIMS) analysis. At relatively low concentrations—below approximately 5×10^{20} cm^{-3}—the activation energy of the diffusion coefficient in nitrogen atmosphere between 1000° and 1200°C is 4.7 eV. At high concentrations—above 5×10^{20} cm^{-3}—it is found that arsenic practically does not diffuse under the above conditions. This phenomenon might be attributed to arsenic-silicon-oxygen complex formation. However, if annealed in a dry oxygen atmosphere, arsenic diffuses at both high and low concentrations with an activation energy of 3.7 eV. It is determined that it is necessary that oxidation of underlying silicon must be taking place for such an enhanced diffusion to occur. The mere presence of oxygen in the annealing ambient, without silicon oxidation, does not have any effect.

Large-scale integration of silicon MOS circuits is partly accomplished via the scaling principle (1), in which vertical as well as horizontal dimensions of MOSFET's are reduced simultaneously. Because of its low diffusivity, arsenic is thus becoming increasingly important as an n-type dopant. Arsenic ion implantation has become a key process for fabricating self-aligned shallow source and drain regions (2) in scaled polysilicon gate circuits. The diffusion coefficient of arsenic (As), in silicon (Si), has been determined accurately (3), and clustering models have been proposed (4), so that chemical and electrically active profiles of arsenic, as well as residual defect penetration (5), resulting from a wide variety of ion implantation based processes are quite predictable. However, diffusion coefficients in silicon dioxide (SiO_2), reported to date, are scattered by more than an order of magnitude (6-8). As SiO_2 layers become thinner, control of impurity profiles increasingly requires better knowledge of impurity diffusion characteristics in SiO_2.

The present work presents a study of As diffusion in thermally grown SiO_2 at temperatures between 1000° and 1200°C in inert-nitrogen- and oxidizing-dry oxygen-ambients. Arsenic was ion implanted into SiO_2 at two doses, 10^{15} cm^{-2} for relatively low concentration study and 10^{16} cm^{-2} for high concentration study. Diffusion coefficients were calculated directly from the as-implanted and diffused profiles in SiO_2 observed by secondary ion mass spectroscopy. This direct observation of profiles eliminates uncertainties introduced by assumed models when As diffusion is extracted by electrical characterization of Si doped via the SiO_2.

Key words: dielectrics, integrated circuits, ion implantation, SIMS.

SIMS is a very powerful tool in determining impurity profiles both in Si and in SiO_2 (9, 10). However, in analysis of SiO_2 or insulating materials in general, a major problem is the electrostatic charge-up of the sample during sputtering. Another problem, of lesser importance, is the redeposition effect from the high concentration edges of the sputtered crater. Here a new sample structure is introduced to avoid these two problems, and is used to analyze the As-doped SiO_2. The results of this study indicate that in inert ambients detectable diffusion takes place at arsenic concentrations less than about 5×10^{20} cm^{-3}. At higher concentrations diffusion appears to stop, suggesting some form of As complexing. In oxidizing ambients, diffusivity is enhanced and the complexing effect is not observed. Further it is determined that the enhancement results from the oxidation of underlying silicon, which clearly suggests an oxidation enhanced diffusion (OED), rather than oxygen enhanced diffusion. Interestingly, the change of activation energy of diffusivity under OED in SiO_2 is similar to that observed under OED in silicon (13).

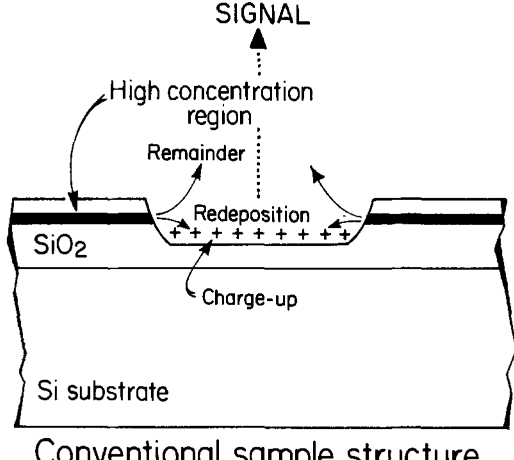
Experimental Procedures

Sample preparation and SIMS measurements.—A 0.5 μm thick SiO_2 layer was thermally grown on a p-type, <100> oriented silicon wafer. As ions were implanted into the oxide layer at 120 keV to doses of between 10^{15} and 10^{16} cm^{-2}. The samples thus prepared were annealed in either dry nitrogen or dry oxygen atmosphere at temperatures between 1000° and 1200°C for times between 15 min and 64 hr. Then the SiO_2 layer was etched to define mesas of 500 μm diam.

SIMS analysis was carried out to measure the As profile in SiO_2. The mesa structure avoids not only the charge-up of the SiO_2 layer but also the redeposition of

sputtered atoms from the high impurity concentration edge of the conventional crater, as schematically shown in Fig. 1. Thus, it makes possible to obtain accurate depth profiles by SIMS analysis. The detection limit was around 10^{18} cm^{-3}, which is sensitive enough to allow determination of the diffusion coefficient in more than 10^{19} cm^{-3} arsenic concentrations. The possible error of the concentration determination was $\pm 30\%$. Residual oxide thickness was measured by laser ellipsometry and by surface profilometer (Dektak), and the possible error in this thickness measurement was around $\pm 5\%$. The sputtering rate was calculated from the thickness measurement and was typically 1.5-3.5 nm/min. Ion current signal of Si^+ was quite stable during the measurement, and the variation was typically less than 10% in 6 hr.

Typical sample structures before and after SIMS analysis measured by Dektak are shown in Fig. 2. The protrusion represents the mesa-etched SiO_2 region. Negative oxygen (O^-) ions were used as the primary ion beam, and were scanned over more than a 700 μm square region. Data acquisition area was 150 μm square at the center of the primary ion beam scanned area, and the raggedness of this area was less than 2.5 nm. The rate of sputtering ratio between Si and SiO_2 is approximately 1:2, as depicted in Fig. 2(b).



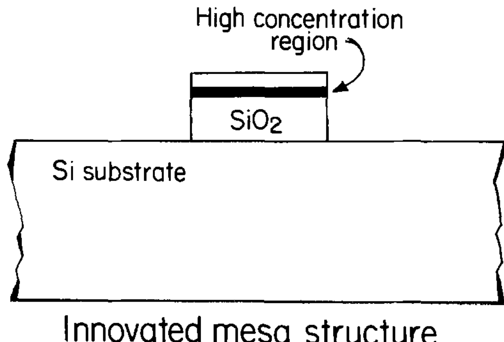


Fig. 1. Schematic cross section of the mesa structure used in the SIMS analysis.

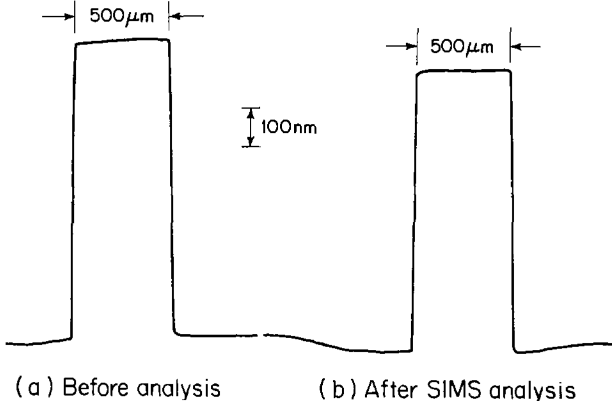

Fig. 2. Typical example of the sample structure (A) before and (B) after SIMS analysis, measured by Dektak.

Diffusion coefficient determination.—The concentration of As atoms in SiO_2 was determined from the signal ratio between $^{75}As^+$ and $^{28}Si^+$. The As concentration of the as-implanted sample was determined quantitatively from the experimentally obtained signal ratio by adjusting the integral of the concentration to the actual implanted dose. The sputtered depth, measured by the previously mentioned method, was used to determine the distance of the peak position from the surface. The diffusion coefficient of As in SiO_2 was derived by fitting calculated profiles to the obtained As profiles by SIMS. Simple gaussian-type diffusion was assumed.

Results and Discussion

Anomalous diffusion of arsenic in silicon dioxide.—Typical As profiles in SiO_2 after annealing at 1100°C for 16 hr in nitrogen are shown in Fig. 3 by broken lines. The fluctuation of $^{28}Si^+$ signal, shown by a chain line, was less than $\pm 10\%$ during the analysis, which usually took 2 hr. In the figure, as-implanted As profiles in SiO_2 are also shown by solid lines to indicate the differences between different As concentrations. The projected range derived from these as-implanted profiles coincide well with the theoretical value (11) within experimental error.

It was found that if the As concentration exceeds about 5×10^{20} cm^{-3}, arsenic atoms practically do not diffuse even after this high temperature treatment. On the other hand, As atoms diffuse with a diffusion coefficient of 3.9×10^{-16} cm^2/sec at 1100°C, if the concentration is lower than this value. In Fig. 3, the surface low concentration region which appears after annealing is probably due to the evaporation of As atoms from the SiO_2 surface. As can be seen, As atoms have diffused significantly deep into the layer under both low and high concentration implantation conditions.

The cause of the nondiffusing high As concentration region could be complexing of As-Si-O to form a

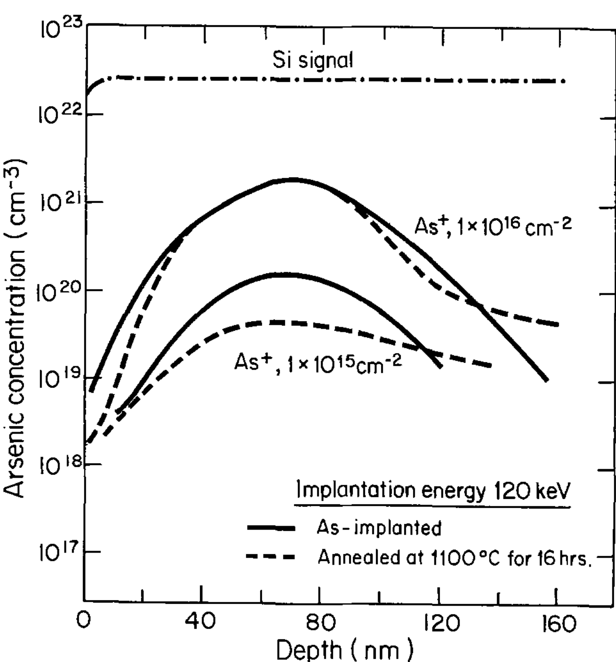

Fig. 3. Arsenic profiles in silicon dioxide measured by SIMS;—— as-implanted, - - - annealed at 1100°C for 10 hr in dry nitrogen atmosphere.

stable phase. The experimentally obtained critical As concentration is around 1 atomic percent (5×10^{20} cm^{-3}), which is probably low enough to form solid solutions for SiO_2-As_2O_3. However, the segregation effect (sinusoidal decomposition) of the impurity in the matrix (12) could cause the formation of a complex. A more detailed understanding of the SiO_2-As_2O_3 system is required before this issue can be settled.

Temperature dependence of diffusion coefficient in inert ambient.—Annealing temperature dependence of the diffusion coefficient was measured in the temperature range of 1000°-1200°C in dry nitrogen. Diffusivity of As in SiO_2 was calculated in the low As concentration region, and the results are shown in Fig. 4. The activation energy derived from the Arrhenius plot is 4.7 eV, and is in general agreement with former results (6-8).

Regions with more than a 5×10^{20} cm^{-3} As concentration yield a diffusion coefficient of at least two orders of magnitude smaller than that of low concentration regions in the same temperature range. In other words, the Si-As-O complex of the high concentration arsenic region is stable up to 1200°C.

Ambient dependence of diffusion coefficient.—The preceding experiments were performed in a dry nitrogen atmosphere. It has been reported that annealing in a dry oxygen atmosphere retards the As diffusion in SiO_2 (7, 13). Therefore, the samples were annealed in a dry oxygen atmosphere in order to examine the ambient effect on the nondiffusing high concentration As region as well as on the low concentration regions.

The samples implanted with 10^{16} cm^{-2} arsenic ions were annealed in a dry oxygen ambient. The resulting As profile is shown by a dotted line in Fig. 5, together with the results of annealing in nitrogen atmosphere at 1200°C for 4 hr. The ambient dependence of As diffusion is clearly shown. The high concentration As region exhibited a marked diffusion in the oxygen atmosphere, which contrasts the nondiffusing As region annealed in nitrogen atmosphere. Also, in the low concentration region, As atoms diffuse faster in SiO_2 under oxygen ambient (1×10^{-15} cm^2/sec at 1100°C), than in a nitrogen atmosphere (3.9×10^{-16} cm^2/sec at 1100°C), as shown in Fig. 6. The diffusion coefficient of As in SiO_2 in the high concentration region was almost the same as that of the low concentration regions.

The temperature dependence of the diffusion coefficient shown in Fig. 7 indicates that the activation energy of As diffusion in SiO_2 in oxygen atmosphere is 3.7 eV, which is 1 eV less than that in nitrogen atmosphere. Therefore, the As diffusion mechanism is

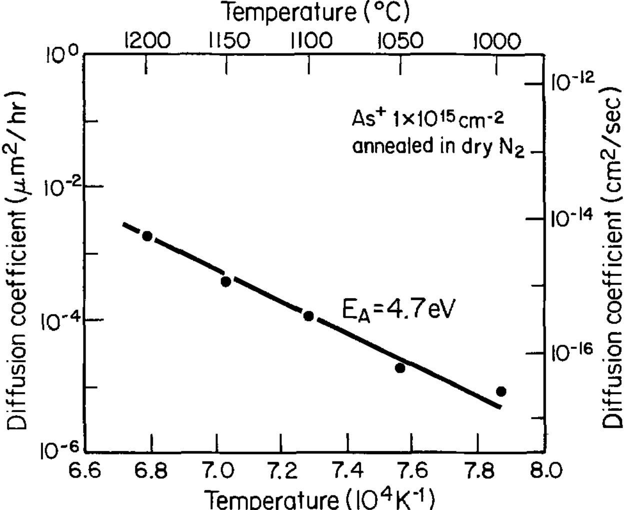

Fig. 4. Temperature dependence of arsenic diffusion coefficient in silicon dioxide in low concentration (<5×10^{20} cm^{-3}) region, annealed in dry nitrogen.

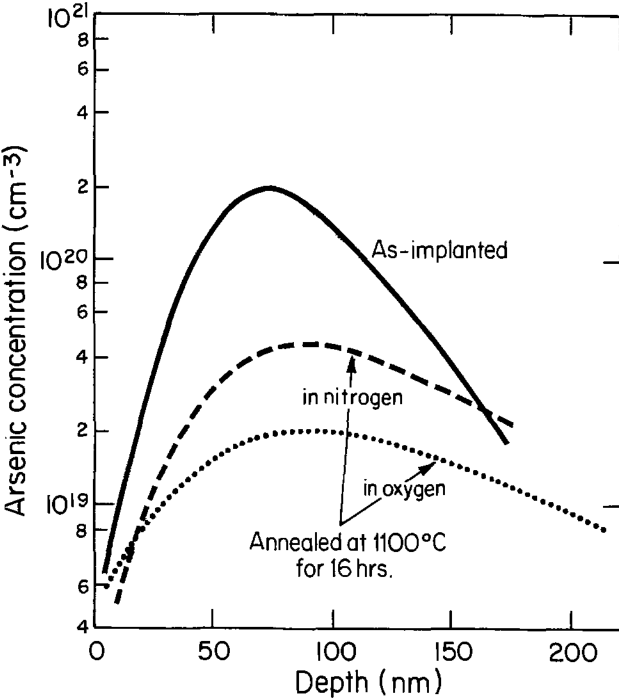

Fig. 6. Low concentration arsenic profiles in silicon dioxide annealed at 1100°C for 16 hr. —— as-implanted, ... annealed in oxygen, - - - annealed in nitrogen.

possibly different, or at least is affected by some extrinsic phenomena. In the figure, the reported values of diffusion coefficient (6-8) are also shown, and are generally in agreement with the present results, considering the differences in sample preparation and measuring method.

The activation energy as well as the relative enhancement of the oxidation enhanced diffusion (OED), reported here are similar to those reported for low concentration arsenic, phosphorus, and boron diffusion in Si by Antoniadis *et al.* (14). The mechanism of OED in Si has been proposed as interstitialcy diffusion (15), and the degree of OED has been related to the rate of oxidation (16). In the case of the As-SiO_2 system, there are three possible causes of OED. One is the presence of excess oxygen ions in the SiO_2 network. Another is the transport of oxygen through SiO_2 and

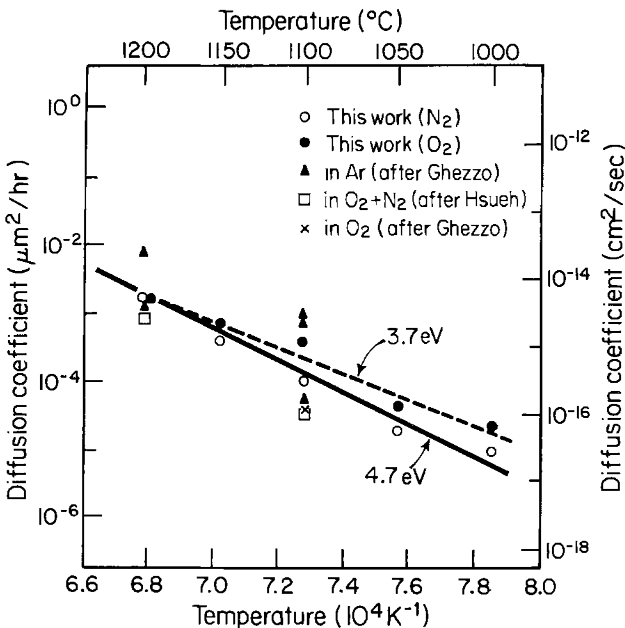

Fig. 7. Temperature of diffusion coefficient, ○ annealed in dry nitrogen, ● annealed in dry oxygen, × △ after Ghezzo, □ after Hsueh.

the last is excess point defect generation (perhaps vacancy), at the SiO_2-Si interface during oxidation.

The following experiment was carried out to shed some light on the mechanism of OED of As in SiO_2. Annealing of As-doped thermal SiO_2 in oxygen ambient without attendant oxidation of underlying silicon was achieved by using samples prepared by completely oxidizing 250 nm of polysilicon deposited on Si_3N_4. These samples were implanted with As and were annealed as described previously in both oxygen and nitrogen. Typical results of SIMS analysis have revealed no ambient related difference in the diffused profiles. It can thus be concluded that the presence of excess oxygen in SiO_2, which would be present at solid solubility levels during oxygen ambient annealing, is not the reason for OED. However, on the basis of the present experiments it is not possible to discriminate between the remaining two possible causes of OED. If transport of oxygen is indeed responsible, one would expect some form of nonuniform diffusivity with the profile shape skewing towards the deep end. Such an effect cannot be concluded from the present data.

The results shown here suggest that it might be difficult to control high concentration arsenic layer diffusion from a doped oxide source. Doped oxide source concentration above 5×10^{20} cm^{-3} is ineffective if the annealing atmosphere is nitrogen. Oxygen atmosphere would increase the diffusivity of higher concentration As in SiO_2, however, the SiO_2 layer formed between doped oxide and silicon during annealing (oxidation) would hinder the diffusion of As into Si. Such an effect has been observed by Reindl (13), who noted that a doped oxide source is more effective at 100% O_2 than 100% N_2, but an optimum efficiency, better than at 100% O_2, is achieved for a 60-40% mixture of $O_2 - N_2$.

Conclusions

Anomalous diffusion phenomena of As in SiO_2 were studied by SIMS using mesa structured samples, which eliminates charge-up and peripheral effect of insulator sample and enables accurate measurements. The results are summarized as follows.

1. At more than a 5×10^{20} cm^{-3} concentration arsenic does not diffuse between 1000° and 1200°C, probably because of complex formation in SiO_2.
2. The activation energies of low concentration ($<5 \times 10^{20}$ cm^{-3}), As diffusion in SiO_2 are 4.7 and 3.7 eV in dry nitrogen and dry oxygen atmosphere, respectively.
3. In dry oxygen atmosphere, the high As concentration region does diffuse. The cause of the oxidation enhancement is the oxidation of the underlying silicon.

The Nature and Rate of Creepage of Copper Sulfide Tarnish Films over Gold

V. Tierney*
Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Tarnish films that form on copper surfaces at high humidity can creep over adjoining gold surfaces, causing increases in the contact resistance of the gold. In many cases, however, when gold-plated contacts having exposed areas of copper are removed from equipment used for extended periods of time in environments known to contain sulfiding compounds, there has been little or no evidence of creepage. This protection against tarnish is caused by a naturally formed oxide and has been duplicated in the laboratory. When copper sulfide tarnish films do creep over gold surfaces, distinctive periodic bands are formed. The humidity dependence of the rate and maximum distance of the creepage have been studied.

When freshly cleaned copper is exposed to an environment containing sulfur, a tarnish film composed of copper oxide and copper sulfide forms. This film can migrate over gold surfaces with which the copper is in contact, causing increases in the contact resistance of the gold. This phenomenon is frequently called creep in the literature.

Gold-plated copper or copper alloy electrical contacts having exposed areas of copper are frequently used in electronic equipment that may be stored, shipped, or used in environments where sulfiding compounds are present.

Plating smaller areas of gold with thinner layers of gold is the result of today's soaring gold prices, increasing the importance of creep as a contact failure mechanism. Since gold contact is now dependent on smaller contact areas, even a slight amount of creepage from pores, which are more likely on thin films, or from the edges of the plating, which are now closer to the contact point, can cause failure.

Since the diffusion of copper through the gold to the gold/air interface is too slow at the temperatures and gold thicknesses under consideration, the degradation of the surface due to the tarnishing of copper is not a likely failure mechanism (1).

In harsh indoor environments, migration of base metal corrosion products over gold can proceed at significant rates (2). Indeed, Antler has observed creepage in an environment that contained both sulfur and chlorine compounds, where a 1.27 cm (0.5 in.) wide gold stripe on CDA 725 was completely covered with tarnish products from the base metal in only 35 days (3). Not surprisingly, this formation of tarnish films, followed by their creepage over adjoining gold surfaces, can result in contact resistance failures. On the other hand, Grau (4) has reported that there is little or no evidence of creepage when gold-plated contacts, having exposed areas of copper, were removed from equipment that had been used for extended periods of time in telephone offices. Thus, we began our study by investigating the reasons for this difference.

In 1926 Vernon (5, 6) showed that an oxidized copper surface tarnishes at a much slower rate than a freshly cleaned surface. More recently, Tierney (2) found that small amounts of cupric oxide (CuO) were responsible for low tarnish rates. Frankenthal has observed that in dry atmospheres, the oxide films on copper protect the copper from sulfidation in flowers of sulfur environments (7). Chessari and Blessington (8) showed that thermal aging could prevent tarnishing in pores.

* Electrochemical Society Active Member.
Key words: contact resistance, humidity, oxidation.

Copper oxide is thermodynamically more stable than Cu_2S or CuS [the standard free energies of formation at 25°C for Cu_2O, Cu_2S, and CuS are -34.98, -20.6, and -11.7 kcal/mole, respectively (9)] and therefore forms more readily on a copper surface. We suspected that the lack of tarnish film creepage in operating equipment is due to the natural formation of a protective oxide that is present on copper before exposure to the sulfiding environment. To test this hypothesis, a thermally produced oxide was investigated to determine if it acted as the natural oxide produced with time and served as a protection against growth of sulfide/oxide films and inhibited their creepage across adjoining gold-plated surfaces.

Experimental

Since Vernon (5) had reported that the tarnish rate could be affected by variation of the surface condition, we paid careful attention to sample preparation. Our samples were 2.54×1.27 cm (1×0.5 in.) OFHC copper coupons cut from rolled copper strip. The coupons were immersed in 1:1 HNO_3 at room temperature for about 45 sec to remove sufficient copper to eliminate the surface defects caused by rolling operations. To obtain relatively smooth reproducible surfaces, the coupons were then immersed for 2 min in a chemical etch.[1]

Tarnish film thicknesses were determined by electrolytic reduction. In this method the amount of each species present is determined from the durations of the potential plateaus exhibited during a constant current reduction. To minimize the problem of film solubility in the electrolyte, 0.1*N* KCl was used. The reduction of sulfide occurs at a potential between that for the reduction of oxide and that for hydrogen evolution. The reduction potential is a function of the current density as well as the reference electrode. The reference electrode used in these investigations was silver/silver chloride and most of the work was done at a current density of 0.25 mA/cm^2.

Under these conditions, copper oxide is reduced at about -0.9V and copper sulfide at -1.2V. In KCl, cupric and cuprous oxides are reduced at the same potential. In NH_4Cl, the two oxide reduction potentials are far enough apart that the separate species can be determined, but this electrolyte was not considered because of its solvent action on copper oxide. Oxygen was excluded from the system by purging the electrolyte with nitrogen both prior to and during reduction in order to minimize errors due to the reduction of dissolved oxygen. Inert platinum anodes completed the cell components.

[1] The chemical etch was 100 ml nitric, 275 ml phosphoric, and 125 ml acetic acids at 75°C.

Since Vernon's earlier work did not contain sufficient data to relate copper oxide thickness to a decrease in tarnish rates, the thermal oxidation rate of copper at 100°C and 125°C was first investigated (10). This resulted in the development of reproducible cuprous oxide tarnish films, which were then evaluated for their ability to protect the underlying surface from further attack. It was found that the 225Å cuprous oxide film that formed during an 18 hr exposure to air at 125°C significantly inhibited the formation of sulfide films during subsequent exposures, and this was therefore established as a standard preoxidizing treatment.

Copper coupons having this standard oxide and freshly cleaned coupons were exposed to flowers of sulfur at 50°C under humidity conditions that were controlled using saturated salt solutions. The resulting concentration of sulfur vapor was much higher than is normally found in most service environments.

Several investigators have discussed the significance of relative humidity. Baker (10) has studied the migration of corrosion products over gold surfaces and shown that the rate of migration increases with increasing relative humidity. Sigsbee (11) has reported that relative humidities in excess of 35% are necessary for appreciable sulfide creepage to occur. Sharma (12) has reported that relative humidity is one of the important parameters in the atmospheric corrosion of copper. He found that copper oxide grown in air (several hundred angstroms thick) provided good protection against H_2S at low relative humidity but little protection at high relative humidity.

The relationship between relative humidity and the degree of protection is shown in Fig. 1. The high humidity tests were carried out at 75% RH. At 25°C, saturated air contains 24 g/m^3 of water. At 50°C, air at 75% RH contains 61 g/m^3 of water, which is equivalent to a relative humidity well in excess of 100% at room temperature. In this extremely severe test environment, the thermally produced oxide did not protect copper from sulfiding. After 71 hr of exposure, 750Å of cuprous sulfide was found in the Cu_2O/Cu_2S tarnish films on both the preoxidized sample and the control.

To test a more realistic humidity, additional samples were exposed to sulfur at 17% RH and 50°C. (This is 14 g/m^3 of water, which would be equivalent to 58% RH at 25°C.) While 300Å of cuprous sulfide was found in the tarnish film on the freshly cleaned copper after the 24 hr exposure, less than 25Å formed on the preoxidized copper in the same period. During more extended exposures the amount of sulfide increased on both the preoxidized copper and the control, but the growth rate on the preoxidized surface was much slower at 71 hr, 100Å compared to 700Å and at 168 hr, 900Å compared to more than 2000Å. This last film, with more than 2000Å of sulfide, was nonadherent and much of it flaked off during cathodic reduction, so that accurate thicknesses could not be determined.

For tests under dry conditions, the saturated salt solution used for humidity control was replaced by a desiccant. After 24 hr exposure under this condition, there was no measurable amount of Cu_2S formed on the preoxidized copper, while 500Å of Cu_2S was present on the control. This difference can be seen in Fig. 2, which shows the samples after 10 weeks exposure in this moisture-free sulfiding environment. The copper surface that was not preoxidized, on the left, is completely blackened indicating a very thick Cu_2S film, but the preoxidized copper surface, on the right, shows only a slight trace of darkening. Subsequent analysis by Auger electron spectroscopy showed the amount of sulfide on the preoxidized surface to be about 25Å.

From this work, we conclude that a thermally produced cuprous oxide film, 225Å thick, greatly reduces the rate of copper oxide/sulfide tarnish at low relative humidities even when the sulfur vapor level is much higher than found in some of the worst field environments. Long time protection is achieved in the absence of moisture. No appreciable protection occurs under conditions of extremely high relative humidity.

These results confirm Vernon's earlier observations and appear to explain why sulfide tarnish formation on copper surfaces and subsequent creepage over adjoining gold surfaces has not been a problem in field environments. The natural oxide formed with the passage of time appears, like the laboratory produced thermal oxide, to provide surface protection.

The samples for creepage studies were prepared on flat ceramic substrates. After vapor deposition of Pd, Ti, and Au, 10 microns of copper followed by 3 microns of gold were plated over the entire surface. A photoresist mask was applied, and portions of the gold deposit were etched away, leaving a sample that had straight boundaries between the gold and copper. Figure 3 shows such a sample. Just before testing, the gold-copper specimens were dipped into a 1:1 HCl solution to remove the small amount of oxide that naturally forms on the copper surface. These samples were then exposed to flowers of sulfur at various humidities at 50°C. The distance the tarnish crept over the gold surface was measured at 12 identifiable points along the Cu/Au interface after various exposure times.

The uppermost picture in Fig. 4 shows four distinct bands in the tarnish film that had crept over the gold during a 22 hr exposure to sulfur at 75% RH and 50°C. The average creepage distance was 0.47 mm, giving an average rate of 0.021 mm/hr (0.00082 in./hr). After measurement the sample was returned to the test environment and subsequently removed for additional readings at 46, 113, 229, and 536 hr. The three remain-

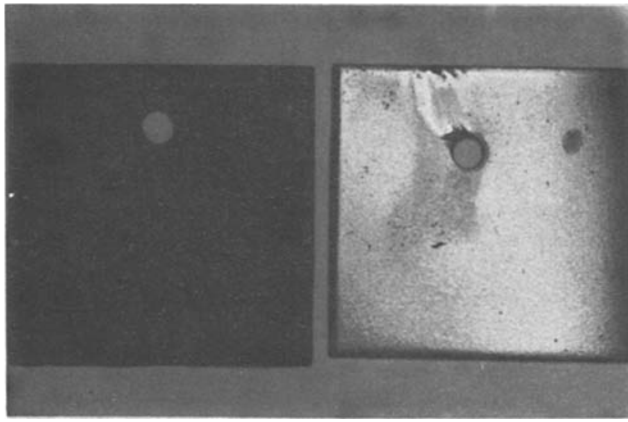

Fig. 2. Copper panels exposed to a moisture-free sulfiding environment for 10 weeks. Panel on the right was preoxidized; panel on the left was not.

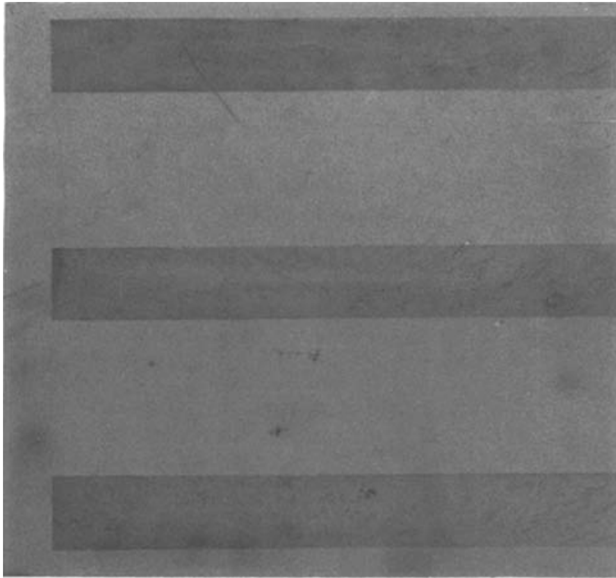

Fig. 3. Gold-copper specimens used for the creepage study. Narrow bands are copper.

ing pictures show that each time the sample was removed, new bands had been formed but the existing bands had not changed either their width or the shape of their leading edges. The bands did, however, darken with increasing exposure time, indicating vertical as well as horizontal growth. In the second picture in Fig. 4, five distinct bands are seen after 46 hr. The next two pictures show six bands after 113 hr and seven bands after 229 hr. At the final reading of 536 hr, the bands were so dark that it was difficult to see them. Table I summarizes the numerical results.

To establish the initial growth rate, measurements were made at shorter times, with the results shown in Table II. After 4 hr most of the gold at the Au/Cu interface had one distinct band of tarnish present, with a second band just beginning to form.

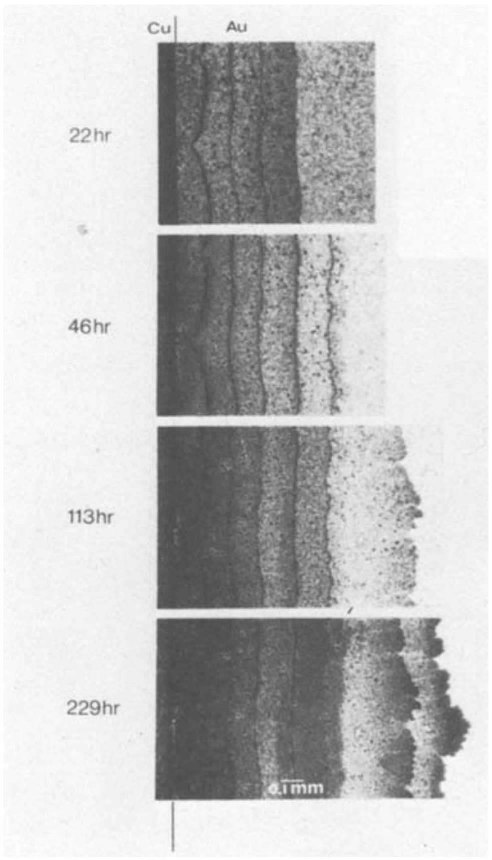

Fig. 4. Copper sulfide creep over gold. Each picture shows same area after different exposure times to sulfur at 75% RH and 50°C.

Table I. Copper sulfide creepage over gold for extended exposure (50°C 75% RH)

Time (hr)	Average rate (mm/hr)	Average distance (mm)	Average No. of bands
22	0.020	0.44	4
46	0.013	0.61	5
113	0.0080	0.90	6
229	0.0046	1.06	7
536	0.0018	0.98	*

* Too dark to be clear.

Table II. Copper sulfide creepage over gold for short exposure (50°C 75% RH)

Time (hr)	Average rate (mm/hr)	Average distance (mm)	Average No. of bands
4	0.055	0.22	1-2
8	0.034	0.27	2-3
22	0.020	0.43	3-4

The creepage distance increased linearly with the square root of time for approximately the first 100 hr of exposure. After 229 hr, as shown in Fig. 5, the creepage stopped and the tarnish product grew only in thickness. To be sure that the removal of the samples from the test environment for measurement had no effect on the creepage rate, one sample was run continuously for 68 hr. As shown in Fig. 5, the creepage distance for this sample lies just slightly above the previously determined curve.

Each data point on the curve represents the average of the 12 identifiable sites that were measured. The number is large enough to make the average significant. No attempt was made to evaluate the reproducibility of the 12 measurements since creepage can be inhibited by random impurities on the surface. Our purpose was to illustrate that creepage can cause failure.

There were, on the average, six bands, but at four of the twelve measuring points, there were only five

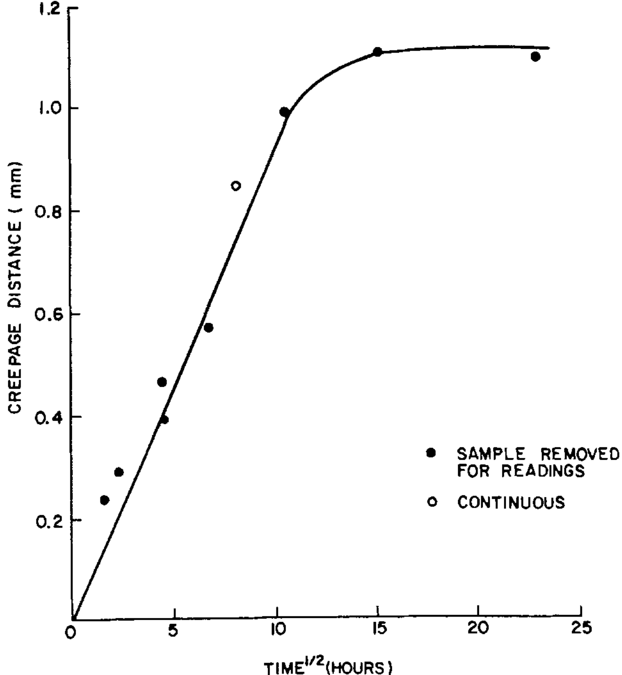

Fig. 5. Creepage distance of copper sulfide over gold as a function of time of exposure to sulfur at 50°C and 75% RH.

bands while at one point there were seven. These results show that the banding effect is not a function of the frequency with which the sample is removed from the test chamber. The bands are discussed later in more detail.

Under the conditions of 17% RH at 50°C, tarnish film creepage was still observed after only 4 hr of exposure. However, as shown by samples 1 and 2 in Fig. 6, the maximum creep distance was reached after only a short time. Sample 3 shows again that there is no significant difference when the sample is not continuously removed from the oven for testing. Sample 4 on Fig. 6 shows the effect of temperature. When the sample was kept at 17% RH and 70°C, a creep asymptote was reached similar to that for the 50°C samples. However, the creepage film on this 70°C was much darker than that on the 50°C samples, indicating a thicker tarnish film. Cathodic reduction of a copper coupon exposed to these conditions confirmed this.

It was shown above that thermally produced oxide prevents the formation of copper sulfide tarnish film under humidity conditions that might be reasonably expected in a controlled indoor environment and reduces the rate of sulfiding even under severe conditions of relative humidity. Figure 7 shows that a protective oxide significantly reduces creepage. The sample on the left shows tarnish creepage over gold from a freshly cleaned copper surface that had been exposed to flowers of sulfur for 75 hr at 17% RH and 50°C. The sample on the right received a thermal oxide before being exposed to these conditions.

Both a freshly cleaned sample and a preoxidized sample were exposed to flowers of sulfur for 68 hr at 50°C and 75% RH. Copper sulfide from the freshly cleaned copper crept over the gold at an average rate of 0.013 mm/hr (0.0005 in./hr), while the average rate of creepage from the preoxidized sample was only 0.005 mm/hr (0.0002 in./hr), as shown in Table III. This is a significant decrease in creepage rate under severe humidity conditions. Another preoxidized sample showed no sign of creepage after 255 hr of exposure to flowers of sulfur at 50°C and 17% RH, while an average creepage rate of 0.02 mm/hr (0.0008 in./hr) over total distance of 0.62 mm (0.0244 in.) was observed after a 28 hr exposure under the same conditions, as shown in Table IV.

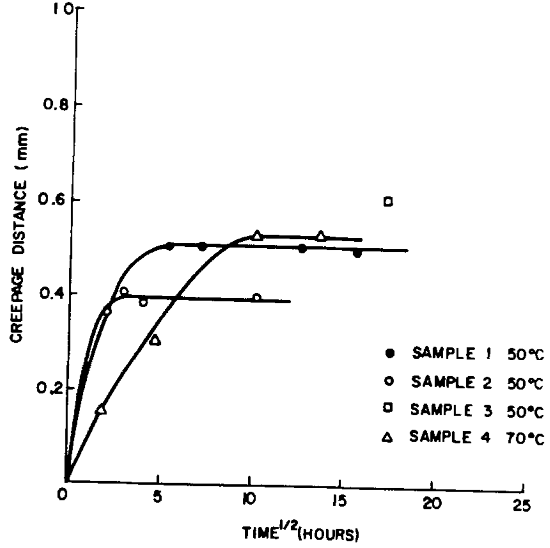

Fig. 6. Creepage distance of copper sulfide over gold as a function of time of exposure to sulfur at 17% RH at both 50°C and 70°C.

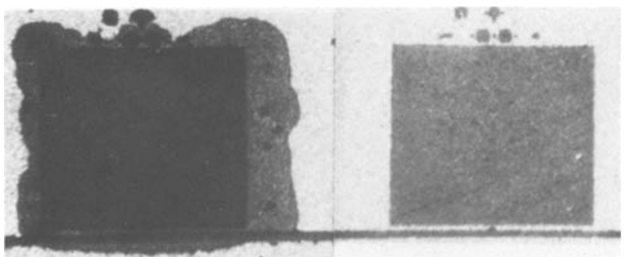

Fig. 7. Effect of preoxidation on copper sulfide creepage after 75 hr exposure to sulfur at 17% RH and 50°C. Specimen on right was preoxidized.

There is some question as to whether creepage can take place in the absence of moisture. When the saturated salt solution used for humidity control was replaced by a desiccant, no creepage occurred for the first 100 hr. However, creepage to a distance of 0.33 mm 0.0130 in.) was observed at 215 hr, which gives an average rate of 0.0015 mm/hr (0.00006 in./hr). Although this is a low rate, it shows that creepage is, in fact, possible in the absence of moisture.

All of the studies described thus far have been at elevated temperatures. To investigate the importance of temperature, a test sample was exposed to flowers of sulfur at 80% RH at room temperature. After 5 weeks (over 800 hr), the first signs of creepage were observed (0.01 mm or 0.0004 in.). This is in sharp contrast to the 0.23 mm (0.0091 in.) of creepage measured after only 4 hr at 50°C and 75% RH.

A freshly cleaned copper sample was put in a sulfur-free environment under the most severe test conditions (*i.e.*, 50°C and 75% RH) to determine whether a Cu_2O tarnish film, in the absence of Cu_2S, would creep. After 1750 hr, the exposed copper had darkened due to the formation of Cu_2O, but there was no creepage of the oxide film over the gold surface. It therefore appears that Cu_2S must be present in the tarnish film in order for creepage to occur.

In all of the creepage studies discussed above, the source of sulfur was flowers of sulfur. Experiments have also been carried out using hydrogen sulfide as the sulfur source. The first such experiment was run at 22°C and 88% RH, with air containing 4 ppm H_2S passed through the test chamber in a gas generation system described by Franey (13). Copper coupons exposed to this environment for 24 hr were cathodically reduced and found to have tarnish consisting of 4000Å of Cu_2S and 225Å of Cu_2O. With 4 ppm H_2S, measured in the manner described by Franey (13), at 50°C and 16% RH, the tarnish consisted of 7500Å of Cu_2S and 140Å of Cu_2O. At a more realistic concentration of H_2S, 8 ± 2 ppb, at 25°C and 81% RH, only 24Å of Cu_2S and 50Å of Cu_2O were found. Table V shows these results compared to those for the tarnish formed from flowers of sulfur during a 24 hr exposure.

An even more striking difference in the tarnish films generated by the two sulfur sources was found in the

Table III. Effect of preoxidation on copper sulfide creepage over gold (50°C 75% RH)

	Time (hr)	Average rate (mm/hr)	Average distance (mm)
No oxide	68	0.013	0.87
Preoxidized	68	0.005	0.35

Table IV. Effect of preoxidation on copper sulfide creepage over gold (50°C 17% RH)

Table VI. Creepage distance

Time (hr)	RH (%)	T (°C)	Source of sulfur	Creepage distance (mm)
49	88	22	4 ppm H_2S	0.1
24	16	50	4 ppm H_2S	0.5
24	81	23	8 ppb H_2S	0
24	17	50	Flowers of sulfur	0.5

nature of the creepage. When viewed with an optical microscope, the film creepage due to an H_2S sulfur source appeared to have bands like those observed with creepage films formed in the flowers of sulfur environment. However, scanning electron microscopy revealed that this creepage was a very thin film, with no indications of raised bands. Thus, the bands seen in the H_2S test are only an optical phenomenon. The creepage distances from these two sulfide sources are shown in Table VI.

The banded creepage that resulted when flowers of sulfur was the sulfur source was examined in detail. It was hoped that this would reveal the mechanism responsible for limiting the creepage distance at various humidities. Figure 4 shows that each of the bands is terminated by a dark edge. As previously discussed, after 536 hr at 75% RH, the tarnish product was too thick to distinguish the bands optically. However, when this sample was examined with the SEM, it was found that the bandedges were actually vertical growth of the tarnish product, as can be seen in Fig. 8. In this picture, the copper surface is on the right and the bands of creepage have grown to the left. The first three bands are shown in Fig. 9a at higher magnification. Figure 9b is an x-ray line scan for copper

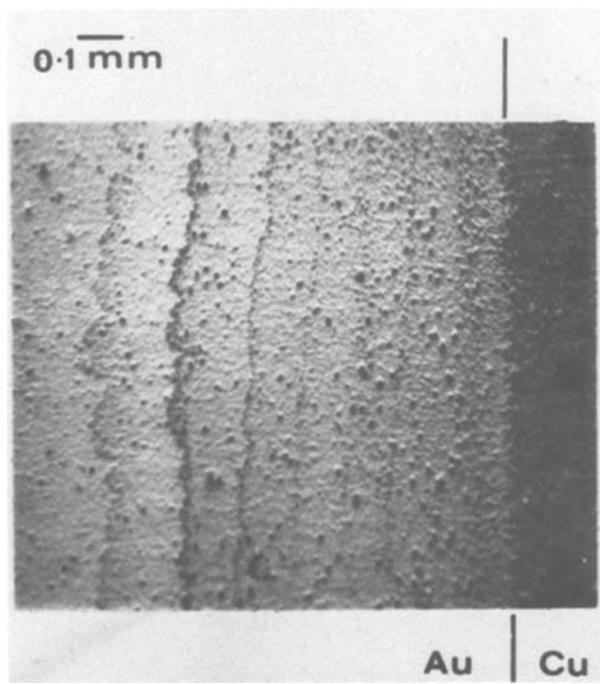

Fig. 8. Vertical copper sulfide growth at bandedges during exposure to sulfur at 50°C and 75% RH.

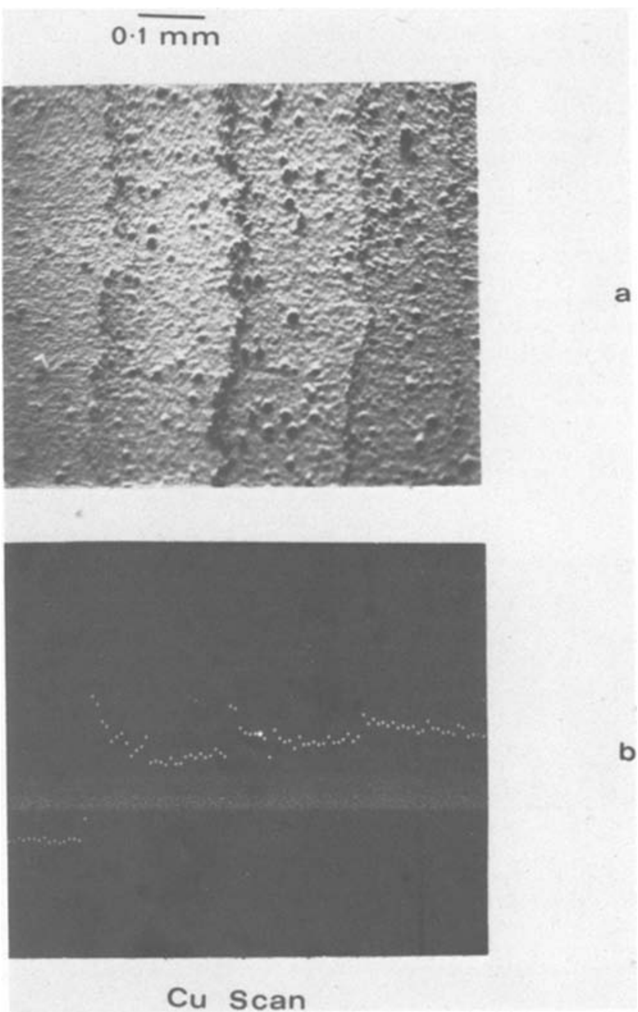

Fig. 9. (a) Higher magnification of the three bands at the left of Fig. 8. (b) X-ray line scan for copper across bands.

through the area shown in Fig. 9a. The scan over the gold is at background level, showing that no copper is seen through the gold. The copper x-ray intensity increases greatly at each bandedge and falls to a plateau along the main body of each band, and the copper signals from the individual bands increase as they approach the copper-gold interface.

To further illustrate this phenomenon, copper x-ray counts in 50 micron windows were taken in a line across the width of the tarnish creepage. The results are plotted in Fig. 10. The bandedges are copper rich

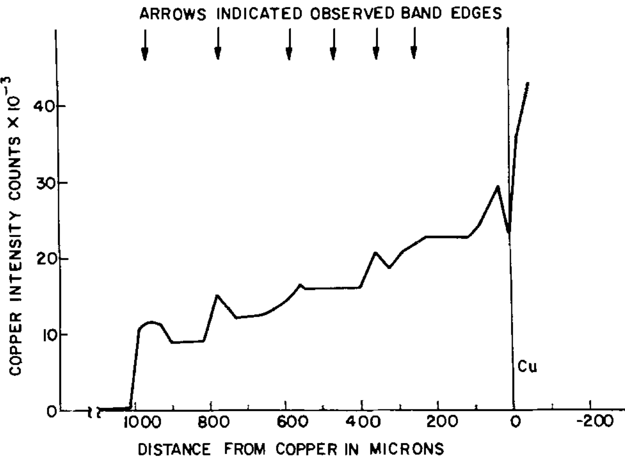

Fig. 10. Copper x-ray counts across width of creepage. Counts taken in 50 micron windows.

and the plateaus of the bands increase in copper toward the metallic copper.

Figure 11 shows two magnifications of the most prominent edge, which was the second from the untarnished gold surface. The small bumps shown near the bands in Fig. 11 are shown in enlargement in Fig. 12. The copper counts within the areas of the bumps were found to be no higher than in the areas surrounding them, showing that the bumps are not vertical copper tarnish film growth but rather the normal thickness of tarnish product following a contour of the underlying gold surface.

All of the bands near the copper/gold interface have about the same width. At present we have no satisfactory explanation for the periodic increase in vertical growth. However, the vertical growth does explain why the band, when formed, does not move across the gold surface. All of the bands pictured were grown at 75% RH. Although creepage was observed at lower humidities, the films never became thick enough to form bands. More recent work has shown that bands form at 17% RH if the temperature is 70°C because under these conditions the thickness of the creepage is increased.

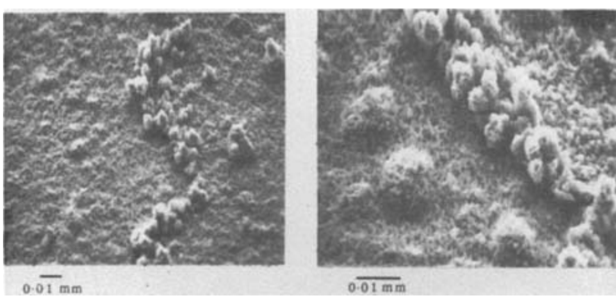

Fig. 11. Two magnifications of most prominent edge—second from untarnished gold surface.

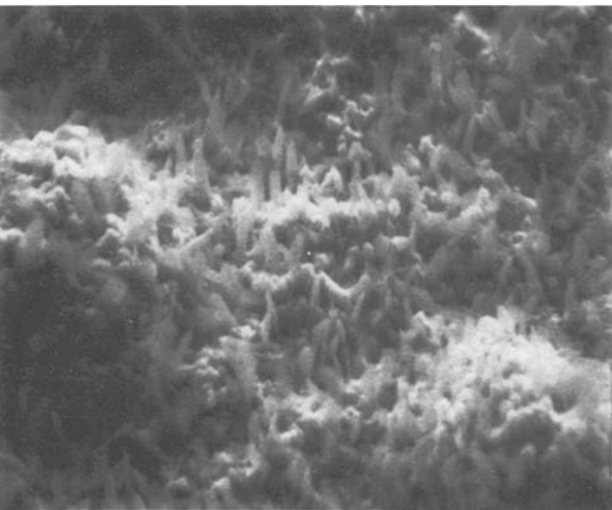

Fig. 12. Small bumps near bands in Fig. 11

Conclusions

1. Thermally produced Cu_2O films can greatly reduce further tarnish of copper surfaces under realistic humidity and temperature conditions.

2. Cu_2S/Cu_2O tarnish products creep over adjoining gold surfaces in a distinct band structure, the edges of which are characterized by vertical growth.

3. On exposure to flowers of sulfur at 75% RH and 50°C, tarnish creepage increases with the square root of time but reaches a limit of 1.1 mm (0.0433 in.) in 229 hr.

4. With flowers of sulfur at 17% RH and 50°C, creepage did not continue after samples were temporarily removed for measurement, but at a temperature of 70°C, the creepage continues and its behavior is more like that at high humidity.

5. When H_2S is the source of sulfur, the tarnish product is richer in Cu_2S, but the creepage at ordinary temperatures does not exhibit periodic vertical growth.

Luminescence of the Bi^{3+} Ion in Compounds $LiLnO_2$ and $NaLnO_2$ (Ln = Sc, Y, La, Gd, Lu)

A. C. van der Steen, J. J. A. van Hesteren, and A. P. Slok

Physical Laboratory, Solid State Chemistry Department, State University, 3508 TA Utrecht, The Netherlands

ABSTRACT

The luminescence properties of the Bi^{3+} ion as an activator in the series of compounds $LiLnO_2$ and $NaLnO_2$ (Ln = Sc, Y, La, Gd, Lu) vary considerably with the host lattice composition. The Stokes shift of the emission varies from 1500 cm^{-1} in the case of $NaScO_2$-Bi^{3+} to 12,800 cm^{-1} in the case of $LiYO_2$-Bi^{3+}. The large variation of the position of the emission band is ascribed to a Jahn-Teller effect in the excited state of the Bi^{3+} ion resulting in different kinds of minima on the ^3P APES. The internal pressure on the Bi^{3+} ion, caused by the differences in the ionic radii of the trivalent cations, can explain the variation in the relative depths of the minima. The Stokes shift of the emission is inversely proportional to the energy difference between the $^3P_1$ and the $^3P_0$ excited levels. For small Stokes shifts we observed vibrational structure in the spectra. The vibrational modes involved are ascribed to more or less localized modes of the BiO_6^{9-} octahedron.

The luminescence properties of the Bi^{3+} ion ($6s^2$) as an activator in oxidic host lattices have been reported by many investigators (1-7). Excitation occurs from the $^1S_0$ ground state to the $^3P_1$ or $^1P_1$ excited state. The emission transition $^3P_1 \rightarrow {}^1S_0$ yields, usually, a single broad band without structure. At relatively low temperatures, however, the lower-lying $^3P_0$ level acts as an optical trap and the $^3P_0 \rightarrow {}^1S_0$ transition is observed (5). This latter transition is strongly forbidden. The temperature dependence of the decay time of the $^3P_1$, $^3P_0 \rightarrow {}^1S_0$ transition can, therefore, deliver the energy difference (ΔE) between the $^3P_1$ and $^3P_0$ levels. This energy difference can vary considerably: e.g., $LaPO_4$-Bi^{3+}: $\Delta E = 16.5$ cm^{-1} (8, 9) and MgO-Bi^{3+}: $\Delta E = 1380$ cm^{-1} (6).

A relation was found between the trap depth ΔE and the Stokes shift of the emission transition. A small Stokes shift corresponds to a large energy difference between the $^3P_1$ and $^3P_0$ levels and vice versa (8). Consequently, vibrational structure is observed in the Bi^{3+} spectra of those compounds where the trap depth is relatively large: MO-Bi^{3+} (M = Mg, Ca, Sr): ΔE = 1030-1380 cm^{-1} (6, 7); $YAl_3B_4O_{12}$-Bi^{3+}: $\Delta E = 1080$ cm^{-1} (10); Cs_2NaYCl_6-Bi^{3+}: $\Delta E = 1150$ cm^{-1} (11), and CaS-Bi^{3+}: $\Delta E = 880$ cm^{-1} (12). In almost all of these cases the Bi^{3+} ion is six coordinated and replaces a smaller cation. This suggests a relatively small Bi^{3+}-anion separation. In the case of MO-Bi^{3+} and CaS-Bi^{3+} this is probably even more reduced by the effective charge of the Bi^{3+} ion in the lattices.

The luminescence spectra of Tl^+ ($6s^2$)-activated alkali halides can show two emission bands (A_T and A_X) due to a combined effect of spin-orbit coupling and electron-lattice interaction (Jahn-Teller effect). The interaction with the ϵ_g and τ_{2g} vibrational modes of the TlX_6^{5-} octahedron (X = Cl, Br, I) results in different kinds of minima on the adiabatic potential energy surface (APES) of the $^3T_{1u}$ ($= {}^3P_1$) relaxed excited state (RES) of the Tl^+ ion (13).

In this paper we report on the luminescence properties of the Bi^{3+} ion in $NaLnO_2$ and $LiLnO_2$ (Ln = Sc, Y, La, Gd, Lu). In these compounds the Bi^{3+} ion is substituted for the trivalent cation. These compounds are very suitable for varying the space available for the Bi^{3+} ion without changing the site symmetry. Except for $LiGdO_2$ these compounds have crystal structures which can be described as ordered variants of the rocksalt structure. The Ln^{3+} ion is octahedrally coordinated by oxygen ions and the site symmetry is determined by the ordering of the monovalent and trivalent cations (Table I). The α-$LiFeO_2$ and α-$NaFeO_2$ structures are presented in Fig. 1. The β-$LiFeO_2$ structure has two different sites for the Ln^{3+} ion.

In these series of compounds the bands in the Bi^{3+} luminescence spectra are either structureless or contain vibrational structure depending on the chemical composition. Also an indication is found for a Jahn-Teller effect in the RES of the Bi^{3+} ion. The Gd^{3+} compounds behave anomalously in certain aspects.

Key words: inorganic, luminescence, synthesis.

Experimental

Sample preparation.—Starting materials were: Na_2O_2 (Merck, p.a.), Li_2CO_3 (Merck, p.a.), Sc_2O_3 (Highways, 99.99%), Y_2O_3 (Fluka AG, puriss. C), La_2O_3 (Highways, 99.999%), Gd_2O_3 (Highways, 99.999%), Lu_2O_3 (Highways, 99.999%), and Bi_2O_3 ("Baker Analyzed" reagent).

$NaLn_{0.995}Bi_{0.005}O_2$ powders were prepared by firing intimate mixtures of Ln_2O_3, Na_2O_2 (40% excess), and Bi_2O_3 in a dry nitrogen atmosphere for 3-4 hr at 850°C. Samples $LiLn_{0.995}Bi_{0.005}O_2$ were prepared by firing intimate mixtures of Li_2CO_3 (10-20% excess), Ln_2O_3, and Bi_2O_3 for about 3 hr at 900°C in a nitrogen atmosphere. The alkaline excess is added to compensate for the sublimation losses from the reaction sample. The samples were checked by x-ray diffraction using CuKα radiation and were kept in a desiccator because they are slightly hygroscopic. We abandoned a study of $LiLaO_2$-Bi^{3+} in view of the marked hygroscopic character of the host lattice. Those samples which, according to their luminescence spectra, contained a small amount

of Bi^{3+}-activated sesquioxide were discarded. According to our experience luminescence is more sensitive in this aspect than x-ray diffraction. High purity Ln_2O_3 is needed, because the luminescence of other rare earth ions (*e.g.*, Pr^{3+}, Tb^{3+}, and Eu^{3+}) will otherwise disturb the measurements (20). Subsequent heating of the samples did not improve their quality. It is realized that samples may be somewhat inhomogeneous due to the single firing procedure.

Apparatus.—The spectra without vibrational structure were recorded on a Perkin-Elmer spectrofluorimeter (MPF-3L) equipped with an Oxford Instruments CF 100 liquid helium flow cryostat and Hamamatsu R928 photomultipliers (spectral resolution ~1 nm). The spectra with vibrational structure were recorded on equipment described in Ref. (11) (spectral resolution 0.1-0.2 nm). The decay experiments were performed using an EG&G 108AU Xe flash lamp (pulse width ~1 μsec). The detection apparatus has been described in detail elsewhere (21). Emission spectra were corrected for photomultiplier sensitivity. The excitation spectra were corrected for the intensity distribution of the excitation source and the transmittance of the excitation monochromator, using lumogen as a standard (22). For the emission spectra, the photon flux per constant energy interval (Φ) is obtained by multiplying the radiant power per constant wavelength interval by λ^3.

Results

$NaLnO_2$-Bi^{3+}.—The Bi^{3+}-activated $NaLnO_2$ compounds emit in the ultraviolet and blue spectral region, except for $NaLaO_2$-Bi^{3+} which has a red emission. The luminescence has a medium to high intensity. The corresponding excitation spectra consist of two bands with maxima at about 39,000 cm^{-1} and about 28,400 cm^{-1} (Table II). It is assumed that the former is the C absorption band and the latter the A absorption band of the Bi^{3+} ion. These correspond to the $^1S_0 \rightarrow {^1P_1}$ and the $^1S_0 \rightarrow {^3P_1}$ transition, respectively. In this paper we only consider A band excitation. The emission spectra under C band excitation do not differ from those under A band excitation. At low temperatures vibrational structure is observed in all spectra except those of $NaLaO_2$-Bi^{3+} (Fig. 2 and 3).

The intensity of the low-energy part of the emission of $NaGdO_2$-Bi^{3+} is sample dependent. For that reason this part of the emission curve is dashed in Fig. 3. Analysis of the spectra excludes the presence of Gd_2O_3-Bi^{3+}. Perhaps this part of the emission is due to Bi^{3+} pairs or to Bi^{3+} centers in inhomogeneous parts of the samples. At higher temperatures this part of the

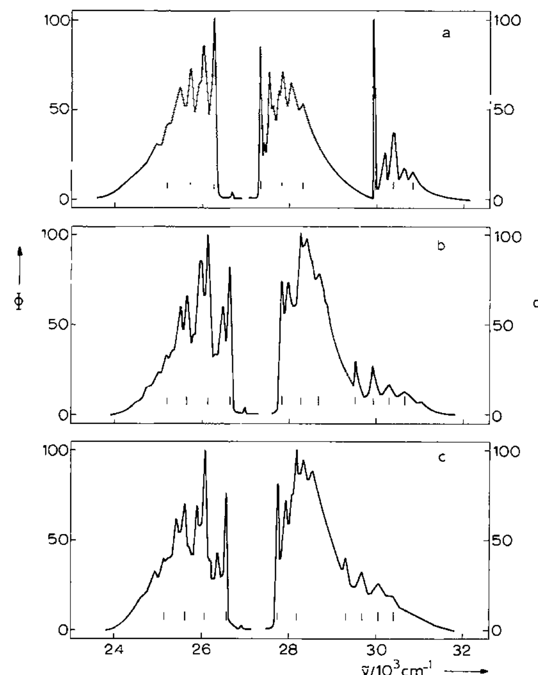

Fig. 2. The emission and excitation spectra of the luminescence of $NaScO_2$-Bi^{3+} (a), $NaLuO_2$-Bi^{3+} (b), and $NaYO_2$-Bi^{3+} (c) at 5 K. The emission spectra are recorded upon excitation into the maximum of the A band. The excitation spectra are obtained by recording the maximum intensity of the emission band. The peak intensities are normalized to unity. The progressions in the mode ν_a upon the electronic origins (in excitation) and upon the one-phonon origin (in emission) are indicated. Φ denotes the photon flux per constant energy interval in arbitrary units. q_r denotes the relative quantum output in arbitrary units.

spectrum gains intensity suggesting energy transfer. This was not studied any further.

At low enough temperatures the A excitation band of $NaYO_2$-Bi^{3+}, $NaLuO_2$-Bi^{3+}, and $NaScO_2$-Bi^{3+} consists of two components. The energy difference between the electronic origins of both bands increases in the order Y < Lu < Sc. At 5 K this difference is 1558, 1710, and 2606 cm^{-1}, respectively.

The electronic origin in the emission spectrum is very weak in the case of $NaLnO_2$-Bi^{3+} (Ln = Sc, Y, Lu; see Fig. 2). The electronic origin of the emission transition and that of the lowest excitation transition do not coincide; their energy difference is tabulated in Table III. No indication for an origin with a very low intensity has been found in the emission spectrum of $NaGdO_2$-Bi^{3+}. The interpretation of the more intense vibronic features in the spectra is given in Tables IV and V and are discussed later. The emission intensity of all compounds starts to quench above room temperature, except for the emission of $NaLuO_2$-Bi^{3+} which quenches above 200 K.

$LiLnO_2$-Bi^{3+}.—The emission intensity of all compounds $LiLnO_2$-Bi^{3+} is medium to high and does not quench below 300 K. The positions of the excitation and emission bands are given in Table II. These spectra do not show vibrational structure, not even at low temperatures (Fig. 4 and 5). $LiScO_2$-Bi^{3+} emits in the blue, whereas $LiYO_2$-Bi^{3+} has a green emission. Two emission bands are observed for $LiLuO_2$-Bi^{3+} (green and blue). The intensity ratio of the blue and green emission varies with temperature. The relative intensity of the blue emission has decreased to 50% of the low temperature value at about 70 K and vanishes at about 100 K. The excitation spectrum of $LiLuO_2$-Bi^{3+} depends on the emission energy. The excitation band of $LiScO_2$-Bi^{3+} is split into three components.

Decay times.—For all compounds the decay time of the emission is temperature dependent as is illustrated for two cases in Fig. 6. The decay curves were exponential within the limitations of the apparatus.

This temperature dependence of the decay time can be treated within the framework of a three-level

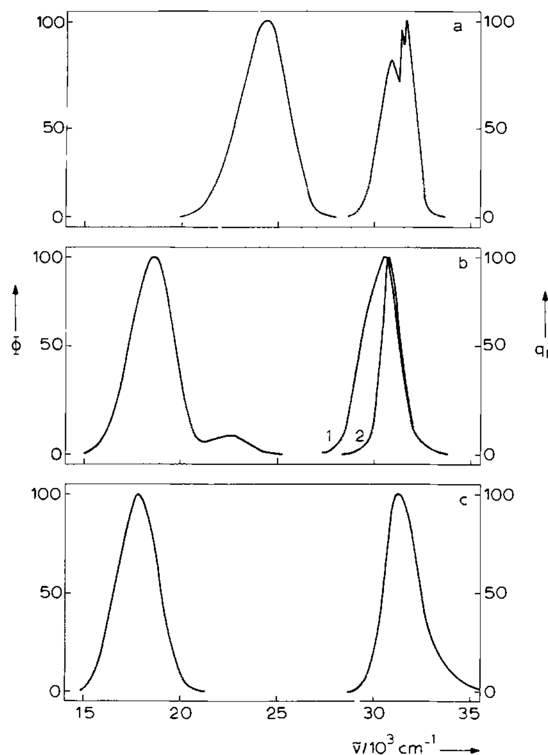

Fig. 4. The emission and excitation spectra of the luminescence of $LiScO_2$-Bi^{3+} (a), $LiLuO_2$-Bi^{3+} (b), and $LiYO_2$-Bi^{3+} (c) at 5 K. For $LiLuO_2$-Bi^{3+} the excitation spectra refer to an emission energy of 18,200, curve 1, and 22,600, curve 2, cm^{-1}. Excitation occurs at 31,000 cm^{-1}. See also Fig. 2.

scheme (see insert Fig. 6) (5, 23, 24). Levels 0, 1, and 2 correspond to the $^1S_0$, $^3P_0$, and $^3P_1$ electronic states of the Bi^{3+} ion. Excitation takes place into level 2. Emission is observed from both levels 1 and 2 to level 0 with probabilities $k_1 = \tau_1^{-1}$ and $k_2 = \tau_2^{-1}$. Further, gk_{12} and k_{21} denote the nonradiative transition probabilities between levels 1 and 2, $k_{12} = k_{21} \exp(-\Delta E/kT)$. The degeneracy of level 2 is called g. In this model two decay times are found. The long decay time can be expressed as follows, assuming $k_2 + k_{21} >> k_1 + k_{12}$

$$\frac{1}{\tau} = k_1 + g\left(\frac{1}{k_{21}} + \frac{1}{k_2}\right)^{-1} \exp(-\Delta E/kT) \quad [1]$$

We fitted our experimental results to Eq. [1] with the parameters k_2 and ΔE. k_1 is obtained from the low temperature limit of the decay time and k_{21}^{-1} is assumed to be negligible compared to k_2^{-1}. The temperature dependence of the radiative transition probabilities and the temperature dependence of the nonradiative transitions have been neglected in this model. The parameters deduced from these fits are presented in Table III. The decay parameters of $LiLuO_2$-Bi^{3+} relate to the green emission, the blue emission being too weak to measure its decay time. The decay time of $LiGdO_2$-Bi^{3+} and $NaGdO_2$-Bi^{3+} was relatively short, even at 10 K.

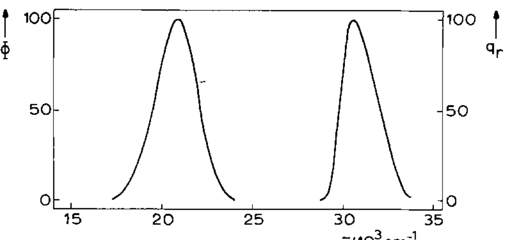

Fig. 5. The emission and excitation spectra of the luminescence of $LiGdO_2$-Bi^{3+} at 5 K. See also Fig. 2.

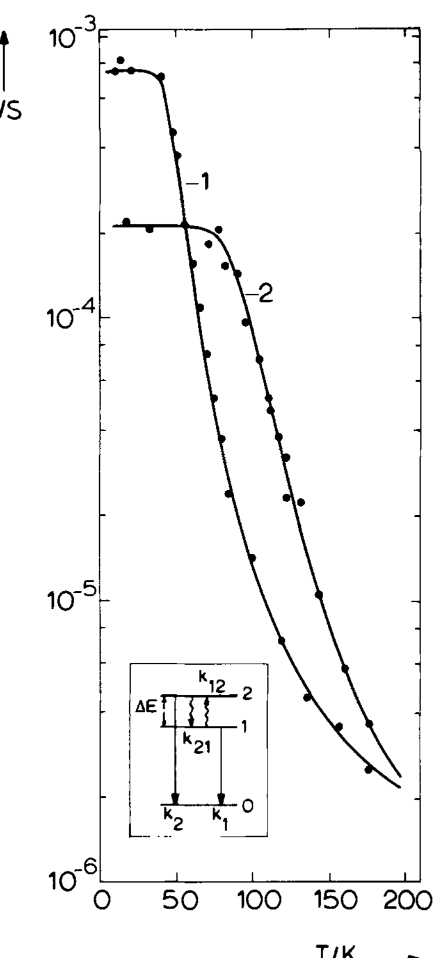

Fig. 6. The decay times of the emission of $LiLuO_2$-Bi^{3+}, curve 1, and $NaScO_2$-Bi^{3+}, curve 2, as a function of temperature. The solid lines give the best fit to the experimental data with Eq. [1]. The schematic representation of the three-level scheme (insert) is discussed in the text.

Discussion

α-$NaFeO_2$ structured compounds.—There are two different sites available for the Bi^{3+} ion in $NaYO_2$ (β-$LiFeO_2$ structure, see Table I). The resemblance between the spectra of $NaLuO_2$-Bi^{3+} and $NaYO_2$-Bi^{3+} suggests that the Bi^{3+} ion is mainly substituted on the site with D_{3d} symmetry in the β-$LiFeO_2$ structure. For this reason we discuss the optical properties of $NaYO_2$-Bi^{3+} together with those of $NaScO_2$-Bi^{3+} and $NaLuO_2$-Bi^{3+}.

Comparison with other work on the Bi^{3+} luminescence in oxidic host lattices confirms that the higher energy excitation band (~39,000 cm^{-1}) corresponds to the $^1S_0 \rightarrow {}^1P_1$ transition and the lower energy excitation band (~28,400 cm^{-1}) to the $^1S_0 \rightarrow {}^3P_1$ transition (2, 4). The two components of the $^1S_0 \rightarrow {}^3P_1$ excitation band are due to the crystal-field splitting of the $^3P_1$ excited state. The layered α-$NaFeO_2$ structure causes a trigonal crystal field on the Bi^{3+} ion which splits the $^3P_1$ ($^3T_{1u}$) level in an orbital doublet (^3E_u) and an orbital singlet ($^3A_{2u}$). The intensity ratio of the two excitation bands suggests that the doublet lies lower in energy than the singlet. In a simple model this corresponds to a situation in which two 6p orbitals are situated in the layer of trivalent cations. They point to the Ln^{3+} ions, whereas the third orbital points to the Na^+ ions which results in a less favorable energy for the latter. The increase of the crystal-field splitting in the sequence $NaYO_2 < NaLuO_2 < NaScO_2$ can be related to the decrease of the radius of the Ln^{3+} ion.

The long decay time indicates that the emission transition at low temperatures is the forbidden $^3P_0 \rightarrow$

$^1S_0$ transition. In spite of the forbidden character of this transition the zero-phonon line is observed in the emission spectrum. At elevated temperatures the $^3P_1$ (^3E_u) level is also populated and the $^3P_1 \rightarrow {}^1S_0$ transition is observed. The agreement between the ΔE values derived from the temperature dependence of the decay time of the emission transition $^3P_0$, $^3P_1 \rightarrow {}^1S_0$ and those obtained from the excitation and emission spectra is reasonable (Table III).

α-LiFeO₂ structured compounds.—The position of the $^1S_0 \rightarrow {}^3P_1$ excitation band does not depend on the crystal structure, but on the monovalent cation. All sodium compounds (with α-$LiFeO_2$ and α-$NaFeO_2$ structure) have their $^1S_0 \rightarrow {}^3P_1$ excitation band at about 28,400 cm^{-1} and all lithium compounds at about 31,000 cm^{-1}. This agrees with the higher polarizing power of the Li^+ ion (3). No crystal-field splitting is observed in the excitation spectra of $NaGdO_2$-Bi^{3+} and $NaLaO_2$-Bi^{3+}. In the lithium series of compounds a splitting of the excitation band is only observed in the case of $LiScO_2$-Bi^{3+}, *viz.*, 680 cm^{-1} (compare $NaScO_2$-Bi^{3+} 2600 cm^{-1}). From this we conclude that the magnitude of the noncubic crystal-field component is much smaller in the α-$LiFeO_2$ than in the α-$NaFeO_2$ structured compounds. This is confirmed by the crystal-field splitting of the $^7F_1$ energy level of the Eu^{3+} ion in these lattices (25). The small splitting of the higher energy component in the excitation spectrum of $LiScO_2$-Bi^{3+} (Fig. 4) is not discussed here.

The emission spectra of the α-$LiFeO_2$ structured compounds can be interpreted assuming a Jahn-Teller effect in the excited state of the Bi^{3+} ion (26). Fukuda pointed out that an s^2 ion in cubic site symmetry can show two emission bands due to a Jahn-Teller interaction in the RES of the ion (13). The noncubic crystal field in the α-$NaFeO_2$ structured compounds is too large to expect such a Jahn-Teller distortion (27). However, the noncubic crystal field in the α-$LiFeO_2$ structured compounds is much smaller. In that case, the Jahn-Teller effect may exceed the effect of the noncubic crystal field. This suggests that: (*i*) the ultraviolet emission of $NaGdO_2$-Bi^{3+} originates from another kind of minimum (A_T) on the $^3P_1$ APES than the red emission of $NaLaO_2$-Bi^{3+} (A_X). This seems to be the only way to understand the pronounced difference between the position of the emission band of the Bi^{3+} ion in $NaGdO_2$ and $NaLaO_2$; (*ii*) the blue emission of $LiScO_2$-Bi^{3+} originates from a T minimum, the green emission of $LiYO_2$-Bi^{3+} from an X minimum; both emissions ($A_T + A_X$, blue + green) can be observed in the spectra of $LiLuO_2$-Bi^{3+}.

Drickamer *et al.* showed that in the case of s^2 ion activated alkali halides, the occurrence of A_T and/or A_X emission depends also on the external pressure on the crystal (28). An increase of the pressure on the crystal destabilizes the X minimum and favors the emission from the T minimum. The change of external pressure can be compared with a change of the "internal pressure" on the Bi^{3+} ion in our series of compounds. The Bi^{3+} ion has to experience a larger internal pressure in $NaGdO_2$ than in $NaLaO_2$, since the ionic radius of the substituted Gd^{3+} ion is smaller than the ionic radius of the La^{3+} ion. The larger internal pressure in the case of $NaGdO_2$-Bi^{3+} results in an ultraviolet emission (A_T), contrary to the red emission (A_X) in the case of $NaLaO_2$-Bi^{3+}, with a relatively low internal pressure. The same observations hold for the lithium series of compounds. The A_T emission is observed when the Bi^{3+} ion is substituted for the smallest ion (blue emission of $LiScO_2$-Bi^{3+}) and the A_X emission is observed when the Bi^{3+} ion replaces the Y^{3+} ion (green emission of $LiYO_2$-Bi^{3+}). An intermediate case is $LiLuO_2$-Bi^{3+} where both emissions can be observed at low enough temperatures. The excitation spectra of $LiLuO_2$-Bi^{3+} (Fig. 4), however, do not agree with this model. We have no explanation for this discrepancy. We tried to find the green emission for $LiScO_2$-Bi^{3+} at higher temperatures, but at room temperature only the blue emission is present. The internal pressure on the Bi^{3+} ion is obviously lower in the lithium compounds than in the sodium compounds, because the variation of the Ln^{3+} ionic radius alone cannot explain the differences between cases (*i*) and (*ii*) mentioned above. Probably the Li^+ ions have a stronger polarizing action on the oxygen anions than the Na^+ ions. This results in a lower pressure on the Bi^{3+} ion in the lithium compounds and explains why the A_X emission is observed in the lithium compounds for smaller Li^{3+} ions than in the sodium compounds.

The interpretation of the emission bands as originating from different kinds of minima on the $^3P_1$ APES is supported by the decay experiments. The radiative decay time of the A_X emission has to be longer than that of the A_T emission because the $^3P_2$ wavefunctions are mixed with the $^3P_1$ wavefunctions near the X minimum (13). The decay time of the $^3P_1 \rightarrow {}^1S_0$ emission (τ_2 in Table III) in the case of $LiScO_2$-Bi^{3+} (A_T emission) is substantially shorter than the corresponding decay times of $LiLuO_2$-Bi^{3+} and $NaLaO_2$-Bi^{3+} (A_X emission).

Our interpretation is in line with model calculations by Masunaga *et al.* for tetragonal and trigonal distortions of the $^3P_1$ and $^3P_0$ APES of an s^2 ion on a cubic lattice site (29). If we consider the normalized configurational coordinates bQ_3/Δ (cQ_5/Δ) [$b(c)$ is the linear coupling constant with the ϵ_g (τ_{2g}) mode and $\Delta = E_C - E_A$] to be proportional to the Stokes shift of the emission, their results can be reformulated as follows: (*i*) the Stokes shift is inversely proportional to the trap depth of the $^3P_0$ level [Fig. 9 of Ref. (29)]; (*ii*) the Stokes shift is proportional to the radiative decay time of the $^3P_1$ level [Fig. 10 of Ref. (29)]. The first relation has already been shown to be valid (8). Both relations are in accordance with our observations on the luminescence properties of the Bi^{3+} ion in α-$LiFeO_2$ and α-$NaFeO_2$ structured compounds (see Tables II and III). The fact that $NaScO_2$-Bi^{3+} with the smallest Stokes shift does not have the largest trap depth must be due to the large crystal-field splitting in this case. This lowers one of the $^3P_1$ components considerably and shows at the same time that the relation between Stokes shift and trap depth can only be used as a rule of thumb. The validity of the relations is another indication that, especially in the α-$LiFeO_2$ structured compounds, we can consider a Jahn-Teller interaction in the ^3P RES of the Bi^{3+} ion to be effective. This is the first observation of such an effect in oxidic host lattices as far as we are aware.

There is some resemblance between the optical spectra of the Bi^{3+}-activated α-$LiFeO_2$ structured compounds and those of $6s^2$ ion activated alkali halides. In the latter compounds the position of the excitation band also does not vary with the monovalent cation, while the position of the emission band can vary considerably [see *e.g.*, Ref. (30)]. Recently a similar phenomenon has been observed for the Pb^{2+}-activated fluorites MF_2 [M = Ca, Sr, Ba; Ref. (31)]. In view of the emission data it cannot be excluded that BaF_2-Pb^{2+} shows A_X and CaF_2-Pb^{2+} and SrF_2-Pb^{2+} A_T emission.

Bi³⁺-activated LiGdO₂ and NaGdO₂.—The compound $LiGdO_2$ has a different structure, *viz.*, the α-$HAlO_2$ structure (16). The Gd^{3+} ions occupy octahedral sites. In fact the spectral properties of $LiGdO_2$-Bi^{3+} are not strikingly different from the other lithium compounds (see Table II and Fig. 5), although they do not fit in the Sc, Lu, Y series (note the relatively small Stokes shift). The most striking property of $LiGdO_2$-Bi^{3+} and $NaGdO_2$-Bi^{3+} is the short decay time at low temperatures (Table III). The temperature dependence of

the decay time can be described with a three-level scheme. The fitted parameters are similar to those found for the other compounds. Recently a similar short decay time was observed for monoclinic Gd_2O_3-Bi^{3+} (32). For cubic Gd_2O_3-Bi^{3+} Boulon has reported the (normal) long decay times (5), but this could not be confirmed in our laboratory (32).

There seems to be no special reason why in the Gd^{3+} compounds either the $^3P_0$ level would not be the lowest level or $^3P_1 \rightarrow {}^3P_0$ relaxation would be very slow. An obvious possibility may be the following. The Gd^{3+} ions surrounding the Bi^{3+} ion may cause a magnetic field at the Bi^{3+} ion site. As a consequence the $^3P_1$ and $^3P_0$ levels will be mixed (33). This results in an increase of the $^3P_0 \rightarrow {}^1S_0$ transition probability and a shorter decay time. Further investigations are necessary to check the feasibility of this possibility.

Vibrational structure.—The vibrational structure in the luminescence spectra of the Bi^{3+} ion in cubic symmetry has been interpreted several times (6, 11, 34, 35). Recently, one of us has analyzed successfully the vibrational structure in the luminescence spectra of Cs_2NaYCl_6-Bi^{3+} by comparing the frequencies found in these spectra with those found from the Raman spectrum of Cs_2NaYCl_6. The following coupling mechanism, using the $k = 0$ internal modes of the $BiCl_6{}^{3-}$ octahedron was proposed (11). The electric dipole allowed $^3T_{1u} \leftrightarrows {}^1A_{1g}$ ($^3P_1 \rightleftharpoons {}^1S_0$) transition can be electric dipole vibronically allowed with the enabling vibrations of E_g and T_{2g} symmetry (ν_2 and ν_5). The $^3T_{1u} \rightleftharpoons {}^1A_{1g}$ emission and excitation bands consist, therefore, of a progression involving the totally symmetric mode (A_{1g}, ν_1) based on the electronic origin (0-0) and on two vibronic origins (ν_2 and ν_5). The emission transition $^3A_{1u} \rightarrow {}^1A_{1g}$ ($^3P_0 \rightarrow {}^1S_0$) is electric dipole forbidden, but vibronically allowed by vibrations of T_{1g} symmetry. The τ_{1g} mode is not an internal vibration of the $BiCl_6{}^{3-}$ octahedron. Vibrational coupling to modes of A_{1g}, E_g, and T_{2g} symmetry, based on the vibronic origin due to coupling with the τ_{1g} mode, is observed.

We realize that this approach will be less successful for the $NaLnO_2$-Bi^{3+} compounds. The BiO_6 octahedra share edges with LnO_6 octahedra, there is possibly more than one type of Bi^{3+} center and the site symmetry of the Bi^{3+} ion is lower than cubic. In the following discussion we nevertheless analyze the main vibronic features of the spectra on the basis of a $BiO_6{}^{9-}$ octahedron assuming that the symmetry of the $BiO_6{}^{9-}$ group is the same as for the $LnO_6{}^{9-}$ group and restricting ourselves to those features which are common to all compounds considered.

The excitation transition has two electronic origins (0-0 and 0-0′) corresponding to the $^1A_{1g} \rightarrow {}^3E_u$ and $^1A_{1g} \rightarrow {}^3A_{2u}$ electronic transitions, respectively (Table IV). The former transition couples with two modes: ν_a and ν_b. A progression occurs in the mode ν_a, whereas ν_b is an enabling vibration (the modes can be compared with the ν_1 and ν_5 vibrational modes in the octahedral case). A progression (ν_a') is also observed for the latter transition, but the frequency is less than in the former case.

The zero-phonon line of the forbidden emission transition $^3A_{1u} \rightarrow {}^1A_{1g}$ has a very weak intensity (Table IV, Fig. 2). The first intense line corresponds to coupling with a mode ν_c (compare the τ_{1g} mode in octahedral symmetry). The remainder of the vibrational structure is based on this one-phonon line. Coupling with the vibrational modes as found in the excitation spectra occurs: a progression involving the ν_a mode is observed on two vibronic origins (ν_c and $\nu_c + \nu_b$). The vibrational frequencies are summarized in Table VI. The frequency of the ν_a mode increases in the order $NaYO_2 < NaLuO_2 < NaScO_2$, which is in line with the expectation that a smaller bond length results in a

Table VI. The phonon frequencies (cm^{-1}) as observed in the excitation and emission spectra of $NaLnO_2$-Bi^{3+} (Ln = Sc, Lu, Y, Gd)

	Excitation			Emission			
	Sc	Lu	Y	Sc	Lu	Y	Gd
ν_a	515	450	445	525	490	475	500
ν_b	210	155	175	240	155	185	145
ν_c	—	—	—	420	367	347	—
ν_a'	~465	~390	~370				

higher frequency for the vibrational mode. The frequency of the ν_a' mode which couples with the $^1A_{1g} \rightarrow {}^3A_{2u}$ transition is lower than that of the ν_a mode which couples with the $^1A_{1g} \rightarrow {}^3E_u$ transition. This reflects the stronger bonding in the doublet.

Let us now turn to the Raman spectra of the host lattices. A factor-group analysis of the α-$NaFeO_2$ structure ($D_{3d}{}^5$, $R\bar{3}m$) shows that there are two modes of even symmetry, *viz.*, $A_{1g} + E_g$ (36). Both modes are Raman active. Our Raman spectra of these compounds contain two intense features at about 90 cm^{-1} and about 380 cm^{-1} ($NaScO_2$: 390 cm^{-1}; $NaLuO_2$: 385 cm^{-1}; $NaYO_2$: 370 cm^{-1}). A broader and weaker structure is observed at about 530 cm^{-1}.

From these data it is hard to assign the vibrational modes with certainty. The 90 cm^{-1} feature can be recognized in the vibrational pattern of $NaScO_2$-Bi^{3+}, but is not general. If we consider the variation of the frequency of the ν_a mode, it seems probable that a model considering more or less localized modes will account for the features observed. The ν_a mode is then the totally symmetric vibration of the $BiO_6{}^{9-}$ octahedron. The vibrational mode ν_c which makes the emission transition partially allowed will be more delocalized and may be correlated to the 380 cm^{-1} feature in the Raman spectra.

Due to the partially $^3P_1$ character of the $^3P_0$ level, the electronic origin is the most intense line in the emission spectrum of $NaGdO_2$-Bi^{3+}. The interpretation of the vibronic features (Table V) is very much like the $^3P_1 \rightarrow {}^1S_0$ transition in the octahedral case of Cs_2NaYCl-Bi^{3+} (11). This suggests that the treatment of the $BiO_6{}^{9-}$ group as an isolated octahedron is more successful in the α-$LiFeO_2$ structure than in the α-$NaFeO_2$ structure.

A Self-Aligned Contact MOS Process for Fabricating VLSI Circuits

M. K. Khan* and G. C. Godejahn, Jr.*

Rockwell International, Microelectronics Division, Newport Beach, California 92663

ABSTRACT

A novel technique is described for fabricating silicon gate NMOSFET's having self-aligned contacts to source, drain, gate, polysilicon line, and diffused line. By employing silicon nitride as a mask in various steps of the process, contact holes were formed by selective oxidation instead of the conventional technique of etching contacts. Diffusion techniques were employed for doping the conductive regions. Electrical properties of the devices are described. The reduction obtained in the size of the individual FET's and the chip area of VLSI circuits by employing this technique are illustrated.

The MOS/VLSI technology requires higher packing density of both transistor elements and interconnect lines. The common approach to achieve higher packing density is to scale down the transistor size and interconnect lines, however, the major limitation to the scaling approach is the mask alignment tolerances which cannot be easily scaled down. The widely used 1:1 projection aligners have an alignment tolerance of typically 1 μm per layer. Because of this limitation and etch tolerance requirements, it is extremely difficult to keep the contact regions less than 3.5 μm away from the nearest active elements in a typical HMOS design as illustrated in Fig. 1.

Tanigaki *et al.* (1) developed a self-aligned contact technique for the source and drain of a silicon gate MOSFET, however, their approach does not allow for self-aligned contacts to the polysilicon gates or to the interconnect lines.

In reality the interconnect lines with the associated contact regions occupy major portions of the chip area and there has been a tendency to waste contact area to the diffused and polysilicon interconnects because of the above-mentioned mask alignment and etching tolerance requirements. A process has been developed to form self-aligned contacts (SACMOS) to source, drain, gates, polysilicon lines, and diffused lines to achieve higher packing density of both active devices and interconnect circuitry.

Process Description

The process utilizes silicon nitride in various steps of the process to form self-aligned contact regions. By a combination of selective oxidation and etch techniques, contact holes are formed in the oxide grown simultaneously over polysilicon and diffused regions. In this respect, the process is different from the conventional method of etching contact holes in the thermal or deposited oxides.

The basic process steps and the cross-section of a device and interconnect poly and diffused lines are illustrated in Fig. 2(a)-2(i). The starting wafers were 15 Ωcm, (100) oriented, p-type silicon. An initial oxide of 500Å was thermally grown and a silicon nitride film 500Å thick was deposited by low pressure CVD technique. The active area was patterned with photoresist and the silicon nitride was etched off the field region. After a boron implant in the field region, a 9000Å oxide was grown over field regions. The initial oxide and nitride were retained as the gate dielectric [Fig. 2(a)]. Next, a 7500Å polysilicon film was deposited by low pressure CVD technique. A 500Å oxide layer was grown on polysilicon followed by deposition of a second layer of 600Å silicon nitride. Another 300Å of polysilicon film was deposited over the nitride II layer and thermally converted to oxide. The intended contact regions to polysilicon (PC) were delineated by photoresist masking as shown in Fig. 2(b) The top oxide and nitride were etched using wet techniques [Fig. 2(c)]. Note that the PC mask (and later NC mask) have enlarged contact areas to allow for noncritical alignment tolerance and insure overlap on polysilicon lines. Next, the gate mask (G) was delineated and the overlapping oxide and silicon nitride edges of the PC region were etched off followed by selective etching of polysilicon. Thus the PC and G mask combination were used to define self-aligned contacts to poly lines [Fig. 2(e)]. A similar technique was used to define a self-aligned contact region directly on the top of the gate where required. Next, a noncritical NC masking was performed to define self-aligned contact regions to the source, drains, and the N-lines [Fig. 2(f)]. The silicon nitride and underlying oxide was etched off from the N-lines. The poly oxide over poly lines and gates was also etched off simultaneously with the oxide over N-lines. During the NC mask etching, the PC nitride was protected by poly oxide II. At this step, all contact regions were covered by self-aligned nitride buttons whereas the polysilicon lines and N-lines were exposed for phosphorus diffusion or ion implantation. In this work, the phosphorus deposition was done using $POCl_3$ at 900°C to dope the polysilicon and N-lines [Fig. 2(g)]. Next, the structure was oxidized to grow an isolation oxide of 5000 and 6000Å over polysilicon and N-lines, respectively. During the oxidation, the SAC regions are protected by silicon nitride buttons. The silicon nitride buttons were next removed by a plasma etch technique and the underlying 500Å of oxide was etched off in buffered HF. Finally, phosphorus was diffused into the source, drain, NC, and PC contact regions [Fig. 2(h)].

To enhance metal step coverage and reduce crossover capacitance, a phosphorus-doped CVD SiO_2 layer was deposited on the top of the structure and a non-critical contact mask was used to etch vias to the underlying SAC's. The process was completed by sputtering Al-1% Si film followed by conventional masking and metal etching [Fig. 2(i)].

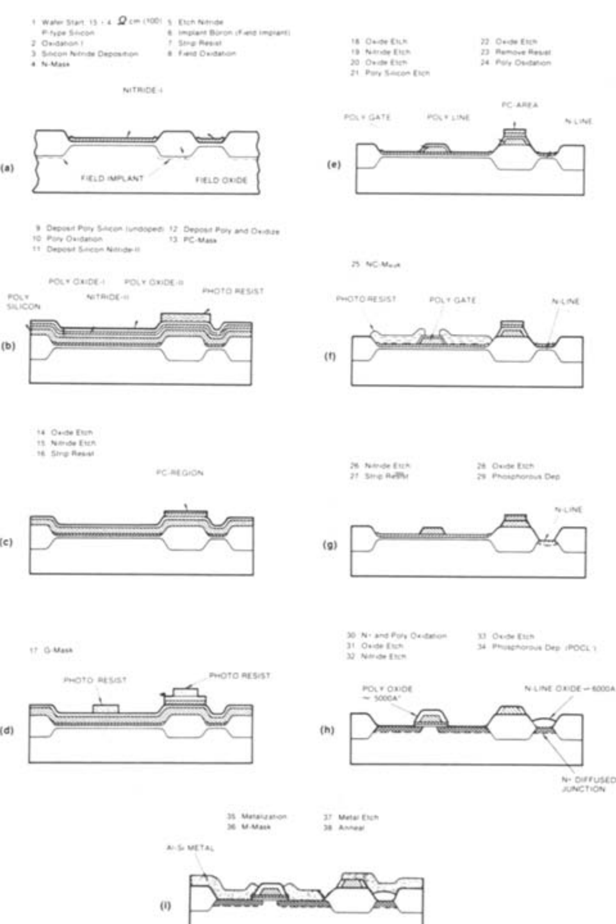

Fig. 2. SAC process flow

Device Characteristics

Using the foregoing process MOSFET devices having two and three-micron electrical channel lengths have been manufactured and characterized. The electrical parameters for a typical MOSFET are given in Table I. As the gate dielectric in these devices consists of silicon dioxide and silicon nitride sandwich, they were tested for threshold voltage stability. Several devices from different lots were packaged and subjected to extensive bias temperature tests at 125°C, 10V for 2000 hr. The threshold voltage shift as a function of B-T stress time is shown in Fig. 3 which indicates that the threshold voltage shift is about 40 ± 15 mV for the total time of 2000 hr. Furthermore, the slope of the curve indicates that the major shift occurs within 600 hr of the B-T stress. The formation of oxynitride film over the silicon nitride during the high temperature field oxidation was found to be an important factor in achieving the threshold stability.

Gain in Circuit Density

By virtually eliminating the contact to gate spacing of 3.5 μm in a typical HMOS process, the length of a

MOSFET is reduced by 8.0 μm in the SACMOS process as shown in Fig. 4. The SAC's to interconnect polysilicon and N-lines provide additional savings in interconnect area. A 32K ROM was designed and fabricated using the SACMOS process which had a chip area of 18,800 mil². Compared to a 32K ROM chip designed to typical HMOS design rules, the SACMOS process chip was about 30% smaller, thus giving a packing density ratio of 1.3:1. It is, therefore, concluded that SACMOS process is very effective for achieving higher packing density required for VLSI.

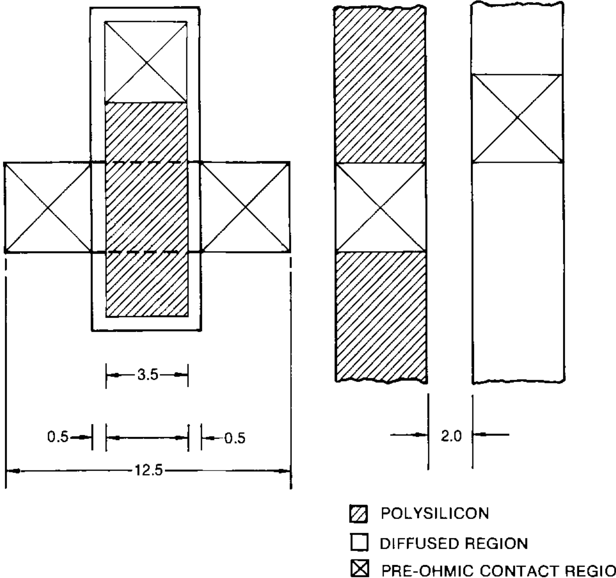

Fig. 4. Layout of a transistor and interconnect lines designed to the SACMOS process. All dimensions are in microns.

Discussion

During the course of this work it was discovered that retention of the thin ~125Å, oxide layer grown on top of the silicon nitride during the field oxidation process was of paramount importance in achieving gate stability as shown in Fig. 3. Devices made without this thin oxide layer on the top nitride-oxide gates exhibited large threshold shifts due to charge trapping. An analysis of this layer by computer-aided ellipsometry indicated a refractive index of 1.46. From this data we conclude that the film was silicon dioxide rather than oxynitride as thought earlier. We think that the thin oxide layer on the top of nitride prevents charge injection from polysilicon gate into the nitride, while the charge injection from the substrate is inhibited by the thermal oxide below the nitride.

It is recognized that the SACMOS process described above is more complex than conventional NMOS but the attendant advantages of self-aligned contacts to achieve higher circuit density with relaxed alignment tolerance requirements offsets this trade-off. For example, a 4 μm NMOS process with self-aligned contacts is equivalent to a 3 μm process as far as circuit density is concerned. However, the SACMOS process has some limitations as far as scalability of the devices are concerned. The scaling principle requires thinning of gate dielectric in proportion to the horizontal shrinking of the device. As the oxide/nitride gate dielectric is made thinner the device will be more susceptible to charge trapping at oxide/nitride interface. Some preliminary work indicates that 300Å oxide and 400Å nitride gate structures could be made stable using the technique of oxidation of nitride described above.

Metal step coverage, was initially a major problem until sputter metallization was introduced and oxide etch process was optimized. Several complex and large circuits having approximately 6 mm on the side have been fabricated using this technology.

Optical and Electrical Characterization of Chemical Defects in GaAs Layers Grown by MBE

W. H. Koschel, R. S. Smith, and P. Hiesinger

Fraunhofer-Institut für Angewandte Festkörperphysik, D-7800 Freiburg, West Germany

ABSTRACT

Careful control of UHV conditions during molecular beam epitaxial growth of thin crystalline gallium arsenide layers has to be accomplished to avoid undesired incorporation of chemical defects. Residual acceptor impurities in the MBE GaAs films were detected through their characteristic photoluminescence spectra, and the effect of these compensating acceptor centers on electron mobility in n-type MBE GaAs was analyzed. A useful procedure for an accurate determination of the residual acceptor concentration in MBE GaAs is presented.

Thin gallium arsenide layers grown by molecular beam epitaxy (MBE) have the advantage of controlled thickness, composition, and doping profile (1). In particular, very thin layers (<0.3 μm) can be prepared by MBE, and successful experiments to obtain abrupt changes in doping profiles have been reported (2, 3). However, the quality of MBE layers depends strongly on the conditions of the UHV system used (4-6). Sensitive methods are required to characterize the electrical and optical properties of the residual chemical defect levels (10^{13}-10^{16} cm^{-3}) in MBE GaAs. The objective of such a characterization is to gain better control of the MBE growth process and to obtain a better understanding of the effect of compensating acceptor centers on electron mobility in n-type MBE GaAs.

This paper reports on the luminescence properties of MBE GaAs layers containing residual acceptor centers, as well as on the information that can be provided on compensation and total impurity concentration by analysis of mobility values as a function of charge carrier concentration. A useful procedure for an accurate determination of the residual acceptor concentration in n-type MBE GaAs is developed.

Experimental

Substrates used for the growth of the MBE GaAs layers were doped with either Cr (semi-insulating), Si, or Te (n^+). The substrates were lapped, then polished using a sodium hypochloride solution, and finally etched for 2 min in hot H_2SO_4:H_2O_2:H_2O (7:1:1) immediately prior to transfer to the MBE growth chamber. The MBE system used was a modified commercial RIBER system with a quadrupole mass spectrometer for residual gas analysis and RHEED and Auger for surface analysis. The base pressure of the system after bakeout and with cryopanel cooling was in the 10^{-10} Torr range and during growth the pressure increased to about 10^{-7} Torr.

Etching the substrates left the surface covered with an oxide layer which was removed in the growth chamber by heating for a few minutes at 560°C in an arsenic atmosphere. The complete removal of the oxide layer was monitored by observing the development of a streaked RHEED pattern due to an As-stabilized, reconstructed (2×4) surface. After the removal of the oxide, the substrate temperature was reduced to 540°C and growth was started by opening the shutter covering the gallium oven. The gallium temperature was adjusted to give a gallium flux of about 6×10^{14} atoms/cm^2 sec which resulted in a growth rate of about 1 μm/hr. The typical growth conditions corresponded to a high As_4/Ga flux ratio. Temperatures were 900°-1000°C for the gallium oven, 350°C for the arsenic oven, and 640°-840°C for the tin oven which was used for n-type doping of the MBE GaAs films. A variety of characterization methods were applied to assess the effect of residual chemical defect levels on the electrical and optical properties of the MBE GaAs layers. Photoluminescence was measured with krypton laser excitation and a McPherson 1m spectrometer using a cooled S1 photocathode for detection of the near band-edge infrared emission of the MBE GaAs films. Cathodoluminescence was recorded using a commercial SEM at electron energies from 5 to 30 keV. Electrical properties of the MBE GaAs films were obtained by standard Hall effect techniques. The free electron mobilities were analyzed in n-type MBE GaAs with respect to the effect of compensating acceptor scattering centers.

Results and Discussion

MBE GaAs layers were grown with thicknesses from 1 to 10 μm. A surface cleaved perpendicular to the growth direction was analyzed using an SEM in the cathodoluminescence mode. A considerable luminescence contrast is obtained at infrared wavelength 865 nm using an 8 nm bandpass (Fig. 1). The increased

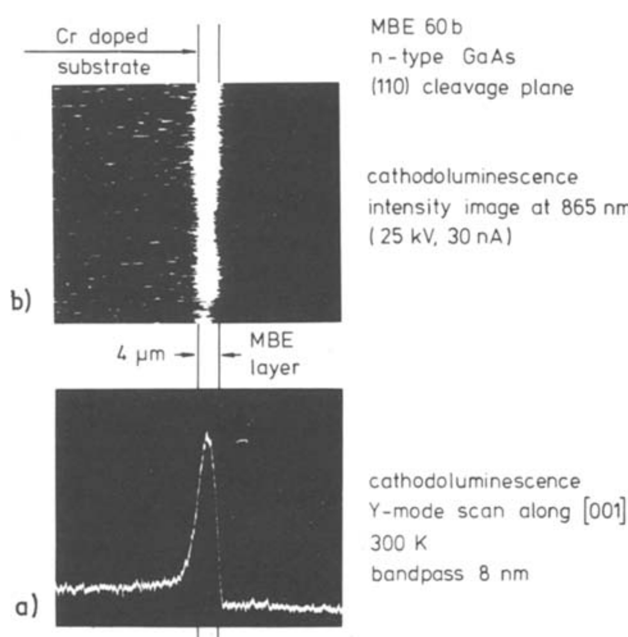

Fig. 1. SEM micrograph and cathode luminescence of an MBE GaAs layer on a GaAs:Cr substrate. (a) Cathodoluminescence (Y-mode); (b) cathodoluminescence (image).

Key words: defects, photoluminescence, MBE.

luminescence efficiency in the MBE GaAs layer is due to the doping level of 10^{15}-10^{16} cm^{-3} in contrast to to the low efficiency of the heavily compensated Cr-doped substrate. Thickness of the layers was obtained either directly from the cathodoluminescence image or by etching the cleaved surface and inspection with an optical microscope.

The residual impurity concentration of GaAs layers of the first MBE experiments in a newly installed system usually ranges from 1×10^{15} to 5×10^{16} cm^{-3}. A sensitive method to assess impurites in this concentration range is low temperature photoluminescence (PL). Figure 2 shows typical luminescence spectra of an n^+ GaAs substrate and an MBE GaAs layer. The MBE layer exhibits the PL lines of the optically active shallow C and deeper Mn acceptors (C: $E_A = 26$ meV (7), Mn: $E_A = 110$ meV (8, 9), and of the bound exciton (BE) recombination. The acceptor band of carbon, as the dominant residual impurity, is always present in the PL spectra of MBE GaAs films since for the small growth rate of 1 μm/hr a very low partial pressure (dependent on the sticking coefficient) of carbon compounds would be required in the UHV system to obtain an impurity concentration below 10^{13} cm^{-3} (4).

Hot steel parts in the original MBE system have been found to be the origin of the Mn contamination. After rebuilding the system with all hot stainless steel parts replaced by molybdenum ones, the Mn contamination was reduced to a value below the detection limit of the PL experiments ($<10^{14}$ cm^{-3}, Fig. 3). One of the main requirements for obtaining high quality n-type MBE layers is the avoidance of such undesired acceptors, which compensate shallow donor impurities and reduce the electron mobility by ionized impurity scattering. At 1.479 eV (838 nm), a further

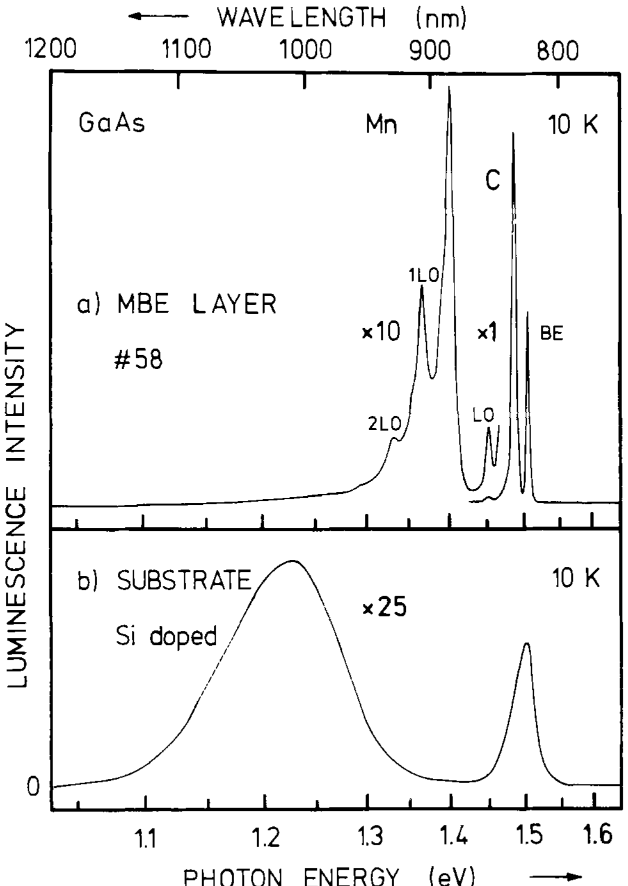

Fig. 2. (a) Photoluminescence spectrum of an MBE GaAs layer showing Mn, C, and bound exciton (BE) peaks. (b) Photoluminescence spectrum of the Si-doped substrate (n+).

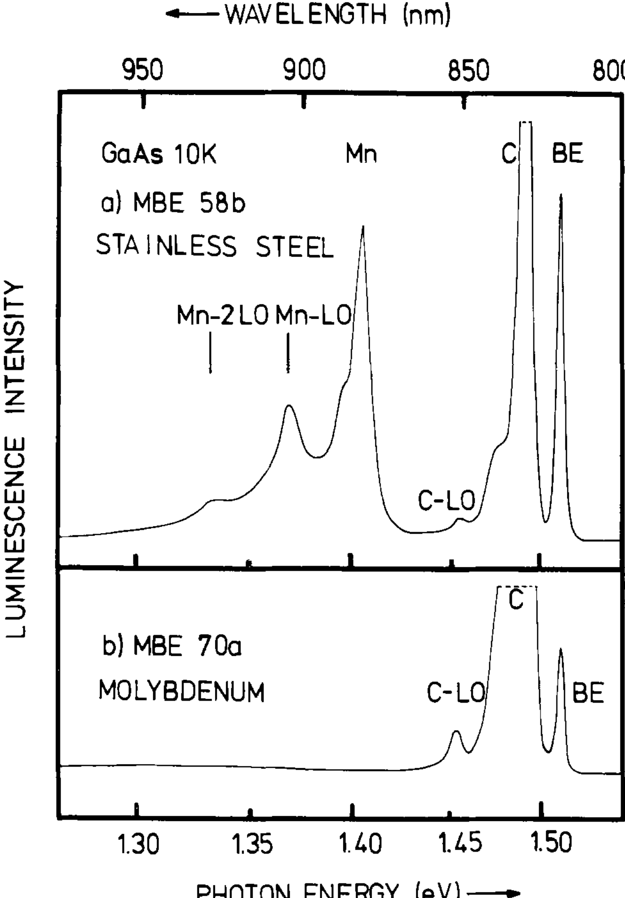

Fig. 3. (a) Photoluminescence spectrum of the Mn acceptor in an MBE GaAs layer prepared with a stainless steel sample holder. (b) Corresponding photoluminescence spectrum of an MBE GaAs layer prepared with a molybdenum sample holder.

typical PL emission in MBE GaAs material appears in Fig. 3 between the carbon line (C) and its phonon replica (C-LO). Usually, this structure is ascribed to band-acceptor recombination at Ge_{As} acceptors ($E_A = 40$ meV) (7). Since Ge is an amphoteric dopant (10, 11) it can also occupy Ga sites in the GaAs lattice (Ge_{Ga}) and become a shallow donor level. This behavior has been demonstrated in intentionally Ge-doped MBE GaAs where the donor or acceptor character of the Ge dopant was controlled through the As_4/Ga flux ratio or the substrate temperature (10, 11).

Reducing the As_4/Ga flux ratio in our MBE experiments indeed resulted in an increase of the 838 nm PL emission (Fig. 4). However, the source of the possible Ge contamination in the growth chamber could not be located.

Therefore, there is still some doubt whether or not the 1.479 eV PL emission in our MBE GaAs samples is due to Ge. The PL emission could also be due to another defect center (simple vacancy V_{As} or vacancy-related defect). The assignment to such an intrinsic defect center is supported by the fact that this PL emission has been found in most of our MBE GaAs samples and also in control samples of other laboratories independent of the As and Ga source materials and the evaporation cells (graphite, pyrolytic boron nitride) used. Since the shallow C acceptor was identified in the same MBE GaAs samples, the 1.479 eV PL emission could also be due to another C related defect center which occurs in addition to the simple C acceptor.

Electrical properties of the MBE GaAs samples were determined by van der Pauw measurements. Results for 300 K are shown in Fig. 5, where the electron mo-

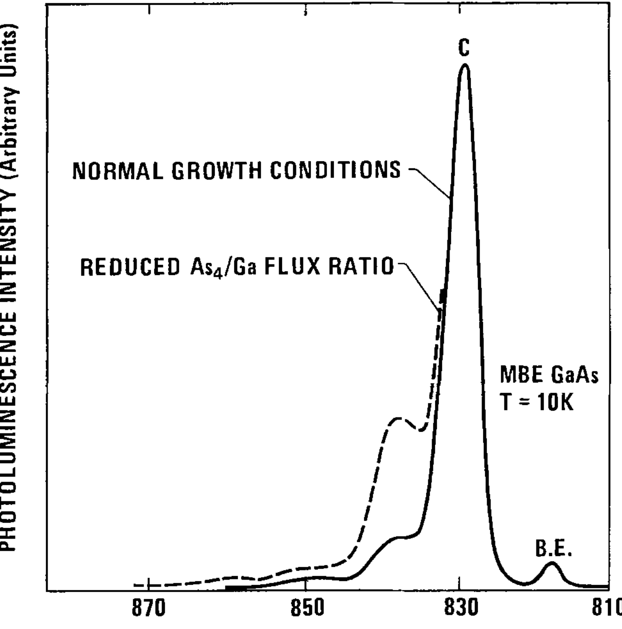

Fig. 4. Photoluminescence spectrum of MBE GaAs layers showing an additional shallow acceptor band under our normal growth conditions and under growth conditions with reduced As_4/Ga flux ratio.

bility values in n-type MBE GaAs are plotted together with the frequently used estimate of the upper mobility limit given by Rode and Knight (12). In the carrier concentration range from 1×10^{15} to 1×10^{16} cm^{-3}, the samples were not intentionally doped, indicating the presence of donor impurities originating from the growth system. If Ge is assumed to be one of the contaminants as discussed above, Ge_{Ga} could be the donor impurity. Another possibility would be the presence of Te or Se donors in our MBE GaAs samples. However, a chemical identification of donor centers in GaAs requires the application of far infrared spectroscopy techniques (13). It is not possible to identify the donors through near infrared PL donor-acceptor spectra since the chemical shifts of the donor levels are too small to be detected.

Additional doping with Sn donors resulted in electron concentrations from 10^{16}-10^{18} cm^{-3}. The 300 K electron mobility values of Fig. 5 are lower than the theoretical limit, indicating a considerable degree of compensation in the n-type MBE GaAs samples. In order to assess the effect of compensating acceptor scattering centers, a careful analysis of the mobility data was performed at a sample temperature of 77 K where the influence of polar optical phonon scattering is small. The mobility data (77 K) of Fig. 6 allow an estimate of the total acceptor concentration for each individual sample. Theoretical curves given in Fig. 6 are different from the usually used treatment by Rode and Knight (12). For higher electron concentrations ($>10^{16}$ cm^{-3}) we give a physically more realistic estimate of electron mobilities and include the pair correlation between donors and acceptors in the calculation of the scattering factors of compensated semiconductors. Therefore, our determination of low temperature mobility values according to the number of ionized impurity scattering centers is similar to the theoretical treatment by Falicov and Cuevas (14).

The experimental mobility data of Fig. 6 can be evaluated with respect to the total number of acceptor centers (N_A). At low electron concentration N_A approaches a value of 5×10^{15} cm^{-3}. The number of donor centers N_D is easily obtained since the net charge carrier concentration is $n = N_D - N_A$. For $N_D < N_A = 5 \times 10^{15}$ cm^{-3} we therefore expect a change from n-type to p-type which was indeed observed experimentally. In Fig. 7 the net charge carrier concentration is plotted *vs.* the donor concentration N_D.

From the PL experiments the dominant shallow acceptor was identified as C_{As}. Our evaluation gives an accurate value of the number of these shallow C acceptors namely 5×10^{15} cm^{-3} for the series of growth experiments considered here. More recent series of growth experiments with improved vacuum conditions and increased area of the liquid nitrogen shroud made it possible to reduce the C contamination to a value below 10^{15} cm^{-3}. Indeed, the C concentration in the MBE GaAs layers was found to be dependent on the vacuum conditions. In recent experiments a more quantitative correlation of the CO partial pressure during growth, the C_{As} acceptor PL intensity, and the number of compensating C_{As} scattering centers in MBE GaAs has been established (15).

Conclusion

Residual shallow acceptor centers were identified in n-type MBE GaAs. The dominant shallow acceptor was found to be C_{As} in concentrations between 5×10^{14} and 5×10^{15} cm^{-3}. The C_{As} concentration was found to be correlated with the CO partial pressure during MBE growth. C_{As} was also identified as the dominant species of compensating acceptor scattering, and is responsible for the reduced electron mobility in n-type MBE GaAs. Contamination with deeper Mn acceptors during MBE growth of GaAs was easily avoided by replacing hot stainless steel parts in the MBE system by molybdenum ones.

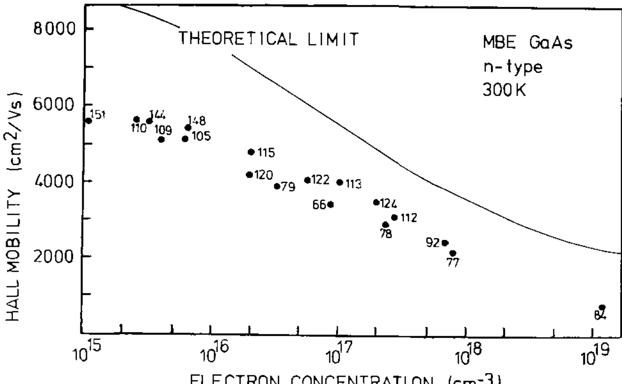

Fig. 5. Electrical properties of n-type MBE GaAs layers at 300 K (Hall mobility *vs.* free electron concentration).

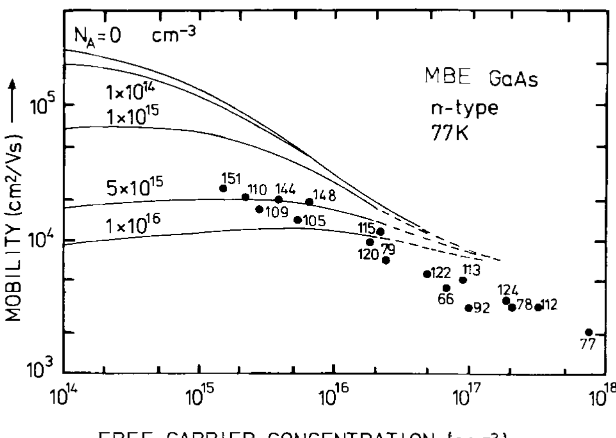

Fig. 6. Electrical properties of n-type MBE GaAs layers at 77 K (Hall mobility *vs.* free electron concentration). Solid lines correspond to the results of the theoretical evaluation for different numbers of compensating acceptors ($N_A = 0$ to 1×10^{16} cm^{-3}).

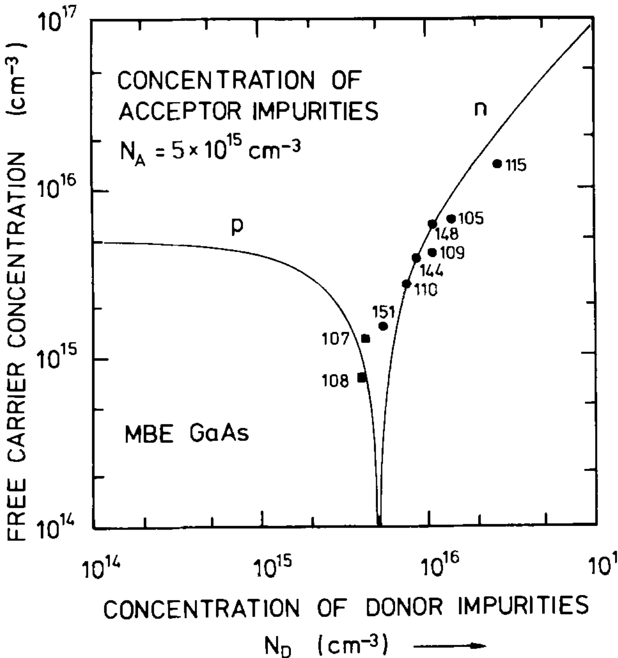

Fig. 7. Free carrier concentration of MBE GaAs layers as a function of donor concentration. The solid lines correspond to the expected behavior for a total acceptor concentration of $N_A = 5 \times 10^{15}$ cm^{-3}. A change from n-type to p-type is experimentally observed for $N_D < 5 \times 10^{15}$ cm^{-3}.

Improved Electrochromic Behavior of Reactively Sputtered Iridium Oxide Films

L. M. Schiavone,* W. C. Dautremont-Smith,* G. Beni,* and J. L. Shay*

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

We report deposition parameters for improved electrochromic behavior of reactively sputtered iridium oxide films (SIROF's). When operated in 0.5M H_2SO_4 electrolyte, SIROF's deposited under these conditions may be bleached to a state exhibiting, to within experimental error (<0.4%), zero transmission loss in the visible. SIROF's which can be fully colored to an optical density (*OD*) of 0.45 (single pass), show a response time for coloring or bleaching (through a ΔOD of 0.3) of 40 msec under constant voltage address. This may be reduced to 20 msec in each direction if *IR* compensation is employed. Preliminary data show no difference in color/bleach cycle lifetime from that of SIROF's deposited under slightly different conditions. No change in contrast is perceivable after 2×10^7 cycles at room temperature.

Iridium oxide films, anodically grown, (AIROF's) have received much recent attention (1-4) by virtue of their many desirable electrochromic properties, in particular their short response time and good corrosion resistance in the appropriate aqueous electrolyte (3). It is accepted that electrochromism in iridium oxide thin films occurs by a reversible ion insertion mechanism, although the nature of the ion responsible for charge transport across the iridium oxide/aqueous electrolyte interface is not agreed upon. Coloration occurs anodically by electron extraction accompanied either by H^+ extraction (3) or OH^- insertion (4). For display applications we have prepared AIROF's on transparent, electronically conducting substrates by complete anodization of a previously evaporated thin film of Ir (5). We have reported the fabrication and performance of a solid-state cell utilizing such a display electrode (6). However, the nature of the anodic growth process restricted the choice of employable solid electrolyte to a material which could be compressed between previously grown iridium oxide films, *i.e.*, an iridium film

* Electrochemical Society Active Member.

Key words: electrochromism, ion-insertion electrode, passive displays.

deposited on an electronically insulating solid electrolyte cannot be completely converted to iridium oxide.

A further limitation of the anodic growth process is the difficulty encountered in obtaining a uniform growth rate for all display elements, even in a simple seven-segment digit. Thirdly, AIROF's may only be grown from a thin film of Ir deposited on a highly conducting substrate, thus preventing measurement of their fundamental electronic transport properties.

All of the above limitations are overcome by a direct deposition technique, and therefore, we attempted to deposit the electrochromic iridium oxide film by reactive sputtering from an iridium target. Since AIROF's are known to be highly hydrated (7), and it was believed that their rapid electrochromic kinetics were dependent on this high degree of hydration, initial attempts utilized a humidified oxygen plasma (8). However, it was determined that the electrochromic response time on subsequent immersion in aqueous electrolytes was independent of the partial pressure of H_2O in the sputtering atmosphere during deposition. Initial results (8) were very encouraging in that these reactively sputtered iridium oxide films (SIROF's) were found to have the same rapid response time as AIROF's. Furthermore, these films were found to have superior stability against both chemical and electrochemical corrosion. In fact, these films (deposited on Ta substrates) have been operated at high oxygen evolution overpotentials, *i.e.*, potentials much higher than those applied for electrochromic behavior, for long periods of time without detectable corrosion(9). SIROF's exhibit the same low oxygen evolution overpotential behavior as do AIROF's, which however, corrode rapidly at these potentials, and are therefore being investigated for use as the anode in water electrolyzers (9). It may be noted that the cyclic voltammograms recorded for these early SIROF's were somewhat different from that of an AIROF, in particular, in their lack of distinct features and their greater current densities at low potentials (in the range 0-+0.5V *vs.* RHE). From the electrochromic viewpoint, the major disadvantage of these SIROF's was a perceivable residual coloration which could not be electrochemically bleached.

In this paper we report the film deposition parameters we have successfully utilized to deposit films which could be completely electrochemically bleached to a state exhibiting effectively zero visible transmission loss. Equilibrium and kinetic behavior of these electrodes is described.

Experimental

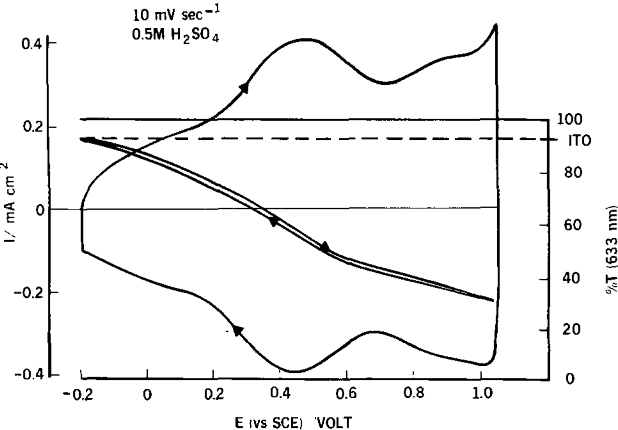
Iridium oxide films were deposited by reactive rf sputtering in a commercial, conventional diode rf sputtering system (Cooke Vacuum Company). The 7.6 cm diam Ir target was presputtered for 20 min at an rf power density of 0.7 W cm^{-2} in pure O_2 at 20 μm pressure. O_2 pressure was reduced to 2 μm and deposition commenced. A target power density of 0.7 W cm^{-2} was again utilized, with a corresponding target bias of ~700V. Of importance was that the substrates were maintained in good thermal contact with the water-cooled platform. A miniature thermocouple attached to the substrate surface indicated that the substrate surface temperature did not exceed 40°C during deposition. However, in the absence of good thermal contact, or in the absence of water cooling, the substrate surface temperature achieved a maximum value of 100°C, which was found to impart some degree of haze to the as-deposited film and to reduce adhesion of at least the upper layer of the film. A deposition rate of approximately 10 Å min^{-1} was obtained, requiring a deposition time of 90 min for a film with an available single pass optical density modulation (ΔOD) in the visible of ~0.4. As deposited, the SIROF is in a close to fully colored state.

The overall display electrode fabrication was as follows. Glass substrates previously coated with a transparent, electronically conducting film of either indium-tin oxide (ITO) or tin oxide, in which the appropriate pattern (10) has been etched if a seven-segment digit was being fabricated, were cleaned with detergent and rinsed in hot water, followed by ultrasonic cleaning in distilled water and isopropyl alcohol, and a final vapor degrease in isopropyl alcohol. Photoresist (AZ 1350J) was spun on, dried, exposed, developed, well rinsed in distilled water, and again dried, to leave transparent conductor exposed in the required display electrode pattern. Since this exposed surface could not be cleaned with organic solvents before SIROF deposition, a dry etch process was used to clean this surface of photoresist residue. Preferably, sputter etching of the substrate *in situ* in the rf sputtering system prior to SIROF deposition was performed, but it was found that when ion beam etching was performed in a different vacuum system, short exposure to atmosphere was not detrimental to subsequent SIROF adhesion. The extent of etching of the transparent conductor coating was generally ~300Å. A further advantage of etching the transparent conductor is that the depth of etching may be chosen so that the combined optical thickness of the bleached SIROF on top of the etched transparent conductor is equal to, or $\lambda/2$ greater than (λ = wavelength = 550 nm), the unetched transparent conductor, whose thickness has generally already been chosen for minimum reflection. Thus, interference contrast between a bleached display segment and its surrounding is eliminated, and display brightness is maximized. Dry etching is followed by deposition of the SIROF as described, and SIROF removed from the areas in which it is not required by dissolution in acetone of the underlying photoresist. An alternative technique has been to cause the SIROF deposited onto the photoresist to lose adhesion to the photoresist by immersion in an aqueous electrolyte combined with potential pulsing between the potential limits used for the electrochromic effect. This technique leaves an insulating, protective photoresist film over the exposed transparent conductor.

Electrochemical measurements were performed in 0.5M H_2SO_4 electrolyte, and the potential applied to the SIROF electrode relative to a saturated calomel electrode (SCE) controlled by a PAR potentiostat, incorporating a coulometer, and programmer. Transmission through the electrode of an He/Ne (633 nm) laser beam was measured using an Si photodiode. Transmission and charge inserted into the electrode were monitored simultaneously on an oscilloscope and recorded photographically. Current *vs.* electrode potential during electrode potential triangular sweeping (cyclic voltammograms) were recorded simultaneously to transmission on a 2-pen X-Y recorder.

Results

Figure 1(a) shows a cyclic voltammogram and corresponding transmission variation of a typical SIROF/ITO electrode, recorded in 0.5M H_2SO_4 electrolyte at 10 mV sec^{-1} scan rate. The data shown is quasi-equilibrium, *i.e.*, is not a function of the potential scan rate (except for the current density scale). The transmission of the SIROF/ITO electrode at −0.2V *vs.* SCE can be seen to be 92%, equal to that of the surrounding ITO alone immersed in the aqueous electrolyte. Sweeping the potential to +1.05V continuously reduces the electrode transmission to 31% as shown, giving a 3:1 contrast ratio between the bleached and colored states equivalent to a 9:1 ratio in a device double pass configuration. In comparison to those of our early SIROF depositions (8), the voltammogram has more structure, tending towards the shape of an AIROF voltammogram (1) with, however, the major peak occurring at a potential ~0.23V less anodic than that for an AIROF. Figure 1(b) reshows this voltammogram with those of SIROF's from two other depositions. Each SIROF is of approximately the same thickness but of different area, so that for clarity of presentation absolute current, rather than current density (which



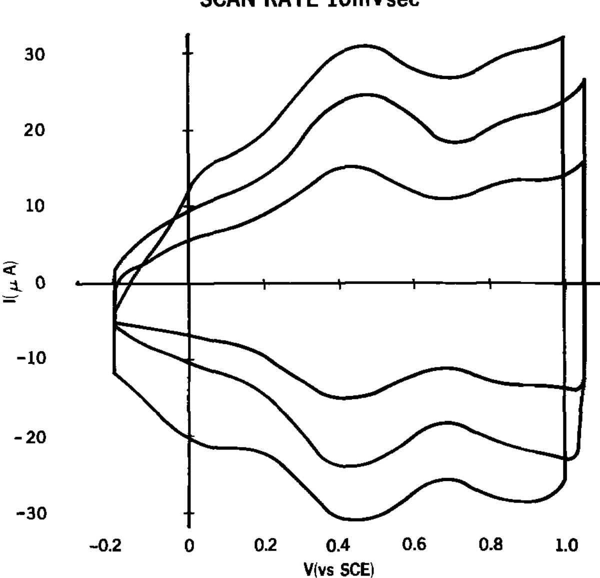


Fig. 1. (a, top) Voltammogram with simultaneous variation in optical transmission of a SIROF, ITO electrode. (b, bottom) Voltammogram of the same SIROF (middle curve) and of SIROF's for two other depositions. All as-deposited film thicknesses were ~900Å. The voltammogram of the largest area sample (with the highest absolute current) was an initial cycle, recorded within a few minutes after immersion. The other two voltammograms were recorded after a number (>30) of color/bleach cycles.

is almost the same in each case), has been plotted. In all cases the main peak occurs at about +0.44V (*vs.* SCE), and a higher potential peak can be observed at ~0.84V as well as a lower potential shoulder around 0.0V. However, the shape of the largest amplitude voltammogram is characteristic of the initial color/bleach cycles of an as-deposited SIROF, whereas the other two are the "steady-state" voltammograms achieved in this case after a number (>30) of color/bleach cycles. The difference is due to hydration of the as-deposited film (11).

The relationship between the SIROF electrode potential E, the charge density inserted ΔQ, and the resultant optical density change ΔOD (633 nm) for a SIROF deposited as described is shown in Fig. 2. The thickness of this SIROF as deposited is ~900Å; the number of electrons extracted and ions inserted (31 mC cm^{-2}) when the electrode potential is stepped from −0.200 to +1.050V (*vs.* SCE) corresponds to ~0.80/Ir atom. The information displayed in the E *vs.* ΔQ curve, although recorded as a number of discrete points at equilibrium, may be obtained by integration of the voltammogram of Fig. 1(a). The right-hand curve shows an almost linear increase in optical density with inserted charge density, with an optical efficiency ($\eta = \Delta OD/\Delta Q$) of 17.9 cm^{2}C^{-1} at low insertion levels.

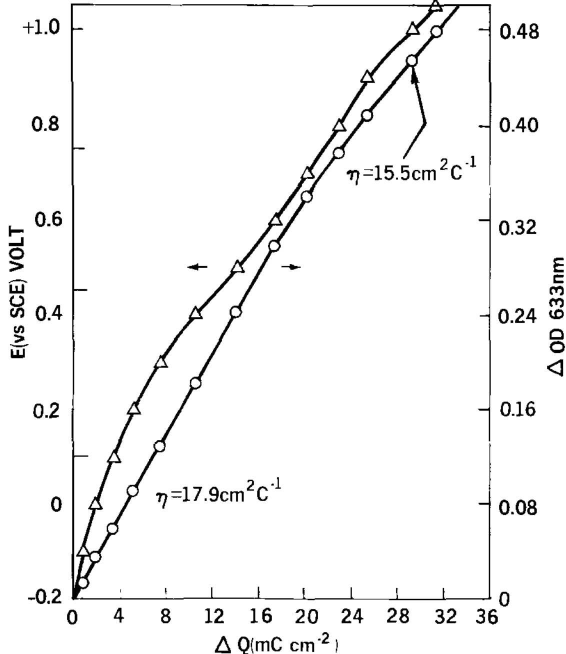

Fig. 2. Relationship between electrode potential E, inserted charge density ΔQ, and induced optical density ΔOD at 633 nm, for the SIROF of Fig. 1(a).

Over the overall voltage range of −0.200-+1.000V, an average optical efficiency of 15.5 cm^{2}C^{-1} is exhibited. This is the same as the effective optical efficiency of an AIROF (10). The absorption spectrum of the induced coloration is featureless over the visible range, other than for interference effects, *i.e.*, the colored state is black, and therefore, this optical efficiency curve, although recorded at 633 nm, applies equally to any visible wavelength.

The kinetics of the electrochromic response of a SIROF are shown in Fig. 3. The SIROF has been deposited on ITO coated glass, to facilitate the transmission measurement recorded in the upper trace, but in a geometry such that the rate of response to a potentiostatic pulse is not restricted by the sheet resistance of the transparent conductor. The lower trace records the charge insertion and extraction from the SIROF electrode, in response to an applied 1.0 Hz square wave potential with limits of −0.250 and +1.050V *vs.* SCE. A ΔOD of 0.45 between the bleached state (of zero absorbance) and the colored state, equivalent to 0.9 in a device configuration utilizing a diffuse backscatterer, is indicated. If one arbitrarily defines the response time of the process as that during which the first two-thirds of the total (equilibrium) ΔOD occurs, in this case the first 0.3, a reasonable practical value equivalent to a 2:1 contrast, then both the coloration and bleaching process have a response time of 40

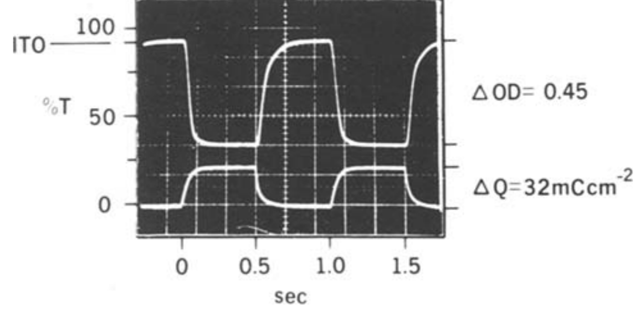

Fig. 3. Optical (%T) and electrical (ΔQ) response of a SIROF electrode (900Å as-deposited thickness) to a 1.0 Hz square wave potential with values of −0.250 and +1.05V (*vs.* SCE) in 0.5M H_2SO_4.

msec. However, complete (to within 1% of the final transmission) coloration and bleaching occur within 150 and 280 msec, respectively. From a perceived contrast point of view for a black-on-white display, coloration and bleaching times are about 50 and 200 msec, respectively. It should be noted that the response shown is not obtained immediately on operation of a freshly deposited SIROF, but only after the film has swelled by hydration (11). The temperature dependence of the response time of a SIROF, deposited under slightly different conditions from those described here, has been reported elsewhere (12).

