Behavior of S_x^{2-} Species in Molten Sodium Polysulfide

T. Yoshida and K. Nakajima

Toyota Central Research and Development Laboratories, Incorporated, Nagakute-cho, Aichi-Ken, Japan

ABSTRACT

An electrolytic cell having four electrodes, each separated by a β-alumina plate or a porous ceramic separator and impregnated with molten sodium polysulfide was constructed. The electrolysis was carried out between two of these two sets of electrodes, and the composition change of the melt in the test electrode was observed from the OCV change during the electrolysis. The results of this study strongly suggested that S_2^{2-} ions migrated preferentially as a carrier on the electrolysis and that they would exist in the equilibrium with S_4^{2-} or S_5^{2-} ions even in a melt with the composition of $Na_2S_{4.66}$. The S_4^{2-} or S_5^{2-} ions also seem to contribute to the charge transport as the depletion of S_2^{2-} ions in the melt, whereas Na^+ is considered not to take part in the charge transport. These phenomena characterize the determination of the distribution of sodium polysulfide in the porous current collector of the sodium sulfur battery.

Since sodium sulfur batteries are expected to have a high energy density of more than 150 W-hr/kg, a considerable number of research and development programs are exploring their applications for load leveling and transportation power source. The behavior of molten sodium polysulfide, Na_2S_x, in a charge-discharge reaction affects the performance of this type of battery, and much effort has been devoted to clarify the properties of the compound, the phase diagram of Na_2S_x (1, 2), and properties such as electrical conductivity (3), density (4), and sulfur activities (5). However, there seem to be few experimental studies on the behavior of molten sodium polysulfides as battery electrode.

The composition of molten sodium polysulfide is known to change ($Na_2S_5 \rightarrow Na_2S_4 \rightarrow Na_2S_3$) progressively during the discharge process. The termination of the reaction is ascribed to the formation of solid sodium polysulfide in the electrode.

The reaction distribution in a porous current collector of a sodium sulfur battery has been estimated (6-9) by applying a network model. However, the reaction distribution would not necessarily correspond with the resultant distribution of the composition, when S_x^{2-} ions formed during the reaction migrate through the current collector. Since the sulfur utilization would be determined by the resultant distribution of the composition, the effect of migration of S_x^{2-} species seems essential.

Cleaver and Davies (5) derived the Washburn number instead of the transference number to observe the activity of sulfur in molten sodium polysulfide. This number only defines the number of moles of sulfur per unit charge passing through a reference frame in the melt, where the frame is chosen so that sodium ion does not pass through it. However, the mutual migrations of Na^+ and S_x^{2-} species should be considered for a better understanding of the resultant distribution of the composition in the porous current collector.

Key words: sodium-sulfur battery, molten salt, sodium polysulfide, transference number.

From these considerations, the migration of S_x^{2-} species for an electrode which is taken as the frame of reference was observed with the composition change in the electrode, when an ionic current was passed through the melt.

Experimental

Figure 1(a) shows a schematic representation of a cell constructed for the present experiment. This cell consists of two flat β-alumina plates (1.0 mm thickness, 20 mm width, and 35 mm height), auxiliary electrodes denoted A and B, testing electrodes A′ and B′, and ceramic separators. A and B are made up of blocks of porous graphite and are mounted on the outsides of both β-alumina plates. The operating cross-sectional area of A and B is 25.0 × 20.0 mm² and the thickness is 10 mm. The area of A′ and B′ is equal to that of A and B, respectively. The thickness of A′ and B′ is taken to be 2.0 mm. The porosity of the graphite block measured by paraffin impregnation method is 46.0%.

Sodium reference electrodes, $R_{A'}$ and $R_{B'}$, were inserted at 5 mm depth for A′ and B′, respectively. The sodium reference electrode was a half-cell of Na/β-alumina which was made of α-alumina tube (100 mm length, 2 mm outer diameter, and 1 mm inner diameter) with a fine rod of β-alumina on the tip and filled with metallic sodium (10).

Ceramic separators with fine pores (average pore diameter: 2 μm, porosity: *ca.* 30%, thickness: 2 mm) were arranged on the insides of both A′ and B′, respectively. SUS 304 wires (0.3 mmφ) were inserted for the potential and current lead of A′ and B′ between A′ and B′ and the ceramic separators. SUS 304 backing plates were used for A and B current lead.

The electrode assemblies were tightly surrounded with glass plates for the side walls and the bottom so as not to leave any clearance between the edge surfaces of the β-alumina plates, ceramic separators, and glass plates. The cell was installed in a Pyrex glass container equipped with a side tube as shown in Fig. 1(b).

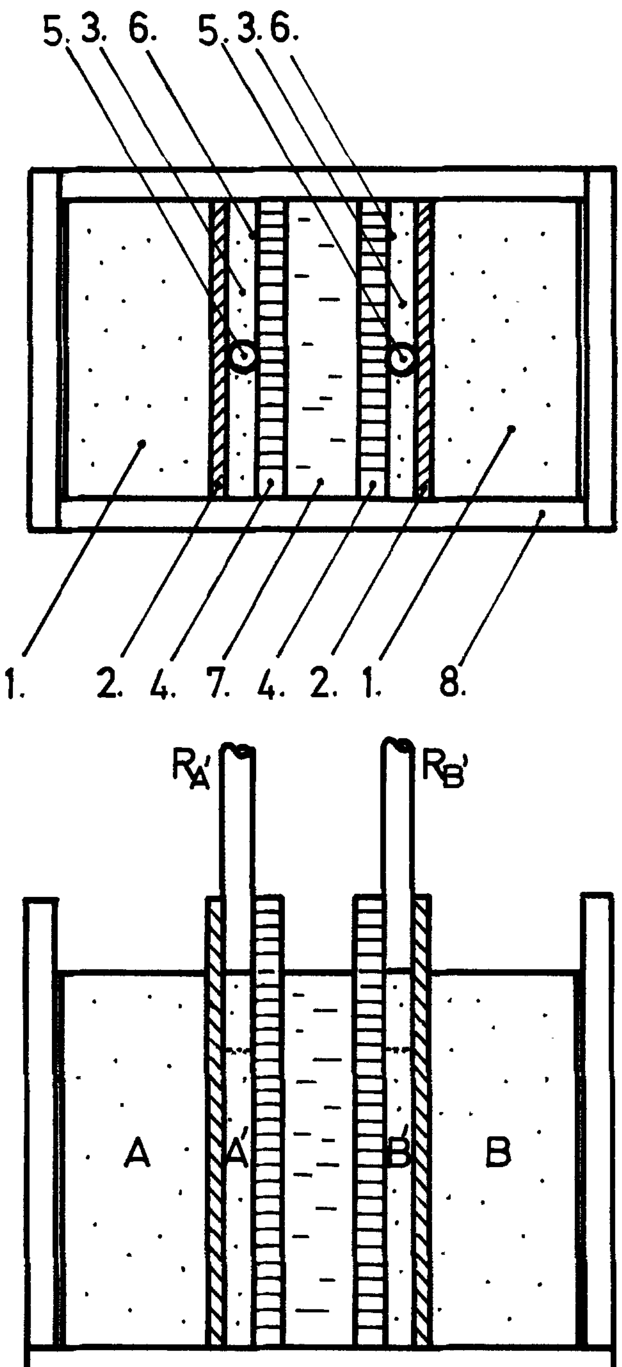

Fig. 1a. Construction of electrolytic cell. 1: Outer electrode, A or B, impregnated with molten Na_2S_x; 2: β-alumina plate; 3: inner electrode, A' or B' impregnated with molten Na_2S_x; 4: porous ceramic separator; 5: sodium reference electrode, $R_{A'}$ or $R_{B'}$; 6: lead for A' or B' (0.3$^\phi$ SUS 304); 7: molten Na_2S_x; 8: glass plate.

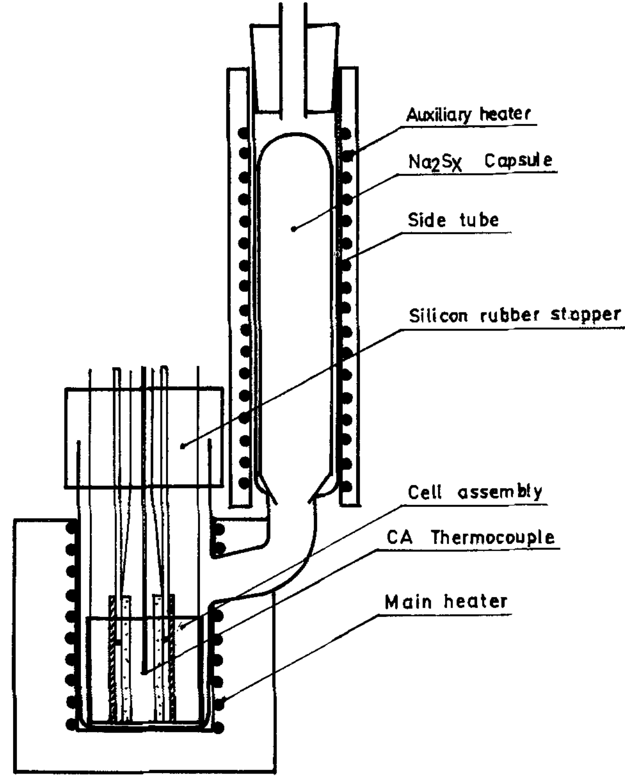

Fig. 1b. Cell container and auxiliary equipment

Sodium polysulfide used in this experiment was prepared by the following method, which is substantially the one as reported by Selis (12). Two hundred gr. of CP grade crystalline $Na_2S \cdot 9H_2O$ was vacuum heated in a Pyrex glass container, being careful to increase the temperature gradually so as not to melt the crystal from room temperature to 200°C over 8 hr. In this procedure almost all of the combined water evaporated and white, porous grains of anhydride were obtained which kept the original shape of hydrate. Then the anhydride was maintained at 350°C and further vacuum dried overnight. The obtained anhydride was maintained at 200°C, 110 gr. of purified sulfur was added, and it was vacuum dried again for 24 hr. After this treatment, the temperature of the mixture was raised to 450°C for a few hours, then the melt of sodium polysulfide was pipetted out into glass capsules, which were stocked in an airtight container.

The prepared capsule was put into the side tube of the cell, heated, and molten sodium-polysulfide was poured down into the cell from the capsule in an argon atmosphere at 300°C. In order to completely impregnate the pores of the electrodes with the molten sodium polysulfide, evacuations and pressurization between 1 Torr and 1 atm in the argon atmosphere were repeated several times. The surface level of molten sodium polysulfide after the impregnation was controlled so as to correspond with the upper surface of the electrodes, A, B, A', and B'.

The cell was maintained at 300° ± 1°C in a small electric furnace, and constant current electrolysis was carried out between A-A', A'-B', A-B, and A-B' by a galvanostat. During the electrolysis, the circuit was opened for 1 sec every 5 min and the differences from the initial open-circuit voltage were measured by a buffer amplifier with a voltage cancellation circuit and recorded with a 5 mV full scale pen recorder. Since the relationship between the OCV and the composition Na_2S_x is given by Gupta and Tischer (1), the following approximation equation obtained from this result was used in this experiment

$$x \text{ in } Na_2S_x = 10.93V - 17.521 \quad [1]$$

where V represents the OCV value (volts) *vs.* Na reference electrode. The range of applicability of Eq. [1] is $2.020 \leq V \leq 2.030$.

Theory—The Composition Change in Electrode A'

Consider the composition change of electrode A' which is placed on the inside of the β-alumina. Although an anodic or cathodic electrolysis of electrode A' against the other electrodes, A, B, or B', necessarily causes a composition change of sodium polysulfide contained in A', the composition of sodium polysulfide in A' also changes even in the electrolysis between A and B or A and B'. This composition change in A' has no charge transfer reaction in itself and is supposed to be caused by mutual migration of ionic species, Na^+ and S_x^{2-}, which consist of molten sodium polysulfide.

Thus the composition change in A′ varies with the electrodes chosen in the electrolysis. In this experiment, the following treatments were derived for each electrolysis.

The constant current electrolysis between A and A′.—When a constant current electrolysis is conducted through β-alumina between A and A′, $it/\mathbf{F}$ moles of Na^+ ion will be transported from A to A′ as shown in Fig. 2(a) if A is the anode and A′ the cathode. Assuming that there are no mass transfers by diffusion through the ceramic separator, the composition change of sodium polysulfide contained in A′ is represented as

$$m\,Na_2S_{x1} + (it/\mathbf{F})Na^+ + (it/\mathbf{F})e^- = m'Na_2S_{x2} \quad [2]$$

Here, m and Na_2S_{x1} are the mole number of sodium polysulfide contained in A′ and its composition before electrolysis, respectively; m' and Na_2S_{x2} are the mole number of sodium polysulfide and the composition also contained in A′ after the electrolysis; moreover, i, t, and $\mathbf{F}$ are the current, electrolysis time, and Faraday constant, respectively. Hereafter, the same symbols are used in all equations for A′. From the material balance in Eq. [2], m' is eliminated and m is calculated as follows

$$m = itx_2/2\mathbf{F}(x_1 - x_2) \quad [3]$$

Similarly, if A′ is the anode and A the cathode

$$m = itx_2/2\mathbf{F}(x_2 - x_1) \quad [3']$$

The constant current electrolysis between A′ and B′.—When B′ is chosen as the anode and A′ the cathode in a constant current electrolysis, transfer of ionic species in the melt is considered to be as shown in Fig. 2(b). Just as before, if the mass transfers by diffusion through the ceramic separator are neglected, the composition change of sodium polysulfide in A′ will be represented as

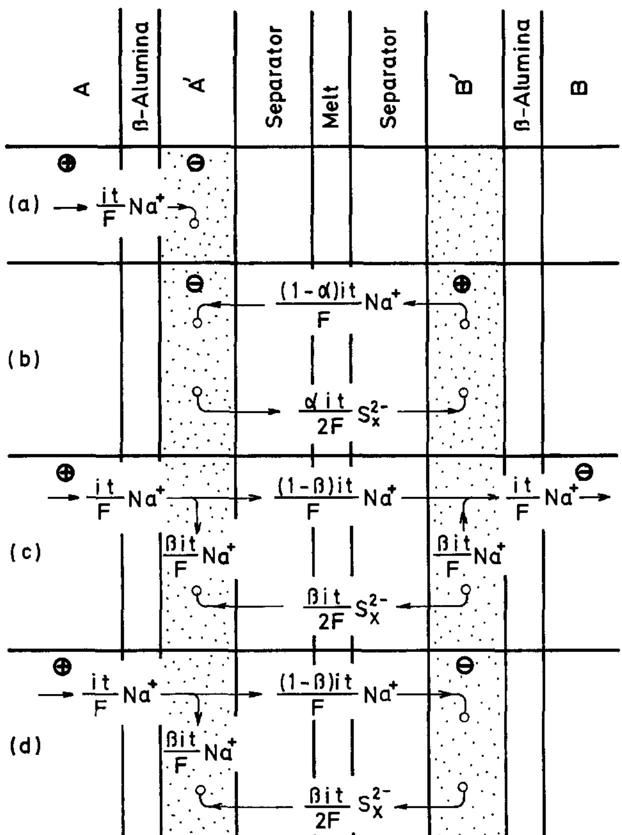

Fig. 2. Migration of ionic species in molten sodium polysulfide. (a) Electrolysis between A and A′; (b) electrolysis between A′ and B′; (c) electrolysis between A and B; (d) electrolysis between A and B′.

$$m\,Na_2S_{x1} + \{(1-\alpha)it/\mathbf{F}\}Na^+ + (it/\mathbf{F})e^- = m'\,Na_2S_{x2} + (\alpha it/2\mathbf{F})S_x^{2-} \quad [4]$$

From the material balance of Na^+ and S_x^{2-} in Eq. [4], the transference number α of S_x^{2-} for the electrode A′ as the reference frame is calculated as

$$\alpha = \{x_2 - 2\mathbf{F}m(x_1 - x_2)/it\}/(x_2 - x) \quad [5]$$

Similarly, when A′ is the anode and B′ the cathode

$$\alpha = \{x_2 - 2\mathbf{F}m(x_2 - x_1)/it\}/(x_2 - x) \quad [5']$$

The constant current electrolysis between A and B.—The constant current electrolysis between A as the anode and B as the cathode leads to Na^+ ion transfers of $it/\mathbf{F}$ moles from A to A′ and B′ to B. These transfers of ionic species in the cell in this case are as shown in Fig. 2(c). If we assume again that there are no mass transfers by diffusion through the ceramic separator, the composition change of Na_2S_{x1} in A′ will conform to the following equation

$$m\,Na_2S_{x1} + (\beta it/\mathbf{F})Na^+ + (\beta it/2\mathbf{F})S_x^{2-} = m'\,Na_2S_{x2} \quad [6]$$

The transference number β of S_x^{2-} for A′, when A′ is taken as the frame of reference, is given by Eq. [7]

$$\beta = 2\mathbf{F}m(x_1 - x_2)/it(x_2 - x) \quad [7]$$

β also represents the ratio of Na^+ ion staying at A′ when an amount of Na^+ ion is transferred into A′ from A. In the case of B as the anode and A as the cathode, β is also expressed by Eq. [7].

Constant current electrolysis between A and B′.—The transfers of ionic species in the melt are considered to be as shown in Fig. 2(d), and the composition change in A′ is represented by Eq. [6], which is the same as in the case of electrolysis between A and B. The transference number β for A′ is also given by Eq. [7].

Results

Determination of the mole number m of sodium polysulfide contained in A′.—The electrode A′ containing $Na_2S_{4.66}$ was electrolyzed against A in the constant current of 0.005A (1 mA/cm²). The measured OCV value of A′ *vs.* the sodium reference electrode $R_{A'}$ changed linearly as shown in solid lines in Fig. 3. The value x in Na_2S_x was obtained from the OCV value using Eq. [1], then m (mole of $Na_2S_{4.66}$ contained in A′) was calculated from Eq. [3] or [3′]. The average value, $m = 3.9 \times 10^{-3}$ moles, was obtained from the results. The calculated m value considering the volume occupied by A′ (2.0 × 20.0 × 25.0 mm³), the porosity of A′ (46.8%), and the volume excluded by the sodium reference electrode was 4.3×10^{-3} moles[1] and corresponded with the measured value of m within a tolerance of about 10%. In this experiment, the value of 3.9×10^{-3} moles was used for m.

The transference number α for A′ in the direct electrolysis of A′.—The OCV change of A′ *vs.* $R_{A'}$ measured every 5 min was shown by the dotted line in Fig. 3 when the electrolysis was carried out between A′ and B′ in 0.005A (1 mA/cm²).

The transference number α of S_x^{2-} species for A′ taken as the frame of reference was calculated from Eq. [1] and [5] or [5′] based on the measured OCV values. The calculated results are given in Fig. 4, where α is plotted in the hyperbolic function of x. These curves in Fig. 4 only signify the mathematical relationship between α and x based on the results and contain regions which are not defined physically, such as $\alpha > 1$. These hyperbolic curves showed a characteristic inclination that passes through an α

[1] The value of 1.892 g/cm³ at 300°C (4) was used for the density of $Na_2S_{4.66}$.

value of about 1 in $x = 2$, irrespective of the polarity of A' or electrolysis time.

The transference number β for A'.—The measured OCV values of A' *vs.* R_A, and B' *vs.* R_B, every 5 min when the constant current electrolysis of 0.005A was carried out between A the anode and B the cathode, are shown in Fig. 5. Figure 5 also shows the OCV change (dotted line) of A' where B is the anode and A the cathode. In this case, the changes of OCV values were larger at an early stage of the electrolysis and became smaller gradually with time. In particular, with the OCV of the electrode placed in the inner side of a cathode and separated by β-alumina (B' when B is the cathode, or A' when A is the cathode), little changed with the passage of time. The transference

number β of S_x^{2-} species for A' taken as the frame of reference was calculated using Eq. [1] and [7]. These results are shown in Fig. 6 and Fig. 7 as the relation between β and x in Na_2S_x. The figures also

indicate the mathematical relationship between β and x based on the results as shown in the case of Fig. 4. Figure 6 represents the case when A is the anode and B the cathode, where hyperbolic curves pass through a β value of 1 in $x = 2$ at an early stage of the electrolysis and shift to the right side with time. Figure 7 represents the case when B is the anode and A the cathode and the tendency to shift of hyperbolic curve with time is more remarkable.

When electrolysis was conducted between A the anode and B′ the cathode, relations between the transference number β of S_x^{2-} species for A′ and x in S_x^{2-} are represented as in Fig. 8. Although the hyperbolic curves tend to shift towards the right side with time, the degree of shift is much smaller than when A is the anode and B the cathode as shown in Fig. 6.

Discussion

S_x^{2-} in molten sodium polysulfide consists mainly of S_2^{2-}, S_4^{2-}, S_5^{2-}, and some S_6^{2-} species (11). Consequently, the elimination of regions, $x < 2$ and $\alpha > 1$, from the curves in Fig. 4 leads to only one valid point, $x = 2$ and $\alpha = 1$. This result shows that Na^+ ions do not move to or from the electrode A′ under the direct electrolysis of A′ and B′, and the composition change of sodium polysulfide contained in the electrode A′ is determined only by the transfers of S_2^{2-} species in the melt. For example, when A′ is the cathode, the following reactions would occur in the electrode (11)

$$S_4^{2-} + 2e^- = 2S_2^{2-}$$

$$2S_5^{2-} + 4e^- = 3S_2^{2-} + S_4^{2-} \quad [8]$$

and the S_2^{2-} ion produced in the reaction processes seems to move from A′ to B′ direction. When A′ is the anode, S_2^{2-} ions brought from the B′ side are oxidized at first at A′ by the reverse reaction of Eq. [8].

On the other hand, when an electrolysis is conducted between A and B, the change in A′ is not as simple as seen before. When A is the anode and B the cathode, OCV in B′ is virtually unchanged after an electrolysis of 20 min, despite the fact that OCV in A′ continues to decrease still more as shown in Fig. 5. Since the change of OCV for A′ or B′ placed on the inside of the cathode (the upper two curves in Fig. 5) is nearly the same in both cases, the behavior of S_x^{2-} species in B′ in this case can be represented by the one shown for A′ in Fig. 7. Thus, when A is the anode and B is the cathode, the behavior of A′ and B′ are explained by Fig. 6 and Fig. 7, respectively. In Fig. 6, if regions $x < 2$ and $\beta > 1$ are eliminated from the curves of 0 ~ 30 min, as in the direct electrolysis mentioned above, $\beta = 1$ in $x = 2$ becomes the only valid point. This means that S_2^{2-} species migrate to A′ during this time to satisfy the condition of electroneutrality for Na^+ ions which are injected into A′ from A continuously through β-alumina. On the other side, the condition, $\beta = 1$ in $x = 2$ is fulfilled for no more than 0 ~ 10 min in B′. Still, the result in A′ by which the charge carrier through A′ to B′ is S_x^{2-} for 10 ~ 30 min implies that curves in Fig. 7 and Fig. 6 are valid not only for $\beta = 1$ in $x = 2$ but also for $\beta = 1$ irrespective of x value, if $x \geqq 2$. This means that the charge carrier in molten sodium polysulfide is only the sulfide ion, S_x^{2-}, and x values change with electrolytic conditions. The crossing point values of x with the straight line of $\beta = 1$ in Fig. 6 and Fig. 7 are depicted in Fig. 9 against electrolysis time.

As there is no charge transfer reaction between A′ and B′, S_2^{2-} ions that migrate from B′ to A′ are not a product of the cathodic reactions as shown in Eq. [8], but may have existed in an equilibrium with other species such as S_4^{2-}, S_5^{2-} in the melt. It is supposed that S_2^{2-} moves out from B′ in the early electrolytic stage, and the gradual depletion of S_2^{2-} with time in B′ causes the migration of larger sulfide ions in B′. The increase of x value with time in Fig. 9 would show the comigration of larger sulfide ions with S_2^{2-}, although the effect of diffusion by concentration gradients would not be negligible in the late stage of electrolysis. As for A′, the period in which only S_2^{2-} ions flow into A′ is much longer. This is attributed to the relatively large volume of the melt in the midst of the cell. But the gradual depletion of S_2^{2-} results with time, and comigration of larger sulfide ions also occurs.

On the contrary, the electrolysis between A as the anode and B′ as the cathode gives a β-x relation for A′ which distributes nearly around the hyperbolic curves of $\beta = 1$ in $x = 2$, and the change of x value with time in $\beta = 1$ in this case reveals that mainly S_2^{2-} ions migrate, as shown in Fig. 9. This is ascribed to the migration of S_2^{2-} ion produced by the cathodic reaction in B′ to A′.

Conclusion

The migration behavior of ionic species in molten sodium polysulfide was investigated using a transport cell of four electrodes. S_2^{2-} ions migrate preferentially into the vicinity of β-alumina to fulfill the electroneutrality for Na^+ ions injected through the β-alumina. S_4^{2-} or S_5^{2-} ions also seemed to contribute to the migration as the depletion of S_2^{2-} ions in the melt, whereas Na^+ ions are considered not to take part in the charge transport. When S_2^{2-} ions are continuously produced by a cathodic reaction in another portion of

the melt, the migration of S_2^{2-} ions towards Na^+ ions injected through β-alumina becomes more remarkable. This phenomenon would be responsible for the determination of the distribution of sodium polysulfide in the porous current collector of the sodium sulfur battery.

Ionic Conductivity and Thermoelectric Power of Pure and Al_2O_3-Dispersed AgI

K. Shahi* and J. B. Wagner, Jr.*

Center for Solid State Science, Arizona State University, Tempe, Arizona 85281

ABSTRACT

Ionic and electronic conductivities, and thermoelectric power have been measured for AgI and AgI containing a dispersion of submicron size Al_2O_3 particles. While the dispersion of Al_2O_3 enhances the ionic conductivity significantly, it does not affect the electronic properties of the matrix. The enhancement is a strong function of the size and concentration of the dispersoid. Various models have been tested to account for the enhanced conduction. However, the complex behavior of the present results points out the need for more sophisticated theoretical models. Ionic conduction and thermoelectric power data suggest that the dispersed Al_2O_3 generates an excess of cation vacancies and thereby enhances the conductivity and suppresses the thermoelectric power of the matrix. The individual heats of transport of cation interstitials and vacancies have been estimated and compared to their respective migration energies.

As a result of intensive efforts in the past decade, many solid ionic conductors that exhibit conductivities in excess of $10^{-2}\ \Omega^{-1}\ cm^{-1}$ at ambient temperatures are now known. Most are stable intermediate compounds between two or more phases with one phase being silver (1) or copper (2) halides or chalcogenides. While the classical doping technique has long been used to increase ionic conductivity, particularly at low temperatures, such an enhancement has been limited to a factor of 2-20, though it has been most useful in the elucidation of ion-transport mechanisms in general.

Recently Liang (3), Liang *et al.* (4), Pack *et al.* (5), and Jow and Wagner (6) studied the effect of Al_2O_3 dispersion in LiI (3-5) and CuCl (6), respectively. These authors reported ionic conductivity enhancements by as much as 2 orders of magnitude. Based on x-ray powder diffraction results the conclusion was that the Al_2O_3 particles are insoluble (3) and hence the classical doping concept cannot be used to explain the enhancement in conductivity. The purpose of the present investigation is (*i*) to examine whether this effect is general and (*ii*) to test the various proposed mechanisms and/or to develop an adequate model.

Experimental

High purity AgI (99.999%) obtained from Apache Chemicals was used without further treatment. Al_2O_3 (99.98%) of different reported particle sizes (0.06, 0.3, 1, 3, 8, and 15 μm) was obtained from Adolf Meller and was also used as received, and in certain experiments it was vacuum dried at $\sim$700°-800°C for at least 12 hr prior to use. Appropriate amounts of AgI (mp 557°C) and Al_2O_3 were intimately mixed in an agate mortar and pestle, vacuum sealed in quartz tube, heated at 800°C for 6-8 hr, and then quenched to room temperature. When undried Al_2O_3 was directly used, the mixture was heated in a sealed quartz tube to a lower temperature (<600°C) to avoid any rupture of the quartz tube due to excessive water vapor pressure. The resultant material prepared by either method was pulverized and pelletized at pressures in the range 70,000-80,000 psi in a nickel-plated steel die. Each sample was annealed for 10-12 hr to relax any stresses and also to homogenize the charge carriers.

The temperature of the furnace was controlled to within ±0.5°C by a Thermac Controller (Series 6000) and measured by Chromel-Alumel thermocouple.

The total conductivity was measured using a cell, Ag|AgI (Al_2O_3) or AgI|Ag, and a GR 1608A impedance bridge in conjunction with GR 1310B oscillator and GR 1232-P2 preamplifier as the null detector. No appreciable frequency dependence was observed except at lower (near room) temperatures where the conductivity at 10 kHz was 5-7% higher than that at 1 kHz. The data reported in this paper are at 1 kHz. The inaccuracy below 1 $\Omega^{-1}\ cm^{-1}$ was less than ±5%.

The d-c polarization technique was used to measure the electronic conductivity using a cell, Ag|AgI (Al_2O_3)

* Electrochemical Society Active Member.

Key words: cations, conduction, thermoelectric power.

or AgI|graphite. In this experiment Keithley 2600 nV source was used as standard voltage source and the current in response to applied polarization potential was measured by measuring the voltage drop by means of Keithley 616 digital electrometer across a known standard resistor.

The thermoelectric power was measured using a sample holder similar to that used for conductivity measurements except the former has Pt-Pt-10% Rh thermocouples welded on the back of each Pt electrode (in contact with the Ag electrode) which are used to record the temperature of each side of the sample. The thermoelectric voltage (ΔV) induced by the small temperature difference (ΔT of the order of 10°C) was also measured by Keithley 616 digital electrometer with an input impedance of $>10^{14}\Omega$ at balance that ensures almost zero current through the specimen under examination. The thermoelectric power was calculated from the ratio $\Delta V/\Delta T$ and assigned the usual sign convention, *i.e.*, it is positive if the hot end is positive.

In the following, the results on ionic conductivity are presented first followed by those on electronic conductivity and thermoelectric power.

Results and Discussion

Ionic Conductivity

Ionic conductivity vs. composition.—Figure 1 shows the total (a-c) conductivity of the AgI(Al_2O_3) system containing both dried and undried alumina particles of 0.06 μm size as a function of the Al_2O_3 content at room temperature. This figure also shows the same results obtained for dried alumina particles of 0.3 and 8 μm sizes. The conductivity of AgI(Al_2O_3) system initially increases with increasing Al_2O_3 content for both dried and undried, and for all sizes of Al_2O_3 particles. It reaches a maximum around 30 mole percent (m/o) Al_2O_3 content and then decreases. The dispersion of undried Al_2O_3 (0.06 μm) leads to a relatively sharp maximum as well as to more enhancement than predried Al_2O_3. This latter result indicates the possibility that the presence of adsorbed water on the Al_2O_3 might be playing an important role in the enhancement of conductivity.

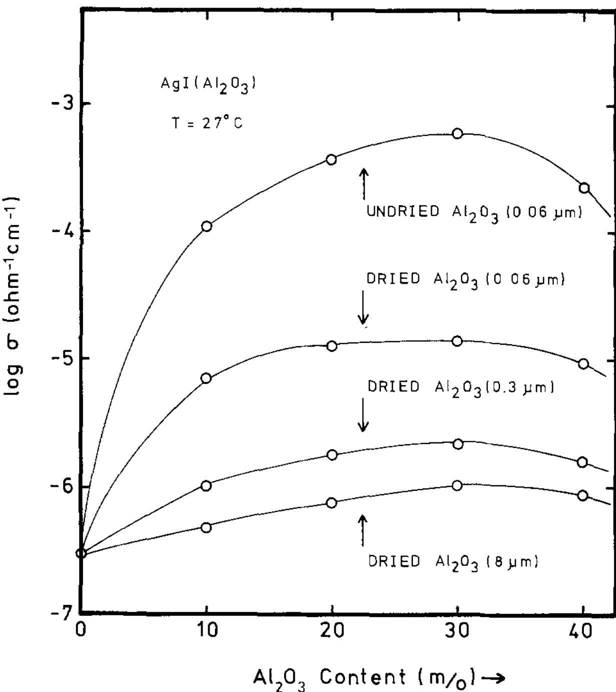

Fig. 1. Logarithm of total (a-c) conductivity of AgI(Al_2O_3) system as a function of the concentration of Al_2O_3 particles at room temperature. Measurements employ silver electrodes and a frequency of 1 kHz.

A maximum conductivity of 6×10^{-4} Ω^{-1} cm^{-1} was obtained for AgI containing 30 m/o undried Al_2O_3 (0.06 μm) at room temperature.

Another point to be emphasized is that the conductivity enhancement is a strong function of the size of Al_2O_3 particles. Figure 1, for example, also shows the results of AgI(Al_2O_3) system containing the dried Al_2O_3 particles of 0.3 and 8 μm sizes. Figure 2 further illustrates the dependence of conductivity of the AgI(Al_2O_3) system as function of the size of Al_2O_3 particles. Obviously the conductivity enhancement is larger for smaller particles. When Al_2O_3 particles as large as 8 or 15 μm are used there is very little or practically no enhancement in conductivity.

Ionic conductivity vs. temperature.—Figure 3 shows the plot of log σ *vs.* $10^3/T$ for AgI and AgI containing a dispersion of dried and undried Al_2O_3 (0.06 μm). A conductivity of 3×10^{-7} Ω^{-1} cm^{-1} at 25°C was obtained for pure AgI, and an overall activation energy of 0.56 eV in the temperature range 300-400 K; these values are in good agreement with some of the previous findings on polycrystalline AgI and also close to single crystal values (1). The rather high conductivity and low activation energy reported by some researchers may have been due to the presence of impurities or γ-AgI in their samples and/or a lack of prolonged annealing of samples used in their experiments. We found the conductivity of freshly prepared samples of AgI decreased and activation energy increased considerably when the samples were annealed overnight at 70°-80°C.

The addition of undried 30 m/o Al_2O_3 of 0.06 μm size increased the conductivity by about 3 orders of magnitude, the room temperature value being $\sim 6 \times 10^{-4}$ Ω^{-1} cm^{-1} as compared to 3×10^{-7} Ω^{-1} cm^{-1} for pure AgI. The enhancement in conductivity by the dispersion of Al_2O_3 is accompanied by a decrease in activation energy as is usual for most high conductivity solid electrolytes. Summarized in Table I are the conductivities and the related parameters for AgI and AgI(Al_2O_3).

The dispersion of predried Al_2O_3 (30 m/o, 0.06 μm) increased the conductivity by about a factor of 50. The larger enhancement caused by undried Al_2O_3 is not quite understood but seems to be related to the adsorbed moisture on the Al_2O_3 particles. Further

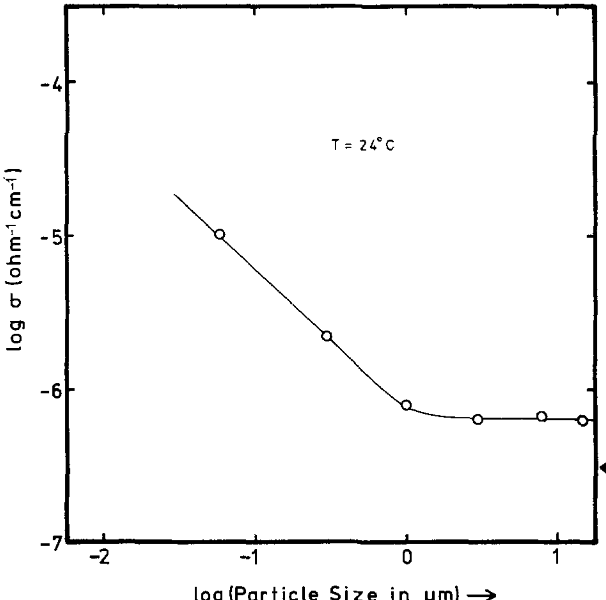

Fig. 2. Logarithm of conductivity of AgI containing 30 m/o dried Al_2O_3 at room temperature as a function of the logarithm of the size (in μm) of Al_2O_3 particles.

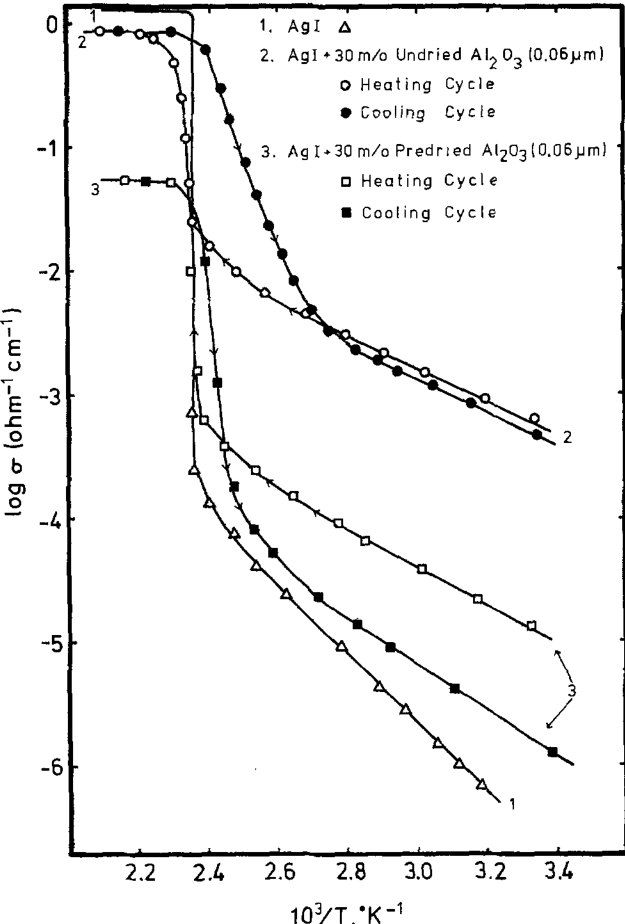

Fig. 3. Logarithm of conductivity of pure AgI and AgI + 30 m/o Al_2O_3 (0.06 μm), using both dried and undried Al_2O_3, as a function of inverse absolute temperature.

experiments to quantify the effect of adsorbed water content on the conductivity enhancement are planned.

The activation energy of 0.31 eV for AgI + 30 m/o Al_2O_3 (0.06 μm) can be compared to the migration energies of Ag^+ interstitials (Δh_i^+) and Ag^+ vacancies (Δh_v^+) in β-AgI. According to one study on polycrystalline AgI (7) Δh_i^+ is ~0.14 eV which is much less than what is observed (0.31 eV) for $AgI(Al_2O_3)$ system suggesting that Ag^+ interstitials are less likely to be a mechanism responsible for conduction in $AgI(Al_2O_3)$. However, the other studies (8-10) on β-AgI reveal that Δh_i^+ and Δh_v^+ are quite comparable; Δh_i^+ is in the range 0.3 eV (8) to 0.4 eV (9) and Δh_v^+ amounts to 0.4 eV (8) to 0.5 eV (8, 10). Therefore, it is very difficult to deduce the type of charge carrier responsible for conduction in $AgI(Al_2O_3)$ from these data.

Another interesting feature of Al_2O_3 dispersion is that it leads to a hysteresis in log σ vs. $10^3/T$ plot (see Fig. 3). When the temperature is cycled through the β → α phase transition temperature (T_c) of AgI (~147°C), the σ decreased by a factor varying between 2 to 10 depending on the temperature, thermal history of the sample, and the Al_2O_3 content. A common feature of these results is that the smaller the width of the hysteresis loop in the log σ vs. $1/T$ plot the larger is the difference in σ's before and after cycling the temperature across T_c. It should be noted however that the σ of AgI with or without Al_2O_3 remained almost the same when temperature was cycled between room temperature and T_c.

Figure 4 compares the conductivity results for usual (cold pressed) pellets to that for hot-pressed (at 300°C) pellets, at different temperatures. A somewhat higher σ for the hot-pressed samples might be due to a better packing than that of the former but there is no significant difference between the two samples.

Neither in conductivity nor in thermoelectric power (to be discussed later) is the effect of Al_2O_3 dispersion pronounced in α-AgI. In general there is a drop in the σ whose magnitude, by and large, solely depends on the content of Al_2O_3. Since at the present time these results do not seem promising technically, nor do they contribute significantly towards the understanding of the mechanism of transport in these dispersed solid electrolyte systems, they will not be discussed further.

Summary of the results.—Table II summarizes some of the characteristics of the $AgI(Al_2O_3)$ and other systems reported thus far, *viz.* $LiI(Al_2O_3)$ (3), $CuCl(Al_2O_3)$ (11), and $HgI_2(Al_2O_3)$ (12). The results of $AgI(Al_2O_3)$ indicate a more complex behavior, *e.g.*, "wet" Al_2O_3 appears more effective than dry ones and log σ vs. composition plot exhibits a rather flat maximum (Fig. 1) similar to that in $HgI_2(Al_2O_3)$ but unlike those in CuCl (Al_2O_3) and $LiI(Al_2O_3)$. In brief, the important features of all these Al_2O_3-dispersed systems can be summarized as follows: (*i*) there is an enhancement in conductivity by a dispersion of sec-

Table I. Electrical conductivity and activation energy in AgI and $AgI(Al_2O_3)$

Material	σ (Ω^{-1} cm^{-1}) at 25°C	Activation energy (eV)	Temperature range (°C)
AgI	3×10^{-7}	0.56	25-120
AgI + 30 m/o undried Al_2O_3 (0.06 μm)	6×10^{-4}	0.26	15-110
AgI + 30 m/o dried Al_2O_3 (0.06 μm)	1.2×10^{-5}	0.31	25-100

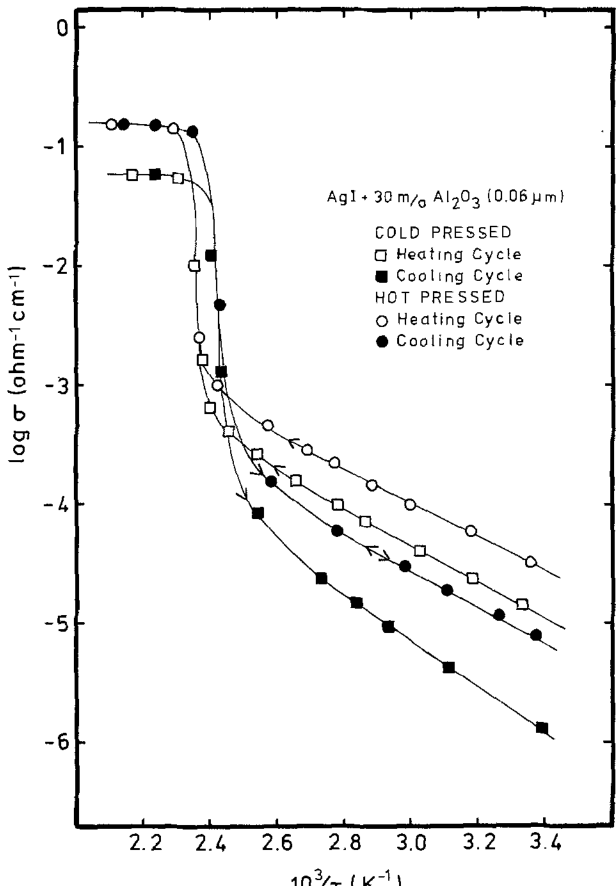

Fig. 4. Logarithm of conductivity of cold and hot (300°C) pressed pellets of AgI + 30 m/o dried Al_2O_3 (0.06 μm) as a function of inverse absolute temperature.

Table II. Some characteristics of solid electrolytes containing a dispersion of dried Al_2O_3

Material	Size of Al_2O_3 (μm)	m/o Al_2O_3 for maximum enhancement	Temp. (°C)	Maximum enhancement in conductivity by a factor of
AgI	0.06	30	25	~50 (this work)
LiI	—	40	25	≥50 (3)
CuCl	0.06	10	60	~50 (11)
HgI_2*	0.06	30	203	~100 (12)

* HgI_2 is not known to be solid electrolyte and the quoted value of the enhanced conductivity corresponds to the inclusion of undried Al_2O_3.

ond phase (such as Al_2O_3); (*ii*) the larger enhancement is due to finer dispersoids; (*iii*) "wet" dispersoids cause a larger enhancement than dry ones; (*iv*) there is larger enhancement at lower temperatures where the intrinsic defect concentration is low compared to that generated by the dispersoids. This also implies a decrease in activation energy in the low temperature regime. However, the data on $LiI(Al_2O_3)$ (3) do not agree with others, *i.e.*, the activation energies are the same with and without Al_2O_3. (*v*) The occurrence of a rather flat maximum for some systems in the log σ *vs.* composition plot, seems to extend from 15 to 35 m/o Al_2O_3 in $AgI(Al_2O_3)$ and up to 80 m/o in $HgI_2(Al_2O_3)$, and (*vi*) the position of maximum for a particular system, *e.g.*, $AgI(Al_2O_3)$, to be independent of the size of the dispersoids but a sensitive function of the matrix, for example, in $CuCl(Al_2O_3)$ the maximum occurs at 10 m/o, in $AgI(Al_2O_3)$ at 30 m/o, and in $LiI(Al_2O_3)$ at 40 m/o Al_2O_3.

Discussion of models.—The electrical transport in multiphase systems has been fundamentally treated by Maxwell (13a) and Lord Rayleigh (13b). However, these models did not consider the possible existence of electrical double layer at the interfaces and thus, in turn, did not predict a higher conductivity for the mixed phases than for the pure single phase materials.

In 1972, Wagner (14) reconsidered the problem and, based on the fact that there can be a space charge layer at the interfaces, he derived an expression that predicted an enhanced electronic conduction in two-phase semiconductors, the enhancement being proportional to the volume fraction of the dispersoid and the square of the Debye length and inversely proportional to the square of the radius of the dispersoid.

Recently Jow and Wagner (6) derived a model for ionic conduction based on the fact that ultrafine dispersoids have some kind of charge at or near their surfaces. Due to formation of the double layer at the dispersoid/matrix interface, the defect concentration and hence conductivity, in the vicinity of the dispersoids differs from that in the bulk. They obtained the following expression

$$\Delta\sigma = 3 \sum_i e\,\mu_i \langle \Delta n_i \rangle \lambda \left(\frac{1}{r_1}\right)\left[\frac{V_v}{1-V_v}\right] \quad [1]$$

where $\Delta\sigma$ is the change in conductivity of the matrix with the dispersoid relative to that of the bulk matrix, e the electronic charge, μ_i the mobility of the ith defect species, $\langle \Delta n_i \rangle$ the average excess density of defects within the space charge region, λ the space charge layer thickness (~Debye length), r_1 the radius (half the size) of the dispersoid, r_2 the distance between two dispersoids, and V_v the volume fraction of the dispersoid. This model predicts that the enhancement in σ is proportional to $(1/r_1)$ $(V_v/1 - V_v)$ **for the cases where $r_1 << r_2$ is satisfied.**

Stoneham *et al.* (15) have extended Landauer's (16) effective medium model which assumes a high conductivity layer around each insulating particle, and shown that the enhanced conduction is possible if one assumes the layer to be of a few hundred angstroms thickness.

According to another (12) so-called interface-capacitor model which also involves the space charge layer between the dispersoid and matrix, the conductivity is given by

$$\sigma = \sigma_1(1-V_v) + G\cdot S(1-V_v)^2 + \sigma_2 V_v \quad [2]$$

where σ, σ_1 and σ_2 are, respectively, the conductivities of the mixed phase, the first phase (or matrix), and the second phase (or dispersoid), S the surface area generated by the dispersoid per cm^3, and G a factor which accounts for the number of excess charge per cm^3.

All these models recognize in some way the existence of a "double layer" or "conducting layer" at the matrix-dispersoid interface and agree qualitatively in their predictions to some extent. While the model of Jow and Wagner (6) works well with respect to both accounting for enhanced conduction and predicting the correct temperature dependence, its applicability is limited to smaller concentrations of the dispersoid ($r_1 << r_2$). The latter two models (12, 15) also explain the "blocking effect" of the dispersoid at larger concentrations but these both lack in predicting the correct temperature dependence. For instance, the σ's of CuCl and $CuCl(Al_2O_3)$ all fall around the same value at $T \geq 300$°C.