Conclusions

Electrochromic iridium oxide films have been deposited by reactive sputtering from an Ir target in a pure O_2 plasma. Under the deposition conditions described here, films which could be completely bleached to zero absorbance (at $-0.2V$ *vs.* SCE in 0.5M H_2SO_4) have been prepared. The colored state of these films is black, and a continuous charge or voltage selectable gray scale is available. These films could be switched through an optical density change of 0.3 in either direction in 40 msec under potentiostatic address; use of *IR* compensated potentiostatic address (10) can reduce this response time to 20 msec in either direction. Useful low temperature response times are also shown, *e.g.*, 0.25 sec at $-10°C$, when *IR* compensation is used to eliminate the effect of increased electrolyte resistivity. The energy requirement per color/bleach cycle for films as described here which show a single pass ΔOD of 0.48 (0.96, or a contrast ratio of 9:1, in a device configuration) is 38 mJ cm^{-2} $cycle^{-1}$ at a response time down to 40 msec. Although this energy requirement is 20% greater than that for an AIROF (due to the 20% larger voltage window utilized with the same charge density for the same contrast), it is close to the requirement of a stable (nonaqueous) WO_3 half-cell for the same contrast but at a slower response time (~0.3 sec). Of course, in many applications a lower contrast is acceptable, permitting the use of a thinner film, with the energy requirement linearly dependent on the required ΔOD. SIROF's deposited under conditions close, but not identical, to those described here have undergone cycle lifetime testing both at room temperature and at elevated temperature in 0.5M H_2SO_4 electrolyte. At room temperature 2×10^7 full color/bleach cycles (with approximately 50% of that time with the SIROF having reached either the fully colored or fully bleached state) were obtained without perceived change in contrast, although a decrease in ΔQ and ΔOD of about 3% was recorded. Under the same conditions at 73°C, 2.5×10^5 cycles were obtained with a 5% decrease in ΔQ and ΔOD. Although similar life-testing of SIROF's deposited exactly as described in this work has not been performed, preliminary data show no significant difference.

Chemical Etching Characteristics of (001)InP

Sadao Adachi and Hitoshi Kawaguchi

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Musashino-shi, Tokyo 180, Japan

ABSTRACT

The chemical etching characteristics of (001)InP are studied through an SiO_2 mask in the solutions of various etching systems: (*i*) HCl, (*ii*) HCl:HNO_3, (*iii*) HBr, (*iv*) H_2SO_4:H_2O_2:H_2O, and (*v*) Br_2:CH_3OH. The etched depth is evaluated by using a calibrated optical microscope. The etching profiles are examined by cleaving the wafer in orthogonal directions along the (110) and $(\bar{1}10)$ planes. Various etching profiles, such as V-shaped, reverse mesa-shaped ones, and nearly vertical walls, are formed by stripes being etched on the (001) planes. The indexes of the etch-revealed planes are identified by making a comparison with the calculated angle between the (001) surface and etch-side plane. The utility of these etching solutions is also discussed for a variety of InP device applications.

Chemical etching of single crystal semiconductors plays an essential role in microelectronic solid-state device technology. Of the compound semiconductors, GaAs is most widely used in solid-state devices for specialized applications. Most of the data on etching of

Key words: chemical etching, InP, etching profile.

GaAs that one can find in the literature (1) involve studies of the mechanisms and kinetics of the dissolution processes. Tarui *et al.* (2) have reported in detail preferential etching characteristics of GaAs in the $Br_2:CH_3OH$ system and have then demonstrated geometrically etched profiles produced in the {001} and {111} planes by employing this system. They have also reported a few examples of practical applications of preferential etching (etching profile) for the device-structure design and fabrication.

InP and its related compounds, such as InGaAsP, are thought to be promising materials for high-speed transistors (IC's) and electrooptical devices. There have been a few reports on the etching characteristics of InP (3-7). Tuck and Baker (4) have studied etching characteristics of InP from crystallographic aspects, *e.g.*, orientation effects on etching rates, shapes of pits and hillocks, and dissolution processes. Huber and Linh (5) have studied defect delineation in InP by using specific etchants. However, to our knowledge, there has been no report on device shaping for InP using preferential etching.

In the present paper, we report chemical etching characteristics of the (001) surface of InP in the solutions of various systems: (i) HCl, (*ii*) $HCl:HNO_3$, (*iii*) HBr, (*iv*) $H_2SO_4:H_2O_2:H_2O$, and (*v*) $Br_2:CH_3OH$ systems. The etching profiles are examined by cleaving the (001) InP wafer in orthogonal directions along the (110) and $(\bar{1}10)$ planes and are discussed in detail from a crystallographic aspect. The profiles applicable to device-structure design and fabrication are also discussed.

Experimental

Sample.—The InP crystals employed were undoped single crystals grown by the liquid encapsulated Czochralski method. All wafers used were of (001) surface orientation with an uncertainty of 1° or less. These wafers were lapped and polished with fine abrasive alumina (0.05 μm particle size). After being degreased and rinsed in deionized water, they were chemically polished to a mirrorlike finish in a $Br_2:CH_3OH$ solution at room temperature. The thickness of these wafers was about 100 μm to permit cleavage for the observation of etching profiles.

Masking pattern.—Etching studies were performed for the etching-selected regions of (001) surface InP through windows in an SiO_2 mask (see Fig. 1). The SiO_2 masks used were approximately 2000Å thick and were prepared with conventional sputtering equipment. The desired geometries, in this case the window width of 30 μm wide, were defined by standard photolithography technique using AZ-1350 and an SiO_2 etchant of the $HF:NH_4F:H_2O$ system.

Etching solution.—The etching solutions employed can be classified into the following five groups: (*i*) HCl system (HCl, $HCl:CH_3COOH$, etc), (*ii*) $HCl:HNO_3$ system, (*iii*) HBr system (HBr, $HBr:CH_3COOH$, etc), (*iv*) $H_2SO_4:H_2O_2:H_2O$ system, and (*v*) $Br_2:CH_3OH$ system. The chemicals used were all of reagent grade. They were as follows: HCl (12*N*), H_2O_2 (30%), CH_3COOH (17*N*), H_3PO_4 (15*N*), HNO_3 (14.5*N*), HBr (9*N*), H_2SO_4 (36*N*), $K_2Cr_2O_7$ (purity $\geqq$ 99.8%), Br_2 (purity $\geqq$ 99%), CH_3OH (purity 99.5%), and H_2O (deionized water). A large quantity of solution was prepared to prevent the etching temperature from rising and the etch-solution composition from varying during the experiments. Etching was carried out in a temperature-controlled water vessel without illumination. The etchant was freshly mixed prior to each experiment. Etching experiments were done by stirring by hand.

Etched depth and etching profile.—After etching, removing the SiO_2 mask, and rinsing in deionized water, the {110} plane perpendicular to the etched one was cleaved with a razor blade and the etched depths of samples were measured with a calibrated optical microscope. The etched depths were also measured from a step height between the etched and unetched surfaces using an interference microscope. Etching profiles were observed on the (110) and $(\bar{1}10)$ cleavage planes perpendicular to the wafer surface under an optical microscope.

Etching Profile

Etch figure.—Figure 2 includes a photograph of etch figures developed on the (001) plane of InP in the $H_2SO_4:H_2O_2:H_2O$ system, where the etch figures were

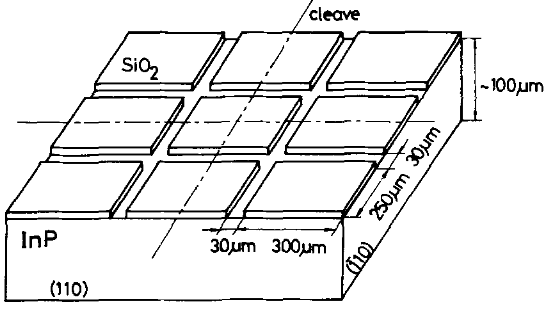

Fig. 1. An SiO_2 masking pattern on (001)InP wafer for chemical etching. The etching profiles are obtained by cleaving the wafer in orthogonal directions along the (110) and $(\bar{1}10)$ planes.

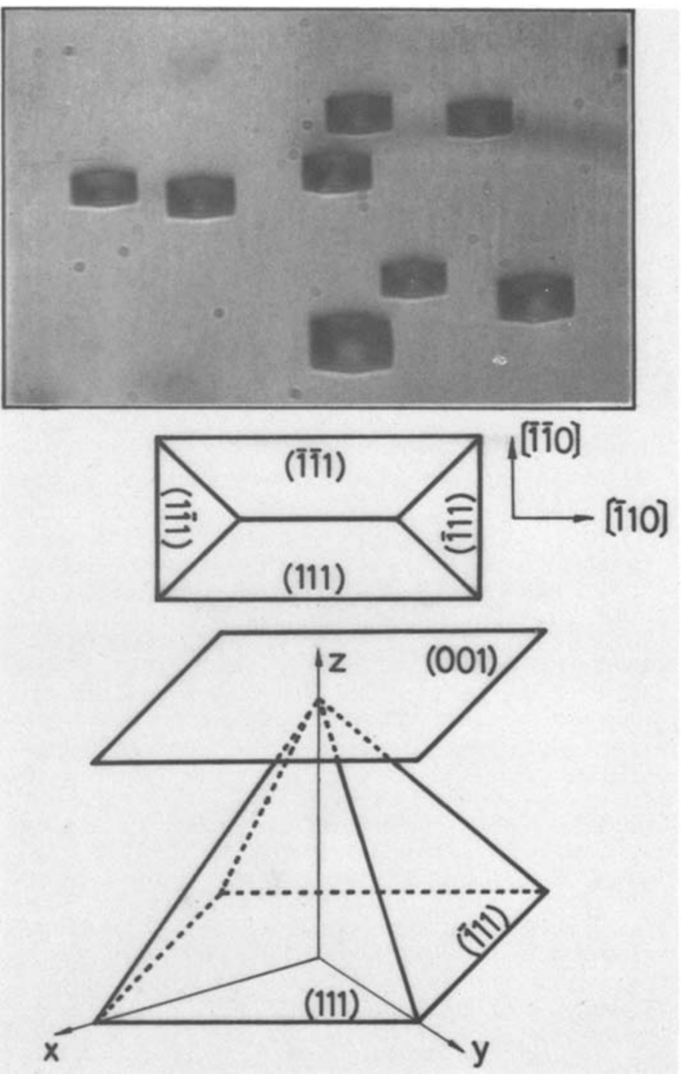

Fig. 2. Etching figures produced on the (001) plane of InP and schematic diagram of the individual etch figures.

produced by etching in the solution through pin-hole windows in an SiO_2 mask. A schematic diagram of the individual etch figures is also shown in the figure. The etch figures exhibit a rectangle-like (elongated) shape.

An important aspect of the arrangement of zincblende type crystals such as InP is the absence of a center of symmetry or inversion. Let the two sublattices of III-V compounds be labeled A^{III} and B^{V}. The A^{III}-B^{V} layers have unique orientations along the $\langle 111\rangle$ crystal direction. The opposed (111) and $(\bar{1}\bar{1}\bar{1})$ faces and opposed [111] and $[\bar{1}\bar{1}\bar{1}]$ directions may have different physical and chemical properties. Such different properties are known to arise from crystallographic polarity. If a unit cell is chosen such that the B^{V} atoms are situated at its corner, then the B{111} planes may be referred to as $(\bar{1}\bar{1}\bar{1})$, $(11\bar{1})$, $(1\bar{1}1)$, and $(\bar{1}11)$, while the A{111} planes will be the corresponding negatives, *i.e.*, (111), $(\bar{1}\bar{1}1)$, $(\bar{1}1\bar{1})$, and $(1\bar{1}\bar{1})$. The pit figures can be successfully interpreted by a geometry constructed from the {111} planes, as shown in the middle and lower parts of Fig. 2. The elongated pits, similar to those of Fig. 2, have also been found in III-V compounds such as GaAs (2, 8), InSb (9), and InP (4). Gatos and Lavine (9) have revealed after geometric examination that the etch figures on (001)InSb are truncated (flat-bottomed) tetragonal pyramid structures, the four sides being {111} planes. The top plane of the truncated pyramid is either flat {100} or has higher order planes ({411}) forming a shallow angle with the $\langle 100\rangle$ direction ($\simeq$ 19°). Olsen *et al.* (8) have also observed in SEM photographs the truncated tetragonal pyramid etch figures on (100)GaAs. Tuck and Baker (4), on the other hand, have observed untruncated tetragonal pyramid etch pits on (100)InP, where the $(11\bar{1})$ and $(1\bar{1}\bar{1})$ planes meet in a ridge at the bottom of the pit. From careful inspection using a differential interference microscope, we have also found that the pit figures on (001)InP have untruncated tetragonal pyramid structures, as shown schematically in the middle part of Fig. 2. The elongated etch figures demonstrate the nonequivalence of $\langle 110\rangle$ and $\langle\bar{1}10\rangle$ type directions lying in a {001} plane in the III-V intermetallic compounds. As mentioned before, this nonequivalence is known to arise from the $\langle 111\rangle$ crystallographic polarity of zincblende type crystal. Elongated etch figures, thus, provide us a means for the unique determination of crystallographic directions between the $\langle 110\rangle$ and $\langle 110\rangle$ type directions.

HCl system.—The etching profiles of (001)InP etched in the solutions of the HCl system are shown in Fig. 3: (a) HCl (25°C, 1 min), (b) $1HCl{:}1H_2O_2$ (25°C, 1 min), (c) $1HCl{:}1CH_3COOH$ (25°C, 1 min), (d) $1HCl{:}1H_3PO_4$ (25°C, 1 min), (e) $1HCl{:}1CH_3COOH{:}1H_2O_2$ (25°C, 1 min), and (f) $1HCl{:}1H_3PO_4{:}1H_2O_2$ (25°C, 1 min). The cross sections are obtained by cleaving the wafers in orthogonal directions along the (110) and $(\bar{1}10)$ planes (see Fig. 1). The determination of crystallographic directions was made by means of the above-mentioned etch-figure test. It is clear from the figure that the etching profiles change in shape with a crystallographic rotation of 90° about the [001] axis and that they exhibit crystal habits. In the case of the (110) cleavage planes, the etching profiles indicate planes are nearly perpendicular to the (001) surface and inclined planes slope downward away from the SiO_2 mask. In the case of the $(\bar{1}10)$ cleavage planes, the profiles indicate only the inclined planes whose sides form angles of about 35° [(a), (c), and (d)] or 55° [(b), (e), and (f)] with respect to the (001) surface. Consequently, the etching profile of the $(\bar{1}10)$ cleavage plane [Fig. 3(a)] clearly shows a V-

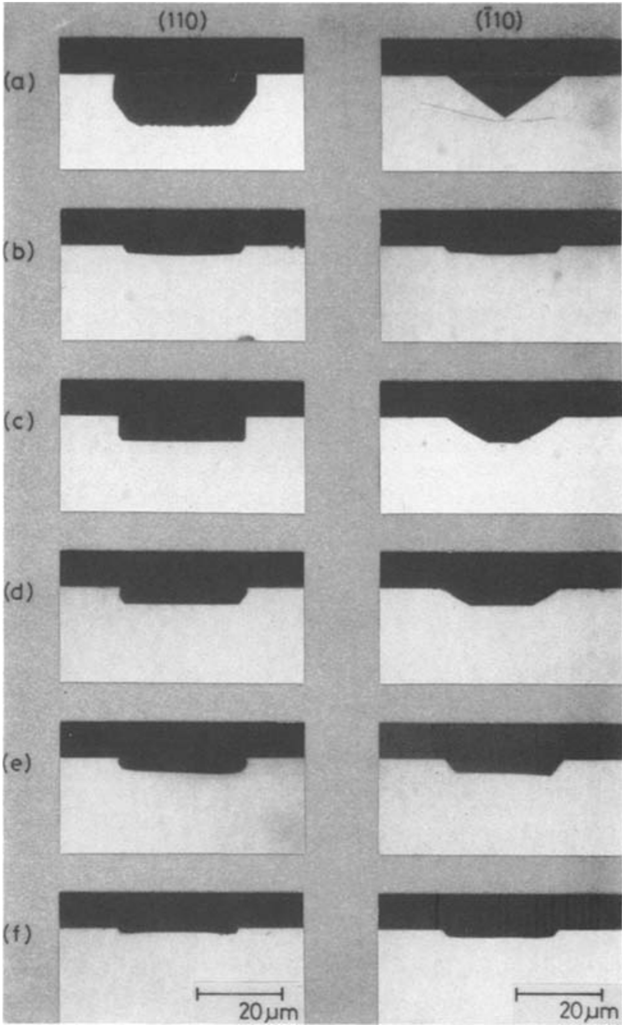

Fig. 3. Etching profiles of (001)InP etched in the solutions of the HCl system: (a) HCl (25°C, 1 min), (b) $1HCl{:}1H_2O_2$ (25°C, 1 min), (c) $1HCl{:}1CH_3COOH$ (25°C, 1 min), (d) $1HCl{:}1H_3PO_4$ (25°C, 1 min), (e) $1HCl{:}1CH_3COOH{:}1H_2O_2$ (25°C, 1 min), and (f) $1HCl{:}1H_3PO_4{:}1H_2O_2$ (25°C, 1 min).

shaped groove profile forming a V-groove angle of 110° (angle between two inclines). If the etching time is properly chosen according to the V-groove width, depth, and corresponding etching rate, one can also easily fabricate the V-shaped groove in the $\langle\bar{1}10\rangle$ direction on (001)InP by chemical etching in solutions such as $1HCl{:}1H_2O_2$ and $1HCl{:}1CH_3COOH{:}1H_2O_2$ (V-groove angle of 70°).

HCl:HNO_3 system.—The etching profiles of (001)InP etched in the solutions of the $HCl{:}HNO_3$ system are shown in Fig. 4: (a) $1HCl{:}1HNO_3$ (25°C, 1 min), (b) $1HCl{:}2HNO_3$ (25°C, 1 min), (c) $2HCl{:}1HNO_3$ (25°C, 1 min), (d) $1(1HCl{:}1HNO_3){:}1H_2O$ (25°C, 1 min), (e) $1(1HCl{:}1HNO_3){:}1H_2O_2$ (25°C, 1 min), and (f) $1(1HCl{:}1HNO_3){:}1CH_3COOH$ (25°C, 1 min). The etching profiles of the (110) cleavage planes [Fig. 4(a), (b), (c), and (f)] indicate the planes are nearly perpendicular to the (001) surface, similar to those of the HCl system. The profile of the $(\bar{1}10)$ cleavage plane [Fig. 4(c)] indicates the inclined planes forming an angle of 35° with respect to the (001) surface, but those of Fig. 4(a) and (b) do not exhibit clear crystal habits. If one chooses proper etching time, the $2HCl{:}1HNO_3$ solution also makes it possible to fabricate a V-shaped groove whose sides form an angle of 110° (*i.e.*, an angle of V-shaped groove). As one can see in Fig. 4(d), (e), and (f), the etching rate reduced abruptly with

an addition of H_2O, H_2O_2, or CH_3COOH in the solution of the HCl:HNO_3 system [see also Table I].

HBr system.—The etching profiles of (001)InP etched in the solutions of the HBr system are shown in Fig. 5: (a) HBr (25°C, 1 min), (b) 1HBr:1H_2O_2 (25°C, 1 min), (c) 1HBr:1CH_3COOH (25°C, 1 min), (d) 1HBr:1H_3PO_4 (25°C, 1 min), (e) 1HBr:1HNO_3 (25°C, 1 min), and (f) 1HBr:1HNO_3:5H_2O (25°C, 1 min). The profiles of Fig. 5(a) indicate the inclined planes for both the (110) and ($\bar{1}10$) cleavage planes forming an angle of 55° with respect to the (001) surface. The side-etch speed of the (110) cleavage plane is faster than that of the ($\bar{1}10$) cleavage plane. The cross sections demonstrated in Fig. 5(b) exhibit a reverse mesa-shaped and mesa-shaped profiles for the (110) and ($\bar{1}10$) cleavage planes, respectively. The etched sides for the (110) and ($\bar{1}10$) cleavage planes form angles of 125° and 55°, respectively, with respect to the (001) surface. Such profiles are quite similar to those on (001)GaAs etched with H_2SO_4:H_2O_2:H_2O (10) and Br_2:CH_3OH solutions (2). The profile shown in Fig. 5(c) [(110) cleavage plane] exhibits the reverse mesa-shaped and mesa-shaped structures in addition to the flat-bottomed plane. The reverse mesa-shaped and mesa-shaped planes form angles of 110° and 55°, respectively, with respect to the (001) surface. The profile of the ($\bar{1}10$) cleavage plane [Fig. 5(c)], on the other hand, exhibits only the inclined planes forming an angle of 55° with respect to the (001) surface. Similar etching profiles have also been obtained by Otsubo *et al.* (11) on (001)GaAs with etching in a solution of the $C_3H_4(OH)(COOH)_3 \cdot H_2O$:$H_2O_2$:$H_2O$ system. The etching profiles of Fig. 5(d) are the same as those of Fig. 5(a). The profiles of Fig. 5(e) and (f) are also quite similar to those of Fig. 5(b), but they do not reveal clear crystallographic planes.

H_2SO_4:H_2O_2:H_2O system.—The etching profiles of (001)InP etched in the solutions of the H_2SO_4 system are shown in Fig. 6: (a) 1H_2SO_4:1H_2O_2 (60°C, 20 min), (b) 3H_2SO_4:1H_2O_2:1H_2O (60°C, 20 min), (c) 1H_2SO_4:1H_2O_2:1H_2O (60°C, 20 min), and (d) 3(2N-$K_2Cr_2O_7$):1H_2SO_4:1HCl (60°C, 20 min). The profiles of the (110) cleavage planes [Fig. 6(a)-(c)] indicate the planes are nearly perpendicular to the (001) surface, while those of the ($\bar{1}10$) cleavage planes indicate the inclined sides that slope downward away from the SiO_2 mask. The profiles of the ($\bar{1}10$) cleavage planes [Fig. 6(a) and (b)] exhibit the mesa-shaped structure, but they do not indicate clear crystal habits, in contrast to that of Fig. 6(c).

The H_2SO_4:H_2O_2:H_2O system is known to be one of the most commonly employed etchants for GaAs (11). Chemical polishing by using this system also gives high-quality GaAs surfaces of low-index orientations except for the Ga{111} surface. However, the etching rates of this system for InP are two or three orders smaller than those for GaAs. The system, moreover, sometimes produces elliptical etch pits on the (001) surface of InP. The photograph of the elliptical etch pits are demonstrated in the lower part of Fig. 6(c). The long- and short-axis directions of the ellipsoid correspond to the [$\bar{1}10$] and [110] directions, respectively. The profile of the (110) cleavage plane of (001)InP etched in the solution of 3(2N-$K_2Cr_2O_7$):1H_2SO_4:1HCl [Fig. 6(d)] exhibits the mesa-shaped structure, in contrast to those of the H_2SO_4:H_2O_2:H_2O systems. The profile of the ($\bar{1}10$) cleavage plane also exhibits the mesa-shaped structure (revealing clear crystal habits), as similar to those found in Fig. 6 (a)-(c). This etchant system produces etch-pit free surfaces and moreover provides high-quality InP surfaces. It was found that the etching rates of this system were increased by increasing HCl at a constant ratio of

Table I. The composition of the etchants in parts by volume, etching condition, etched depth, and identified crystallographic planes revealed by etching

† Etching profile does not exhibit clear crystal habits.

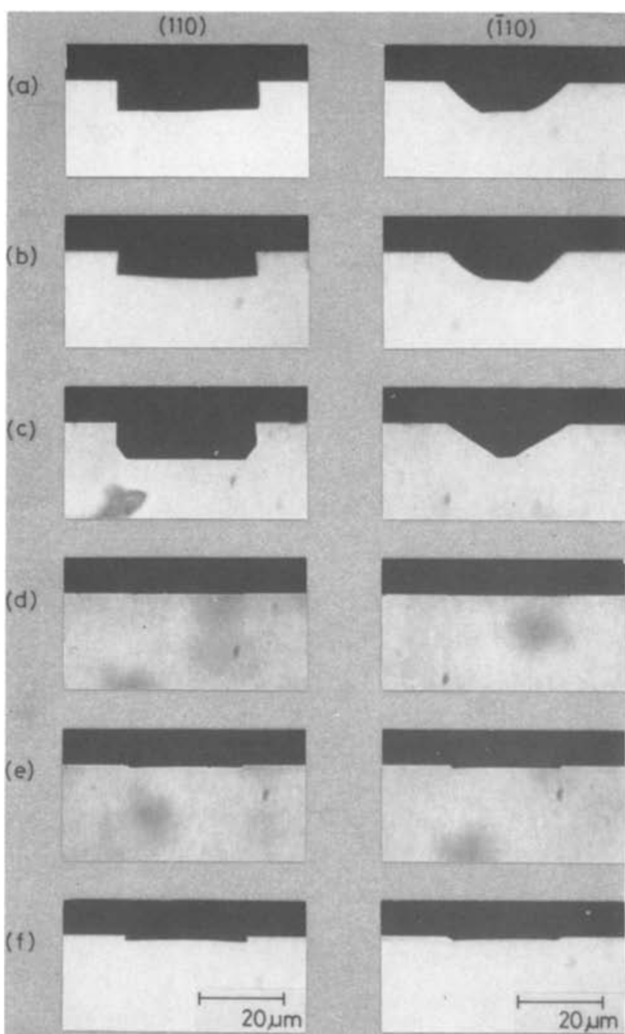

Fig. 4. Etching profiles of (001)InP etched in the solutions of the $HCl:HNO_3$ system: (a) $1HCl:1HNO_3$ (25°C, 1 min), (b) $1HCl:2HNO_3$ (25°C, 1 min), (c) $2HCl:1HNO_3$ (25°C, 1 min), (d) $1(1HCl:1HNO_3):1H_2O$ (25°C, 1 min), (e) $1(1HCl:1HNO_3):1H_2O_2$ (25°C, 1 min), and (f) $1(1HCl:1HNO_3):1CH_3COOH$ (25°C, 1 min).

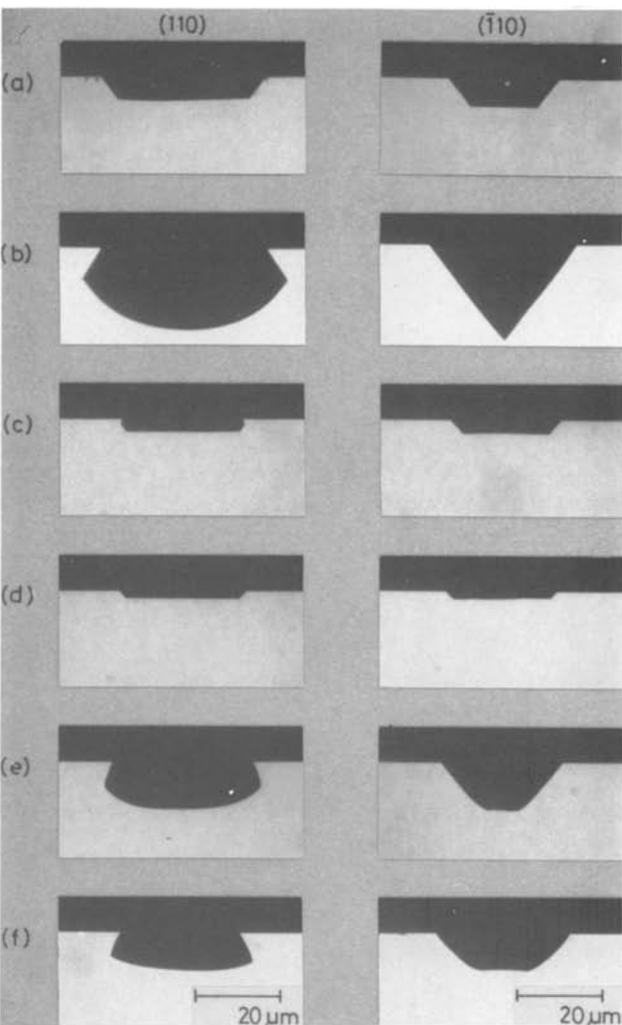

Fig. 5. Etching profiles of (001)InP etched in the solutions of the HBr system: (a) HBr (25°C, 1 min), (b) $1HBr:1H_2O_2$ (25°C, 1 min), (c) $1HBr:1CH_3COOH$ (25°C, 1 min), (d) $1HBr:1H_3PO_4$ (25°C, 1 min), (e) $1HBr:1HNO_3$ (25°C, 1 min), and (f) $1HBr:1HNO_3:5H_2O$ (25°C, 1 min).

$2N\text{-}K_2Cr_2O_7$ and H_2SO_4 without any change of the surfaces states; $\simeq 0.1$ µm/min [$3(2N\text{-}K_2Cr_2O_7):1H_2SO_4:1HCl$], $\simeq 1.0$ µm/min [$3(2N\text{-}K_2Cr_2O_7):1H_2SO_4:2HCl$], and $\simeq 2.0$ µm/min [$3(2N\text{-}K_2Cr_2O_7):1H_2SO_4:3HCl$] at 60°C. Details of these etching solutions will be presented in the near future.

Br_2:CH_3OH system.—It is well known that the $Br_2:CH_3OH$ systems give good results for preferential etching of GaAs(2). The etching rates can be easily controlled by varying the Br_2 concentrations in CH_3OH. These systems are also usually employed as the etchants, capable of producing highly polished surfaces on GaAs. Figure 7 shows the etching profiles of (001)InP etched in the solutions of the $Br_2:CH_3OH$ system: (a) 4% by volume $Br_2:CH_3OH$ (25°C, 1 min), (b) 2% by volume $Br_2:CH_3OH$ (25°C, 1 min), (c) 1% by volume $Br_2:CH_3OH$ (25°C, 1 min), (d) 0.2% by volume $Br_2:CH_3OH$ (25°C, 2 min), and (e) 0.1% by volume $Br_2:CH_3OH$ (25°C, 4 min). The profiles of the (110) cleavage planes exhibit the reverse mesa-shaped structure forming an angle of 125° with respect to the (001) surface, while those of the $(\bar{1}10)$ cleavage planes exhibit the mesa-shaped structure forming an angle of 55° with respect to the (001) surface. Such features are quite similar to those of (001)GaAs etched with the $Br_2:CH_3OH$ (2) and $H_2SO_4:H_2O_2:H_2O$ systems (10). The profiles are also the same as those of InP etched with the $1HBr:1H_2O_2$ solution [see Fig. 5(b)]. The etching rates are found to vary from 2 µm/min (0.1% by volume) to 25 µm/min (4% by volume) with the Br_2 concentrations in CH_2OH.

Crystallographic aspect.—In this subsection, we discuss the etching profiles of (001)InP demonstrated in Fig. 3-7 from a crystallographic aspect. Figure 8 shows two-dimensional schematic representations of two orthogonal (110) and $(\bar{1}10)$ planes of a (001)InP layer. The open and solid circles indicate the In and P atoms, respectively. The (110) and $(\bar{1}10)$ planes, thus, represent the interchange of In-P atomic species of the zinc-blende type crystal InP upon a rotation of 90° about the [001] axis. The {001} surfaces, in principle, consist either of the In or P atoms. However, neither is preferred since both types are doubly bonded to the crystal lattice at the surface, and real {001} surfaces consist of a mixture of the In and P atoms. On the other hand, the intermetallic compound InP has two types of {111} surfaces, *i.e.*, In{111} and P{111} surfaces, resulting from the crystallographic polarity of the {111} directions. The outermost atom layer in each surface consists of either In or P atoms which are triply bonded to the crystal lattice. The In and P atoms have three and five bonding electrons per atom, respectively. The {111} surface In atoms have no spare electrons because they are all used up in hanging on to the crystal lattice. The {111} surface P atoms, on the other hand, have two electrons per atom available

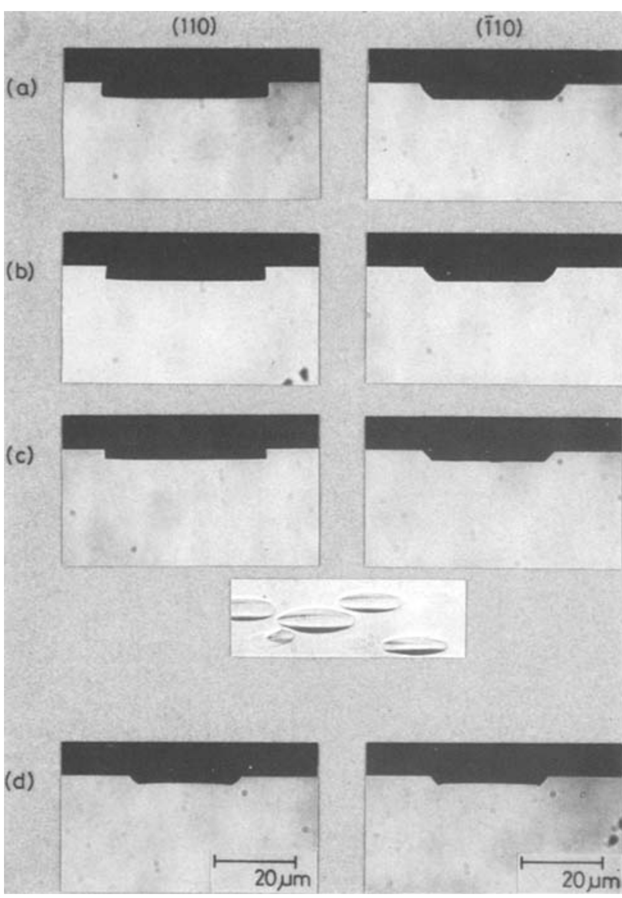

Fig. 6. Etching profiles of (001)InP etched in the solutions of the H_2SO_4 system: (a) $1H_2SO_4$:$1H_2O_2$ (60°C, 20 min), (b) $3H_2SO_4$:$1H_2O_2$:$1H_2O$ (60°C, 20 min), (c) $1H_2SO_4$:$1H_2O_2$:$1H_2O$ (60°C, 20 min), and (d) 3(2N-$K_2Cr_2O_7$):$1H_2SO_4$:1HCl (60°C, 20 min).

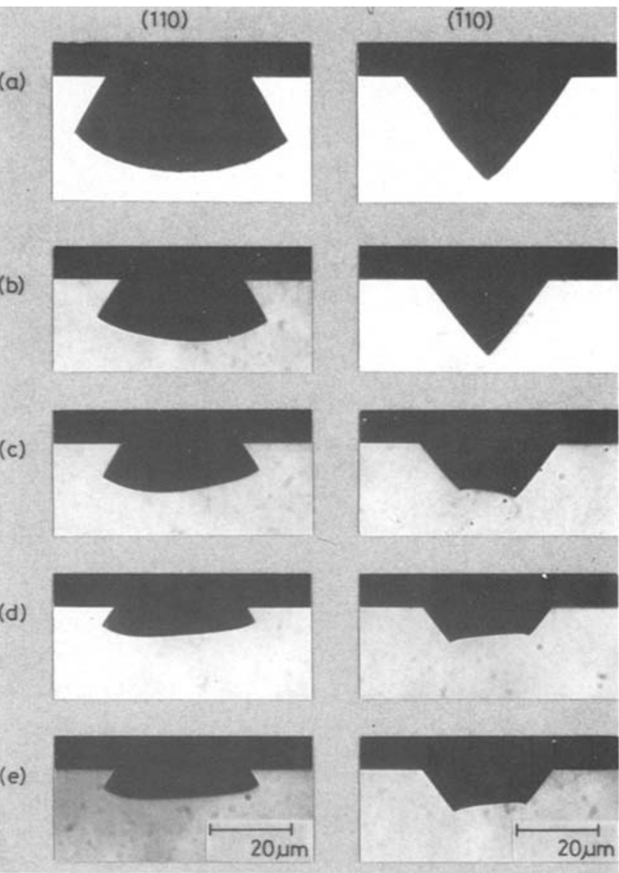

Fig. 7. Etching profiles of (001)InP etched in the solutions of the Br_2:CH_3OH system: (a) 4% by volume Br_2:CH_3OH (25°C, 1 min), (b) 2% by volume Br_2:CH_3OH (25°C, 1 min), (c) 1% by volume Br_2:CH_3OH (25°C, 1 min), (d) 0.2% by volume Br_2:CH_3OH (25°C, 2 min), and 0.1% by volume Br_2:CH_3OH (25°C, 4 min).

to take part in a reaction. Thus, the P{111} planes are very reactive compared with the In{111} planes.

From a viewpoint of crystallography, we can classify the etching profiles shown in Fig. 3-7 into the four individual groups, as demonstrated in Fig. 9. Details of two-dimensional schematic diagrams corresponding to Fig. 9(d) are also shown in Fig. 8. The etch-revealed walls perpendicular to the (001) surface, observed on the (110) cleavage plane in the solutions of the HCl, HCl:HNO_3, and H_2SO_4:H_2O_2:H_2O systems, correspond to the {$\bar{1}$10} crystallographic planes. The inclined planes forming an angle of 55° with respect to the (001) surface [see, *e.g.*, Fig. 5(a)] correspond to the In{$\bar{1}$11} [(110) cleavage plane] and In{111} crystallographic planes [($\bar{1}$10) cleavage plane], where the {$\bar{1}$11} or {$\bar{1}\bar{1}$1} planes, in principle, form an angle of 54°44′ with respect to the {001} planes. The inclined plane forming an angle of 35° with respect to the (001), shown in Fig. 9(a), correspond to the In{$\bar{1}\bar{1}$2} crystallographic planes [see, *e.g.*, Fig. 3(a)]. The {$\bar{1}\bar{1}$2} planes, in principle, form an angle of 35°16′ with respect to the {001} planes. The etching profile of the (110) cleavage plane, shown in Fig. 5(c), is composed of two individual planes, forming angles of 109° and 55° with respect to the (001) surface, while that of the ($\bar{1}\bar{1}$0) cleavage plane exhibits only the mesa-shaped structure forming an angle of 45° with respect to the (001) surface. As shown in Fig. 9(c), the most probable planes deduced from these angles are In{2$\bar{2}\bar{1}$} and In{$\bar{1}$11} planes for the (110) cleavage plane and {0$\bar{1}$1} planes for the ($\bar{1}$10) cleavage plane. The reverse mesa-shaped and V-shaped groove structures were formed on the (110) and ($\bar{1}$10) cleavage planes, respectively, with etchants such as 1HBr:$1H_2O_2$ [Fig. 5(b)] and Br_2:CH_3OH solutions (Fig. 7). These structures form angles of 125° (reverse mesa-shaped) and 55° (mesa-shaped) with respect to the (001) surface [Fig. 9(d)], which agree reasonably with angles between the {001} and {$\bar{1}\bar{1}$1} planes. The etch-side planes can, thus, be identified to be the In{$\bar{1}\bar{1}$1} planes (see Fig. 8). The etching proceeds up to the In{111} planes, because the P{111} planes are very reactive compared with the In{111} planes. Consequently, the reverse mesa-shaped and V-shaped groove structures are formed on the (110) and ($\bar{1}$10) cleavage planes, respectively, whose sides in principle form angles of 125°16′ and 54°44′ with respect to the (001) surface.

The dissolution process under consideration is far too complex and the available information rather limited to allow a quantitative development of the dissolution mechanism. Moreover, it is difficult to obtain a complete explanation of the difference in the etching profiles with various etching solutions. However, we suggest that this difference is due to the differences of the etching rates in the various crystallographic planes (*i.e.*, the slowest-etching-rate planes will play an important role on the etching profiles. The etch-side planes identified are summarized in Table I along with the etching time, temperature, and etched depth.

Proposed Device Application

The etching profiles obtained here should be very useful for the design and fabrication of electron and electrooptical devices. Comerford and Zory (12) have used selective etching techniques to fabricate V-groove

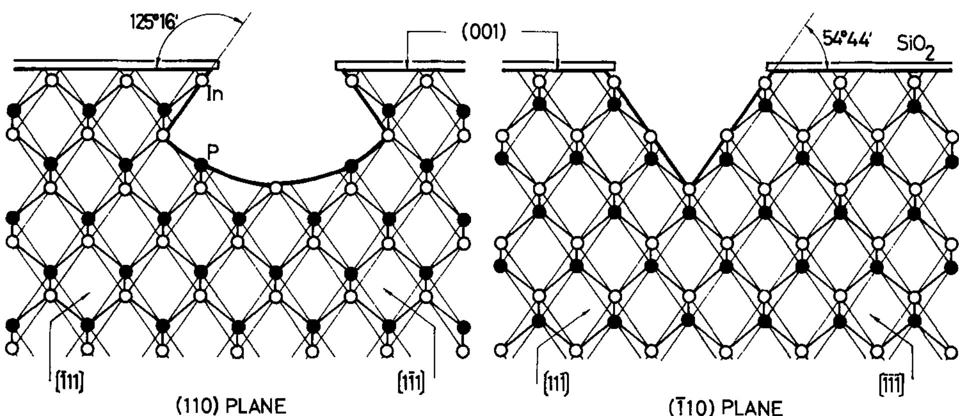

Fig. 8. Two-dimensional schematic representations of two orthogonal (110) and $(\bar{1}10)$ planes of a (001)InP layer. The open and solid circles indicate the In and P atoms, respectively. The round hole bottom on the left side is not necessarily the precise atomic configuration.

diffraction grating on the (001) surfaces of GaAs using the Br_2:CH_3OH solution as the preferential etchant. Tsang and Wang (13) have also fabricated the diffraction grating on the (001) surface of GaAs, where the H_2SO_4:H_2O_2:H_2O system has been used as the preferential etchant. The results demonstrated in this paper also indicate that the V-groove diffraction grating on the (001) surface of InP should be fabricated by chemical etching with proper choice of direction of grating-mask groove openings and controlling the width of the groove openings and/or etching time.

Gannon and Nuese (14) have discussed the utility of the NH_4OH:H_2O_2 preferential etchant for GaAs device preparation and have demonstrated its application to the fabrication of integrated GaAs bipolar transistors. The NH_4OH:H_2O_2 etchant has been found to provide a flat etching bottom and a slow etching rate for {001}GaAs, which led to the success of the transistor fabrication procedure. The etchants, such as the 1HCl:1CH_3COOH [Fig. 3(c)], 1HCl:1H_3PO_4 [Fig. 3(d)], 1HBr:1CH_3COOH [Fig. 5(c)], and 1HBr:1H_3PO_4 solutions [Fig. 5(d)], also provide a flat etching bottom and a relatively slow etching rate for {001}InP. These etchants should, therefore, be useful for producing high-quality InP transistors and IC's. The lateral definition, which is especially required and important in a number of passive optical components such as waveguides and directional couplers, can also be achieved by a chemical etching technique employing these solutions as the etchant.

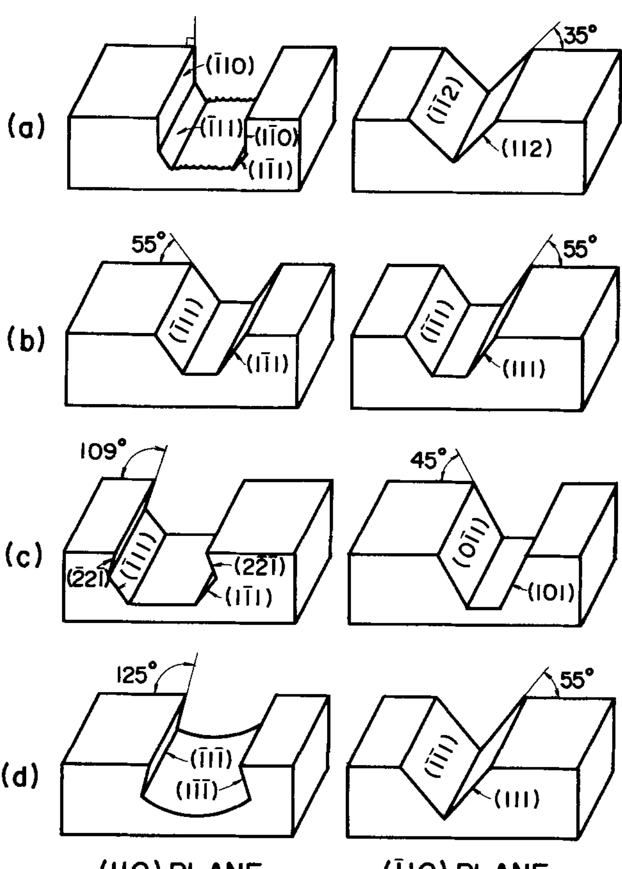

Fig. 9. Schematic diagrams of the etching profiles produced in the (001) planes of InP by the various etching solutions (see text).

Realization of monolithic integration of optical circuits will require a conventional means of routing optical signals on integrated chips (15). The fabrication of double heterostructure lasers, which incorporate chemically etched mirrors, has been reported to realize the monolithic fabrication of integrated optical devices (16, 17). In such works, much attention has been paid to produce smooth-mirror Fabry-Perot resonator by chemical etching because it improves the characteristics of laser diodes such as threshold current density, quantum efficiencies, and lasing modes. Therefore, in the fabrication of etched-mirror laser diodes, it is important to produce the vertical walls which give a high value of the mirror reflectivity. The etching solutions, such as the HCl (Fig. 3) and H_2SO_4:H_2O_2:H_2O systems (Fig. 6), are thought to be useful for the monolithic fabrication of etched-mirror laser diodes. Recently, Miller and Iga (17) have successfully fabricated InGaAs/InP laser diodes emitting at 1.3 μm by wet chemical etching with a solution of 1HCl:2CH_3COOH:1H_2O_2 [see Fig. 3(e)]. The geometric profiles are also applicable to the fabrication of lateral-confinement laser diodes such as the buried-heterostructure laser and channeled-substrate laser diodes (18).

Conclusion

In summary, we have studied chemical etching characteristics of (001)InP in the solutions of various systems: (*i*) HCl, (*ii*) HCl:HNO_3, (*iii*) HBr, (*iv*) H_2SO_4:H_2O_2:H_2O, and (*v*) Br_2:CH_3OH systems. The etch figures developed on (001)InP have indicated that it has untruncated tetragonal pyramid structure, in contrast to that on (001)GaAs or (001)InSb [truncated (flat-bottomed) tetragonal pyramid structure]. The etching profiles exhibiting crystal habits, *e.g.*, V-shaped groove, reverse mesa-shaped ones, and nearly vertical walls, have been found to be formed by stripes parallel to the [110] and $[\bar{1}10]$ directions being etched on the (001) planes. The indexes of the etch-revealed planes have been identified by making a comparison with the calculated angle between the (001) surface and etch-side plane. The etching profiles applicable to the device-structure design and fabrication have also been discussed.

Auger Depth Profile Studies of Diffusion at Iron Phthalocyanine/Copper Phthalocyanine Interfaces

Robert E. Davis* and Larry R. Faulkner**

Department of Chemistry and Materials Research Laboratory, University of Illinois, Urbana, Illinois 61801

ABSTRACT

Elemental depth profiles of thin molecular films have been obtained using Auger electron spectroscopy in conjunction with ion etching by reducing the average electron current density and using a conducting substrate. The minimum observed interface width of CuPc (800Å thick)/FePc (800Å thick) in unannealed samples was approximately 300-400Å. Evidence is presented that this broad interface is due to the microcrystalline morphology of these physically vapor-deposited molecular solids. Annealing under various conditions has provided insight into the diffusion and consequent degradation of these assemblies, apparently through a grain boundary mechanism.

Thin molecular films have been utilized recently as means for organizing a variety of chemical systems, including modified electrodes and photoelectrochemical devices (1-8). Although surface analysis techniques such as x-ray photoelectron spectroscopy (XPS or ESCA) have been used effectively to characterize the surfaces of such systems (5, 7, 9, 10), there is a crippling lack of knowledge about the validity of methods for characterizing them as a function of depth. Auger electron spectroscopy, with ion-beam etching, and secondary ion mass spectrometry have been widely employed for that purpose in dealing with multilayer assemblies of thin films of conventional materials, such as metals and semiconductors (11, 12). However, with molecular materials there is added concern over artifacts resulting from molecular degradation (13) and diffusional mixing (14) under the beams of charged particles.

In this paper, we communicate the successful Auger depth profiling of phthalocyanine (Pc) thin films, which are interesting for their electrocatalytic (15-18) and photovoltaic (6, 19, 20) properties. The results suggest that accurate profiles, without artifacts from beam damage, can be obtained. Data from annealed samples provide information about diffusional degradation of the film assemblies.

Key words: analysis, organic, films, sputtering.

Experimental

The samples were prepared by physical vapor deposition in a vacuum of less than 10^{-6} Torr using a commercially available bell jar (Varian Model 3117). First, silver (3000Å) was deposited onto 1×1 in. microscope cover glasses (Corning No. 2) held at room temperature. This layer was intended to provide for thermal and electrical conduction away from the semiconducting thin layers (~800Å each) of two different metal phthalocyanines, which were vapor deposited next at rates from 0.5 to 1 Å-sec^{-1} from quartz or alumina crucibles heated to ~400°. Changing of the deposition source necessitated exposure of the samples to the atmosphere between each step. Film thickness and deposition rate were monitored by a quartz crystal balance (Sloan DTM-200) and verified by interferometry (Varian Å-scope).

Analysis was done at a typical background pressure of 2×10^{-9} Torr with a scanning Auger microprobe (Physical Electronics Model 545). Excitation was by a coaxial 3 keV electron beam, typically of 2.0 μA. The electron beam of 20-40 μm diam) was rastered over an area approximately 167×167 μm to reduce the average current density. Ion etching was obtained with 60 $\mu A/cm^2$ of 1 keV argon from a single, 20.7° off-normal ion gun at a rate of approximately 20 Å/min. We will use the term sputtering with caution in the current context of molecular solids. Argon ion etching of polymers has been shown to be a very complex process, involving

mechanisms of fragmentation, cross-linking, and desorption (13), in addition to hard-sphere collisions.

Results and Discussion

A typical depth profile of a freshly prepared, unannealed sample is shown in Fig. 1, without smoothing or background subtraction. (The nitrogen profile was omitted from Fig. 1-4 for clarity.) The initial ratio of the nitrogen peak-to-peak amplitude to that for carbon was 0.30 ± 0.05, averaged over several samples. This figure is equivalent to the value of 0.29 ±0.015 reported ealier by Buchholz (21) for oxygen-saturated CoPc films with a 2 keV primary beam. He predicted an amplitude ratio of 0.254 for an atomic ratio of 8/32 on the basis of relative cross sections at 2 keV and the estimated electron escape depths. Buchholz vapor-deposited and Auger-analyzed his samples *in situ,* whereas ours had to be exposed to air.

No iron is detected at the surface of the unannealed sample (Fig. 1), and there is no additional broadening of the CuPc/FePc interface for samples stored at room temperature for over a week, compared to samples stored below −20°. A similar FePc/CuPc sample does, however, show traces of copper on the surface after 53 days at room temperature. For several CuPc/FePc samples (including that of Fig. 1), the surface Cu/C amplitude ratio is 0.078 ± 0.011, while unannealed FePc/CuPc or FePc-only samples have surface Fe/C ratios of 0.060 ± 0.005. Iron and copper become detectable at metal/carbon amplitude ratios just below 0.01. While oxygen is observed in relatively large amounts at the surface (O/C peak-to-peak amplitude ratios as high as 0.4) and, to a much lesser extent (typically O/C ratios of 0.015) evenly throughout both Pc layers, there is no oxygen excess at the CuPc/FePc interface. Since the FePc was exposed to air between depositions, such an excess might be expected. Its absence may be due to desorption by the impinging, thermally excited CuPc during vapor deposition, or to a leveling of the oxygen concentration by diffusion after assembly. Using Buchholz's values for a 2 keV primary beam, one can calculate an O/C amplitude ratio of approximately 0.18 for a monolayer coverage of oxygen on phthalocyanine. The minimum detectable amount of oxygen corresponds to an O/C ratio less than 0.005.

Figure 2 shows data for an equivalent CuPc/FePc sample that was annealed at 200°C for 24 hr in a rotary-pumped vacuum oven; it offers clear evidence of mass transport between the two phthalocyanine layers.

Artifacts of the Auger depth profiling technique were not found to be severe. In every case the carbon

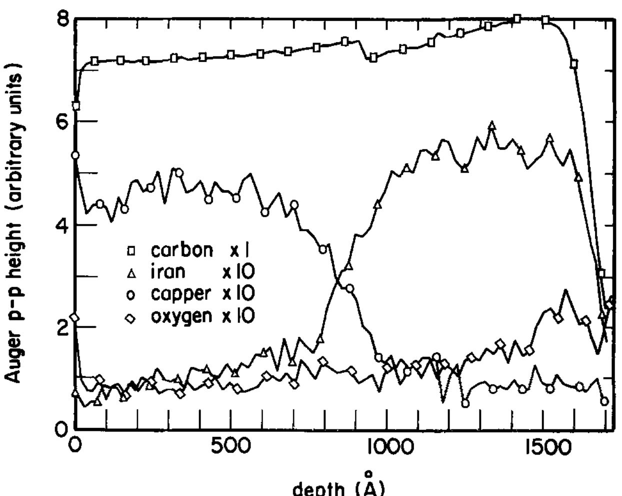

Fig. 1. Auger depth profile of a CuPc (800Å)/FePc (800Å)/Ag (3000Å)/glass sample with no annealing, other than storage for 5 days at room temperature. Etching was obtained with 55 $\mu A/cm^2$ of 1 keV Ar^+. Traces connect consecutive data points. Symbols are inserted only at every fourth point.

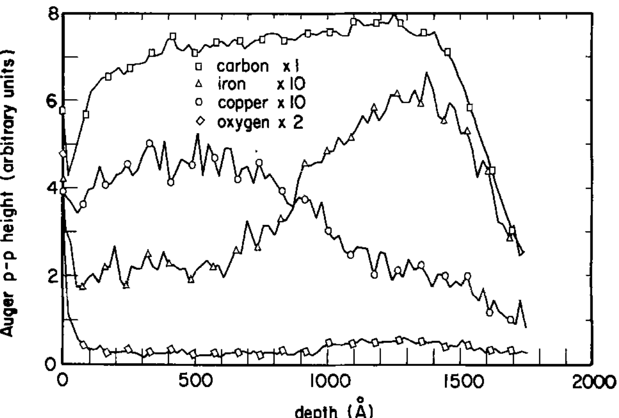

Fig. 2. Auger depth profile of a CuPc/FePc/Ag sample equivalent to that of Fig. 1, but annealed *in vacuo* for 24 hr at 200°C (in addition to storage for 11 days at room temperature).

signal shows a very rapid initial decrease followed by gradual recovery to a steady value, which is maintained through the Pc/Pc interface. The initial decrease in carbon signal may be due to adsorbed hydrocarbon contaminants. During the subsequent increase in carbon signal, the nitrogen signal (not shown) decreases, and the N/C ratio reaches an average steady-state value of 0.2. This coincidence leads us to suspect what might be described loosely as a "preferential sputtering" mechanism, involving molecular degradation. We cannot rule out changes in the Auger line shape of carbon as contributing to the fluctuations in the peak-to-peak signal, since the negative dN/dE peak of carbon near 265 eV initially, is shifted by ~3 eV to higher energy by ion bombardment. At the same time the positive peak remains unshifted. Broadening of peaks in the integral $N(E)$ spectrum would lead directly to decreases in peak-to-peak height in the dN/dE spectrum.

Electron beam damage is not a severe problem for these studies, although some chemical damage undoubtedly occurs, as evidenced by changes in the secondary and backscattered electron emission and the optical properties of the assemblies. The net absorbed sample current, when used to obtain an SEM-like picture, reveals the Auger-analyzed area to be slightly darkened, due to increased secondary and backscattered electron yields, which have been demonstrated to be a sensitive criterion for beam damage (22). Also, visual examination of the sample after exposure to electron and/or ion beam reveals qualitatively changes from the initial blue or blue-green to green. However, under the conditions described above (minimum current density, maximum sample stability), the Auger spectrum remains constant for well over 1000 sec, without an initial transient, in the absence of ion etching. Furthermore, the electron beam does not appear to contribute to interface broadening, since the minimum interface width is approximately constant over a wide range of electron current densities and dosages (Table I). In addition, compared to other organic compounds such as aliphatic hydrocarbons, CuPc has been shown to be greater than two orders of magnitude more stable to electron radiation damage (23).

Contributions to the observed width of the CuPc/FePc interface were expected from many sources. Several factors, whose contribution is expected to vary with the depth of the interface and the electron and ion beam parameters, may properly be considered artifacts in that they do not reflect the true composition of the sample before analysis. First, the phenomenon of cascade or atomic mixing has been shown to cause interface broadening due to penetration and resulting collision cascades by the ions (24, 25). Based on the

Table I. Typical interface widths for unannealed samples

Sample (thickness A)	Interface width, 10-90% (A)	Primary electron current (μA)	Etch rate (A/min)	Ion
ZnPc (170)/MnPc (670)	275	2.0	22	1 keV Ar^+ at 41 μA/cm²
ZnPc (670)/MnPc (670)	270	1.0	15	1 keV Ar^+ at 38 μA/cm²
FePc (670)/CuPc (>2000)	350	1.0	28	1 keV Ar^+ at 45 μA/cm²
FePc (670)/CuPc (>2000)	390	1.0	24	1 keV Ar^+ at 45 μA/cm²
FePc (670)/CuPc (>2000)	310	1.0	25	1 keV Ar^+ at 45 μA/cm²
FePc (670)/CuPc (>2000)	390	2.0	20	1 keV Ar^+ at 41 μA/cm²
FePc (800)/CuPc (800)	220	2.0	15	1 keV Ar^+ at 61 μA/cm²
FePc (800)/CuPc (800)	230	2.0	25	3 keV Ar^+ at 61 μA/cm²
FePc (800)/CuPc (800)	230	2.0	23	1 keV Ar^+ at 51 μA/cm²
H_2Pc (800)/FePc (800)	210	2.0	18	1 keV Ar^+ at 51 μA/cm²
CuPc (800)/FePc (800)	260	2.0	21	1 keV Ar^+ at 55 μA/cm²

available data on ion implantation ranges (26), one would expect penetration by the relatively low energy 1 keV argon beam to be substantially less than the observed CuPc/FePc interface width. This expectation was confirmed by depth profiling equivalent samples with 1 and 3 keV argon beam energy, with no observable changes other than sputter rate (Fig. 3 and 4).

Sputter-induced roughness has also been known to degrade interface resolution. However, if this were the case one would expect the interface width to increase approximately as the square-root of depth (27). Clearly this is not observed experimentally in Fig. 1, where the CuPc/FePc interface is broader than the deeper FePc/Ag interface.

Electron and ion beams have also been observed to cause mass transport via thermal diffusion (28) or electrostatic migration (29). However, these observations were under rather extreme conditions, such as

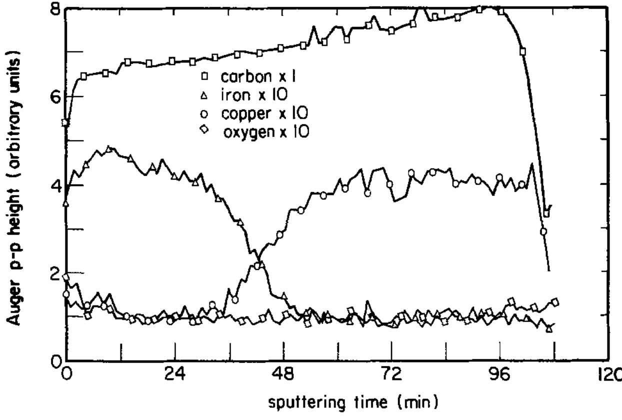

Fig. 3. Auger depth profile of FePc (800Å)/CuPc (800Å)/Ag (3000Å), after storage at room temperature for 18 days, etched with 61 μA/cm² of 1 keV Ar^+ ions.

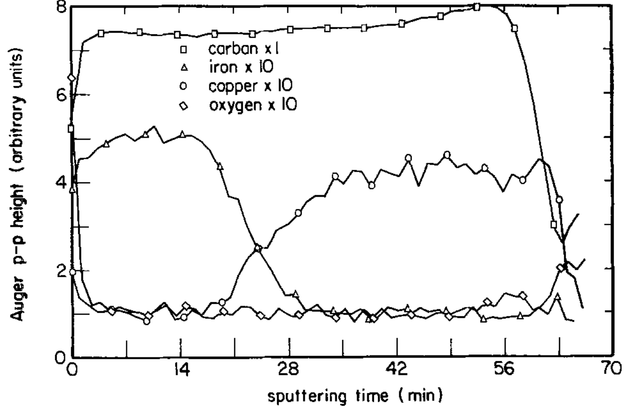

Fig. 4. Auger depth profile of a sample equivalent to that in Fig. 3, etched with 61 μA/cm² of 3 keV Ar^+ ions.

low thermal or electrical conductivity samples, high power and current densities, and highly mobile species. For the samples that we have constructed and the beam parameters that we use, we have seen no evidence of this type of transport phenomenon. Poor electrical conductivity would be manifested by charging and subsequent shifting of the Auger electron energies. Beam heating would cause the bottom layer to diffuse to the surface with long electron beam exposure.

The inelastic mean-free path (IMFP) of electrons also contributes to the observed interface width of Auger depth profiles, but in a manner which is independent of beam parameters or sample history, and depends principally on the characteristic electron energy and, to a greater or lesser extent, the sample matrix. The value of the inelastic mean-free path for molecular materials has been the subject of debate (30, 31). We can conclude from the lower FePc/Ag interface width of approximately 100Å (measured from 90% to 10%) of the carbon signal, that for electrons of 271 eV energy traveling through FePc (albeit damaged by electron and ion bambardment), the IMFP is less than 50Å, since a distance twice the mean-free path would cause attenuation by 86%.

Another factor contributing to the CuPc/FePc interface width in Fig. 1, independent of analysis conditions or sample history, is expected to be the microcrystalline dimensions of the vapor-deposited phthalocyanines. Electron microscopic examination of Pc films evaporated under similar conditions indicate that the microcrystalline dimensions are typically on the order of 200Å (32, 33). This evidence, coupled with our observation of the relative sharpness of the FePc/Ag interface leads us to conclude that the unannealed CuPc/FePc interface width is dominated by this microcrystallinity.

The original goal of this research was to develop the capability of directly monitoring the integrity of interfaces in these organic thin film assemblies, as a function of sample history. Thus, we were encouraged to find that when sample preparation, history, and analysis parameters were held constant, the interface depth profiles were reproducible. When these samples were compared to identically prepared samples that received different annealing treatments, dramatic changes resulted from chemical, as well as physical, phenomena. The chemical changes, which took place during annealing in air, have been reported orally (34), and will be described in detail at a later data. The physical changes, which were observed following annealing in a vacuum oven that was repeatedly purged with argon and rotary-pumped before heating, evident in Fig. 2, can be explained by diffusion and changes in morphology.

These morphology changes may take place in either the molecular or metallic layers of these assemblies. Phthalocyanines are known to vapor deposit onto a room temperature substrate in the α-("tile") form. The transition to the β-("herringbone") form has been reported to occur at temperatures as low at 60°C (35).

Consequently, any detailed explanation of the mechanism of mass transport during annealing may need to involve morphology. It was our intention in this preliminary report to use higher temperatures and longer times, such that any mass transport due to morphological change is small in comparison to that due to diffusion.

Figure 2 clearly shows degradation of the FePc/Ag, as well as the CuPc/FePc, interface, although the Pc/Ag interface of comparable samples annealed for 14 hr at 175°C show no degradation. This observation, coupled with the absence of any detectable Ag accumulation at any MPc/MPc interface or at the surface of any Pc layer is strongly indicative of a change in the topography of the Ag layer. This change may be the result of a variety of mechanisms. The silver microcrystals could coalesce into larger crystallites, or the silver might migrate to fill voids occurring in the Pc layers. Filaments of metal, observed by electron microscopy of sectioned, vapor-deposited metal/Pc/metal assemblies have been ascribed to this mechanism (32). Scanning electron microscopy of the craters remaining after the Auger depth profiles reveals the sputtered silver surface of an annealed sample to be anisotropically irregular (Fig. 5), while an unannealed sample had a flat-bottomed crater (Fig. 6). This observation leads us to assume that both thermal and ion beam effects are involved in these changes in the silver surface and the consequent Pc/Ag interface broadening.

The nature of the mass transport of FePc through the CuPc was expected to be by a grain boundary mechanism, due to the microcrystalline nature of the Pc. The surface excess of FePc could be accounted for either by a predominantly grain boundary mechanism, or by a bulk diffusion mechanism coupled with a thermodynamic preference for FePc over CuPc at the residual vacuum/Pc interface or surface. This latter possibility is ruled out, since comparably annealed FePc/CuPc samples show a surface excess of CuPc.

Further details of the diffusion mechanism are at this point not completely clear. Two possibilities are molecular diffusion of intact metal phthalocyanines or demetallation and atomic diffusion of the metal atoms from molecule to molecule. A comparison of H_2Pc/FePc samples to CuPc/FePc samples shows roughly comparable diffusion upon identical annealing conditions, which supports, but does not prove, the former hypothesis. Further experiments utilizing secondary ion mass spectrometry are underway to resolve this question.

In conclusion, we have described the successful use of Auger depth profiling, traditionally an atomic analysis technique, applied nontraditionally to molecular thin solid films to investigate diffusion. We have clearly demonstrated that any future applications of such molecular solid assemblies intended for long-term or high temperature use must give careful consideration to grain boundary diffusion as a mechanism of aging or failure.

The Nucleation of CVD Silicon on SiO_2 and Si_3N_4 Substrates

III. The SiH_4-HCl-H_2 System at Low Temperatures

W. A. P. Claassen and J. Bloem*

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

The growth of polycrystalline silicon layers on SiO_2 and Si_3N_4 substrates can be hampered in the early stages of growth by the presence of different species adsorbed on the surface. In this article nucleation experiments with silicon on SiO_2 and Si_3N_4 are described in the SiH_4-H_2-HCl system at temperatures between 600° and 900°C. In this temperature regime (and without HCl addition) the saturation nucleus density of silicon clusters on SiO_2 substrates shows a decrease in density with decreasing temperature, whereas on Si_3N_4 substrates the opposite occurs. Experiments with nitrogen as a carrier gas, however, give almost the same saturation nucleus densities of silicon clusters on SiO_2 and Si_3N_4 substrates. Additions of HCl to the SiH_4-H_2 system produce a decrease in the nucleus saturation density on SiO_2 and Si_3N_4 substrates, and the density also decreases with decreasing temperatures below 900°C. It is further shown that selective growth of silicon on partly coated silicon substrates becomes more difficult at lower growth temperatures. Adsorption of different surface species (H, Cl, $SiCl_2$, and SiH_2) on SiO_2 and Si_3N_4 substrates is discussed and it is concluded that a strong adsorption of atomic hydrogen, notably on SiO_2 surfaces, may explain the difference in nucleus densities on SiO_2 and Si_3N_4 substrates at temperatures below 900°C.

In two preceding papers (1, 2) (referred to in the following as Part I and Part II) nucleation experiments are described on SiO_2 and Si_3N_4 substrates. Part I contains experimental data on the SiH_4-HCl-H_2 system at temperatures between 925° and 1200°C, while Part II describes the nucleation behavior in the SiH_2Cl_2-H_2-N_2 system at temperatures between 800° and 1100°C. In Parts I and II it was demonstrated that nucleation of silicon on a foreign substrate involves the presence of free silicon adatoms, acting as nucleation centers, whereas on a silicon substrate growth proceeds via the incorporation of adsorbed species (SiH_2, $SiCl_2$) at surface steps. As long as this layer growth is possible there is no need for separate nucleation between the steps, and therefore growth can proceed at low supersaturations. This effect also

explains the selective growth found under conditions of low supersaturations (3, 4). It is not known in what way the nucleation of silicon proceeds at lower temperatures, where an increased surface adsorption could change the nucleation behavior. For this reason nucleation and growth experiments were performed for the SiH_4-H_2-HCl system at temperatures between 600° and 900°C, on SiO_2 and Si_3N_4 substrates.

Experimental and Experimental Results

The nucleation experiments were performed in a horizontal air-cooled, rf heated reactor. The experimental conditions have been described in Parts I and II, but some additional information is given below. The carrier gases hydrogen and nitrogen were purified to water and oxygen concentrations below 1 ppm. The flow rates of the carrier gases, silane (5% in hydrogen) and hydrogen chloride, both electronic grade, were controlled by means of automatic mass-flow controllers. The temperature was measured with the aid of a calibrated radiation pyrometer on an uncoated silicon slice. Silicon slices covered with an amorphous 1500Å thick LPCVD layer of SiO_2 or Si_3N_4 were used as substrates. Because of the relatively high temperatures used and the small partial pressures of oxygen and water present it can be assumed that the Si_3N_4 surface is free of oxygen in contrast with Si_3N_4 which is exposed to air (5). After the nucleation experiments SEM and TEM photomicrographs were used to count the density of the nuclei formed.

Just as in the SiH_4-HCl-H_2 system at high temperatures (Part I), it is found that after an incubation period the concentration of stable clusters very quickly reaches a saturation density with respect to exposure time. This incubation period becomes longer with decreasing temperature and high hydrogen chloride concentrations combined with low silane concentrations. Furthermore, these periods are longer for SiO_2 substrates than for Si_3N_4 substrates, notably when hydrogen is the carrier gas. Figure 1 shows TEM photomicrographs for an input of 0.1 volume percent (v/o) silane in hydrogen as a carrier gas at 800°C on SiO_2 substrates and different exposure times. As noted before, the nucleus density of silicon clusters, after the incubation period, remains almost constant until coalescence occurs. In the following, therefore, only saturation nucleus densities of silicon clusters (referred to as N_s) will be used. Figure 2 gives N_s values as a function of temperature on SiO_2 and Si_3N_4 sub-

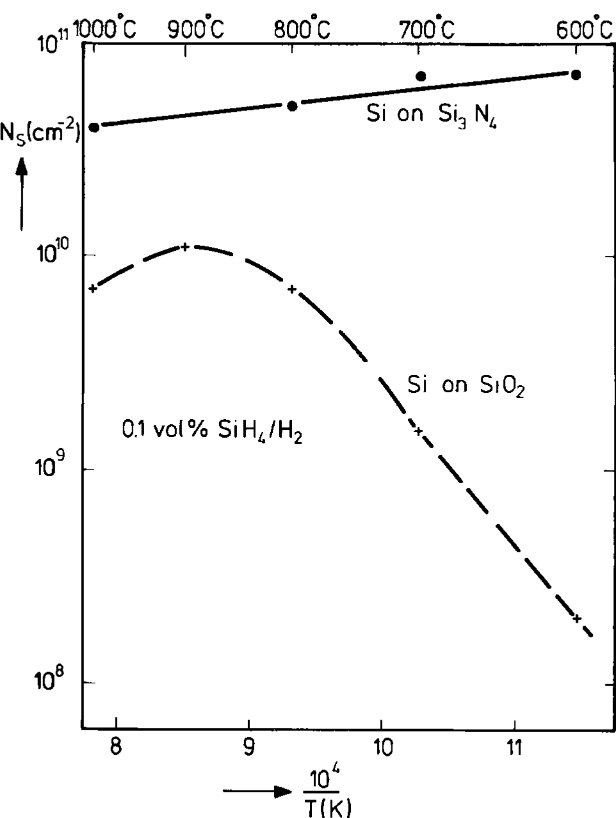

Fig. 2. The saturation density of silicon clusters (N_s) as a function of temperature for an input of 0.1 v/o silane in hydrogen as a carrier gas on SiO_2 and Si_3N_4 substrates.

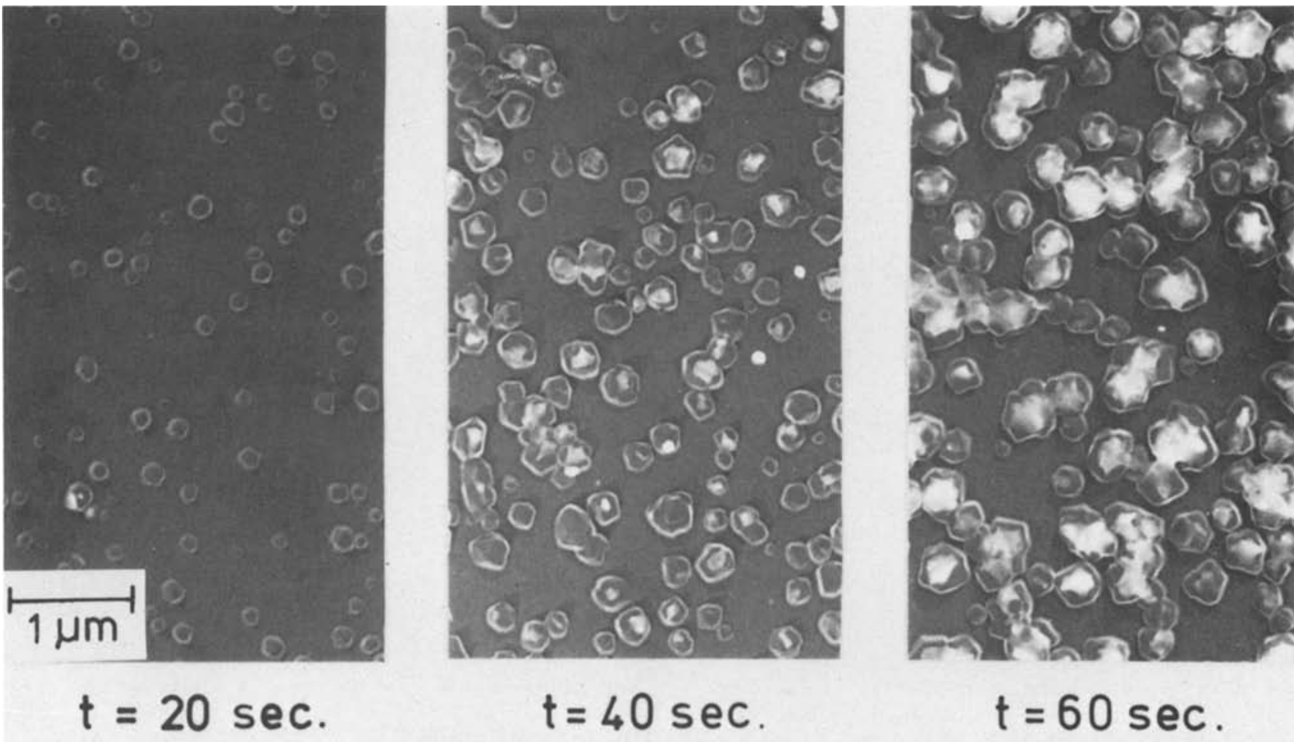

Fig. 1. TEM photomicrographs of the nucleus density on an SiO_2 substrate for an input of 0.1 v/o silane in hydrogen at 800°C as a function of the exposure time.

strates and an input of 0.1 v/o silane in a hydrogen ambient. The experimental data at temperatures above 925°C are discussed in Part I and are only given here for comparison. As will be noticed, N_s decreases with decreasing temperature on SiO_2 substrates at temperatures below 900°C, while at temperatures above 900°C the opposite occurs. On Si_3N_4 substrates N_s varies only slightly with temperature; in the temperature region under discussion no maximum in N_s is observed. It was expected that hydrogen adsorption would strongly reduce the saturation nucleus density of silicon clusters, notably for SiO_2 substrates, in analogy with the SiH_2Cl_2-H_2-N_2 system (Part II). Such an effect is indeed observed: for 0.01 v/o SiH_4 in hydrogen at 700°C the nucleus density is extremely low and is estimated at $2 \times 10^7/cm^2$, whereas when nitrogen is the carrier gas (0.2 v/o H_2 is present from the silane source, being 5 v/o SiH_4 in H_2) the nucleus density rises to $1.2 \times 10^{11}/cm^2$. The corresponding TEM photomicrograph for the SiO_2 substrate after an exposure time of 30 sec is shown in Fig. 3. From the N_s values in hydrogen and nitrogen a variation of N_s proportional to $p_{H_2}^{-3/2}$ can be deduced. Figure 4 shows the influence of hydrogen pressure on N_s for Si_3N_4 substrates and an input of 0.01 v/o SiH_4. It can be observed that N_s decreases with increasing hydrogen pressure: by plotting N_s^{-1} *vs.* p_{H_2} a linear relationship can be obtained. Figure 5 gives N_s values on SiO_2 and Si_3N_4 substrates at 700°C as a function of input concentrations of silane. For the input concentrations used in these experiments, N_s is linearly proportional to the silane input pressure in a first approximation. Addition of HCl to the SiH_4-H_2 mixtures greatly reduces the number of stable silicon clusters as can be seen from Fig. 6. In this figure N_s is plotted as a function of the input concentration of HCl at 800°C on SiO_2 substrates and for an input of 0.1 v/o SiH_4. For higher input concentrations of hydrogen chloride than those given in Fig. 6 no nucleation is observed. Figure 7 shows the influence of the addition of various amounts of HCl to the SiH_4-H_2 mixture on the density of nuclei as a function of temperature, both for SiO_2 and for Si_3N_4 substrates. At 900°C N_s shows a distinct maximum, for both SiO_2 and Si_3N_4 substrates.

Another point appears from the observation that silicon layers can be grown selectively on partly oxide-coated or nitride-coated silicon slices (3, 4). The selectivity is explained on the basis of a more difficult nucleation on foreign substrates. In Fig. 8 this selectivity is shown as a function of temperature for the SiH_4-HCl-H_2 system in which the ratio p_{SiH_4}/p_{HCl}^2 is used as a measure of the supersaturation. Three regions can be distinguished: I, no selective growth; II, selective growth; and III, etching of the silicon slices. It will be seen that with decreasing temperatures the region where selective growth can take place becomes smaller, and at temperatures below 800°C the selectivity between silicon and SiO_2 or Si_3N_4 has disappeared.

Discussion

In Part I it was concluded that an expression given by Venables (6) could be used to characterize the saturation density of silicon clusters (N_s) in the present case where incomplete condensation has to be assumed. Venable's expression for the case of mobile clusters can be rewritten as

$$\frac{N_s}{n_0} \cong \left(\frac{n_1}{n_0}\right)^{(i+1)/2} \exp\left[(E_i + E_m - E_d)/2kT\right] \quad [1]$$

where i is the number of atoms in the initial cluster, E_i the heat of formation of a cluster consisting of i atoms, E_m is the activation energy for surface diffusion of mobile clusters, E_d the activation energy for surface diffusion of adatoms, n_1 the concentration of adatoms per unit area, and n_0 the total number of surface sites per unit area. If only small clusters are mobile at low temperatures Eq. [1] has to be replaced by

$$\frac{N_s}{n_0} \cong \left(\frac{n_1}{n_0}\right) \exp\left[(E_m - E_d)/2kT\right] \quad [2]$$

In the Appendix we give reaction schemes in order to arrive at expressions for n_1/n_0.

Interpretation of the results.—The expression as obtained by Venables (Eq. [1]) for the saturation nucleus density of silicon clusters can be compared with the experimental data in the SiH_4-H_2 system on SiO_2 and Si_3N_4 substrates in the temperature range under discussion. In the Appendix an expression has been found for the concentration of SiH_2 monomers (Eq. [A-12]), with Eq. [1] this then leads to

$$\frac{N_s}{n_0} = \left(\frac{K_1K_3p_{SiH_4}}{p_{H_2}}\right)^{(i+1)/2} \exp\left[(E_i + E_m - E_d)/2kT\right] \quad [3]$$

In order to arrive at an expression describing the experimental data, the following remarks can be made:

1. N_s is almost equal for SiO_2 and Si_3N_4 substrates in the SiH_4-N_2 system at 700°C, as discussed before. Be-

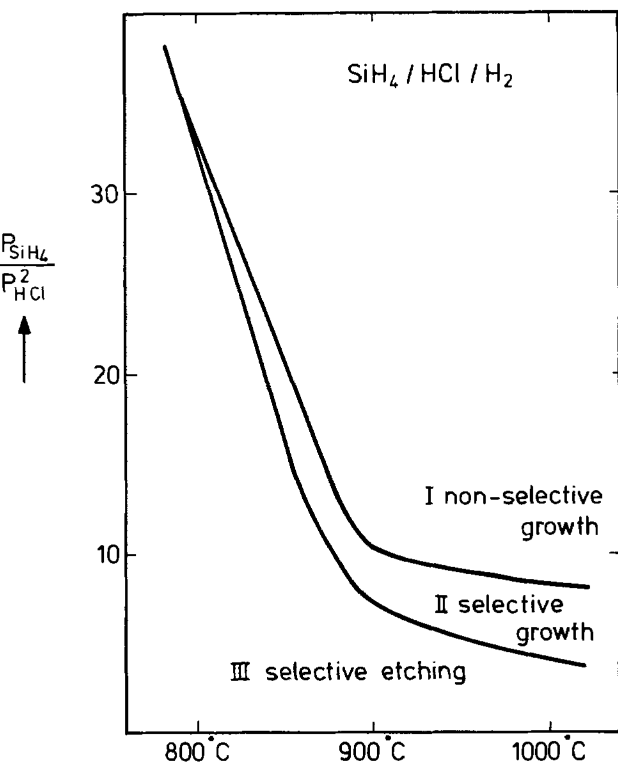

Fig. 8. The temperature dependence of selective growth of silicon on silicon slices partly coated with oxide or nitride as a function of temperature and supersaturation, expressed as p_{SiH_4}/p_{HCl}^2 in hydrogen as a carrier gas.

tween 800° and 1100°C the SiH_2Cl_2-N_2 system showed the same behavior (Part II), giving comparable results on SiO_2 and Si_3N_4 substrates.

2. The saturation nucleus density of silicon clusters on Si_3N_4 substrates is in a first approximation inversely proportional to p_{H_2} ($N_s \propto p_{H_2}^{-1}$) (Fig. 4). In the case of SiO_2 substrates the hydrogen pressure is observed to have a stronger influence on N_s ($N_s \propto p_{H_2}^{-3/2}$). In Part II it was concluded that adsorption of atomic hydrogen could explain the differences in N_s between SiO_2 and Si_3N_4 in the SiH_2Cl_2-H_2 system ($N_s \propto p_{H_2}^{-1/2}$).

3. The saturation density of silicon clusters on SiO_2 and Si_3N_4 substrates is in a first approximation linearly proportional to the input concentration of silane (Fig. 5).

The remarks made above lead to the conclusion that the experimental data on Si_3N_4 substrates ($N_s \propto p_{SiH_4}/p_{H_2}$) can be described by Eq. [3], leading to a critical cluster with $i = 1$ and SiH_2 as the predominant surface species. The differences in nucleation behavior between SiO_2 and Si_3N_4 substrates at temperatures below 900°C can be explained by a strong hydrogen adsorption on SiO_2 substrates. As is discussed in the section on adsorption, this is due to a large difference in the bond strength between the NH and the OH bonds. In that case a competition between the adsorption of atomic hydrogen and SiH_2 monomers occurs and the simplification made in Eq. [A-10] of the Appendix is no longer valid. For $K_4 p_{H_2}^{1/2} > (1 + K_1 K_2 p_{SiH_4}/p_{H_2})$ (Eq. [A-8]) this then leads to a decrease in the saturation density proportional to $p_{H_2}^{3/2}$ in agreement with the experimental data on SiO_2 below 900°C.

If HCl is introduced to the SiH_4-H_2 system SiH_2 will be converted to $SiCl_2$ (7, 8) and the SiH_2 monomer concentration decreases with increasing HCl concentrations

$$n_1 = [SiH_2^*] \propto p_{SiH_4}/p_{HCl}^2 \qquad [4]$$

In Part I an extensive discussion is devoted to experimental data on the SiH_4-HCl-H_2 system on SiO_2 and Si_3N_4 substrates at temperatures above 925°C. From plots of log N_s *vs.* log p_{SiH_4}/p_{HCl}^2 it was shown that, if the input concentrations of hydrogen chloride are not too high N_s is linearly proportional to p_{SiH_4}/p_{HCl}^2, indicating that $i = 1$ and $[*]$ is constant at those temperatures. At higher HCl concentrations the initial cluster size changes from $i = 1$ to $i = 4$. At temperatures below 925°C, N_s decreases with decreasing temperatures in contrast to the situation at higher temperatures where the opposite occurs (Fig. 7). In order to interpret the experimental data below 900°C growth rate measurements for silicon on silicon in the SiH_4-HCl-H_2 system are helpful (7). At temperatures above 900°C the growth rate is gas phase diffusion-controlled and is relatively high compared with the etch rate given by the presence of HCl for not too high input concentration of HCl. As discussed in Part I, N_s is linearly proportional to p_{SiH_4}/p_{HCl}^2 ($i = 1$) for $p_{SiH_4}/p_{HCl}^2 > 50$ (p in bars) at temperatures above 925°C. At lower values of p_{SiH_4}/p_{HCl}^2 the critical cluster size increases and for $p_{SiH_4}/p_{HCl}^2 < 8$ no nucleation is observed at these temperatures. At temperatures below 900°C the growth rate of silicon on silicon is kinetically or surface-controlled in the SiH_4-H_2 system and a strong decrease in the growth rate with decreasing temperatures is apparent. Addition of HCl to this system at temperatures below 900°C leads to an additional lowering of the growth rate as measured in the SiH_4-H_2 system, due to the conversion of SiH_2 into $SiCl_2$ which easily desorbs (7, 8). At 800°C no nucleation is observed on SiO_2 and Si_3N_4 substrates for $p_{SiH_4}/p_{HCl}^2 < 30$ (Fig. 7 and 8) as is discussed later in connection with selective growth. In the regime where the growth of silicon on silicon is surface-controlled ($T <$ 900°C) N_s is linearly proportional to p_{SiH_4}/p_{HCl}^2 ($i =$ 1) only for relatively high values of this parameter (> 100 as obtained from Fig. 6). Or, in other words, when hydrogen chloride is added to a certain amount of silane the critical cluster size deviates from $i = 1$ for much smaller hydrogen chloride concentrations at 800°C than at temperatures above 900°C. This leads to a decrease in N_s, the term between the brackets in Eq. [3] being smaller than unity (n_1/n_0). A second possibility which could explain the decrease in N_s below 900°C as shown in Fig. 7 for the SiH_4-HCl-H_2 system is given by a strong adsorption of atomic chlorine. As is discussed in the section on adsorption, chlorine will be preferentially adsorbed on the silicon surface atoms of the SiO_2 and Si_3N_4 substrates, but there is evidence that above 700°C the interaction between chlorine and the silicon surface atoms is only weak, leading to a small concentration of chlorine surface atoms ($[Cl^*] << n_0$).

According to Fig. 8 silicon can be grown selectively on silicon slices partly coated with oxide or nitride at temperatures above 800°C. As the growth of silicon on silicon in the SiH_4-HCl-H_2 system can be given by $R = k_a p_{SiH_4} - k_b p_{HCl}^2$ leading to $R = 0$ for $p_{SiH_4}/p_{HCl}^2 = k_b/k_a$, this relation is used as a parameter in Fig. 8. In the gas phase diffusion-controlled regime of the growth of silicon on silicon above 900°C, as discussed above, surface diffusion and incorporation of silicon at the atomic steps are relatively fast compared to the diffusion of reactants toward the surface. In the same temperature regime the nucleation of silicon on silicon is surface controlled (Part I), leading to desorption of $SiCl_2$ if no growth centers are present. Consequently a selective growth can become apparent. At temperatures below 900°C the growth of silicon on silicon becomes surface controlled, the reduction of $SiCl_2$ at the atomic steps being rate limiting (8). Nucleation of silicon on SiO_2 and Si_3N_4 in the SiH_4-H_2-HCl system below 900°C is also surface controlled, as discussed before. At low temperatures, therefore, nucleation and growth are both limited by the reduction of $SiCl_2$ by hydrogen. This explains the loss of selectivity at lower temperatures in the Si-H-Cl system. According to Fig. 2 some selectivity in the growth of silicon on SiO_2 and Si_3N_4 can be expected in the SiH_4-H_2 system at low temperatures and low input concentrations of silane.

Adsorption on SiO_2 and Si_3N_4 substrates.—In this section we discuss adsorption of H, Cl, SiH_2, and $SiCl_2$ in connection with the nucleation experiments on SiO_2 and Si_3N_4 substrates. We also give a comparison with adsorptions of the same compounds on silicon. The concentration of free surface sites on a SiO_2 substrate, $[*] = [*_{ox}] + [*_{si}]$ (where the subscripts ox and si refer to the surface atoms oxygen and silicon), can be given by

$$[*_{ox}] = n_{ox} - [H^*_{ox}] - [SiH^*_{2,ox}] - [Cl^*_{ox}] - [SiCl^*_{2,ox}] \qquad [5]$$

$$[*_{si}] = n_{si} - [H^*_{si}] - [SiH^*_{2,si}] - [Cl^*_{si}] - [SiCl^*_{2,si}] \qquad [6]$$

where $n_0 = n_{ox} + n_{si}$ is the total number of surface sites per unit area. The concentration of free surface sites on Si_3N_4 can be given in a similar way. Making use of the equilibrium partial pressures of the various species in the gas phase, one can calculate the surface concentrations of the different compounds if values for the adsorption energies of these species are known (8). If no direct measurements are available, an upper limit of these adsorption energies (E_a) can best be given by the dissociation energy (D) of the corresponding diatomic molecules. Table I gives accepted values for D, according to the JANAF tables (9) for most of the bonds. D values for Si—O, O—Cl, and N—Cl have been reported by Roberts and Caserio (10), who give average values for polyatomic molecules. Since, as far as

Table I. Accepted adsorption energies in kcal/mol (9, 10)

Adsorbed atoms	Substrate atoms		
	Si	O	N
Si	73	108	92
H	70	102	83
Cl	90	52	46

the authors are aware, no dissociation energy for the single bond of Si—N is known, an estimate of D_{SiN} can be given by equating $D_{Si\text{-}N}/D_{Si\text{-}O} = D_{C\text{-}N}/D_{C\text{-}O}$. Using values for the single bonds derived from measurements on polyatomic molecules (10), this yields $D_{Si\text{-}N} = 92$ kcal/mol (Table I).

Adsorption of monoatomic hydrogen.—As discussed before, the nucleation experiments on SiO_2 and Si_3N_4 substrates indicate a strong adsorption of atomic hydrogen on SiO_2 and a weak hydrogen adsorption on Si_3N_4. According to Table I this could be due to the differences in bond strengths between OH and NH. It is therefore also to be expected that adsorption of atomic hydrogen on silicon will be relatively weak, leading to a small coverage with hydrogen atoms (8). More evidence of a strong hydrogen adsorption on SiO_2 comes from the work of Morterra and Low (11) and of Lawrenko *et al.* (12). Morterra and Low studied the reaction between porous silica and molecular hydrogen. They found that this silica reacts with molecular hydrogen. Infrared studies have shown that if molecular hydrogen reacts with porous SiO_2 at temperatures above 650°C, silanols (Si—OH) are formed while SiH groups are totally absent. Lawrenko *et al.* studied the adsorption of hydrogen on monocrystalline SiO_2. Measuring the weight changes of the samples by means of a microbalance they found that at temperatures below 900°C measurable quantities of hydrogen are adsorbed on the SiO_2 substrates, indicating the formation of SiOH groups. They also observed that the adsorption is reversible. Stein and Wegener (13) found that CVD Si_3N_4 contains chemically bonded hydrogen.

Annealing experiments showed that the SiH bonds are annealed out more easily than the NH bonds. It can therefore be concluded that adsorption of atomic hydrogen on SiO_2 substrates blocks adsorption sites, leading to a decrease in the saturation density of silicon clusters, whereas in the case of Si_3N_4 and silicon surfaces this adsorption is only weak at temperatures exceeding 600°C.

Adsorption of atomic chlorine.—According to Table I, chlorine does not adsorb preferentially on oxygen or nitrogen, and it may therefore be assumed that adsorption of chlorine on SiO_2 and Si_3N_4 can be treated as adsorption on the silicon surface atoms. Adsorption of atomic chlorine on silicon has been discussed previously in connection with growth rate measurements of silicon on silicon (8). It was concluded there that at temperature above 700°C the fractional surface concentration of atomic chlorine is much smaller than unity, in agreement with evolution measurements reported by Miyamura *et al.* (14).

Adsorption of SiH_2 and $SiCl_2$.—Because of the relatively high values of $D_{Si\text{-}N}$ and $D_{Si\text{-}O}$ in contrast to $D_{Si\text{-}Si}$ (Table I) it can be assumed that the surface species SiH_2 and $SiCl_2$ adsorb predominantly on top of oxygen or nitrogen atoms of the SiO_2 or Si_3N_4 substrates. After adsorption of the first monolayer of silicon the surface mobility of further SiH_2 or $SiCl_2$ monomers will be enhanced. This postulation could explain the similarity in nucleation densities on SiO_2 and Si_3N_4 with sapphire and spinel substrates as observed by Cullen and co-workers (15). As discussed before, N_s is linearly proportional to the input concentration of silane on SiO_2 and Si_3N_4 substrates, indicating a small coverage of SiH_2 monomers. As discussed previously, the surface concentrations of $SiCl_2$ on silicon in the SiH_4-HCl-H_2 systems are considered to be small (8). A strong adsorption of $SiCl_2$ on SiO_2 or Si_3N_4 substrates cannot be ruled out completely, but according to the experimental data as described in Part II (the SiH_2Cl_2-H_2 system) the surface coverage of $SiCl_2$ is much smaller than that of atomic hydrogen, notably for SiO_2 substrates.

Conclusions

In our study of the nucleation of silicon on SiO_2 and Si_3N_4 substrates at temperatures between 600° and 900°C in the SiH_4-HCl-H_2 system, it was observed that the saturation nucleus density on SiO_2 substrates in the SiH_4-H_2 system shows a maximum at approximately 900°C, whereas for Si_3N_4 substrates this density increases slightly with decreasing temperatures. Addition of nitrogen to the SiH_4-H_2 systems produces a strong increase in the saturation density of silicon clusters, notably on SiO_2 substrates. Analysis of the experimental data suggests that atomic hydrogen is strongly adsorbed on SiO_2 because of the formation of OH bonds, whereas on Si_3N_4 substrates adsorption of atomic hydrogen leads to only small coverages. The introduction of HCl strongly reduces the nucleus density, notably at temperatures below 900°C. It is concluded that this additional reduction at temperatures below 900°C is comparable to the decrease in growth rate in the case of silicon on silicon. The adsorption of H, Cl, $SiCl_2$, and SiH_2 on SiO_2 and Si_3N_4 substrates is discussed and compared with the adsorption of these species on silicon surfaces. It is concluded that only adsorption of atomic hydrogen on SiO_2 is needed to explain the experimental results: this adsorption blocks the adsorption sites, leading to a decrease in the saturation density of silicon clusters.

APPENDIX

In order to describe the nucleation experiments in the SiH_4-HCl-H_2 system at temperatures below 900°C it is necessary to consider a number of possible reactions that can take place at or near the surface. The reaction scheme as proposed for the SiH_4-HCl-H_2 system at temperatures above 925°C (Part I) can be used with some additional assumptions concerning the species present on the surface. The reaction between silicon adatoms and SiO_2 to give volatile SiO can be neglected below 1000°C (16).

If no HCl is present in the gas phase the following reaction scheme will be used:

a. Gas phase dissociation of SiH_4 near the surface (17)

$$SiH_4(g) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} SiH_2(g) + H_2(g) \quad [A\text{-}1]$$

b. Adsorption of SiH_2 on a free surface site (the latter denoted by $*$). On an SiO_2 or Si_3N_4 substrate, $[*] = [*_z] + [*_{si}]$, where the subscripts z and si refer to the surface atoms oxygen (or nitrogen) and silicon, respectively

$$SiH_2(g) + *_z \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} SiH_2{}^{*_z} \quad [A\text{-}2]$$

$$SiH_2(g) + *_{si} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} SiH_2{}^{*_{si}} \quad [A\text{-}3]$$

c. Adsorption of atomic hydrogen

$$\tfrac{1}{2} H_2(g) + *_z \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} H^{*_z} \quad [A\text{-}4]$$

$$\frac{1}{2} H_2(g) + *_{si} \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} H^{*}{}_{si} \qquad [A-5]$$

The concentration of free surface sites on SiO_2 and Si_3N_4 substrates $[*_z]$ and $[*_{si}]$ can be given by

$$[*_z] = n_z - [H^{*}{}_z] - [SiH_2{}^{*}{}_z] \qquad [A-6]$$

$$[*_{Si}] = n_{Si} - [H^{*}{}_{Si}] - [SiH_2{}^{*}{}_{Si}] \qquad [A-7]$$

where $n_o = n_z + n_{si}$ is the total number of surface sites per unit area. The concentrations of the surface species $[SiH_4{}^{*}]$, $[SiH_3{}^{*}]$, $[SiH^{*}]$, and $[Si^{*}]$ are assumed to be small compared with the concentration of $[SiH_2{}^{*}]$, according to the experimental data concerning the growth of silicon on silicon in the SiH_4-H_2-N_2 system at 700°C (8). In a steady-state situation the concentration of SiH_2 admolecules reaches a constant value, which before the onset of silicon cluster formation can be expressed by

$$[SiH_2{}^{*}{}_z] = \frac{K_1K_2p_{SiH_4}}{p_{H_2}} \times \frac{n_z}{(1 + K_4p_{H_2}{}^{1/2} + K_1K_2p_{SiH_4}/p_{H_2})} \qquad [A-8]$$

$$[SiH_2{}^{*}{}_{Si}] = \frac{K_1K_3p_{SiH_4}}{p_{H_2}} \times \frac{n_{Si}}{(1 + K_5p_{H_2}{}^{1/2} + K_1K_3p_{SiH_4}/p_{H_2})} \qquad [A-9]$$

As the SiO and SiN bonds are strong compared with the Si-Si bond (Table I), it is likely that nucleation on SiO_2 and Si_3N_4 substrates starts with the adsorption of SiH_2 on oxygen and nitrogen atoms of the substrate. For an adsorption of SiH_2 exceeding that of atomic hydrogen, *i.e.*

$$K_1K_2p_{SiH_4}/p_{H_2} > (1 + K_4p_{H_2}{}^{1/2})$$

this then leads to

$$[SiH_2{}^{*}{}_z] = n_z \qquad [A-10]$$

After adsorption of this monolayer of silicon the surface mobility of further SiH_2 monomers will be enhanced and silicon clusters can be formed, according to

$$SiH_2{}^{*} + SiH_2{}^{*} \xrightarrow{k_6} Si_2H_2{}^{**} + H_2(g) \qquad [A-11]$$

$$Si_2H_2{}^{**} + SiH_2{}^{*} \xrightarrow{k_7} Si_3H_2{}^{***} + H_2(g), \text{ etc.}$$

The mobile SiH_2 concentration is then given by Eq. [A-9] in which n_{Si} is now equal to the total number of surface sites ($n_{Si} = n_o$). For a small surface coverage we have

$$n_1 = [SiH_2{}^{*}] = \frac{K_1K_3p_{SiH_4} \cdot n_o}{p_{H_2}} \qquad [A-12]$$

Oxidation, Impurity Diffusion, and Defect Growth in Silicon—An Overview

R. B. Fair*

Bell Laboratories, Reading, Pennsylvania 19604

ABSTRACT

As a result of a large body of literature on oxidation, impurity diffusion, and defect growth in silicon, a consistent picture has emerged of oxidation-enhanced diffusion (OED) and oxidation-induced stacking fault growth (OISF). It is believed that silicon self-interstitials can be generated at an oxidizing Si/SiO_2 interface as a result of an incomplete half-cell reaction involving silicon and oxygen. Those interstitials that do not participate in surface regrowth participate in raising the steady-state concentration of self-interstitials in the surface region. OED can be explained in terms of a partial interstitialcy mechanism involving the surface-generated self-interstitials. The growth of OISF will occur if the relative steady-state self-interstitial concentration around the fault exceeds the emitted concentration of interstitials from the fault line. It is shown that this model predicts that OISF growth is limited by the production rate of self-interstitials at the Si/SiO_2 interface. The retrogrowth of OISF and the reduction of OED both occur when the concentration of generated self-interstitials decreases. The introduction of chlorine-bearing compounds into the oxidation tube can also cause retrogrowth. The reaction of chlorine with silicon at the interface creates vacancies which can recombine with generated self-interstitials and reduce their concentration. Calculations show that the chlorine compound formed at the interface is SiCl.

Thermal oxidation of silicon is known to promote the growth of stacking faults (1-18) and dislocations (19). The stacking faults may be extrinsic or intrinsic. Extrinsic faults are formed by the insertion of an additional layer of atoms in the atom plane stacking sequence and are the type normally observed in oxidized silicon (6, 8). Stacking fault nuclei lie in the wafer prior to oxidation. Several causes of the nuclei have been observed, including mechanical damage, impurity centers, crystal growth defects, and ion implantation damage. During oxidation the stacking faults grow as two-dimensional structures lying on inclined (111) planes bounded by partial dislocations.

Also occurring during oxidation is the enhanced diffusion of dopant impurities in silicon (20-25). The growth of stacking faults and the enhancement of impurity diffusion during oxidation have some similarities:

1. Both the growth of oxidation-induced stacking faults (OISF) and oxidation-enhanced diffusion (OED) depend upon crystal orientation of surface planes. The rates of these effects increase in the order of (111), (110), and (100) (7, 20, 23, 26).

2. Both phenomena occur more rapidly in steam than in dry oxygen (5, 9, 23). This correlates with the higher oxidation rate in steam.

3. Both phenomena are the consequences of a long-range process. The density of bulk OISF decreases with increasing depth from the Si/SiO_2 interface (27). The effect of OED has been observed to reach ~ 10 μm below the interface (23).

4. Both OED and OISF phenomena are suppressed in the presence of HCl gas during oxidation (28).

5. Mechanical damage on the back side of a wafer eliminates stacking faults but does not affect OED (29).

Several models have been proposed to explain these results (2, 30, 31). Leroy (30) has shown that stacking fault growth models involving either the absorption of self-interstitials or emission of vacancies favor the model of interstitial absorption. It will be shown in this paper that by considering OED, OISF, oxidation and its doping dependence, retrogrowth of stacking faults, and the role of HCl gas in OED and OISF, a similar conclusion can be drawn. The model we favor is that of a super-saturation of silicon self-interstitials generated at the oxidizing Si/SiO_2 interface as a result of incomplete oxidation (2). The way in which these interstitials are generated and contribute to OED and OISF are described in the following sections. The role of chlorine in these phenomena is also discussed.

Oxidation

During silicon oxidation two types of reactions can occur at the Si/SiO_2 interface involving the diffusing oxidant species (presumably $O_I^=$ — interstitial oxygen ions). One involves $O_I^=$ and silicon, and this reaction dominates in lightly doped material (31)

$$O_I^= + Si \rightarrow Si_I\text{—}O + 2e^- \quad [1a]$$

$$O_I^= + Si_I\text{—}O \rightarrow SiO_2 + 2e^- \quad [1b]$$

$$2O_I^= + Si \rightarrow SiO_2 + 4e^- \quad [1c]$$

Ionized oxygen reacts with lattice-bound silicon and displaces the silicon to an interstitial position (reaction [1a]) to form Si_I—O. Presumably, reaction [1b] occurs a short time later. The net result is reaction [1c]. These reactions involving interstitial silicon are consistent with the results of Feldman *et al.* (32) who found from backscattering-channeling studies that the silicon atoms in the interface layer have a displacement from the bulk position between 0.1 and 1.0Å.

The possibility of creating a free self-interstitial would be greatest for the Si_I—O pair, were it to dissociate before SiO_2 is formed. It has been estimated that such an incomplete oxidation step occurs for 1 silicon atom out of 1000 (2).

The other reaction occurring at the Si/SiO_2 interface involves vacancies and $O_I^=$. Ho and Plummer (33, 34)

* Electrochemical Society Active Member.
Key words: silicon oxidation, stacking faults, diffusion, chlorine.

have modeled the enhanced oxidation of heavily doped silicon by correlating oxidation rate with the vacancy concentration dependence on doping. For vacancies generated at the interface in the rth charge state, V_{Si}^r, the primary reactions are (31) (see Fig. 1)

$$2\,O_I^{=} + 2\,V_{Si}^{r} \rightarrow 2\,O + (4 - 2l)e^- \quad [2a]$$

$$Si + 2\,O \rightarrow SiO_2 \quad [2b]$$

$$2\,O_I^{=} + Si \rightarrow SiO_2 + (4 - 2l)e^- \quad [2c]$$

In these reactions the charge state multiplicity of the vacancy is l, where $l = -2, -1, 0$, or $+1$ $(+2)$ corresponding to $V^{=}$, V^-, V^x, or V^+ (V^{++}) vacancies. Since there are no silicon interstitials generated in these reactions, one would not expect any concentration dependence in the phenomena of oxidation-enhanced diffusion. This agrees with initial experimental evidence (26), but additional data are needed for verification.

Silicon Self-Interstitial Generation

From the interface reaction [1a] we see that the concentration of Si_I—O pairs created is proportional to $[O_I^{=}]$. From the ionization reaction at the SiO_2 surface (see Fig. 1), $[O_I^{=}] \propto P_{O_2}^{1/2}$, where P_{O_2} is the O_2 partial pressure in the gas phase (14, 30). Since the oxidation rate is proportional to P_{O_2}, then, assuming a parabolic oxidation rate, the generation rate of silicon self-interstitials is

$$R_{gen} = \theta K_{Si}(T) \left(\frac{B^{1/2}}{2v_m}\right)^{1/2} t^{-1/4}$$

$$= K_{gen}\, t^{-1/4} \quad [3]$$

where $K_{Si}(T)$ is a complex equilibrium and proportionality constant, B is the parabolic rate constant, v_m is the molecular volume of SiO_2, and θ is the fraction of Si_I—O bonds which dissociate to form self-interstitials, Si_I. Equation [3] differs from the assumption of Hu (2) that the generation rate of Si_I was directly proportional to the oxidation rate. Hu's assumption leads to $R_{gen} \propto t^{-1/2}$ and stacking fault length $\propto t^{1/2}$. This assumption has also been criticized by Leroy (30).

Silicon interstitials may be captured at surface kink sites and contribute to surface regrowth at a rate (2)

$$R_{reg} = (\pi \rho \alpha_o D_{ISi})\,(C_I - C_I^o)$$

$$= K_{reg}\,(C_I - C_I^o) \quad [4]$$

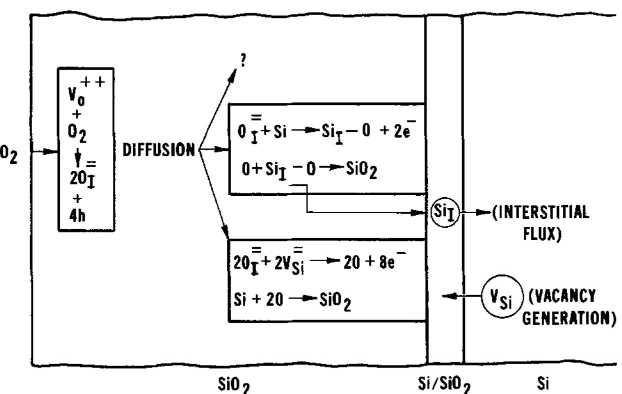

Fig. 1. Detailed reactions in the linear-parabolic oxidation model. Oxygen reacts at the oxide surface to create interstitial oxygen, $O_I^{=}$, and holes. $O_I^{=}$ ions drift to the Si/SiO_2 interface to react with either *(i)* silicon to form interstitial silicon and atomic oxygen which can combine to form SiO_2, or *(ii)* a silicon vacancy to form bound atomic oxygen which can react with silicon to form SiO_2. In the former process a silicon interstitial flux can occur if all of the interstitial silicon does not combine to form SiO_2. The latter process will only be significant if sufficient numbers of vacancies are present in the silicon (heavy doping case).

where ρ is the density of surface kinks ($\sim 10^{12}$ cm^{-2}), D_{ISi} is the silicon interstitial diffusivity, $C_I = [Si_I]$ is the concentration of self-interstitials, C_I^o is the equilibrium concentration, and α_o is the capture radius of interstitials by kinks.

Following the arguments of Hu (2) and knowing that the rate of self-interstitial formation is

$$h_t \frac{dC_I}{dt} = R_{gen} - R_{reg} \quad [5]$$

where h_t is the wafer thickness, it can be shown that for $t \gtrsim 6/K_{reg}$ ($t \geq 0.1$ sec for typical numbers)

$$\int_0^t (C_I - C_I^o)\,dt = \frac{4K_{gen}}{3K_{reg}}\, t^{3/4} \quad [6]$$

The rate of growth of stacking faults is given by

$$\frac{dr}{dt} = \pi \alpha_o^2 D_{ISi}\,(C_I - C_I^o) \quad [7]$$

and the time-dependent stacking fault length becomes

$$r = \frac{4\alpha_o\, K_{gen}\, t^{3/4}}{3\rho} \quad [8]$$

Equation [8] predicts a $t^{3/4}$ growth of stacking faults. Most of the reported data on stacking fault growth show a t^n dependence with n varying between 0.62 and 0.9 (4, 5, 7, 9, 16, 35).

In Eq. [8] the only temperature-dependent parameter is K_{gen}. Contained in K_{gen} is (from Eq. [3]) $K_{Si}(T)$ which has the exponential of the Si_I—O binding energy, and $B^{1/4}$. The parabolic rate constant has an activation energy, E_{par}, (36), so the total activation energy for stacking fault growth is

$$Q_{SF} = E_b\,(Si_I\text{—}O) + \frac{E_{par}}{4} \quad [9]$$

Equation [4] predicts that stacking fault growth is only limited by the generation of self-interstitials at the oxidizing Si/SiO_2 interface, and is not diffusion limited as assumed by Leroy (30). The energy of the silicon-oxygen bond is $\sim$2.2 eV (37). However, a large strain is likely to exist at the interface as a result of the molecular size mismatch. This strain should influence self-interstitial production. Tiller (38) has proposed that in the initial stages of oxidation silicon atoms form SiO bonds which are highly strained. He estimates that $\lesssim$ 2.6 eV elastic energy is stored in the interface which drives the flux of silicon self-interstitials so as to provide the free volume space for the SiO_2. Therefore, if we take $E_b(Si_I\text{—}O) \simeq 2.2$ eV and $E_{par} = 1.23$ eV for dry O_2 oxidation and $E_{par} = 0.78$ eV for wet O_2 oxidation (36), we find from Eq. [9]

$$Q_{SF}\ (\text{dry oxidation}) = 2.51\ \text{eV}$$

$$Q_{SF}\ (\text{wet oxidation}) = 2.4\ \text{eV}$$

This result agrees well with the measurements of Murarka and Quintana (16) who found Q_{SF} (dry oxidation) = 2.55 eV and Q_{SF} (wet oxidation) = 2.37 eV.

Stacking Fault Retrogrowth

An anomalous temperature effect has been observed in the growth of OISF (35). For a given oxidation time the size of the OISF first increases with temperature with an activation energy of $\sim$2.5 eV, reaches a peak length at some temperature, and then decreases with temperature. The temperature above which retrogrowth occurs is dependent upon the crystal orientation as well as oxidation ambients. Examples of the growth *vs.* temperature of OISF in dry oxygen for 3 hr (35) are shown in Fig. 2.

In order to account for growth and retrogrowth, Eq. [7] needs to be modified. If we define C_I^L as the con-

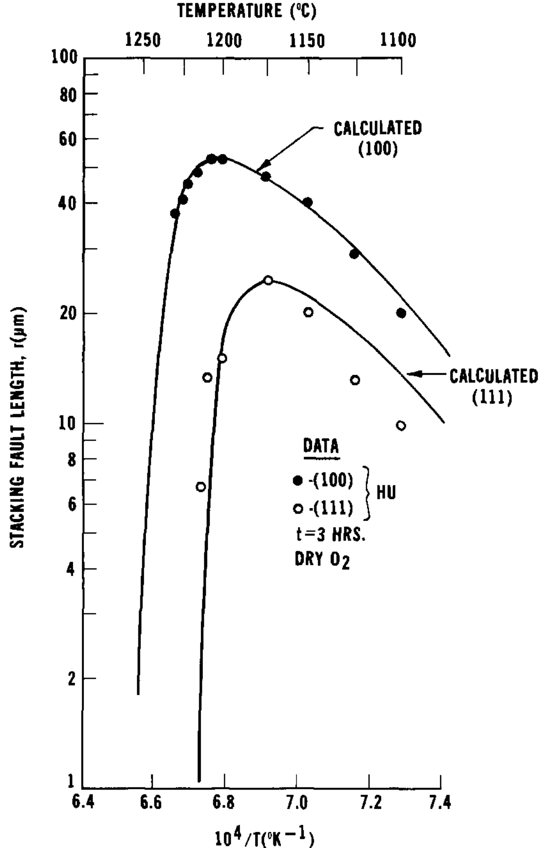

Fig. 2. The growth vs. temperature of oxidation-induced stacking faults in dry O_2 for 3 hr.

centration of self-interstitials at the dislocation line, then a stacking fault will grow if the steady-state interstitial concentration surrounding the dislocation is greater than C_I^L. Figure 3 represents the boundary conditions of this model. Thus

$$\frac{dr}{dt} = \pi\alpha_o^2 D_{ISi} (C_I - C_I^L) \quad [10]$$

Referencing these concentrations to C_I^o, the equilibrium concentration, then (39, 40)

$$\frac{C_I^L}{C_I^o} = \exp(\Delta F_L/kT) \quad [11]$$

where ΔF_L is the change in dislocation loop free energy per additional incorporated atom. The silicon interstitial supersaturation, C_I/C_I^o, can be estimated by integrating Eq. [6]. The result is

$$\frac{C_I}{C_I^o} = 1 + \frac{\theta K_{Si}(T) B^{1/4}}{\sqrt{2v_m}\, \pi\rho\alpha_o D_{ISi} C_I^o t^{1/4}} \quad [12]$$

Little is known about the term ($D_{ISi}C_I^o$). Therefore it will be assumed that the flux of self-interstitials is some fraction of the flux of silicon atoms diffusing via the vacancy mode of self-diffusion (24, 31)

$$D_{ISi}C_I^o = f_I\, n_H\, D_{Si} \quad [13]$$

where f_I is the fractional interstitial contribution, n_H is the number of host lattice sites, and D_{Si} is the self-diffusion coefficient of silicon. Finally, Eq. [10] becomes

$$\frac{dr}{dt} = \pi\alpha_o^2 \left[- n_H D_{Si} f_I \left\{ \exp\left(\frac{\Delta F_L}{kT}\right) - 1 \right\} + \frac{\theta K_{Si}(T)\, B^{1/4}}{\sqrt{2v_m}\, \pi\rho\alpha_o\, t^{1/4}} \right] \quad [14]$$

By using the relations above we have separated the growth rate expression into two parts. The first term in brackets is always negative since $\Delta F_L > 0$. This term is related to the emission of interstitials from the fault line (or absorption of vacancies). The second term is the relative steady-state concentration of generated interstitials under oxidizing conditions. The relative magnitudes of these two terms will determine whether dr/dt is positive (growth) or negative (retrogrowth).

Equation [14] has been fitted to OISF growth data in order to estimate f_I and θ. The surface kink density for <100> silicon was taken to be $\rho \simeq 10^{12}$ cm^{-2} and the atomic volume is $v_m \simeq 2 \times 10^{-23}$ cm^3. Hu (2) estimated the capture cross section of a kink for an interstitial to be $\sim \pi\alpha_o^2$, where α_o is on the order of the surface step height (3.85×10^{-8} cm). ΔF_L is the sum of the dislocation line energy and the stacking fault energy, γ. Since the line energy varies inversely with the line length, we consider only large interstitial-type stacking faults in which the line energy can be neglected. For silicon, $\gamma \simeq 3 \times 10^{13}$ eV/cm^2 (40). For an atomic cross section in the (111) plane of 12.77 $\times 10^{-16}$ cm^2 (39), $\Delta F_L = 0.04$ eV. It will be shown later that a better fit to OISF shrinkage data occurs when $\Delta F_L = 0.15$ eV, so that this value will be used in our calculations.

The two terms in Eq. [14] are plotted *vs.* temperature in Fig. 4. It can be seen that at $T \simeq 1210°$C, $dr/dt = 0$. Above this temperature the emission of silicon interstitials exceeds their generation at the silicon surface, and $dr/dt < 0$. This result is also shown in Fig. 2 where at $T \simeq 1210°$C, stacking fault growth has stopped for <100> silicon.

By integrating Eq. [14] we can obtain the time dependence of OISF growth. Thus, substituting in the appropriate numbers for <100> silicon we find for dry O_2 oxidation in 100% O_2

$$r = 4017 t^{3/4} \exp\left(\frac{-2.51 \text{ eV}}{kT}\right) - 3.6 \times 10^{10}\, t \exp\left(\frac{-5.02 \text{ eV}}{kT}\right) \left[\exp\left(\frac{0.15 \text{ eV}}{kT}\right) - 1\right] \quad [15]$$

This equation is similar to the result obtained by Leroy (30), even though some of his assumptions and analyses were different. Also, Lin *et al.* (41) arrived at a similar result empirically. The major differences between the model described here and Leroy's model are: (*i*) we assume OISF growth is limited by the generation of self-interstitials at the Si/SiO_2 interface, rather than limited by diffusion, (*ii*) we calculate C_I^L from the dislocation free energy, (*iii*) we assume silicon self-diffusion occurs via a fractional interstitialcy mechanism as proposed by Antoniadis *et al.* (24).

Equation [15] is plotted in Fig. 2 for 3 hr oxidations performed at various temperatures in dry O_2 (35). An excellent fit to the data is obtained. The calculation for <111> silicon was made by increasing the kink density, ρ, 1.5 times over the <100> case. This reduces the growth term in Eq. [14] and [15]. From the fitted coefficients in Eq. [15] we find $f_I = 0.19$ and $\theta = 0.043$.

Doping Dependence of OISF Shrinkage

In the retrogrowth term, D_{Si} is doping dependent. The shrinkage of stacking faults in doped layers annealed in dry N_2 becomes (31, 42)

$$\frac{dr}{dt} = -\pi\alpha_o^2 n_H f_I \left[D_{Si^x} + D_{Si^-}\left(\frac{n}{n_i}\right) + D_{Si^+}\left(\frac{p}{n_i}\right)\right]\left[\exp\left(\frac{\Delta F_L}{kT}\right) - 1\right] \quad [16]$$

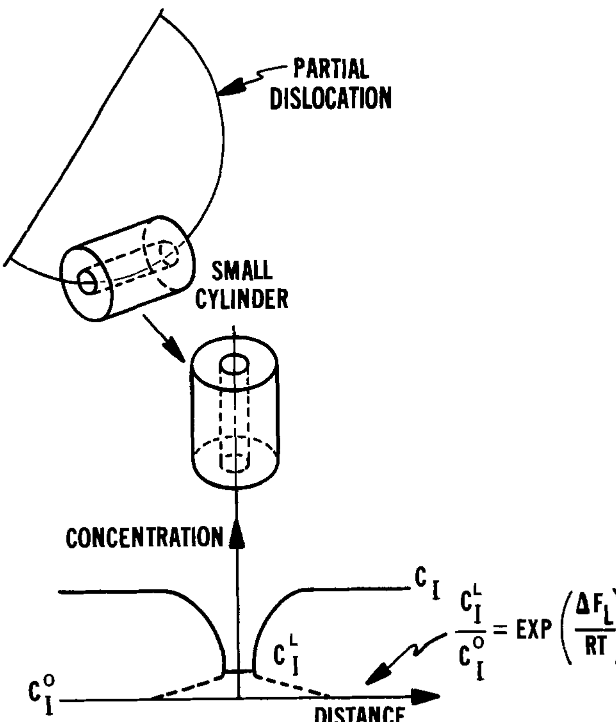

Fig. 3. A model of self-interstitial diffusion from the bulk to the partial dislocation bounding a stacking fault. Under nonoxidizing conditions, the concentration of self-interstitials at the fault line, C_I^L, is greater than the equilibrium bulk interstitial concentration C_I°. Under oxidizing conditions, $C_I > C_I^L$ until the retrogrowth temperature is reached.

where D_{Si} is the silicon diffusivity via vacancies in the rth charge state. Using the empirically determined values of D_{Si}^x, D_{Si}^-, and D_{Si}^+, (42), dr/dt is shown plotted in Fig. 5 *vs.* n and p at 1100°C. For this calculation $\alpha_0 = 3.85 \times 10^{-8}$ cm^{-2}, $f_I = 0.19$, and $\Delta F_L = 0.04$ eV. Also shown are 1100°C estimated OISF shrinkage rates from the data of Hashimoto *et al.* (43) for both n and p-type silicon. The calculated curves show a similar dependence on doping for both n and p-type silicon. By setting $\Delta F_L \simeq 0.15$ eV we can make the data and calculations agree well (dashed curves in Fig. 5). However, the data are not sufficiently accurate in absolute value to decide if this larger stacking fault energy is real.

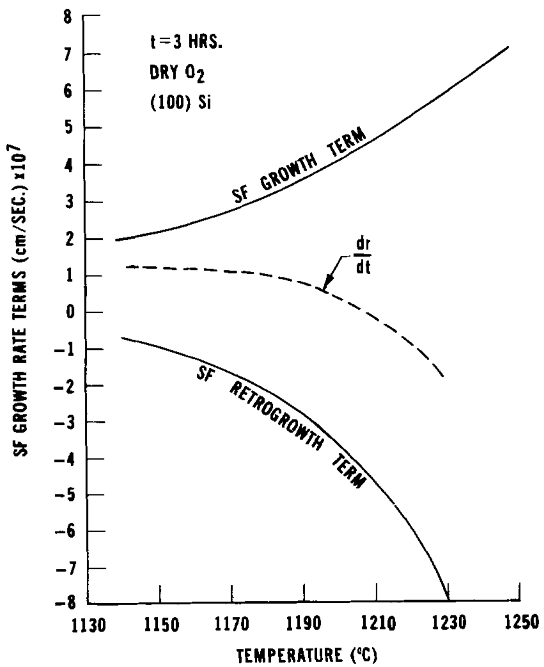

Fig. 4. Stacking fault growth rate term and retrogrowth rate term summed to give the net rate.

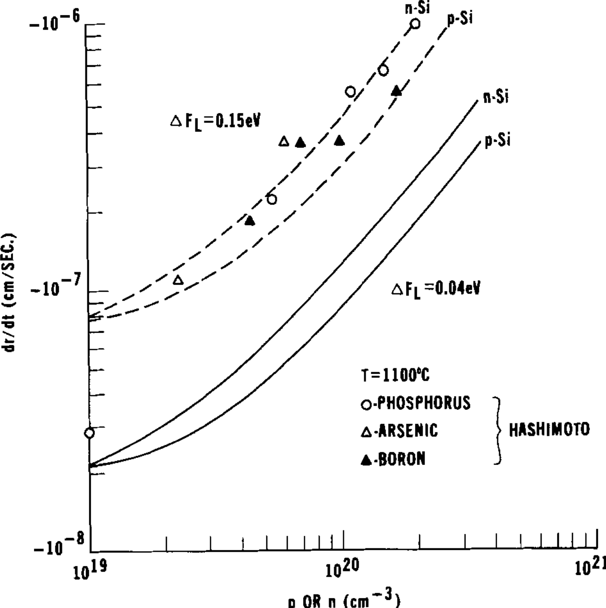

Fig. 5. Donor and acceptor doping effect on stacking fault shrinkage rate at 1100°C.

The implication here is that the emission of silicon atoms from a stacking fault is enhanced at large doping concentrations by the presence of additional vacancies, as proposed by Hashimoto *et al.* (43). It has been shown how additional vacancies generated near the surface can account for the doping-enhanced oxidation rate (linear rate constant only) (33, 34). Likewise, in a heavily doped layer that is not being oxidized, the increase in the equilibrium vacancy concentration with doping can account for the enhanced migration of silicon atoms away from the stacking fault or for increased absorption of vacancies by the fault.

Effect of Chlorine on OISF Growth

It has been reported that the introduction of small amounts of chlorine or chlorine-containing compounds during silicon oxidation in dry O_2 causes the retarded growth or annihilation of OISF (44-47). The higher the chlorine concentration, the more rapid is the OISF retrogrowth. Also, the temperature at which retrogrowth occurs decreases with increasing chlorine concentration.

Because chlorine atoms localize at the Si/SiO_2 interface, Murarka (48) has proposed a two-step mechanism that can reduce the number of silicon interstitials that flow into the silicon substrate. In the first step, chlorine reacts with silicon atoms on lattice sites to form $SiCl_u$ by the reaction

$$Si + \frac{u}{2} Cl_2 \leftrightarrows SiCl_u + V_{Si} \quad [17]$$

In the process a silicon vacancy is generated. This vacancy then is available to recombine with a silicon interstitial produced due to oxidation

$$Si_I + V_{Si} \leftrightarrows Si \quad [18]$$

The condition for retrogrowth would then depend upon whether the chlorine concentration was sufficient to produce enough vacancies to cause $dr/dt = 0$.

Reaction [17] is consistent with the observation that the presence of HCl during dry O_2 oxidation increases the linear rate constant, B/A (49-51). The doping dependence of B/A has also been described as a vacancy enhancement effect.

In terms of Eq. [14] then, the effect of chlorine at the Si/SiO_2 interface is to increase B, but also to decrease θ. From published data (50) $B \propto p_{HCl}^{1/8}$. From Eq. [17] and [18], (48)

$$[Si_I] \propto p_{Cl_2}^{-u/2} \qquad [19]$$

Thus, since $\theta \propto [Si_I]$ we have

$$\theta B^{1/4} \propto p_{Cl_2}^{(1/32-u/2)} \qquad [20]$$

since $p_{HCl} \propto p_{Cl_2}$ (48). Substituting Eq. [20] into Eq. [14] and integrating for stacking fault length for a 2 hr, 1100°C dry O_2/HCl oxidation we find for $p_{Cl_2} > 0$

$$r = K_c p_{Cl_2}^{(1/32-u/2)} \ (\mu m) \qquad [21]$$

At $p_{Cl_2} = 1\%$, $r = 6.0\ \mu m$ after 2 hr. Using this boundary condition, Eq. [21] is plotted with $u = 1$ in Fig. 6 *vs.* percent HCl in oxygen. Also plotted are data of Shiraki (46) obtained under these same conditions. The agreement is quite good. This result implies that only one chlorine atom is involved in the reaction at the Si/SiO_2 interface which generates a vacancy. On the other hand, Murarka's analysis (48) yields $u = 2$, implying that a Cl_2 molecule is involved. The difference is a result of our assumption that the generation of self-interstitials is proportional to $P_{O_2}^{1/2}$ rather than P_{O_2} as Murarka assumed.

We can conclude that the model of chlorine combining with silicon to form SiCl and a vacancy is consistent with the observed increase in the linear rate constant, B/A. Also, the subsequent reduction in stacking fault growth rate is consistent with the reduction in the number of silicon interstitials which are generated during oxidation. This reduction is brought about by the trapping of interstitials by excess vacancies created when SiCl is formed (48).

Oxidation-Enhanced Diffusion

A model explaining orientation-dependent diffusion has been proposed by Hu (2). Briefly, this model is based upon the super-saturation of silicon interstitials at concentrations dependent on the oxide growth rate and silicon orientation. These interstitials are responsible for the growth of stacking faults, and by invoking a partial interstitialcy diffusion mechanism, also influence impurity diffusion enhancement.

To show how the enhancement of impurity diffusion by self-interstitials can act while the dominant diffusion mechanism is a vacancy-assisted process (31, 42), it will be assumed that exchanges can take place between the various species in the silicon lattice (vacancies, self-interstitials, interstitial impurities, and substitutional impurities). Interstitial impurities, I_I, can be created by the exchange between a self-interstitial, Si_I, and a substitutional impurity, I_S (the Watkins replacement mechanism) (52)

$$Si_I + I_S \xrightarrow{k_{SI}} I_I \qquad [22]$$

Interstitial impurities can return to substitutional sites primarily by recombination with vacancies

$$I_I + V_{Si} \xrightarrow{k_{VS}} I_S \qquad [23]$$

These processes are illustrated in Fig. 7. If it is assumed that vacancies and self-interstitials are very mobile compared to impurities, and if we assume a steady-state concentration of these point defects, then we can write down a set of coupled equations following the work of Baruch (53)

$$\frac{\partial C_{II}}{\partial t} = D_{II}\frac{\partial^2 C_{II}}{\partial x^2} - \frac{C_{II}}{\tau_I} + k_{SI}C_I C_{SI} \qquad [24]$$

$$\frac{\partial C_{SI}}{\partial t} = D_{SI}\frac{\partial^2 C_{SI}}{\partial x^2} + \frac{C_{II}}{\tau_I} - k_{SI}C_I C_{SI} \qquad [25]$$

In the above equations C_{II} is the concentration of interstitial impurities, C_{SI} is the concentration of substitutional impurities, C_I is the self-interstitial concentration, k_{SI} and k_{VS} are the rate constants of reactions [22] and [23], respectively, and

$$\tau_I^{-1} = k_{VS}\, C_V \qquad [26]$$

If we define the total impurity concentration as $C_T = C_{II} + C_{SI}$, then it can be shown that by adding Eq. [24] and [25], the resulting continuity equation is (31)

$$\frac{\partial C_T}{\partial t} = D_{SI}\left(1 + f_{II}\frac{C_I}{C_I^\circ}\right)\frac{\partial^2 C_{SI}}{\partial x^2} \qquad [27]$$

where C_I° is the equilibrium self-interstitial concentration, f_{II} is the fractional partial-interstitialcy contribution to impurity diffusion, and C_I/C_I° is the self-interstitial supersaturation given by Eq. [12].

In Eq. [27] we have defined an effective diffusivity of doping impurities for the case where vacancy-dominated diffusion is supplemented by a partial interstitialcy diffusion process. The fraction of the substitutional flux that occurs by this latter mechanism is f_{II}. Values of f_{II} for boron, phosphorus, and arsenic have been obtained by fitting the effective diffusivity to OED data (31). For example, the diffusivity of boron in <100> silicon in dry O_2 is shown plotted in Fig. 8 (54). Also shown is the diffusivity of boron, $D = D_{SI}$, under a nonoxidizing surface. Good agreement with the measured data occurs when $f_{II} = 0.17$ in the equation for effective diffusivity (Eq. [27]). Thus, under nonoxidizing conditions, $C_I/C_I^\circ = 1$ and ~17% of the flux of boron is due to the proposed partial interstitialcy process driven by the equilibrium self-intersti-

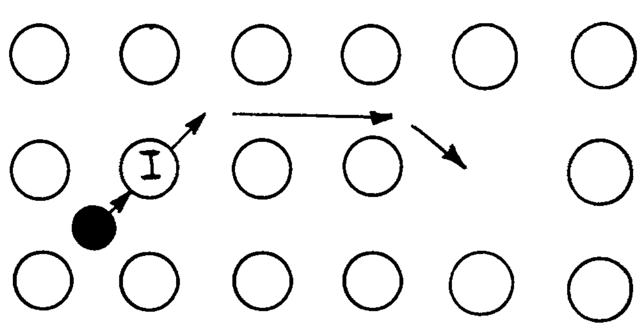

Fig. 7. Schematic diagram of the partial interstitialcy diffusion model (Watkin's replacement mechanism). A silicon self-interstitial replaces a substitutional impurity atom. The interstitial impurity migrates until it combines with a vacancy.

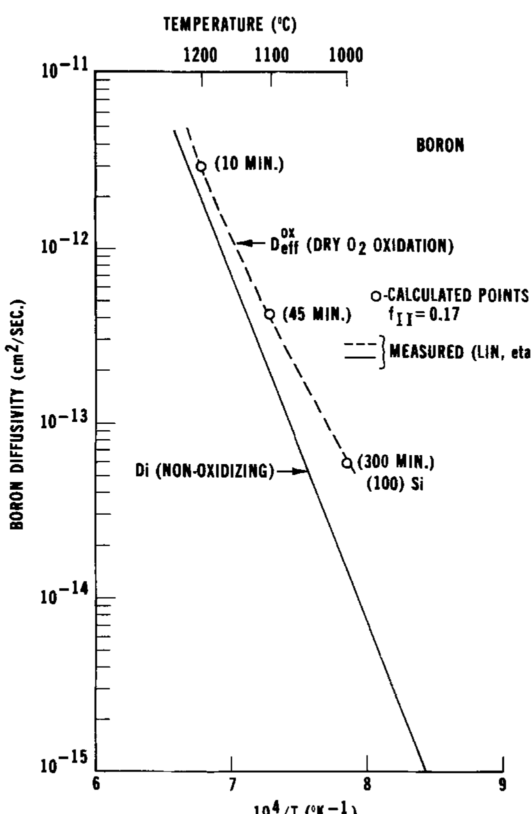

Fig. 8. Boron diffusivity in <100> silicon in nonoxidizing and dry O_2 oxidizing ambients. The solid and dashed curves were measured [Ref. (54)], and the points are calculated from Eq. [27].

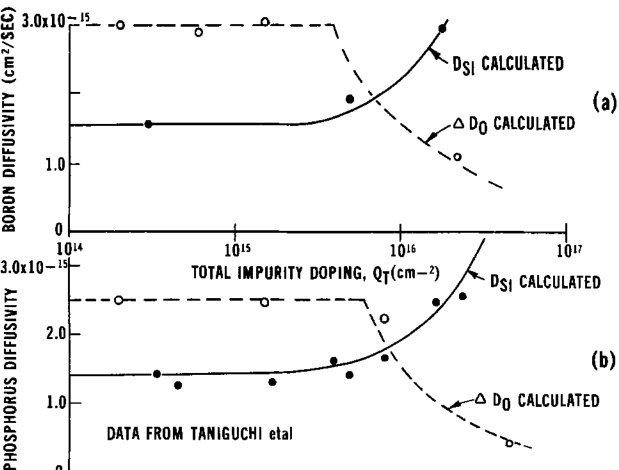

Fig. 9. Diffusivities of (a) boron and (b) phosphorus during wet O_2 oxidation at 1100°C, *vs.* the total amount of impurity.

tial concentration. For phosphorus, $f_{II} = 0.12$ and for arsenic, $f_{II} = 0.09$. These factors correlate with the energy required to create an interstitial impurity (31).

An additional observation of OED was recently made by Taniguchi *et al.* (55). They found that OED decreased as the concentration of the diffusing impurity increased beyond the point where normal concentration dependent diffusion occurs. This effect was explained in terms of the reduction of oxidation-produced self-interstitials by recombination with the increasing concentration of vacancies. If we assume that the equilibrium vacancy concentration is unaffected by the self-interstitials generated at the interface, but that the quasi-steady-state value of C_I/C_I^o is inversely proportional to the vacancy concentration, then the effective diffusivity in Eq. [27] can be written generally as

$$D_e \simeq D_n + \Delta D_o$$

$$\simeq D_{SI}\left(\frac{C_v}{C_v^i}\right) + D_{SI} f_{II}\left(\frac{C_I}{C_I^o}\right)_i \left(\frac{C_v^i}{C_v}\right) \quad [28]$$

where $(C_I/C_I^o)_i$ is the self-interstitial supersaturation under intrinsic doping conditions, and C_v/C_v^i is the vacancy enhancement that occurs when $n > n_i$ or $p > n_i$. Equation [28] has been divided into the contribution to diffusion under nonoxidizing conditions, D_n, and the OED enhanced contribution.