In brief, the results on dispersed-systems point out the need for more sophisticated models capable of explaining the additional features such as (*i*) the larger effectiveness of "wet" dispersoid, (*ii*) the occurrence of flat maximum in some systems, *e.g.*, $AgI(Al_2O_3)$, and (*iii*) the position of maximum which is a sensitive function of the matrix.

Electronic Conductivity

Since in many electrochemical applications it is desired that electronic conductivity be small (or preferably negligible) compared to the ionic part, a d-c polarization cell of the type

$$(-)\text{Ag}|\text{AgI}(Al_2O_3) \text{ or } \text{AgI}|\text{C}(+)$$

was constructed for this measurement. When a potential (V) less than the decomposition potential of the electrolyte is applied with positive polarity on the right side, the Ag^+ ions move initially from right to left side (toward Ag electrode). Since graphite is an inert (so-called blocking) electrode, there is no supply of Ag^+ ions and hence a depletion of Ag^+ ions results at the $C/AgI(Al_2O_3)$ interface. At steady state the potential gradient due to electric field is just balanced by that due to the chemical potential gradient and then the ionic current is zero. Under these conditions the current is solely due to diffusional flow of electrons or holes. Wagner (17) has shown that the steady-state current (I) is given by

$$I = I_e + I_h = \frac{kTA}{eL}\left[\sigma_e\left\{1 - \exp\left(-\frac{eV}{kT}\right)\right\} + \sigma_h\left\{\exp\left(\frac{eV}{kT}\right) - 1\right\}\right] \quad [3]$$

where σ is the conductivity and the subscripts e and h refer, respectively, to electrons and holes, L the length and A the area of the sample, k the Boltzmann constant, and V the polarization potential. When $eV >> kT$, which is often satisfied except at very low polarization potentials and very high temperatures, the above expression simplifies to

$$I = I_e + I_h = \frac{kTA}{eL}\left[\sigma_e + \sigma_h \exp\left(\frac{eV}{kT}\right)\right] \quad [4]$$

Generally the conductivity due either to electrons or to holes is predominant, and hence we have

$$I \simeq I_e = \frac{kTA}{eL}\sigma_e \quad (\text{when } \sigma_e >> \sigma_h) \quad [5]$$

and

$$I \simeq I_h = \frac{kTA}{eL}\sigma_h \exp\left(\frac{eV}{kT}\right) \quad (\text{when } \sigma_h >> \sigma_e) \quad [6]$$

According to Eq. [5] the current is independent of V when electron conduction is dominant while in case of predominant hole conduction (Eq. [6]) the current varies exponentially with V. Thus in the former case, the limiting current can be used to obtain σ_e while in the latter case the slope of linear log I *vs.* V plot yields the σ_h.

The log I *vs.* V plot for the cell ⊖Ag|AgI(Al_2O_3)|C⊕ at different temperatures is shown in Fig. 5, which suggests that the hole conduction is predominant in AgI(Al_2O_3). We do not know of any polarization measurements on β-AgI, but there are results available for α-AgI ($T > 146°C$) (18). α-AgI is known to be a p-type conductor. The electronic conductivity measurements on β-AgI are now in progress. Preliminary results show that β-AgI without Al_2O_3 is essentially a p-type conductor. Thus it can be concluded that dispersion of Al_2O_3 does not affect the nature of electron (hole) conductivity, nor does it significantly change its magnitude. The values of σ_h at different temperatures are given in Table III. When hole conduction is predominant, Eq. [6] predicts that log I *vs.* V plot will display slopes which are independent of any transport parameters related to the material studied. These slopes, $e/2.3026\ kT$, which depend only on $1/T$ are compared with experimental slopes in Table III. The good agreement indicates that the polarization technique is quite successful in AgI(Al_2O_3) system. The log σ_h *vs.* $10^3/T$ plot for AgI(Al_2O_3) is shown in Fig. 6 and can be expressed by

$$\sigma_h = 13.3 \exp(-1.13\ eV/kT) \quad (300\text{-}420\ K) \quad [7]$$

Although the concentration of electron holes depends strongly on the concentration of silver (or of iodine), the concentrations of lattice defects do not and hence the activation energy of 1.13 eV may be identified as the activation energy for the migration of electron holes, $\Delta h_h{}^{\cdot *}$, plus the partial enthalpy of mixing of I_2 per molecule of AgI. In conclusion, while a dispersion of second phase such as Al_2O_3 enhances the ionic conductivity significantly, it does not affect the electronic transport properties, for instance the nature and magnitude of electron hole conductivity.

Table III. Data obtained from polarization measurements on the cell ⊖ Ag | AgI(dried-Al_2O_3) | C⊕

Temp. (°C)	Hole conductivity (Ω^{-1} cm^{-1})	Slope of log I *vs.* V plot: Theoretical (V^{-1})	Expt'l. (V^{-1})
50	3.5×10^{-17}	15.58	15.62
80	2.6×10^{-15}	14.25	14.46
110	1.2×10^{-14}	13.14	14.21
140	2.2×10^{-13}	12.18	13.05

Thermoelectric Power

When a temperature gradient is applied across a solid, MX, containing lattice defects, owing to the increased concentration and increased jump frequency of the defects near hot end, a flow of defects from hot to cold region is set up. At steady state a voltage across the sample appears which directly reflects the

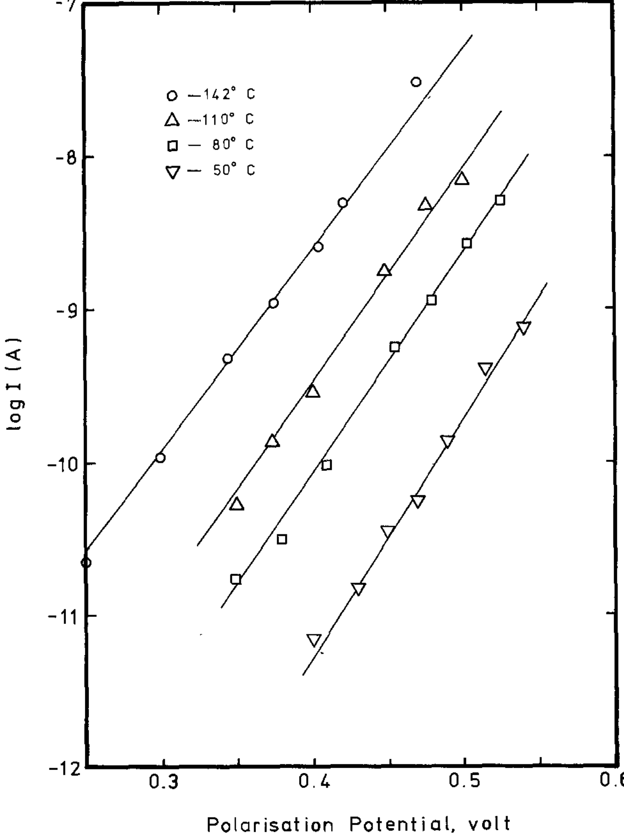

Fig. 5. Logarithm of steady-state current (*I, A*) in the asymmetric cell (—)Ag | AgI + 30 m/o Al_2O_3 (0.06 μm) | C(+) as a function of the applied polarization potential (*V*) at four different temperatures.

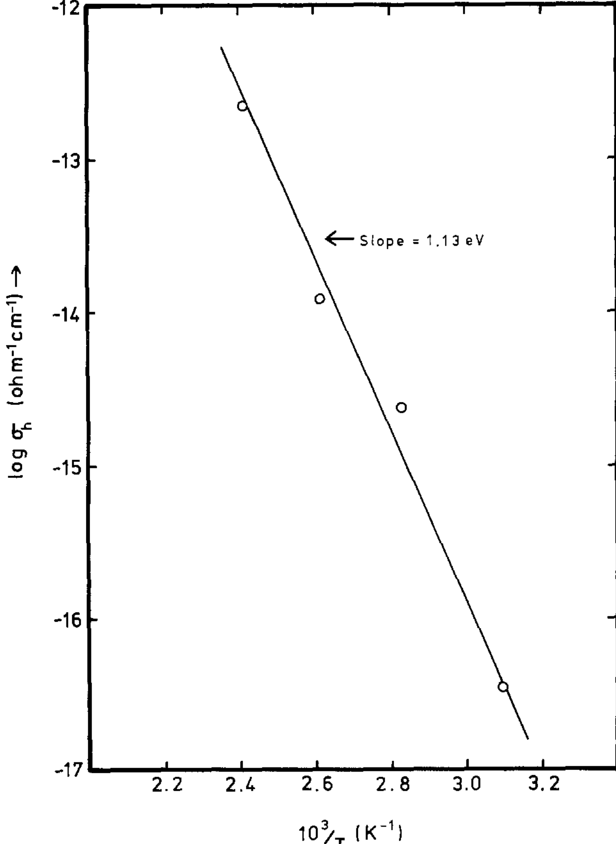

Fig. 6. Logarithm of electron hole conductivity (σ_h) of AgI + 30 m/o dried Al_2O_3 (0.06 μm) equilibrated with silver as function of inverse absolute temperature.

sign of charge carriers in the system. Thus the thermoelectric power measurement is the most powerful tool for examining the nature of charge carriers in any system. In fact this measurement combined with the conductivity data has revealed a number of key features of solid electrolytes (1, 19) rarely disclosed by any other technique.

The homogeneous thermoelectric power (θ_{hom}) which arises due to a temperature gradient across the solid is given by (1, 20)

$$\theta_{hom} = \frac{1}{eT}\frac{(q_v^+ + h) - \phi q_i^+}{1+\phi} - \frac{kT \,\mathrm{grad}\, n_i}{e n_i \,\mathrm{grad}\, T} \quad [8]$$

for thermocells of the type $(T)\mathrm{M}|\mathrm{MX}|\mathrm{M}(T + \Delta T)$, where q_i^+ and q_v^+ are the heats of transport of Ag^+ ion interstitials and vacancies, respectively, h the heat of formation of a pair of Schottky or Frenkel defects, ϕ the ratio of interstitial to vacancy mobility, k the Boltzmann constant, and n_i the concentration (number per cm^3) of each kind of defects and the other symbols have their usual meaning. The above equation states that the θ_{hom} is a direct function of $1/T$ provided other quantities are not strong functions of temperature.

However the situation gets complicated because of the heterogeneous thermoelectric power (θ_{het}) which arises as a result of temperature dependence of the contact potential between the electrode and electrolyte. For reversible thermocells using Ag electrodes it is given by (1, 20, 21)

$$\theta_{het} = \frac{k}{e}\ln\left(\frac{n_i}{N}\right) + \frac{kT \,\mathrm{grad}\, n_i}{e n_i \,\mathrm{grad}\, T} + \frac{1}{e}S_{Ag^+}{}^{Ag} - \frac{1}{e}S_{Ag^+} \quad [9]$$

where N is the number of normal cation sites per cm^3, S_{Ag^+} is the entropy of a silver ion in AgI or $AgI(Al_2O_3)$ and $S_{Ag^+}{}^{Ag}$ is the entropy of a silver ion in silver metal. The latter can be approximated by the entropy of silver metal since the free electrons supposedly contribute very little to the total entropy. Thus approximate value of $S_{Ag^+}{}^{Ag}$ could be obtained, for example, from the free electron theory or from the thermionic emission experiments. However the molar entropy of the defects in solid electrolytes, S_{Ag^+}, is the most tedious quantity to determine either from theory or from experiments. The most straightforward way to determine these entropies of defect formation is from the detailed analysis of conductivity (or diffusion) measurements (22). However such an analysis yields only the sum of the entropies of the two complementary defects rather than individual molar entropies as these are not independent thermodynamic quantities. Several approximate methods have been used to separate these quantities and are reviewed (23, 24) elsewhere.

The total thermoelectric power (θ) is obtained on adding Eq. [8] and [9] which is not always too simple to yield defect parameters of interest. However there are some special cases of interest as indicated below.

Interstitial dominant conduction.—When cation interstitials are much more mobile than vacancies *viz.* $\phi >> 1$, and their concentration is an exponential function of temperature, Eq. [8] reduces to a simpler form which, on adding to Eq. [9], gives

$$\theta = \frac{q_i^+ + \frac{1}{2}h}{eT} + \frac{1}{e}S_{Ag^+}{}^{Ag} - \frac{1}{e}S_{Ag^+} \quad [10]$$

Considering the sum $1/e(S_{Ag^+}{}^{Ag} - S_{Ag^+})$ to be small and independent of T as discussed elsewhere (1), Eq. [10] can be used to obtain q_i^+ from the slope of linear θ *vs.* $1/T$ plot provided the h is known from independent experiments such as conductivity or diffusion measurements.

Vacancy dominant conduction.—When cation vacancies are the only charge carriers *viz.* $\phi << 1$ and their concentration is almost independent of T, *e.g.,* in the extrinsic region, Eq. [8] and [9] reduce to simpler forms and their sum is given by

$$\theta = \frac{q_v^+}{eT} + \frac{k}{e}\ln\left(\frac{n_v}{N}\right) + \frac{1}{e}S_{Ag^+}{}^{Ag} - \frac{1}{e}S_{Ag^+} \quad [11]$$

Since n_v is independent of T, the last three terms could be considered as independent of T and then the slope of θ *vs.* $1/T$ plot can be used to obtain the q_v^+.

Figure 7 shows the plot of θ *vs.* $10^3/T$ for AgI and AgI containing a dispersion of dried 30 m/o Al_2O_3 of 0.06 μm size with silver electrodes. For AgI, θ is large and negative which could be attributed to Ag^+ interstitials. The θ increases initially, attains a maximum around 80°C and then it decreases with increasing temperature which is in qualitative agreement with a recent measurement (25) of θ on β-AgI. The behavior at $T \geq 80$°C, *viz.* decreasing θ with increasing temperature, is typical of solid electrolytes and is also in accord with theory. The behavior at $T \leq 80$°C, *viz.* increasing thermal power with increasing T, is not well understood. However, the increasing θ from a less negative to a more negative value is attributable to increasing dominance of cation interstitials and consequently the maximum in θ *vs.* $1/T$ plot could be correlated to a switchover in the transport mechanism of β-AgI. It seems reasonable to consider that at near room temperature the conduction is dominated by Ag^+ vacancies while at $T \geq 80$°C it is the Ag^+ interstitials which are responsible for conduction. Such a switchover in the transport mechanism should be observable, in principle, in a log σ *vs.* $1/T$ plot. However our results (Fig. 3) do not reveal any change in slope perhaps because of the very small difference in the two migration energies (9), *viz.* Δh_i^+ (0.4 eV) and Δh_v^+ (0.5 eV). There are a number of other studies (1, 7-10) on pure and doped β-AgI. Most studies, particularly those on polycrystalline samples, do not yield more than one slope indicating no obvious change in the transport mechanism. Although a mere change in the slope of log σ *vs.* $1/T$ plot is not always an indication that more than one mechanisms are in operation. A more straightforward answer is provided

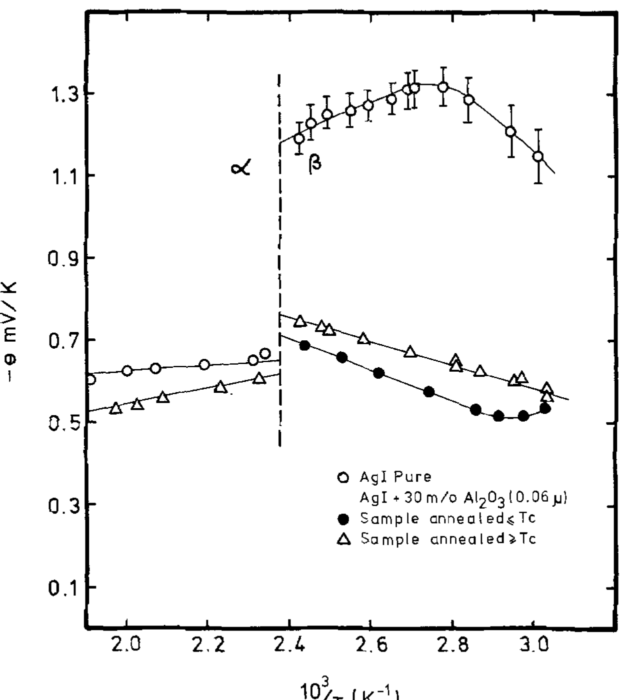

Fig. 7. Thermoelectric power (θ) of pure AgI and AgI containing 30 m/o dried Al_2O_3 of 0.06 μm size with reversible silver electrodes as a function of inverse absolute temperature.

by the conductivity data on pure and doped samples. While for AgCl and AgBr there exists a wealth of data, few conclusive studies exist on β-AgI. The main reason appears to lie in the fact that AgI is too reactive a solid to accommodate impurity atoms substitutionally. Intermediate compounds are formed instead, for instance, $AgI + CdI_2 \rightarrow Ag_2CdI_4$ (26, 27), $AgI + Ag_2S \rightarrow Ag_3SI$ (28). A part of the reason also seems to be the presence of the violent ($\beta \rightarrow \alpha$) phase transition at 147°C that prevents the growth of good crystals containing divalent impurities from the melt. Nevertheless, defect properties have been studied (8-10, 24) and it is generally agreed (1) that cationic Frenkel disorder prevails in β-AgI and that the Ag^+ vacancies are the dominant (8) charge carriers. At high temperature, the conduction is however solely attributed (8) to Ag^+ interstitials. While Govindacharyulu *et al.* (9) conclude that Ag^+ interstitials are the dominant charge carriers over the entire temperature range, our prediction based on thermoelectric power data precisely agrees with (8) and also with the latter (9) at higher temperatures (intrinsic region).

The θ of β-AgI in the vacancy dominant region (<80°C), see Fig. 7, is rather limited in range and involves large uncertainty and therefore it may not be used to obtain q_v^+. However, the data at $T \geqq 80°C$ can be expressed by

$$-\theta = 0.43\left(\frac{10^3}{T}\right) + 0.16\ \text{mV/K} \qquad [12]$$

and can be used to calculate q_i^+. Comparing Eq. [10] and [12], we get $q_i^+ + \frac{1}{2}h = 0.43$ eV. Since h is reported to be 0.60, 0.64, and 0.68 eV, we obtain $q_i^+ = 0.11 \pm 0.02$ eV, using the intermediate value of $h = 0.64$ eV, which can be compared with the value of 0.06 eV obtained in a previous investigation (29).

The θ *vs.* $10^3/T$ plots for AgI containing 30 m/o Al_2O_3 are also shown in Fig. 7. The θ of the sample annealed below T_c is smaller than that annealed above T_c which is consistent with the conductivity data and may again be attributed to the changes in dispersoid distribution resulting from the phase transition of the matrix at 147°C. The net effect of dispersion is to decrease the magnitude of θ from a more negative (for pure β-AgI) to a less negative value. Recalling that negative charge carriers (Ag^+ vacancies) give rise to a positive θ, the above behavior is compatible with the increased dominance of Ag^+ ion vacancies in $AgI(Al_2O_3)$, *i.e.*, with the hypothesis that dispersed Al_2O_3 generates excess silver ion vacancies and thereby enhances the σ and suppresses the θ. Moreover, the fact that θ *vs.* $1/T$ plot for AgI (Al_2O_3) exhibits a negative slope, *i.e.*, θ is increasing with increasing temperature, might be considered as well (compare Eq. [10] and [11]) an indication of the presence of excess cation vacancies. Also the concentration of these vacancies could be considered as almost independent of T as the thermally generated defects would form only a negligible fraction of the total defect concentration in low temperature regime. Under these circumstances the slope of the linear θ *vs.* $10^3/T$ plot that can be expressed by

$$-\theta = -0.28\left(\frac{10^3}{T}\right) + 1.43\ \text{mV/K} \qquad [13]$$

can be used to extract q_v^+. Comparing Eq. [11] and [13], we get $q_v^+ = 0.28$ eV. The heats of transport (q_i^+ and q_v^+) thus obtained are compared with their respective migration enthalpies in Table IV. These parameters for AgCl and AgBr are also quoted in the above table. The fair agreement between the two transport parameters, *viz.* the heat of transport and activation energy for isothermal migration, and their consistency with those in AgCl and AgBr provide further support to the model used in this paper.

Table IV. Heat of transport and activation energy for migration in AgI and their comparison with AgCl and AgBr (all energies are in eV)

Solid	Δh_i^+	q_i^+	Δh_v^+	q_v^+	Ref.
AgI	0.14-0.4	0.11	0.31	0.28	This work
AgCl	0.15	0.18	0.30	0.31	(30)
AgBr	0.15	0.08	0.30	0.50	(31)

In summary, the studies so far indicate that the effect of Al_2O_3-dispersion is quite general, and that it can be used to increase the ionic conductivity by orders of magnitude in a solid electrolyte without altering the electronic conductivity significantly. The existing models explain some of the features satisfactorily but the very complex behavior of the observed results points out to the need for more sophisticated theoretical models. The thermal power data suggests that dispersed Al_2O_3 introduces an excess of Ag^+ ion vacancies and thereby enhances the conductivity of the matrix.

$LiB(CH_3)_4$-Dioxolane Electrolyte in Rechargeable Li/TiS_2 Cells

Lawrence P. Klemann* and Gerald H. Newman*

Exxon Research and Engineering Company, Corporate Research Laboratories, Linden, New Jersey 07036

ABSTRACT

$LiB(CH_3)_4$ is an example of a large class of boron complex anion salts which are very soluble and highly conductive in dioxolane. Solutions of $LiB(CH_3)_4$ have been investigated as electrolytes in Li-TiS_2 cells. At room temperature such cells have been operated as rechargeable energy storage devices which are capable of continuous discharge (5 mA/cm^2) and charge (1.25 mA/cm^2) cycling. While solutions of $LiB(CH_3)_4$-dioxolane appear stable over long periods, contact with TiS_2 results in anion oxidation with concomitant formation of Li_xTiS_2 ($x < 1$). The oxidation products are gases whose apparent rate of generation is proportional to the concentrations of solute and TiS_2. The product distribution depends on whether $LiB(CH_3)_4$-dioxolane solution contacts TiS_2 alone, or in a Li-TiS_2 cell. The electrolyte-cathode reaction is thought to involve transient methyl radicals which are formed during a concerted process involving anion oxidation and TiS_2 lithiation.

The discovery in our laboratories of the reversible intercalation of lithium into titanium disulfide (1) spurred investigations into other components of advanced battery systems. Extensive research into lithium alloy (2) and pure lithium anodes and organic electrolytes led to the development of a rechargeable, ambient temperature Li-TiS_2 cell with a lithium perchlorate electrolyte (3, 4). However this electrolyte, due to its explosion hazard (4), posed unacceptable risks for further system development and a safe replacement for the perchlorate salt was sought.

In our search for an alternate organic electrolyte, dioxolane, by virtue of its high kinetic stability toward alkali metals (a feature considered essential for efficient operation of a rechargeable lithium electrode) was retained. As the likelihood of encountering a suitable replacement solute from the stocks of commercially available lithium salts seemed increasingly remote, a different approach was chosen. We reasoned that a desirable set of electrolyte properties was intimately related to fundamental properties of the anion (*i.e.*, spatial shape, ion-pairing tendencies, charge to size ratio, charge delocalization, oxidation potential, etc.). If one had adequate synthetic freedom to modify anion structure and thereby affect these fundamental properties, a proper balance of bulk electrolyte properties would be achievable by design.

The potential scope for anion structure modification is unsurpassed in a complex (multicomponent) anion, and a particularly rich synthetic chemistry for lithium tetraorganoborate salts has been well documented (5-7). A straightforward synthetic access to these salts and evidence for their favorable ion-pair dissociation (8) relative to $LiClO_4$ in dilute ether solutions (9) prompted our choice of borate salts as a launching point for this investigation. Lithium tetramethylborate whose tetrahedral symmetry and ionic dimensions (10) closely resemble those of $LiClO_4$ (11) was one of first model solutes whose ionic properties were examined in detail.

Experimental

Dioxolane (Burdick and Jackson) was distilled from sodium benzophenone ketyl under N_2. Low halide methyllithium was supplied by LITHCOA. BF_3·etherate (Ventron) was distilled before use. CH_3MgBr (Aldrich), butyllithium, and tributylborane (Ventron) were used to prepare $LiB(CH_3)_4$ and $LiB(C_4H_9)_4$ in accordance with published procedures (12, 13). Both borate salts were isolated free of solvent by means of vacuum drying. The dimethoxyethane (DME) solvate of $LiB(CH_3)_4$ was prepared by dissolving the salt in DME followed by vacuum evaporation. TiS_2 was used either as the dry powder or admixed wtih approximately 10 weight percent Teflon binder for cathode construction. Cathodes were prepared by pressing the TiS_2-Teflon mixture into 6.5 cm^2 tantalum Distex® screens which had ~8 cm long tabs for electrical connection. Anodes were prepared by pressing 6.5 cm^2 sections of 20 mil lithium foil (Foote) onto carbon fiber supports or tantalum Distex® screens. Cells consisted of a cathode sandwiched between two lithium electrodes; polypropylene mat and microporous polypropylene separators were placed between the electrodes. The cells were inserted into polypropylene bags and electrode alignment was maintained by means of small clamps. About 5 ml of electrolyte was added to the bag and the cell assembly was mounted upright in a glass test vessel which had a ground glass joint (for sealing) and glass sealed metal through-puts (for electrical connection to the cell electrodes). Cell test-

ing was accomplished using Propel automatic battery cycling equipment. Unless otherwise specified, cycling was done at constant current to preset voltage cutoff limits.

NMR spectra were recorded on a Varian A-60 spectrometer and chemical shifts are reported in parts per million (ppm) *vs.* tetramethylsilane (TMS) reference (internal or external as indicated). Specific resistivities were measured in a Vacuum Atmospheres N_2 drybox at room temperature with a Barnstead Model PM-70CB Bridge (1000 Hz a.c.) and a Yellow Springs Instrument Company dip cell (cell constant 1/cm).

The gas containment jar (14) used to study $LiB(CH_3)_4$ decomposition consisted of a large tube (~1.5 in. diam × ~6 in. long) with a 45/50 standard taper male joint at the upper end (*cf.* Fig. 7). At the bottom, a U-tube (~8 mm OD) was attached which had sufficient length so as to allow about one-half of the volume of the large tube to be filled with mercury before equal heads of mercury inside and outside of the large tube were achieved. Above the level of the mercury inside the large tube, indentations which protruded into the tube provided support for a small (~20 ml) cup used to contain the sample. Samples in specific experiments were $DME \cdot LiB(CH_3)_4$-dioxolane solutions alone or in contact with one of four substrates: TiS_2, $LiTiS_2$, Li, and a Li-TiS_2 cell. After loading the sample, the upper portion of the jar was closed by means of a cap made with a 45/50 standard taper female joint. During closing, in a helium dry box, mercury was displaced so as to maintain the sample at 1 atm. The jar and its contents generally equilibrated rapidly to the 28°C test temperature with additional mercury displacement. Once thermally equilibrated, production of volatile products could be followed by weighing the mercury which had been displaced out the top of the U-tube. Mercury displaced was usually monitored as a function of time.

To sample the gas generated and trapped in the upper portion of the jar, a short length of polyethylene tubing (~1.5 mm OD) was inserted down the U-tube and finally up into the gas space above mercury level. The flow of gas through the tube was controlled by connecting the accessible end of the polyethylene tube to a Hamilton miniature metering valve which was in turn attached to a syringe needle which penetrated the rubber septum of an evacuated, 50 ml side arm flask. As the gas sample was withdrawn the mercury level in the U-tube dropped and additional mercury was added to the U-tube by means of a hypodermic syringe. Once transferred, gases contained in the 50 ml storage flask were sampled through a Fischer-Porter valve into a CEC-103 mass spectrometer for qualitative and quantitative analysis.

Results

In agreement with the literature (12), solid samples of lithium tetramethylborate did not show visual evidence for reactivity with dry air. On the other hand, solvent free samples of $LiB(C_4H_9)_4$ prepared for comparison with lithium tetramethylborate were found to be pyrophoric under similar conditions of exposure (13).

Dioxolane solutions of lithium tetramethylborate were characterized by proton NMR which showed the methyl proton resonance as a quartet ($J_{BH} = 3.7$ Hz) centered 0.7 ppm upfield of external tetramethylsilane reference (Fig. 1, curve A). No changes in the position, appearance, or relative intensities of the anion or the solvent proton resonances were evident in samples that had been sealed and stored for up to 14 months. Neither were any new proton resonances observed in these samples (Fig. 1, curve B). Dissolution of approximately equal molar amounts of $LiB(CH_3)_4$ and methyl-lithium in excess dioxolane produced an exothermic reaction with vigorous CH_4 evolution. Subsequent NMR analysis of the resulting cloudy solution

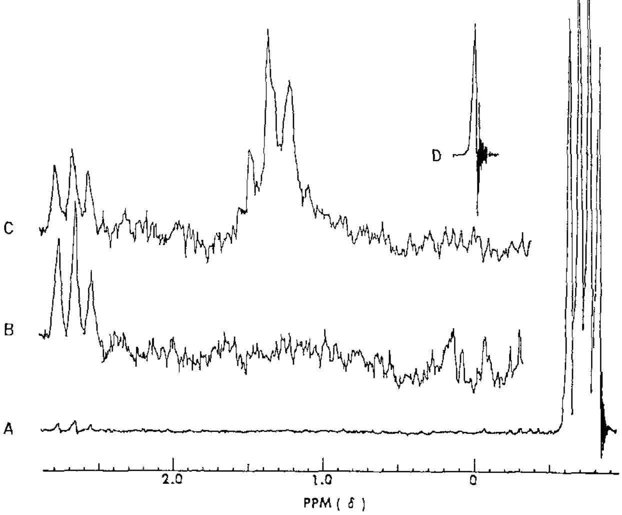

Fig. 1. ^1H NMR spectra in dioxolane: curve a, methyl quartet for $LiB(CH_3)_4$; curve b, high gain scan of 14 month old $LiB(CH_3)_4$ sample; curve c, high gain scan of CH_3Li-$LiB(CH_3)_4$ mixture; curve d, external TMS reference.

revealed a complex pattern of new proton resonances between 1.1 and 1.6 ppm (Fig. 1, curve C). The chemical shift positions of the dioxolane protons were sensitive to the concentration of dissolved tetramethylborate. Figure 2 demonstrates that the dioxolane proton resonances are shifted downfield as the concentration of $LiB(CH_3)_4$ increases.

The solubilities of $LiB(CH_3)_4$ and $LiB(C_4H_9)_4$ in dioxolane are approximately 3m. Resistivity measurements made on dioxolane solutions of these salts reveal that the specific resistance is a function both of the particular anion as well as the concentration of solute (*cf.* Fig. 3). At comparable concentrations, solutions of $LiB(CH_3)_4$ exhibit a lower specific resistance than $LiB(C_4H_9)_4$. The increase in specific resistance which is evident at higher solute concentrations is more pronounced in the case of lithium tetrabutylborate.

A dioxolane solution approximately 2.5m in $LiB(CH_3)_4$ concentration was employed as the electrolyte in an Li-TiS_2 cell which was discharged at 2.5

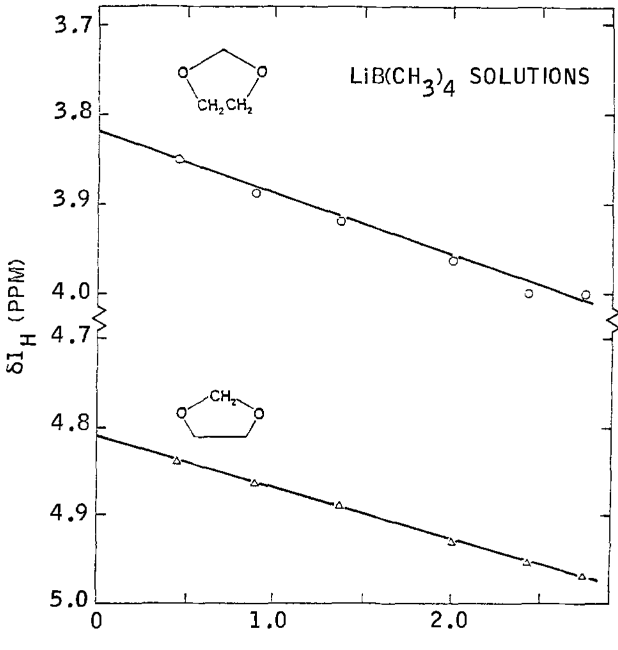

Fig. 2. Effect of $LiB(CH_3)_4$ concentration on dioxolane proton chemical shifts.

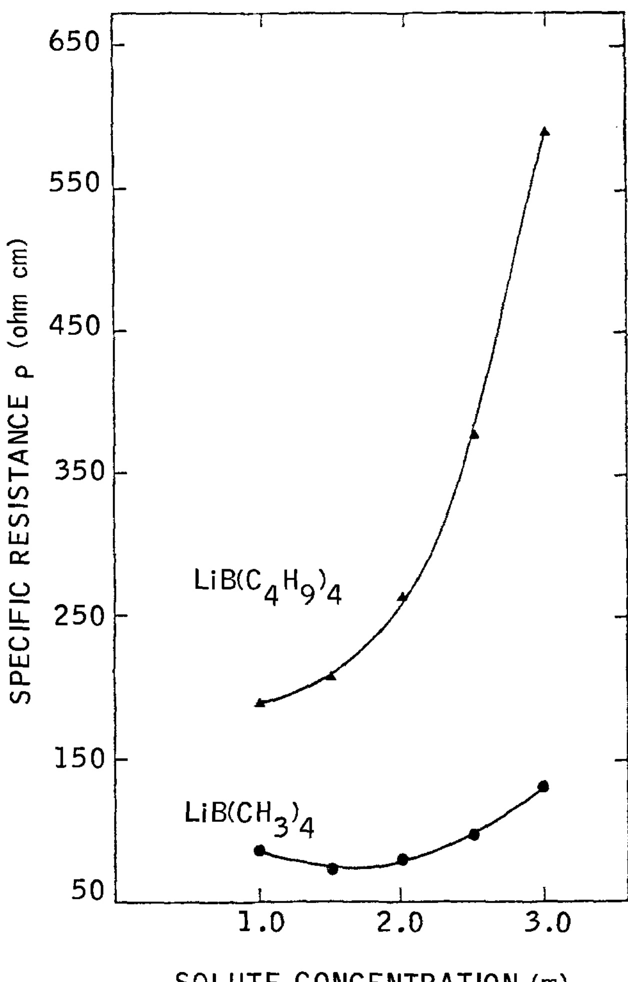

Fig. 3. Specific resistance of LiBR$_4$ salts in dioxolane

mA/cm^2. At 105 sec intervals a 15 sec 10 mA/cm^2 pulse was drawn. The curves in Fig. 4 record the dynamic cell emf (in volts) observed during this mode of discharge. Nearly 90% of the theoretical TiS$_2$ capacity was actually realized before the cell cutoff voltage was reached. The long term cycling results obtained with another Li-TiS$_2$ cell containing ~1.5m LiB(CH$_3$)$_4$-dioxolane electrolyte are given in Fig. 5. The figure shows the percentage of the theoretical cathode capacity (which was available for discharge on each cycle at 5.0 mA/cm^2) plotted as a function of cycle number. Following each discharge this cell was charged at 1.25 mA/cm^2. After the initial rapid loss in TiS$_2$ utilization which occurred in the first nine discharge/charge cycles, the discharge capacity decreased in an essentially linear manner at less than 0.3% per

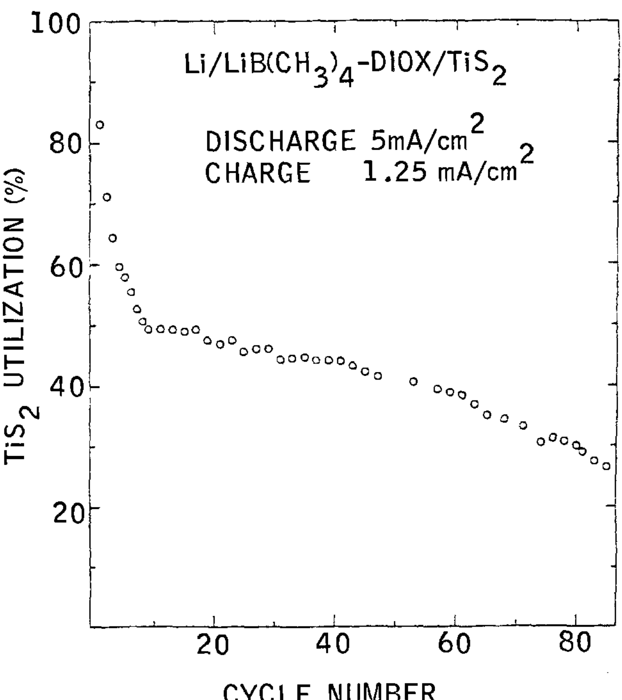

Fig. 5. Charge-discharge cycling of Li-TiS$_2$ cell in LiB(CH$_3$)$_4$-dioxolane electrolyte.

cycle. Cycling was terminated after 85 cycles at which point 4 A-hr of discharge capacity had been accumulated with the 105 mA-hr TiS$_2$ cathode and the ~600 mA-hr lithium anode. Another cell was assembled and its open-circuit voltage (OCV) was monitored as a function of time. As shown in Fig. 6, the OCV of this cell, after an initial fairly rapid decrease, asymptotically approached an equilibrium value of about 1.98V.

Dioxolane solutions of LiB(CH$_3$)$_4$ or DME·LiB(CH$_3$)$_4$ undergo slow decomposition in the presence of various substrates. Application of the apparatus (14) shown in Fig. 7 allowed investigation of the LiB(CH$_3$)$_4$ decomposition reaction which was responsible for the decrease in cell OCV. The major hydrocarbon products from LiB(CH$_3$)$_4$ decomposition were gases, specifically, trimethylboron, methane, ethane, and ethylene in the approximate proportions shown in Table I. Extensive LiB(CH$_3$)$_4$ decomposition occurred only in the presence of titanium disulfide and concomitantly produced partially lithiated TiS$_2$. As is shown in the table a very small amount of CH$_4$ was generated when a solution of LiB(CH$_3$)$_4$ was contacted with

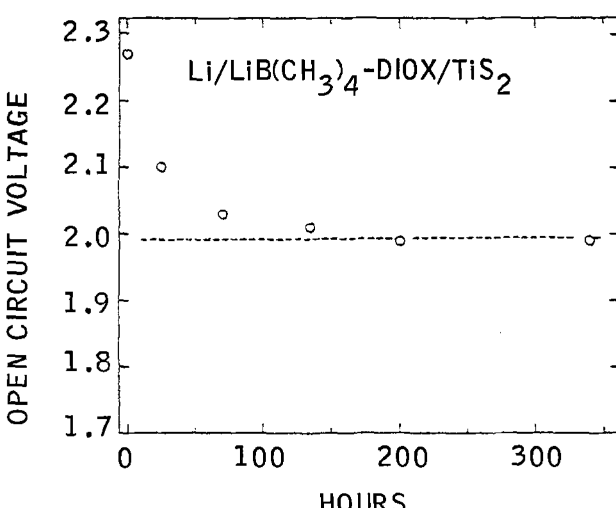

Fig. 6. Open-circuit voltage of Li-TiS$_2$ cell

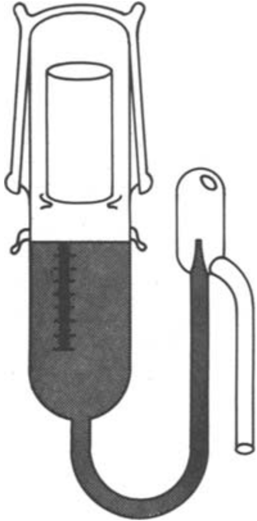

Fig. 7. Gas containment jar

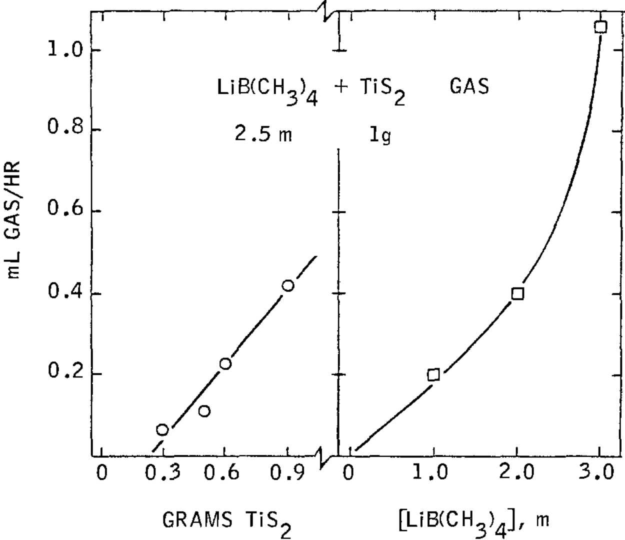

Fig. 8. Effect of TiS_2 weight and $LiB(CH_3)_4$ concentration on apparent rate of gas generation.

$LiTiS_2$. In contact with TiS_2 which was formulated as the cathode of an Li-TiS_2 cell, the $LiB(CH_3)_4$ solution gave rise to ethylene along with a different distribution of $B(CH_3)_3$, CH_4, and C_2H_6 compared with the case of powdered TiS_2. In the presence of a metallic lithium substrate alone, CH_4 and ethylene were observed. As shown in Fig. 8 the apparent rate of production of volatile hydrocarbon products from the reaction between $LiB(CH_3)_4$ and TiS_2 is a function of the weight of TiS_2 substrate (at constant concentration of tetramethylborate), and $LiB(CH_3)_4$ concentration (at a fixed weight of TiS_2).

Discussion

From the results of single crystal x-ray crystallographic investigations of $LiB(CH_3)_4$ (10) and $LiClO_4$ (11), the similarities in anion symmetry and steric size for these two lithium salts are clearly recognizable. Our interest in investigating the possible existence of less obvious parallels in the solution properties of these salts prompted a detailed examination of $LiB(CH_3)_4$, in dioxolane.

Since dioxolane, a cyclic five-membered ring containing an acetal functional group, polymerizes in the presence of Lewis acids (15), the question whether dissociation of the $B(CH_3)_4^-$ anion occurs and can thereby generate solvent incompatible reagents was raised. Proton NMR was used to periodically monitor dioxolane solutions of $LiB(CH_3)_4$ (external TMS) which had been stored at room temperature for up to 14 months. No change was apparent in the chemical shift (−0.7 ppm) or the intensity of the anion —CH_3 resonance (Fig. 1, curve A), or in the dioxolane resonances (not shown). A significant observation was the fact that no new proton resonances appeared between 0-2 ppm during the extended period of time over which the sample was monitored even when this region was scanned at an approximately 20-fold gain in signal intensity (Fig. 2, curve B; the apparent triplet at ~2.6 ppm is a ^{13}C satellite of the higher field dioxolane resonance). The importance of this negative finding became evident when the NMR spectrum of a mixture of $LiB(CH_3)_4$ and methyllithium in dioxolane was obtained. This mixture had given rise to an exothermic reaction and CH_4 evolution. The high gain NMR spectrum of the resulting solution contained new peaks between 1.1-1.6 ppm (Fig. 1, curve C). While we have not characterized the material responsible for this complex resonance pattern, we believe it to be the soluble product(s) from a reaction between CH_3Li and dioxolane. This proton resonance between 1.1-1.6 ppm serves then as a fingerprint for dioxolane solutions which have been in contact with methyllithium. From the absence of this fingerprint in the aged dioxolane solution of $LiB(CH_3)_4$ we infer that the $B(CH_3)_4^-$ anion does not spontaneously dissociate to $B(CH_3)_3$ and CH_3Li in dioxolane. Reported chemical evidence for the integrity of the tetramethylborate anion in ether (16) is consistent with this conclusion.

Relative to internal TMS reference, the proton chemical shift of the $B(CH_3)_4^-$ anion remained invariant in dioxolane over an $LiB(CH_3)_4$ concentration range of ~0.47-2.75m. This was not the case for the singlet resonances of the dioxolane protons. The data presented in Fig. 2 shows that dioxolane proton resonances are shifted progressively downfield as the concentration of $LiB(CH_3)_4$ increases. Similar downfield shifts for the alpha-CH_2 protons in tetrahydrofuran (THF) solutions of $LiClO_4$ have been reported (17, 18) and have been attributed to a polarizing effect of the Li^+ cation on the C—H bonds adjacent to oxygen in the donor solvent.

The high solubility of $LiB(CH_3)_4$ in dioxolane enabled a-c resistivity measurements to be made on solutions over a wide range of solute concentrations. The results, presented in Fig. 3, reveal a resistivity minimum around 1.7m for $LiB(CH_3)_4$ in dioxolane. The resistivity value (~75 Ω cm) at the minimum is actually less than was found for an equivalent concentration of $LiClO_4$ in dioxolane. As the concentration of $LiB(CH_3)_4$ in dioxolane increases above 1.7m, the solution resistivity rises. As shown in Fig. 3, this increase in resistivity is much more pronounced in dioxolane solutions of $LiB(C_4H_9)_4$ at high concentrations. It is obvious that the solution resistivity is a function of the relative size of the tetraalkylborate anion; however, a more detailed interpretation of these apparent differences must be deferred until more is known about fundamental solution properties such as ion-pair association and quadrupole formation, etc.

Table I. Decomposition studies on dioxolane solutions of DME · $LiB(CH_3)_4$

Substrate	Normalized volume percent*				Σ
	$B(CH_3)_3$	CH_4	C_2H_6	C_2H_4	
TiS_2	38	13	20	—	71
$LiTiS_2$	—	5	—	—	5
Li-TiS_2 cell	1	4	27	9	41
Li	—	1	—	1	2

* Normalized v/o = [v/o product gas]/[v/o helium] (×100).

The parallels in electrolyte properties for dioxolane solutions of $LiClO_4$ and $LiB(CH_3)_4$ again became apparent when the latter solute was investigated in $Li-TiS_2$ cells. Using a dioxolane solution containing approximately 2.5m $LiB(CH_3)_4$ in a limited electrolyte configuration $Li-TiS_2$ cell, a pulsed discharge was performed to evaluate the high rate current carrying capability of the electrolyte. The pulsed discharge consisted of a base 2.5 mA/cm^2 current that was interrupted at 105 sec intervals by the imposition of a 15 sec, 10 mA/cm^2 current pulse. The base load-pulse sequence was repeated until the predetermined cell cutoff voltage was reached. The results (Fig. 4) show that nearly 90% of the theoretical TiS_2 capacity was available using this pulsed discharge technique. The solid curve tracks the total cell voltage during the 2.5 mA/cm^2 base load, while the broken curve records the cell voltage during the 10 mA/cm^2 pulse. Cell resistance losses during the pulse account for the ~200 mV drop in total cell voltage (difference between the solid and broken curves in Fig. 4). This magnitude of increased cell polarization during periods of high current drain, and the overall cell performance closely parallel the results reported for $Li-TiS_2$ cells containing $LiClO_4$-dioxolane (3, 4).

Also analogous to results reported (4) for $Li-TiS_2$ cells containing $LiClO_4$ electrolyte is our finding that repetitive charge-discharge cycling of $Li-TiS_2$ cells can be achieved in $LiB(CH_3)_4$-dioxolane. The results of one such experiment are presented in Fig. 5. As can be seen in Fig. 5, after the ninth discharge, the percentage of the theoretical amount of TiS_2 available for discharge at 5 mA/cm^2 (following each recharge at 1.25 mA/cm^2) showed a nominal incremental decrease of about 0.3% per cycle. Over 85 complete cycles, 4 A-hr of discharge capacity had been realized from a cell constructed with a 105 mA-hr TiS_2 cathode and an anode which contained ~600 mA-hr of lithium. After termination of cycling, a visual examination of the anode revealed the presence of metallic lithium beneath a layer of porous material. This observation strongly suggests that considerably less than 600 mA-hr of Li was actually involved in the successive plating-stripping cycles.

Monitoring of the open-circuit voltage (OCV) of a freshly prepared $Li-TiS_2$ cell containing $LiB(CH_3)_4$-dioxolane revealed that this parameter changed with time. Specifically, as is shown in Fig. 6, the OCV dropped over 200 hr reaching an equilibrium value of ~1.98V. That this drop in OCV was the result of spontaneous discharge was confirmed by the identification of partially lithiated TiS_2 in the final cathode material. Using published voltage-composition data (19) and our equilibrium OCV value, the final stoichiometry of $Li_{0.8}TiS_2$ is indicated for the spontaneous redox reaction.