The data of Taniguchi *et al.* (55) are shown in Fig. 9 for OED of phosphorus and boron *vs.* the total number of impurities/cm², Q_T. For the boron data in Fig. 9a, D_n becomes concentration dependent at $Q_T \simeq 4 \times 10^{15}$ cm^{-2}, corresponding to prediffused layers ($X_J = 3.2$ μm) which were subsequently diffused at 1100°C in wet O_2. According to Eq. [28], ΔD_o should decrease when $C_v > C_v^i$ or when $p > n_i$. For extrinsic boron diffusion we know that $Q_T \propto C_S^{3/2}$ (56), where $C_s \simeq p_s$ is the surface concentration. Thus, we expect that $\Delta D_o \propto Q_T^{-2/3}$ for $p_s > n_i$. Similarly, since $D_n \propto p/n_i$, then $D_n \propto Q_T^{2/3}$ for $p_s > n_i$. These results are plotted in Fig. 9a, and the agreement with the data is reasonable.

For the phosphorus case diffusion is controlled primarily by $V^=$ vacancies which form $P^+V^=$ pairs in the high concentration region, and which subsequently dissociate and flood the bulk. This increase in the steady-state vacancy concentration raises the diffusivity of phosphorus and creates a tail on the profile (57). If it is assumed that diffusion in the tail dominates, then $D_n \simeq D_i^x + D_{TAIL}$, where D_i^x is the intrinsic phosphorus diffusivity via neutral vacancies. It can be shown (58) that since $n_s \propto Q_T^{1/2}$, where n_s is the surface electron concentration, then

$$D_n \simeq D_i^x + K_i(T)\, Q_T^{3/2} \quad [29]$$

$K_i(T)$ is a collection of terms from the Fair-Tsai model (57) that can be directly calculated. Equation [29] is shown plotted in Fig. 9b and agrees well with the D_n data (55) for phosphorus. It can also be shown then that for $n >> n_i$ this model predicts

$$\Delta D_o \propto Q_T^{-1} \quad [30]$$

This result is also plotted in Fig. 9b starting at $Q_T = 6 \times 10^{15}$ cm^{-2}. This total doping corresponds to $n_s \simeq 6 \times 10^{19}$ cm^{-3}. It is known (57) that at 1100°C, D_{TAIL} begins to show a strong concentration dependence at this surface concentration.

In summary it has been shown that Taniguchi's model (55) of self-interstitial recombination with vacancies is consistent with the high concentration diffusion models for boron and phosphorus. In addition, the observed decrease in OED with increasing concentration lends support to the notion of two separate but interdependent diffusion mechanisms operating during oxidation.

The Effect of Chlorine on OED

If chlorine or chlorine-bearing compounds are added to oxygen in sufficient concentrations that the resulting mixture in a furnace will cause stacking fault retrogrowth in silicon, oxidation-enhanced diffusion will also become negligible (28). In order to understand the effect of chlorine compounds on OED, recall that the concentration of generated silicon interstitials depends on the partial pressure of HCl through the relation (from Eq. [19])

$$C_I \propto (p_{HCl})^{-1/2} \quad [31]$$

Thus, the effective impurity diffusivity during HCl oxidation is

$$D_{eff}^{ox} = D_{SI}\,(1 + K_H\,(p_{HCl})^{-1/2}) \quad [32]$$

where K_H is temperature and orientation dependent. This equation has been adjusted through K_H to fit the

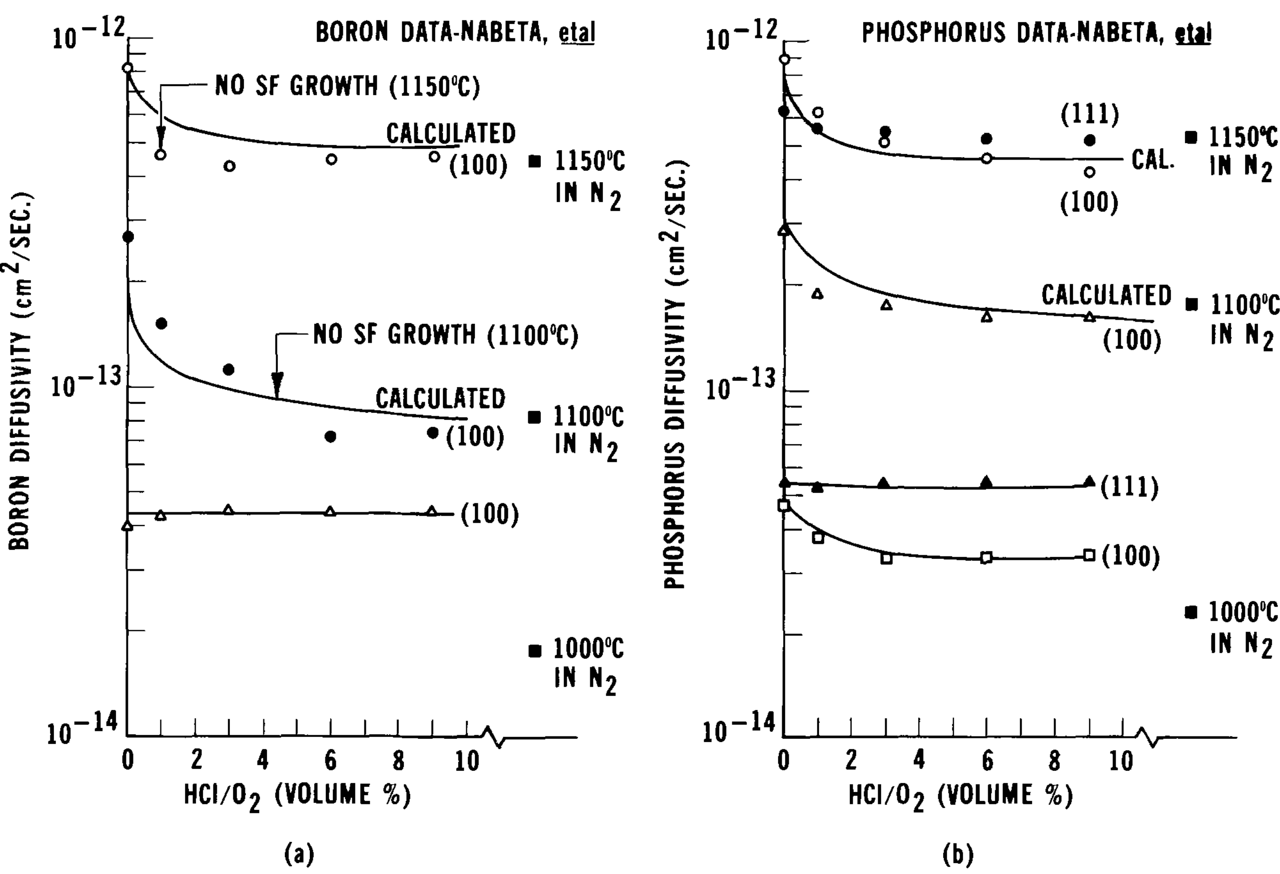

Fig. 10. Diffusivities of (a) boron and (b) phosphorus during $HCl-O_2$ oxidations vs. HCl concentration in the ambient

data of Nabeta *et al.* (28) shown in Fig. 10. The agreement with the data is reasonable for the case of boron.

The OED of phosphorus shown in Fig. 10b has some anomalies which appear to contradict the model presented here. It can be seen that at 1150°C phosphorus diffuses more rapidly in <100> silicon as compared to <111> when the HCl volume ratio is $<2\%$. At higher HCl flow the diffusivity in <111> silicon is greater. At 1000°C the OED of phosphorus is greater in <111> than <100> for HCl volume ratios $>0\%$. However, the reduction of OED to the neutral ambient case does not occur over the range of HCl flows investigated.

In order to understand these results we need to be aware of the concentration of phosphorus used in the experiments as well as the diffusion times and temperatures. Nabeta *et al.* (28) whose data are shown in Fig. 10b started with prediffused phosphorus layers whose surface concentrations were greater than 2×10^{20} cm^{-3}. Masetti *et al.* (59) who also saw significant OED in <111> silicon at 1000°C prediffused their wafers with highly doped phosphorus (final C_s after OED drive-in was $\sim 5 \times 10^{19}$ cm^{-3} and $X_J \simeq 5$ μm). Similar results were obtained by Francis and Dobson (60) who observed OED in <111> silicon epitaxial layers doped to $\sim 5 \times 10^{17}$ cm^{-3}. However, their results have been put into question because the OED enhancement was referenced to diffusion under an Si_3N_4 mask deposited directly on the silicon surface. It has been shown that the compressive stress in the silicon due to the Si_3N_4 overlayer can reduce the diffusion of low concentration profiles (61).

It has been shown that phosphorus diffusion at high concentrations in nonoxidizing ambients is greater in <111> silicon than in <100> (62). An example is shown in Fig. 11 where measured profiles are plotted of 60 min 900°C $POCl_3$ diffusions. At low concentrations the diffusivities in <100> and <111> silicon are the same with nonoxidizing furnace ambients.

The effective diffusivities plotted by Nabeta *et al.* (28) can be estimated as

$$D_e = D_n + \frac{K_H'}{p_{HCl}^{1/2}\, \rho} \left(\frac{C_v^{i}}{C_v} \right) \quad [33]$$

where ρ is the surface kink density and $K_H' \alpha$

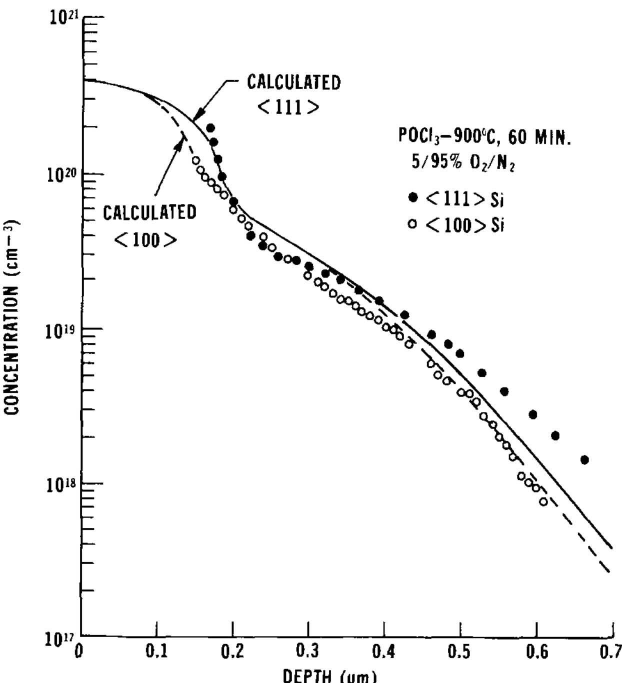

Fig. 11. Measured (62) and calculated profiles of phosphorus diffused for 60 min at 900°C in <111> and <100> silicon in a $POCl_3$ in N_2 furnace ambient. Calculations are based on the Fair-Tsai model (57) with orientation-dependent strain distribution.

exp (2.5 eV/kT) D_{SI}. At high phosphorus concentrations [$n_s > n_e$ where n_e increases from 10^{20} cm^{-3} at 900°C to 2×10^{20} cm^{-3} at 1150°C (57)] diffusion in oxidizing ambients is such that $D_e \simeq D_n$ (see Fig. 9b). Then

$$\frac{D_e(111)}{D_e(100)} \sim \frac{D_n(111)}{D_n(100)}$$

and $D_e(111) > D_e(100)$. From Fig. 11 this ratio is $\simeq$1.4. From Fig. 10b the 1000°C data show $D_e(111)/D_e(100) \simeq 1.3$. At low phosphorus concentrations ($n_s < n_i$) and 0% HCl/O_2

$$\frac{D_e(111)}{D_e(100)} \simeq \frac{\rho(100)}{\rho(111)} \simeq \frac{2}{3}$$

From Fig. 10b the 1150°C data show $D_e(111)/D_e(100) \simeq 2/3$ at $p_{HCl} = 0$. As p_{HCl} increases the OED term in Eq. [33] becomes smaller relative to D_n. And $D_e(111)/D_e(100) = > D_n(111)/D_n(100) \simeq 1.4$. This reversal in the relative enhancement of $D_e(111)$ to $D_e(100)$ can be seen to occur at 1150°C in Fig. 10b as p_{HCl} increases. However, further discussion of these data would require more complete knowledge of the diffusion profiles.

The only remaining question regarding the orientation dependence of phosphorus diffusion concerns the question of why $D_n(111) > D_n(100)$ at high doping levels. This has not been observed for other dopants, and it is believed to be due to the unusual way in which phosphorus diffuses in the presence of its own strain distribution. It has been observed that the misfit tensile stress of phosphorus at $C_s \gtrsim 3 \times 10^{20}$ cm^{-3} is sufficient to retard diffusion significantly due to narrowing of the silicon bandgap (63). Bandgap narrowing can reduce the number of $P^+V^=$ pairs which dominate diffusion at high doping levels (57). Fukuhara *et al.* (64) have calculated the strain distributions of diffused phosphorus layers in <100> and <111> silicon. They have shown that the strain component parallel to the <100> surface is 1.23 times larger than the corresponding strain in <111> silicon. As a result, the amount of bandgap narrowing in <100> is also 1.23 times as large as in <111>. Then, the ratio of diffusivities in the phosphorus tail region can be written as (63)

$$\frac{D_{TAIL}(111)}{D_{TAIL}(100)} = \exp \frac{3(\Delta Eg(111) - \Delta Eg(100))}{kT} \quad [34]$$

Using $\Delta Eg(100) = 1.23\, \Delta Eg(111)$ and for tensile stress (63)

$$\Delta Eg(111) = -0.7 \times 10^{-22} C_s \quad [35]$$

we find that for $C_s = 5 \times 10^{20}$ cm^{-3} and $T = 900°C$

$$\frac{D_{TAIL}(111)}{D_{TAIL}(100)} \simeq 1.3$$

This result is in good agreement with the data in Fig. 11. Further illustration that the strain effect can account for high concentration, orientation-dependent diffusion is shown in Fig. 11 where computer-generated profiles are compared with the data. The agreement is good.

We can conclude then that studies of the effect of HCl on OED of phosphorus should be conducted with $C_s \lesssim n_e$ in order to avoid complications in interpreting the results. However, from the preceding analysis it is believed that the phosphorus data in Fig. 10b are consistent with the proposed model of HCl reducing the extent of OED.

Summary and Conclusions

We have presented a consistent picture which ties together numerous observations and models of the oxidation process, the growth of stacking faults, enhanced diffusion, and the effects of chlorine compounds on these processes. Silicon self-interstitials generated at the Si/SiO_2 interface as a result of incomplete oxidation (Hu's model) (2) raise the concentration of self-interstitials in the silicon surface region. Some of these interstitials participate in surface regrowth which is orientation dependent. The number of surface kinks or regrowth sink sites increases with the order (100), (110), and (111). Thus, the number of self-interstitials that are available for OED and OISF growth decreases in the same order. OED can be explained in terms of a partial interstitialcy mechanism which kicks impurities into the silicon interstices so that interstitial diffusion occurs until recombination of the impurity with a vacancy takes place (Watkin's replacement model) (52).

Retrogrowth of stacking faults and reduced OED both occur when the concentration of generated self-interstitials decreases. We view OISF growth as a dynamic process whereby growth will occur if the relative steady-state self-interstitial concentration around the fault exceeds the emitted concentration of interstitials from the fault line. Retrogrowth occurs when the reverse is true. The introduction of chlorine-bearing compounds into the oxidation tube can bring about retrogrowth and reduced OED if the chlorine concentration is large enough. The reaction of chlorine with silicon at the interface creates vacancies which can combine with generated self-interstitials and reduce their concentration (Murarka's model) (48).

Interaction of CVD Silicon with Molybdenum Substrates

M. J. Rice, Jr.* and K. R. Sarma*

Motorola Incorporated, Solar Energy R&D Department, Phoenix, Arizona 85008

ABSTRACT

The interaction of CVD silicon with bulk molybdenum substrates was studied as part of a project to grow thin sheets of polysilicon. Deposited silicon sheets separate from the substrate by the thermal expansion shear separation (TESS) technique. The silicide formation was found to play an essential role in the shear separation mechanism. Two silicide phases were formed and identified as $MoSi_2$ and Mo_5Si_3. The diffusive processes were studied and growth rates of $MoSi_2$ determined. Void formation was observed and concluded to be necessary for shear separation to occur. Silicon was the primary diffuser in $MoSi_2$ leading to the void formation at the Si-$MoSi_2$ interface. The presence of oxygen in the process gases decreased the growth rate of $MoSi_2$. It is postulated that oxygen inhibits silicon diffusion which in turn affects void formation and reliable shear separation. Silicon nucleation characteristics with various substrate surface preparations were investigated.

The formation of transition metal silicides has been the subject of many papers and symposia in recent years (1-3). The great interest has been generated from the use of transition metals for ohmic or rectifying contacts to single crystal silicon for electronic applications. Another area of interest has been the formation of silicides on refractory metals to protect the metal against high temperature oxidation (4-6). Whether dealing with a thin metal film on a silicon substrate or bulk metal substrates reacting with silicon, it is important to understand the diffusive processes taking place during silicide formation. The present study is concerned with the interaction of chemical vapor deposited silicon with bulk molybdenum. This work was part of a project to grow silicon in the form of thin sheets for low-cost solar cells.

The process for producing self-supporting polysilicon films consists of depositing silicon on temporary substrates and separating the silicon from the substrate by the thermal expansion shear separation (TESS) technique (7). The silicon is deposited from a silicon bearing gas at a high temperature, 1000°-1200°C. Subsequent cooling of the substrate and silicon film releases the deposited silicon from the substrate. The shear stresses generated at the substrate-silicon interface due to differences in their thermal expansion coefficients, coupled with a weak bond across the interface, make the separation process feasible. It will be shown that void formation plays an important role in the separation. Molybdenum, as well as the chemically

* Electrochemical Society Active Member.

Key words: diffusion, interfaces, nucleation, semiconductor.

similar tungsten, have proven to be reliable and reusable temporary substrates.

The silicide formation was found to play an essential role in the shear separation mechanism of silicon from molybdenum substrates. The diffusive processes were studied and pictures of Kirkendall voids (9) were obtained. They are not only necessary for the shear separation observed in this work but could have significance in thin film contact adhesion on silicon. Silicon nucleation characteristics with various substrate surface preparations and growth conditions were also investigated.

Experimental

Molybdenum substrates were cut from 0.040 in. thick sheets with a class 300 finish. Typical analyses showed <15 ppm Fe and Ca and other impurities <10 ppm. The substrates were cleaned by washing in a detergent solution, rinsed in DI water, and degreased in organic solvents unless otherwise noted.

Depositions were carried out in a conventional, horizontal, induction heated CVD reactor using $SiCl_4$ and H_2 process gases. The hydrogen was withdrawn from a liquid source and contained <2 ppm H_2O and <1 ppm O_2. The $SiCl_4$ was semiconductor grade used in epitaxial growth. Temperatures were measured with a disappearing filament pyrometer which had been calibrated to account for emissivity, absorption by the quartz reaction tube, and the mirror used to view the susceptor and substrate. Substrates were placed on a silicon carbide-coated graphite susceptor, and a mask cut from 0.015 in. thick molybdenum was placed on top to mask the edges so that silicon did not deposit over the edges of the substrate. In this way a rectangular sheet of silicon would shear from the substrate without cracking. After purging the furnace with nitrogen, the substrate was heated to the deposition temperature (1150°C) in hydrogen and the temperature allowed to stabilize for 15 min. $SiCl_4$ was then added to the gas stream as well as dopant gas, B_2H_6 or PH_3. Microcrystalline silicon sheets 150-250 μm thick were grown in 90 min with areas from 75 to 210 cm². Upon completion of the deposition, the rf power was turned down so that the cooling rate was about 30°C/min. Under these conditions, the silicon separated from the $MoSi_2$ layer on the substrate in the range of 700°-1000°C. Special experiments were carried out in similar fashion except for substrate size, cooling rate, deposition temperature, or process gases as noted in the results and discussion. Silicide layer thicknesses were measured microscopically by averaging ten observations. Samples were mounted and polished by standard metallographic techniques. It was found that staining the samples with an $FeCl_3$ solution (10g $FeCl_3$, 2 ml HCl, 95 ml H_2O) for a few seconds aided in identifying phase boundaries and various layers.

Results

In Fig. 1 and 2 are presented the data for the growth of $MoSi_2$. The plot of the thickness squared *vs.* time in Fig. 1 indicates that the kinetics follow a parabolic law for long times but not in the initial portion of the reaction since the extrapolated curve does not pass through the origin. The experimental points for short times are high because it was not possible to quench the samples in the apparatus used and the small amount of growth which continued during cool-down would be a significant amount of the total growth for short times. It should be pointed out that the data for times longer than 90 min are the result of repeated 90 min runs on the same substrates. A normal run to produce silicon sheets was 90 min so that cross sections were made on substrates used for consecutive depositions, with the silicon shearing off after each run. The data of Gage and Bartlett (8) are shown in Fig. 2, with their growth rates considerably higher. However, they packed molybdenum rods in silicon and NaF to form $MoSi_2$ at high temperatures and obtained only

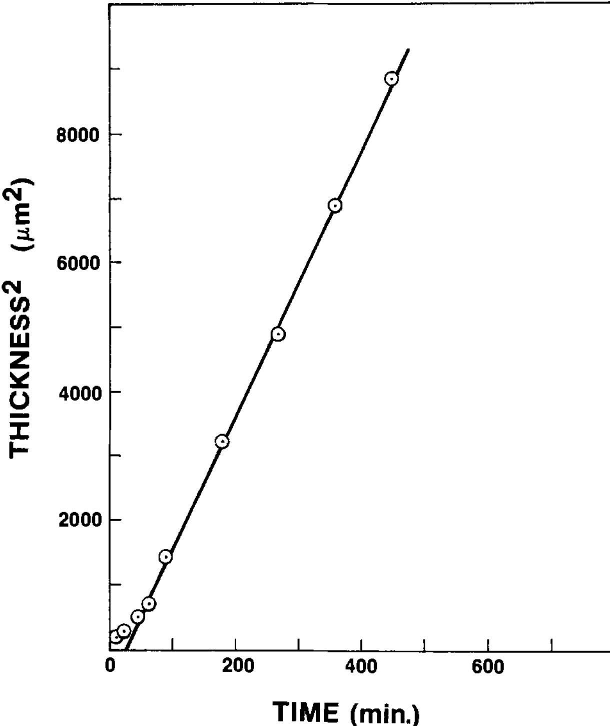

Fig. 1. Growth rate of $MoSi_2$ layer as a function of time at 1150°C, indicating parabolic behavior.

the disilicide phase. In the CVD method, two silicide phases were always found, although the molybdenum-rich silicide was very thin, on the order of 2-4 μm. The thin layer appeared to grow to a maximum thickness of approximately 4 μm and stay at that thickness. Figure 3 shows a typical cross section with a thick $MoSi_2$ layer and a thin molybdenum-rich silicide. Samples of molybdenum with an adherent silicon layer were prepared by deposition at 1000°C for short times. After a further anneal at 1150°C in argon for 1 hr, half the samples were quenched by withdrawing from the furnace and dropping them into water. The other half were left in the furnace and cooled at a rate of 10°C/min. In each case two silicide phases were present with the thin molybdenum rich silicide slightly thicker in the slow cooled samples.

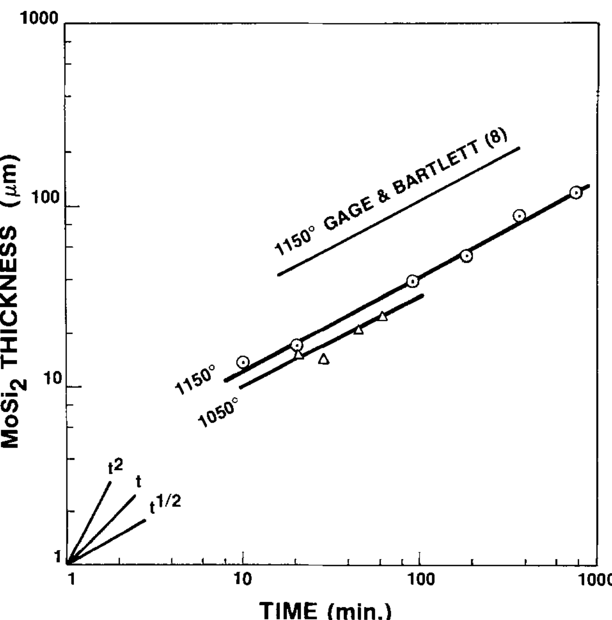

Fig. 2. Effect of temperature on the growth rate of $MoSi_2$ layer. Note the difference in the growth rate from our measurements and the ones from Gage and Bartlett (8).

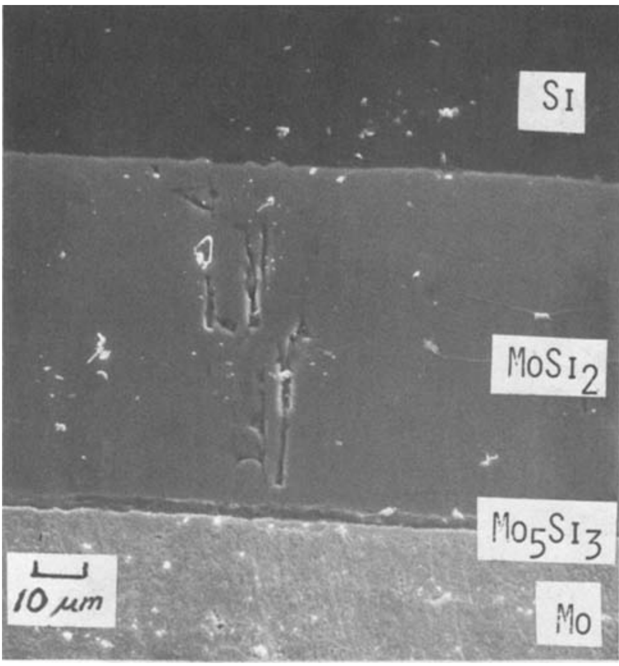

Fig. 3. Cross-sectional view of a substrate showing the interfacial layers; Mo-rich silicide and $MoSi_2$.

The effect of impurities, particularly oxygen, in the process gases was studied. Small amounts of oxygen were added to the process gas stream. The growth rate of $MoSi_2$ was markedly decreased by the addition of oxygen, as shown in Fig. 4. It has been found that thin layers (1000-2000Å thick) of SiO_2 deposited on the substrate prior to deposition impede silicon diffusion so that $MoSi_2$ formation is drastically decreased. It is possible that the thin layers were not continuous, with many pinholes, and therefore did not act as a barrier. Thick layers of SiO_2 (5000-10,000Å thickness) acted as a barrier preventing interdiffusion. The SiO_2 layers were deposited on the substrates in the CVD furnace by reaction of O_2 with $SiCl_4$ in H_2 at 1000°C. Then the silicon deposition was carried out without having to remove the substrate from the furnace. Figure 5 shows a barrier layer in cross section with no evidence of silicide formation.

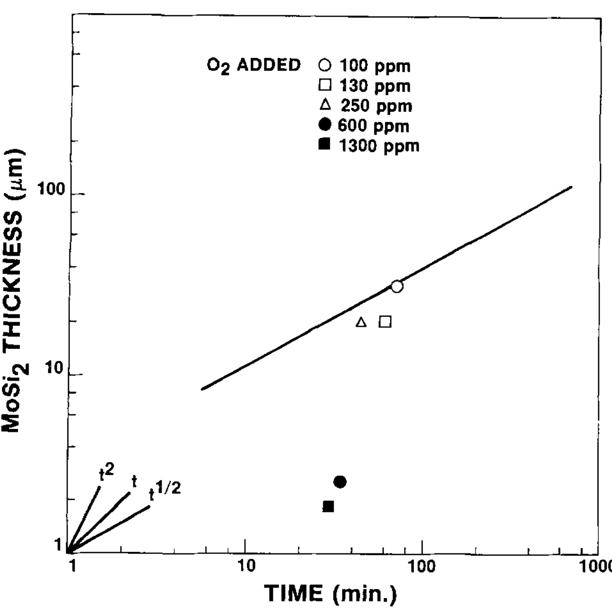

Fig. 4. Effect of presence of oxygen in the process gases during silicon film deposition on the growth rate of $MoSi_2$.

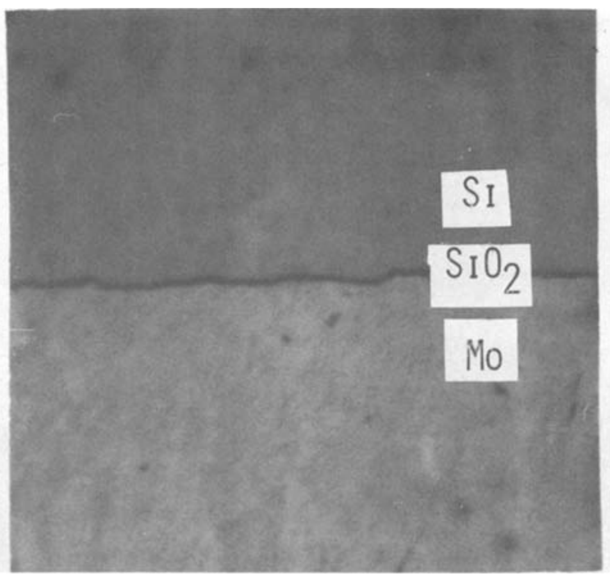

Fig. 5. Cross-sectional view of an SiO_2 coated Mo substrate with an adherent silicon film. Absence of silicide interfacial layers indicates the effectiveness of SiO_2 as a diffusion barrier, 400×.

An electron probe x-ray microanalysis of the thick silicide layer indicated a 1:2 atom ratio for Mo:Si and approximately 1:1 for the thin molybdenum-rich silicide layer. To confirm this observation, an x-ray diffraction scan was taken of the thin silicide layer. The sample was prepared by etching the molybdenum substrate away from the silicide layers with solution B (5% HNO_3, 5% CH_3COOH, 80% H_3PO_4, 10% H_2O, 60°C). In this way the x-ray beam could be directed onto the thin silicide layer. Table I shows the results of the diffractometer scan obtained from this sample. All peaks could be attributed to be due to $MoSi_2$ or Mo_5Si_3, thus identifying the thin molybdenum-rich silicide as Mo_5Si_3, and thick silicon rich silicide as $MoSi_2$.

Discussion

Growth rate.—The growth rate for $MoSi_2$ obtained in this investigation is lower than that observed by Gage and Bartlett (8) who used a pack cementation method for silicide formation. In their method, molybdenum rods were packed in a mixture of NaF and silicon held at temperature for varying periods of time. By this method, the only silicide observed was $MoSi_2$ and a parabolic growth rate was obtained. This was interpreted as indicating a diffusion-controlled reac-

tion with the diffusion of silicon through the silicide the rate-controlling factor. In the present work a parabolic growth rate for $MoSi_2$ was obtained for reaction times of more than a few minutes. The initial stage of the reaction is controlled by the nucleation of silicon, island formation, and surface coverage before the diffusion of silicon becomes the rate-determining factor. Figure 6 shows the initial stage of nucleation and island formation on several surfaces. In the surfaces studied, $MoSi_2$ showed complete coverage while Mo, SiO_2, and Si_3N_4 were not completely covered in the first 5 min. Nuclei were counted from the 100× SEM photographs with the results listed in Table II.

Two effects were observed when oxygen was added to the reactant gases; the rate of formation of $MoSi_2$ was reduced and the silicon did not shear from the substrate on cooling when greater than 100 ppm of oxygen was added. This indicates that silicide formation is a necessary part of the shear separation mechanism. It is posulated that oxygen impeded silicon diffusion through the $MoSi_2$ layer. The addition of oxygen for the first 2-5 min of deposition also very significantly reduced the rate of $MoSi_2$ formation.

Separation mechanism.—It is essential to have an accurate understanding of the shear separation mechanism for reliably producing thin polysilicon sheets using temporary and reusable Mo substrates. Several factors are found to contribute to the shear separation mechanism as discussed below.

The thermal expansion of silicon and molybdenum are significantly different (18) as shown in Fig. 7 which

can generate large stresses upon cooling from the deposition temperature. Calculated values (13) of the stresses developed in a simple silicon-molybdenum couple on cooling from 1100° to 700°C are shown in Fig. 8. The stresses in the silicon film and the molybdenum substrate were calculated using a computer program, LAMIN 1, which is based on linear composite theory (14). The following assumptions were made in the analysis.

1. The silicon film and temporary substrate adhere to each other and comprise a laminated composite with no slip at their interface.
2. A zero stress state exists at the deposition temperature and cooling of the composite is uniform.
3. The strain variation through the thickness of the composite is linear.
4. The material properties are isotropic.
5. While the material properties are temperature dependent, the computations were made using the average values over the temperature range.

The stresses were found to vary strongly with the thicknesses of the silicon and the substrate, but the

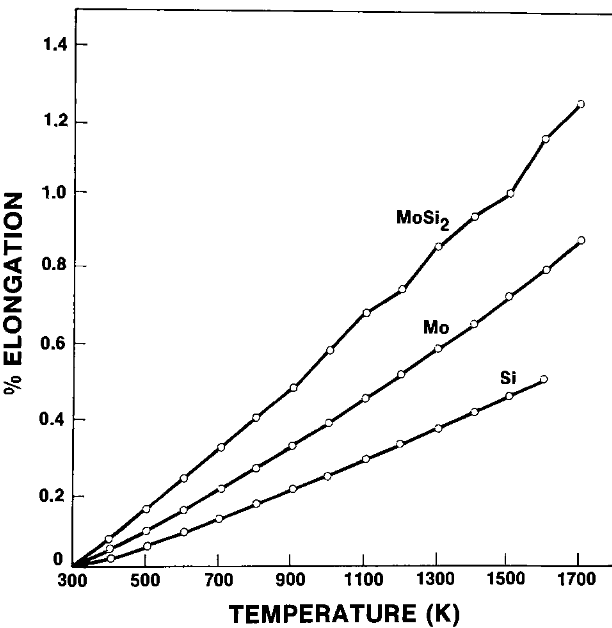

Fig. 7. Thermal expansion of Si, Mo, and $MoSi_2$ (18)

example shown serves to illustrate the very high stresses developed. This in itself is found not to be sufficient to cause shear separation. Silicon films deposited at 1000°C tended to adhere while deposition temperatures higher than 1100°C always resulted in shear separation. Even when higher stresses were developed in "stuck" ribbons deposited at 1000°C, by cooling them to liquid nitrogen temperature, no shearing took place. As expected, the calculated stress levels were found to increase as the composite is cooled to lower temperatures from deposition temperature (13). Also, while the calculated stresses in the composite were found to be dependent on the relative thicknesses of the Mo substrate and the silicon ribbon, they were not found to correlate well with the shear separation observations. Polysilicon ribbons of very large (>100 cm^2) areas with thickness in the range of 0.003-0.020 in. have been separated from Mo substrates with thickness in the range of 0.005-0.050 in. (However, Mo substrates with a thickness greater than 0.030 in. were found to be desirable, since they are less flexible and retain their flatness with repeated silicon deposition-separation cycles.) We believe that, while the stresses generated in the composite are necessary for shear separation, they are not sufficient. A second condition for shear separation was found to be the creation of discontinuities (voids) at the substrate-silicon interface which act as stress raisers as discussed below.

An important factor involved in shear separation is found to be the formation of Kirkendall voids in the silicon adjacent to the $MoSi_2$ layer. An SEM photograph of such a void is shown in Fig. 9. The formation of

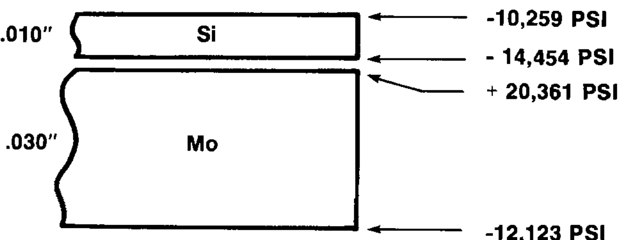

Fig. 8. Calculated stress levels in an Si (0.010 in. thick)/Mo (0.030 in. thick) couple due to cooling from silicon deposition temperature (1100°C) to a temperature of 700°C. — compression, + tension.

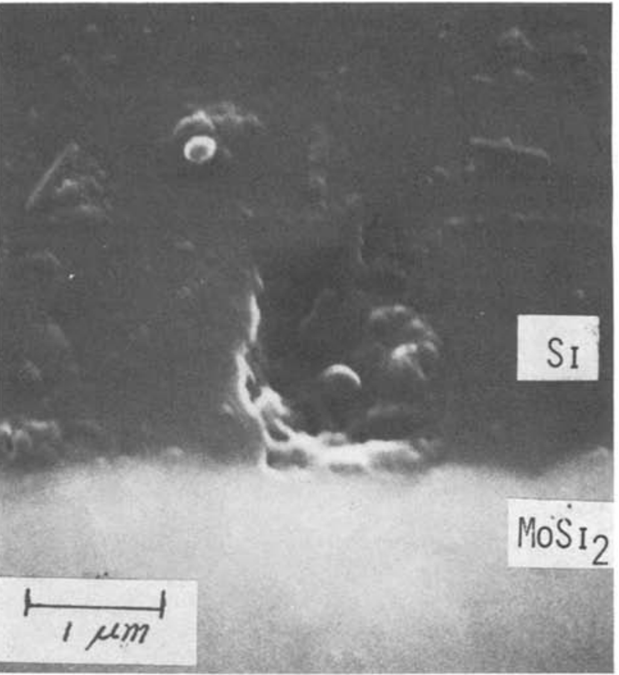

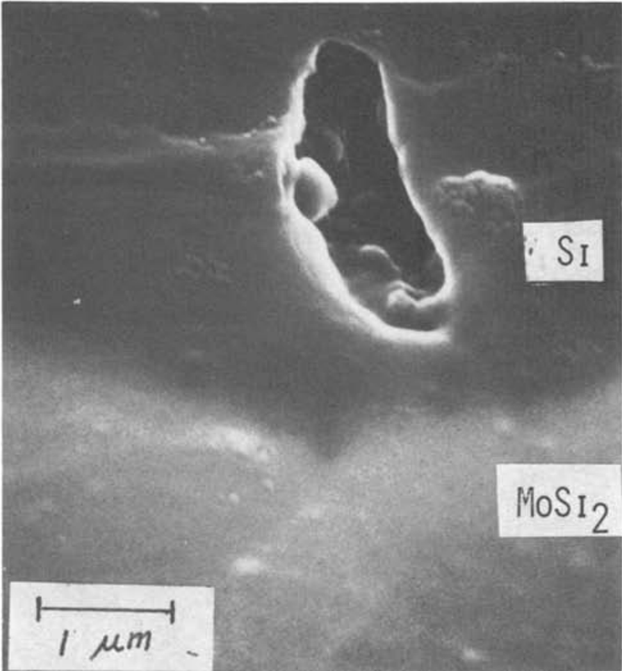

Fig. 9. SEM photographs of a cross-sectional view of the $MoSi_2$-Si interface showing a Kirkendall void. 18000×.

these voids can be explained if Si is the major diffusing species in $MoSi_2$, forming vacancies in the silicon which aggolmerate to form voids. Borders and Sweet (15) also observed such voids in Si-Ge alloys and W couples where Si was the diffusing species. In a material under stress, any hole or discontinuity acts as a stress concentrator (16) with stress at the edge of the hole many times greater than the average stress. Thus very high stress regions result in the silicon adjacent to the $MoSi_2$ layer due to the presence of voids. The shear separation appears to occur in this region. Energy dispersive x-ray analysis in an SEM of the separated silicon films in this region showed no Mo. A SIMS analysis (7) of the separated silicon film showed Mo present only in ppm levels while Auger analysis of the $MoSi_2$ surface after shear separation showed Si in a thin layer of about a few hundred angstroms. Thus it

is clear that the shear separation occurs in the deposited silicon film and the formation of the silicide, in which Si is a faster diffuser than the metal, and formation of Kirkendall voids is essential for reliable shear separation. Further experiments were performed to confirm that silicon diffusion and Kirkendall void formation are essential for reliable shear separation by testing the time-temperature dependence of shear separation. It was found that shear separation occurred when a 1000°C deposition for 90 min was carried out followed by an anneal at 1200°C for 20-30 min. Further, when a "stuck" ribbon on the substrate was annealed for 80 hr at 800° and cooled, over ¾ of the silicon ribbon separated. After 40 hr of additional annealing at 800°C the remainder of the silicon separated from the substrate.

Experiments carried out using SiO_2 diffusion barriers clearly indicate the requirement of silicon diffusion and Kirkendall void formation for shear separation to occur. With SiO_2 diffusion barriers, silicon strongly adhered to the substrate and resulted in a sharply bent bimetallic couple of silicon and molybdenum.

From these results, one would predict that as a substrate is used again and again the $MoSi_2$ growth becomes less and less with each succeeding run. A point would be reached where silicon diffusion becomes less and insufficient voids are formed so that shear separation does not occur. This is actually observed in practice so that substrates can only be used a few times. Then the $MoSi_2$ layer must be removed or the time at deposition temperature extended to allow sufficient silicon diffusion to occur, to ensure shear separation.

It has indeed been found that substrates can be used for repeated deposition cycles until the increasing thickness of the silicide layer limits the layer growth to 9 μm during one cycle. Thus, for the growth conditions being used, the $MoSi_2$ must be removed after seven cycles. Considering a safety factor and assuming substrate resurfacing following every six depositions a 100 μm layer of $MoSi_2$ must be removed. This correponds to 30 μm of consumed Mo. Allowing for grinding tolerances and cost of grinding, the Mo substrate cost contribution was estimated to be about $0.08/peak watt (in 1980 dollars) as an upper limit. The continued shear separation from a given substrate with periodic substrate resurfacing has been observed experimentally.

Conclusions

The interaction of molybdenum and silicon has been investigated by depositing silicon on molybdenum substrates at 1000°-1200°C. Upon cooling the thin silicon sheets sheared from the substrates. Several factors were found to be important in the shear separation mechanism: (*i*) The thermal expansion mismatch of silicon and molybdenum (or tungsten) generates large stresses upon cooling; (*ii*) Kirkendall void formation occurs because silicon is the primary diffuser in $MoSi_2$; and (*iii*) Voids formed in the silicon film at the $MoSi_2$-Si interface act as stress raisers.

Two silicides were formed, a thick layer of $MoSi_2$ and a thin layer of Mo_5Si_3. The growth rate of $MoSi_2$ was found to be parabolic, after an initial nucleation period, indicating a diffusion-controlled reaction.

Oxygen in the reactant gases, at levels greater than 100 ppm, decreased the growth rate of $MoSi_2$ and void formation, which caused failure of the shear separation mechanism.

Acknowledgments

This research was supported in part by DOE/SERI under Contract ET-78-C-03-2207. The authors would like to express their appreciation to G. Thome for the SEM work. The stress calculations were performed by L. Moore and L. Harrel of the Motorola Government Electronics Division.

Electrical Properties of Divalent Europium Niobium Bronzes Eu_xNbO_3

Kenji Ishikawa, Gin-ya Adachi, Masatake Hasegawa, Kazunao Sato, and Jiro Shiokawa

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita-shi, Osaka-fu, Japan

ABSTRACT

The electrical resistivity and thermoelectric power of the europium (II) niobium bronzes, Eu_xNbO_3, were measured as a function of europium concentration from $x = 0.51$-0.92 over temperatures of 4.2-373 K. All samples in tetragonal form ($x = 0.51$-0.65) showed semiconducting conduction, while the samples in cubic form ($x = 0.65$-0.92) exhibited metallic conduction. A Goodenough model for the tungsten bronze, Na_xWO_3, was employed for the difference in the electrical conduction behavior between the two bronzes. Residual drift mobility for the cubic bronze decreased with x except for $x = 0.76$ and on this point an irregularly high value was obtained. The temperature-dependent part of the drift mobility for the cubic one was found to be describable by the perturbation theory of Howarth and Sondheimer. An effective mass of the electron for each cubic bronze was about $2m_o$ (m_o is the electronic rest mass), and the quasi-free electron model was roughly applicable.

Only a few metal oxide systems have metallic properties. Most of them are lower oxides of transition metals, *e.g.*, ReO_3, NbO, and VO (1). Some of the tungsten bronze type oxides, their general formula A_xBO_3, also exhibit metallic conduction (1). Especially, a number of experimental and theoretical works were done to describe the electrical properties of the cubic sodium tungsten bronze. A strontium niobium bronze, which was first prepared by Ridgley *et al.* (2), also has the cubic structure and has a metallic character (1). The ionic radius of Eu^{2+} ion is analogous to that of Sr^{2+} ion (3), and the analogy leads to preparation of Eu^{2+} compounds which are isostructural with Sr^{2+} compounds (4). Fayolle *et al.* (5) first reported the preparation of a europium niobium oxide Eu_xNbO_3 and showed that this oxide was isostructural with Sr_xNbO_3. Studer *et al.* (6) reported the electrical properties of the bronzes, although their study was limited to the semiconducting tetragonal bronzes ($x =$ 0.5 and 0.6). Work covering a wider range of x is desirable. In this paper, the electrical resistivities and the Seebeck coefficients of Eu_xNbO_3 are reported as a function of europium concentration from $x = 0.51$-0.92 over a temperature range of 4.2-373 K.

Experimental

Preparation and Analysis.—A mixture of Eu_2O_3, Nb_2O_5, and Nb powder was ground together in an agate mortar and pressed into pellets and then heated in vacuo (10^{-2} Pa) at 1173 K for 2 hr. After cooling, the pellets were ground and again pressed into pellets. They were packed into an Mo box, sealed under vacuum (10^{-3} Pa) in a silica capsule, and heated at 1473 K for 48 hr. The reaction was completed during the procedure and was assumed to occur according to reaction [1]

$$5xEu_2O_3 + a(6x - 2)Nb + (5 + a - 3ax)Nb_2O_5 \rightarrow 10Eu_xNbO_{3-y} \quad [1]$$

Niobium metal was used "a" times the amount needed to prepare Eu_xNbO_3 in order to compensate for a slight oxidation loss of the bronzes during the course of synthesis, and $a = 1.05$ was adopted for all samples. The deviation of oxygen content from O/Nb = 3 was represented by "y," and the actual value of $3 - y$ used for each sample is given in Table I. The electrical measurements were performed on sintered polycrystalline pellets. The pellets were prepared by pressing the powder sample and then sintering them at 1473 K for 10 hr in sealed silica capsules.

Key words: niobates, electrical resistivity, thermoelectric power.

The phase purities and structural type of the sintered sample were characterized by x-ray powder analysis, using a Rigaku Denki Rotor-flex diffractometer. The atomic ratios (Eu:Nb) were determined with a Rigaku Denki energy dispersion type x-ray fluorescent spectrograph unit, ultra trace systems, and the oxygen compositional states were determined by a gravimetric technique. The magnetic moments were obtained with a Shimadzu MB-11 magnetic balance. The pycnometric densities of the pellets were also obtained.

Electrical resistivity measurements.—The electrical resistivity measurements for the sintered samples were carried out in a helium atmosphere from 4.2 to 373 K. A simple four-probe d-c method was employed for the resistivity measurements of the samples. Rectangular samples of about 2 mm^2 in cross section and 8-12 mm long were taken for the measurements with the four-probe method. The samples were cut from the sintered pellets of 13 mm in diameter and 1 mm in thickness, and the surfaces of the samples were finished with No. 1000 carborundum paper. Electrical leads were attached to the faces of each sample with Ag paste. The resistivity measurements were performed in the potential region in which the samples behaved ohmically. Furthermore, to avoid any contributions to the measured potential from thermally generated emf's, readings were taken in both forward and reverse directions and the averaged values were recorded.

Thermoelectric power measurements.—Thermoelectric power measurements were carried out in a helium atmosphere from 100 to 373 K. A rectangular sample of about 2 mm^2 in cross section and about 4 mm long was attached to two copper blocks with Ag paste. A thermal gradient was produced across the sample by small heaters attached to the copper blocks, and the temperature difference across the sample was regulated so as to fall within 10 K. The Seebeck coefficient of the sample was determined according to the relation

$$S = S_{Cu} - \Delta V/\Delta T \quad [2]$$

where S_{Cu} is the absolute Seebeck coefficient of copper (7), ΔV is the thermoelectric voltage of the sample, and ΔT is the temperature difference across the sample.

Results and Discussion

The compositional, crystal, and magnetic data for the sintered samples are given in Table I. It is seen that the samples ranging in europium concentration from x =0.51-0.65 have a tetragonal form, while the samples ranging from x = 0.65-0.92 have a cubic form. Each of the observed magnetic moments is close to the calculated value, and most of the europium in the sample is considered to be in a 2+ state.

Results of the resistivity measurements are shown in Fig. 1 and 2. The resistivities are found to decrease with decreasing reciprocal temperature for the samples of low europium concentration (x = 0.51-0.65) (Fig. 1), and the changes are expressed by the well-known equation

$$\rho = \rho_0 \exp(Ea/kT) \quad [3]$$

where Ea is related to the activation energy for conduction. The activation energy of each sample is tabulated in Table I. Thermoelectric power measurements reveal that the samples are n-type semiconductors. However, the resistivities are found to decrease on decreasing the temperature for the samples of high

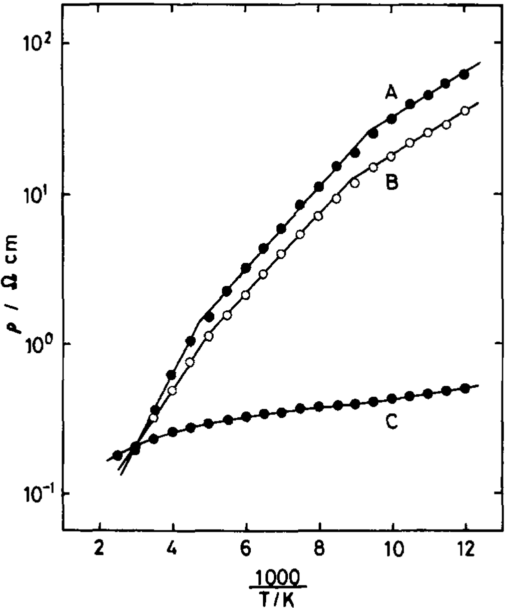

Fig. 1. Specific resistivities of Eu_xNbO_3. A, $Eu_{0.60}NbO_{3.03}$; B, $Eu_{0.58}NbO_{3.02}$; C, $Eu_{0.51}NbO_{3.03}$.

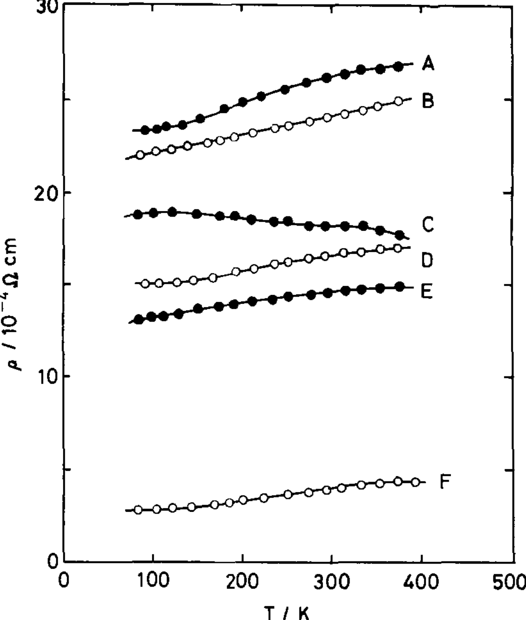

Fig. 2. Specific resistivities of Eu_xNbO_3. A, $Eu_{0.90}NbO_{3.10}$; B, $Eu_{0.70}NbO_{3.09}$; C, $Eu_{0.68}NbO_{3.05}$; D, $Eu_{0.82}NbO_{3.03}$; E, $Eu_{0.88}NbO_{3.03}$; F, $Eu_{0.76}NbO_{3.03}$.

europium concentration (x = 0.65-0.92). In other words, the tetragonal samples are n-type semiconductors and the cubic samples are metallic conductors. An interpretation of the electrical resistivity data for the tetragonal and cubic samples is given on the basis of Goodenough's model (1) for the tungsten bronze. The schematic band models for both cubic and tetragonal phases are illustrated in Fig. 3. The conduction bands are formed by the 4d orbitals of niobium and the 2p orbitals of oxygen. All the $4d(t_{2g})$ orbitals of niobium are considered to be degenerate for the cubic samples [Fig. 3(a)], and the number of conduction electrons is the same as the number of Nb^{4+} in this case. The number of Nb^{4+} in the general formula Eu_xNbO_{3-y} can be provided by the relation

$$n = 2(x + y) - 1 \quad [4]$$

The equation suggests that some conduction electrons exist in the conduction band of the cubic samples ($x > 0.65$), giving all the cubic samples metallic properties. On the other hand, the $4d(t_{2g})$ orbitals of niobium in the tetragonal phase split into two states [Fig. 3(b)] and a localized nonbonding level ($4d_{xy}$) is formed below the bottom of the conduction band. The conduction electrons are considered to be trapped by the level, and the tetragonal bronzes exhibit semiconducting properties. From the analysis of the resistivity curve, the level is determined to be 0.1 eV below the bottom of the conduction band.

The resistivity of a metallic compound can be separated into two components. One of them is a residual

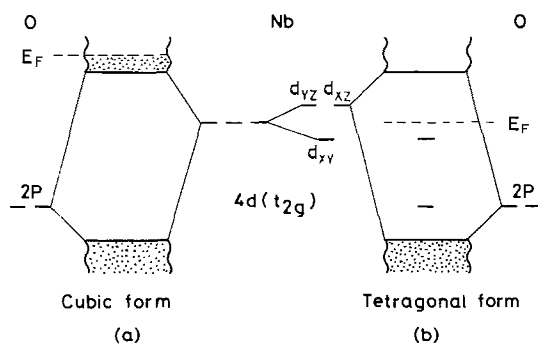

Fig. 3. Energy-level diagram for Eu_xNbO_3

component ρ_0 which is ascribed to electron scattering by impurities and the scattering is temperature independent. The other one, ρ_T, is temperature dependent and is due to electron scattering by lattice vibrations. The total resistivity is therefore the sum of the temperature-independent, or residual, and temperature-dependent, or thermal, components

$$\rho = \rho_0 + \rho_T \quad [5]$$

Figure 4 shows the drift residual mobilities as a function of europium concentration for the cubic samples. On determination of the drift mobility, the carrier concentration is assumed to be equal to the Nb^{4+} concentration and is derived from the following relation

$$N = \frac{dL}{M} [2(x + y) - 1] \quad [6]$$

where d is the pycnometric density of the sample, L is Avogadro's number, M is the formula weight of the sample, and x and y are defined by the formula Eu_xNbO_{3-y}. The drift mobility is calculated from the following relation

$$\mu_0 = 1/Ne\rho_0 \quad [7]$$

The drift residual mobility decreased with increasing europium concentration of $x = 0.68$-0.92 except for a range around $x = 0.75$. At $x = 0.75$ an irregularly high value was found. The values of mobility for these samples are considerably lower than the value for single crystals of other metallic compounds, *e.g.*, Na_xWO_3 (8-10). A degree of sintering will be a dominant factor for determining the value, and the degree is considered to decrease with europium concentration. An irregularly high mobility at $x = 0.7$ was also found in the studies of Na_xWO_3 (11, 12). Ellerbeck *et al.* (13) pointed out that the electrical homogeneity of the sample was an influential factor in the value of mobility and showed that there was no minimum in resistivity near $x = 0.7$ for electrically homogeneous Na_xWO_3. The homogeneity of the sample is an important factor for determining the value of resistivity, and the homogeneity should be maximum at $x = 0.76$.

Figure 5 shows the temperature dependence of the thermal part for $Eu_{0.76}NbO_{3.03}$. The thermal part of the resistivity is proportional to $T^{3.5}$ below 49 K, indicating that the mobility of electrons increases proportional to $T^{-3.5}$. Bardeen and Shockley (14) have proved that the mobility follows $T^{-1.5}$ dependence when the conduction electrons are scattered by the lattice vibrations for an acoustic mode. On the other hand, Greener *et al.* (15) suggest that a mobility of a polar semiconductor, in which the conduction electrons are scattered by the optical mode lattice vibrations, can be approximated by the relation at low temperature

$$\mu \propto T^{-n} \quad [8]$$

where n is a constant of magnitude 2-3.5. It is apparent that the conduction electrons of the niobium bronze are scattered by the optical mode lattice vibrations. The interaction between electron and phonon is describable by the perturbation theory of Howarth and Sondheimer (16) in which the conduction electrons were assumed to degenerate and to be scattered by polarization waves in the crystal. Crowder and Sienko (17) successfully applied the perturbation theory to the tungsten bronze. The thermal part of the electrical resistivity for the metallic compound is given in the relation

$$\rho_T = AT^{-1} \sinh^{-2}(\theta/2T) \quad [9]$$

where A is a constant and θ is the Debye factor. The Debye temperature is conventionally estimated by a method proposed by Kunder and Sienko (18). That is the transition temperature of resistivity from T^n to T^1 dependence in the resistivity curve (Fig. 5) is approximately $\theta/7$. The constant A is evaluated from the measured value of the thermal part at 250 K and from an estimated θ. The Debye temperature and the constant are evaluated as 343 K and 1.41×10^{-2} ΩK, respectively. Figure 6 shows the results. The agreement between the observed and calculated values is satisfactory.

The Seebeck coefficients of the cubic samples are given as a function of the temperature in Fig. 7. For

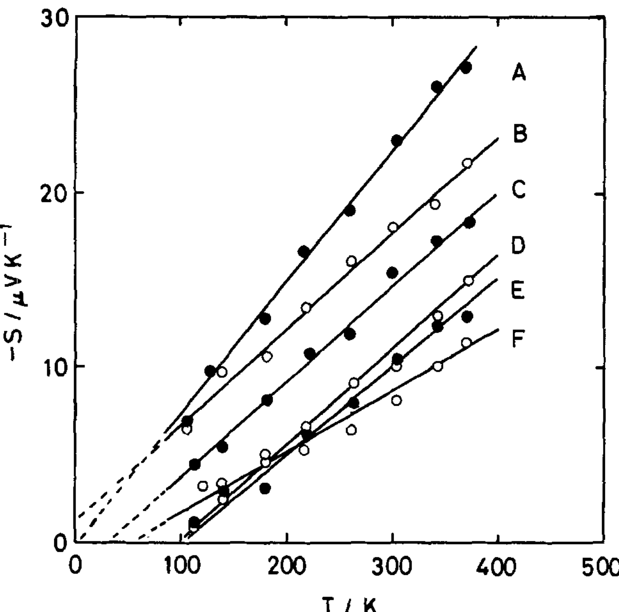

Fig. 7. Temperature dependence of the Seebeck coefficient for Eu_xNbO_3 in cubic form. A, $Eu_{0.68}NbO_{3.05}$; B, $Eu_{0.70}NbO_{3.09}$; C, $Eu_{0.76}NbO_{3.03}$; D, $Eu_{0.82}NbO_{3.03}$; E, $Eu_{0.90}NbO_{3.10}$; F, $Eu_{0.88}NbO_{3.03}$.

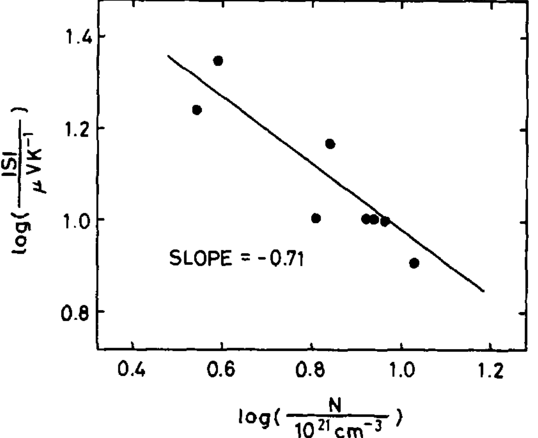

Fig. 8. Seebeck coefficient of Eu_xNbO_3 at 300 K vs. Nb^{4+} concentration.

the free-electron approximation, the Seebeck coefficient is given by the relation

$$S = \frac{2}{3}\left(\frac{\pi}{3}\right)^{2/3} \frac{m^* k^2 T}{e(h/2\pi)^2} N^{-2/3} \quad [10]$$

An almost linear dependence of the Seebeck coefficient with temperature (Fig. 7) suggests that the conduction electrons are close to free electrons. The Seebeck coefficients at 300 K are plotted in Fig. 8 as a function of the carrier concentration given by Eq. [6]. The Seebeck coefficients vary as $N^{-0.71}$ and this is close to $N^{-0.67}$ predicated by the free-electron model (Eq. [10]). Therefore, the conduction electrons of the cubic samples are considered to be close to free electrons. An effective electronic mass for each cubic sample is also evaluated by comparison of the observed Seebeck coefficients with the calculated values ($m^* = m_0$). The effective mass is about $2m_0$ for each sample.

Technical Notes

Characterization of Films Formed by Pyrolysis of Borazine

A. C. Adams*

Bell Laboratories, Murray Hill, New Jersey 07974

A previous publication describes the deposition and characterization of films containing boron, nitrogen, and hydrogen formed by the reaction of diborane and ammonia at 300°-400°C and at about 0.4 Torr (1). The films, which have a composition of approximately B_6NH_x with $7 < x < 10$ (2), are used in the fabrication of masks for x-ray lithography (3). The film deposition rate is related to the concentration of the reactants and is limited by the concentration of the diborane starting material that is readily usable, about 15% diborane in an inert carrier gas. Pure diborane is available and has been used for the deposition of boron coatings (4), but requires refrigerated storage at temperatures below −20°C to prevent decomposition. Pure boron trichloride has been investigated as the starting material for the reaction with ammonia, but the resulting films react with atmospheric moisture to form crystalline boron oxide, possibly by hydrolysis of residual chlorine in the film (1).

An alternate starting material which may provide a high deposition rate is borazine, $B_3N_3H_6$. Borazine, a liquid at room temperature with a vapor pressure given by $\log P \text{ (mm)} = 7.714 - 1609/T$ (5), is prepared by the controlled reaction between diborane and ammonia or by the thermal decomposition of the solid ammonia borane, NH_3BH_3 (6). Borazine is known to thermally decompose by condensation reactions to produce less volatile products (7). In this note, the films formed by the pyrolysis of borazine are compared to the material produced by reacting diborane and ammonia.

The depositions occur in the hot wall, low pressure CVD reactor described previously (1). The substrates are 75 mm diam silicon wafers. Borazine, obtained from Callery Chemical Company, Callery, Pennsylvania, is stored and used in a constant temperature bath at 0°C. The pressure in the reactor is controlled by a needle valve between the borazine container and the reactor. All depositions use pure borazine to obtain high deposition rates; no diluent gas or reactive gases are present. Pressures and temperatures are varied from 0.1 to 0.8 Torr and 300°-650°C.

The deposition rate and refractive index (measured at a wavelength of 0.5461 μm) are shown for different deposition temperatures in Fig. 1. Data for films formed from the reaction of diborane and ammonia are shown for comparison (1). The deposition rate for the borazine reaction is low at all temperatures in spite of the relatively high pressure of borazine. The deposition rate increases with increasing temperature and goes through a maximum followed by a rapid decrease caused by depletion due to reaction on the hot reactor walls. This is similar to the behavior observed with diborane and ammonia except the maximum occurs at about 550°C instead of 450°C. The apparent activation energy at the lower temperatures is 9.6 kcal/mole, much lower than the values measured for the diborane and ammonia reaction, 20-25 kcal/mole (1). The deposition rate increases with increasing partial pressure of borazine and appears to follow a square-root dependence.

At deposition temperatures greater than 550°C, the refractive index is the same as observed for films deposited from diborane and ammonia. However, at lower deposition temperatures the refractive index is much lower. This is a strong indication that the films formed at low temperature from the two reactions are not the same. The refractive index increases linearly with borazine pressure at 500°C, ranging from 1.75 at 0.1 Torr to 2.15 at 0.8 Torr.

Films deposited at temperatures greater than 550°C have infrared spectra that are similar to those observed for the diborane-ammonia reaction. However, at lower deposition temperatures, there are considerable differences. Films deposited from borazine still have B-N adsorptions at about 1360, 900, and 750 cm^{-1}, and a B-H absorption at 2520 cm^{-1}. However, the strong NH_2 absorptions previously observed at 3220 and 1540 cm^{-1} have been replaced by a single N-H

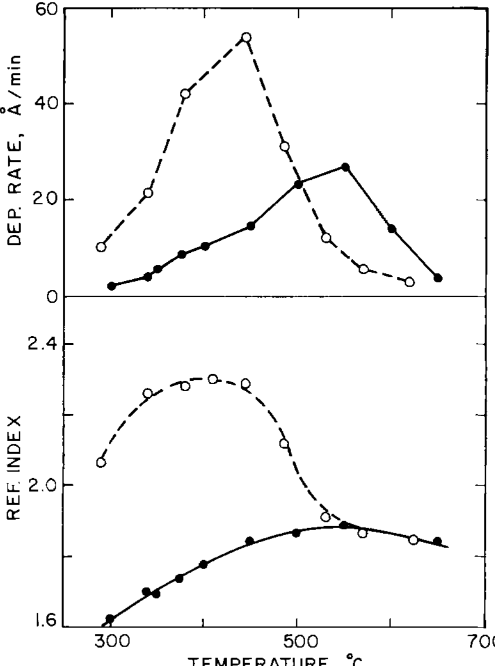

Fig. 1. Deposition rate and refractive index for different deposition temperatures. The partial pressures are: solid points, borazine, 0.3 Torr; open points, diborane, 0.005 Torr, ammonia, 0.006 Torr, and argon, 0.49 Torr.

* Electrochemical Society Active Member.

Key words: deposition, films, masks.

stretching mode at 3420 cm^{-1}. The replacement of the NH_2 groups by NH shows that large differences in the chemical bonding exist between the films from the two reactions.

These differences are also indicated by the increased reactivity of the material formed by pyrolysis of borazine. The films formed from diborane and ammonia at 300°-400°C do not change after long times at room ambient, and the films are inert towards water and aqueous solutions (1). In contrast, the films formed by borazine pyrolysis at 300°-450°C react with atmospheric moisture. After a few weeks, the intensity of the B-N absorption at 1360 cm^{-1} has decreased by at least 50%, a broad absorption appears at about 3400 cm^{-1}, probably OH, and a H_2O absorption at 1630 cm^{-1} is observed. In addition a B-O absorption at 1410 cm^{-1} is observed in many samples. These changes are probably caused by hydrolysis of the B-N bond to form B-OH. The films formed from borazine also dissolve in water with dissolution rates at room temperature of 100-500 Å/min.

In conclusion, significant differences in the films formed by reacting diborane and ammonia and by pyrolyses of borazine at 300°-500°C have been observed. The films formed from borazine have NH groups instead of NH_2, have a lower refractive index, and are more reactive. The low deposition rate and the reaction with water make these films unsuitable for fabrication of masks for x-ray lithography. The films formed by pyrolysis of borazine at temperatures greater than 500°C have not been thoroughly investigated, primarily due to the low deposition rate caused by the reactions on the hot walls. The limited amount of data available indicate that these films are identical to the films formed at similar temperatures by reacting diborane and ammonia. However, a complete investigation of these high temperature films will require depositions in a cold wall reactor.

Evaluation of the Pinhole Density in SiO_2 Film by Plasma Etching

Takashi Meguro, Hidekazu Kurita, and Tadatsugu Itoh

School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160, Japan

It has been reported that various radicals are generated in the case of CF_4 plasma etching. Among them, fluorine radical F* and fluorocarbon ion such as CF_3^+ selectively etch silicon and silicon dioxide, respectively (1). Also it has been observed that the addition of oxygen to CF_4 causes the etch rate of silicon to increase because of the increase of F* (2). We obtained the high Si-to-SiO_2 etch rate ratio of 130 using a CF_4 + O_2 mixture gas in rf plasma etching and applied this technique to the detection of the pinhole density in the SiO_2 film by the etching of underlying Si substrate with **F***.

To detect pinholes in SiO_2 films, the Cu-decoration method and the PAW(pyrocathecoal-amine-water) method are most commonly used. In the Cu-decoration method (3) an electroplating technique is utilized. If there are pinholes in the SiO film, dissolved Cu from the anode in the form of oxysalts precipitates on the pinhole. In this method, a localization of decorated Cu can be seen when a nonuniform electric field is applied to the SiO_2 film, and a dissolved Cu precipitates on the contamination when the SiO_2 film surface is not clean.

In the case of the PAW method (4), a solution of pyrocathecoal and amine can etch Si but not SiO_2. If a sample is kept in the solution at 110°-115°C for 1-2 hr, Si is etched through pinholes in the SiO_2 film. After the removal of SiO_2 film, the pinhole density can be measured by counting the number of etch pits formed on Si substrate. The disadvantages of this method are as follows: (*i*) ventilation is necessary to exhaust H_2 gas generated from the solution, and (*ii*) N_2 ambient is necessary to prevent oxidation of amine.

The plasma etching method acts the same as the PAW method in principle. The fluorine radical in the

Key words: etching, Cu-decoration method, radicals.

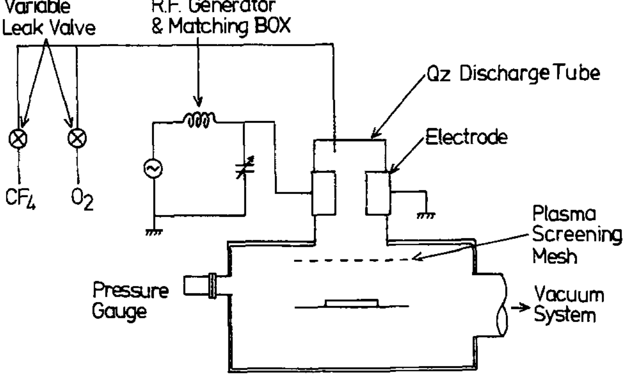

Fig. 1. Schematic diagram of the plasma etching apparatus

$CF_4 + O_2$ plasma etches the Si surface. Figure 1 shows a schematic diagram of the plasma etching apparatus used in this experiment. The reactor is made of a quartz tube 100 mm in diameter and 150 mm in height. The distance between the bottom of the discharge column and the surface of the sample is 70 mm, where the plasma screening mesh is set up to confine the plasma. This reactor is similar to the downstream-type reactor (2). RF power of 13.56 MHz is coupled capacitatively by electrodes around the quartz tube. The etching gas, a mixture of CF_4 and O_2, is introduced into the discharge column through variable leak valves after evacuating the chamber below 5×10^{-6} Torr.

First, we studied the etching conditions so as to maximize the Si-to-SiO_2 etch rate ratio by varying the gas pressure, rf power, and the fraction of O_2 in the etching gas. Unless the ratio is large, the SiO_2 film is also etched off before etch pits become of measurable size. The maximum value of the ratio was obtained at total pressure of 0.25 Torr, rf power of 50W, and the O_2 fraction of 10% in volume. In these conditions, the etch rates of Si and SiO_2 are 400 and 3 nm/min, respectively; therefore, the Si-to-SiO_2 etch rate ratio reaches 130. The reason for the so large ratio is considered as follows: (*i*) the increase of F* by oxygen released from the etching of the quartz wall and additional O_2 (*ii*) the etching of an extremely small area of Si substrate masked by the SiO_2 film which has many pinholes.

To measure the pinhole density, the SiO_2 film on (100) Si substrate was formed by rf sputtering with 200-700 nm and the films with a large number of pinholes were especially prepared for the comparison between the plasma etching method and the PAW method. The number of etch pits measured by these methods decreases with increasing the thickness of the SiO_2 film, as shown in Fig. 2. It also shows that the number of etch pits detected by the plasma etching method is 10-15% less than those by the PAW method. It is considered that active species recombine to stable gases such as CF_4 and COF_2 because of the small conductance of pinholes. On the other hand, pinhole density detected by the Cu-decoration method was about 50% less than those by the PAW method. The decorations grow in size as a function of time, but do not increase in number, because excessive decorations give rise to the coalescence of Cu.

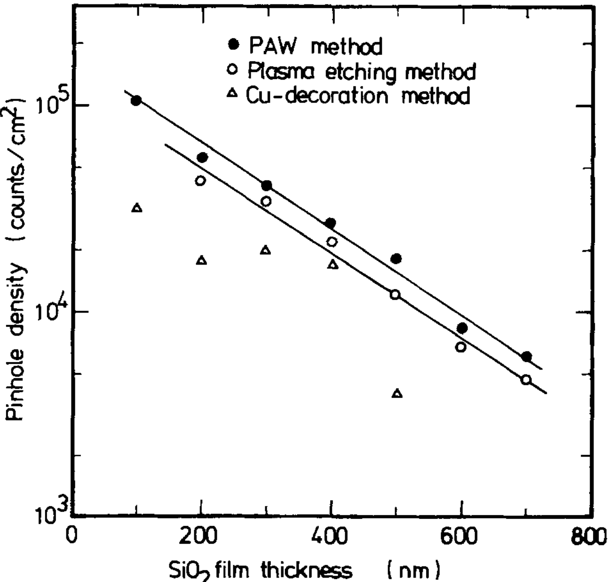

Fig. 2. Pinhole density detected by plasma etching method (○), PAW method (●), and Cu-decoration method (△).

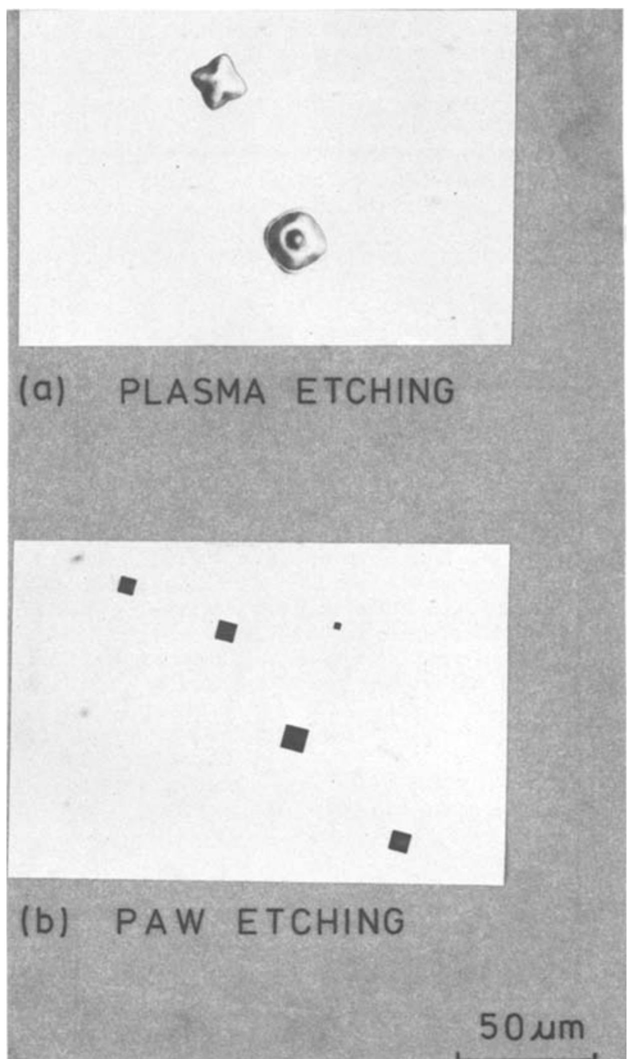

Fig. 3. Figures of etch pits formed by plasma etching method and PAW method.

The present etch rate ratio of 130 is not large enough compared with the ratio of 1000 in the PAW method. Therefore the SiO_2 films thinner than 100 nm are etched off before the etch pits grow to a measurable size in the plasma etching method. The plasma etching method is, however, very useful for the pinhole detection of the SiO_2 film even under the present conditions. The advantages of this method are as follows: (*i*) identification of pinholes is very easy because of clear etch pits as shown in Fig. 3, (*ii*) the process is very simple, and (*iii*) etching time of about 45 min is less than that by the PAW method.

In conclusion, the pinhole detection in SiO_2 films deposited on Si can be carried out rapidly by the $CF_4 + O_2$ plasma etching, and the measured value of the pinhole density is considered to be reliable. The plasma etching method is also profitable for evaluating SiO_2 films because of its simplicity.

The Quenching of Y_2O_3:Eu Luminescence by Cerium

Martin J. Fuller

Thorn Lighting Limited, Enfield, Middlesex, EN1 1UL, England

The effect on plaque brightness of doping all the naturally occurring lanthanide elements into Y_2O_3:Eu phosphor is shown in Fig. 1. All these and subsequently described rare-earth doped Y_2O_3 preparations were obtained by oxalate coprecipitation from neutral nitrate solutions followed by air firing at 1550°C. The preparations shown in Fig. 1 were white after this treatment, with the exception of the praseodymium and terbium-doped samples, which required subsequent treatment at 1000°C in 10% H_2 in N_2 to remove a pale yellow body color. This treatment, which has no significant effect on either the luminescence intensity or emission spectrum of undoped Y_2O_3:Eu, presumably reduces the Pr and Tb species from oxidation states >3 to the trivalent state.

The existence of significant quenching by the trivalent ions praseodymium, neodymium, dysprosium, holmium, erbium, and thulium can be qualitatively related to the presence of at least one 4f-4f transition in the quenching ion at an energy above ground state approximately resonant with a $^5D_0 \rightarrow {}^7F_n$ (n = 0-6) transition in Eu^{3+} (1). This suggests nonradiative multipolar energy transfer from the $^5D_0$ level of the Eu^{3+} to the killer ion as being the process responsible for quenching by these ions.

Key words: inorganic, luminescence, energy transfer.

The extensive quenching of Y_2O_3:Eu luminescence by cerium, which has also been reported by other workers (2), can obviously not be ascribed to a similar 4f-4f energy transfer scheme. However, the effect does have particular industrial relevance to the combined preparation and use of Y_2O_3:Eu with cerium and terbium coactivated phosphors as the respective red and green components in the multiphosphor approach to white light production in fluorescent lamps (3). For this reason it would be beneficial to gain more insight into the killer mechanism of cerium.

An interesting aspect of the quenching of Y_2O_3:Eu luminescence by cerium is a time-dependent and cerium concentration-dependent photolytic quenching as shown in Fig. 2. In this experiment the samples were exposed in a double monochromator spectrophotometer (Perkin-Elmer MPF-44A) to the 250-270 nm radiation from a 150W high pressure xenon discharge, and the red luminescence monitored as a function of exposure time. In addition to the initial quenching there is, par-

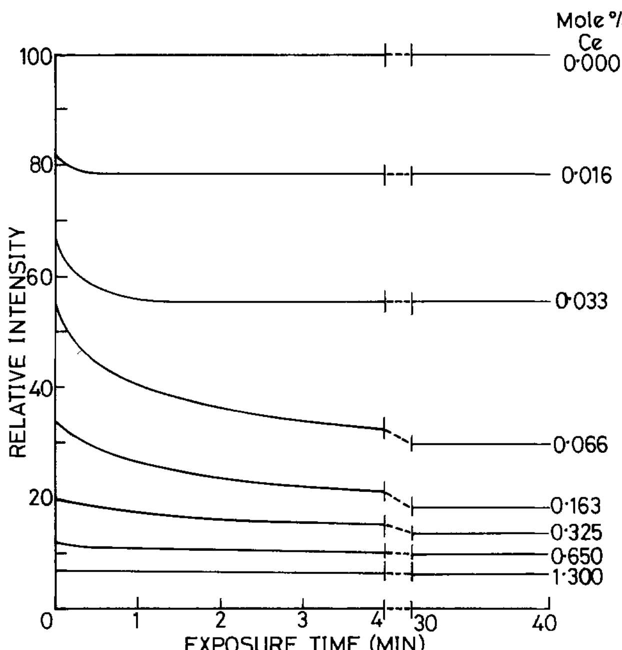

Fig. 2. The time-dependent quenching by Ce of $^5D_0 \rightarrow$ luminescence from Y_2O_3:5.0 m/o Eu excited at 250-270 nm.

ticularly at the intermediate cerium concentrations investigated, a significant additional time-dependent quenching effect accompanied by a proportionate photochromic darkening of the initially white phosphor to a pinkish color. This u.v. photochromism is only slowly reversible on removal from the u.v. irradiation and exposure to ambient light, but is rapidly bleached by high intensity visible light. An indication of the contribution of this photochromic quenching is shown in the solid curves of Fig. 3, where the overall equilibrium quenching has been resolved into its initial and time-dependent photochromic components. This clearly shows the photochromic effect to peak at about 0.1 mole percent (m/o) cerium.

Thermal reduction of the cerium-containing phosphors at 1000°C in N_2-10% H_2 results in an increasing darkening to a yellow-brown color with increasing cerium concentration. At cerium concentrations below about 0.1 m/o, where this discoloration is relatively weak, there is no evidence of further darkening by photochromism, which is consistent with the fact that no time-dependent quenching is observed in these reduced samples. The quenching characteristics of these reduced samples, together with the corresponding curve for Y_2O_3:Eu doped with neodymium are shown in the dotted curves of Fig. 3. These S-shaped quenching curves obtained on these axes and over these concentration ranges are typical for trivalent lanthanide ion quenching of Eu^{3+} luminescence in Y_2O_3 (4, 5) and can be correlated with the r^{-n} (n = 6-10) dependence expected for nonradiative multipolar energy transfer from the excited Eu^{3+} center over a distance r to the killer ion (5). The curves obtained both for the initial and the overall quenching effect of cerium in the nonreduced samples are not characteristic, suggesting the possibility that an alternative killer mechanism is coming into play.

Insight into this is given by diffuse reflectance spectra obtained on Y_2O_3:Ce samples without Eu^{3+}, as shown in Fig. 4. These clearly show that in the nonreduced samples the cerium species present give rise to a very strong u.v. absorption band at <230-300 nm. This absorption, which is not accompanied by any detectable luminescence, causes photochromic darkening to about the same extent as in europium-containing samples with the same amount of cerium. Thus the photochromism is not attributable to redox interactions between the cerium and europium species. Further evidence for the nonparticipation of Eu^{3+} in redox reactions in the systems investigated in this work is the fact that in no case was Eu^{2+} band emission observed.

In contrast to the nonreduced cerium-containing samples, the reduced samples show relatively much less strong absorption of 230-300 nm radiation, but do show an absorption band beginning at about 350 nm and extending up to about 500 nm, which can fairly confidently be assigned to a 4f-5d transition in trivalent cerium. This obviously accounts for the yellow-brown color of the reduced samples. There is no evidence of this band in the nonreduced samples, and the inference must be that the cerium exists in the tetravalent form in these samples.

The presence of this tetravalent cerium causes a very strong absorption band at <230-300 nm, and it is this absorption competing with the O-Eu charge transfer absorption (Fig. 4) responsible for europium excitation in Y_2O_3:Eu (6), which accounts for the initial quenching. We have found no evidence to suggest that a multipolar quenching mechanism between excited europium and "tetravalent" cerium occurs. For example, if the europium in the nonreduced Y_2O_3;Eu,Ce samples is directly excited into its $^5D_1$ (535 nm) and $^5D_2$ (466 nm) levels, then no quenching of the $^5D_0$ Eu luminescence occurs over the range of cerium concentrations investigated. Excitation into the $^5D_3$ (395 nm) level does give rise to slight quenching, but this can be attributed to some residual competitive absorption at this wavelength, as shown in Fig. 4. Direct excitation into these europium ^5D levels does not result in photochromism.

The additional time-dependent and cerium-concentration dependent quenching, however, is not due to further competitive absorption of the u.v. radiation since the onset of photochromism has been found not to be accompanied by more extensive u.v. absorption. Thus the photochromic quenching occurs by a different mechanism.

Substitution of tetravalent cerium into yttrium sites in a Y_2O_3 lattice would be expected to produce a defect

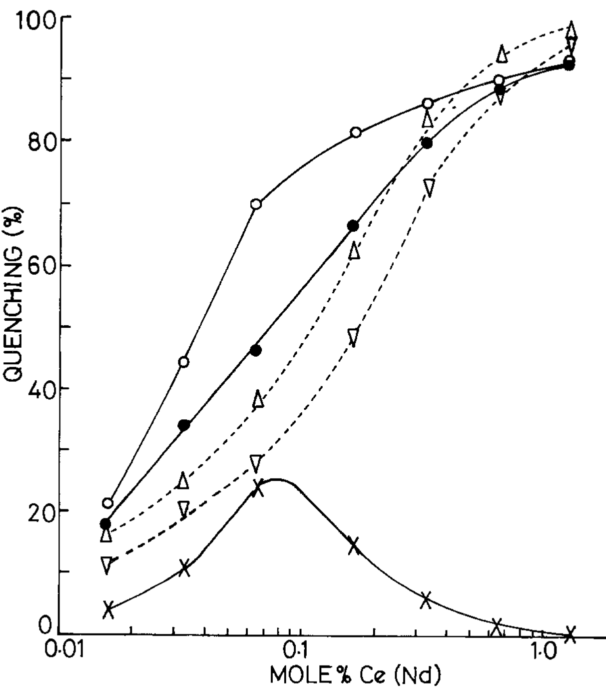

Fig. 3. The quenching by Ce and Nd of $^5D_0 \rightarrow$ luminescence from Y_2O_3:5.0 m/o Eu excited at 250-270 nm. —○—, Ce overall quenching; —●—, Ce initial quenching; —X—, Ce photochromic quenching; - - -△- - -, thermally reduced Ce samples; - - -▽- - -, Nd.

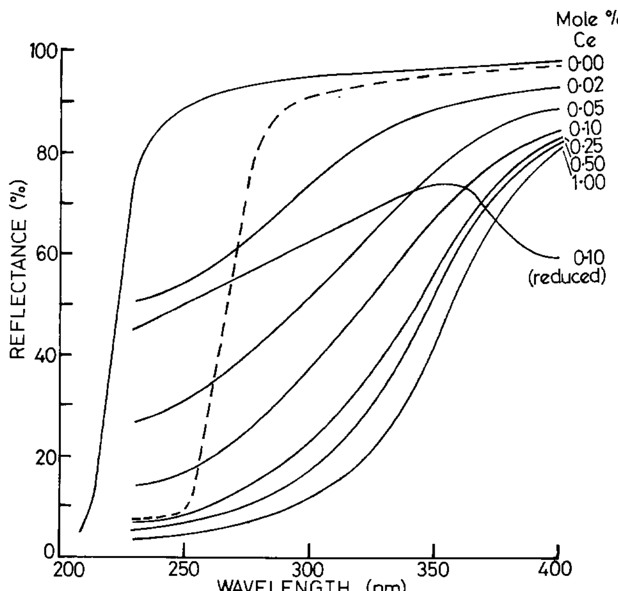

Fig. 4. Diffuse reflectance spectra of Y_2O_3:Ce samples and (dotted) Y_2O_3:5 m/o Eu.

structure in order to maintain electroneutrality. The most likely defect is an yttrium vacancy, *i.e.*, for every three substitutional Ce^{4+} ions introduced a cation vacancy is produced. Cation vacancies are not normally color centers, which is consistent with the fact that the nonreduced cerium samples are white. In addition, these defects are not traps for luminescence from the ^5D manifold of europium since no quenching by cerium is observed upon direct excitation into this manifold. However, if it is assumed that upon u.v. irradiation the Ce^{4+} in the defect lattice shows a tendency to photochemically reduce, then the creation of other defect sites such as anion vacancies, O^- sites, or F centers could be envisaged. Defects of this type are well-recognized color centers and luminescence traps and could thus account for the photochromism and its accompanying quenching. The cerium concentration dependence of this photochromism is presumably due to the fact that the Y_2O_3 lattice will only tolerate a limited concentration of defects before structural rearrangement occurs in order to eliminate these.

Manuscript submitted Oct. 7, 1980; revised manuscript received Jan. 27, 1981. This was Paper 579 RNP presented at the St. Louis, Missouri, Meeting of the Society, May 11-16, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Achievement of High Lifetime by a Combination of HCl Oxidation and POGO Gettering Techniques

Jacobus W. Swart* and E. Charry**

Microelectronics Laboratory, University of Sao Paulo, 05508 Sao Paulo, Brazil

Many devices or integrated circuits such as CCD's and MOS dynamic circuits require, for better performance, that their crystal presents, after completion of the fabrication process, a high lifetime. This means that the crystal must have a very low density of defects, *e.g.*, dislocations, stacking faults, and metal impurities. These crystal defects can also reduce device yield dramatically in bipolar and MOS devices. To reduce or eliminate them, many methods have been described, known as gettering techniques, which promote an increase in lifetime due to the capture of metal impurities and native defects and the suppression of stacking faults. The most usual techniques are: phosphorus gettering (1), back-side abrasion (2), ion implantation damage gettering (3), POGO by misfit dislocations due to phosphorus diffusion (4), POGO by strain gradient due to a silicon nitride layer deposited directly on the silicon substrate's back side (5), and oxidation in an atmosphere of oxygen added by an appropriate amount of chlorine (6-8). The POGO technique by misfit dislocations has been shown (4, 9) to be very efficient in suppressing nucleation centers for stacking faults in addition to capturing impurities introduced in the wafer before and during processing. In addition, the gettering technique by HCl oxidation at high temperature is very efficient in removing stacking fault nucleation centers (8) and metallic impurities (10).

We present in this article an experimental work utilizing a combination of the gettering techniques by HCl oxidation together with POGO by misfit dislocations and also utilizing them separately for the purpose of comparison. For practical reasons the gettering by oxidation is done before the POGO, since an oxide (thermal + silox) on the frontal side of the wafer is needed for masking against the phosphorus diffusion, and in addition thermal oxide is very clean and passivated.

It has been shown that at 1200°C there is a gettering effect of the S.F. nucleation centers without etching the silicon surface, depending on the HCl/O_2 ratio and the oxidation time (8). We used 1200°C, 0.6% as the HCl/O_2 ratio, and 3 hr as the oxidation time. With these oxidation parameters, etching of the silicon will not occur and we are clearly within the conditions where gettering occurs.

With reference to the conditions necessary to introduce misfit dislocations by phosphorus diffusion, Rozgongi *et al.* (4) have shown that the deposition temperature has to be higher than 1050°C and suggest times longer than 1 hr be used. We choose the temperature of 1150°C and time varying from 90 to 150 min.

For the wafers which were processed by POGO only as the gettering step, the initial oxidation was done at 1000°C for 4 hr in an atmosphere of O_2 plus 5% HCl, since during this oxidation S.F.'s do not grow and a gettering effect does not occur (8).

Besides the study of these two gettering techniques we investigated the influence on the lifetime of thermal processes after the gettering steps. We also present the effect of a steam atmosphere thermal treatment on the wafers submitted to the HCl oxidation gettering process.

Experimental Procedures

To study and evaluate the gettering techniques, we performed three different runs fabricating MOS capacitors using the sequence described below.

1. Oxidation at 1200°C in O_2 + 0.6% HCl for 3 hr or at 1000°C in O_2 + 5% HCl for 4 hr.
2. Silox deposition at 410°C on the wafer's front side to achieve 1 μm thickness oxide.
3. Silox densification at 1000°C, 20 min, in dry O_2 or in steam.

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.

Key words: silicon defects, S.F. nucleation centers, silicon surface etching, thermal stress.

4. Back-side oxide etching.
5. Phosphorus deposition at 1150°C for 90, 130, or 150 min, using $POCl_3$ as the doping source.
6. 1 μm thickness silox deposition on the wafer's back side.
7. High temperature treatment in a dry O_2 atmosphere.
8. Frontal oxide etching by "buffered HF."
9. Oxidation at 1000°C, in O_2 + 3% HCl, obtaining a 100 μm oxide layer.
10. PSG deposition for Al-gate wafers only.
11. Annealing at 1000°C, 30 min in an argon atmosphere.
12. Aluminum deposition using a tungsten crucible or a polysilicon deposition followed by a phosphorus deposition.
13. Definition by photolithography of circular capacitors with 1.32×10^{-3} cm^2 area and guard ring as shown in Fig. 1.
14. Back-side oxide etching.
15. Aluminum deposition on the wafers back side.
16. Annealing at 450°C, 30 min in forming gas.

The fabrication process parameters and variables of the three runs are outlined in Tables I, II, and III. The objectives of each run and the description of the wafers used are as follows.

First run: This run had as its objective to compare, by means of wafers with the silox densified in a steam atmosphere, the gettering by the combination of the two techniques with the gettering by HCl oxidation alone. The second objection was to investigate the difference on the interface quality by obtaining the gate oxide by stripping off the initial oxide and reoxidizing, or by chemically thinning the initial oxide. The wafers used were n-type, (100), 1.5 Ωcm, CZ, and made at our laboratory. They were cut in halves and numbered N_{5r}, N_{5l} to N_{8r}, N_{8l}.

Second run: The objectives of this run were to observe the influence of the phosphorus deposition time (POGO); high temperature treatment after the gettering stages; and the silox densification atmosphere. The wafers were n-type, (100), 4.5 Ωcm, CZ, and made at our laboratory. They were also cut in halves and numbered N_{9r}, N_{9l} to N_{13r}, N_{13l}.

Third run: This run had the same objectives as the second run as well as to study in a comparative form the two gettering steps separately and the combination of the two. The wafers were p-type, (100), CZ. Two wafers with $\rho \simeq 25$ Ωcm and 3 in. diam made by Wacker were used. They were cut into four pieces each and numbered W_1 to W_4 and W_5 to W_8. Two other wafers made at our laboratory, with $\rho \simeq 12$ Ωcm were cut in halves and numbered L_{r1}, L_{l1}, L_{2r}, and L_{2l}.

In the first and second runs the electrode material used was aluminum while in the third run it was polysilicon.

With reference to the third run, in all the thermal stages the entrance and exit of the wafers were done with the furnace at 800°C. The heating of the furnace and wafers from 800°C to the desired temperature was done at a rate of 10°C/min and the cooling down to 800°C was done at a rate of 3°C/min.

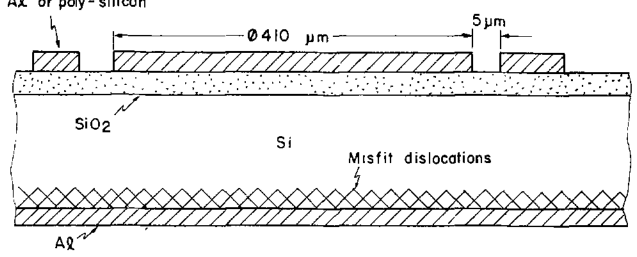

Fig. 1. Sketch of the MOS capacitor

During the third run (initial oxidation), the wafers marked with W were laid horizontally on a quartz susceptor and were supported only at their edges by the quartz bars of the susceptor, while the wafers marked with L were placed vertically on the susceptor.

Measurements.—Storage time, t_f, was measured (at least on ten samples per wafer) by the C-*t* technique using pulses with 6V amplitude and going from the inversion region into stronger inversion. During these measurements, the guard ring was polarized in the strong accumulation region. For some representative samples, relative to the wafer's mean t_f value, we plotted the C-*t* curve and using the Zerbst method we got the shielded surface recombination velocity, *s*, and the generation lifetime, τ_g, where τ_g is twice the value of the bulk lifetime, τ_o (11).

After these measurements, the electrode material and the oxide were stripped off and the crystallographic defects were revealed by a 5 min etching with Wright solution (12).

Results and Discussion

The experimental results of the three runs are shown in Tables I, II, and III. In these tables we have also specified a classification in accordance with the results obtained by the capacitors' C-*t* measurements, with a lower number representing a higher quality structure.

The wafers marked W and having the initial oxidation at 1200°C showed many structural defects due to bending caused by the manner in which they were supported during the initial oxidation. We arrived at this conclusion by comparing the results of group L with M or O_1 with O_2. We can see from our results that although W_7 was within the gettering condition, the result was worse than for W_8 which was not treated within these conditions. The comparison of O_1 with O_2 indicates the same tendency using the same parameters for the two groups. These defects, produced by stress and strain, were substantially eliminated during the POGO stage as the comparison of the results of the group M with O_2 indicates.

Comparing the results of group A with B or C with D, we observe that the combination of the two gettering techniques presents a more powerful gettering action than the HCl oxidation gettering alone. Analogously, comparing group O with N, we observe the same relation between the gettering action of the combination of the two techniques and gettering by POGO alone. These facts indicate that the two techniques have gettering actions at least partially distinct. This means that they complement each other.

Another fact we observed was that the final quality of the wafers was adversely affected by increasing the number of thermal steps after the gettering steps. This can be seen comparing the results of group F with G, H, and I; O with Q; or R with S. Also, longer phosphorus deposition times decrease the crystal quality. This appears to be similar to the former situation, since after a certain time the charge deposition rate or the misfit-dislocation generation rate becomes very small and in this way the process is transformed into an annealing process. To see this, compare the results of group F with J, O with R, or Q with S. These observations suggest that the device fabrication processes, after the gettering stages, have to be as cool as possible.

The wafers with their silox densified in a steam atmosphere presented a grainy appearance. This phenomenon is caused by the silicon etching due to the reaction of the steam with the high amount of chlorine contained in the initial oxide. This event is in accordance with the observations of Claeys *et al.* (13). These wafers also gave worse results than the wafers which had their silox densified in a dry O_2 atmosphere, where this phenomenon did not occur. To see this, compare

Table I. First run wafers' process parameters and variables and experimental results

Group	Wafer	Main thermal treatments: Initial oxidation temperature (°C)	Silox densification atmosphere	Time of POGO (min)	High temperature treatment in O_2	Gate oxidation	Experimental results: $\bar{t}_t \pm \sigma$	Average total etch pit density (10^4 cm^{-2})	Classification

the results of group E with F or O with P. The SiO_2/Si interface that had been etched due to the chlorine had its quality improved by removing the first oxide and oxidizing again, this fact being more evident in the case where a POGO step was not done. This observation can be seen by comparing the results of group A with C or B with D.

Comparing the results of the second run with the third run, one observes that the last ones are better. The factors that must have contributed to this are: (*i*) the method used for the wafer's entrance and exit from the furnace in the thermal steps, (*ii*) the use of polysilicon as an electrode material which brings about a cleaner process, as can be seen by the average interface charge, Q_{SS}/q, of the two runs, which are 6×10^{10} and 1×10^{10} cm^{-2}, respectively, (*iii*) the n-type wafers used may have a lower initial quality.

As to the total number of etch pits, it is interesting to note that the third run wafers presented the lowest numbers, except wafer W_7 which maintained the defects acquired by the bending during the HCl oxidation at 1200°C. Also, the revealing of etch pits shows the absence of stacking faults, as was expected by the oxidations employed.

Conclusion

We obtained a minority carrier generation lifetime of some miliseconds (4-8 msec) on silicon substrates in large-area structures using a basic procedure described in this work. Besides this fact, the contributions that this work adds to this subject are the following.

1. The combination of the two gettering techniques gives better results than one alone, which indicates that the gettering action of the two techniques complement each other.
2. In the fabrication of devices or IC's with high yield and good performance, the thermal processes after the gettering stages have to be as cool as possible.
3. After carrying out the initial oxidation at 1200°C for the conditions described, any thermal treatment in a steam atmosphere should not be done without the removal of this first oxide layer.

4. It is important not to inflict mechanical damage or contamination in the wafer. In addition, precautions should be taken to not introduce defects caused by the manner in which the wafers are supported during thermal treatment or due to thermal stresses.

GaAs Oxidation and the Ga-As-O Equilibrium Phase Diagram

C. D. Thurmond, G. P. Schwartz, G. W. Kammlott, and B. Schwartz (pp. 1366-1371, Vol. 127, No. 6)

V. I. Belyi, A. N. Golubenko, T. P. Smirnova, and K. P. Lelkin:[1] The paper under discussion concerns an important problem: The investigation of phase composition of GaAs oxide films.

The investigation deals with the experimental data obtained by modern analytical techniques and with theoretical consideration by taking into account Ga-As-O ternary phase diagram. In our investigation[2] we also came to the conclusion that such a combined approach is the most informative one and allows us to clear up the layer by layer distribution of the oxide phases in the oxide films on InSb, which is the same type of chemical formation as the oxide films on GaAs.

But from our point of view there are some uncertainties in the paper in question which may ultimately lead to some wrong conclusions.

The authors of the paper have taken into account seven individual phases of the Ga-As-O system: Ga(l,s), Ga_2O_3(s), GaAs(s), As(s), As_2O_3(s), As_2O_5(s), $GaAsO_4$(s) but for some unaccountable reason they have not considered the individual susbtance arsenic tetroxide, As_2O_4. According to Long and Sackman, arsenic tetroxide may be obtained from a mixture of $As_2O_3 + As_2O_5$ and does exist at room temperature up to 400°C.[3]

The enthalpy of formation change of As_2O_4 from individual elements by the reaction

$$2As_{(s)} + 2\,O_{2(g)} = As_2O_{4(s)} \quad [1]$$

is equal to $\Delta H_{298}{}^{of} = -191.1$ kcal · mol^{-1} according to footnote 4 or $\Delta H_{298}{}^{of} = -189.7$ kcal · mol^{-1} according to footnote 5. The calculated standard enthalpy change of As_2O_4 for the reaction

$$As_2O_{3(s)} + As_2O_{5(s)} = 2As_2O_{4(s)} \quad [2]$$

according to 4 is equal to $\Delta H_{298}{}^{o} = -3.3$ kcal with As_2O_3-claudetit and $\Delta H_{298}{}^{o} = -2.5$ kcal with As_2O_3-arsenolite.

As a rule for solid-state chemical processes, the change of entropy ΔS is close to zero and hence it is possible to judge a process taking in consideration the change of enthalpy only. However, the lack of the entropy meaning does not allow us to calculate the change in the Gibbs energy and to make an absolutely correct conclusion.

On the base of the change enthalpy for reaction [2], we suggest the phase equilibrium diagram which is shown in our Fig. 1. In this diagram the two new phase fields are plotted in.

In the paper under discussion, the mixture of As_2O_5 and GaAs in the mole ratio 2:1 was heated at 600°C during 48 hr and by means of Raman scattering it was shown that the products of the reaction are $GaAsO_4$ and As_2O_3. But the mole ratio of the initial substances equal to 2:1 does not give the possibility of getting into the phase field As_2O_3-As_2O_5-$GaAsO_4$ of the diagram (see Fig. 2 in the paper under discussion). In order to reach that field and to have the possibility of detecting arsenic tetroxide, the initial mole ratio of As_2O_5 and GaAs has to be ≥4:1. We have to point out that arsenic tetroxide is unstable above 400°C.[3]

[5] "Selected Values of Chemical Thermodynamic Properties," NBS Technical Note, 270-3, Washington, D.C. (1968).

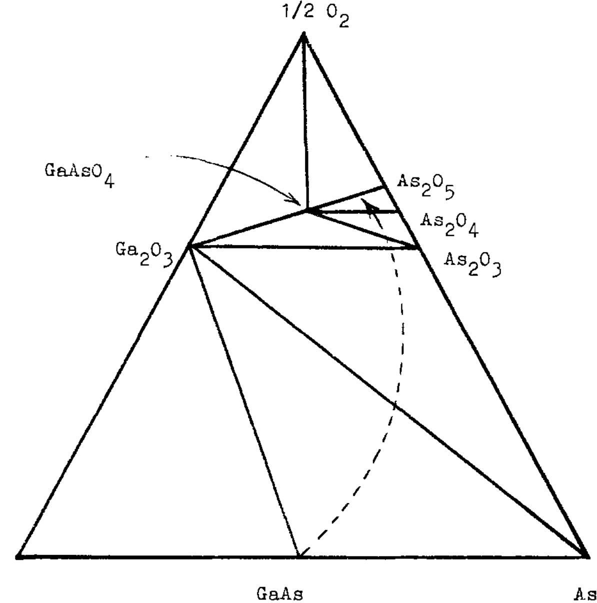

Fig. 1. The Ga-As-O ternary diagram in 25°-400°C temperature region and $P_{O_2} = 1.01 \times 10^3$ hPa.

We repeated the experiment according to footnote 3 with the mixture of $As_2O_3 + As_2O_5$ taken in mole ratio 1:1, and by means of x-ray diffraction technique detected the As_2O_4 phase.

In our works[2,6,7] we showed that in the case of oxygen oxidation of the InSb process the spatial distribution of indium and antimony oxides and elemental antimony in oxide film corresponds to the theoretical distribution which may be obtained from In-Sb-O equilibrium diagram. By the experimental method developed in our Institute,[6] we also found that oxide films on InSb have multilayer composition. For example, when the mole ratio In:Sb is equal to 1:1, we detected the following phase complexes alternating from the InSb-oxide film interface up to the top of the film: InSb, InSb + In_2O_3 + Sb, $In_2O_3 + Sb_2O_3$ + Sb, $In_2O_3 + Sb_2O_3 + Sb_2O_4$, $In_2O_3 + Sb_2O_4 + InSbO_4$.[7]

It seems to us that on the basis of the ternary diagram it is possible to reach more varied conclusions than were offered in the paper under discussion. For instance, it is possible to predict the alternating phase composition when the Ga:As ratio differs from 1:1. When an oxidation of GaAs process takes place in the $As_2O_3 + O_2$ mixture, the Ga:As ratio is ≤ 1 and the phase composition change along the route given in Fig. 1 by a dotted line (the line is drawn arbitrarily) is: GaAs, GaAs + Ga_2O_3 + As, $Ga_2O_3 + As_2O_3$ + As, $Ga_2O_3 + As_2O_3 + GaAsO_4$, $As_2O_3 + As_2O_4 + GaAsO_4$, $As_2O_4 + As_2O_5 + GaAsO_4$.

In conclusion, we should like to emphasize that the good agreement between the final results of the paper under discussion on the Ga-As-O system and our results on In-Sb-O system makes it possible to claim that there exists some general approach to the understanding of the mechanism of $A^{III}B^{V}$ semiconductor compounds oxidation processes.

C. D. Thurmond and G. P. Schwartz:[8] The authors of the comment have pointed out that As_2O_4 as evidenced by the investigations of Long and Sackman[9-11] was not included in an article on the Ga-As-O phase diagram which entailed the specification of the condensed phases in that system. Although we were aware of some earlier (1933) data by Brityke, Kapustinskii, and Chentzova,[12] we must acknowledge having overlooked the more current references by Long *et al.* and failure to comment on our reservations concerning the existence of As_2O_4 as a stable oxide phase.

Whereas the data by Long and Sackman[9-11] clarifies many of the inconsistencies present in the earlier literature on As_2O_4, we remain cautious in our acceptance of their conclusion concerning the existence of this compound. The following comments express the basis for our concern.

1. The authors use a thermodynamic argument in support of their conclusion that As_2O_4 is stable. The Gibbs energy change of the reaction $As_2O_3 + As_2O_5 = 2\ As_2O_4$ is obtained from the enthalpy change. The entropy contribution was assumed to be negligible since, in general, the entropy change for a reaction among solids is small. However, when the enthalpy change is small, as it is for this reaction, the sign of ΔG° will be sensitive to small values of ΔS° (*i.e.*, $T\Delta S^\circ$). Thus the use of ΔH° for ΔG° does not provide significant support for the conclusion that As_2O_4 is stable with respect to As_2O_3 and As_2O_5.

A related aspect of this problem also suggests that the stability of As_2O_4 is not yet known. The authors do not give uncertainties for the enthalpies of formation used in their calculation. If we use the uncertainties recommended by Kubaschewski, Evans, and Alcock,[13] ± 0.8 kcal/mol for both forms of As_2O_3 and ± 1.5 kcal/mol for As_2O_5, and assume no uncertainty in the enthalpy of formation of As_2O_4, a lower limit to the magnitude of the reaction enthalpy uncertainty can be estimated. The uncertainty is ± 2.3 kcal and is seen to be very close to the two calculated enthalpies of -3.3 kcal (claudetite) and -2.5 kcal (arsenolite). With the inclusion of an uncertainty in the enthalpy of formation of As_2O_4, the possibility arises that the reaction enthalpy, and, with the authors assumption, the Gibbs energy, may be positive rather than negative. It is possible, then, that As_2O_4 is not stable.

2. Long and Sackman demonstrated that As_2O_4 could not be produced as a pure, single phase product from an anhydrous reaction of $As_2O_3 + As_2O_5$. Some water is evidently necessary in order to produce the assigned product in high yield. However, it was stated in footnote 9 that the hydrated form of the tetroxide of formula $6As_2O_4 \cdot 5H_2O$ produced the same diffraction lines as anhydrous As_2O_4. By "anhydrous" the authors mean dried to constant weight. One might reasonably ask if the diffraction technique is in fact sensitive to distinguishing between As_2O_4 and materials of the form $As_2O_4H_x$, where x might take on values of 1-4 for hydroxides or oxy-hydroxides, or higher values for incompletely hydrated products. These compounds, of course, would not be part of the Ga-As-O ternary phase diagram.

3. Rather complete synthetic and structural data exist for the formation of two claudetite modifications of As_2O_3.[14-17] These structures are layer like and quite distinct in their x-ray diffraction patterns from octahedral As_2O_3 (arsenolite). *They are also distinctive in that they require approximately 1% of H_2O in order to stabilize.* Although Long and Sackman demonstrated that the diffraction pattern of As_2O_4 did not replicate

the lines of either As_2O_3 (octahedral) or As_2O_5, they do not appear to have excluded the possibility that the compound generated involved a claudetite modification of As_2O_3.

4. The question of whether claudetite or some other hydrogen-bearing compound might be involved deserves careful consideration. We intend to study these questions in more detail using infrared and Raman scattering. The latter technique has already been used to characterize claudetite.[17] Until those studies are complete, we remain cautiously skeptical of the existence of As_2O_4.

The authors make several points about the interpretation of the Ga-As-O phase diagram with the phase As_2O_4 included. One of these points, however, is incorrect, namely that to form As_2O_4 the initial mole ratio of As_2O_5 to GaAs must be $\geqq 4$. This statement overlooks the As_2O_4-As_2O_3-$GaAsO_4$ field. The proper criterion for the formation of As_2O_4 from ratios of As_2O_5 to GaAs is that the ratio be > 2.

Finally, we wish to concur in the conclusions of Belyi *et al.* that the phase diagram approach is a useful tool in studying the oxidation and reaction patterns of certain semiconductors. We would point out for the readers, however, that the form of the In-Sb-O diagram clearly differs from that of Ga-As-O as indicated by the observed phase fields listed by the authors of the comment. The "good agreement" mentioned by these authors should not be construed to mean that the form of the phase fields is identical for the two systems.

On High Temperature Oxidation of Chromium
I. Oxidation of Annealed, Thermally Etched Chromium at 800°-1100°C
II. Properties of Cr_2O_3 and the Oxidation Mechanism of Chromium

K. P. Lillerud and P. Kofstad (pp. 2397-2410 and 2410-2419, Vol. 127, No. 11)

D. Caplan and G. I. Sproule:[19] In these two papers on the oxidation of Cr, Lillerud and Kofstad examine the effect of temperature and pressure, the properties of Cr_2O_3, and the oxidation mechanism. We would like to comment on the following points.

1. In comparing the parabolic rate constants obtained with their thermal-etch oxidation procedure to our results[20] for monocrystalline Cr_2O_3 scales, the authors indicate that our much lower values are in error because no correction was made for volatilization of CrO_3. In fact, we guarded against oxide evaporation by providing a Cr_2O_3 crucible in the hot zone so that the specimens hung in essentially stagnant oxygen saturated with Cr oxide vapor.[20] Additional evidence that our low values of K_p are not caused by oxide volatilization is that, as the authors show in their Fig. 1 (page 2398), our results for polycrystalline scales, similar in structure to their blistered and wrinkled scales, show comparably high K_p values.

2. In the oxidation procedure used by the authors, hot, oxide-free Cr is exposed abruptly to oxygen gas. As a result, very many randomly oriented oxide nuclei form on the metal and produce a fine-grained scale with many oxide grain boundaries to act as preferential diffusion paths. The consequent rapid oxidation rate and high rate of stress generation within the oxide promote separation of the scale from the metal and the wrinkling and lateral growth seen in the authors' illustrations. Values of K_p calculated for such scales are too high because (*i*) the effective specimen area is larger than the geometric area used to calculate the weight gain; (*ii*) the larger area means that the real thickness of the layer is less and diffusion is therefore faster; and (*iii*) in multilayered scaling, the oxide formed before the failure of a layer by perforation is no longer part of the protective diffusion layer. The authors' assumption that the initial scale is dense, plane-parallel, uniform, and adherent is not supported by the photomicrographs. Previous work would indicate that separation and buckling begin early [Ref. (1), Fig. 5] when the vacancy flux is highest.

Hot-bare oxidation also maximizes the overtemperature effect[21] which further increases the initial flux of cation vacancies and the compressive stress. Comparable oxidation conditions were found in our experiments with electropolished Cr on which fine-grained, blistered scale also developed.[20] When this separated layer failed by cracking, oxygen gas rushed into the vacuum gap between scale and metal, contacted the hot, bare Cr (equivalent to the authors' thermal-etch conditions), and formed a second blistered layer. Electropolishing was judged to be an unsuitable preparation method for Cr oxidation because of these defects in scale structure. Because of fine oxide grain size, hot-bare oxidation was also found to have a large effect on Ni oxidation;[22] oxidation constants were as much as 10,000 times higher than for oxidation procedures which formed coarse-grained NiO scales.

3. The authors compare the experimentally determined parabolic rate constants with K_p values calculated from diffusion data for Cr in Cr_2O_3. They consider the approximate agreement between the two sets of data to be evidence of the validity of their high measured K_p values. Such correspondence is to be expected, however, since the diffusion coefficients used for the comparison are themselves high, having been measured on polycrystalline specimens of hot-pressed Cr_2O_3 (Fig. 5, page 2413). It seems probable that the true oxidation constants and diffusion constants are both orders of magnitude lower.

4. When oxidation runs were discontinued by pumping off the oxygen, the specimens were found to lose weight for as long as they were held at temperature in vacuum. The authors conclude that the weight loss is due to the loss of Cr metal which "may penetrate the scale by lattice diffusion and by transport along grain boundaries, easy diffusion paths, and microcracks." Weight loss via microcracks is probable since Cr evaporating from the bare metal surface could migrate through pores or cracks in the separated scale as Cr vapor. In the absence of an oxygen atmosphere, however, there will be no concentration gradient as a driving force for cation diffusion through the oxide whether by lattice or other diffusion paths.

5. The authors observe that oxygen pressure has a major effect on oxidation rate and on whether "logarithmic," "parabolic," or "linear" kinetics are followed. Because of the structural irregularities in the scales the probability is that these changes are from the effect of pressure on the physical structure of the scale. With dense uniform adherent scale the effect of pressure would be minor.

6. The authors observe apparently cubic crystallites of oxide under the blistered scale and attribute them to CrO. Elsewhere they report cubic crystallites of Cr metal under the scale. Perhaps the "cubic" oxide crystals are Cr crystals (formed by evaporation and condensation in the gap between scale and metal), which oxidized to Cr_2O_3 while preserving their former topography.

To conclude, in our view specimen preparations such as the authors' thermal-etch and our electropolishing technique are unsatisfactory for studying the

oxidation of Cr in that they produce fine-grained oxide and promote loss of adhesion and blistering. The major structural irregularities in the scale invalidate the oxidation constants deduced and the subsequent interpretation of oxidation mechanisms. We believe that the Caplan-Sproule parabolic rate constants, which the authors refer to as "extremely low," reliably describe the growth of monocrystalline Cr_2O_3 scales on Cr. Theoretical modeling, such as the mechanism of Cr transport through Cr_2O_3, should be based on "ideal" scales of this type rather than on structurally irregular scales.

P. Kofstad and K. P. Lillerud:[23] We appreciate the interest by D. Caplan and G. I. Sproule on our paper.

Chromium exhibits a complex oxidation behavior. Large growth stresses develop in the scale and cause cracking, plastic deformation, and detachment of the scales. Depending upon the microstructures of the scales important transport processes comprise lattice, grain boundary, and "easy" diffusion and vapor transport in microcracks. Other aspects to be considered are CrO_3 evaporation (at high oxygen pressures and temperatures), vapor transport of chromium from the underlying metal to the detached scale, etc. In view of the complexity it is not surprising that the reaction kinetics and behavior may vary considerably with experimental conditions.

Previous work has demonstrated that the behavior of chromium is highly dependent on specimen, and particularly, surface preparation. In our opinion the reason for these large differences has not been adequately explained. In our work the chromium was thermally etched. This gives an oxide-free surface at the start of the reaction and a reproducible reaction behavior under the various conditions. It is not surprising that this surface preparation may, at least initially, exhibit different reaction behavior compared to surface preparations or experimental procedures whereby an oxide film is established on the metal surface at lower temperature prior to the recorded experiments. No method of surface preparation is more "correct" than other ones. The important point is to demonstrate what takes place under different conditions and to obtain an overall consistent interpretation. We believe that our work has provided additional information on the reaction behavior of chromium.

In our work we have found that specimens lose weight when oxidation runs at high temperatures are discontinued by pumping high vacuum on the system. This has been concluded to be due to loss of Cr metal through the scale. Caplan and Sproule claim that such loss can only take place by Cr vapor transport via microcracks and state that there can be no loss by solid-state chromium diffusion through Cr_2O_3 scales in high vacuum as there will be no concentration gradient as a driving force. Let us analyze their comments. The driving force for chromium transport can, for instance, be considered in terms of the chromium potential gradient through the scale. During oxidation or the high vacuum treatments of oxidized specimens there is a chromium potential gradient through the scale: At the inner scale surface the chromium vapor pressure can be considered equal to that of the vapor pressure of chromium metal; at the outer surface the chromium vapor pressure is smaller. This chromium potential gradient (which will depend upon the chromium potential at the inner and outer surface and the thickness of the scale) is the driving force for the chromium transport regardless of whether this takes place by vapor transport or solid-state diffusion processes. Caplan and Sproule apparently agree that such a driving force is present when chromium is transported as vapor species through the scale, but claim that this driving force is no longer present if the transport takes place by solid-state diffusion. We fail to understand the consistency in their comment. The other important point to consider as regards chromium transport is the mobility (*i.e.*, the diffusion coefficients) involved in the different transport processes. The mobility of the chromium atoms is considerably higher for vapor transport, but chromium is also transported outward through solid-state diffusion processes. If there is no oxygen available at the outer surface to react with the outwardly moving chromium, chromium will evaporate.

Ideal, diffusion-controlled growth of Cr_2O_3 can be correlated with the proper self-diffusion coefficients of the reactants in Cr_2O_3. For ideal parabolic oxidation of metals, it is always of interest to correlate the transport processes with other defect-dependent properties of Cr_2O_3. One should be able to correlate these properties in an overall consistent model for the system. In our work we have attempted to do so by evaluating available data on Cr_2O_3. In this respect there is, however, a very large inconsistency as regards the measured self-diffusion coefficients and the lowest reported values for the apparent parabolic rate constant for oxidation of chromium. These rate constants were estimated from the oxide thickness on some single grains in oxidized Cr specimens. Caplan and Sproule believe that the true self-diffusion coefficients are "orders of magnitude lower" than the measured values. Their reason is that the tracer diffusion studies were done on polycrystalline Cr_2O_3 (hot-pressed specimens, Hagel and Seybolt). However, they fail to quote that Hagel and Seybolt's results are in essential agreement with those of Walters and Grace on single crystal Cr_2O_3 at 1300°C (see our paper II). Furthermore, if grain boundary diffusion were the important process for the hot-pressed specimens, this would be expected to be noted in the tracer penetration profiles.

We believe there is need for further studies. But in general: Polycrystalline material should not necessarily be disqualified for studies of lattice diffusion; the relative importance of lattice and grain boundary diffusion will be a function of grain size, temperature, and ambient partial pressure of oxygen (*i.e.*, bulk defect concentration in the oxide samples).

In our publication we speculated if the large discrepancy between the diffusion data and oxide thicknesses measured in local areas on some oxidized Cr specimens could be due to CrO_3 evaporation or that diffusion in Cr_2O_3 is highly dependent on crystal orientation. We do not have an explanation for the discrepancy at this stage. But in an attempt to contribute to a clarification of the matter we are presently studying chromium transport through dense Cr_2O_3 scales with the aim of delineating the contribution due to lattice diffusion. This work will be submitted for publication in the near future.

We would like to emphasize that from our analysis of defect-dependent properties of Cr_2O_3 it seems most probable that the important defects in Cr_2O_3 at low partial pressures of oxygen are chromium interstitials. Correspondingly we do not believe that chromium diffuses by the vacancy mechanism and that there are vacancy fluxes as suggested by Caplan and Sproule. Also, if chromium interstitials are important, the ideal parabolic rate constant should be independent of the ambient partial pressure of oxygen. This is not the case if vacancy diffusion predominates (see paper II).

In our work we have demonstrated large differences in oxidation behavior when individual runs are made at different oxygen pressures. We conclude that this is related to the microstructures of the scale, and that

[23] Department of Chemistry, University of Oslo, Blindern, Oslo 3, Norway.

transport can take place both by solid-state diffusion and vapor transport through microcracks. As we point out in our publication (II) the larger activation energy of our work compared to several earlier studies is presumably "related to a higher amount of easy diffusion paths and microcracks in the Cr_2O_3 scales when specimens are pretreated through thermal etching."

Caplan and Sproule suggest that overtemperature effects may be important in our work. For the relatively slow rate of reaction, specimens with a thickness of 1 mm, and high temperatures employed in our work any such effects are of no or but minor significance as regards the overall oxidation behavior.

In conclusion we may mention that we are also currently studying other aspects of oxidation of chromium such as the effect of cold-work and oxidation of pre-oxidized Cr with dense Cr_2O_3 scales. These results will be published in due time.

Electrochromism in Solid Phosphotungstic Acid

B. Tell (pp. 2451-2454, Vol. 127, No. 11)

P. G. Dickens and R. H. Jarman:[24] In this discussion we propose a simple electrochemical explanation for the salient phenomena observed by Tell in his recent investigation of $H_3PO_4 \cdot W_{12}O_{36} \cdot 29H_2O$ (PWA) as a self-contained electrochromic cell. Schematically the cell consists of

$$\text{glass, } SnO_2 \ |PWA| \text{ graphite}$$

Both the SnO_2 coated glass and graphite electrodes are good electronic conductors. The PWA is a fast proton conductor in which acid dissociation occurs

$$HA \cdot nH_2O = H_3O^+ + [A \cdot (n-1)H_2O]^-$$

and the presence of a connected pathway of H_2O molecules facilitates proton transfer through a Grotthus-type mechanism

$$H_3O^+ + H_2O \ldots H_2O \ldots H_2O = H_2O \ldots H_2O \ldots H_2O + H_3O^+$$

(Here and subsequently the symbols H_3O^+ and H_2O imply hydronium and H_2O molecules in a mobile phase of the solid hydrate.) The cathodic reaction (coloration process) which occurs at the SnO_2/PWA interface is

$$H_3O^+ + e = H_2O + H(sol) \qquad [1]$$

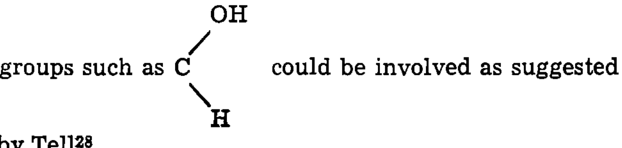
where H(sol) represents H chemically attached to a polytungstate anion (most probably as —OH). This chemical attachment is associated with the creation of a formal W(V) oxidation state and a blue coloration (*c.f.*, H_xWO_3-hydrogen tungsten bronze[25]). By analogy with the values measured for H_xWO_3 and heteropoly "blues,"[26,27] we estimate a standard electrode potential for reaction [1] in the range 0.1-0.4V. This is effectively the same coloration process as described by Tell.

At the graphite/PWA interface, a balancing proton injection reaction is necessary. Possible candidates for this, which would occur at increasing anodic potentials, are

$$2H_2O - e = H_3O^+ + OH(ads) \qquad [2]$$

$$3/2H_2O - e = H_3O^+ + 1/4\,O_2 \qquad [3]$$

where OH(ads) represents hydroxyl groups attached to the carbon surface Alternatively, oxidizable surface groups such as C(OH)(H) could be involved as suggested by Tell[28]



$$+ 2H_2O - 2e = {>}C{=}O + 2H_3O^+ \qquad [4]$$

The overall cell reaction

$$1/2H_2O = H(sol) + \text{oxidized products}$$

will clearly be associated with a positive free energy change, since reactions [2]-[4] will, so far as can be reasonably estimated, have standard electrode potentials in excess of 0.8V.[29] The observed bleaching of the cells with graphite electrodes under short-circuit conditions confirms this (see paper under discussion).

Moreover, for each proposed anodic reaction there is a strong possibility that free oxygen will be evolved, either by direct reaction [3] or by subsequent chemical recombination of —OH or —O groups. This will certainly be so if high coloring voltages are employed. This in turn could lead to a slow bleaching effect on open circuit, even within a totally encapsulated cell, when oxygen evolved at the anode during coloration subsequently diffuses to and reacts with reduced PWA in the cathode region

$$H(sol) + 1/4\,O_2 = H_2O$$

Passivation of Fe/Cr Alloys Prepared by Laser-Surface Alloying

P. G. Moore and E. McCafferty*

Naval Research Laboratory, Washington, D.C. 20375

Laser-surface alloying is a relatively new technique for modifying the chemical composition of metal surfaces (1-4). In this process, a metallic coating and the underlying metal substrate are rapidly melted using a high power, continuous wave CO_2 laser. This rapid melting and concomitant mixing followed by rapid resolidification serves to alloy the metals contained in the coating and the substrate. The depth of the laser-surface alloyed region is typically 10 to 100 μm.

The manufacture of chromium steel surface alloys has been previously reported (1-4). These surface alloys have been characterized by metallography, microprobe analysis and hardness tests, but to our knowledge, the electrochemical behavior of such alloys has not yet been published. The purpose of this communication is to describe briefly the preparation of iron/chromium surface alloys, and to report initial results regarding their electrochemical behavior.

PROGRESS

Specimens of AISI 1018 steel (0.18% C, 0.8% Mn) were coated with electroplated or sputter deposited chromium layers ranging in thickness from 10 to 20 μm. These specimens were irradiated with a CO_2 continuous laser (λ = 10.6 μm) at power outputs up to 7.5 kw. The laser was focused to a spot approximately 0.15 mm in diameter, so that power densities as high as 10^7 w/cm^2 were obtained. The specimens were mounted on a turntable and were swept into the laser beam at linear velocities of 10 to 375 cm/sec. The depth of melting, and hence the alloy composition, was controlled by varying the sweep velocity. Samples were laser-processed in a helium gas shield to minimize oxidation of the metal surface.

For a typical processing speed of 50 cm/sec, a point on the surface is illuminated by the laser for less than 0.5 msec. and the metal remains molten for less than about 1 msec. At the edge of the melt where only the fringe of the beam is seen, these times approach zero while near the center of the molten zone the times are longer. The molten metal is quenched by the cold substrate at cooling rates of 10^6-10^7 K/sec. This rapid resolidification is the central feature of laser processing.

Figure 1 shows a micrograph of a cross section through an Fe/Cr surface alloy produced by a single pass of the

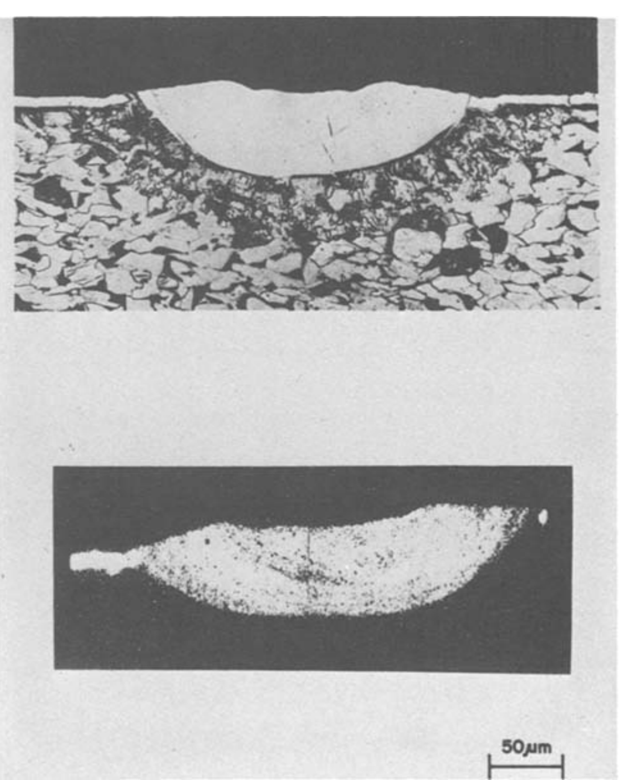

Fig. 1. A transverse cross section of an Fe/Cr laser-surface alloy with average Cr content of 20% shown at the top. Below is a chromium x-ray display of the same melt.

*Electrochemical Society Active Member
Key words: Lasers, surfaces, alloy, passivity

laser. The cross sectioned sample has been etched with Nital. This etchant attacks the steel substrate but does not bring out the metallurgical structure of the surface alloy. Figure 1 also shows a Cr x-ray display of the melt as determined with an electron microprobe. As is evident from the x-ray display, substantial mixing has taken place throughout the depth of the melt even though the laser interaction time was only 0.5 msec and the material was molten for less than 1 msec. The effects of surface tension gradients and fluid flow in the mixing process have been considered by various investigators (5,6). To produce a surface alloy over an extensive area, successive laser passes, spaced a fraction of a melt width apart, have been employed. A cross section of such a surface alloy is shown in Fig. 2. Electron microprobe analysis indicates that the distribution of components is similar to that observed for individual melts.

Figure 3 shows anodic polarization curves for 1018 steel and three different Fe/Cr laser-surface alloys in deaerated 0.1M Na_2SO_4. Each sample was immersed for 30 minutes and then held cathodically at -1.0V vs. S.C.E. for 5 minutes. Following this cathodic treatment, steady state open circuit corrosion potentials were attained by each sample after an additional 30 minute immersion period. Anodic polarization curves were determined potentiodynamically at a scan rate of 10 mV/min.

As seen in Fig. 3, 1018 steel undergoes extensive dissolution at all anodic potentials, but the Fe/Cr surface alloys passivate. With increasing Cr content, there are decreases in both the critical current density for passivation and the current density in the passive region. The laser surface alloy with the highest Cr content passivates without undergoing an active-passive transition. However, it should be noted that the current densities in the passive region are higher than those usually observed for the corresponding Fe/Cr bulk alloys. For example, the passive current density for the 20% Cr surface alloy is about 5 times that observed by Lumsden (6) for bulk Fe-18 Cr and about 50 times the value observed by Lislovs and Bond (7) for bulk Fe-25 Cr in 1N sulfuric acid.

SUMMARY

Laser-surface alloys containing chromium passivate in 0.1M Na_2SO_4, with the ease of passivation increasing with increasing Cr content. Optical microscopy and electron microprobe analysis show that chromium is dispersed uniformly through the melt region.

Poly p-Substituted Phenyl Isopropenyl Ketones for Positive Photoresists

K. Nate and T. Kobayashi

Hitachi Limited, Production Engineering Research Laboratory, Yoshida-machi, Totsuka-ku, Yokohama-shi, Japan

Positive photoresists for photolithography divide roughly into, (I) an alkaline-soluble UV resist composed of phenolic novolac - quinonediazide type and, (II) ketone polymers such as poly methyl isopropenyl ketone (PMIPK) and poly methyl methacrylate (PMMA) for deep UV lithography. One problem with a positive alkaline-soluble UV resist is lack of resistance to chemical agents. On the other hand, positive deep UV resists are excellent in resistance to chemical agents, but are not sufficient in photosensitivity to achieve practical photolithography. In this paper, highly photo-sensitive positive resists consisting of poly p-substituted phenyl isopropenyl ketones, which are excellent in resistance to chemical agents, are reported.

Ketone polymers undergo severe degradation when exposed to ultraviolet light, and it is shown that the photolysis could be explained on the basis of the Norrish type I and type II reactions (1). PMIPK is a ketone polymer which is highly photo-sensitive to deep UV radiation, having a wavelength for maximum absorption of 285 nm (2). In this paper, the photolysis of the copolymers of p-substituted phenyl isopropenyl ketone (p-X-PhIPK, X=H, CH_3, and CH_3O), which has an aromatic ring conjugated to a carbonyl group in order to shift the absorption of copolymers to the longer wavelength region, and MMA, is discussed.

The monomers were synthesized by ordinary methods, and identified by nuclear magnetic resonance spectra. The copolymers were prepared by free-radical polymerization in sealed tubes under vacuum using azobisisobutyronitrile as an initiator. The purified copolymers were dissolved to 15 weight percent in methyl isobutyl ketone. The resist films were coated using a spinner on silicon wafers with a thickness of about 1 μm, and prebaked at 150 °C for 30 minutes. All exposures were carried out with a Xe - Hg lamp. After exposure, the resist films were developed by dipping them in a mixture of methyl isobutyl ketone - xylene (70 : 30 by vol. %) for 2 minutes at 23 °C, and then rinsing them in xylene - isopropyl alcohol (50 : 50 by vol. %) for 1 minute.

The sensitivity and the spectral sensitivity of P(p-X-PhIPK - MMA) are shown in Table I and Figure 1, respectively, compared with PMIPK and PMMA. The spectral sensitivity was measured using Koana's apparatus, whose UV source consisted of a Xe lamp (3). As shown in Table, the resists consisting of P(p-X-PhIPK -MMA) have a higher sensitivity than those of PMIPK and PMMA, and the sensitivity of P(p-X-PhIPK - MMA) greatly depends on the molecular weight and the initial

Table I. Sensitivity of Positive Photoresists

Polymer*	MW	t_0** (μm)	Sensitivity***
A P(PhIPK(6.4)-MMA)	7.6×10^4	0.6	600
B P(PhIPK(16)-MMA)	3.2	0.9	550
C P(PhIPK(24)-MMA)	2.0	0.9	250
D P(PhIPK(28)-MMA)	1.4	0.6	100
E P(p-Me-PhIPK(34)-MMA)	0.5	0.4	150

thickness of resist films. P(p-MeO-PhIPK - MMA) has a higher sensitivity than other polymers. As shown in Figure, it is obvious that P(p-X-PhIPK - MMA) undergoes photodegradation in a longer wavelength region compared with deep UV resists, and the sensitivity at a longer wavelength increases with the content of p-X-PhIPK in copolymers.