The agent responsible for the partial reduction of the titanium disulfide is the $B(CH_3)_4^-$ anion whose corresponding oxidation products were gases. The $TiS_2 + LiB(CH_3)_4$ reaction was investigated in detail using the apparatus pictured in Fig. 7. The rate of production of hydrocarbon products was monitored by following the weight of mercury displaced from this apparatus as a function of time, and these results are given in Fig. 8. These experiments demonstrated that the apparent rate of the decomposition reaction is a function of the $LiB(CH_3)_4$ concentration as well as weight of TiS_2 substrate used. The presence or absence of a stoichiometric amount of DME relative to $LiB(CH_3)_4$ did not affect either the apparent rate of decomposition or the distribution of volatile products.

The gaseous decomposition products collected from the gas generation apparatus were characterized and analyzed quantitatively by mass spectrometry. The data, obtained for a powdered TiS_2 substrate as well as for samples of $LiTiS_2$, Li metal, and an $Li-TiS_2$ cell, are summarized in Table I.

In Table I the normalized volume percent (v/o) for each component was derived by dividing the observed v/o by the v/o He background. Extensive decomposition occurs when $LiB(CH_3)_4$-dioxolane contacts TiS_2, whereas with fully lithiated TiS_2, decomposition is virtually negligible. When $LiB(CH_3)_4$ reacts with TiS_2 alone three volatile products, $(CH_3)_3B$, methane, and ethane, are formed; the relative amounts of these three products change when the layered dichalogenide is configured as the cathode of an $Li-TiS_2$ cell and in this case ethylene is also observed. The decrease in $(CH_3)_3B$ seen in the $Li-TiS_2$ cell experiment is particularly dramatic compared with the experiment with TiS_2 alone. While it is tempting to invoke a redistribution reaction between $(CH_3)_3B$ and Li to give $LiB(CH_3)_4$ and a boron residue as an explanation for this finding we have no independent evidence to support such a reaction pathway. In the control experiment with a metallic lithium substrate alone, the $LiB(CH_3)_4$-dioxolane solution produced traces of methane and ethylene.

Observation of C_2 hydrocarbon products, particularly ethane ((CH_3CH_3), from a reaction between TiS_2 and $LiB(CH_3)$ suggests a mechanistic pathway whereby methyl fragments, probably $\cdot CH_3$ radicals, dimerize. That such dimerization is a fate of short-lived hydrocarbon radicals generated under such conditions was postulated by Dines (20) who studied $n-C_8H_{18}$ formation from the reaction between TiS_2 and $CH_3CH_2CH_2CH_2^-Li^+$. Since we find no evidence for $B(CH_3)_4^-$ dissociation in dioxolane (*loc. cit.*) to give trimethylboron and CH_3^- Li^+, we prefer to picture $\cdot CH_3$ radicals arising from $B(CH_3)_4^-$ oxidation at a TiS_2 surface with simultaneous intercalation of Li^+ ion into the layered compound. Once generated, the methyl radicals either dimerize or abstract $\cdot H$ from solvent to give CH_3CH_3 or CH_4, respectively.

Conclusions

Dioxolane solutions of $LiB(CH_3)_4$ appear to be stable indefinitely at room temperature. These solutions are highly conductive and show utility as electrolytes in ambient temperature, rechargeable, lithium battery systems wherein a high rate of current drain is a desirable feature. However the oxidation potential of the $B(CH_3)_4^-$ anion renders it reactive toward TiS_2 and long duration contact with this layered compound produces $(CH_3)_3B$, CH_4, and CH_3CH_3. Due to this reactivity, $LiB(CH_3)_4$ is not ideally suited for long term use as an electrolyte in $Li-TiS_2$ cells. Nevertheless, the feasibility of its successful application in cells with potentials below about 2.0V is certainly not precluded.

ABSTRACT

The iron-redox battery is a low power density energy storage device that may be attractive for applications such as load leveling and solar energy storage. During the charge cycle of this battery, the ferrous ion from an aqueous chloride electrolyte plates onto the negative electrode and is oxidized to ferric ion at the positive electrode. A solid graphite or titanium plate can be used for the iron electrode while a high specific area material is necessary for the redox electrode. A 100 cm^2 single cell with a microporous plastic separator has been cycled at a current density of 60 mA/cm^2 at 60°C. The cell was capable of storing and discharging energy at a round trip current efficiency of 90% and an energy efficiency of 50%, with a maximum discharge power density of 50 mW/cm^2. The largest voltage losses occurred at the iron electrode and to a lesser extent at the redox electrode. Factors affecting voltaic and coulombic losses including electrolyte composition and temperature, cell separators, electrode materials, and electrolyte additives have been studied and the results reported.

Several electrochemical energy storage batteries are under development for bulk energy storage (1, 2). These batteries are often characterized by their low power density, but are attractive as stationary storage devices for load leveling and solar applications because of their potentially low cost. One such battery which has undergone rapid development over the past several years is the redox battery (3-6). In the redox battery, both the products and reactants of electrolysis are soluble salts. In order to prevent chemical shorting and irreversible loss of reactants, a highly efficient anion permeable membrane separator must be employed. An alternative method of preventing the irreversible loss of reactants is through utilization of a reactant couple which involves three different valence states of a single metallic element. One such device is the iron-redox battery ($Fe^0/Fe^{+2}/Fe^{+3}$), which is the subject of this paper.

The half-cell reactions for the iron-redox battery can be expressed as follows:

Charge

$$Fe^{+2} + 2e^- \rightarrow Fe^0 \quad \text{Negative electrode}$$

$$2Fe^{+2} \rightarrow 2Fe^{+3} + 2e \quad \text{Positive electrode}$$

Discharge

$$Fe^0 \rightarrow Fe^{+2} + 2e \quad \text{Negative electrode}$$

$$2Fe^{+3} + 2e^- \rightarrow 2Fe^{+2} \quad \text{Positive electrode}$$

Electrochemically, this battery can be viewed as a hybrid of more common battery types. The negative or iron electrode utilizes plating and dissolution of iron as a solid plate, similar to Zn/Cl_2 or Fe/Ni batteries. The positive electrode, however, uses a carbon structure to oxidize and reduce iron cations which remain in solution. Ideally, upon complete discharge, the battery would be brought to its initial state with ferrous ion as the only active cation in the system. Other advantages of the iron-redox battery include: low temperature aqueous electrolytes with inexpensive reactants that are readily available in large quantities; the use of inexpensive materials of construction; the use of electrodes which are not subject to shape change or dendrites; the distinction of being the least hazardous of any advanced battery system.

A disadvantage with the iron-redox battery is its inherently low cell voltage (1.21V as compared to 2.12V for Zn/Cl_2 and 1.98V for Pb/acid) which tends to limit the power density and efficiency of the battery. The actual operational characteristics of the battery must be measured experimentally. Develop-

mental work on an iron-redox battery has been reported previously (7, 8), but data on factors controlling energy efficiency and on cell operation are limited.

The results obtained in this experimental study indicate the energy levels that can be obtained from the iron-redox battery and identify factors which limit its performance.

Experimental

The studies reported herein were primarily experimental. Separators and electrode materials were commercial, readily available items. The salts were all of reagent grade and deionized water was used for electrolyte makeup.

The electrolyte resistivity measurements were taken with a standard H-type conductivity cell with platinized platinum electrodes (cell constant of 0.1). The cell was immersed in a temperature bath and the resistance was measured with a Beckman Instruments a-c bridge operating at a frequency of 1000 Hz.

Daily cycle tests were performed in a 100 cm^2 rectangular acrylic laboratory cell. Each half-cell was equipped with electrolyte inlet and outlet manifolds and viton O-rings were used for sealing. Chlorided silver wires were employed as reference electrodes. The electrolyte circuit is depicted schematically in Fig. 1. All components of the test system were made of polypropylene, PVC, or glass.

Results and Discussion

Electrolyte properties.—The primary ionic reactants of the iron-redox battery are the ferric and ferrous ions. Since these reactants are soluble in aqueous solution their salts serve as the battery electrolyte. In order to operate a cell at high voltaic efficiency the electrolyte resistivity must be maintained as low as possible. For this reason we chose the chloride salts of iron as our solute (the chloride salts will also have greater charge carrying capacity per gram of salt as compared to other salts such as sulfates or nitrates). An examination of solution conductivity data is useful for identifying a promising concentration range for cell operation. Measured resistivity data for both ferric and ferrous chloride solutions at 18°C are given as a function of concentration in Fig. 2. The data agree with published data (9). The useful concentration range can be established from these data as *ca.* 100-500 gpl of iron chloride. At lower concentrations the charge carrying density becomes too low and concentration polarizations become too high. At high concentrations the forces related to interionic attraction predominate and ionic mobility decreases. By knowing the workable concentration range, the minimum volume of electrolyte for a given coulombic capacity of the battery can be estimated.

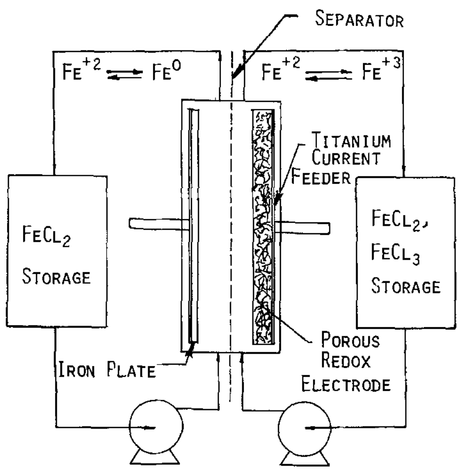

Fig. 1. Schematic of iron-redox laboratory cell and electrolyte circuit.

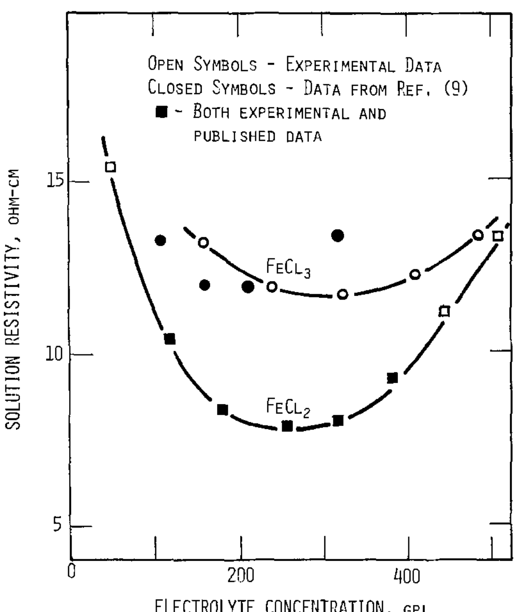

Fig. 2. Measured and published resistivity data of iron chloride aqueous solutions at 18°C.

For example, considering an initial concentration of both catholyte and anolyte to be 500 gpl ferrous chloride and after full charge there is 50 gpl ferrous chloride remaining in the anolyte, the charge density of the battery is 63.5 A-hr/liter.

As will be shown later, *p*H control is essential in order to maintain a high faradaic efficiency and good plating morphology. Since parasitic reactions in this battery do result in an alteration of the electrolyte pH, it is quite important to use an electrolyte having a *p*H response that is moderate and not abrupt when the concentration is perturbed. We have found the ferrous chloride electrolyte to be well behaved as demonstrated by the data reported in Fig. 3.

In order to reduce voltaic losses, an indifferent but conductive solute can be added to the electrolyte. The resistivities of a 250 gpl ferrous chloride electrolyte with additions of several indifferent solutes are shown in Fig. 4. The top curve is for the addition of calcium chloride. Although this additive is common in iron plating baths, it has no advantage as a conductivity

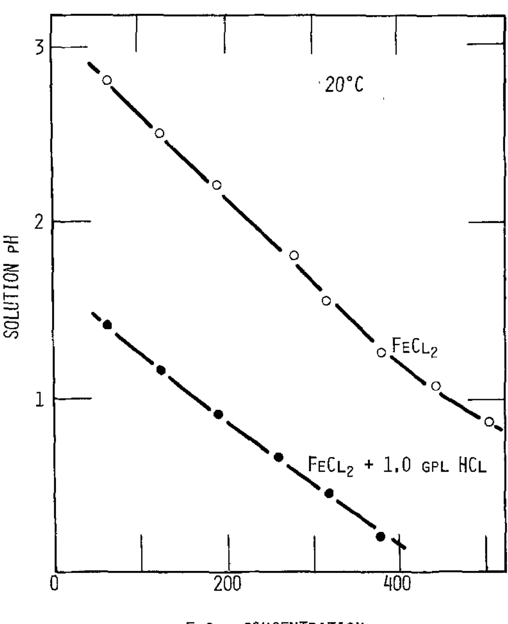

Fig. 3. Measured *p*H of ferrous chloride solutions at 20°C

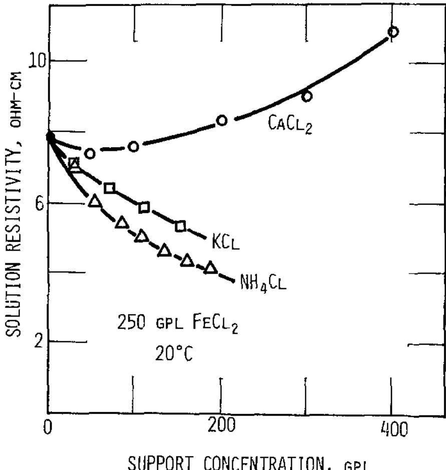

Fig. 4. Measured effect of supporting electrolyte on the resistivity of a 250 gpl ferrous chloride aqueous solution at 20°C.

support. The addition of sodium or potassium chloride, however, lowers the resistivity significantly. One difficulty found with using a sodium or potassium chloride additive was the poor quality and nonadherence of the iron plate deposited from electrolytes having these salt additives.

The most effective conductivity support tested was ammonium chloride. The addition of 3.5 moles of ammonium chloride to a liter containing 2.0 moles ferrous chloride (nearly saturated solution) will reduce the electrolyte's resistivity from 7.8 to 4.0 Ω-cm at 20°C. Further testing has shown that good quality iron plates can be obtained in the presence of ammonium chloride additives. In fact, the iron deposit had very little tendency to dendrite, powder, crater, peel-off, or exhibit the other problems that are generally associated with many of the metallic plates used for battery applications. A further reduction in resistivity of the ferrous-ammonium chloride solution can be achieved at elevated temperatures. This effect is shown in Fig. 5. The resistivity of 4 Ω-cm at 20°C can be reduced to 2 Ω-cm at 77°C. For a cell with a 2 mm gap operating at a current density of 60 mA/cm², this represents an overall voltaic loss of 4% (as compared to 16% at 20°C with no addition of indifferent electrolyte). The ferrous chloride/ammonium chloride electrolyte was chosen for further battery studies.

Cell separators.—At the fully discharged state iron is not in metallic form and the ferrous concentration is at its maximum (perhaps 500 gpl $FeCl_2$ and 50 gpl $FeCl_3$). During charge, ferrous ion is oxidized at the anode to produce the ferric ion. Simultaneously, at the cathode the ferrous ion is reduced to metallic iron. The ferric ion produced at the anode is then capable of reacting directly with the iron plate according to the chemical reaction

$$Fe^0 + 2Fe^{+3} \rightarrow 3Fe^{+2}$$

This reaction is limited by mass transport of the ferric ion to the electrode surface and can be a primary source of coulombic efficiency loss (other losses are discussed in later sections). The current efficiency (based on iron plate) when discharging an unseparated cell was found to be about 60%. This corresponds to the level of efficiency loss that would be expected from mass transfer control of the above reaction (see Table I).

In order to reduce the coulombic efficiency loss caused by the oxidation of the iron plate, microporous materials were evaluated as cell separators. Ferric ion diffusion data and membrane resistivity data are presented in Fig. 6 and 7 for two commercial materials. Using these data, calculations were made on the expected performance of these separators in cell operation. The Celgard® separator (Celanese Corporation)

I_c = charge current; I_D = discharge current.
i_{corr} = calculated diffusion controlled corrosion current.

offers some improvement in coulombic efficiency. On the other hand, the Daramic® separator (W. R. Grace Corporation) should limit the ferric ion diffusional loss to about 3% for both charge and discharge modes of operation. Daily operation of laboratory size (100 cm²) redox cells with the Daramic separators gave coulombic efficiencies of 93%-96% during charge and 90% during discharge. The chemical resistances of both Celgard and Daramic separators in iron electrolytes were excellent at pH = 0.

Studies on electrode polarizations (which are reported later in this paper) indicate the optimum catholyte (on charge) to have a pH of 3-4 while the anolyte must be kept at or below a pH of approximately 1.0 to maintain stability of the ferric ion. In order to maintain a pH difference of this magnitude across the cell, a highly efficient anion permeable membrane must be used as the separator. Two commercial membranes were evaluated in this study: Neosepta ACH-45T (Tokuyama Soda Company, Limited) and Selemion® DMV (Asahi Glass Company Limited). Both of these membranes had an initial resistivity of approximately 7 Ω-cm² in a ferric-ferrous chloride solution (420 mV loss at 60 mA/cm²). Upon evaluation in laboratory cells, the membranes discolored giving evidence of deterioration and the resistivity of the membrane increased significantly. The increased resistivity is attributed to $FeCl_4^-$ fouling and is not an uncommon phenomena among anion membranes (2, 3, 10). In spite of the poor voltaic performance of the membrane, the overall coulombic efficiency was found to be exceptionally good (CE ~ 96%).

Characteristics of the iron electrode.—Electrode polarization.—During cell charging the ferrous ion is reduced at the iron electrode

$$Fe^{+2} + e^- \rightarrow Fe^0$$

The plating reaction is carried out on a nonreactive substrate. In this way complete discharges eliminate shape change of iron plate, limited cycle life, etc. Both titanium and graphite are suitable substrates and have been utilized in laboratory cell studies. Although both of these materials are resistant to corrosion and good iron plate morphology has been obtained on both of them, they do suffer from degradation if polarized anodically to a great extent (as during overdischarge). Graphite will anodically corrode excessively at higher pH's (pH 3-4) (11) while bare titanium will dissolve anodically at sufficiently positive potentials. A titanium substrate used in our laboratory cell had experienced massive pitting during an overdischarge. One of the positive aspects of utilizing graphite as a substrate is the low cost. On the other hand, titanium is more conductive and is weldable (for bus bar connections), thus capable of higher loads for a given level of substrate/bus bar voltage loss.

The polarization curves (steady state) of the iron electrode in 250 gpl $FeCl_2$/150 gpl NH_4Cl are given in Fig. 8. Although the data reported are for a titanium substrate, similar data were obtained for the Fe^{+2}/Fe^0 reaction on a graphite substrate. With a nominal current density of 60 mA/cm², at 90°C and pH = 1, the cathodic and anodic polarizations are 95 and 135 mV, respectively. This represents a voltaic efficiency for the iron electrode of 70%. The iron electrode polarization can be decreased by adjusting the electrolyte pH to higher values. For example, at the same conditions as above but with a pH = 3, the voltaic efficiency would be 83%. The pH dependence of the electrode polarization is in agreement with the following reaction mechanism as put forth in the literature (12)

$$Fe^{+2} + H_2O \leftrightharpoons FeOH^+ + H^+$$

$$FeOH^+ + e^- \rightarrow FeOH \text{ (rds)}$$

$$FeOH + H^+ + e^- \leftrightharpoons Fe^0 + H_2O$$

Finally, as would be expected, the electrode polarization was found to be temperature sensitive (see Fig. 8). For example, reducing the electrolyte temperature from 70° to 60°C will decrease the voltaic efficiency to 75% (at 60 mA/cm², pH = 3.7).

Plating current efficiency.—The coulombic efficiency of the iron-redox battery is controlled by reactions at the iron plate (the ferric/ferrous redox reaction is nearly 100% efficient). One source of efficiency loss is the reaction of ferric ion with the iron plate

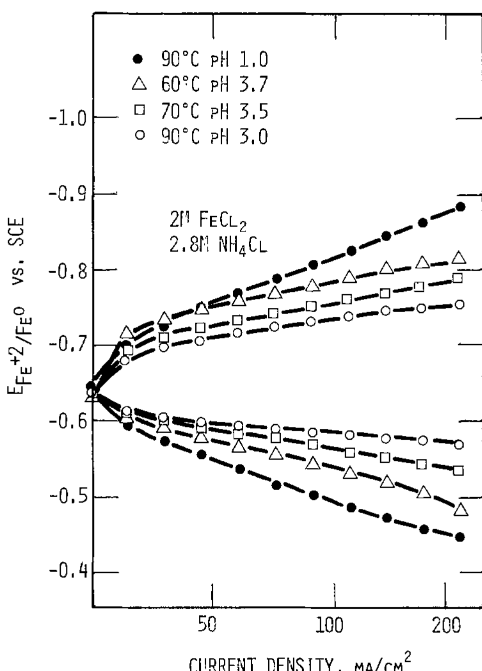

Fig. 8. Measured polarization of an iron electrode on a titanium substrate.

$$Fe^0 + 2Fe^{+3} \rightarrow 3Fe^{+2}$$

This reaction has been discussed earlier and can be minimized by the use of a suitable microporous separator.

A second source of coulombic efficiency loss can be represented by the following reaction

$$Fe^0 + 2HCl \rightarrow FeCl_2 + H_2$$

Chemical corrosion of this type results in hydrogen gassing which has been confirmed by analysis of gases above electrolyte storage bottles. A lowered coulombic efficiency has been measured even when the cell was at open circuit. It is therefore desirable to minimize the rate of this reaction. Studies in our laboratory have shown the above reaction to have a corrosion rate strongly dependent on electrolyte *p*H and on plate composition (*i.e.*, additives in the plate).

The *p*H effect on chemical corrosion is demonstrated by the results presented in Fig. 9. According to these results the desired electrolyte *p*H should be greater than *p*H 1-1.5. (Note: the higher *p*H electrolyte also contributes to more favorable polarizations of the iron electrode.) On the other hand, in order to prevent the formation of insoluble ferric oxides and hydroxides, the electrolyte must be kept below *p*H = 1.5. Since protons are highly mobile, the electrolyte *p*H must be similar on both sides of the cell. Consequently, chemical corrosion can be minimized by altering the composition and morphology of the iron plate (open-circuit corrosion can be avoided by draining the cell of electrolyte, a feature of the iron-redox battery system).

It is well known that small quantities of metal ions in the electrolyte will affect the properties of the iron plate. Tests have shown that some additives result in iron with a lower corrosion rate in acidified ferrous chloride solution. The measured corrosion rates of samples plated from solutions containing 0.01-10.0 gpl of several metal ion additives along with a standard base rate for pure electrolytic iron are presented in Fig. 10. Three of the metal ion additives reported (Zn, Mn, Cr) have electroplating potentials more

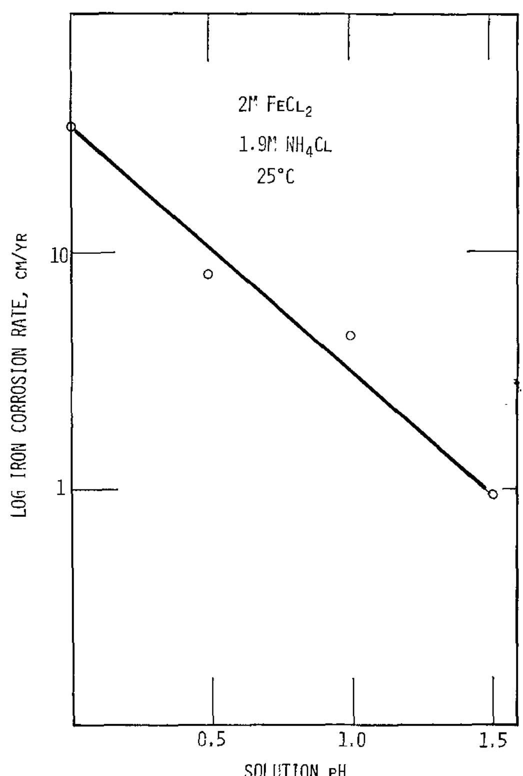

Fig. 9. Measured dependence of electrolytic iron corrosion rate on solution *p*H.

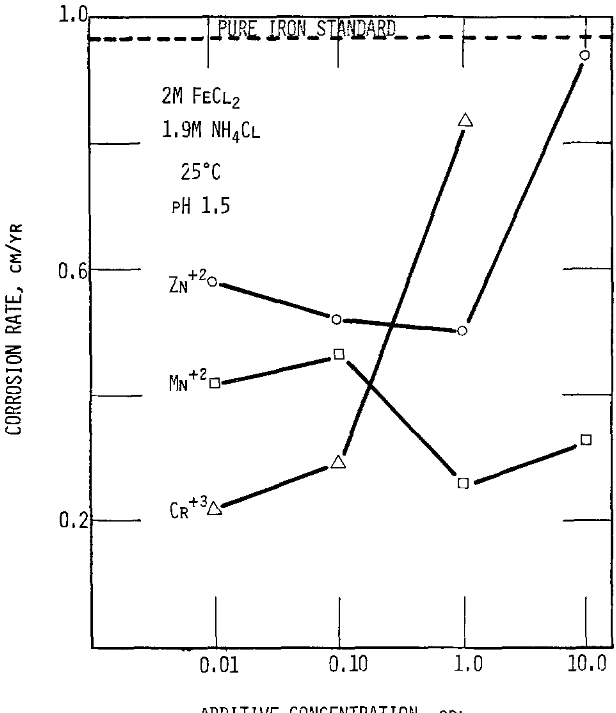

Fig. 10. Measured corrosion rate for iron samples plated from solutions containing metal ion additives.

cathodic than iron. When added to the plating bath, all were generally effective in reducing the corrosion rate as measured by weight loss. Four other metal ion additives tested, cobalt, nickel, cadmium, and lead, have plating potentials less cathodic than iron and were generally ineffective in reducing the chemical corrosion mechanism. One exception was a 1 gpl nickel ion addition which resulted in an iron dissolution rate 91% lower than the standard. However, this beneficial effect was not present at the lower concentrations, and chemical analysis of the plating solutions showed the nickel ion to be present at a much higher concentration in the plate than in the initial solution. This concentrating effect would remove the nickel ion from the electrolyte at the start of plating, leaving an ineffectively low concentration of nickel ion in the electrolyte. Consequently, nickel cannot be considered a good additive.

Characteristics of the redox electrode.—In a single cell, counter to the iron electrode is the ferrous/ferric redox electrode. The reaction at this electrode can be written as follows (during charge)

$$Fe^{+2} \rightarrow Fe^{+3} + e^-$$

This reaction has been selected previously for application in Fe/Ti and Fe/Cr redox batteries and its polarization has been shown to be small (13-15). One of these studies (15) used a rotating disk electrode of edge-on pyrolytic graphite and has shown the reaction mechanism in $FeCl_3$/3M HCl to be by simple electron transfer. Of course, in order to minimize unfavorable diffusional effects, a high surface area porous electrode must be used.

In Fig. 11, a comparison between smooth graphite and porous carbon electrodes is shown for the oxidation of ferrous ion in the $FeCl_2/NH_4Cl$ electrolyte. Although the single electrode potentials are not reported, the beneficial effect that the porous electrode has on the ferrous ion oxidation is demonstrated. This is especially true at lower temperatures and higher current densities.

A polarization curve of the ferrous-ferric reaction on porous carbon, during charge, is given in Fig. 12. Although not reported, the Fe^{+3} reduction curve is

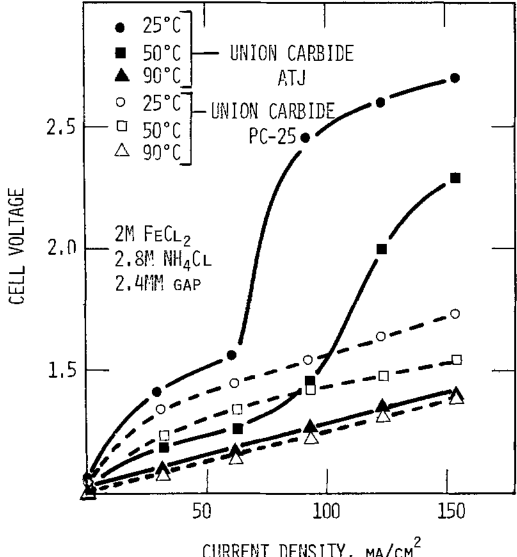

Fig. 11. Comparison of measured charge voltage between laboratory cells having a smooth graphite redox electrode (Union Carbide ATJ) and one having a porous carbon redox electrode (Union Carbide PC-25).

symmetrical when a clean electrode is used. Some other observations made during our studies may be worth mentioning at this time. For instance, the voltaic efficiency of the ferrous/ferric electrode was greatest on a fresh carbon surface. Oxides accumulating on the electrode surface quickly deteriorated the voltage performance of this electrode. These oxides precipitated when solution *p*H became greater than 1.5 and they have been identified as mixed oxides and hydroxides, noncrystalline, and primarily of ferric ion. The solution *p*H would increase because of proton discharge at the iron cathode during charge and because of air oxidation. The second factor was eliminated by sealing the electrolyte tanks and nitrogen blanketing. The activity of the electrode could be restored to its original state by applying an acid wash.

Unlike the graphite electrode for the zinc/chloride battery (16), the surface activity of the electrode in this system was not important and no activation procedures were required. Poor electrode performance was noted for the ferrous ion oxidation when Fe^{+2} concentration dropped below 50 gpl. A reticulated vitreous carbon showed acceptable activity although it had poor electronic conductivity. A ruthenized porous titanium electrode also showed good activity and has a very conductive substrate.

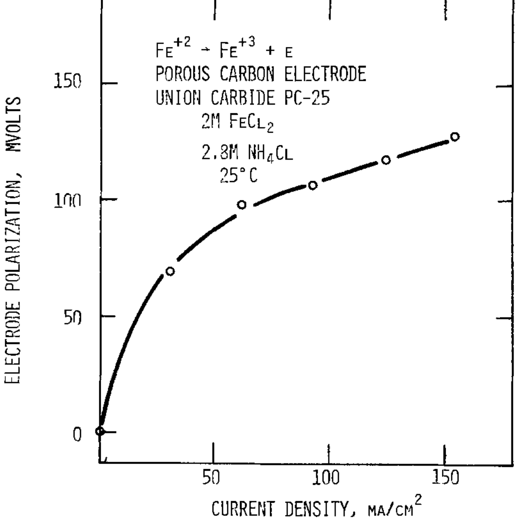

Fig. 12. Measured polarization of ferrous ion oxidation at a porous carbon electrode.

The coulombic efficiency of the ferrous/ferric couple was always measured to be near 100%; that is, no side reactions (O_2 or Cl_2 evolution during charge) were observed. The only coulombic loss was due to ferric ion migration through the separator. The high coulombic efficiency of the ferrous/ferric reaction coupled with the competing proton reaction at the iron electrode lead to an accumulation of ferric ion. This charge/discharge imbalance causes operational problems of a battery and is discussed in the next section.

Daily cycle performance.—In order to measure the actual current and energy efficiencies of an iron-redox cell, daily cycling operation is necessary. Cycle tests were performed in our laboratory with a 100 cm² cell and using a catholyte and anolyte volume of 2 liters each. Generally the cell was charged for 3 hr then discharged until a lower limit of zero volts was reached. Both the charging and the discharging were at constant current density of 60 mA/cm². During cell cycling, solution *p*H (*p*H = 1) and temperature (60°C) were held constant.

A graph showing the current and energy efficiencies for 57 cycles is shown in Fig. 13. It is obvious that cell performance is highly variable from one cycle to the next, not attributable to any intentional change in operating parameters. The major changes that were made during this period are given in Table II. The effects from many of these changes have already been discussed. Current efficiencies of 80%-90% could be routinely obtained but the best energy efficiency was around 50%. The low energy efficiency then, of course, was due to the poor voltaic efficiency (55% at best).

Measurements with silver/silver chloride reference electrodes identified the source of electrode polarizations that occurred during cell cycling. A typical voltage breakdown at the start of cell cycling is given in Fig. 14. As can be seen, during charge 50% of the voltage loss is due to the iron electrode, 27% due to the redox electrode, and 14% due to the separator resistance. During the first cycle the voltage loss across the Daramic separator was about 50-60 mV. This polarization increased rapidly to about 120 mV shortly thereafter. The increase in diaphragm resistivity has been attributed to $Fe(OH)_2$ blockage of the separator pores. The conductivity of the separator could be returned to its original state by applying an acid wash. Eventually, a thicker (2.4 mm) Daramic sep-

arator with a ribbed structure was evaluated and found to have a longer life (greater than 20 cycles).

The largest voltage loss is caused by the polarization at the iron electrode. This polarization may be reduced by adjusting the electrolyte pH to higher values. We attempted to maintain a pH differential in laboratory cells by using an anion selective membrane separator. But, as discussed previously, the separators quickly fouled. The fouling problem may be avoided in the future by incorporating recent advances in membrane technology from the NASA redox program (2).

The second most significant voltage loss was at the redox electrode. Although not large initially, the polarization increased during cell operation. The loss of electrode performance was associated with a passivating film accumulating on the electrode surface. As stated earlier, electrode performance was restored by applying an acid wash.

The operating cycle of 100%-83% depth of discharge in these tests do not represent a practical operating cycle such as 90%-10% depth of discharge. However, it was sufficient to note the occurrence of electrolyte imbalance and further charging only would compound the problem at this time. The electrolyte imbalance is brought about by proton reduction (during charge) which in turn affects electrolyte pH and causes an accumulation of ferric ion. As a result, hydrochloric acid and ferrous chloride had to be routinely added to the electrolyte. Later in the program (at about 100 cycles) two metal ion additives were evaluated in the cell after obtaining the results from the iron corrosion tests. The zinc ion caused a reduction in observed current efficiency to 70% as compared to the usual 90%. Although not confirmed at this time, we speculate the zinc addition caused a shift to more negative potentials of the iron plating reaction and, consequently, increased the significance of the proton reduction reaction. The addition of manganese ion improved battery operation substantially. Although no increase in current efficiency was obvious, the electrolyte pH remained stable thus eliminating the need for acid addition.

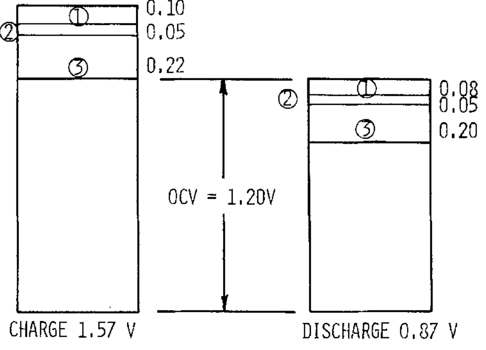

Fig. 14. Measured voltage breakdown for the initial cycle of a 100 cm² laboratory cell at 60 mA/cm², 60°C, and pH = 1.

Conclusions

An iron-redox single cell, at 60°C and using a microporous plastic separator, has been shown to be capable of storing and discharging energy at a round trip current efficiency of 90% and energy efficiency of 50%. A discharge power density of 50 mW/cm² has been obtained.

Several factors affecting the cell performance have been investigated. A ferrous-ammonium chloride electrolyte was found to be a highly conductive medium capable of yielding good quality electrolytic iron plate. Both titanium and graphite were found to be suitable substrates for iron plating. The largest voltage loss observed occurred at the iron electrode for both charge and discharge. Attempts at lowering this polarization by maintaining a pH differential across the cell with commercial anion membranes were unsuccessful because of membrane fouling. To a lesser extent, but not inconsequential, was the polarization at the high specific area porous redox electrode. The addition of small amounts of manganese ion was beneficial to cell performance in that ferrous chloride and acid additions during cycle tests become unnecessary.

The Effect of Zirconium on the Cyclic Oxidation of NiCrAl Alloys

C. A. Barrett, A. S. Khan,[1] and C. E. Lowell*

NASA-Lewis Research Center, Cleveland, Ohio 44135

ABSTRACT

Cyclic oxidation tests of Ni-(9-20)Cr-(15-30)Al-xZr alloys were carried out at 1100° and 1200°C in static air. In these alloys the concentration of zirconium varied from 0 to 0.63 atomic percent (a/o). The phases found in the cast alloys were γ, γ', β, and α. The oxidized surfaces were characterized by metallography, XRD, and electron microscopy. Although the alloys were basically alumina/nickel aluminate formers, the zirconium-containing alloys also formed small amounts of ZrO_2. The metallographic and electron microscopic examination of oxidized surfaces revealed significant aluminum oxide(s) penetration. The depth of attack and the degree of oxide penetration, however, strongly depended on the zirconium content of the alloy. The zirconium-free alloy had massive penetration of aluminum oxide(s). Small amounts of zirconium led to minimal penetration. However, as the zirconium content increased, the oxide penetration again became more pronounced. All of the weight change ($\Delta W/A$)-time data were fitted to the paralinear oxidation model: $\Delta W/A = k_1^{1/2}t^{1/2} - k_2t$ where $k_1^{1/2}$ represents the rate of scale formation and k_2 the rate of oxide spalling. The Zr-containing alloys had relatively good cyclic oxidation resistance as a result of intraoxide spalling at low rates. The Zr-free alloys had relatively poor cyclic oxidation resistance due to massive alumina spalling to bare metal, which resulted in a shift to NiO-controlled oxidation and even greater rates of attack. The derived parameters K_a (which equals $k_1^{1/2} + 10\ k_2$) and W_m (metal consumption) which indicate the degree of total oxidation attack were also estimated as a function of zirconium content. All four parameters showed minimums in the range of 0.03 to about 0.20 a/o zirconium. Further addition of zirconium beyond 0.20 resulted in increased values of $k_1^{1/2}$, K_a, k_2, and W_m. Alloys with zirconium contents between 0.03 and 0.20 a/o seemed to have the best cyclic oxidation resistance over the range of compositions tested, while oxidation resistance was essentially independent of Cr and Al content over the compositional range evaluated for these alloys.

The improvement of the oxidation resistance of alloys by the addition of reactive elements such as Y, Si, etc. has been known for several years (1-8). However, the mechanism by which these elements improve oxidation resistance has not yet been satisfactorily explained. In this respect several mechanisms have been proposed assuming that the added elements produce beneficial effects due to some interaction either at the alloy-oxide interface, in the oxide layer, or in the matrix. Pettit and co-workers (7, 8, 11) proposed that the internal rare earth oxide which is formed during oxidation mechanically keys the external oxide to the alloy and also prevents void formation at the alloy-oxide interface. Allam *et al.* make a similar case for oxide adhesion by pegging in the CoCrAl system(s). Their work indicated not only an improved adhesion of the scale by the addition of Y or Hf, but also made a case for an optimum concentration of these elements below 1 weight percent (w/o). On the other hand, in a recent paper Golightly *et al.* (9) proposed that the addition of rare earth elements prevents oxide formation within the existing oxide layer, probably by altering the outward diffusion of aluminum. Subsequent oxide growth occurs at the alloy-oxide interface forming an adherent scale.

[1] Present address: Pratt & Whitney Aircraft, West Palm Beach, Florida 33402.

Key words: scale adhesion, oxide spalling, Al_2O_3 formation, oxidation attack parameters.

The subject of oxide adhesion by small additions of rare earth or other reactive elements has also been treated extensively by Wright (10). However, no theory yet developed accounts for all of the observations.

Earlier work at this laboratory showed the beneficial effects of small amounts of Zr for Ni-Cr-Al alloys in the general range [9-20 atomic percent (a/o) Cr, 15-30 a/o Al] (12, 13), and a paper on the effect of zirconium on the isothermal oxidation of Ni-Cr-Al alloys has recently been published (14). This work showed that Zr additions resulted in a minimum in the parabolic scaling constant of Ni-14Cr-24Al alloys. Just as important as the effect of Zr was the drastic reduction in spalling at the end of the tests. While some oxide penetration was noted, it was concluded that "pegging" was not the mechanism of improved adhesion, but rather a reduction in void formation at the oxide/metal interface and an improved oxide/metal bond. The present paper describes the effect of Zr on the cyclic oxidation behavior of this class of Ni-Cr-Al alloys. This paper attempts to relate cyclic oxidation resistance with zirconium content. It is hoped that the study will provide additional information on the mechanism of oxide adhesion by tramp elements. The relatively large solubility of zirconium in the alloy permitted evaluation of oxidation properties without intermetallic compound formation which would have led to segregation of the zirconium.

Materials

The alloys investigated are mainly in the $\beta + \gamma/\gamma'$ regions of the Ni-Cr-Al phase diagram (15), and Fig. 1 shows a general map of the alloys tested. In the as-cast condition some nonequilibrium α-Cr was detected. This phase was not present in the oxidized samples. The thermal history and chemical composition of many of the alloys have been described in previous publications (12, 13) and are presented in Table I for reference. In the present paper the general compositions of the alloys studied are expressed as Ni-14Cr-24Al-xZr (a/o) for convenience during description, while Table I lists the actual composition of each alloy. The zirconium content varied from 0 to 0.63 a/o (1.10 w/o Zr). In several alloys, zirconium was added as an element during induction melting, while the rest of the alloys picked up zirconium from the zirconia crucible used in melting. Besides chemical analysis, the phases present in the alloys were characterized by SEM, optical microscopy, and energy dispersive analysis. In Ref. (14) an elemental x-ray micrograph was obtained for zirconium and showed a uniform distribution of zirconium in the matrix. Therefore, the zirconium content of the alloys studied was thought to be below its solubility limit.

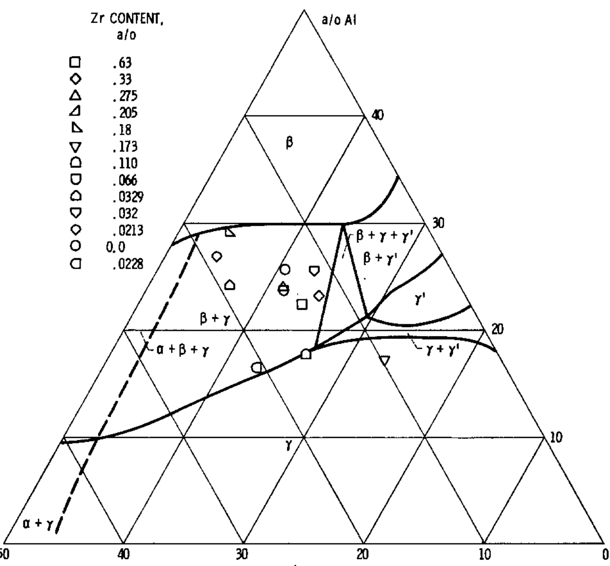

Fig. 1. Map of test alloys. Ni-Cr-Al, 1100°-1200°C

Procedure

Experimental.—The Ni-14Cr-24Al-xZr alloys were cyclically oxidized at 1100° and 1200°C. The experimental apparatus which has been described elsewhere (16) is shown in Fig. 2 and is briefly outlined here. Six samples were suspended individually in alumina furnace tubes. The suspended specimens were automatically raised and lowered by pneumatic cylinders controlled by reset timers. As the samples were raised, individually shielded cups automatically slid under the samples to catch the oxide spall. Each coupon used for oxidation was 22 × 10 × 2 mm with a small hole drilled in one end for wire suspension in the furnace. Samples were cleaned ultrasonically in alcohol before testing. Each cycle consisted of 1 hr heating and a minimum of 20 min cooling. Samples were periodically weighed throughout the test and data obtained were used to generate specific weight change *vs.* time curves. The samples were also examined by x-ray diffraction periodically to identify the oxides formed. The oxide scales were characterized by metallography and were analyzed by electron microprobe.

Treatment of experimental data.—In previous reports from this laboratory cyclic oxidation attack has been estimated by two parameters, K_a and W_m, both of which can be derived from sample weight change/time data. First the specific weight change data are regression fitted to the approximate paralinear equation

$$\Delta W/A = k_1{}^{1/2}t^{1/2} - k_2t \pm \sigma \quad [1]$$

where $\Delta W/A$ is the specific weight change at any time t, A is the area of the specimen, $k_1{}^{1/2}$ and k_2 are the growth and spalling constants respectively, and σ is the standard error of estimate.

The attack parameter is then defined as

$$K_a = (k_1{}^{1/2} + 10\,k_2) \quad [2]$$

where the coefficient 10 was derived empirically [Ref. (12)]. As K_a increases, oxidation resistance decreases. W_m, on the other hand, is the total specific amount of metal converted to oxide up to any time regardless of whether all or part of the oxide is retained or has spalled and/or vaporized. W_m can be estimated directly from weight change data only when no spalling and/or vaporization has occurred in the oxidation process (*i.e.*, parabolic oxidation). Otherwise W_m must be inferred from the mass balance equation for any time t

$$W_m = W_r - \Delta W/A \quad [3]$$

where W_m is the specific amount of metal consumed and W_r the specific amount of oxide retained and $\Delta W/A$ the specific weight change at any time. If paralinear kinetics are assumed, Eq. [3] has been solved in terms of specific weight change/time values and set up as a computer program termed COREST to handle conventional oxidation data as input [Ref. (17)]. The relationship between K_a and W_m is linear for values derived from the same weight change data with W_m shifted because it increases with time [Ref. (12)].

It should be reemphasized that W_m should be a universal measure of corrosion attack always a positive value and always monotonically increasing as time increases and environmental factors become more severe. No matter how complicated the actual kinetics, W_m estimates are required to fully satisfy any particular oxidation model. This has the additional advantage that the W_m can also be measured directly based on thickness change and alloy depletion.

Results and Discussion

Characterization of oxides.—Retained oxide and spalled oxides obtained at 1100° and 1200°C during cyclic oxidation of Ni-14Cr-24Al-xZr were identified by XRD and the results are shown in Table II. All alloys formed predominantly alumina and nickel aluminate (a_o = 8.05-8.10A) scales. Zirconium-containing alloys also produced small amounts of ZrO_2 (both cubic and monoclinic form). The Zr-free alloy spalled to bare metal during cooling, resulting in accelerated metal loss. This profuse spalling depleted Al from the Zr-free alloys and led to the formation of less protective NiO with a further acceleration of metal loss. On the other hand, the zirconium-containing alloys, which spalled only at the outer parts of the oxide, retained the basic alumina/aluminate scale after prolonged cycling. An exception was the case of the higher zirconium content alloys which formed some NiO at high temperature. For example, at 1200°C the alloys containing 0.33 and 0.63 a/o Zr spalled extensively, although not to bare metal, and produced considerable amounts of NiO on the surface.

This behavior is consistent with that expected from isothermal oxidation (14). The extensive bare metal spalling of Zr-free alloys at the conclusion of the isothermal testing also occurs with repeated cycles [see also (18)]. Similarly, the lesser oxide spalling tendency of the Zr-containing alloys also persisted and resulted, for the most part, in substantially reduced metal loss.

Metallography.—Figures 3 and 4 contain photomicrographs of several of the alloys, which span the range of zirconium contents, after 200 cycles at both 1200° and 1100°C, respectively. One of the most striking features of these microstructures is oxide penetration into the metal. All of the alloys containing zirconium displayed this oxide penetration as a feathery oxide, largely Al_2O_3. This is consistent with the isothermal work previously cited (14). The extent of this attack is proportional to the extent of metal loss which is, in turn, proportional to the zirconium level. However, oxide penetration was also found in the cyclic testing of the Zr-free alloy, which is not consistent with isothermal testing (14). This penetration was by massive oxide globules, largely Al_2O_3. This penetration undoubtedly contributes to the extensive loss of metal caused by the massive spalling to bare metal associated with this type of "pure" Ni-Cr-Al or Ni-Al alloy (18).

Kinetic data.—The specific weight change data are plotted in Fig. 5 and 6 at 1200° and 1100°C, for selected alloys over the range of Zr levels. In general, the alloys gained weight initially as the weight of oxygen consumed in forming the oxide layer was greater than the oxide weight lost by spalling. At longer times, especially at 1200°C the spalling rate overtook the oxygen pick up rate, and the net specific weight *vs.* time slope decreased and ultimately became negative. Eventually, the net weight of the sample became negative. This behavior is typical of such tests, *e.g.*, Ref. (12) and (16). In contrast, the alloys containing no Zr started with a nearly constant, negative slope since the massive spalling greatly exceeded the oxygen weight gain.