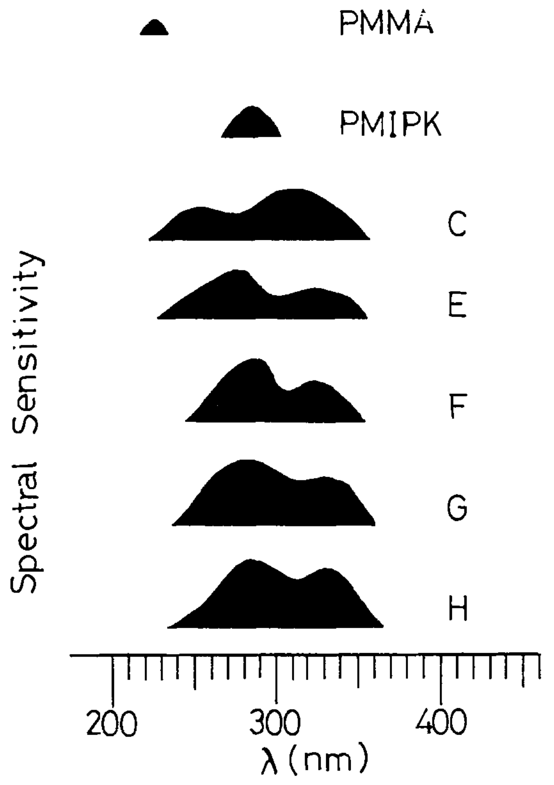

Fig. 1. Spectral sensitivity of positive photoresists.

It was ascertained by gel permeation chromatography that the molecular weight of these resists decreased with UV radiation, in analogy with PMIPK and PMMA. Infrared (IR) evidence showed that the peak of the carbonyl group at 1720 cm^{-1} decreased in the case of PMIPK with UV radiation. But a change in IR spectrum was hardly visible in the case of P(p-X-PhIPK - MMA). It was ascertained that the Norrish type I reaction occurred in the photolysis of PMIPK (4, 5), and that the polymer containing pendant chromophoric groups of $C_6H_5C(=O)$- behaved differently from those containing aliphatic carbonyl groups in the polymer backbone.

The detailed photolithographic performance and the characteristics of electron beam exposure of poly p- substituted phenyl isopropenyl ketones will be described in a subsequent paper.

Estimation of Series Resistance Losses and Ideal Fill Factors for Photoelectrochemical Cells

P. Singh,* K. Rajeshwar, R. Singh,**,[1] and J. DuBow

Department of Electrical Engineering, Colorado State University, Fort Collins, Colorado 80523

ABSTRACT

A simple method is presented for estimating series resistance losses and ideal fill factors for a given photoelectrochemical device from current-voltage measurements at varying light intensity. This method is demonstrated on a model PEC device comprising the n-GaAs|$A\ell C\ell_3$-n-Butyl Pyridinium Chloride, Ferrocene/ Ferricenium ion couple |C system. The extent to which the photovoltaic output is degraded by high series resistance losses can be directly estimated using the present approach.

INTRODUCTION

There has been much discussion in recent years on photoelectrochemical (PEC) methods of solar energy conversion (1,2). Two key factors which may dictate the feasibility of PEC devices for terrestrial applications are electrode stability and energy conversion efficiency. The problem with photoanodic dissolution of n-type small band-gap semiconductors in contact with aqueous electrolytes, has been effectively tackled by the use of aprotic, nonaqueous solvents (3-5). On the other hand, fabrication of efficient devices based on nonaqueous electrolytes, requires minimization of the series resistance losses in the system. The manner in which a high series resistance degrades PEC performance may be understood with reference to Fig. 1 which shows a simplified equivalent circuit for a PEC cell under operating conditions. The photocurrent, J_{ph} is represented by a constant current generator (6) opposite in direction to the dark current, J_{dark} of the device. The faradaic resistance, R_f denotes the resistance associated with leakage currents flowing across the semiconductor/electrolyte interface and in an ideal device should be infinitely large. R_L is the external load resistor and J_{out} and V_{out} represent the current and voltage output generated by the device. The series resistance, R_s comprises the contributions from the back metal contact, semiconductor bulk and the interfacial and bulk resistances of the electrolyte. R_s should be minimized to obtain a high device efficiency.

In this paper, we present a simple method whereby the magnitude of R_s and the maximum fill factor may be estimated for a given PEC device from current-voltage measurements at varying light intensity. A model system comprising the n-GaAs/ Aluminum Chloride-n Butyl Pyridinium Chloride (BPC) molten salt electrolyte interface, was chosen for the present analyses. The Ferrocene/Ferricenium ion couple was used as the redox system.

EXPERIMENTAL

Electrodes were fabricated from single-crystal n-GaAs (<$\bar{1}\bar{1}\bar{1}$> orientation, donor density: $2.17 \times 10^{17}/cm^3$) obtained from commercial sources. Details on electrode preparation and electrolyte handling are given elsewhere (5,7). The electrolyte was adjusted to be slightly basic of the neutral 1:1 (relative molar ratio of $A\ell C\ell_3$ and BPC) composition for the present measurements. Nominal concentrations of ferrocene and ferricenium chloride were 200 mM and 20 mM respectively. Short-circuit currents (I_{sc}) and open-circuit voltages (V_{oc}) were measured under illumination with a tungsten-halogen lamp using instrumentation previously described (5,7).

RESULTS AND DISCUSSION

The equivalent circuit shown in Fig. 1 leads to the following relationship between the output current, J_{out} and voltage output, V_{out} (6):

* Electrochemical Society Student Member.
**Electrochemical Society Active Member.
[1]Present address: Energy Conversion Devices, Troy, Michigan 48084

Key words: equivalent circuits, open-circuit voltage, short-circuit current density.

$$J_{out}(1+R_s/R_f) = J_{ph}-(V_{out}/R_f)-J_{dark} \quad [1]$$

The dark current is given by the equation:

$$J_{dark} = J_o\ [\exp\ (qV_j/nkT) - 1] \quad [2]$$

where J_o is the reverse saturation current density, V_j is the voltage appearing across the junction and n is the junction ideality factor. If we assume a device such that R_f is very large (i.e., $V_{out}/R_f \simeq 0$ and $R_s/R_f << 1$), we get on substituting Eq. [2] in Eq. [1]:

$$J_{out} = J_{ph} - J_o\ [\exp\ (qV_j/nkT) - 1] \quad [3]$$

In the above expression, note that V_j is given by $(V_{out} + J_{out}R_s)$ (cf. Figure 1). For small R_s, however, $V_j \simeq V_{out}$. The maximum power output, P_m ($P_m = J_mV_m = (J_{out}V_{out})_{max}$) may be found by differentiating the product $J_{out} \times V_{out}$ and setting it equal to zero. The fill-factor, FF which is equal to the ratio $J_mV_m/J_{sc}V_{oc}$ is given by the expression (8):

$$FF = \frac{V_m}{V_{oc}}\left\{1 - \frac{[\exp\ (q\ V_m\ /nkT)\ -1]}{[\exp\ (q\ V_{oc}/nkT\ -\ 1]}\right\} \quad [4]$$

According to Eq. [4], FF should improve with increasing values of V_{oc} and with decreasing values of n ($n = 1$ for an ideal device, Ref. 7).

In the presence of high R_s and low R_f, the approximations leading to Eq. [3] break down. The current-voltage relationship in the presence of a high R_s may be written as (9)

$$J_{out} = J_{ph}-J_o\{\exp(\frac{q(V_{out} + J_{out}R_s)}{nkT})-1\} \quad [5]$$

The fill-factor now is decreased below the value given by Eq. [4] and is equal to (9):

$$FF = \frac{(V_{out}J_{out})_{max}}{V_{oc}J_{sc}}$$

$$= \frac{J_{out}}{J_{sc}}\ \{(1 - \frac{J_{out}}{J_{sc}}\frac{J_{sc}\ R_s}{V_{oc}}) + \frac{nkT}{q\ V_{oc}}$$

$$\times\ \ell n[1- \frac{J_{out}}{J_{sc}}\ x(1-\exp(\frac{q\ V_{oc}}{nkT}\ (\frac{J_{sc}R_s}{V_{oc}}\ -1))]\}_{max} \quad [6]$$

The deleterious influence of high R_s on cell performance manifests in the effect on FF (Eq. [6]) and overrides the influence on J_{sc} as given by the expression:

$$J_{sc} = J_{ph} - J_o\ (\exp\ (\frac{q\ J_{sc}R_s}{nkT}) - 1) \quad [7]$$

Equation [6] may be used to calculate the ideal FF for a particular device in the absence of any series resistances. J_{out}/J_{sc} is varied to find the maximum value for the ratio $V_{out}J_{out}/V_{oc}J_{sc}$. The ideal FF thus determined should correspond to those estimated directly from J_{sc} versus V_{oc} plots for the particular device at varying light intensity. Figure 2 illustrates a typical plot for the n-GaAs|$A\ell C\ell_3$-BPC, Ferrocene/Ferricenium | C system. An ideal FF of 0.74 was calculated from the data in Fig. 2. This calculation follows the usul procedure of estimating FF from J-V plots (once the values on the current axis in Fig. 2 are transposed so that the maximum V_{oc} value corresponds to the "current zero") and is consistent with the value obtained by iterative procedures using Eq. 6.

To obtain R_s, the ratio $V_{out}J_{out}/V_{oc}J_{sc}$ is calculated for various values of J_{out}/J_{sc} using R_s as a variable parameter in Eq. [6]. The maximum value of $V_{out}J_{out}/V_{oc}J_{sc}$ is then compared with the experimentally observed FF values. For the model PEC system in the present study, the ratio $V_{out}J_{out}/V_{oc}J_{sc}$ was found to peak at 0.43

for J_{out}/J_{sc} = 0.75 when a series resistance of 225 Ω was assumed. The experimental FF values (0.44) and the current ratio J_{out}/J_{sc} at an incident light intensity of 100 mW/cm^2 for the n-GaAs|AℓCℓ$_3$-BPC, Ferrocene/Ferricenium ion |C (7) are in good agreement with the above values. The R_s value computed above may be compared with that reported for the resistivity of the Aℓ Cℓ$_3$-BPC electrolyte by previous authors (125 Ω -cm, Ref. 10). For the electrode spacing employed in the present case (~ 0.5 cm) and within the limits of error introduced by neglecting the influence of redox species on electrolyte resistivity and the other contributions to the R_s term (e.g., Ohmic contact resistance, semiconductor bulk resistance, interfacial effects), agreement between the two values is considered satisfactory.

To summarize, the present method enables an estimation of series resistance losses and the maximum fill-factor for a given PEC device from measurement of J_{sc} and V_{oc} at varying light intensity.

ABSTRACT

By electrochemical oxidation of $NaCrS_2$ in Li cells, phases of the type Na_xCrS_2 ($x \geqq 0.1$) have been prepared, which provide host structures for Li^+ intercalation. More than 1 eq. Li^+/mole $NaCrS_2$ may be reversibly intercalated at sufficiently high rates. The three-dimensional layered structure of these phases proves to be particularly rugged, thus allowing repeated cycling with minor performance losses. The high potentials of Li/Na_xCrS_2 couples allow high energy densities to be obtained. Starting from a theoretical value of 518 W-hr/kg, a calculation based on the performance at 1.0 mA/cm^2 and on the real battery weight still gives a value of 142 W-hr/kg for an 8 hr discharge rate. Values of the Li^+ chemical potential in Na_xCrS_2 and of the free energy of intercalation have large negative values typical of efficient chalcogenide cathodes. Nonlinearly and continuously decreasing E-x plots seem to indicate the formation of a single phase through Li^+ occupation of energetically different lattice sites.

Among the group IVb to VIb transition metals, Cr is the only one which cannot form the corresponding CrS_2 or $CrSe_2$ stable chalcogenides. Schöllhorn (1) has reported on the possibility of oxidizing ternary phases $ACrX_2$ (A = Li, Na, K; X = S, Se) in aqueous solutions, thus obtaining $A_x^+(H_2O)_y(CrX_2)^{-x}$ phases which could be reversibly oxidized/reduced in the range $0.1 < x < 0.5$. For $x < 0.1$ the metastable CrX_2 could be formed.

The closest approach to CrS_2 was obtained by Murphy (2, 3) who was able to prepare $Cr_{0.75}V_{0.25}S_2$ by partial substitution of V by Cr in VS_2. This mixed chalcogenide has fairly high voltages and improved capacity over VS_2. However, as also pointed out by Whittingham (4), both its capacity and current capability are still unsatisfactory and undergo further decrease on cycling.

Attempts to prepare CrS_2 by oxidation of $LiCrS_2$ with I_2 in CH_3CN solutions only allowed the formation of $Li_{0.7}CrS_2$ (2). Indeed, I_2 allows one to obtain VS_2 from $LiVS_2$ but is not strong enough to oxidize $LiCrS_2$ to CrS_2 (3). Efforts to synthesize CrS_2 with the stronger oxidant Br_2 gave a substantial amount of chromium dissolution (3). The use of $LiCrS_2$ as a cathode in an Li cell assembled in the discharged state (4), only permitted 20-30% Li removal at C.D. $\geqq$ 1 mA/cm^2, this matching the result obtained by chemical oxidation.

Key words: $NaCrS_2$, Li secondary batteries, Li^+ intercalation in host structures.

$LiCrS_2$ is a hexagonal compound with Li^+ octahedrally coordinated by S atoms arranged in hexagonally close-packed layers (5). It is isostructural with $LiTiS_2$ but, unlike the latter, is characterized by high ionicity (4, 5). Indeed, its paramagnetic moment, 3.83 magnetons, corresponds to a number of unpaired electrons of 2.96, *i.e.*, the degree of ionization of Cr^{+3} is 99%. The Li-S distance is 2.62Å (5).

$NaCrS_2$ has a rhombohedral structure formed by CrS_2^- layers with Na^+ layers intercalated in between (5, 6) (Fig. 1). The succession of layers is that of a cubic close-packing and leads to an octahedral coordination for both Cr and Na. This structure can be considered as a layered three-dimensional one (7). From Rüdorff's data (6) a value of 3.63 magnetons was calculated for the paramagnetic moment, thus giving 2.81 for the number of unpaired electrons. This means that $NaCrS_2$ is still characterized by high ionicity but shows, unlike $LiCrS_2$, weak covalent bonds as also may be inferred by the Cr-Cr distance of 3.53Å (8) *vs.* 3.46Å in $LiCrS_2$ (5). The Na-S distance is 2.77Å (6).

As pointed out by Whittingham (4), a reduced ionicity of the lattice is beneficial for chemical ion diffusion due to charge shielding. The c/a ratio in $NaCrS_2$ is higher than in $LiCrS_2$ [1.84Å (6) *vs.* 1.74Å (5)]

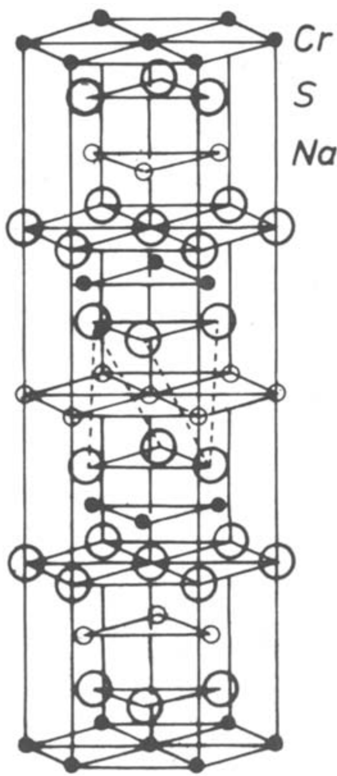

Fig. 1. Crystal structure of $NaCrS_2$ [Ref. (6)]

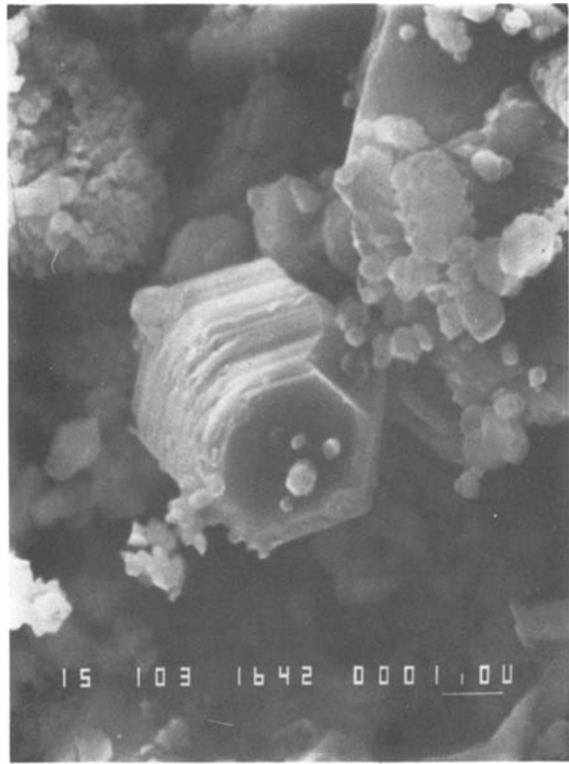

Fig. 2. SEM picture of $NaCrS_2$ crystals

due to increased ionic distances along the c-axis. This allows one to foresee wider pathways through which alkali ions can move.

Further, as noted by Murphy *et al.* (3) the emf's of Li/MX_2 cells are expected to increase in the order Ti < V < Cr, based on the oxidation potentials of the respective M_{ox}/M_{red} couples, leading to a corresponding increase of the theoretical energy density. This assumption was corroborated by the finding of the same authors (3) that the emf's at $x = 0.5$ eq. of Li are: 2.30V for $Li/Li_{0.5}VS_2$ and 2.65V for $Li/Li_{0.5}Cr_{0.75}V_{0.25}S_2$, while it is only 2.10V for $Li/Li_{0.5}TiS_2$.

Preliminary tests with $Li/LiClO_4$-PC/$NaCrS_2$ cells have indeed shown the possibility of removing consistent amounts of Na^+ (~70% at 1 mA/cm^2). On the subsequent cycling, it was seen that alkali ions could enter/leave the CrS_2^- layers with high efficiency, thus encouraging a more extended investigation.

In the preliminary reports of Basu and Worrell (9) on $Li/Na_{0.18}TS_2$ cells (T = Ta or Ti), it was shown that these cathodes could intercalate up to 3 eq. Li as a result of an increased c lattice parameter over that of TiS_2 or TaS_2. This result supports our expectation of good performance by $NaCrS_2$.

Experimental

$NaCrS_2$ was initially prepared according to a method described by Rüdorff (6). Basically, K_2CrO_4 was mixed with Na_2CO_3 and S in 1:30:30 weight ratio and heated in an alumina crucible at 650°-700°C for 30-60 min. The synthesized material was verified to be single phase by x-ray diffractometry. Chemical analyses showed compositions close to the stoichiometric, and emission spectral analysis revealed no appreciable amounts of potassium in the product. The brick-red crystal powder had 1.0-1.6 m^2/g specific surface area (BET) and the SEM pictures exhibited the typical hexagonal platelets (Fig. 2).

Initial electrochemical experiments showed, however, that cathodes prepared from this product have low coulombic efficiencies which were assigned to the low specific surface area. Indeed, a marked improvement was achieved with $NaCrS_2$ samples having higher specific surface area. The highly dispersed $NaCrS_2$ powder was synthesized by a modification of Rüdorff's method (to be disclosed in a subsequent paper), whereby $NaCrS_2$ powder with a specific surface area up to 20 m^2/g could be obtained.

Since $NaCrS_2$ is not a good electronic conductor ($\rho \simeq 10^5$ Ω·cm) it appeared necessary to use cathode formulations with conductive additives. Good results were obtained by adding to $NaCrS_2$ a 2:1 carbon black Teflon mixture (30%) and then intimately dry mixing these components. The cathodes (exposed geometric area 1-5 cm^2), prepared by pressing the mixture on an Ni exmet grid at 500 kg/cm^2, had a mean porosity of 30%.

The cathode thickness was varied from 0.3 to 2.5 mm corresponding to 50-400 mg/cm^2 of the cathode mixture.

In the experimental cells the Li anode, wrapped in a polypropylene nonwoven separator, had a surface area exceeding that of the cathode by a factor of 5-8. The electrolyte solution, 1M $LiClO_4$ in PC with a water content less than 60 ppm (as determined with the Fischer method), was also in a great excess. All operations for the cell assembly were performed in a dry box (H_2O < 50 ppm, monitored by an electrochemical sensor based on phosphoric acid as a hygroscopic substance).

In the cyclic voltammetry experiments and the preliminary diffusion coefficient experiments, $NaCrS_2$ without additives was used. In the first case this was justified by the observation that better shaped curves with very limited background currents were obtained. In the second case, this allowed us to obtain cathodes which, by virtue of the high compacting pressure (8500 kg/cm^2), had a real surface area close to the geometric one. *D* values are currently being investigated as a function of cathode composition using the current pulse technique described by Worrell (10, 11).

The *E*-*x* plot was obtained with a galvanostatic technique which allowed the determination of quasi-thermodynamic *E* values. A thin $NaCrS_2$ cathode (50

mg/cm^2) was charged at low rate (0.1 mA/cm^2) until the $Na_{0.1}CrS_2$ composition was reached. After OCV stabilization, the cathode was discharged at 0.1 mA/cm^2 down to 1V and then recharged at the same C.D. The average of the E values during second charge and discharge for a given composition was taken. This technique, which allows a faster determination of the E-x characteristics in comparison with real OCV determination, is in a way similar to the potentiostatic technique described by Thompson (12).

After assembling, the Li/$NaCrS_2$ cells (initial OCV, 2.8-2.9V) were charged to 3.5V, at 0.5 mA/cm^2, whereby oxidation degrees corresponding to formulas in the range $Na_{0.2}CrS_2$-$Na_{0.3}CrS_2$ were attained.

Results of Discussion

Quasi-thermodynamic studies.—By oxidizing a thin cathode (50 mg/cm^2) up to 3.5V at a low rate (0.1 mA/cm^2) we were able to reach $Na_{0.1}CrS_2$. This material, representing so far the closest approach to CrS_2, was used to obtain the quasi-thermodynamic E-x plot in Fig. 3. In spite of the low voltage at the end of discharge (1.15V at $x = 1.1$) the hysteresis during the subsequent charge was limited and allowed us to put some confidence on the E-x curve thus plotted. Preliminary OCV-x measurements with $NaCrS_2$ charged up to $Na_{0.3}CrS_2$ have allowed us to ascertain that the quasi-thermodynamic plot coincides well with the OCV-x plot.

It is seen in Fig. 3 that the emf of Li/$Li_xNa_{0.1}CrS_2$ with x up to 0.75 is higher than that of TiS_2. It exceeds also that of VS_2 as anticipated in the introduction.

The right-hand ordinate in Fig. 3 presents the values of μ_{Li^+}, *i.e.*, the chemical potential of the intercalated cation in kJ/mole.

The data in Fig. 3 can also be used to estimate the free energy of intercalation ΔG by the expression

$$\Delta G = -F \int_0^x E dx$$

as recently proposed by Nagelberg and Worrell (13). The value of ΔG for $Li_{1.0}Na_{0.1}CrS_2$ is -56.0 kcal/mole which compares well with those of other Li dichalcogenides: -57.4 for $Li_{1.0}TiS_2$, -53.1 for $Li_{1.0}VS_2$, and -50.5 for $Li_{1.0}TaS_2$ (13).[1]

As found for TiS_2 (see Fig. 3) and other layered dichalcogenides (4) the E-x plot of $Li_xNa_{0.1}CrS_2$ falls nonlinearly with the increase of x. The absence of true voltage plateaus is indicative of the formation of a single phase all over the intercalation range. Preliminary x-ray data substantiate this assumption. Both upon charge (Na^+ removal) and upon discharge (Li^+ intercalation) no new peaks appear, thus excluding the nucleation of new phases. Instead, $NaCrS_2$ peaks are slightly shifted, so indicating minor lattice parameters variations.

[1] Whittingham (4) reports -49.3 kcal/mole for TiS_2.

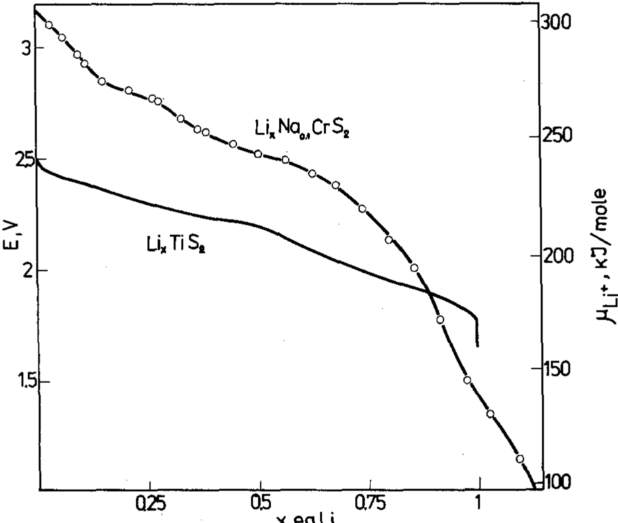

Fig. 3. *E*-*x* plot of an Li/$Li_xNa_{0.1}CrS_2$ cell [curve for TiS_2 from (Ref. 12).

In the crystal lattice of $NaCrS_2$ (Fig. 1) (6) the octahedral positions of the alkali metal atoms are not equivalent. The top and bottom Na layers are made each of 3 Na atoms which are below 3 and above 6 S atoms. The middle Na layer is made of 6 Na atoms placed between two layers of S atoms each comprising 3 atoms. It might be supposed that the occupancy of the middle Na layer would require different energy than the 2 remaining Na layers. This could be the reason for the changes in the slope of the E-x curve. Rouxel (14) had explained similarly a knee found in the E-x curve of $NiPS_3$.

There is little doubt that Li^+ ions occupy the vacant octahedral sites in Na_xCrS_2. However, tetrahedral sites are also available. It is known that in TiS_2 Li^+ is inserted in octahedral positions which are energetically more favorable than the tetrahedral ones (4). Indeed, the radii of the two sites are 0.89Å and 0.64Å, respectively (radius of Li^+, 0.7Å). However, as Li^+ diffuses in TiS_2 on its way between two octahedral sites, it has to pass through a tetrahedral one (4, 14). NaS_6 octahedra are larger than LiS_6 octahedra (Li-S distance, 2.57Å; Na-S distance, 2.77Å) so that the corresponding tetrahedra are also larger. This is to say that temporary occupation of tetrahedral sites by Li^+ in Na_xCrS_2 is even more probable than in Li_xTiS_2.

Furthermore, as the ratio between intercalated Li^+ and deintercalated Na^+ may well exceed one, it is highly probable that, at high x, some reorganization of Li^+ coordination might take place, *i.e.*, tetrahedral sites could also be permanently occupied. The sum of ionic radii of Li and S (2.49Å)[2] does not exclude the existence of Li^+ in tetrahedral sites. The Li-S distance is shortened by about 0.3Å when passing from octahedral to tetrahedral coordination (4, 15). If we suppose that a similar decrease occurs for Na_xCrS_2, the tetrahedral Li-S distance should be near to 2.45Å, which is not too far from 2.49Å. Tetrahedral coordination has already been found for Cu^+ and Ag^+ in $CuCrS_2$ and $AgCrS_2$ (5).

Li^+ may occupy the empty positions in the lattice of $NaCrS_2$ in an ordered way. The formation of an ordered Li^+ superlattice in transition metal dichalcogenides has been already observed (12-14). Thompson (12) has investigated this phenomenon in TiS_2 in depth, reaching the conclusion that Li^+ occupies preferential positions in the layers as a function of x in Li_xTiS_2. According to this author, the E-x plot and the related ($-\Delta x/\Delta V$) *vs.* x plot are indicative of such ordering. In particular, the "incremental capacity" ($-\Delta x/\Delta V$) would show maxima at compositions corresponding to ordered structures. This view was strongly criticized by Berlinsky (15) who, on the basis of statistical mechanics considerations, has concluded that minima, rather than maxima, should be found at the composition, corresponding to ordering.

The "incremental capacity" *vs.* x plot (Fig. 4) of $Li_xNa_{1-x}CrS_2$ reveals two maxima at $x \sim 0.25$ and $x \sim 0.5$ and two minima at $x \sim 0.3$ and $x \sim 0.9$. Presently, we are not in a position to interpret more closely the significance of the maxima and minima. We can only observe that, since the structure of $NaCrS_2$ is an ordered one, $Li_{0.9}Na_{0.1}CrS_2$ is expected also to be ordered. The minimum at $x \sim 0.9$, although rather flat, could be related to this situation.

[2] Average of best literature values.

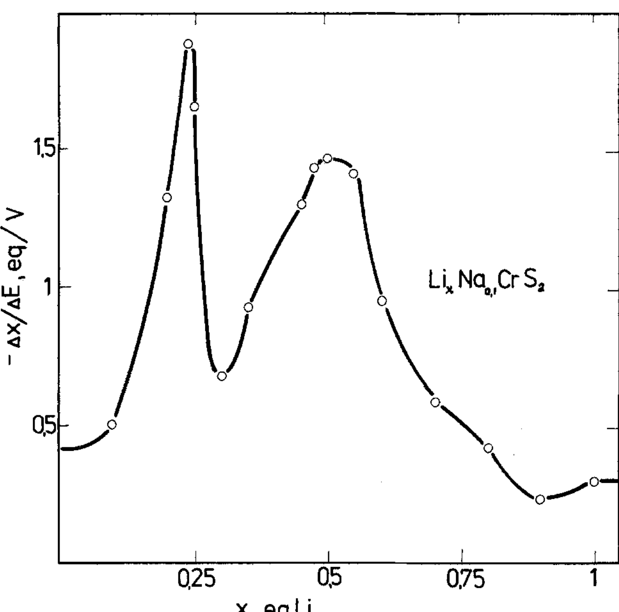

Fig. 4. The incremental capacity *vs.* composition plot obtained from data in Fig. 3.

We have been supposing throughout this discussion on Li^+ intercalation that the structure and lattice parameters of Na_xCrS_2 do not differ significantly from those of $NaCrS_2$. Our first results from x-ray analysis confirm that the $NaCrS_2$ structure is maintained and limited variations (few unit percent) of the *a* and *c* parameters occur during both charge and discharge. This was in a way expected on the basis of the rigid crystal structure of $NaCrS_2$ brought about by its high ionicity.

Initial performance of Na_xCrS_2 cathodes.—Preliminary experiments proved that performance of Na_xCrS_2 cathodes can be significantly improved by increasing the specific surface area of the initial $NaCrS_2$ material. The results of a more systematic study in this respect is shown in Fig. 5, where the specific capacity of comparatively thick electrodes (2.5 mm, 400 mg/cm²) obtained at three C.D.'s and 1.5V cutoff is plotted *vs.* the surface area (BET) of $NaCrS_2$. At the lower and medium C.D. there is an initial steep rise of the specific capacity, whereafter a saturation is attained. The almost linear plot at the higher C.D. (2.0 mA/cm²) suggests that a further improvement could be expected in cathodes prepared with a higher dispersity (> 12 m²/g) $NaCrS_2$. Samples with BET area higher than 20 m²/g are now available and will be shortly investigated.

The effect of particle size on performance of chalcogenide cathodes has been pointed out by various authors. Chianelli (16) has shown that in a small TiS_2 crystal (5.6 μm between opposite edges in the hexagonal layers) the intercalation flux of Li^+ is 18×10^{-8} g/cm² sec, whereas in a larger crystal (40 μm) it is only 1.3×10^{-8} g/cm² sec. This behavior was related to the higher strain induced by intercalation of Li^+ in the larger crystal due to the reduced layer flexibility. Whittingham (17) has shown that 2.7 m²/g TiS_2 has a higher capacity and discharge voltage in comparison with 0.3 m²/g TiS_2. Atlung (18) has related the cathode efficiency of porous cathodes to the radius *r* of the particles through the characteristic ratio $Q = TD/r^2$, where *T* is the stoichiometric discharge time and *D* the chemical diffusion coefficient. It is obvious from the above ratio that a low *r* can offset low diffusion coefficients.

We have ascertained the relation between cathode performance and thickness at various C.D.'s. Figure 6 shows that with 12 m²/g $NaCrS_2$, good specific capacities are obtained also with thick cathodes. We are inclined to relate the flat maxima observed around 1.8 mm (more evident at higher C.D.) to the competition between two opposite effects. By increasing the thickness of the porous electrode the true volumetric C.D. decreases. On the other hand, the electrolyte diffusion resistance grows, due to the increased length of the pores in the thicker cathode and the cutoff voltage is attained earlier.

The cell discharge voltage is plotted in Fig. 7 as a function of composition at various current drains. The pattern observed at the lower load (0.5 mA/cm²) allows some considerations. First, the potential decreases below the value one would expect if $NaCrS_2$ were formed again upon discharge. Secondly, 1 eq. Li^+ may be intercalated, although the cathode composition at the beginning of discharge, *i.e.*, $Na_{0.2}CrS_2$-$Na_{0.3}CrS_2$, would lead one to expect no more than 0.7-0.8 eq. Li^+ intercalated. The first result indicates that the alkali ion entering the empty positions created in the $NaCrS_2$ lattice by Na^+ removal is essentially Li^+. In view of the considerable electrolyte excess in the experimental cells, the probability of Na^+ reentering the Na_xCrS_2 lattice is very small.

From the second result it is evident that the compound $Li_{1-x}Na_xCrS_2$ may be further reduced. Whittingham (4) has observed the same behavior with an $LiCrS_2$ cathode. As $Li_{1-x}Na_xCrS_2$ can be reoxidized

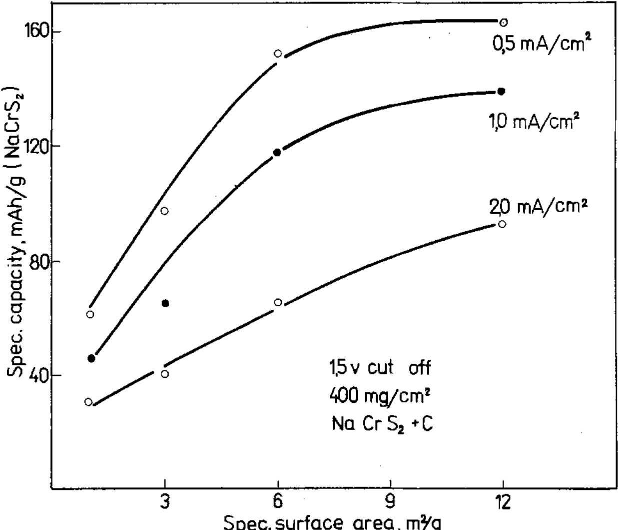

Fig. 5. Effect of specific surface area (BET) on the specific capacity of $Li/Li_xNa_{0.2}CrS_2$ cells at various C.D.

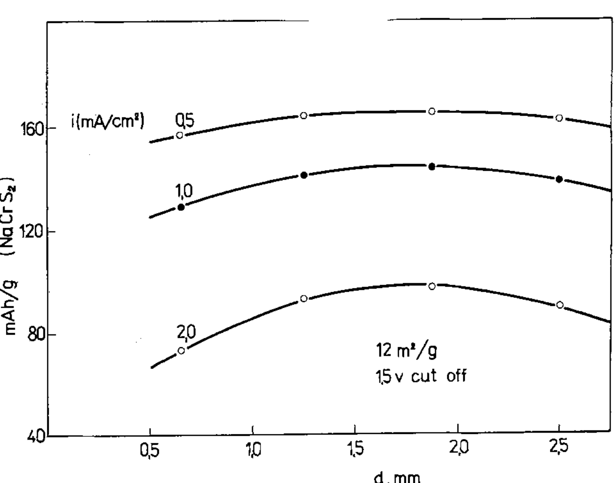

Fig. 6. Effect of cathode thickness on the capacity of Li/Li_x-$Na_{0.2}CrS_2$ cells.

after accepting more than 1 eq. Li^+, we suppose that even excess Li^+ could enter lattice positions without causing structural degradation.

Figure 7 shows the moderate ability of $Li/NaCrS_2$ cells to sustain high current drains. Power density in chalcogenide cathodes primarily depends on the diffusion coefficient of the alkali ion in the host lattice and on the possibility of accommodating an electron in the conduction band. As is well known, TiS_2 fulfills both these requirements, thus explaining its very high rate capability (4). Our preliminary measurements of Li^+ diffusion in Na_xCrS_2 gave D values in the range 10^{-10}-10^{-11} cm²/sec [for TiS_2 $D = 1$-$2 \cdot 10^{-8}$ (19, 20) — $5.6 \cdot 10^{-9}$ (11)]. This is sufficient to explain the modest performance of Na_xCrS_2 at high C.D.

This is also evident from the curves of Fig. 8, where the cathodic volumetric energy density is seen to decay with volumetric C.D. This decay, more pronounced for thick cathodes, does not hinder achieving comparatively good energy values, as will be later confirmed.

The high temperature performance of $NaCrS_2$ as a cathode material was exhibited in a preliminary experiment in an Li, Al/LiCl, KCl/Na_xCrS_2 cell at 430°C. A coulombic efficiency of *ca.* 20% was achieved at a high C.D., 0.2 A/cm².

Cycling performance.—The intrinsic reversibility of the phases Na_xCrS_2 obtained by electrochemical oxidative deintercalation of $NaCrS_2$ is demonstrated by the typical voltammetric curve in Fig. 9. A thin film cathode prepared by pressing $NaCrS_2$ powder without carbon black on an Ni grid was used for this measurement. Both the small peak-voltage separation and the equality of the cathodic and anodic area are characteristic of a reversible cathode material. Repeated cycling did not exhibit any appreciable alterations in the curves.

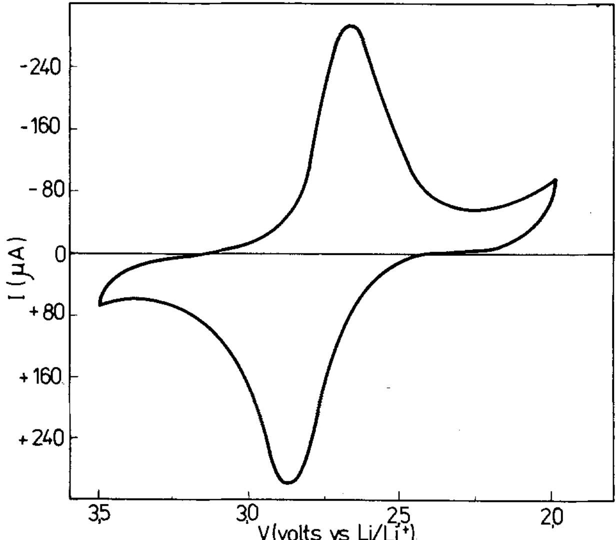

Fig. 9. Cyclic voltammetry of a thin film $NaCrS_2$ cathode. Scan rate 25 mV/min.

The cycling capability of $NaCrS_2$ was explored also in experimental cells with porous cathodes. The first experiment was carried out with cathodes (1.5 mm) prepared with the low dispersity $NaCrS_2$ (1.5 m²/g). The charge and discharge C.D. was 0.5 mA/cm² provided by a galvanostat. The cycles were time limited (3 hr for each half-cycle) so that the d.o.d. was 22% in all cycles (Fig. 10). The initial decay of the average discharge voltage up to 200 cycles was stronger, whereafter it diminished at a lower rate. The overall decrease in the discharge voltage during the 500 cycles in over 4 months was 0.22V. This result provided the first evidence for the good cycling capability of Li/Na_xCrS_2 cell.

The next experiments were carried out with cathodes prepared with a more dispersed $NaCrS_2$ (12

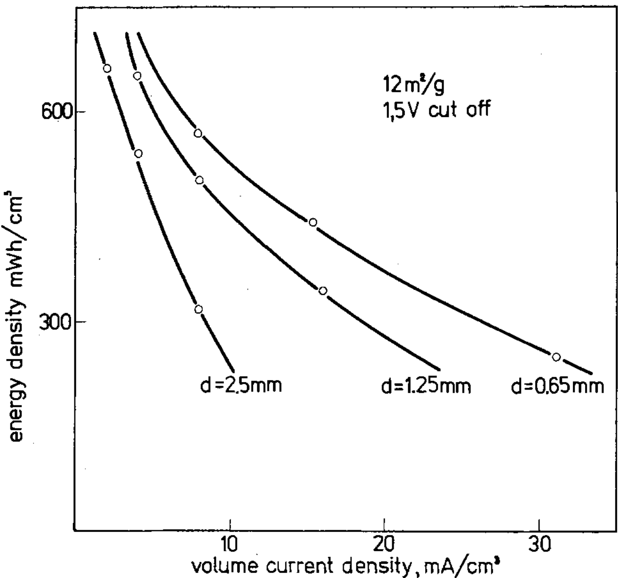

Fig. 8. Volumetric specific energy of $Li/Li_xNa_{0.2}CrS_2$ cells as a function of volumetric current density.

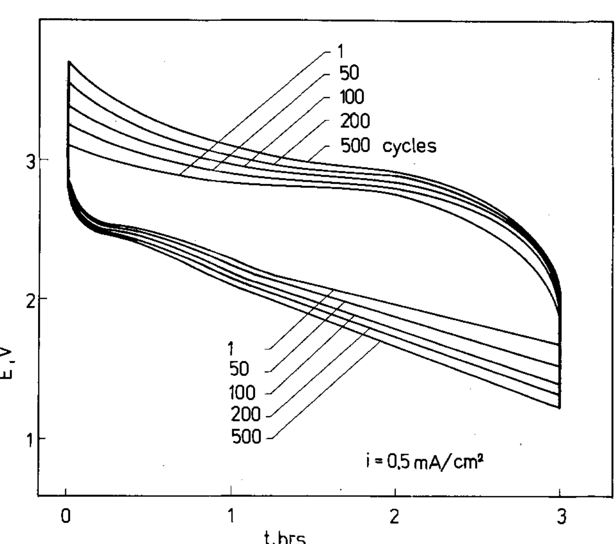

Fig. 10. Charge-discharge curves obtained on cycling of an $Li/Li_xNa_{0.2}CrS_2$ cell at 0.5 mA/cm². D.o.d. = 22%.

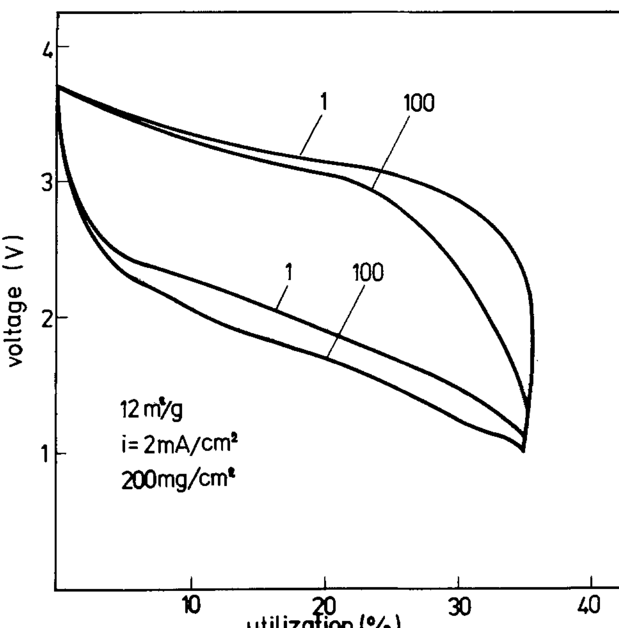

Fig. 11. Charge-discharge curves obtained on cycling of an $Li/Li_xNa_{0.2}CrS_2$ cell at 2 mA/cm^2 cathode prepared with dispersed $NaCrS_2$ (12 m^2/g).

m^2/g) synthesized by the improved technique. Figure 11 presents the 1st and 100th cycle of a cell with a cathode 1.25 mm thick cycled at 2 mA/cm^2 between 1.1 and 3.5V with the aid of automatic equipment with voltage control. The initial practical energy density (referred to the weight of anode and cathode only) of 134 W-hr/kg decreased to 120 W-hr/kg after 100 cycles, *i.e.*, by only 10%. The cycling was terminated due to failure in the equipment.

The comparison between the discharge curves in Fig. 10 and 11 reveals the beneficial effect of the increased surface area of the $NaCrS_2$ cathodes on the energy and power capabilities under cycling conditions as well. Indeed, the discharge curves of the 1st and the 100th cycles in Fig. 11 are only slightly lower than the respective curves in Fig. 10 in spite of the fact that they are obtained at a C.D. 4 times higher and at a d.o.d. 13% larger than those in Fig. 10.

The energy storage capabilities of the Li/Na_xCrS_2 cell are reviewed in Table I in comparison with those of well-known ambient temperature Li secondary cells with dichalcogenide cathodes: TiS_2 and $V_{0.25}Cr_{0.75}S_2$. The semi-theoretical energy densities for the Li/Na_xCrS_2 cell, estimated from the data in Fig. 7, are referred to weights of the active materials only. The energy densities of real cells can be acquired by multiplying this figure by the packaging coefficient (18), which represents the ratio of the weight of the active materials to the weight of all materials in the cell. A realistic evaluation for the packaging coefficient yields 0.50, from which a 10% reduction is made for the container and terminals. The expected energy density of a real Li cell with an Na_xCrS_2 cathode 0.7 mm thick at a C.D. of 1 mA/cm^2 (8 hr discharge rate) will be 142 W-hr/kg. This compares well with the evaluation of Gaines (22) for an Li/TiS_2 cell at the 1-6 discharge rate, 1.34 W-hr/kg.

Table I.

	TiS_2	$V_{0.25}Cr_{0.75}S_2$	$Na_{0.1}CrS_2$
ΔG intercalation (kcal/mole)	−49.3	—	−56.0
Initial emf (V)	2.47	2.8	3.15
emf at $x = 1$ (V)	1.87	2.4	1.35
Theoretical energy density (W-hr/kg)	481	550	518
Semi-theoretical energy density (W-hr/kg) (1st cycle)	420[a]/350[b]	360[c]	410/315/190[d]

[a] 1.0 mA/cm^2, 1.5V cutoff [Ref. (17)].
[b] 2.5 mA/cm^2, 1.5V cutoff [Ref. (21)].
[c] 0.4 mA/cm^2, 2.0V cutoff [Ref. (2)].
[d] 0.5, 1.0, and 2.0 mA/cm^2, 1.5V cutoff (This paper).

In view of the promising energy storage characteristics of the Na_xCrS_2 cathode in Li secondary cells, further work is in progress aimed to improving its energy and power density mainly by using high dispersity $NaCrS_2$ material.

Other areas of research include: compositional variation of the diffusion coefficient, structural investigation of $Li_{1-x}Na_xCrS_2$ phases by SEM and x-ray analysis, cycling at high rates, and temperature dependence of cell performance.

Further investigation on $NaCrS_2$ is justified not only by the reported performance of Li/Na_xCrS_2 cells[3] but also by economic considerations. Indeed, $NaCrS_2$ is prepared in the air from very cheap chemicals unlike other transition metal dichalcogenides which have to be prepared in evacuated quartz ampuls from very pure elements.

Current Density and Electrolyte Distribution in Motive Power Lead-Acid Cells

Won G. Sunu* and Brian W. Burrows*

Gould Incorporated, Gould Laboratories, Rolling Meadows, Illinois 60008

ABSTRACT

Current density and electrolyte distributions were investigated in a lead-acid cell of the industrial motive power type. The current density distribution was calculated from the measured potential distribution using a treatment based on the terminal effect. Results show that the current density is strongly nonuniform and dependent on plate height. The acid density distribution was measured directly under both stationary and circulating electrolyte conditions over a range of discharge rates. Analysis of the data confirms that, under stationary conditions, stratification develops due to natural convection and shows that the electrode capacity is limited by the availability of electrolyte within the electrode pores.

Lead-acid cells designed for industrial motive power use are relatively tall (400-800 mm) with a small cross-sectional area. This design is dictated by the need to assemble cells into batteries of a variety of voltages and capacities in a restricted area as in fork-lift trucks, underground mining vehicles, and diesel-electric submarines.

For some time it has been recognized that tall cells of this type will have a nonuniform distribution of current density in the vertical direction during cycling (1-3). At the beginning of discharge, the current density in the upper part of the electrodes, near the current collecting tab, will be higher than in the lower part. The distribution will vary with time depending on the factors that limit the utilization of active material. As Bagshaw *et al.* (4) have shown, increasing the grid conductivity in tall plates, while keeping the current density constant, results in an increase in capacity and in energy per plate. This effect is especially marked at high discharge rates.

The influence of electrode resistance on current density distribution is called the terminal effect. This effect describes the nonequipotential condition of the electrode resulting from ohmic potential drops in the electrode (1). Tobias and Wijsman (2) developed a theoretical treatment of the terminal effect and showed that for plane parallel electrode systems with small interelectrode-electrode length ratios, parallel current flow can be assumed, resulting in an expression in closed form for current density distribution. Despite the availability of the theoretical tools, no experimental measurements of potential distribution in lead-acid cells have previously been reported with the aim of using the theory to calculate current density distribution.

Not only is the current density in tall cells nonuniform during cycling, the electrolyte concentration is also nonuniformly distributed. This vertical gradient of concentration, or stratification as it is commonly called, is a well-known phenomenon in lead-acid batteries. The authors recently reported some detailed measurements of acid stratification in 400 A-hr motive power cells (5). In the present work, the investigation of acid density gradients was extended to cover several discharge rates and the effect of electrolyte circulation. The aim was to elucidate further the influence of acid density gradients on active material utilization, and hence on capacity, and to determine, if possible, the effect of nonuniform current density distribution on the extent of stratification.

Our interest in obtaining a better internal characterization of motive power lead-acid cells arose from our involvement in the development of and experience with semi-industrial cells used in battery-powered vans in the U.S. Postal Service fleet (6). It was recognized that the current density and electrolyte distribution would be nonuniform over the height of the cells during discharge and that this nonuniformity would influence the cell performance; however, no data were available. Thus, the aim of this work was to determine the current density distribution and electrolyte distribution as a function of distance from the top of the electrodes. To this end we measured, during cycling, (*i*) the ohmic potential losses in the grids and the electrode polarization, and (*ii*) the variation of acid density (and capacity) both without and with electrolyte circulation.

Experimental

A five-plate cell was built for this work using production plates (Gould 66E type) and a clear PVC container. The two positives and three negatives were separated by microporous rubber separators. The positive and negative grids were 3.8 and 3.0 mm thick, respectively. Both grids were 142 mm wide and 432 mm long. The plate separation was 4.1 mm compared to 3.5 mm in the production cell. The positives were wrapped

* Electrochemical Society Active Member.

Key words: potential distribution, natural convection, stratification.

with the usual fiberglass mat and perforated PVC retainer to minimize the shedding of active material.

Measurements of ohmic potential losses, electrode polarization, and acid density were made via probes placed equidistantly along the length of the cell. The location of these probes is indicated in Fig. 1. Ohmic potential losses in the current collector were measured via insulated lead wires soldered to the grids at five, equally spaced, vertical locations. Five wires were soldered to the surface of the positive grid and five to the negative grid. In addition, wires were attached to the tops of the terminal posts. Plate polarization during cycling was measured using ten Luggin capillary probes from individual Hg/Hg_2SO_4 reference electrodes. The capillaries were positioned on either side of a separator at the same five vertical locations as the wires attached to the grids. Acid density was measured via five sampling tubes placed vertically between the separator and the wrapping of one of the positive plates. The tubes were of flexible polyethylene of 0.9 mm internal diameter.

The test cell was equipped with a pump for electrolyte circulation with removal of electrolyte at the base of the cell and addition at the top. The cell element fitted snugly into the cell case with a clearance of 1 mm between the outside negatives and the container. The cured plates were formed in conventional fashion and the final acid density adjusted to 1.290 g-cm^{-3}. The total volume of acid in the cell was 1800 cm^3.

The rated capacity of the positives is 66 A-hr per plate at the C/6 rate. In the test cell containing two positives, the actual capacity was 140 A-hr at the C/5.5 rate. This increase was due to the fact that the acid was circulated prior to each half-cycle to ensure an initially uniform acid distribution from top to bottom of the cell. Furthermore, to provide sufficient space for the probes, the plate separation was slightly greater than normal.

Discharges were run manually at three different currents, namely; 26, 50, and 100A, corresponding to discharge times of 5.5, 2.5, and 1 hr, respectively. A two-step, constant-current, charge regime was used. A 30A current was applied until about 85% of the discharged capacity had been replaced, followed by a finishing rate of 10A with an overcharge of between 10 and 20%. All experiments were carried out at room temperature.

During cycling, values of grid potentials and electrode potentials were monitored by a data logger (Fluke 2240B). At intervals small volumes of acid (1 cm^3) were withdrawn from each of the five positions with syringes for measurement of density with a digital density meter (Mettler/PAR). After each density measurement, the withdrawn acid was returned to the cell.

Results

Potential distribution.—The internal potential losses were first measured along a current path through the center of the cell. The current path is shown schematically in Fig. 1 as a resistance network and the measured values are plotted in Fig. 2. The following potential differences were measured during a discharge-charge cycle: cell polarization (E_o); positive electrode polarization (E_p); negative electrode polarization (E_n); sum of ohmic drops between the terminals and the grid centers ($E_g^+ + E_g^- + E_t^+ + E_t^-$). The potential drop across the separator (E_s) was calculated as a residual on the assumption that the sum of the internal potential differences must equal the potential difference at the terminals. The term "polarization" as used here refers to the difference between the measured voltage during discharge or charge and the initial open-circuit voltage.

Figure 2 shows that the cell was positive-limited on discharge with the positive electrode polarization being 70% of the total cell polarization at the voltage cutoff (1.7V per cell). The combined positive and negative electrode polarization accounted for 94% of the polarization at the end of discharge. On charge, the polarization losses at the positive again account for most of the cell polarization except toward the end of the charge steps (near 4 and 7 hr) where the negative electrode polarization increases sharply. This sharp increase corresponds to the onset of hydrogen evolution, indicating that the negative electrode is almost fully charged.

A more complete characterization of the internal potential losses is shown in Fig. 3 and 4 for discharge and charge, respectively. The current paths between

the probes are indicated as a resistance network with the potential differences between the probe locations indicated in millivolts. The potential differences across the separator are residuals and the experimental uncertainty was such that these values cannot be considered meaningful due to the errors in the electrode polarization measurements.

Figure 3 shows that at the start of discharge, the electrodes are more polarized at the top, near the terminal, than at the bottom. This nonuniform polarization and, hence current distribution, is due to the terminal effect as there was no vertical gradient of acid concentration or of temperature at the start of discharge. After 4 hr, the nonuniformity of the potential distribution is reduced. On charge, Fig. 4 shows that the terminal effect is still evident at the negative, even after 4 hr of charge, but the positive electrode was more uniformly polarized both initially and after charging for 4 hr.

For both discharge and charge, the negative electrode polarization was always less than that at the positive. This was due to the three negative/two positive electrode arrangement which results in a lower apparent current density at the central negative plate. It is also clear that the ohmic drops in the grid were smaller for the negative even though the negatives were thinner and contained less lead than the positive grids (380 *vs.* 510g). This observation can be attributed in part to the electrode arrangement, as discussed above, and partly to the role that the negative active material plays as an electronic conductor. Further evidence of this latter effect is clearly shown in Fig. 5 where the grid potentials at different locations, measured with respect to the top of the plate, are plotted as a function of the discharge time. The potential loss of the negative plate increases with time;

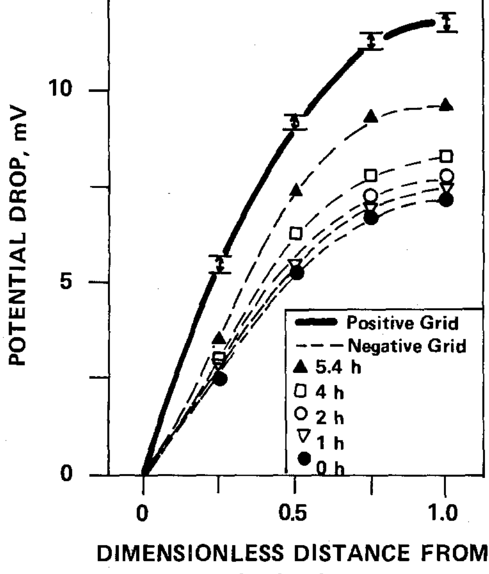

Fig. 5. Potential drops in grids of motive power cell *vs.* position on grid for various times during a discharge at 26A.

namely, from 7.2 mV initially (at the bottom) to 9.7 mV at the end of discharge, due to the increasing degree of conversion of Pb into $PbSO_4$. On the other hand, potential losses in the positive grid essentially remained constant during discharge, indicating that the positive active mass, PbO_2, has no significant effect on the grid resistance.

Electrolyte distribution and capacity.—The acid stratification that developed during discharge at the C/5.5, C/2.5, and C/1 rates is shown in Fig. 6. The extent of the stratification, *i.e.*, difference between the density at the bottom and top of the cell, at the end of the discharge was not strongly dependent on the discharge rate being 0.08 g-cm^{-3} at the end of the 5.5 hr discharge and 0.06 g-cm^{-3} at the end of the 1 hr discharge. On the other hand, the absolute values of the acid densities increase with increase in the discharge rates from 1.13 to 1.21 g-cm^{-3} at the top of the cell at the end of the 5.5 and the 1 hr discharges, respectively. This behavior is expected in view of the decreasing utilization of active material, and hence, decreasing consumption of H_2SO_4, as the discharge rate increases. On open-circuit stand, following the end of discharge, it should be noted that the absolute values of acid density continue to decline for several hours before stabilizing, while the extent of stratification remains relatively constant. The continued decline on open-circuit stand is due to the diffusion of more concentrated acid between the plates into the acid-depleted pores of the electrodes.

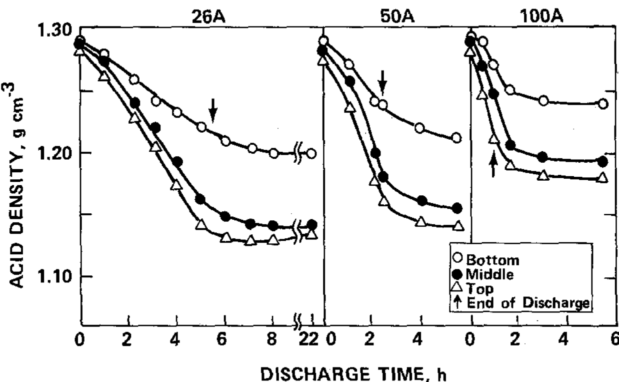

Fig. 6. Acid density *vs.* discharge time for three discharge rates as measured in a motive power cell.

The effect of electrolyte circulation on the distribution of acid density at the 5.5, 2.5, and 1 hr rates is shown in Fig. 7. It should be noted that the acid densities measured at five different heights, at any given time, formed single data points. In other words, circulation resulted in a uniform mixing of the acid with the elimination of stratification. Two cases are shown in Fig. 7, *viz.*, circulation with and without an external 1400 ml reservoir of acid. As expected, the acid density at the end of discharge was higher with an external reservoir except at the 1 hr rate where no difference was observed. This high-rate behavior suggests that only the acid in the pores of the electrodes is effectively utilized during discharge.

The effect of electrolyte circulation on cell capacity at the 5.5, 2.5, and 1 hr rates is shown in Fig. 8. Electrolyte circulation without an external reservoir had only a small effect on capacity, increasing it by about 4% over the range of rates from 5.5 to 1 hr. This increase is attributed to the absence of acid stratification (see Fig. 7). The inclusion of an external reservoir of 1400 ml further increased the capacity by 15% at the 5.5 hr rate and by 9% at the 2.5 and 1 hr rates. The larger increase in capacity at the 5.5 hr rate can be attributed to the increased time during which higher density acid is available in relation to the rate of acid consumption during discharge. At higher discharge rates, the denser acid is still available between the plates, but the imbalance between the faster rate of consumption of acid and the rate of mass transfer of acid through the plate wrapping into the pores of the electrodes limits the increase in capacity to only 9%. An increase in capacity beyond what was observed could be achieved by forcing electrolyte to flow through the porous electrode.

Discussion

Current density distribution.—The vertical variation in potential as measured during discharge and charge (see Fig. 3 and 4) indicates that the current density distribution is nonuniform over the height of the plates. Potential data were also obtained for discharges at 50 and 100A (see Table I). This nonuniform distribution of current density can be caused by the terminal effect and, to some extent, by the development of acid stratification.

The theoretical treatment of the terminal effect developed by Tobias and Wijsman (2) was simplified by Shepherd (7). We have used a variation of Shepherd's treatment to analyze our potential distribution data to calculate current density distribution.

Following the previous authors (2, 7), we assume (*i*) linear polarization and (*ii*) that current flow in the electrolyte is perpendicular to the electrodes. Both of these assumptions are reasonable since the apparent current densities were relatively low and the

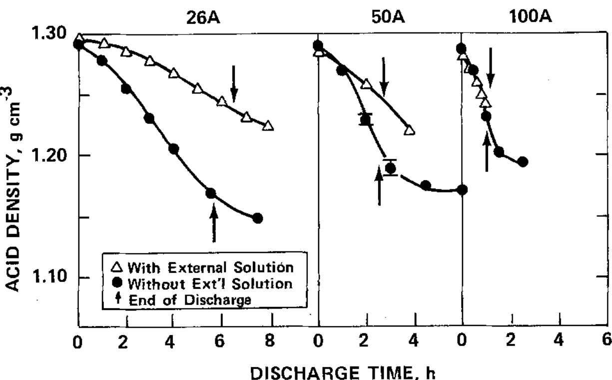

Fig. 7. Acid density vs. discharge time for three discharge rates showing effect of acid circulation (at 92 ml/min) both with and without an external reservoir.

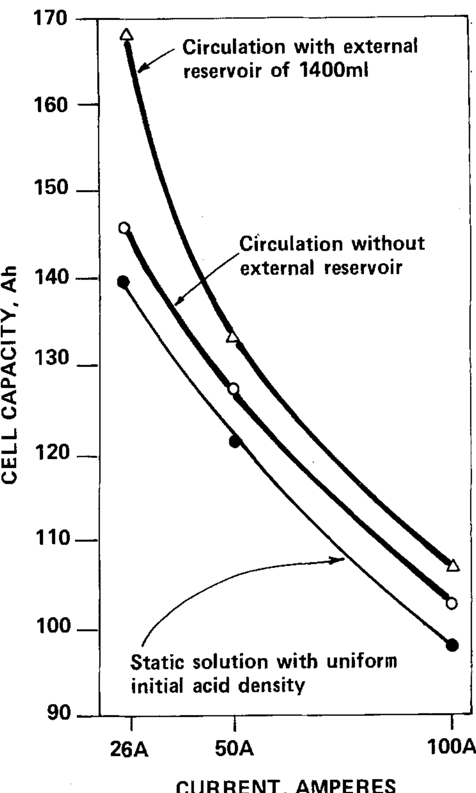

Fig. 8. Capacity vs. discharge current for three electrolyte circulation conditions. Circulation rate was 92 ml/min.

small separation between the plates was significantly less than their height. Other assumptions are discussed by Shepherd (7).

The second assumption greatly simplifies the analysis as it assumes that the current density distribution is the same in both negative and positive electrodes. Under this condition, the apparent current density, $i(y)$, the potential drops across the negative and positive grids, $E_g^-(y)$ and $E_g^+(y)$, and those across the horizontal component, $E(y)$, can be written as a function of the vertical distance y as shown below

$$\frac{dE_g^-(y)}{dy} = R_g^- i_g(y) \quad [1]$$

$$\frac{dE_g^+(y)}{dy} = -R_g^+ i_g(y) \quad [2]$$

$$i(y) = -\frac{1}{W}\frac{di_g(y)}{dy} \quad [3]$$

$$E(y) = E_g^+(y) - E_g^-(y) = (R_s + R_n + R_p)i(y) \quad [4]$$

where y is the distance from the top of the plate in centimeters, $i_g(y)$ is the vertical current across the electrode section of one-half the thickness of the actual electrodes in amperes, R_s is the resistance across the electrolyte and separator in the interplate space in Ω-cm^2, R_n and R_p are the polarization resistances of the negative and positive electrodes in Ω-cm^2, respectively, R_g^+ and R_g^- are the resistances, measured vertically, of the positive and negative electrode sections of unit length and one-half the thickness of the actual electrodes in Ω-cm^{-1}, respectively, and W is the width of the electrode.

The boundary conditions are $y = 0$, $i_g = I$, $E_g^- = 0$, $E_g^+ = E_o$, $y = H$, $i_g = 0$ where H is the height of the plate in cm, E_o is the voltage loss at the top of the positive plate when that of the negative is taken as zero, and I is one-half of the applied current per plate in amperes. The total discharge current is $2NI$ amperes where N is the number of the positive plates per cell.

Table I. Calculated (observed) potentials in mV as a function of dimensionless distance from top of plate for various discharge and charge rates.

Discharge and charge rate	Dimensionless distance from top of plate

The solutions of Eq. [1] to [4] are as follows

$$\frac{i(y)}{i_{avg}} = \frac{Q \cosh Q\left(1 - \frac{y}{H}\right)}{\sinh Q}; \quad i_{avg} = \frac{I}{WH} \qquad [5]$$

$$E_g^-(y) = -R_{g^*}^- \left(\frac{H}{Q}\right)^2 [i(y) - i(0)] \qquad [6]$$

$$E_g^+(y) = -R_{g^*}^+ \left(\frac{H}{Q}\right)^2 [i(y) - i(0)] + E(0) \qquad [7]$$

$$E(y) = (R_s + R_n + R_p)i_{avg} \left[\frac{Q \cosh Q\left(1 - \frac{y}{H}\right)}{\sinh Q}\right] \qquad [8]$$

with

$$Q = H\sqrt{\frac{R_{g^*}^+ + R_{g^*}^-}{R_s + R_n + R_p}} \qquad [9]$$

where $R_{g^*}^+$ and $R_{g^*}^-$ are resistances of the positive and negative electrode sections of unit length, unit width, and one-half the thickness of the actual electrodes; namely, $R_{g^*}^+ = R_g^+W$ and $R_{g^*}^- = R_g^-W$. The parameter Q above depends on the ratio of the sum of grid resistances to the resistance of the horizontal components and on the height of the plates.

To avoid the complications that arise from the development of electrolyte stratification during discharge (see Fig. 6), the analysis can only be applied to the data at the start of discharge, or of charge, for the case where there is no stratification.

The values of the resistances in Eq. [5]-[9] were selected to give the best fit between measured potentials and the calculated values of $E_g^-(y)$, $E_g^+(y)$, and $E(y)$ (see Table I). These best fit values were used in Eq. [5] to predict the current density distribution as a function of distance from the top of the plates. Figure 9 shows the normalized current density distribution for discharge at 26, 50, and 100A and for charge at 30A. As expected, the current density distribution becomes more nonuniform with increase in the discharge rate. For discharge at 100A, the initial current density at the top of the plates is 22% higher than the average current density whereas near the bottom it is 11% lower than the average. For discharge at 26A, the current density at the top is 16% higher and at the bottom it is 9% lower than the average. Thus, the nonuniformity is skewed toward the top of the plates where current is entering or leaving via the current-collecting tabs. The current density distribution on charge at 30A is more uniform compared to that on discharge at 26A. This is due to the large horizontal polarization loss on charge, especially at the positive electrode, which results in a smaller value of Q.

The dimensionless parameter, Q, depends on the plate height as shown in Eq. [9]. As the plate height increases so does Q and hence, the nonuniformity of current density distribution. In view of this, it was of interest to compare the current density distribution for three plate heights. To facilitate the comparison, the grid resistances and plate thicknesses were kept constant. Figure 10 shows the normalized current density distribution for (*i*) motive power plates used in this work (H = 432 mm), (*ii*) a tall plate such as is used in submarine propulsion or in standby power applications (H = 800 mm), and (*iii*) a short plate of similar height to automotive battery plates (H = 120 mm). Examination of Fig. 10 shows the effect of plate height on current density distribution. Increasing the plate height to 800 mm results in the current density at the top of the plate being 50% higher than average at 10.4 mA cm^{-2} and 70% higher than average at 40 mA cm^{-2}. At the plate bottom, the current density is 25% less than the average at 10.4 mA cm^{-2} and 35% less at 40 mA cm^{-2}. In the case of the short plate, the current density distribution is essentially uniform. Cells with plates of 120 mm in height are used in automotive batteries. Such plates are very much thinner than motive power plates and are discharged at very high rates (100C) during engine

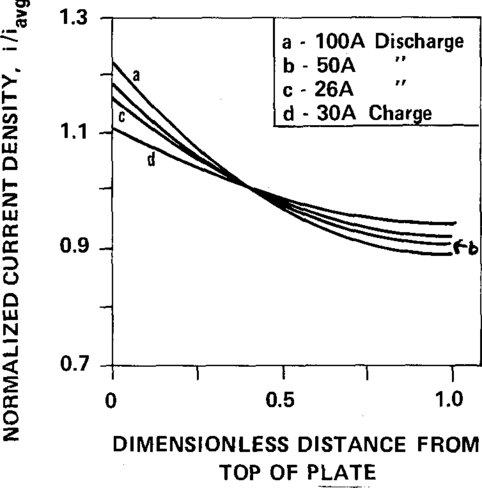

Fig. 9. Normalized current density in the y-direction determined at the start of discharge and charge. i_{avg} is 40 mA/cm^2 for 100A discharge.

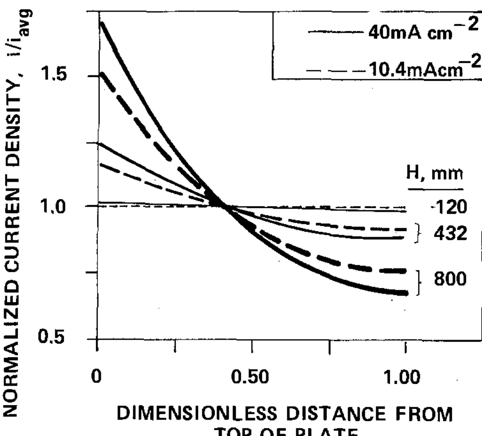

Fig. 10. Normalized current density in the y-direction at two discharge rates for three different plate heights. Current was 100 and 26A for 432 mm high plate.

starting. In these plates, the terminal effect can be expected to be significant. In order to retain a given or acceptable degree of nonuniformity in the current density distribution, the scale-up or scale-down from a particular plate design should be made by varying the value of $(R_{g^*}{}^+ + R_{g^*}{}^-)/(R_n + R_p + R_s)$ such that Q remains constant.

Electrolyte distribution.—The acid density distribution was measured directly and is shown for various times, as a function of distance from the top of the plates in Fig. 11. During discharge, a nonuniform distribution develops that is heavily skewed toward the bottom of the plates. On charge (with an initially uniform acid density), a nonuniform distribution develops but, in contrast to the discharge case, is skewed toward the top of the plates. Near the end of charge, the nonuniformity is markedly reduced by gas evolution at the electrodes.

The development of a nonuniform acid density distribution in the vertical direction can be qualitatively explained in terms of a natural convection mechanism (5): during discharge, the dilute acid in the pores of the positive and negative plates flows to the top of the cell while the denser acid in the interplate space flows to the bottom.

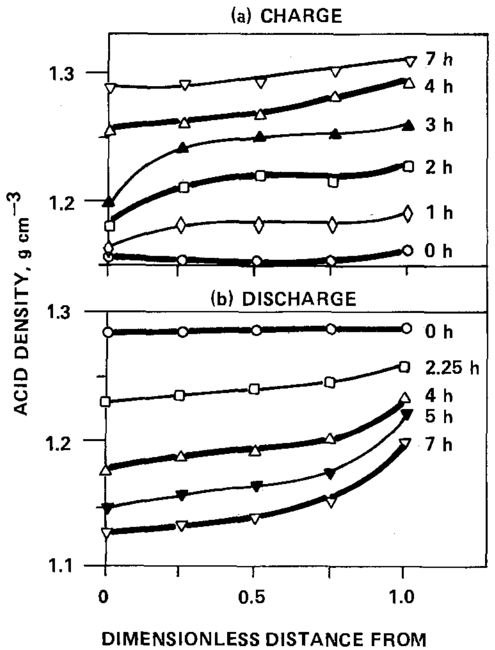

Fig. 11. Acid density distribution in the y-direction for various times during (a) discharge at 26A and (b) charge (4 hr at 30A followed by 3 hr at 10A). Electrolyte distribution was made uniform through circulation prior to charging or discharging.

In addition to the natural tendency of the acid to stratify on discharge due to gravitational forces, the nonuniform current density distribution (see Fig. 9) will favor a rapid consumption, and hence dilution, of acid at the top of the cell. This will amplify the tendency for stratification to develop and Fig. 11 shows that the rate of decrease of acid density is higher at the top of the cell than at the bottom.

On charge, the situation is reversed with the more dense acid that is formed in the pores flowing toward the cell bottom and displacing the more dilute acid in the space between the plates to the top of the cell. On the other hand, the nonuniform current density distribution present during charge (due to the terminal effect) will minimize this tendency for stratification as the plates will be accepting more ampere hours and producing denser acid at the top than at the bottom. The observation that the acid density increases more rapidly at the bottom than at the top during charge (see Fig. 11) indicates that stratification develops primarily due to natural convection: the countereffect of a nonuniform current density distribution is dominated by convection. Near the end of charge, gas evolution at the plates stirs the electrolyte and causes a rapid rise in the acid density at the top of the plates.

During discharge with circulation, the acid density is uniformly distributed over the height of the plates independent of the discharge rate (see Fig. 7). On open-circuit stand, the acid density continues to decline (see Fig. 6 and 7), indicating that dilute acid in the electrode pores is mixing with the denser acid between the plates. Thus, at the end of discharge, there must be a large, horizontal gradient of acid density from the interior of the porous electrodes to the bulk electrolyte. To better understand this phenomenon, the acid density distribution under uniform circulating electrolyte conditions (as shown in Fig. 7) was analyzed further.

In Fig. 12, three acid density distributions are plotted: the observed acid density, the theoretical acid density, and the density in the pores of the electrodes. The experimental data are taken from Fig. 7. The theoretical acid density was estimated from the actual ampere hours discharged and is the average density of the total 1800 ml of acid within the cell. Clearly, the acid density as measured in the interplate space (1300 ml volume) was higher than the theoretical

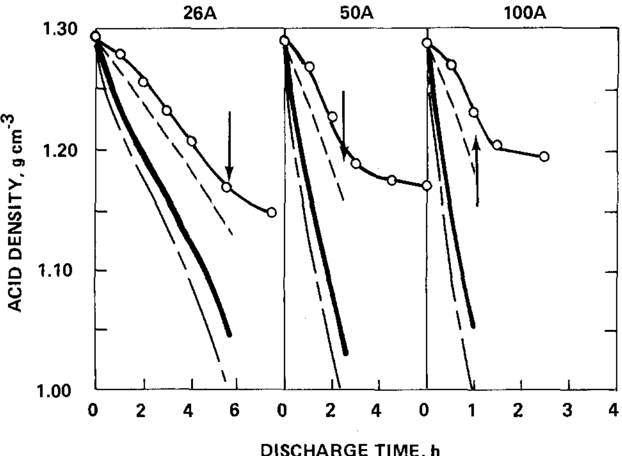

Fig. 12. Variation in acid density during discharge at three discharge rates, ○—○, measured value in the interplate space; - - - calculated average value; ——— predicted value in the pores assuming a 500 ml pore volume; — — — — predicted value in the pores assuming a 400 ml pore volume (arrows indicate end of discharge).

average density. Based on these two curves, acid densities in the electrode pores were estimated by assuming that the densities were uniform over the length of the plates.

Two cases were considered; namely, pore volumes of 500 and 400 cm^3. These pore volumes were chosen to represent a range of likely pore volumes. Using data on plate porosities and allowing for the volumes occupied by the grids, it was estimated that the total pore volume of both negative and positive electrodes was 610 cm^3 while that of the positives was 250 cm^3.

Figure 12 shows that the acid densities in the pores decreased to 1.01, 1.00, and 1.00 $g\text{-}cm^{-3}$ at the end of discharge at 26, 50, and 100A, respectively for a volume of pore solution of 400 ml. At all three rates, the densities in the pores were much lower than the measured values of 1.17, 1.20, and 1.23 $g\text{-}cm^{-3}$. These results suggest that plate capacity is limited by the depletion of electrolyte in the porous electrode structure. The discrepancy between the observed densities and the estimated pore densities become larger with increasing rate of discharge. At high rates, the time for replenishment of electrolyte in the pores by diffusion is reduced and the capacity declines accordingly as shown by the results in Fig. 8. In practice, electrolyte diffusion is also impeded by the wrapping around the positive plates. The limited rate of diffusion of electrolyte into the porous electrodes explains the results in Fig. 7 and 8. In Fig. 7, for example, the difference in acid density for discharge with and without an external reservoir is negligible at the 100A rate, since at this high rate only the acid in the pores is being utilized. In Fig. 8, the capacities corresponding to the discharges in Fig. 7 were not of the magnitude expected from the measured acid densities. Only by forcing electrolyte through the porous structure would the capacity be increased.

The deduction that capacity is limited by the availability of electrolyte in the pores was subsequently verified experimentally and a model developed that predicts positive plate capacity as a function of discharge rate, acid concentration, temperature, plate thickness, plate porosity, interplate space, and the characteristics of the wrapping material (8).

Conclusions

Discharge or charge of a motive power cell, *i.e.*, a cell with relatively tall, narrow plates is accompanied by the development of a nonuniform current density and electrolyte distribution in the vertical direction. The current density distribution was determined indirectly from measurement of grid potentials and electrode polarization. A treatment based on the terminal effect was used. Calculation showed that the current density was significantly higher at the top of the electrode than at the bottom and that the overall nonuniformity was strongly dependent on the plate height.

Electrolyte or acid density distribution is also nonuniform over the height of the cell. During discharge under stationary electrolyte conditions, stratification develops due to natural convection and is not notably influenced by the nonuniform distribution of current density. Under circulating electrolyte conditions stratification is eliminated and capacity is increased. Analysis of the data shows that capacity is limited by the availability of electrolyte within the pores and that a strong horizontal gradient of acid density must exist at the end of discharge with the acid density in the pores approaching 1.00 $g\text{-}cm^{-3}$.

The Behavior of the Zinc Electrode in Alkaline Solutions

V. Supersaturated Zincate Solutions

T. P. Dirkse*

Calvin College, Grand Rapids, Michigan 49506

ABSTRACT

Light scattering, density, and viscosity data are presented for electrolytically prepared supersaturated zincate solutions that were allowed to decay naturally. The results indicate that the solute species in the supersaturated solutions are not completely different from those in saturated or unsaturated zincate solutions. An explanation for the formation and behavior of the supersaturated solutions is given based on various solute species that are formed by the reaction of OH^- ions and H_2O molecules with $Zn(OH)_2$ and the subsequent formation of polynuclear zincate species. The rate and extent to which these are formed depends on the availability of OH^- ions and unbound H_2O molecules at the electrode surface.

When zinc is treated anodically in KOH solutions, the product of the charge transfer reaction is $Zn(OH)_2$ (1). This substance then dissolves in the electrolyte, and if the anodic process is continued long enough the electrolyte eventually becomes turbid and solid ZnO begins to precipitate from it. The extent to which the $Zn(OH)_2$ can dissolve in the electrolyte, however, is far greater than the equilibrium solubility of ZnO in the KOH solutions (2). These solutions have a fair degree of stability but the excess zincate is eventually precipitated as ZnO. While the solutions do not have the characteristics of supersaturated solutions (seeding with a crystal does not produce a rapid precipitation of the ZnO in excess of the equilibrium value) they will be referred to as "supersaturated" solutions. The term zincate will be used to refer to any dissolved zinc species.

A few attempts have been made to characterize the solute species in the "supersaturated" solutions but the matter has not yet been resolved. The suggestion that some of this excess zincate is present as colloidal material (3, 4) has not been conclusively disproved, nor has positive evidence been presented for this conclusion. In fact, some work has indicated the absence of colloidal material (5 ,6).

One general approach that can be used to determine whether the "supersaturated" zincate species are the same as those found in unsaturated solutions of ZnO in KOH, *i.e.*, $Zn(OH)_3^-$ or $Zn(OH)_4^{2-}$, is to measure some property of these solutions as a function of zincate concentration. If discontinuities are observed in the property studied, then the indications are strong that a new species has replaced the others in the solution. Some work along this line using NMR as the property studied has been reported (5). No discontinuities were observed, suggesting that the zincate species in "supersaturated" solutions were not different from those in unsaturated solutions. However, the "supersaturated" solutions used in that work were synthetically prepared by dilution of a stock "supersaturated" solution that had been prepared electrolytically. This is a matter of expediency because the "supersaturated" zincate solutions precipitate out ZnO very slowly.

The work reported here was carried out in order to obtain more information about these "supersaturated" solutions. Furthermore, the "supersaturated" solutions studied were all prepared by natural decay of an electrolytically prepared "supersaturated" solution rather than being prepared by dilution. Again, the purpose was to observe whether or not discontinuities appeared in certain properties measured at various zincate concentrations.

Key words: electrolyte, battery, discharge, solvation.

Experimental

The solutions of KOH + ZnO were prepared from reagent grade solids and doubly distilled deionized water. The "supersaturated" solutions were prepared by treating zinc electrodes anodically in a solution of KOH that had been saturated with ZnO and then filtered through a Pyrex glass frit to remove undissolved ZnO. To do this, two sheet zinc (99.999%) electrodes were placed on either side of a commercial nickel oxide electrode in the saturated solution and a low current rate was passed through the electrodes until the solution became turbid. At this time the electrolyte was removed, filtered through a Pyrex glass frit, and analyzed for zincate content. The solutions were then set aside and from time to time samples were removed, filtered, and used for analysis or other measurements. All the work was carried out at room temperature, about 20°C.

The zincate content was determined by titration with EDTA using Calmagite as indicator. Densities were measured in a 5 ml pycnometer at 25° ± 0.1°C and viscosities were measured in an Ostwald viscometer also at 25° ± 0.1°C. Turbidity or light scattering data were obtained with a Coleman Model 14 Spectrophotometer having a nephelometric attachment and using radiation of 560 nm.

Results

Numerous results indicate that there is no one solubility value for the "supersaturated" solutions (2). The zincate content can be varied easily by changing the current rate and the time allowed for the process. For example, in one cell in which the electrolyte was a 40% KOH solution the zincate content was 13.9% when the solution became turbid. The current was continued and 5 hr later the zincate content had risen to 15.1%. Apparently, the concentration at any one time is more like a steady-state value than an equilibrium value (6).

This is illustrated by some preliminary work. Three separate series of "supersaturated" solutions (each series consisted of five different starting KOH concentrations) were prepared and allowed to decay normally. A typical set of data is shown on Fig. 1. The dashed line represents the zincate concentration of that KOH solution saturated with ZnO. The zincate content in each of the three series is different at the beginning of each run (when turbidity first appeared).

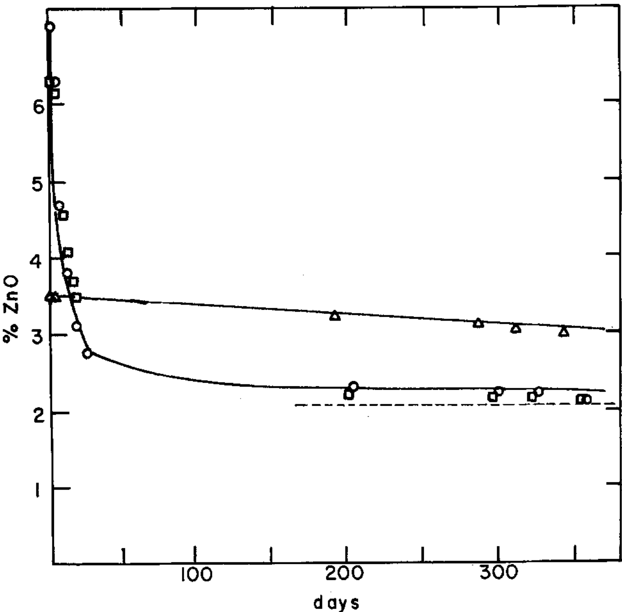

Fig. 1. Decomposition of "supersaturated" zincate solutions in 20% KOH at room temperature. The different symbols refer to separate runs beginning with different extents of supersaturation.

In each instance it required about a year for the zincate content to decrease to that of the equilibrium value. The initial rate of decay depends, in part, on the initial zincate concentration. The greater this is, the faster the rate of decay. Results similar to those on Fig. 1 were obtained for KOH concentrations ranging from 20 to 45 weight percent (w/o) KOH.

Figure 2 illustrates the decay of 6.15M KOH (~30% KOH) solution "supersaturated" with zincate. Figure 3 shows the density and the viscosity of the solutions on Fig. 2. Also included on Fig. 3 are unsaturated solutions that were prepared by diluting with 6.15M KOH a 6.15M KOH solution which had previously been saturated with ZnO.

Some of the solutions represented on Fig. 2 and 3 were also subjected to light scattering measurements to determine whether there was evidence for the presence of colloidal material, especially in the "supersaturated" solutions. The instrument was calibrated by setting the percent light scattering to zero when doubly distilled deionized water was placed in the cuvette. Table I summarizes the results of the physical measurements of these solutions. The results of light

scattering measurements show no indication of the presence of colloidal material. The lines on Fig. 3 show no evidence of discontinuities, suggesting that similar zincate species are present at all concentrations, and are not completely replaced by other species.

The three solutions represented by arrows on Fig. 3 were prepared, about a year after the series was begun, by dilution of the electrolytically "supersaturated" solution. The viscosity and density of these solutions show no significant deviation from the values of "supersaturated" solutions that had decayed during stand. This indicates that the work reported earlier and based on synthetically prepared "supersaturated" solutions (5) does give a fair representation of "supersaturated" zincate solutions, *i.e.*, dilution of these solutions does not alter the properties of the solution compared to solutions which decay on stand.

Discussion

The lack of discontinuities on Fig. 3 argues against the assumption that the zincate species in the "supersaturated" region are completely different from those in saturated or unsaturated zincate solutions. However, there is other evidence that different species are present. Hampson *et al.* (7) found that the emf of a zinc electrode became insensitive to zincate concentration in the "supersaturated" region. They concluded, therefore, that some electroinactive zincate species must be present instead of, or in addition to, the $Zn(OH)_4^{2-}$ ion. Also Jackovitz and Langer, using Raman spectroscopy, observed that the concentration of $Zn(OH)_4^{2-}$ did not increase in the "supersaturated" region (8). Later work with Raman spectroscopy (9) was interpreted to indicate the existence of $Zn(OH)_2(H_2O)_2$, $Zn(OH)_3(H_2O)^-$, and $Zn(OH)_4^{2-}$ in concentrated zincate solutions but that only small amounts of

Table I. Characteristics of various KOH and zincate solutions

Solution	Molarity of KOH	Molarity of ZnO	Density, g ml^{-1}	Relative viscosity	Percent light scattering

B*	6.15	0.65	1.3152	2.59	0
C#	6.15	1.94	1.4178	3.88	0

* 6.15M KOH saturated with ZnO.
# 6.15M KOH "supersaturated" with zincate.

$Zn(OH)_4^{2-}$ are present in solutions containing 1.5M ZnO in 15M KOH. This is in contrast to earlier reported work where the concentration of $Zn(OH)_4^{2-}$ was said to increase with increasing KOH concentration while that of $Zn(OH)_3^-$ decreased (10).

The above results indicate that the "supersaturated" region does not represent the replacement of the zincate species present at concentrations less than that of saturated solutions. Rather, the zincate species present in saturated and unsaturated solutions are also present in the "supersaturated" region but in this region other zincate species also begin to appear. This interpretation is consistent with the absence of discontinuities such as in Fig. 3 and with the work mentioned earlier (7, 8). Thus the problem stated earlier amounts to identifying the other zincate species that appear in the "supersaturated" region as suggested by others (7, 8).

Some attempts have been made to characterize these zincate species by the use of Raman spectra (7, 9). However, there is disagreement as to what the interpretation is. The work of Sharma and Reed (9) does offer a resolution to the problem of interpreting the data for "supersaturated" zincate solutions. They suggest that both OH^- and H_2O serve as ligands for the zinc atom in $Zn(OH)_2$. Therefore, three solute species are possible if one assumes a coordination number of 4 for the zinc atom: $Zn(OH)_2(H_2O)_2$, $Zn(OH)_3(H_2O)^-$, and $Zn(OH)_4^{2-}$. Some have also suggested the presence of $Zn(OH)(H_2O)_3^+$ (11). As the $Zn(OH)_2$ is produced by the charge transfer reaction at the electrode any of these species may form. Which particular one is formed will depend on the availability of the ligands OH^- and H_2O at the electrode surface. If one assumes a hydration number of 4 for the K^+ ion (12) and of 3 for the OH^- ion (13), then the amount of unbound water molecules in the KOH solutions is shown in Table II. In solutions more concentrated than about 33 w/o KOH there is insufficient water to hydrate the K^+ and OH^- ions normally. Thus, in these solutions the initial dissolution of the $Zn(OH)_2$ is limited to reaction [1]

$$Zn(OH)_2 + 2\,OH^- \rightarrow Zn(OH)_4^{2-} \quad [1]$$

However, as the OH^- ions combine with the $Zn(OH)_2$ they release their water of hydration and at the electrode surface the following two reactions may then occur in addition to that of Eq. [1]

$$Zn(OH)_2 + OH^- + H_2O \rightarrow Zn(OH)_3(H_2O)^- \quad [2]$$

$$Zn(OH)_2 + 2H_2O \rightarrow Zn(OH)_2(H_2O)_2 \quad [3]$$

For KOH solutions less concentrated than 33 w/o (about 7M), all three reactions may occur immediately following the formation of $Zn(OH)_2$ at the electrode surface. Thus all three possible zincate species may form at the zinc electrode during anodization, and the amount of OH^- and H_2O at the electrode surface will determine in which manner the $Zn(OH)_2$ will dissolve in the electrolyte. Of these species only the $Zn(OH)_4^{2-}$ appears to be the electroactive one for determining the emf of the zinc electrode (14).

Analysis of saturated solutions of ZnO in aqueous KOH indicate that the amount of $Zn(OH)_4^{2-}$ in these solutions is limited by equilibrium considerations. The equilibrium constant expression for Eq. [1] is

$$K = \frac{a_{Zn(OH)_4^{2-}}}{a_{Zn(OH)_2} \cdot (a_{OH^-})^2} \quad [4]$$

Assuming the $Zn(OH)_2$ to be a pure solid, the above expression becomes

$$K = a_{Zn(OH)_4^{2-}}/(a_{OH^-})^2 \quad [5]$$

The activities of the two species in Eq. [5] are not known for these solutions but if molarities are substituted for them, and if the assumption is made that $Zn(OH)_4^{2-}$ is the dissolved zincate species, then the experimentally determined ratio shown in Eq. [5] is 0.026 ± 0.002 for saturated solutions of ZnO in aqueous KOH ranging from 20 to 40 w/o KOH.

On the basis of the above information, a possible explanation for the "supersaturated" zincate solutions is the following. As $Zn(OH)_2$ is formed at the electrode it first dissolves according to Eq. [1] and this continues until the zincate content reaches the equilibrium value for ZnO in aqueous KOH. By this time even a 40 w/o solution will have some unbound water molecules in it because of the water of hydration released by the OH^- ions as they react according to Eq. [1]. If the zinc electrode is to be oxidized beyond this, the $Zn(OH)_2$ must dissolve some alternate way, Eq. [2] or [3], or else the electrode surface will become covered with solid $Zn(OH)_2$ and be passivated. Either the $Zn(OH)_3(H_2O)^-$ or the $Zn(OH)_2(H_2O)_2$ then is unstable with respect to ZnO and the following reactions occur slowly

$$Zn(OH)_3(H_2O)^- \rightarrow ZnO + OH^- + 2H_2O \quad [6]$$

$$Zn(OH)_2(H_2O)_2 \rightarrow ZnO + 3H_2O \quad [7]$$

The ZnO precipitates out of the solution. Reaction [6] can occur only as water becomes available to hydrate the released OH^- ions. This scenario is summarized in Fig. 4.

The scheme outlined on Fig. 4 is consistent with the published information concerning "supersaturated" zincate solutions. It explains the fact that while the dissolved zincate concentration increases in the "supersaturated" solutions, the $Zn(OH)_4^{2-}$ concentration does not increase (8). It also accounts for the insensitivity of the emf of the zinc electrode to increasing zincate concentrations in the "supersaturated" region (7). The fact that no discontinuities are observed on Fig. 3 nor were observed in earlier NMR work (5) can be explained by noting that the $Zn(OH)_4^{2-}$ ions are present at all concentrations and do not disappear in the "supersaturated" region. In fact, it is quite likely that several of the zincate species are present at all times with the $Zn(OH)_4^{2-}$ form being the most abundant up to the equilibrium concentration of ZnO. There is emf evidence for this (3). In that work the emf of the zinc electrode, when plotted to conform to the

Table II. Amount of solute ions and unbound water molecules in 1 liter of aqueous KOH solutions

w/o KOH	Moles of K+	Moles of OH-	Moles of unbound water

28	6.5	6.5	12
33	8.0	8.0	0
40	10.1	10.1	0

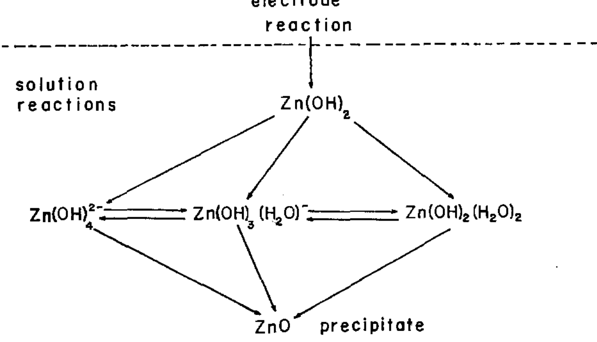

Fig. 4. Summary of reactions to form zincates

Nernst equation, showed discontinuities. The first part corresponded to Eq. [1], the second part to Eq. [2], and the third part to Eq. [3].

A linear potentiodynamic study of the passivation of the zinc electrode in KOH solutions showed the presence of two peaks at a slow scan rate (15). These peaks were at that time interpreted as corresponding to reactions [1] and [2] and referring to the dissolution processes of the charge transfer product. At faster scan rates the charge transfer product is produced faster than it can be dissolved and the electrode then becomes covered with a layer of the reaction product resulting in temporary passivation of the electrode.

Thus, the interpretation presented here for the composition and formation of "supersaturated" zincate solutions is consistent with previously reported data and provides a ready explanation of them. It is basically the interpretation that has been reported earlier (3). Which of the three zincate species is produced at any one time will depend on the availability of OH^- and H_2O ligands at the electrode surface. In the more concentrated KOH solutions, reaction [1] is favored up to the saturation concentration of ZnO in KOH while reactions [2] and [3] will not take place until sufficient H_2O has been released by the OH^- ions in forming $Zn(OH)_4^{2-}$. In the more dilute KOH solutions, reactions [1], [2], and [3] are equally likely except that reactions [2] and [3] appear to proceed much more slowly than does reaction [1].

However, there is an alternate scheme that should also be considered. This involves the formation of polynuclear zincate species in the "supersaturated" region. This has been suggested in the case of aluminate ions (16). The common zincate ion, $Zn(OH)_4^{2-}$, is considered to have a tetrahedral configuration. The loss of H_2O between zincate ions could give rise to polynuclear species of the type shown on Fig. 5. The bridging elements in these species may be OH groups as well as the O atoms shown on Fig. 5. Polynuclear species of types II and III, Fig. 5, are probably less likely because the bond angles in the cyclic parts of the structures would be under some strain. Thus, if the polynuclear species do form they would most likely be of the type I variety.

Fig. 5. Polynuclear zincate species

As these polynuclear species form and grow they will eventually become large enough to form colloidal or suspended particles, leading to turbidity and the formation of a precipitate. In order to precipitate ZnO these polynuclear species would first release OH^- ions and H_2O molceules.

Conclusion

The solute species in the "supersaturated" zincate solutions may to a large extent be either of those shown on Fig. 4 or the type I shown on Fig. 5. At present there is no direct experimental method readily available to identify any of these species positively. Even the *IR* and NMR data that are available have been the subject of some disagreement and the interpretation of these data even more so, as noted above. However, the existence of any of these solute species is dependent on the availability of OH^- ions and unbound H_2O molecules in the electrolyte. In all likelihood, such solutions consist of a variety of the species indicated.

Acknowledgment

This work was made possible by a research grant from the General Electric Company. Dr. Roger DeKock and Dr. W. VanDoorne gave considerable help in interpreting the data and discussing the nature of the solute species.

Lead Acid Battery Expander

II. Expander Activity Correlation Between Microelectrode and Pasted Electrode

B. K. Mahato*

Johnson Controls, Incorporated, Electrochemical Research, Milwaukee, Wisconsin 53201

ABSTRACT

The efficacy of the microelectrode cycle life index in predicting the influence of expander on the pasted electrode performance was carried out from the simultaneous testing of four lignosulfonate expanders by the microelectrode and pasted electrode. Expander was included in the test solution for the microelectrode and in the paste for the pasted electrode. The studies of the effect of expander concentration on both the microelectrode cycle life index and 90% DOD cycle life of negative limited 98 A-hr test cells were identical, showing an optimum expander concentration for a maximum cyclic performance. Testing of three expander materials obtained from the process variations of the same source material also showed a correlation between the microelectrode cycle life index and the specific capacity of the pasted electrode. Expander activity on the lead electrode performance was observed to vary with the quality and concentration of expander. The application of the microelectrode technique as a quality control tool of the expander material was established.

The word "expander" is used here to mean the lignin constituent of the conventional lead acid battery expander, which is a composite of a sulfonate derivative of lignin, barium sulfate, and carbon black. Expander present in the test system either in the paste or in the test electrolyte influences the lead electrode performance, particularly its dischargeability and its capacity maintenance behavior during cycling. The determination of expander activity outside the test battery was proposed by Mahato (1) from the relative change in the microelectrode capacity that occurs when a microelectrode is potentiostatically cycled between −1160 and −860 mV (*vs.* $Hg/Hg_2SO_4/mH_2SO_4$) at 0.5 mV/sec in 1.250 sp gr sulfuric acid solution with expander for a period of 48 hr. This expander activity was termed as the cycle life index (η) and defined as $\eta = (Q_f - Q_o)/Q_o$ where Q_o and Q_f are initial and final capacity of the electrode, respectively. The major advantages of this technique are the straightforward measurement, the elimination of the complexities of the pasted electrode, and the capability the technique provides for evaluating the expander material outside the test battery, which has to date been the only vehicle in determining the efficacy of the expander material. However, application of this cycle life index in predicting the expander's influence on the pasted electrode performance has remained ambiguous. This is primarily due to the difference in the mode of inclusion of expander in the two systems; it is included in the test solution for the microelectrode system and in the paste for the pasted electrode system. The objective of the present work is to correlate the microelectrode cycle life index and the pasted electrode performance, *i.e.*, the dischargeability of the lead active mass and its capacity maintenance behavior during deep discharge cycling.

Experimental

Materials.—Four lignosulfonate compounds designated A, B, B′, and B″ were obtained from American Can Company, Rothschild, Wisconsin. The type A compound which is very similar to "Maracell-XC" is a brown color material with 0.8% total sulfur, 0.1% inorganic sulfur, 0.3% Ca, 6.5% Na, 0.2% reducing sugar, and 13.9%-OCH_3. The B, B′, and B″ were modified versions of A and their compositions were not known. The ultraviolet absorption spectra of all four samples at *p*H 7.0 were identical showing a weak peak at 320 nm, moderate peak at 280 nm, and a shoulder at 235 nm. In all cases the differential spectra at *p*H 11.8 *vs.* 1.7 showed strong peaks at 355 and at 250 nm and a shoulder at 295 nm wavelength. All these materials were completely soluble in water, but their solubility decreased with increasing acid concentration.

The test and counterelectrodes of the microelectrode system were prepared out of 99.999% Pb (Cominco). The test electrode was 2 mm diameter and 2 cm long. The counter was a 1.27 cm diam cast rod.

The current collector grids of the pasted negative and positive electrodes were made out of Pb-0.13Sr-0.04Al-1.00Sn and Pb-4.67Sb-0.20As-0.19Sn alloy, respectively. The conventional ball mill oxide with 33 ± 5% free lead, barium sulfate, and carbon black, all available at the laboratory, were used for the leady oxide paste preparation. Test solutions were made out of the reagent grade chemicals and laboratory distilled water.

Microelectrode technique.—The microelectrode technique uses a test cell with a 2 cm long, 2 mm diam lead electrode, an oversized lead counterelectrode, and an $Hg/Hg_2SO_4/mH_2SO_4$ reference electrode, all immersed in 50 ml sulfuric acid test electrolyte. The preparation of a porous electrode out of the well-defined microelectrode was carried out by linear potential sweep cycling of the microelectrode between −1160 and −860 mV (*vs.* Hg/Hg_2SO_4) at 0.5 mV/sec in 1.050 sp gr H_2SO_4 solution for a 2 day period. The experimental details along with the automatic data collection system are described elsewhere (1).

Pasted electrode evaluation.—Two types of pasted negative electrodes were prepared out of experimental paste made from the dry blended mixture of ball mill oxide, barium sulfate, carbon black, lignin compound, and dynel fiber with 110 ml 1.325 sp gr sulfuric acid and 110-130 ml water per kilogram oxide. The concentration of barium sulfate, carbon black, and dynel fiber in the blend were 0.3, 0.15, and 0.06%, respectively, based on the weight of oxide. The pasted electrodes were conventionally cured and dried. The dry paste density was 4.25 ± 0.05 g/cm^3.

* Electrochemical Society Active Member.

Key words: lead electrode, voltammetry, additive.

The type I test electrodes had dimensions of 18.92 × 22.66 × 0.152 cm in which the concentration of type A expander varied from 0 to 0.5% based on the weight of oxide. The test electrodes thus prepared were assembled with matching 18.92 × 22.66 × 0.203 cm size positive electrodes and microporous PVC separators to prepare thirteen plate element negative limited test cells. The positive electrodes were overpasted to obtain a theoretical capacity in excess of 3.5 times that of the negatives. The particulars of the negative limited test cell series in terms of dry paste weight and expander concentration in the test negatives are given in Table I. The average theoretical capacity of these test cells based on 0.93g metallic lead per gram of paste and 53% coulombic efficiency at the 3 hr discharge rate was 98 A-hr. These test cells were electroformed in triplicate in 1.100 sp gr H_2SO_4 under 2.50V constant voltage with 40A maximum current for a 40 hr period. This was followed by the adjustment of acid concentration to 1.290 ± 0.010 sp gr, initial capacity testing at 40A, and the continuous deep discharge cycling of the test cells. The deep discharge cycle was arbitrarily selected as a 6 hr cycle with 132 min discharge at 40A followed by 228 min constant voltage (2.50V) charge with 33A current maximum. The 132 min discharge at 40A (88 A-hr) corresponds to 90% depth of discharge of the 98 A-hr test cells. The cycling of the test cells was continued to the point at which they could not sustain 90% DOD. The capacity checks of test cells were carried out at different points of cycling. Following the capacity test the cells were recharged approximately 10% excess of the amount of discharge. At no time was extra charge or boosting allowed outside the test mode described during cycle life test.

The type II electrodes had grid dimensions of 19.30 × 33.17 × 0.191 cm and were prepared using a negative paste identical with type I except for the type of expander included. The expander formulations used in preparing this new series of pastes are given in Table II. The objective of testing this new series of electrodes was to determine the efficacy of type B expander with and without type A expander. The follow-up electrode preparation, *i.e.*, curing and drying of the electrodes, was identical to the type I electrodes. The type II electrode thus prepared was then assembled with two counter preformed positives and microporous PVC separators in between to compose a test cell. This was followed by constant voltage electroformation in 1.100 sp gr H_2SO_4 at 26° ± 2°C at 2.60V with 15A current maximum and subsequent adjustment of electrolyte concentration at 1.300 ± 0.005 sp gr H_2SO_4. Formation was followed by testing the cells in duplicate for the steady state material utilization of the active mass at 16.6 A/plate, which corresponds to the 3 hr discharge rate. In every case the test electrode was discharged up to −0.500V (*vs.* Hg/Hg_2SO_4). The steady-state capacity was achieved between the 10th and 15th discharge. At the end of the test, the electrode was washed with water followed by rinsing with acetone and drying under a vacuum at 70° ± 2°C. This was followed by active material analysis for specific surface area and microstructure. The specific surface area was determined by BET nitrogen adsorption using a Quantasorb analyzer and the morphology of the freshly fractured cross section was examined by JEOL U3 Scanning Electron Microscope.

Results and Discussion

Evaluation of type A expander.—Figure 1 shows the effect of type A expander concentration in 1.250 sp gr H_2SO_4 on the microelectrode cycle life index (CLI). The presence of an optimum concentration for a maximum cycle life index is evident. It suggests that the cyclic behavior of the lead electrode is sensitive to expander concentration in the test solution. The influence of expander on the discharge as well as charge kinetics of the lead electrode is well known and its possible role on the reaction mechanism and electrode structure have recently been discussed (1). In acidic environment it remains within the electrode matrix as surface adsorbed and/or suspended material. During discharge as the acidity of the reaction interface changes it desorbs from the lead sites, forms a transient Pb-lignin complex, and adsorbs on the freshly precipitated lead sulfate, all of which are responsible in delaying the electrode passivation process. At the end of discharge as the acidity of the reaction product phase approaches that of the bulk concentration the expander stays within the lead sulfate matrix with a strong tendency of being adsorbed on the metallic lead sites. This in turn brings charge inhibition which is mostly due to lack of deposition sites for electrochemically reduced lead adatoms and to a small extent due to retardation in the lead sulfate dissolution process. However, this charge inhibition, if not excessive,

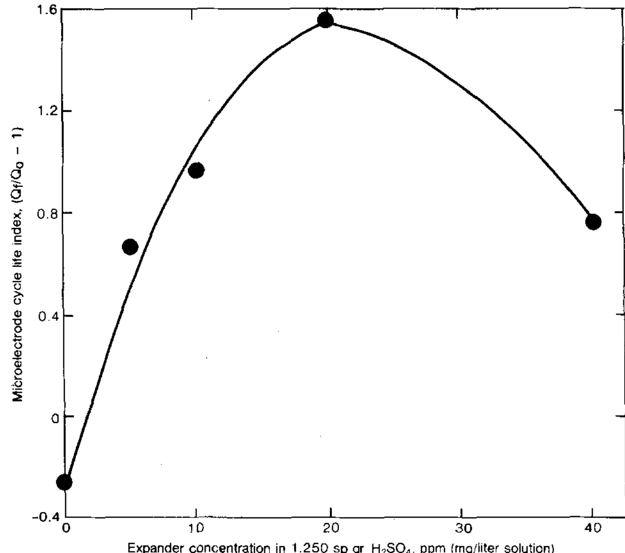

Fig. 1. Effect of type A expander concentration in the test solution on the lead microelectrode cycle life index values.

helps to improve and/or to maintain the surface area of the electrode matrix.

In the absence of expander in the test solution the CLI value of the electrode takes a negative value (Fig. 1). This is indicative of the gradual loss of electrode capacity or the effective surface area on repeated charge-discharge cycling, in agreement with the reported agglomeration of the lead active mass during cycling (2).

Expander in the test solution alters the electrode kinetics by physical adsorption on the electrode surface whether or not it takes part in the cyclic electrode reactions. Presence of an optimum expander concentration for a maximum cycle life index (Fig. 1) suggests that the modifying influence of expander on the cyclic electrode reaction may be controlled by two diverse processes: (*i*) physical adsorption on the electrode surface and (*ii*) the sensitivity of the ionic adsorbed material to desorb, to migrate to the high energy surface, to dissolve or reprecipitate in the interfacial electrolyte depending on the *p*H, and to form a transient compound with the opposite ionic species. At higher expander concentration adsorption continues on the electrode surface until it suppresses the rates of the cyclic electrode reactions. This is partly illustrated in Fig. 2d from the voltammogram of the test electrode taken with 40 ppm expander concentration in the test solution.

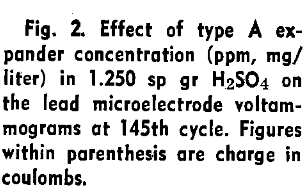
Figure 2d also shows a significant charge inhibiting influence of the expander. The expander affects the charge kinetics by blocking coverage of the deposition sites for lead adatom and by restricting the dissolution rate of lead sulfate precipitates. The microcrystalline structure of the lead dendrites observed in the test electrode when cycled in the test electrolyte with 40 ppm expander (Fig. 3d) indicates that the charge kinetics are mostly controlled by the blocking coverage of the deposition site and not by the dissolution behavior of the lead sulfate layer. This is apparent from the low electrode capacity (Fig. 2d) in spite of the extremely fine nature of the electrodeposit (Fig. 3d).

The charge inhibiting influence of the expander may also be related to the physical nature of the expander and its *p*H dependent adsorption behavior on the electrode surface. The conventional lignosulfonate expander is an anionic polymer with coiled structure (3). During discharge as the *p*H of the reaction interphase increases the coiled structure of the lignin stretches and to some extent dissolves and takes part in the electrode reactions with available Pb^{2+} ions. During discharge as the *p*H of the reaction interphase increases the coiled structure of the lignin shrinks or moves to high energy sites providing a chance for formation of high surface area electrodeposit. However, at a higher expander concentration, as adsorption continues, the adsorbed molecule may become oriented more and more perpendicular to the surface with its hydrophilic head oriented toward the bulk solution (4), causing the noticeable charge inhibition shown in the voltammogram in Fig. 2d.

At expander concentrations lower than the optimum (Fig. 1), the cyclic electrode reaction is favorably influenced by increasing expander concentration in the test solution as noted by the increasing CLI values (Fig. 1) as well as by the voltammograms (Fig. 2) and the electrode surface morphology as observed by SEM (Fig. 3).

Figure 2 demonstrates the effect of expander concentration in the test solution on the lead electrode voltammograms. The increased charge inhibition of the lead electrode with increasing expander concentration is apparent from these voltammograms. This is noted from the gradual reduction in the cathodic peak current with increasing expander concentration in the test solution. The reduction in the cathodic peak current is accompanied by broadening of the peak area and increased current acceptance at the end of the cathodic sweep. This in turn results in an overall increase in charge input with increasing expander concentration in the test solution up to 20 ppm. The anodic portions of the voltammograms, which show a corresponding increase in electrode capacity up to 20 ppm, indicate that the greater charge input to the system is associated with the electrode quality improvement (*i.e.*, surface area) rather than any secondary electrochemical reaction. At an expander concentration greater than 20 ppm in the test electrolyte, a decline in electrode CLI (Fig. 1) is associated with the excessive charge inhibition apparently caused by multilayer surface adsorption of expander material and/or its orientation on the electrode surface.

The effect of expander concentration on the cycled lead electrode morpology is shown in Fig. 3. An agglomerated nodular mass with large voids was typical for the test electrode cycled in pure sulfuric acid solution. This electrode morphology, however, was altered in presence of expander in the test solution and



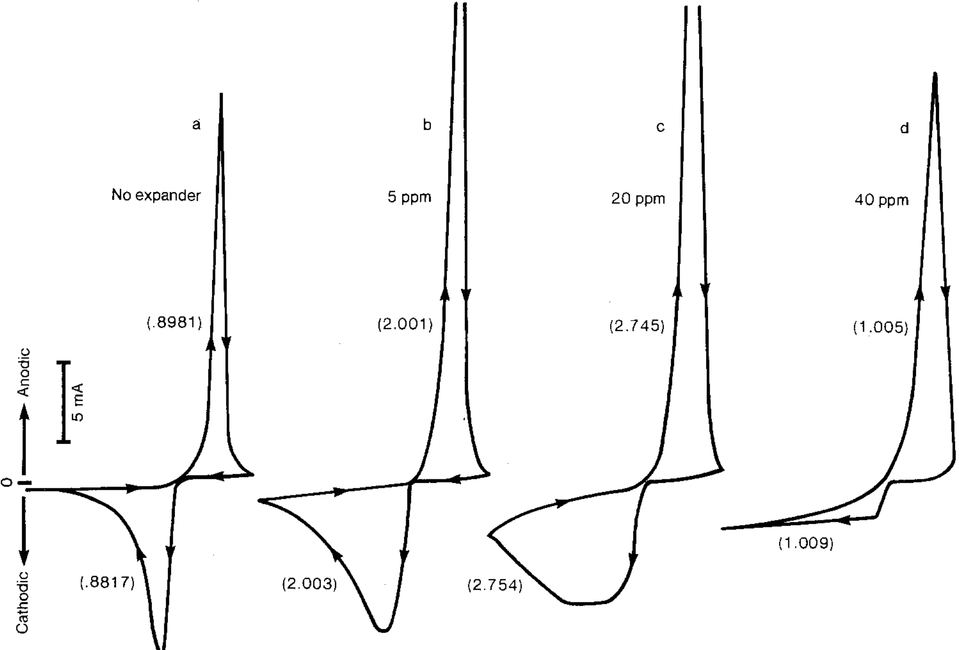


Fig. 2. Effect of type A expander concentration (ppm, mg/liter) in 1.250 sp gr H_2SO_4 on the lead microelectrode voltammograms at 145th cycle. Figures within parenthesis are charge in coulombs.

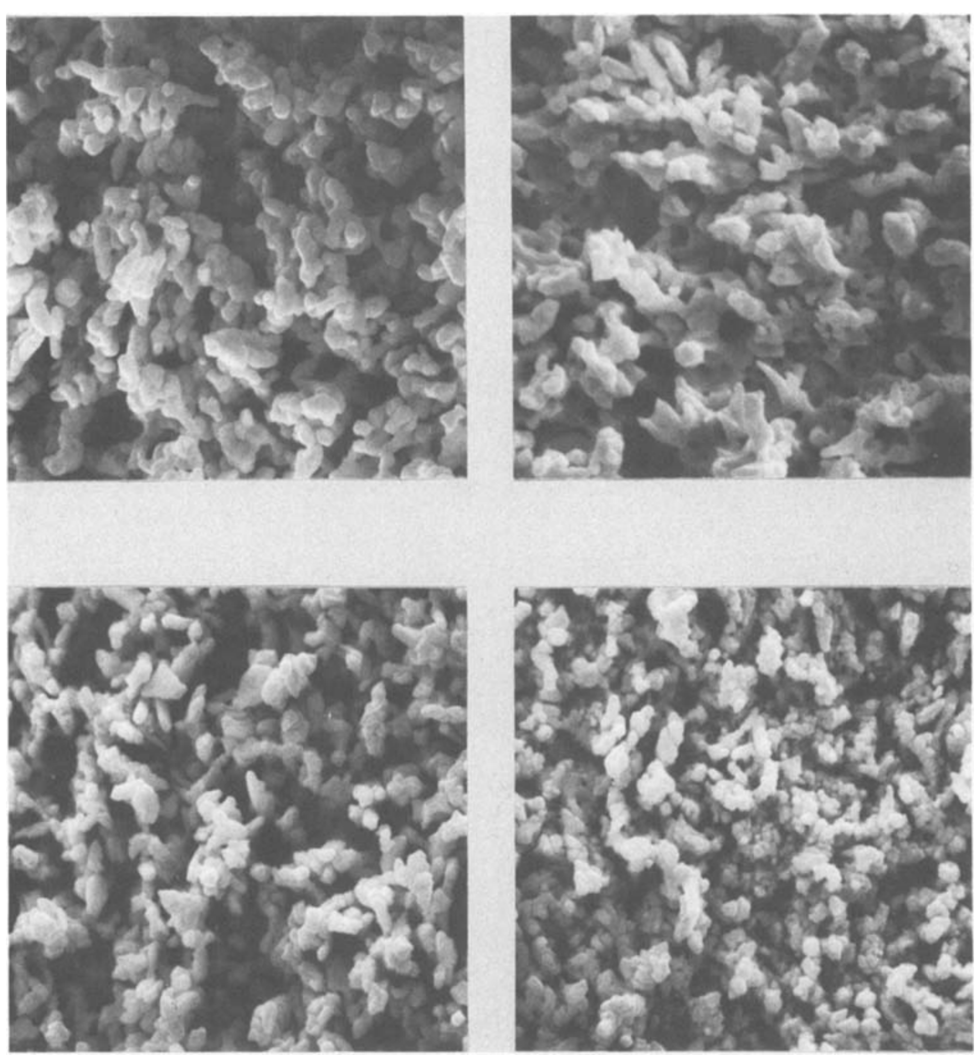

Fig. 3. The influence of expander concentration in the test solution on lead microelectrode surface morphology at 145th cycle; (a, top left) 0 (b, top right) 5 ppm (c, bottom left) 20 ppm and (d, bottom right) 40 ppm. Magnification 3000×.

became increasingly finer with increasing expander concentration in the test solution. The morphology of the test electrode cycled in test solution with 40 ppm expander was basically very fine (Fig. 3d) and close to the structure obtained after the development cycle. The retention of this fine structure after 48 hr cycling was caused by the protective coverage of expander as evident by the highly suppressed electrode kinetics (Fig. 2d).

Figure 4 is a plot of 90% DOD cycle life of 98 A-hr negative limited test cell *vs.* the type A expander concentration in the negative paste. Each test cell had 760g of negative paste in which the concentration of expander was varied from 0 to 0.5 weight percent (w/o) based on the weight of oxide. The average capacity of these test cells based on five identical discharges immediately after electroformation and adjustment of acid concentration to 1.290 $\pm$ 0.010 sp gr were 77.0, 91.8, 99.1, 104.5, and 106.7 A-hr for 0, 0.02, 0.10, 0.30, and 0.50 expander concentration in the negative paste, respectively. The nominal capacity of these test cells was considered to be 98 A-hr at the 40A rate. These test cells cycled with 90% DOD per cycle. The cycle mode was arbitrarily selected as 132 min discharge at 40A followed by 228 min charge with 2.50V constant voltage charging with 33A maximum current per cycle. The test cells which had no expander in the negative paste had initial capacities less than that required to sustain 90% DOD cycling and hence were not cycled. In the test the capacity of the negative electrode was always limiting. This was checked by the half-cell potential measurement during test cycling and periodic capacity measurement.

The presence of an optimum expander concentration in the paste for a maximum 90% DOD cycle life of the negative limited test cells is evident from Fig. 4. The optimum concentration of type A expander in the paste was 0.3 w/o. The 90% DOD cycle lives of the test cells with 0.3 w/o expander in the negative paste were 65 and 106% superior to the test cells with 0.1 and 0.5 w/o expander in the negative paste. The effect

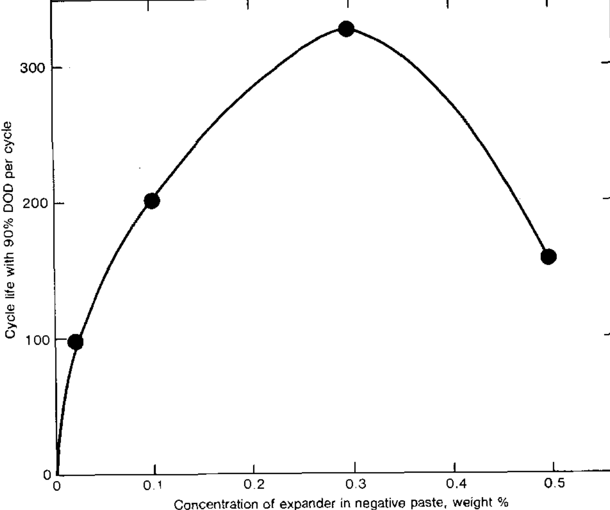

Fig. 4. Effect of type A expander concentration in the negative paste on the cycle life of negative limited test cells with 90% DOD per cycle.

of type A expander concentration on the electrode morphology after formation is shown in Fig. 5. A highly sintered nodular structure lead active mass with large voids was dominant in absence of expander in the paste matrix. This structure was modified in the presence of 0.1 w/o expander in the paste to form a coherent porous active mass consisting of well-distributed acicular dendrites covered with nodular deposits. Upon increasing expander concentration to 0.3 w/o the deposits became finer and well separated from each other to cause a highly microporous matrix (Fig. 5c). At 0.5 w/o expander the deposit structure became extremely fine and dense and the pore size appeared to have reached a submicron size. The physical examination of these micrographs (Fig. 5a, b, c, and d) did indicate the seemingly better structure of Fig. 5c compared to Fig. 5a, b, and d and explains the superior performance of the test cells with 0.3 w/o expander in the negative paste. The specific surface area of the test negatives were 0.37, 0.50, 0.65, and 0.69 m^2/g for electrodes with expander concentration 0, 0.1, 0.3, and 0.5 w/o, respectively.

A strong similarity exists between the effect of expander concentration on the microelectrode cycle life index (Fig. 1) and the 90% DOD cycle life of the pasted electrode (Fig. 4). This is true in spite of the fact that the expander is included in the electrolyte for the microelectrode system and in the paste for the pasted electrode system. The almost identical influence of expander concentration on the microelectrode cycle life index and the 90% DOD cycle life of the pasted electrode suggests that the microelectrode cycle life index (CLI) could be used to determine either the optimum expander concentration or the deep discharge cycle life of the pasted electrode or both. This also reveals that this technique could be economically used for selective evaluation of expander candidate materials for application-oriented lead acid battery test cells. This is highly attractive since the expander selection is usually based on its evaluation in a lead acid battery, which is often time consuming and costly. The analogous behavior of Fig. 1 and 4 points out that the 20 ppm type A expander concentration in the microelectrode system is equivalent to 0.3 w/o in the pasted electrode system based on the weight of the oxide.

A comparison of Fig. 3 and 5 indicates that the expander's influence on the lead electrode morphology is very similar for the microelectrode system in which it is included in the test solution and for the pasted electrode in which it is incorporated in the paste. This similarity of expander action on the electrode morphology suggests that the mechanism of expander action must in the case of the pasted electrode involve dissolution from the paste matrix followed by the adsorption on the electrode surface.

Comparison of type A and B expanders.—The microelectrode test data of type A and B expanders at 60 ppm concentration in 1.250 sp gr H_2SO_4 are given in Table III. Type B material is noted to be significantly different and superior to type A, particularly at 60 ppm concentration. The inferior cycle life index of type A is the result of its excessive charge inhibition as noted in Fig. 6 from the cyclic voltammograms taken at the end of the test. Due to this wide difference in their cycle life index values, the type A and B expanders were chosen to test the efficacy of the microelectrode

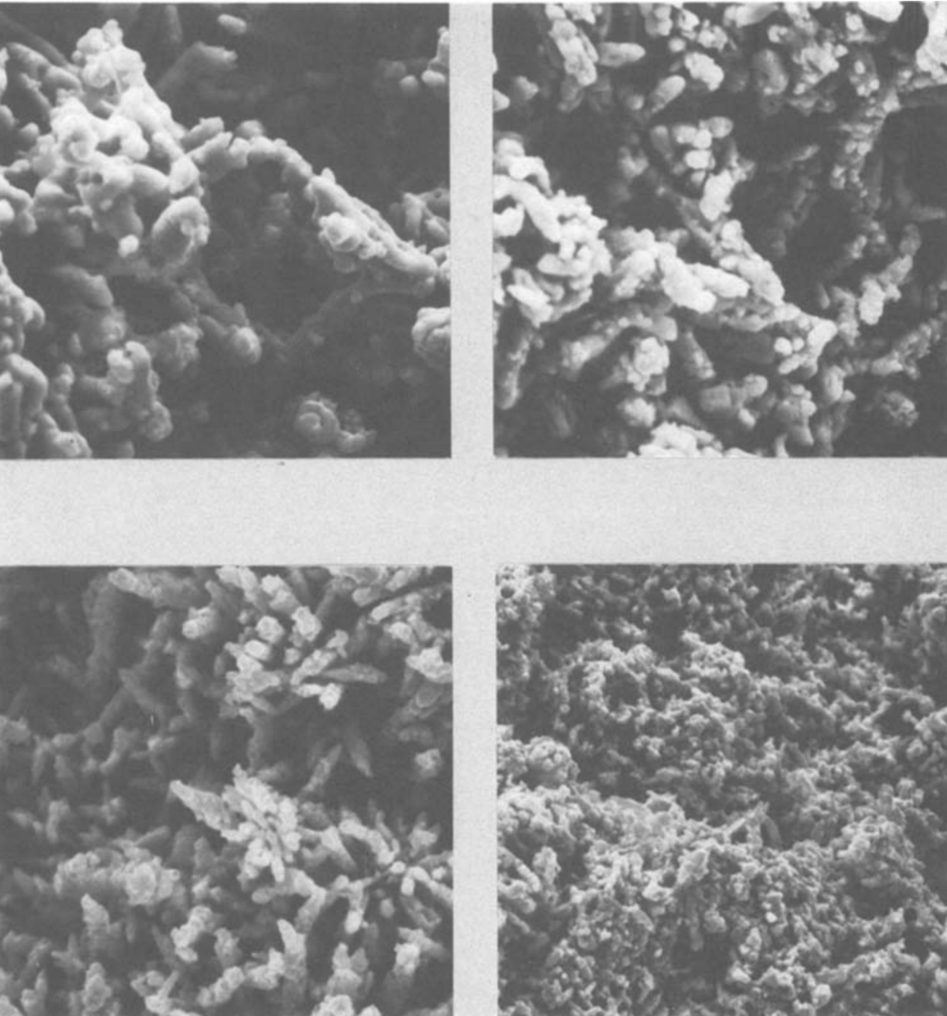

Fig. 5. Structure of freshly formed fractured negative as affected by type A expander concentration in the paste: (a, top left) no expander, (b, top right) 0.1 w/o, (c, bottom left) 0.3 w/o and (d, bottom right) 0.5 w/o. Micrographs were taken close to the edge. Magnification 3000×.

Table III. Microelectrode evaluation of type A and B expanders at 60 ppm (mg/liter) in 1.250 sp gr H_2SO_4

Expander material	Q_{in} (C)	Q_f (C)	Cycle life index, $\frac{Q_f - Q_{in}}{Q_{in}}$
Type A	1.354	1.131	−0.17
Type B	1.293	2.463	0.91

technique in predicting the influence of expander quality on the deep discharge cycle life of the pasted electrode. The 60 ppm concentration in the microelectrode system was assumed to be equivalent to close to 0.5 w/o in the pasted electrode. The test electrodes with 0.5 w/o type A and B were prepared according to the procedures given in the experimental section. These test electrodes were assembled with the heavily pasted counter positives to form 98 A-hr negative limited test cells.

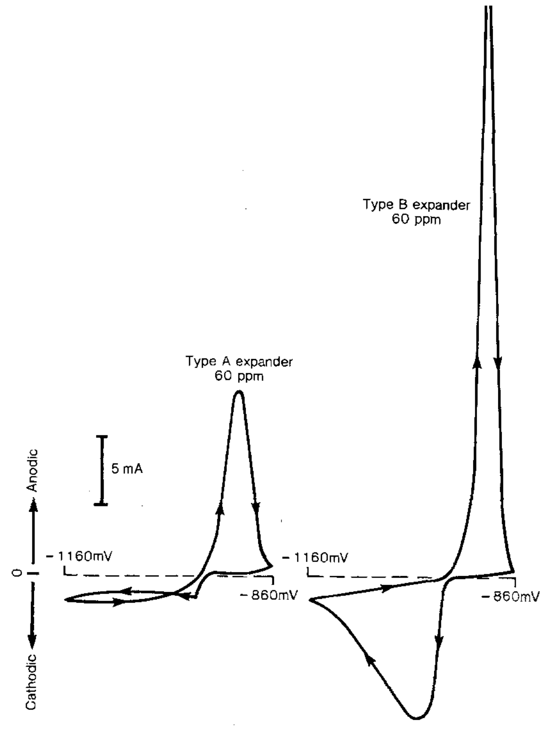

Fig. 6. Lead microelectrode voltammograms taken at 145th cycle demonstrate a strong charge inhibition of type A expander compared to type B in 1.250 sp gr H_2SO_4 solution.

The capacity maintenance behavior of these two test series during cycle life testing with 90% DOD per cycle are given in Fig. 7. Test cells with type B expander had relatively low initial capacity which, however, did gradually build up to an equivalent level to that of the previous series within 30 cycles and showed a 90% DOD cycle life close to 330. This demonstrates that the type B expander is superior to type A in improving the deep discharge cycle life of the pasted electrode system (Fig. 7), in agreement with the microelectrode observation (Fig. 6).

Relation between CLI and electrode capacity.—The expander present in the test solution alters the lead matrix morphology during linear potential sweep cycling of the microelectrode. Thus the cycle life index reflects the expander's influence on the steady-state capacity of the microelectrode. Analogous to this, expander present in the pasted electrode matrix is expected to alter the lead matrix morphology during formation and subsequently to help the electrode attain a steady-state capacity on repeated deep discharge cycling. Thus a correlation between the expander's influence on the microelectrode cycle life index and the dischargeability or the specific capacity of the pasted electrode (A-hr/kg active mass) is anticipated. This was carried out with the simultaneous evaluation of three B-type expanders by the microelectrode and the pasted electrode.

The B, B′, and B″ type expanders were experimental lignosulfonate samples prepared by American Can

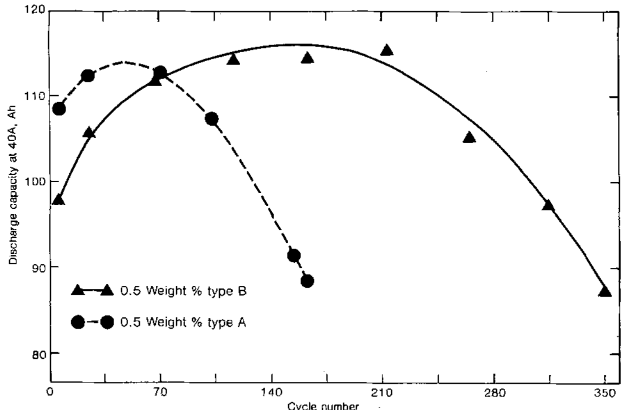

Fig. 7. Effect of expander type in the negative paste on the capacity maintenance behavior of 98 A-hr negative limited test cells.

Fig. 8. The effect of three type B expanders on the specific discharge capacity of lead electrode with and without type A expander and $BaSO_4$ at 52.7 A/kg and 25° ± 1°C in 1.300 ± 0.005 sp gr H_2SO_4 solution.

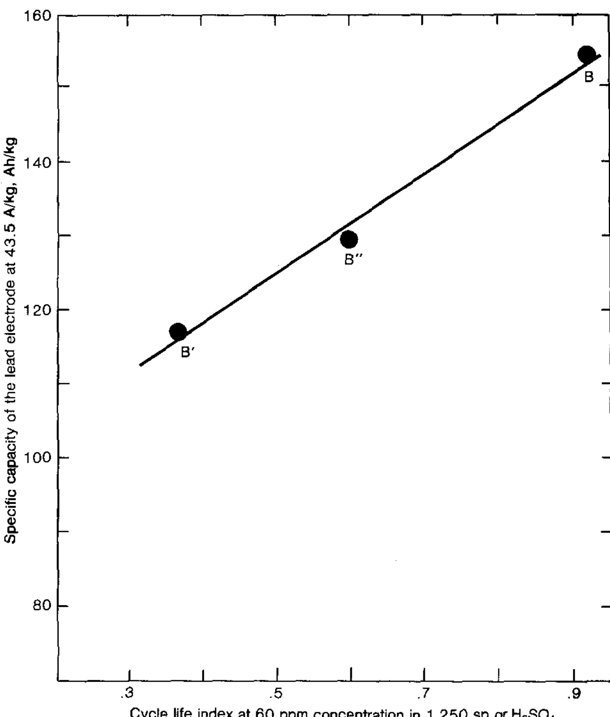

Fig. 9. Correlation between the effect of three B-type expanders on the lead electrode specific capacity and the microelectrode cycle life index.

Company, Rothschild, Wisconsin, for this test. All these materials were prepared from the same source material with some unknown change in processing conditions. The variation of these samples was not detected by u.v. and infrared spectroscopy. However, the microelectrode testing of these materials had shown the CLI values to be 0.91, 0.36, and 0.59 for B, B′, and B″, respectively, at 60 ppm concentration in 1.250 sp gr H_2SO_4 solution.

The efficacy of these expanders on the steady-state capacity development was tested on type II electrodes prepared out of conventional paste in which the type B, B′, and B″ expanders were included with and without type A expander. The test plates were conventionally formed and tested in duplicate in a three-plate element test cell.

The summary results of the five test series measured in duplicate are shown in Fig. 8 in the form of a bar diagram. This diagram indicates that the material utilization of the lead active mass is not significantly influenced by the 0.3 w/o type A lignin in the presence of 0.3 w/o type B lignin; second, the influence of $BaSO_4$ in promoting the material utilization of the active mass under this composition range is heavily controlled by the type B lignin. The material utilization shows that the expander activity of B, B″, and B′ are in the decreasing order in agreement with the cycle life index value of these materials at 60 ppm mentioned earlier.

Figure 9 is a plot of steady-state capacity of the pasted electrode and the microelectrode cycle life index for B, B′, and B″ expanders. It shows a linear correlation between the cycle life index and the specific capacity of the pasted electrode and further demonstrates the predictability of the microelectrode technique in determining the efficacy of expander on the lead electrode performance.

Conclusions

Microelectrode cycle life index is shown to have an acceptable correlation with the expander's influence on the deep discharge cycle life and the material utilization of the pasted type lead electrode. An optimum concentration of expander exists both in the paste matrix and in the test solution for a maximum deep discharge cycle life. The prediction of this optimum concentration in the pasted electrode is possible from the microelectrode test data. However, it is highly likely that this optimum concentration may vary with the nature of the material. The microelectrode cycle life index has been noted to be sensitive to the quality of expander prepared from the same source material and has proved to be useful as a quality control tool. The fundamental reasons for an optimum expander concentration for a maximum deep discharge cycle life, whether they are related to physical properties or to the chemical structure and associated reactions, are not clear. More work is needed to elaborate the expander activity as function of the chemical structure and the physicochemical properties of the expander. The microelectrode technique as an economic screening technique of candidate expanders appears to be extremely helpful in finding a better material which in turn could improve the energy density and cycle life of the lead electrode or the whole lead acid battery.

Composite Cell Testing of Corrosion-Resistant Pasted Lead-Acid Battery Grids

I. Weight Loss and Grid Integrity of Low Antimony and Antimony-Free Grids

E. M. L. Valeriote*

Cominco Limited, Product Research Centre, Mississauga, Ontario, Canada, L5K 1B4

ABSTRACT

A comprehensive set of long duration corrosion tests was carried out under conditions closely approaching those in a lead-acid battery to compare the corrosion characteristics of twelve different materials, including expanded mesh grids produced from cast strip and rolled strip as well as book-mold cast grids. Seven lead-calcium-tin grids, one lead-calcium grid, one lead-strontium-tin grid, and two lead-antimony grids were included as pasted plates in each composite cell, along with a coupon sample of unexpanded, unpasted, cast lead-calcium-tin strip. Tests were conducted under well-defined conditions of temperature and electrode potential, simulating conditions of SLI service in a vehicle. Weight loss and grid integrity measurements were supplemented by metallographic examinations. Rate laws indicated a change in corrosion mode for lead-calcium-tin alloys as test conditions were made more severe. A semi-quantitative model was developed indicating that this change in corrosion mode was associated with more deeply penetrating corrosion. This behavior contrasted to that for antimonial and strontium-lead alloys and for a low-calcium-lead alloy for which the same form of rate law was observed under all conditions. The corrosion characteristics of two particular expanded grids were outstanding. One of these was an expanded cast strip grid of composition Pb-0.09Ca-0.3Sn; the other was a soft expanded cast-strip grid of composition Pb-0.007Ca.