Regression analysis was performed on all test data fitted to Eq. [1] and the results are presented in Table III. In general, the R^2 values are quite high, showing that a paralinear model is a reasonable approach to analyzing the data. The 0.0 a/o Zr samples were also fitted to the paralinear model equation even though the weight loss was massive. The apparent $k^{1/2}$ and k_2 values were extremely large and represent a different class of alloys, *i.e.*, bare metal oxide spallers with strong NiO formation.

The values (exclusive of the 0.0 a/o Zr data) for $k_1{}^{1/2}$, k_2, K_a, and W_m were then individually fitted to second-degree polynomial equations at 1200° and 1100°C by multiple linear regression as a function of Zr content and plotted in Fig. 7-11 and listed in Tables IIIa and IIIb. An evaluation of the R^2 values of these equations shows that most of the total variability can

[e] Check run (see Fig. 7 to 10).

mate shown in the plot. The dark circle point represents an alloy that was run later to test how well the estimated life predicts results for other Zr levels. The closeness of the shaded point to the predicted value for the various parameters lends confidence to this approach. It should be reemphasized the 0.0 a/o Zr data points were not included in the curve fits since they represent a different class of oxide formers and spallers.

Figure 7 is a plot of $k_1^{1/2}$ *vs.* Zr. The growth constant increases monotonically with Zr after a large discontinuous drop from the 0.0 a/o Zr level at 1200°C and the same type of behavior was observed at 1100°C. This increase in growth constant with Zr content is consistent with an effect observed during isothermal oxidation in Ref. (14). However, the increased scaling rate primarily results in increased oxide penetration rather than increased scale thickness. During cyclic oxidation the situation is complicated by the accelerating effects of spalling which can in turn lead to the formation of different oxides, *e.g.*, NiO, which may be less protective and lead to an even greater metal loss rate and correspondingly higher growth constants.

Likewise, a plot of k_2, the spalling constant (Fig. 8) shows similar results. There is a drastic reduction in the spalling constant as the Zr level goes from 0 to about 0.06 a/o where it reaches a minimum, rises slowly at first, and then increases rapidly. The initial rapid decrease in spalling as the Zr content increases from 0 to about 0.06 a/o appears to be the result of a strengthening of the oxide-metal bond which prevents spalling to bare metal. The cause of the gradual in-

(a) 0.0 a/o Zr. (b) 0.066 a/o Zr.

(c) 0.33 a/o Zr. (d) 0.63 a/o Zr.

Fig. 4. Selected Ni-Cr-Al alloys at 1100°C in static air after 200 1-hr cycles with 0.0, 0.066, 0.33, and 0.63 a/o zirconium content; magnification 250×.

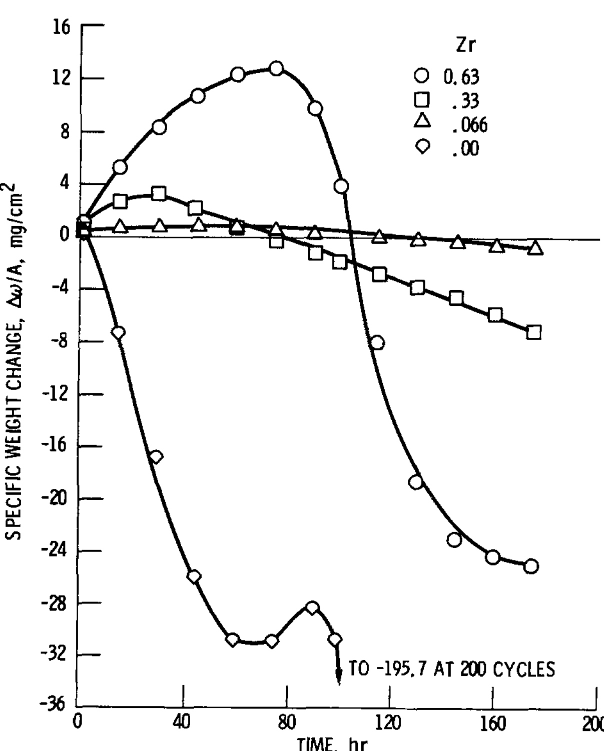

Fig. 5. Effect of Zr on cyclic oxidation of some NiCrAl alloys at 1200°C.

crease with increasing Zr is unclear. Perhaps Zr in solution in the alumina scale has increasingly damaging effects on the mechanical properties of the scale. Or the combination of spalling and high growth rates results in the formation of more spall-prone oxides, *e.g.*, NiO.

To assess a combined effect of oxide growth and spalling, Fig. 9 and 10 should be evaluated. These curves show K_a at 1200° and 1100°C and W_m at 1200°C for 500 hr and 1100°C for 200 hr. W_m is the parameter directly measuring total oxidation attack. The shapes of the W_m curves are similar to the K_a *vs.* Zr data in that they have minimums in the range of 0.03-0.20 a/o

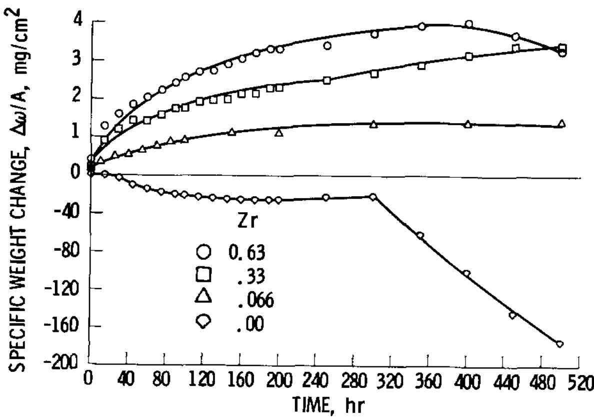

Fig. 6. Effect of Zr on cyclic oxidation of some NiCrAl alloys at 1100°C.

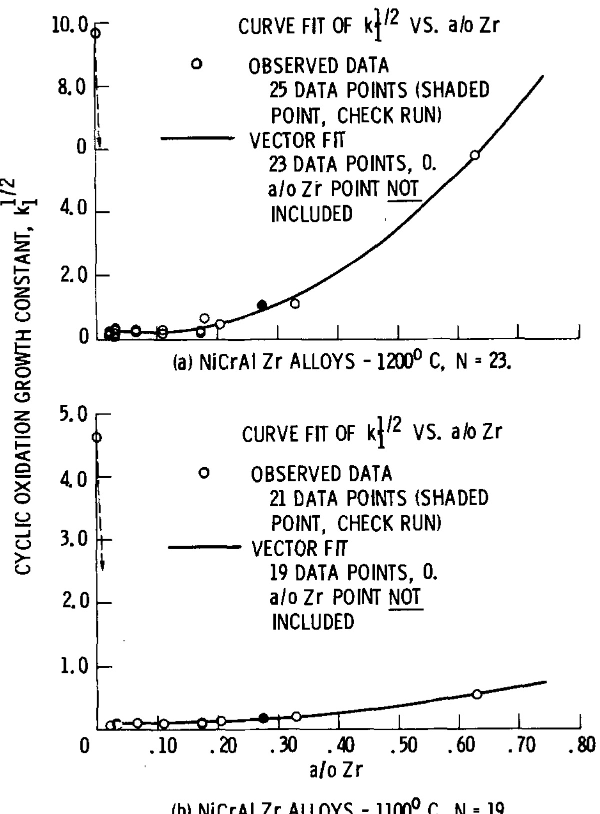

Fig. 7. Derived $k_1^{1/2}$ scale growth constants as a function of a/o Zr in $\gamma/\gamma' + \beta$-NiCrAl alloys tested in cyclic oxidation at 1200° and 1100°C in static air for 1 hr exposure cycles. $k^{1/2}$ values from: $\Delta\omega/A = k_1^{1/2}t^{1/2} - k_2t$ fits.

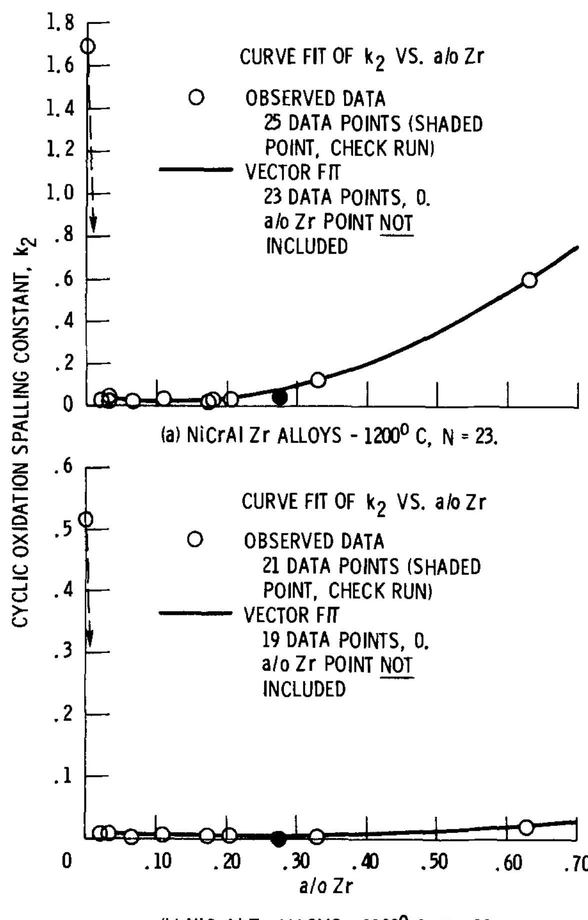

Fig. 8. Derived k_2 scale spalling constant as a function of a/o Zr in $\gamma/\gamma' + \beta$-NiCrAl alloys tested in cyclic oxidation at 1200° and 1100°C in static air for 1 hr exposure cycles. k_2 values from: $\Delta\omega/A = k_1^{1/2}t^{1/2} - k_2t$ regression fits.

Zr. As shown in Ref. (12), the relationship of K_a to $k^{1/2}$ and k_2 is useful only if W_m is linear in K_a. This relationship was tested and the results plotted in Fig. 11. Since the slopes of log $(W_m)_T$ *vs.* log K_a are essentially unity, K_a may be used to scale the degree of cyclic oxidation attack of these alloys. This emphasizes the spalling mechanism's overriding effect in cyclic oxidation degradation.

Summary of Results

The results obtained during the cyclic oxidation of Ni-(9-20)Cr(15-30)Al-xZr alloys at 1200° and 1100°C are summarized below:

1. The addition of Zr at concentrations between 0.03 and 0.20 a/o gives optimum cyclic oxidation resistance to NiCrAl alloys.
2. The Zr-free alloys spalled to bare metal during cycling. The addition of zirconium significantly decreased spalling to some critical Zr content of the alloys near 0.066 a/o. The spalling increased gradually with further addition of zirconium above this level. Additions of Zr also changed the nature of spalling, *i.e.*, from spalling at the oxide/metal interface to intraoxide spalling.
3. $\Delta W/A$ *vs.* time data for all the alloys were fitted with good correlation to a paralinear model. The derived growth and spalling constants showed strong dependence on the zirconium content of the alloys.
4. A number of kinetic parameters, $k_1^{1/2}$, k_2, K_a, and W_m, were estimated as a second-degree function of Zr content of the alloys at both 1200° and 1100°C. They all showed minimums ranging from 0.03 to about 0.20 a/o Zr above which they increased with Zr content. Most of the variation of the various parameters could be explained by changes in Zr level alone. Comparable fits based on Cr and Al levels indicated the Cr and Al level effects were minimal.
5. Metallography of the oxidized samples showed some oxide penetration. The amount and type of oxide penetration strongly depended on the zirconium content of the alloys. The addition of zirconium significantly decreased the penetration up to about 0.066 a/o. Above this, penetration increased with the Zr content.
6. The alloys studied are basically alumina/$NiAl_2O_4$ spinel formers. The zirconium-containing alloys also produced small amounts of ZrO_2 (both cubic and monoclinic form). After prolonged cyclic attack NiO tends to form on the less resistant alloys.

Concluding Remarks

This study confirmed that small additions of Zr to NiCrAl alloys can have a beneficial effect on their cyclic oxidation resistance. While the exact mechanism of such an effect remains unclear, the Zr (similar to Y, etc.) improves the oxide-metal bond so that spalling no longer takes place at the oxide-metal interface, but instead occurs within the oxide. At low Zr levels this results in a marked reduction in metal consumption. However, at higher Zr levels spalling, while still an intra-oxide failure, increases gradually. But even at the highest Zr level studied the metal consumption rates are still well below those of the pure alloy. How this increase occurs needs further investigation, but may be related to changes in the mechanical properties of the oxide. The optimum Zr content for maximum cyclic oxidation resistance was found to be between 0.03 and 0.20 a/o Zr.

The Electrochemical Behavior of Scratched Iron Surfaces in Aqueous Solutions

G. T. Burstein* and D. H. Davies

Department of Metallurgy and Materials Science, University of Cambridge, Cambridge, CB2 3QZ, England

ABSTRACT

A technique involving rapid scratching of rotating disk electrodes under potential control is presented and used to examine rapid reaction steps in the anodic behavior of iron in aqueous solutions of pH 0-14. Both anodic and cathodic reaction rates are greatly accelerated during scratching; current densities of up to ~10 A cm^{-2} of bare metal surface were observed. The results obey Tafel's law and demonstrate the formation of an adsorbed layer of FeOH by: (*i*) $Fe + H_2O \rightleftharpoons Fe \cdot H_2O_{ads}$, followed by (*ii*) $Fe \cdot H_2O_{ads} \rightarrow FeOH_{ads} + H^+ + e^-$ for pH < 7, or (*iii*) $Fe \cdot H_2O_{ads} \rightleftharpoons Fe \cdot OH^-_{ads} + H^+$, and (*iv*) $Fe \cdot OH^-_{ads} \rightarrow FeOH_{ads} + e^-$ for pH > 7. The layer of adsorbed FeOH is formed at potentials negative with respect to the reversible potentials for oxide formation and exists on the surface during steady-state anodic oxidation of Fe and during cathodic reduction of H^+ from solution. The results are discussed in terms of the mechanism of steady-state dissolution of Fe.

The technique of investigating the electrochemical mechanisms of a bare metal surface reactions in solution by scratching a specimen while it is held under potential control has received little attention since its inception. Measurements of bare surface corrosion potentials on Al made by cutting a lacquered electrode with a ruby stylus (1, 2) showed that the metal adopts a very low potential on cutting; the potential then rises owing to the evolution of hydrogen followed by repassivation. Later work on evaporated Al films (3) confirmed that this behavior is a feature of a bare Al surface and does not arise from stress or heating effects during cutting and subsequent relaxation or cooling. Similar measurements have been made on a large number of metals by high speed drilling with a dentist's drill-bit (4). It was concluded that several metals such as Fe, Co, and Ni have bare surface exchange current densities orders of magnitude greater than those obtained by steady-state techniques. Schwabe *et al.* (5-7) and Tomashov *et al.* (8) used a carborundum disk to scour potentiostatically controlled specimens of Fe, Ni, and stainless steel in aqueous solutions. They showed that the current densities were considerably larger than those observed during steady-state voltammetry. Polarization of scraped Al was performed by Hagyard *et al.* (2). The results agree with more recent work using a scratched rotating disk electrode of Al-7 weight percent Mg (9), showing the first step in the oxidation process to be loss of a single electron to produce Al(I) as an intermediate in both dissolution and passivation. Hydrogen evolution was also found to be greatly accelerated on the bare metal surface. Beck *et al.* (10-12) used a rotating ring scraped disk electrode to show that some Ti(III) is produced during anodic oxidation of Ti.

A large amount of work dealing with the kinetics of the anodic dissolution of Fe in aqueous solutions has been published. Tafel behavior has been observed in a variety of electrolytes with steady-state slopes ranging from 30 to 100 mV depending on the content of the solution and the experimental conditions (13). Mechanisms involving two single electron transfer steps have been proposed by Kabanov *et al.* (14), Bockris *et al.* (15), and Kelly (13). All three mechanisms involve formation of adsorbed FeOH in a rapid electron transfer step with subsequent oxidation of this intermediate as the rate-determining step. Heusler (16) also proposes rapid formation of adsorbed FeOH as a step in the dissolution reaction, but in his mechanism FeOH acts as a catalyst for a rate-determining two-electron transfer reaction between Fe and OH^-.

No direct evidence has, however, been provided for the formation or existence of FeOH and attempts to describe its formation have been speculative. In this paper we describe the electrochemical behavior of scratched Fe electrodes, showing how the technique elucidates reactions of a bare Fe surface with isolation of the rapid first oxidative step in the anodic dissolution and passivation process.

Experimental

All chemicals were of analytical grade except $K_2B_4O_7 \cdot 4H_2O$ which was laboratory grade. Electrolytes were made with doubly distilled water and were deoxygenated with purified nitrogen prior to and during experiments. Rotating disk electrodes were made from deoxidized, high purity iron (supplied by British Iron and Steel Research Association) (C 0.006%, Si 0.001%, S 0.0066%, Al 0.004%, O 0.0017%, N 0.0016%, Mn <0.005%). The metal was spark-cut into disks (diameter 8 mm), cleaned, and mounted into Perspex holders with Araldite. The electrodes were ground to a 1200 grit finish, ultrasonically cleaned, and washed thoroughly in doubly distilled water.

The scratched rotating disk assembly was described by Lees and Hoar (17) and Ford *et al.* (9). It consists of a belt-driven electrode rotated by a d-c motor; rotation rates ω, of up to 200 Hz could be achieved, although the results reported in this paper were taken at 100 Hz. A circular platinum counterelectrode of diameter 50 mm was mounted symmetrically about 60 mm below the working electrode. A small hole cut through the center of the counterelectrode allowed a Luggin capillary to emerge through it from the bottom of the cell. The capillary tip of internal diameter ~1 mm was positioned ~40 mm from the working electrode surface, this distance being employed to allow easy access of the scratching stylus. In terms of ohmic resistance measurements of the electrolyte this probe distance is effectively infinity and is consequently easily reproducible. The scratching stylus consisted of a glass-cutter's diamond tool whose steel shank was liberally and completely coated with Araldite. The diamond tool was mounted onto a Perspex arm which was free to rotate about a horizontal axis through the cell. An electromagnet mounted outside the cell attracted a steel bolt which

* Electrochemical Society Active Member.

Key words: rotating disk electrodes, steady-state dissolution of iron.

was screwed into the top of the arm: this held the stylus away from the working electrode surface at a distance of 1-2 mm. On breaking the electromagnet circuit the inertia of the arm allowed the stylus to swing upward, striking the working electrode surface with a tracking weight of ~2g, then bouncing away when it was again picked up by the reactivated electromagnet. The diamond thus caused a scratch on the rotating metal surface with a contact time of up to ~1.8 msec (although generally 1.0 msec), generating a bare metal surface at a rate of 1.6 $msec^{-1}$, the radius of curvature of the scratch being typically 2 mm. The scratch appeared as an arc of ~1.5 μm depth, 30 μm width, and ~1.6 mm length; its area was therefore ~0.1% of the total working electrode area. Because of the small depth to width ratio of the scratch the cross-sectional curvature was ignored for calculation of the scratch area.

Specimens were held at constant potential with a fast response potentiostat (Wenking Type OPA 69, response time <1 μsec) until a steady-state current density on the electrode as a whole was achieved. The stylus was then released and the current transient arising from the resulting scratch captured in a transient recorder (Datalab Type DL 905), which was triggered either from the electromagnet circuit or from the current transient itself. All transients showed a rise in current (either anodic or cathodic depending on potential) for the period of stylus contact, followed by a decay when the stylus fell away. The direction of flow of current on the scratch was not necessarily the same as that flowing on the remaining electrode surface. The current rise was linear for most of its length (see below), but tailed at the beginning and end. This tailing is due to the changing scratch width when the stylus makes or breaks contact with the electrode and constitutes an insignificant fraction of the total scratch length. Tailing at the top of the transient can also occur because of significant repassivation of the scratch during stylus contact. Experiments were carried out at 298 ± 2 K.

The current density on the bare surface, i_s, was determined from the gradient of the linear rising part of the current transient by the formula

$$i_s = \frac{1}{2\pi r \omega y} \frac{dI}{dt}$$

where dI is the change in the total current in time dt, r is the radius of the scratch (*i.e.*, its distance from the center of rotation), ω is the rotation rate (Hz), and y is the width of the scratch. Where tailing occurred on the rising part of the transient the maximum slope dI/dt was used to determine i_s since this gives the fastest rate of reaction of the scratch and therefore the most bare surface.

Potentials were measured with respect to a saturated calomel or saturated $Hg/Hg_2SO_4/K_2SO_4$ reference electrode and are presented on the normal hydrogen scale. Where necessary, corrections have been made for the liquid junction potential between the working and reference electrolytes by the formula of Henderson (18) and for the ohmic potential drop due to the steady-state base current density (*i.e.*, that current flowing from the disk as a whole) by the formula of Newman (19).

The ohmic potential drop in the electrolyte due to the current from the scratch could not readily be measured because of the nature of the transient electrochemical response of the scratch itself. Instead, the scratch situation was simulated using the edge of a foil electrode made of copper in the following way (20). A sheet of copper foil was mounted edge-on into Araldite to form a rotating disk with the edge of the foil forming the actual electrode and the Araldite forming the rest of the disk. The ohmic potential drop to this electrode was then measured by applying a double galvanostatic pulse and measuring the transient potential response using a similar cell geometry to that described above for scratching experiments. To ensure that the measured potential change was indeed ohmic the height of the first current pulse was varied while that of the second pulse (used to determine the ohmic resistance) was held constant. Thus pulsing first from 0 to 1 mA and then directly to 2 mA gave a similar resistance as pulsing first from 0 to 9 mA and then directly to 10 mA. Similarly the measured resistance was independent of the height of the second pulse itself. In this way values of the ohmic resistance were determined as a function of foil length, foil width, and solution conductivity, allowing values representing the dimensions of the scratches to be interpolated. The results agree well with a theoretical solution to the problem full details of which will be presented elsewhere (20).

Results

A typical graph of the bare surface current density i_s is shown in Fig. 1 as a function of potential. This type of graph is referred to as a "bare surface polarization curve" (even though the surface may not be fully bare at all potentials). The bare surface polarization curve lies at current densities which are orders of magnitude greater than those of the steady-state polarization curve (also shown in Fig. 1 for the same electrolyte). Both the anodic and cathodic regions of i_s are shown, with the mixed potential E_{ms} of the bare surface at −860 mV (NHE). This value is more negative than that for the steady-state curve [E_m = − 615 mV (NHE)]. The large acceleration of both the anodic and cathodic reactions on scratching was found for all electrolytes. Figures 2 and 3 show

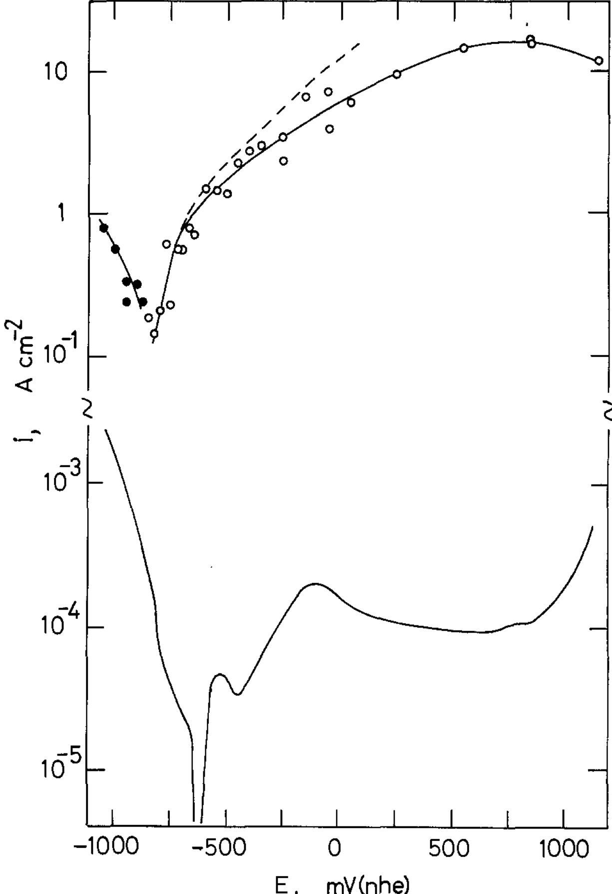

Fig. 1. Steady-state (lower) and bare surface (upper) polarization curves for Fe in 1.0M K_2CO_3, pH 11.6. Steady-state curve swept at 15 mV sec^{-1}. ○, anodic; ●, cathodic. Broken line shows ohmic potential correction for the scratch surface.

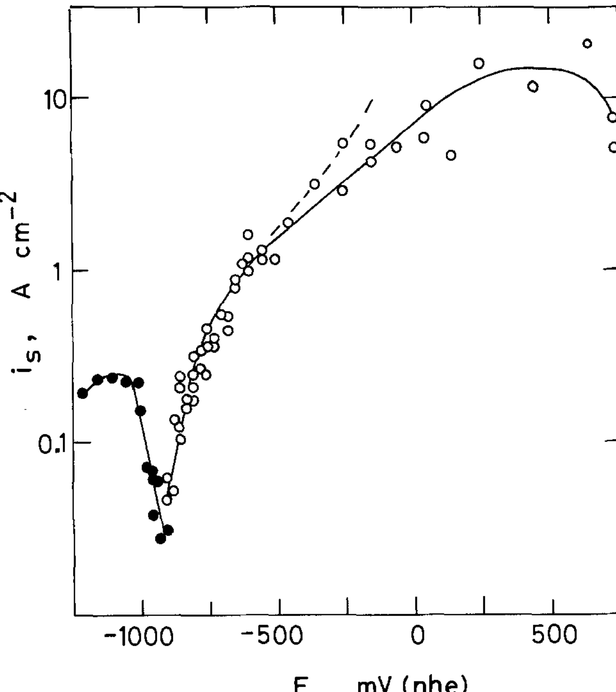

Fig. 2. Bare surface polarization curve for Fe in 1.0M KOH, pH 14. ○, anodic; ●, cathodic. Broken line shows ohmic potential correction for the scratch surface.

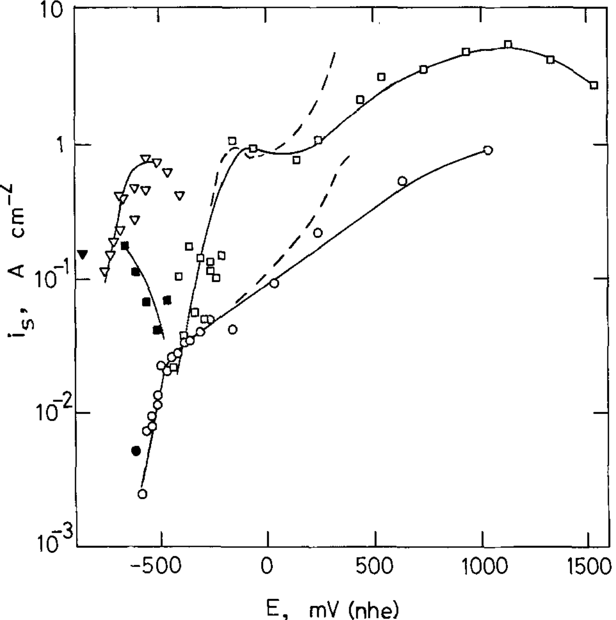

Fig. 4. Bare surface polarization curves for Fe in: 0.5M H_3BO_3, 0.05M $K_2B_4O_7$, pH 7.6 (○, ●); 0.75M HOAc, 0.75M NaOAc, pH 4.9 (□, ■); 0.5M $KHCO_3$, 0.5M K_2CO_3, pH 9.8 (▽, ▼). White points anodic, black points cathodic. Broken lines show ohmic potential corrections for the scratch surfaces.

bare surface polarization curves in 1.0M KOH, pH 14 and in 1.0M H_2SO_4, pH 0, respectively. Similar trends are shown; the current density increases in both the anodic and cathodic directions from E_{ms}. For H_2SO_4 the potential range is restricted because of the high base currents at higher anodic and cathodic potentials, which obscure the current transient due to scratching. There is an effect of pH, with E_{ms} lying at more negative values for higher pH. This is shown for an intermediate pH range in Fig. 4 for acetate (pH 4.9), borate (pH 7.6), and bicarbonate (pH 9.8) solutions.

All bare surface polarization curves show a linear Tafel region over approximately 1-2 orders of magnitude in i_s from E_{ms} in the anodic direction. The Tafel parameters are presented in Table I for each electrolyte. Anodic Tafel slopes are all in the range 121 ± 15 mV, the error bar representing the maximum deviation from this value. Owing to the scatter in the experimental points on the bare surface polarization curves the Tafel slope for each curve was measured by linear regression successively over a progressively increasing potential range: those presented in Table I were those which showed the highest correlation coefficient with the data points.

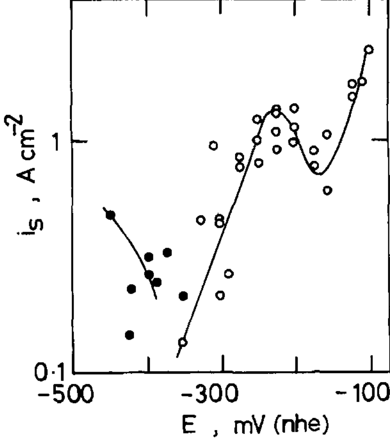

Fig. 3. Bare surface polarization curve for Fe in 1.0M H_2SO_4, pH 0. ○, anodic; ●, cathodic.

Corrections for the ohmic resistance of the electrolyte arising from the current density on the scratch were made to all anodic bare surface polarization curves using the values obtained by the method described above. These corrections are shown as the broken lines in Fig. 1-5. In every case the anodic Tafel region is unaffected by such corrections, although at current densities higher than the Tafel regions significant corrections are observed. Thus, for example in Fig. 2 at an anodic scratch current density of 300 mA cm^{-2} (representing the highest point of Tafel linearity), the ohmic potential drop due to the scratch is 8 mV, whereas at 10 A cm^{-2} the value is 267 mV. In no case does this ohmic potential correction enable the linear Tafel region to be extended to higher anodic current densities.

The effects of bicarbonate anions were investigated by comparing bare surface polarization curves in bicarbonate and borate electrolytes of the same pH (8.8), and this is shown in Fig. 5. The linear Tafel region is extended to higher potentials in the bicarbonate, but does not accelerate the Tafel region itself. Thus the Tafel regions in the two electrolytes are common. Part of this difference arises, of course, from the different ohmic resistances of the two electrolytes. However, that determined for the bicarbonate electrolyte (145Ω) is only 0.27 of that determined for the borate electrolyte (547Ω), and this difference is insufficient to account for the order of magnitude difference in the maximum current density in the Tafel region (300 and 25 mA cm^{-2}, respectively).

Table I. Parameters for the anodic behavior of scratched iron electrodes in various electrolytes

Electrolyte	pH	E_{ms} [mV (NHE)]	$\partial E/\partial \log i_s$ (anodic) (mV)	q_D (C cm^{-2})
1.0M H_2SO_4	0	−365	114	98
0.75M HOAc, 0.75M NaOAc	4.9	−445	128	61
0.5M H_3BO_3, 0.05M $K_2B_4O_7$	7.6	−545	109	15
0.32M H_3BO_3, 0.19M $K_2B_4O_7$	8.8	−705	112	11
0.75M $KHCO_3$, 0.05M K_2CO_3	8.8	−705	112	69
0.5M $KHCO_3$, 0.5M K_2CO_3	9.8	−765	132	117
1.0M K_2CO_3	11.6	−865	124	108
1.0M KOH	14.0	−920	136	149

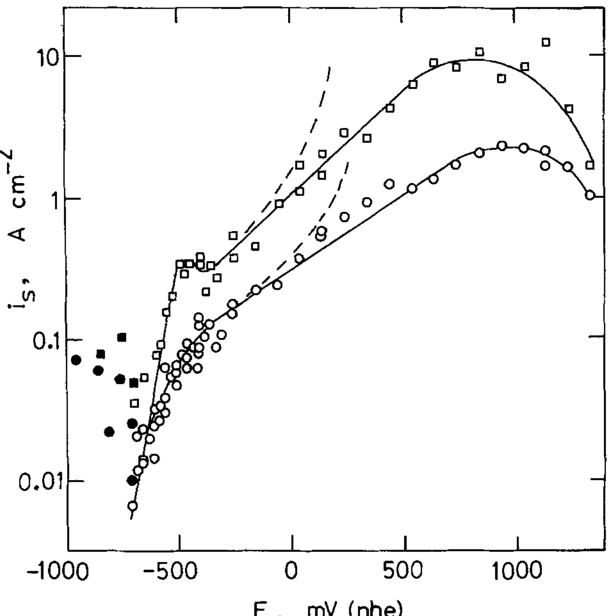

Fig. 5. Bare surface polarization curves for Fe at pH 8.8. 0.32M H_3BO_3, 0.19M $K_2B_4O_7$ (○, ●); 0.75M $KHCO_3$, 0.05M K_2CO_3 (□, ■). White points anodic, black points cathodic. Broken lines show ohmic potential corrections for scratch surfaces.

At potentials more anodic than the linear Tafel regions all bare surface polarization curves tend toward higher values of $\partial E/\partial \log i_s$, becoming almost independent of E at high potentials.

Values of E vs. pH at constant i_s were measured at $i_s = 100$ mA cm^{-2}. This current density lies in the linear Tafel region for all electrolytes except those containing borate for which the Tafel regions were extrapolated to 100 mA cm^{-2}. The values are shown in Fig. 6. They give $\partial E/\partial$ pH $= 0$ for pH < 7, $\partial E/\partial$ pH $= -114$ mV for $7 <$ pH < 11.7, and $\partial E/\partial$ pH $= 0$ for pH > 11.7.

Cathodic scratch transients, representing reduction of hydrogen ions or water on the scratch surface, showed very large scatter. Values of i_s as a function of E in the cathodic region were therefore in general difficult to quantify. Figure 2 shows a linear Tafel region in the hydrogen evolution reaction with a Tafel slope of -116 mV. The potential range over which the cathodic process could be detected was small since the currents on the electrode as a whole quickly become quite large with increasing overpotential: large base currents tend to obscure the small transients arising from the scratch.

Three types of anodic current transient are depicted in Fig. 7. Type A scratches were observed within the Tafel regions, type B scratches at the upper potential limits of the Tafel regions, and type C scratches only at potentials higher than the Tafel regions. Some idea of the origins of these three basic types of scratches may be obtained by considering the value of q_p which represents the charge density that has flowed from the scratch at the time that the stylus leaves the surface. Transients of type A were obtained where $q_p << 100$ μC cm^{-2}; those of type B gave $q_p \sim 100$ μC cm^{-2}; those of type C gave $q_p >> 100$ μC cm^{-2}. Values of q_p for the top of each Tafel region are shown in Table I.

In some instances the rising current on the transient showed two or three small peaks or points of inflection separated by times of <1 msec. This is probably due to a stick-slip type of scratching process, where the

debris may pile up in front of the stylus to a sufficient extent for the stylus to have to jump over the pile before continuing the scratch. However, microscopic examination of the scratch scars showed little evidence of this. Similarly there was very little debris piled up at the sides of the scars and none at the ends. While the exact mode of machining of this type is still under investigation, it appears that the metal is removed in very small pieces rather than in long strips since no strips of debris were found in the cell after experiments. As such, the added area of bare metal caused by the still-electrically coupled debris in front of the stylus during scratching is small. It is worth noting, however, that much of the scatter in the results probably arises from variation in scratch width and depth during a run (giving scatter in the scratch area) as well as from pile-up of debris.

The bare surface current densities were unaffected by electrode rotation rate ω (and therefore scratching rate) for 200 Hz $> \omega >$ 16.7 Hz. Rotation rates less than 16.7 Hz generally gave current transients too small to quantify while for $\omega >$ 150 Hz visible turbulence occurred. The work presented here was performed at 100 Hz.

Discussion

Comparison of the values of E_{ms} shown in Table I with the equilibrium potentials for oxide formation given by Pourbaix (21) shows that in the intermediate pH range Fe oxidizes anodically below the minimum theoretical potential for oxide formation. Bearing in mind that the total charge passed from the scratch $q_t > 2q_p$ (q_p represents only that fraction passing during stylus contact) then, with the exception of the two borate electrolytes, the charge densities shown in Table I are too large for i_s to be controlled solely by nonfaradaic double layer charging processes. For the two borate electrolytes the top of the Tafel regions are probably controlled by the ohmic resistance of the electrolytes, as was indicated by the fact that no type B transients were observed. In other words for the borate electrolytes $q_t >> 2q_p$. The charge densities clearly must contain a nonfaradaic double layer component; nevertheless the bare surface current densities are controlled by charge transfer electrochemical reactions. In the anodic Tafel region which exists in all electrolytes (see Table I) the charge transfer reaction is the first oxidative step in the total dissolution (or passivation) of Fe.

The initial step must be the adsorption of water onto the fresh metal surface which proceeds rapidly to completion immediately behind the stylus

$$Fe + H_2O \rightleftharpoons Fe\cdot H_2O_{ads} \quad [1]$$

Reaction [1] is followed by one of two mechanisms as follows

$$Fe\cdot H_2O_{ads} \rightarrow FeOH_{ads} + H^+ + e^- \quad [2]$$

or

$$Fe\cdot H_2O_{ads} \rightleftharpoons Fe\cdot OH^-{}_{ads} + H^+ \quad [3]$$

$$Fe\cdot OH^-{}_{ads} \rightarrow FeOH_{ads} + e^- \quad [4]$$

By considering the coverage of adsorbed water to be complete, and the coverage of FeOH to be small, reaction [2] gives

$$i_s = Fk_2 \exp\left[\frac{\beta FE}{RT}\right] \quad [5]$$

and $\partial E/\partial \log i_s = 118$ mV, $\partial E/\partial$ pH $= 0$ for $\beta = 0.5$. Reaction [3] forms a rapid equilibrium prior to reaction [4], with

$$K_3 = \theta[H^+]/(1-\theta) \quad [6]$$

where θ is the coverage of adsorbed OH^-, and

$$i_s = Fk_4\theta \exp\left[\frac{\beta FE}{RT}\right] \quad [7]$$

provided the coverage of the oxidized product FeOH is not large. In practice, because of the scatter in the results, this means a coverage of FeOH of $< \sim 0.5$. For $\theta \rightarrow 0$, $\theta[H^+] \rightarrow K_3$ (from Eq. [6]), whence

$$i_s = Fk_4K_3[H^+]^{-1} \exp\left[\frac{\beta FE}{RT}\right] \quad [8]$$

and $\partial E/\partial \log i_s = 118$ mV, $\partial E/\partial$ pH $= -118$ mV for $\beta = 0.5$. For $\theta \rightarrow 1$, Eq. [7] gives

$$i_s = Fk_4 \exp\left[\frac{\beta FE}{RT}\right] \quad [9]$$

and $\partial E/\partial \log i_s = 118$ mV, $\partial E/\partial$ pH $= 0$ for $\beta = 0.5$. In the above equations K_j and k_j are the equilibrium and rate constants, respectively, for reaction j. It should be noted that $\theta = 1$ does not necessarily define a complete monolayer of adsorbed OH^- (which would imply enormous lateral repulsion between adjacent adsorbed ions), but rather the coverage beyond which the anodic reaction can no longer be accelerated.

Three regions of anodic behavior are observed from Fig. 6 (and Table 1), all in excellent agreement with the equations above. Between pH 0 and 7, Eq. [5] controls the bare surface reaction rate, and reaction [2] (pH independent) is rate controlling. For $7 <$ pH < 11.7 the scheme represented by reactions [3] and [4] controls the reaction rate, with $\theta \rightarrow 0$; the rate is given by Eq. [8], which is first order in pH. For pH > 11.7, $\theta \rightarrow 1$ and Eq. [9] (pH independent) is rate determining. In practice, of course, there must be a continuous change through the pH $= 11.7$ region controlled by the Langmuir isotherm given in Eq. [6], which would cover 1 to 2 units of pH, for which

$$i_s = Fk_4K_3([H^+] + K_3)^{-1} \exp\left[\frac{\beta FE}{RT}\right] \quad [10]$$

The following points should be realized in the above mechanisms. (*i*) Reaction [1] must proceed rapidly and to completion. In this sense the term "bare surface" actually applies to that surface on which reaction [1] has already occurred. If this were not the case a void would form on the metal surface immediately behind the stylus and render that part of the scratch surface electrochemically inactive. (*ii*) Reactions [3] and [4] must proceed through OH^- adsorbed by rapid equilibration on the surface (reaction [3]). A reaction of the type $Fe + OH^-{}_{aq} \rightleftharpoons Fe\cdot OH^-{}_{ads}$ would have a diffusion-controlled rate given by $i = FD\Delta c/\delta$, where D is the diffusion coefficient of OH^- and δ the diffusion layer thickness. For pH $= 7$ and $\delta = 10^{-3}$ cm, $i \approx 10^{-5}$ A cm^{-2}, which is far less than the observed bare surface current densities. (*iii*) In the Tafel regions the coverage of adsorbed FeOH which is formed during scratching must be sufficiently low to be ignored for the purposes of the kinetic treatment of the mechanisms above. In this connection it is to be noted that the maximum charge densities which flow from the surface, q_p, are all less than that required to oxidize a monolayer of Fe. One would expect the charge required to oxidize a monolayer of Fe to FeOH to be around 200 μC cm^{-2}, depending on which crystal orientations are exposed by scratching. Bearing in mind that (*i*) the surface density of Fe in FeOH is unknown, but probably less than that in the substrate and (*ii*) the roughness factor of the surface is unknown, but probably between 1.5 and 2 (22), the maximum values of q_p shown in Table I are all significantly less than one monolayer of FeOH. These values are observed at the upper potential limit of the Tafel regions; at lower potentials q_p (given approximately by 0.5 i_st_c, where t_c is the contact time of the stylus) is also lower. At potentials below the steady-state reversible potentials reactions [2] and [4] must of course cease when the coverage of FeOH reaches one monolayer.

The upper limit of Tafel linearity can be controlled by a number of factors. (*i*) A significant ohmic potential drop in the electrolyte occurs at higher bare surface current densities: thus the borate electrolytes show low values of q_p (see Table I) and do not show type B transients (see Fig. 7b). It is, however, significant in this respect that correction of the polarization curves for the ohmic potential drop does not extend the Tafel lines to higher potentials (see Fig. 1-5). (*ii*) A significant coverage of FeOH during scratching would cause the rate of reactions [2] and [4] to decrease. At higher potentials where the values of q_p are large (see Fig. 7c) the values of i_s are not true bare surface current densities. (*iii*) Above the steady-state reversible potential for Fe(II) formation partial coverage of a thicker film containing Fe(II) can also occur during scratching. In either case (*ii*) or (*iii*) the true bare surface current density above the Tafel region is actually greater than that shown in Fig. 1-5, but the rate of scratching cannot outrun the rate of reaction. However, some bare surface must always exist during scratching. The rate of scratching would have to be increased enormously in order to extend the range of linear Tafel behavior to significantly higher potentials. This has been noted previously (4) during studies of open-circuit scrape potentials.

Of the several mechanisms proposed for the steady-state anodic dissolution of Fe (13-16), most have involved either reactions [2] or [4] as initial electron transfer steps in the process. This arises from steady-state Tafel parameters that have previously been observed, which range upward from 30 mV. Despite the diversity of previous results there seems to be general agreement that steady-state measurements involve subsequent reactions as rate determining and that these reactions are preceded by a single electron transfer step which is fast. The above results support these theories and establish the kinetics of the first step; subsequent steps are slow compared with the rate of bare surface reaction from the scratched electrode, as demonstrated by the high current densities in Fig. 1-5. The fact that the scratched iron electrode reacts anodically below its equilibrium potentials also indicates that some early oxidation step is occurring, a reaction which has a reversible potential more negative than those quoted by Pourbaix (21) for the iron oxides. A similar effect has been observed for the anodic behavior of scratched silver electrodes (22); in this case the reversible potential for the reaction of Ag to form a monolayer of adsorbed AgOH was isolated. In the present work the reversible potential for FeOH formation cannot be found since it lies in the region obscured by the accelerated hydrogen discharge reaction. These first electrochemical steps shown by reactions [1]-[4] are followed by the slower steps measured in the steady state, in which FeOH on the surface is oxidized to Fe(II) in solution or as a surface film. It should be noted that reactions [1]-[4] are precursor reactions to both dissolution and passivation and that a high coverage of FeOH occurs. Whereas dissolution occurs exclusively through these reactions (in the absence of electroactive anions), passivation occurs by oxidation of the FeOH layer to produce a thicker film of some higher oxide of Fe. Once this passive film is formed, the FeOH layer is no longer in contact with the electrolyte solution. In this case it may remain as an interfacing layer between the metal and the film, or it may be entirely oxidized and disappear. The thickening of the passive film may therefore not necessarily require the formation of the precursor FeOH.

Interference by the accelerated hydrogen discharge reaction on the scratched surface prevents measurement of E_0 and hence i_0 (reversible potential and exchange current density, respectively) for reactions [2] and [4]. Nevertheless, the fact that these reactions occur at very low potentials means that the adsorbed FeOH species must exist on the metal at potentials where Fe(II) can be reduced from solution. The adsorbed layer must thus be an intermediate in low overpotential electroreduction of Fe(II) and H^+ from solution. Scratching of Fe at potentials in the cathodic regions shown in Fig. 1-5 shows greatly accelerated H^+ reduction current densities, with a Tafel slope (at pH 14) of 116 mV. The reaction involved is probably the reduction of a proton, *viz.*, $H_3O^+ + e^- \rightarrow H + H_2O$, but now it occurs on the bare metal surface instead of a surface covered by a layer of FeOH, which exists during steady-state hydrogen evolution. It would be expected that below the reversible potential for FeOH formation cathodic reduction processes would not be significantly accelerated by using scratched metal electrodes. For Fe these potentials are inaccessible because of the large proton reduction current densities which occur on the remaining unscratched area of the electrode.

It is of some consequence that the anodic transfer coefficients, β, for reactions [2] and [4] do not differ significantly from 0.5, despite the high current densities of up to 1 A cm^{-2} which emanate from the scratched surface (see Fig. 1-5). It is possible that the exchange current densities for these reactions are high and the anodic Tafel regions shown in Fig. 1-5 for the scratched surfaces do not represent very high overpotentials [in agreement with the conclusions of Andersen *et al.* (4)].

While some difference in ohmic potential drop occurs between borate and bicarbonate electrolytes of similar pH, this difference is insufficient to account quantitatively for the extension of the linear Tafel range by bicarbonate, as shown in Fig. 5. Bicarbonate does not affect the rate of bare surface reaction, but does appear to hold the surface bare for a longer period of time. In another paper we have shown (23) that HCO_3^- forms soluble complexes with Fe(II) and thus strongly affects the steady-state anodic dissolution and passivation of Fe. The effects in the scratching experiments are probably to accelerate the oxidation of FeOH to dissolved Fe(II), thereby allowing more charge to flow before the surface becomes covered by FeOH. Other anions may affect the actual bare surface reaction itself (*e.g.*, chloride) and these are presented in another paper (24).

It has been shown that rapid scratching of electrodes under potentiostatic control enables fast steps in electrode reactions to be elucidated. Whereas potentiostatic pulse experiments also measure fast reaction steps, the case of the anodic behavior of Fe could not be revealed by pulse measurements since cathodization of the metal prior to the anodic pulse either produces hydrogen which can then be oxidized, or does not reduce the FeOH layer. Further, potentiostatic pulse experiments are particularly susceptible to impurities adsorbed on the electrode surface. In scratching experiments trace impurities from the electrolyte are not important, and those arising from preparation of the metal surface are scratched away. It has been suggested earlier (4) from open-circuit scraping experiments on some metals that inhibiting films or layers of molecules occur on active metals like Fe, such that the slow step in the metal oxidation reaction in aqueous solution is not the transfer of an ion into solution from the bare metal surface. The present results confirm the existence of such a film (FeOH) on Fe and demonstrate the suitability of the scratching technique to elucidate the kinetics of its formation.

Conclusions

1. The scratching of metals under potentiostatic control can reveal the presence of intermediates in electrode reactions, and elucidate the kinetics of fast electron transfer processes.

2. Anodic and cathodic reactions on Fe are greatly accelerated when the metal is scratched to remove surface films.

3. The kinetics of the first oxidative step in the anodic dissolution and passivation of Fe over the pH range 0-14 follows Tafel's law with a single electron transfer. For pH <7 reaction [2] occurs, and the process is independent of pH. For pH > 7 the reaction occurs by Eq. [3] and [4], with first-order kinetics in OH^- in the pH range 7-11.7 and zero order for pH > 11.7.

4. The formation of FeOH by reactions [2], [3], and [4] occurs at potentials below the thermodynamic reversible potentials for equilibrium film formation. The FeOH layer is an intermediate in the anodic dissolution and passivation of Fe and is also an intermediate in the cathodic reduction of H^+ and Fe^{2+} from solution, since it exists at potentials where each of these processes can occur.

5. Deviation from linear Tafel behavior in the anodic bare surface polarization curve results from rapid partial repassivation or from the ohmic potential drop in the electrolyte.

Use of Activity Coefficients to Calculate the Equilibrium Conditions within a Localized Corrosion Cell on Iron

E. McCafferty*

Naval Research Laboratory, Washington, D.C. 20375

ABSTRACT

The equilibrium electrochemical conditions within a localized corrosion cell on iron have been calculated using activity coefficients to take into account the high ionic concentrations which occur within the occluded corrosion cell. The calculations utilize Pourbaix's model that the stable solid phases within a corrosion pit, crevice, or stress-corrosion crack are Fe, Fe_3O_4, and $FeCl_2 \cdot 4H_2O$. The calculated equilibrium conditions are: $E = -0.385V$ *vs.* NHE, pH $= 5.2$, $[Fe^{++}] = 4.5$ moles/liter, and $[Cl^-] = 9.0$ moles/liter. If the occluded corrosion cell is limited to atmospheric pressure conditions, the internal conditions are calculated to be: $E = -0.281V$ *vs.* NHE, pH $= 4.8$, $[Fe^{++}] = 4.5$ moles/liter, and $[Cl^-] = 9.0$ moles/liter. With both sets of results, the internal pH is only slightly higher and the electrode potential slightly more negative than in the original Pourbaix calculations. Thus, the calculated results support the basic ideas first proposed by Pourbaix.

Pitting, crevice corrosion, stress-corrosion cracking, and other forms of localized corrosion all develop a local electrolyte of different chemical composition than the bulk solution. These compositional differences, including changes in local pH, arise due to a limited mass transport from the "occluded corrosion cell" (1).

A guide as to the equilibrium conditions within such "occluded corrosion cells" for iron has been given by the thermodynamic calculations of Pourbaix (2). Pourbaix has suggested that the internal electrolyte within an occluded corrosion cell on iron is highly concen-

* Electrochemical Society Active Member.
Key words: iron, localized corrosion, thermodynamics, activity coefficients.

trated in both Fe^{++} and Cl^- ions. The proposed solid phases are $FeCl_2 \cdot 4H_2O$ and Fe_3O_4, existing as deposits on the iron substrate. Based on thermodynamic data, and as a first approximation, Pourbaix has calculated the equilibrium conditions within localized corrosion cells involving iron to be

$$\left.\begin{aligned} E &= -0.368\text{V } vs. \text{ NHE} \\ pH &= 4.80 \\ [Cl^-] &= 556 \text{ moles/liter} \\ [Fe^{++}] &= 278 \text{ moles/liter} \end{aligned}\right\} \quad [1]$$

These calculations predict concentrations of Fe^{++} and Cl^- which are enormously high and far in excess of the solubility (4.5 moles/liter) of ferrous chloride. This particular result seems to be generally overlooked. This is probably because of the agreement between calculated and experimental values of E and pH, as has been reported for a number of different types and instances of localized corrosion of iron (3-9), see Table I. Nevertheless, the calculated equilibrium values of internal E and local pH are directly related to the concentrations of Fe^{++} and Cl^-. In the strictest sense then, an overestimation of the concentrations of Fe^{++} and Cl^- must impart some error to the calculation of the local pH and internal electrode potential.

Pourbaix has suggested that the high calculated values of Fe^{++} and Cl^- arise from the failure of dilute solution approximations to hold in more concentrated solutions. The purpose of this communication is to recalculate the equilibrium conditions for occluded corrosion cells on iron making two modifications. The first is the use of activity coefficients in the treatment of the concentrated electrolyte. Secondly, account is taken that one of the solid phases is $FeCl_2 \cdot 4H_2O$ rather than the anhydrous salt. Pourbaix's calculations have utilized thermodynamic data for the anhydrous salt $FeCl_2$ rather than for the hydrate $FeCl_2 \cdot 4H_2O$.

When these modifications are made, the resulting calculated values of $[Fe^{++}]$ and $[Cl^-]$ are those of an aqueous solution saturated in ferrous chloride. The revised calculated pH value is slightly higher, and the revised calculated electrode potential slightly more negative than the Pourbaix results. However, the present calculations support the basic features of the model as proposed by Pourbaix.

In addition, calculations are also made assuming that the surface oxide formed within the localized cell, rather than being magnetite, is each of the following: $Fe(OH)_2$, α-FeOOH, γ-FeOOH, α-Fe_2O_3, or γ-Fe_2O_3.

Analysis and Calculations

Pourbaix's model.—When there is a lack of oxygen, as within occluded corrosion cells (10, 11), the overall iron dissolution reaction is

$$Fe \rightleftharpoons Fe^{++} + 2e^- \quad [2]$$

The preponderance of ferrous ions (rather than ferric ions) within occluded corrosion cells on iron has been demonstrated for crevice corrosion by several investigators (5, 12, 13) and for stress-corrosion cracking by Brown and co-workers (8). At equilibrium, Eq. [2] is described by

$$E = E^\circ + \frac{2.303\, RT}{2F} \log a_{Fe^{++}}$$

or

$$E = -0.440 + 0.0295 \log a_{Fe^{++}} \quad [3]$$

Ferrous ions then hydrolyze with acidification, according to several possible reactions (12, 14)

$$Fe^{++} + H_2O \rightleftharpoons FeOH^+ + H^+ \quad [4]$$

$$Fe^{++} + 2H_2O \rightleftharpoons Fe(OH)_2 + 2H^+ \quad [5]$$

$$3Fe^{++} + 4H_2O \rightleftharpoons Fe_3O_4 + 8H^+ + 2e^- \quad [6]$$

In the absence of oxygen, the thermodynamically favored corrosion product is Fe_3O_4 (14, 15). The presence of magnetite has been observed experimentally in several studies which simulated occluded cell corrosion through the use of scaled-up macro-facsimile cells (14, 16, 17). In addition, the corrosion products within crevices on 304 stainless steel in seawater were found to be black with no indication of red rust (12). For Eq. [6]

$$E = 0.980 + 0.2364 \log a_{H^+} - 0.0886 \log a_{Fe^{++}} - 0.1182 \log a_{H_2O} \quad [7]$$

It should be noted that the term in a_{H_2O} is necessary for concentrated solutions, although this term vanishes for dilute solutions, where the activity of water is unity.

With the buildup of Fe^{++} and H^+ ions within the confined local electrolyte, Cl^- ions migrate into the occluded cell to preserve charge neutrality. That is, $\Sigma c_i z_i = 0$, or in terms of molalities

$$2m_{Fe^{++}} + m_{H^+} = m_{Cl^-} \quad [8]$$

The resulting increased local concentration of ferrous chloride is limited by the reaction

$$Fe^{++}{}_{(aq)} + 2Cl^-{}_{(aq)} + 4H_2O_{(l)} \rightleftharpoons FeCl_2 \cdot 4H_2O_{(s)} \quad [9]$$

The solid phase in equilibrium with a bulk saturated solution of ferrous chloride at 25°C is the hydrate $FeCl_2 \cdot 4H_2O$ (18). The existence of this solid phase within the confined local electrolyte, as proposed by Pourbaix, has been verified by the macro-facsimile cell studies of Fujii (17) and Sathler and Van Muylder (14).

Equilibrium calculations.—The need for using ion activities rather than concentrations is seen in Fig. 1, which shows activity coefficients for aqueous solutions of the transition metal chlorides (19-21). As seen in Fig. 1, the mean molal activity coefficient for ferrous chloride is greater than unity for concentrations above 2.5m.

For the ferrous chloride 2:1 electrolyte

$$a = a_{Fe^{++}} a_{Cl^-}{}^2 = a_\pm{}^3 \quad [10]$$

The relationship between the ionic activities and activity coefficients is $a_{Fe^{++}} = \gamma_+ m_{Fe^{++}} = \gamma_+ m$, and $a_{Cl^-} = \gamma_- m_{Cl^-} = 2\gamma_- m$, where m is the molal concentration of ferrous chloride. Thus

$$a_\pm{}^3 = 4m^3\gamma_+\gamma_-{}^2$$

or

$$a_\pm{}^3 = 4(m\gamma_\pm)^3 \quad [11]$$

where $\gamma_\pm$ is the mean molal activity coefficient for the 2:1 electrolyte and is given by $\gamma_\pm{}^3 = \gamma_+\gamma_-{}^2$.

The equilibrium constant for Eq. [9] is

$$K_{eq} = \frac{1}{a_{Fe^{++}} a_{Cl^-}{}^2 a_{H_2O}{}^4} \quad [12]$$

with

$$\Delta G^\circ = -2.303\, RT \log K_{eq} \quad [13]$$

where

$$\Delta G^\circ = \Delta G^\circ_f(FeCl_2 \cdot 4H_2O_{(s)}) - \Delta G^\circ_f(Fe^{++}{}_{(aq)}) - 2\Delta G^\circ_f(Cl^-{}_{(aq)}) - 4\Delta G^\circ_f(H_2O_{(l)}) \quad [14]$$

where ΔG°_f (i) is the standard free energy of formation (per mole) of the ith ion or compound. Using the appropriate values listed in Table II, Eq. [12]-[14] combine to give

$$\frac{1}{a_{Fe^{++}} a_{Cl^-}{}^2 a_{H_2O}{}^4} = 10^{-3.0521} \quad [15]$$

Equations [3], [7], and [15] combine to give

$$a_{H^+} = (2.370 \times 10^{-6}) \ (a_{Fe^{++}})^{0.375} (a_{Cl^-})^{-0.250} \quad [16]$$

Using Eq. [16] and the definition of single-ion activity coefficients in Eq. [8] gives

$$2a_{Fe^{++}} \left\{ \frac{1}{\gamma_{Fe^{++}}} + \frac{1}{\gamma_{H^+}} [(1.185 \times 10^{-6})(a_{Fe^{++}})^{-0.625}(a_{Cl^-})^{-0.250}] \right\} = \frac{a_{Cl^-}}{\gamma_{Cl^-}} \quad [17]$$

As is well known, individual ionic activity coefficients cannot be measured but can be calculated at low concentrations. Recently Bates and co-workers (23, 24) have derived a method for calculating individual ionic coefficients in concentrated solutions. Their results for a variety of chlorides suggest that as a first approximation, the order of activity coefficient for Fe^{++} and H^+ can be taken to be the same. That is, $O(\gamma_{Fe^{++}}) = O(\gamma_{H^+})$. Also

Table II. Standard free energies of formation at 25°C

Species	ΔG°_f (kcal/mole)	Source
$Fe^{++}{}_{(aq.)}$	−20.30	Pourbaix (22)
$Cl^-{}_{(aq.)}$	−31.35	Pourbaix (22)
$H_2O_{(l)}$	−56.690	Pourbaix (22)
$FeCl_2 \cdot 4H_2O_{(s)}$	−305.6	Susarev *et al.* (21)
$Fe(OH)_{2(s)}$	−116.3	Wagman *et al.* (28)
α-$Fe_2O_{3(s)}$	−177.4	Pourbaix (30)
γ-$Fe_2O_{3(s)}$	−169.466	Pourbaix (30)

$$1 >> (1.185 \times 10^{-6}) \ (a_{Fe^{++}})^{-0.625} (a_{Cl^-})^{-0.250}$$

so that Eq. [17] reduces to

$$2\frac{a_{Fe^{++}}}{\gamma_{Fe^{++}}} \cong \frac{a_{Cl^-}}{\gamma_{Cl^-}} \quad [18]$$

or, $2m_{Fe^{++}} \cong m_{Cl^-}$. Thus, the electrolyte in the occluded corrosion cell is essentially ferrous chloride (with lesser amounts of hydrogen ion).

The factor $a_{Fe^{++}} a_{Cl^-}{}^{2}$ in Eq. [15] can thus be replaced by $a_\pm{}^3$, the mean molal activity of ferrous chloride. The activity of water in aqueous ferrous chloride solutions has been determined from vapor pressure measurements (20, 21). The water activity varies from unity for the dilute electrolyte to 0.59 for saturated ferrous chloride. The water activity is shown in Fig. 2 as a function of the mean activity $a_\pm$ of the electrolyte. For concentrations of ferrous chloride greater than 2m, the following empirical least squares relationship holds

$$a_{H_2O} = -0.2977 \log a_\pm + 0.9863 \quad [19]$$

Equations [15], [10], and [19] combine to give

$$f(a_\pm) = a_\pm{}^3[-0.2977 \log (a_\pm) + 0.9863]^4 = 1127 \quad [20]$$

Equation [20] can be solved graphically for $a_\pm$. From Fig. 3, the solution is $a_\pm = 20.8$. Use of this value in Eq. [11] gives $m\gamma_\pm = 13.11$. Figure 4 shows Fig. 1 replotted as $m\gamma_\pm$ *vs.* m for ferrous chloride. The product $m\gamma_\pm = 13.11$ corresponds to a ferrous chloride concentration of 5.15m (and to $\gamma_\pm = 2.55$). From the density data of Ionen and Kozhakova (25), a 5.15m solution of ferrous chloride corresponds to a molal concentration of 4.5 moles/liter.

To calculate the electrode potential and pH using Eq. [3] and [16], it is first necessary to calculate single ion activities for the Fe^{++} and Cl^- ions. As noted earlier, Bates and co-workers (23, 24) have developed a method for calculating individual ionic activities in concentrated solutions. Their method is based on the Stokes and Robinson (26) hydration theory for calculating mean activity coefficients in concentrated solutions. According to Stokes and Robinson

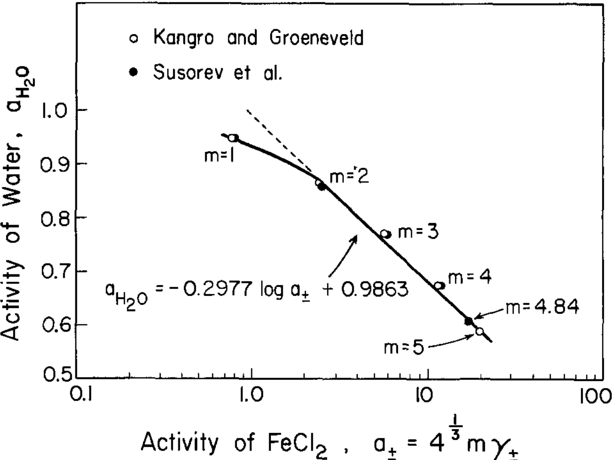

Fig. 2. Activity of water in ferrous chloride solutions

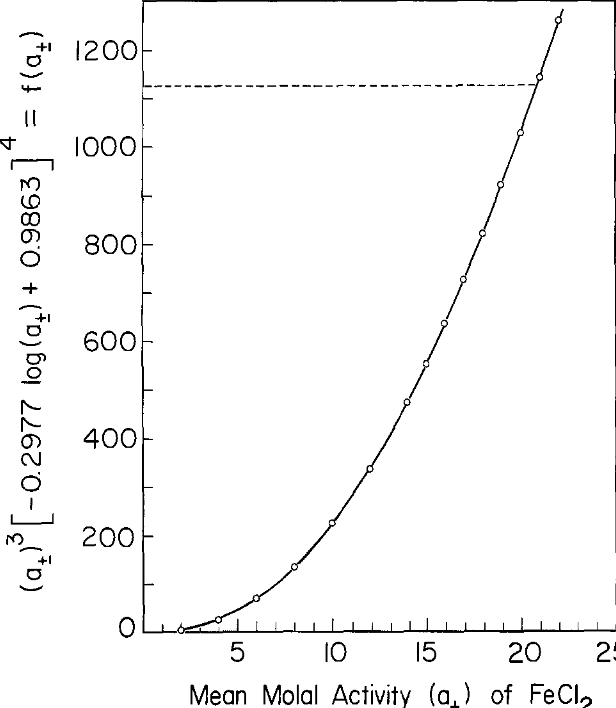

Fig. 3. Graphical solution of Eq. [20]. The solution to $f(a_\pm) = 1127$ is: $a_\pm = 20.8$.

$$\log \gamma_\pm = -\frac{0.5092|z_1z_2|\sqrt{\mu}}{1 + 0.3286\,\overset{\circ}{a}\sqrt{\mu}} - \frac{h}{\nu}\log a_{H_2O} - \log\left[1 - 0.018(h - \nu)m\right] \quad [21]$$

where z_1 and z_2 are the valencies, μ the ionic strength in molality units, ν the number of ions per molecule (3 for $FeCl_2$), and $\overset{\circ}{a}$ and h are two adjustable parameters related to the ion size and hydration, respectively. Using $\overset{\circ}{a} = 4.8$ and $h = 12$ for $FeCl_2$, Stokes and Robinson obtained good agreement between calculated and measured values of $\gamma_\pm$ for concentrations up to about 2m. As noted by these authors, at higher concentrations the "hydration number" h must decrease due to increased competition between neighboring ions for available water molecules. Figure 5 shows the concentration dependence of h which enables Eq. [21] to hold over the entire concentration range for $FeCl_2$ solutions.

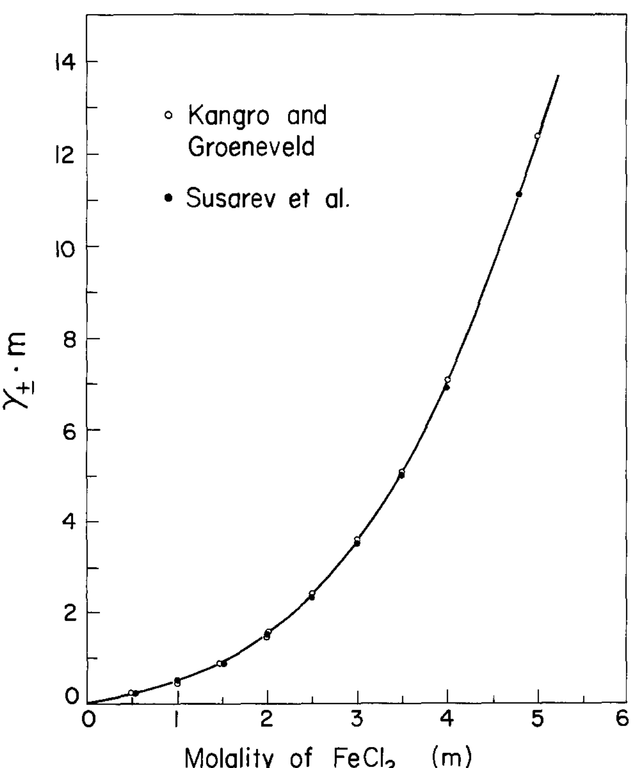

Fig. 4. Data in Fig. 1 for $FeCl_2$ replotted as $m\gamma_\pm$ vs. m

Assuming that $h = 0$ for the chloride ion, Bates and co-workers developed the following equations for a bi-univalent electrolyte, such as ferrous chloride

$$\log \gamma_{M^{2+}} = 2\log\gamma_\pm - \frac{h}{3}\log a_{H_2O} + \log\left[1 + 0.018(3 - h)m\right] \quad [22]$$

$$2\log\gamma_{Cl^-} = \log\gamma_\pm + \frac{h}{3}\log a_{H_2O} - \log\left[1 + 0.018(3 - h)m\right] \quad [23]$$

The solution to Eq. [20], as cited earlier, is: $a_\pm = 20.8$, $m = 5.15$, and $\gamma_\pm = 2.55$. From Fig. 5, the Stokes and Robinson hydration number corresponding to $m = 5.15$ is $h = 8.5$. From Eq. [15] or Eq. [19], $a_{H_2O} = 0.594$. Using these data in Eq. [22] and [23] gives: $\gamma_{Fe^{++}} = 13.941$ and $\gamma_{Cl^-} = 1.091$. Also, $a_{Fe^{++}} = m\,\gamma_{Fe^{++}}$ and $a_{Cl^-} = 2m\gamma_{Cl^-}$ yields: $a_{Fe^{++}} = 71.80$ and $a_{Cl^-} = 11.24$. Use of these activities in Eq. [16] and [3] gives the pH of the occluded corrosion cell as 5.2 and the electrode potential as -0.385V *vs.* NHE.

The calculated results for the occluded corrosion cell on iron are summarized in Table III. Comparison of these calculated results with Eq. [1] shows that the calculated value of the internal pH is slightly higher than the Pourbaix result (5.2 compared to 4.8). Also, the calculated electrode potential is slightly more negative (-0.385 compared to -0.368). However, the present calculations predict more realistic concentrations of dissolved Fe^{++} and Cl^- ions.

These calculated results apply to equilibrium and not to those stages of localized corrosion when there are concentration gradients within or ionic migration across the crevice, crack, or pit. Thus, these calculations describe the localized cell at times beyond the initiation stage and well into the propagation stage. For the crevice corrosion of iron and steels for example, the observation of constant internal electrode potentials with time (6, 10, 27) is an indication of the approach to the steady state.

Atmospheric pressure model.—Figure 6 illustrates the equilibria considered in the previous section. The diagram is essentially the same as that given earlier by Pourbaix (2). The only difference is that Fig. 6 is based on the present results: $a_{Fe^{++}} = 71.80$ and $a_{H_2O} = 0.594$. The equilibrium conditions (as calculated above) lie below the "a" line for hydrogen

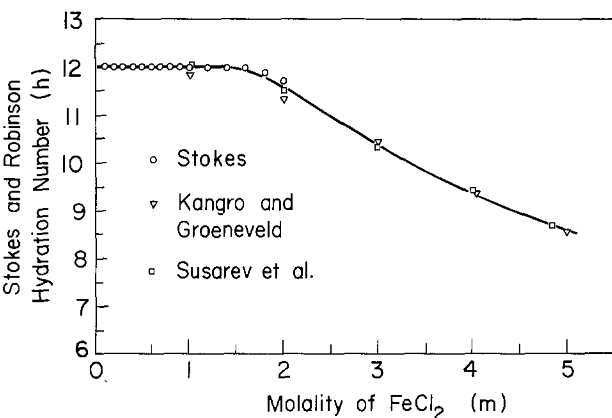

Fig. 5. Calculated values for the Stokes and Robinson hydration number h for aqueous solutions of $FeCl_2$. (Sources of experimental data used in Eq. [21] are indicated on the figure.)

Table III. Summary of calculated and experimental results for the occluded corrosion cell on iron

	Equilibrium model	Atmospheric pressure model			
		Calculations		Experimental	
	Present calculations	Present results	Pourbaix (2)	Fujii (17)	Sathler and Van Muylder (14)
E vs. NHE	−0.385	−0.281	−0.254	−0.332	−0.330
pH	5.2	4.8	4.3	3.8	3.8
$[Fe^{++}]$	4.5 moles/liter	4.5 moles/liter	276 moles/liter	4.2 moles/liter	4.6 moles/liter
$[Cl^-]$	9.0 moles/liter	9.0 moles/liter	552 moles/liter	8.4 moles/liter	9.2 moles/liter

evolution

$$2H^+ + 2e^- \rightleftharpoons H_2$$

Thus, hydrogen evolution can occur within the occluded corrosion cell, and at equilibrium, the pressure of hydrogen given by

$$E = 0.000 - 0.0591\,pH - 0.02955 \log p_{H_2} \quad [24]$$

is $p_{H_2} = 400$ atm for the conditions $E = -0.385V$ and $pH = 5.2$.

If the pressure of hydrogen gas within the occluded corrosion cell is restricted to 1 atm, then the equilibrium conditions are given by the intersection of line 26 with line "a" rather than with line 23. That is, simultaneous solution of Eq. [7], [8], [15], and [24] ($p_{H_2} = 1$ atm) gives the results: $E = -0.281V$ vs. NHE, $pH = 4.8$, and the concentration of ferrous chloride equals 4.5 moles/liter. These results are summarized in Table III, which also lists the experimental results from the macro-facsimile cell studies of Fujii (17) and Sathler and Van Muylder (14).

Calculations based on $Fe(OH)_2$.—The above calculations assume that the thermodynamically favored oxide (Fe_3O_4) is formed on the iron surface within the localized corrosion cell. If instead, the formation of $Fe(OH)_2$ is considered, as in Eq. [5], then

$$\frac{a_{H^+}{}^2}{a_{Fe^{++}} a_{H_2O}{}^2} = K_5 \quad [25]$$

From the free energy of formation data listed in Table II, K_5 is calculated to be 1.774×10^{-13}. Equations [25], [3], [8], and [15], in conjunction with the single-ion activity coefficient calculations in Eq. [22] and [23] give the results: $pH = 5.7$, $E = -0.385V$ vs. NHE, $[Fe^{++}] = 4.5$ moles/liter, and $[Cl^-] = 9.0$ moles/liter.

Calculations based on ferric oxyhydroxides or oxides.—It is well known that corrosion products formed in natural environments contain oxyhydroxides, usually α-FeOOH or γ-FeOOH (29). Although occluded corrosion cells are low in oxygen content, the formation of hydrated ferric oxides might occur through the hydrolysis reactions

$$Fe^{++} + 2H_2O \rightleftharpoons \alpha\text{-}FeOOH + 3H^+ + e^- \quad [26]$$

or

$$Fe^{++} + 2H_2O \rightleftharpoons \gamma\text{-}FeOOH + 3H^+ + e^- \quad [27]$$

In each case

$$E = E^\circ + 0.1773 \log a_{H^+} - 0.0591 \log a_{Fe^{++}} - 0.1182 \log a_{H_2O} \quad [28]$$

where $E^\circ = 0.655$ for α-FeOOH and 0.919 for γ-FeOOH (29). Solution of Eq. [28], [3], [8], and [15] again using the Bates single-ion activity coefficients gives: $pH = 5.4$ for α-FeOOH and 6.9 for γ-FeOOH. For both cases, $E = -0.385V$ vs. NHE, $[Fe^{++}] = 4.5$ moles/liter, and $[Cl^-] = 9.0$ moles/liter.

If the ferric oxides are not hydrated

$$2Fe^{++} + 3H_2O \rightleftharpoons \alpha\text{-}Fe_2O_3 + 6H^+ + 2e^- \quad [29]$$

or

$$2Fe^{++} + 3H_2O \rightleftharpoons \gamma\text{-}Fe_2O_3 + 6H^+ + 2e^- \quad [30]$$

then

$$E = E^\circ + 0.1773 \log a_{H^+} - 0.0591 \log a_{Fe^{++}} - 0.08865 \log a_{H_2O} \quad [31]$$

Based on the free energies of formation listed in Table II, $E^\circ = 0.721$ for α-Fe_2O_3 and 0.893 for γ-Fe_2O_3. With Eq. [31] in place of Eq. [28], the pH within the occluded corrosion cell is calculated to be 5.7 based on an α-Fe_2O_3 layer and 6.7 based on a γ-Fe_2O_3 layer. For both cases, the calculated electrode potential is $-0.385V$ vs. NHE with $[Fe^{++}] = 4.5$ moles/liter and $[Cl^-] = 9.0$ moles/liter.

Discussion

The available experimental evidence indicates that magnetite is the stable oxide phase formed within localized corrosion cells on iron. The occurrence of magnetite was shown by Sathler and Van Muylder in their macrofacsimile cell studies (14). Moreover, if it is assumed that the stable oxide phase is ferrous hydroxide or one of the ferric oxides or oxyhydroxides (instead of magnetite), then the calculated pH's are substantially higher than those observed in various experimental studies (3-9) or in the scaled up macrofacsimile cells (14,17).

Table III summarizes the present calculations based on the Pourbaix model of a magnetite-covered iron surface in contact with a concentrated solution of acidified ferrous chloride. Results are given for both

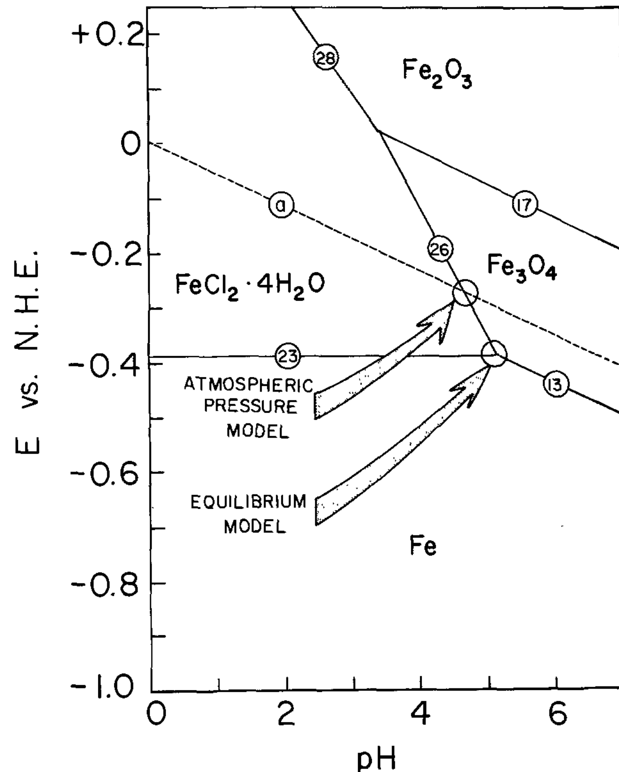

Fig. 6. Equilibrium diagram for an occluded corrosion cell on iron. After Pourbaix (2). The encircled numbers correspond to reactions given in Ref. (22).

the equilibrium model and for the case where the localized cell is maintained under 1 atm pressure of hydrogen gas. In both instances, the calculated local pH is slightly higher and the calculated internal potential slightly more negative than in the original Pourbaix calculations. But these are minor differences; the main difference is in the results for the concentrations of Fe^{++} and Cl^-.

Table III also gives the experimental results from the macro-facsimile cell studies of Fujii (17) and Sathler and Van Muylder (14). Fujii immersed an iron electrode in a simulated pit consisting of a deaerated saturated solution of $FeCl_2$ mixed with excess $FeCl_2 \cdot 4H_2O$, magnetite, and powdered iron. Sathler and Van Muylder used a deaerated saturated solution of $FeCl_2 \cdot 4H_2O$, which also contained iron powder. Table III shows that the electrode potential of iron in these synthetic occluded corrosion cells is closer to the present results than to Pourbaix's calculated value. The reverse is true with the pH comparisons.

The present calculations also predict that the internal electrolyte is saturated in ferrous chloride. A direct comparison with the concentrations of Fe^{++} and Cl^- in the experimental macro-cells cannot be made, of course, because the macro-cell electrolytes were intentionally made up to saturation in these two ions. However, recent studies on the solution chemistry within corrosion pits on stainless steels have established that the local electrolytes are concentrated in both Fe^{++} and Cl^- ions. Chloride concentrations of 3-6*N* (4) and 3-12*N* (31) have been reported. Ferrous ion concentrations of 2-4*N* have been observed, accompanied by Cr^{+++} concentrations of about 1*N* (4). Although these studies were made on stainless steels, rather than on pure iron, the evidence is that the local electrolyte is concentrated in the metallic cation and in chloride ion, as predicted by Pourbaix and supported by the present calculations.

It should be emphasized that the present calculations apply to localized corrosion processes on pure unalloyed iron. Various experimental studies have shown that the internal pH is much lower for the localized corrosion of stainless steels, due to the hydrolysis of certain alloying elements, especially Cr^{+++} (4, 5, 12).

Summary

1. The equilibrium electrochemical conditions within a localized corrosion cell on pure iron have been calculated using the thermodynamics of concentrated aqueous solutions.

2. The internal pH is calculated to be between 4.8 and 5.2, and the electrode potential of internal iron to be between -0.280 and -0.385V *vs.* NHE. (Both pH and *E* depend on the pressure of hydrogen within the occluded cell.)

3. The composition of the internal electrolyte is calculated to be saturated in $FeCl_2$; *i.e.*, 4.5 moles/liter Fe^{++} and 9.0 moles/liter Cl^-.

4. The calculated internal pH is slightly higher and the electrode potential slightly more negative than in the original Pourbaix calculations. In general, the present calculations support the Pourbaix model of the iron occluded corrosion cell.

Effect of Plating Parameters on Electrodeposited NiFe

Jean Horkans*

IBM, Thomas J. Watson Research Center, Yorktown Heights, New York 10562

ABSTRACT

Films of NiFe alloys were deposited under galvanostatic conditions from solutions containing no stress-relieving additives and no surfactants. The composition of the films and the deposition efficiency were determined as a function of current density, pH, the identity of the anion (SO_4^{2-} or Cl^-), and the boric acid content of the solution. The Fe content is lower in deposits from chloride solution than from sulfate solution and is increased by the addition of H_3BO_3. The efficiency increases with increasing current density and increasing pH, is higher in deposits from chloride solution, and is little affected by H_3BO_3. The observations are interpreted in terms of suppression of Ni deposition by a surface iron hydroxide precipitated when the local surface pH rises during deposition. The way in which the solution components and conditions of deposition influence the formation of this hydroxide determines their effect on deposit properties. Increasing current density causes greater hydroxide precipitation and thus increases the Fe content of the film up to the point where ionic diffusion in the hydroxide limits the rate of Fe deposition. Chloride ion forms a weak complex with Fe^{2+} and thereby limits hydroxide formation, lowering the percentage Fe in the deposits. Boric acid has its greatest effect under conditions where hydroxide formation is most extensive. It does not act as a buffer, but apparently adsorbs on the hydroxide-covered surface.

The composition and properties of electrodeposited NiFe alloys are known (1) to be highly dependent on the composition of the solution from which they are plated and the conditions of deposition. Variables which are significant in the deposition process include mass transport conditions, current density, temperature, and variation in concentration of all of the solution components (including pH). A large number of deposit properties, including composition, magnetic properties, and metallurgical properties, depend on these plating variables, but the interdependence is not yet well understood.

Strong evidence exists that the simultaneous evolution of H_2 during deposition is a dominant factor in determining the composition and properties of NiFe alloys. This is a system which displays the phenomenon of anomalous codeposition (2), *i.e.*, the less noble metal, Fe, appears at unexpectedly high concentration in the deposit. Although several explanations of this phenomenon exist [see, *e.g.*, (3)], the one which is most consistent with the observations is the model of Dahms and Croll (4, 5). These authors note that H_2 evolution during deposition will cause a local pH rise near the electrode surface. This surface elevation in pH has been measured for Ni deposition (6) and deposition of NiFe (7). Dahms and Croll hypothesize that the high local pH can cause precipitation of $Fe(OH)_2$ on the electrode surface. Such hydroxide precipitation has been shown (4) to impede the discharge of other metal ions, and thus suppresses the rate of Ni deposition in the alloy.

A recent paper (8) from this laboratory reported on an investigation of the role in NiFe deposition of two important factors, the nature of the anion and the presence of boric acid, H_3BO_3, in solution. Boric acid was investigated because of its common use in Ni and NiFe plating. There is a persistent lore [*e.g.*, (9)] that H_3BO_3 serves as a buffer to oppose the pH rise caused by H_2 evolution. Because H_2 evolution plays such an important role in NiFe deposition, the influence of these two solution components on H^+ reduction from solutions containing no Ni^{2+} or Fe^{2+} was also studied. The nature of the anion influences both metal discharge and H_2 evolution. It was found that limiting currents for H^+ reduction were lower in NaCl solutions than in Na_2SO_4 solutions at the same pH; this was attributed to different diffusion coefficients for H^+ in the two solutions. Overpotentials for reduction of Ni^{2+} and Fe^{2+} are lower in Cl^- than SO_4^{2-} solution, probably due to catalysis through a Cl^- bridge between the electrode and the metal ion. Boric acid was shown not to have a significant buffering effect either during H_2 evolution from NaCl and Na_2SO_4 solutions or during metal deposition. While having little effect on the current-potential behavior in Ni^{2+} and Fe^{2+} solution, it greatly influences the appearance of the deposit. It was proposed that H_3BO_3 influences deposition through adsorption on the electrode surface.

The present work expands on the earlier investigation. The composition of NiFe films and the efficiency of deposition have been measured as a function of current density, pH, anion (SO_4^{2-} or Cl^-), and the presence of H_3BO_3 in solution. The results are interpreted in terms of the theory of Dahms and Croll (4, 5).

Experimental

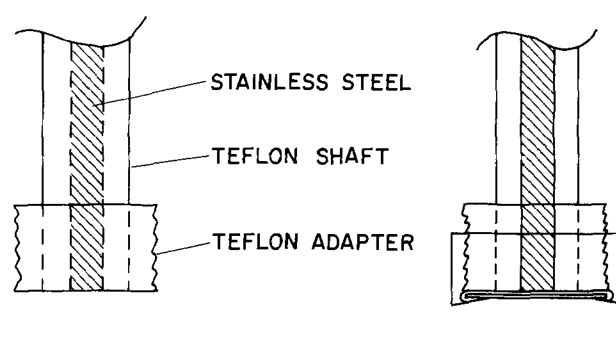
The NiFe films were deposited at constant current density under conditions of controlled mass transport (using a rotating disk electrode). The cathode was a 3.18 cm (1.25 in.) diam disk of Corning 0211 glass. On this was evaporated 200Å of Nb (as an adhesion layer) followed by 2000Å of Au. This wafer was contacted and mounted on the shaft of a Pine Instruments rotating disk in the manner shown in Fig. 1. A strip of Au foil was wrapped around the wafer to contact the edge of the evaporated film. The foil on the back side was pressed against the stainless steel disk by a Teflon holder, which also served to mask the contact from the solution. The exposed area of the cathode was 2.91 cm^2.

The hydrodynamic characteristics of this rotating disk assembly were compared with those of a 0.7 cm diam Ni disk in a straight Teflon cylinder (*i.e.*, a disk not modified by the wafer holder). Limiting currents on an Ni electrode were measured in alkaline ferrocyanide-ferricyanide solution. Ferrocyanide oxidation in both cases showed a dependence of limiting current on the square root of rotation rate which is linear and extrapolates through (0, 0). The results were the same within experimental error for the two electrodes.

Rotation rate was controlled with a Pine Instruments ASR speed control. The effect of mass transport was

* Electrochemical Society Active Member.

Key words: alloy, current efficiency, electrodeposition.



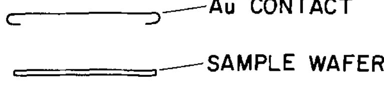


Fig. 1. Method of mounting a 1.25 in. diam wafer in the rotating disk assembly. Left side shows the components; right side shows the assembled system. All films in this study were deposited at 200 rpm.

not investigated. A single rotation speed of 200 rpm was used. This was found (10) to give approximately the same rate of mass transport to the surface as the paddle cell (11) used in this laboratory for NiFe deposition.

Solutions of eight different compositions were studied, as shown in Table I. The concentrations of Ni^{2+} and Fe^{2+} were kept constant at 0.50M and 0.01M, respectively; the metal salts were either sulfates or chlorides. Films were deposited from solutions containing either no H_3BO_3 or 0.40M H_3BO_3. Two pH values, 2.0 and 3.0, were investigated. In each of these solutions, films were deposited at 1, 2, 5, 10, and 20 mA/cm².

The current was controlled with an Electronic Measurements Model C621 constant current supply. A Koslow Model 541 coulometer was used to monitor the amount of charge passed during deposition. Knowledge of total charge allowed calculation of the current efficiency after analysis of the total deposited Ni and Fe. The NiFe films were dissolved from the substrate in a small amount of concentrated HNO_3, diluted to volume, and analyzed by atomic absorption spectroscopy.

Results

The film composition and deposition efficiency are shown in Table II and represented graphically in Fig. 2-5.

Composition.—The Fe content of the film goes through a maximum as a function of current density (Fig. 2 and 3). At pH 3.0 (Fig. 2), this maximum occurs between 2 and 5 mA/cm². There are not sufficient data in this current range to determine precisely the location of the peak; the apparent shifts in peak position in Fig. 2 may not be significant. At pH 2.0 (Fig. 3), the maximum occurs at higher current density and is broader than at pH 3.0. As at pH 3.0, the precise location of the peak at pH 2.0 is not known, but it is ~10 mA/cm².

Deposition from SO_4^{2-} solution results in a larger proportion of Fe in the film than deposition from Cl^-. This is true at both pH values and in the presence and absence of H_3BO_3.

The effect of H_3BO_3 on composition depends on pH. At pH 3.0, addition of H_3BO_3 leads to a large increase in Fe content of deposits from both SO_4^{2-} and Cl^-

Table I. Compositions of the solutions studied

solution. This effect also occurs in SO_4^{2-} solutions at pH 2.0, but it is less pronounced. In pH 2.0 Cl^- solutions, H_3BO_3 has little effect on composition.

The effect of pH on composition is complicated. At current densities above 10 mA/cm², (*i.e.*, above the current density of the peak Fe content at either pH), the Fe content is always appreciably higher in deposits from the pH 2.0 than from the pH 3.0 solution. Generally, however, the pH 3.0 solution gives the higher Fe content at lower current densities. (This is indeterminate for the SO_4^{2-} solution containing no H_3BO_3, since at pH 2.0, no deposit is obtained below 5 mA/cm².)

Efficiency.—The efficiency of deposition shows the expected increase with increasing current density and increasing pH (Fig. 4 and 5).

Deposition from Cl^- solution occurs with higher efficiency than deposition from SO_4^{2-} solution, the difference between the two being larger at pH 2.0. Deposits can be obtained from Cl^- solutions under conditions (low i, low pH) where no deposition occurs from SO_4^{2-} solutions.

The effect of H_3BO_3 on current efficiency is small. In pH 3.0 SO_4^{2-} or Cl^- solutions, the efficiency is nearly independent of H_3BO_3. In pH 2.0 solutions, the effect of H_3BO_3 varies with anion. Boric acid increases efficiency at 1 and 2 mA/cm² in SO_4^{2-} solutions, but has little effect at higher current densities. In Cl^- solutions, H_3BO_3 results in a small decrease in efficiency over the entire current range studied.

Appearance.—The appearance of the films also varies considerably with the conditions of deposition (Table II). The appearance tends to deteriorate with increasing current density, although in some solutions films of good appearance can be obtained over the entire range examined. Appearance is slightly better in deposits from Cl^- than in those from SO_4^{2-} solutions.

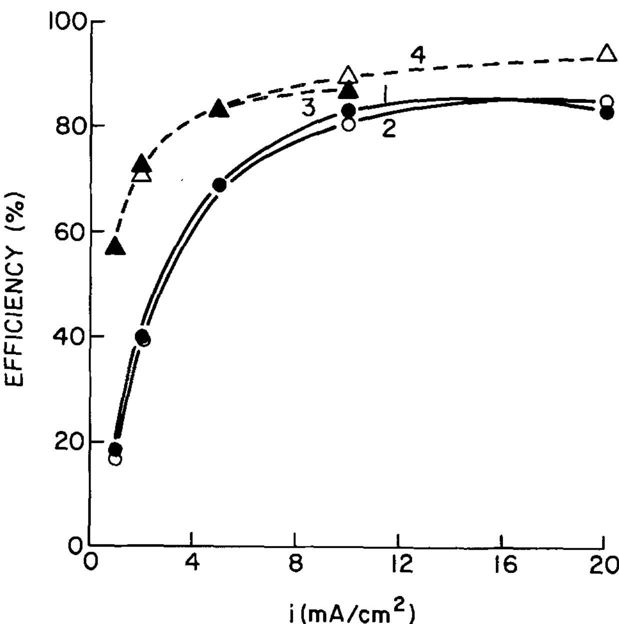

Fig. 4. Dependence of deposition efficiency on current density in various pH 3.0 solutions: 1, ●; 2, ○; 3, ▲; 4, △. Solution key is given in Table I.

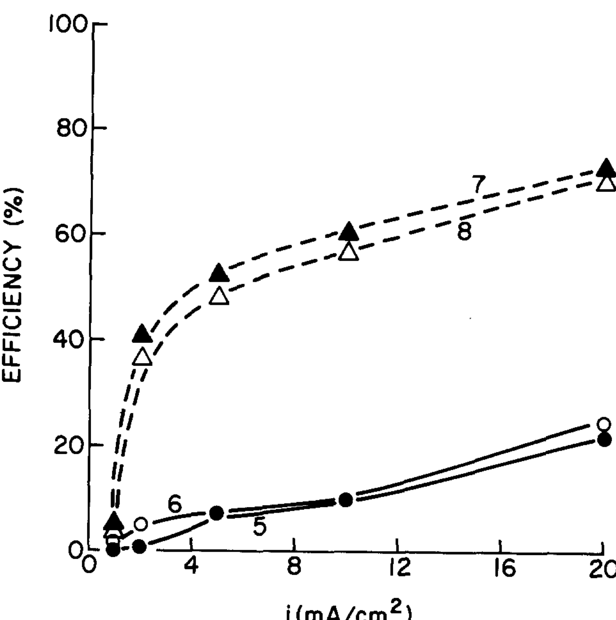

Fig. 5. Same as Fig. 4 for pH 2.0 solutions: 5, ●; 6, ○; 7, ▲; 8, △. Solution key is given in Table I.

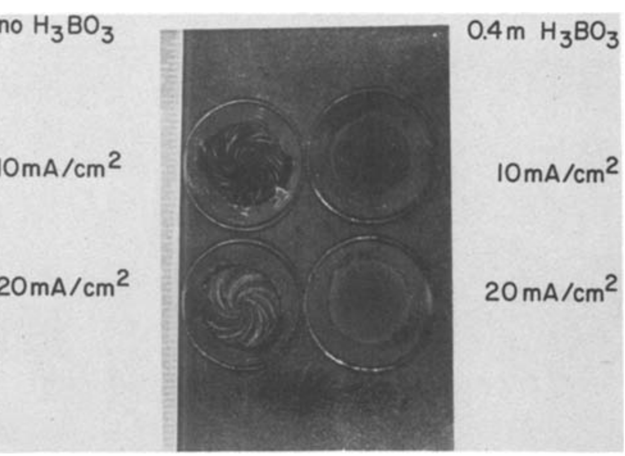

Fig. 6. Effect of H_3BO_3 on the appearance of NiFe deposited from 0.50M $NiCl_2$, 0.01M $FeCl_2$, pH 3.0, (solutions 3 and 4). Only the center portion of the wafer was exposed to the solution.

For a *p*H 3.0 solution containing no H_3BO_3, deposits at current densities of 5 mA/cm² or greater are dark to black and show spirals marking the pattern of solution flow over the surface of the electrode. The spirals are not seen at *p*H 2.0, but films obtained from the low *p*H solution tend to have pinholes or dark spots.

Addition of H_3BO_3 markedly improves the appearance of deposits from both SO_4^{2-} and Cl^- solution, at both *p*H values (the effect being stronger at *p*H 3.0), and at all currrent densities. A typical illustration is given in Fig. 6. The dark spirals occurring in the absence of H_3BO_3 are completely eliminated in its presence.

Discussion

All of the deposits, at all current densities examined and at both *p*H values, show the phenomenon of anomalous codeposition; the Fe content is unexpectedly high.[1] If the data are interpreted in terms of the theory of Dahms and Croll (4, 5), this result is consistent with observations (7) of measurable surface *p*H rises even at the lowest current densities used.