During the 1970's the lead-acid battery industry experienced a major processing change toward high volume plate manufacturing technology based on the fabrication of continuous strip and conversion to grid mesh. Coincidental with this change was the introduction of battery alloys which reduce water loss, thus allowing batteries to be partially sealed and permitting maintenance-free operation. Certain of the contending alloys have sufficiently narrow freezing ranges to be cast continuously as strip by solidification on a rotating drum caster (1-4).

These, as well as other alloys, may also be rolled into strip form or cast by the conventional book-mold process. The most important commercially are the lead-calcium-tin alloys, which are currently produced both as discrete cast grids and as rolled or cast strip. The strip can be converted into grids by punching or by metal expansion methods.

For several years, sealed cylindrical lead-acid cells have been produced commercially with grids punched from cast strip. On an even larger scale, automotive starting-lighting-ignition (SLI) batteries are produced with book-mold-cast grids or with grids made by expanding heavily rolled (wrought) strip. Book-mold casting involves a batch process which is highly labor intensive and skill demanding. Expansion involves the partial slitting and separation of strip to form a network of diamonds.

Expanded diamonds are formed by three distinct actions: slitting, stretching, and expanding. Slitting creates a pattern of interrupted cuts in the material. Nodes are located in the area where no slitting occurs while the slit sections become the strands. In order to maintain the required node-to-node length the strands are stretched or elongated to prevent the contraction of the diamond during the final expansion step. Either a rotary or a reciprocating-type action can be applied to metal expansion. The reciprocating method has hitherto been most widely used commercially. Patents for the rotary equipment are pending or granted (5). The Cominco rotary method carries out the three operations in two steps: first a simultaneous slitting and stretching action, followed immediately by the expansion or pulling apart of the diamond components to produce a mesh. The reciprocating method combines all three actions by means of an up-and-down punch press operation whereby the strip material is indexed rapidly through the expander where the tooling slits, stretches, and expands one row of strands and nodes during each stroke.

In spite of rapidly growing industrial acceptance of both cast and wrought ternary lead-calcium-tin grid alloys, very few results of corrosion testing of these alloys have been published (6-13). Even fewer results are available for corrosion of expanded grids (11) and none for rotary-expanded grids. Since the metal deformation which occurs during strip expansion or rolling results in substantial changes of metallurgical structure, and thus to possible changes in electrochemical characteristics, it is desirable to test alloys in their final form, *i.e.* as expanded grids. The results of bare metal corrosion tests may also not be directly relatable to pasted plate/battery grid performance (7). It has been shown that similar rates of corrosion are obtained for pasted and unpasted halves of a grid under float charge conditions (11). However, this might not hold if periodic discharges are experienced (as occurs in battery service) because of the mass transfer characteristics of the porous active mass in a pasted plate in comparison to that of the free electrolyte at the surface of the corrosion film on bare metal. Thus, it is desirable to test pasted plates in a battery environment under well-defined conditions relevant to the intended application.

Key words: alloy, battery, potential, corrosion.

This paper describes corrosion testing of grid materials related to maintenance-free SLI battery applications. Alloys were selected having calcium and tin contents within the range normally used by the SLI battery industry. In addition, a composition typical of cylindrical sealed cells (Pb-0.007Ca) was chosen as well as a strontium alloy and two low-antimony alloys. Cast strip, rolled strip, and book-mold grids were fabricated into test cells as described below.

The tests were carried out under constant potential charging conditions, interrupted periodically by shallow discharges, or under open-circuit stand conditions. Tightly supported pasted grids, contained in composite cells (*i.e.*, each cell contained all of the twelve test materials selected for this investigation), were tested at various temperatures and overpotentials. The cells were constructed so as to be as similar as possible to cells in SLI batteries except for the unusual multicomponent positive plate arrangement. Weight loss, grain size, depth of penetration, tensile strength, and various other physical measurements were made for grids before and after the corrosion test. The weight loss and grid integrity results are discussed below.

Experimental

Thirty-seven experimental cells, each containing the twelve test materials were constructed in cell containers made by cutting up group 24 battery cases and covers. Normally sized expanded grids were hand-pasted for negatives with a leady oxide mix having a wet paste density of 4.7 ± 0.1 g-cm^{-3}. After curing, the negative plates were enveloped and post straps were cast on to produce a normal negative plate group. Expanded mesh for positive mini-grids was made by rotary expansion of 0.9 mm thick strip followed by the punching out of mini-grids 5 cm wide and 10 cm high (excluding tab) from the expanded mesh. The grid materials and fabrication methods are shown in Table I. The cast strip lead-calcium-tin alloys were expanded 8 weeks after casting the strip. Alloys K and R were rolled within one day of casting. Alloy S was expanded the same day as it was cast. Alloy B was well aged (>6 months) after rolling and expanding. Commercial book-mold grids, having wires with cross sections comparable in size to the expanded grids, were cut to the same plate dimensions. One of the positive plate test materials (Lab code A) was unexpanded strip, 2.5 cm wide × 10 cm high, which was to remain unpasted. The other eleven mini-grids were hand-pasted using a positive mix of wet density 4.27 ± 0.07 g-cm^{-3}, which was cured in the same manner as the negatives, *i.e.*, 40°C, 100% RH for ~3 days. The elemental compositions of major alloying agents, as determined by AA spectroscopy, are given in Table I. For the first nine alloys, the first digit of the mnemonic code indicates the nominal calcium content in hundredths of a percent, and the next two digits indicate the nominal tin contents in tenths of a percent. The portion of the mnemonic code following the hyphen indicates fabrication method, as explained by the entries in the final column of Table I.

For each cell two positive mini-groups, containing six plate types each, were assembled by casting on a strap-post to each mini-group. Before pasting, each of the 444 (37 × 12) grids was individually coded, detailed metallographic and dimensional measurements were made, grid surface area was estimated, and the grids were stripped in an alkaline hydrazine-mannitol stripping solution (14) at 60°-70°C. The stripping solution contained approximately 10% sodium hydroxide, 1% hydrazine dihydrochloride, and 2% mannitol. The ratios of tab/grid weights were determined for similar grids prepared at the same time since it would be necessary to detach the tab (by cutting along the top of the upper grid bar) after exposure to the corrosion test, in order to determine final weights and corresponding weight loss. The standard deviation of this ratio was ~2% for each grid type.

The two positive mini-groups and the negative group were sandwiched together to form assembled elements, as shown schematically in Fig. 1. The two positive posts (shown as one in Fig. 1) were burnt together and appropriate leads were soldered to each of the terminal posts. All cells were given a 24 hr formation in 1.115 sp gr forming acid, initially at 10A (8.4 mA/cm^2) for 16 hr by which time the cell voltage reached the limit set of 2.67 V/cell. This corresponded to a positive plate potential (E_+) of 1.40V with respect to an Hg/Hg_2SO_4/1.30 sp gr H_2SO_4 reference electrode, to which all electrode potentials in this work are referred. Formation continued for another 8 hr at the constant voltage limit of 2.67 V/cell, during which time E_+ decreased to 1.35V, current decreased to a final value of 2.5A (2.1 mA/cm^2), and temperature also decreased. Electrolyte temperature above the plates was 32°-50°C during the entire formation period, reaching a maximum 3 hr after formation began and attaining a lesser maximum at the time when the cell voltage limit was reached. The forming acid was then replaced by 1.30 sp gr sulfuric acid and the cells were further charged overnight at 2.67 V/cell ($E_+ = 1.37$V). The specific gravity in the test cells was 1.27 ± 0.02 at 25°C. Water was regularly added to a reference mark in the cells undergoing testing.

After formation and charging, one cell was dismantled and, after removal of active material and chemical stripping, weight losses were determined before metallographic examination began. The remaining thirty-six cells were divided into six equal groups. Each group was maintained under the following conditions for the test durations indicated, with periodic cell removals for weight loss and other measurements: (*i*) 40° ± 2°C, open-circuit (OC) stand, E_+ decreased from 1.18 to 1.10V during the 18 week duration; (*ii*) 50° ± 3°C, OC, E_+ decreased from 1.18 to 1.11V during the 15 week duration; (*iii*) 50° ± 3°C,

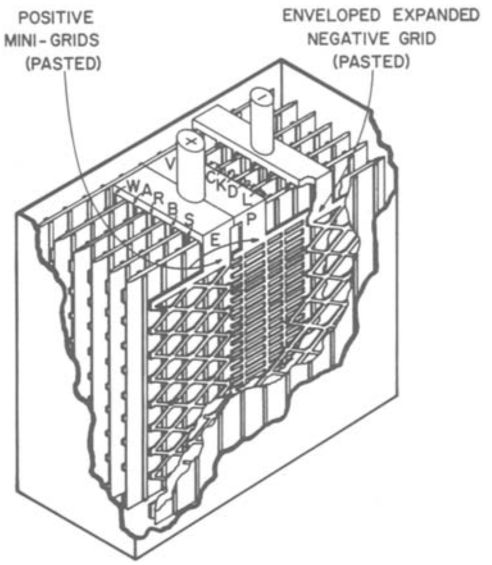

Fig. 1. Artist's schematic illustration of composite pasted plate test cell, indicating positions of test alloys.

$E_+ = 1.280 \pm 0.014$V ($\eta = 100$ mV), 15 weeks; (*iv*) 40° ± 2°C, $E_+ = 1.382 \pm 0.011$V ($\eta = 200$ mV), 10 weeks; (*v*) 50° ± 3°C, $E_+ = 1.381 \pm 0.015$V ($\eta = 200$ mV), 46 days; and (*vi*) 65° ± 1°C, $E_+ = 1.380 \pm 0.014$V ($\eta = 200$ mV), 27 days.

The electrode potentials were controlled by manual adjustment of cell voltage using power supplies. They remained within the indicated error limits for cells maintained at constant potential except for the approximately 1 hr required for cells controlled at 200 mV overpotential to recover from a discharge of 100 A-min each working day and the approximately 3 hr required for recovery of the 100 mV overpotential cells.

As cells were periodically removed from test, the positive mini-plates were individually stripped, the tab was removed along a line coincident with the top of the upper grid bar, and the grids were weighed. Metal surface areas were calculated from grid wire and frame dimensions with an accuracy of about 8% for expanded metal grids (48 cm^2), 6% for book-mold grids (60 cm^2), and 1.5% for the bare coupon sample (55 cm^2). Weight losses were expressed per unit area of metal immersed in the electrolyte in the test cell. Measurements were made to determine both vertical and horizontal growth of the grids for each cell on test. However, because of the uncertain effects of handling the expanded grids on their dimensions and the breakage of many grids due to wire severance, these data appeared unreliable and have not been reported. All grids were examined closely and rated with respect to integrity on a scale of 1 (best: no broken wires) to 5 (disintegrated into many fragmented wires) before being mounted for metallographic examination and measurements.

Results

Weight loss results are shown in Fig. 2 for cells tested at 50°C and at an overpotential, η, of 200 mV. Experimental points are indicated using the lab code given in Table I to indicate grid and alloy type and both lab and mnemonic codes are shown on the figure. High correlation coefficients, r, were obtained for a linear least squares fit of the weight loss (w) data with time (t)

$$w = a + bt \quad [1]$$

for alloys V(r = 0.966), W(0.996), S(0.997), L(0.984), A(0.983), D(0.983), and C(0.962). The latter four, however, had comparable and usually somewhat higher correlation coefficients, L(0.983), A(0.989), D(0.993), C(0.965), when fitted to an exponential function

$$w = a \exp(bt) \quad [2]$$

For the remaining grids, the exponential function clearly gave the best fit: K(0.9998), B(0.998), P(0.994), R(0.993), and E(0.936). The grids best described by exponential rate laws have been included in Fig. 2 and have been replotted on a semilogarithmic scale in Fig. 3. The standard error of the fit is indicated only for the fit of the data having the highest correlation coefficient in each figure. Power ($w = at^b$) and logarithmic ($w = a + b \log t$) two parameter rate laws were also tested but gave relatively poor correlations

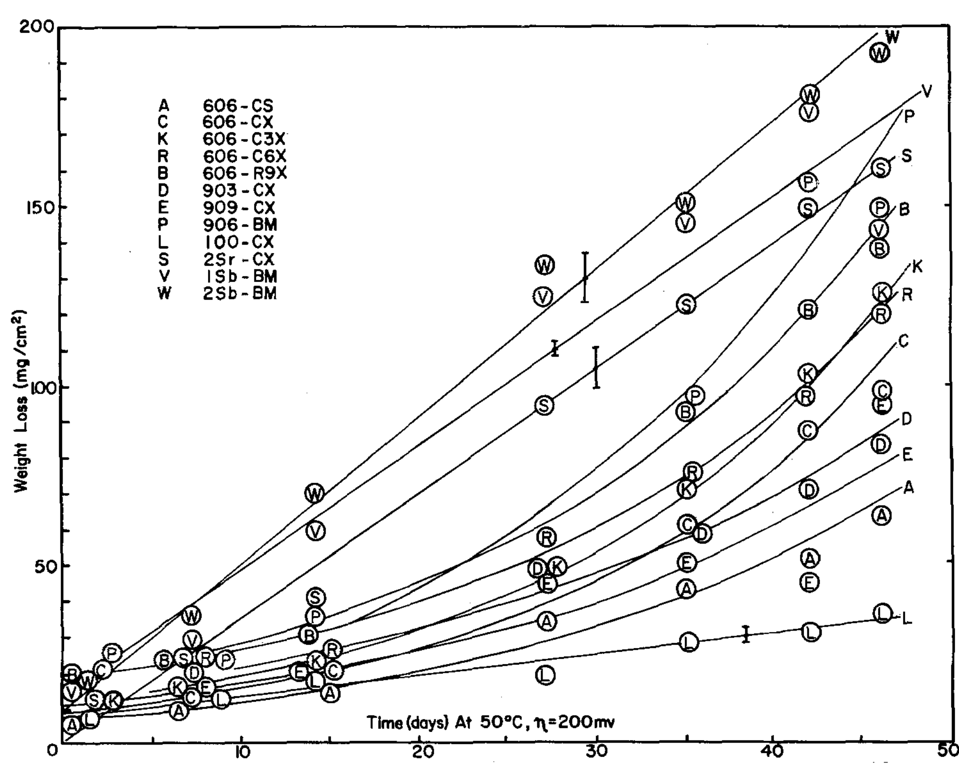

Fig. 2. Weight loss time-dependence for test materials at 50°C and 1.38V. Circled letters are experimental points and refer to the alloys of Table I. Error bars are shown for linear time dependences. Curves are exponential fits. Some points have been offset or omitted for the sake of clarity.

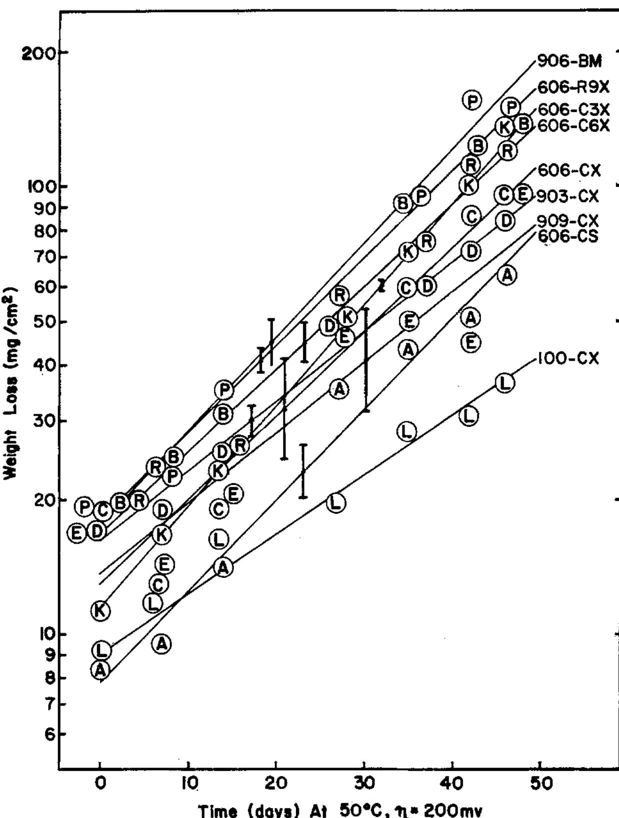

Fig. 3. Data of Fig. 2, for lead-calcium alloys, replotted on a logarithmic scale to indicate exponential dependence on time. Error bars are given for the eight ternary alloys best fitted by an exponential rate law.

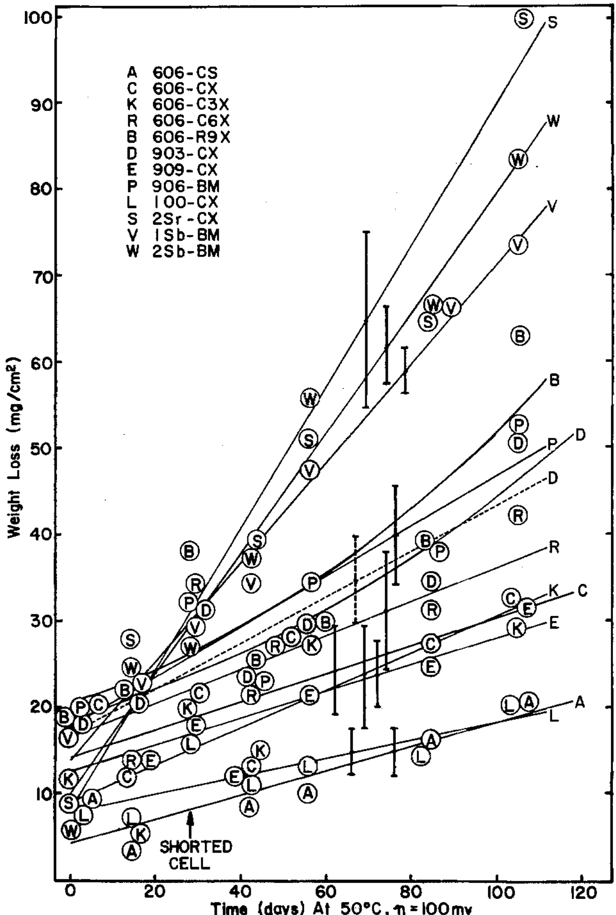

Fig. 4. Dependence of weight loss on time for test materials anodized at 50°C, 1.28V positive potential. Both the marginally better exponential fit (solid curve) and linear fit (broken line) are given for alloy D. Error bars are given only for linear fits.

in almost all cases for these and the other data described in this paper. In most cases where the exponential fit was best of all the two parameter rate laws tested, a higher correlation could be obtained with a second-order polynomial. However, often a fourth, or even higher, order polynomial was required to match the goodness of fit of the exponential function. "Paired-t" statistical analysis of the correlation coefficients for linear and exponential fits indicated, with a high level of confidence (>97.5%), that the exponential function described the data for the lead-calcium grids better than a linear function.

For these eight grids the correlation coefficients were 0.98 ± 0.02 s.d. For the other four grids, it could not be stated at the 90% confidence level that the linear fit was superior, because of the limited data under these conditions. When considered in association with the data obtained under other experimental conditions, it was possible to state, at the 99% confidence level (c.l.) that V, W, and S were best described by the linear function. The apparent preference for the linear fit with alloy L, however, could have occurred by chance with at least 10% probability.

The weight loss results for cells tested at 50°C, $\eta = 100$ mV, are shown in Fig. 4. Under these conditions, all of the grids, with two possible exceptions (B and D), appeared to be best described by a linear rate law. For the alloys containing calcium, however, correlation coefficients for the linear fits were relatively low ($r = 0.86 \pm 0.05$ s.d.). Even though higher values of r were obtained, for the antimony and strontium alloys, comparable to those at 50°C, $\eta = 200$ mV, it was still impossible (using the 50°C, $\eta = 100$ mV data only) to show at the 90% c.l. that the linear function gave a better fit than the exponential for either the calcium or the noncalcium groups.

The cell removed at 28 days had accepted a substantially higher current (2.15 ± 0.26A for the last 21 days) than the other cells (0.32 ± 0.08A for the same period) during the entire duration of the test, suggesting an internally shorted cell. When dismantled, visual inspection revealed that a short had developed between electrode A and the negative strap. The weight loss for A was very high due to loss of lead through fusion caused by the short. Weight losses for most of the grids from this cell seemed somewhat high, but since the electrode potentials were maintained at acceptable values (1.260 ± 0.015V) in a potential region where corrosion is relatively insensitive to potential, the results were not discarded (except for one damaged grid, S). Other cells which developed shorts were removed from test as soon as possible after shorts were discovered and confirmed.

Under open-circuit stand conditions at 40° and 50°C (see Fig. 5), all of the alloys were best described by linear rate laws at the 95% c.l. However, the preference for a linear fit was not large. The difference in r values (Δr) between the two functions was 0.05 ± 0.07 s.d. All but two alloys gave r values ≥ 0.92 at 40°C and all but one gave $r \geq 0.95$ at 50°C for the linear fit.

At 200 mV overpotential, the results at 40°C were very similar to those at 50°C (Fig. 3), apart from the time scale, with all eight lead-calcium-tin alloys being well described by exponential rate laws ($\bar{r} = 0.98 \pm 0.01$ at 40°C and $\bar{r} = 0.98 \pm 0.02$ at 50°C) at the 99% c.l. and the other four alloys being well described by linear rate laws (90% c.l.). The ratio of the b parameter of the exponential law at 50°C (slope in Fig. 3) to that at 40°C was 1.93 ± 0.24 for the eight alloys. The corresponding b parameter ratio for the linear laws was 1.75 ± 0.13 for alloys V, W, and S

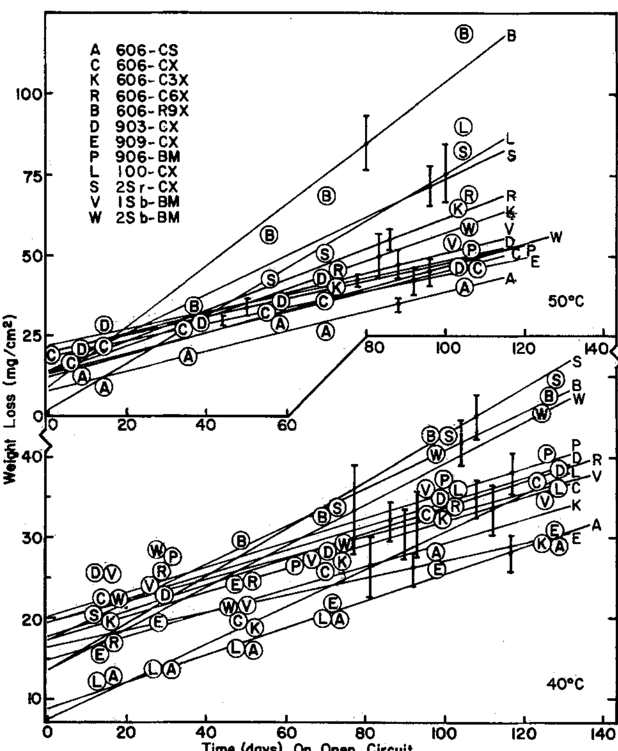

Fig. 5. Dependence of weight loss on time on open circuit at 40°C (lower) and 50°C (upper). Many points have been omitted or offset for clarity.

and 1.30 for alloy L. At 65°C, the pattern was noticeably different. Whether the data were grouped as before or taken all together, it was impossible at the 90% c.l. to show that one function fitted the data better than the other. The weight losses are shown as a linear function of time in Fig. 6. Linear fits for the three alloys (C, D, and L), which gave (insignificantly) higher r values for the exponential law, are shown with broken error bars. Further experiments were carried out with unpasted unexpanded cast strip coupons of alloys C, D, and two other compositions at 50°C and $\eta = 200$ mV. A potentiostat was used to control the potential much more accurately than was possible for the composite pasted plate cells. The current was observed to increase exponentially with time for as long as 70 days before reaching a constant value.

The data for B, C, and P at 65°C, shown in Fig. 6, have been replotted on a semilogarithmic scale in Fig. 7 for comparison with earlier results obtained in another experiment using unpasted grids from the same lots, B′, C′, and P′. The data for the unpasted grids appeared to fit exponential rate laws better than linear rate laws, although the preference was not significant, even at the 75% c.l., and data have been plotted on the semilogarithmic scale only for convenience. Weight losses for the expanded heavily rolled strip grids were greater than those for expanded cast strip grids by factors of 1.3-2.2. The results for alloy C were similar for pasted and unpasted expanded grids except that the unpasted grids required 2 weeks more to attain the same weight losses. A somewhat shorter delay was observed for alloy B (approximately 1 week at mid-experiment) and the slopes of the fitted line for B and B′ were significantly different. For alloy P, as for alloy C, the same slopes were obtained for pasted grids as for bare grids; however, the weight losses were very much larger for the pasted grids than for the bare grids, corresponding to a 3 week delay in reaching a similar weight loss for unpasted grids. Of even more consequence is the apparent reversal of the order of corrosion rate for alloy P, in comparison to B and C, with P being the most corrosion resistant of the three materials for most of the life of the bare grids, but the least corrosion resistant when compared as pasted grids. Alloy P′ also had a much higher slope than the other bare grids B′ and C′, in-

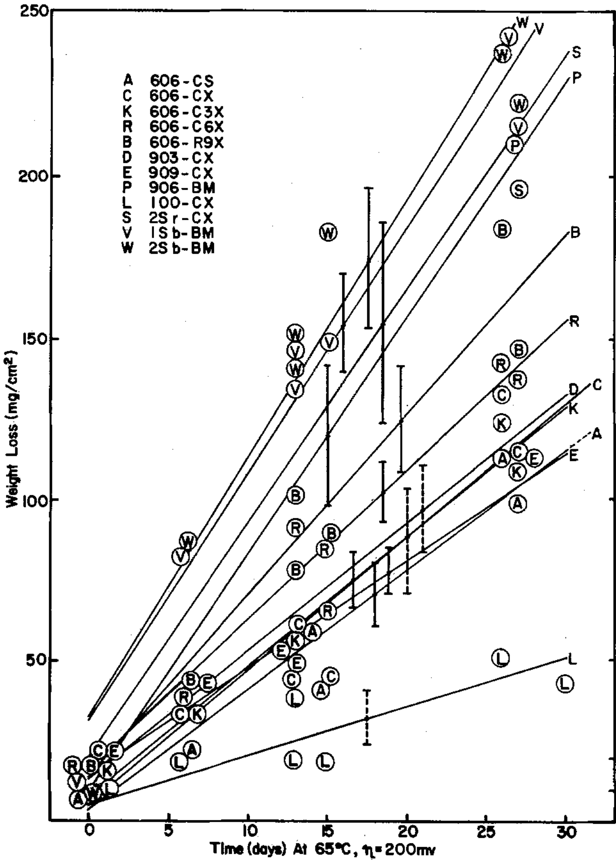

Fig. 6. Linear fit of weight loss data at 65°C, 1.38V positive potential.

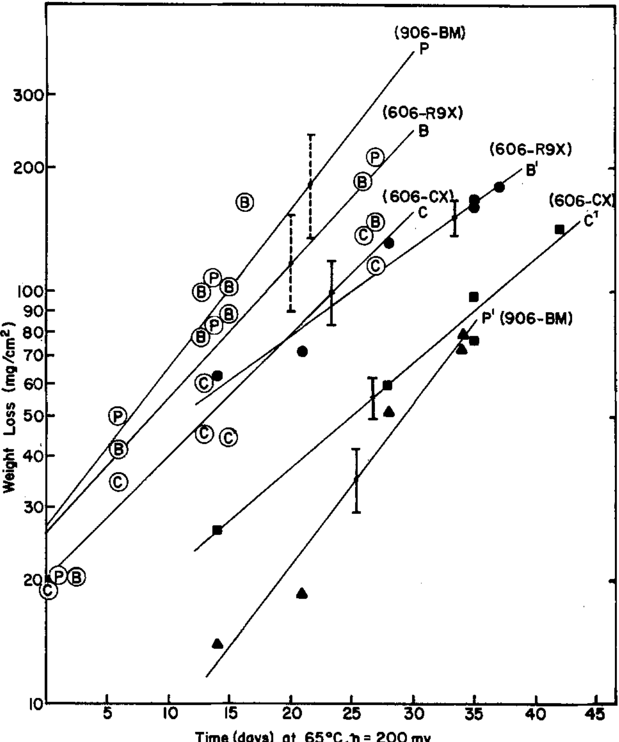

Fig. 7. Dependence of weight loss on time at 65°C and 1.38V potential for unpasted grids (B′, C′, and P′) from same lots as pasted grids B, C, and P.

dicating a possible change of corrosion resistance for the P′ grids during the experimental run. In fact, similar tests on other well-aged book-mold grids of somewhat different compositions (Pb-0.03Ca-0.6Sn and Pb-0.09Ca-1.0Sn) from a different source gave a lower slope, similar to those for B′, C′, and to other expanded grids of similar composition. The expanded mesh was tested as bare grids within a few weeks of expanding from strip. The cast strip was expanded 2 months after casting. The commercial heavily rolled strip was aged at least 6 months after rolling and before expansion. The book-mold grids were cast approximately 1 month before being tested as bare grids. However, these same materials were not tested as pasted plates for an additional 4-6 months. The high slopes for P′ and possibly P may have been due to an aging process, taking place at an accelerated rate during the 65°C test, and possibly at room temperature in the interval between bare grid and pasted grid testing. Metallographic results and tensile testing indicated that changes in metallurgical structure and strength, due to elevated temperature of the test, does occur for B grids (15). These results will be discussed in a later publication (16). Such changes may have also caused the increase in slope for B in comparison to B′, although this seems less likely since this material was already well aged before either test. No significant difference in slopes was obtained for C in comparison to C′.

The weight loss results, while important, are not sufficient to evaluate the usefulness of these alloys for an intended application. Accordingly, such metallurgical and dimensional parameters as grain size, depth of corrosion penetration, and grid growth were also measured. This work is still in progress and is not presented here. However, a macroscopic assessment of grid integrity has been completed for all cells. Figure 8 shows the stripped (and in some cases, reconstructed) grids of a cell, which had been controlled at 50°C and 200 mV overpotential for 35 days. The weight losses (mg/cm^2) are given below each grid, along with the lab and mnemonic codes. In Fig. 9, a similar comparison is presented for grids taken from another cell after 46 days at 50°C and η = 200 mV. As is apparent, grids having very similar weight losses often suffered markedly different losses of grid integrity as judged by broken wires. Loss of grid integrity was quantified on a scale from 1 to 5, with 1 indicating excellent retention of grid integrity, with no broken wires and little thinning (*e.g.*, grids D and L in Fig. 8 and 9) and 5 indicating complete disintegration (grid S). Intermediate figures of merit were assigned, according to the number of broken wires and degree of grid fragmentation. The results of this assessment are displayed for the data obtained at 200 mV positive overpotential and at 40°, 50°, and 65°C in Fig. 10. Ranking of grid integrity, as based on such assessments, is given in Table II for 0, 100, and 200 mV overpotentials. Grids should only be compared within a column since comparison between columns is dependent on the duration of the tests at each overpotential. Grids in the same row within a column are approximately equal but superior to grids in lower rows. Where more than one test temperature was used, the ranking was averaged over all temperatures. A slight rearrangement of order is possible if ranking at only one temperature is of interest.

Discussion

Examination of the corrosion (weight-loss)-time dependences observed indicated that, with a high degree of confidence (99% c.l.) the antimonial alloy grids (V and W) and the strontium-tin alloy grids (S) had linearly increasing weight losses (*i.e.*, constant corrosion rate) at all the temperatures and potentials investigated. The tin-free, low calcium grids (L) also appeared to show linearly increasing weight losses,

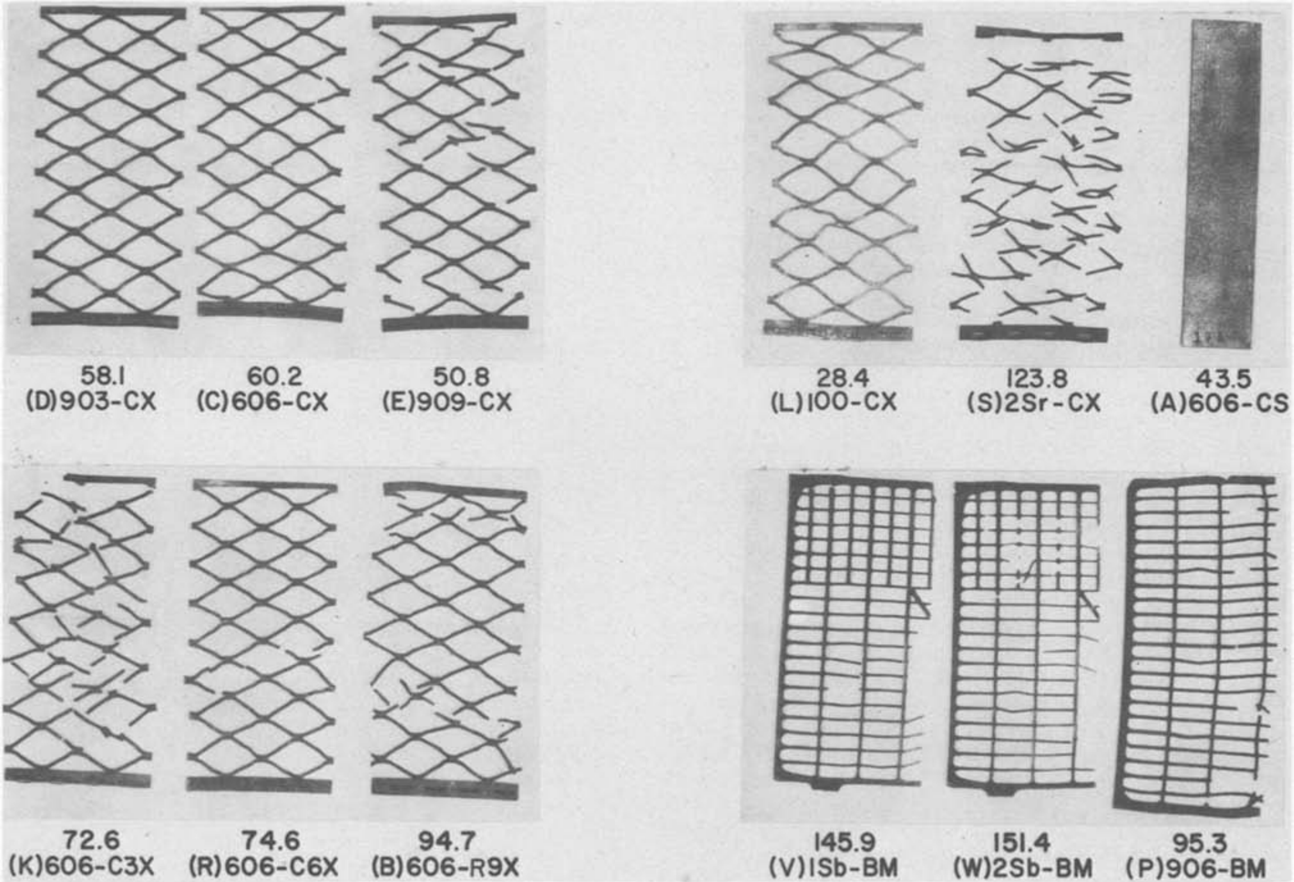

Fig. 8. Stripped grids and coupon from composite cell after anodization at 50°C, 1.38V (η = 200 mV) potential for 35 days. Codes identifying alloys and weight losses (mg/cm^2) are indicated below each grid.

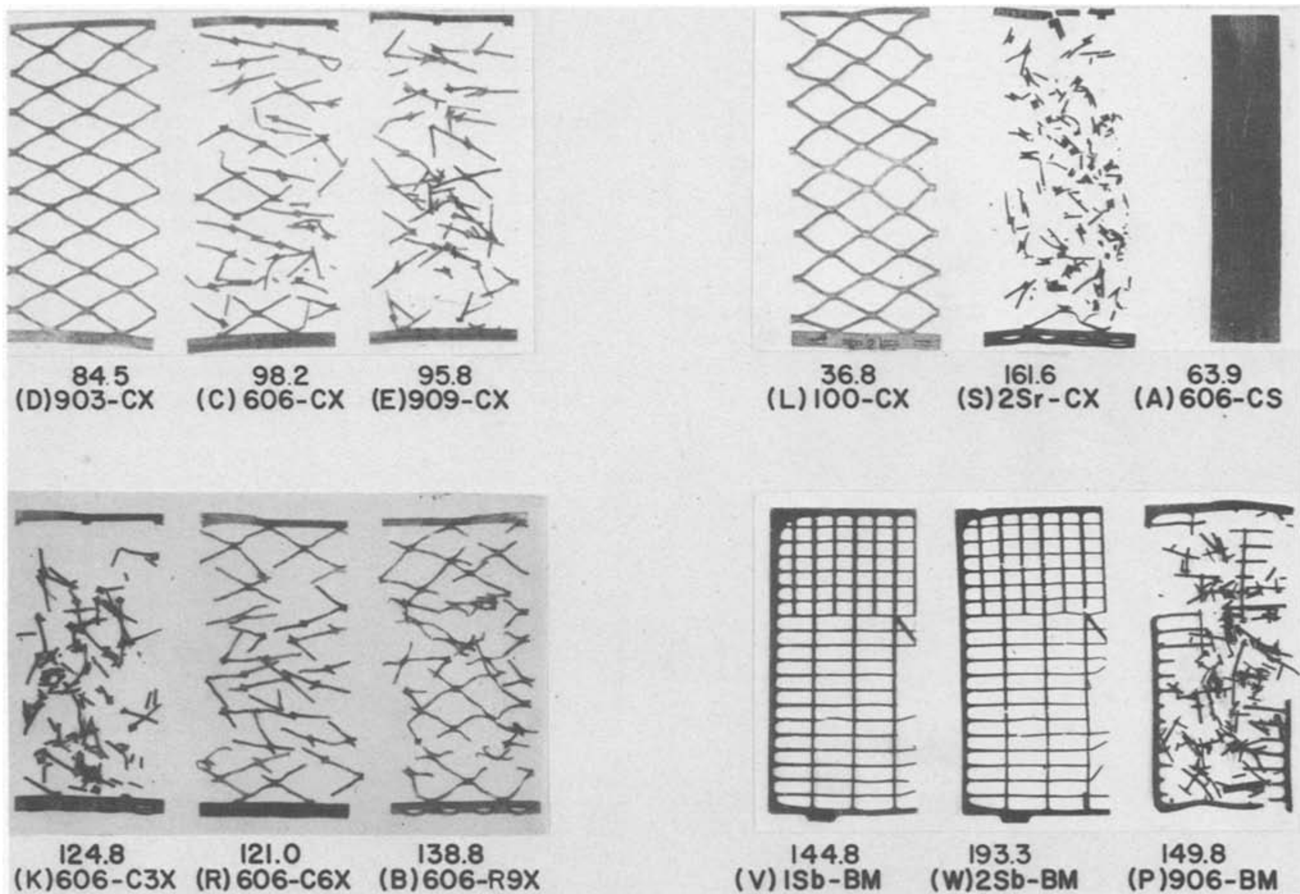

Fig. 9. Stripped grids and coupon from composite cell after anodization at 50°C, 1.38V (η = 200 mV) potential for 46 days. Identifying codes and weight losses (mg/cm^2) are indicated in the figure.

but the slopes and corresponding correlation coefficients were low (due to the high corrosion resistance of this alloy) and there was a probability of over 10% that the preference for the linear fit was only due to chance.

For the lead-calcium-tin grids, however, the pattern was more complicated. At $\eta = 200$ mV a temperature dependence appeared such that all the lead-calcium-tin alloys clearly best fit exponential rate laws at 40° and 50°C. However, the preference for an exponential over a linear time dependence was reduced from the 99.5% c.l. at 40°C to the 97.5% c.l. at 50°C. At 65°C, the lead-calcium-tin grids showed no clear preference for exponential or linear behavior. As the potential was reduced from $\eta = 200$ mV at 50°C, the preference for exponential behavior again disappeared. At $\eta = 100$ mV, it was impossible to support one dependence over the other at the 90% c.l. At $\eta = 0$, the same was true if the lead-calcium-tin alloys were considered alone as a group. However, if all 12 alloys were grouped together at 50°C (or at 40°C) a linear dependence was preferred at the 95% c.l.

Thus, it appears that a change in the mode of corrosion must occur as overpotential is increased from the range of normal SLI operating conditions (η = 0-100 mV) to the more severe charging conditions (η = 200 mV) corresponding to ~2.8 V/cell for a battery. In addition, as the temperature of the test is increased, the mode of corrosion either reverts to that under the milder conditions or else a third mode appears, which also follows a linear increase of weight loss. For the grids which did not contain calcium and tin, however, linear behavior was observed under all conditions. In the latter case, the more severe conditions appear to accelerate the relevant corrosion modes but for lead-calcium-tin alloys, it is possible that other corrosion modes irrelevant to the application may be induced if inappropriate choices of temperature and potential are made.

Table II. Grid integrity ranking

η	0 mV	100 mV	200 mV
E_+	OCV	1.28 V	1.38 V
Best	L, D, V	D, C, V, R	L
	W, P, C	E, K, P, B	D
	—	L, W	V, W, R
	E	—	P, C
	K, R	S	B
	B, S		K, E
Worst			S

In the case of alloy B, preliminary metallography and tensile measurements (16) indicated that this material was undergoing metallurgical changes under the elevated temperatures of the experiment. For the other alloys, the reason for the complicated behavior was less obvious. However, it is possible to propose a model, consistent with most of the data. At least two obvious modes of corrosion were observed with these alloys. One was an apparently uniform corrosion, which would be expected to result in a constant corrosion current and, therefore, a linear increase of weight loss. The other was an intergranular, more penetrating, corrosion which would be expected to result in an increasing corrosion current, due to the generation of new electroactive area with time. If the current, i, is assumed to increase with time due to an increase of electrochemical area, A, then the rate of current increase can be expressed as

$$\frac{di}{dt} = j\frac{dA}{dt} \quad [3]$$

where j is the real current density. In the case of

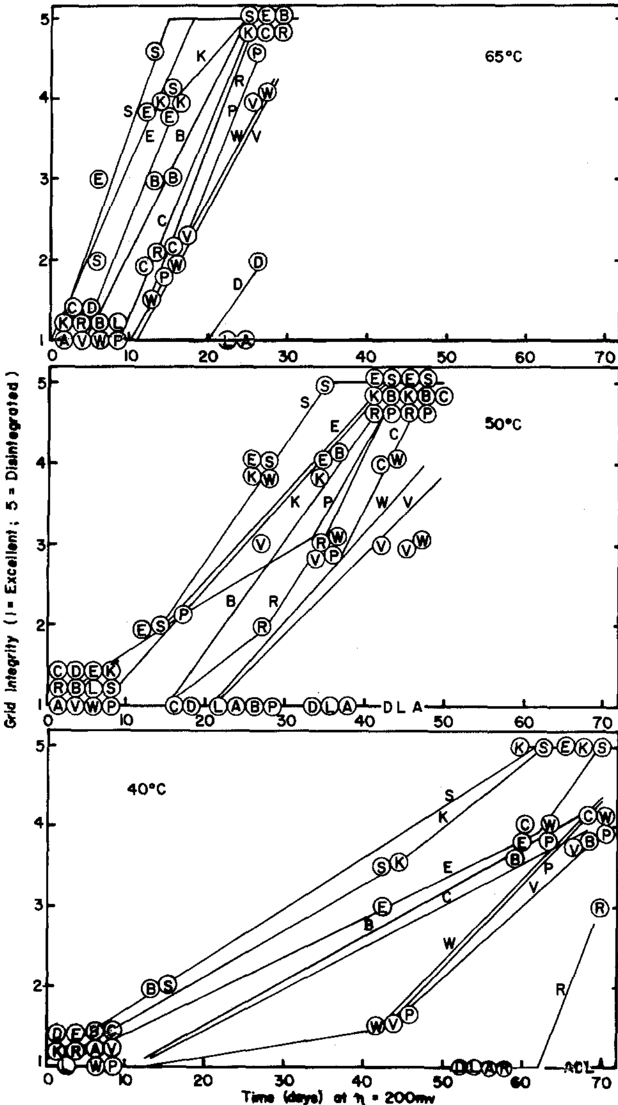

Fig. 10. Variation of grid integrity (see text) with time for grids corroded at 1.38V potential at three temperatures. Uncircled letters identify lines joining circled experimental points. Some points have been offset for clarity.

purely penetrating corrosion, if the increase of electrochemical area is f_A cm^2 C^{-1}, then

$$dA = f_A dq = f_A i dt \quad [4]$$

Upon integration

$$i = i_0 \exp (bt) \quad [5]$$

where $b = (i_0 f_A / A_0) s^{-1}$ and i_0 and A_0 are the initial current and electrochemical area, respectively. To exemplify the meaning of f_A, consider a model representing the lead lattice by an array of cubes having faces of area a_0. For removal of one cube (atom) from a partially corroded surface layer, no new area is generated and $f_A = 0$; if a cube is removed from a new layer, however, four additional cube faces are exposed and $f_A = 4a_0\ N/nF$ where N is Avogadro's constant and nF is the number of equivalents per mole of charge passed.

Integration of Eq. [5] to obtain the weight loss due to pure penetrating corrosion, w_p, gives

$$w_p = \frac{Mi_0}{bnF} [\exp (bt) - 1] \quad [6]$$

where M is the atomic weight of lead. In addition a constant current component, i_u, and a linearly increasing weight loss, w_u, will also occur due to uniform corrosion. The relative contributions of w_p and w_u to the total weight loss will change with time since the currents in Eq. [3] and [4] are only identical if the current is solely due to one mode of penetrating corrosion. For large enough values of bt, the second term in Eq. [6] can be neglected as an approximation. For very small values of bt, $\exp (bt) - 1 \approx bt$ and Eq. [6] becomes linear in time.

Unfortunately the value of b and the relative contributions of i_p and i_u cannot be obtained *a priori* or treated exactly. Furthermore, using values of b obtained from the fits of Eq. [2], values of bt were found to be $\sim$ 1-2 at the end of all experiments. Iteration methods might have been attempted to obtain an improved exponential fit using Eq. [6], rather than the more approximate Eq. [2]. However, this was not considered worthwhile in view of the other approximations involved and since only part of the total weight loss consists of w_p. Thus the degree of exponential behavior can only be taken as an indication of the relative extent of penetrating corrosion. Development and testing of a more detailed or exact model requires additional metallographic or other data.

Comparison of Fig. 2-6 indicates that ranking of the corrosion resistance of the alloys changes according to the applied potential. Thus at $\eta = 200$ mV, the lowest corrosion rate at the end of the test was found for L and the highest for V and W, followed by S, P, and B. This ranking was also true at $\eta = 100$ mV except that alloy S suffered relatively more corrosion and P relatively less in comparison to the ranking at 200 mV. Under open-circuit conditions (Fig. 5), L corroded relatively rapidly and antimonial grids (V and W) were relatively much more corrosion resistant. In the absence of an applied potential, a corrosion cell exists between the alloys with this experimental arrangement so that the differences in corrosion rate will be reduced in comparison to the results expected with isolated grids. However, the order of corrosion rates should not be affected. The cast lead-calcium-tin grids remained slow to corrode, with the book-mold grids behaving much more like the expanded grids than they had at the higher overpotentials. The grids made from expanded rolled strip (B, R, and K) corroded relatively rapidly on open circuit, the corrosion rate increasing with degree of rolling at all potentials. However, as is evident from Fig. 8, a light rolling appeared to give rise to more localized attack at $\eta = 200$ mV than either a reduction of at least 60% or no rolling at all. Such an increase in macroscopically observable localized attack (*i.e.,* broken wires) was also seen for the cast grids having higher calcium and tin levels (E and P) at $\eta = 0$ and 200 mV, and for the rolled grids under open-circuit conditions.

The preliminary metallography generally supported these observations and the model discussed above. However, rather than the sharp penetration observed for some of the cast alloys, B (and R) appeared to suffer a broader localized attack with the formation of hemispherical pits of about 200 μm diam (see Fig. 11, top). The merging of these pits generated localized thinning. L also suffered localized thinning, but in this case, the attack at the corroding surface was uniform and the thinned areas extended over macroscopic dimensions, noticeable with the unaided eye. Grids S, E (Fig. 11, center), and K tended to exhibit a very sharply localized penetrating corrosion apparently either intergranular in nature or due to crack propagation. The other cast lead-calcium-tin grids (C, P, and D) show a limited intergranular attack ranging from moderate for C and P to slight for D (Fig. 11, bottom). This was combined with hemispherical pitting for the significantly rolled grids (B and R). The intergranular nature of the attack, even for heavily rolled, fine grained lead-calcium-tin can be seen in the high magnification photomicro-

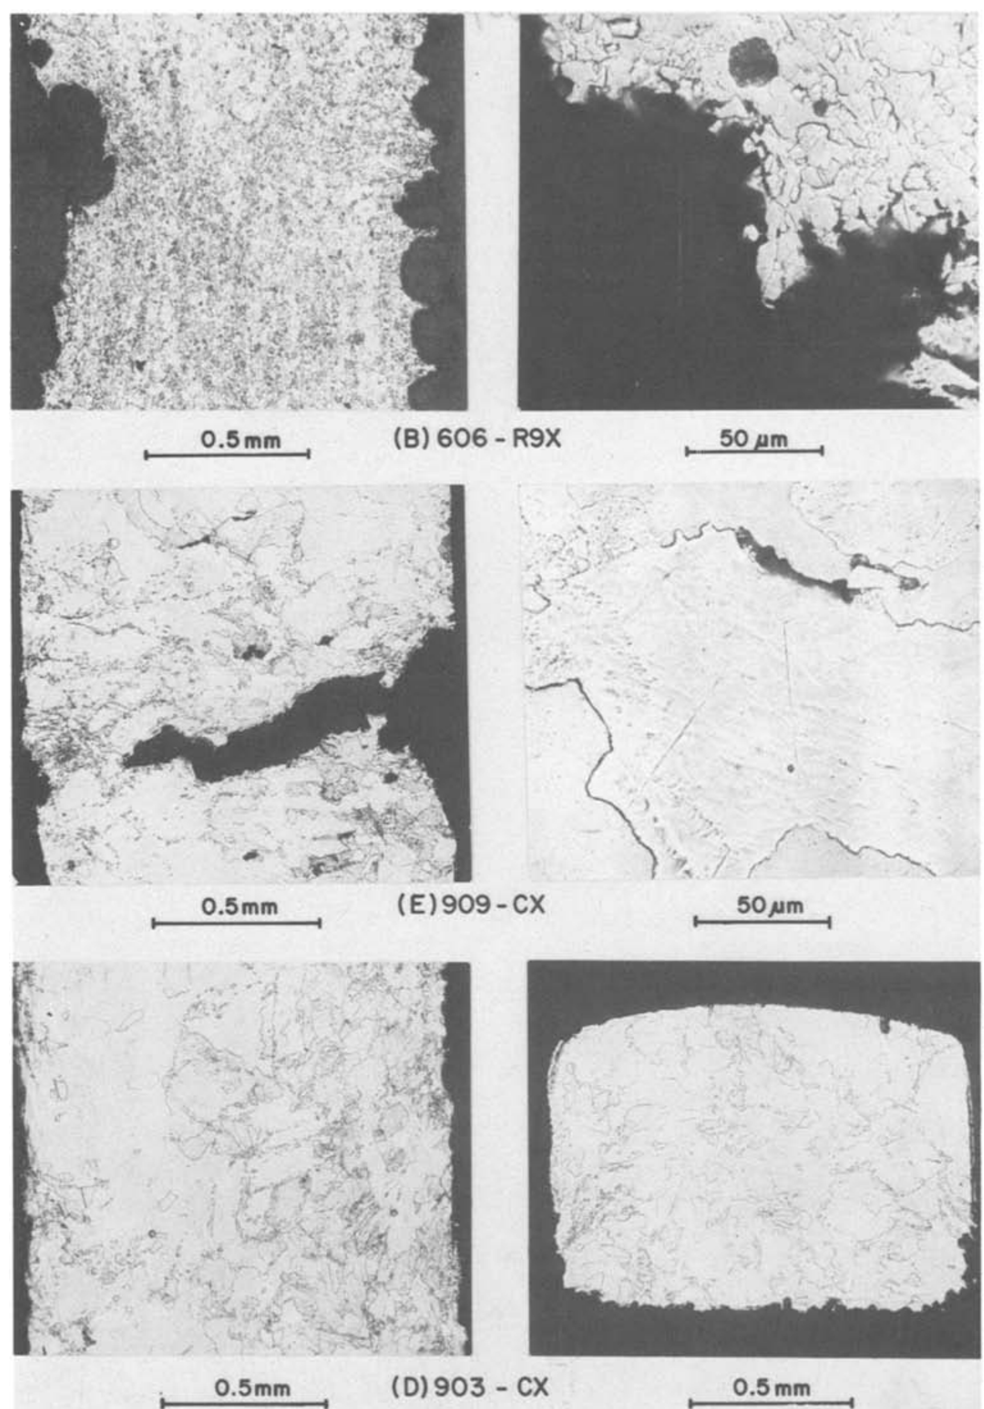

Fig. 11. Photomicrographs of longitudinally sectioned stripped grid samples after an open-circuit stand (following formation) of 105 days at 50°C. A transverse section is also shown for D, which showed the best corrosion characteristics of all the SLI grids tested.

graphs of Fig. 11. The antimonial grids, V and W, corroded very uniformly with minor surface pitting except for a few deep, highly localized penetrations, particularly near the wire intersections, believed to be due to casting defects. The results shown in Fig. 11 are similar to the metallography obtained for two cells at 200 mV overpotential, one at 50°C for 35 days and the other at 65°C for 13 days.

The exponential increase in weight loss with time is attributable to an increase in surface area as discussed above, whereas a linear increase indicates constant corrosion current (and thus area) with time. The increase in the rate constant for the exponential growth law from its initial value can be used to estimate this area increase. For the linear law, the rate constant is equal to the slope of the fitted line by differentiation of equation (1)

$$\frac{dw}{dt} = b \quad [7]$$

For the exponential fit

$$\frac{dw}{dt} = ab \exp(bt) \quad [8]$$

and the rate constant increases with time due to the increasing area available for corrosion. The initial grid area and the rate constant ab, referred to this initial area, were determined; the factor exp (bt) represents the dependence of electrode area on time during the course of each experiment. This factor ranged from 5 to 8 for the lead-calcium-tin grids which behaved exponentially at $\eta = 200$ mV. Grid B may have obeyed an exponential dependence for the tests at 0 and 100 mV. However, this can be confirmed only at the 75% c.l. and tensile testing and metallography indicated weakening and recrystallization occurring at the elevated temperature of the test (16). Recrystallization results in a thermally induced grain growth which may result in an increase in weight

loss and in depth of penetration (7-10). Such a dependence on grain size has only been shown to exist for grains grown from wrought samples by heat-treatment (10). Thus, the exponential increase in weight loss for the B grids may indicate an increasing susceptibility to corrosion with time as the unstable wrought structure recrystallizes, rather than solely an increase in area, as is probably the case for the cast lead-calcium-tin grids. After moderate lengths of time (2-7 weeks) at 0 and 100 mV, relatively uniform corrosion (not as uniform as for the antimonial grids) with some shallow pitting was observed. This is in agreement with previously reported results under similar conditions (10). However, after longer times or under more severe conditions, pitting effects became increasingly apparent.

In an effort to obtain further information about the corrosion kinetics, activation energies were determined from Arrhenius plots for the data obtained at $\eta = 200$ mV and 40°, 50°, and 65°C. Plots of ln *b* *vs.* $1/T$ and ln (ab) *vs.* $1/T$ were constructed for alloys with linear and exponential weight loss characteristics, respectively. For the eight lead-calcium-tin alloy samples obeying an exponential rate law, activation energies of 12.4 ± 1.0 kcal/mol[1] were obtained. For the other four alloys (L, S, V, and W) corroding at constant rate, activation energies were 10.7 ± 0.6 kcal/mol at $\eta = 200$ mV. At $\eta = 0$ (less reliable because only two data points could be used for the Arrhenius plot and because of possible electrochemical interaction between the coupled grids) activation energies were 17.2 ± 8 and 15.6 ± 7 kcal/mol for the eight lead-calcium-tin and four other alloys, respectively. These values are similar to one of two sets of values reported earlier for very low temperatures (*i.e.*, −50°C to 0°C) of approximately 10 kcal/mol (17, 18) and 13 kcal/mol (19) for certain stages of the anodic oxidation, derived from experiments of much briefer duration (~ minutes or hours). Such values suggest that the rate-limiting process is either solid-state diffusion or a surface diffusion process through partially blocked pores. Pavlov reported activation energies of 7-11.5 kcal/mol which he ascribed (20) to solid-state diffusion of O_2^- ions through a PbO layer at potentials below the open-circuit value, and values of 10-17 kcal/mol have been reported (21-23) for open-circuit self-discharge. Regardless of the exact nature of the activation process, it is apparently the same at a given potential for all the alloys tested and so the activation energies give no information relevant to the differences in corrosion modes among the alloys. The activation energies at $\eta = 0$ were not sufficiently accurate to indicate a difference in corrosion mode from that at $\eta \sim 200$ mV, although it is likely that such a difference exists in view of the minimum in the corrosion rate at overpotentials of ~ 100 mV (23-26).

The exponential dependence of the weight loss results obtained for lead-calcium grids appear to be explained by the generation of additional electrochemically accessible surface due to intergranular penetration under the moderately severe (40° and 50°C, $\eta = 200$ mV) test conditions. Under milder conditions, more uniform and time-independent corrosion occurs. Changes of the metallurgical structures with time for heavily worked materials or the emergence of an additional, as yet unknown, factor at higher temperatures introduce new variables, which require further investigation.

This explanation is consistent with the linear weight loss increases observed for alloys V, W, and probably L and the metallographic results which indicate very uniform corrosion modes. It is not consistent with the results for the strontium-tin alloy (S), however, which also followed a linear weight loss law, but exhibited a very nonuniform, intergranular or interdendritic mode of corrosion, in agreement with observations by Bagshaw (27) under corrosion conditions which were much more severe but of shorter duration than those used in the present work. While the Al content in the melt of the alloy tested here (0.03%) was similar to that of the cast alloys tested elsewhere (26, 27), the aluminum content of our cast expanded grid was much lower (0.003% Al), indicating that most of the aluminum in the melt was not incorporated into the strip during casting. Test conditions comparable to those reported here (but of shorter duration) have also been applied to the study of lead-strontium-tin-aluminum coupons (26) and no evidence was found for interdendritic penetration at the potentials investigated. It is hoped that further metallographic results and additional experimental work currently in progress will resolve the inconsistency of interpretation raised by the results for alloy S.

[1] 1 kcal = 4.18 kJ.

Notwithstanding this one possible anomaly, the weight loss and preliminary metallography suggest that the corrosion results obtained at higher potentials ($\eta = 200$ mV) are indicative of those which would occur under charging conditions corresponding to normal service (*i.e.*, $\eta = 0$ and 100 mV) for the low antimony alloys tested (V and W) and the binary alloy (L) with very low calcium content. The same conclusion might tentatively be reached based on the weight loss data alone for the lead-strontium-tin alloy. However, for lead-calcium-tin alloys, whether produced as cast grids, or as expanded wrought or cast strip, corrosion modes at $\eta = 200$ mV may be more penetrating than those at lower potentials and further differences may appear at high temperatures. Thus, the predictive value of accelerated corrosion testing has not been clearly established for lead-calcium-tin alloys and will depend on the appropriateness of the accelerating conditions chosen.

In particular, constant current overcharge tests currently prescribed, such as the overcharge life test in SAE J-537j (28), are unsuitable for lead-calcium-tin batteries unless modified to limit the voltage to values that accelerate the normal corrosion modes (or actual failure modes if not corrosion-related) and do not induce or accelerate irrelevant modes. There are also some indications that elevated temperatures must be similarly limited and it is hoped to clarify this by work in progress.

Conclusions

Comparisons of corrosion rates for pasted lead-calcium-tin and lead-strontium-tin rotary expanded grids made from cast and/or rolled strip and book-mold lead-calcium-tin and low antimony grids indicated that all had acceptable weight losses under environmental and electrical conditions corresponding to normal vehicle service. However, there were appreciable differences in weight loss and grid integrity between the alloys. The antimonial and strontium grids gave the highest weight loss under charging conditions. Weight loss of the cast lead-calcium-tin alloys increased with degree of rolling. Results for pasted book-mold grids appeared anomalously high. A tin-free low-calcium soft grid suffered the lowest weight losses under charging conditions but relatively high weight loss after long periods on open circuit. The antimonial grids gave relatively low weight loss on open circuit.

Changes of the rate laws for the lead-calcium-tin grids with increases in potential and temperature suggest changes in corrosion mode with these parameters. This indicates the need for further definition of the conditions which accelerate the relevant corrosion modes without inducing new modes, and

reassessment of standard corrosion or failure-accelerating tests in terms of their applicability to nonantimonial batteries. No change in corrosion mode with temperature or potential could be deduced from the weight loss data for the antimonial or the tin-free grids within the limits investigated. This was also true for the strontium-tin alloy, although preliminary metallographic data were in conflict with interpretations of the rate laws observed in this case.

Consideration of macroscopically observable grid integrity indicated wide variations in degrees of susceptibility to a penetrating corrosion attack. The lightly rolled (30%) Pb-0.06Ca-0.6Sn grids, the lead-strontium-tin grids, and the Pb-0.09Ca-0.9Sn grids showed a high vulnerability to such attack, which preliminary metallography indicated was intergranular and/or due to the wedging action of corrosion products on preexisting cracks (29), generated during fabrication. For all of the lead-calcium-tin grids, regardless of whether or not they had been rolled before expansion, the attack appeared to be intergranular. This attack eventually led to nonuniform corrosion or to localized penetration for all SLI compositions (including the uniformly corroding antimonial alloys) except Pb-0.09Ca-0.3Sn. The latter alloy exhibited no broken wires under any of the test conditions, except at the end of the most severe test (65°C, $\eta = 200$ mV). Almost all other SLI compositions showed some wire breakage half-way through the test. For rolled materials in comparison to cast, the localized corrosion tended to appear more as hemispherical pits, as a result of grain undercutting. On the basis of observations of grid integrity, the Pb-0.09Ca-0.3Sn expanded cast strip clearly showed the best corrosion resistance of the SLI compositions; its performance was exceeded only by the soft Pb-0.007Ca binary alloy grid.

Further work is planned or in progress to clarify some of the new questions raised by the results discussed, including quantitative metallography on samples of the grids reported and new corrosion testing of further compositions of interest.

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California 91103

ABSTRACT

In order to elucidate the physical and chemical characteristics of the anode passivating film in secondary lithium batteries, we have conducted ESCA (electron spectroscopy for chemical analysis) and SEM (scanning electron microscopy) studies of lithium electrode surfaces. The samples include lithium metal as-received from the vendor, and lithium electrodes which were cycled in a 1.5M lithium arsenic hexafluoride/two-methyl tetrahydrofuran ($LiAsF_6$/2-Me-THF) electrolyte. The results of studies of the as-received lithium indicate that the surface is covered by a film containing only carbon, oxygen, and lithium. Binding energy analysis and model compound studies indicate that this "native" film has a probable two-layer structure consisting of Li_2O covered by an outer Li_2O-CO_2 adduct, at a total thickness of 100-200Å. No evidence of Li_3N was found. ESCA/SEM studies of cycled lithium electrodes reveals the presence of a second film formed in the electrochemical environment. This film appears to consist, in some part, of degradation products and impurities associated with the $LiAsF_6$/2-Me-THF electrolyte, possibly in the form of lithium arsenic oxyfluorides.

The battery system consisting of a lithium anode, a lithium arsenic hexafluoride/two-methyl tetrahydrofuran ($LiAsF_6$/2-Me-THF) electrolyte, and a titanium disulfide (TiS_2) intercalatable cathode shows promise of yielding high energy density and cycle life (1). However, the organic electrolyte is unstable in the presence of lithium. Cells of this type function only because a reaction occurs at the lithium anode/organic electrolyte interface which results in the formation of a passivating film on the anode surface (2-4). This film, in turn, imparts some degree of kinetic stability to the system. In order to evaluate, and hopefully exploit, the beneficial characteristics of these ambient temperature lithium cells, a fundamental understanding of the basic physical and chemical processes which occur in this film and relate to battery performance is required. Surface spectroscopy studies involving the use of ESCA (electron spectroscopy for chemical analysis) and SEM (scanning electron microscopy) offer the opportunity to directly determine and correlate the chemical and morphological characteristics of the passivating film. We report the results of our ESCA and SEM studies of lithium electrodes both before and after exposure to an electrochemical environment.

Experimental

The ESCA spectrometer used in this work is a modified HP 5950A system (5). Aluminum K_α radiation (1486.6 eV) is used and all data are referenced to the Fermi level of gold. Samples were loaded into dessicators while in an argon glove box. Upon evacuation, the dessicators were transported to the spectrometer where the samples were mounted while in a high purity argon atmosphere maintained in a stainless steel dry box connected to the instrument. Spectra were accumulated at pressures not exceeding 5×10^{-10} Torr and a resolution of 0.4 eV. The spectrometer senses a sample area of 1×5 mm with an observation depth, for these studies, of ~100Å. The ESCA spectra give information on elemental composition, but more importantly, permits assignment of the chemical state of various surface species. The SEM studies were carried out using in-house facilities. The scanning electron microscope is a Cambridge S4-10 Stereoscan instrument equipped with an energy dispersive spectrometer (EDS) which permits detection of all elements of atomic number greater than nine, within the field of view. The spectrometer utilizes energy dispersive analysis by x-rays (EDAX) for element detection. The lithium samples were studied using a 20 kV beam voltage which yields an observation depth of ~20 μm and an element detectivity of approximately 1% by weight.

Two types of lithium samples were examined: (*i*) lithium metal as-received from the vendor (Foote Mineral Company); and (*ii*) lithium electrode surfaces which have undergone stripping and plating in a 1.5M $LiAsF_6$/2-Me-THF electrolyte. For this experiment, a cell containing two lithium electrodes (3 cm^2 area per electrode) was used. Lithium was stripped and plated at constant voltage (0.8 and 2.1V) corresponding to current densities of ~3 and 8 mA/cm^2, respectively, at room temperature.

The electrolyte salt, $LiAsF_6$, (from U.S. Steel Corporation) was outgassed at 75°C for 12 hr to remove any volatile impurities (6). The electrolyte solvent, 2-Me-THF, was purified by column distillation (~40 theoretical plate number) after being stirred with CaH_2 for three days. The solvent was then vacuum distilled from a sodium-potassium (NaK) napthalide solution to further remove trace amounts of H_2O and active hydrogen containing compounds, *e.g.*, alcohols. A final vacuum distillation from a lithium napthalide solution was carried out to remove lithium-sensitive impurities, *i.e.*, THF. The solvent was analyzed by gas chromatography, high pressure liquid chromatography, and gas chromatography/mass spectroscopy (GC/MS). The results of these analyses indicated that commercial 2-Me-THF (as received) is quite impure, containing methyl-furan, higher alcohols, and an inhibitor. Column and vacuum distillation procedures successfully remove most of these impurities, but methyl-furan remains at a significant level (~0.4% by weight). Thus, the presence and possible contribution of this compound must be considered when investigating electrochemical degradation mechanisms.

* Electrochemical Society Active Member.
Key words: secondary lithium battery, ESCA/SEM studies, passivation, degradation, organic electrolyte.

Two model compounds, Li_2O which was deliberately exposed to air and Li_2CO_3, were also examined by ESCA in order to assist the interpretation of the ESCA chemical shift data taken on lithium electrode surfaces. These compounds were outgassed at 200°C for 2 hr prior to study. Special techniques were used to transfer all of the samples from the glove box to the ESCA and SEM facilities in order to insure that they were never exposed to any atmosphere other than argon or high vacuum during the duration of this investigation.

Results and Discussion

ESCA/SEM studies of as-received lithium.—A typical ESCA spectra of the surface of as-received lithium metal is shown in Fig. 1. The spectra is a 0-1280 eV binding energy scan of the kinetic energy distribution. The ordinate reflects the number of photoelectrons and the abscissa shows the binding energy (eV) increasing from right to left. Since it is often necessary to take spectra under different conditions, only the relative intensities are important. The important feature to notice is that only carbon, oxygen, and lithium were detected. Figure 2(a), (b), and (c) show expanded (high resolution) views of the spectra associated with each of these elements. Two types of carbon, two types of oxygen, and two types of lithium are observed. Based on binding energy analysis, we find: (a) one type of carbon is associated with hydrocarbons (from the pumping facility and hydraulic press in the dry box) adsorbed on the lithium surface while the other carbon indicates polar bonding, *e.g.*, C-O; (b) one type of oxygen is associated with lithium as Li_2O while the other oxygen appears bonded to carbon and also associated with lithium; and (c) both types of lithium present are ionic. It was initially thought that the second type of oxygen and lithium were combined in the form of Li_2CO_3. However, measurement of binding energy differences, a measure of charge transfer (5), for the model compounds, Li_2O exposed to air and Li_2CO_3, indicate that pure Li_2CO_3 is not present on the surface of as-received lithium. Instead, it is an Li_2O/CO_2 adduct. This adduct occurs upon exposure of the Li_2O to air which contains moisture and CO_2. The hydrogen bonding associated with the moisture encourages the adduct formation. Note that lithium metal, Li°, was not observed. Thus, it appears that the surface of as-received lithium is covered by a "native" film consisting of Li_2O and an Li_2O/CO_2 adduct.

In order to assess the ability to remove this native film, the lithium surface was etched with an argon ion beam (1 mA for as long as 90 min) while in the ESCA facility. Initial etching removes the hydrocarbons. Continued etching results in the increase of

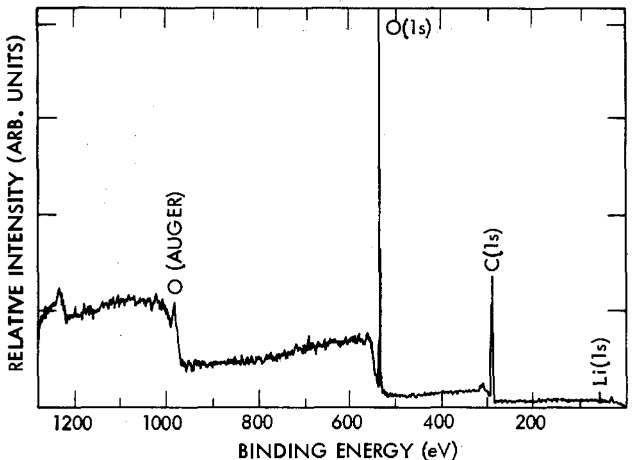

Fig. 1. ESCA spectra (wide scan) of as-received lithium

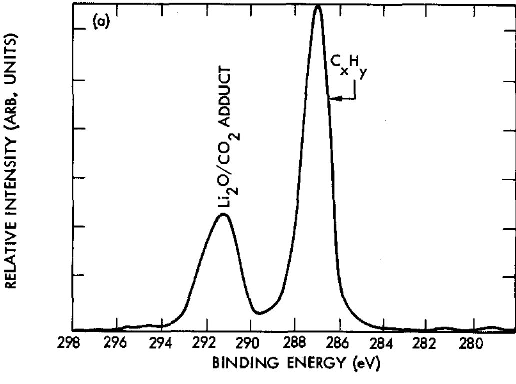

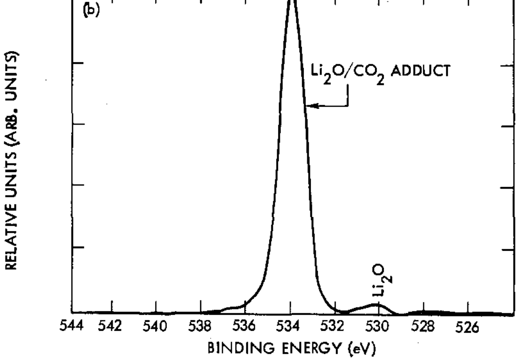

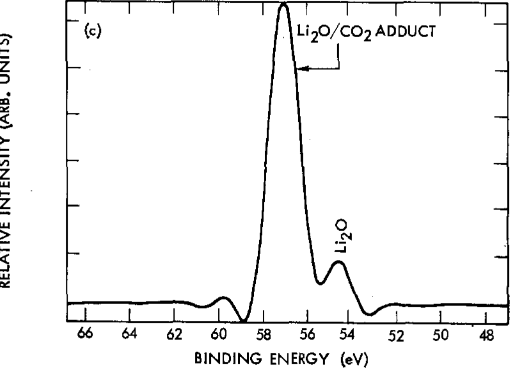

Fig. 2. As-received lithium: (a) smoothed carbon 1s spectrum; (b) smoothed oxygen 1s spectrum; and (c) deconvolved lithium 1s spectrum.

the oxygen component associated with lithium only (*i.e.*, Li_2O) compared to that associated with the Li_2O/CO_2 adduct [compare Fig. 3(a) with Fig. 2(b)]. This could indicate removal of CO_2 from the adduct or removal of the Li_2O/CO_2 adduct layer. Prolonged etching reveals the emergence of the underlying bulk lithium metal, Li° [compare Fig. 3(b) with Fig. 2(c)]. No evidence of lithium nitride was observed, reflecting the absence of moisture in the environment in which the metal was prepared and handled. The etching experiments also revealed the presence of Si, in the form of lithium silicate [Fig. 3(a) and (b)] as well as fluorine, possibly in the form of LiF. Note that neither silicon nor fluorine were observed by ESCA on the surface of as-received lithium prior to etching. The source of the fluorine is attributed to previous etching experiments using HF in the ESCA facility. The silicate is a bulk impurity in lithium. These results indicate that the surface of as-received lithium is covered by an Li_2O film which is then covered by an outer Li_2O/CO_2 adduct film. The thickness of this native film was determined to be between ~100-200Å from the etching experiments.

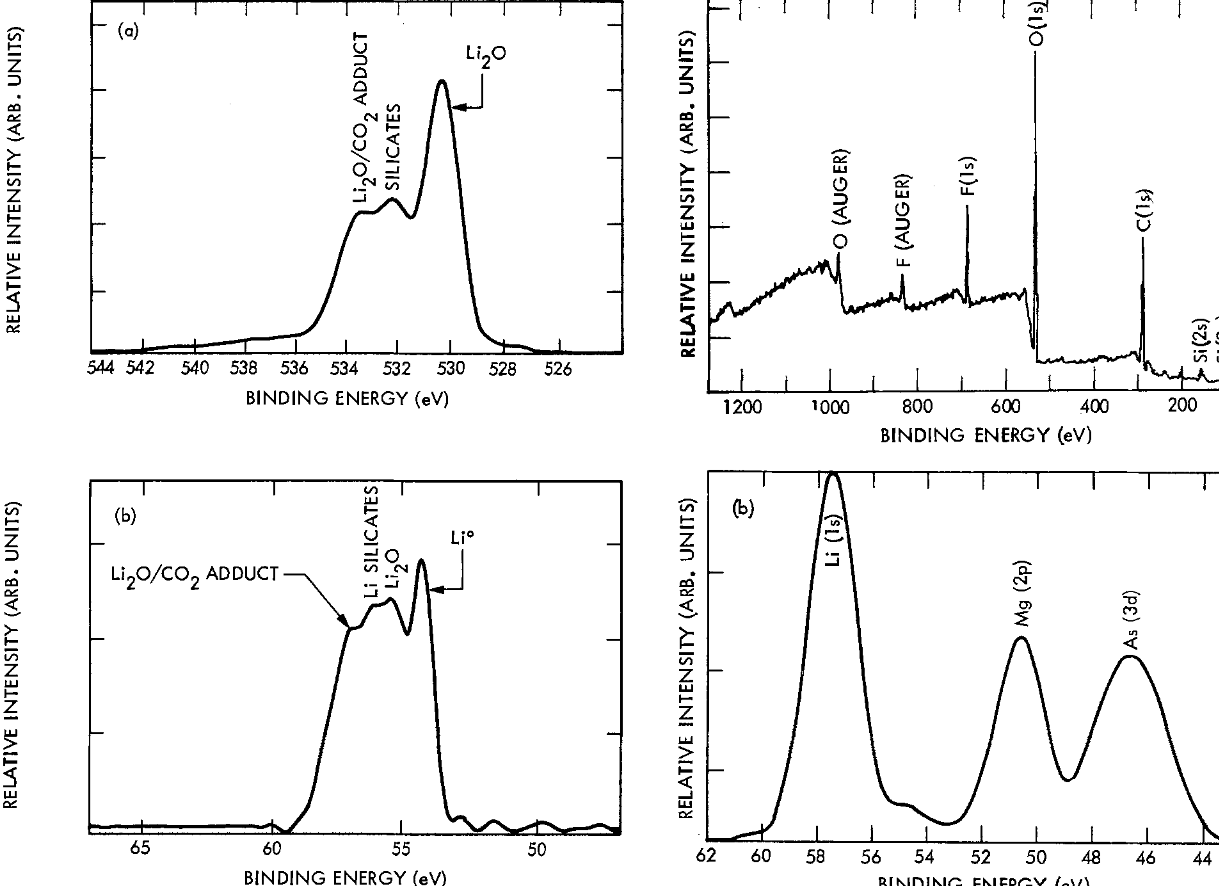

Fig. 3. As-received lithium after etching with an argon ion beam: (a) smoothed oxygen 1s spectrum and (b) smoothed lithium 1s spectrum.

Fig. 4. ESCA spectra of a lithium electrode surface which has undergone one stripping half-cycle: (a) wide scan; and (b) smoothed lithium 1s, magnesium 2p, and arsenic 3d spectra. The arsenic Auger and 3p peaks are also observed. The narrow, well-defined arsenic 3d peak has been singled out for study.

SEM studies of the surface of as-received lithium reveal the presence of sizable defects, pinholes, and ridges on the scale of 1-10 microns. In addition, the surface does not appear dense and flat, but rather exhibits a rippled appearance. Argon etching (to remove the oxide and adduct films) does not appear to further degrade the surface. Energy dispersive spectroscopy (EDS) studies also show Si to be present in the bulk of the sample, in agreement with the ESCA results on etched samples. No black spots were observed on the lithium surface (7).

ESCA/SEM studies of cycled lithium electrode surfaces.—Initial ESCA/SEM studies were carried out on lithium electrode surfaces which had undergone one stripping or plating half-cycle.

Stripped electrode surfaces.—Upon stripping (discharge), examination of the surface by ESCA revealed the presence of As, F, Si, and Mg in addition to the usual Li, O, and C elements, Fig. 4(a) and (b). ESCA studies were also carried out on $LiAsF_6$. The results of this work confirm that $LiAsF_6$ is not absorbed on the lithium electrode surface and, thus, indicate that the presence of As and F are the results of electrolyte degradation. Although Si was found in the bulk of as-received lithium by EDS, the Si observed on the surface by ESCA, as well as Mg, are believed to originate from the $LiAsF_6$ salt where they are present as trace impurities (6). A careful analysis of the binding energies of the observed peaks plus the absence of any high binding energy peak which would be associated with LiF indicates that neither LiF nor arsenic oxides are present. While the actual chemical form of the elements observed by ESCA on the stripped electrode surface is uncertain at present, the most likely candidates appear to be lithium arsenic oxyfluorides and, possibly, lithium fluorosilicates, *e.g.*, Li_2SiF_6. This suggestion is based on two facts: (*i*) the binding energy of the fluorine peak is shifted upward relative to that observed in $LiAsF_6$, indicative of fluorine-oxygen binding; and (*ii*) the $LiAsF_6$ salt is unstable in the presence of 2-Me-THF degradation products, in which case lithium arsenic oxyfluorides may be formed (6, 8). In addition, during synthesis, $LiAsF_6$ may be hydrolyzed, in the presence of silica [*e.g.*, 100 ppm Si impurity in the $LiAsF_6$ salt (6)], to yield fluorosilicate impurities. Upon cycling, the fluorosilicate anions may react with lithium to form insoluble lithium fluorosilicates on the electrode surface.

SEM studies of the stripped electrode surface reveal the presence of black spots formed randomly on the surface (Fig. 5). As mentioned above, no black spots were observed prior to placing the lithium electrode into the cell. EDS analysis indicates that these spots contain As and Si. It should be stressed that unlike ESCA, EDS cannot detect fluorine or discriminate between Mg and As due to similarities in their binding energies. A "white" fluffy compound is also observed over many of the black spots (Fig. 5). Measurements of the count rate of x-ray emitted during EDS measurements suggests that the white fluffy material may be more electrically conductive than the black spots or the Li_2O/CO_2 adduct substrate. The white material contains As and Si. Studies of the stripped surface which had been exposed to a 2-Me-THF vapor environment revealed the following results: (*i*) the white compound has limited solubility in this solvent; and (*ii*) upon prolonged exposure to the solvent vapor and subsequent drying, the white compound dissolves and recrystallizes as small cubic-

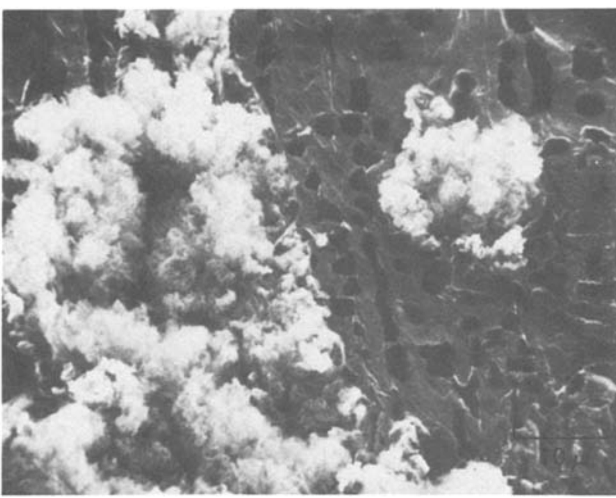

Fig. 5. Scanning electron micrograph of a lithium electrode surface which has undergone one stripping half-cycle.

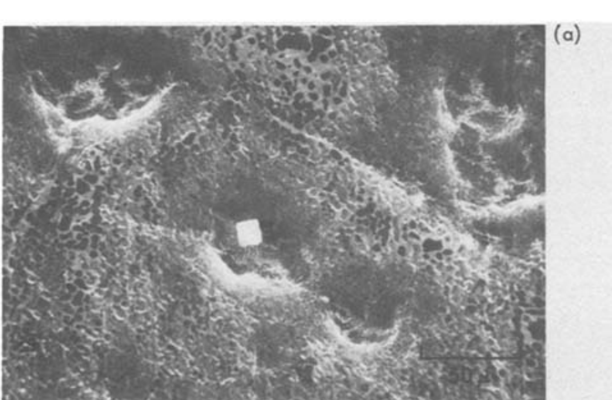
shaped crystals, thereby revealing the presence of pits in the stripped lithium electrode surface which were formerly covered by the fluffy compound [see Fig. 6(a) and (b)].

Studies of a stripped electrode surface which had previously undergone three complete cycles gave similar results except that the white fluffy compound covered the entire surface uniformly [Fig. 7(a) and (b)] at a thickness of ~8-10 μm [Fig. 7(b)]. Another exception was the absence of any evidence of lithium fluorosilicates on the stripped lithium surface as indicated by the absence of Si and F (associated with lithium fluorosilicates). As mentioned above, the lithium fluorosilicate formation may be catalyzed by the silicates present as impurities in the $LiAsF_6$ salt. The absence of these compounds on stripped cycled lithium surfaces suggests that the silicate impurities were depleted in the lithium fluorosilicate formation during the initial cycling.



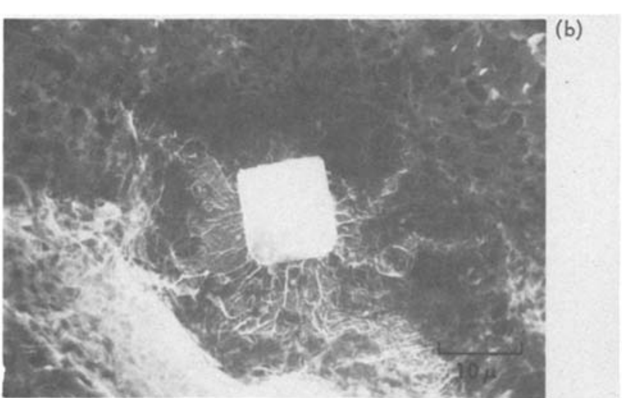


Fig. 6. Scanning electron micrographs of a stripped lithium electron surface which has been exposed to a 2-Me-THF vapor environment (see text). (a) and (b) are at different magnifications.

Fig. 7. Scanning electron micrographs of a stripped lithium electrode surface which has undergone three complete cycles. In (b), the sample has been tilted ~90° with respect to the substrate in order to estimate film thickness.

Plated electrode surfaces.—ESCA studies of lithium surfaces which have undergone one plating half-cycle indicate the presence of the same elements as observed on stripped surfaces except that the fluorine content (shown full scale, Fig. 8) increased relative to that observed on stripped surfaces, Fig. 5. This reflects the fact that the newly deposited lithium metal is in a highly exposed, or unprotected, state and can more readily react with the electrolyte. The observation of Si on the plated surface supports the

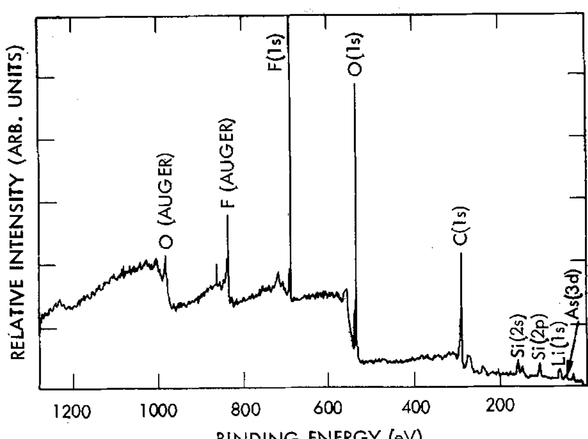

Fig. 8. ESCA spectra (widescan) of a lithium electrode which has undergone one plating half-cycle.

contention that the source of this element is the $LiAsF_6$ salt and not the bulk lithium metal. High resolution ESCA data clearly indicate a greater concentration of silicon on plated electrodes compared to stripped electrodes. The concentration of silicon on both electrodes decreases with cycling and is below the detection limit of the instrument after three cycles. This suggests that cycling a lithium electrode in an $LiAsF_6$/2-Me-THF electrolyte may be an effective way of purifying the electrolyte of the silicate impurities prior to actual use in a cell. SEM studies show that the white fluffy compound forms preferentially along grain boundaries and surface defects, Fig. 9. In contrast to the stripped electrode surface, no pits or black spots are observed. EDS analysis of the white compound indicates the presence of As and Si in agreement with the ESCA results. In all of the measurements mentioned above, no evidence of Li_3N was found.

The Li^+ transport process through this native film and the channel formation mechanism must be established. The above results suggest the following scenario. Upon stripping (discharge), lithium ions migrate through the native film creating channels, or pathways, through which the electrolyte, electrolyte degradation products, or impurities can react with the bare Li° surface. The black spots may reflect the chemical diffusion and associated chemical reactions which can occur in the reducing environment of the anode. The pits in the surface reflect these reaction processes. When these processes give rise to larger channels, and thereby expose the lithium metal to more electrolyte, the white fluffy compound forms, normally in the vicinity of the black spots. Upon charge, the Li^o substrate is protected and the black spots and pits do not form. The increase in the fluorine content reflects the reaction between the salt/solvent and the newly plated lithium. Another possibility involves the native passivating film initially having small, undetectable channels filled with electrolyte. Then large inhomogeneous electric fields (and, hence, a large local current density) could develop at the lithium metal/electrolyte interface. This could lead to breakdown of the native film and to the growth of larger channels, or pathways, as reflected by the black spots.

Conclusions

The surface of the as-recieved lithium metal is found to be already covered by a "native" film composed of LiO_2 and an Li_2O/CO_2 adduct. This film is between ~100-200Å thick, although its actual thickness is unknown. This film can be removed via ion beam etching (*i.e.*, sputtering) but the effectiveness of this procedure remains to be determined. No evidence of Li_3N was found. Upon exposure of the lithium electrode (covered by the native passivating film) to a 1.5M $LiAsF_6$/2-Me-THF electrochemical environment, a second film is observed to form on the surface. This film consists primarily of As, Si, and F, possibly in the form of lithium arsenic oxyfluorides or lithium fluorosilicates. The film does appear to have a slight solubility in 2-Me-THF. There is a question whether this film forms instantly upon exposure to the electrolyte or requires electrochemical action. It does appear that the $LiAsF_6$ salt degrades to some extent, with its degradation products combining, or reacting, with its impurities to contribute to the film formation. It is likely that electrochemical action encourages this effect. It will be useful to carry out surface studies of lithium electrodes exposed to the electrolyte, but without undergoing the stripping and plating process. It should also be realized that the chemical composition of the film formed upon prolonged cycling (8) may be somewhat different from that reported here, since modest cycling may yield films which represent precursor, or intermediate, compounds.

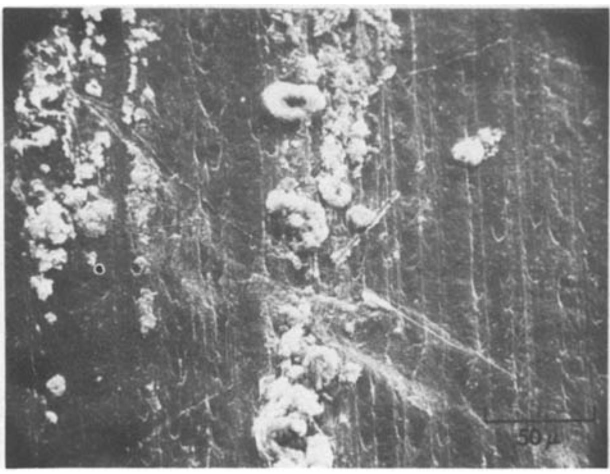

Fig. 9. Scanning electron micrographs of a lithium electrode surface which has undergone one plating half-cycle.

The results of this work have provided some insight into the nature of the passivating films on lithium electrodes exposed to a 1.5M $LiAsF_6$/2-Me-THF electrochemical environment. It has also raised numerous new questions, *e.g.*, what is the actual chemical composition of the second film, which film is most important to the passivating action, how do processes in the two films couple, etc. It is hoped that this work will stimulate further efforts towards answering these and similar questions.

Acknowledgments

It is a pleasure to thank W. Worrell, B. Brummer, V. Koch, and A. Rembaum, for their encouragement and useful discussions. We also wish to acknowledge K. Evans for carrying out the SEM/EDS experiments. This work represents one phase of research performed by the Jet Propulsion Laboratory, California Institute of Technology, sponsored by the National Aeronautics and Space Administration, Contract NAS7-100.

A-C Modulation of a Rotating Zinc Electrode in an Acid Zinc-Chloride Solution

D-T. Chin* and S. Venkatesh*,[1]

Department of Chemical Engineering, Clarkson College of Technology, Potsdam, New York 13676

ABSTRACT

A study has been made of the effect of alternating current (a.c.) on the behavior of a rotating zinc hemispherical electrode in an acid zinc-chloride solution. It was found that a.c. shifted the rest potential of the zinc electrode toward the negative direction and caused a change in the shape of the cathodic polarization curve. Visual observation under a scanning electron microscope revealed that a.c. initiated pitting corrosion when the electrode was polarized in the anodic direction. For the cathodic deposition reaction, a.c. greatly increased the rate of nucleation and produced a more uniform deposit on the zinc electrode. The result was substantiated with the numerical computation of a three-dimensional nucleation model.

The zinc electrode plays an important role in electrochemical energy conversion systems. The zinc-chlorine cell is one of the systems that has attracted interest recently (1). The zinc electrode in this system dissolves into the circulating zinc chloride electrolyte during discharge and is plated out as a porous deposit from the flowing electrolyte during charge. A state-of-the-art review of the zinc electrode has been given by McBreen and Cairns (2).

Gaiser and Heusler (3) reported that the zinc deposition is a first-order reaction. Hurlen *et al.* (4, 5) examined the kinetics of the Zn, Zn(Hg)/Zn^{2+} in acidified chloride solutions. The effect of alkali cations and halides on the Zn(Hg)/Zn^{2+} reaction was studied by Eriksurd (6). Sierra Alcazar and Harrison (7) proposed a two-electron transfer step for the cathodic reduction of zinc ions in chloride solutions with the Zn^{2+}/Zn^{+} step being the rate-controlling step. A complex reaction scheme was suggested by Epelboin and co-workers (8-11). Weber and Tomassi (12) investigated the electrodeposition of zinc in sulfate and chloride solutions. Hurlen and Breivik (13) reported the activities of Zn^{2+} in aqueous sulfate solutions. Kim and Jorne (14) studied the transport properties and the kinetics of zinc electrode in acidic chloride solutions.

One major problem in the development of the zinc electrode is the dendrite growth and the electrode shape changes caused by nonuniform zinc deposition during the charge cycles. In the electroplating industry, superimposed alternating current (a.c.) has been used to increase the rate of electroplating (15). It appears that a.c. gives more compact deposit with better adhesion to the substrate. Carlin (16) demonstrated that superimposed a.c. altered the nature of anodic dissolution of nickel in a nickel plating electrolyte and eliminated sponge formation and undesired residues at certain *p*H levels. Jeney and Lengyel (17) have studied the effects of superimposed a.c. on nickel deposits produced from a sulfamate solution. They found that the deposits had a highly disoriented texture, high hardness, and low internal stress. Rectangular a.c. (18) has been used to inhibit the polarization of a base metal and to improve the current distribution on the electroplating of cylindrical surfaces. The influence of sinusoidal a.c. on the plating of cadmium, nickel, and tin was considered by Rehim *et al.* (19-21). Krondrashin *et al.* (22) have examined the kinetics of an oxide coating produced by a.c. Superimposed a.c. has been found to improve the epitaxy in zinc, cadmium, tin, and lead electrodeposits (23-24). Ahmed *et al.* (25) studied the electrocrystallization of zinc on single copper crystal planes under the influence of a.c. Sheshadri (26) examined the copper deposits under the influence of a.c. and concluded that a.c. reduced grain size and produced more leveled and smoother deposits. Enchev (27) used a.c. in the electrowinning of nonferrous alloys; he obtained higher quality deposit and higher current efficiency. The electrodeposition of zinc on nickel electrodes has been studied by Jovicevic *et al.* (28) with a potential pulse technique. They found that the morphology of the zinc deposit varied with the amplitude of the pulses.

In view of the foregoing background, it seems that superimposed a.c. might help to prevent the dendrite formation and to improve the uniformity of zinc deposits during the charge of the zinc electrode. The method would be useful to the zinc-chlorine battery, where the dendritic zinc deposits during the charge process still pose a problem. This paper describes a study of the effect of a.c. on the behavior of the zinc electrode in an acid $ZnCl_2$ solution.

Experimental

A rotating zinc hemispherical electrode was used for the study (29). The electrode consisted of a replaceable zinc[2] hemispherical head mounted on one end of a Teflon cylindrical rod; the other end of the rod was attached to the spindle shaft of a high speed rotator. The zinc hemispherical head was 0.317 cm in diameter and had a surface area of 0.628 cm^2 exposed to the electrolyte. A Pyrex cell containing a stationary zinc counterelectrode and a saturated calomel reference electrode was used for the experiment. The electrolyte used was 0.5M $ZnCl_2$ in 1.0M KCl ($pH = 4.0$).

The method of a-c modulation (30) was used to measure the anodic and the cathodic polarization curves of the zinc electrode. In this method, a constant a.c. superimposed to a given direct current (d.c.) was applied to the zinc electrode, and the resulting potential fluctuations as well as the time averaged (or d-c) electrode potential was measured as a function of d-c densities. The details of the experimental setup and the measuring circuit have been described elsewhere (31-32) and are not repeated here.

The electrode was pretreated by polishing with a 600 grit emery paper and was rinsed in distilled water before being transferred to the cell. The anodic and the cathodic polarization curves were obtained with two separate runs because zinc had a tendency to de-

* Electrochemical Society Active Member.

Key words: zinc-chlorine battery, surface morphology, electrodeposition, nucleation.

[2] The zinc used as 99.99% pure (Alfa zinc).

posit as dendrites during the cathodic polarization run. Scanning electron micrographs of the surface were taken after each cathodic and anodic experiment. The range of a.c. investigated was 0-100 mA/cm^2 rms (root mean square) at 60 Hz. All the measurements were performed at a constant room temperature of 21° ± 1°C.

Results and Discussion

Figure 1 shows a set of steady-state polarization curves for the zinc electrode in 0.5M $ZnCl_2$ and 1.0M KCl solution (pH = 4.0). In these runs, the speed of rotation of the zinc electrode was maintained at 2500 rpm. At this speed, no concentration polarization was observed. It is seen that the cathodic curve for the run without superimposed a.c. exhibits two reduction waves. This phenomenon has not been reported in the literature, and at present we do not have suitable explanations. The anodic and the cathodic Tafel slopes were found to be 125 and −140 mV, respectively, in good agreement with the values of 109 and −138 mV reported by Kim and Jorne (14). The exchange current density was found to be 19 mA/cm^2. This value was one order of magnitude greater than Kim and Jorne's value of 1.36 mA/cm^2 for a pH 2 solution containing 0.5M $ZnCl_2$ and 1M KCl. Since a pH 4 solution was used in the present study, the increase in the exchange current density was probably due to the difference in the pH values. A similar pH dependence has also been reported by Sierra Alcazar and Harrison (7) for the zinc electrode in 0.003M $ZnSO_4$.

The effect of superimposed a.c. was to shift the rest potential toward the negative direction. The reason for the potential shift has been discussed in Ref. (31, 33-35), and is not repeated here. A.C. did not appear to have a significant effect on the anodic polarization curve. For the cathodic polarization curves, a.c. increased the current densities at low overpotentials and eliminated the presence of the first reduction wave. With a 100 mA/cm^2 rms a.c., the first reduction wave completely disappeared. At high cathodic overpotentials, the effect of a.c. diminished, and the data points for three different superimposed a-c levels seem to merge together into a single curve.

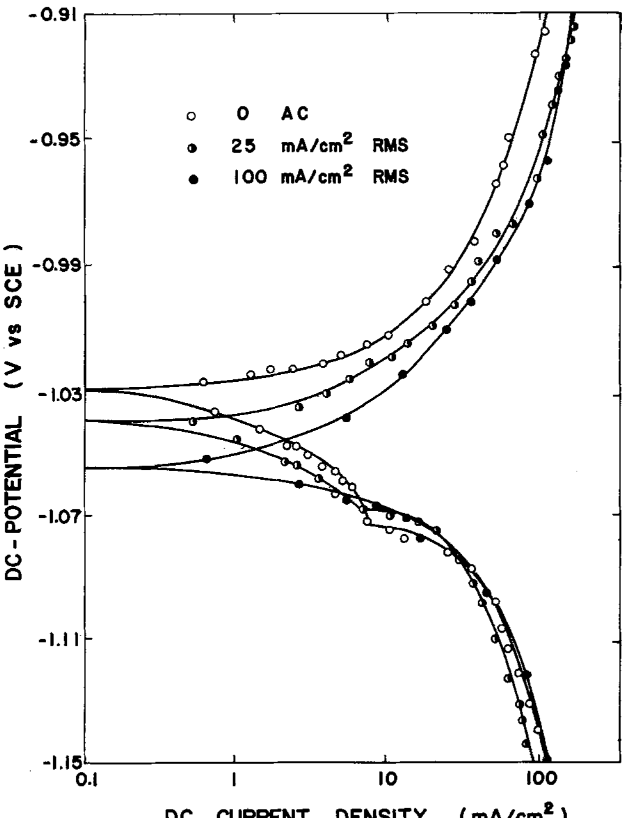

Fig. 1. Effect of a.c. (60 Hz) on the polarization curves of the zinc electrode in 0.5M $ZnCl_2$ + 1.0M KCl. The speed of rotation was 2500 rpm.

The surface of the zinc electrode was examined under a scanning electron microscope at the end of each polarization run. The photomicrographs are shown in Fig. 2; these pictures were taken at a magnification of 30×. The fine striation lines on the photomicrographs were caused by the mechanical polishing of the zinc hemispherical electrodes before the electrolysis. Figure 2a shows the surface of the zinc electrode after the anodic dissolution with 25 mA/cm^2 rms a.c. It is seen that pitting corrosion occurred under the superimposed a-c condition. The pits were probably caused by localized breakdown of oxide film by a.c. and the phenomenon was the same as the a-c corrosion of copper and mild steel (30, 36). Figure 2b shows the zinc deposits of the cathodic polarization run without any superimposed a.c. The effect of a.c. on zinc deposits is shown in Fig. 2c-2d. It seems that a.c. greatly increased the nucleation rate. When 25 mA/cm^2 rms a.c. was superimposed onto the zinc electrode, the grain size of zinc deposits decreased, and the number of grains increased. At 100 mA/cm^2 rms a.c., the number of zinc grains became so numerous that they clustered together to form a zinc layer. Also the distribution of zinc grains on the electrode surface appeared to be more uniform at high a-c values.

The foregoing phenomenon can be explained with a three-dimensional nucleation theory. For a number of electrode deposition reactions, the relationship between the nucleation rate N, and the overpotential η follows the correlation (37)

$$N = N_\infty \exp\left(-\frac{B^2}{\eta^2}\right) \quad [1]$$

where N_∞ is the nucleation rate at infinitely large overpotentials, and B is a constant whose value depends on the temperature and the nature of the electrode deposition reaction. Equation [1] has been confirmed for the cathodic deposition of silver, lead, and mercury (38, 39), and for the anodic deposition of lead dioxide and manganese dioxide (40, 41). When the electrode is polarized with a d-c overpotential, $\eta_{d.c.}$, plus a superimposed a.c. potential, $\eta_{a.c.}$

$$\eta = \eta_{d.c.} + \eta_{a.c.} \quad [2]$$

the nucleation rate will be fluctuated with time and can be considered to consist of a time-averaged component, $\overline{N}_{a.c.}$ and a fluctuating component, n

$$N = \overline{N}_{a.c.} + n \quad [3]$$

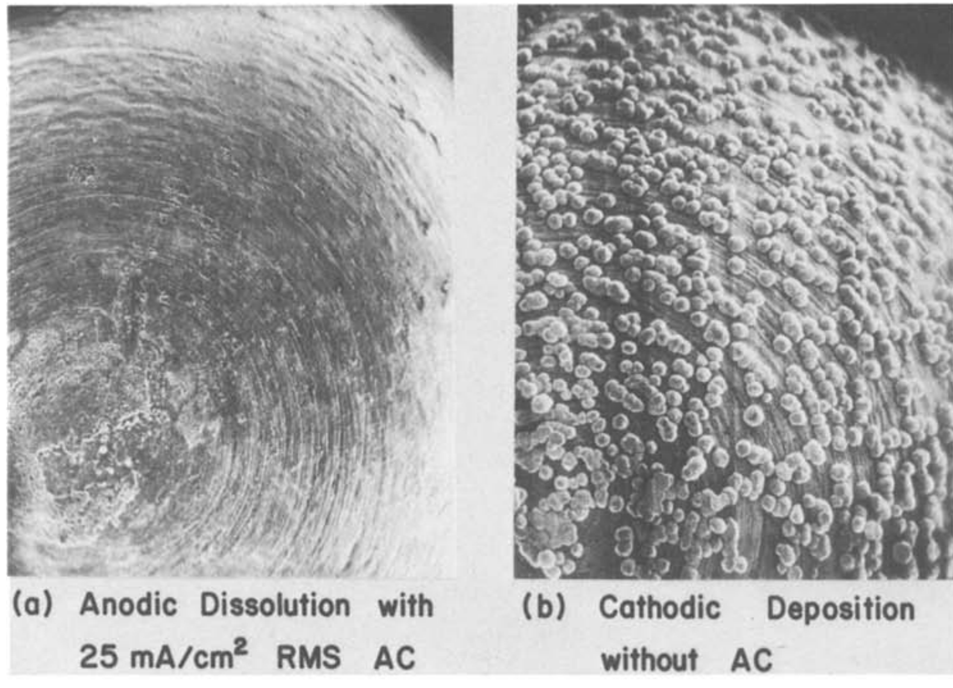
Substituting Eq. [2] and [3] into Eq. [1] and taking the time-average on both sides of the resulting equation, one has

$$\overline{N}_{a.c.} = N_\infty \overline{\exp\left[-\frac{B^2}{(\eta_{d.c.} + \eta_{a.c.})^2}\right]} \quad [4]$$

The overscore in the above equation designates the time-averaging operation. The details of the time-averaging technique have been discussed in previous publications (31, 33) and is not repeated here. Equation [4] can be normalized with the nucleation rate without superimposed a.c.; the result can be rearranged as

$$\frac{\overline{N}_{a.c.}}{N_{d.c.}} = \frac{\overline{\exp\left[-\frac{1}{(1 + \eta_{a.c.}/\eta_{d.c.})^2(\eta_{d.c.}/B)^2}\right]}}{\exp\left[-\frac{1}{(\eta_{d.c.}/B)^2}\right]} \quad [5]$$

Here $\overline{N}_{a.c.}/N_{d.c.}$ is the ratio of the time-averaged nucleation rate when the electrode is polarized by a d-c



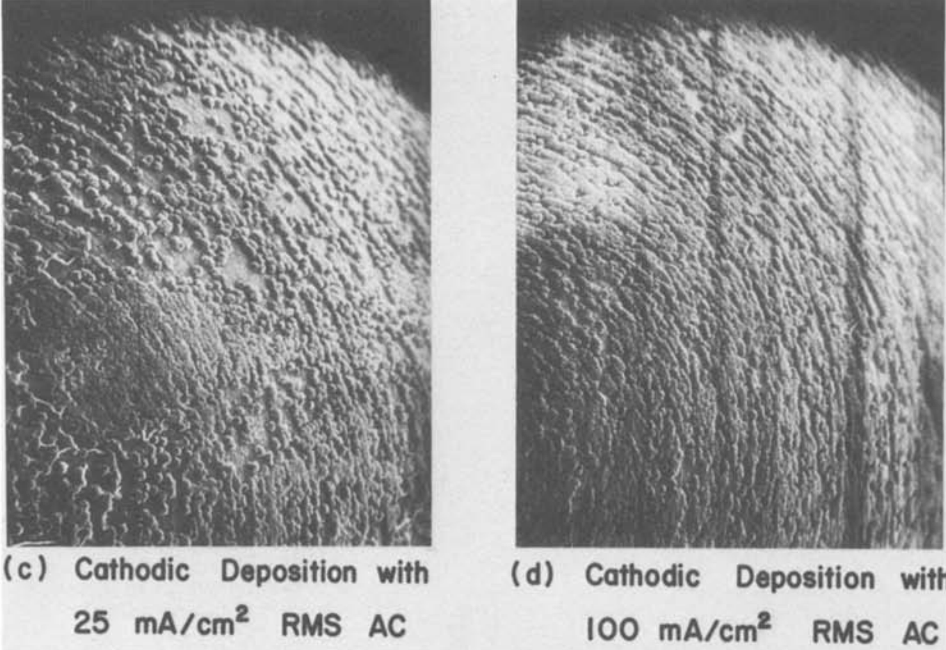


Fig. 2. Photomicrographs of the zinc surface after the polarization measurement. The magnification was 30×.

overpotential plus an a-c potential, $\eta_{d.c.} + \eta_{a.c.}$, to the nucleation rate when the electrode is polarized only by a d-c overpotential, $\eta_{d.c.}$. Equation [5] has been numerically evaluated for a square-wave a.c., and the results are plotted in Fig. 3 in the form of $\overline{N}_{a.c.}/N_{d.c.}$ *vs.* $\eta_{d.c.}/B$. The parameter in the figure is the root mean square of superimposed a-c potential, $\sqrt{\overline{\eta_{a.c.}^2}}$, normalized by the d-c overpotential. It is seen that at low d-c overpotentials, a.c. can increase the nucleation rate by several orders of magnitude. The result clearly agrees with the experimental observations shown in Fig. 2. Also the effect of a.c. diminishes as the d-c overpotential increases and becomes negligible in the region of $\eta_{d.c.}/B > 1$. It is interesting to note that a large a.c. can slightly reduce the nucleation at large d-c overpotential, as indicated by the $\sqrt{\overline{\eta_{a.c.}^2}}/\eta_{d.c.} = 1$ curve.

Conclusions

In conclusion, a study has been made of the effect of a.c. on the behavior of the zinc electrode in an acid zinc-chloride solution. A.C. was found to shift the rest potential of the zinc electrode toward the negative direction and caused pitting corrosion when the electrode was polarized at the anodic potentials. With superimposed a.c., the rate of nucleation was greatly enhanced during the cathodic deposition reaction. This resulted in a more uniform zinc deposit on the electrode. The phenomenon was explained with the time-averaging analysis of a three-dimensional nucleation model.

The Stability of β-Al_2O_3($Na_2O \cdot 11Al_2O_3$) in Oxygen Atmospheres

F. A. Elrefaie and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada, L8S 4M1

ABSTRACT

The sodium oxide activity in the α-Al_2O_3 + β-Al_2O_3 coexistence was determined between 823 and 1198 K by relating measured values of the electromotive force of cells of the type

$$Pt|M, MX_2, Na_mX|\beta\text{- and } \alpha\text{-}Al_2O_3|M', M'_nO|Pt$$

and the Gibbs energy change of the cell reaction which can be written as

$$M + 2Na_mX + mM'_nO = mNa_2O_{(\beta)} + MX_2 + mnM'$$

where X refers to halide or sulfide anion. The dependence of activity, a_{Na_2O}, on temperature, T(K), is

$$\log a_{Na_2O} = -\frac{16{,}400}{T} + 3.60 \qquad (823 \leq T \leq 1198\text{ K})$$

Accordingly, the variation of the sodium vapor pressure of the α-Al_2O_3 + β-Al_2O_3 coexistence, p_{Na} (atm), with temperature and oxygen pressure, p_{O_2} (atm), follows the relation

$$\log p_{Na} = -\frac{24{,}250}{T} - 0.25 \log p_{O_2} + 9.94 \qquad (823 \leq T \leq 1198\text{ K})$$

Extrapolation of this relation to higher temperatures demonstrates that p_{Na} attains 1 atm at 1350 K in the environment of the Al,α-Al_2O_3 imposed oxygen pressure.

Probes based on β-Al_2O_3($Na_2O \cdot 11Al_2O_3$) as solid electrolyte have been developed to monitor oxygen pressures as low as those of the Al,α-Al_2O_3 coexistence (1) and to sense sodium contents of liquid aluminum in the ppm range (2). The stability of this compound, however, is not well established in such reducing atmospheres. The sodium vapor pressure of the coexistence α-Al_2O_3 + β-Al_2O_3 in air has been reported between 1300 and 1900 K (3). From these results, one estimates a value of $-200{,}832$ J mol^{-1} for the standard Gibbs energy of formation of β-Al_2O_3 from its binary oxides at 1000 K. This value is to be compared to other reported values of $-322{,}168$ (1), and $-247{,}199$ J mol^{-1} (2) at the same temperature. The corresponding values of sodium oxide activity in the α-Al_2O_3 + β-Al_2O_3 coexistence are 3.2×10^{-11} (3), 1.5×10^{-17} (1), and 1.2×10^{-13} (2). In light of these discrepancies, we initiated this investigation to establish the stability of β-Al_2O_3 using solid-state electrochemical cells with β- and α-Al_2O_3 as a two-phase electrolyte.

Experimental

Materials used in this investigation are listed in Table I. Wustite powder was prepared by reducing hematite at 1173 K in a flowing CO-CO_2-N_2 atmosphere.

β- and α-Al_2O_3 electrolyte tubes were prepared by slip casting an aqueous suspension containing 40g α-Al_2O_3, 360g β-Al_2O_3, 6 ml HCl, and 3g Darvin C deflocculant in 300 ml distilled water. Before preparing a slip, the β-Al_2O_3 powder (−120 mesh) was ground to less than 8 μm in diameter in an isopropyl alcohol medium for 24 hr in a porcelain ball mill using α-Al_2O_3 balls.

The following procedure was found to be best for preparing a smooth slip: The acidified solution containing the deflocculant was charged to the ball mill followed by the subsequent addition of the β-Al_2O_3 and α-Al_2O_3 powders; the mixture was tumbled for 3 hr, its pH being readjusted to 7 each 15 min. The slip was poured into wetted plaster molds, and maintained at the level of the mold top during the casting period of 30 sec. Cracking of a tube was minimal if its upper edge separated from the mold wall using a spatula within 5 min of the casting. A tube was left to dry in its plaster mold for 48 hr which led to a shrinkage of ~10% in its length. The green tubes, ~2 mm wall thickness, were dried for a week in air at room temperature; outer surfaces and edges were then polished using 320 grit emery paper. Tubes were prefired in a covered Al_2O_3 crucible packed with a coarse powder at 700°C for 14 hr to allow complete drying before sintering at 1800°C for 3 hr in a propane-combustion gas furnace. X-ray diffraction analyses and electron probe tracing of sintered tube cross sections indicated that the α-Al_2O_3 phase, ~3 volume percent (v/o), was homogeneously distributed as discrete particles within the β-Al_2O_3 matrix of the electrolyte tubes, ~10 cm in length and 1.5 cm in diameter. Approximately 80% of the sintered tubes exhibited 10^{-8} Torr He-leakage resistance.

Table I. Materials used in this investigation and its sources

Material	Source and type
Nickel, iron, copper, and hematite powders	Ventron, Alfa Products — 99.9%
Tungsten powder	Fisher Scientific — purified
Nickel oxide powder	Fisher Scientific — 99.8%
Cuprous oxide powder	Fisher Scientific — 99.3%
Tungsten sulfide and sodium sulfide (anhy.) powders	Ventron, Alfa Products — laboratory grade
Nickel sulfide powder (anhy.)	J. T. Baker Chemical — laboratory grade
Sodium fluoride powder	J. T. Baker Chemical — 99.5%
β-Al_2O_3 powder	ALCOA — superground high quality grade
Autostic cement	Carlton Brown & Partners Ltd.
Darvin C	R. T. Vanderbilt Company, Inc.

A schematic of the electrochemical cell is shown in Fig. 1. The cell generally consisted of a W,WS_2,Na_2S anode, an Fe,FeO, Ni,NiO, or Cu,Cu_2O cathode, the β- and α-Al_2O_3 solid electrolyte tube, and an α-Al_2O_3 crucible. The M',M'_nO electrodes were tablets, 0.6 cm in diameter and 0.3 cm in thickness, pressed from 1:1 (molar ratio) mixture of the metal and oxide phases using an hydraulic press. The pellets were sintered at 1000°C under purified flowing argon for 18 hr and metallographically polished before incorporating into the inner compartment of a solid electrolyte tube. The M',M'_nO electrode and the Pt electrical lead were covered by a protective layer, ~2 cm deep, of a powder with the same composition as the tablet. A cathode of one cell was composed of a 3 cm deep compact of Ni,NiF_2,NaF with the molar ratio of 1:1:4; this mixture was dried for 3 hr at 180°C in vacuum. The cathode compact was covered by α- and β-Al_2O_3 powder upon its placement in the electrolyte tube. The W,WS_2,Na_2S electrode consisted of a 1:1:4 (molar ratio) mixture of the dried powders (4). Electrode compartments were sealed using Autostic Cement under an argon atmosphere.

A mullite-glass tubular cell assembly was positioned vertically in a tubular electric resistance furnace equipped with a Kanthal noninductively wound heating element (5). The cell was positioned in the constant temperature zone of the furnace, ~5 cm in length, which was controlled within ±2°C as measured by means of a Chromel-Alumel thermocouple. This assembly was evacuated and flushed with argon several times at room temperature, 200°, 400°, and finally at 925°C for cells containing the M',M'_nO electrodes or at 750°C for the cell containing the Ni,NiF_2,NaF electrode. During emf measurements a continuous flow of argon was held at a head of 4-6 cm Hg. Argon, containing <5 ppm impurities, was purified by passage over copper and copper oxide at 180°C, ascasite, $CaSO_4$, and silica gel. A cell was left overnight before commencing emf measurements for both increasing and decreasing temperature cycles. When the temperature was changed, a new steady emf was reached after 2-3 hr.

Results and Analyses

The emf as a function of temperature of cells I, II, III, and IV are shown in Fig. 2-5

$$Pt|W,WS_2,Na_2S|\beta\text{- and }\alpha\text{-}Al_2O_3|Cu_2O,Cu|Pt \quad [I]$$

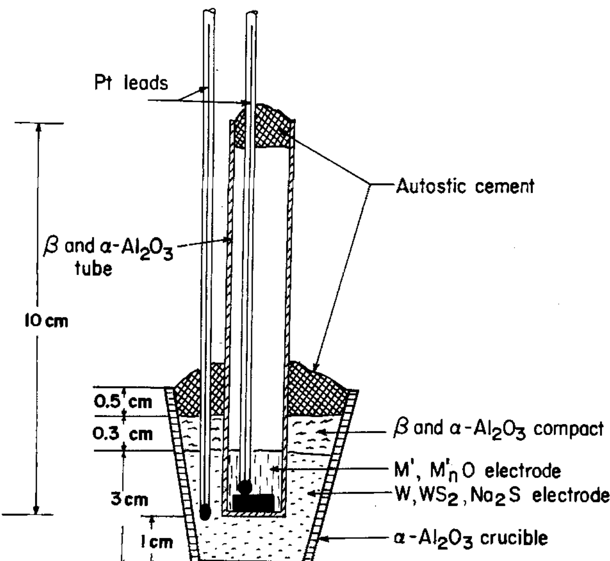

Fig. 1. Schematic of the electrochemical cell utilizing a β- and α-Al_2O_3 two-phase electrolyte.

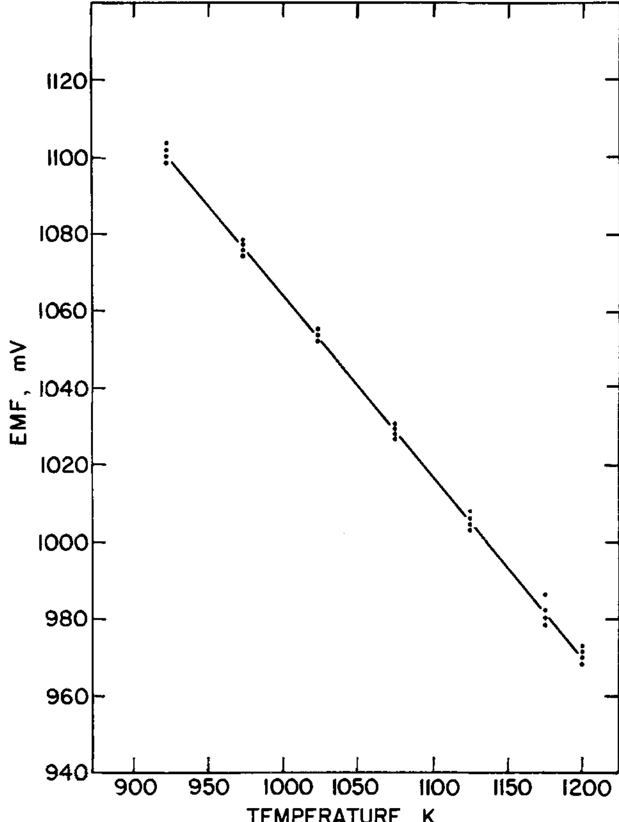

Fig. 2. Variation of emf with temperature for cell [I]

$$Pt|W,WS_2,Na_2S|\beta\text{- and }\alpha\text{-}Al_2O_3|NiO,Ni|Pt \quad [II]$$

$$Pt|W,WS_2,Na_2S|\beta\text{- and }\alpha\text{-}Al_2O_3|FeO,Fe|Pt \quad [III]$$

$$Pt|W,WS_2,Na_2S|\beta\text{- and }\alpha\text{-}Al_2O_3|NaF,NiF_2,Ni| \quad [IV]$$

Linear plots were obtained by least-squares analyses and their equations are given in Table II.

Reaction for cells [I], [II], and [III] can be written as

$$W + 2Na_2S + 2M'_nO = WS_2 + 2Na_2O_{(\beta)} + 2nM' \quad [1]$$

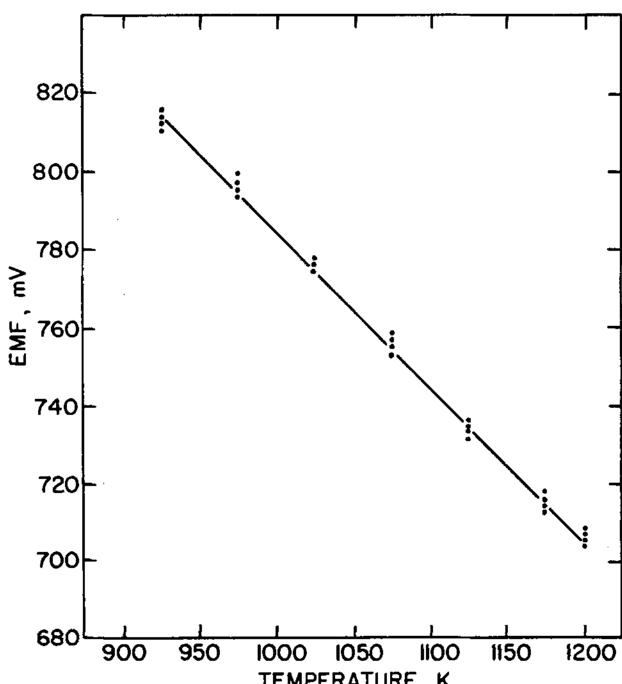

Fig. 3. Variation of emf with temperature for cell [II]

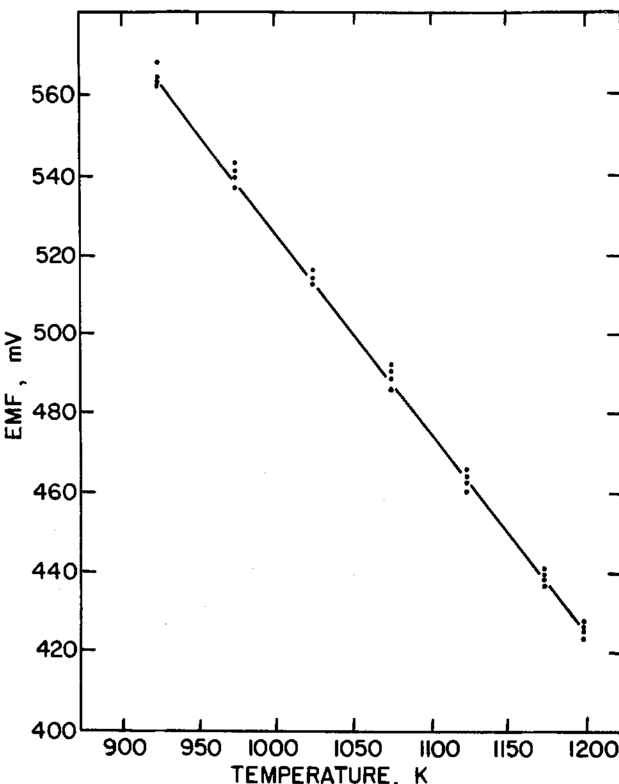

Fig. 4. Variation of emf with temperature for cell [III]

where M'_nO and M' are the oxide and metal phases of the cathode compartment. The Gibbs energy change of reaction [1] is expressed as

$$\Delta G = -4\mathbf{F}E = 2RT \ln a_{Na_2O} + \sum_i \nu_i \Delta G^\circ_f(i) \quad [2]$$

where $\mathbf{F}$ is the Faraday constant, R is the gas constant, ν_i is the number of moles of compound i, and $\Delta G^\circ_f(i)$ is the standard Gibbs energy of formation of compound i. Using relation [2], the values of log a_{Na_2O} shown in Fig. 6 were calculated between 923 and 1198 K using the emf results for cell [I], [II], and [III] and the required thermodynamic data from Table III.

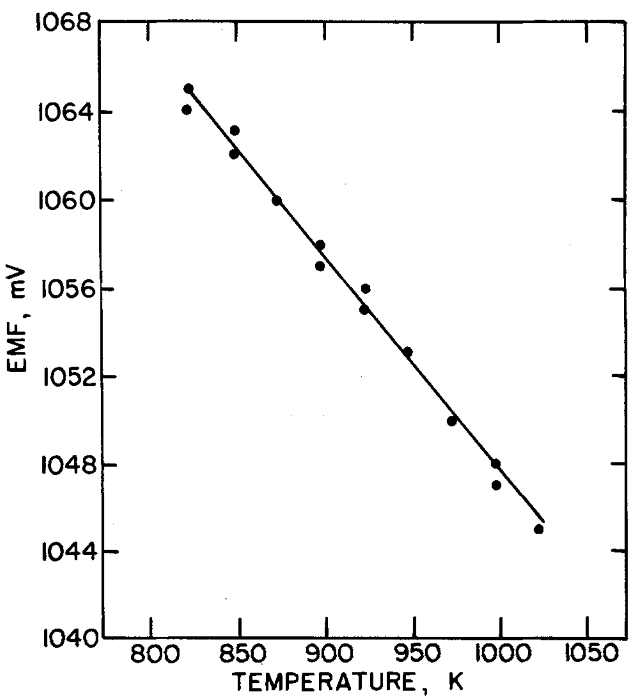

Fig. 5. Variation of emf with temperature for cell [IV]

Table II. Least squares analyses of the emf results of cells [I], [II], [III], and [IV]

Cell	Temperature range (K)	E(mV) = $a(\pm S_a) - b(\pm S_b)T$				Standard deviation (mV)
		a	S_a	b	S_b	
[I]	923-1198	1538	4	0.474	0.004	±2
[II]	923-1198	1180	4	0.396	0.004	±2
[III]	923-1198	1032	4	0.506	0.004	±2
[IV]	823-1023	1146	2	0.098	0.0002	±1

Table III. Thermochemical data used in this investigation

Compound	Temperature range (K)	ΔG°_f (cal/mol) = $A + BT$		Ref.
		$-A$	$+B$	
$Al_2O_{3(\alpha)}$	300-900	1,674,977	312.963	(7)
	1000-1900	1,685,922	325.515	(7)
$NiO_{(s)}$	900-1400	234,158	84.893	(8)
$Cu_2O_{(s)}$	900-1300	167,046	71.463	(8)
$FeO_{(s)}$	873-1600	264,575	65.396	(8)
$Na_2O_{(s)}$	400-1100	420,015	146.022	(9)
$Na_2S_{(s)}$	400-1100	440,232	131.378	(9)
$WS_{2(s)}$	1370-1565	336,394	156.482	(10)
$NiF_{2(s)}$	298-1300	654,796	138.072	(11)
$NaF_{(s)}$	371-1178	571,806	104.579	(11)

Combination of the emf-T relations obtained for cells [1] and [IV], Table III, yielded Eq. [3] which gives the emf between Ni,NiF_2,NaF and $CuCu_2O$ electrodes

$$E(\text{mV}) = 392 - 0.376T \quad [3]$$

For this cell, the reaction is

$$\text{Ni} + 2\text{NaF} + Cu_2O = NiF_2 + Na_2O_{(\beta)} + 2\text{Cu} \quad [4]$$

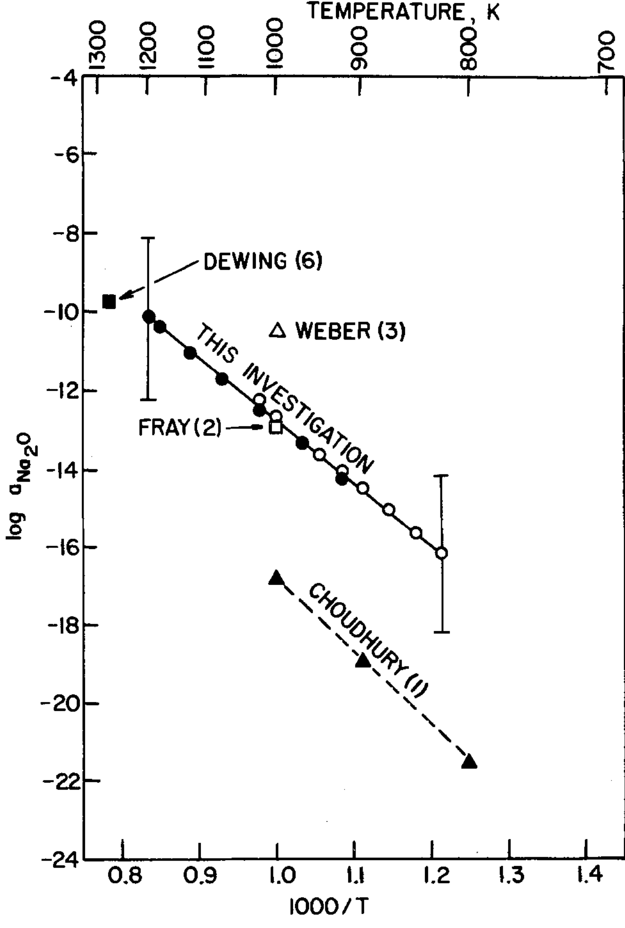

Fig. 6. Dependence of the sodium oxide activity in the α-Al_2O_3 + β-Al_2O_3 coexistence on temperature.

Values of $\log a_{Na_2O}$ between 823 and 1023 K were calculated using relation [3]; the results are plotted in Fig. 6.

Least-squares analyses of the calculated values for the Na_2O activity in β-Al_2O_3 coexisting with α-Al_2O_3 from the emf measurements between 823 and 1198 K yielded the relation

$$\log a_{Na_2O} = -\frac{16{,}400}{T} + 3.60 \quad [5]$$

which is shown as a solid line in Fig. 6. The estimated uncertainties in the values of $\log a_{Na_2O}$ is ± 2 due to the high uncertainties in the values of $\Delta G°_f$ of the halides and sulfides.

Discussion and Conclusions

The temperature variation of the Na_2O activity in the α-Al_2O_3 + β-Al_2O_3 coexistence obtained in this investigation and the previously reported values of log a_{Na_2O} are shown in Fig. 6. The value of Na_2O activity determined in this investigation at 1000 K is 1.6×10^{-13} which is in close agreement with the value calculated from Fray results (2), 1.2×10^{-13}, at the same temperature. Extrapolation of Eq. [5] yields a value of 5.2×10^{-10} for the Na_2O activity at 1273 K which is in good agreement with the value calculated by Dewing (5), 1.5×10^{-10}, for the equilibrium

$$34\alpha\text{-}Al_2O_3 + 6NaF_{(l)} \rightleftarrows 3\beta\text{-}Al_2O_3 + AlF_{3(l)}$$

However, the results obtained by Choudhury (1) for a_{Na_2O} is 4-5 orders of magnitude more negative than the above results, and the extrapolation to 1000 K of the values based on Weber results (3) at higher temperatures shows positive divergence. The divergence between the a_{Na_2O} values determined in this investigation and values extrapolated from Weber's results (3) may be due to the coexistence of sodium aluminate, $NaAlO_2$, with a sodium-rich β-Al_2O_3 (12) or β''-Al_2O_3, $Na_2O \cdot 5Al_2O_3$ (13), rather than its coexistence with β-Al_2O_3 of single composition as assumed by Weber (3). The discrepancy between the values of a_{Na_2O} obtained in this investigation, however, with those reported by Choudhury (1) cannot be explained because the same electrochemical reaction (4) has been investigated.

One can calculate from Eq. [5] for the Na_2O activity in β-Al_2O_3 the standard Gibbs energy changes of the following reactions

$$Na_2O_{(s)} + 11\alpha\text{-}Al_2O_3 = Na_2O \cdot 11Al_2O_3 \quad [6]$$

and

$$2Na_{(l)} + 22Al_{(l)} + 17\, O_{2(g)} = Na_2O \cdot 11Al_2O_3 \quad [7]$$

The obtained relations are

$$\Delta G°_{f'}(\beta\text{-}Al_2O_3) = -314{,}000 + 68.920\, T \quad [8]$$

$$\Delta G°_f(\beta\text{-}Al_2O_3) = -19{,}279{,}200 + 3795.607\, T \quad [9]$$

$\Delta G°_{f'}(\beta$-$Al_2O_3)$ is the standard Gibbs energy of formation of β-Al_2O_3 from $Na_2O_{(s)}$ and α-Al_2O_3 in joules and $\Delta G°_f(\beta$-$Al_2O_3)$ is the standard Gibbs energy of formation of β-Al_2O_3 from $Na_{(l)}$, $Al_{(l)}$, and $O_{2(g)}$. The estimated uncertainties in the values of $\Delta G°_{f'}(\beta$-$Al_2O_3)$ and $\Delta G°_f(\beta$-$Al_2O_3)$ are $\pm$42,000 and 63,000 J mol^{-1}, respectively. The value of $\Delta G°_{f'}(\beta$-$Al_2O_3)$ at 1000 K calculated from Eq. [8] is $-245{,}080$ J mol^{-1} which is in very good agreement with the value determined by Fray (3), $-247{,}199$ J mol^{-1}, at 1000 K but it is 77,088J more positive than the value given by Choudhury (1).

The variation of the sodium vapor pressure of the α-Al_2O_3 and β-Al_2O_3 coexistence can be determined by considering the following reaction

$$2Na_{(v)} + \tfrac{1}{2}\, O_{2(g)} \rightleftarrows Na_2O_{(\beta)} \quad [10]$$

for which

$$\Delta G°_{f'}(Na_2O) = -RT \ln \frac{a_{Na_2O}}{p_{Na}^2 \cdot p_{O_2}^{1/2}} \quad [11]$$

where $\Delta G°_{f'}(Na_2O)$ is the standard Gibbs energy change of reaction [10]. The standard Gibbs energy of formation of $Na_2O_{(s)}$ from $Na_{(l)}$ and $O_{2(g)}$ is (9)

$$\Delta G°_f(Na_2O) = -420{,}015 + 146.022\, T \quad [12]$$

The phase transformation of Na from the liquid state to monoatomic gas occurs at 1176.9 K with $\Delta H°_v$ = 97,424 J mol^{-1} (7). Therefore, for the following reaction

$$Na_{(v)} = Na_{(l)} \quad [13]$$

the Gibbs energy change, $\Delta G°_l(Na)$, can be expressed as

$$\Delta G°_l(Na) = -97{,}424 + 82.780\, T \quad [14]$$

The dependence of $\Delta G°_{f'}(Na_2O)$ on temperature is obtained by combining Eq. [12] and [14]

$$\Delta G°_{f'}(Na_2O) = -614{,}863 + 311.582\, T \quad [15]$$

Equations [5], [11], and [15] yield the following expression

$$\log\ p_{Na} = -\frac{24{,}250}{T} - 0.25 \log p_{O_2} + 9.94 \quad [16]$$

The estimated error is ± 2 for the values of $\log p_{Na}$. Equation [16] was used to construct Fig. 7, which shows the variation of $\log p_{Na}$ with $1/T$ between 823 and 1198 K at oxygen pressures imposed by the ambient atmosphere (p_{O_2} = 0.21 atm), Fe,FeO, and Al,α-Al_2O_3 coexistences. By considering the $\log p_{Na}$ – $1/T$ relation for the Al,α-Al_2O_3 coexistence, one estimates that p_{Na} equals 1 atm at 1350 $\pm$ 100 K. The values of p_{Na} in air between 1300 and 1900 K obtained by Weber and reported by Kummer (3) are also plotted in Fig. 7. These values extrapolate at lower temperature to values larger than those determined in this investigation.