The maximum in percentage Fe *vs.* current density is related to the relative importance of mass transport control and activation control of the various species undergoing electroreduction reactions.[2] At low *i*, where the surface *p*H rise is small, little iron hydroxide forms and the Ni content of the film is relatively high. Increasing *i* results in a larger *p*H rise, and thus the Fe content of the film increases. Since at any given total current the surface *p*H is always lower in the *p*H 2.0 than in the *p*H 3.0 solution, the Fe content rises more slowly as a function of *i* at the lower *p*H. At higher current densities, the proportion of Fe in the film decreases. Examination of Table II shows that the partial Fe current at the peak is well below its diffusion-limiting current, and thus the decrease in percentage Fe with *i* is not due solely to mass transport limitation of Fe^{2+} in solution. The hypothesis that Fe(II) discharge takes place through the hydroxide leads to the conclusion that the decrease in percentage Fe at higher current densities is caused by rate limitation due to slow ionic diffusion in the $Fe(OH)_2$.

Two factors work together to cause a higher deposition efficiency in Cl^- than in SO_4^{2-} solution. The Cl^- ion catalyzes the discharge of the metal ion (8). However, the observed effects (especially at *p*H 2.0) are too large to be explained by this alone. The explanation must involve a difference in diffusivities of H^+ in the two solutions similar to that observed (8) in NaCl and Na_2SO_4 solutions. A lower H_2 limiting current in Cl^- than in SO_4^{2-} solution would result in the observed higher efficiency in the Cl^- solution.

The anion also markedly affects the Fe content of the deposits; the percentage Fe is smaller when depositing from Cl^- than from SO_4^{2-} solutions. This suggests that Cl^- ion hinders the formation of surface iron hydroxides through weak complexation of Fe^{2+} (13).

Boric acid, which has only small effects on the current-potential dependence of an Ni electrode in these solutions (8), nonetheless has a large effect on film composition. Its effects are not those predicted for a buffer. A buffer, by maintaining a low surface *p*H and providing a reservoir of readily available H^+ ions, would be expected to lead to a less anomalous deposit and to decrease the efficiency of the deposition process. Instead, the deposit is generally more anomalous (*i.e.*, the Fe content is higher) in films deposited from solutions containing H_3BO_3. Boric acid has a stronger effect on composition under conditions where the formation of surface iron hydroxides is more extensive, that is at higher *p*H and in SO_4^{2-} solutions. The H_3BO_3 molecule may adsorb more readily on the hydroxide covered surface than on the bare metal. The effects of H_3BO_3 on the efficiency of NiFe deposition are somewhat different than those on deposition of unalloyed Ni (8). In the case of Ni, addition of H_3BO_3 to *p*H 2.0 solutions causes a small increase in efficiency in SO_4^{2-} solutions and a larger efficiency increase for Cl^- solutions. The different effect of H_3BO_3 in Ni and NiFe systems is apparently due to an interaction of H_3BO_3 with surface iron hydroxide.

Boric acid is extremely important to the appearance of electrodeposited NiFe. It extends the current den-

[1] If the Fe:Ni ratio in the deposit were the same as the Fe^{2+}:Ni^{2+} ratio in solution, the film would contain <2% Fe.

[2] The limiting currents for Fe^{2+} reduction and H_2 evolution in this solution are not known but can be estimated from other work. Horkans (8) found that limiting currents for H^+ reduction were lower in NaCl solutions than in Na_2SO_4 solutions at the same *p*H; this was attributed to different diffusion coefficients for H^+ in the two solutions. Under the conditions of the present study, the H^+ limiting currents were 8 mA/cm² for NaCl and 27 mA/cm² for Na_2SO_4 at *p*H 2.0. At *p*H 3.0, the limiting currents were a factor of 10 lower. Diffusivities in the nickel-iron solutions may differ from those in solutions containing only Na^+ cations, but these numbers can be used as a guide. The diffusivity of Fe^{2+} is less than that of H^+ by a factor of ~10 (12), and the Fe diffusion limiting current should thus be about half that of H_2. As the solutions of the present study do not contain supporting electrolyte, it might be argued that migration is an important mode of mass transport and thus limiting currents will be higher than the diffusion limitation. However, the total current density is a very small fraction of the sum of the limiting currents for Ni, Fe, and H_2. The excess of Ni^{2+} present serves to increase the conductivity of the solution and to cause migration to be a less important mode of mass transport than diffusion. Hence, migration effects are not expected to lead to major error in the interpretation.

sity range over which good quality deposits can be obtained, eliminating the "burned" appearance and the dark spirals at higher currents. The influence of H_3BO_3 on appearance is presumably also related to its adsorption on the hydroxide.

The formation of spiral patterns during deposition on a rotating disk has been discussed by Hill *et al.* (14) and Pleskov and Filinovskii (15). They claim that even submicroscopic protrusions and depressions on the surface can cause wakes which result in the observed spirals. In the present investigation, the arms of the spiral appear to originate in small macroscopic protrusions on the surface. The formation of these protrusions occurs in conjunction with a "burned" deposit and is probably associated with the inclusion of oxides or hydroxides. Such inclusions are less favorable at low *p*H, and thus the spiral patterns are not observed at *p*H 2.0. The pinholes which occur at *p*H 2.0 are due to blocking of the surface by H_2 bubbles.

The evidence concerning the role of H_3BO_3 remains incomplete. Its influence on composition and efficiency appears to rule out a buffering role. It strongly affects both appearance and composition of NiFe deposits, but the effect on efficiency is small. Neither the present analysis of composition nor the earlier linear potential sweep measurements, however, is adequate for determining the mechanism through which H_3BO_3 influences the deposition process. The hypothesis that it adsorbs on hydroxide-covered surfaces is consistent with the data, but remains to be confirmed experimentally.

Conclusions

The results of the present investigation are generally consistent with the theory of Dahms and Croll (4, 5) concerning the mechanism of anomalous codeposition of Ni and Fe. The high Fe content of the alloys is apparently caused by inhibition of Ni^{2+} discharge by surface $Fe(OH)_2$ precipitated when H_2 evolution causes the local surface *p*H to rise. Factors which affect H_2 evolution and hydroxide precipitation thus influence the composition and properties of the deposit.

The deposit properties are strongly dependent on current density. Appearance degrades and efficiency increases with increasing current density. The Fe content of the NiFe films shows a maximum as a function of current density. This peak results from the simultaneous interaction of several factors. Increased H_2 evolution causes increased surface alkalization, leading to greater formation of iron hydroxides and the inhibition of Ni deposition. At sufficiently high currents, however, ionic diffusion in the hydroxide becomes rate limiting for Fe deposition and the Fe content of the films drops.

A decrease in *p*H generally causes a decrease in efficiency and an improvement in appearance. The decrease in efficiency is due to the larger $[H^+]$ at low *p*H. Appearance improves because less hydroxide is incorporated in the deposit at low *p*H. The maximum in the percentage Fe *vs.* i dependence occurs at higher i for lower *p*H since, at a given current density, the surface *p*H is lower in this case.

The anion affects the deposition efficiency and the composition of the deposit. The data suggest that Cl^- hinders the formation of a surface iron hydroxide, resulting in a lower Fe content in deposits from Cl^- solution than from SO_4^{2-} solution. The better appearance of deposits from chloride solution is probably also related to chloride's hindering surface hydroxide formation. Efficiency is higher in Cl^- solutions, apparently due to a lower H_2 limiting current in these solutions.

Addition of H_3BO_3 causes an increase in the Fe content of the deposits and does not greatly affect efficiency; neither result would be expected of a buffer. It greatly alters the appearance of deposits and extends the range of current densities over which good quality deposits may be obtained. Boric acid has the strongest effects under conditions where surface iron hydroxides are expected to form; evidence suggests that H_3BO_3 adsorbs on the hydroxide-covered surface.

EMF Measurements in Nickel Chloride-Sodium Chloride Melts with Beta-Alumina Electrolytes

R. Roumieu and A. D. Pelton

Ecole Polytechnique, Université de Montréal, Montréal, Québec, Canada H3C 3A7

ABSTRACT

Emf's were measured for the cell

$$\mathrm{Ni} \left| \begin{matrix} \mathrm{NaCl\text{-}NiCl_2} \\ \mathrm{(I)\ reference} \end{matrix} \right| \text{beta-alumina} \left| \begin{matrix} \mathrm{NaCl\text{-}NiCl_2} \\ \mathrm{(II)} \end{matrix} \right| \mathrm{Ni}$$

in the temperature range 800°-1000°C where the chloride solutions are liquid and in the range of mole fractions $0 < X_{NiCl_2} < 0.6$. The use of beta-alumina tubes, sealed in the hot zone, permitted separate gas-tight electrode compartments to be realized. Only very slight attack of the beta-alumina by the melts was observed after several days at open circuit. When a current was passed, however, nickel rapidly entered into the beta-alumina. A coulometric titration was nevertheless possible via the stratagem of titrating from a bath of pure NaCl. Through integration of the Gibbs-Duhem equation, partial properties of NaCl could be obtained from the results with no knowledge of the emf of the reference electrode being required. The precision of the results was such as to permit partial enthalpies and entropies to be obtained from the temperature dependence of the emf. The results are discussed in terms of ordering in the melts near $X_{NiCl_2} = 1/3$.

Despite the recent interest in beta-alumina because of its potential usefulness in batteries and other devices, very few studies have been made of the applications of this solid electrolyte to the measurement of thermodynamic properties. Beta-alumina is stable up to approximately 1200°C and is so highly conducting that equilibrium emf measurements can be made below 0°C. It is a relatively unreactive ceramic which can be fabricated in the form of vacuum-tight tubes. These properties, coupled with its negligibly small electronic conductivity, low polarizability, and high selectivity for the transport of Na^+ ions, make beta-alumina an excellent candidate for use in electrochemical cells for the precise measurement of the thermodynamic properties of a large number of systems.

In the present article, the use of beta-alumina for measurements in molten salt systems is examined. The following cell was studied

$$\mathrm{Ni_{(sol)}} \left| \begin{matrix} \mathrm{NaCl\text{-}NiCl_{2\,(liq)}} \\ \mathrm{(I)\ reference} \end{matrix} \right| \text{beta-alumina} \left| \begin{matrix} \mathrm{NaCl\text{-}NiCl_{2\,(liq)}} \\ \mathrm{(II)} \end{matrix} \right| \mathrm{Ni_{(sol)}}$$

The $NaCl\text{-}NiCl_2$ solutions in the reference electrode compartment (I) and in the working compartment (II) are of different compositions. If the transport number of Na^+ ions in the beta-alumina is unity, then the overall cell reaction on the passage of 2 Faradays is

$$2NaCl_{(I)} + NiCl_{2(II)} \rightarrow 2NaCl_{(II)} + NiCl_{2(I)} \quad [1]$$

and the open-circuit emf, E, is given by

$$E = \frac{RT}{2\mathbf{F}} \ln (a_{NiCl_2}/a_{NaCl}^2)^{I} (a_{NaCl}^2/a_{NiCl_2})^{II} \quad [2]$$

where a_{NaCl} and a_{NiCl_2} are the activities of NaCl and $NiCl_2$, $\mathbf{F}$ is the Faraday, and T is the temperature in Kelvins. As is shown in a later section, if E is measured for several different compositions in the working electrode compartment, integration of the Gibbs-Duhem equation then permits the activities of NaCl and $NiCl_2$ to be calculated separately.

Experimental

The apparatus is shown schematically in Fig. 1. In order to prevent losses by volatilization, that can be appreciable at temperatures of 800°-1000°C, both the working and reference electrode compartments were sealed in beta-alumina tubes. The two electrode assemblies were then immersed in a $NaCl\text{-}NiCl_2$ bath which served simply to provide electrical contact between them.

The beta-alumina tubes were fabricated in this laboratory by a slip-casting technique (1). They are 98% of theoretical density and are vacuum tight.[1] The dimensions are approximately 6-8 cm long by 1.5 cm diam with wall thicknesses of 0.2 cm. The electrical resistance across these tubes in the cell at 800°-1000°C is much less than 1Ω. The tubes were dried at 120°C under vacuum for 3 days before use.

Small alpha-alumina tubes, about 2 cm long, with inside diameters just large enough to accept the Ni electrodes and with outside diameters so as to just fit inside the beta-alumina tubes, were then cemented into place as shown in Fig. 1. This was done to reduce the amount of cement required. "Autostic" cement (Carlton-Brown Partners Limited, Elford Mill, Elford, North Tamworth, Staffordshire, England) was used. This cement must be applied in two or three layers, each of which is allowed to dry overnight. The cement is then treated by heating slowly to 150°C. Thereafter it is very crack resistant and can be heated and cooled rapidly. $NiCl_2$ (Analar Reagent, 99.9%) and NaCl (Baker Reagent 99.9%) were vacuum dried at 400°C and were then further dehydrated with HCl gas at 500°C. The salts were weighed, mixed, and introduced into the beta-alumina tubes in a glove box under purified argon. The 0.2 cm diam 99.7% nickel wires were then introduced and alumina wool was packed in the annular space around the wires to prevent the entry of cement. The electrodes were then cemented into place and the cement was allowd to dry in the glove box. Finally, long alpha-alumina tubes, their lower ends embedded in the cement, were attached in order to protect the Ni wires from the salt vapor in the outer compartment. If this was not done, the Ni

Key words: beta-alumina, nickel chloride, sodium chloride, molten salts, emf measurements, thermodynamic properties, coulometric titration.

[1] These tubes are commercially available from Polyceram Incorporated, Ecole Polytechnique, Montreal.

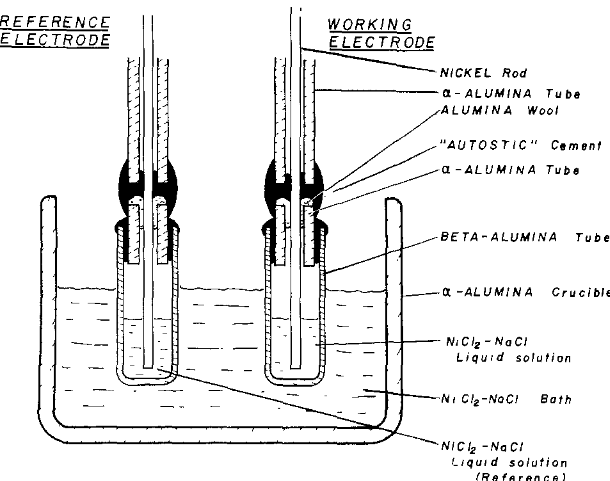

Fig. 1. Experimental apparatus

wires rapidly became embrittled due to grain boundary attack by the salt vapor.

The outer crucible containing the salt bath was 5 cm in diameter and 8 cm high. The entire assembly was maintained under purified argon in a vertical resistance-heated tube furnace fitted with a grounded metal sheath to eliminate induced emf's. Temperatures were measured with a Chromel-Alumel thermocouple immersed in a tube in the outer bath, and were controlled to ±1°C.

No attack on the Autostic cement by the salt vapor was evident after several days of operation at up to 1000°C.

Results

Emf's were measured with various compositions of the melt in the working electrode compartment and with the mole fraction of $NiCl_2$ in the reference electrode compartment held constant at $X_{NiCl_2} = 0.1589 \pm 0.0005$. Emf's were stable to ± 0.2 mV over several days and after several heating and cooling cycles. If the cells were polarized for several seconds in either direction the emf returned to within 0.1 mV of its former value within a few seconds after the polarization was terminated.

Results are shown in Table I for emf's at 1073, 1173, and 1273 K. Each value shown is the average of at least two measurements made at the same temperature (±1°) before and after a thermal cycle. These values always agreed within ± 0.2 mV except at high values of X_{NiCl_2} where the reproducibility was only ± 1 mV. Hence, the last two entries in Table I for $X_{NiCl_2} > 0.5$ are reported only to the nearest millivolt. Because of this observed lower reproducibility at high concentrations of $NiCl_2$ and because the phase diagram limits measurements to higher temperatures at high $NiCl_2$ concentrations (the melting point of $NiCl_2$ being 1303 K), no values are reported for X_{NiCl_2} greater than 0.6.

Calculation of thermodynamic properties.—The Gibbs-Duhem equation at constant temperature may be written as follows

$$X_{NaCl} dg^E_{NaCl} + X_{NiCl_2} dg^E_{NiCl_2} = 0 \quad [3]$$

where g^E_{NaCl} and $g^E_{NiCl_2}$ are the partial molar excess free energies of NaCl and $NiCl_2$. This equation may be rearranged to give

$$dg^E_{NaCl} = \frac{X_{NiCl_2}}{1 + X_{NiCl_2}} (2dg^E_{NaCl} - dg^E_{NiCl_2}) \quad [4]$$

Now, Eq. [2] may be written as

$$2FE = RT \ln(X_{NaCl}^2/X_{NiCl_2})^{II} + (2g^E_{NaCl} - g^E_{NiCl_2})^{II} + RT \ln(a_{NiCl_2}/a_{NaCl}^2)^{I} \quad [5]$$

The term $RT \ln(a_{NiCl_2}/a_{NaCl}^2)^I$ contains the unknown activities in the reference electrode compartment. However, this term is, of course, independent of the composition in the working electrode compartment and hence drops out when the derivative is taken. Differentiating Eq. [5] and substituting into Eq. [4] we obtain

$$dg^E_{NaCl} = \frac{X_{NiCl_2}}{1 + X_{NiCl_2}} d(2FE - RT \ln(X_{NaCl}^2/X_{NiCl_2})) \quad [6]$$

where the compositions refer to the working electrode compartment. Equation [6] may be integrated with the lower limit taken at $X_{NiCl_2} = 0$ where $g^E_{NaCl} = 0$ to give

$$g^E_{NaCl} = \int_{X_{NiCl_2}=0}^{X_{NiCl_2}} \frac{X_{NiCl_2}}{1 + X_{NiCl_2}} d\,(2FE - RT \ln(X_{NaCl}^2/X_{NiCl_2})) \quad [7]$$

In this way, g^E_{NaCl} can be calculated. It is not necessary to know the voltage of the reference electrode. It is only necessary that it be constant.

In Fig. 2 is a plot of $X_{NiCl_2}/(1 + X_{NiCl_2})$ *vs.* $(2FE - RT \ln(X_{NaCl}^2/X_{NiCl_2}))$ at 1073 K. A smooth curve is obtained which is easily integrated. Plots at 1173 and 1273 K gave similar curves. These were integrated graphically to give the values of g^E_{NaCl} listed in Table I. A plot of g^E_{NaCl} *vs.* X_{NiCl_2} at 1073 K is shown in Fig. 3. A smooth curve can be drawn through all the points except the last two points at high X_{NiCl_2}. The plots of g^E_{NaCl} at 1173 and 1273 K are similarly smooth.

Substitution of the calculated values of g^E_{NaCl} back into Eq. [5] will then permit $g^E_{NiCl_2}$ to be calculated provided that the value of $a_{NiCl_2}{}^I$ in the reference electrode compartment is known. Hamby and Scott (2) have measured a_{NiCl_2} in NaCl-$NiCl_2$ melts using a formation cell with Ni and Cl_2 electrodes. With the value of Hamby and Scott for $a_{NiCl_2}{}^I$ at $X_{NiCl_2} = 0.1589$ in

** Values of $g^E_{NiCl_2}$ for the reference electrode from Ref. (2).

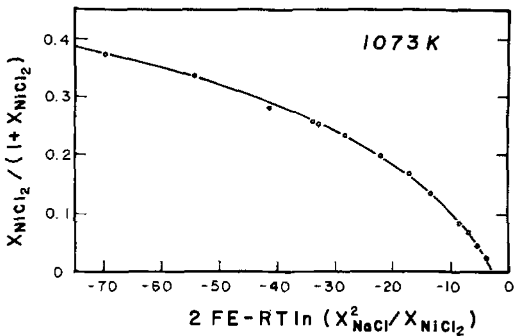

Fig. 2. Plot of experimental results at 1073 K such as to permit g^E_{NaCl} to be calculated by integration of Eq. [7].

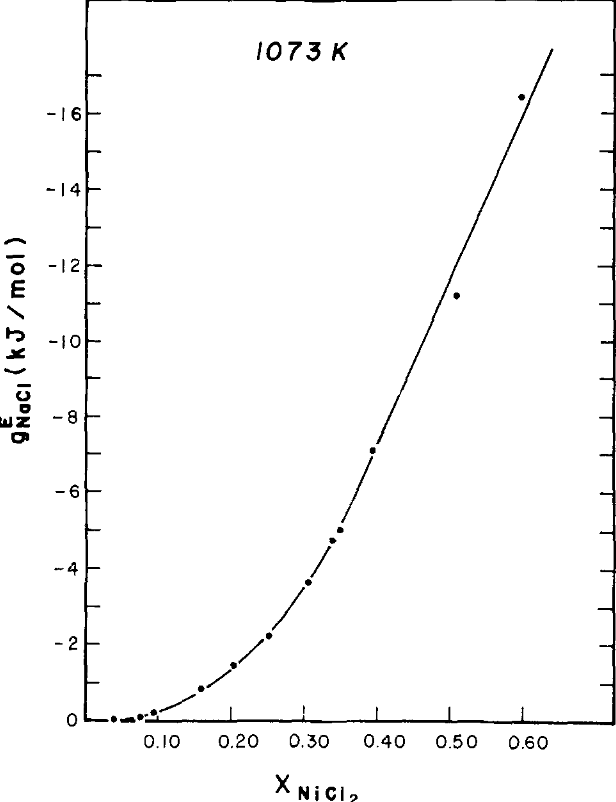

Fig. 3. Partial molar excess free energy of NaCl in NaCl-$NiCl_2$ melts at 1073 K.

the reference electrode compartment, $g^E_{NiCl_2}$ was calculated from Eq. [5]. Results are shown in Table I. In Fig. 4, $g^E_{NiCl_2}$ at 1073 K from Table I is compared with the measurements of Hamby and Scott. Similarly good agreement is also obtained at 1173 and 1273 K.

If measurements had been made over to $X_{NiCl_2} = 1$, then an equation similar to Eq. [5] could have been written to permit $g^E_{NiCl_2}$ to be calculated without the necessity of knowing the activities in the reference electrode compartment. Since this was not the case, however, the present results permit only the partial properties of NaCl to be calculated completely independently of any other measurements.

Activities of NaCl and $NiCl_2$ at 1073 K are plotted in Fig. 5. The values of g^E_{NaCl} in Table I were expressed as linear functions of temperature by a least squares regression analysis. Only very slight deviations from linearity were observed, and these were not systematic but random. Hence, the partial molar entropy and excess entropy of NaCl are quite constant over the temperature range 1073-1273 K. These were calculated from the equation

$$g^E_{NaCl} = \Delta h_{NaCl} - Ts^E_{NaCl} \quad [8]$$

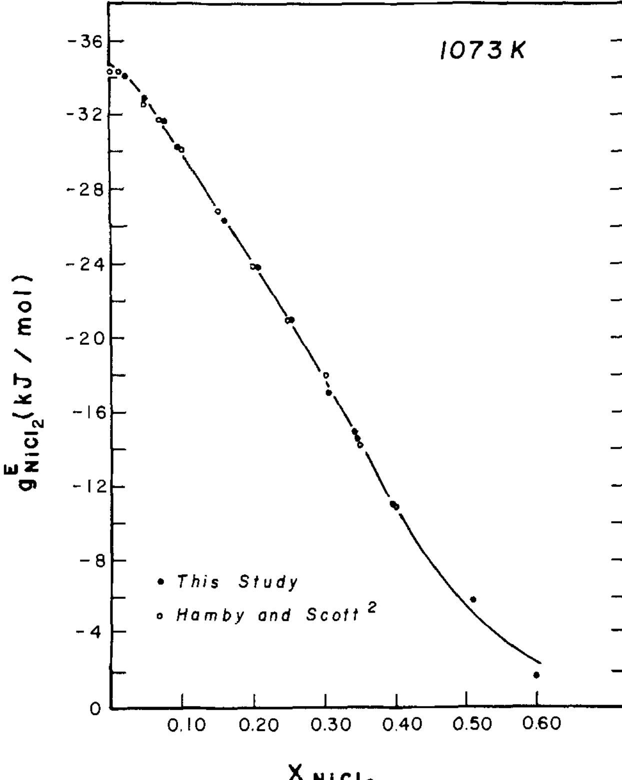

Fig. 4. Partial molar excess free energy of $NiCl_2$ in NaCl-$NiCl_2$ melts at 1073 K.

Results are listed in Table I and are plotted in Fig. 6 and 7.

Papatheodorou and Kleppa (3) have measured the enthalpy of mixing of NaCl-$NiCl_2$ solutions by solid-liquid mixing experiments at 810°C. They fitted their measured integral enthalpy of mixing to a series expansion in the mole fractions. From their equation the partial molar enthalpy of NaCl was calculated and is also plotted in Fig. 6. Very good agreement with the present results is obtained.

Stability of beta-alumina in the chloride melts.—After several days in the NaCl-$NiCl_2$ melt, the beta-alumina tubes were removed and examined. A very thin blue-green layer was observed on the inner and outer surfaces of the tubes which were in contact with the melt. When the tubes were broken it was observed that the interior of the beta-alumina was white. After

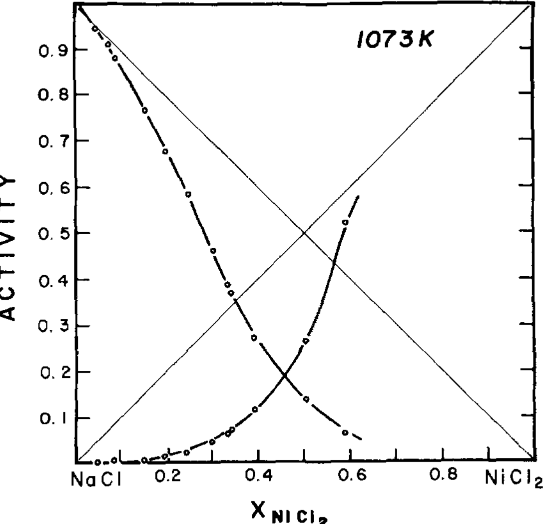

Fig. 5. Activities of NaCl and $NiCl_2$ in NaCl-$NiCl_2$ melts at 1073 K.

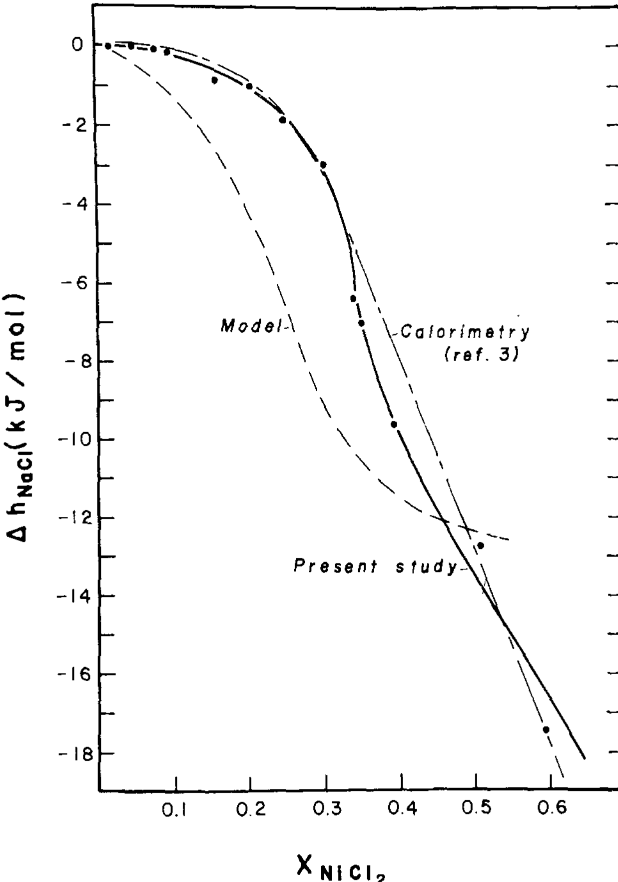

Fig. 6. Partial molar enthalpy of mixing of NaCl in NaCl-$NiCl_2$ melts.

the blue-green surface layer was removed, chemical analysis of the tubes showed no detectable nickel content.

A source of experimental error which must be considered is the exchange reaction

$$NiCl_{2(liq)} + Na_2O_{(in\ beta\text{-}alumina)} \rightarrow 2NaCl_{(liq)} + NiO_{(in\ beta\text{-}alumina)} \quad [9]$$

At 1200 K, $\Delta G°$ for reaction [9] is -375 kj (4). The activity of Na_2O in beta-alumina is approximately 10^{-12} at 1200 K (5). This is not low enough to counteract the very negative $\Delta G°$, and so beta-alumina should be thermodynamically unstable in the NaCl-$NiCl_2$ melts. (Although, for melts dilute in NaCl it is just possible within the various experimental error limits that ΔG of the exchange reaction could be positive.) However, the mobility of Ni^{2+} ions in beta-alumina would be expected to be many orders of magnitude lower than that of the Na^+ ions. Yao and Kummer (6) found that many divalent ions could enter the structure of beta-alumina, but that these ions diffuse only very slowly. Hence, if the exchange reaction proceeds with Ni^{2+} diffusion, it may occur so slowly that the cell emf is still effectively given by Eq. [2].

If, on the other hand, the Ni^{2+} does not enter the beta-alumina but, instead, if a layer of pure NiO forms on the surface, then the beta-alumina will become impoverished in Na_2O near its surface such that a surface layer of alpha-alumina will form, greatly retarding further reaction by hindering sodium transport. Whatever the exact reason, the stability and reproducibility of the experimental results together with the excellent agreement with previous studies show that the exchange reaction is not a problem in this system and that the open-circuit emf is given by Eq. [2]. The blue-green surface layer indicates that the exchange reaction has occurred, but only to a very limited extent. The absence of any nickel within the solid electrolyte indicates that no nickel transport has occurred. The aforementioned diminished reproducibility when $X_{NiCl_2} > 0.5$ may be due to interference from the exchange reaction which would become more pronounced at higher $NiCl_2$ concentrations.

Coulometric titration.—It was decided to attempt to vary the composition in the working electrode compartment by coulometric titration. This technique was found earlier (7) to work very well in concentration cells containing Na-Sn alloys, the beta-alumina permitting the transport only of Na^+ ions.

Accordingly, a Ni wire was placed in the outer NaCl-$NiCl_2$ bath (see Fig. 1) and a fixed current of 96.4 mA was passed between this wire and the working electrode for measured periods of time with the aid of a Sargent-Welch Model IV Coulometric Current Source. Under the assumption that only Na^+ ions can cross the beta-alumina, the composition of the working electrode compartment could be calculated after each passage of current.

However, when cell emf's were measured after the passage of current they did not correspond to those in Table I. When the beta-alumina tubes were removed and cracked open, they were found to be blue-green right through. Analysis of a tube through which 28 meq of charge had been passed showed it to contain 1.8 weight percent nickel. Rough calculations show that this means that between 1% and 10% of the current was carried by nickel ions.

Thus, the coulometric titration was unsuccessful since nickel entered the beta-alumina. This is surprising in view of the aforementioned observation that upon open circuit the Ni^{2+} does not penetrate the solid electrolyte and in view of Yao and Kummer's (6) observation of very low diffusivities in beta-alumina. If the mobility of Ni^{2+} in beta-alumina is so low, why is so much Ni^{2+} transported upon passage of current? A possible explanation is that the thermodynamic equilibrium favors the formation of nickel beta-alumina at the surface, so that a large fraction of the mobile cation sites at the surface are always occupied by nickel ions. The nickel ions are not sufficiently mobile to diffuse into the beta alumina upon open circuit, but when a potential is applied they are forced to enter. Flinn and Stern (8) observed a similar effect in the case of beta-alumina in NaCl-$ZnCl_2$ melts. No zinc entered the beta-alumina upon open circuit, but when current was passed their cell resistance rose very sharply. This behavior of beta-alumina in divalent halide melts merits further study.

The coulometric titration was repeated, but this time the outer bath contained only pure NaCl and current was passed only in the direction such as to cause Na^+ ions to pass through the beta-alumina from the pure

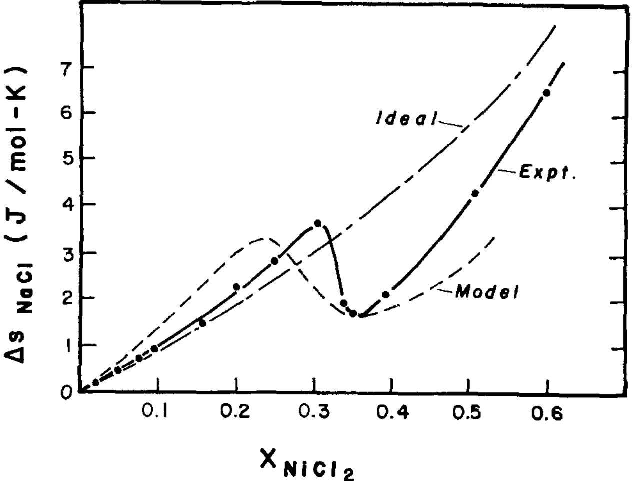

Fig. 7. Partial molar entropy of mixing of NaCl in NaCl-$NiCl_2$ melts.

NaCl bath into the working electrode compartment. After each passage of 2000 meq the current was interrupted and the open-circuit emf was measured. It required only about 5 sec for equilibrium to be established after the polarization was terminated. In this way the composition of the working electrode compartment was varied by 27 mole percent. (The total mass of salt in the working electrode compartment was approximately 5g.) Results at 1173 K are shown in Table II where comparison is made with the previous results from Table I. Very good agreement is obtained until X_{NiCl_2} has been reduced from 0.38 to about 0.25. Thereafter, upon further titration, the emf's measured in the titration experiment deviated more and more from the previous results. The direction of the deviation was the same as that of the polarization and was the same as that which was observed when the outer bath contained $NiCl_2$ as well as NaCl. The explanation is most likely as follows. As the titration proceeds, Ni^{2+} ions enter the outer bath from the Ni electrode to replace the Na^+ ions which have gone through the beta-alumina. Hence, the concentration of $NiCl_2$ in the outer bath builds up and eventually these Ni^{2+} ions start to enter the beta-alumina.

Discussion

The rapid decrease in Δh_{NaCl} near $X_{NiCl_2} = 1/3$ in Fig. 6 and the anomaly in Δs_{NaCl} in Fig. 7 near the same composition are indicative of a stabilization and structural ordering of the melt around $X_{NiCl_2} = 1/3$ which is the composition represented by Na_2NiCl_4. (The shape of the partial entropy curve in Fig. 7 corresponds to an integral curve with a minimum near $X_{NiCl_2} = 1/3$.) This type of behavior has been observed in a large number of other $AX\text{-}MX_2$ systems (where A = alkali, X = halogen, and M = divalent metal). See, for example, Ref. (9).

A simple "discrete complex anion model" has been suggested (9) for these systems. The existence of $NiCl_4^{2-}$ complex anions is proposed. These anions are in equilibrium with Ni^{2+} and Cl^- ions in the melt

$$Ni^{2+} + 4Cl^- \rightleftharpoons NiCl_4^{2-} \qquad [10]$$

A parameter α is defined which gives the fraction of total nickel existing in the $NiCl_4^{2-}$ complexes. The entropy of the melt is then written as a function of α by assuming an ideal Temkin solution of Ni^{2+} and Na^+ cations on the cation sublattice and of Cl^- and $NiCl_4^{2-}$ anions on the anion sublattice. The enthalpy of mixing is assumed to arise from the formation of complexes according to Eq. [10]. Hence, the enthalpy can also be written as a function of the degree of complexing α as well as of two adjustable parameters b_1 and b_2 which give the energy change of reaction [10] as a function of composition. The parameter α is then determined by minimizing the free energy: $d\Delta G/d\alpha = 0$. Details are given in Ref. (9). Plots of Δh_{NaCl} and of Δs_{NaCl} calculated via this model with $b_1 = -62.5$ kj and $b_2 = 0$ are shown in Fig. 6 and 7. These values of b_1 and b_2 were chosen to give the best "by eye" fit to the experimental curves, but with consideration given to the values of b_1 and b_2 required for many other $MCl_2\text{-}ACl$ systems as discussed in Ref. (9). [The values originally suggested in Ref. (9) for this system were $b_1 = -58.5$ kj and $b_2 = +2.0$ kj which give virtually identical results to those obtained with the present values.] It is seen that the model predicts the shapes of the curves, but that the anomaly in Δs_{NaCl} as well as the rapid drop in Δh_{NaCl} are predicted to occur at lower values of X_{NiCl_2} than are observed. Were the calculations to be repeated with assumption of $NiCl_3^-$ complexes rather than $NiCl_4^{2-}$, the anomalies would occur near $X_{NiCl_2} = 0.5$. This would give very poor agreement with the measured values. Possibly some $NiCl_3^-$ complexes are formed along with the $NiCl_4^{2-}$ complexes. This is equivalent to saying that there is a preferred coordination of chlorine around nickel which is slightly less than 4.

Table II. Results of coulometric titration at 1173 K

	X_{NiCl_2}	E (mV)	E (mV) from previous results
Start of titration	0.3800	−199.7	−199.4
	0.3563	−176.3	(−174.3)*

* These values are placed in parentheses because it is difficult to interpolate the experimental emf's accurately in the composition region near $X_{NiCl_2} = 1/3$ where s^E and Δh vary rapidly.

Conclusions

Beta-alumina solid electrolytes can be used to measure the thermodynamic properties of $NaCl\text{-}NiCl_2$ melts in the temperature range 800°-1000°C. The use of beta-alumina tubes, sealed in the hot zone, permitted separate gas-tight electrode compartments to be realized and eliminated all problems of volatilization. Very stable reversible emf's were obtained. The cells are of very low polarizability. Entropies and enthalpies could be calculated with good accuracy from the temperature dependence of these emf's.

Although the emf of the cell at any given melt composition gives only a ratio of activities in the melt, integration of the Gibbs-Duhem equation permits the individual activities to be determined as long as measurements have been made for compositions over to the pure component in question.

The beta-alumina was attacked to only a negligible extent by the $NiCl_2$ melts and no Ni^{2+} entered the solid electrolyte at open circuit. However, when current was passed the Ni^{2+} rapidly entered the beta-alumina. It is proposed that the presence of Ni^{2+} in the beta-alumina blocks the transport of Na^+ ions. This observation may have practical consequences for the use of beta-alumina in electrochemical devices. If divalent ions are present as impurities, even in small quantities, they may accumulate with time and poison the beta-alumina.

It is possible, nevertheless, to vary the composition of the fused salt under study by coulometric titration provided the titration is made from a bath containing only NaCl. The fact that the composition can be precisely varied *in situ* by several mole percent will decrease the time required to study a system.

The results for the enthalpy and entropy of the $NaCl\text{-}NiCl_2$ solutions indicate a stabilization and structural ordering of the melts near an $NiCl_2$ mole fraction of 1/3.

Diffusion-Controlled Polarization of Pt, Ag, and Au Electrodes with Doped Ceria Electrolyte

Da Yu Wang* and A. S. Nowick*

Henry Krumb School of Mines, Columbia University, New York, New York 10027

ABSTRACT

The nature of electrode polarization, previously investigated for Pt paste electrodes, is now studied for Pt foil, Ag and Au paste, and Ag foil electrodes. The current interruption method with a reference electrode is employed in the temperature range 500°-800°C under O_2-Ar gas mixtures. Electrode structures are also examined by optical and electron microscopy. The principal experimental feature is that the Butler-Volmer equation is obeyed with cathodic and anodic transfer coefficients of 1/2 and 3/2, respectively, and an effective exchange current which varies as the 3/8 power of p_{O_2}. Also, transient decay curves are much slower than for the pure charge transfer mechanism. These features can be interpreted in terms of a model in which charge transfer takes place in the two-phase region between electrode and electrolyte, but where the rate is controlled by interfacial diffusion of oxygen atoms along the electrode, except when the electrode particles are extremely small. For extreme cases of diffusion limitation, the adatom concentration over most of the two-phase region becomes so low that electrolyte reduction takes place. The resulting appreciable electronic contribution can be treated in terms of the Wagner polarization-cell theory.

This is the fourth of a series of papers dealing with electrode polarization in high temperature cells that involve oxygen transport. In the previous papers (1-3) use was made of a current interruption method in combination with a reference electrode to study the nature of electrode processes occurring at Pt paste electrodes (composed of fine Pt particles) on a doped ceria electrolyte. With this method, it is possible to determine separately the anodic and cathodic overpotentials as well as the ohmic polarization of the electrolyte. Steady-state measurements were reported in (1) and both transient and a-c measurements in (2). These studies showed that electrode polarization is controlled by a charge transfer (or "activation") mechanism. Study of the exchange current as a function of p_{O_2} (oxygen partial pressure) and temperature showed that oxygen for the charge transfer process is supplied from adsorbed atoms on the Pt electrode surface which obey the Langmuir isotherm. The fraction of adsorbed sites, θ, is found to be large at low temperatures and small at high temperatures, giving rise to a charge transfer rate that switches over from a $p_{O_2}^{-1/4}$ to a $p_{O_2}^{+1/4}$ dependence in these two ranges, respectively. Observations of the electrodes were also made by scanning electron microscopy to show the changes in microstructure that occur during aging.

At high overpotential or low p_{O_2}, limiting-current behavior was observed at the cathode. For even higher overpotentials, it was shown (3) that reduction takes place at the cathode and electrons are directly injected into the electrolyte. The steady-state behavior associated with this reduction phenomenon has been explained in terms of the Wagner polarization-cell model, while the transient behavior was interpreted in terms of diffusion of electrons from the cathode to other regions of the electrolyte.

In the previous papers, little was said about the region between the electrode and electrolyte where the charge transfer process takes place. These electrochemically active sites might be located in the three-phase region (electrode-gas-electrolyte) or in the more extensive two-phase region (electrode-electrolyte). In the literature the two-phase region is generally preferred (4, 5) because, otherwise, extremely high local ionic current densities would be required. However, this has never been established conclusively.

If the reaction takes place in the two-phase region, oxygen atoms must diffuse laterally inward along the interface from the three-phase region. This is particularly true for Pt electrodes since oxygen solubility and diffusivity in the bulk are extremely small (6). The concentration of oxygen in the two-phase region will then depend on the interfacial diffusion rate as well as on the local charge-transfer exchange rate. The relative ratio of these two rates can be modified by varying the particle sizes of the electrode. Thus, different electrode morphologies should give rise to different overall polarization behavior.

In the present study, we first examine the cathodic and anodic polarization of Pt foil electrodes using the current interruption method. The results are quite different from those of the previous Pt paste electrodes and are interpreted in terms of a model in which the reaction occurs over the two-phase region, with oxygen diffusing along the electrode from the three-phase region. The theory is similar to that of Wills (7, 8) who dealt with a surface diffusion problem in

* Electrochemical Society Active Member.

Key words: ceramics, fuel cell, chemisorption, Tafel slope.

a system consisting of a liquid aqueous electrolyte, a metal electrode, and a gas.

Morphologically, silver and gold electrodes are similar to platinum, and one would therefore expect to be able to interpret polarization phenomena in cells employing Ag and Au electrodes in a similar way. The present work explores such systems and shows the similarities and differences as compared to Pt.

Theory

When current passes through an oxygen-ion conducting electrolyte, oxygen atoms and electrons must be exchanged between the electrolyte and the ambient gas by way of the metal electrode. Generally the rate of diffusion through the bulk of the metal electrode is so small that only diffusion which proceeds along the interface between the electrode and the electrolyte is important for maintaining the supply of oxygen. Therefore, a concentration gradient may be built up on this interface. Such a gradient depends on the local rate of the charge transfer reaction which, in turn, is dependent on the local concentration of the reactants $C(u, v)$ (or the adatom concentration) where u, v are coordinates in the interface. The total current per unit area, I, will be the integral over the plane of the local current density, $I_w(u, v)$

$$I = \frac{1}{A} \oint\oint I_w(u, v)\, du dv \quad [1]$$

where the subscript w denotes the direction perpendicular locally to the (uv) plane and A is the area. The function $I_w(u, v)$ is proportional to the local rate of the charge transfer reaction and is given for high temperatures or $\theta << 1$ (θ being the fraction of available surface active sites on the electrode that are occupied by chemisorbed oxygen adatoms), as (1)

$$I_w(u, v) = I_0\{\exp[\alpha_a e\eta(u, v)/kT] - [C(u, v)/C_0]\exp[-\alpha_c e\eta(u, v)/kT]\} \quad [2]$$

where I_0 is the exchange current, e is the electronic charge, $\eta(u, v)$ is the overpotential, α_a and α_c are the anodic and cathodic charge transfer coefficients (here $\alpha_a = \alpha_c = 1$), C_0 is the equilibrium concentration of oxygen adatoms, and kT has the usual meaning. Generally, the metal surface is an equipotential so that the overpotential $\eta(u, v)$ can be taken as constant. Accordingly, only the function $C(u,v)$ must be known in order to carry out the integration of Eq. [1]. For mass conservation, $C(u,v)$ must satisfy the continuity equation

$$D\nabla^2 C(u,v) + I_w(u,v)/2e = 0 \quad [3]$$

where D is the interfacial diffusion coefficient of oxygen and the total number of transferred charges per reactant is assumed to be equal to 2. We will consider two possible boundary conditions for Eq. [3], either

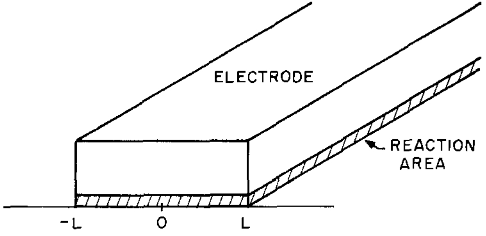
$$C(u,v)|_B = C_0 \quad [4]$$

or

$$D\nabla C(u,v)|_B = \gamma(C_0 - C_B) \quad [5]$$

where B stands for the boundary (*i.e.*, the three-phase periphery) of the metal-electrolyte interface region and γ is a constant. The first condition assumes that thermal equilibrium between gas and chemisorbed adatoms is maintained on the boundary. Alternatively, the second condition assumes that, on the boundary, the interfacial diffusion rate of chemisorbed adatoms is proportional to the difference between the actual concentration and the thermal-equilibrium concentration; it is just this condition that gives rise to limiting-current type behavior (1).

For simplicity we consider an electrode with the geometry shown in Fig. 1 (with concentration independent coordinate v and boundaries at $u = \pm L$). For



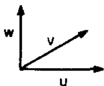


Fig. 1. Schematic diagram of an electrode particle of simple geometry on an electrolyte.

this case, the solution of Eq. [3] for the first boundary condition, Eq. [4], is

$$C(u)/C_0 = [1 - \exp(2e\eta/kT)][\cosh(Gu/L)/\cosh G] + \exp(2e\eta/kT) \quad [6]$$

where

$$G \equiv Q \exp(-e\eta/2kT) \quad [7]$$

and

$$Q \equiv [I_0 L^2/2eDC_0]^{1/2} \quad [8]$$

The total current per unit area of electrode is then

$$I = (I_0/Q)[\exp(3e\eta/2kT - \exp(-e\eta/2kT)] \tanh G \quad [9]$$

The quantity Q defined by Eq. [8] is a measure of the relative ratio of the charge exchange rate and the interfacial diffusion rate. If the latter is much greater than the former, we have $Q << 1$. In this case, tanh $G \cong G$ in Eq. [9] and that equation becomes

$$I = I_0[\exp(e\eta/kT) - \exp(-e\eta/kT)] \quad [10]$$

which is the same as Eq. [2] with $C(u,v) = C_0$. Therefore, under these conditions, the interfacial diffusion has no effect on the total current. Alternatively, if the diffusion rate is much smaller than the exchange rate, or $Q >> 1$, the tanh function will then equal unity and Eq. [9] becomes

$$I = (I_0/Q)[\exp(3e\eta/2kT) - \exp(-e\eta/2kT)] \quad [11]$$

Comparing Eq. [11] and [10], we find that both are of the Butler-Volmer form except that in Eq. [11] I_0, α_a, and α_c take on new (primed) values

$$I_0' = I_0/Q \quad [12]$$

$$\alpha_a' = 3/2 \quad [13]$$

$$\alpha_c' = 1/2 \quad [14]$$

At low $|\eta|$ ($<<kT/e$), Eq. [11] can be linearized to obtain

$$I = I_0'(2e\eta/kT) \quad [15]$$

Thus, at low $|\eta|$ the electrode polarization is ohmic, while at large $|\eta|$ a plot of ln $|I|$ *vs.* $|\eta|$ gives a Tafel slope of $(3e/2kT)$ at the anode and $(e/2kT)$ at the cathode.