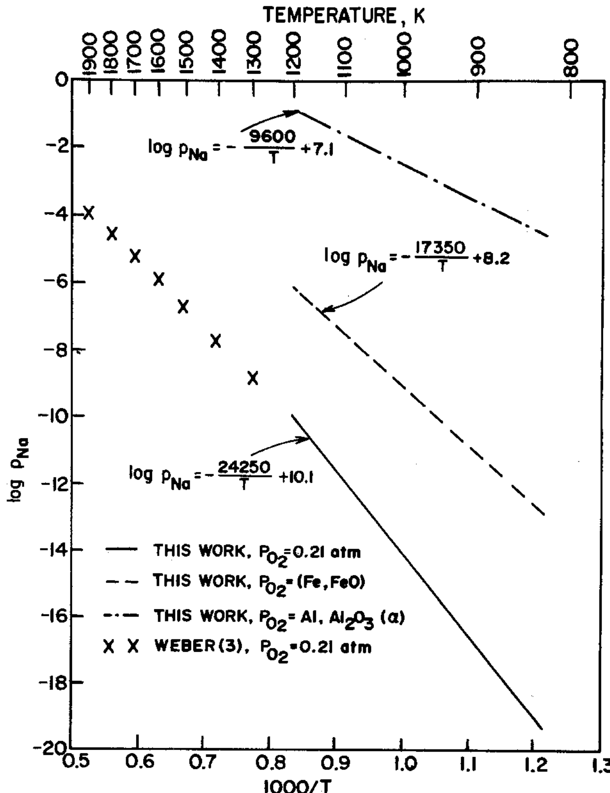

Fig. 7. Variation of the sodium vapor pressure of the α-Al_2O_3 + β-Al_2O_3 coexistence with temperature and oxygen pressure.

Iron Oxide Film Formed on Platinum During Fe_3O_4 Formation by Air Oxidation of an $Fe(OH)_2$ Suspension

Yutaka Tamaura, Chika Kameshima, and Takashi Katsura

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152, Japan

ABSTRACT

The iron oxide film formed on platinum was studied under conditions where Fe_3O_4 is readily formed by the air oxidation of an $Fe(OH)_2$ suspension at pH 9.5 and 65°C. Stoichiometric Fe_3O_4 was formed on platinum before the air oxidation, and the potential before the air oxidation was due to the cathodic reaction

$$3Fe(OH)_2 = Fe_3O_4 + 2H_2O + 2H^+ + 2e$$

The Fe_3O_4 film on platinum became thick during the air oxidation, and it was shown that $FeOH^+$ is continuously supplied to the surface of the Fe_3O_4 film by the dissolution of the $Fe(OH)_2$ particles in the reaction suspension and that the Fe_3O_4-formation reaction takes place on the surface of the Fe_3O_4 layer. The rapid change in the oxidation potential (ORP) at the end of the reaction was due to a change from the electrode potential of Fe_3O_4 (slightly oxidized) to that of γ-Fe_2O_3, which is formed on the surface of the Fe_3O_4 film by the air oxidation at the end of the reaction.

The formation of ferrites by air oxidation of $Fe(OH)_2$ suspensions containing metal ions has been studied; and Mg-, Cd-, Ti-, Cr-, V-, and Pb-bearing ferrites have been synthesized (1-6). In these studies, the progress of the air oxidation reaction has been measured by following the oxidation potential (ORP) using a platinum electrode (1-9). When an $Fe(OH)_2$ suspension is oxidized by air at pH 9-10 and at temperatures above 60°C, Fe_3O_4 is formed (10). In this paper, the $Fe(OH)_2$ suspension is referred to as "the reaction suspension." As the oxidation reaction proceeds, the Fe^{2+} content in the reaction suspension decreases and the ORP value is kept constant. However, at the end of the reaction, the Fe^{2+} content becomes constant and the ORP value changes rapidly from about −800 to 0 mV (*vs.* SCE). During the course of the investigation of the ORP value, we found that some iron oxide film was formed on the platinum electrode. The ORP value measured during the air oxidation seems to be due to the iron oxide film formed on platinum. The deposition of iron oxide films on platinum from the solution containing ferrous ions has been studied by Cohen *et al.* (11-13) and Formaro (14). Their studies at room temperature have suggested that γ-FeOOH or ferric iron oxide films are formed on platinum (11-14).

Key words: surfaces, potential, growth.

In this paper, we studied the ORP value and the iron oxide films formed on platinum during the Fe_3O_4-formation reaction by air oxidation of $Fe(OH)_2$ suspensions. The rapid ORP change at the end of the reaction was also studied.

Experimental

Reagents.—Chemical reagents of analytical grade were used. NaOH solutions (0.5 and 3*N*) were prepared by dissolving NaOH in distilled water free from CO_2 and O_2. Acetate buffer solution (20 mM, pH 4.1) free

from O_2 was used for the dissolution of the outer layer of the iron oxide film.

Apparatus.—The reaction vessel for the Fe_3O_4 formation was similar to that used earlier (3-6) (volume 1 liter). Platinum electrodes or plates can be removed from the reaction vessel under a nitrogen atmosphere in the course of the air oxidation. Before every experimental run, the platinum electrodes or plates were treated with concentrated HCl and rinsed with enough water to remove Cl^- as completely as possible. A saturated calomel electrode was used as a reference electrode.

Procedure.—After passing the nitrogen gas into the distilled water (780 ml) at 65°C to remove dissolved CO_2 and O_2, $FeSO_4 \cdot 7H_2O$ (14.4g) was added and dissolved completely. The *p*H was adjusted with NaOH solution and controlled within ± 0.01 *p*H using a *p*H-stat. After standing for 1 hr under a nitrogen atmosphere, the oxidation reaction was initiated by passing air in place of nitrogen gas. During the oxidation, the *p*H value was kept constant at *p*H 9.50 ± 0.01, and the temperature was controlled at 65° ± 0.1°C. The ORP value was measured using a platinum electrode.

For the identification of the phases formed in the reaction suspension during the course of the reaction, an aliquot portion of the reaction suspension was taken out by using a syringe without air contamination, washed with acetone free from oxygen to remove the water as completely as possible, and dried by passing nitrogen gas at room temperature. The sample thus obtained was sealed with Cellophane tape and analyzed by x-ray diffraction measurements.

For the analyses of the Fe^{2+} content of the reaction suspension during the air oxidation, about 20 ml of the suspension was taken out by a syringe. Fe^{2+} and Fe_{total} content in the samples were determined by the titration method using a $K_2Cr_2O_7$ standard solution. Fe_{total} was determined after reducing with zinc amalgum (15).

In the course of the reaction, the platinum plate (cylindrical type, 5.5 × 10 cm) was taken out under a nitrogen atmosphere, and chemical compositions (Fe^{2+} and Fe_{total}) of the iron oxide film formed on the platinum were determined by spectrophotometric method using 2,2′-bypyridyl (16) after dissolving the film in the acetate buffer solution (*p*H 4.1) or HCl (1:1) solution. For the measurement of Fe_{total} content, samples were reduced with hydroxylamine. The reflection electron diffraction patterns of the iron oxide films formed on platinum were examined using a smaller platinum plate (1 × 1 cm). After taking the smaller platinum plate from the reaction suspension, it was rinsed with the acetate buffer solution (*p*H 4.1) free from oxygen and dried by passing nitrogen gas. Although it seems that reorientation and recrystallization of the iron oxide formed on the platinum plate occurs during the course of the drying, the reflection method would be helpful in identifying iron oxides.

Cathodic reduction.—The cathodic reduction of the iron oxide film formed on the platinum electrode was carried out galvanostatically at a constant current (10 $\mu A/cm^2$) in a stagnant borate buffer solution (*p*H 8.4, consisting of equal volumes of 0.15*N* $Na_2B_4O_7 \cdot 10H_2O$ and 0.15*N* H_3BO_3 solutions) at 25°C under a slow nitrogen gas stream (17). The borate buffer solution was deaerated before the measurement by passing nitrogen gas for several hours. A Beckman Electroscan Model 30 was used for the electrical measurements.

All potential data (ORP) reported in this paper are referred to the saturated calomel electrode.

Results and Discussion

Iron oxide film formed on platinum before the air oxidation at pH 9.5 and 65°C.—Kiyama (10) has studied the reaction conditions for the formation of Fe_3O_4 with respect to temperature and *p*H values and has suggested that Fe_3O_4 is most readily obtained in a *p*H range from 8 to 10 and at temperatures above 60°C. Here, we investigated the iron oxide film formed on platinum under conditions where Fe_3O_4 is most readily formed. Curve A in Fig. 1 shows a change of ORP value during the Fe_3O_4-formation reaction at *p*H 9.5 and 65°C. Curve B shows the change of the Fe^{2+} content in the reaction suspension. When $FeSO_4 \cdot 7H_2O$ was added at point a (Fig. 1), the ORP value decreased to around 0 mV. At point b, where an alkaline solution was added, the ORP value rapidly decreased to around −800 mV and became constant after standing for 1 hr. At point c, the oxidation reaction was initiated by passing air in place of nitrogen. As seen by curve B, the Fe^{2+} content decreased linearly with the oxidation time and became constant at point d (end point of the oxidation reaction). During the air oxidation reaction (from point c to d), the ORP value was constant, but at the end of the reaction (point d), the ORP value increased rapidly up to nearly 0 mV.

We studied first the iron oxide film formed on the platinum before the air oxidation (point P in Fig. 1). The platinum was taken out from the reaction suspension just before the air oxidation, rinsed with distilled water free from oxygen, and kept in the acetate buffer solution (*p*H 4.1) free from oxygen for 3 hr to dissolve the ferrous ions on the surface of the iron oxide film. In the reflection electron diffraction patterns of the iron oxide film thus obtained, only the lines due to Fe_3O_4 appeared (Table I). Chemical analyses showed that the amount of the iron in the iron oxide film was 1.45×10^{-4} $mmol/cm^2$ and that the Fe^{2+}/Fe_{total} molar ratio of the iron oxide film was 0.334 ± 0.01. Thus, before the air oxidation at *p*H 9.5 and 65°C, stoichiometric Fe_3O_4 is formed on the platinum. Formaro (14) has reported the mechanism of the deposition of an iron oxide film on platinum which is immersed in a solution containing ferrous ion and has suggested that the deposition is caused by a short-circuit galvanic coupling between the (cathodic) reaction of hydrogen adsorption on platinum according to the reaction

$$Pt + H_2O + e \rightarrow Pt \cdot H + OH^-$$

and the (anodic) oxidation of Fe^{2+} to Fe^{3+}

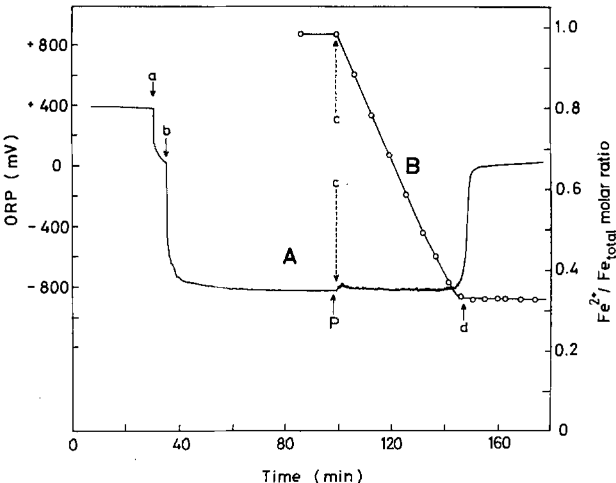

Fig. 1. Changes of ORP value (curve A) and Fe^{2+} content (curve B) in the reaction suspension during the Fe_3O_4-formation reaction by air oxidation of the $Fe(OH)_2$ suspension at *p*H 9.5 and 65°C.

$$Fe^{2+} \rightarrow Fe^{3+} + e$$

From the mechanism presented by Formaro, it can be seen that Fe^{3+} ion is formed on platinum. Under the conditions where Fe_3O_4 is formed (65°C, pH 9.5) by air oxidation of $Fe(OH)_2$ suspensions, the Fe^{3+} ion formed on the platinum, by the mechanism suggested by Formaro, seems to react with ferrous ion to form the Fe_3O_4 film. Leibenguth and Cohen (12) and Hashimoto and Cohen (13) have studied the deposition of an iron oxide film on platinum by anodic oxidation. They have reported that a γ-FeOOH film is formed on platinum from the ferrous sulfate or perchlorate solution at 25°C and pH 6.6-8.4. Kiyama (10) has reported that γ-FeOOH (with α-FeOOH) is formed by the air oxidation of $Fe(OH)_2$ suspensions at lower temperatures (below 40°C) and at a pH below 8. Thus, when the temperature is low (below 40°C), the Fe^{3+} ion, formed by the anodic oxidation or the air oxidation of Fe^{2+}, is hydrolyzed readily to form γ-FeOOH. On the other hand, at a higher temperature (65°C), stoichiometric Fe_3O_4 film is formed on the platinum by anodic oxidation, as observed in the present work. There seems to be an agreement in the reaction conditions for the formation of iron oxides by air oxidation of $Fe(OH)_2$ suspensions and the formation of iron oxide films on platinum by anodic oxidation.

Under the present experimental conditions, there is a possibility that the reaction suspension is contaminated by a small amount of Cl^- from the saturated calomel electrode and that some Cl^- ions remain on the platinum after cleaning with HCl and washing with water. It seems that these Cl^- ions affect the formation of the iron oxide on the platinum electrode. Foley *et al.* (18) reported that when an iron bar is anodically oxidized in the presence of Cl^-, Fe_3O_4 or γ-Fe_2O_3 is not deposited, but γ-FeOOH. In the present work, however, this effect of the Cl^- ions, which would exist in the reaction suspension, was not observed.

Potential-pH diagrams for the Fe-H_2O system have been established by Pourbaix and his co-workers (19) who considered $Fe(OH)_3$ and Fe_2O_3 as the favored ferric solid substances. Other diagrams considering α- and γ-FeOOH have been presented by Misawa (20). According to these diagrams, ferrous hydroxide is thermodynamically stable in alkaline solution and will be oxidized to Fe_3O_4 or α-FeOOH with an increase of oxidation potential and to γ-FeOOH at a higher oxidation potential. This suggests that Fe_3O_4 can be formed as a stable phase at the pH and electrode potential where the present study was carried out.

Thus, the ORP value measured before the air oxidation can be considered as the potential of the Fe_3O_4 immersed in the reaction suspension. Thuru *et al.* (21) have suggested that Fe_3O_4 immersed in solution is covered with a thin $Fe(OH)_2$ layer, and that the electrode potential is determined by a cathodic reaction. If so, the cathodic reaction occurring on the immersed Fe_3O_4 may be given by

$$3Fe(OH)_2 = Fe_3O_4 + 2H_2O + 2H^+ + 2e \quad [1]$$

In the reaction suspension, there exists many $Fe(OH)_2$ particles, and the solution is considered to be saturated with ferrous ions. This would facilitate the deposition of the $Fe(OH)_2$ layer which covers the Fe_3O_4 film formed on the platinum electrode. The pH dependence of the potential derived from Eq. [1] is 67 mV/pH (65°C). Figure 2 shows the relationship between the pH value and the ORP value before the air oxidation. As can be seen, a linear relationship with a slope of 64 mV/pH (65°C), which is nearly equal to that of Eq. [1], was obtained. If the ORP value is the potential due to reaction [1], some ferrous ions of the $Fe(OH)_2$ layer should be determined on the Fe_3O_4 layer. To dissolve the $Fe(OH)_2$ layer without dissolving the Fe_3O_4 layer, the electrode was taken out of the reaction suspension and was rinsed with distilled water free from oxygen and kept in the acetate buffer solution (pH 4.1) for 3 hr. The ferrous content determined from the ferrous concentration in the acetate buffer solution was 1.50×10^{-4} mmol/cm^2. This amount of the $Fe(OH)_2$ layer is approximately equal to that of the inner Fe_3O_4 layer. These results suggest that the ORP value measured before the air oxidation is the potential due to the cathodic reaction [1]. Here, we call the layer which dissolves in the acetate buffer solution the "outer layer," and that which dissolves in the HCl solution the "inner layer."

Growth of the Fe_3O_4 inner layer formed on the platinum during the air oxidation.—Table II shows the chemical compositions of the inner layer of the iron oxide film formed on the platinum in the course of the air oxidation. As seen in the table, the inner iron oxide layer becomes thick with the oxidation time ($1.45\text{-}6.10 \times 10^{-4}$ Fe mmol/cm^2) and the Fe^{2+}/Fe_{total} molar ratios are 0.31-0.32. In the reflection electron diffraction pattern of the inner layer obtained in the course of the air oxidation, lines due to Fe_3O_4 were seen. On the other hand, in the outer layer, iron contents (mostly ferrous ions) determined during the air oxidation were less than 0.02×10^{-4} Fe mmol/cm^2, which is about $1/10^3\text{-}1/10^4$ of that of the inner layer. Thus, although the amount of fer-

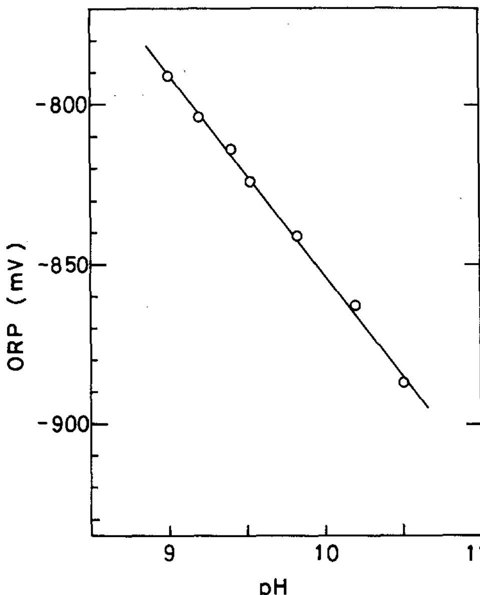

Fig. 2. pH dependency of ORP value before the air oxidation at 65°C.

Table II. Iron content in the inner layer of the iron oxide film formed on platinum during the air oxidation at pH 9.5 and 65°C

	Fe_{total} ($\times 10^{-4}$ mmol/cm²)	Fe^{2+}/Fe_{total}
Just before the air oxidation	1.45	0.334
10 min oxidation time	4.10	0.312
Just before the rapid ORP change	6.10	0.322
After the rapid ORP change	6.05	0.320

rous ions in the outer layer was very small, the inner layer (slightly oxidized Fe_3O_4) became thick during the air oxidation. This shows that some dissolved species such as $FeOH^+$ are being supplied continuously to the surface of the Fe_3O_4 layer (slightly oxidized) during the air oxidation and that a reaction takes place on the surface to precede the crystal growth. Figure 3 shows the changes of peak intensities (peak area) of $Fe(OH)_2$ ($2\theta = 47.5°$, Fe K_α) (curve A) and Fe_3O_4 (45.0°) (curve B) in x-ray diffraction patterns of the reaction suspensions during the air oxidation. As seen here, the peak intensities of Fe_3O_4 (curve B) increase with the oxidation time, but those of $Fe(OH)_2$ (curve A) decrease. Thus, in the reaction suspensions, the growth of Fe_3O_4 particles proceeds with the dissolution of $Fe(OH)_2$ particles, and the ORP value changes rapidly just at the time when all the $Fe(OH)_2$ particles are completely dissolved. (The broken line represents the end point of the reaction.) This means that $FeOH^+$ is continuously supplied during the air oxidation by the dissolution of the $Fe(OH)_2$ particles. Kiyama (10) has suggested that Fe_3O_4 will be formed by the precipitation of $FeOH^+$ with the ferric oxyhydroxide complex ion which is formed by the oxidation of $FeOH^+$. The growth of the Fe_3O_4 layer as seen in the table shows that the reaction as suggested by Kiyama seems to take place on the surface of the Fe_3O_4 layer. The reaction will continue as long as $FeOH^+$ is being supplied.

In the outer layer, as mentioned above, a small amount of ferrous ion was determined during the air oxidation. The pH dependence of the ORP value in the course of the air oxidation was 63 mV/pH. These results suggest that the ORP value measured during the air oxidation is due to an electrode potential of the Fe_3O_4 (slightly oxidized) which is covered with a thin $Fe(OH)_2$ layer. However, as seen by Fig. 4 (the ORP change recorded on an expanded scale), a stable ORP value is measured before the air oxidation, but when the oxidation was initiated (point c in Fig. 4), the ORP value became unstable and slightly increased by 40-60 mV. This shows that some discharge (*e.g.*, oxidation of $FeOH^+$) owing to the Fe_3O_4-formation reaction takes place on the surface of the Fe_3O_4 layer, and the unstable ORP value seems to be due to the reaction occurring on the surface of the layer.

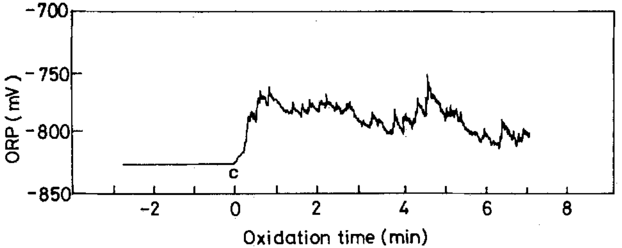

Fig. 4. ORP change recorded on an expanded scale before and after the initiation of the air oxidation.

Rapid ORP change at the end of the air oxidation.—Curves A-E in Fig. 5 show the changes of the potential during the cathodic reduction of the iron oxide films formed on the platinum in the course of the air oxidation, and curve F is for the iron oxide film deposited on the iron by the anodic oxidation at 300 mV in the borate buffer solution (pH 8.4) according to the method by Markovac and Cohen (17). As seen in curve F, two arrests appear in the profile of the oxide film formed on the iron, one corresponding to the reduction of γ-Fe_2O_3 (period a-b of curve F) and the other to the reduction of Fe_3O_4 (period b-c) as shown by Nagayama and Cohen (22) and Markovac and Cohen (17). Recently, Haruyama and Thuru (23) and Thuru and Haruyama (24) have reported the results which support the γ-Fe_2O_3 and Fe_3O_4 bilayer model of the iron oxide film on iron. They suggested that when the first wave (period a-b) appears at a much higher potential (−500 mV *vs.* SCE), it is mainly due to the existence of γ-Fe_2O_3 as the outer layer (17, 22-24). In an interval from before the air oxidation until just before the rapid ORP change (curve A-C in Fig. 5), similar cathodic reduction profiles are obtained, but a marked difference is seen between just before (curve C) and just after (curve D) the rapid ORP changes; *i.e.*, only a single wave appears just before the rapid ORP change, but two waves just after the rapid ORP change. When air is

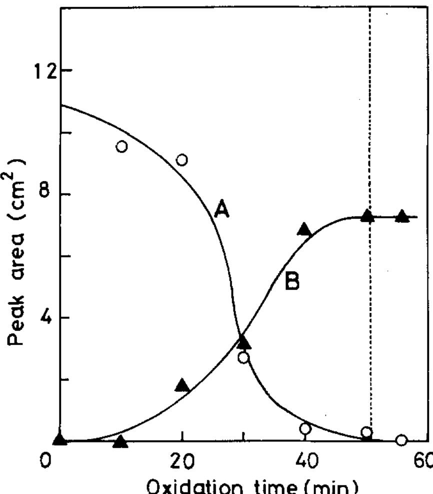

Fig. 3. Changes of peak intensities (peak area) of $Fe(OH)_2$ ($2\theta = 47.5°$ Fe K_α) (curve A) and Fe_3O_4 (45.0°) (curve B) in x-ray diffraction patterns of the reaction suspensions during the air oxidation at pH 9.5 and 65°C.

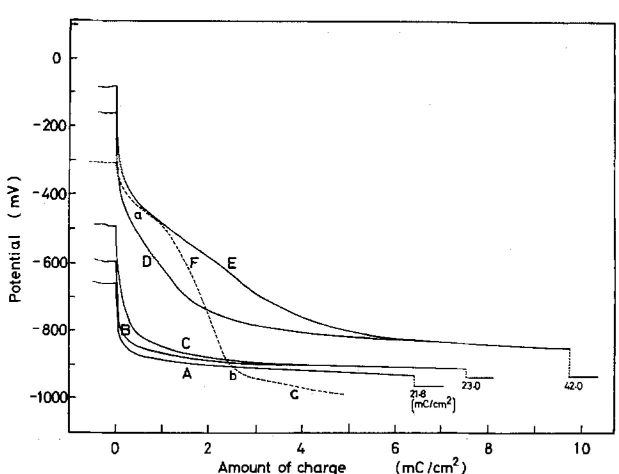

Fig. 5. Cathodic reduction profiles of the iron oxide films formed in the course of the air oxidation (10 μA/cm²). A, before the air oxidation; B, 30 min oxidation time; C, just before the rapid ORP change; D, just after the rapid ORP change; E, 15 min after the rapid ORP change; F, iron oxide film formed on iron by cathodic oxidation at 300 mV in the borate buffer solution (pH 8.4).

passed further after the rapid ORP change, the first wave becomes large, as seen by curve E. The appearance of the first wave in curves D and E seems to be due to the formation of γ-Fe_2O_3 on the surface of the iron oxide film, and it becomes thick by passing air further after the rapid ORP change. The reflection electron diffraction pattern of the iron oxide film obtained after the rapid ORP change gave lines which differ from those of Fe_3O_4, but are due to γ-Fe_2O_3 ($a = 8.30 \pm 0.03$Å) (Table I). As seen by curves D and E, a steady potential (−920 mV) (17) corresponding to that of the reduction of Fe_3O_4 is seen after a prolonged cathodic reduction. This shows that Fe_3O_4 is formed inside of the γ-Fe_2O_3 layer just after the rapid ORP change or 15 min after. As seen by curves D and E, higher electrode potentials appear, which are characteristic of the γ-Fe_2O_3 formed on the surface of Fe_3O_4 by air oxidation (25, 26). The high electrode potential has been considered to be due to cation-deficient γ-Fe_2O_3 (25, 26) or to the adsorption of oxygen on γ-Fe_2O_3 (24). The rapid ORP change at the end of the reaction seems to be due to the change of the electrode potential of the Fe_3O_4 (slightly oxidized) to that of the γ-Fe_2O_3 which is formed on the surface of the Fe_3O_4 by the oxidation with oxygen at the end of the reaction.

Conclusions

1. Stoichiometric Fe_3O_4 is formed on platinum which is immersed in the $Fe(OH)_2$ suspension at pH 9.5 and 65°C.

2. During the course of the air oxidation of the $Fe(OH)_2$ suspension, growth of the Fe_3O_4 film on the platinum takes place.

3. At the end of the air oxidation of the $Fe(OH)_2$ suspension, the surface of the Fe_3O_4 film is oxidized to γ-Fe_2O_3, which causes a rapid change in the ORP value.

Electrochemical Study of an SnO_2-Sb_2O_5 Semiconducting Glaze

P. G. Orsini,* P. Pernice, and L. Egiziano

Faculty of Engineering, University of Naples, Naples, Italy

ABSTRACT

Small electrodes of semiconducting glaze, containing around 30% SnO_2 doped with Sb_2O_5, have been prepared by peeling electrical insulators and have been put in contact with Na_2SO_4 solution or with metallic gold. Alternating or direct current-voltage curves at temperatures between ambient and 60°C, current-time curves, harmonic analysis, and SEM micrographs of the corroded areas are reported. This study was made to simulate the corrosion of high voltage insulators with resistive glazes, operating in salt-contaminated areas and also to obtain a better understanding of conduction in mainly amorphous systems which are heterogeneous on a very small scale.

Resistive glazes, relying on semiconducting properties of doped SnO_2, have been used on high voltage electrical insulators to control flashover caused by pollution (1, 2). Their use has proved only partially successful as result of a relatively rapid deterioration (3).

A previous study (4) performed on a glaze obtained by the addition of SnO_2, doped with Sb_2O_5, to an alumi-

* Electrochemical Society Active Member.

Key words: coating, cathode, corrosion, reduction.

nosilicate base glaze, pointed out characteristic "pitting" corrosion of the contact glaze/pollutant electrolytic solution when an alternating voltage was applied to the system. An unexpected rectification effect at this contact was also found.

A more detailed knowledge of these phenomena is believed to be fundamental to a deeper understanding not only of the specific problem of the degradation of the glaze in service, but also of the general problem of amorphous semiconducting materials.

Moreover, the distribution of micro-inhomogeneities within the thickness of glaze on porcelain poses various problems of general interest, also in connection with the different nature of air/glaze and glaze/porcelain boundaries.

Characterization of the Glaze

The semiconducting glaze samples were manufactured by a porcelain electric insulator manufacturer. Reagent grade SnO_2 with 2.5 mol percent Sb_2O_5 was calcined for a few hours at 1200°C. The resulted semiconducting powder was mixed, in the proportion 1:2, with a traditional insulating glaze of approximate composition 70% SiO_2, 9% Al_2O_3, 4.5% $(Na, K)_2O$, 9% CaO, 7.5% ZnO, and sprayed onto unfired electrical porcelain tiles. After firing, a semiconducting glaze coated the porcelain to an average thickness of 150 μm. Such glazes have proved (2, 3, 5, 6) to be the best resistive glazes on high voltage insulators of traditional shape.

The scanning electron microscope (SEM) image of a polished section, cut along a plane normal to the glaze surface, is shown in Fig. 1. The semiconducting layer is confined between air/glaze (AG) and glaze/porcelain (GP) boundaries which have been indicated in the figure. The presence, in its thickness, of several gas bubbles having almost spherical shape, indicates that the glaze was a high viscosity liquid at firing temperature. While the formation of a liquid has allowed a good "vitrification" of the system, a high viscosity has prevented the escaping of bubbles.

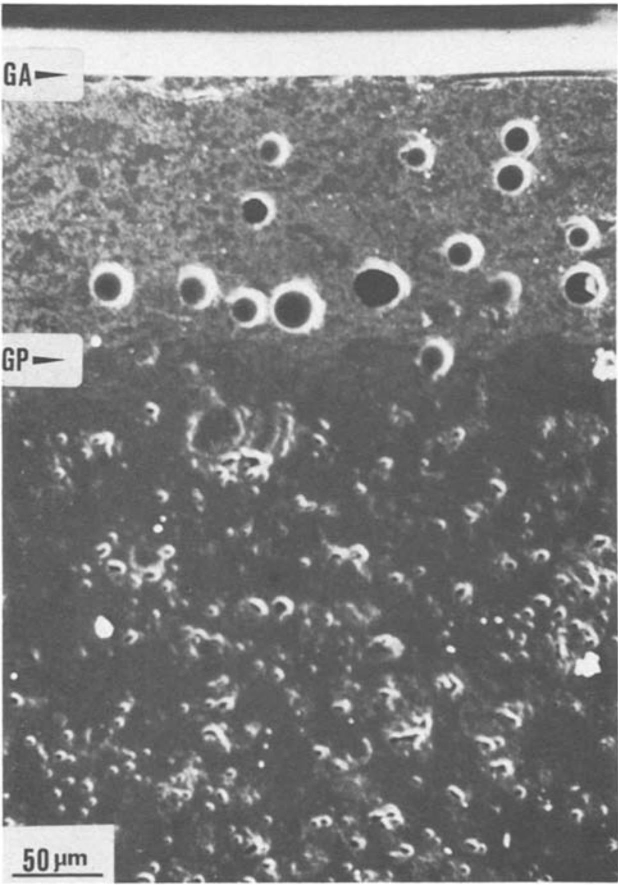

Fig. 1. SEM micrograph of polished transverse section of semiconducting glaze on porcelain. AG and GP: air/glaze and glaze/porcelain boundaries.

Two distinct phases are present in the glaze: one internal, darker, less abundant; the second external, lighter, continuous. The overall conductivity of this system, measured along a direction parallel to AG and GP boundaries, is $\sigma = 5.5 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$ at $T = 31°C$, under an electrical field $E = 500\ V\ cm^{-1}$. Dependence of σ upon T and E has been reported elsewhere (4).

On the basis of previous detailed structural studies (5, 7, 8) by SEM and electron probe microanalysis (EMA), which have revealed the existence and the composition of two different phases in these glazes, considering the relative proportion of the two phases in Fig. 1, and the relative amount of SnO_2 in the glaze, it seems reasonable to conclude that the darker phase corresponds to the SnO_2-rich, more conductive, phase. According to the x-ray diffraction spectrum of the whole glaze, which shows only the following peaks: d = 3.36, 2.66, 2.36, 2.31, 1.76, 1.67 AU, all corresponding to SnO_2 (9), the SnO_2-rich phase seems to be the only crystalline phase in the glaze system.

The Cell with a Glaze Electrode

Thin slabs of semiconducting glaze have been prepared by cutting a tile along the GP boundary (see Fig. 1) with a low speed saw (200 rpm) equipped with a thin (0.25 mm) diamond disk. Approximately square chips, with 50 mm^2 area and 0.15 mm thickness were obtained, one face being the "external" glossy glaze surface (AG, in Fig. 1), the other being the saw-cut surface, finished with grit 600 SiC to remove traces of porcelain.

Each slab was cemented, with the cut surface, to the end of a glass tube (5 mm bore) using a silicone rubber cement. A few drops of Hg in the tube provided the contact with glaze material. This "electrode" was usually dipped in a 25 weight percent Na_2SO_4 solution. Care was taken to minimize current leakage. The counterelectrode in the cell was a Pt wire or net of large area. Such a cell with a glaze electrode was initially prepared to study the effect of a.c. on resistive glazes of insulators in contact with polluting salt solution. The idea was to localize in a definite area any eventual alteration of the glaze surface that can be related to insulator decay, and study it by microscopy. In fact, a glaze electrode, a-c operated for few hours at 10 mA cm^{-2}, presents an appreciable distribution of microscopical corrosion craters. A typical SEM image of corroded glaze surface is shown in Fig. 2. The right lower corner corresponds to an uncorroded area; the rest corresponds to part of a crater on the bottom of which a bubble, like those in Fig. 1, can be seen. Bubbles on the bottom of corrosion craters are a common feature of SnO_2 glaze corrosion morphology.

Besides this surface alteration, the glaze also showed compositional change. During a-c operation, in addition to gas evolution at electrodes corresponding to electrolysis of water, the reduction of SnO_2 to metallic Sn resulted (4). A deposit of metallic tin onto the glaze electrode surface in the central area corresponding to passage of current has been identified by x-ray diffraction. An electrode with metallic deposit showed, in addition to those already reported, the following peaks: d = 2.92, 2.79, 2.02 AU which correspond (10) to metallic tin (strongest intensities).

I-V Curves

The unidirectional component of current flowing through the cell powered with a 50 Hz sinusoidal voltage, corresponding to the net reduction of tin, has been systematically measured. The rms value, i_a, and the unidirectional value, i_d, in a cell with a typical glaze electrode and a 25% Na_2SO_4 solution at 20°C are plotted against the rms value V_a of the applied voltage in Fig. 3. This voltage is consistent with the relatively

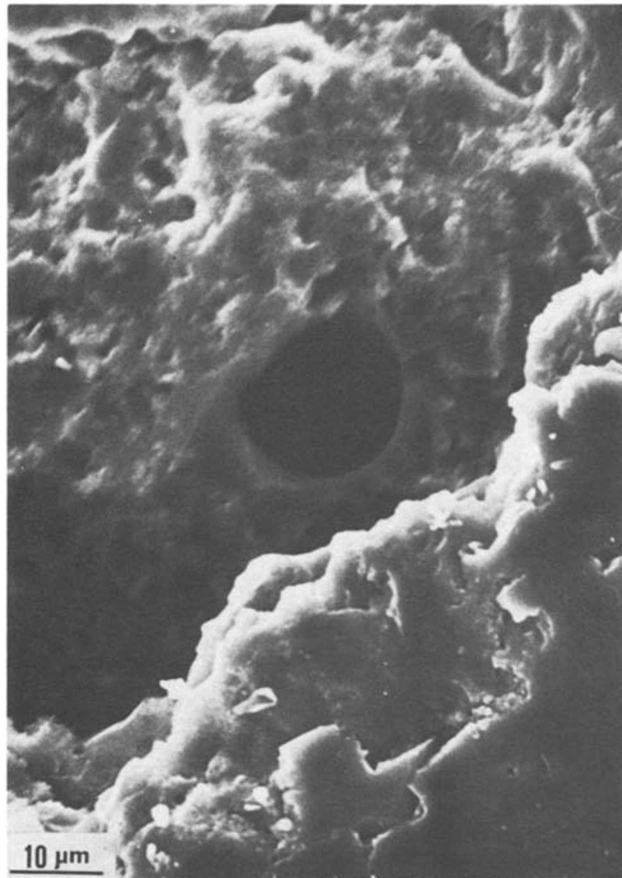

Fig. 2. SEM micrograph of corroded glaze surface

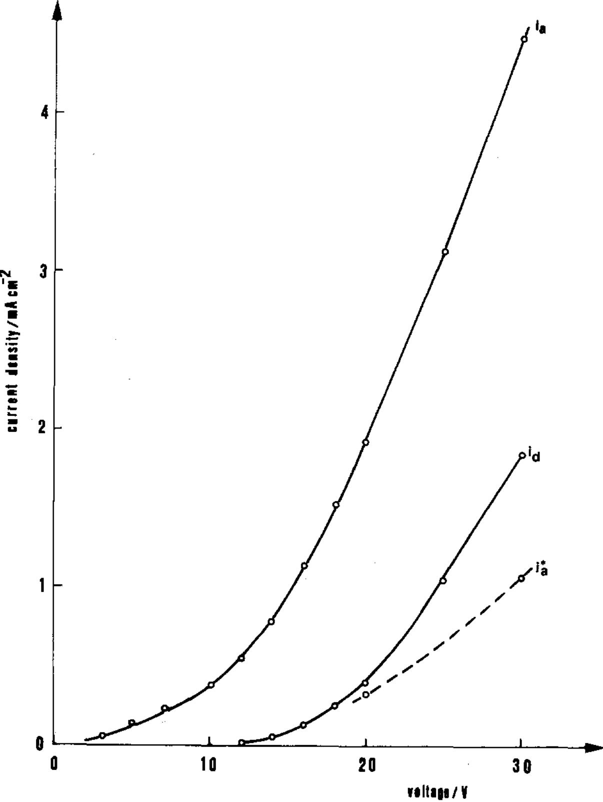

Fig. 3. Current densities vs. 50 Hz sinusoidal voltage (rms) applied to the electrochemical cell. i_a, rms value; i_d, unidirectional component; i_d*, surface glass taken away.

large voltage drop inside the glaze. A variable autotransformer on the main supply line, an electronic microammeter, and a galvanometer completed the measuring circuit.

Values of current were determined 10 min after each new voltage was set: the system showed a certain delay in reaching a steady value after each voltage change. Stability was reached more rapidly when the voltage was decreased. A really stable current is never obtained because of the progressive chemical change in the glaze. An example gives an idea of the order of magnitude of these variations: an initial alternating current of 350 μA fell to 320 μA in few minutes. Afterward it fell to 300 μA over 40 hr, at a constant rate of 0.5 μA hr^{-1}. In fact, limiting the sensitivity of current measurement to 0.5 μA, readings after the initial transient can be considered to be stable within 1 hr.

The rectifying effect raises progressively at $V_a >$ 10V. No threshold value can be given because the i_d curve takes off with zero slope. By increasing the voltage, the ratio i_d/i_a may become as high as 0.4. In any case, different electrodes give slightly different values of i_a and i_d for equal applied voltage, because the natural undulation of the air/glaze surface causes the slab thickness to vary. The dashed curve in Fig. 3 corresponds to i_d values when the gloss on the external surface of the electrode is taken away with an abrasive. The i-V characteristic curve of the same cell when direct voltage is applied gives a better account of the rectification. Measurements are reported in Fig. 4. Again, the voltage reported is the total value applied to the system. This voltage corresponds almost entirely to the drop inside the slab. This is true even when current approaches zero because, as is shown later, glaze resistance increases considerably when the field applied to it is lowered. From this point of view, rather than of an electric cell, one should think of a semiconductor with one electrolytic contact. No values are reported where the current is vanishingly small because a completely steady state is not attained there.

Figure 4 shows the asymmetric behavior of the cell under investigation when positive or negative voltages are applied. It suggests that in applying to the cell a sinusoidal voltage with high peak-to-peak value the corresponding current will be periodic, not sinusoidal, with an average value within the period differing from zero. Decreasing this voltage, the average value of the current progressively vanishes ($i_d = 0$).

Current Wave Shape

The wave shape of the current through the cell, powered by 50 Hz sinusoidal voltage, has been developed by Fourier analysis with the aid of an HP 2100 calculator.

The voltage drop in a 1 kΩ ohmic resistor in series with the cell (R = 1 MΩ), was passed through a low-pass filter (cut-off frequency 1 kHz) and an analogue-digital converter, ADC, and then into the calculator.

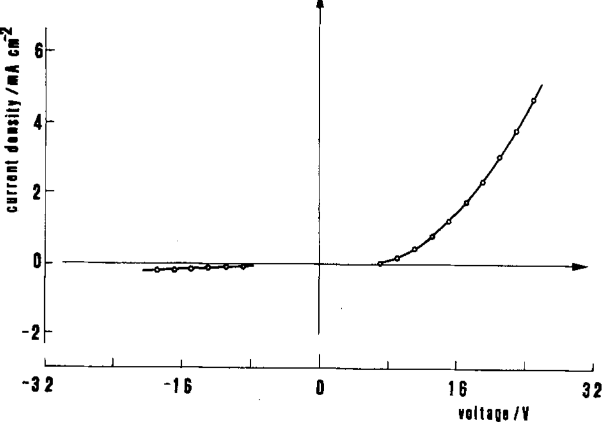

Fig. 4. Current density vs. direct voltage applied to the electrochemical cell.

The noise level of the filter and ADC was to 6×10^{-2} μA. The sampling frequency was 20 kHz.

In Fig. 5 the amplitude spectrum of the current flowing through the cell at three different voltages is shown. At all voltages lower than 30V the spectra are like Fig. 5a: i_d and even harmonics are negligible. At higher voltages spectra are like those shown in Fig. 5b and c: i_d and even harmonics have progressively higher values.

This behavior is in good agreement with that drawn as a conclusion in describing the "static" characteristic in Fig. 4. On the basis of results like those reported in Fig. 5, at different voltages, we have calculated i-V curves similar to those reported in Fig. 3: the ratio i_d/i_a shows the same trend.

Specimen with Two Metallic Contacts

The role of the contact glaze/electrolytic solution is better understood if the results reported in Fig. 3 and 4 are compared with the i-V curves of a glaze with two metallic contacts.

Thin slabs of semiconducting glaze similar to those used in the electrolytic cell have had gold sputtered onto the central zone of both surfaces (GP and AG, Fig. 1). Contacts between gold deposit and copper leads were secured with Silverdag®.

Values of i_a and i_d, *vs.* V_a for a temperature of 20°C when a 50 Hz sinusoidal voltage is applied, are reported in Fig. 6; this is the "dry" counterpart of Fig. 3. In the specimen with two gold contacts, the unidirectional current i_d assumes relatively very low values. It vanishes when the external gloss is taken away.

The i-V characteristic curve of the same cell at 31°C when direct voltage is applied is reported in Fig. 7. Positive and negative halves are almost symmetric. This is true at all temperatures between 15° and 60°C. The conductivity of the glaze, calculated at 10V, *i.e.*, at a field of 500 V cm^{-1}, and 31°C, is $\sigma = 2.62 \times 10^{-6}$ Ω^{-1} cm^{-1}.

Current, as a function of direct voltage can be described by the equation

$$|I| = K\ |V|^{3/2} \quad [1]$$

The plot of I *vs.* $V^{3/2}$ reported in Fig. 8 at 31° and 51°C, is linear to a good approximation in the range of voltages explored at both 31° and 51°C for forward and reverse flow. A positive sign is given when flow of positive charges enters into the glaze through the glossy surface, in accordance with results presented in Fig. 3, 4, 5, 7, and 8.

With the method of least squares the following values for the K parameter have been found at 31° and 51°C:

$K_{31}{}^{+} = 2.98$, $K_{31}{}^{-} = 2.92$, $K_{51}{}^{+} = 3.58$, $K_{51}{}^{-} = 3.48$ $\mu AV^{-3/2}$.

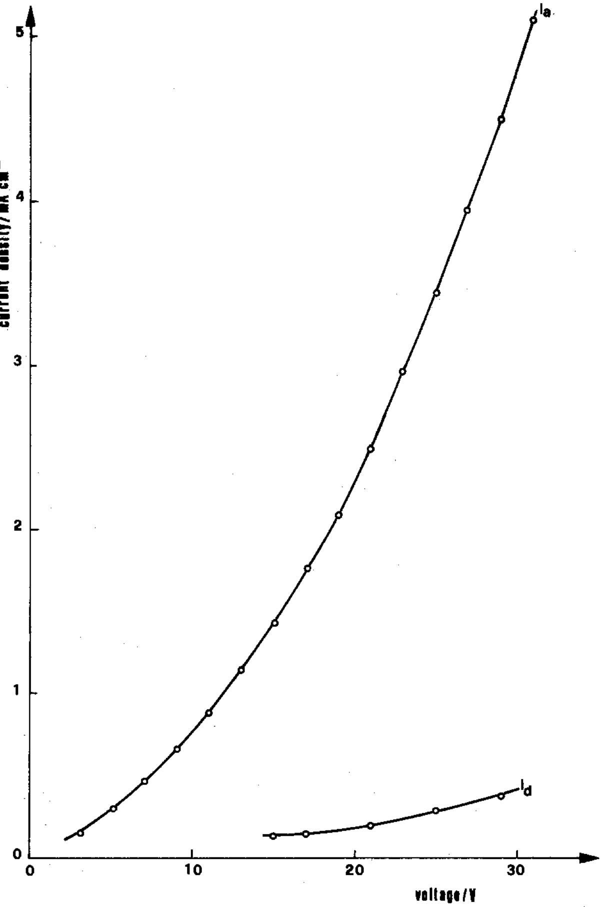

Fig. 6. Current densities vs. 50 Hz sinusoidal voltage, rms, applied to the glaze with two gold contacts. i_a, rms value; i_d, unidirectional component.

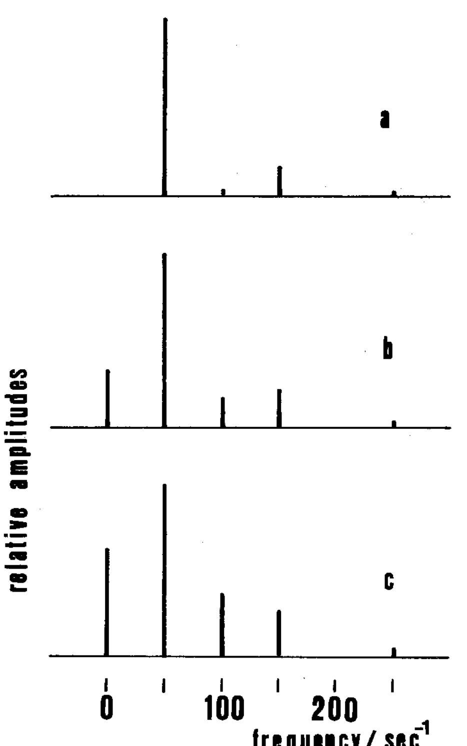

Fig. 5. Amplitude spectra of current through the electrochemical cell. Voltage applied: (a) 25V; (b) 40V; (c) 60V, rms value.

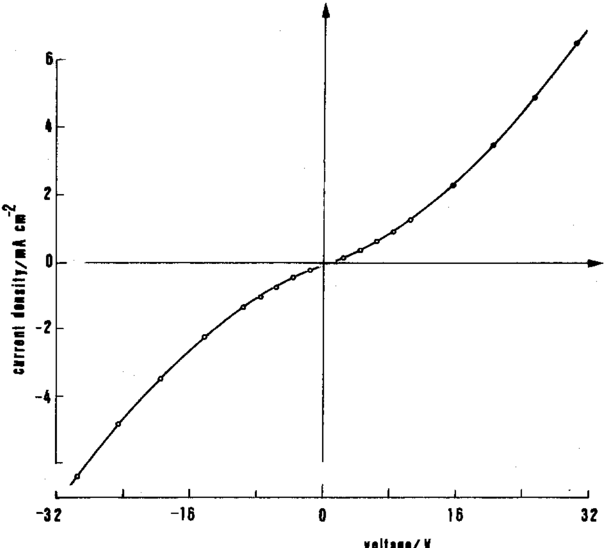

Fig. 7. Current density vs. direct voltage applied to the glaze with two gold contacts, at 31°C.

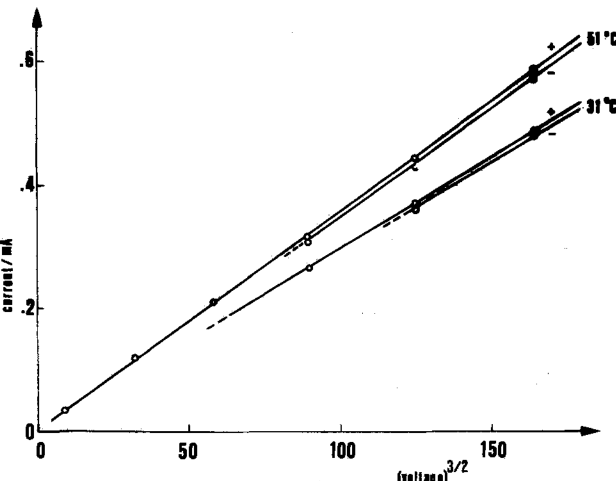

Fig. 8. Test of interpolating function $|V|^{3/2}$. Values measured at 31° and 51°C on the same specimen as in Fig. 7.

The activation energy for the conduction calculated from these values, 0.080 ± 0.001 eV, is independent of the current flow direction, within the limits of error. Experiments have also been performed on a specimen with glaze/silver contacts made with Silverdag directly facing the glaze, instead of glaze/gold/silver. Results are similar to those in Fig. 7 and 8, but steady currents are obtained only after a transient period whose duration depends on experimental conditions. Moreover, current values are very dependent on the sign of voltage applied.

In Fig. 9 a typical transient behavior of current is reported for a specimen with glaze/silver contact at 31°C. Closing the circuit at t_1, a steady current is attained only after about 1 hr. After changing direction of current at t_2, a small initial overshoot is followed by a relatively slow rise. A second change of direction at t_3, produces a larger overshoot which is slowly relaxed. At higher temperatures, e.g., 51°C, the effects are much the same, but the time to attain steady-state results is much shorter.

If the tests reported in Fig. 9 are applied to a specimen with two gold contacts steady current occurs immediately at all temperatures with only slightly differing values of current for either polarity, as already reported in Fig. 7.

The same test, applied to a specimen in which the current flow is parallel to the surface, produces immediately steady values, not dependent either on the polarity or on the material of the two contacts.

Conclusions

A delicate cutting has allowed the separation of glaze from the porcelain and the construction of electrodes, while preserving unaltered the morphology of the coating. Thus besides the characterization of the coating material one can investigate the behavior (chemical, electrical, or mechanical) of the coating layer itself which is responsible for the changes on polluted semiconducting glazed insulators.

A marked rectifying effect originates at the glaze/solution contact. This effect is shown in Fig. 3 and 4 and it seems to be mainly due to the contact between the semiconductor and the electrolytic solution. In fact these curves are influenced only to a very limited extent by changing the concentration of electrolyte solution (*e.g.*, from 25 to 2.5%) or changing electrolyte (*e.g.*, NaCl instead of Na_2SO_4).

On the other hand, at the contact glaze/metal (Au) only a very small rectifying effect exists: the static characteristic curve in Fig. 7 is very nearly symmetric, while in a.c. the ratio i_d/i_a, for equal voltages, assumes much lower values. Even this small residual rectifying effect, whose dependence of intensity on polarity is seen in Fig. 8, can be ascribed to the incomplete symmetry of contacts, because the external glaze surface is relatively SnO_2 poor.

A very thin layer, less than 1 μm thick, of SnO_2-free glaze has been found by Taylor (4) with ESCA in proximity to the air/glaze surface. In this layer crystallites of SnO_2 are possibly excluded by a surface tension effect, so that the two gold contacts do not face glaze of equal composition. Where the two contacts are made symmetric by polishing away the external SnO_2-poor layer the unidirectional component vanishes as shown in Fig. 6.

In fact, even during electrolysis, when the effect of contact with electrolytic solution is largely prevailing, the influence of external SnO_2-poor layer is still evident. The removal of this layer produces a slight reduction of i_d (dashed line in Fig. 3).

The transient behavior depicted in Fig. 9 is also an indirect proof of the existence of an external layer with different composition. When contacts do not face this layer, as in the case of current flow parallel to the external surface, steady values are immediately obtained. The transient phenomena seem to depend on metal-glass diffusion because: (*i*) at higher temperature steady state is attained more rapidly; (*ii*) gold, compared with silver, has a much lower diffusivity in accordance with their ionic diameters; (*iii*) when one of the Ag contacts faces the SnO_2-poor layer, the rate of diffusion depends on polarity: reversing polarity causes different transient phenomena (t_2 and t_3, Fig. 9).

Values of conductivity are fairly dependent on direction of current flow. Again, this can be ascribed to the presence of a thin SnO_2-poor layer. Along a direction parallel to the surface, the conductivity is 5.55×10^{-6} Ω^{-1} cm^{-1} at 31°C and 500 V cm^{-1}. In the same conditions, along the direction normal to the surface, the conductivity was only 2.62×10^{-6} Ω^{-1} cm^{-1}. The difference is well above any uncertainty due to experimental errors.

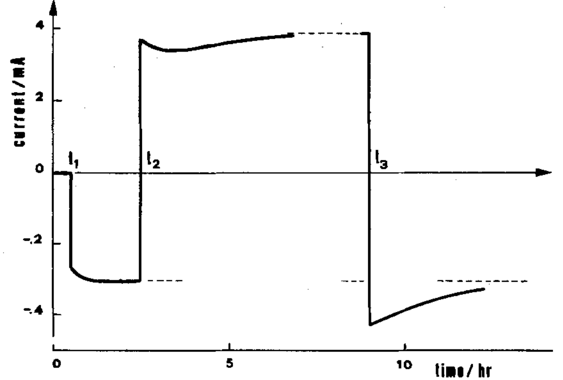

Fig. 9. Plot of current vs. time. Glaze with two silver contacts, at 31°C. Direct voltage applied at t_1; sign reversed at t_2 and t_3.

Mössbauer Spectroscopic Study of the Chemical State of Cobalt in an Electrodeposited Zinc-Cobalt Alloy

H. Leidheiser, Jr.,* A. Vértes,* and M. L. Varsányi*

Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015 and Loránd Eötvös University, Budapest, Hungary

ABSTRACT

An electrogalvanized steel containing small amounts of cobalt and chromium is of interest because of its claimed corrosion resistance under service conditions. Zinc-cobalt-chromium alloys were electrodeposited from a sulfate bath at 35° and 60°C and a current density range of 2-10 A/dm². The baths were doped with ^{57}Co so that emission Mössbauer spectroscopy could be employed. The cobalt content of the deposits was 0.01-2%. In the case of all deposits the cobalt was present as isolated atoms in the zinc matrix. No evidence was found for aggregates of cobalt atoms. The electrodeposited zinc-cobalt alloys thus represent supersaturated solutions of cobalt in zinc. Cobalt probably functions as a corrosion inhibitor because of its influence on the properties of the surface oxide film which it enters during active corrosion.

Much interest exists in the development of a more corrosion-resistant galvanized steel. Galvanized steel consists of a substrate that provides structural strength and resistance to deformation and a zinc coating that is anodic to steel. The lifetime of the coating, and hence corrosion protection, may be thought of in terms of two stages: (*i*) the time during which the zinc coating is the only metal exposed to the atmosphere, and (*ii*) after corrosion has occurred, the time during which the zinc coating and the steel substrate are both exposed. Corrosion of zinc during the second stage generally occurs at a faster rate because the exposed steel serves as cathode and accelerates the anodic reaction of the zinc. The ideal type of zinc coating is one which corrodes at a very low rate and yet provides protection to the steel substrate at those sites where steel becomes exposed. As pointed out previously (1), the development of such a coating appears practical because the rate of corrosion of zinc under mildly corrosive conditions is controlled by the cathodic reaction, $H_2O + \frac{1}{2} O_2 + 2e^- = 2\,OH^-$. If the zinc could be made a very poor cathode, it would corrode at a lower rate, yet would still protect steel at exposed sites because the steel would serve as the cathode when the bimetallic couple was in contact with an aqueous corrosive environment.

Recently, an electrogalvanized steel containing chromium and cobalt that is claimed to have excellent corrosive resistance (2, 3) has appeared on the market. Work by one of us (4) has also shown that pretreatment of zinc in a cobalt-containing solution results in corrosion inhibition in 3% NaCl solution. The present work was undertaken as one phase of a program designed to understand the role of cobalt in enhancing the corrosion resistance of zinc. The specific objective of the present work was to determine the chemical state of cobalt in zinc since Adaniya (3) was unsuccessful in his attempts to gain information about the chemical state of cobalt from x-ray photoelectron studies. He was, however, able to show that the chromium was present in the form of an oxide. The question of the chemical state of cobalt in zinc is not a trite one since it has been established that a significant amount of cobalt is present in cobalt-hardened gold electrodeposits in the form of an hydroxyoxide and a cyanide complex (5, 6).

* Electrochemical Society Active Member.

Key words: alloy, coatings, electrodeposition, metals.

Experimental Procedure

All electrodeposits were prepared from a plating solution of the composition

$ZnSO_4 \cdot 7H_2O$	150 g/liter
$Na_2SO_4 \cdot 10\,H_2O$	45 g/liter
$CoSO_4 \cdot 7H_2O$	10-95.4 g/liter
$Cr_2(SO_4)_3 \cdot 18H_2O$	0.3 g/liter
Sodium acetate $\cdot 3H_2O$	75 g/liter
pH	4.2

The deposits were formed on steel cathodes and a zinc sheet was used as a counterelectrode. The plating bath was doped with ^{57}Co such that the plating bath volume, 10 cm³, had an activity equivalent to 2.4×10^8 Bq in the case of the more dilute solutions and 3.7×10^8 Bq for the more concentrated solutions. The ^{57}Co was added to the plating bath as a solution of the chloride. The clarity of the plating bath indicated that all the constituents were solvated. It is assumed, and there was no reason to believe otherwise, that the ^{57}Co in the plating bath existed in the same chemical state as the natural cobalt. The determinations of the cobalt content of the electrodeposit from the radioactivity measurements are based on this assumption. The current efficiency for all depositions was very close to 100% as determined by gravimetric measurements. Seventeen radioactive deposits were prepared and studied. The conditions under which they were prepared are summarized in Table I. Samples 1-11 yielded deposits which were

light in color and typical of a normal zinc deposit and samples 15-17 were darker in color. Samples 12-14 were prepared from a plating bath that was aged for 3 months. The deposits in this case had a blackened appearance. Mössbauer emission spectra were obtained for frozen solutions of an unaged and an aged plating bath but no obvious difference was observed in the two spectra.

Deposition conditions were selected so as to give a very low cobalt content (samples 1-8) and a relatively high cobalt content (samples 9-17). A cobalt content of 0.5% (samples 9-11) represents the high end of the cobalt content of commercial material.

The cobalt content of equivalent nonradioactive deposits was determined by a method outlined by Okác (7). The zinc electrodeposit was dissolved in 0.025M H_2SO_4 and 10 ml of this solution was adjusted to pH 3.5. Approximately 10g of solid NH_4SCN was added to the solution in order to form the blue cobalt thiocyanate complex. The complex was extracted with 10 cm^3 of a diethyl ether-amyl alcohol mixture and the cobalt concentration was determined colorimetrically by comparison with a series of cobalt standards.

All Mössbauer spectra were obtained using $K_4[Fe(CN)_6] \cdot 3H_2O$ as an absorber, but the Mössbauer parameters are given relative to iron.

Experimental Results

Composition of the deposit.—The chemical analyses of the deposits from samples 1-8 yielded cobalt contents ranging from 0.008 to 0.014% with the higher values originating from the deposits formed at 60°. Calculations based on the radioactivity of the sample and the radioactivity of the solution confirmed that the cobalt content of the deposits was of the order of 0.01%. The data shown in Table I, although giving no quantitative information about absolute composition, do indicate that the cobalt content of the deposit from baths containing 10 g/liter of $CoSO_4 \cdot 7H_2O$ is not strongly a function of the current density.

The cobalt content of the radioactive deposits (samples 9-17) was not determined chemically. However, nonradioactive deposits were analyzed and the approximate concentration of the cobalt in the radioactive deposits was calculated from the radioactivity of the deposits, the radioactivity of the solution, and the ratio of radioactive cobalt/nonradioactive cobalt in the solution. The concentration of cobalt in samples 9-11 was thus approximately 0.5%; in samples 15-17 it was approximately 0.75%; and in samples 12-14 it was approximately 2%.

Table II. Correlation between the Co concentration and pH of the plating solution and the Co concentration in the electrodeposit. Plating conditions: 4 A/dm^2, 35°C

$CoSO_4 \cdot 7H_2O$ in the plating solution (g/liter)	pH of the plating solution	Measured Co concentration in dissolved Zn-Co electrodeposit, %
75	4.2	0.68-0.90
75	6	0.12-0.24
10	5	0.08-0.12
10	6	0.03-0.1

Although no extensive study was made of the effect of pH on the composition of the deposit, it was observed that the cobalt content of the deposit decreased with increase in pH as shown by the data in Table II.

Chemical nature of the cobalt in the electrodeposit.—Mössbauer spectra of all deposits were obtained in emission geometry. Representative spectra for samples 11 and 14 at room temperature are given in Fig. 1. It will be noted from an inspection of the Mössbauer parameters listed in Table III that the values of the isomer shift and the full width at half maximum are approximately the same for all deposition conditions. Aging samples containing 0.01% cobalt at room temperature for approximately 9 months did not cause any measurable change in the Mössbauer spectrum.

Sample 1 was heated for 6 hr at 300°C in a hydrogen atmosphere, cooled to room temperature in hydrogen, and the Mössbauer spectrum again obtained. Figure 2 shows the Mössbauer spectrum of the heat-treated specimen. It will be noted that the room temperature peak broadened considerably from 0.39 mm/sec to 0.74 mm/sec after heat-treatment.

Discussion

The Mössbauer data conclusively show that the electrodeposited cobalt is present in the metallic form on the basis of a comparison with the work of Dezsi *et al.* (8) and that of Qaim (9), both of which workers studied very dilute solutions of ^{57}Co in zinc formed by a diffusion process. Comparative values are listed below

	Isomer shift (mm/sec)	Quadrupole splitting (mm/sec)
This work	−0.49 (average value)	0.30-0.51 (range of values)
Qaim	not given	0.52
Dezsi *et al.*	−0.50	0.37

* Line in table differentiates experiments done at different times. Each set (1-8 and 9-17) are normalized to a different sample (No. 6 in upper set and No. 15 in lower set).

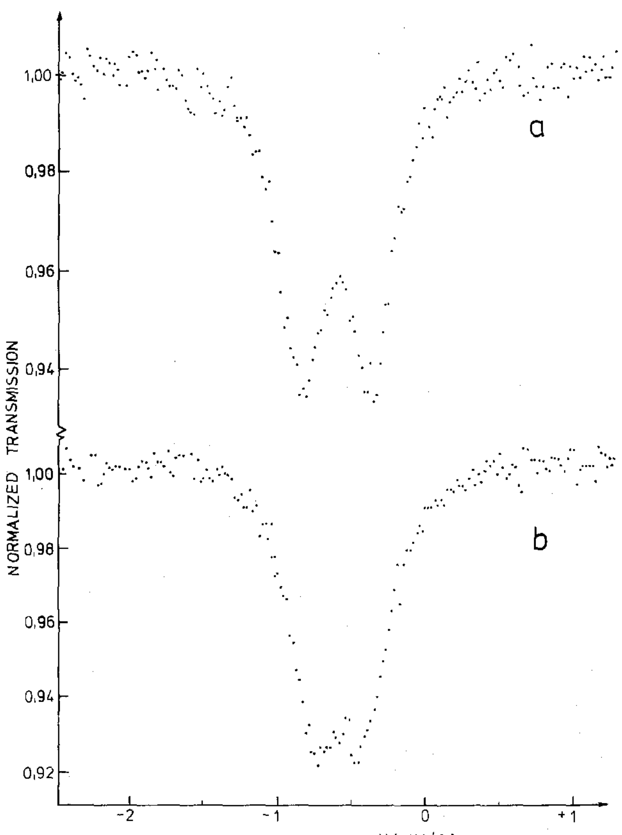

Fig. 1. Mössbauer emission spectra at room temperature of (a) sample No. 11 and (b) sample No. 14.

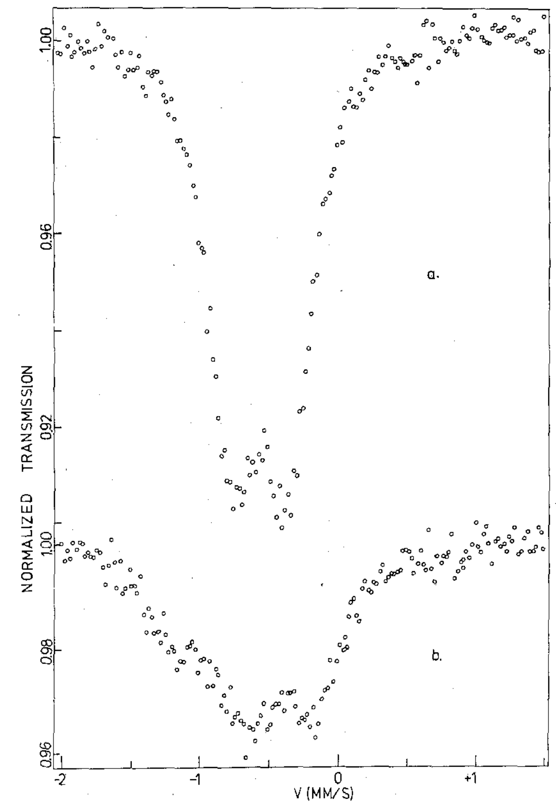

Fig. 2. Mössbauer emission spectra of sample No. 2: (a) before heat-treatment and (b) after heating for 6 hr at 300°C in a hydrogen atmosphere. Spectra were taken at room temperature.

The narrow linewidth (0.4 mm/sec) in the present work is indicative of the fact that the cobalt atoms occupy substitutional sites in the zinc matrix and that there is no clustering of the cobalt atoms. Comparable values for the linewidth for cobalt codeposited with gold have been observed by Cohen *et al.* (6) where the evidence was that cobalt atoms existed substitutionally at gold atom sites.

The research reported herein on zinc-cobalt alloys and the prior work on gold-cobalt alloys (5) provide excellent support for the concept that electrodeposition is a method for preparing supersaturated solutions in two-component alloy systems. The solubility of cobalt in zinc is less than 0.01% (10) and yet the Mössbauer spectra of the deposits containing 2% cobalt indicated solid solution, as opposed to phase separation.

As is noted from Table III, the values of the quadrupole splitting were different in the case of deposits containing 0.5-2% cobalt than those observed with the dilute alloys. The average values at the different concentrations were

Concn. of cobalt in zinc-cobalt alloy	Average Quadrupole splitting value
0.01%	0.40 mm/sec
0.5%	0.47
0.75%	0.32
2%	0.37

The range of values of the quadrupole splitting (0.3-0.5 mm/sec) obtained in the present study encompasses the values obtained by Dezsi *et al.* and by Qaim. It is probable that this range of values is real and is not reflective of imprecision in the experimental measurements. A survey of the data in Table III indicates that similar sets of samples, each prepared in a separate experiment, give approximately the same quadrupole splitting value. For example, samples 1-8 give a range of 0.39-0.42 mm/sec; samples 9-11 give a

Table III. Mössbauer parameters for zinc-cobalt electrodeposits

14	RT	−0.516 ± 0.002	0.326 ± 0.004	0.386 ± 0.008
15	RT	−0.516 ± 0.004	0.360 ± 0.006	0.40 ± 0.01
16	RT	−0.514 ± 0.003	0.377 ± 0.005	0.38 ± 0.01
17	RT	−0.504 ± 0.004	0.381 ± 0.007	0.37 ± 0.01

range of 0.44-0.51 mm/sec; samples 12-14 give a range of 0.30-0.33 mm/sec; and samples 15-17 give a range of 0.36-0.38 mm/sec. It also should be pointed out that the samples with quadrupole splitting values of 0.39-0.51 were zinc in color; those having values of 0.36-0.38 mm/sec were slightly darkened; and those having values of 0.30-0.33 mm/sec were black in color. In other words, there was a trend to lower values of the quadrupole splitting as the deposit became darker in color. At the present time, we consider it appropriate to point out these facts but insufficient information is available to give an interpretation.

The absence of any magnetic hyperfine splitting (hfs) in the spectrum taken at liquid nitrogen temperature provides additional evidence that the cobalt is not aggregated, at least in sufficient amount, to show magnetic behavior. This absence of hfs at liquid nitrogen temperature is a consequence of the fact that as the size of a ferromagnetic cobalt particle is reduced, the magnetic anisotropy energy becomes comparable in magnitude to the thermal excitation energy. The magnetization direction of the particle fluctuates rapidly and the lifetime approaches or becomes less than the lifetime of the excited state of the ^{57}Fe daughter. The net effect is that the hfs is not detected in the Mössbauer spectrum and only a quadrupole-split line is observed. No data on the effect of particle size on the hfs of cobalt particles in a zinc matrix are available. Krop and Williams (11) showed that hfs only occurred with cobalt particles in a copper matrix when the particle diameter was greater than 2.6 nm. Cohen *et al.* (12) studied cobalt particles in a gold matrix and found a good hfs spectrum when the particle diameter was 9 nm; they did not determine experimentally the minimum particle size at which the hfs spectrum disappeared.

Simmons (13) has carried out an extensive study of the Mössbauer emission spectra of a variety of cobalt oxides, hydroxides, and oxyhydroxides. Since it is reasonable to expect that such materials might be occluded in the deposit as a result of precipitation in the vicinity of the cathode, or migration as a colloid to the cathode, it is important to examine the possibility of their presence in the deposit. The presence of cobalt oxyhydroxide and cobalt cyanide complexes in gold deposits (5, 6) was an additional incentive to explore the likelihood of the occlusion of a cobalt compound in the deposit. Comparison of our Mössbauer parameters with the data of Simmons indicated that none of the oxygen-containing compounds was a reasonable candidate to explain the features of the spectrum.

The broadening of the absorption peak after heating the zinc-0.01%-cobalt deposit at 300°C in hydrogen probably results from a clustering of cobalt atoms. The cluster size should be very small at cobalt concentrations of 0.01% because of the absence of any hyperfine spectrum (Fig. 2b). The larger value of the half-width after heat-treatment is suggestive of a range of cobalt cluster geometries and sizes.

The conclusion reached herein that the cobalt is present in the zinc deposit as isolated atoms in substitutional sites in the zinc suggests that cobalt enters the oxide film on zinc during the corrosion process as an isolated atom or ion. Since it is known that metallic cobalt on the surface of zinc accelerates the corrosion of zinc in 3% NaCl solution (4), the absence of clustered cobalt atoms in the zinc electrodeposit is very favorable for corrosion inhibition.

Solution Redox Couples for Electrochemical Energy Storage

I. Iron (III)-Iron (II) Complexes with O-Phenanthroline and Related Ligands

Yih-Wen D. Chen, K. S. V. Santhanam,[1] and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Iron (III)-Iron (II) complexes with o-phenanthroline and related ligands have been examined by electrochemical techniques in aqueous H_2SO_4 media with respect to their suitability as redox couples for electrochemical energy storage. The iron (II) complexes undergo a rapid 1 electron oxidation at graphite and platinum electrodes to yield iron (III) complexes; these complexes showed varying stabilities depending on the nature of the substituents on the complexes. The iron (II) complexes examined in this study were formed with (*i*) monodentate, (*ii*) bidentate, or (*iii*) tridentate ligands. The redox couples have a higher E^o value which has been a positive consideration in the storage. Although the aquo iron (II)- iron (III) couple has an E^o less than the complexes, it certainly has shown greater promise in terms of storage stability. The kinetics of iron (II) complexation has been followed by cyclic voltammetry.

A redox flow cell (or battery) (1-8) is one in which the chemical species which participate in the electrode reactions are soluble. The cell is charged with the input of electrical energy to drive the overall cell reaction in a thermodynamically uphill direction and the oxidized species produced at an inert electrode in one half-cell and the reduced form from the other are stored in external vessels. Electricity is produced in these cells when the stored reactants flow back into the cell and react at the electrodes. Thus these cells are of interest as secondary or rechargeable batteries. The energy densities of these systems (*i.e.*, energy stored per unit weight of battery) suffer in comparison to more conventional secondary batteries which utilize solid reactants, because of the weight of the solvent and electrolyte. However, they offer the possibility of much better cycle life, since the repeated charge and discharge cycles do not involve phase changes and the accompanying changes of electrode morphology. These systems are of interest in stationary applications such as electrical energy storage and in utility load leveling.

Another related area involving soluble redox couples in energy devices is that of photoelectrochemical (PEC) (or liquid junction photovoltaic) cells with semiconductor electrodes (9). These cells, which are based on the light-driven redox processes of solution species at semiconductors, are of two types. In the PEC cell without energy storage, a single redox couple is employed, and the electrode reaction at the counterelectrode is the reverse of the photo-redox process at the semiconductor. In PEC cells with storage [types of photoelectrosynthetic cells (9)], the reactants formed during irradiation are stored and employed to generate electricity, in the same or a separate cell, during dark periods.

The redox couples for these applications, represented by the reaction in [1]

$$O + ne \rightleftarrows R \quad [1]$$

must satisfy a number of requirements: (*i*) both forms, O and R, must be highly soluble to minimize the storage volume and mass and to allow high mass transfer rates and current densities during charging and discharging; (*ii*) the formal potential, $E^{o\prime}$, of one couple must be highly positive, and $E^{o\prime}$ of the other highly negative to maximize the cell voltage and energy density; (*iii*) the heterogeneous reaction rate for the charging and discharging reactions at the inert electrodes should be rapid (*i.e.*, the standard rate constant, k^o, for [1] should be large) so that the electrode reactions occur at their mass transfer controlled rates; (*iv*) both O and R should be stable during generation and storage, and this stability pertains to reaction with solvent, electrolyte, atmosphere, and electrode materials, and, for metal complexes, stability with respect to ligand loss; (*v*) the materials should be safe, inexpensive, and abundant; (*vi*) the couple should not be corrosive and react with cell materials, or the storage vessel, indeed, in PEC cells the redox couple is often called upon to stabilize and protect the semiconductor electrode from photocorrosion (10, 11); and (*vii*) for PEC cells, the redox species should not absorb light in the wavelength region of semiconductor absorption.

A number of redox couples have been proposed for such systems. These include Fe(III)/Fe(II) (HCl) (5, 6); Cr(III)/Cr(II) (HCl) (4-6); Ti(IV)/Ti(III) (7); Br_2, Br^- (12-14); and, for PEC cells, S^{2-}, S_x^{2-} and Se^{2-}, Se_2^{2-} (15, 16). A difficulty in a storage cell is the possible intermixing of the components of the two half-cells, because of imperfect separators or membranes, which leads not only to loss of capacity and efficiency but more seriously to cross-contamination of the redox solutions. Approaches to minimizing this intermixing problem include the use of a single element system in three oxidation states [*e.g.*, Cr(VI), Cr(III)//Cr(III), Cr(II) (4)] or the use of two oxidation states of the same element with the redox potentials shifted by complexation with different ligands.

The work reported here, as well as other current investigations (1, 2), is concerned with the application of metal ion coordination compounds as redox

Key words: battery, voltammetry, solubility, chelates.

couples in flow cells. By suitable choice of ligand the formal potential of the couple can be shifted in the desired direction. Moreover such complexes may show improved characteristics with respect to stability and color in comparison to the uncomplexed species. The chemical principles related to the formation and properties of metal complexes are well developed and many new and potentially useful ligands have been reported. We describe here investigations of the Fe(III)/Fe(II) couple with ligands related to o-phenanthroline and bipyridine. Iron species were chosen for this initial investigation because iron is an abundant and inexpensive element with many highly soluble compounds. Such couples may be useful in the positive half-cell of redox flow systems or with n-type semiconductors in PEC cells.

Experimental

Reagents.—1,10-(or o-)phenanthroline (phen), 2,9-dimethylphenanthroline (2,9-dmp), 4,7-dimethylphenanthroline (4,7-dmp), and 4-methylphenanthroline (mp) were obtained from Alfa Chemicals. 2,2′-Bipyridine (bpy) was obtained from Aldrich Chemical Company. Tripyridine triazine (tpt), 4-cyanopyridine (cp), and 2-pyridine carboxaldehyde-2-pyridyl hydrazine (p-cph) were obtained from J. T. Baker Company. $FeSO_4 \cdot 7H_2O$ was reagent grade (Matheson, Coleman and Bell). Surfactants IGEPAL-Co430 (MW = 396) and 530 (MW = 484) were obtained from GAF Corporation (Atlanta, Georgia) and "Texas-1" (MW = 404) was made by Dr. Y. B. Youssef of The University of Texas. The former two surfactants carry ethylene oxide groups and the latter is the sodium salt of 8(p-phenyl sulfanato) hexadecane. All solutions were prepared with doubly distilled water and the solutions were degassed with prepurified gas that was passed through a chromous sulfate solution and then distilled water.

Apparatus.—A Model 173 potentiostat in combination with a Model 179 digital coulometer (Princeton Applied Research Corporation, Princeton, New Jersey) was employed for all electrochemical experiments. The current-voltage curves were recorded on a Houston Instruments Model 2000 X-Y recorder. The current time curves were recorded on a Model 564 storage oscilloscope (Tektronix) during potential-step chronoamperometry and on a National Panasonic strip-chart recorder during coulometric experiments.

Procedure.—The usual supporting electrolyte was aqueous H_2SO_4 prepared by suitable dilution of concentrated H_2SO_4. All solutions were degassed with nitrogen before the electrochemical experiments. The complexes were usually prepared directly in the electrochemical cell by mixing known concentrations of ferrous sulfate and the ligand. A mole ratio of ligand/Fe(II) of greater than 5 was used. Controlled potential electrolyses were conducted with a large area graphite sheet electrode (area, 6.5 cm^2) (Ultra Carbon, Sherman, Texas) with continuous nitrogen gas bubbling. Some of the electrochemical experiments were carried out in the dark. All of the potentials were measured with respect to an aqueous saturated calomel electrode (SCE). An H-cell with a porous sintered-glass disk separating the two compartments was used in coulometric investigations. For cyclic voltammetric investigations, a single compartment cell with a solution capacity of 5 ml was employed, with either platinum wire ($A = 0.12$ cm^2), platinum disk ($A = 0.14$ cm^2), or graphite rod (taken from a C-cell battery, area $A = 0.14$ cm^2) working electrodes. The platinum electrodes were pretreated by fast pulsing between +1.0 to −1.0V in H_2SO_4.

The solubilities of the complexes were estimated by dissolving the specified concentration of $FeSO_4 \cdot 7H_2O$ and an excess of ligand in 0.5M H_2SO_4. The complex formed would precipitate at this initial ion concentration. The precipitate was then just dissolved in the solution by adding 0.5M H_2SO_4 solution gradually. The concentration and the solubility were then estimated by the degree of the dilution of the solution (Table I). These measurements were done at room temperature.

The stabilities of ferrous and ferric complexes were monitored with a Cary 14 spectrophotometer. The ferric complexes were prepared either by electrochemical oxidation of the ferrous complexes or by Ce(IV) oxidation in H_2SO_4 medium.

Results

To shift the potential of the half-reaction

$$Fe^{3+} + e = Fe^{2+} \qquad [2]$$

toward values positive of the E^o (+0.77V *vs.* NHE), ligands which form more stable complexes with Fe(II) are required. Since Fe^{2+} (d^6) is a good π-donor cation, ligands with low-lying vacant π^* orbitals complex strongly with it (17). Fe^{3+} has poorer π-donor properties because of its higher charge. Thus ligands such as bpy and phen (Fig. 1) are known to shift the potential of the redox couple in a positive direction. Further manipulation of the potential is possible by substitution on the rings of these ligands. A number of highly stable complexes of these ligands are known (17). The structure and abbreviations for those ligands used in this study are shown in Fig. 1 and Table II.

Solubilities.—Table I is a list of the solubilities of the complexes in aqueous 0.5M H_2SO_4. Uncomplexed Fe(II) and Fe(III)-sulfate salts are quite soluble and yield solutions with metal ion concentrations ~1M. The solubility of the complexes vary with the nature of the ligand. The ligands themselves are soluble in acidic media to ~2M (*e.g.*, phen, 2,9-dmp). The complexes in 1M concentrations form solutions which are viscous and deeply colored. The uncomplexed Fe(II) and Fe(III) ions in H_2SO_4 are quite transparent in the visible region.

$E^{o\prime}$ values.—The formal potentials of the various Fe(II)/Fe(III) complexes were evaluated from the cyclic voltammetric peak potential values at low scan rates ($E_{pa} = E^{o\prime} + 0.028/n$) (see Table II). The complexes with cp, tpt, 2,9-dmp, and p-cph show more positive peak potentials, but the reversible potential values are difficult to estimate because of the instability of the ferric complex. The $E^{o\prime}$-values for the other ligands are all more positive than $E^{o\prime}$ for the aquo Fe (3+/2+) couple in H_2SO_4. In the phen-complexes substitution of methyl groups produces less positive peak potentials; while nitro- and chloro-group substitution yields more positive potentials compared to complexes with the unsubstituted ligand. Similar observations have been made by Fan and

Cyclic Voltammetric Measurements

Electron transfer kinetics.—Cyclic voltammetry (*cv*) was employed to survey a system with respect to heterogeneous electron transfer kinetics and stability of the Fe(III)-L species. Since the heterogeneous electron transfer rate constants, k^o, are all moderately large ($>10^{-3}$ cm/sec), at low scan rates, v, the electrochemical behavior (in the absence of fast following reactions) is characteristic of a Nernstian reaction and show ΔE_p-values $\sim$60 mV ($\Delta E = E_{pa} - E_{pc}$). When v is increased, shifts of E_{pa} and an increase in ΔE_p are observed signaling the onset of effects of the heterogeneous electron transfer rate (in the absence of uncompensated resistance effects) (19-21). Information about k^o can then be obtained from the variation of E_{pa} or ΔE_p with v using methods developed by Matsuda and Ayabe (19) and Nicholson (20). The approach taken here was to determine the value of ψ from the E_p-v behavior (assuming $\alpha \sim 1/2$), where

$$\psi = \frac{k^o}{\sqrt{\pi a D_{Fe^{++}}}} \qquad [3]$$

where $a = nFv/RT$ and $D_{Fe^{++}}$ is the diffusion coefficient of the Fe(II) ion in the medium employed. The diffusion coefficients of Fe(II) and Fe(III) were determined from the peak currents i_{pa} and i_{pc}. For the aquo-species in 0.5M H_2SO_4, $D_{Fe^{2+}} = D_{Fe^{3+}} = 2.5 \times 10^{-6}$ cm²/sec. Typical D-values for the complexed Fe(II) species determined by *cv* are listed in Table II. With these D-values and the measured ψ-values, k^o was obtained. These are also listed in Table II. For example, in a typical study with 10 mM Fe(II)-phen complex in 0.5M H_2SO_4, the *cv* wave showed $E_{pa} = 0.85$V and, on scan reversal, $E_{pc} = 0.79$V at $v = 50$ mV/sec. When v increased, ΔE_p increased, and at $v = 50$ V/sec, $\Delta E_p = 0.09$V; $v = 100$ V/sec, $\Delta E_p = 0.10$V; $v = 200$ V/sec, $\Delta E_p = 0.12$V; $v = 500$ V/sec, $\Delta E_p = 0.18$V. These measurements were made with full iR compensation. From these values, an average value of $k^o = 5.8 \times 10^{-2}$ cm/sec was obtained. With the Fe(II) coordination compounds only values for 0.5M H_2SO_4 are listed in Table II, since in 3M H_2SO_4 protonation of the ligands (with pK_a's $\sim$ 4-6) competes very strongly with complexation with Fe(II) and appreciable complexation does not occur.

Values of k^o for the Fe(3+/2+) couple in the absence of added ligand were also obtained in 0.5 and 3M H_2SO_4, yielding values of 1.6×10^{-3} and 1.2×10^{-2} cm/sec, respectively. Typical *cv* curves are shown in Fig. 2. The electrochemical oxidation of Fe(II) in aqueous H_2SO_4 has been previously investigated at platinum and carbon paste electrodes (22, 23). The results are in general agreement with those found here. The rate of the electrode reaction appears to depend on the concentration of the acid as well as the nature of the electrode surface (*e.g.*, the presence of oxide films). However, the coordinated species generally have larger k^o-values than the aquo-species under similar conditions (0.5M H_2SO_4).

Stability (cv).—Stability of the coordination compound and the product of the electrode reaction can also be monitored by *cv*. Consider the oxidation of FeL_x^{2+}. The observed *cv* behavior depends on the ligand, L, and the tendency of FeL_x^{3+} formed during the anodic sweep to decompose (Fig. 3). During the time scale of the *cv* sweep the Fe(III) complexes with phen (or bpy) and tp are stable while that with cp is not. In the latter case oxidation of the stable Fe(II) complex leads to the Fe(III) form which decomposes rapidly, probably by loss of ligand to form a different Fe(III) species. The general reaction sequence is thus

$$FeL_x^{2+} \overset{k^o}{\rightleftharpoons} FeL_x^{3+} + e \qquad [4]$$

$$FeL_x^{3+} \xrightarrow{k_f} FeL_{x-y}^{3+} + yL \qquad [5]$$

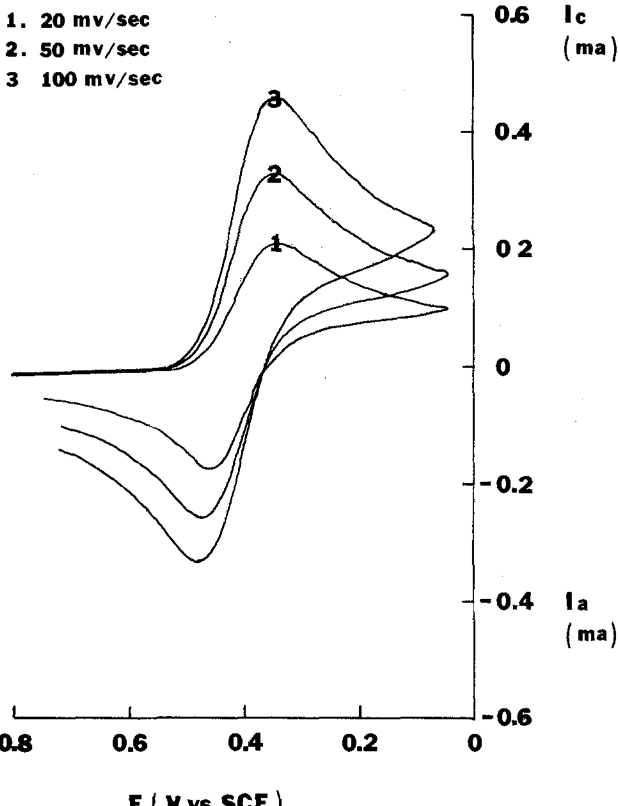

Fig. 2. (b) The current-voltage curve after controlled potential exhaustive electrolysis at +0.80V in 0.5M H_2SO_4.

(for simplicity, the state of protonation of the ligand is not indicated in the equations). Instability on the *cv* time scale for v up to 50 V/sec was also found for 2.9-dmp and several other ligands, as indicated in Table II.

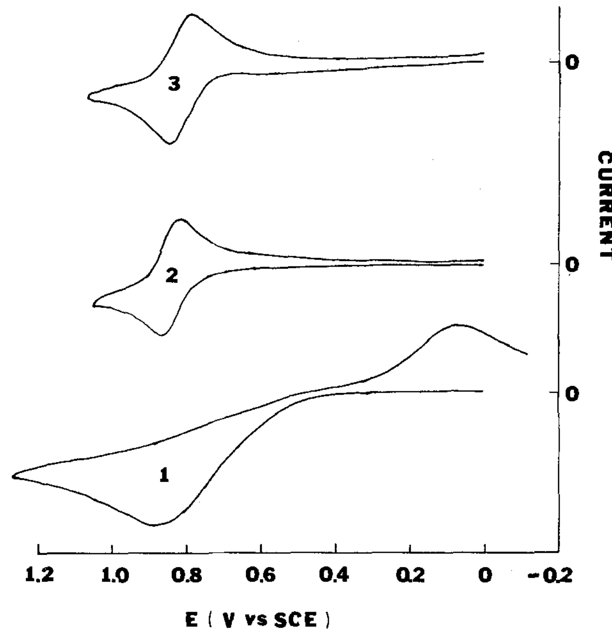

Fig. 3. Cyclic voltammetric curves for Fe(II) ion coordinated with: 1, monodentate (cp); 2, bidentate (bpy); 3, tridentate (tp) at graphite electrode. Solution contained 10 mM aquo Fe(II) ion and at least 50 mM ligand. v = 0.05 V/sec.

The rate of formation of the Fe(II)-ligand complexes was also of interest and this was determined by *cv* for complexes with bpy, phen, 4,7-dmp, and tp. In all cases the Fe(III) complex is thermodynamically unstable in 0.5M H_2SO_4, although it is kinetically inert so that it decomposes to Fe^{3+} and free ligand quite slowly. Thus if one prepares a solution containing a mixture of free Fe^{3+} and L essentially no complexation occurs. Upon reduction of the Fe^{3+} to Fe^{2+} rapid reaction with L takes place so that on scan reversal oxidation of Fe(II) occurs both as free Fe^{2+} and as FeL_x^{2+}, *i.e.*, the reaction sequence is

$$Fe^{3+} + e \overset{k^{o\prime}}{\rightleftharpoons} Fe^{2+} \quad [6]$$

$$Fe^{2+} + xL \xrightarrow{k_f'} FeL_x^{2+} \quad [7]$$

$$FeL_x^{+2} \overset{k^{o}}{\rightleftharpoons} FeL_x^{3+} + e \quad [8]$$

Typical results for a solution containing 5 mM Fe^{3+} and 300 mM phen in 0.5M H_2SO_4 at a Pt electrode are shown in Fig. 4. Note that at very slow sweep rates (v = 20 mV/sec) the anodic peak for Fe^{2+} oxidation following Fe^{3+} reduction is barely detectable, while the $Fe(phen)_3^{2+}$ oxidation wave is fully developed. At higher sweep rates i_{pa} for Fe^{2+} oxidation increases and the $Fe(phen)_3^{2+}$ oxidation wave becomes relatively smaller. At very high sweep rates (v = 100 V/sec) only the Fe^{2+} oxidation is observed with the same general characteristics as the uncomplexed Fe^{3+} couple in the absence of phen at this v. The rate constant, k_f' for Fe^{2+} disappearance can be estimated from the ratio of i_{pa}/i_{pc} for the $Fe^{3+/2+}$ couple. Typical data for the *cv* of these complexes is shown in Table III along with the rate constants obtained using the treatment of a second-order following (EC) reaction (24). Since the ligand concentrations are high, the EC reaction is essentially pseudo-first order and the treatment of this EC-reaction scheme (25) also applies. The calculated values of k_f' are based on the free ligand concentration, [L], at the given H_2SO_4 concentration which is in equilibrium with the various protonated forms. The pK_a values employed in calculation of [L] were:

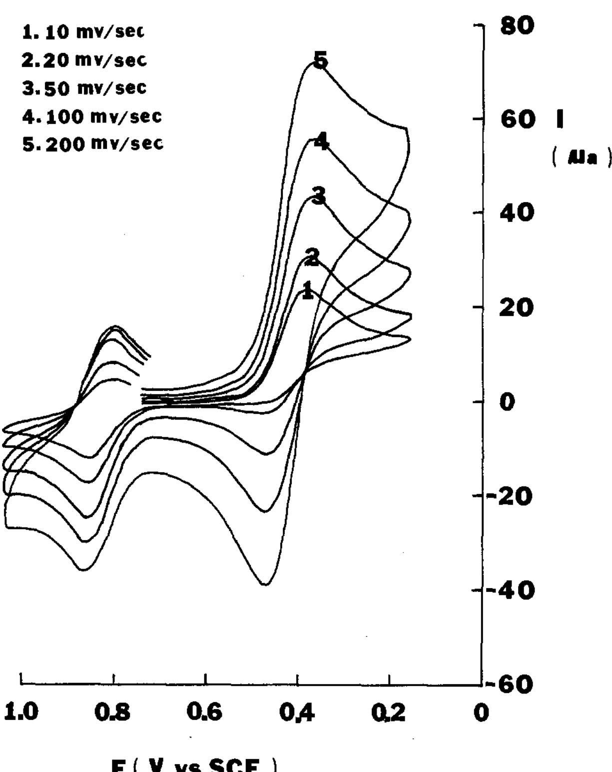

Fig. 4. Cyclic voltammetric curve for 5 mM Fe(III) reduction in the presence of phenanthroline (300 mM) at a platinum electrode.

bpy, pK = 4.47; phen, pK = 4.98; tp, pK_1 = 2.64, pK_2 = 4.33 (26, 27). The k_f'-values obtained by this procedure are listed in Table II.

A digital simulation of current-voltage curves was carried out for the reduction of Fe(III) in the presence of the ligands. In this simulation the following mechanism was assumed. Reaction [6] was followed by

$$Fe^{2+} + L \rightleftharpoons FeL^{2+} \quad [9]$$

$$FeL^{2+} + L \rightleftharpoons FeL_2^{2+} \quad [10]$$

$$FeL_2^{2+} + L \rightleftharpoons FeL_3^{2+} \quad [11]$$

and reaction [8], where k^o and $k^{o\prime}$ are heterogeneous electron transfer rate constants. If [9] is taken as the rate-determining step and neglecting dissociation rate, the simulated curves are nearly identical to the experimental one as shown in Fig. 5. The small discrepancy for the Fe^{3+} reduction wave might be due to the onset of background reduction. The second oxidation wave (that of FeL_3^{2+}) and its corresponding reversal reduction wave might also be perturbed by the occurrence in homogeneous solution of the reaction

$$Fe^{2+} + FeL_3^{3+} \xrightarrow{k''} Fe^{3+} + FeL_3^{2+} \quad [12]$$

Although the Fe^{2+} concentration in the vicinity of the electrode at the potentials of these waves is small, this reaction is known to be rapid, k'' = 2.2 × 10^5 M^{-1} sec^{-1} for L = bpy in 0.5M H_2SO_4 (28). The inclusion of this reaction in the simulation did not affect the observed i-E curves for k''-values up to 10^4 M^{-1} sec^{-1}. Within the number of iterations used in the simulation explicit values of k'' higher than this could not be employed. However, even if k'' is assumed to be at the mass transfer controlled limit, so that Fe^{2+} and FeL_3^{3+} cannot coexist in a simulation space element, the effect of the i-E curves, shown as dashed lines in Fig. 5, is small.

It is interesting to compare these results of complexation of Fe^{2+} by bpy with those obtained by stopped flow methods (29), where a second-order

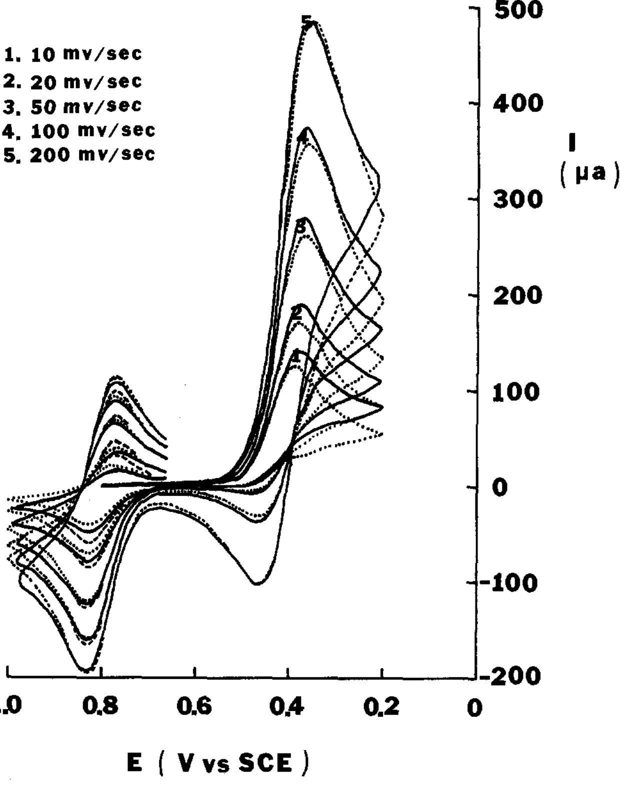

Fig. 5. Digital simulation for the ECE process of the ferric-bipyridine system in 0.5M H_2SO_4. (——) Experimental curves; digital simulation curves (- - -) assuming infinite rate of reaction [12] and (···) assuming rate of reaction [12] = 0. $C_{Fe^{3+}}$ = 20 mM, C_{bpy} = 300 mM, k_{app} = 2.5 M^{-1} sec^{-1}; $D_{Fe^{3+}}$ = 2.5 × 10^{-6} cm^2/sec, $D_{Fe(bpy)_3^{3+}}$ = 2.6 × 10^{-6} cm^2/sec. Area of platinum electrode = 0.148 cm^2.
$E^{o\prime}(Fe^{3+,2+})$ = 0.41V, $E^{o\prime}(Fe(bpy)_3^{3+,2+})$ = 0.80V, $\alpha(Fe^{3+,2+})$ = 0.5, $\alpha(Fe(bpy)_3^{3+,2+})$ = 0.5, $k_s(Fe^{3+,2+})$ = 1.61 × 10^{-3} cm/sec, and $k_s(Fe(bpy)_3^{3+,2+})$ = 5.64 × 10^{-2} cm/sec.

rate constant of $2.8 \times 10^4\ M^{-1}\ sec^{-1}$ at 0.2°C was reported. This rate constant was assigned to the first step in the complexation formation of $Fe(bpy)^{2+}$ (reaction [9]). The addition of the second and third bpy ligands is faster; for the third step the rate constant is $1.4 \times 10^5\ M^{-1}\ sec^{-1}$, while for phen the rate of addition of the third ligand is $1.5 \times 10^6\ M^{-1}\ sec^{-1}$ (29). The medium and temperature effects on the dissociation rates of the bpy and phen complexes have been investigated by Basolo *et al.* (30).

Controlled Potential Coulometric (cpc) Measurements

The long term stability and current efficiency for the processes on cycling were investigated by controlled potential electrolysis techniques. The oxidation of Fe^{2+} in the uncomplexed form carried out at 0.2V past the anodic *cv* peak showed an n_{app} (faraday/mol) of 0.98-1.00. The current decayed smoothly to the background value and a plot of log *i* *vs.* *t* yielded a straight line (31) (Fig. 6). Reversal electrolysis, reduction of the electrogenerated Fe^{3+}, carried out at ~0.10V, consumed essentially the same number of coulombs as in the forward electrolysis. These experiments were carried out at concentrations up to 1M and electrolysis times of ~0.5 hr.

Oxidation of Fe(II)-complexes with bpy, phen, 2,9-dmp, and tp were carried out at 1.0V vs. SCE at a graphite electrode. In all cases the oxidations consumed 0.95-1.00 faraday/mol (see Table IV) and the current-time curve decayed smoothly to background. For electrolysis times ~1.0 hr, reversal electrolysis of the solution at 0.10V consumed about the same number of coulombs as the forward electrolysis. Repetitive electrolysis, cycling between the oxidized and reduced forms four times at 0.5 hr intervals produced similar results.

To examine the lifetime of the complex Fe(III) species, *cv* experiments were undertaken on solution following cpc oxidation. For ordinary cpc electrolysis of 30 min to 1 hr duration, *cv* showed reduction waves of height and location consistent with the presence of FeL_x^{3+}. However, when these solutions were allowed to stand for times of 10-20 hr (Fig. 7), *cv* revealed that i_{pc} for FeL_x^{3+} reduction decreased and a wave for uncomplexed Fe^{3+} appeared. Thus a slow decomposition of the FeL_x^{3+} species (L = bpy, phen, mp, 4,7-dmp) does occur. The rate of decomposition of the FeL_x^{3+} was determined by spectrophotometry, as described below.

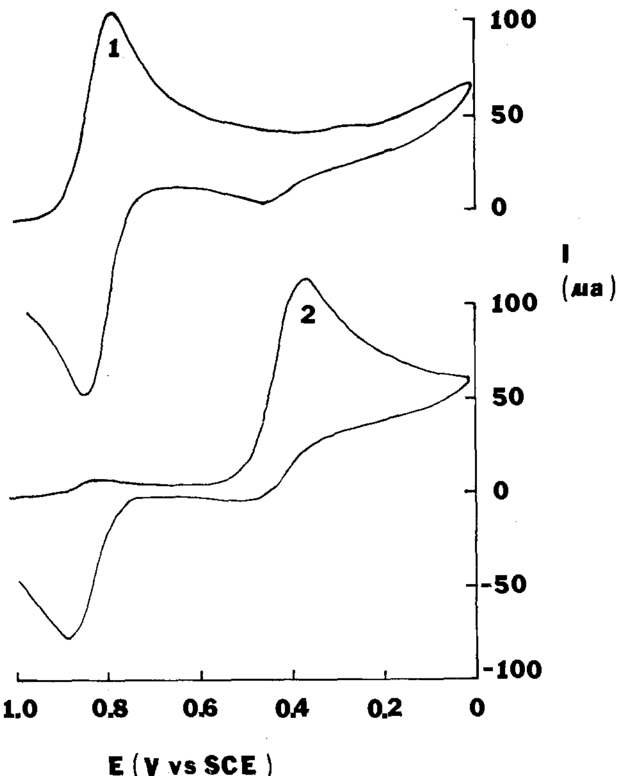

Fig. 7. Stability of Fe $(phen)_3^{3+}$ in 1*N* H_2SO_4. Upper curve: cyclic voltammetric curve for 10 mM Fe $(phen)_3^{2+}$ immediately after controlled potential electrolysis at +1.0V at graphite electrode. Lower curve: cyclic voltammetric curve of the same solution after standing 24 hr in air.

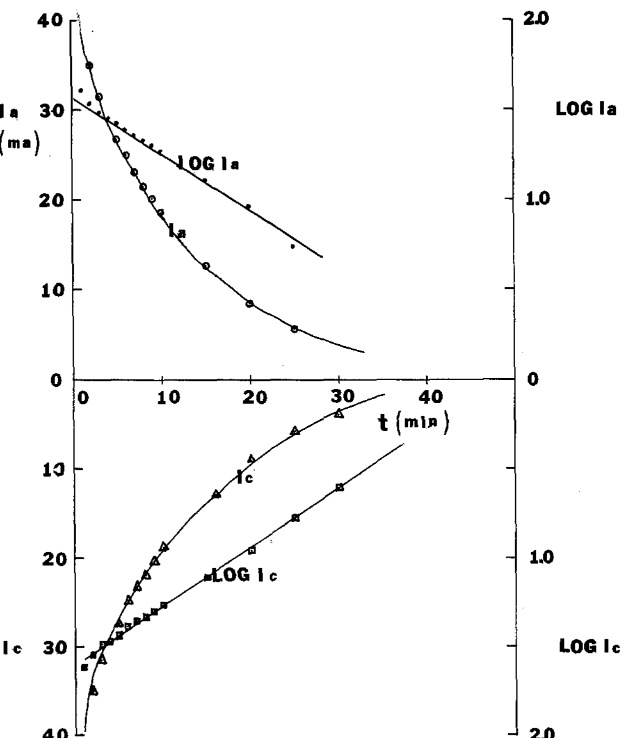

Fig. 6. Current-time curve during exhaustive electrolysis of 10 mM Fe $(phen)_3^{2+}$ in aqueous H_2SO_4 at a graphite working electrode.

Stability of Fe(III) Species

Since the long duration storage capabilities of these systems appear limited by the stability of FeL_x^{3+}, measurements of the rate of decomposition of the Fe(III) species and some attempts at stabilization were carried out. The stability of Fe(III) complexes were examined spectrophotometrically. The Fe(III) complexes were formed by chemical oxidation by mixing millimolar concentrations of Fe(II) complexes and excess Ce(IV) sulfate in 0.5M H_2SO_4 and monitoring the disappearance of the Fe(III) complex absorption (32). The rate constants for the first-order decay of the FeL_x^{3+} species, k_f, are listed in Table V. Substitution of a methyl group on phen more than doubles the half-life with 4,7-dmp being the most stable of the complexes examined. The 2,9-dmp complex is very unstable, because in this case the placement of the methyl groups produces steric hindrance to bonding between the Fe(III) and the phenanthroline nitrogens.

The background medium also appears to play a role in the rate of decomposition of Fe(III) complexes. Thus $Fe(phen)_3^{3+}$ is reported to be stable in high concentrations of H_2SO_4 (22, 23). We found, in bulk electrolysis experiments with the complexes, that the stability was decreased in H_2SO_4 solutions at a *p*H of ~1, compared with 0.5M H_2SO_4. The stability of Fe(II) and Fe(III) complexes has been studied previously (33, 34). The general conclusions are that the instability of the complex can be attributed to nucleophilic attack by water, resulting in replacement of the ligands by water molecule. The exact nature of

the intermediate complex is not clear. Some authors (35) favor the reaction sequence

$$FeL_3^{3+} + H_2O \rightleftharpoons FeL_2(L \cdot H_2O)^{3+} \quad [13]$$

$$FeL_2(L \cdot H_2O)^{3+} \rightleftharpoons FeL_2(L \cdot OH)^{2+} + H^+ \quad [14]$$

In our studies we observed the formation of free Fe^{3+} in 0.5M H_2SO_4 from FeL_x^{3+} upon standing for long duration, even in the presence of excess ligand. This demonstrated that total replacement of the ligand by H_2O eventually occurs, *i.e.*

$$FeL_3^{3+} \rightleftharpoons Fe^{3+} + 3L \quad [15]$$

(where L = phen, bpy). When excess ligand is not present, a cathodic peak at +0.10V appears on standing, which might represent dimeric species such as a bridge complex formed (18) by the following reaction

$$2FeL_3^{3+} + 3H_2O \rightleftharpoons Fe_2L_4O(H_2O)_2^{4+} + 2H^+ + 2L \quad [16]$$

* Measurements were made at graphite electrode in the same medium used for controlled potential electrolysis.

Since attack by water causes decomposition of the Fe(III) species, blocking of the central metal ion by a hydrophobic environment or decreasing the water activity in the bulk solution may improve stability. Indeed the improved stability of the 4-mp and 4,7-dmp may partially represent such an effect, although the electron-donating properties of the methyl groups may also play a role. Attempts at providing a more hydrophobic environment were made by introducing various surface active agents and monitoring the concentration of the Fe(III) complex by *cv*. Results for the $Fe(bpy)_3^{3+}$ complex are shown in Fig. 8 in 0.5M H_2SO_4 solutions containing butanol, heptanol, and the surfactant IGEPAL. Considerable improvement was noticed with 1-butanol in the medium. The abrupt changes in cyclic voltammetric peak current in the presence of a few surfactants (*e.g.*, curve 8) occurs when phase separation takes place.

Electrolysis of Fe(II) complexes was also conducted in the presence of 1M $AlCl_3$ or 1M $MgSO_4$ or saturated solutions of Li_2SO_4. The decay of the Fe(III) complex concentration was noticed even in the presence of the above salts. When saturated solutions were used, the solutions became viscous and the

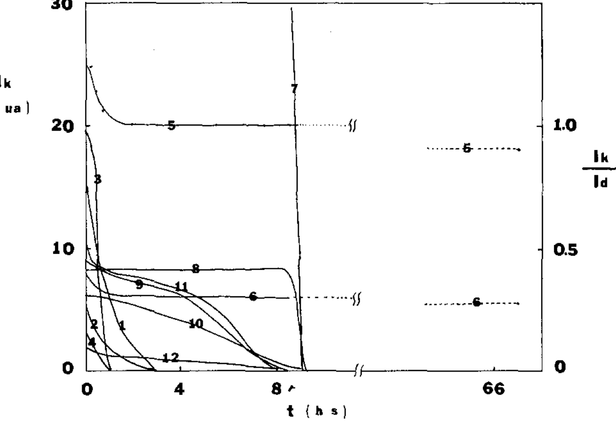

Fig. 8. The decay of Fe(III)-bpy complex in 1*N* H_2SO_4 in the presence of stabilizing agents. The Fe(III)-bpy complex was obtained by controlled potential electrolysis of Fe(II)-bpy complex. i_k = cyclic voltammetric peak current after controlled potential electrolysis (cathodic peak at +0.80V) i_d is the diffusional peak current. i_k = 1, 3, 5, 7, 9, and 11 and i_k/i_d = 2, 4, 6, 8, 10, and 12, i_k (t = 0) = 36 μA for line 7. 1, 2 = No stabilizer; 3, 4 = Texas-1 (excess); 5, 6 = 5 ml 1-butanol; 7, 8 = IGEPAL Co-430; 9, 10 = IGEPAL Co-530; 11, 12 = 1-heptanol.

duration of electrolysis was very long; with Li_2SO_4 saturated solution in 0.5M H_2SO_4, electrolysis of 12.6 mmols $Fe(phen)_3^{3+}$ took about 4 hr. At the end of electrolysis, a cathodic peak at 0.31V for free Fe(III) was observed in the cyclic voltammograms.

Discussion

Aquo Fe(II)/Fe(III) couple in 6*N* H_2SO_4 appears to be well suited as a redox positive couple for an extended period of time and appears to meet the major requirements of stability, solubility, fast electron exchange, and high electrical conductivity in the acid medium. A measurement of electron transfer rate constant in the 2*N* HCl medium was undertaken to compare it with H_2SO_4 medium. At platinum disk or graphite electrodes, an average of five measurements gave k^o values of 1.9×10^{-3} and 1.34×10^{-3} cm/sec, respectively. These values are slightly smaller than the value obtained in H_2SO_4 (see Table I). However, a disadvantage of using HCl medium is the somewhat less positive background limiting potential value compared with H_2SO_4 (22). An advantage of H_2SO_4 medium over Cl for PEC cells is the lighter colors of the Fe(II) and Fe(III) species in this medium.

Complexation of Fe(II)/Fe(III) couple can provide higher $E^{o\prime}$-values [*e.g.*, 1.07V for np compared to 0.53V (*vs.* SCE)] and faster electrode kinetics. The solubility of the complexes is approximately the same as uncomplexed Fe(II) or Fe(III). While the Fe(II) complexes are highly stable over days in the absence of O_2, Fe(III) complexes decay in the medium employed by loss of ligand (see Fig. 7). This process results in loss of stored energy since the redox couple so produced is at a less positive potential. However, this loss is slightly compensated by the fast complexation of Fe(II) by ligand during a discharge cycle. Note that if the rate of complexation of Fe(II) were rapid enough, the Fe(III) reduction wave would shift to potentials near those for the oxidation of the complexed Fe(II) species.

Conclusions

The results here describe how coordination of the central metal ion can affect the potential and the kinetics of the electrode reaction to produce systems which might be utilizable in redox flow batteries. The aquo iron (3+/2+) system in H_2SO_4 appears to be an alternative to the iron (3+/2+) system in HCl media currently under investigation. Complexation with phenanthroline or bipyridyl-type ligands results in significant positive shifts in the potential of the redox couple. The solubility of these couples appears satisfactory, but instability of the ferric form results in partial loss of capacity upon long-term storage.

On Fitting Error Functions to Data

R. Ghez* and M. B. Small*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Error functions, which offer solutions to a wide variety of diffusion problems, contain unknown physical parameters in a nonlinear way. We propose a simple iterative method that takes advantage of the geometry of these functions. The method rests on simple analytic relations between the parameters and the first two moments of the distribution. The requisite numerical integrations do not add noise to the data as do methods that estimate slopes. Our method is applied to measured profiles in LPE (GaAl)As. It is simple, efficient and accurate.

Statement of the Problem

Fitting a given function to experimental data is difficult when that function is nonlinear in the unknown parameters. The usual method consists in fitting data in asymptotic regions where the function might have a simpler form, presumably linear in these parameters. This is hazardous both because one must choose, somewhat arbitrarily, what data points to retain, and because these points are often subject to larger experimental uncertainties than those which were deleted. Of course, one can use nonlinear least squares procedures (1), but their application is sometimes nothing short of an art.

Contrary to the above methods that seek to pass a "best" curve through the data, we propose a method that takes advantage of the geometric properties of the function to be fitted. In particular, our method computes areas rather than slopes, a procedure that smoothes data rather than enhancing the noise. We develop the method for error functions of the form

$$x(z,t) = x_0 \frac{\operatorname{erfc}\,[z/2(Dt)^{1/2} - \beta]}{\operatorname{erfc}\,(-\beta)} \quad [1]$$

and apply it to measured Al profiles in LPE-processed $Ga_{1-x}Al_xAs$ wafers (2). Here, z is the distance into the wafer, t is the processing time, x is the mole fraction of AlAs, x_0 is the surface concentration, D is the diffusivity, and β is a constant proportional to the growth rate. The function [1] is linear in x_0, but it is nonlinear in both D and β. This function is also representative of a large class of similarity solutions of the Stefan Problem.

We note that our method is only applicable when it is otherwise known that the experimental data are correctly described by a given functional form such as Eq. [1]. In the present case, this means that some underlying theory (3, 4) predicts error function behavior, and that the parameters x_0, D, and β are truly constants. In particular, since we develop no measure of "goodness of fit," it is not as yet possible to discriminate between competing functional forms (*i.e.*, theories) for a given set of data.

Solution of the Problem

When the solid grows ($\beta > 0$), the function [1] has the appearance shown on Fig. 1; it has an inflection point characteristic of sharp junctions. One shows easily that this inflection has the coordinates

$$z_i = 2\beta(Dt)^{1/2} \quad [2a]$$

$$x_i = \frac{x_0}{\operatorname{erfc}\,(-\beta)} \quad [2b]$$

Moreover, the total area A under the curve is

$$A = \int_0^\infty x(z,t)\,dz = 2x_0(Dt)^{1/2} \frac{i^1 \operatorname{erfc}\,(-\beta)}{\operatorname{erfc}\,(-\beta)} \quad [3a]$$

where $i^n \operatorname{erfc}\,(\bullet)$ is the nth iterated error function (5). Likewise, the area A_i reckoned from the inflection point forward is

$$A_i = \int_{z_i}^\infty x(z,t)\,dz = \frac{2x_0}{\operatorname{erfc}\,(-\beta)}(Dt/\pi)^{1/2} \quad [3b]$$

Finally, the centroid $\bar{z}$ of the distribution is

$$\bar{z} = A^{-1}\int_0^\infty z\,x(z,t)\,dz = 2(Dt)^{1/2}\frac{i^2 \operatorname{erfc}\,(-\beta)}{i^1 \operatorname{erfc}\,(-\beta)} \quad [3c]$$

The idea of the method is now very simple. If one eliminates $(Dt)^{1/2}$ from Eq. [3] by using Eq. [2a], then these are three equations in the three unknowns x_0, z_i, and β, in terms of the three measurable quantities A, A_i, and $\bar{z}$. Equation [2a] then yields the diffusivity D. Now the quantities A, A_i, and $\bar{z}$ are reckoned by numerical integration over the experimental data, to which one adjoins the estimated initial and inflection points, $(0, x_0)$ and (z_i, x_i). The process can then be iterated.

Simplified formulas obtain when the growth constant β is large. In fact, for $\beta \gtrsim 2$, the following asymptotic expansions hold to better than 1%

$$\operatorname{erfc}\,(-\beta) \sim 2 \quad [4a]$$

$$i^1 \operatorname{erfc}\,(-\beta) \sim 2\beta \quad [4b]$$

$$i^2 \operatorname{erfc}\,(-\beta) \sim \beta^2 + 1/2 \quad [4c]$$

Terms neglected in Eq. [4] are of order $\exp(-\beta^2)$. In

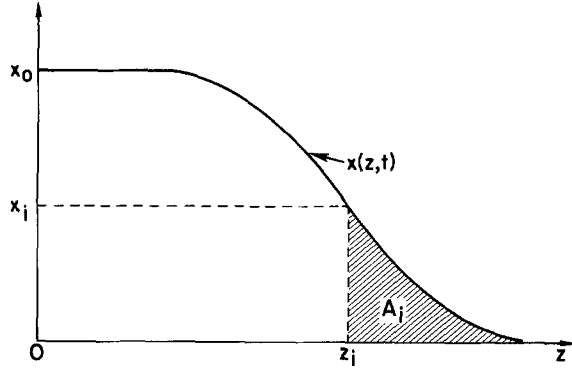

Fig. 1. Schematic of the error function profile, Eq. [1], for positive values of the growth constant β. It displays the relevant geometrical features: Inflection point, surface concentration, and area beyond the inflection.

* Electrochemical Society Active Member.

Key words: data-fitting, error function, diffusion coefficient.

this case, Eq. [3] become simply

$$A = x_o z_i \quad [5a]$$

$$A_i = \frac{x_o z_i}{2\pi^{1/2}\beta} \quad [5b]$$

$$\bar{z} = \frac{z_i}{2}\left(1 + \frac{1}{2\beta^2}\right) \quad [5c]$$

and these are invertible algebraically to give the unknowns

$$x_o = A/z_i \quad [6a]$$

$$\beta = A/2\pi^{1/2} A_i \quad [6b]$$

$$z_i = 2\bar{z}/[1 + (2\beta^2)^{-1}] \quad [6c]$$

Our iterative procedure begins with an initial guess of x_o and z_i. One then adjoins the estimated initial point $(0, x_o)$ and inflection point $(z_i, x_o/2)$ to the experimental data. Next, one evaluates numerically the areas A and A_i, and the centroid $\bar{z}$; in practice the trapezoidal rule is sufficient. These values are inserted into Eq. [6] to give new values of x_o and z_i, and the process can be repeated. At each iteration one can compute the diffusivity D and the growth constant β according to Eq. [6b] and [2a]. This procedure is illustrated in the next section.

Numerical Results

Figure 2 shows three Al profiles obtained by SIMS measurements. The open symbols correspond to the experimental data; the closed ones stand for the computed values of the surface concentrations and inflection points. Because of a longitudinal temperature gradient in the furnace, these profiles correspond to different undercoolings between a single wafer and its solution. The processing time t was 309 sec. The experiment has been fully described and analyzed elsewhere (2), and a review of ternary III-V LPE is also available (6). We note that the data appear to have the shape of Fig. 1, but that data points are quite sparse, particularly in the neighborhood of the inflection point. This experiment provides therefore an ideal test of our method.

We purposely choose a "bad" initial guess: $z_i = 350$, 250, and 110 nm for the positions of the inflection points, and $x_o = 0.9$ for the surface composition of all three profiles. Figures 3 and 4 show how the growth constant β and the diffusivity D converge as a function of the number of iterations. The symbol code on these figures is the same as that of Fig. 2 and Table I. We find that at most 15 iterations are sufficient to ensure a relative error less than 1%. As was also noted elsewhere (2), the diffusivity D of Al in (GaAl)As increases with decreasing growth constant β. This was even more noticeable (2) for dissolving crystals ($\beta < 0$). Table I shows the final value, after 15 iterations, of all the variables we have been discussing: The measured values A, A_i, and $\bar{z}$, and the unknown parameters x_o, β, and D. We also list the final abscissa z_i of the inflection point. We emphasize that the estimation of all these quantities never required numerical differentiation of the experimental data. The solid lines on Fig. 2 correspond to the function [1] computed with these values of the parameters. The fit is excellent, particularly in view of the sparseness of the data.

The method we have presented is heuristic in the sense that we attempted no investigation of its convergence. However, it is presumably a one-point iteration method (1) of the form $x_{n+1} = \phi(x_n)$, whose properties are well known. It is also obvious that similar procedures could be devised for other functional forms different from error functions.

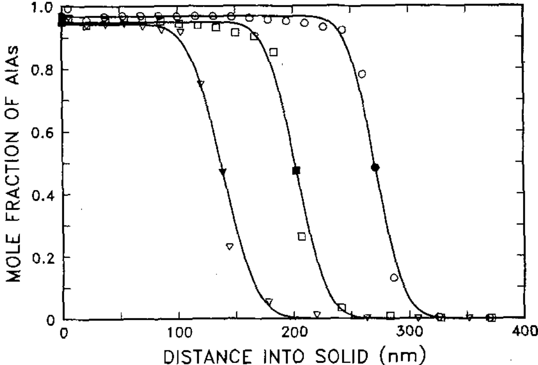

Fig. 2. Three profiles in (GaAl)As obtained by SIMS (2). The open symbols represent the experimental data, the closed symbols are the computed inflection points and surface concentrations, and the solid lines show how Eq. [1] fits the data.

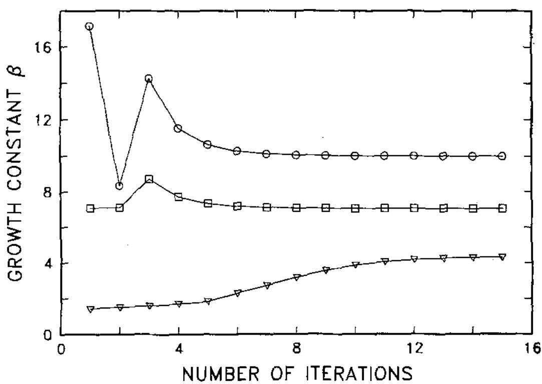

Fig. 3. The growth constants β in Eq. [1] as a function of number of iterations for the three profiles of Fig. 2. The symbol code is the same as in that figure. The deepest profile has the largest β, i.e., the growth rate was largest here.

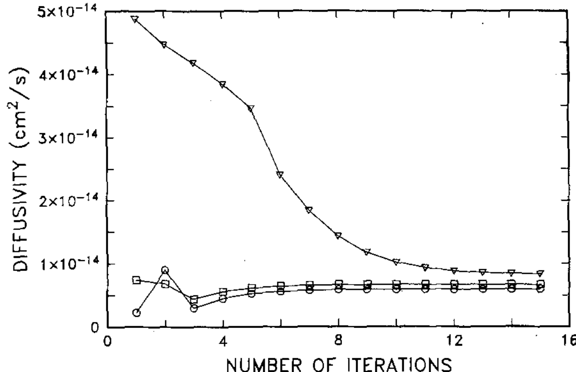

Fig. 4. Same as Fig. 3 for the diffusivity D of Al in (GaAl)As. Comparing Fig. 3 and 4, one sees that D increases as the growth rate decreases.

Table I. Shows the final computed values, after 15 iterations, of the measured quantities and the unknown parameters. The numbers are accurate to at least two decimal places.

The Cathodic Cleavage of Ethanetetracarboxylate Esters

Donald A. White[1] and John H. Wagenknecht*

Monsanto Company, Corporate Research and Development Staff, St. Louis, Missouri 63166

ABSTRACT

The electrochemical reduction of tetramethyl ethane-1,1,2,2-tetracarboxylate to dimethyl propanedioate (dimethyl malonate) and the similar cleavage of some substituted and some cyclic analogs are reported.

The cleavage of carbon-carbon single bonds is an unusual, though not unreported (1-4), phenomenon in cathodic processes. *A priori* facile cleavage might be expected when the carbon atoms bear substituents likely to stabilize carbanionic intermediates. Ethanetetracarboxylate esters (**1**, **3**) are a very favorable case, but their electrochemical reduction has not been reported previously. Furthermore, there is only a single example of a similar chemical reaction, and this uses sodium metal in a mixture of liquid ammonia and tetrahydrofuran as the reducing agent (5). The results reported here provide a more convenient way of carrying out such reactions as well as establishing their generality by the presentation of several examples.

Experimental

Reagents.—Dimethylformamide (DMF) and tetraethylammonium perchlorate were obtained from Fisher Scientific Company, Fairlawn, New Jersey. The former was used as supplied. The latter was recrystallized from water, then from methanol before use. Literature procedures were used for the preparation of **1a**, **1b**, **3** (6), and **1c** (7, 8).

Equipment.—A Varian 3700 gas-liquid chromatograph fitted with a thermal conductivity detector and with a stainless steel column (0.32 × 50 cm) packed with 5% OV101 on Chromosorb G-HP (100/120) was used for the analysis of reaction mixtures. The ^1H-NMR spectra of the products were obtained using a Varian EM-390 spectrometer. The power supply for preparative electrolyses was a Lambda Model LP-412A-FM. Cyclic voltammetry was carried out using a PAR Model 173 potentiostat, PAR Model 175 Universal Programmer, and Houston Model 2000 X-Y recorder. The cyclic voltammetry cell consisted of a modified beaker with SCE separated by a glass frit, Pt wire secondary electrode, and hanging Hg drop working electrode. Air was excluded from the voltammetry cell by a blanket of flowing dry N_2.

Reduction of ethanetetracarboxylate esters.—The ethanetetracarboxylate ester (0.010 mol) and tetraethylammonium perchlorate (2.30g; 0.010 mol) were dissolved in a mixture of DMF (50 ml) and water (5 ml) at *ca.* 60°C. A current of 0.25A was passed through the solution for 2.5 hr (0.023 F) for all compounds except **1c**, 3.25 hr (0.030 F), while the electrolyte temperature was kept at 60°-65° by external heating. A mercury pool (*ca.* 3.5 cm diam) and platinum sheet (*ca.* 2 cm^2 area) were the cathode and anode, respectively. The anode was horizontal and *ca.* 1 cm above the mercury surface. Agitation was provided by a small magnetic stirring bar floating on the mercury.

In the case of **1a** the electrolyte was cooled, dimethyl succinate was added as an internal standard, and unchanged starting material and product (**2a**) were determined by gas-liquid chromatography.

In the case of **1b** the solvent was removed *in vacuo*. The solid/liquid mixture obtained was stirred with chloroform (*ca.* 20 ml) and filtered to remove the majority of the electrolyte. Evaporation of the filtrate gave a viscous oil (5.70g). Analysis by NMR showed it to consist of **1b** and **2b** (3.67g combined), DMF (0.86g), and hydroxymethyl(methyl)formamide (0.71g). The oil was stirred with ether (100 ml). The solid (1.05g) formed was removed by filtration and was found by NMR to consist of electrolyte (0.46g) and unchanged starting material (**1b**; 0.59g; this value used for computing the data in Table I). This solid was recrystallized from methanol (30 ml) to give pure **1b** [0.51g; mp, 170°-2°; lit. (6), mp 169°-70.5°]. The ether filtrate gave on evaporation a liquid (4.32g) consisting (by NMR analysis) of DMF (0.65g), hydroxymethyl(methyl)formamide (0.66g), and **2b** (3.01g; this value used for computing the data in Table I). The liquid was again taken up in ether. The ether solution was washed six times with water to remove the amides. It was then dried ($CaSO_4$), filtered, and evaporated. The residue

Table I. Reduction of ethanetetracarboxylate esters

Starting material (0.01 mol)	Unchanged starting material[a] (%)	Products[a] (% yield)[b]	E_p[c] vs. SCE (V)
1a	1	2a (89)	−2.64
1b	16	2b (97)	−2.64
1c	nd	2c (72), 4a (24)	−1.37
3a	<1	4a (95)	−2.29
3b	19	4b (100)	−2.56

[a] After passage of 2.3 F/mole (except for 1c, 3 F/mole); nd = not detected.
[b] Yield based on starting material consumed.
[c] Potential of the first cathodic peak observed via cyclic voltammetry for the starting material (*ca.* 1.1×10^{-3}M) in dry DMF containing $[(C_2H_5)_4]ClO_4$ (0.1M). No reverse peaks at scan rates up to 1000 mV/sec.

was distilled to give pure dimethyl-3-cyanopropane-1,1-dicarboxylate [**2b**, 2.21g, bp 108°-10° (0.05 mm)]. Found: C, 52.0, 52.1; H, 6.0, 6.0; N, 7.4, 7.6%; M, 173 (by osmometry in chloroform). $C_8H_{11}NO_4$ requires: C, 51.9; H, 6.0; N, 7.6%; M, 185.

For **1c** and **3** procedures similar to those described above for **1b** were used to generate the data shown in Table I. Compounds **2c** [mp, 49°-51°; lit. (8), mp 49°-50°] and **4a** [mp, 46-8°; lit. (9), mp 48°] were obtained as white crystalline solids from ether and **4b** [mp, 77°-8°; lit. (10), mp 77.6°-8.4°] in similar form from methanol.

The ^{1}H-NMR spectral data for the products are shown in Table II.

Oxidation of dimethylformamide.—A current of 0.25A was passed through a solution of tetraethylammonium perchlorate (2.30g; 0.010 mol) in a mixture of DMF (150 ml) and water (5 ml) at 60°-65°C in the cell used for the ester reductions. As soon as the current flow was initiated, the formation of a black solid, assumed to be tetraethylammonium amalgam (12), was noted on the surface of the mercury cathode. It dissolved within a few seconds after a temporary discontinuation of current flow. After 22.5 hr (0.21**F**), the electrolysis was stopped. The solution was evaporated. The residue was taken up in ether (*ca.* 100 ml) and the electrolyte was removed by filtration. The filtrate was evaporated to give an oil (4.50g) containing (by NMR analysis) hydroxymethyl(methyl)formamide (3.53g), methylformamide (0.90g), and DMF (0.07g). Distillation gave hydroxymethyl(methyl)-formamide containing *ca.* 10 mole percent (m/o) methylformamide as a water-white liquid [1.03g; bp, 108°-10° (0.2 mm)]. In its ^{1}H-NMR spectrum hydroxymethyl(methyl)formamide shows, in common with other amides, peaks for two isomers due to restricted rotation about the N-CO bond. The major isomer (80%) showed peaks at 2.91 (CH_3), 4.78 (CH_2), and 8.13 (CHO) ppm downfield from an internal tetramethylsilane reference. The minor isomer showed similar peaks at 3.04, 4.81, and 8.00 ppm. In addition, a common hydroxyl peak was observed at *ca.* 5.4 ppm which was broad and exchanged with D_2O. Hydroxymethyl(methyl)formamide contaminated with a little methylformamide was also obtained by reaction of methylformamide with paraformaldehyde (12) and its NMR spectrum is identical to that of the anodically formed material.

Table II. ^{1}H-NMR spectral data for the cleavage products

Compound	Chemical shifts[a]

[a] Measured in ppm downfield from internal tetramethylsilane reference in $CDCl_3$ solution at 90 MHz. Relative area is shown in parentheses. The multiplicity (*d* = doublet, *t* = triplet, *m* = multiplet) and coupling constants of nonsinglet resonances are indicated below the chemical shift data.

Results and Discussion

Tetramethyl ethane-1,1,2,2-tetracarboxylate (**1a**), some substituted derivatives (**1b, c**), and cyclic analogs (**3a, b**) undergo reductive cleavage at a mercury cathode in aqueous DMF. High yields and current efficiencies are obtained at high conversions in an undivided cell using a constant current mode of operation (Table I). In the case of **1c**, $(CH_3OCO)_2C{=}CH{-}C(COOCH_3)_2{-}C(COOCH_3)_2{-}CH{=}C(COOCH_3)_3$, electrochemical reduction has been reported previously (7). The formation of a cyclopentane derivative by saturation of one double bond followed by an intramolecular Michael addition to the other has been claimed. While the formation of the cyclopentane on catalytic hydrogenation of **1c** (8) has been confirmed, its formation on electrochemical reduction of **1c** could not be reproduced. In both aqueous DMF and methanol containing sulfuric acid, *cf.* (7), the initial product was **2c**, $(CH_3OCO)_2C{=}CHCH(COOCH_3)_2$, which underwent further reduction to **4a**, $(CH_3OCO)_2CHCH_2CH(COOCH_3)_2$. The reduction potential of **2c** in DMF is slightly more negative (E_p = 1.54V) than that of **1c** (E_p = −1.3V *vs.* SCE).

The anode reaction accompanying the cathodic cleavages is the oxidation of DMF to hydroxymethyl(methyl)formamide, Eq. [2]. This is not

$$HCON(CH_3)_2 + H_2O \rightarrow HCON(CH_3)CH_2OH + 2H^+ + 2e^- \quad [2]$$

surprising as this compound is an intermediate in the formation of the ether, $[CHON(CH_3)CH_2]_2O$, which results when a stoichiometric quantity of water is used (13). In the absence of an ethanetetracarboxylate ester, hydroxymethyl(methyl)formamide is the sole product isolated.

The reductive reactions reported here are a reverse of the anodic oxidation of propanedioate esters, which proceeds via direct oxidation (14) of the carbanion or indirectly via anodically generated halogen, especially iodine (6). Use of neutral conditions, partially aqueous solvent, and a nonhalide electrolyte avoids these anodic reactions and permits the convenience of an undivided cell. The esters **1b** and **1c** are not very soluble, and the reaction temperature used (60°-5°C) was that required to keep these compounds in solution. In spite of this elevated temperature and the presence of water, hydrolysis of ester groups did not seem to be a problem, perhaps because of the relatively short reaction times (usually 2.5 hr) used.

The first reduction peak (Table I) for the esters **1** and **3** corresponds in all cases to an irreversible process. For **1b, c,** and **3** the peak height is comparable to that of tetramethyl ethenetetracarboxylate which corresponds to a two-electron process. For these compounds the peak height and peak potential are not affected by addition of a proton donor (1×10^{-2}M phenol) or by carrying out the voltammetry in dry DMF in the presence of a water scavenger (alumina, Woelm grade I). For **1b, c,** and **3** the peak appears to correspond to the process shown in Eq. [3]. For **1a**

$$RC(COOCH_3)_2C(COOCH_3)_2R + 2e^- \rightarrow 2\bar{C}(COOCH_3)_2R \quad [3]$$

$$2HC(COOCH_3)_2C(COOCH_3)_2H + 2e^- \rightarrow \bar{C}(COOCH_3)_2C(COOCH_3)_2H + \bar{C}H(COOCH_3)_2 + CH_2(COOCH_3)_2 \quad [4]$$

the peak height is approximately half the height observed for the other compounds. This is attributed to **1a** acting as a proton donor (in dry DMF), which should lead to approximately equal quantities of the dimeric and monomeric carbanions because of the comparable acidities of the two carbon acids. This leads to the stoichiometry shown in Eq. [4]. As expected, addition of a proton donor (diethylmalonate) approximately doubles the height of this peak.