In Fig. 2, Eq. [9] is plotted as log (I/I_0) *vs.* η for various values of Q. We see that for $Q < 0.4$ Eq. [10] is a good approximation, while for $Q > 4$ Eq. [11] suffices.

At high temperature and/or low p_{O_2}, where $\theta << 1$, according to the previous study (1), $I_0 \propto p_{O_2}^{1/4}$ and $C_0 \propto p_{O_2}^{1/2}$. Substituting these results into Eq. [8] and [12], we find that I_0' should have the following p_{O_2} dependence

$$I_0' \propto p_{O_2}^{3/4} \quad [16]$$

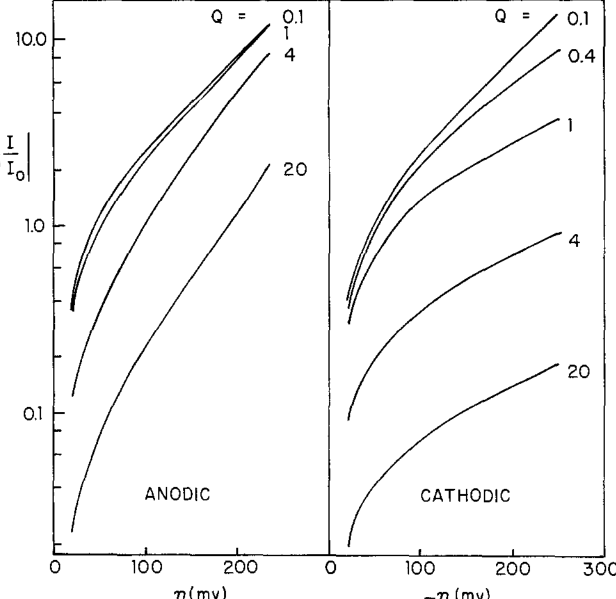

Fig. 2. Plot of log I/I_0 vs. η (both cathodic and anodic) as calculated from Eq. [9] for different values of Q at a temperature of 800°C.

Alternatively, we may choose Eq. [5] as the boundary condition instead of Eq. [4]. Following a procedure similar to the one above, we obtain for the total current density

$$I = (I_0/Q)\{[\exp(3e\eta/2kT) - \exp(-e\eta/2kT)]/[(DG/\gamma L) + \coth G]\} \quad [17]$$

For $Q << 1$, this equation becomes

$$I = [\exp(e\eta/kT) - \exp(-e\eta/kT)]/[I_0^{-1} + \exp(-e\eta/kT)/I_l] \quad [18]$$

where I_l is defined as

$$I_l \equiv 2e\gamma C_0/L \quad [19]$$

which is the general form for the current when there is a limiting current density I_l (1). For $Q >> 1$, Eq. [17] becomes

$$I = [\exp(3e\eta/2kT) - \exp(-e\eta/2kT)]/[Q/I_0 + \exp(-e\eta/2kT)/I_l] \quad [20]$$

Comparing Eq. [19] and [20], we find that both take the same form, if for the interfacial-diffusion controlled case (Eq. [20]) we let I_0, α_a, and α_c be replaced by new (primed) values, exactly as given in Eq. [12]-[14].

Equation [20] can be linearized for $e|\eta| << kT$ and becomes

$$I = I_0''(2e\eta/kT) \quad [21]$$

where

$$I_0'' = I_0'I_l/(I_0' + I_l) \quad [22]$$

The above derivation, Eq. [6]-[22], can be generalized for other geometrical shapes of the electrodes. The solutions for diffusion-limited behavior should be similar to Eq. [11] and [20], except that Q will then involve different geometrical parameters.

Experimental Methods

Doped ceria electrolytes and platinum paste electrodes were prepared as described previously (1). The arrangement for the current interruption method is also described in Ref. (1)-(3), as are the sample chamber and gases used (O_2-Ar mixtures).

The platinum foil electrodes utilized platinum foil 12.7 μm thick and of 99.99% purity. An unfluxed Pt paste (Engelhard 6926) was first brushed on the surface of the electrolyte, onto which the Pt foil was pressed under an alumina disk weighing 23g. This combination was fired at 950°C for 7 days (denoted electrode A) or at 1500°C for 4 hr in an argon atmosphere (denoted electrode B).

Silver electrodes generally were prepared by painting flexible silver coating (Engelhard No. 16) on the electrolyte, then firing at 600°C in open air for 2 hr. Silver foil (127 μm thick, 99.99% purity) was rolled down to 50.8 μm, after which it was lightly etched in cold 30% HNO_3 to eliminate any possible surface contamination. It was then rinsed in distilled water and finally in acetone. Silver foil electrodes were prepared by first brushing the surface of the electrolyte with silver paste (Engelhard No. 16), then pressing the foil on it with a 23g alumina disk, and finally, firing at 700°C for 8 hr.

Gold electrodes were prepared by brushing gold paste (Engelhard A-2123) onto the surface of the electrolyte and firing at 800°C in open air for 4 hr. The average thickness of paste electrodes (silver and gold) is estimated by weighing the samples with and without the electrodes. The difference in weight was then divided by the density of the metal and nominal electrode area. Generally the average thickness ranges from 1.0 to 1.8 μm.

After the electrical experiments were completed, some samples were cut into small pieces (<0.6 × 0.8 cm^2) and placed into a JEM-100C electron microscope for electrode surface scanning at a magnification of 1000×. Platinum foil and silver foil electrodes were also examined by an optical microscope at a magnification of 778×; in this way the entire sample could be examined without being destroyed.

Results

It was previously demonstrated (1) that for chemisorption of oxygen on Pt, θ becomes rather high at the lower temperatures (with $\theta = ½$ at $p_{O_2} = 0.94 \times 10^{-3}$ atm and $T = 550°C$). In the present study of Pt-foil electrodes, the temperature was limited to values near 800°C so as to keep $\theta << 1$.

Two platinum foil electrodes (A and B) which were prepared differently (see Experimental Methods) were tested, and typical results are shown in Fig. 3. The

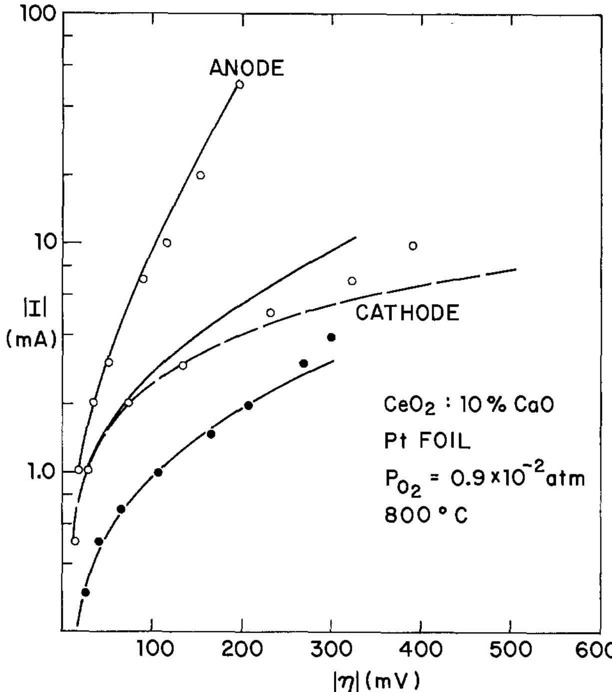

Fig. 3. Anodic and cathodic polarization curves for the two Pt foil electrodes at 800°C. Open circles are for electrode A and filled circles for electrode B. Solid lines and dashed lines are, respectively, the fits to Eq. [11] and [20].

anodic results could always be fitted to Eq. [11], in which the one adjustable parameter (I_0') was obtained from the linear range (where $|\eta| << kT$) by utilizing Eq. [15]. (For clarity, the anodic results for electrode B are omitted in Fig. 3.) The cathodic data were fitted either in the same way (solid curves) or to Eq. [20] (dashed curve), which involves I_l as a second parameter. For electrode A this second fitting is more satisfactory, indicating the need to include a limiting current. Using previously published values of I_0 [(1), Fig. 13] and Eq. [12], values of Q of 9.5 and 26 are obtained for electrodes A and B, respectively.

Results for the p_{O_2}-dependence of I_0' for both foil electrodes are given in Fig. 4. The two solid lines are drawn with the slope of 3/8, in agreement with Eq. [16]. The reproducibility of the data is good, in contrast to those for the Pt paste electrodes where changes could be produced by high applied currents (1). No time-dependent effects were detected in the present range of temperature and p_{O_2}.

The observed polarization of silver paste electrodes can also be described by Eq. [11] or [20]. Typical results are given in Fig. 5, where both anodic and cathodic data are presented and fitted to Eq. [11]. The circled numbers mark the values of overpotentials at which transient behavior is studied, as given in Fig. 6. Comparison with Ref. (2) shows that the overpotentials decay very slowly in this case, clearly suggesting that activation polarization is not the rate-controlling process.

Results for the p_{O_2}-dependence of I_0' for the Ag electrodes are given in Fig. 7 in the temperature range between 700° and 500°C. The solid lines in this log-log plot are drawn with a slope of 3/8. It is clear from Fig. 7 that the same power-law dependence of I_0' on p_{O_2} is obeyed over the entire temperature range, in contrast to the results for Pt paste electrodes (1). The temperature dependence of I_0' at constant p_{O_2} is given in Fig. 8 along with data for other paste electrodes. The straight line drawn through the Ag data in this plot gives an activation energy of 1.1 eV.

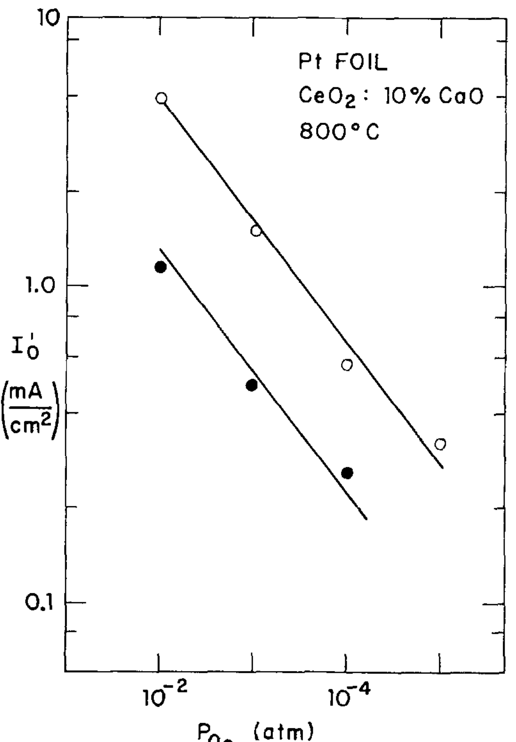

Fig. 4. Dependence of I_0' on p_{O_2} for the two Pt foil electrodes. Open and filled circles are for electrodes A and B, respectively. The straight lines are both drawn with slope of 3/8.

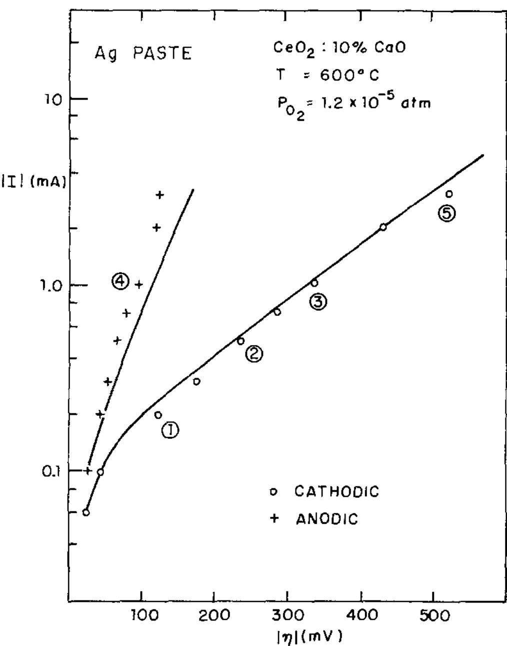

Fig. 5. Anodic and cathodic polarization curves for Ag paste electrode at 600°C. Solid lines are the fits to Eq. [11]. Circles mark the overpotentials at which the transient data of Fig. 6 are obtained.

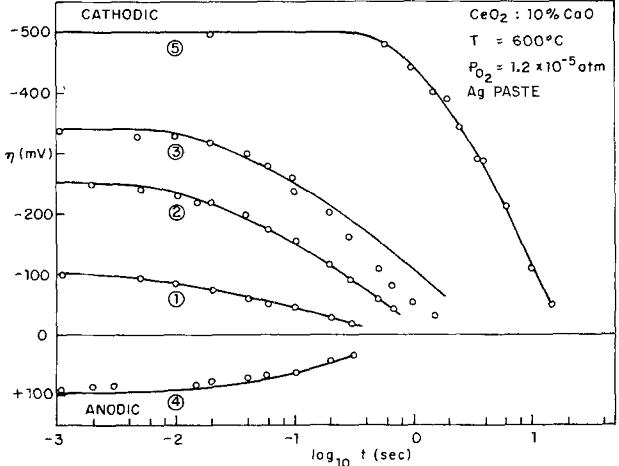

Fig. 6. Decay of cathodic and anodic overpotentials with time corresponding to the five points marked on Fig. 5.

Silver foil electrodes give results similar to the silver paste except that, at the cathode, limiting current effects are more prevalent in the case of the foil. Figure 9 shows a typical result, with the anodic data fitted to Eq. [11] and the cathodic data to Eq. [20]. The quantity I_0' is similar in magnitude to that for silver paste electrodes. At low overpotentials ($<kT/e$) the polarization again shows linear behavior in accordance with Eq. [15] and [21].

In Fig. 10, I_0' and I_l are plotted as functions of temperature; I_0' is found to have an activation energy of 1.1 eV, the same as that of the Ag paste electrodes. In the case of I_l, as well as I_0'' (not shown), a straight line is not obtained over this range. These same data, when plotted *vs.* p_{O_2} at constant temperature show that $I_0' \propto p_{O_2}{}^{3/8}$ in agreement with the results for Ag paste electrode (Fig. 7), while I_0'' and I_l show roughly $p_{O_2}{}^n$ behavior with $n = 1/2$ and 1, respectively.

The polarization of gold paste electrode can also be described by Eq. [11]. The p_{O_2}-dependence of I_0' at 785°C is shown in Fig. 11, where the solid line is again drawn with a slope of 3/8; however, there is a deviation from this power law at low p_{O_2}. The tem-

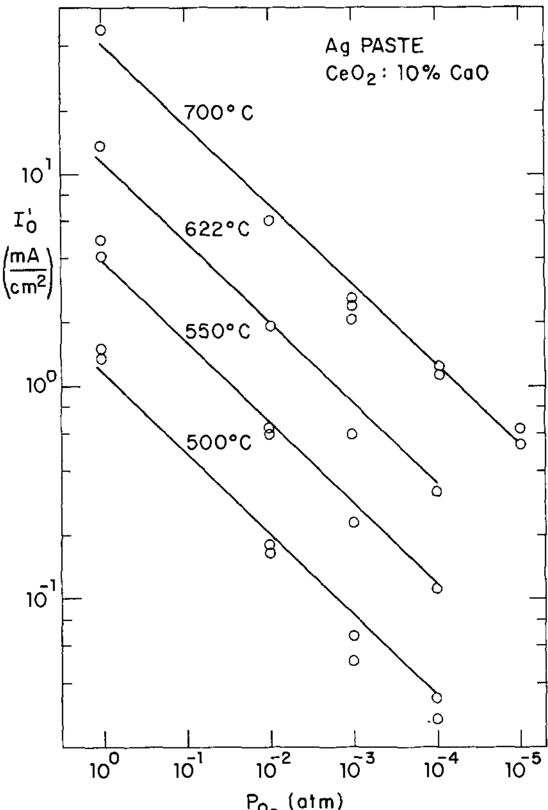

Fig. 7. Variation of I_0' with p_{O_2} for Ag paste electrodes at various temperatures. The straight lines are all drawn with slope of 3/8.

perature dependence of I_0' is given in Fig. 8 (open circles) for two different p_{O_2}; in both cases the slope corresponds to an activation energy of 1.69 eV.

At sufficiently low p_{O_2}, we find that the entire range of the cathodic polarization cannot be fitted very well by either Eq. [11] or [20]. A typical example for an Ag foil electrode at 735°C is given in Fig. 12. The open circles are the data and the solid line A is the fit of Eq. [20]. The solid circles give the difference of current $\Delta|I|$ between the measured values and line A. The plot of this difference as log $\Delta|I|$ *vs.* $|\eta|$ shows a linear region of slope $2.3e/kT$. For Pt foil electrodes, similar behavior has also been observed, an example of which is given in Fig. 13 for a temperature of 600°C. The open circles represent the data and line A is the best fit of Eq. [11]. Again, the difference of current between the data and line A gives a slope of $2.3e/kT$.

Finally, we present results of scanning electron microscope and optical microscope examination of the various electrodes in order to relate the structures to the polarization behavior.

Figure 14(a) shows a freshly prepared platinum paste electrode without flux. The sizes of particles are the same as for the electrode with flux (1). Since this electrode is freshly prepared, the coarsening effect which we have reported previously has not taken place, and the width of Pt particles is around 1 μm. Figure 14(e) shows platinum foil electrode B. There are many pores, both along the grain boundary and inside the grains, which expose the electrolyte to the ambient gas; therefore, this electrode will not function as an oxygen-blocking electrode, as one might otherwise have expected.

Figure 14(b) shows the fresh silver paste electrode heated only to 500°C, while Fig. 14(c) represents the same electrode after heating to 700°C showing that sintering has taken place. Both of these Ag paste electrodes show considerably larger particles than the Pt electrode of Fig. 14(a). In Fig. 14(f), the silver foil electrode is shown. Again, we see that along the grain boundary and inside the grain there are many pores which expose the electrolyte to the am-

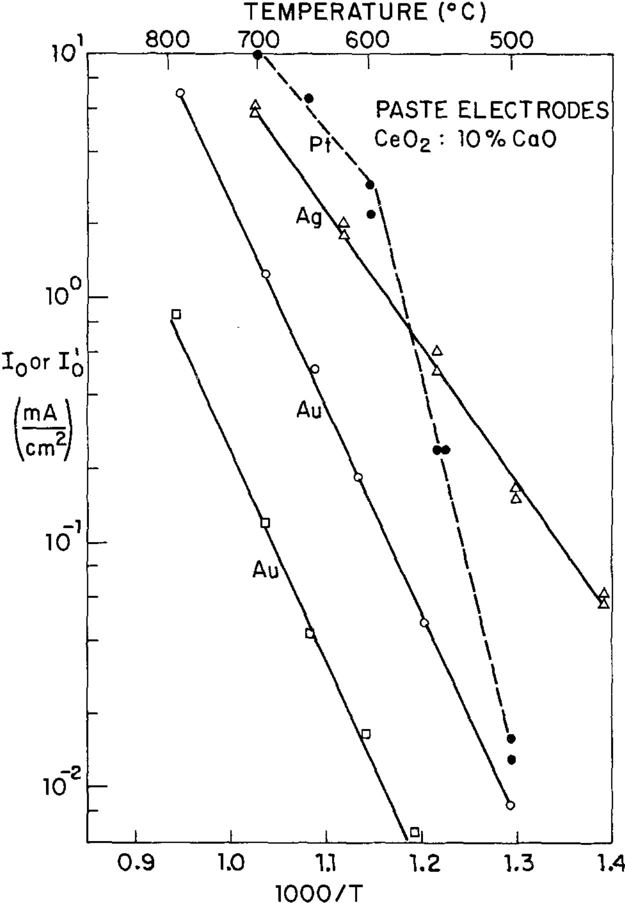

Fig. 8. Variation of I_0' (or I_0, for Pt paste) with reciprocal absolute temperature for the various paste electrodes. All data are taken at $p_{O_2} = 0.9 \times 10^{-2}$ atm except for the lowest curve (squares) which was taken at 1.2×10^{-5} atm.

bient gas. Finally, Fig. 14(d) shows the gold paste electrode. The particles are larger than those of platinum paste and comparable to those of the silver paste electrodes.

Examining the dendrite-like structure of the metal paste electrodes [Fig. 14(a)-(d)], we conclude that morphologically Fig. 1 provides a reasonable approximation to the actual structure. On the other hand, for

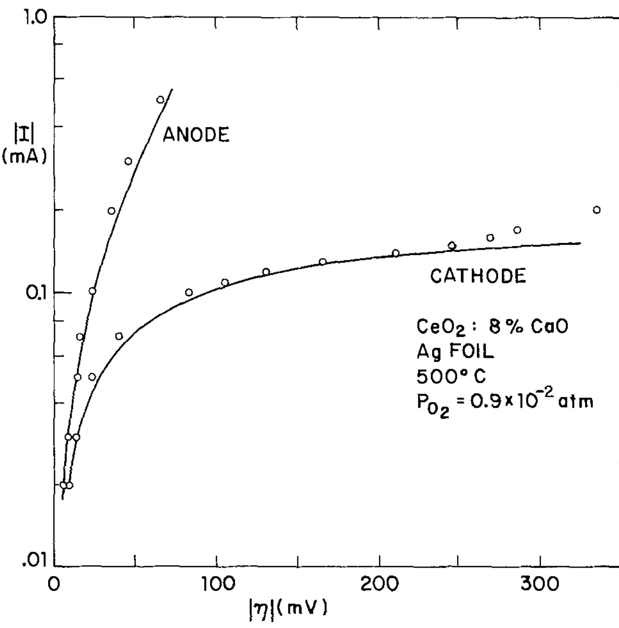

Fig. 9. Polarization curves for Ag foil electrodes at 500°C. The anodic data is fitted to Eq. [11] and the cathodic to Eq. [20].

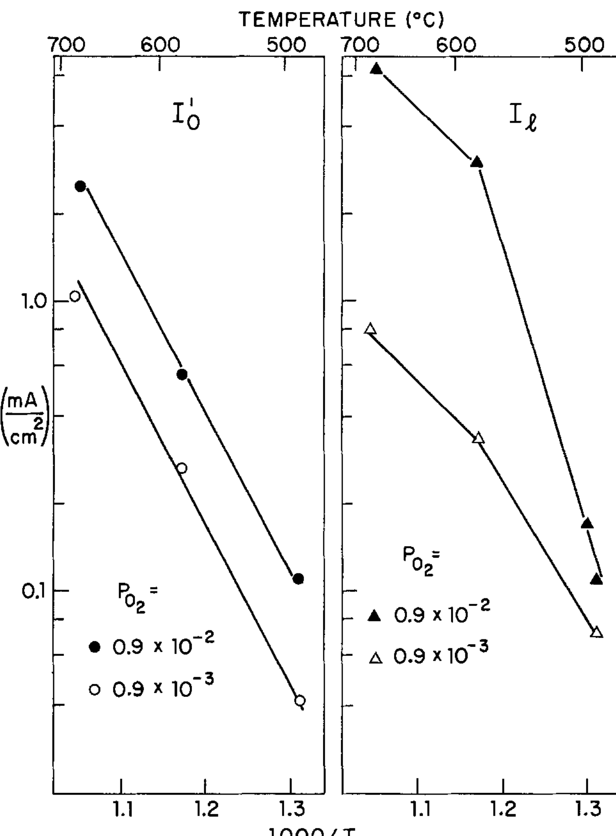

Fig. 10. Variation of I_0' and I_l with 1000/T for Ag foil electrodes at two values of p_{O_2}.

the foil electrodes [Fig. 14(e) and (f)], Fig. 1 is a poor representation; rather, a grid-like geometry would provide a better representation.

Discussion

Pt electrodes.—An important result of the present work is the clear demonstration that, for platinum foil electrodes, polarization at both the anode and the cathode is controlled by interfacial diffusion. The verification of this statement follows from the observation that the Butler-Volmer equation is obeyed with $\alpha_a' = 3/2$, $\alpha_c' = 1/2$, and $I_0' \propto p_{O_2}{}^{3/8}$, in agreement with the

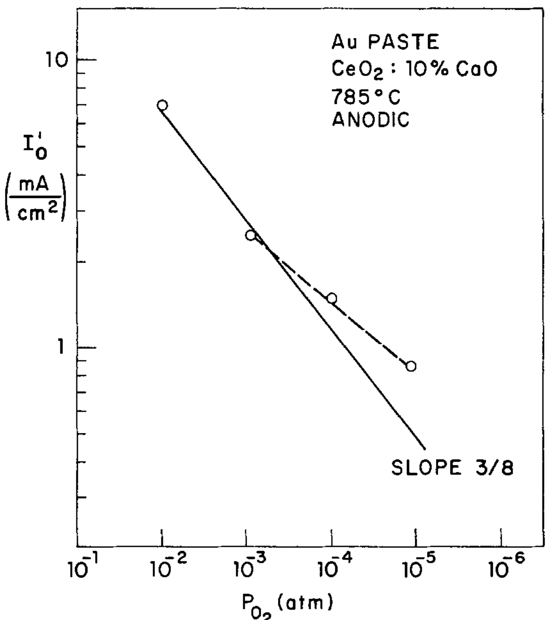

Fig. 11. Variation of I_0' with p_{O_2} for Au paste electrode at 785°C. The solid line is drawn with slope of 3/8.

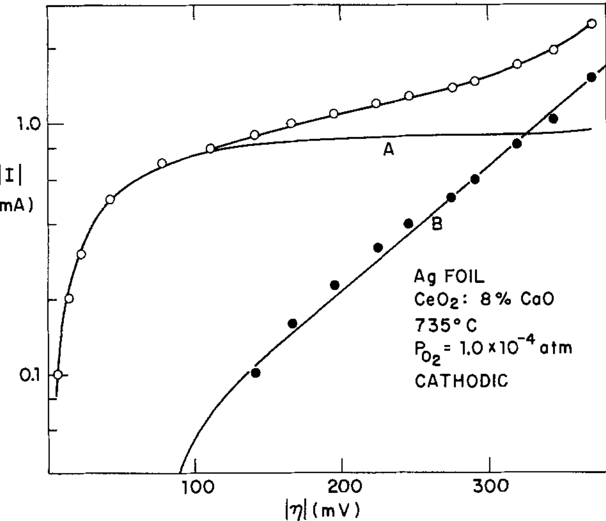

Fig. 12. Cathodic polarization curve for Ag foil electrode at 735°C and $p_{O_2} = 10^{-4}$ atm (open circles). Line A is the fit to Eq. [20]. Filled circles are obtained by subtracting line A from the data. Line B is obtained from Eq. [24] with E replaced by $|\eta|$.

theory (see Eq. [13], [14], and [16]), in contrast to the previous result (1) that under charge-transfer process control, platinum paste electrodes show $\alpha_a = \alpha_c = 1$ and $I_0 \propto p_{O_2}{}^{1/4}$.

Next we discuss the quantity Q. Based on Eq. [8], it involves the exchange current I_0, oxygen adatom concentration C_0, interfacial diffusivity D, and the geometrical parameter L. Values of I_0 and C_0 are available from the previous study (1), while microscopic observations of the electrodes (as in Fig. 14) give the magnitudes of L. Lewis and Gomer (9) have measured the surface diffusion rate of oxygen on (100)- and (111)-oriented Pt field emitters and expressed the results as

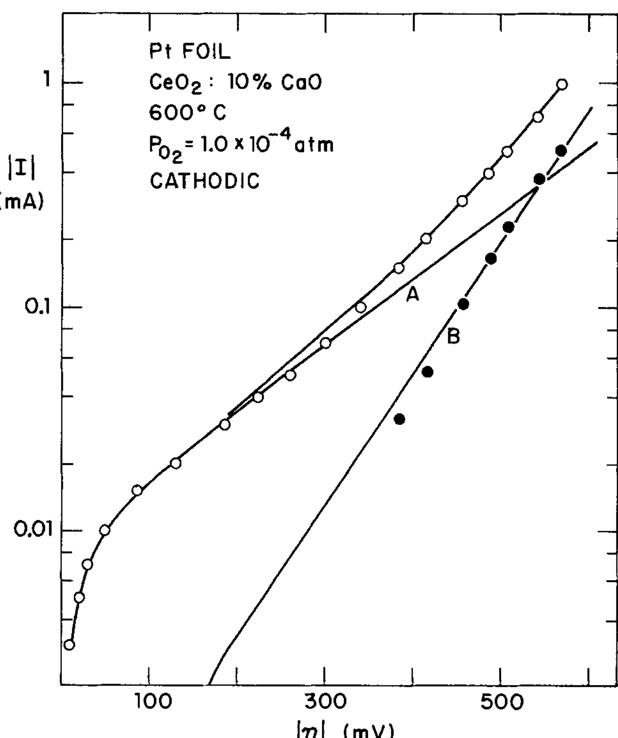

Fig. 13. Cathodic polarization curve for Pt foil electrode B at 600°C and $p_{O_2} = 10^{-4}$ atm (open circles). Line A is the fit to Eq. [11]. Filled circles and line B are as in Fig. 12.

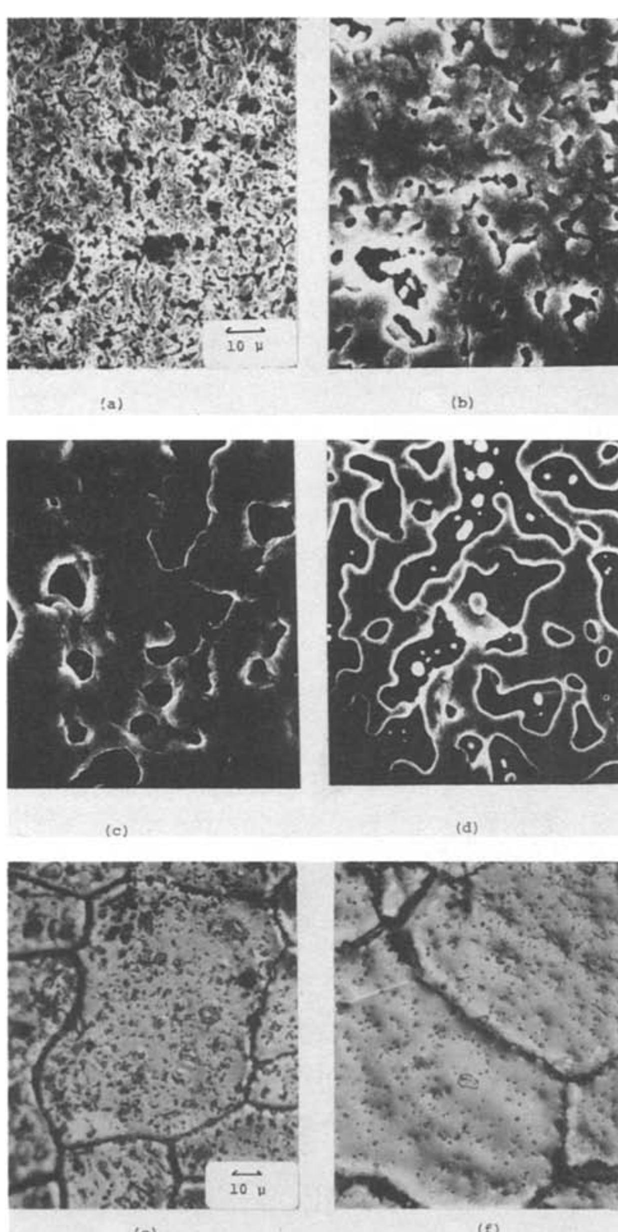

Fig. 14. Surface scanning electron micrographs (magnification 1000×) of various paste electrodes: (a) Pt (without flux), (b) Ag, freshly prepared and heated to 500°C, (c) Ag, after several cycles of measurement up to 700°C, (d) Au. $$D = a^2\nu \exp(\Delta S/k) \exp(-E_d/kT) \quad [23]$$

with a = 3A, ΔS = 17 eu, $\nu = 10^{12}$ sec^{-1}, and E_d = 1.48 eV, for temperatures above 500 K and with low oxygen adsorption ($\theta << 1$). In the absence of better information, we tentatively use Eq. [23] for the interfacial diffusion coefficient. With all of this data, we are able to estimate values of Q for Pt electrodes. Table I lists the calculated values of Q for the various p_{O_2} employed here, for $T = 800°C$ and $L = 1$ μm. (Since Q is linearly proportional to L, the Q value for a given p_{O_2} and another value of L can easily be obtained.)

From Fig. 2, we see that, in order to have a pure charge transfer process, the value of Q must be less than unity. Referring to Table I, this means the Pt particles should not be larger than 0.2 μm (or $L \leq 0.1$ μm). The width of platinum particles of a freshly prepared electrode, as determined by SEM, is ~1 μm [Fig. 14(a)]. However, considering the curvature of the Pt particles and the surface roughness of the electrolyte, it is reasonable to expect that the actual

Table I. Values of Q for Pt electrodes calculated from Eq. [8] for $T = 800°C$ and $L = 1$ μm. [D is obtained from Ref. (9) and I_0 and C_0 from Ref. (1)].

p_{O_2} (atm)	Q
0.92×10^{-2}	9.5
0.94×10^{-3}	13
1.0×10^{-4}	17
1.2×10^{-5}	22

contact between the particles and the electrolyte involves a smaller value of L. It is thus understandable why freshly prepared Pt-paste electrodes give polarization behavior characteristic of the simple charge transfer process (1). For Pt foil electrode A (which had a relatively low heat-treatment temperature), it is probably the Pt paste between foil and the electrolyte, and not the foil itself, which controls the polarization. Previous results (1) have demonstrated that a heat-treatment like the one used in the preparation of electrode A can cause the Pt particles to coarsen by a factor of 3 (1 → 3 μm). In addition, the placing of a weight on top of the Pt foil during firing can only have served to enlarge the actual contact area. Taking $2L = 3$ μm (for $p_{O_2} = 0.92 \times 10^{-2}$ atm) gives $Q = 14$, in reasonable agreement with the actual value of 9.5. Figure 2 shows that such a Q value is well into the range where interfacial diffusion controls the polarization. For Pt foil electrode B we believe, based on Fig. 14(e), that actual contact between electrolyte and Pt foil has been established; therefore the Pt foil plays the major role. Figure 14(e) shows that pores in the foil have an average separation ~5 μm; using Table I this corresponds to $Q \cong 24$, in good agreement with the actual value of 26.

There is reason to question whether oxygen adatoms can diffuse into the interface region between electrode and electrolyte and, if so, whether the diffusivity is the same as that measured for oxygen over the free and clean surface of a Pt crystal. It appears reasonable to expect that, as long as there is no strong chemical bonding between the platinum and the electrolyte, oxygen adatoms should have no difficulty in diffusing along the interface, and with a diffusivity that is similar (at least in order of magnitude) to that for the free surface. That bonding is indeed very weak between Pt and doped CeO_2 is supported by the fact that the unfluxed Pt paste electrode can easily be rubbed off with the finger tips.

Multilayer oxide films can be grown on the surface of high purity polycrystalline Pt under appropriate temperatures and oxygen pressures. If this had occurred in the present experiments, it would be the platinum oxides that act as the electrode, not the platinum. A recent study (10) which establishes the dissociation pressure-temperature relationship between Pt oxide and Pt shows, however, that within the present experimental range of p_{O_2} and T no Pt oxide layer will form. This is also consistent with our observation that the electrode polarization is reproducible and not time dependent.

Ag electrodes.—The solubility and diffusivity of oxygen in solid silver is relatively high (11). Assuming that the outer surface layer of the silver is always saturated with an equilibrium concentration of chemisorbed oxygen and that the diffusion of the oxygen from this saturated layer through the body of the silver is the rate-limiting step, one can calculate limiting currents, I_l, for cases such as those given by Fig. 5 and 9. The values obtained are consistently at least one order of magnitude too small. It is therefore reasonable to conclude that bulk diffusion cannot be the rate-controlling step. In fact, silver paste electrodes behave like platinum foil electrodes in that the anodic and cathodic polarizations can be described by the

Butler-Volmer equations with $\alpha_a' = 3/2$ and $\alpha_c' = 1/2$, I_0' has a 3/8 power dependence on p_{O_2}, and the overpotentials decay slowly (see Fig. 6). [If the polarization were of the activated type, η should decay to zero within 10^{-4} sec (2).] Therefore, we conclude that for Ag electrodes, polarization is also controlled by interfacial diffusion.

Oxygen chemisorption on the surface of silver single crystals has been widely studied (12-14). It has been shown that oxygen adsorbs on the surface and dissociates into oxygen atoms, similarly to the case of platinum, although the equilibrium adatom concentration is lower. Thus, for example, on the silver (110) face, $\theta = 1/2$ is obtained at 500 K and $p_{O_2} = 10 \times 10^{-4}$ Torr (11); assuming that adsorption obeys the Langmuir equation, we calculate that $\theta = 1/2$ at $T = 500°C$ for $p_{O_2} = 1.6$ atm. Such estimates show that, within the present experimental ranges of temperature and p_{O_2}, θ is always less than 1/2. This explains why there is no change of slope in the isothermal plot of I_0' *vs.* p_{O_2} for silver electrodes, while there is a sharp change for platinum paste electrodes (see Fig. 8).

Both Ag paste and Ag foil give not only the same p_{O_2}- and temperature-dependence of I_0', but also the same magnitude of I_0'. This is probably because of the many pores that exist in the silver foil [see Fig. 14(f)], which expose the electrolyte to the ambient gas.

Tannenberger *et al.* (15) have studied silver paste electrodes with a doped zirconia electrolyte using a current-interruption method. This method differs from the present one only in that it did not use a reference electrode, and therefore they measured the total overpotential, $\eta_t = (\eta_a - \eta_c)$, instead of η_a and η_c separately. In their work, ohmic behavior was observed in the range below 300 mV. At 811°C and air atmosphere their data yield $I_0' = 76$ mA/cm². By adding the present cathodic and anodic polarizations for Ag paste electrodes and extrapolating the data to their experimental conditions, a linear range for η_t up to 300 mV was found, as well as a value of I_0' of 85 mA/cm². This agreement between these two diverse studies is most satisfactory.

The results for the limiting current density, I_l, reported in Fig. 10 show that the behavior of this quantity is more complex than that of I_0' and indicates that different mechanisms may be involved at high and at low temperatures. In previous work on Pt paste electrodes (1), we also found that the quantity I_l was more difficult to control or reproduce than the exchange current I_0. Since the quantity I_0'' obtained from the ohmic range involves both I_0' and I_l, (see Eq. [21] and [22]), we must conclude that, until there is better control and understanding of the limiting-current behavior, measurements of I_0'' (or of the resistance in the ohmic range) are not as meaningful as one might have hoped. In support of this statement, it is noteworthy that measurements of ohmic resistance with Ag electrodes by a-c or d-c methods have yielded no distinct p_{O_2} dependence or activation energy (16-18).

Au electrodes.—Gold is one of the least active metals in chemisorption; none of the common adsorbates, including oxygen, have been found to chemisorb at room temperature (19). At high temperatures, substantial evidence is available for the existence of chemisorption at moderate p_{O_2} ($> 10^{-5}$ atm) but not at low p_{O_2} ($\sim 10^{-8}$ atm) (20-23). For the present experimental range of temperature and p_{O_2}, there is no doubt that some chemisorption of oxygen occurs on the gold paste electrodes, although to a lesser extent than for silver and platinum ($\theta_{Au} < \theta_{Ag} < \theta_{Pt}$).

The polarization behavior of Au paste electrodes is sufficiently similar to that of silver paste and platinum foil electrodes as to lead to the conclusion that, also in this case, it is controlled by surface diffusion. However, the departure, at low p_{O_2}, from a slope of 3/8 (Fig. 11) is not understood.

In Fig. 8, we have collected data for I_0' of Au and Ag and I_0 of Pt paste electrodes for comparison. The fact that the activation energies are different for various metals supports the present model that the controlling diffusion process occurs on the metal surface, rather than, say, on the electrolyte. It is also noteworthy that the relatively high activation energy (1.69 eV) of gold electrodes serves to bring the magnitude of I_0' close to that for Pt and Ag electrodes at high temperatures (800°-1000°C).[1]

Reduction phenomenon.—The departure from the fitted curves at high $|\eta|$ in Fig. 12 and 13, is very interesting and can be explained with the help of the present model. Using Eq. [6], we plot in Fig. 15, the relative surface concentration of oxygen $C(u)/C_0$ as a function of the relative distance u/L on a log-log scale for various cathodic overpotentials at $T = 700°C$. As clearly shown in this figure, the concentration gradient is significant only at the periphery ($u/L \simeq 1$); further, the larger Q (or $|\eta|$) the more extreme is this effect. Over most of the electrode area $C(u)/C_0$ is nearly constant. Equation [3] shows that in such regions there will be almost no ionic current. Physically, what happens is that almost all of the oxygen adatoms leaving the edge are immediately drawn into the electrolyte because of the relatively high local charge transfer rate. The rest of the area is then left without a supply of reactants, forming a so-called ionically blocking electrode.

According to Wagner's polarization theory (24), an electronic current will flow as a result of reduction of the electrolyte adjacent to an ionically blocking cathode to give an electronic current I^e of

$$I^e = I_0^e\,[1 - \exp(eE/kT)] \qquad [24]$$

where I^e_0 is a constant and E is the total emf across the sample. This equation follows under the assumptions that there is no ohmic polarization from electrode leads

[1] This fact can have practical significance in that it suggests that Au (or Au alloy) paste may be useful for high temperature electrodes in a range ($\gtrsim$ 800°C) where Ag is not suitable because of its high vapor pressure and Pt because of the difficulty in producing adhesion.

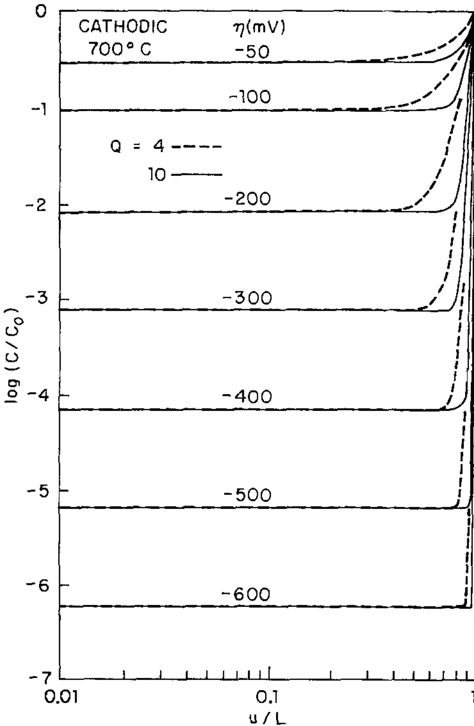

Fig. 15. Dependence of (C/C_0) on the fractional distance from center of the electrode at 700°C for various cathodic overpotentials, as calculated from Eq. [6] for $Q = 4$ and 10 (dashed and solid curves, respectively).

or electrolyte and that the anode is reversible to the conducting ion. In a previous study (3), we have shown that for the case of incomplete blocking at the cathode and $\eta_a \neq 0$, Eq. [24] remains valid but with E replaced by $|\eta|_c$, which is measurable using the current interruption method with the help of a reference electrode.

Under the conditions shown in Fig. 15, the current is, therefore, ionic in the peripheral region while over the rest of the electrode it is predominantly electronic, and the total current should be the sum of both. The electronic current is given by Eq. [24] with E replaced by $|\eta_c|$. Thus, at high $|\eta_c|$ ($|\eta_c| > kT$), a slope of $2.3e/kT$ is predicted for the plot of log I^e *vs.* $|\eta_c|$, in agreement with the observations in Fig. 12 and 13.

Another consequence of Fig. 15 is that, since the ionic current is only concentrated in the peripheral region, the electrolyte polarization is of the constriction type. Indeed, constriction polarization has been observed in the work of Tannenberger *et al.* (15) with silver paste electrodes. By varying the thickness of an yttria-stabilized zirconia electrolyte, they found a residual resistance which they attributed to the fact that the electrodes are active only on discrete spots, although they had no further explanation.

Conclusions

1. The charge transfer reaction takes place in the two-phase region between the metal electrode and the oxygen-ion conducting electrolyte. For most electrodes, the rate of this reaction is limited by diffusion of oxygen atoms on the metal surface along the electrode-electrolyte interface, a mechanism often neglected when the totality of possibilities is considered (25). Only if the electrode particle dimension ($2L$) is small enough, as in the case of freshly prepared Pt paste electrodes, have we observed the pure charge transfer mechanism.

2. If the rate of surface diffusion is lower than the local rate of charge transfer, ionic current will flow predominantly near the three-phase (gas-electrode-electrolyte) region. In that case, the central area of the electrode particle becomes initially blocking and electrons may be injected into the electrolyte. The Wagner polarization-cell theory can then be used to describe the behavior.

Bubble Effects on the Terminal Voltage of a Vertical Cell with Perforated Electrodes

Fumio Hine* and Koichi Murakami[1]

Nagoya Institute of Technology, Nagoya 466, Japan

ABSTRACT

Effect of bubbles on terminal voltage, solution *IR*-drop, and overvoltage in a vertical cell with perforated electrode were investigated. Cell voltage was minimized by use of properly designed perforated electrode. Reduction of the surface area of such machined electrodes is an important disadvantage. With the experimental results obtained, an optimum was estimated to be in the range of 5-15% perforation depending on the current and the rate of gas evolution.

Vertical cells equipped with a pair of plate electrodes are a common style of electrolyzers such as found in water electrolysis cells and diaphragm-type chlorine cells. Such electrolyzers liberate gases at the electrodes, and the gas bubbles disperse in the electrolyte resulting in large solution *IR*-drops. Some bubbles may adhere or cover the electrode surface, in which case the overvoltage rises due to a significant increase of the actual current density. Such difficulties with gas bubbles must be minimized to save energy for the electrolytic process considered.

We have shown in a previous paper that circulation of electrolytic solution between two electrodes is of great importance for reducing the bubble effects in a vertical cell equipped with flat plate electrodes (1). For example, a solution downcomer was provided for this purpose.

Perforated electrodes employed in practical cells are useful to remove electrolytic gas bubbles quickly from the electrolysis zone to the back side. The dimensionally stable anodes (DSA) in modern diaphragm cells consisting of titanium mesh allow the mixture of chlorine gas and brine to pass through toward the inside space of the box-type electrode. Jorné and Louvar have published a paper on the effectiveness of the gas-diverting electrodes of various shapes, which enable the diversion of the electrolytic gas bubbles to the back side of the electrode (2).

This paper deals with the effectiveness of the perforated electrodes on reducing the terminal voltage of vertical cells in which gas evolution takes place. Complicated patterns of the solution flow containing gas bubbles were observed. The electric resistivity of the gas-solution mixture and the overvoltage on the working electrode were measured. The current distribution along the vertical electrode was also studied.

As reference for discussion, results previously obtained for three types of vertical cells with a pair of nonperforated plate electrodes arranged in parallel for blocked convection, for natural circulation, and for pumped circulation, were used [see Fig. 2 in Ref. (1)].

Experimental Procedure

The flowsheet and the electrolytic cell employed were essentially the same as of the previous work with flat plate electrodes (1). That is, a vertical Lucite resin cell, 1m high, had a flat plate counterelectrode made of 304 stainless steel (SS) in parallel with a perforated plate test electrode, also SS, of 3 cm wide, 89 cm long, and 3 mm thick. The total area of perforation of the test electrode was varied in the range 0-60%. In the preliminary experiment, the hole diameter was changed from 3 to 8 mm, but had almost no effect on the experimental results obtained, whereas the percent perforation was an important factor. Therefore, most experiments were conducted with test electrodes having 3 mm diam holes.

The test electrode was sectioned into ten segments to determine the current distribution. Each electrode segment had a shunt, of which one side was connected with a common copper bus bar.

Three pairs of the Luggin-Haber probes connected with respective reference electrodes consisting of Hg/HgO were provided at 8, 44, and 80 cm above the cell bottom to obtain the solution *IR*-drops at those respective points. The potential drop of the Luggin-to-electrode was also measured, and was referred to the polarization potential.

Caustic soda solutions, 0.5*N* and 2.0*N* NaOH, were electrolyzed, thus oxygen and hydrogen were liberated from the anode and the cathode, respectively, and those gases mixed together because there was no separator between the two electrodes. Caustic soda solution was circulated between the back-side space of the counterelectrode and the electrolyte reservoir to keep the solution temperature constant at 40°C. Its pumped circulation did not affect the gas-solution mixture in the electrolysis zone.