The observed reduction potential (−1.37V) for **1c** is clearly remote from those of the other compounds examined but is close to that of **2c** (−1.54V). For the reduction of **1c** it is suggested that initial electron transfer to one of the double bonds occurs and is followed by cleavage and a second electron transfer to the radical species formed (Scheme 1). Similar cleavage following a remote electron transfer has been suggested in the Birch reduction of some strained bibenzyl derivatives (15). For the reduction of **1a**, **1b**, and **3**, remote electron transfer to a carbonyl group (Scheme 3) may occur. Other observed ester reductions may be rationalized in these terms, *e.g.*, the reduction of propanedioate esters to the corresponding carbanions (6, 16) as shown in Scheme 4, or the cleavage of esters of benzyl alcohols (17). Additionally, these mechanisms are similar to that suggested for the cathodic reduction of cyclohexane-1,4-dione to hexane-2,5-dione (18).

In the undivided cell, the carbanions formed in the cathodic processes (Eq. [3], Schemes 1, 2, and 3) are neutralized by anodically generated (Eq. [2]) protons. In the case of **1a**, it is easily seen that this will also result in a net two-electron reaction, even though the cathodic process (Eq. [4]) involves only one electron per mole of substrate. The net cell reaction for compounds **1** is then as shown in Eq. [5] and a similar equation may be written for the cyclic compounds **3**.

$$RC(COOCH_3)_2C(COOCH_3)_2R + HCON(CH_3)_2 + H_2O \xrightarrow{2F} 2RCH(COOCH_3)_2 + HCON(CH_3)CH_2OH \quad [5]$$

SCHEME 1 ($X = COOCH_3$)

$$X_2C{=}CHCX_2CX_2CH{=}CX_2 \ (\mathbf{1c}) \xrightarrow{e^-} X_2\bar{C}{-}\dot{C}HCX_2CX_2CH{=}CX_2 \rightarrow X_2\bar{C}CH{=}CX_2 + \dot{C}X_2CH{=}CX_2 \xrightarrow{e^-} 2\bar{C}X_2CH{=}CX_2$$

Another possible reaction pathway is the disproportionation (19) of the initially formed anion-radical of **1c** to form the dianion of **1c** which could cleave to give the observed product (Scheme 2). A similar scheme can be written for the reduction of **1a**, **1b**, and **3**.

SCHEME 3

Selective Electrosyntheses on Chemically Modified Electrodes

III. Regio-Selective Anodic Chlorination of Some Benzene Derivatives with a Cyclodextrin Chemically Modified Electrode

Tomokazu Matsue, Masamichi Fujihira, and Tetsuo Osa*

Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980, Japan

ABSTRACT

The regio-selective anodic chlorination of some benzene derivatives with an α-cyclodextrin (α-CD) chemically modified graphite electrode via "ester bonding" (α-CD-CME) and with an α-CD adsorbed graphite (α-CD-AE) was studied. In the C 1s ESCA spectrum of the α-CD-CME, a small peak which is considered to be based on carbon atoms in α-CD appeared at a higher binding energy side of the main peak, indicating that α-CD can be immobilized on the electrode surface. The immobilized α-CD as well as the adsorbed α-CD had a pronounced effect on the *para*-position selective chlorination of anisole and toluene, but such an effect could not be observed in the chlorination of chlorobenzene. Increasing the conversion of a substrate resulted in a decrease in the ratio of *para*- to *ortho*-chlorination product, *p/o* ratio, since the products have an inhibition effect on the inclusion of the substrate in α-CD's cavity. Although the homogeneous chlorination by NaOCl in the presence of α-CD in solution also showed a relatively high *p/o* ratio, it revealed that the ratio observed in the electrochemical method was slightly higher than that observed in the homogeneous method. The α-CD-CME used repeatedly showed relatively high regio-selectivity even after a month of immersion of the electrode in water, whereas the α-CD-AE showed decrease of the *p/o* ratio with increasing immersion time.

With the progress of chemical modification of adsorbents for chromatography, new means for alteration of electrode surface have been devised. Miller and his co-workers put a chiral field at an electrode surface by immobilizing optically active compounds to use for asymmetric electrolyses (1-3). However, the optical yields in their works were not high. To realize a high selective electrosynthesis with a chemically modified electrode (CME), not only a strong interaction with a substrate but also a sufficient stability toward redox reactions are the requirements for modified species. Among the compounds meeting such requirements are cyclodextrins (CD's). These molecules are cyclic 1,4-linked D-glucopyranose oligomers containing several glucose units and have the shape of hollow truncated cones. One of the most remarkable properties of the compounds is the ability to include a variety of organic compounds of appropriate size in their hydrophobic interiors (4) and, in some cases, to catalyze a reaction of guest molecule with the assistance of secondary hydroxyl group at the rim of the cavities (5). Because of their enzyme-like behaviors, the CD's have received a great deal of attention. Taking advantage of the specific environment of the cavity of α-CD (containing 6 glucose units), we carried out the regio-selective anodic chlorination of anisole with α-CD bound on a graphite electrode surface and present in solution (6, 7). From the results by Breslow *et al.* (8), the anodic chlorination with the α-CD chemically modified graphite electrode (α-CD-CME) would proceed via selective donation of chlorine from one of the C-3 hydroxyl groups of α-CD to *para*-position of an aromatic ring as shown in Scheme 1. In our previous paper (7), a high regio-selectivity was observed in the anodic chlorination of anisole when α-CD was in solution; however, the α-CD-CME via "ether linkage" showed only a slight selectivity. This low regio-selectivity on the α-CD-CME via "ether linkage" might be attributed to the low surface concentration of α-CD at the electrode surface by ESCA analysis. In order to enhance the surface concentration of α-CD, an alternative method for the modification of a graphite surface with α-CD via "ester linkage" was planned. This paper describes the selective chlorination of anisole, toluene, and chlorobenzene with the α-CD-CME via "ester linkage" including the results in the previous communication (6) in detail together with the stability of the α-CD-CME toward repetition of electrolyses.

Experimental

A polycrystalline graphite plate was obtained from Tokai Carbon Company (G 2080) and cut into 30 × 20 × 2 mm plates for electrolyses and 17 × 5 × 2 mm plates for ESCA measurements. All electrolyses were carried out using a Yanaco VE-8 controlled potential electrolyzer. The electrolysis cell was a divided H-type with a graphite anode (30 × 20 × 2 mm), a platinum gauze cathode, and a saturated calomel electrode (SCE) as the reference electrode inserted near the anode. The analyte consisted of 1.0×10^{-3}M substrate (anisole, toluene, and chlorobenzene) and 5.0×10^{-1}M NaCl or HCl as the supporting electrolyte dissolved in 50 ml of distilled water (nonbuffered), and was stirred with a magnetic bar. The cell was kept at a constant temperature by thermostatic control. After the electrolysis, the anolyte was extracted with ether three times. The extracted ethereal solution was dried with Na_2SO_4 and concentrated under a reduced pressure for gas chromatography. Gas chromatographic analyses were carried out by using a Shimadzu gas chromatograph Model GC-6A equipped with a flame ionization detector. Nitrogen was used as the carrier gas. The column used for the analyses of the reaction products in the chlorinations of anisole and chlorobenzene was 2m × 3 mmφ SUS packed with 10% Carbowax 20M on Chromosorb W. For the analysis in the toluene chlorination, a 2m × 3 mmφ SUS column packed with 10% 4,4′-azoxydianisole on Uniport B was used. Quantitative analyses of the chlorination products formed in the electrolyses were carried out by comparison with a calibration line of authentic samples. The ratio of *p*- to *o*-isomer (*p/o* ratio), the conversion of substrate, and the yield of monochlorides of all products were deter-

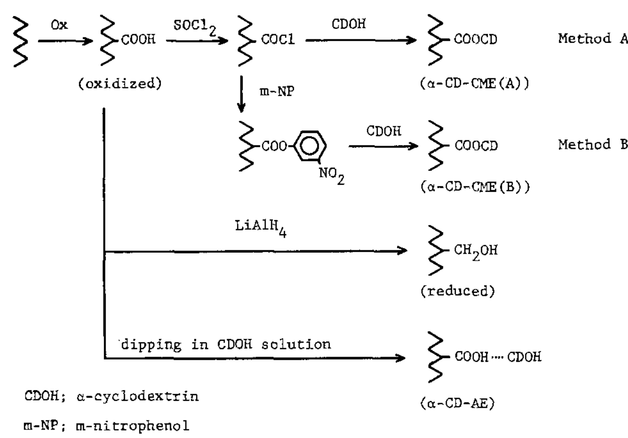
mined by using these gas chromatographic data. The homogeneous chlorination was also carried out. In this reaction, a specific amount of NaOCl was added to aqueous 1.0×10^{-1}M HCl solution containing a substrate (1.0×10^{-3}M), and the solution was stirred with a magnetic bar for 1 min. After the reaction the solution was extracted with ether, and was analyzed with the same gas chromatographic method as described above.

An AEI Model ES-200 was used for ESCA measurements with an Mg anode under a vacuum of 10^{-8}-10^{-9} Torr. The binding energies were computed and corrected for charging effect by referencing to the 285 eV C 1s peak and the 532 eV O 1s peak (9, 10).

The dissociation constants of α-CD complexes were determined by the spectrophotometric method (11).

Synthetic procedure for α-CD-CME.—The graphite plates were first dipped in water for 2 hr to remove water soluble impurities from the electrode surfaces, treated with a solution of 0.2M $K_2Cr_2O_7$ in concentrated H_2SO_4 for 2 hr to introduce the surface functional groups containing oxygen, and then thoroughly washed with water and dried. The carboxyl groups thus introduced on the oxidized graphite were converted to chlorocarbonyl groups by refluxing in $SOCl_2$. After 1 day's treatment, the electrode was removed from the solution and then washed with dry benzene repeatedly. The graphite plate thus obtained was rapidly dipped in an α-CD saturated dry pyridine and dimethylformamide solution. The solution was refluxed 1 day followed by standing at room temperature for a week. After the reaction, the α-CD-CME was taken out of the solution and washed with water (method A in Scheme 2).

In order to compare the regio-selective ability of the α-CD-CME with that of a physically adsorbed α-CD graphite electrode (α-CD-AE), the α-CD-AE was prepared by dipping in aqueous 1.0×10^{-1}M α-CD solution for 1 day. A reduced graphite electrode was prepared by reducing the oxidized graphite with $LiAlH_4$ (12) in tetrahydrofuran for 2 days. To obtain the ESCA spectrum of α-CD, the α-CD on silicon chip was also prepared by dropping the aqueous α-CD solution on the chip followed by drying.



Scheme 2. Synthetic procedures of various surface derivatizations

The α-CD-CME's were also prepared by the ester-exchange reaction between the *m*-nitrophenol modified graphite and α-CD (method B in Scheme 2), and by the direct condensation between the oxidized graphite and α-CD using dicyclohexylcarbodiimide, but these α-CD-CME's did not show good results. Therefore, the following discussion is concentrated on the α-CD-CME obtained via method A.

Results and Discussion

ESCA results.—Figure 1 shows wide ESCA spectra of the oxidized graphite, the reduced graphite, the α-CD-CME, and α-CD on a silicon chip. There are strong peaks of O 1s at 532 eV and C 1s at 285 eV on the oxidized graphite, which are almost the same as those obtained for glassy carbon baked in air (13). No peak either for Cr or for K from $K_2Cr_2O_7$ appears. In the ESCA spectra of other types of graphites, no peaks, except O 1s and C 1s, were observed. Higher resolution ESCA spectra of O 1s on the above three types of electrodes and the α-CD on silicon chip are shown in Fig. 2. The relative peak height of O 1s on the reduced graphite was lower than that on the oxidized one, indicating that some amount of oxygen atoms on the

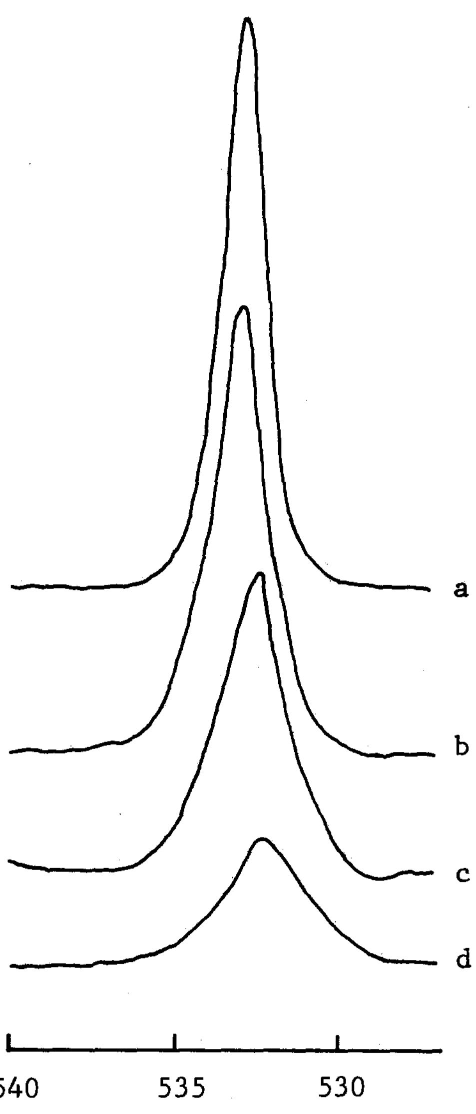

Fig. 2. O 1s ESCA spectra of the α-CD on silicon chip (a), the α-CD-CME(A) (b), the oxidized (c), and the reduced (d) graphite electrodes.

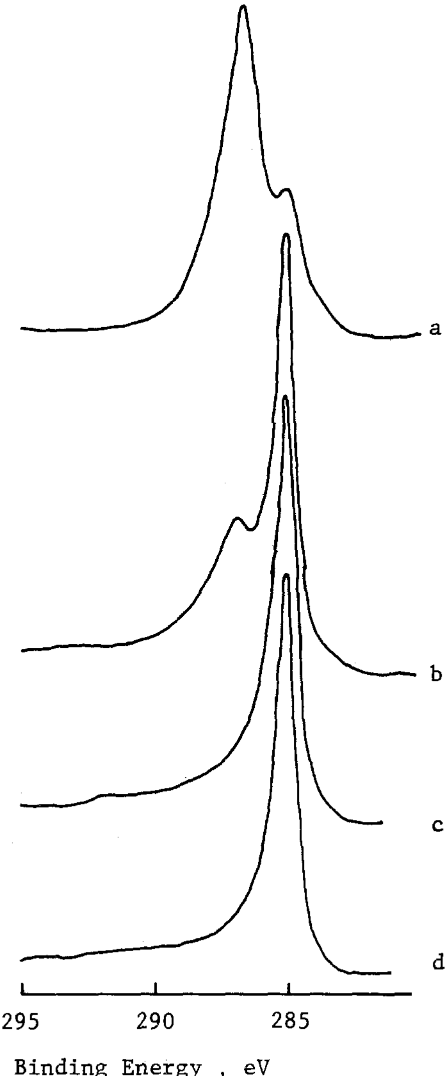

Fig. 3. C 1s ESCA spectra of the α-CD on silicon chip (a), the α-CD-CME(A) (b), the oxidized (c), and the reduced (d) graphite electrodes.

oxidized graphite was removed by the reduction with $LiAlH_4$. On the other hand, the intensity of the peak was increased by the chemical modification of the oxidized graphite with α-CD. The enhancement in the peak in the spectrum of the α-CD-CME is attributed to the oxygen atoms in the α-CD molecule immobilized on the electrode surface. This is reinforced by the results of the wide ESCA spectrum of the α-CD on silicon chip as shown in Fig. 1, *i.e.*, the O 1s peak is large compared with the C 1s peak. A slight shift of the O 1s peak on the α-CD-CME toward a higher binding energy side was also observed. It is, however, difficult to assign the chemical shift since the shift was too small; furthermore, various types of oxygen atoms, including contamination, exist on the graphite surfaces. The changes in higher resolution ESCA spectra of C 1s for the same kind of samples used in O 1s ESCA measurements are shown in Fig. 3. By performing chemical modification of α-CD on the oxidized graphite surface via method A, a small peak appeared at a higher binding energy side (*ca.* 287 eV) of the main peak at 285 eV. The peak at *ca.* 287 eV could not be observed in the spectra of the oxidized and the reduced graphites. The small peak may be attributed to the carbon atoms in α-CD immobilized on the graphite surface, since, in the C 1s ESCA spectrum of the α-CD on silicon chip, the main peak appeared at the same binding energy. This chemical shift in the C 1s peak is accounted for by considering the charge (14) on every carbon atom in α-CD molecule which adjoins oxygen atoms of high electronegativity. In comparison of the present results with the previous one on α-CD-CME (via ether bonding) (7), α-CD can be more easily introduced by the ester linkage than by the ether linkage because the peak at 287 eV was observed as only a small shoulder in the C 1s ESCA spectrum of the α-CD-CME (via ether bonding). The α-CD-CME's prepared by the ester-exchange reaction and by the direct condensation showed no peak at 287 eV in the C 1s ESCA spectra.

Chlorination of anisole.—The anodic chlorination of anisole using various types of electrodes was carried out at a constant potential. Excellent yields of monochloroanisoles were observed for all cases. The current efficiencies of the electrolyses were within a range of 40-60%, and the values were almost independent of the surface derivatizations. Although most of the reaction products at low conversion of anisole were monochloroanisole isomers, the yield of *m*-isomer was only a trace amount. The results in the absence and presence of α-CD in solution are summarized in Table I. The *p/o* ratio on the oxidized graphite in the present study was slightly higher than that observed in the previous one (7). This might be attributed to the difference in the surface properties of the graphite plate used. The electrode potential seemed to have some influence on the *p/o* ratio. The ratio on the reduced graphite electrode was higher than that on the oxidized

one; however, the ratio decreased with repetition of electrolyses owing to the oxidation of electrode surface. The addition of α-CD to the solution made the *p*/o ratio become high. This indicates that p-isomer was formed with considerably high selectivity in the presence of α-CD in solution, because the o-position of anisole is blocked by the inner wall of α-CD (6, 7, 15). Nevertheless only 54% of anisole was included in α-CD in bulk solution [as the dissociation constants for α-CD-anisole and α-CD-Cl^- complexes are 3.75×10^{-3}M (8) and 3.9×10^{-1}M (16), respectively], high selectivity was observed in the presence of α-CD in solution. This is mainly due to the fact that the chlorination rate of the included substrate is rapid compared with that of the free substrate (8). Another probable cause for this observation is higher concentration of α-CD at the electrode surface due to adsorption compared with that in bulk solution.

The homogeneous chlorination of anisole by NaOCl in an acidic medium proceeded very fast. Table II shows the results. The *p*/*o* ratio in this chlorination in the absence of CD showed lower values than those observed in the anodic chlorination. By the addition of α-CD to the reaction solution, the ratio was increased. However, the ratio was not high as that observed in the anodic chlorination in the presence of α-CD in solution. In the anodic chlorination, the concentration of α-CD at the electrode surface may be higher than that in bulk solution, so that *p*-position chlorination proceeds effectively at the electrode since α-CD can promote the chlorination of the included anisole (8). Increasing the concentration of NaOCl in solution in the homogeneous reaction resulted in a decrease in the yield of monochlorides accompanied by an increase in the yields of di- and trichlorides.

The results of the anodic chlorination of anisole with the α-CD-CME and the α-CD-AE are summarized in Table III. By performing chemical modification and adsorption of α-CD on the oxidized graphite surfaces, the *p*/*o* ratio increased. In particular, in the case of the α-CD-AE, the ratio exceeded 25, which indicates that the p-isomer was formed in more than 96%. The α-CD-CME also showed a high *p*/*o* ratio of 18 at 1.10V *vs.* SCE. However, the ratio seems to contain the contribution of adsorbed α-CD on the α-CD-CME. The *p*/*o* ratio on the α-CD-CME became 10 by dipping the electrode in water for several days. Consequently, the difference in the *p*/*o* ratio observed before and after the immersion would be due to desorption of the adsorbed α-CD on the α-CD-CME. The electrode potential has an influence on the *p*/*o* ratio. The ratio on the α-CD-CME at 1.20V *vs.* SCE was lower than that observed at 1.10V *vs.* SCE. At high electrode potential, the relative contribution of the chlorination of free anisole becomes large compared with that of included anisole in α-CD's cavity, since the concentration of HOCl at the electrode surface becomes high. Accordingly, the ratio is considered to be low at high potentials. Increasing the conversion of anisole resulted in a decrease in the *p*/*o* ratio. This decrease in the ratio is interpreted as due to the inhibition effect of chloroanisoles on the inclusion of substrate in the cavity of α-CD. The dissociation constants for α-CD-p-chloroanisole and α-CD-o-chloroanisole complexes are 3.3×10^{-4}M and 2.6×10^{-3}M, respectively. These values are sufficiently small compared with that for α-CD-anisole complex (3.75×10^{-3}M).

Inhibition is more pronounced with *p*-chloroanisole. At the initial stage of the electrolysis, the concentration of the monochlorides in the vicinity of the electrode surface is low, so that the inhibition effect is small. After a long electrolysis, the effect becomes large due to the increase of the concentration of monochlorides at the electrode surface. The temperature during the electrolysis also affected the regio-selectivity. When the electrolysis was carried out at 5°C, the *p*/*o* ratio was observed to be 10 which was higher than the 6.3 value observed at 20°C. This phenomenon must be a reflection of the thermodynamic nature of α-CD complex in which CD includes substrate(s) more easily at low temperature (13). The dependence of the ratio on the temperature was also observed in the anodic chlorination of anisole in the presence of β-CD in solution (7). The *p*/*o* ratio on the α-CD-CME using HCl as the supporting electrolyte did not show a large discrepancy with that using NaCl. When the α-CD-CME and the α-CD-AE were treated with $K_2Cr_2O_7$ for 2 hr, the ratios decreased to 3.7 and 4.3, respectively, owing to the elimination of α-CD on the electrode surfaces by the oxidative degradation.

[c] Result before thoroughly washing with water; electrode potential, 1.10V *vs.* SCE.
[d] From this result, the turnover number of the immobilized α-CD may be $>10^3$. In order to obtain the turnover number, the surface concentration of immobilized α-CD was determined by the capacitance measurement of the α-CD-CME since the other methods such as cyclic voltammetry and ESCA were not suitable for the α-CD-CME. Although the method is not accurate enough, the surface concentration of α-CD was roughly estimated to be 10^{-10}-10^{-11} mol/cm². The turnover number was obtained on the assumption that the difference in the p/o ratio on the oxidized graphite and on the α-CD-CME was attributable to the immobilized α-CD on the α-CD-CME.

[g] Results after the treatment by $K_2Cr_2O_7$ for 2 hr.

Chlorination of toluene.—The anodic chlorination of toluene also resulted in the formation of chlorotoluene isomers. Benzyl chloride formed by the side-chain chlorination could not be detected. The results are summarized in Table IV. In this chlorination, the *p/o* ratio on the oxidized graphite electrode at low conversion showed *ca.* 0.5 which is almost a statistical ratio of *p*- to o-positions. This tendency was also observed in the homogeneous chlorination of toluene by NaOCl in an acidic medium. From these results, it seems that there is nearly no difference in the reactivity between *o*- and *p*-positions of toluene toward the chlorination by HOCl. The *p/o* ratio on the oxidized graphite became large with the addition of α-CD to the solution. However, the ratio in this case was not as high as that observed in the anodic chlorination of anisole in the presence of α-CD in solution. As the dissociation constant of α-CD-toluene complex is *ca.* 3×10^{-3}M, there is no significant difference in the values between α-CD-toluene and α-CD-anisole complexes. However, the ability of α-CD to the regio-selectivity was greatly different between both compounds. The difference between *p*-position of toluene and the catalytic site of α-CD, C-3 hydroxyl group, may be long compared with α-CD-anisole complex. The anodic chlorination in the presence of α-CD in solution showed a higher selectivity than the homogeneous one. With the α-CD-CME, the *p/o* ratio became large compared with that observed before the modification, although the ratio was not as high as that observed in the presence of α-CD in solution. The ratio was gradually decreased with increasing the conversion of toluene due to the inhibition effect of chlorotoluenes. High yields of monochlorides were observed in this reaction, and current efficiencies of the electrolyses ranged from 40 to 60%. No significant difference in the yields and the current efficiencies was observed among three conditions, *i.e.*, in the absence of CD, in the presence of α-CD in solution, and in the presence of immobilized α-CD on the electrode surface.

Chlorination of chlorobenzene.—The results of the anodic chlorination of chlorobenzene, together with those of the homogeneous chlorination, are summarized in Table V. The *p/o* ratio observed on the oxidized graphite electrode became large by the addition of α-CD to the solution. However, the increase in the ratio by the addition of α-CD in this case was not large compared with the trends observed in the anodic chlorination of anisole and toluene. This is mainly caused by the low complex formation of chlorobenzene with α-CD since the dissociation constant for α-CD-chlorobenzene complex is *ca.* 1×10^{-2}M which is *ca.* three times larger than those for α-CD-anisole and α-CD-toluene complexes. The current efficiencies in these cases were only 1-2%, and the conversions of chlorobenzene in the homogeneous chlorination were less than 4%, even in the same reaction time as the chlorinations of anisole and toluene. From these results, the chlorination rate for chlorobenzene by HOCl seems to be very slow. This is also considered to be one of the reasons for this low regio-selectivity. The *p/o* ratio on the α-CD-CME(A) was almost equal to that observed on the oxidized graphite, indicating that immobilized α-CD on the electrode surface had very little contribution to the regio-selectivity. Because of the low chlorination rate, the chlorination would proceed in bulk solution in this case, so that α-CD on the electrode surface could not affect the chlorination position of chlorobenzene.

[a] Results in the presence of 1.0×10^{-2}M α-CD in solution.

Stability of the α-CD-CME(A).—Finally, we examined the stability of the α-CD-CME(A) toward repetition of electrolyses. The results of occasional anodic chlorination of anisole with the α-CD-CME and the α-CD-AE, both dipped in distilled water, are shown in Fig. 4. The α-CD-AE showed a high regio-selectivity at the initial stage of the immersion, but the *p/o* ratio gradually fell with increasing immersion time. After 17 days, the ratio on the α-CD-AE reached below 6 because of the desorption of the α-CD from the electrode surface. On the other hand, the adsorbed α-CD on the reduced graphite was removed with ease by washing with water (7). The difference in these phenomena observed on the oxidized and the reduced graphites may imply that there is a specific interaction, although unknown, between the adsorbed α-CD and functional groups on the oxidized graphite surface. The ratio on the α-CD-CME was also decreased within a few days to *ca.* 10, owing to the desorption of the adsorbed α-CD on the electrode surface, but the value, *ca.* 10, was maintained even after a month of immersion in water. These results indicate that the ester linkage on the α-CD-CME was considered to be relatively stable, although the α-CD on the α-CD-CME was removed by treatment with a strong oxidant such as $K_2Cr_2O_7$. The α-CD-CME had an advantage from a viewpoint of stability over the α-CD-AE (although the former was inferior to the latter in the regio-selectivity at the initial stage).

Conclusions

The α-CD-CME (via ester bonding) as well as the α-CD-AE showed regio-selectivities in the anodic chlorinations of anisole and toluene. However, the regio-selectivity observed in the chlorination of toluene with the α-CD-CME was lower than that observed in the chlorination of anisole, although the binding

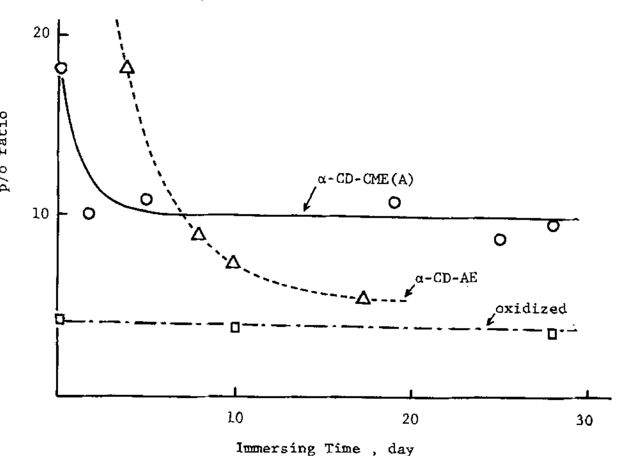

Fig. 4. Time dependence of *p/o* ratios of chloroanisole isomers

abilities of α-CD for both substrates are almost equal. This indicates that the distance between the p-position of toluene included in α-CD and the catalytic site of α-CD, C-3 hydroxyl group, may be longer than that in the α-CD-anisole complex. In the chlorination of chlorobenzene the regio-selectivity on the α-CD-CME could not be observed, probably due to the slow chlorination rate. The aromatic substrate substituted by an electron-donating group is necessary to attain a certain regio-selectivity in this reaction. The regio-selectivity in the anodic chlorination with the α-CD-CME may be also affected by the orientation of immobilized α-CD on the electrode surface as well as by the surface concentration of α-CD. It is, however, difficult to determine the number of ester linkage between the oxidized electrode surface and one α-CD molecule and which of the hydroxyl group in α-CD, primary or secondary hydroxyl group, is bound to the electrode surface. The α-CD-CME revealed to have considerable stability toward repetition of the anodic chlorination.

Theoretical Approach to the Resistive Behavior of Thin Solid Film Electrodes under Direct Current Polarization

R. I. Tucceri and D. Posadas[1]

Instituto de Investigaciones Fisicoquimicas Teoricas y Aplicadas (INIFTA), Sucursal 4, Casilla de Correo 16, 1900 La Plata, Argentina

ABSTRACT

The problem of the potential distribution along a thin metal film electrode under d-c polarization is reconsidered assuming that the electrode process fits a Butler-Volmer current-potential relationship and that the potential within the electrode can be linearized. The solution of the potential distribution along the film is applied to develop the theory of the method of electrode resistivity measurement in the presence of a faradaic electrochemical process. The possibility of coupling between the faradaic and measuring currents within the electrode is taken into account. Under the assumption of not too high electrochemical currents, this coupling effect is found to be negligible. An equation is obtained from which it is possible to evaluate the resisivity of the film.

Thin film electrodes are receiving increasing attention since the advent of transparent electrodes (1) and their application to the study of different electrochemical reactions (2, 3).

It is well known that when the thickness of a metal film is smaller than the mean-free path of the conduction electrons inside the metal, its electronic con-

[1] Present address: Case Laboratories for Electrochemical Research, Case Western Reserve University, Cleveland, Ohio 44106.

Key words: electrode resistivity, thin metal film electrode, electrode potential distribution.

ductivity is diminished (4, 5). This thickness dependence of the conductivity can be accounted for in terms of the Fuchs-Sondheimer model (5). When ions or neutral molecules from a gaseous phase are adsorbed on such a thin film, the decrease in conductivity is enhanced (5). This phenomena has been applied to the study of the adsorptive behavior of molecules from gas phase (5) and, in recent years, it has also been applied to the study of adsorption of ions and molecules, and the electrosorption of molecules and intermediates of electrochemical reactions (6-15). In this case one is mainly concerned with the conductivity changes produced as the potential difference at the metal solution interface is changed.

Two major phenomena are involved in the potential dependence of the resistivity change of a thin metal film electrode (11, 13). The first is associated with the change of the concentration of the electrical carriers (electrons) at the surface of the metal as the electrical state of the interphase is changed, giving way to the so-called field effects (5). These effects have been first observed experimentally by Anderson and Hansen (10) in an electrochemical system. Thus

$$\frac{\Delta\sigma}{\sigma} = \frac{\Delta q}{q} \qquad [1]$$

where σ is the conductivity and q is the total charge per unit surface, of the carriers.

The second is due to the formation of the adsorptive bond that perturbs the electron velocity distribution in the film and thus changes the conductivity (5). It may also be considered, in terms of Sondheimer's-like models, by the formation of dispersion centers at the surface of the metal that changes the specularity parameter of the surface (16). In this case

$$\frac{\Delta\sigma}{\sigma} = \alpha\frac{\Delta n}{n} \qquad [2]$$

where n is the coverage by the adsorbed species and α is a proportionality constant.

The change of resistivity can, in principle, provide information about: (*i*) changes of the electrical state of an ideally polarizable interface; (*ii*) changes of the amount of adsorbed species and/or changes of the nature of the adsorption bond; and (*iii*) information complementary to modulated spectroscopy since as is well known the real component of the complex conductivity is directly related to the imaginary part of the complex refractive index (17).

The experimental technique, which has already been applied to different electrochemical systems (6-14), measures the change of resistance along the length of the thin film electrode while applying d-c polarization at the midpoint of the film. For this purpose either a-c or d-c resistance bridges as well as d-c polarization methods have been used (6-10, 13, 14, 16, 18, 19) (see Fig. 1). From the experimental point of view two cases could be distinguished: (*i*) at the potential of adsorption the electrode behaves as an ideally polarizable interphase and (*ii*) faradaic current flows during the resistance measurement. The first case poses no special requirements on the resistance measurement. In the latter the faradaic current generates a p.d. at the extremes of the film which adds to that due to the resistance measuring device. Thus, when a faradaic current flows through the thin film-electrolyte interface, a potential drop along the thin film electrode is produced due to the thin film resistance. This causes a potential distribution which depends, in principle, on the current-potential relationship governing the electrochemical process. On the other hand, when the resistivity of the thin film is measured, an additional "measuring"

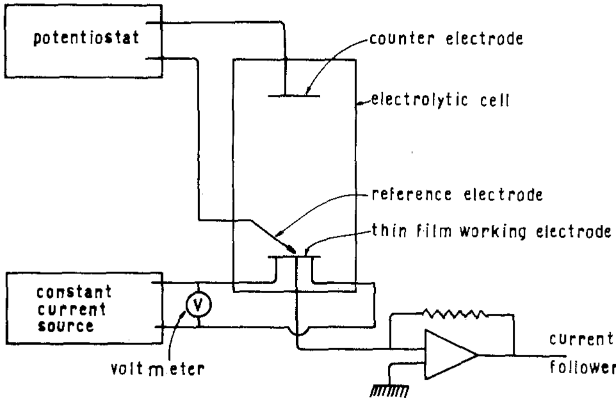

Fig. 1. Circuitry to measure the resistance of an electrode in the presence of faradaic current.

current is fed along the electrode which may couple with the faradaic current. In order to obtain the resistivity of the electrode, the polarization (faradaic) current contribution to the potential difference due to the measuring current must be negligible.

The potential distribution problem of a wire subject to a constant external current assuming a linear current potential relationship for the electrode process was considered by Harvey (20).

Conway *et al.* (21) have treated the potential distribution problem of a wire of length L assuming a Tafel relationship, *i.e.*, high overpotentials, and that the p.d. within the electrode can be linearized. These authors did not consider the value of the current at the end of the wire ($x = L$) thus leaving the potential along the wire (partially) undetermined {see Eq. [10] and [12a] of Ref. (21)}. Further inconsistencies if $L = \infty$ were pointed out by Rangarajan, Dignam, and Conway (22). The latter extended the mentioned treatment to any value of the p.d. within the electrode under the assumption of equal anodic and cathodic Tafel slopes obtaining a formal solution in terms of Jacobi's elliptic functions. Thus, the solution must be calculated numerically for each particular case. Other approaches consider the electrode divided in discrete portions (18, 23). This allows one to handle more general current-potential relationships. Since this treatment leads to numerical solutions they will not be considered in the present work.

On the other hand, the theory of the resistance measurement was considered by Sutton and Dickinson (12) who obtained an equation for the p.d. at the extremes of a thin film electrode in the presence of a measuring current and assuming a linear current-potential relationship. However, their results are not physically sound since the p.d. between the ends of the film does not reduce to the simple Ohm's law in the absence of the faradaic process {see Eq. [1], Ref. (12)}.

This short analysis shows the convenience of reconsidering both the potential distribution problem and the theory of electrode resistance measurements. Here we will consider an electrochemical reaction that fits a Butler-Volmer current-potential relationship. Mass transfer complications are assumed negligible. It will also be assumed that the p.d. within the thin film can be linearized, *i.e.*, it is smaller than $RT/\alpha F$. This assumption, as shown below, is well justified for thin film electrodes. The equations derived from the present treatment can be straightforwardly applied to the interpretation of the thin film electrode resistance measurements under d-c polarization.

The Potential Distribution Problem

Let us first consider a homogeneous and isotropic film on an inert substrate, of thickness h, width D,

height l, and resistivity ρ. One of the film faces of area $s = Dl$, is exposed to the electrolytic solution. The bottom of the film (see Fig. 2) ($x = l$), which is in contact with the polarization (electrochemical) current, I_p, measuring device, is grounded. I_p results from the integration of i_x, the local current density at the point x over the whole surface area

$$I_p = \int_0^s i_x ds = D \int_0^l i_x dl \quad [3]$$

It is further assumed that the polarization current density is given by a Butler-Volmer relationship

$$i = i_o \left[\exp\left(\frac{\alpha_a \eta \mathbf{F}}{RT}\right) - \exp\left(-\frac{\alpha_c \eta \mathbf{F}}{RT}\right) \right] \quad [4]$$

where i_o is the exchange current density, α_a and α_c are the electrochemical transfer coefficients for the anodic and cathodic currents, respectively, η, is the overvoltage and $\mathbf{F}$, R, and T have their usual meanings. The C.D. is positive for the anodic reaction and negative for the cathodic one.

Inside the film a positive current flows from points of higher to lower potential. However, for a positive current, the overpotential η_x at the point x is smaller by V_x, the potential difference from the point x to the bottom inside the film. V_x ($x = l$) is arbitrarily taken as zero. Thus, the overpotential at the point x can be written as

$$\eta_x = \eta_x (x = l) - V_x \quad [5]$$

Taking into account Eq. [5], the local current density can be written as follows

$$i_x = i_o \left\{ \exp\left[\frac{\alpha_a(\eta - V_x)\mathbf{F}}{RT}\right] - \exp\left[-\frac{\alpha_c(\eta - V_x)\mathbf{F}}{RT}\right] \right\} \quad [6]$$

When V_x is sufficiently small, after expanding the corresponding exponential, Eq. [7] results

$$i_x = a - bV_x \quad [7]$$

where a is the current density (Eq. [4]) at $x = l$ ($V_x = 0$) and

$$b = \frac{i_o \mathbf{F}}{RT} \left[\alpha_a \exp\left(\frac{\alpha_a \eta \mathbf{F}}{RT}\right) - \alpha_c \exp\left(-\frac{\alpha_c \eta \mathbf{F}}{RT}\right) \right] \quad [8]$$

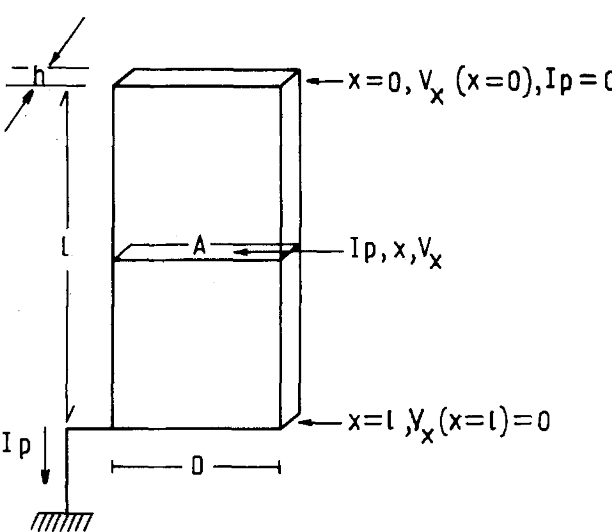

Fig. 2.

In the homogeneous thin film E_x, the field strength is proportional to J_x, the current density across the film

$$E = -\frac{dV_x}{dx} = J_x = \frac{I_{p,x}}{A} \quad [9]$$

where $A = Dh$ is the cross section of the film. $I_{p,x}$, the current at x can be written as

$$I_{p,x} = D \int_0^x i_x d_x = D \int_0^x (a - bV_x) dx \quad [10]$$

because $I_p = 0$ at $x = 0$. Thus, after replacing [10] into [9], it follows that

$$\frac{d^2V_x}{dx^2} = -\frac{\alpha^2 a}{b} + \alpha V_x \quad [11]$$

where

$$\alpha = \left(\frac{\rho D b}{A}\right)^{1/2} \quad [12]$$

The solution of Eq. [11] is of the type (12)

$$V_x = C_1 e^{\alpha x} + C_2 e^{-\alpha x} + \frac{a}{b} \quad [13]$$

The constants C_1 and C_2 can be evaluated with the boundary conditions[2]

$$\left(\frac{dV_x}{dx}\right)_{x=0} = 0 \quad [14]$$

and

$$V_x(x = l) = 0 \quad [15]$$

or

$$\left(\frac{dV_x}{dx}\right)_{x=l} = -\frac{\rho}{A} I_p \quad [16]$$

Conditions [14]-[16] are equivalent.

From the boundary conditions [14]-[16] it results

$$C_1 = C_2 = -\frac{a}{2b} \frac{1}{\cosh \alpha l} \quad [17]$$

When C_2 is replaced into Eq. [13] one obtains

$$V_x = \frac{a}{b} \left(1 - \frac{\cosh \alpha x}{\cosh \alpha l}\right) \quad [18]$$

and the potential at $x = 0$ is

$$V_x(x = 0) = \frac{a}{b} \left(1 - \frac{1}{\cosh \alpha l}\right) \quad [19]$$

A plot of $V_x/V_{(x=0)}$ as a function of x/l is shown in Fig. 3.

I_p is calculated through Eq. [3] and [18] as

$$I_p = \frac{aD}{\alpha} \tanh \alpha l \quad [20]$$

The parameter α corresponds to a reciprocal length and depends, among other things, on the exchange C.D. and the overpotential, that is, on the actual current flowing through the interface. For not too highly conductive materials and relatively low currents is $\alpha l < 1$. In Fig. 4 αl is plotted as function of η for different values of i_o.

Under the condition $\alpha l < 1$ after expanding in series tanh αl and neglecting higher order terms, Eq. [17] becomes

$$I_p \simeq aDl \quad [21]$$

Thus, if $\alpha l < 1$, the current density at any point along

[2] Boundary condition [14] implies $I_{p,o} = 0$. This is correct since mathematically $I_{p,x}$ can be considered as a distribution function, the corresponding density function being $i_x = a \cosh \alpha x / \cosh \alpha l$ which is different to zero even at $x = 0$.

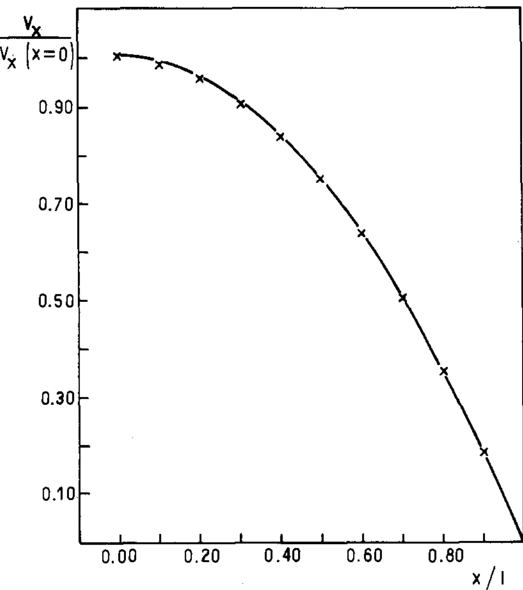

Fig. 3. V_x/V_x ($x = 0$) as a function of x/l, $i_o = 10^{-6}$ A cm^{-2}, $\rho = 6.14 \times 10^{-6}$ Ω cm; $D = 0.215$ cm, $l = 1.65$ cm, $h = 25$ nm, $\eta = 20$ mV, $\alpha_a = \alpha_c = 0.5$.

the film is equal to the current density at $x = l$. Hence, the potential drop along the film has no influence on the current density distribution.

On the other hand, after expanding cosh αl in Eq. [20], it results in

$$V_x(x = 0) = \frac{aD \cdot l^2 \rho}{2A} = \frac{I_p}{2} R \qquad [22]$$

where

$$R = \frac{\rho l}{A} \qquad [23]$$

It is interesting to note that $I_p/2$ is just the average current, I_p, over the electrode surface of the polarization current I_p as given by Eq. [21].

Equation [20] is plotted as $V_x\mathbf{F}/2RT$ against $\eta\mathbf{F}/2RT$ for different values of i_o in Fig. 5. As η increases, $V_x\mathbf{F}/2RT$ tends to unity. This upper limit should be considered carefully since it was assumed $V_x < RT/\alpha\mathbf{F}$. Figure 5 shows, however, that for reasonable

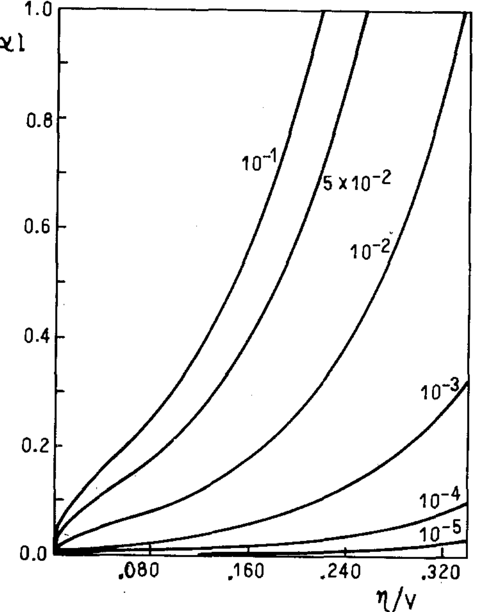

Fig. 4. αl as a function of η for the values of i_o in A cm^{-2} indicated in the graph. Calculated with the same parameters as those indicated in Fig .3.

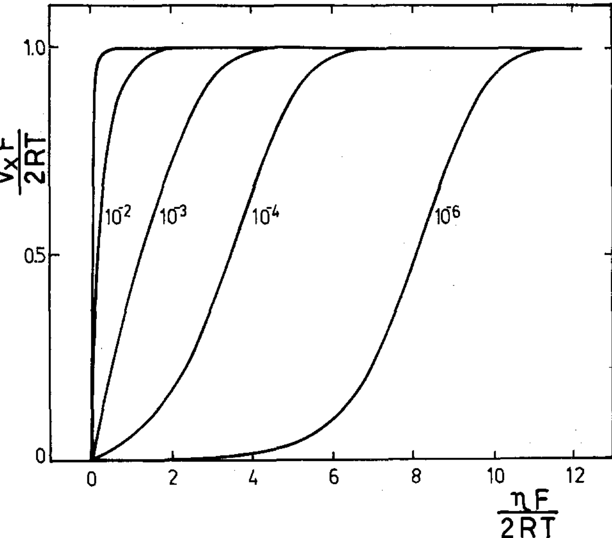

Fig. 5. $V_x\mathbf{F}/2RT$ as a function of $\eta\mathbf{F}/2RT$ for different values of i_o in A cm^{-2}. Calculated with the same parameters as those indicated in Fig. 3.

values of i_o, V_x is small even at relatively high values of η.

Notice that Eq. [19] does not directly relate the potential drop along the film with the polarization current and therefore can not be tested experimentally unless the complete V_x *vs.* η behavior is measured. Alternatively, at low values of i_o and η, Eq. [22] relates the two experimentally measurable magnitudes V_p and I_p.

The Measurement of the Resistivity Change

To measure the potential dependence of the resistivity, a three contact method is usually employed. The central contact is at ground and imposes the overvoltage to the interface. At the extremes (see Fig. 1) a constant current I_m is fed along the electrode. The principle of the method is to measure the potential drop produced by I_m which should be proportional to the electrode resistance. However, the faradaic process will produce an additional potential drop that interferes with the measurement. The central problem is to investigate under what conditions the latter can be diminished or completely eliminated. Therefore, we will consider the potential distribution along the resistive electrode in the presence of a superimposed constant current I_m. To start with, we will treat, by simplicity, the two contact problem. The extension to the three contact case is almost immediate.

A constant current I_m is introduced at $x = 0$ (Fig. 1) and as before the ground potential is maintained at $x = l$. It is assumed that effects of co-conduction in the solution can be neglected. It has been shown that this effect contributes in the order of 1% to the total resistivity (6).

For the constant current, I_m, a constant field E_m should contribute to the total field along the film

$$E_m = \frac{\rho I_m}{A} = -\frac{dV_m}{dx} \qquad [24]$$

The corresponding potential V_m at different points in the film varies linearly according to

$$V_m = \frac{\rho(l - x)I_m}{A} \qquad [25]$$

Obviously, the solution to this problem is, in virtue of the superposition principle

$$V_t = V_m + V_x \qquad [26]$$

that is

$$V_t = \frac{a}{b}\left(1 - \frac{\cosh \alpha x}{\cosh \alpha l}\right) + \frac{\rho(l-x)}{A} I_m \quad [27]$$

The result of Eq. [27] should be considered as a first approximation. We may further consider that the overpotential η_x comprises both V_x and V_m. By mathematical convenience, currents flowing opposite to the anodic electrochemical current are taken as positive. According to [24] and [25] a positive (negative) value of I_m will set a V_m value that should increase (diminish) η_x and vice versa. Then

$$\eta_x = \eta(x=0) - (V_x \pm V_{m,x}), \quad \text{for} \mp I_m \quad [28]$$

and the i_x is

$$i_x = i_o\left[\exp\left\{\alpha_a[\eta - (V_p \pm V_{m,x})]\frac{F}{RT}\right\} - \exp\left\{-\alpha_c[\eta - (V_x \pm V_{m,x})]\frac{F}{RT}\right\}\right] \quad [29]$$

where the $\pm$ sign is chosen accordingly to $\mp I_m$.

The field along the film in terms of the potential, V, can be written as

$$E = -\frac{dV}{dx} = I_m\frac{\rho}{A} + \frac{D\rho}{A}\int_o^x i_x dx \quad [30]$$

or

$$E = \frac{I_m \rho}{A} + \frac{D\rho}{A}\int_o^x (a - bV_x)dx \mp \frac{\rho D b}{A}\int_o^x V_{m,x}dx \quad [31]$$

According to Eq. [19] and [25], the solution is

$$V = \frac{\rho I_m(l-x)}{A} - \frac{a}{b}\left(1 - \frac{\cosh \alpha x}{\cosh \alpha l}\right) \pm \alpha^2\left(cl\frac{x^2}{2} - \frac{cx^3}{3}\right) \mp \frac{1}{3}\alpha^2 c l^3 \quad [32]$$

where $c = \rho I_m/A$ and the first term of the rhs is $V_{m,x}$, the second is V_x, and the last two terms represent the coupling of the two current terms. When $x = l$, these terms reduce to $\pm$ 1/3 α^2 cl^3, which is of the order of α^2 l^2 for $I_m < 1$ A. As in general $\alpha l < 1$, the interaction of the two currents is a second-order correction term and can, therefore, be neglected.

The three contact method provides, in principle, a way to evaluate the resistivity with only one measurement. In this case the polarization current is determined in the middle of the film (Fig. 6). At the experimental middle point, the film comprises one portion of length l, and another of length l $(1 + g)$, where $0 < g < 1$. Consequently, I_p is divided into two contributions $I_1 = yI_p$ in the upper half of the film and $(1 - y)$ $I_p = I_2$, in the lower half of the film (Fig. 5), where $0 < y < 1$. The factor y can be calculated from [10] and [20]

$$\frac{1}{y} = \frac{I_p}{I_1} = 2 + \frac{\int_l^{(1+g)l}(a - bV_x)dx}{\frac{aD}{\alpha}\tanh \alpha l} \quad [33]$$

After taking into account Eq. [19] into [33], it results

$$\frac{1}{y} = 2 + 2\frac{\cosh\frac{1}{2}[\alpha l(1+g) + \alpha l]\sinh\frac{1}{2}\alpha l g}{\sinh \alpha l} \quad [34]$$

The potential distribution is obtained by applying to each half of the film the result of Eq. [27], V_1 for the upper half; and V_2 for the lower one. Thus

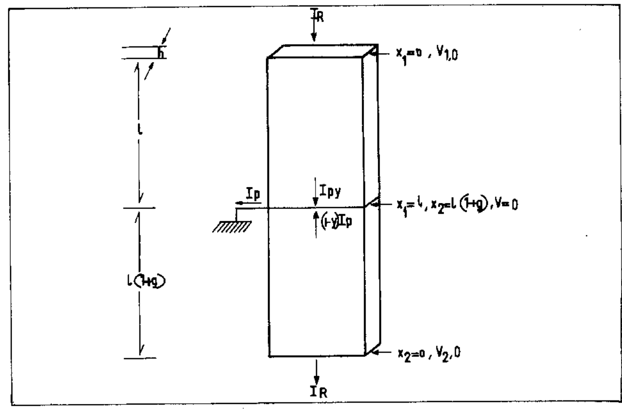

Fig. 6.

$$V_1 = \frac{a}{b}\left(1 - \frac{\cosh \alpha_1 x}{\cosh \alpha_1 l}\right) + \frac{\rho(l-x)}{A} I_m \quad [35]$$

and

$$V_2 = \frac{a}{b}\left(1 - \frac{\cosh \alpha_2 x}{\cosh \alpha_2 l(1+g)}\right) - \frac{\rho[l+g) - x]}{A} I_m \quad [36]$$

where

$$\alpha_1 = \alpha y^{1/2}, \quad \alpha_2 = \alpha(1-y)^{1/2} \quad [37]$$

From [35] and [36], the potential difference between the extremes of the film are

$$({}^1\Delta^2 V)_1 = V_1(x=0) - V_2(x=0) = \frac{a}{b}\left[\frac{1}{\cosh \alpha_2 l(1+g)} - \frac{1}{\cosh \alpha_1 l}\right] - \frac{\rho(2l+g)}{A} I_m \quad [38]$$

If the direction of the current I_m is reversed

$$({}^1\Delta^2 V)_2 = \frac{a}{b}\left[\frac{1}{\cosh \alpha_2 l(1+g)} - \frac{1}{\cosh \alpha_1 l}\right] + \frac{\rho(2l+g)}{A} I_m \quad [39]$$

then, from [38] and [39] it results

$$\frac{({}^1\Delta^2 V)_1 + ({}^1\Delta^2 V)_2}{2} = \frac{a}{b}\left[\frac{1}{\cosh \alpha_2 l(1+g)} - \frac{1}{\cosh \alpha_1 l}\right] \quad [40]$$

Equation [40] gives only the potential due to the faradaic process. The difference

$$\frac{({}^1\Delta^2 V)_1 - ({}^1\Delta^2 V)_2}{2} = \frac{\rho(2l+g)}{A} I_m \quad [41]$$

Thus, the conductivity of the film free from the effect of the faradaic process can be determined through Eq. [41].

Equation [41] differs from that previously obtained (12) in that, besides the sign, it does not depend on the polarization parameters, thus effectively allowing one to determine the resistivity changes in the presence of a faradaic process.

Equation [39] implies, in agreement with previous results (12), that as g tends to zero, the value of V corresponds exclusively to the resistive contribution. This would allow the evaluation of ρ with only one measure of ${}^1\Delta^2 V$.

Conclusions

Assuming that the p.d. along the electrode can be linearized, a solution to the potential distribution for a resistive electrode, valid for both anodic and cathodic currents, is obtained. This is a generalization of

previous results and free from the inconveniences pointed out in the introduction.

When the applied overpotential is sufficiently small, the C.D. equals the polarization current divided by the electrode area and the p.d. in the film follows a simple Ohm's law relationship which involves the average current in the film.

The theory of the method to obtain the resistivity change of an electrode is developed. For not too high electrochemical and measuring currents, the coupling between them can be ignored. Under these conditions the p.d. between the extremes of the film in the three contact method can be split and the ohmic contribution determined. The latter allows the evaluation of the resistivity of the electrode if the dimensions of the film are known. Alternatively, if the film does not dissolve, the change of resistivity with overpotential can be obtained from the change of resistance. If the film is symmetric with respect to the central contact, one measure of the p.d. at the extremes will suffice to obtain the resistance. Since these points have not been seemingly taken into account before, previous results concerning resistivity changes in the presence of faradaic current should be considered carefully if no other means have been employed to diminish the V_p contribution.

Experimental work is underway in our laboratory to test Eq. [20], [22], and [41] which will be the subject of a future publication.

Changes in Surface Crystallinity and Morphology of CdS and CdSe Photoelectrodes upon Use in Polysulfide Electrolyte

ABSTRACT

Surface changes that occur when CdS and CdSe photoelectrodes are used in photoelectrochemical cells containing polysulfide redox couples are investigated using low angle x-ray diffraction, reflection electron diffraction, and scanning electron microscopy. Both single crystal CdS and CdSe, and thin layer polycrystalline CdSe samples are used and in all cases restructuring of the surface, accompanied by some decrease in crystallinity of the surface layer, exposed to the electrolyte, is observed. For CdSe samples, crystallographic evidence for a predominant CdS top layer was seen after deactivation. Impurities in thin film CdSe samples are not affected by deactivation and they themselves do not seem to influence electrode activity or stability. These results support the occurrence of a dynamic restructuring process of the electrode surface in this system, which can cause electrode deactivation, by the formation of a layer that impedes charge transfer, if high current densities are used. Evidence is presented that surface recrystallization can occur in the dark, when such a process occurs probably very slowly.

n-CdS and CdSe have attracted much attention as photoelectrodes in photoelectrochemical cells (PEC's) containing polychalcogenide ($S_x^=$, $SSe_x^=$, $Se_x^=$) redox couples because of the possibility to stabilize the photoelectrodes against photocorrosion in such systems, and the use of such PEC's for practical solar energy conversion devices (1-8).

Several explanations have been presented for the stabilizing influence of the chalcogenide redox couples in these systems. They include the common ion effect (for the $CdS/S_x^=$ and $CdSe/Se_x^=$ systems) (9), the relative positions of the $S_x^=$, $SSe_x^=$, and $Se_x^=$ redox potentials with respect to the semiconductor bandedges and decomposition potentials (10, 11), specific adsorption of $S_x^=$ on CdS (and $Se_x^=$ on CdSe) (2, 12), and the favorable kinetic behavior of the chalcogenide redox couples which facilitates proper matching of the rate of the electrochemical reaction to that of the light-induced charge carrier generation, and especially the rate at which these carriers reach the semiconductor/electrolyte interface (13).

It is quite likely that no one of these alone explains the stabilization effect and that a combination of them is responsible. Any explanation, however, should account for the fact that the system's stability is not absolute, *i.e.*, conditions can be defined under which for example the $CdSe/S_x^=$ system is grossly unstable, while under different conditions it may be stable for at least months under normal day/night solar illumination (12). Various factors are involved in determining the behavior of this kind of PEC. They include illumination intensity (actually, real current density across the semiconductor/electrolyte interface), composition of the electrolyte (*e.g.*, ratio of added S to added $S^=$; presence or absence of Se in the solution), temperature, and stirring rate (12, 14, 15).

The exchange of Se by S in CdSe photoanodes was one of the first observations made on the $CdSe/S_x^=$ system (2) and several subsequent studies, by photoelectron and Auger spectroscopy (12, 15-17), electron beam-induced luminescence (15), and by photocurrent spectroscopy (18) have corroborated the initial observations and defined the degree and rate of exchange. This exchange reaction (which takes place in the dark as well, at least to a small extent) can be explained by: (*i*) the instability of CdSe in $S_x^=$ solution (with respect to CdS), and (*ii*) a certain degree of photocorrosion. This last process can be written as

$$CdSe + 2h\nu \rightarrow CdSe + 2e^- + 2h^+ \quad [1]$$

$$CdSe + 2h^+ \rightarrow Cd^{2+} + Se \quad [2]$$

$$Cd^{2+} + S^= \rightarrow CdS \quad [3]$$

Ideally, reaction [2] should not occur at all and instead

$$S^= + 2h^+ \rightarrow S \quad [4]$$

or its polysulfide equivalent should take place. It has been suggested that the extent to which [2] occurs instead of [4] and the (in)ability of the photogenerated holes to reach the surface, through the CdS layer formed by [3] determines the long-term stability of the system (12, 13).

Because reactions [2] and [3] give rise to a reprecipitation of CdS, out of the solution layer immediately adjacent to the surface, onto the electrode, a change in surface morphology and possibly surface crystallinity is expected, especially for a photocorroded electrode. The same holds for the $CdS/S_x^=$ system, where no change in chemical composition should accompany the surface restructuring.

The formation of a polycrystalline layer on a single crystal CdSe photoanode, after use in polysulfide solution was inferred from preliminary ellipsometry experiments (12). Gerischer and Gobrecht made a similar suggestion for CdS and CdSe photoanodes, based on Mott-Schottky plots, which indicate an increase of charge in the semiconductor surface layer after use in a polysulfide PEC (18). Noufi *et al.* deduced from SEM pictures for single crystal CdS photoanodes, after use in polyselenide solution an increase in surface roughness (16).

In this study we report direct experimental evidence for surface restructure in single crystal CdS, and single

Key words: photoelectrochemistry, surface restructure, SEM.

crystal and polycrystalline CdSe photoanodes, after deactivation in polysulfide solutions, as detected by Guinier thin film x-ray diffraction (GXD), reflection electron diffraction (RED), and scanning electron microscopy (SEM). Such a study was deemed important to try to define the surface changes taking place, especially in as far as they influence PEC output stability, and as a basis for comparison with similar studies on surface changes observed for $CuInS_2$ photoanodes in $S_x^=$ solutions (19), where output stability behavior quite different from that of Cd chalcogenides is observed (20).

Experimental

CdS and CdSe crystals were obtained from Cleveland Crystals, Cleveland, Ohio (CdS: 1.1 Ω-cm; CdSe: 1.3 Ω-cm). Unless specified, the $(11\bar{2}0)$ (CdS) or $(10\bar{1}0)$ (CdSe) face was exposed to the electrolyte and contacts were made with an In-Ga alloy and Ag paint. Polycrystalline thin film CdSe photoelectrodes were prepared by electroplating on Ti (21) and also by applying a slurry containing CdSe powder to Ti substrate (22). The electrolyte was 1M each in KOH, $Na_2S \cdot 9H_2O$, and S, prepared and kept under N_2.[1] Except for a small surface area exposed to the solution, the electrodes were covered with tar or an insulating epoxy. After the use, described below, this layer was dissolved in toluene or warm dimethyl sulfoxide. In case of thin film samples, two pieces, from the same electrode, one, solution-exposed, the other, originally covered by epoxy or tar, were cut out and used for further study.

Single crystals were first polished flat (3 μm alumina). The CdS single crystal samples were etched prior to use in a 3M HCl solution (30 sec), rinsed with H_2O, etched in Br_2/MeOH (30 sec), and rinsed. The CdSe single crystal samples were etched for 30 sec in aqua regia, rinsed with water, put for 30 sec in 10% KCN solution, and rinsed again. The thin film polycrystalline CdSe electrodes were etched for 10 sec in 5% aqua regia solution, and treated further as the single crystals. This etching treatment, which improved output stability, was also used to prepare the samples in a reproducible manner for further experiments. After deactivation all samples were washed with sulfide solution and rinsed with water.

The electrodes were used in a 2-electrode PEC, and run under short-circuit conditions, where a large surface area carbon ring constituted the counterelectrode whose polarization was shown to be minimal at the current densities used (~1-2 mV/mA photocurrent). Oxygen-free N_2 was bubbled through the solution during the experiment. Illumination was provided by a 150W tungsten-halogen lamp (Oriel Corporation) through Pyrex or quartz windows. Light intensities were adjusted to obtain the desired initial photocurrents, and varied between ~100 and ~600 mW/cm². A Schoeffel GM 250 monochromator was inserted for photocurrent spectra (3.3 nm bandpass). The exciting beam was modulated at 100 Hz and the true photocurrent detected by a Brookdeal 9505SC lock-in amplifier.

For the x-ray diffraction (GXD) a Huber-Guinier thin film camera was used with a low angle of incidence (~5°) on the specimen and monochromatic Cu $K_{\alpha 1}$ radiation. The penetration depth is at least one micron. For RED a General Electric electron diffraction camera was used. The electron beam energy was adjusted to 50 keV. The information obtained is due to the crystallinity of approximately the first 100Å from the sample surface. Scanning electron microscope pictures were obtained on an ETEC AUTOSCAN or JEOL SEM at 20 or 25 keV, respectively. Information is obtained from within 200 to 300Å of the sample surface.

[1] Experiments with photoelectrodes in solutions containing, in addition, 5 mM Se and $Se^=$ gave results similar to those reported here. Generally some improvement in output stability was observed for both CdS and CdSe photoelectrodes, as compared to selenide-free solutions, in agreement with (7) and supporting the thesis forwarded in (14).

Results

Deactivation of photoanodes.—A CdS single crystal electrode, 0.2 cm² of which was exposed to the solution, declined gradually in short-circuit photocurrent over a period of 98 hr from 1.3 to 0.5 mA/cm².[2] The higher the initial photocurrent the more rapid the deactivation (Fig. 1). A total photocharge of ~460 C/cm² was passed before the electrode was taken out for further study. Figure 2 shows the photocurrent spectra of the electrode before and after deactivation.

The output of ~0.15 cm² CdSe single crystal electrode declined over a period of 2 hr from 50 to 1 mA/cm², with a total passage of 180 C/cm², in a manner similar to that reported previously (12, 15) (Fig. 3).

[2] The relatively low photocurrents are due to solution absorption. This solution was used as it provides better stabilization than less-absorbing, S-poor, solutions (12, 14).

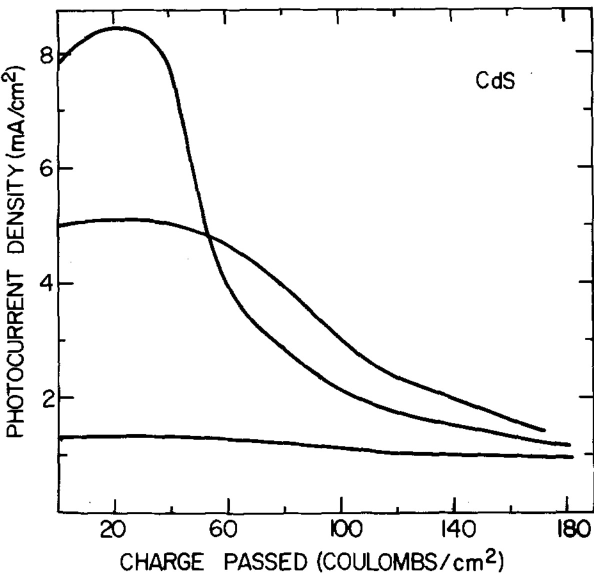

Fig. 1. Output stability of CdS photoanodes for several initial photocurrent densities. The sample with the lower initial photocurrent density, which passed the largest amount of photocharge, was used for further study. Solution temperature: 35° ± 2°C.

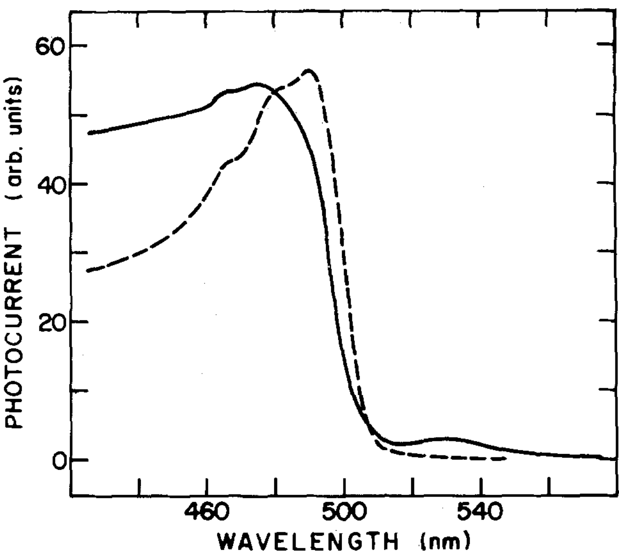

Fig. 2. Wavelength dependence of short-circuit photocurrent of single crystal CdS photoanode before (dashed) and after deactivation. Electrolyte: 1M in OH^- and $S^=$. Data corrected for wavelength dependence of lamp + monochromator. The photocurrent at 480 nm was used to normalize the spectra. The scale for the deactivated sample is some five times more sensitive than that for the freshly etched one. Re-etching of the deactivated sample very nearly restores the behavior of the original, etched electrode.

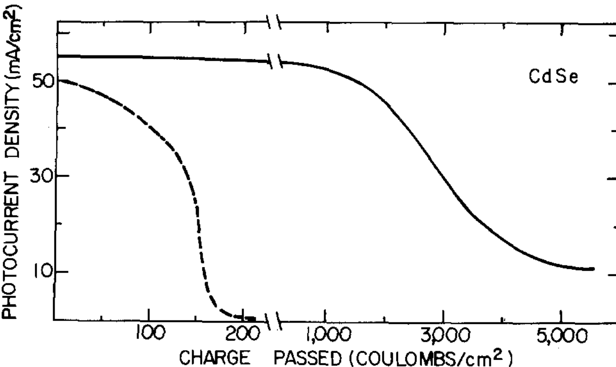

Fig. 3. Output stability of single crystal (dashed line) and painted thin film polycrystalline (solid line) CdSe photoelectrodes. Solution temperature: 35° ± 2°C.

A 0.2 cm^2 area of a 4 cm^2 polycrystalline electroplated CdSe electrode was exposed, and declined in a near-linear fashion from 37 to 12 mA/cm^2 over a period of 85 hr, passing some 9000 C/cm^2.

A 0.2 cm^2 area of a 1 cm^2 electrode prepared with CdSe-containing slurry went from 55 to 10 mA/cm^2 over a period of 48 hr, passing a total of 5600 C/cm^2 (Fig. 3).

Approximate initial AM1 conversion efficiencies were ~1% for the CdS single crystal, ~6% for the CdSe single crystal, and ~3% for the polycrystalline samples.

GXD, RED, and SEM results.—In the GXD of CdS crystal the diffraction spots that were obtained from an unused crystal disappeared after deactivation. This indicates that the top layer of the sample becomes either amorphous or polycrystalline with crystallite size less than ~500Å. The single crystal RED diffraction pattern of unused CdS changes to diffraction rings after deactivation, indicating a polycrystalline top layer. The SEM micrographs (Fig. 4) indicate severe restructuring of the surface upon deactivation [*cf.* Ref (16)], which can be attributed, when the GXD and RED results are taken into account, to the formation of a polycrystalline surface layer.

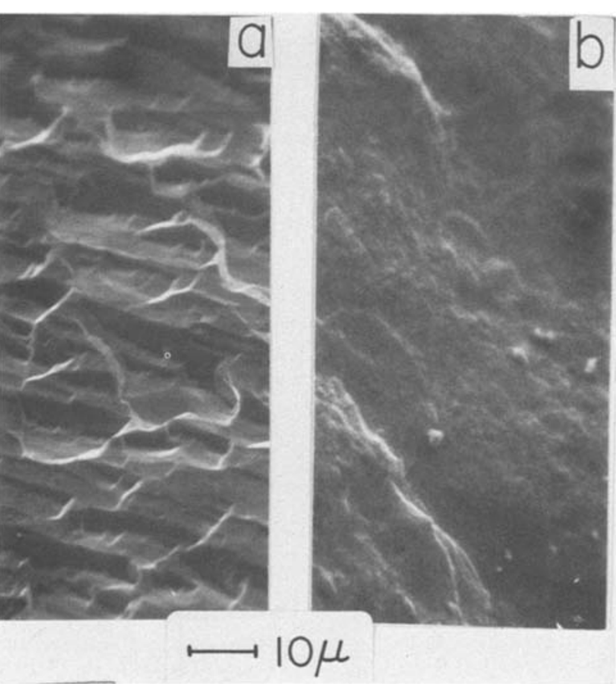

Fig. 4. SEM pictures of CdS crystal: (a) not exposed to solution (after polishing and etching); (b) after deactivation in polysulfide solution. 1000× magnification.

In the GXD of CdSe crystal one very weak single crystal spot is still observed after deactivation, together with very weak lines of hexagonal CdS and CdSe. The superposition of one sharp RED diffraction pattern, and a broad one with a ~3% smaller spacing, shows the presence of both single crystal CdSe and polycrystalline Cd(S, Se). Apparently the single crystal surface is partly maintained. This agrees with the SEM micrograph which shows less of a surface change than is observed for the CdS crystal.

Because of the uneven surface of the thin film polycrystalline CdSe samples, a result of their method of preparation, it was impossible to obtain RED results for them. For comparison sputtered layers were used. These layers (on Ti) gave rather poor photocurrents (a few mA/cm^2 only, under conditions where electroplated samples gave ~35-45 mA/cm^2 short-circuit photocurrents), as their method of preparation was not optimized.

The electroplated layers of CdSe, prepared from reagent-grade materials (21), contain a considerable amount of impurities, which show up in the GXD as strong background intensity, as well as a pattern of broad spotty lines, which can be identified as the high pressure phase of Se (a by-product of the electroplating). These impurities do not seem to influence the photoelectrochemical behavior of these electrodes in an adverse manner. Also, they are not affected by deactivation, while the intensities of the hexagonal CdSe lines drop to about half after deactivation. This decrease is probably due to a decrease in grain size.

The samples that were prepared using the CdSe-containing slurry presented a cleaner and somewhat sharper diffraction pattern. A slight decrease in cell dimensions (~0.02%) is seen upon deactivation indicative of some S/Se exchange as well as a slight decrease in line intensity of the CdSe lines. The RED experiments on sputtered layers showed a clear decrease in line intensity for the deactivated samples. It was not possible to see changes in lattice dimensions here.

The SEM pictures (Fig. 5 and 6) show a restructuring of the surface upon deactivation, and a decrease in average particle size consistent with previous results (16). Figure 5b shows the effect of keeping the electrode in $S_x^{=}$ solution in the dark, resulting in some surface restructure, while Fig. 5d illustrates the often occurring "charging" on deactivated samples.

Discussion

The results can be summarized as follows. The SEM pictures show in all cases surface changes upon electrode deactivation. The nature of these changes is explained by the results from the diffraction experiments.

In the case of CdS crystal a complete restructuring of the surface through the formation of a finely poly-

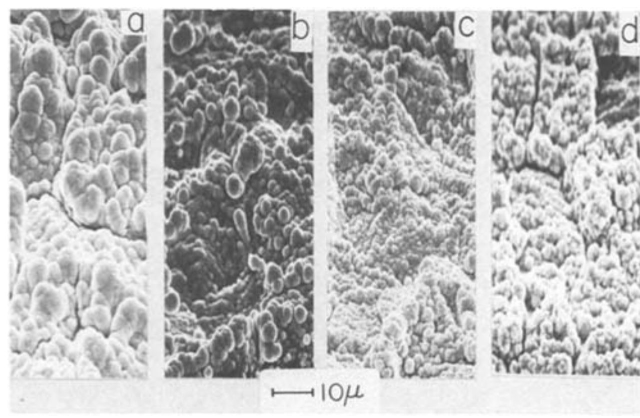

Fig. 5. SEM pictures of electroplated CdSe thin film polycrystalline photoanode. (a) Not exposed to solution (after etching); (b) after standing in the dark in polysulfide solution, overnight; (c) after passing 4 C/cm^2 under illumination; (d) after deactivation. 1000× magnification.

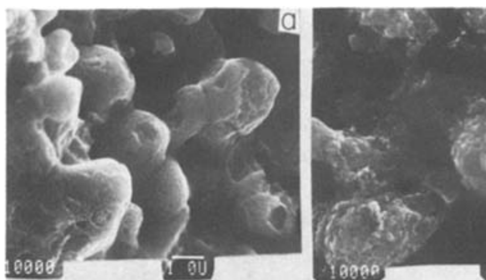

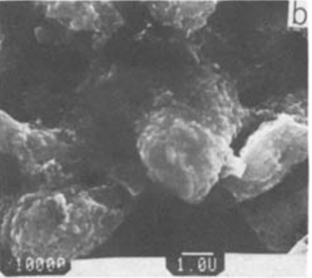

Fig. 6. SEM pictures of painted CdSe thin film polycrystalline photoanode. (a) Not exposed to solution (after etching); (b) after deactivation. 10,000× magnification.

crystalline layer is found. This conclusion is supported by the capacitance measurements of Ref. (18) and by the spectral response data from Fig. 2. Those show a photoresponse at energies less than that of the optical bandgap of CdS, for the deactivated sample. This response indicates the presence of defect states within the forbidden gap [also observed for nonetched samples, especially the peak around 540 nm; *cf.* Ref. (23)]. Such states can be caused by lattice defects and/or impurities within individual grains, or by grain boundaries. In small grain size semiconductor layers, recombinations at grain boundaries will impede the charge transfer of both minority and majority carriers, thus explaining the decrease in absolute photoresponse (quantum efficiency) upon deactivation. The fact that the original photoresponse behavior is restored upon re-etching the deactivated electrode proves that only a (near) surface layer is involved. The rather strong decrease in photoresponse at shorter wavelengths can be due to surface recombination. It is possible that, at the much lower photocurrents obtained with the deactivated sample, this loss mechanism is less important. The sometimes observed initial increase in short-circuit current (*cf.* Fig. 1) may be a trivial effect, due to a decrease in reflectivity of the electrode surface, which occurs already after passage of a small amount of photocharge [*cf.* Fig. 5c; Ref. (16), Fig. 8b; earlier mentioned ellipsometry results).

For the CdSe single crystal electrodes a less dramatic surface change is observed by SEM. Here deactivation causes only partial surface degradation. The diffraction data show that while some of the top layer remains single crystalline, some of it is transformed into polycrystalline Cd(Se, S). The mixed composition of the restructured layer fits the earlier Auger and XPS data (15, 16) especially if we realize that in all experiments averaging over some sample depth occurs. Spectral response changes are less than observed for CdS crystal but the same long wavelength response effect is seen [*cf.* also data on nonetched and etched samples in Ref. (23)]. The polycrystalline nature of the restructured part of the surface is again supported by the data from Ref. (18). Also photoacoustic (PA) measurements on similar CdSe crystal samples show an increase in PA signal after sample deactivation. The fact that this increase is larger ($\sim 2\times$) than the decrease in sample reflectivity can be explained by an increase in real surface area. [In PA measurements the signal is inversely related to the particle size of the probed top layer (24)]. The decreased reflectivity of deactivated samples and the ellipsometry data mentioned in (12) support this conclusion.

In the case of polycrystalline CdSe samples, Fig. 5 and 6 clearly show the surface restructuring upon deactivation. The diffraction experiments indicate that smaller crystallites are present, the composition of which, from the x-ray data, seems to be Cd(Se, S). This agrees with results from XPS for such samples (12, 17). Again, PA experiments show an increase in signal for deactivated samples, as compared to freshly etched ones (24) and the decrease in reflectivity can be observed easily visually.

An interesting additional observation is the occurrence of "charging" in several SEM experiments on deactivated samples (*cf.* Fig. 5d). This can indicate that the restructured top layer has, effectively, a rather high resistance to current flow, as assumed in the earlier proposed electrolyte-insulator-semiconductor (EIS) model (12). The results from (18) support this explanation.

The thickness of the restructured surface layer is difficult to estimate. It will probably vary between single crystal and polycrystalline samples [*cf.* Ref. (16) and (12), respectively]; it will depend on the amount of photocharge passed [*cf.* Ref. (17)], and on the conditions under which the charge is passed (such as real current density, solution composition, and temperature). The surface structure that is present also on etched single crystal surfaces (*cf.* Fig. 4a) adds another complicating factor. Photoelectron and Auger spectroscopic data suggest thicknesses of $\sim$100-200Å for single crystal and polycrystalline CdSe electrodes that passed small to moderate amounts of photocharge, without deactivation (12, 16). However, these values can be considered rough estimates only, because of unavoidable mixing of the top layers upon ion beam sputtering. The results from our RED experiments, which probe the top few hundred angstroms, suggest that these estimates are reasonable ones also for deactivated CdSe single crystals, while thicker layers are probably present on deactivated CdS crystals [*cf.* also Ref. (16)].

Combining our results with those from Ref. (12, 15-18), it seems probable that a dynamic breaking up and rebuilding of the electrode surface takes place when CdS or CdSe electrodes are used in polysulfide solutions. This process takes place also in the dark [*cf.* Fig. 5b and Ref. (12)]. It may very well be that such a process, when not going too far, takes care of rejuvenating the electrode surface continuously, so that "bad spots" may not last very long.[3] Figure 7 shows strong (accidental) evidence for such a rebuilding of the (0001) surface, for a CdS electrode that was kept in the dark (with very little charge passed) for a prolonged period (26). Although different crystal faces are involved {Fig. 7 can be compared with Fig. 4a [or Fig.

[3] The result of deactivation of the slurry-prepared CdSe electrode (Fig. 6b) resembles somewhat the effect of "photoelectrochemical etching" of such electrodes (25), the result of which has been explained, in part, by removal of recombination centers. The often observed improved performance of slightly "aged" (in $S_x^=$) CdSe electrodes [(12); G. Hodes *et al.*, unpublshed results] could possibly be caused by such photoelectrochemical etching in $S_x^=$ solutions, during the passage of an initial, small amount of photocharge.

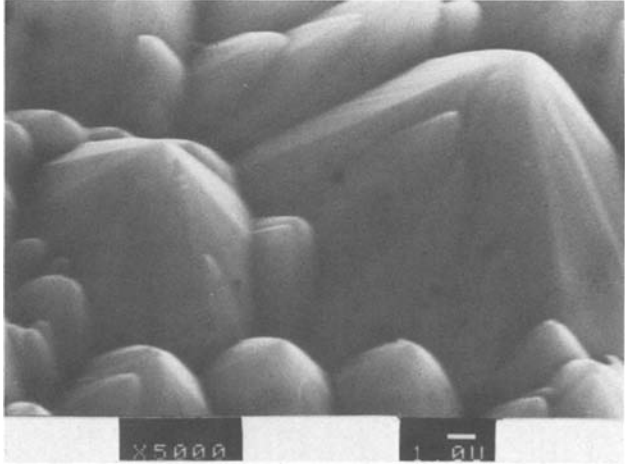

Fig. 7. SEM picture of single crystal CdS electrode [(0001), S-face] after standing in the dark in polysulfide solution, short-circuited to the counterelectrode, for two months. During this period the electrode was used for studies of the temperature dependence (51°C-0°C) of the current under forward and reverse bias (between 0.22 and —0.22V *vs.* rest potential, *i.e.*, S/S= potential) (26).

8a in Ref. 16); here the exposed crystal face is not specified]}. No such organized rebuilding occurs, however, when the electrode is pushed too hard, *i.e.*, too high a local current density passes through the electrode/electrolyte interface. Then this dynamic process dooms the electrode, and thus the PEC. This is caused probably by a combination of factors, such as very much decreased grain size (because of too fast a destruction and reprecipitation), too thick a restructured surface layer, which may present too high a resistivity for current to pass because of different dopant concentration of this layer, and/or bad contacts between the newly formed grains. The importance of the illumination intensity here lies in the way it influences the local current density at the surface. While the electrochemical and corrosion reactions (reactions [4] and [2]) seem to take place simultaneously all the time, there exists apparently a limiting current density above which reaction [2] occurs so fast that the surface restructuring becomes destructive in terms of electrode performance {severe rate mismatch between reactions [1] and [4], *cf.* Ref. (13)}. The results presented here, especially Fig. 7, suggest furthermore that accelerated continuous illumination tests of electrode stability [(12), (15); Hodes, Manassen, Cahen, submitted] may be even more severe ones than previously thought, because of the possible beneficial effect of the dark (night) "breathing" period on the surface restructuring process.

High Rate Discharge of $Ca/LiClO_4$-$LiNO_3$ Thermal Battery Cells

M. H. Miles* and A. N. Fletcher*

Naval Weapons Center, Chemistry Division, China Lake, California 93555

ABSTRACT

The high rate discharge of the $Ca/LiClO_4$-$LiNO_3/Ni$ thermal battery cell is limited by the reduction of the oxidizing molten salts on the nickel current collector. With the addition of $AgNO_3$ to improve the cathodic reaction, this cell can sustain current densities of 100 mA/cm^2 at 350°C to give cell voltages in excess of 2V for several minutes. In cells containing added $AgNO_3$, the source of eventual polarization is the anode rather than the cathode. Based upon the weight of the calcium and electrolyte, cell discharge at 100 mA/cm^2 gives a power density of 740 W/kg and an energy density of 120 W-hr/kg. At a lower rate of discharge (10 mA/cm^2), these cells give very stable potentials of about 2.5V for time periods exceeding 60 min. These cells, therefore, show promise for both high and low rate applications of thermal batteries.

Nitrate and perchlorate salts are attractive for use in thermal batteries since these molten salts have relatively low melting points and can function as both the electrolyte and oxidizer. Eutectic mixtures of these oxidizing molten salts generally have much lower melting points than the conventional LiCl-KCl mixtures used in thermal battery cells (1-3). For example, $LiNO_3$-KNO_3 mixtures melt at temperatures as low as 132°C (4) while an equimolar $LiClO_4$-$LiNO_3$ mixture melts at about 150°C (5). For thermal battery cells using molten salt mixtures containing $LiClO_4$, the operating temperature range is expected to be about 250°-400°C (5). The nature of the molten salt cation plays an important role in the reactions of both nitrates (6, 7) and perchlorates (5). The small lithium ion is more effective than the larger alkali metal cations in catalyzing the electrochemical reduction of molten nitrates.

Thermochemical calculations for the cell reaction

$$Ca_{(s)} + LiNO_{3(l)} \rightarrow CaO_{(s)} + LiNO_{2(l)} \quad [1]$$

at 350°C indicate a cell potential of about 2.8V and a theoretical energy density of 1380 W-hr/kg. For the $Ca/LiClO_4$ cell reaction

$$Ca_{(s)} + LiClO_{4(l)} \rightarrow CaO_{(s)} + LiClO_{3(l)} \quad [2]$$

at 350°C, an even higher cell potential of about 3.2V is calculated that yields a theoretical energy density of 1170 W-hr/kg. Open-circuit cell potentials close to these calculated values have been observed at 350°C in the presence of chloride ions that attack the passivating film on the anode (8, 9).

Previous studies showed that $Ca/LiNO_3$-LiCl-KCl [50-25-25 mole percent (m/o)] thermal battery cells gave promising results when discharged at 10 mA/cm^2 over a temperature range of 250°-450°C (9). At current densities above 20-30 mA/cm^2, however, the cell performance deteriorates due to polarization at the anode. The rate of the calcium anode reaction in molten nitrates is determined largely by the passivating film that hinders the passage of calcium ions across the oxide layer (8). Comparisons of measured and calculated cell resistances suggest that the anodic oxide film makes a sizeable contribution to the total cell resistance (9). This study shows that the presence of $LiClO_4$ improves the performance of the anode during high rate discharge.

* Electrochemical Society Active Member.

Key words: current density, films, fused salts, passivity.

Experimental

The electrochemical cells were fabricated from calcium disks (ROC/RIC, 99%) and fiberglass filter paper disks (Gelman, type A) that contained the electrolyte. The calcium disk was spot-welded to a Ca/Fe bimetallic disk and an aluminum lead wire was spot-welded to the Fe side of the bi-metal. The back side and edges of this disk were masked off by a thin layer of Sauereisen cement (No. 1). All types of disks used were 6.35 mm in diameter (0.32 cm^2).

The molten salt mixture was prepared by weighing out equimolar amounts of $LiClO_4$ (Baker, anhydrous reagent) and $LiNO_3$ (Baker reagent) that had been dried in a vacuum oven at 130°C. Silver nitrate was added to some of the $LiClO_4$-$LiNO_3$ mixtures since this salt had a marked beneficial effect on the cathodic reaction. Dried helium was bubbled through the molten salt mixture at 300°-350°C for several hours to remove the final traces of water. The electrolyte wafers were prepared by simply immersing the fiberglass disks in the molten salt and storing in a desiccator until needed. Cells were assembled and heated as quickly as possible to minimize moisture pick-up. Cell tests with no precautions to minimize moisture gave no unusual results nor did several studies in an argon-filled dry box. The lack of any large effects due to moisture was not unexpected since previous cell studies using $LiNO_3$ in closed and open systems showed that the presence of air or moisture had little effect on test results (9).

Single cell tests were conducted using an open nickel lid placed on a hot plate (S/P Tek Plate 20) with part of the nickel lid serving as the electrode surface for the cathodic reaction. A slight depression in the center of this lid minimized the spread of excess electrolyte away from the surface in contact with the cell. A metal rod was used with a spring and soapstone spacers to maintain a positive face pressure on the cell (9). An L-shaped reference electrode (0.1m Ag^+/Ag) was used to monitor the potential of either the anode or the cathode. The temperature of the cell was read to 1°C with a stainless steel-covered thermocouple probe used with a Fluke Model 2165A digital thermometer readout; temperature control during an experiment was generally within 5°C. The electrochemical cells contained about 60 mg of calcium, 40 mg of the electrolyte, and 4 mg of fiberglass filter paper. Constant current cell discharge was maintained by a PAR Model 173 potentiostat/galvanostat and cell and reference potentials were

plotted using a strip chart recorder (HP 7100B). The cell potential was also read with a Fluke Model 8040A multimeter while the digital readout on the PAR instrument gave the electrode potential *vs.* the reference electrode.

Results and Discussion

Separate studies of cells with $LiNO_3$ or $LiClO_4$ electrolytes were made for comparisons with results for the Ca/$LiClO_4$-$LiNO_3$/Ni cells. The Ca/$LiClO_4$/Ni cells show a marked improvement in the open-circuit potential as the temperature increases above 250°C. The use of the Ag^+/Ag reference electrode reveals that this change is due to the anodic potential suddenly becoming more negative by as much as 1.3V. Investigations of Ca/$LiNO_3$/Ni cells show much lower cell potentials and no spontaneous improvements as the temperature increases. The addition of about 10 m/o LiCl to the $LiNO_3$ electrolyte, however, produces a sudden improvement in the open-circuit cell potential that also corresponds to the potential of the calcium anode becoming about 1.3V more negative. Tests in an argon-filled dry box gave almost identical results, suggesting that any moisture retention by the lithium salts is not a major factor in the activation of the anode. Previous studies have shown the beneficial effect of added chloride ions upon the calcium anode and indicate that the chloride ions cause a breakdown of the passivating calcium oxide film (8-10). It is likely, therefore, that the direct reaction of calcium with molten $LiClO_4$ produces sufficient chloride ions to cause a breakdown of the passivating film.

The open-circuit potential of the Ca/$LiNO_3$/Ni cell at 350°C was generally about 1.5V but increased to about 2.8V in the presence of 10 m/o LiCl while the Ca/$LiClO_4$/Ni cell gave an open-circuit potential of about 3.2V at 350°C. The open-circuit potential of the calcium anode was about -3.1V in $LiClO_4$ and about -3.0V in $LiNO_3$ containing LiCl, hence the cathode contributes about 0.3V to the higher open-circuit cell potentials observed in $LiClO_4$. Upon drawing current from the cell, the cathode polarizes considerably in both molten $LiNO_3$ and molten $LiClO_4$, while the calcium anode potential remains fairly constant at moderate current densities.

The Ca/$LiClO_4$-$LiNO_3$/Ni cell activates similarly to the Ca/$LiClO_4$/Ni cell as the temperature increases above 250°C. Typical open-circuit measurements give potentials of about 2.8V for the cell, -3.0V for the anode potential, and about -0.2V for the cathode potential. Single cell discharge tests of the Ca/$LiClO_4$-$LiNO_3$/Ni cell showed that while the anode could sustain current densities as great as 100 mA/cm^2, the cathode showed considerable polarization and limits the cell performance. The electrochemical reduction of both $LiNO_3$ and $LiClO_4$ produces insoluble Li_2O (5, 7) hence the blocking of the electrode surface by this insoluble product is the likely cause of the polarization of the cathode (11).

The use of an $LiClO_4$-$LiNO_3$-$AgNO_3$ (40-40-20 m/o) mixture greatly improves the performance of the cathode. The reduction reaction of nickel readily sustains 100 mA/cm^2 with very little polarization in the presence of $AgNO_3$. The performance of the calcium anode, however, is poor when placed in direct contact with this mixture. The calcium anode is erratic and slow in attaining its expected large electronegative potential and cannot sustain high current densities. Problems with the calcium anode in the presence of $AgNO_3$ is likely related to the removal of chloride ions as insoluble AgCl (12). This removal of the chloride ions that are formed by the reaction of calcium with $LiClO_4$ would hinder the breakdown of the passivating film on the calcium anode. The preparation of an $LiNO_3$-$LiClO_4$-$AgNO_3$-KCl (40-40-10-10 m/o) mixture showed that a yellowish solid substance forms upon melting. Tests on the liquid portion of the melt indicated that very little silver or chloride ions were present; therefore, the Ag^+ and Cl^- ions apparently separate from the molten salt mixture as insoluble AgCl.

The best cell performance was obtained by using an $LiClO_4$-$LiNO_3$ (50-50 m/o) electrolyte wafer next to the calcium anode and an $LiClO_4$-$LiNO_3$-$AgNO_3$ (40-40-20 m/o) disk next to the nickel electrode. Results for the discharge of this cell at 100 mA/cm^2 are shown in Fig. 1. In this cell test at 350°C, the cell voltage remained above 2V for 7 min, and the lifetime to 75% of the peak voltage was 9 min. The eventual voltage drop of this cell was due to polarization of the anode rather than the cathode. Figure 1 shows that the potential of the cathode remains quite steady at about -0.4V throughout the cell discharge. Based upon the weights of the calcium, electrolyte, and fiberglass, the energy density for this cell was 120 W-hr/kg while the power density was 740 W/kg. From the weight of calcium consumed, the current efficiency for the anode was 15% in this test. For the conventional Ca/LiCl-KCl-$CaCrO_4$/Ni thermal battery cell operating at about 500°C, typical values are 2.8V for the open-circuit potential, 50 W-hr/kg for the energy density, and about 100 W/kg for the power density (13). Such comparisons, however, suffer from the lack of standard methods for the calculations. Furthermore, experimental power densities for a cell designed for short operating times can be considerably higher than for the same cell designed for long operating times.

Although the emphasis of this study is on high rate discharge, these cells also give very stable potentials for long time periods during low rate discharge. Figure 2 shows the discharge of a Ca/$LiClO_4$-$LiNO_3$-$AgNO_3$/Ni cell at 10 mA/cm^2. In this test at 350°C, the cell potential remained above 2.5V for over 70 min and above 2.0V for slightly over 2 hr. The eventual cell voltage drop is again due to polarization of the anode. In another experiment at 350°C on a

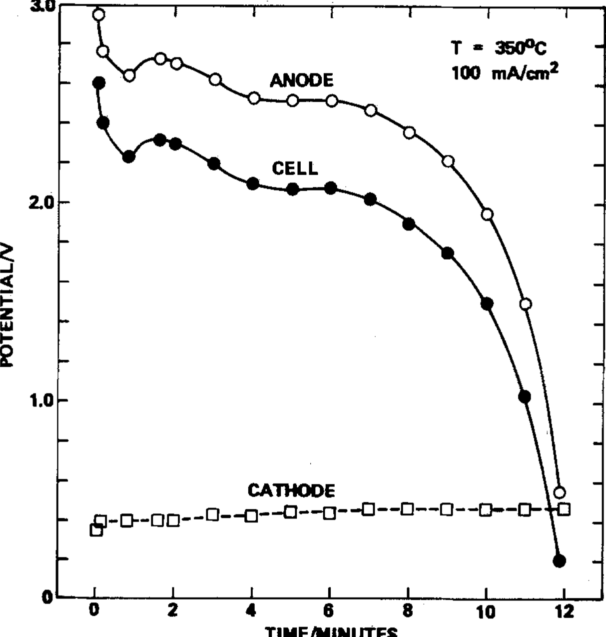

Fig. 1. Cell discharge at 100 mA/cm^2 at 350°C showing anode, cathode, and cell potentials with time. This Ca/$LiClO_4$-$LiNO_3$-$AgNO_3$/Ni cell consisted of an $LiClO_4$-$LiNO_3$ (50-50 m/o) electrolyte wafer next to the calcium anode and an $LiClO_4$-$LiNO_3$-$AgNO_3$ (40-40-20 m/o) wafer next to the nickel electrode. The anode and cathode potentials are both negative in sign as measured against the Ag^+/Ag reference electrode.

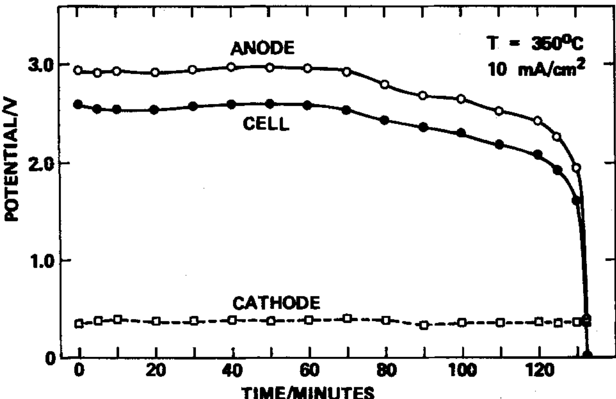

Fig. 2. Discharge of the $Ca/LiClO_4$-$LiNO_3$-$AgNO_3/Ni$ cell at 10 mA/cm^2 at 350°C showing anode, cathode, and cell potential with time. The anode and cathode potentials are both negative in sign as measured against the Ag^+/Ag reference electrode. This cell was discharged for several minutes at both 100 and 50 mA/cm^2 prior to this experiment at 10 mA/cm^2.

cell of this type, discharge at 10 mA/cm^2 gave a cell voltage that remained above 2.4V for 90 min. In fact, all experiments at low discharge rates gave stable cell potentials for long time periods.

Despite the anode polarization that eventually occurs at 100 mA/cm^2, the cell is still capable of further discharge and good performance at smaller current densities. For example, in the experiment shown in Fig. 2, the cell was discharged at 100 mA/cm^2 and again at 50 mA/cm^2 until cell potentials fell below about 1V due to anode polarization prior to conducting the experiment at 10 mA/cm^2. The total energy density for this study was about 240 W-hr/kg.

Although the exact role of $AgNO_3$ has not been determined, it is an obvious possibility that silver ions are being reduced at the cathode. However, the open-circuit and operating cathodic potentials of −0.3 to −0.4V *vs.* Ag^+/Ag (Fig. 1 and 2) suggest that the reaction is more complex than this. Another possibility is that AgCl is involved. The use of an AgCl electrode as the cathode in an experiment gave about the same cathodic potentials as the $LiClO_4$-$LiNO_3$-$AgNO_3/Ni$ electrode. Chloride ions are a likely final product of various reduction or decomposition reactions involving $LiClO_4$ (5, 12).

Calculations show that reduction of all the $AgNO_3$ present would account for only about 30% of the total cathodic current passed in Fig. 1, yet no obvious change in the cathodic potential occurs that indicates a change in the reaction. In the experiment shown in Fig. 2, prior cell discharge at 100 mA/cm^2 would have theoretically consumed all the $AgNO_3$ present. These results suggest a recycling of the silver, perhaps by reactions such as

$$AgCl + e^- \rightarrow Ag + Cl^- \quad [3]$$

$$2Ag + LiClO_4 + 2LiCl \rightarrow 2AgCl + LiClO_3 + Li_2O \quad [4]$$

It is also possible that the deposition of silver particles on the nickel surface increases its effective surface area, thereby aiding the reduction of $LiClO_4$ and $LiNO_3$.

Any use of an active metal anode with an oxidizing electrolyte presents a possible safety hazard. No problems, however, were observed in any cells using the $LiClO_4$-$LiNO_3$ mixtures. In one study of the effect of temperature in molten $LiClO_4$ during cell discharge at 10 mA/cm^2, the calcium anode was stable up to about 450°C whereupon it suddenly reacted with a flash of light rather than with an actual explosion. Explosive reactions have been reported following the deposition of lithium metal at the cathode in molten $LiClO_4$ (14, 15). These results were confirmed by depositing lithium onto the nickel cathode at high rates and then switching to open circuit. Passivating oxide films provide limited stability to the molten lithium metal (mp = 181°C).

The Transport and Kinetics of Minority Carriers in Illuminated Semiconductor Electrodes

W. John Albery and Philip N. Bartlett

Department of Chemistry, Imperial College, London SW7 2AY, England

and Andrew Hamnett and Martin P. Dare-Edwards

Inorganic Chemistry Laboratory, Oxford, England

ABSTRACT

The differential equation describing the transport and kinetics of photogenerated minority carriers in a semiconductor electrode is solved analytically to obtain a solution in terms of confluent hypergeometric functions. Much simpler approximate solutions are also obtained. Comparison of these solutions with results from the full expression show that the approximate solutions hold to within 5%. A simple physical significance can be attached to the different terms in the approximate solutions. The form of the photocurrent voltage curves that arise from the different solutions is discussed.

The recent development of semiconductor electrodes as photocatalysts for solar energy conversion has stimulated several treatments of the kinetics of electron and hole transport and recombination processes within the semiconductor (1-4). Absorption of light of sufficient energy by the semiconductor will generate minority carriers. Electrochemical processes involving these minority carriers at the surface of the electrode will generate a gradient in their electrochemical potential, leading to the transport of further minority carriers to the surface. The observed photocurrent will be equal to the net flow of minority and majority carriers at any point and if we can calculate the net flow at any one point this will be sufficient.

The problem of electrode processes in illuminated semiconductors has been tackled by a number of authors. Gärtner (1) and later Wilson (2) obtained analytical expressions under very limited conditions. Laser and Bard (3) used digital simulation, but because the minority carrier concentration varies over many orders of magnitude in a small region of the space-charge layer they could only obtain results for times very close to the onset of illumination. Reiss (4) made an attempt to include both minority and majority carriers but avoided the field coupling terms, which lead to analytically intractable semilinear equations. Unfortunately the resulting expressions are quite unwieldy and of little value to the experimentalist. Much more rigorous treatments have been proposed, but invariably the resulting equations are too complex to solve analytically.

In this work we follow the approach of Gärtner and Wilson. We make fewer simplifications and in particular our model includes the recombination of holes and electrons in the depletion layer. We show that the results can be described by simple analytical expressions in which each of the terms corresponds to a simple physical process. Furthermore, from the treatment we obtain relatively simple expressions for the concentration profile of the minority carriers.

The Model

The model for the illuminated electrode is illustrated in Fig. 1 where we have chosen to discuss a p-type semiconductor. The semiconductor is divided into two regions. That nearest the surface is the depletion layer and the potential in this region is given by

$$\theta = \theta_0 (1 - x/\sqrt{2\theta_0}\, L_D)^2 \quad [1]$$

Key words: photoelectrochemistry, energy conversion, current.

where

$$\theta = VF/RT \quad [2]$$

$$\theta_0 > 4$$

L_D, the Debye length, is given by

$$L_D = (\epsilon\epsilon_0 kT/e^2 N_D)^{1/2} \quad [3]$$

where N_D is the doping density of the semiconductor. The light of irradiance I_0 mol cm^{-2} sec^{-1} is normally incident on the surface of the electrode and absorption is assumed to follow the exponential Beer-Lambert law with a characteristic absorption coefficient α cm^{-1}. To avoid inverse units we define the absorption length

$$L_\epsilon = 1/\alpha \quad [4]$$

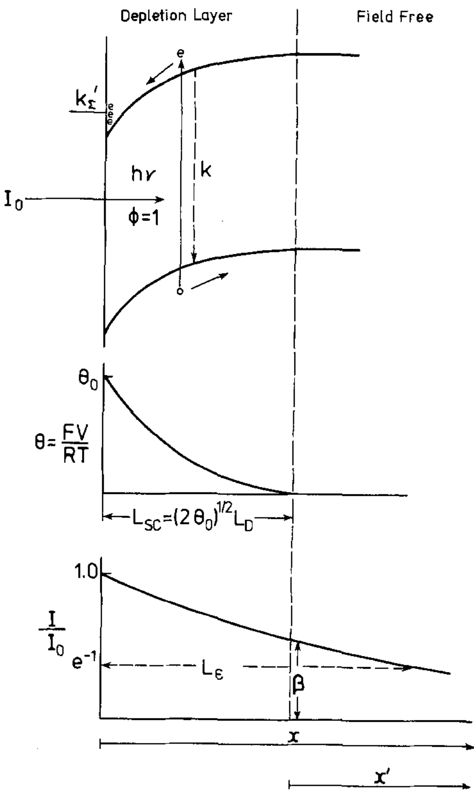

Fig. 1. The model for the semiconductor

In order to avoid cross-coupling terms with the majority carriers, we assume that the buildup of minority carriers at the surface under illumination does not affect the distribution of potential. This important simplification permits us to consider only the equation of motion of the minority carriers. We examine the extent to which this approximation is justified in Appendix A.

The second region $x > \sqrt{2\theta_o L_D}$ is essentially field free. Minority carriers generated in this region diffuse under a concentration gradient only. To deal with the two regions, Wilson used the principle of superposition of charges to evaluate the flux. We use the alternative procedure of matching the concentration and flux of minority carriers at the boundary of the depletion layer.

The Equation of Motion for Minority Carriers

In a steady state the equation of motion describing the transport and kinetics of the minority carriers (electrons for a p-type semiconductor) is

$$D\frac{\partial}{\partial x}\left(\frac{\partial c}{\partial x} - c\frac{\partial \theta}{\partial x}\right) + \frac{I_o}{L_\epsilon}\exp\left(-\frac{x}{L_\epsilon}\right) - kc = 0 \quad [5]$$

where we have assumed that the carriers have a sufficiently low mobility for this equation to be applicable. In this expression c is the concentration of electrons with diffusion coefficient D. The field in the depletion layer is described by the dimensionless variable θ defined in Eq. [1]. The first two terms therefore describe transport by diffusion and migration. The next term describes the photogeneration of the carriers by light with a Beer-Lambert profile characterized by L_ϵ. The last term describes the loss by recombination. In this paper we assume that the electrons recombine by first-order kinetics with a rate constant k. This is likely to be true in the field-free region. In the depletion layer traps can be filled or emptied by the field and so the order of kinetics may change. The concentration of majority carriers will be less at the surface because of the band bending. This may decrease the recombination. Reichman (5) has recently considered a particular case using the Sah, Noyce, and Shockley approximation (6). However first-order kinetics will be maintained under conditions of low illumination and if θ_o is not too large. In this paper we treat this case rigorously. In a subsequent paper we shall extend our treatment to include the other kinetic cases.

Equation [5] must be solved with the two boundary conditions as

$$x \to \infty \qquad c \to 0 \quad [6]$$

and at $x = 0$

$$NI_o = D\left[\left(\frac{\partial c}{\partial x}\right)_o - c_o\left(\frac{\partial \theta}{\partial x}\right)_o\right] = k_\Sigma' c_o \quad [7]$$

The boundary condition as $x \to \infty$ assumes that the thermal population of minority carriers is negligible compared to the population generated by the light. The boundary condition at $x = 0$ relates the flux described by either NI_o or the transport terms to the kinetics on the surface of the semiconductor described by the overall heterogeneous rate constant k_Σ'. The collection efficiency, N, compares the flux of minority carriers lost at the surface by, for instance, recombination and faradaic processes to the flux of incoming photons. When surface recombination (k_R') and a faradaic reaction (k_F') are the two main processes we define a faradaic collection efficiency, N_F, where

$$N_F = (k_F'/k_\Sigma')N \quad [8]$$

and

$$k_\Sigma' = k_F' + k_R' \quad [9]$$

To solve Eq. [5] we first solve the equation with boundary condition [6] for the field-free region with $\theta = 0$ for x greater than W where W is the width of the depletion layer

$$W = (2\theta_o)^{1/2} L_D \quad [10]$$

We thereby obtain a relation between the concentration, c_W, and the flux, c_W', at $x = W$. Similarly we solve Eq. [5] for the depletion layer with boundary condition [7] and Eq. [1] for θ, to obtain a second relation for the concentration and the flux at $x = W$. Elimination of c_W and c_W' will then lead to an expression for N.

The Field-Free Region

Using Laplace transforms Eq. [5] with boundary condition [6] gives

$$Dc_W' = -\frac{Dc_W}{L_k} + \frac{L_k}{L_k + L_\epsilon}\beta I_o \quad [11]$$

and

$$c = c_W \exp\left(-\frac{x'}{L_k}\right) + \frac{\beta I_o L_\epsilon k^{-1}}{L_k^2 - L_\epsilon^2}\left\{\exp\left(-\frac{x'}{L_k}\right) - \exp\left(-\frac{x'}{L_\epsilon}\right)\right\} \quad [12]$$

where

$$x' = x - W$$

$$\beta = \exp(-W/L_\epsilon) = \exp[-(2\theta_o)^{1/2}L_D/L_\epsilon] \quad [13]$$

and

$$L_k = (D/k)^{1/2} \quad [14]$$

The parameter β describes the fraction of the light that is absorbed in the field-free region, and the length L_k is the diffusion length or reaction layer thickness (7). These results are identical to those obtained for the similar concentration profile for photogeneration in a homogeneous photogalvanic cell (8). Equation [11] shows that the flux at the edge of the depletion layer can be either negative or positive. The first negative term describes the diffusion of electrons out of the space charge layer and their subsequent loss by recombination in a reaction layer of thickness L_k. The second positive term describes the injection of electrons into the depletion layer from photogeneration in the field-free region; the light absorbed is βI_o and the fraction recovered is $L_k/(L_k + L_\epsilon)$. For good recovery L_k must be larger than L_ϵ.

The Depletion Layer

We start by writing

$$c = ue^\theta \quad [15]$$

Substitution in Eq. [5] together with Eq. [1] then gives

$$\theta\frac{\partial^2 u}{\partial \theta^2} + (\theta + 1/2)\frac{\partial u}{\partial \theta} - 1/2\gamma u = -1/2 g e^{-\theta} \quad [16]$$

where

$$\gamma = L_D^2/L_k^2 \quad [17]$$

and

$$g = \frac{\beta I_o L_D^2}{D L_\epsilon}\exp\left[\frac{L_D(2\theta)^{1/2}}{L_\epsilon}\right] \quad [18]$$

Equation [16] is an inhomogeneous Kummer equation (9) and is solved below. However, more insight into the physical significance of the mathematics can be obtained from simple analytical expressions found using approximate methods of solution.

The Approximate Method for $L_D < L_k$

In this approach we integrate Eq. [5] using boundary condition [7] to obtain

$$D\left(\frac{\partial c}{\partial x} - c\frac{\partial \theta}{\partial x}\right) = I_o[N - 1 + \exp(-x/L_\epsilon)] + k\int_0^x c\,dx' \quad [19]$$

Substitution from Eq. [1], [13], [15], and [17] gives

$$\frac{\partial u}{\partial \theta} = -\frac{I_0 L_D}{D}\left\{N - 1 + \beta \exp\left[\frac{(2\theta)^{1/2} L_D}{L_\epsilon}\right]\right\}\frac{\exp(-\theta)}{(2\theta)^{1/2}} - \gamma\frac{\exp(-\theta)}{(2\theta)^{1/2}}\int_\theta^{\theta_0}\frac{u\exp(\theta')}{(2\theta')^{1/2}}d\theta' \quad [20]$$

We assume first that $L_D^2 < L_\epsilon^2$, which is almost certain to be true for any practical case. Then, when the γ term is negligible, Eq. [20] can be integrated to obtain

$$u_{\gamma=0} = u_0 - \frac{I_0 L_D}{D}\frac{\pi^{1/2}}{2^{1/2}}(1-\beta-N)\left[\text{erf}\,\theta_0^{1/2} - \text{erf}\,\theta^{1/2}\right] \quad [21]$$

$$N = \frac{1 - \beta + \dfrac{\beta L_k}{L_k + L_\epsilon}f}{1 + \dfrac{kL_D}{k_\Sigma'(2\theta_0)^{1/2}} + \dfrac{D\exp(-\theta_0)f}{k_\Sigma' L_k}} \quad [27]$$

where

$$f = \frac{1 - \gamma\ln(1 + \pi^{1/2}\theta_0^{1/2})}{1 + (\pi\gamma/2)^{1/2}} > 0 \quad [28]$$

and

$$\gamma = L_D^2/L_k^2$$

Now f will differ significantly from unity only when $L_k \lesssim L_D$. Since we have assumed that $L_D << L_\epsilon$ the third term in the numerator will be negligible under these conditions. Also under the same conditions the third term of the denominator will be very much smaller than the second. So for most cases we can put $f = 1$ and using Eq. [13] write

$$N \simeq \frac{1 - \exp\left[\dfrac{-(2\theta_0)^{1/2}L_D}{L_\epsilon}\right] + \dfrac{L_k}{L_k + L_\epsilon}\exp\left[\dfrac{-(2\theta_0)^{1/2}L_D}{L_\epsilon}\right]}{1 + \dfrac{k}{k_\Sigma'}\left[\dfrac{L_D}{(2\theta_0)^{1/2}} + \dfrac{L_k}{\exp(\theta_0)}\right]} \quad [29]$$

In this expression the first term on the right-hand side describes the equilibrium distribution of carriers in the field and is dominant near the surface of the semiconductor where θ is close to θ_0. The second term arises from the transport of carriers in or out of the depletion layer. Its sign depends on $1 - \beta - N$ because the fraction of light absorbed in the depletion layer is $(1 - \beta)$ and the fraction of all the photogenerated carriers that are destroyed at the surface is given by N. When the kinetics in the depletion layer are negligible, then, if $1 - \beta$ is greater than N, carriers are lost to the field-free region and the erf term describes a drop in carrier concentration at the boundary of the depletion layer. Conversely if N is greater than $1 - \beta$ carriers are supplied from the field-free region and the erf term describes a buildup of carriers. In either case the erf term is the dominant term at the boundary of the depletion layer; it arises, because in this region transport by migration is inefficient.

Returning to Eq. [20] we show in Appendix B that for $\gamma < 1$ and $\theta_0 > 6$ the solution for u has the same form as Eq. [21]

$$u \simeq u_0 - B\left[\text{erf}\,\theta_0^{1/2} - \text{erf}\,\theta^{1/2}\right] \quad [22]$$

where B, a constant fixed by the boundary conditions, is

$$B = \frac{\dfrac{\pi^{1/2}}{2^{1/2}}\left\{\dfrac{I_0 L_D}{D}(1-\beta-N) - \gamma\dfrac{c_0}{(2\theta_0)^{1/2}}\right\}}{1 - \gamma\ln(1 + \pi^{1/2}\theta_0^{1/2})} \quad [23]$$

The physical significance of the terms is the same as discussed above. In the numerator of Eq. [23] the γ term allows for the fact that not all the species generated in the depletion layer $(1 - \beta)$ react at the surface (N) or are lost to the field-free region. The term in the denominator means that the solution only holds for

$$\gamma < [\ln(1 + \pi^{1/2}\theta_0^{1/2})]^{-1} \quad [24]$$

From Eq. [15] and [22] we obtain

$$c_W = \exp(-\theta_0)\,c_0 - B \quad \textbf{[25]}$$

where we have assumed that θ_0 is large enough for $\text{erf}\,\theta_0^{1/2} \simeq 1$. Differentiation of Eq. [25] gives

$$c_W' = -2^{1/2}B/\pi^{1/2}L_D \quad [26]$$

Elimination of c_0, c_W, c_W', and B between Eq. [7], [11], [23], [25], and [26] gives

In obtaining this result we have made the following approximations and assumptions

$$\theta_0 > 6$$

$$L_D^2 << L_\epsilon^2$$

$$L_D^2 < L_k^2/\ln(1 + \pi^{1/2}\theta_0^{1/2})$$

$$f = 1$$

As shown in Fig. 2 each of the terms in Eq. [29] has a simple physical significance. The first two terms in the numerator describe the fraction of light that is

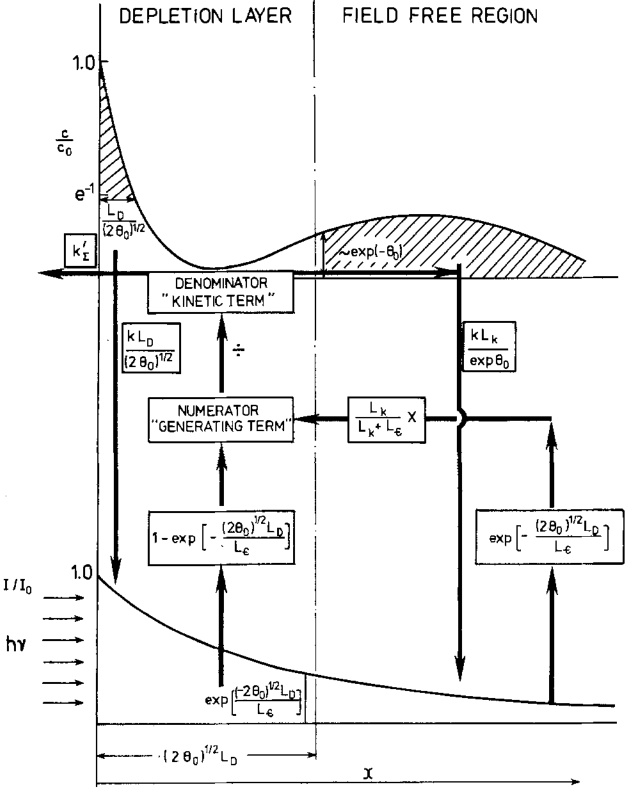

Fig. 2. Diagram illustrating the significance of the various terms in Eq. [29]. The hatching indicates where minority carriers are lost through recombination.

absorbed in the depletion layer; the third term describes the fraction absorbed in the field-free region multiplied by the fraction of those generated that reach the depletion layer boundary. Thus the numerator describes the supply of minority carriers to the surface of the electrode. We call this part of the expression the "generating term." The denominator describes their subsequent fates: the first term reaction at the surface, the second term recombination in the depletion layer, and the third term recombination in the field-free region, where each of the terms is compared to reaction at the surface. We call this group of terms the "kinetic term." Each of the recombination terms contains a characteristic length which describes the volume in which the recombination takes place. In the depletion layer this length is $L_D/(2\theta_o)^{1/2}$. This is because the concentration of minority carriers is largest at the surface of the electrode, and hence for first-order kinetics most recombination takes place close to the surface. At a distance of $L_D/(2\theta_o)^{1/2}$, $c/c_o \simeq e^{-1}$ and thereafter the concentration continues to fall off as θ drops; this is shown in Fig. 2. For the recombination in the field-free region the characteristic length is L_k. The exponential term describes the difference in concentration between the surface and the boundary of the depletion layer. Therefore the collection efficiency, N, consists of the generating term which describes the supply of minority carriers to the electrode surface divided by the kinetic term which compares the proportion of the carriers which then react at the surface with those which recombine either in the depletion layer or in the field-free region.

From Eq. [7], [15], [22], [23], and [29] we can now write down an expression for the concentration profile of minority carriers in the depletion layer

$$c = \frac{I_o \exp(\theta)}{k_\Sigma' + \dfrac{kL_D}{(2\theta_o)^{1/2}} + \dfrac{D\exp(-\theta_o)}{L_k}} \left\{ \left(1 - \beta + \frac{\beta L_k}{L_k + L_\epsilon}\right)\exp(-\theta_o) + \frac{(\pi/2)^{1/2}(L_D/D)}{1 + \pi^{1/2}L_D/2^{1/2}L_k} \left[\frac{\beta L_k}{L_k + L_\epsilon}\left(k_\epsilon' + \frac{kL_D}{(2\theta_o)^{1/2}}\right) - \frac{(1-\beta)D\exp(-\theta_o)}{L_k}\right] [\mathrm{erf}\,\theta_o^{1/2} - \mathrm{erf}\,\theta^{1/2}] \right\} \quad [30]$$

By putting $\theta = 0$ this equation gives the value of c_W to use in Eq. [12] for the field-free region.

Concentration Profiles

Figure 3 shows typical concentration profiles calculated from Eq. [12] and [30]. Note the good join at the boundary of the depletion layer and the way that the depletion layer spreads further into the semiconductor as θ_o increases. The concentration passes through a minimum in the depletion layer where there need not be many carriers because the transport by migration in the field is efficient. It rises through several orders of magnitude at the surface. This is because there must be sufficient carriers to carry the current into the electrolyte. It is while waiting to react at the surface that the minority carriers are most likely to be destroyed in the depletion layer. It is this feature which, despite the complexities of the differential equation, means that the results are so simple. The profiles are similar to those simulated by Laser and Bard (3), but in our case they are the steady-state profiles.

The Approximate Method for $L_D > L_k$

When $L_D > L_k$ the recombination kinetics are so rapid that, in order to reach the surface, carriers have to be generated in the depletion layer; carriers generated in the field-free region are destroyed before they reach the surface. This means that the important region in determining N is a very thin layer close to the surface of the electrode. Returning to Eq. [5] we can then make a simple approximation; we replace $(\partial\theta/\partial x)$ with its value at the surface

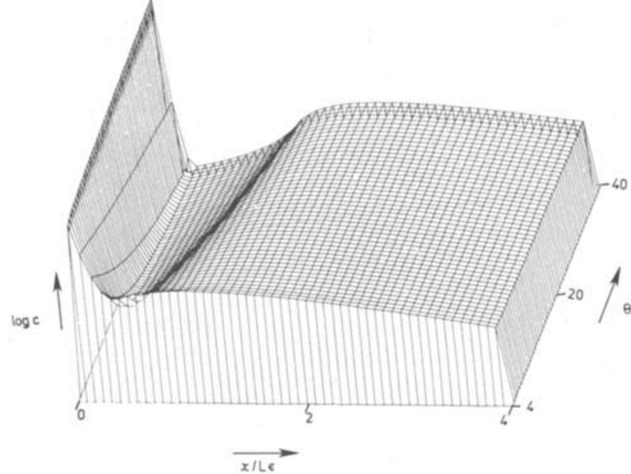

Fig. 3. Typical concentration profiles calculated from Eq. [12] and [30] showing how the concentration varies with distance and the potential across the depletion layer. The following parameters were used: $L_\epsilon/L_D = 6.90$, $L_k/L_D = 6.97$, $k_\Sigma'L_D/D = 1.45 \times 10^{-2}$.

$$(\partial\theta/\partial x) \simeq (2\theta_o)^{1/2}/L_D \quad [31]$$

Equation [5] can then be integrated, using Laplace transforms, to give

$$N = \frac{(1 + L_\epsilon/L_A)^{-1}}{(1 + D/k_\Sigma'L_A)} \quad [32]$$

$$c = \frac{NI_o}{k_\Sigma'}\exp\left(-\frac{x}{L_B}\right) + \frac{I_oL_\epsilon/D}{\left(\dfrac{L_\epsilon}{L_k}\right)^2 + \dfrac{(2\theta_o)^{1/2}L_\epsilon}{L_D} - 1} \times \left[\exp\left(-\frac{x}{L_\epsilon}\right) - \exp\left(-\frac{x}{L_B}\right)\right] \quad [33]$$

where

$$L_A = \frac{L_D}{(2\theta_o)^{1/2}}[(1/4 + \gamma/2\theta_o)^{1/2} - 1/2]^{-1} \quad [34]$$

and

$$L_B = \frac{L_D}{(2\theta_o)^{1/2}}[(1/4 + \gamma/2\theta_o)^{1/2} + 1/2]^{-1} \quad [35]$$

When

$$L_D < (2\theta_o)^{1/2}L_k \quad [36]$$

$$L_A \simeq (2\theta_o)^{1/2}L_k^2/L_D \quad [37]$$

$$L_B \simeq L_D/(2\theta_o)^{1/2} \quad [38]$$

and

$$N \simeq \frac{(1 + L_\epsilon L_D/(2\theta_o)^{1/2}L_k^2)^{-1}}{(1 + kL_D/(2\theta_o)^{1/2}k_\Sigma')} \quad [39]$$

On the other hand, when

$$L_D > (2\theta_o)^{1/2}L_k \quad [40]$$

$$L_A \simeq L_B \simeq L_k \quad [41]$$

and

$$N \simeq \frac{(1 + L_\epsilon/L_k)^{-1}}{1 + D/k_\Sigma'L_k} \quad [42]$$

Under these extreme conditions the kinetics are so rapid that a simple photostationary state is established inside one Debye length. The field has no effect and we obtain the same result as for a photogalvanic cell (8). In the expression for c the effect of the surface

reactions perturbs the concentration profile over a distance $\sim L_B$. As shown by [38] or [41] this distance is very short and thereby justifies the approximation in [31]. When $x > 5L_B$ the dominant term in [33] is the Beer-Lambert exponential term in (x/L_ϵ). The expressions for N in [39] and [42] again consist of a generating term, the numerator, and a kinetic term, the denominator. It is satisfactory that the kinetic term of Eq. [32] for N is the same as the kinetic term in the previous result which was derived for the opposite condition that $L_D < L_k$.

The Rigorous Solution

Although the results derived so far are simple and satisfyingly transparent, we can obtain a rigorous solution to the inhomogeneous Kummer equation [16]. The homogeneous equation

$$\theta \frac{\partial^2 u}{\partial \theta^2} + (\theta + ½) \frac{\partial u}{\partial \theta} - ½\gamma u = 0$$

has two independent solutions (10)

$$G_1(-\theta) = {}_1F_1(-1/2\gamma; 1/2; -\theta) \quad [43]$$

$$G_2(-\theta) = \theta^{½}{}_1F_1(1/2 - 1/2\gamma; 3/2; -\theta) \quad [44]$$

where ${}_1F_1$ is a confluent hypergeometric function (10). The inhomogeneous equation can then be solved by constructing a Green's function and we obtain

$$c \exp(-\theta) = c_W G_1(-\theta) + \frac{G_2(-\theta)}{G_2(-\theta_o)} \left\{ c_o \exp(-\theta_o) - c_W G_1(-\theta_o) - 2G_1(-\theta_o) \int_0^{\theta_o^{1/2}} g G_2(-\theta') d(\theta')^{½} \right\} + 2G_1(-\theta) \int_0^{\theta^{1/2}} g G_2(-\theta') d(\theta')^{½} + 2G_2(-\theta) \int_{\theta^{1/2}}^{\theta_o^{1/2}} g G_1(-\theta) d(\theta')^{½} \quad [45]$$

When γ is small then (10)

$$G_1(-\theta) \simeq 1 \quad [46]$$

$$G_2(-\theta) \simeq ½\pi^{½} \operatorname{erf} \theta^{½} \quad [47]$$

If we also assume that $L_D << L_\epsilon$ then [45] reduces to the corresponding Eq. [22].

Differentiation of [45] to find c_W' followed by elimination using [7], [11], and [13] gives

$$N = \frac{\beta \left[\frac{L_k}{L_k + L_\epsilon} + \int_0^{\theta_o^{1/2}} g' G_1 d\theta^{½} + \frac{2^{½} L_D}{L_k} \int_0^{\theta_o^{1/2}} g' G_2 d\theta^{½} \right]}{G_1(-\theta_o) + \frac{2^{½} L_D G_2(-\theta_o)}{L_k} + \frac{D}{2^{½} k_\Sigma' L_D} G_1'(-\theta_o) + \frac{D}{k_\Sigma' L_k} G_2'(-\theta_o)} \quad [48]$$

where

$$g' = \frac{2^{½} L_D}{L_\epsilon} \exp\left[\frac{(2\theta)^{½} L_D}{L_\epsilon} \right]$$

$$G_1'(-\theta) = \partial G_1(-\theta)/\partial\theta^{½} = 2\gamma\theta^{½}\, {}_1F_1(1 - 1/2\gamma; 3/2; -\theta) \quad [49]$$

$$G_2'(-\theta) = \partial G_2(-\theta)/\partial\theta^{½} = {}_1F_1(1/2 - 1/2\gamma; 1/2; -\theta) \quad [50]$$

This general expression for N again consists of a generating term, the numerator, and a kinetic term, the denominator. For small values of γ the confluent hypergeometric functions may be simplified, as given in Eq. [46] and [47] and

$$G_1'(-\theta_o) \simeq 2\gamma \operatorname{Daw}(\theta_o^{½}) \simeq \gamma\theta_o^{-½} \quad [51]$$

$$G_2'(-\theta_o) \simeq \exp(-\theta_o) \quad [52]$$

where Daw (λ) is Dawson's integral (11). For values of $\theta_o^{½} > 3$ we can make the further approximation in Eq. [51]. Substitution in [48] followed by integration gives

$$N \simeq \frac{1 - \beta + \frac{\beta L_k}{L_k + L_\epsilon} \left(\frac{1}{1 + \pi^{½} L_D / 2^{½} L_k} \right)}{1 + \frac{k L_D}{k_\Sigma' (2\theta_o)^{½}} + \frac{D}{k_\Sigma' L_k} \frac{\exp(-\theta_o)}{(1 + \pi^{½} L_D / 2^{½} L_k)}} \quad [53]$$

This expression is identical with [27] when, for the same reasons as we could put $f = 1$ in [27], the terms in $\pi^{½} L_D / 2^{½} L_k$ are ignored. For large values of θ_o alternative expressions for the confluent hypergeometric functions may be used (10) giving

$$N = \frac{\left(\frac{W}{L_\epsilon}\right)^{-\gamma} \exp\left(-\frac{W}{L_\epsilon}\right) \int_0^{W/L_\epsilon} \lambda^\gamma \exp(\lambda) d\lambda + \frac{\beta L_k \theta_o^{-½\gamma}}{L_k + L_\epsilon} \cdot \left[\frac{\Gamma(½)}{\Gamma(½ + ½\gamma)} + \frac{\Gamma(½) L_D}{2^{½}\Gamma(1 + ½\gamma) L_k} \right]^{-1}}{1 + k L_D / k_\Sigma' (2\theta_o)^{½}} \quad [54]$$

This result confirms the expression for the kinetic term obtained in the approximate treatments for large values of θ_o, regardless of whether L_k is greater or smaller than L_D. For the generating term, when γ is small ($L_k^2 > L_D^2$), the numerator reduces to the result in [29]. When γ is ~ 1 and $W < L_\epsilon$, the generating term reduces, after integration, to

$$\text{G.T.} = \frac{W/L_\epsilon}{1 + \gamma} \quad [55]$$

This result may be compared with the two approximate solutions from [29] and [39]

$$\text{G.T.} \simeq W/L_\epsilon \quad \text{for} \quad \gamma << 1 \quad [56]$$

and

$$\text{G.T.} \simeq W/L_\epsilon\gamma \quad \text{for} \quad \gamma >> 1 \quad [57]$$

We can therefore extend the validity of the approximate solution for $\gamma > 1$ by writing, instead of [39]

$$N = \frac{\left[1 + \frac{L_\epsilon}{W} \left(1 + \frac{L_D^2}{L_k^2} \right) \right]^{-1}}{1 + k L_D / (2\theta_o)^{½} k_\Sigma'} \quad [58]$$

This expression holds to within 10% for most cases where $2\theta_o^{½} > L_D/L_k > 1$. Similarly for $\gamma < 1$ we can modify the complete Eq. [29] using [54] to give

$$N \simeq \frac{\frac{1 - \beta}{1 + \beta^{0.3}\gamma} + \frac{\beta L_k}{L_k + L_\epsilon} \cdot \frac{\theta_o^{-½\gamma}}{1 + (2\gamma)^{½} + \gamma}}{1 + \frac{k L_D}{k_\Sigma' (2\theta_o)^{½}} + \frac{D}{k_\Sigma' L_k} \exp(-\theta_o)} \quad [59]$$

where the exponent 0.3 has been found to give the best fit to results from the complete equation.

Comparison with Previous Results

Our expression for N may be compared with the previous results obtained by Wilson (2). Using our notation rearrangement of his Eq. [11] and using his Eq. [18] (after correcting a typographical error) we obtain Eq. [29] without the second term in the denominator which describes recombination in the depletion layer. This is because Wilson did not include this effect.

Current Voltage Curves

In dimensionless notation current voltage curves are plots of N_F against θ_0, where N_F is defined in [8]. While it is always possible that the electrochemical rate constants k_F' and k_R' may depend on potential because, for instance, the reactions may involve surface states, one cannot have a general theory for this effect. We can, however, discuss how N depends on θ_0 and therefore see how far the observed current voltage behavior can be attributed to the transport and kinetics in the semiconductor as opposed to the ubiquitous explanation of surface states (2, 12), remembering always that in this paper we have assumed that the recombination kinetics are first order throughout the depletion layer.

Typical results for N as a function of θ_0 are displayed in Fig. 4, 5, and 6. There is less than 5% difference between those results calculated using the appropriate approximate equations [58] or [59] and those obtained using a computer to evaluate the functions in the complete Eq. [48]. This good agreement justifies the approximations used.

In considering the variation of N with θ_0 it is helpful to depict the various types of behavior that can be found from the generating and kinetic terms; this is done in Fig. 7 for the generating term. The diagram shows different approximate expressions for the generating term and the conditions in terms of θ_0 and L_k/L_D for which the approximations hold. Near the boundary lines between the different approximations the full expression has to be used. We have obtained the expression $(2\theta_0)^{1/2}L_D/L_\epsilon$ in the hatched area by following Butler (13) and expanding the exponential terms which is justified in this region. It is interesting that this solution passes smoothly over into the equivalent $\sqrt{\theta_0}$ expression from [39]. In general if there is any variation with potential of the generating term it will vary with $\sqrt{\theta_0}$. The solid lines in the diagram depend only on θ_0 and L_k/L_D, the broken lines depend on L_ϵ. The inset shows how their location varies with L_ϵ/L_D. It can be seen that for $L_\epsilon/L_D > 14$ the broken lines do not appear on the diagram at all. Typical

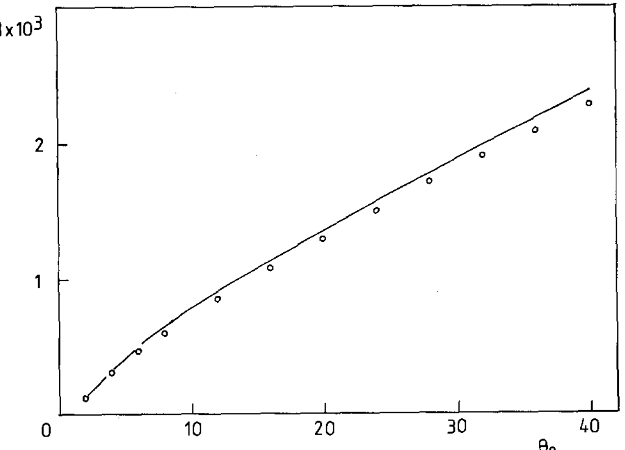

Fig. 4. A current voltage curve for $L_\epsilon/L_D = 20$, $L_k/L_D = 4$, $k_\Sigma'L_D/D = 4 \times 10^{-5}$. The line is calculated from the approximate Eq. [59] (or Eq. [7]) and the points from the full solution Eq. [48].

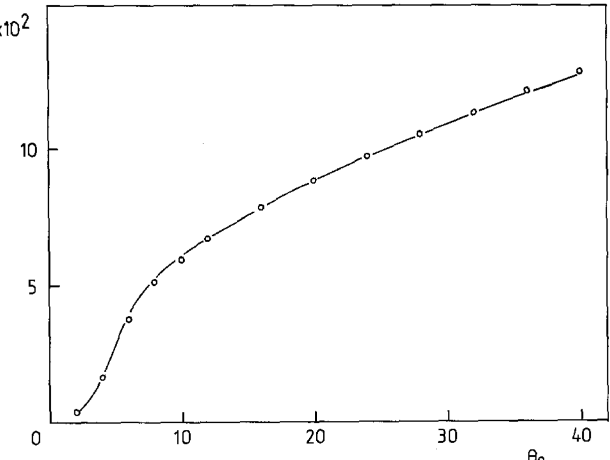

Fig. 5. A current voltage curve for $L_\epsilon/L_D = 20$, $L_k/L_D = 25.1$, $k_\Sigma'L_D/D = 4 \times 10^{-5}$. The line is calculated from the approximate Eq. [59] and the points from the full solution Eq. [48].

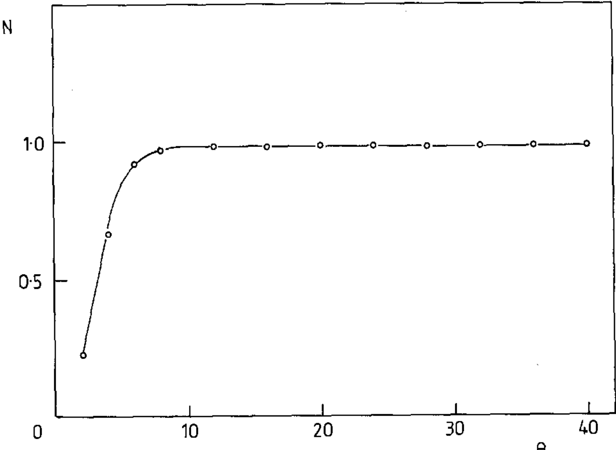

Fig. 6. A current voltage curve for $L_\epsilon/L_D = 20$, $L_k/L_D = 1 \times 10^3$, $k_\Sigma'L_D/D = 4 \times 10^{-5}$. The line is calculated from the approximate Eq. [59] and the points from the full solution Eq. [48].

values of L_ϵ and L_D are 10^{-4} and 10^{-6} cm, respectively, so for most cases the diagram simplifies to the unhatched area where the field has no effect on the generating term and the hatched region around $L_k = L_D$ where the term depends on $\theta_0^{1/2}$. In Fig. 7 for $L_k > 20L_D$ nearly all the carriers are generated in the field-free region and the supply of these carriers to the surface is determined by the kinetics and transport in that region. On the other hand, when $L_k < L_D/20$ the recombination rate is so rapid that for carriers to reach the surface they have to be generated very close to the surface and the extent of the depletion layer is unimportant. Only when $L_k \simeq L_D$ is the width of the depletion layer important in determining how many carriers reach the surface. The more rapid transport by migration in the depletion layer means that carriers generated within the depletion layer have a better chance of reaching the surface than those generated in the field-free region. However we must emphasize that this feature of semiconductor transport and kinetics is only important when L_k is within an order of magnitude of L_D.

Figure 8 is the equivalent diagram for the kinetic term. Again the solid lines depend only on θ_0 and L_k/L_D, while in this case the location of the broken lines depends on the value of $(k_\Sigma'L_D/D)$, as shown in Fig. 9. In general Fig. 8 is divided into four regions. For large values of L_k the recombination kinetics are slow and the kinetic term tends to unity. In the extensive hatched area the kinetic term depends on $\theta_0^{1/2}$ and hence the competition is between k_Σ' and recom-

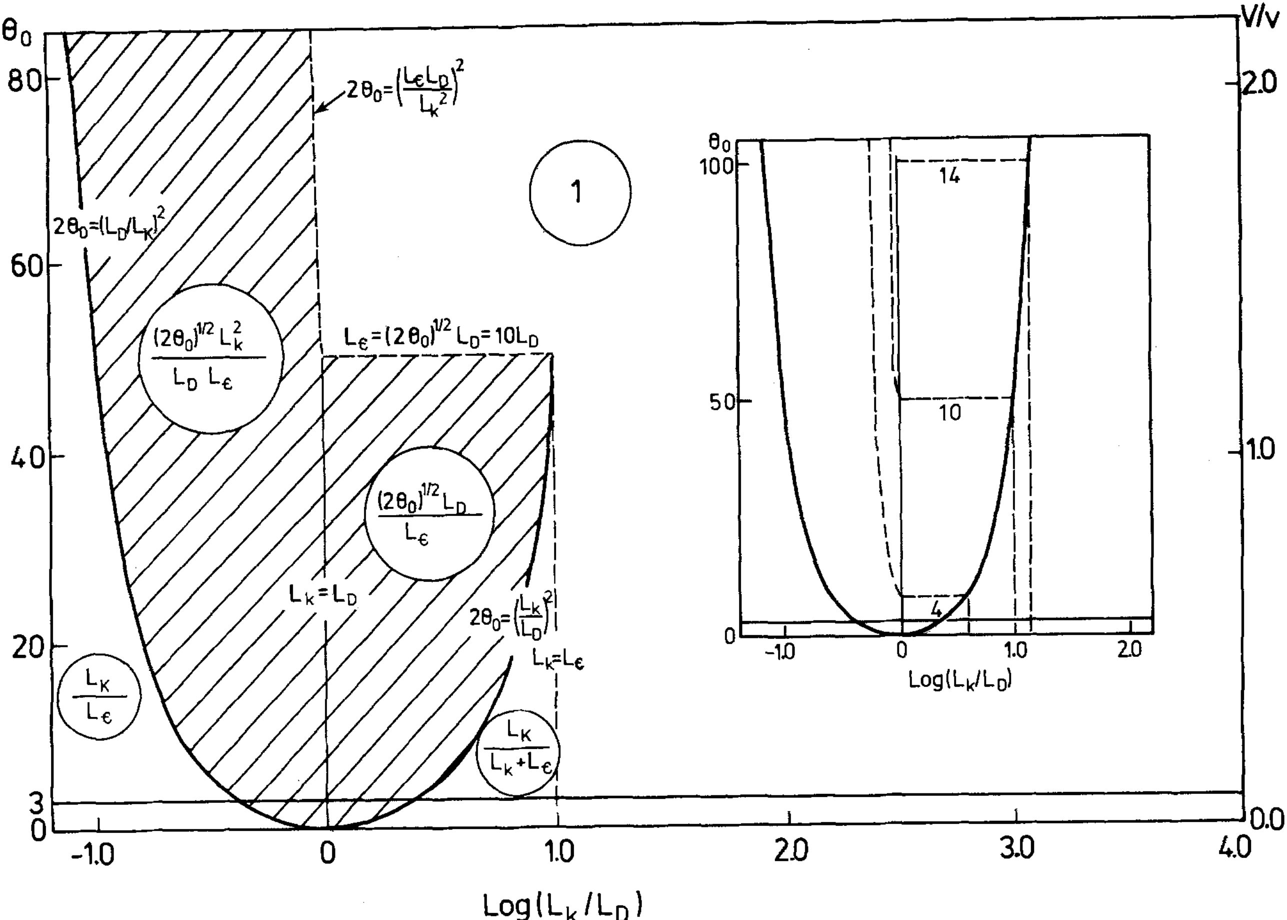

Fig. 7. Approximate solutions for the generating term as a function of L_k/L_D and the applied potential θ_0. The broken lines also depend on the value of L_ϵ, and the inset shows how their position varies with L_ϵ/L_D. Note that the generating term only varies with θ_0 when $L_k \sim L_D$.

bination in the depletion layer. In the speckled area the current depends on exp (θ_0) and the competition is between k_Σ' and loss in the field-free region. Finally at low values of L_k, as with the generating term, the recombination kinetics are so rapid that the width of the depletion layer is unimportant. The boundaries between the hatched or the speckled areas and the region where the term is unity represent the half-wave potentials of the current voltage curves (providing that k_R' and k_F' do not depend on potential). It can be seen that because of the exponential term the speckled area is only found at low values of θ_0. A potential difference from the flatband of less than 0.3V will usually be sufficient to reach the half-wave potential. By contrast the dependence of current on $\theta_0^{1/2}$ is rather a weak dependence. So in many cases the limiting value for the kinetic term of unity is never reached, and the kinetic term depends on $\theta_0^{1/2}$ over an extensive potential range. Finally in Fig. 10 we combine the results to show how N depends on θ_0. We have assumed, as discussed above, that $L_k > 20\ L_D$. It can be seen that if

$$k_\Sigma' < 10^{-4} D/L_D \quad [60]$$

then N depends on $\theta_0^{1/2}$ because of the $\theta_0^{1/2}$ region in the kinetic term rather than the $\theta_0^{1/2}$ region in the generating term. Hence there are two possible explanations of an observed dependence of N on $\theta_0^{1/2}$. The first explanation is that of Butler. This requires that

$$L_k \sim L_D \quad [61]$$

and that

$$k_\Sigma' > D/L_D \quad [62]$$

The last condition ensures that the kinetic term is unity and is equivalent to Butler (13) and Gärtner's (1) assumption of rapid interfacial kinetics. With typical values of D and L_D of 1 cm² sec⁻¹ and 10^{-5} cm, respectively, we find that

$$k_\Sigma' > 10^5 \text{ cm sec}^{-1} \quad [63]$$

This condition is a severe one since a rough estimate suggests that the upper limit for such an electrochemical rate constant is $\sim 10^5$-10^6 cm sec^{-1}. In Butler's case D/cm² sec^{-1} = 0.25 and L_D/cm = 3.4×10^{-5} so he required $k_\Sigma' > 10^4$ cm sec^{-1}.

In our view it is more probable that the condition in Eq. [60] will be satisfied and that the explanation of N being linear with $\theta_0^{1/2}$ involves recombination in the depletion layer, always with the assumption that the kinetics are first order throughout. If this explanation is correct, then the gradients of $N/\theta_0^{1/2}$ plots will depend on k_Σ' and therefore will depend on the medium and the concentrations of electrochemical reactants. This type of behavior has been found, for instance, by Gautron *et al.* (14) for ZnSe. The gradients in $HClO_4$, KCl, and KOH are all different. This cannot arise from the Butler explanation because in that case the gradient only depends on the properties of the semiconductor L_ϵ, L_k, and L_D. Hence this is a simple diagnostic test for the two different explanations.

APPENDIX A

In our treatment we have assumed that the variation of potential with distance is given by [1]. However, the buildup of minority carriers at the surface of the semiconductor (see Fig. 3) may alter the potential distribution. Close to the surface the concentration of minority carriers is given by

$$c \simeq c_o \exp(\theta - \theta_o)$$

The Poisson-Boltzmann equation is then

$$\partial^2\theta/\partial \chi^2 = 1 + \rho \exp(\theta - \theta_o)$$

where

$$\chi = x/L_D$$

and

$$\rho = \frac{c_o}{N_D} = \frac{NI_o}{k_\Sigma' N_D} \quad \text{[A-1]}$$

Integration, assuming $\rho \exp(-\theta_o) << 1$ gives

$$\partial\theta/\partial\chi = -[2\theta + 2\rho \exp(\theta - \theta_o)]^{1/2} \quad \text{[A-2]}$$

and

$$2^{1/2}\chi = \int_\theta^{\theta_o} [\theta' + \rho \exp(\theta' - \theta_o)]^{-1/2} d\theta' \quad \text{[A-3]}$$

To evaluate the integral we split it at θ_* where for $\theta < \theta_*$, $\theta \simeq \theta_o \simeq \theta_*$ and for $\theta > \theta_*$ the term in ρ is negligible.

For $\theta < \theta_*$

$$I_1 = \int_\theta^{\theta_*} \theta^{-1/2} d\theta = 2(\theta_*^{1/2} - \theta^{1/2}) \quad \text{[A-4]}$$

For $\theta > \theta_*$

$$I_2 = \int_{\theta_*}^{\theta_o} \frac{d\theta'}{[\theta_* + \rho \exp(\theta' - \theta_o)]^{1/2}}$$

$$= \theta_*^{-1/2} \ln\left[\frac{P-1}{P+1} \cdot \frac{Q+1}{Q-1}\right] \quad \text{[A-5]}$$

where

$$P = (1 + \rho/\theta_*)^{1/2}$$

and

$$Q = [1 + (\rho/\theta_*) \exp(\theta_* - \theta_o)]^{1/2}$$

Assuming that $\rho/\theta_* < 1$, we use the binomial expansion for P and Q to obtain for I_2

$$I_2 \simeq \theta_*^{-1/2} [\theta_o - \theta_* - 1/2(\rho/\theta_*)\{1 - \exp(\theta_* - \theta_o)\}]$$

Substitution in [A-3] gives for $\theta < \theta_*$

$$\chi \simeq (2\theta_o)^{1/2}[1 - \rho/4\theta_o^2] - (2\theta)^{1/2} \quad \text{[A-6]}$$

Hence for most of the depletion layer the parabolic form of [1] still holds and furthermore the effect of the buildup of minority carriers on the actual potential distribution is negligible if

$$\rho = \frac{NI_o}{k_\Sigma' N_D} << 4\theta_o^2 \quad \text{[A-7]}$$

With the values $N = 1$, $I_o = 2 \times 10^{-7}$ mol cm^{-2} sec^{-1}, $k_\Sigma' = 1$ cm sec^{-1}, and $N_D = 10^{17}$ cm^{-3}, ρ is approximately unity. The effect of the term in ρ is shown in Fig. A-1. It can be seen that the buildup of minority carriers reduces the potential and the width of the layer. From Eq. [A-2] the potential gradient at the surface is steeper

$$(\partial\theta/\partial\chi)_o = -[2(\theta_o + \rho)]^{1/2}$$

This means that, even though [A-7] holds, ρ will have an effect on this gradient when $\rho \sim \theta_o$ and this in turn will affect the loss of minority carriers from recombination in the depletion layer. Hence if ρ is significant compared to θ_o then in [27], [29], [30], [39], [53], [54], [58], and [59] $(2\theta_o^{1/2})$ should be replaced by $[2(\theta_o + \rho)]^{1/2}$ in the depletion layer recombination term in the denominator.

APPENDIX B

In this Appendix we integrate Eq. [20] for the conditions $\alpha < 1$ and $\theta_o > 6$. We start by assuming that the solution has the same form as Eq. [21]

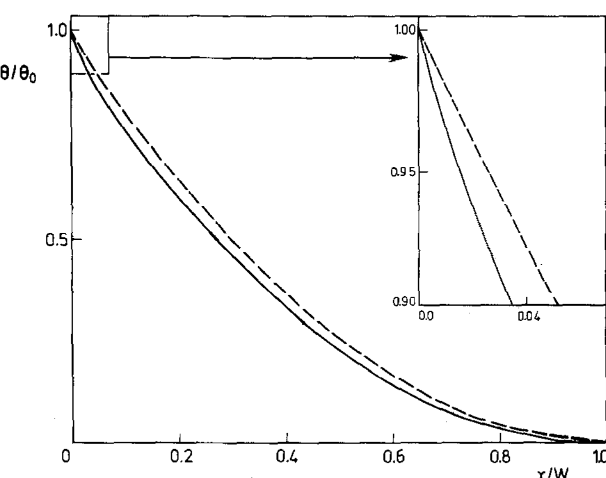

Fig. A-1. The effect of the buildup of minority carriers at the surface on the distribution of potential in the depletion layer, for $\rho = \theta_0 = 10$. The broken line is calculated from Eq. [1] ($\rho = 0$) while the solid line is calculated from Eq. [A-6].

$$u = u_0 - B\,[\mathrm{erf}\,\theta_0^{1/2} - \mathrm{erf}\,\theta^{1/2}] \qquad \text{[B-1]}$$

where B is a constant. A simple approximation for the error functions, which is at worst only 18% in error, is

$$\mathrm{erf}\,\theta_0^{1/2} - \mathrm{erf}\,\theta^{1/2} \simeq \exp(-\theta)/(1 + \pi^{1/2}\theta^{1/2}) \qquad \text{[B-2]}$$

Substitution of [B-1] and [B-2] in [20] followed by integration gives

$$u = u_0 - \frac{I_0 L_D}{D}\frac{\pi^{1/2}}{2^{1/2}}(1 - \beta - N)\,[\mathrm{erf}\,\theta_0^{1/2} - \mathrm{erf}\,\theta^{1/2}] + \gamma \int_\theta^{\theta_0} \frac{\exp(-\theta')}{(2\theta')^{1/2}}\left[u_0 \int_{\theta'}^{\theta_0} \frac{\exp(\theta'')}{(2\theta'')^{1/2}}\,d\theta'' - B\int_{\theta'}^{\theta_0} \frac{(2\theta'')^{-1/2}}{1 + (\pi\theta'')^{1/2}}\,d\theta''\right] d\theta' \qquad \text{[B-3]}$$

The integrals in the γ term are evaluated as follows: First

$$\int_\theta^{\theta_0} \frac{\exp(-\theta')}{(2\theta')^{1/2}} \int_{\theta'}^{\theta_0} \frac{\exp(\theta'')}{(2\theta'')^{1/2}}\,d\theta'' = \int_\theta^{\theta_0} \frac{\exp(-\theta')}{(\theta')^{1/2}} [\exp(\theta_0)\mathrm{Daw}\,(\theta_0)^{1/2} - \exp(\theta')\,\mathrm{Daw}\,(\theta')^{1/2}]d\theta'$$
$$\simeq \tfrac{1}{2}\pi^{1/2}\theta_0^{-1/2}\exp(\theta_0)\,[\mathrm{erf}\,\theta_0^{1/2} - \mathrm{erf}\,\theta^{1/2}] - \tfrac{1}{2}\ln(\theta_0/\theta) \qquad \text{[B-4]}$$

where Daw (λ) is Dawson's integral (11) and for $\lambda > 2$

$$\mathrm{Daw}(\lambda) \simeq \tfrac{1}{2}\lambda^{-1}$$

In [B-4] the ln term can be ignored with respect to the first term.

Second

$$\int_\theta^{\theta_0} \frac{\exp(-\theta')}{(2\theta')^{1/2}} \int_{\theta'}^{\theta_0} \frac{(2\theta'')^{-1/2}}{1 + (\pi\theta'')^{1/2}}\,d\theta'',\ d\theta'$$
$$= \pi^{-1/2}\int_\theta^{\theta_0} \frac{\exp(-\theta')}{(\theta')^{1/2}}\left[\ln\left\{\frac{1 + (\pi\theta_0)^{1/2}}{1 + (\pi\theta')^{1/2}}\right\}\right] d\theta'$$
$$\simeq \ln\,[1 + (\pi\theta_0)^{1/2}]\,[\mathrm{erf}\,\theta_0^{1/2} - \mathrm{erf}\,\theta^{1/2}] \qquad \text{[B-5]}$$

Substitution of [B-4] and [B-5] in [B-3], followed by comparison with [B-1] and using $c_0 = u_0 \exp(\theta_0)$ gives the expression for B in [23]

The Electrochemical Behavior of Synthetic Reformate Fuels on Platinum Electrodes in Trifluoromethanesulfonic Acid Monohydrate

Grayson W. Walker*

ABSTRACT

Electrode performance of two synthetic reformates, one a 3% CO-12% CH_4-85% H_2 mixture and the other a 2% CO-26% CO_2-72% H_2 mixture, were investigated in trifluoromethanesulfonic acid monohydrate (TFMSA · H_2O). These reformate fuels were found to significantly reduce electrode performance when compared to pure H_2 performance, but the reformate performance in TFMSA · H_2O was superior to pure H_2 performance in 85% H_3PO_4. Comparisons in polarization data and activation energies between the reformates and several CO-H_2 mixtures have shown that CO was the rate-limiting component in the reformate mixtures. Voltammetric techniques were employed as a means of studying CO adsorption in TFMSA · H_2O in more detail.

In the past five years, there has been renewed interest in finding alternative electrolytes for fuel cells which combine the stability of phosphoric acid with the desirable electrochemical properties found in acids such as HF or H_2SO_4. The fluorinated alkanesulfonic acids have been investigated extensively (1-8), and trifluoromethanesulfonic acid monohydrate (TFMSA · H_2O), in particular, has exhibited many desirable properties such as low vapor pressure, high ionic strength, and a noninterfering anion group. Adams *et al.* have shown that, kinetically, hydrogen and propane oxidation reactions proceed at rates 3-10 times faster in TFMSA · H_2O than in H_3PO_4, and the open-circuit potential for oxygen on platinum is approximately 150 mV higher in TFMSA · H_2O (4-6).

If TFMSA · H_2O is to be realistically considered as an alternative to phosphoric acid, it must be characterized under all fuel cell conditions. The need for a synthetic source of hydrogen has been established; therefore, a comprehensive characterization of TFMSA · H_2O should include a study of cell performance with reformate fuels where the effect of the various constituents, particularly carbon monoxide, could be observed. The reformer constitutes a large percentage of total fuel cell cost and the higher the grade of reformate required by the fuel cell, the more complex and costly the system becomes. If it could be shown that any detrimental effects produced by the reformate constituents are reduced in the presence of TFMSA · H_2O, then improved cell performance and cheaper system costs through down-scaling of the reformer should be possible. Such a result would undoubtedly enhance the economic value of the fuel cell.

The purpose of this investigation has been to examine the effect of representative reformate fuel feeds on platinum in TFMSA · H_2O and to attempt to determine if TFMSA · H_2O is a viable alternative to H_3PO_4 for use with reformate fuels.

Experimental

The electrochemical tests were carried out in a three-compartment cell made of Pyrex glass similar in design to the cell described by Adams *et al.* (1). The center compartment housed the test electrode and was connected to the reference compartment by a Luggin capillary and a fine pore frit and to the counterelectrode compartment by another fine pore firit. The test electrode was made from a piece of 1 cm^2 platinum gauze which had been electrolytically platinized to give a real surface area of $\sim$30 cm^2 as measured by the cathodic hydrogen deposition technique (9). The reference electrode was a Giner-type dynamic hydrogen electrode (10) which produced hydrogen *in situ* on a platinized platinum electrode, thereby enabling recorded potentials to be referenced to the hydrogen electrode potential.

A block diagram of the electrochemical test station used in these studies is shown in Fig. 1. With this arrangement, all the necessary electrochemical techniques such as electrode surface area measurement, cyclic voltammetry, and single and multi-step potentiokinetic measurements could be employed. The potentiokinetic technique was used extensively to measure the current-voltage dependence of the anodic reactions on the working electrode at various temperatures. These measurements were made using the potential step-timer circuit coupled to the potentiostat. With this circuit, the working electrode could be cycled through a maximum of 15 independently controlled steps ranging in voltage from 0 to $\pm$2.0V and in time from 30 sec to 15 min. A PAR Series 2000 data acquisition system recorded the data on punched paper tape at the end of each potential step. Upon completion of the voltage cycling, the data were then fed to a Xerox computer which averaged the 15-20 current-voltage readings per step, converted the current to current density, and tabulated the complete cycle into voltage, current, and current density.

The TFMSA · H_2O used in this study was prepared by a modification to the Gramsted-Hazeldine technique (11) in which TFMSA (3M Corporation FC-24) and 50% excess water rather than stoichiometric portions of acid and H_2O, were refluxed together and distilled either by the standard ambient pressure technique or by vacuum distillation. The pure acid monohydrate distilled at 217°-219°C at atmospheric

Key words: fuel cell, electrolyte, reformate, carbon monoxide.

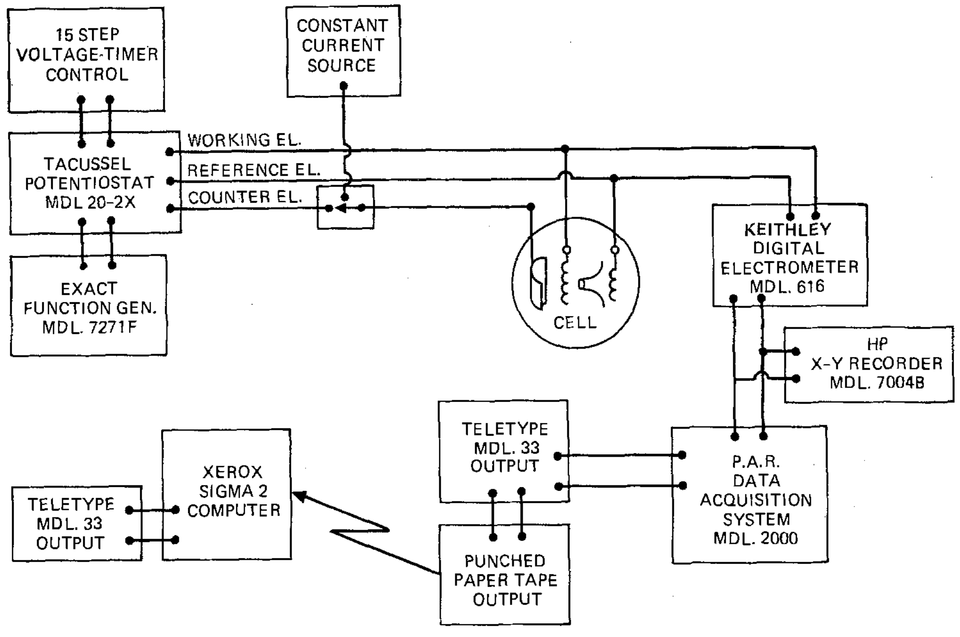

Fig. 1. Schematic diagram of automated electrochemical station.

pressure and at 120°-122°C at 35 mm of pressure. Although both distillation techniques gave the same product, the vacuum technique proved the more desirable because the acid vapor at 120°C was less corrosive to the glass apparatus. The purity of the acid was not determined by separate analysis, but a good qualitative estimation of purity could be made by observing the color, crystallinity of the distillate, and the freezing point of the liquid. Pure TFMSA · H_2O is a white crystalline solid at room temperature, while the refluxed acid-water mixture is a tan, syrupy liquid. With successive distillations, the clarity and ease of crystallization increased to the point that spontaneous crystallization of the product within the condenser became a continual problem. To ensure electrolyte purity, the initial monohydrate product was redistilled at least once, and usually twice, even though little or no change in electrochemical behavior was observed after the first distillation stage.

The commercially purchased reactant gases used in these studies consisted of pure hydrogen (Airco), 3% CO in H_2 (Matheson), 6% CO in H_2 (Matheson), 10% CO in H_2 (Matheson), 3% CO-12% CH_4-85% H_2 (Airco), and 2% CO-26% CO_2-72% H_2 (Matheson). N_2-H_2 and CH_4-H_2 mixtures were also used, but these were blended in the laboratory and their concentrations determined by gas chromatography. During experimentation with the laboratory prepared mixtures, the gas inlet line was monitored continuously to ensure that variation of the component concentrations did not occur. All gas flows were set to the same rotometer setting which for H_2 corresponds to 60 cm^3 min^{-1}. This flow rate was selected after a preliminary study of the effect of flow rate on oxidation current. The current rises rapidly with increase in flow rate to a relatively steady value. The measurements were made at rates greater than those at which current was dependent of flow rate.

Results and Discussion

The investigation of reformate performance was begun by first determining baseline performance with pure hydrogen on platinized platinum in the TFMSA · H_2O. The polarization curves for hydrogen oxidation at various temperatures are shown in Fig. 2. All four curves are characterized by a rapid rise in current followed by a relatively broad limiting current region which extends from 70 mV. Normally, one would expect to observe a Tafel region beginning about 25 mV and extending out as far as 300 mV during which the

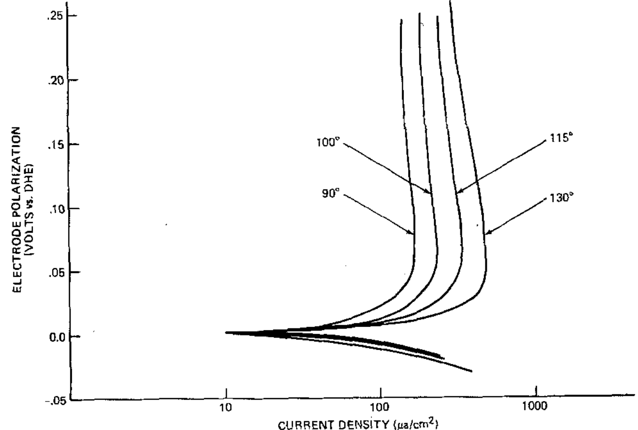

Fig. 2. Hydrogen polarization curves at various temperatures

logarithm of the current would display a linear dependence on potential change (12), but it is obvious from the figure that there is no Tafel region present and that the limiting current region has been attained within only 70 mV of polarization, desirable for an operating fuel cell.

The H_2 oxidation reaction displays a definite positive temperature dependence. Plotting ln i at 50 mV overpotential $vs.$ $1/T$ yields a straight line (Fig. 3),

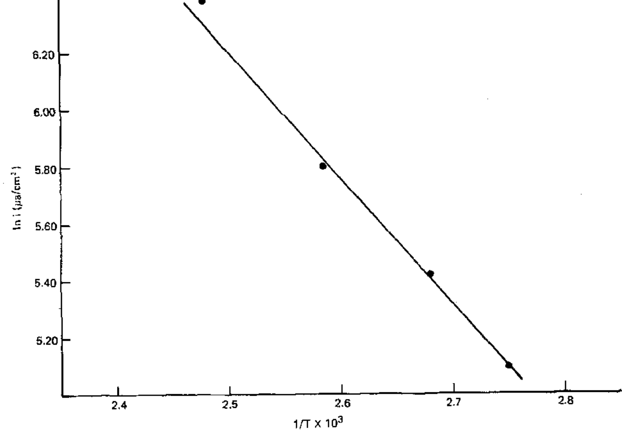

Fig. 3. Temperature dependence of the hydrogen oxidation rate as determined for an electrode held at 50 mV vs. DHE.

corresponding to an activation energy of 9.32 kcal/mol. From similar work published by Adams *et al.* (1), we calculate an activation energy of 7.62 kcal/mol which is in general agreement with our data. Comparing the polarization curves, we observed that the Adams' curves exhibited more gradual increases in current resulting in lower limiting current values. The only obvious difference between the two studies is that we used a platinized platinum electrode (~30 cm^2) while Adams and co-workers used a smooth platinum wire (<0.6 cm^2). While the discrepancy cannot be explained by a simple difference in surface area since all activities have been reported as current/real surface area, the differences in crystallite structure and size might affect the curve shape and ultimately the limiting current and activation energy.

Reformate Performance

Reformate activity with the acid monohydrate was investigated using two synthetic reformate mixtures, one consisting of 2% CO and 26% CO_2 with the balance H_2 and the other containing 3% CO and 12% CH_4 with the balance H_2. (It should be noted that to simulate exactly the effluent from a methane cracker, the second mixture should have contained CO_2 as well.) Under actual reformer conditions, H_2O would also be a component of the reformate in concentrations as high as 12%, but for these studies, the mixtures were not humidified (13).

Comparisons between pure H_2 and the two reformate mixtures at 100°C are shown in Fig. 4. As expected, both reformate polarization curves indicate decreased kinetics compared to pure H_2. At an anode polarization of +50 mV, there is a decrease in performance of 89%. In comparing the two reformate mixtures, the CO/CO_2 mixture exhibits a slight improvement in performance over the CO/CH_4 mixture, even though total percentage in diluents is higher in the CO/CO_2 mixture (28% compared to 15%). This would suggest that the electrode performance is controlled by a more complex mechanism than simple dilution of the hydrogen. The temperature dependence of the reformate reaction is shown in Fig. 5. At the higher temperatures, 115° and 130°C, there is no difference in performance between the two mixtures while at the lower temperatures, 90° and 100°C, there is a measurable difference and, in both cases, it is the CO/CO_2 mixture which exhibits the higher activity. Arrhenius plots of the temperature dependence are represented in Fig. 6: the two plots represent activation energies of 13.2 and 14.6 kcal/mol corresponding to the CO/CO_2 and the CO/CH_4 mixtures, respectively. The activation energies were obtained by linear regression analysis which yielded correlation coefficients of 0.99 for each calculation. The similarity in activation energy between the two mixtures and the similarity in the kinetics at 115° and 130°C would suggest that not only is the nature of the components a key factor in determining performance, but that there may be a common controlling factor for both of the reformates (14). Carbon monoxide is the only common species in the two reformates other than hydrogen, and to determine if, in fact, CO is the component which most strongly influences the overall reformate performance, mixtures of the individual components with hydrogen were investigated. Hydrogen-carbon monoxide mixtures containing 3%, 6%, and 10% CO were studied at the same temperatures used in the experiments described above. Figure 7 illustrates the performance of these mixtures at 100°C and compares them to pure H_2 and the two reformate mixtures. As expected, the performance decreases with increasing CO concentration. With gas flow rates equal to those used for H_2, 3% CO-H_2 causes an 86% decrease in current density at 50 mV polarization. The 6% and 10% CO mixtures further reduce current density by 91% and 93%, respectively. It can be seen

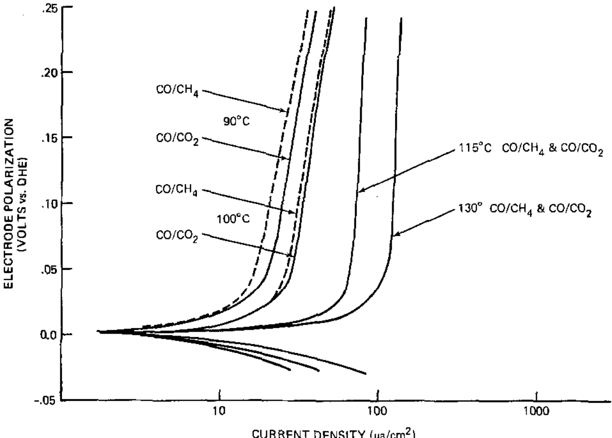

Fig. 5. Comparison of CO/CO_2 and CO/CH_4 reformate polarization curves at various temperatures.

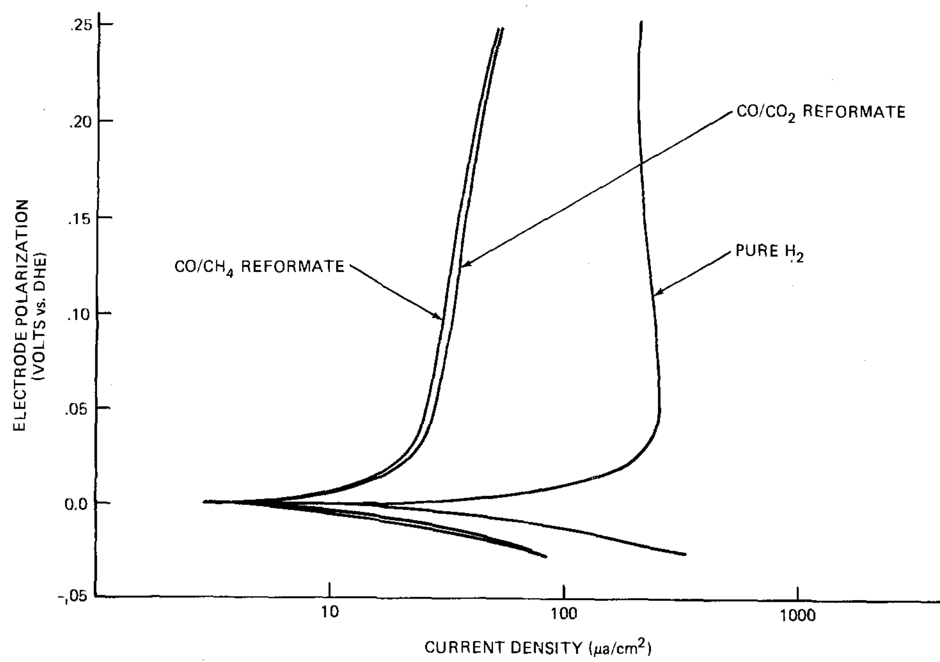

Fig. 4. Comparison of hydrogen and reformate polarization curves at 100°C.

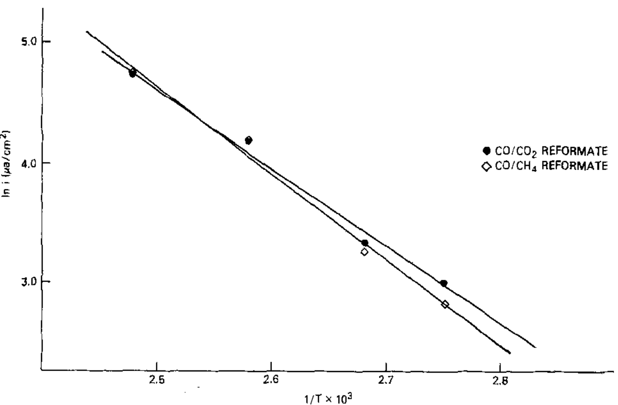

Fig. 6. Comparison of Arrhenius plots for CO/CO_2 and CO/CH_4 reformates as determined for an electrode polarization of 50 mV vs. DHE.

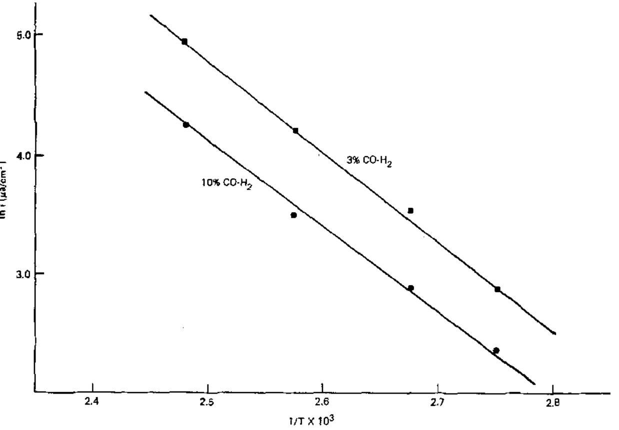

Fig. 8. Arrhenius plots for 3% CO and 10% CO in H_2 as determined for an electrode polarization of 50 mV vs. DHE.

from the plot that both reformate performance curves fall between the 3% CO and 6% CO and correspond to an 89% reduction for CO/CO_2 and a 90% reduction for CO/CH_4 at 50 mV polarization. The sequence of increased performance with decreased CO concentration holds for all temperatures, but the percentage is diminished as the temperature is increased from 90° to 130°C.

An inverse dependence between the current density and temperature (ln *i* vs. $1/T$) was also found to exist for the electro-oxidation of the H_2-CO mixtures in the acid monohydrate (Fig. 8). Activation energies of 14.9 and 13.8 kcal/mol were calculated for the 3% and 10% CO mixtures, respectively. The similarity between the two mixtures is to be expected since activation energy is dependent on the specific reacting species involved in the rate-controlling step, but is independent of their concentration. Taking 14.3 kcal/mol as the average activation energy for the CO-H_2 mixture and comparing it with the activation energies for the CO/CO_2 and CO-CH_4 mixtures (13.2 and 14.6 kcal/mol), we observe a close similarity which further suggests that a surface reaction involving carbon monoxide is the rate-controlling step in the reformate oxidation reaction. This does not necessarily mean that the other components do not affect performance, but that in this particular temperature range, their inhibiting effect is small, and they behave more as diluting agents. At the other temperatures (90°, 115°, and 130°C) reformate performance also fell between the 3% CO-H_2 and the 6% CO-H_2 performance curves, and any variation within these limits appeared to be random in nature.

If CH_4 and CO_2 are acting primarily as diluents in the mixtures, their performance, if observed separately, should resemble that of a true diluent. Under these mild reaction conditions, nitrogen would certainly not be expected to interact catalytically with the electrode, and anode performance of N_2-H_2 mixtures would illustrate a diluent's effect on H_2 performance. Figure 9 shows a comparison between pure H_2 and two N_2-H_2 mixtures. Three percent N_2-H_2 and 17% N_2-H_2 mixtures were chosen so that the total diluent content would approximate the nonhydrogen content of the 3% CO-H_2 and the CO/CH_4 reformate mixtures which were 3% and 15%, respectively. The N_2-H_2 performance would demonstrate the manner in which the CO-H_2 and the CO-CH_4 reformate mixtures should perform if the components were only diluents. The figure shows that at 80°C, the N_2-H_2 performance closely approximates the pure H_2 performance, being far superior to that of the CO/CH_4 reformate. At high temperatures the N_2-H_2 performance would probably becomes indistinguishable from pure H_2. Carrying the diluent test even further, we examined the effect on performance when hydrogen was diluted with 15% CH_4. In Fig. 10, we observe that the 15% CH_4-H_2 has a greater effect on performance than the 17% N_2-H_2 mixture, but the CH_2-H_2 performance is still greater than the CO/CH_4 reformate performance by a factor of 10×. Considerable work has been carried out on the adsorption and oxidation of methane on platinum in various electrolytes, including TFMSA · H_2O. Because methane is electro-oxidizable, it certainly cannot be expected to operate as a diluent, but in this case, its behavior more closely resembles that of a diluent than that

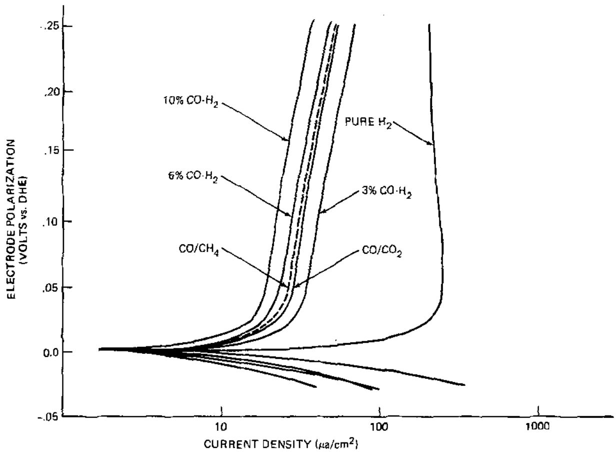

Fig. 7. Performance variation as a function of CO concentration in H_2 at 100°C. Comparisons are made with pure H_2 and the reformate mixtures.

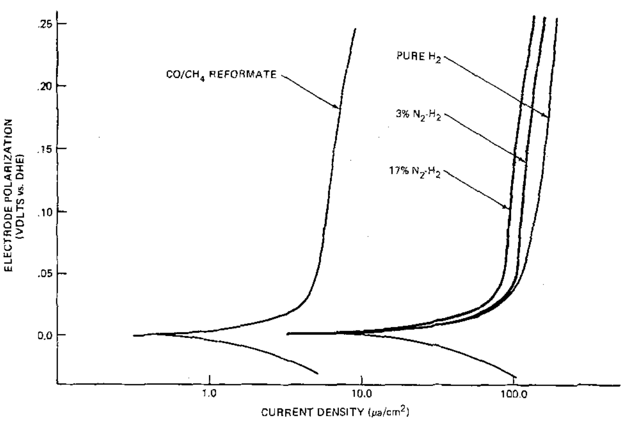

Fig. 9. Electrode performance at 80°C as a function of N_2 concentration in H_2. Comparisons are made with pure H_2 and reformate performance.

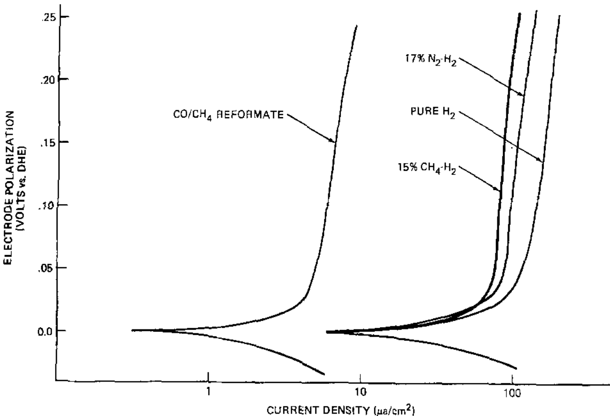

Fig. 10. Electrode performance of 15% CH_4 in H_2 at 80°C compared with pure H_2, 17% N_2 in H_2, and reformate performance.

of an inhibitor. When the N_2-H_2 and the CH_4-H_2 results are combined with the similarities in limiting currents and activation energies for the CO/CH_4 reformate and the CO-H_2 mixtures, the data strongly support the supposition that the carbon monoxide concentration is the rate-controlling factor in the observed reformate performance. The similarity in performance between the CO/CH_4 and the CO/CO_2 reformate mixtures suggests that the CO_2 is also a diluent; a truer diluent, in fact, since in every case in which a difference in performance occurred between the two reformates the CO/CO_2 level was always greater.

The cumulative nature of CO inhibition was examined by observing the effect of residual CO on pure H_2 performance. At a temperature of 115°C, the test electrode was cleaned at 1.50V under H_2, potentiostated to 100 mV, and then the anode reactant was cycled back and forth between 10% CO-H_2 and pure H_2. Beginning with a freshly cleaned electrode, Fig. 11 illustrates the decay in pure H_2 performance resulting from exposure to 10% CO. Actually, the figure represents seven complete cycles since the performance loss resulting from the initial exposure to CO repeated exactly for three consecutive cycles; however, to conserve space in Fig. 11 these three cycles were condensed into one cycle. During the first three cycles, electrode exposure to 10% CO-H_2 lasted 10 min and exposure to pure H_2 lasted 30 min. The pure H_2 performance (~330 μA/cm^2) was in excellent agreement with the corresponding 100 mV performance in the 115°C polarization experiments. This agreement coupled with the scatter in the H_2 performance observed immediately after the 1.50V treatment would indicate that the initial H_2 performance level in Fig. 11 was artificially high. In our first experiment of this type, we terminated the test after the third cycle and concluded that residual CO, if present, had no effect on pure H_2 performance. A second cycling experiment was conducted and again we observed that through three cycles H_2 performance was unaffected by exposure to CO, but at this point we continued the cycling and at the same time, extended the H_2 exposure time to 60 min. The extended H_2 exposure was instituted in order to determine if the high performance observed immediately after the 1.50V cleaning step could be achieved, but to our surprise, each successive cycle resulted in performance decays 4.3%, 3.7%, 2.5%, and 1.0%, respectively.

According to Breiter (15), the presence of adsorbed CO does not significantly affect hydrogen oxidation until CO coverage has reached about 50%. This would suggest that in these experiments, CO accumulates on the surface during cycling and reaches half-coverage during the fourth cycle. One difficulty presented with this explanation is that the drop-off in electrode activity at half-coverage, as reported in the literature, is truly significant, whereas, in this study the total decrease in oxidation current was only about 11%, and the percent decrease per cycle steadily decreased from 4.8% to 1% from the fourth to the seventh cycle. This question is discussed further below.

In order to explore CO inhibition more fully, surface adsorption techniques such as triangular sweep voltammetry were employed. A background voltammogram for platinum in the acid monohydrate (Fig. 12) was typical of aqueous acid systems exhibiting two reversible hydrogen peaks in the 0.0-0.3V region and an irreversible oxide couple in the 0.8-1.2V region. Single cathodic sweep voltammograms for CO adsorbed at 0.1V have been included in the figure to illustrate the reduction in hydrogen charge associated with the presence of CO. The greater the amount of adsorbed CO on the electrode, as determined by the area under the CO oxidation peak at 0.80V, the smaller is the charge associated with adsorbed hydrogen. This behavior is quite similar to the observations of Kohlmayr and Stonehart for CO on Pt in

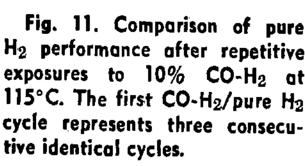

Fig. 11. Comparison of pure H_2 performance after repetitive exposures to 10% CO-H_2 at 115°C. The first CO-H_2/pure H_2 cycle represents three consecutive identical cycles.

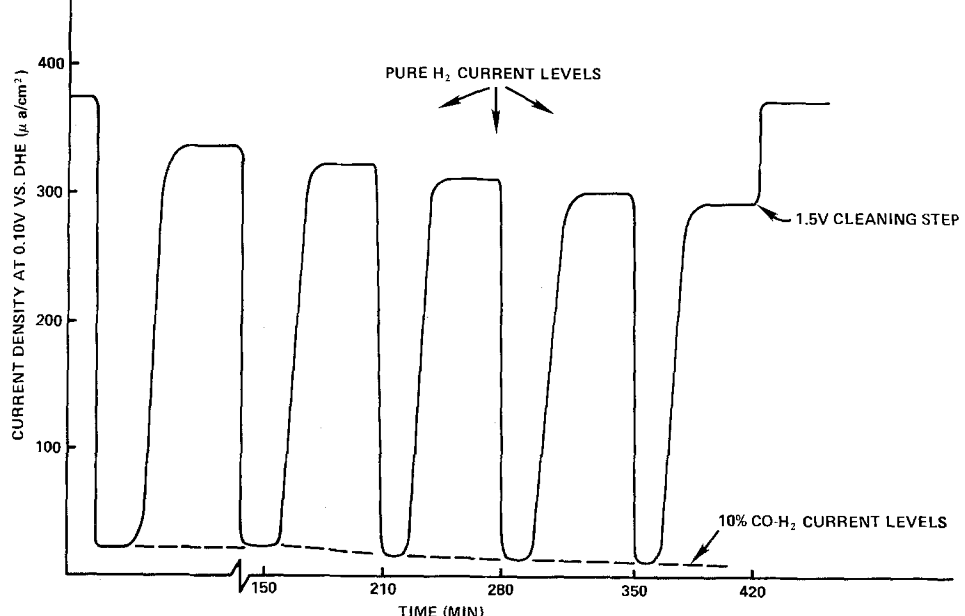

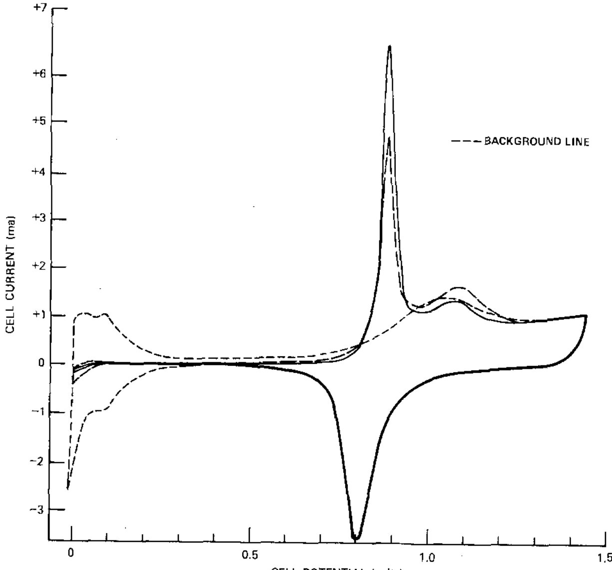

Fig. 12. Voltammogram of N_2 background (- - -) and two different CO coverages on Pt in TFMSA·H_2O at 115°C. The two curves with adsorbed CO began at 0.45V in the cathodic direction.

H_3PO_4 (16). The relationship between adsorbed CO and potential of adsorption is shown as a function of temperature in Fig. 13. In determining the charge of adsorbed CO as a function of potential and temperature, the electrode was first cleaned at 1.35V under nitrogen, then stepped to the desired adsorption potential, and the inlet gas switched from N_2 to 10% CO-H_2. After exposure to CO for 3 min, the cell was then purged with N_2 to remove all CO and H_2 not adsorbed on the electrode. A linear potential change which went up to 1.5V was applied to the electrode to remove the adsorbed CO. This sequence was run for adsorption potentials ranging from 0.05 to 1.00V and was repeated at five temperatures between 61° and 127°C. Although the general curve shape is the same at all temperatures (*i.e.*, two maxima and a minimum), a number of features exhibit a dependence on temperature. The most obvious of these is the total CO adsorption charge which when measured by the area under the curve is seen to decrease with increasing temperature. This trend is consistent with previous studies in both the aqueous and gas phases (17, 18). The position (potential) of the second adsorption maximum, as well as its height relative to the first maximum, also exhibits a dependence on temperature and this is in contrast to the positions of the first maximum and the minimum which exhibit little or no temperature variation. Related closely to the potential variation of the adsorption maximum is the variation in potential of the CO oxidation peak. Figure 14 illustrates this relationship and compares it to the temperature dependence of the oxide formation and the oxide reduction peaks shown in Fig. 12. While oxide formation and reduction are virtually independent of potential, CO oxidation and the second adsorption maximum exhibit identical slopes (5 mV/deg) separated by a constant 350 mV. The similarities in slope for these two features can be used to explain the truncation of the adsorption curve with increasing temperature. CO adsorption appears to be inhibited at low potentials (<50 mV), but as the adsorption potential increases, CO coverage rises rapidly to a maximum at about 100 mV. With continued increase in potential, coverage remains high until the adsorption potential has advanced to within 350 mV of the oxidation potential at which time coverage drops off sharply. Since the CO oxidation potential decreases as the temperature increases, and the 350 mV region of nonadsorption below the oxidation potential remains constant, the adsorption curve must be continually truncated at the high potential end. The data in Fig. 14 were also based on a 3 min adsorption time using 10% CO-H_2 followed by a 10 min N_2 sweep; longer sweep periods with N_2 further reduced CO coverage and this desorption process was also found to be sensitive to temperature change. Figure 15 demonstrates the dependence of CO desorption on temperature using an adsorption potential of 100 mV. At 85°C, desorption appears to cease after 20 min, but at the higher temperatures, desorption continues through the 45 min sweeping period. As the adsorption potential is increased, the desorption rate at a given temperature increases with the result that at 127°C and an adsorption potential of 600 mV, complete desorption of CO occurred after only 10 min of N_2 sweeping. Looking more closely at the 114°C curve, one observes that 25% of the CO on the surface after 5 min of sweep still remains on the surface after 45 min of sweep. Assuming the dual site adsorption mechanism for H_2 oxidation and the equivalency of sites for CO adsorption and H_2 oxidation, then the adsorbed CO should have affected H_2 performance, but recalling the cycling experiments in Fig. 11, no effect was observed in the first three cycles and the cumulative effect after seven cycles was only an 11% decrease in performance. Although a value for the saturation coverage of CO could not be determined by these measurements, it could be determined that saturation coverage was attained within the first 3 min of electrode exposure to CO. This would mean that a decreased hydrogen oxidation rate should be observed in the first cycle. Another observation from the 114°C curve in Fig. 15 is that after 30 min of N_2 sweep only 42% of the CO present on the surface after 5 min of sweep still remains on the platinum and after 60 min of N_2 sweep, only 28% still remains. This argues that if 50% coverage is required to retard the oxidation reaction, then a decrease in H_2 oxidation rate should not have been observed in any of the seven cycles. In any event, the relationship between adsorbed CO and H_2 oxidation appears to be more complicated than one would expect if Q_{CO}/Q_H were unity. This is not surprising since there is equal uncertainty in the literature regarding Q_{CO}/Q_H on plati-

num in H_2SO_4, $HClO_4$, and H_3PO_4. Stonehart *et al.* report a range of 0.83-0.96 depending on the catalyst crystallite size and based on single site adsorption (19). Brummer and Ford (20) and Gilman (21) have proposed a combination of single and bridged (two site) CO adsorption with Q_{CO}/Q_H values of 0.87 and 0.64, respectively, and Warner and Schuldinger (22) have reported single site coverage ($Q_{CO}/Q_H = 1.08$) based on a Q_H of 453 $\mu C/cm^2$ at full coverage. We observed in both 5*N* and 85% H_3PO_4 that the CO oxidation peak is composed of a major peak and a shoulder while the oxidation peak in TFMSA·H_2O is a single peak. This would suggest dual site CO adsorption in the case of H_3PO_4 and single site adsorption in TFMSA·H_2O, but we would be hesitant to completely rule out multiple site adsorption in TFMSA·H_2O without more data on Q_{CO}/Q_H.

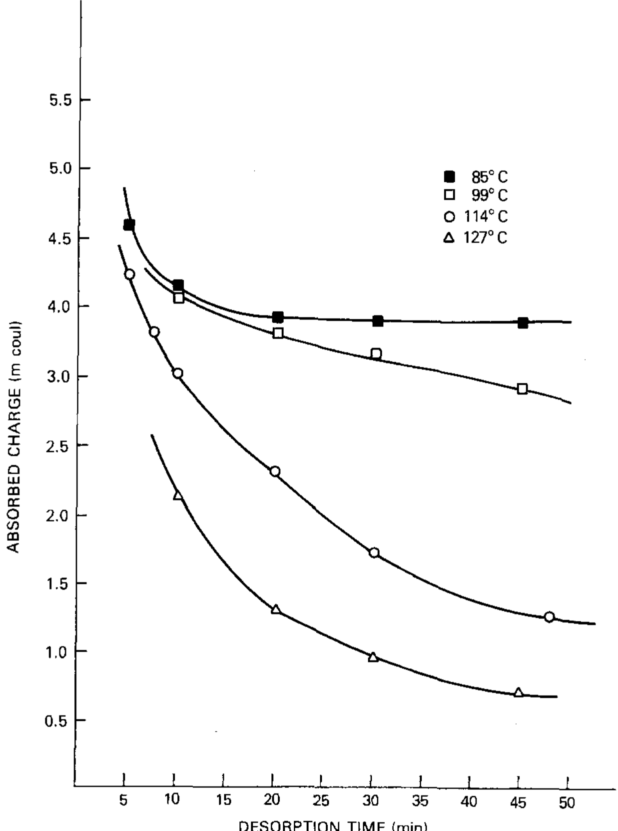

Fig. 15. Variation in CO desorption rate with temperature from an electrode held at 100 mV vs. DHE.

A remaining point to be discussed is the adsorption minimum observed in Fig. 13. This was not expected, and to the best of our knowledge has not been addressed in the literature. The most logical explanation seems to be that some species preferentially adsorb at that potential (350 mV) blocking the adsorption of CO. Although polarization curves developed with pure H_2 and 10% CO-H_2 in this same solution showed no minima, there have been occasions in which minima in the H_2 polarization have been observed in our work. In each case, the decrease in performance was attributed to an acid level imbalance between the cell compartments which resulted in mixing of the solutions in the three compartments. The problem is believed to originate at the counterelectrode where uncontrolled potential excursions could result in decomposition of the acid. In support of this, an odor of sulfide in the counter compartment has also been detected on occasion. These observations agree to some extent with the conclusions of Hughes *et al.* (8), but it should be emphasized that the performance decay has never been observed in the absence of electrolyte mixing between the cell compartments. If the minimum is a result of adsorption from solution, one must then question why, for the same acid sample, a minimum was not observed in the polarization curve, or why the adsorption potential was so specific and why the adsorption potential was not affected by temperature. Further investigation into the nature of the adsorbing species will be necessary in order to adequately answer these questions.

Conclusions

In this investigation, the performance of two synthetic reformates have been compared with that of pure hydrogen and the expected decrease in activity associated with the reformate constituents has been observed. Comparisons of performance between CO-H_2, CH_4-H_2, and N_2-H_2 mixtures and the reformate samples have further shown that CO is the rate-limiting constituent and that CO_2 and CH_4 have very little effect on performance, particularly at the higher temperatures. Finally, the potential sweep studies have shown that the inhibition by CO was due mainly to its resistance to desorption. These experiments and results by themselves cannot yield a complete evaluation of TFMSA·H_2O as an electrolyte since they follow

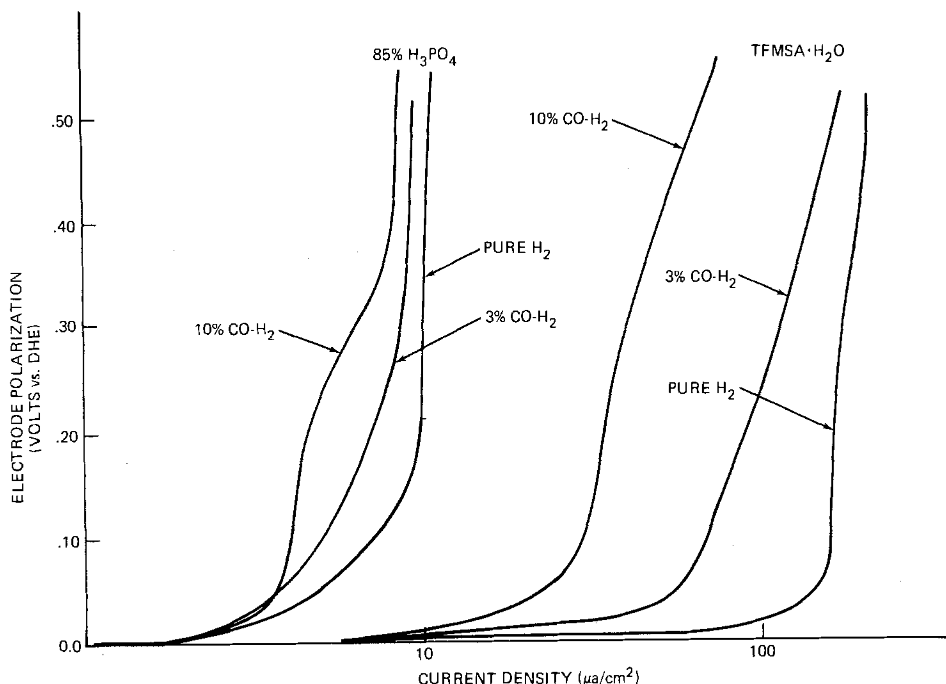

Fig. 16. Electrode performance comparisons in 85% H_3PO_4 and TFMSA·H_2O at 115°C.

in a qualitative way with results reported on the electrochemical behavior of CO in other acids. Therefore, a direct comparison between TFMSA·H_2O and H_3PO_4 is desirable. Figure 16 makes such a comparison utilizing polarization curves for H_2 and CO-H_2 mixtures at 115°C (23). On a percentage basis, the activity decrease due to the presence of 3% and 10% CO is less in H_3PO_4 than in the monohydrate, 13% compared to 56% for 3% CO, and 27% compared to 81% for 10% CO. However, more significant is the fact that with 10% CO, a concentration far greater than that produced in a modern reformer, performance in the monohydrate is four times greater than pure H_2 performance in H_3PO_4. This clearly indicates that at moderate temperatures and with a suitable electrode structure, a TFMSA·H_2O electrolyte fuel cell operating on reformate fuels would yield improved performance over a phosphoric acid cell.

Deposition and Dissolution of Lithium-Aluminum Alloy and Aluminum from Chloride-Saturated $LiCl-AlCl_3$ and $NaCl-AlCl_3$ Melts

Ronald A. Carpio and Lowell A. King*

Frank J. Seiler Research Laboratory (Air Force Systems Command), United States Air Force Academy, Colorado 80840

ABSTRACT

Metal deposition-dissolution studies in the LiCl(satd.)-$AlCl_3$ melt were conducted primarily on an aluminum substrate, using the techniques of cyclic voltammetry, chronoamperometry, chronocoulometry, and chronopotentiometry. A lithium-aluminum alloy was deposited. The LiAl alloy is formed predominately by a deposition process on the surface of the aluminum substrate rather than by conversion of the aluminum into the alloy by an implantation mechanism, as is the case in other electrolytes. The LiAl electrode would be electrochemically reversible, were it not for a corrosion reaction between the alloy and the melt. For comparison, similar studies were conducted on the behavior of aluminum in the NaCl(satd.)-$AlCl_3$ melt. The superiority of LiAl in the LiCl(satd.)-$AlCl_3$ melt to aluminum in the NaCl(satd.)-$AlCl_3$ melt for battery applications is indicated. A significant finding is that nondendritic, adherent, dense deposits of aluminum or an aluminum alloy, having less than 50 mol percent lithium content, can be electroformed via initial formation of β-LiAl.

A great deal of attention has been focused recently on using the LiAl solid alloy as a negative electrode in secondary batteries employing an LiCl-KCl eutectic melt which is a liquid above 352°C (1-7) or in ambient temperature organic electrolytes (8, 9). However, there has been only one report of the utilization of the LiAl alloy in an $AlCl_3$-based electrolyte: namely, a patent by Senderoff which claimed a thermal, rechargeable, electrochemical cell having a lithium monoaluminide electrode and lithium tetrachloroaluminate electrolyte (10). Although details are lacking, Senderoff reported that lithium monoaluminide could be deposited from the $LiAlCl_4$ electrolyte and that this alloy showed less than 0.050V anodic polarization at current densities ranging from 30 to 100 mA/cm^2. Pure aluminum polarized by more than 0.4V when run anodically at 30 mA/cm^2. In primary, thermal batteries which are being developed in this laboratory and which employ an NaCl(satd.)-$AlCl_3$ molten salt electrolyte and a metal chloride cathode such as $MoCl_5$, we also have found that an LiAl anode is superior in performance to an aluminum anode (11).

We are presently interested in developing a molten salt secondary battery employing an LiAl negative and an LiCl(satd.)-AlCl electrolyte. This particular electrolyte was selected because of its relative ease of preparation, low melting point (*ca.* 143°C), low volatility (12), good conductivity (13), voltage window greater than 2V, and Li^+ content. It was necessary to characterize the electrochemical behavior of LiAl. In previous investigations employing other electrolytes, LiAl alloy was formed by the electrochemical incorporation of lithium into an aluminum cathode [*e.g.*, (5, 6, 9)]. In the case of the LiCl(satd.)-$AlCl_3$ melt, the formation of the alloy directly from the constituents of the melt on a substrate could be possible. When an aluminum substrate is employed, the conversion of the aluminum cathode into LiAl as well as simultaneous or subsequent deposition of LiAl on the substrate surface must be considered. In fact, it is remarkable that LiAl can be electroformed in this melt at potentials so near the Al/Al^{3+} potential. From our potentiometric measurements of molten sodium contained within an Na-β''-alumina tube in the NaCl(satd.)-$AlCl_3$ melt, we have found that the Na/Na^+ couple is approximately -1.6V with respect to the Al/Al^{3+} reference. We would expect the Li/Li^+ to be even more negative relative to Al/Al^{3+} in the LiCl(satd.)-$AlCl_3$ melt.

Lithium tetrachloroaluminate is used as a solute in organic solvents which are employed as electrolytes in lithium secondary batteries (14, 15). In the thionyl chloride solvent containing $LiAlCl_4$, the electrodeposition and electrodissolution of lithium are reversible (16). Small amounts of aluminum codeposited with the lithium from some organic solutions such as propylene carbonate containing $AlCl_3$ and LiCl. The amount depends on the composition of the electrolyte and the current density (17). Also of relevance are recent studies on solutions of the type $AlBr_3$/MX/ArH, where M^+ is an alkali metal ion, X^- is Cl^-, Br^-, or I^-, and ArH is an aromatic hydrocarbon (18). Cathodic deposition of either aluminum or an alkali metal was observed, depending on the $AlBr_3$:MX ratio.

For the sake of comparison, the electrochemical behavior of the aluminum electrode in the NaCl(satd.)-$AlCl_3$ melt was investigated. This comparison is particularly revealing since sodium forms no solid solutions with aluminum.

Experimental

All measurements were performed in an argon-filled glove box with a Model MO-40 DRI-TRAIN (Vacuum/Atmospheres Company), having moisture and oxygen concentrations less than 10 ppm.

The Pyrex electrochemical cell fit snugly into a center well in an insulated, cylindrical block of aluminum. The aluminum furnace block was heated by cartridge heaters, also imbedded symmetrically in the block; the temperature was regulated by a Bayley Model 124 proportional temperature controller. Temperature oscillations did not exceed $\pm$0.1°C during an experiment. Temperature was measured by a Chromel-Alumel thermocouple attached to a DORIC Trendicator 400A, which is precise to $\pm$0.05°C. Cylindrical internal cell geometry was employed in the majority of cases to achieve a uniform current distribution on the working electrode and to minimize the *IR* drop. This geometry is similar to that employed by others (6, 19) with the

* Electrochemical Society Active Member.

Key words: electrode, fused salts, polarization, voltammetry.

exception that in the present study the working electrode was partially clad in shrinkable Teflon (Pope Scientific).

An aluminum reference electrode was always employed and either an aluminum or tungsten counterelectrode was used. Working electrodes were aluminum (Alfa/Ventron, m5n) and tungsten (Alfa/Ventron, m3n) wires or lithium monoaluminide rod (Foote Mineral Company). The aluminum electrode was electrically cycled in the melt until an open-circuit voltage of 0 ± 1 mV was attained with respect to the reference electrode. Tungsten electrodes were cleaned in molten $NaNO_2$, then washed, and dried. The exposed portion of the LiAl rod was polished with fine grade emery cloth.

Details of the electrolyte preparation are given elsewhere (20). The LiCl(satd.)-$AlCl_3$ electrolyte has the composition 49.25 mol percent (m/o) $AlCl_3$ (20); the NaCl(satd.)-$AlCl_3$ electrolyte, 49.75 m/o $AlCl_3$ (21). They were water-clear and free from any impurities which could be detected by cyclic voltammetry.

The majority of potentiostatic and galvanostatic measurements were made with a Princeton Applied Research Model 173 potentiostat/galvanostat, equipped with a Model 179 plug-in coulometer. A few measurements were made with an AMEL Model 551 potentiostat/galvanostat either alone or in conjunction with a Princeton Applied Research Model 379 digital coulometer. The desired electrode perturbations were obtained with a Princeton Applied Research Model 175 programmer. Cell responses were recorded with a Houston Instrument Model 2000 X-Y recorder.

The IR drop, which generally was less than 0.1Ω, was measured using the a-c approach described by Peled and Gileadi (22).

Results and Discussion

Voltammetric measurements.—Cyclic voltammetry.— In the cyclic voltammogram shown in Fig. 1A, an aluminum electrode in the LiCl(satd.)-$AlCl_3$ melt was swept first in an anodic direction from its rest potential of 0 mV. There was some hint of passivation in this anodic segment. Cathodic current occurred in the reverse scan at potentials positive of the aluminum reference. Another important feature was the appearance of a loop in the cathodic current when the direction of sweep was reversed, which is a normal consequence of crystal growth requiring nucleation (23). The structure on the dissolution segment of the scan is evidence for alloy stripping. Furthermore, it can be seen that the deposit polarized significantly less than the pure aluminum wire, which agrees with Senderoff's observation (10), cited above. The alloying resulted in a shift of the rest potential of the aluminum electrode in the negative direction by approximately 8 mV.

Figure 1B shows the effect of applying the voltage scan initially in a cathodic direction to a pure aluminum electrode in the LiCl(satd.)-$AlCl_3$ melt. The current-voltage scan was reproducible over multiple scans. The current on the cathodic side rose at a rather slow rate until it reached approximately -0.45V, then it rose much more rapidly with further increase in cathodic overpotential. The cathodic current loop was much more prominent here than in Fig. 1A.

Cyclic voltammograms also were made on a tungsten wire working electrode in the LiCl(satd.)-$AlCl_3$ melt. No alloy formation involving the tungsten substrate reasonably could be expected. The initial sweep was cathodic. The resemblance to Fig. 1B was striking. The rapid current rise in this case commenced approximately 1V cathodic of the aluminum reference electrode potential. This overpotential was larger than that observed for deposition on the aluminum substrate, and it increased on successive scans. It has been found that the efficiency of the plating-stripping process of lithium on a foreign substrate decreases markedly with cycle (24). The explanation given was that a blockage of portions of the substrate with reaction

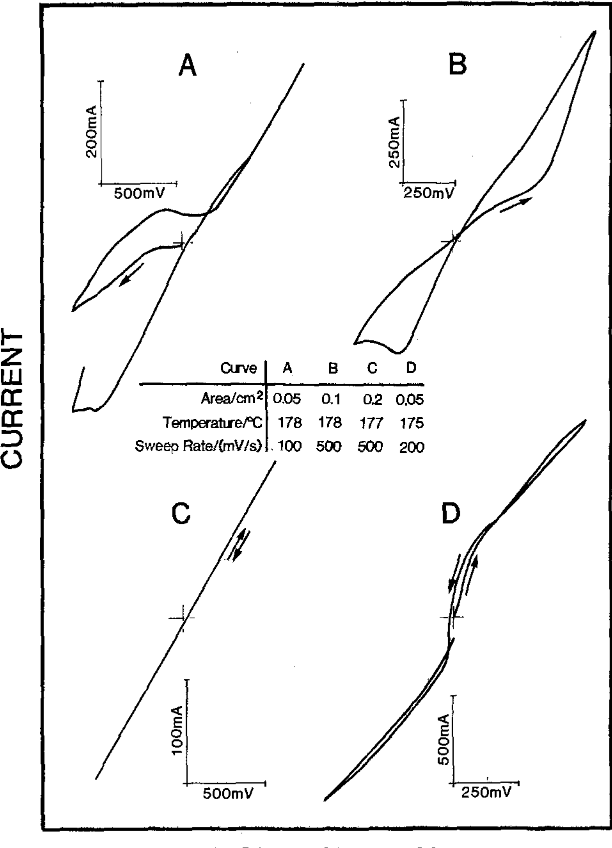

Fig. 1. Cyclic voltammograms: A, on aluminum in LiCl(satd.)-$AlCl_3$, proceeding first anodically; B, on aluminum in LiCl(satd.)-ACl_3, proceeding first cathodically; C, on lithium monoaluminide in LiCl(satd.)-$AlCl_3$; D, on aluminum in NaCl(satd.)-$AlCl_3$, proceeding first cathodically.

products and an accumulation of insulated lithium occurred. A process resulting in the reduction of active surface area of the substrate with cycling also could be operative here. As has been stated already, a loss of efficiency was not observed on the aluminum substrate. It is interesting to note that the highest efficiencies for lithium cycling have been obtained with metal substrates such as platinum, gold, and aluminum, with which lithium forms alloys (17). Stripping chronopotentiograms following deposition on tungsten from the LiCl(satd.)-$AlCl_3$ melt showed two transitions. It appears that aluminum was laid down first on the tungsten substrate, and then LiAl was deposited on the layer of aluminum. In view of these results obtained for the tungsten substrate, we decided to restrict further studies to aluminum substrates.

The reversibility of the LiAl electrode in the LiCl(satd.)-$AlCl_3$ melt is shown clearly in Fig. 1C. The working electrode was a commercial rod of lithium monoaluminide, sealed in a shrinkable Teflon tube, and then ground in the dry box flush with the layer of insulation. Although it is not obvious, multiple cyclic voltammograms are superimposed in this recording.

The cycling behavior of aluminum in NaCl(satd.)-$AlCl_3$ melts is more difficult to interpret. Surprisingly, an overpotential for aluminum dissolution in this melt has been reported previously (25). In this study no such overpotential was found. The electrode pretreatment consisted of anodizing the aluminum electrode and then allowing it to equilibrate. Measurements were not begun until an open-circuit voltage of 0 mV *vs.* an aluminum reference electrode was attained. It was then possible to scan either in a cathodic or anodic direction without the appearance of an overpotential for deposition or dissolution, respectively. However, once the cyclic voltammograms were begun, the re-

cordings never again passed through the origin *i.e.*, 0 mV *vs.* the aluminum electrode. A typical cyclic voltammogram between the limits of −0.5 and +0.5V is shown in Fig. 1D. Current loops were present on both the cathodic and anodic sides, and this cyclic behavior was very reproducible. The cathodic current loop suggests a nucleation process.

In the 60-40 m/o $AlCl_3$-NaCl melt, Uhlig also found that the cyclic voltammograms for an aluminum electrode never passed through the null once the scan was started (26). He reported a hysteresis on the cathodic side.

Interpretation of cyclic voltammograms on aluminum in NaCl-$AlCl_3$ melts is clouded by possible complications introduced by dissolved oxygen species in the melt (26-28). We believe that an in-depth study which is beyond the scope of this paper is warranted in order to clarify the role of oxide formation on the deposition-dissolution behavior of aluminum in the NaCl(satd.)-$AlCl_3$ melt.

Chronoamperometry.—A typical cathodic chronoamperogram taken of an aluminum working electrode in the LiCl(satd.)-$AlCl_3$ melt, followed by an anodic chronoamperogram which was obtained using an overpotential of equal height, is shown in Fig. 2. The anodic portion illustrates the larger current initially obtained from the deposited alloy, followed by a smaller current when presumably the pure aluminum substrate was anodized. The first part of the cathodic chronoamperograms was characterized by a sharp drop in current to a minimum (region A). This initial current drop was due in part to the normal decay of the charging current and also was likely due to the penetration of lithium into aluminum. The linearity of plots of current *vs.* the negative square root of the electrolysis time, $t^{-1/2}$ (Fig. 3A) indicates that this process was diffusion limited, as has been found recently for the penetration of silver into gold (29) and of aluminum into nickel (30).

Fomichev and Chovnyk (31) showed for certain conditions of penetration of one metal into another, the squares of the slopes of curves analogous to those of Fig. 3A should be linearly related to the polarizing potential. This was demonstrated for the penetration of lead into platinum (31) and of aluminum into

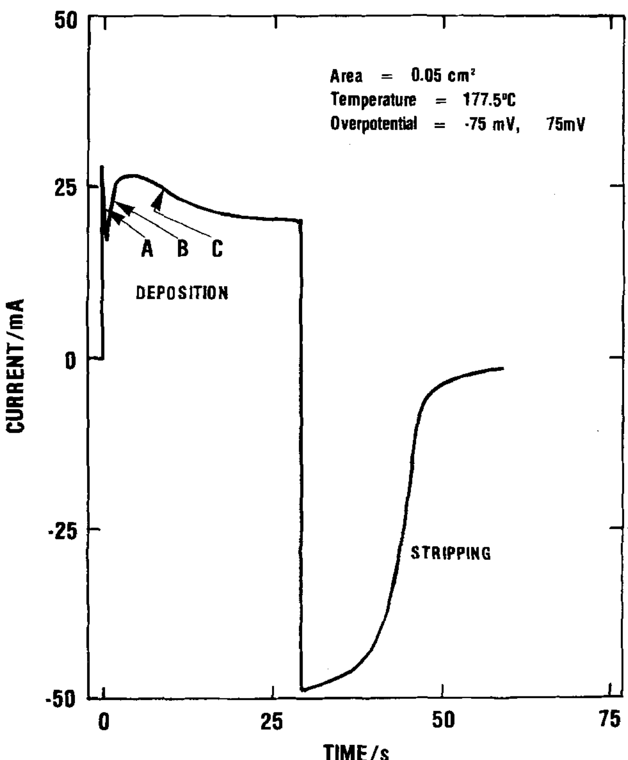

Fig. 2. Deposition and stripping chronoamperograms on aluminum in LiCl(satd.)-$AlCl_3$.

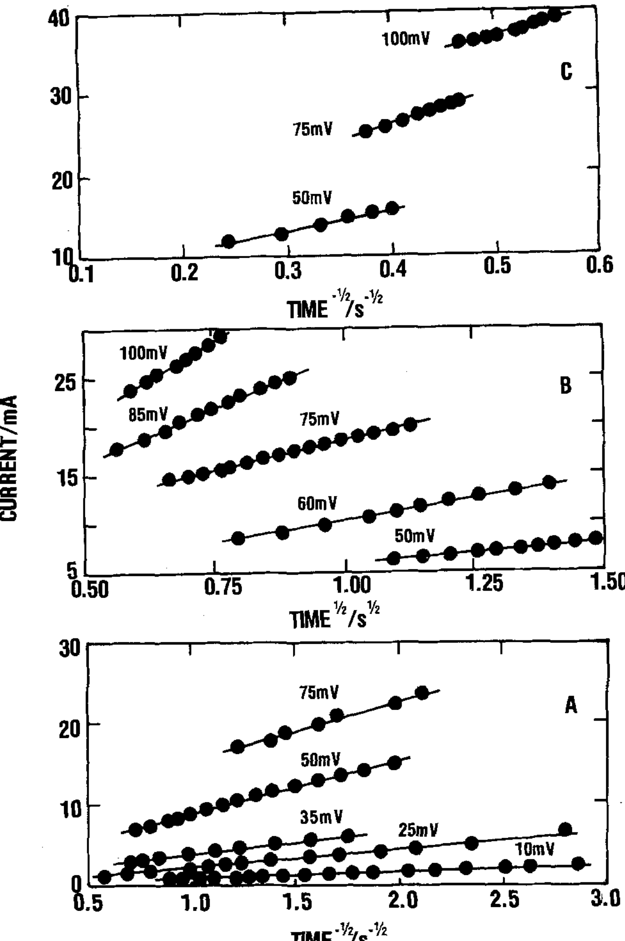

Fig. 3. Portions of cathodic chronoamperograms on aluminum in LiCl(satd.)-$AlCl_3$: A, initial current decay region; B, current increase region; C, final current decay region. Imposed overpotentials are given above each curve.

nickel, cited above. The same behavior was observed in the present study for low overpotentials, as shown in Fig. 4. At an overpotential greater than −35 mV there was a departure from linearity. We could not tell if the relationship was again linear at higher overpotentials because the initial descending portion of the cathodic chronoamperogram (corresponding to region A in Fig. 3) became smaller and eventually disappeared at the large overpotentials.

We conclude that for overpotentials smaller than *ca.* 35 mV the cathodic process was penetration of lithium into an aluminum matrix. At overpotentials greater than *ca.* 35 mV the deposition mechanism changed probably to alloy formation from the constituents of the melt. This process presumably was necessitated by the small diffusion coefficient of lithium in aluminum. More evidence for this conclusion is presented below.

The cathodic chronoamperograms then showed an increase in current to a maximum, followed by a gradual decay until a plateau was reached (regions B and C on Fig. 2, respectively). The current growth was found to be linear with $t^{1/2}$ and the slope increased with an increase in overpotential as can be seen in 3B. Chronoamperograms displaying such current growth behavior have been reported for other studies of metal deposition processes occurring in molten salts (32-37) and have been considered evidence for three-dimensional nucleation. The current decay observed late in the chronoamperogram was approximately linear with $t^{-1/2}$ (Fig. 3C), again indicative of a diffusion-limited process.

Chronocoulometry.—More insight into the cathodic processes can be attained from an analysis of chronocoulometric curves. A typical set of cathodic and

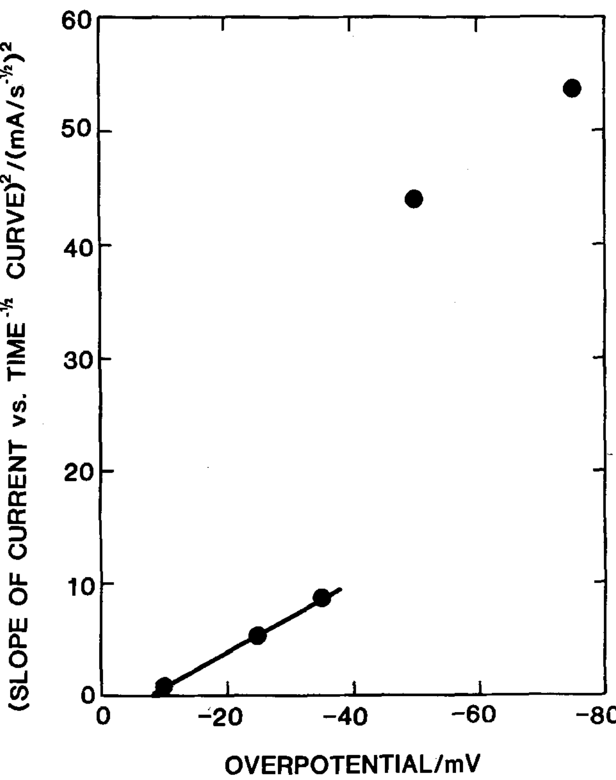

Fig. 4. Linearity test for squares of slopes of current vs. inverse square root of time: initial current decay regions of cathodic chronoamperograms.

anodic chronocoulograms is shown in Fig. 5. In a theoretical examination of electrochemical incorporation of one metal into another, Astakhov (38) postulated that if the incorporation rate were limited by diffusion of one metal into the other, the amount of metal incorporated would be proportioned to $t^{1/2}$. If the rate were limited by a reaction to form an intermetallic compound, the amount of metal incorporated would be directly proportional to t. Melendres (6) observed both types of behavior chronocoulometrically for lithium incorporation into aluminum. At low current densities, lithium penetrated at a diffusion-limited rate into aluminum (or α-LiAl). At higher current densities β-LiAl was formed, followed later by diffusion of lithium into the β phase.

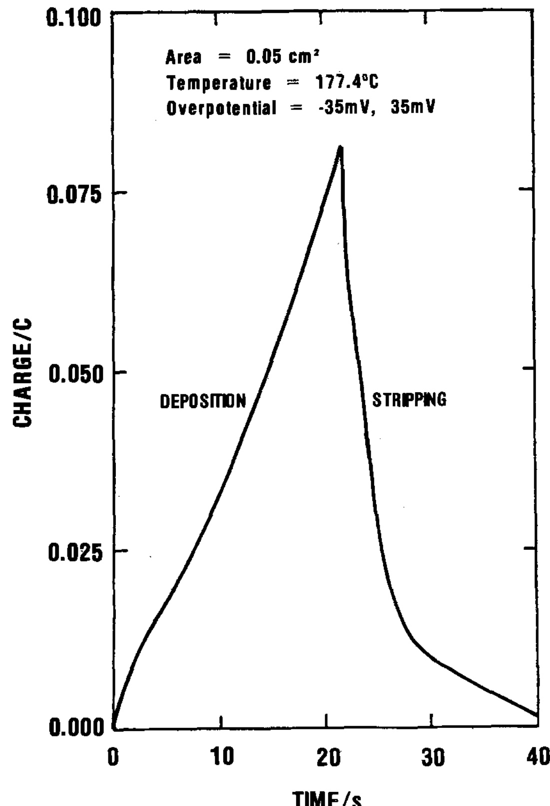

Fig. 5. Cathodic and anodic chronocoulograms on aluminum in LiCl(satd.)-$AlCl_3$.

We observed similar behavior in the present study. For a short time after onset of cathodic polarization the number of coulombs passed, Q, was proportional to $t^{1/2}$. The incorporation rate then changed to a linear dependence on t, as seen in Fig. 5. The duration of the diffusion-limited incorporation regime diminished with increased overpotential. This behavior is expected on the basis of the low diffusion coefficient of lithium in aluminum [$D = 4\text{-}5 \times 10^{-10}$ cm²/sec at 430°-450°C (5, 6)], which would enhance the formation of a surface layer, and thereby account for the Q *vs.* t behavior at longer times. At very long times, Q was no longer proportional to either $t^{1/2}$ or t.

Anodic chronocoulograms following the cathodic chronocoulograms were characterized by an approximately linear dependence of Q on t, indicating that the LiAl was being anodized. The recovery of LiAl was always less than 100%. Transition from LiAl anodization to aluminum anodization was signaled by a sharp change in the slope of the Q *vs.* t curve.

Galvanostatic measurements.—From a battery viewpoint, the charge and discharge processes at constant current are of greatest interest. A typical cathodic chronopotentiogram of aluminum in the LiCl(satd.)-$AlCl_3$ melt followed by an anodic chronopotentiogram at the same current density is shown in Fig. 6. Notice the superpolarization at the onset of the cathodic chronopotentiogram. This phenomenon has been observed previously in the electrochemical incorporation of lithium into aluminum from the LiCl-KCl melt (6). Melendres attributed the superpolarization in this latter case to the difficulty of initially forming the surface layers of β-LiAl, or stated in different terms, it indicated the onset of electrocrystallization of the intermetallic compound and the large overpotential due to slow nucleation. The superpolarization observed in this study increased with current density.

An example of cyclic chronopotentiograms of an aluminum electrode in the NaCl(satd.)-$AlCl_3$ melt is shown in Fig 7. The alternate cathodic and anodic galvanostatic pulses were of equal height and duration. No superpolarization occurred in the cathodic portions. The polarization was almost identical for the cathodic and anodic processes.

In the LiCl(satd.) melt (Fig. 6), it is apparent in the anodic chronopotentiogram that the polarization was very small during discharge of LiAl. As soon as the deposited LiAl had been completely discharged, a transition to the aluminum anodization potential was observed. When deposits were made at lower current densities or allowed to stand before stripping, the transition to the aluminum anodization potential occurred sooner and was more gradual, implying either the diffusion of deposited lithium into the substrate, or corrosion, or both. The discharge region of the LiAl always was shorter than the corresponding cathodic, deposition step. A similiar qualitative relationship was observed by James (5) in charge-discharge curves for the LiAl electrode in LiCl-KCl at 430°C.

Figure 8 shows a plot of the ratio r of the transition time for anodic stripping [determined using the procedure described in Ref. (39)], τ_a, and the time of deposition, t_c; *i.e.*, $r = \tau_a/t_c$. Although there was some scatter in the results, it can be seen that r increased with an increase in the charging current, and then after reaching a maximum, it began to decrease. Some of the scatter could be due to the fact that t_c was varied in the range 30-600 sec. In fact, in a separate study, it was determined that with a constant charging current, the scat-

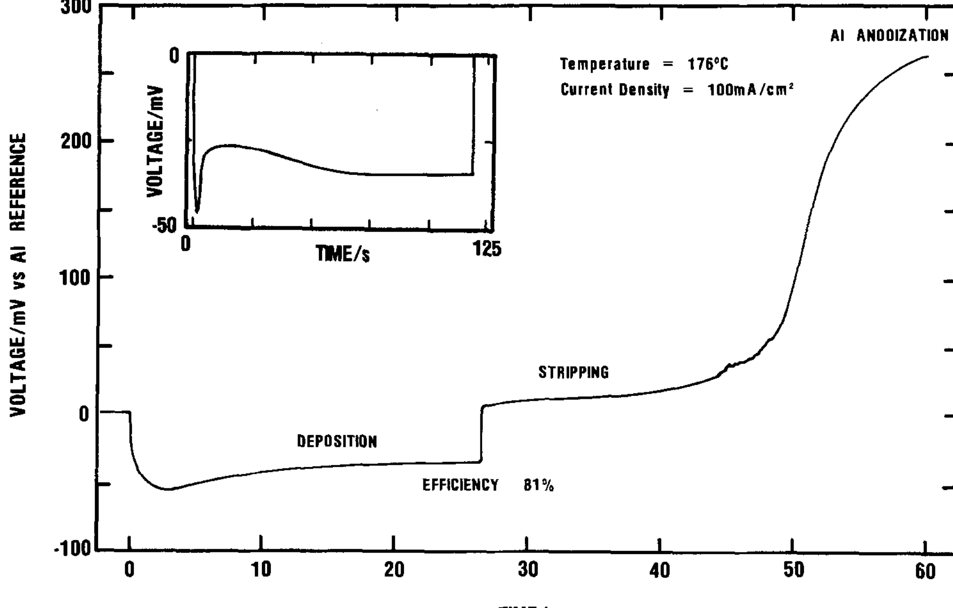

Fig. 6. Cathodic and anodic chronopotentiograms on aluminum in LiCl(satd.)-$AlCl_3$.

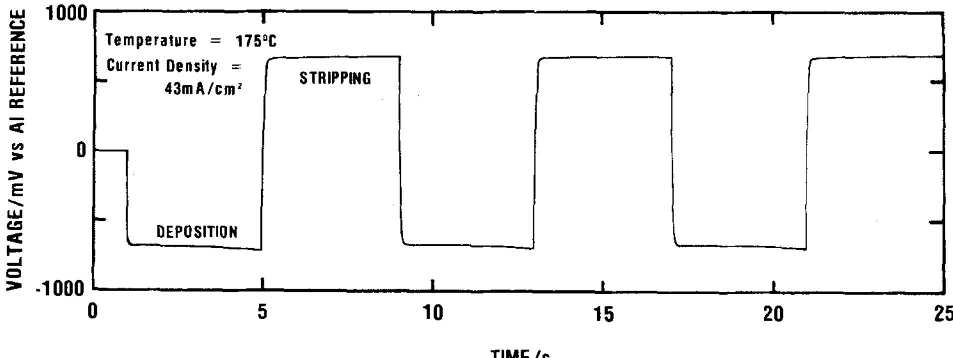

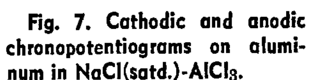

Fig. 7. Cathodic and anodic chronopotentiograms on aluminum in NaCl(satd.)-$AlCl_3$.

ter in r decreased with an increase in t_c, but the values of r obtained at the different t_c's did not differ considerably. The lower values of r at the lower current densities would suggest that the solid solution phase was formed by the implantation of lithium into the aluminum electrode. The lithium could not all be extracted in the transition time of the anodic process. As the current density increased, more of the intermetallic LiAl was formed on the surface of the aluminum and was readily accessible for dissolution. Finally, at still higher current densities, a solid solution of lithium with the β phase probably began to form. A portion of this lithium probably reacted with the melt.

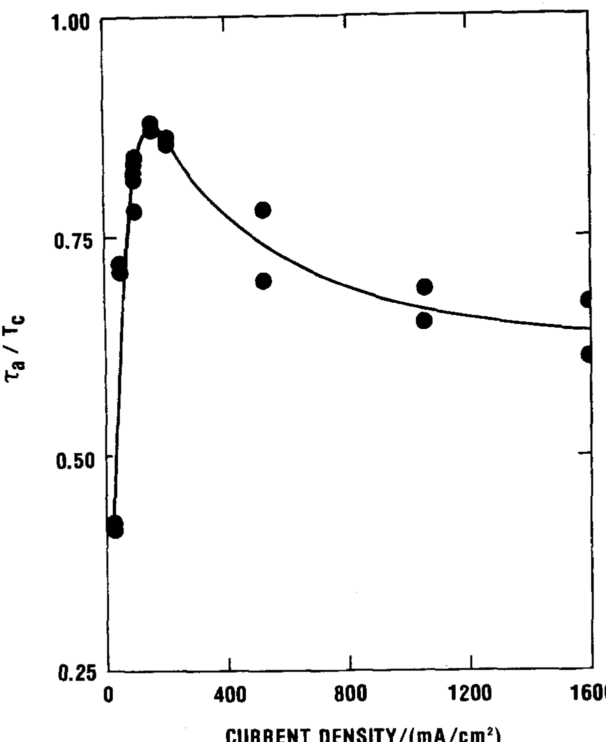

Fig. 8. Cycling efficiency for LiAl retention on aluminum in LiCl(satd.)-$AlCl_3$.

In contrast to the work of Besenhard (9), the cycling efficiencies did not improve after repeated cycling. Besenhard explained the improvement he observed on the basis of retention of lithium in the aluminum substrate. The picture which emerges from our work is that the predominant process is the deposition of LiAl on the surface of the aluminum electrode; the incorporation of lithium into aluminum plays only a minor role at the outset of charging. Support for this conclusion comes in part from an experiment in which the charging process was extended to a point where the aluminum working electrode could have been converted totally into lithium monoaluminide. No transition was observed, in contrast to the case for the charging of lithium into aluminum in molten LiCl-KCl (5). The important implication is that the cycling process will not lead to electrode disintegration in $AlCl_3$ melt as rapidly as it will in the LiCl-KCl melts or the Li^+-containing organic melts in which cycling results in major structural expansions during the charging process.

Anodic chronopotentiograms observed during the LiAl discharge were very smooth in the plateau region. However, when the voltage rise commenced, noise traces often were observed (see Fig. 6). This suggests

that precipitation of LiCl was occurring on the electrode surface, which is not at all surprising considering that the melt was saturated with respect to LiCl. The LiCl which precipitated on the electrode surface insulated the surface, giving rise to the noisy overvoltage. No noise was observed in the discharge of LiAl in LiCl-KCl (5).

When cathodic chronopotentiograms such as illustrated in Fig. 6 were continued for much longer times, the overpotential decay region following the initial superpolarization was in turn followed by a region of again increasing overpotential. The latter rate of increase was very gradual, and eventually a constant cathodic overpotential was reached. This behavior is illustrated in the inset of Fig. 6, where both cathodic chronopotentiograms were conducted at the same temperature and current density.

In the region of increasing overpotential, overpotential was linear in the square root of time, as shown in Fig. 9. Melendres (6) found similar behavior, which he interpreted as the diffusion of lithium through β-LiAl. He calculated a diffusion constant from the slopes of overpotential *vs.* $t^{1/2}$ plots, viz., $2\ RTi/\sqrt{\pi}\,n^2\,\mathbf{F}^2\,C_o\sqrt{D}$. Here the symbols have their usual electrochemical significance. C_o is the lithium concentration in β-LiAl, 0.045 mol/cm^3, and i is current density, A/cm^2.

We obtained $D = 6 \times 10^{-7}$, 2×10^{-7}, and 7×10^{-7} cm^2/sec at $i = 0.1$, 0.15, and 1.0 A/cm^2, respectively. We can find no other studies of lithium diffusion into LiAl or aluminum conducted in the temperature region in which we worked. Several higher temperature studies have been made (5, 6, 40, 41) and report widely divergent values of D, ranging from 5×10^{-5} (5) to 10^{-8} cm^2/sec (6) at 430°-450°C.

Stability of the deposit.—The measured open-circuit voltage of a newly electroformed deposit in the LiCl(satd.)-$AlCl_3$ melt was approximately −7 mV *vs.* the aluminum reference electrode. After allowing the deposit to stand in the melt, the open-circuit voltage decayed to near 0 mV. This, of course, suggests that the deposit was unstable. In fact, stability tests conducted by deposition on an aluminum cathode followed by anodic stripping after increasing time intervals revealed that the deposit was indeed unstable. This is not unexpected, since at 500 K for the reaction

$$3Li(s) + AlCl_3(l) = 3LiCl(l) + Al(s)$$

$K = 10^{-54.5}$ (42). The activity of LiCl is unity in an LiCl(satd.)-$AlCl_3$ melt. The activity of $AlCl_3$ is undeniably lower than unity, but it is far from $10^{-54.5}$, which would be the needed activity for the above reaction to be reversed. This differs from Senderoff's contention that LiAl is stable in the $LiAlCl_4$ melt (10). On the other hand, we did find that a 1/2 in. diam LiAl (1:1 alloy) rod, prepared by metallurgical procedures, did not show any visible changes after remaining in the melt at approximately 175°C for several weeks.

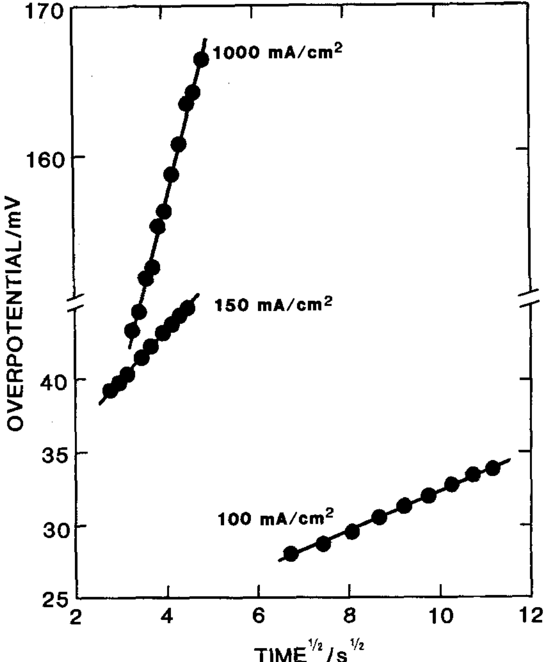

Fig. 9. Slowly increasing overpotential region of cathodic chronopotentiograms on aluminum in LiCl(satd.)-$AlCl_3$.

Cyclic chronopotentiometric experiments provide insight into the nature of the deposit that is formed on the surface of the substrate, provided that the deposition step is followed immediately by stripping. If the substrate is aluminum, allowing the deposit to stand at open circuit could result in a chemical reaction between the deposit and the electrolyte at the interface, diffusional penetration of the lithium from the deposit into the aluminum substrate to produce a homogeneous phase, or both. Thus stripping a thin deposit after a time interval should reveal the effect of any processes potentially contributing to the instability of the deposit. In experiments in which a deposit was laid down on an aluminum substrate and various stand times were allowed before stripping, the low polarization plateau became progressively smaller as the stand times were increased. In addition, the rising portion of the chronopotentiogram between this low polarization plateau and anodization of pure aluminum had a decreasing slope (*i.e.*, the transition to aluminum anodization became less sharp), suggesting the presence of an increasing amount of the α solid solution phase. Thus, this re-establishment of a homogeneous phase cannot be discounted.

To exclude the formation of α-LiAl as the major contributor to the instability of the deposit, a tungsten substrate was used in place of the aluminum. The results obtained were even worse from the standpoint of recovery of total deposited metal than those obtained using an aluminum substrate. Thus we can conclude that a chemical reaction between the LiAl deposit and the melt plays a prominent role in the stability of the alloy. This type of behavior is not unprecedented, for reactivity has been demonstrated between the lithium contained in lithium alloys other than lithium-aluminum alloys, and other solvents (43, 44).

The most plausible chemical reaction is that between the lithium which diffuses out of the intermetallic and the melt, whose primary species is $AlCl_4^-$ (45, 46). The following reactions are expected

$$AlCl_4^- \rightleftarrows AlCl_3 + Cl^-$$

$$3Li + AlCl_3 \rightarrow 3LiCl\downarrow + Al\downarrow$$

Any LiCl which is formed should precipitate, since the melt is saturated with LiCl. However, of great significance is that the reaction will also lead to additional aluminum being laid down on the aluminum matrix remaining from the LiAl deposit.

To explore further this stability problem from a macroanalytical approach, a massive amount of the deposit was laid down on a 1 mm diam aluminum wire in an LiCl-$AlCl_3$ solution to which an excess of solid LiCl was added. An aluminum wire of about the same dimensions as the cathode was employed. Electrolysis was conducted at roughly 50 mA/cm^2. After electrolysis was terminated, the deposit remained in the melt for less than 1 hr. Quite surprising is that even though the deposition was conducted at a current density which was not symmetrically uniform about the wire, the deposit itself was almost perfectly uniform, as shown in Fig. 10. The deposit had a thickness of 0.75 mm and adhered tenaciously to the aluminum wire substrate. Scanning electron photomicrographs show clearly the lack of dendrites. A photomicrograph obtained under higher magnification is shown in Fig. 11. Features of

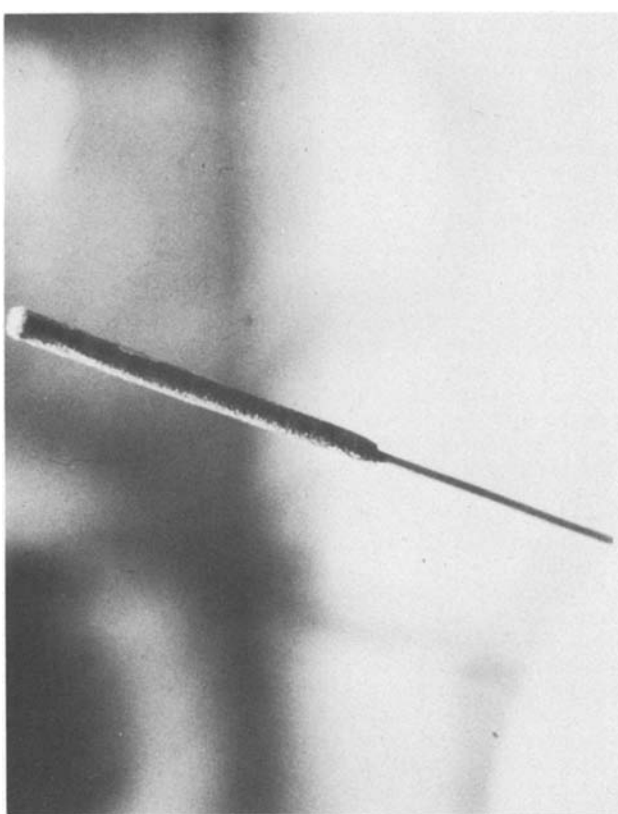

Fig. 10. Electrodeposited LiAl on aluminum in LiCl(satd.)-$AlCl_3$

note are the presence of cracks and differences in optical reflectivity over the surface. Melendres and Sy (7) found both characteristics in their study of β-LiAl formed in LiCl-KCl. They established that areas of different reflectivity varied in aluminum content, with light areas being richer in aluminum (lower lithium) than darker areas.

The x-ray powder diffraction lines for this deposit along with the ϕ values for lithium, aluminum, and LiAl are listed in Table I. Although there is not a perfect match, it appears that lithium, aluminum, and LiAl lines all were present. A better identification was possible by running a sample of the deposit in a gold pan in a Perkin-Elmer DSC-2 differential scanning calorimeter. A high intensity temperature peak commencing at 605°C and a second, well resolved, lower intensity peak terminating at approximately 665°C were identified. Acording to the Li-Al phase diagram (48)

this corresponds to a composition of approximately 35 m/o lithium and consists of a mixture of the α and β phases.

Our results appear to support the ideas that lithium is being removed from the electroformed β-LiAl and that the chief driving force for this extraction is the chemical reaction between lithium and the melt. This reaction probably does not proceed to the point where all the lithium has been removed; rather a protective barrier of aluminum and LiCl appeared to be formed at the electrolyte interface. This is analogous to the film which protects lithium in organic electrolytes. Quite significant is the fact that nondendritic, adherent, dense deposits of aluminum or an aluminum alloy having less than a 50 m/o lithium content can be electroformed via the route of initial formation of β-LiAl. Even though the stabilized deposit has inferior properties to pure β-LiAl from a battery standpoint, we have at last the ability to use an aluminum electrode. When compared to other anode candidates, aluminum is highly desirable in the areas of cost, equivalent weight, and electromotive potential. To highlight this discovery is the fact that the deposition of aluminum from the $2AlCl_3$-NaCl melt is accompanied by dendritic deposits when coatings over 20 μm thick are deposited.

Studies are now underway to explore in greater detail the effect of current density, temperature, cycling, etc. on the morphology of the deposit. Cross-sectional elemental profiling and anodic polarization properties of the electroformed alloy after long-term equilibration in the melt are being investigated. In addition, more insight into the reaction mechanisms is being sought using a-c impedance measurements.

Electrochemical Behavior of Methylene Blue and Its Leucoform at the Mercury Electrode

G. Papeschi, M. Costa, and S. Bordi*

Istituto di Chimica Fisica, Università di Firenze, I-50121, Firenze, Italy

ABSTRACT

The electrochemical behavior of methylene blue (MB) and its leucoform (LMB) in aqueous solutions at *p*H 7.9 was investigated with a mercury electrode. The polarographic results showed that at very low concentrations (4×10^{-6} M/liter) and $E_{1/2}$ of "Brdička's prewave" is the same as the standard potential of the MB/LMB couple and moves from about −0.290 to −0.180V (NCE) as the concentration increases. The electrocapillary curves indicate the following: (*i*) at low concentrations the LMB is less adsorbed than the MB; (*ii*) γ decidedly decreases when the surface concentration of LMB reaches a value high enough to form a solid deposit on the mercury surface. We suggest that: (*a*) "Brdička's prewave" which occurs at the lowest concentrations is actually the normal wave of the MB/LMB couple; (*b*) "Brdicka's normal wave" is a step that develops at the standard potential, but on an electrode covered by an insoluble film of LMB.

The electroreduction of methylene blue (MB) to leucomethylene blue (LMB) on a mercury electrode takes place with an anomalous behavior. This system was studied polarographically by Brdička (1, 2) and it is the classical example of reduction product adsorption cited in every textbook of polarography (3-5).

Brdička shows that at *p*H = 7.96 at concentrations of MB below 6×10^{-5}M a single step ("prewave") is observed, while at higher concentrations a second step ("normal wave") appears at more negative potentials.

In the interpretation of Brdička the "prewave" corresponds to reduction of unadsorbed MB to adsorbed LMB; the height of this step is limited, not by the rate of diffusion of MB, but by the surface available for adsorption of the reduced molecules. He states that the product of MB reduction is adsorbed at the electrode surface as soon as it is formed and this facilitates, from an energy point of view, the reduction itself by allowing it to take place at a potential less negative than the standard potential of the MB/LMB couple. According to Brdička, the "normal wave" is observed when the surface is fully occupied by LMB and requires a more negative potential since the reduced form finds itself in a higher energy state (unadsorbed as opposed to adsorbed). Under these conditions there is no process aiding the reduction and therefore the normal wave should develop in the neighborhood of the standard potential.

After Brdička much work was done (6-14) using different techniques in order to provide the MB/LMB redox couple with new information. Although the majority of these investigations have retained substantially unchanged Brdička's point of view, experimental evidence exists and points out that the MB/LMB system is actually more complicated than Brdicka's scheme assumes it to be.

Recently Baumgartner *et al.* (15) have shown by using multiple specular reflection spectroscopy applied to a thin layer electrochemical cell, that, in the first 0.5 sec of the (1×10^{-5}M) MB reduction process, the LMB formed precipitates on the gold electrode surface.

We are presenting here experimental evidence pertaining to the MB/LMB redox system drawn from studies of electrocapillary curves, normal polarographic curves, and anodic voltammetry.

* Electrochemical Society Active Member.
Key words: adsorption, voltammetry.

Experimental

The capillaries used either for drop-time measurements or for polarographic investigations were drawn from 2 × 10 mm Pyrex tubes and dewetted with dimethyldichlorosilane vapors. Finally by trial those capillaries were chosen which gave a drop time of about 20 sec.

The concentration range 1×10^{-5}-1×10^{-4} M/liter of MB was explored with 16 electrocapillary curves (Fig. 1) obtained with the drop-time method. The range of potentials +0.1 to −1.3V (NCE) was traversed at 25 mV intervals between +0.1 and −0.6V and at 50 mV intervals between −0.6 and −1.3V. The

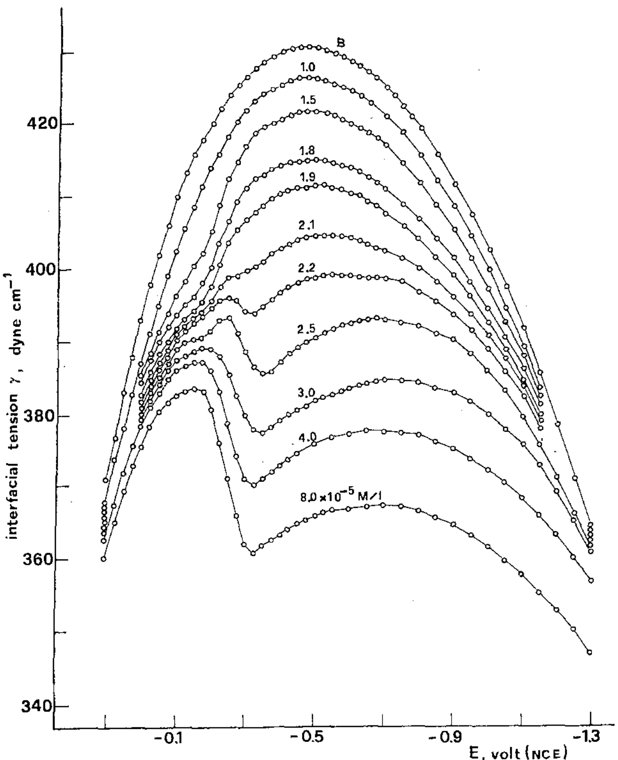

Fig. 1. Electrocapillary curves due to buffered solutions (*p*H = 7.9) of methylene blue at the given concentrations (the curves of concentrations 0.20, 0.23, 0.35, 0.60, 1.0 × 10^{-4} M/liter are not shown).

apparatus and other experimental details were as described previously (16).

With an E261 Metrohom polarograph, 20 polarograms were recorded over the concentration range 4×10^{-6}-5×10^{-4} M/liter. With the same apparatus the remaining polarographic investigation was conducted.

All the potentials were referred to 1*N* KCl calomel electrode. Both the reference half-cell as well as the working solutions were kept at a constant temperature of 25.0 ± 0.1°C.

A phosphoric buffer solution at *p*H 7.9 (0.05M KH_2PO_4 and 0.046M NaOH) was used as base electrolyte.

All the chemicals, except the dye, were of Analar Grade, and the water was distilled three times in an all-Pyrex-glass still (17). Merk reagent methylene blue was used without further purification.

Air was bubbled for a long time through the mercury in contact with 5% HNO_3. After washing and drying it was distilled twice under vacuum.

Results

Excellent agreement is observed between Brdička's and our polarographic results in the field of analytical MB concentration greater than 5×10^{-5} M/liter, where the dye undergoes electroreduction with two different waves, the former with half-wave potential approximately the same as the standard potential, the latter with half-wave potential shifted by about 100 mV toward more positive values.

Our polarographic investigation was extended to MB concentrations below 5×10^{-5}M in order to observe the development of the prewave up to the lower limit of 4×10^{-6} M/liter. This enabled us to verify that the $E_{1/2}$ of the prewave at the lowest concentrations to be the same as the standard potential calculated by Clark, Cohen, and Gibbs (18) at concentrations $< 5 \times 10^{-5}$M in neutral or alkaline solutions, $pH > 6$, with the Nernst equation

$$E = E_o + \frac{RT}{2F} \ln \frac{[MB] \cdot [H^+]}{[LMB]} \qquad [1]$$

where

$$E_o = + 0.226V \text{ (NCE)}$$

Moreover as the concentration of MB was increased, the $E_{1/2}$ of the prewave was observed to move from about -0.290V up to -0.180V (NCE). The shift takes place essentially while the concentration is increased from the lowest values to that one at which the second step appears ($c = 5 \times 10^{-5}$ M/liter). In Fig. 2 the half-wave potential of the two reduction steps are plotted against the concentration of MB.

At $pH = 7.9$ the LMB is slightly soluble and when, for instance, an 8×10^{-5}M MB solution is electroreduced at a constant potential of -0.5V *vs.* NCE, *i.e.*, at a potential corresponding to the diffusion current of the normal wave, a turbid colorless suspension is obtained. The height of the anodic wave developing in the LMB saturated solution is equal to the height of the cathodic step given by a 1×10^{-5}M solution of MB. It is of interest to note that the half-step potential of both polarograms is the same $E_{1/2} = -0.270 \pm 0.015$V (NCE) and in good agreement with the equilibrium potential as calculated by Eq. [1]. If air is bubbled through the solution the LMB is quickly oxidized to MB; consequently the precipitate dissolves while the deep blue color reappears.

Experiments with a stationary mercury electrode have emphasized the consequences of the low solubility of the LMB in aqueous solution buffered at $pH = 7.9$. When the hanging mercury drop electrode was held for a few minutes under polarization in an 8×10^{-5}M solution of MB at the potential of -0.5V *vs.* NCE, the formation of a white insoluble film on the mercury surface was observed. Upon shifting the applied potential to a value corresponding to the foot of the prewave, the white precipitate was oxidized back to the soluble form of MB and the mercury drop became clean and bright again.

The formation of an insoluble LMB film was also detected for shorter polarization times. The hanging mercury drop electrode was held at -0.5V for 60 sec in the same 8×10^{-5}M MB solution, and then the potential was shifted at a sweep rate of 4.7 mV/sec toward more positive values. The current flowing through the electrode, as recorded against the potential, exhibits an anodic peak (Fig. 3) at -0.200V. For the $E_{1/2}$ of the prewave at this concentration we read

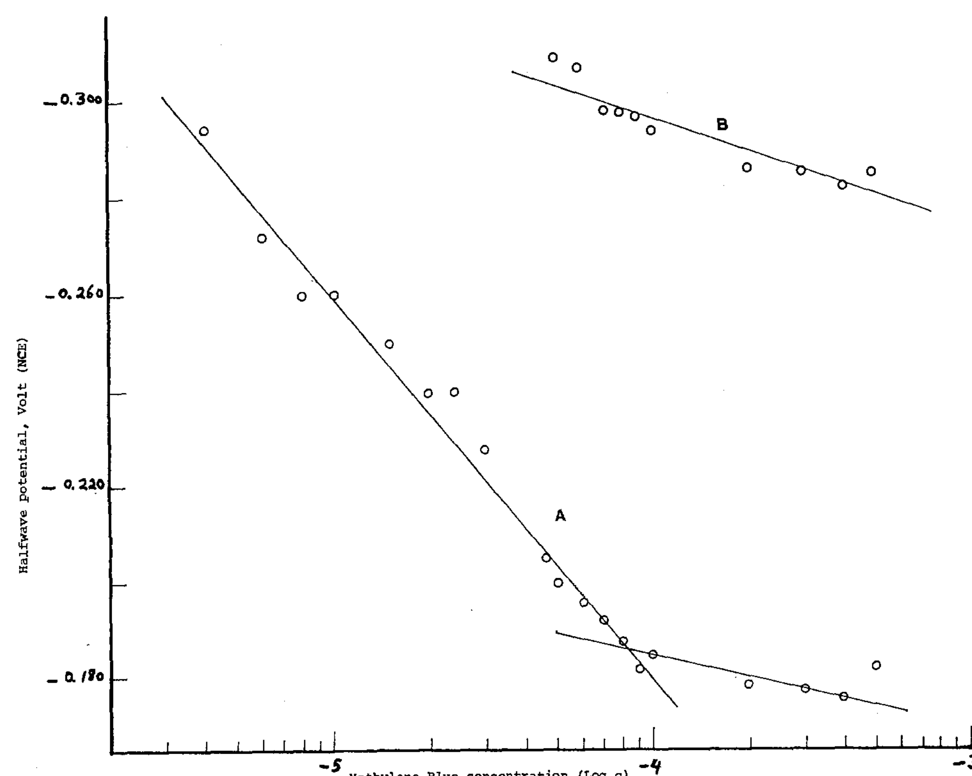

Fig. 2. Half-wave potential of "Brdička's prewave" (curve A) and of "Brdička's normal wave" (curve B), plotted against the MB concentration, as obtained from the polarograms at $pH = 7.9$.

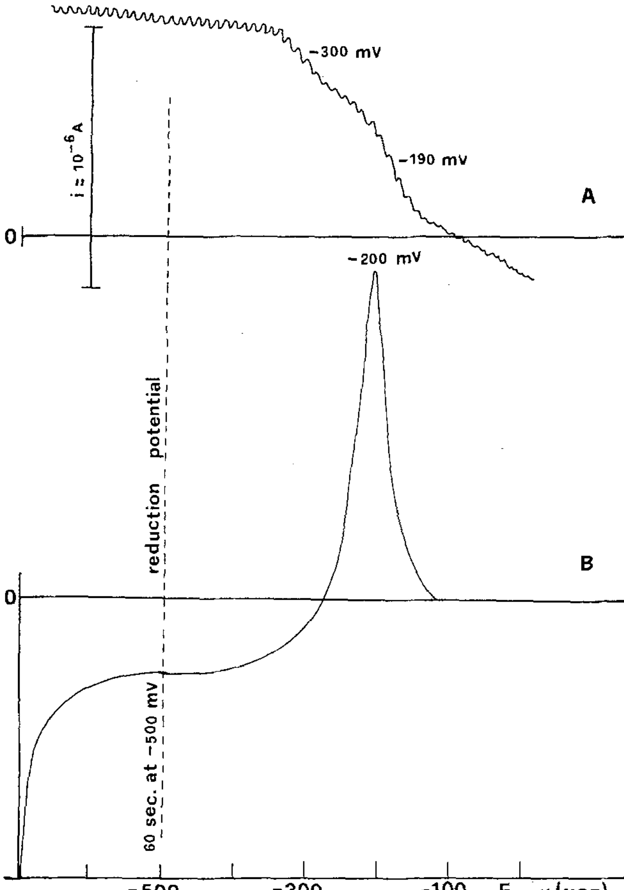

Fig. 3. Curve A: polarogram for MB 8×10^{-5} M/liter at pH = 7.9; curve B: anodic peak due to oxidation of the LMB accumulated on the mercury electrode during 60 sec of electrolysis, in the 8×10^{-5} M/liter MB solution, at −0.5V (NCE). The potential was shifted at a sweep rate of 4.7 mV/sec toward the anodic values. (Drop surface 4.57 mm^2; coulombs 31.0×10^{-6}; molecules/drop 96.6×10^{12}; number of layers 21).

−0.190V. The area under the peak indicates the presence of about 20 monolayers of LMB on the electrode surface, provided we attribute a value of 100Å^2 to the area of one molecule of LMB. An anodic peak is also recorded for polarization times of the order of tens of seconds.

One of the most convincing proofs of the strong adsorption of the LMB, was considered by Brdička the change of the shape of the electrocapillary curves obtained in buffered solution of MB. For this reason our investigation was extended to the study of the electrocapillary curves of this dye in phosphoric buffer at pH = 7.9.

In the region of the electrocapillary curves where the adsorption at the interphase is not accompanied by a faradaic process, the lowering of the interfacial tension is simply due to the adsorption of MB on mercury. By using the Gibbs equation

$$\Gamma = -\frac{1}{RT}\left(\frac{\partial \gamma}{\gamma \ln c}\right)_{E,T} \qquad [2]$$

where γ is the interfacial tension, c the MB analytic bulk concentration (in place of the activity), Γ the surface excess, R the gas constant, T the absolute temperature, and E the potential, we have calculated Γ and then the area S taken up by one molecule of the dye

$$\Gamma = 1.3 \times 10^{-10} \text{ mol cm}^{-2}$$

$$S = 125\text{Å}^2 \text{ molecule}^{-1}$$

The S value agrees satisfactorily with that attributed to MB molecule when it is placed flat on the electrode surface.

For concentrations below 2.7×10^{-5}M at a potential value of approximately −0.175V corresponding to the beginning of the MB reduction, the interfacial tension steps up rapidly as if the product were less adsorbed than the reactant.

For concentrations above 2.0×10^{-5}M in correspondence to a potential of about −0.250V the interfacial tension decreases ever so rapidly with the increasing concentration and then increases again at about −0.325V.

Discussion

Let us bear in mind the following main facts arising from our experimental work:

1. The half-wave potential of the prewave shifts toward more positive values with increasing concentration and becomes nearly constant when the second wave appears (Fig. 2).
2. The half-wave potentials of the anodic step for a solution saturated in LMB as well as the half-wave potential of the cathodic wave of equal height for a MB solution, agree within ± 15 mV with the standard potential of the MB/LMB couple as determined by Clark and co-workers at concentrations below 10^{-5} mol/liter and pH greater than 6.
3. An insoluble film of LMB is formed on a stationary mercury electrode after a few of tens of seconds of electrolysis at a potential of −0.500V (NCE) in an 8×10^{-5}M MB solution.
4. The white precipitate of LMB dissolves with an anodic peak at a value of about −0.200V; very close to the half-step potential of the prewave recorded at the same MB concentration (Fig. 3).
5. From the electrocapillary curves we can observe the following: (*i*) at concentrations below 2.7×10^{-5}M and at a potential of about −0.175V, corresponding to the beginning of the MB reduction, the interfacial tension steps up rapidly (Fig. 1 and 4); (*ii*) at concentrations above 2.0×10^{-5}M, and at a potential of about −0.250V the interfacial tension falls down ever so rapidly as the concentration increases, and then rises again at about −0.325V to reach the electrocapillary maximum (Fig. 1).

Our findings show that the product of reduction is less adsorbed than the oxidized form, as we can observe in the electrocapillary curves, when at the point corresponding to the beginning of the reduction of MB, the interfacial tension decidedly steps up (Fig. 1, and better visible in Fig. 4, points m). When the concentration of LMB produced in the reduction process reaches the saturation limit on the electrode surface, a precipitate of LMB is deposited on the mercury. The interfacial tension at this point is lowered and the greater the amount of LMB deposited, the greater the lowering of γ (Fig. 4, points n).

On this account Brdička's prewave displacement will stop when the amount of MB undergoing reduction is large enough to produce a film of LMB shielding the mercury drop entirely.

Any further reduction of MB to LMB on the electrode covered by the precipitate will proceed in a separate wave.

Many theories have been proposed in the attempt to explain the reduction process of a substance on an electrode covered by an insoluble film of the product: (*i*) the film of the reduction product is further reduced; (*ii*) the film undergoes a severe change in its structure at a definite potential; and (*iii*) a progressive migration of the depolarizer takes place through the film.

In our case one important fact is to be noted: the slope of the normal wave is approximately 20-25 mV. This critical dependence of the penetration current on the applied potential seems to suggest that the charge

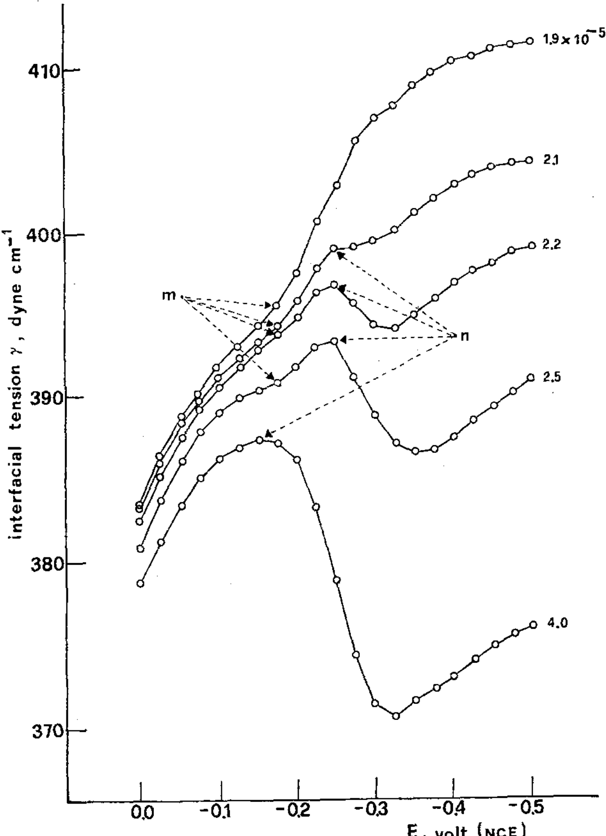

Fig. 4. Detail of the electrocapillary curves in the region where the MB undergoes electroreduction.

carrier through the insoluble film is not the depolarizer but rather the electron. It is known that the probability for an electron to tunnel through a rectangular energy barrier depends exponentially on the product of the thickness of the barrier by the square root of the difference between the energy corresponding to the peak of the barrier and the Fermi level energy in the metal. A shift of the applied potential toward more negative values causes a linear increase in the Fermi level energy and the barrier is rendered more penetrable to electrons. The consequent increase in the cathodic current leads to an increase in the barrier thickness due to the continuous deposition of the reduction product. Both at a dropping and at a hanging drop electrode, however, the thickness of the insoluble film may reach, at the most, a certain maximum value, which is obtained at the end of the electrolysis period, under diffusion control conditions. A sufficiently negative potential may, therefore, be reached at which the electron tunneling through the barrier is so fast that the current is controlled exclusively by the depolarizer diffusion toward the insoluble film surface.

This preliminary examination of the experimental data seems to suggest that the polarographic step which occurs at the lowest concentrations (Brdička's prewave) is actually the normal wave, and that Brdička's normal wave is a step that develops at the standard potential of the MB/LMB couple, but on an electrode covered by an insoluble film of LMB.

Technical Notes

Alloy-Anodes in Fluoride Solid-State Batteries

J. Schoonman* and A. Wolfert

Solid State Department, Physics Laboratory, State University, 3508 TA Utrecht, The Netherlands

Solid-state batteries with a metal anode, a fluoride ion conducting solid electrolyte, and a metal fluoride as cathode are known (1-5). Much attention has been directed toward optimizing the ionic conductivity of promising solid electrolytes. Particularly suitable are concentrated anion-excess solid solutions based on fluorites (6). They have been utilized successfully as solid electrolytes in batteries with pure metals as anode (3-5). However, in such batteries anode passivation will limit the current as fluoride ions react to form pure low-conducting metal fluorides at the anode/solid electrolyte interface (5).

It is the purpose of this note to show that the use of $Ca_{1-x}Yb_x$ alloy-anodes in $Ca_{1-x}Yb_x/BiO_{0.1}F_{2.8}$ solid-state batteries considerably reduces anode passivation. This is ascribed to the formation of anion-excess solid solutions upon discharge.

Small disks of $Ca_{1-x}Yb_x$ $(0 \leq x \leq 0.25)$ with a diameter of 8×10^{-3}m and a thickness of about 5×10^{-3}m were prepared by melting appropriate mixtures of the metals in graphite crucibles under argon at about 1000°C. The surfaces of the disks were polished under nitrogen in a glove box. They were examined for their composition with a Cambridge Stereoscan 150 electron microscope, equipped with an energy dispersive elementary analysis apparatus.

Solid-state batteries $Ca_{1-x}Yb_x/BiO_{0.1}F_{2.8}$ with $Ca_{0.68}U_{0.02}Ce_{0.30}F_{2.34}$ as solid electrolyte were fabricated using a technique which has been reported before (4, 5). The present $5.03 \times 10^{-5}m^2$ area cells contain $\sim 1.5 \times 10^{-5}$ kg solid electrolyte, and $\sim 1 \times 10^{-5}$ kg cathode: capacity $\sim$ 10C. Open-circuit voltages (OCV) and load-circuit voltages (LCV) were measured with a Keithley Model 616 digital electrometer. Load currents i_l were measured with a Keithley Model 445 digital picoammeter and a Solartron data transfer unit, which transferred time and current data to a Facit 4070 tape punch.

Elemental analysis of the surfaces of the anodes revealed complete solid solubility to exist in the system $Ca_{1-x}Yb_x$ $(0 \leq x \leq 0.25)$. Normalized load-circuit voltages LCV/OCV *vs.* load-current densities were linear, indicating the absence of polarization. In this respect batteries with alloy-anodes do not differ from batteries with pure metal anodes (4, 5). The d-c resistance of the batteries, having OCV's of 2.6-3.0V in the temperature region 25°-180°C, was calculated using the expression

$$\frac{\text{LCV}}{\text{OCV}} = -\frac{R_{dc}}{\text{OCV}} i_l + 1$$

In these batteries the thickness of the solid electrolyte layer is about 75 μm and of the cathode layer about 30 μm. At 227°C these layers have resistances of $4.93 \times 10^4 \Omega$, and 23.2Ω (7, 8) thus indicating that for fresh batteries the solid electrolyte limits the current. Upon discharge R_{dc} increases. As R_{dc} for fresh batteries is governed by the resistance of the solid electrolyte, the R_{dc} data for partly discharged cells yield the resistance R_{ap} of the anode passivation layers by subtracting R_{dc} of the fresh cells. Plots of log $(R_{ap}^{-1}T)$ *vs.* T^{-1} are linear in the temperature region 25°-200°C. They reveal activation enthalpies in the range 0.90-0.95 eV for ϕ, the number of coulombs expended, up to 3C. In the analysis of the d-c resistance data it is assumed that the discharge product is present as a layer between the anode and the solid electrolyte. Plots of log R_{ap} *vs.* log ϕ are linear, as is shown in Fig. 1. The curves reveal slopes of 1.16 (a and b), 1.0 (c), and 1.5 (d), indicating a tendency for R_{ap} to be directly proportional to the number of coulombs expended, which is in accordance with the assumed layer geometry.

Figure 2 presents log R_{ap} *vs.* x in $Ca_{1-x}Yb_x$ alloy anodes for different numbers of ϕ. After passage of 0.2C the conductivity of the passivation layer on the Ca-anode is 7.2×10^{-7}S at 127°C. Literature data of nominally pure CaF_2 (9) lead to the value of 5 ×

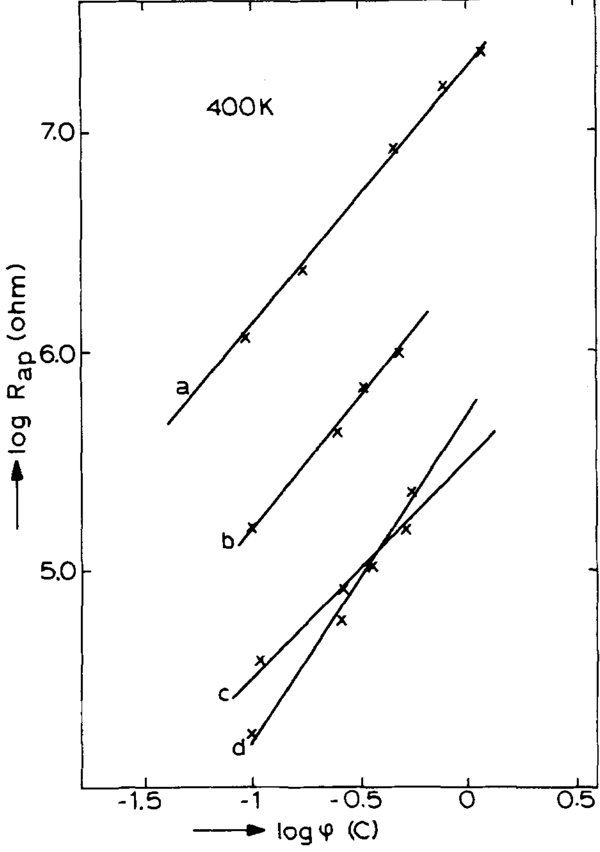

Fig. 1. The resistance R_{ap} *vs.* the number ϕ of coulombs expended presented as log R_{ap} *vs.* log ϕ. Curve a, Ca; curve b, $Ca_{0.915}Yb_{0.085}$; curve c, $Ca_{0.75}Yb_{0.25}$; curve d, $Ca_{0.865}Yb_{0.135}$.

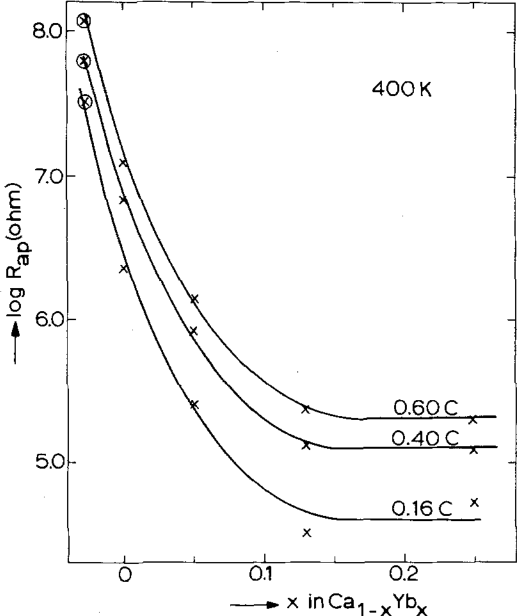

Fig. 2. The dependence of R_{ap} on the composition of $Ca_{1-x}Yb_x$ alloy-anodes at 127°C for several values of ϕ. Included are data (⊗) calculated from the conductivity of normally pure CaF_2 (10). See text.

10^{-8}S for this passivation layer. Atomic absorption analysis of the employed Ca revealed the presence of 0.9% Al and 0.9% Si as the predominant impurities. This impurity content is equivalent to $x = 0.027$. The calculated R_{ap} values based on the literature data for CaF_2 (9) have been included in Fig. 2 (⊗) at $x = -0.027$. These data indicate that for the Ca-anodes employed in this study, doped anode passivation layers result. The data in Fig. 2 clearly show that anode passivation is reduced substantially if $Ca_{1-x}Yb_x$ alloy-anodes are employed. A decrease in R_{ap} by a factor of 10^2-10^3 is obtained for x up to about 0.13. For larger values of x saturation occurs. As tysonite related $BiO_{0.1}F_{2.8}$ behaves as oxide-doped BiF_3 (8), it is proposed that the alloy-anodes are in principle involved in the following cell reaction

$$Ca_{1-x}Yb_x + \left(\frac{2+x}{3}\right) BiF_3 \rightarrow Ca_{1-x}Yb_xF_{2+x} + \left(\frac{2+x}{3}\right) Bi$$

which describes the formation of anion-excess solid solutions as discharge products, in which Yb^{3+} ions are electrically compensated for by F^- interstitials. The enthalpy for migration of fluoride interstitials in doped CaF_2 is found to be 0.92 eV (10). The enthalpy values obtained from the temperature dependence of R_{ap}^{-1} agree very well with this migration enthalpy, thus sustaining the proposed cell reaction.

The present study clearly reveals that alloying Ca with metals M that lead to anion-excess solid solutions $Ca_{1-x}M_xF_{2+x}$ or $Ca_{1-x}M_xF_{2+2x}$ provides a means of reducing anode passivation in this type of solid-state batteries.