The electrode gap was varied in the range 3-25 mm, and the back-side space behind the test electrode was also changed from 0 to 30 mm.

The current density in this paper was based on the plain electrode. Therefore, the actual current density is about twice of the nominal value in the case of 50% perforation, for example.

Electrolysis was conducted up to 100A of total current, in which case the current density was 37.4 A/dm^2 on a test electrode of 3×89 cm^2 superficial area. In some cases, however, electrolysis was carried out with a part of the sectioned electrode to confirm the effect of the electrode height on the current distribution on a vertical electrode. For this purpose, some segments located at the bottom, the center, and the top were employed.

The voltage drops of the Luggin-to-Luggin and of the Luggin-to-electrode (referred to the solution *IR*-drop and the polarization potential, respectively) were measured to obtain the voltage balance through the cell. The terminal voltage was also measured. The Luggin probes were arranged from the back side of the electrode at those respective points to avoid turbulence of solution flow. Although the tip of the probe was located close to the electrode surface, the potential difference of Luggin-to-electrode contained some ohmic voltage drops along with the overvoltage.

Results and Discussion

The flow pattern of solution in a vertical cell during electrolysis was complicated, and affected greatly by the current density or the total current. Drawing A

Key words: electrolytic gas bubbles, electrolyte resistivity, cell voltage, current distribution, perforated electrodes.

in Fig. 1 illustrates a sketch of the flow pattern in a cell operated at 100A. The gas-solution mixtures passed through the perforated electrode all the way around, the back-side space was crowded, and complicated flow occurred. A part of the solution was recirculated through the holes at the bottom to the electrolysis zone. At low currents, such as 5A or at about 2 A/dm^2, gases liberated at the lower part of the electrode rose along the electrode and did not escape to the back-side space at the bottom. Those mixtures accumulated to pass through the holes of the electrode at a certain height, say 40 cm. The solution free of gas bubbles at the bottom of the back-side space was, of course, clear. The level at which the gas-solution mixture in the electrolysis zone diverted to the back side of the working electrode was related to the current up to 30A or *ca.* 10 A/dm^2 as shown in Fig. 1(B), but it remained almost constant at about 10 cm at higher currents. Also the level was dependent on the inter-electrode gap, *i.e.*, the level became low in narrow channels due to the increase of gas void fraction even at the same current density. The flow pattern was almost independent of the percent perforation of the electrode in the range more than 10%.

Figure 2 shows the resistivity *vs.* current density curves at the top (80 cm above the cell bottom), the center (44 cm), and at the bottom (8 cm) in a cell equipped with a 20% perforated electrode positioned 10 mm away from the counterelectrode (the open points). The ordinate is the reduced resistivity ρ/ρ_0, where ρ and ρ_0 are the resistivity of electrolytic solution with and without gas bubbles, respectively, and the abscissa is the local current density at the respective points.

Since the solution at the cell bottom is free of bubbles, the reduced resistivity is nearly unity over the wide range of current density. On the other hand, the resistivity increases with increasing current density at the center and the top of cell. The resistivity has a linear relationship with the current density at those points whereas the slope differs because of different fraction of gas void.

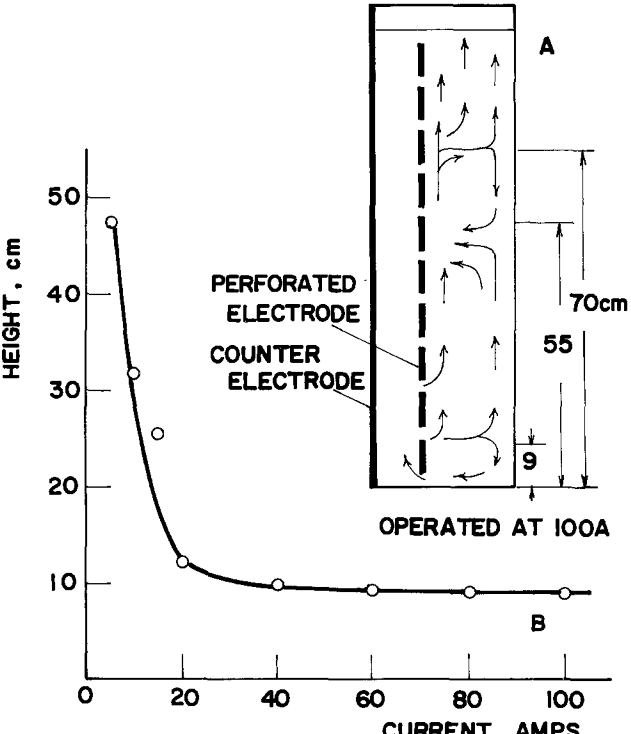

Fig. 1. Flow pattern of gas-solution mixture in a cell operated at 100A (A), and the lowest height for passing two-phase mixture as a function of current (B). Electrode gap = 1.1 cm; back-side space = 2.2 cm; electrolyte = 2*N* NaOH at 40°C.

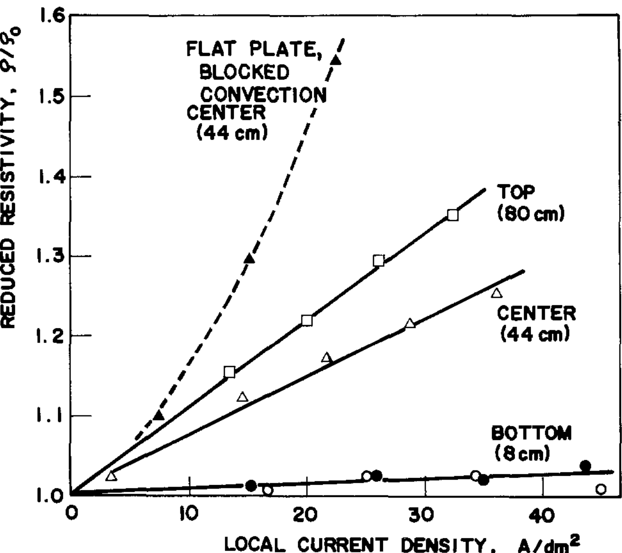

Fig. 2. Reduced resistivity *vs.* local current density curves at the top, the center, and the bottom of cell. Electrode gap = 1.9 cm; electrolyte = 2*N* NaOH at 40°C.

The experimental results obtained with a flat plate electrode under blocked convection are plotted as reference, shown by the closed points. No difference between the two cases can be found at the cell bottom, but the resistivity in a cell having a nonperforated electrode increases greatly with increasing current density at the center of cell (the dotted line). This tendency is more significant at the upper part of cell due to accumulation of electrolytic gas bubbles. The resistivity can be reduced considerably by solution circulation as described previously (1).

Variation of the resistivity causes the current distribution along the vertical electrode as shown in Fig. 3. The ordinate is the reduced height, x/h, where x is the distance from the bottom and h is the total height. The abscissa is the reduced current density, i_x/i_a, where the subscripts x and a refer to local and average, respectively. Drawing A illustrates the effect of the total current or the average current density. It is clear that the current distribution becomes uniform when the current density decreases because of the small volume of gas bubbles. The current density at a 40-50% height is about equal to the average value in all cases.

Figure 3B shows the current density *vs.* height curves obtained with the perforated electrodes of different sizes and locations. The test electrode had ten segments of equal size. Of these, three, five, and seven segments were employed as the working electrode to determine the effect of size. The location of the working surface was also changed: the top, the center, and the bottom of the cell. Although the plots fluctuated somewhat, we

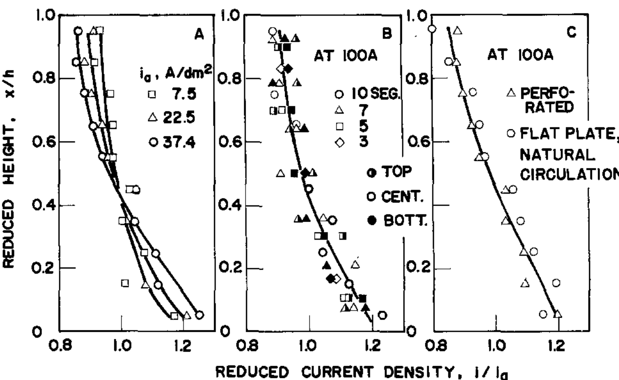

Fig. 3. Current distribution on the electrode as a function of the average current density (A), the electrode size and location (B), and the type of electrode (C). Electrode gap = 1.9 cm; electrolyte = 0.5*N* NaOH at 40°C.

considered that there was no significant effect of the electrode size and of the location on the i_x/i_a vs. x/h curve. Consequently, the current distribution on a tall electrode is relatively uniform in comparison to that on a short electrode.

Figure 3C shows the i_x/i_a vs. x/h curve for a perforated electrode operated at 100A compared to a flat plate electrode under natural circulation. The current distribution in both cases is almost the same. This is reasonable because the local current density is a function of the dimensionless height, $X = x/h$ (3)

$$i_x/i_a = 8(K + 2)^2/(K + 4)(KX + 2)^2 \quad [1]$$

Although the gas effect parameter K contains many factors, it is in the range of 0.2-0.7, depending on the gas void fraction in the electrolysis zone, over the wide range of experiments (1). In the present case with the perforated electrode, electrolytic gases pass through the holes to the back-side space resulting in low gas void fraction. On the other hand, the electrolytic solution leaving excessive gas bubbles at the cell top with a flat plate under natural circulation through the downcomer provided at the back side of the electrode. The gas void fraction and the solution resistivity in both cases were confirmed to be about the same all the way along the electrode.

In a cell having a pair of flat plate electrodes operating under blocked convection, the local current density along the electrode varies greatly and the current distribution depends on the electrode gap at high current densities. In narrow channels less than 1 cm gap, the gas-solution mixture was slug flow, and the potentials to be measured fluctuated.

The current distribution with the perforated electrode is relatively uniform especially in narrow channels, and is a weak function of the electrode gap.

At small currents such as 20A or 7.6 A/dm² of the average current density, there is no significant difference of the current distribution between the flat plate electrode and the perforated electrode, and, of course, the current density along the electrode is uniform.

Drawing B in Fig. 4 shows the solution resistivity in the electrolysis zone as a function of the electrode gap. With a pair of the flat plate electrodes under blocked convection, the resistivity increases largely when the gap decreases. In a case of natural circulation, on the other hand, the solution resistivity is small except in narrow channels less than 7 mm in gap, and is a weak function of the electrode gap because the flow velocity of gas-solution mixture increases with decrease of the electrode gap, that is, the resistivity depends on the flow velocity (1, 4).

The solution resistivity in the electrolytic cell having a perforated electrode is kept low even if the electrode gap is small, say 3 mm.

The terminal voltage reflects this phenomenon as shown in Fig. 4A. The terminal voltage of a cell with a perforated electrode is a linear function of the electrode gap even in a narrow channel at high current densities. On the contrary, the voltage of the cell with a flat plate under natural convection rises greatly when the electrode gap becomes smaller than 5 mm.

However, it is important that the terminal voltage of the cell with a flat plate electrode is slightly lower compared to that of the perforated electrode when the electrode gap is larger than 10 mm. This is reasonable because the surface area of the perforated plate employed is 20% less than that of the flat plate of the same outside geometry. Therefore, this causes an increase in the solution IR-drop in a cell with perforated electrodes. Also the increase in overvoltage due to reduction of the surface area would be a factor.

Figure 5 illustrates that the solution resistivity decreases significantly when the perforation area increases from 0 to 10% as shown in Fig. 5C, but remains almost constant thereafter.

The overvoltage at 100A or 37.4 A/dm² is recorded to be a minimum in the range 5-15% of the perforation area (drawing B), but increases with increasing percent perforation.

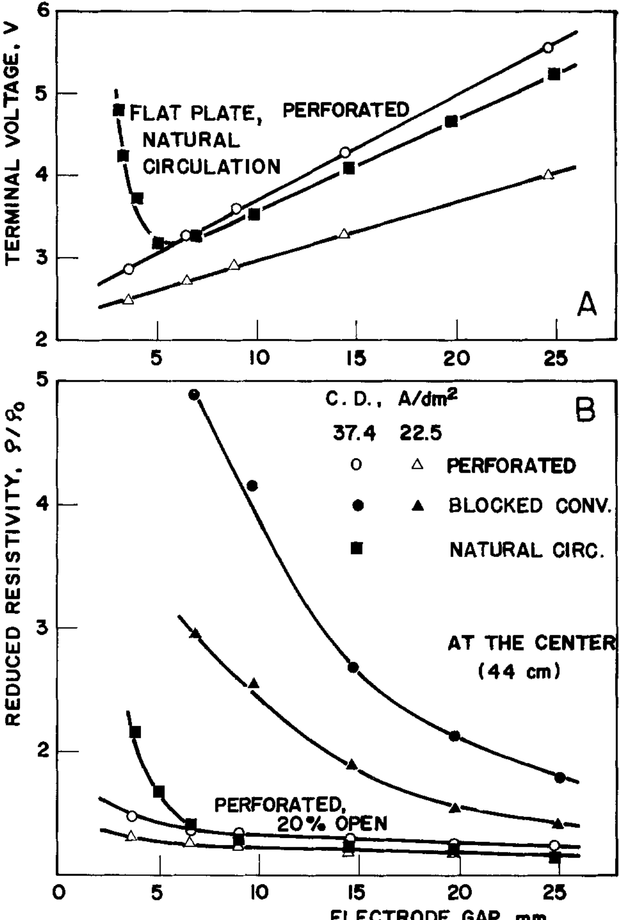

Fig. 4. Terminal voltage and solution resistivity as functions of the electrode gap. Back-side space = 1.2 cm; electrolyte = 2N NaOH at 40°C.

According to the previous study on the current distribution in an electrolytic cell equipped with a pair of the flat plate electrodes in parallel, the ratio of the electrode-to-cell wall gap to the inter-electrode gap is an important factor on the current distribution and the total current under a given terminal voltage, that is, the larger the ratio the larger the current on the back side of electrode (5). With this concept, the effectiveness of the back-side area of the perforated electrode, also of the side wall of the holes, increases with decrease of the electrode gap. Since the current density decreases, the overvoltage is reduced slightly in a narrow channel.

Consequently, the terminal voltage depends on the percent perforation as shown in Fig. 5A. The voltage with a flat plate electrode (0% open) is very high because of a large fraction of gas void, but it decreases significantly with increasing area of holes. The terminal voltage becomes minimum in the perforation range 5-15% at 100A for example, and it rises gradually with increasing percent perforation because of excessive reduction of the electrode surface by machining. It was not significant, but the optimum point of perforation was dependent on the operating conditions, especially the current, *i.e.*, the larger the current the more the perforation.

Increase of the resistivity in the perforated electrode itself is also a factor of the terminal voltage if the percent perforation is large. The resistance of the electrode did not change significantly up to 15% perforation at about 3 mΩ for the longitudinal direction of the plate (89 cm), but it increased gradually with an increase in perforation area. At 55%, for example, the resistance was 9 mΩ.

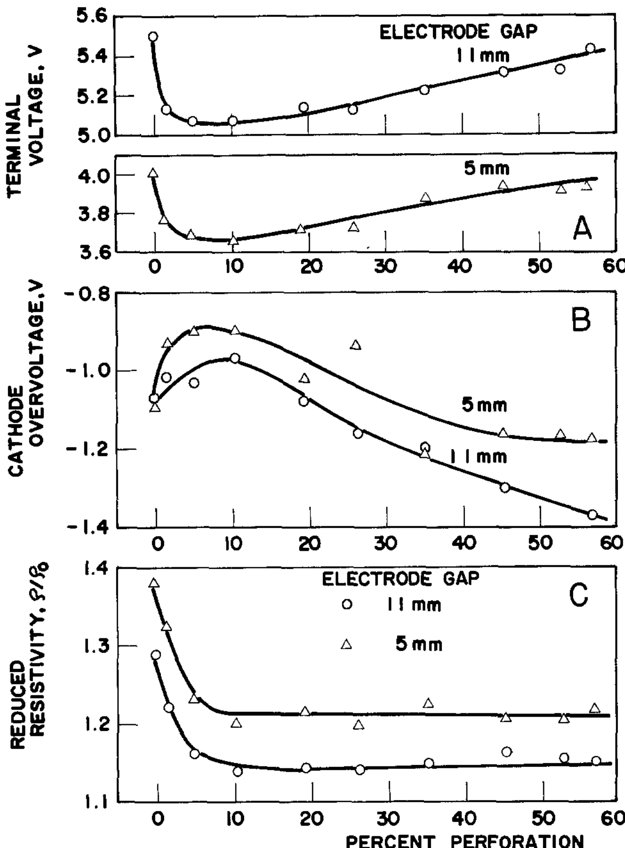

Fig. 5. Terminal voltage, cathode overvoltage, and solution resistivity as functions of the percent perforation of electrode. Backside space = 2.2 cm; electrolyte = 0.5N NaOH at 40°C; total current = 100A.

Experimental results described that the back-side space could be minimized to be 3-5 mm thick, no large space was required in a cell with the perforated electrode, compared to 12-15 mm thick of the downcomer in a cell operated under natural circulation [see Ref. (1)].

Those experiments were conducted with NaOH solutions of 0.5*N* and 2.0*N*, and showed essentially the same results in both solutions.

Oxygen and hydrogen were liberated at the anode and the cathode, respectively, and those gases were mixed because there was no separator between two electrodes as stated above. It is obvious that the size of bubbles and their separation from the electrolytic solution are different for oxygen and hydrogen (6). In alkali solution, hydrogen bubbles were very small in size, and hence the gas void fraction was large in comparison with oxygen. Thus the lack of a separator makes an investigation unrealistic from the viewpoint of the industrial cells. However, the bubble effects in the electrolytic cell, especially the increase of the solution resistivity depends on the gas void fraction, but is almost independent of gas and the cell configuration (1). For one Faraday passed, 1/4 mole O_2 plus 1/2 mole H_2 were evolved, so that the experimental data in Fig. 2 and 3, for example, overrated the effects of gas void in comparison to a practical cell equipped with a separator in which either hydrogen or oxygen may evolve at the working electrode.

The gas void fraction increases with increasing distance from bottom to top in a vertical cell. It causes an increase in the cell voltage at a given current or an average current density, or a reduction in the total current at a given cell voltage. We will calculate a simple case as example. The cell height is h, the width is a, and the depth (the electrode gap) is b. The solution resistivity varies continuously from ρ_0 at the cell bottom to ρ_h at the top. The terminal voltage V_T consists of the decomposition voltage, the overvoltages at the anode and the cathode, and the solution *IR*-drop. The terminal voltage may also contain the *IR*-drop through the separator in some cases. Of these, only the solution *IR*-drop is assumed to vary with the height due to the gas void.

The current I_x at a cross section of $a \cdot dx$ at height x, at which the resistivity of the electrolyte-gas mixture is ρ_x, is represented by Eq. [2]

$$dI_x = \frac{a\,V_T}{b}\,\frac{dx}{\rho_x} \qquad [2]$$

Therefore, the total current I is

$$I = \frac{a\,V_T}{b}\int_0^h \frac{dx}{\rho_x} \qquad [3]$$

For simplicity, we may assume a linear distribution of the resistivity of the electrolyte-gas mixture along the vertical cell

$$\rho_x = \rho_0 + (\rho_0 - \rho_h)\,x/h \qquad [4]$$

From Eq. [3] and [4]

$$I = \frac{a\,V_T\,h}{b\,\rho_0}\,\frac{\ln k}{k-1} \qquad [5]$$

$$i_a = I/a\,h \qquad [6]$$

$$V_T = i_a\,b\,\rho_0\,\frac{k-1}{\ln k} \qquad [7]$$

where

$$k = \rho_h/\rho_0 \qquad [8]$$

and

$$F = \frac{\ln k}{k-1} \qquad [9]$$

We may call k the resistivity ratio, and F is the current road factor. It is evident from Eq. [5] that the total current may decrease greatly when the resistivity ratio increases at a given terminal voltage. The electrolytic solution at the cell bottom is almost free of bubble as shown in Fig. 2. On the other hand, the reduced resistivity at the top of the cell equipped with a pair of the flat plate electrodes was 2.0 or more at 30 A/dm^2. From Eq. [5], the total current becomes as low as 70% of the cell free from gas bubble. More exact evaluation can be carried out if ρ_x is given as a real function instead of a simple assumption such as shown in Eq. [4].

Ibl and his co-workers have described a relationship between the solution conductivity and the gas void fraction (7). They measured the resistivity of the gas solution mixture directly with a conductivity probe. Gas was sent to the measurement cell from the frit, but was not generated by electrolysis. However, the technique might be useful for determining the resistivity of the solution containing electrolytic gas bubbles as a function of the height in the vertical cell.

For example, an estimated terminal voltage of the membrane-type chlor-alkali cell operated at 30 A/dm^2 and 80°C is about 2.9V, if the overvoltage and the solution *IR*-drop are assumed to be freed of bubble, compared to 3.9V of an experimental cell. A 1V difference is the unwanted bubble effects, that is, the voltage drop due to the bubble effects is surprisingly a quarter of the terminal voltage. It is a reason why we need to purge electrolytic gas bubbles from the interelectrode gap. Of the effectiveness of the gas-diverting electrodes in various types, such as mesh and expanded metal, there is no doubt. But a comparison of the performance of such materials is somewhat difficult and care must be taken. The detailed experiments with those electrodes under well-designed configuration and conditions of electrolytic cell must be conducted for the purpose.

In conclusion, bubble effects on the terminal voltage and its components such as the solution *IR*-drop and the overvoltage in a vertical cell equipped with the

perforated electrode were investigated. The flow pattern of gas-solution mixture in a cell was complicated. It depended on the electrolytic current, but was almost independent of the perforation in the range more than 10%.

The reduced resistivity of a gas-solution mixture in a cell with the perforated electrode was a weak function of the electrode gap, but it increased with increasing distance from the cell bottom due to accumulation of bubbles depending on the depth. The terminal voltage of a cell with the perforated electrode was a linear function of the electrode gap in a wide range whereas the voltage of a narrow cell with the flat plate electrode rose with a decrease of the electrode gap less than 7 mm. However, reduction of the surface area by machining becomes a penalty of the perforated electrode when disengagement of gases from the solution is easy in wide channels. A desirable size of the gap between the perforated electrode and the counterelectrode was estimated to be 5-10 mm (see Fig. 4A).

Since the gas void fraction in the elecrolysis zone in a cell using the perforated electrode is low compared to cells having the solid plate electrode, the current distribution along the perforated electrode is relatively uniform, and is similar to that in a well-designed cell under natural circulation.

The perforation area is also an important factor for reducing the cell voltage and its components. The solution resistivity was almost independent of the perforation area more than 10%, while it increased quickly when the open area was insufficient for escape of gas-solution mixture. The overvoltage decreased with increase of perforation up to 10% because of reducing the surface coverage of the working electrode with gas bubbles. On the other hand, the overvoltage increased when the working area became small by machining. Consequently, a minimum cell voltage could be obtained by the perforated electrode in the range 5-15% open.

It was clarified that only a small compartment such as 5 mm thick of the back side of the electrode was required to provide the space for disengagement of gases from the electrolytic solution so as to keep the cell voltage low.

An Electrochemical Model for Oxide Growth on Zircaloy-2

N. Ramasubramanian*

Atomic Energy of Canada Limited, Materials Science Branch, Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada K0J 1J0

ABSTRACT

The kinetics of Zircaloy-2 oxidation were followed at 573 K in oxygen-free steam and dry air. At various stages during the oxidation polarization measurements were made in molten alkali nitrates and nitrite at 573 K. These measurements provided a comparison of the ionic conductivity of the zirconia and the electrical conductivity of the oxide on the intermetallics, grown in steam and air with those of the oxides grown in the molten salts. A model is proposed for thermal oxide growth on Zircaloy-2. During oxidation in steam, protons are conducted in the adsorbed water phase and reduced by the electron transport occurring at the conducting intermetallic sites. Thus, the oxidation behavior is similar to that in the molten salts, where nitronium and nitrosonium ions are reduced to complete the oxidation. The low rates of oxidation observed in air are attributed to a high resistance for the surface conduction of electrons, and the absence of a conduction and reduction step involving cationic species. Therefore, the rest potential is not lowered as effectively as that during oxidation in steam and the molten salts, in spite of the electron conduction at the intermetallic sites. The molten salts are suitable media for studying, in general, the mechanism of oxide growth on Zircaloy-2; the information obtained is relevant either directly or indirectly.

It is known that the metal-oxide interface, during oxide growth on zirconium and Zircaloy-2, is at a negative potential relative to the oxide-oxidation medium interface. This is demonstrated by the oxidation studies in various media, such as aqueous electrolyte solutions (1, 2), oxygen (3, 4), molten salt (5-7), and steam (8). The attainment of this negative rest potential is determined by the relative ease of transport of oxygen ions and electrons through the growing oxide. An electrochemical interpretation of the kinetics

* Electrochemical Society Active Member.
Key words: fused salts, polarization, charge, transport.

of oxide growth is therefore based on the ionic and electronic conductivities of the growing oxide and their variations, if any, with the oxide growth.

When oxidizing in air, oxygen, or steam, the poor conductivity of the oxidation medium makes the use of an auxiliary electrode, contacting the oxide surface, a necessary requirement for electrochemical measurements. Such *in situ* measurements have been reported using evaporated or sputtered platinum layers (4, 8) and lithium-doped nickel oxide powder (3). In these types of experiments difficulties in interpreting the data were usually associated with an ill-defined contact area and the unknown factor of the influence of the contacting electrode on the oxidation itself.

It was shown that molten alkali nitrates and nitrites are convenient and suitable media for studying the mechanism of oxide growth on zirconium and Zircaloy-2 when the oxidation is also carried out in the molten salt (7). Unlike the evaporated metal and powdered semiconducting contacts, the contact area in the molten salt was well defined. We were, therefore, interested in extending the electrochemical polarization measurements in the molten salt to study the oxidation behavior of zirconium alloys in steam and air. In the study reported here, we have oxidized Zircaloy-2 in steam and air at 573 K and carried out polarization measurements at 573 K in the molten nitrite and nitrates at various stages during the oxidation. A model for thermal oxide growth on Zircaloy-2, which is essentially Cox's model (9) modified to account for the observed dependence of oxidation rate on the medium of oxidation in the early stages, is proposed.

Experimental

The molten salt baths used, and the procedures for sample preparation and polarization measurements following oxidation have been described elsewhere (7). All oxidation and polarization were carried out at 573 K. Samples, paddle-shaped and ≈8 cm^2 in area, were oxidized in oxygen-free steam at atmospheric pressure and dry air. In the closed steam loop, presence of air was avoided by flushing with argon before start-up and keeping it bubbling through the condensed water which returned to the boiler. At various times during the oxidation, the samples were withdrawn, weighed, polarized successively in molten KNO_3-$NaNO_3$, $NaNO_2$-$NaNO_3$-KNO_3, and $NaNO_2$, weighed again, and returned to their appropriate medium (steam loop or furnace) for further oxidation. Prior to polarization, sufficient time, usually half an hour, was allowed for the attainment of steady potential following immersion of the oxidized sample in the molten salt. The potentials are quoted relative to an Ag/Ag^+ (0.07M in $NaNO_3$-KNO_3) reference. Only weight gain measurements were made with some control samples.

Results

Oxidation of Zircaloy-2 in steam and polarization in the molten nitrates and nitrite.—The rates of oxidation in steam at atmospheric pressure were generally faster than those in the molten nitrates and nitrite and dry air. The results are shown in Fig. 1 where the data obtained in the molten salts and dry air are included for the sake of comparison. After a period of oxidation in steam, when the samples were polarized in the three molten salt baths in turn, the changes in the weight gain caused by the polarizations were quite small. They decreased from ≈0.3 mg/dm^2 in the initial stages, 28 hr oxidation, to nondetectable amounts towards the final stages, 700 hr, of oxidation.

A set of polarization curves, obtained subsequent to a 28 hr oxidation in steam, is shown in Fig. 2. The anodic portions showed well-defined plateaus which were spaced fairly closely to each other, within a range of 1-2 μA. However, the cathodic portions showed large differences; the resistance to the cathodic

current was much higher in the nitrite and ternary melts than in the binary melt. The oxidation currents (*i.e.*, the currents at the rest potentials on the extrapolated anodic plateaus) corresponded reasonably well with the rate of oxidation obtained from the kinetic data. Nearly identical oxidation currents were obtained by extrapolating the anodic plateaus in the linear plots of polarization current against applied potentials. Similar results were obtained from polarization measurements carried out after various periods of oxidation in steam. The cathodic portions of the polarization curves traced in the nitrite and ternary melts showed negative resistance regions; in the nitrite melt these were associated with a large shift by about 0.25V in the rest potential towards anodic values.

In Fig. 3(a), the rates of oxidation calculated from the oxidation currents and the kinetic data obtained in steam are compared at a series of weight gains. The agreement between the two sets of data is not as good as that reported previously for Zircaloy-2 when both the oxidation and polarization were done in the same melt (7). The differences between the rates calculated from the polarization data in the three melts, at any weight gain, were more than the differences between the polarization derived rate in one melt and the kinetic rate. However, all the data showed the same trend of a decreasing rate with increase in weight gain. The oxygen ionic conductance of zirconia, at any oxide thickness, was calculated as the ratio of the oxidation current, obtained from the polarization data, to the anodic shift in the rest potential from the immersion potential. Immersion

potentials for Zircaloy-2 in the three melts at 573 K have already been reported (7); they varied from −1.8V in the binary and ternary melts to −1.6V in the nitrite. The ionic conductivities calculated are shown in Fig. 3(b) as a function of weight gain. The behavior is quite similar to that of the rate of oxidation shown in Fig. 3(a) and of the ionic conductivity of the oxide grown in the sodium nitrite melt reported elsewhere (7).

The variation of the resistance to cathodic current flow with time of oxidation is shown in Fig. 4. In the binary and ternary melts a systematic increase in the resistance was observed and the rest potentials were steady at ≈ −0.7 and −0.85V during most of the oxidation. The rest potentials obtained in the three melts are listed in Table I. When the results were compared with the oxides grown in the molten salts (7) the steam-grown films were found to be more resistive.

Oxidation of Zircaloy-2 in dry air and polarization measurements in molten nitrates and nitrite.—The rate of oxidation in dry air was much slower than those in the molten salts and steam. When the samples were polarized in the molten salts the resulting changes in the weight gain were very considerable, especially in the initial stages. These changes are shown in Fig. 5 where the kinetics of oxidation in dry air of a control sample are compared with those of another sample on which intermittent polarizations in the molten salts were carried out. The changes in the weight gain as a result of these immersions and polarizations in the melts are shown by the dashed portions. In the initial stages the weight gained during one set of polarizations, *i.e.*, in a total time of 5 hr of immersion and polarization in the three melts, was as much as that gained in 30 hr of oxidation in air. In the first 200 hr the weight gained as a result of three sets of immersions and polarizations, lasting nearly 18 hr, was more than half of the total weight gained.

In Fig. 6, the results are plotted on linear scales and the transfers made, from the dry air to the molten salts for polarization measurements and vice versa for continuing the oxidation in dry air, are shown by the horizontal dashed lines and are listed in alphabetical order. The direction of the arrows identifies the transfer made. The data for the control samples oxidized in air and the molten salts are shown by the solid curves; the curve for the latter is the average of the weights gained in the three melts. The data for the sample oxidized in air and polarized in the melts at various times during the oxidation are shown by the solid circles. When a transfer was made, *e.g.*, from the air to the molten salts, the location corres-

Solid curves—weight gained in air and dashed curves—weight gained in the salts.

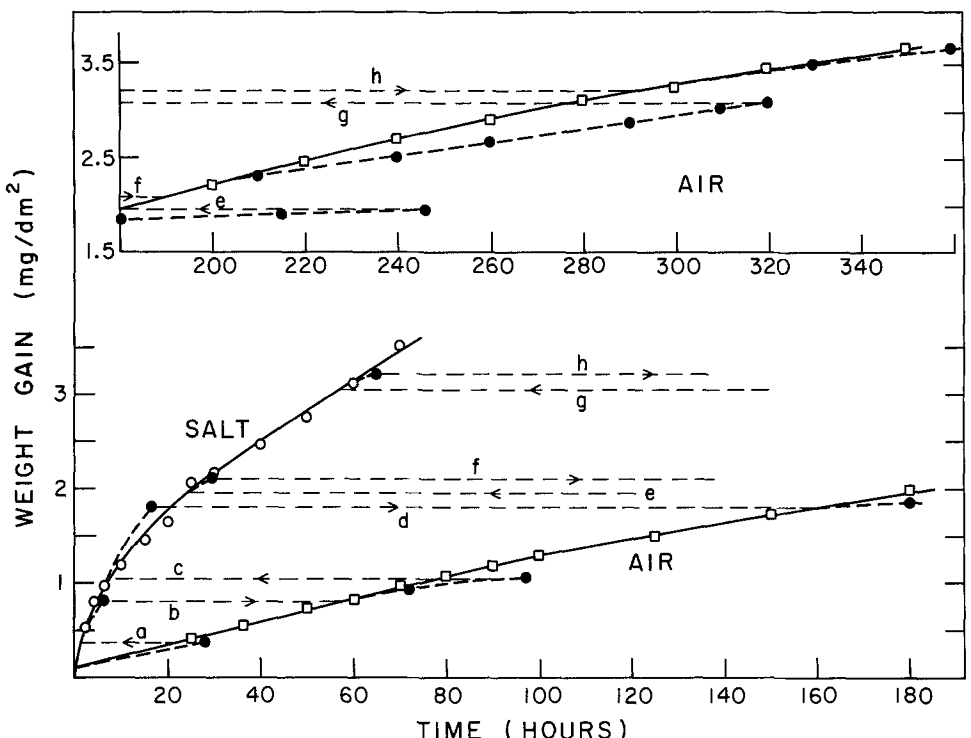

Fig. 6. Oxidation occurring, in the molten salts, during the polarization measurements on a Zircaloy-2 sample oxidized in dry air. Comparison of the kinetics of oxidation with those of the control samples oxidizing only in air or the molten salts. ○, control oxidizing in the molten salts at 573 K; average of the weights gained in the three melts; □, control oxidizing in dry air at 573 K; and ●, oxidized in dry air at 573 K and polarized in the three melts at 573 K. a, c, e, and g—transfers to the salts and b, d, f, and h—transfers to dry air.

ponding to the weight gain at the time of transfer is identified on the oxidation curve of the control sample in the melts and further weight gain is plotted from this location. A similar procedure is followed when the sample was returned to the air for further oxidation. It is readily seen that in all the transfers, excepting d, the kinetics of oxidation of the sample in air and the molten salts follow closely the kinetics of oxidation of the control samples in the respective medium. Therefore, the oxidation behavior of a sample oxidized both in dry air and in the molten salts, the latter resulting from the polarization measurements, is the same as that of an oxide of equivalent thickness growing only in air or the molten salts.

In order to separate the contributions to the weight gain changes in the melts caused by the immersion from those caused by anodic polarization, the following types of measurements were carried out with pairs of samples oxidized in dry air for various times. When a pair of samples oxidized for the same length of time was immersed in a melt, one of the pair was left unpolarized while the other was polarized to give current-voltage data. The changes in the weights gained by both were compared at the end of the experiment. When the initial weight gain in air was ≈ 0.4 mg/dm², immersion in the molten salt alone was responsible for $\approx 80\%$ of the increase in weight gain and anodic oxidation (resulting from the polarization) contributed to the remaining 20% increase. However, the latter decreased to $\leq 10\%$ at a total weight gain of ≈ 1 mg/dm² and was negligibly small at higher weight gains.

A set of polarization curves in the three melts following a 28 hr oxidation in air is shown in Fig. 7. The anodic plateaus were well defined and placed one below the other in the same order as the polarizations; the spread amongst the plateaus was about 10 μA. With increasing oxidation, the anodic plateaus were still well defined, but the spread amongst them decreased to 1-2 μA. The negative values of the rest potentials varied as sodium nitrite < binary nitrates < ternary nitrates and nitrite; these are listed in Table I. Negative resistance regions were observed in the cathodic portions of the polarization curves traced in the two nitrite-containing melts.

When the anodic plateaus were extrapolated, the oxidation currents obtained at the rest potentials were too high to correspond to the rates of oxidation in air calculated from the kinetic data. However, the oxidation currents from the polarization data agreed well with the changes in the weight gain resulting from immersion and polarization in the melts, *i.e.*, with the rates evaluated from the dashed portions in Fig. 5. These rates were also found to be comparable to the rates obtained in molten salt oxidation (7).

The results are shown in Fig. 8(a) where the rates of oxidation calculated from the polarizations, the oxidation kinetics in air, and the weight gain changes due to immersion in the melts are compared at different weight gains. Because the weight gain changed considerably due to immersion in the salt, the total weight gained by the sample at the end of a polarization step, rather than that due to oxidation in air, was used in plotting the data. At any weight gain the difference between the rates, calculated from the polarization data obtained in the ternary eutectic and the sodium nitrite melt, was rather large. In Fig. 8(b) the variation of the ionic conductivity of the oxide with the weight gain is shown. The conductivities and their variation in behavior were found to be similar to those reported for oxides grown in the three melts (7). When the results from the polarization data are compared the rate of oxidation decreased initially, up to a weight gain of ≈ 2.5 mg/dm², and the ionic conductivity stayed

nearly steady at 2×10^{-11} Ω^{-1} cm^{-1}. With further increase in weight gain the rate of oxidation and the ionic conductivity increased; in the case of the binary and ternary melts the rate of oxidation showed a maximum and this corresponded to an inflection in the conductivity curve.

The resistance to cathodic current flow as a function of weight gain is shown in Fig. 9. The rest potential decreased with increasing oxidation; the resistance in the three melts varied as sodium nitrite < binary nitrates < ternary nitrate-nitrite. At comparable weight gains, the air-grown films were found to be more conducting than films grown in steam and less conducting than films grown in the molten salts (7).

Discussion

Anodic and cathodic processes during thermal oxide growth on Zircaloy-2.—In a discussion about the relation between the type of rate law obeyed, during the thermal oxidation of zirconium and Zircaloy-2 at 473-573 K, and the oxide thickness it was concluded that the anodic process is controlled by a field dependent rate-determining process within the oxide film and that the weak field approximation of the equation usually employed for anodic oxide growth is applicable (1). This was confirmed by the results

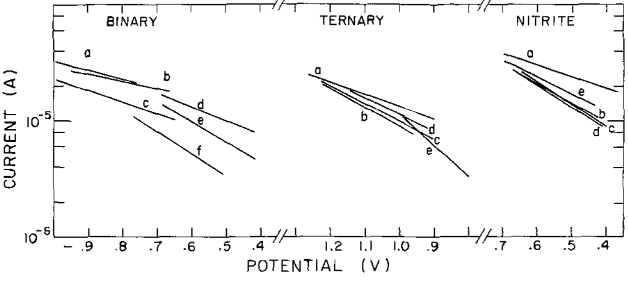

Fig. 9. Variation of the resistance to cathodic current flow at 573 K in the three molten salt baths with time of oxidation of Zircaloy-2 in air at 573 K. Time of oxidotion in hours: a, 28; b, 76; c, 172; d, 316; e, 503; and f, 670.

obtained in the oxidation and polarization experiments in the molten salts at 573 K; it was shown that the potentials corresponding to the linear anodic plateaus in the polarization curves were essentially across the zirconium oxide and the anodic process of oxygen ion transport was determined by the ionic conductivity of the oxide (7).

Bacarella and Sutton had interpreted the cathodic process on the basis of a dual barrier model; the zirconium oxide was assumed to be a semiconductor having an electron transfer coefficient close to unity; a part of the potential drop was considered to be across this oxide barrier and the remaining at the oxide-solution interface controlling a charge transfer reaction (1). However, it has recently been shown that when the zirconia thickness is less than the average size of the intermetallic precipitates in the alloy, the electron transport, completing the oxidation, occurs predominantly at the oxidized zirconium-iron intermetallic precipitates (5, 6). The composition of the oxides grown on these second phase precipitates and its variation with the temperature and extent of oxidation have not been investigated in detail. In addition, the cathodic portions of the analyzed polarization curves generally showed two "Tafel" regions; the data could also be fitted to, sometimes better than a Tafel relation, a Schottky type of emission process. The variation of the resistance to cathodic current flow with increasing oxidation was found to depend on the medium in which the alloy was oxidized. Therefore, in the absence of definitive experimental evidence, of the fit of the data to a single type of electron transport mechanism, the cathodic process is simply considered to be determined by the conductivity of the oxide grown on the second phase intermetallic precipitates.

Oxidized Zircaloy-2 sample immersed in molten alkali nitrates, nitrites, and their eutectics.—The reactions occurring in molten alkali nitrates, nitrites, and their eutectics and their relevance to the mechanism of oxide growth on Zircaloy-2 in these melts have been discussed elsewhere (7). The oxide thicknesses investigated in the present study are well below 1 μm (equivalent weight gain is ≈15 mg/dm²), the average size of the intermetallics. Therefore, irrespective of which medium the alloy was oxidized in, when it is immersed in the molten salt it can be expected to acquire a rest potential determined by the ionic conductivity of the zirconia and the electronic conductivity of the oxide grown on the intermetallic precipitates. The kinetics of oxidation of a Zircaloy-2 sample, oxidized in steam or aqueous solutions or molten salts and intermittently polarized in the molten salts, is found to be nearly identical to that of a control sample which had not been polarized. It can be concluded therefore, that immersion and polarization in the molten salts are not affecting the conduction properties of the zirconia and the oxide on the intermetallic precipitates and information on these oxide conductivities can be obtained from the polarization data. This is the basis for exploring the possibility of using molten alkali nitrates and nitrites as polarization media for studying oxide growth in other media such as air and steam.

However, the reactions on the alloy and the intermetallics at the oxide-molten salt interface would be different from those that occurred at the oxide-oxidation medium interface during the oxidation. Therefore, the polarization data obtained in the molten salts might correspond more closely to the oxidation behavior of a preoxidized sample in the salt than to the previous history of oxidation in another medium. But, apart from these differences (due to the different interfacial reactions at the oxide surface during oxidation and polarization) the data obtained in the molten salts should provide information on the variation of the oxide conductivities with increase in oxidation,

and a comparison amongst the oxides grown in various media. Such information is important in interpreting the mechanism of oxide growth.

Oxidation in steam.—Following a period of oxidation in steam, when a sample was polarized in the three melts it was observed that the anodic plateaus in the polarization curves were quite close to each other. As the plateaus are identified with the oxygen ionic transport in the zirconia (7, 9) this observation indicates that the ionic conductivity of the zirconia had remained the same during the polarization. But there were variations in the values of the ionic conductivity calculated, at any weight gain, as shown in Fig. 3(b). These might be due to small differences in the measured anodic currents resulting from the repeated polarizations within a short time and to some extent also due to the slightly different values of the measured immersion potentials used for the three melts. Unlike the ionic currents, the cathodic reduction currents in the three melts showed large variations indicating that the resistance of the same oxide film, grown in steam on the intermetallics, was different in the three melts. The interpretation is that the surface reactions involved and their current-voltage characteristics are different in the three melts; *viz.*, reduction of NO_2^+ in the binary nitrates, NO^+ in the nitrite, and possibly both of these species in the ternary nitrate-nitrite melt.

Thus, when the results from the polarization curves are correlated with the reactions occurring during the oxidation in steam, the ion transport can be expected to be in better agreement than the electron transport. The ion transport, determined by the conductivity along the crystallite boundaries, occurs through the same oxide during oxidation in steam and polarization in the three melts. The ionic conductivities shown in Fig. 3(b) are thus characteristic of the oxide grown in steam and the same as those that existed during the oxidation. The electron transport, on the other hand, is not only related to different reactions in the three melts during polarization but is also associated with a completely different reaction, the reduction of protons to hydrogen, during the oxidation in steam. Thus, the different rest potentials and oxidation currents measured in the three melts (subsequent to a period of oxidation in steam) and the differences in the oxidation rates calculated from the polarization data in the three melts and the kinetic data in steam (at a weight gain) are to be attributed mainly to the different cathodic reduction reactions. For the same reason the rest potential during the oxidation in steam would have been different from those observed during polarization.

In spite of only a reasonable agreement between the rates of oxidation calculated from the polarization and kinetic data, it can be stated that the polarization data do reflect changes in the ionic conductivity of the oxide grown in steam and also changes in the rate of oxidation in steam with the weight gain. The same trend is seen in the rates of oxidation derived from the kinetics as is seen in the calculated ionic conductivities [*cf.* Fig. 3(a)]. The ionic conductivity of the steam grown oxide (as revealed by polarization) is slightly higher than but close to that of the oxide grown in the nitrite melt (7). The kinetics of oxidation in steam are faster than in the molten salts to begin with, but at a weight gain >4 mg/dm^2 the kinetics become comparable to those in the nitrite melt. This similarity between oxidation in steam and molten sodium nitrite might be attributed to a higher water content in the nitrite melt (present as an impurity) than in the binary and ternary eutectics (7). However, a high ionic conductivity for the oxide grown in steam is revealed by polarization in all the three melts. The similarity to oxidation in the nitrite melt then suggests that the current-voltage characteristics of the cathodic reduction of protons to hydrogen during steam oxidation are similar to those of the reduction reactions occurring in the nitrite melt. Therefore, it can be concluded that molten alkali nitrates, nitrites, and their eutectics, in general, are suitable polarization media for studying the oxide growth on Zircaloy-2 in steam.

Oxidation in dry air.—The behavior of samples oxidized in dry air, when immersed in the molten salts, was very different from that of the steam-oxidized samples in that considerable additional oxidation occurred in the salt. The kinetic and polarization characteristics of this additional oxidation are seen to be nearly the same as those of an oxide of equivalent thickness grown in the molten salts. Therefore, it has to be concluded that the ionic conductivity of the zirconia and the electronic conductivity of the oxide on the intermetallics grown in air are not very different from those of the oxides grown in the molten salts. This is confirmed by the ionic conductivities and the resistances to cathodic current flow calculated from the polarization data.

There was no agreement between the rates of oxidation calculated from the polarization and kinetic data at any weight gain; the rates derived from the polarization data, however, corresponded to the additional oxidation occurring in the melts. The variation in the rates of oxidation, calculated from the polarization data obtained in the three melts, could also be related to the resistance of the oxide on the intermetallics to the cathodic current and the rest potentials. In the ternary melt the latter were high and the oxidation rate was low; in the nitrite melt, the resistance and the rest potentials were low and the oxidation rate was high. Therefore, the behavior of the air-grown oxide in the molten salts represents the oxidation occurring in the salt during immersion rather than the previous history of air oxidation. The polarization data are, therefore, not relevant to air oxidation.

The near linearity of the oxidation rate in the initial stages, of the control sample, suggests that the oxidation in dry air is controlled by a surface reaction. Similar low and near linear rates were observed in the case of samples oxidized in air and polarized intermittently in the molten salts. These results indicate that in spite of the electrical conduction properties of the oxides grown in air and/or the molten salts being basically the same the oxidation in dry air proceeds at a slower rate. As will be discussed later, this is to be attributed to a basic change in the mechanism related to the conduction properties of the oxide surface. Therefore, inferences regarding oxide growth in air could be drawn by comparing the polarization behavior of the oxide with those grown in steam and the molten salts.

Model for thermal oxide growth on Zircaloy-2.—The kinetics of oxidation in steam, though resulting in a faster rate of oxidation than in the molten salts, are seen to be close to those in the nitrite melt at weight gains ≥ 4 mg/dm^2. The mechanism of oxide growth in steam is, therefore, likely to bear some analogy to that in the molten salts (7). As the oxygen ions for the oxidation have to come from the water molecules the cathodic reaction completing the oxidation has to be the reduction of protons. The mechanism, generally proposed, for oxidation in aqueous electrolyte solutions is the reduction of water to hydroxyl ions (mostly localized at the intermetallic sites) and the reaction of a pair of hydroxyl ions from the solution on the zirconia surface producing oxygen ions and water (2). If the same scheme is to be applied for oxidation in steam, the hydroxyl ions produced at the intermetallic sites have to be transported by surface conduction to reaction areas on the zirconia. But the mobility of protons is considered to be generally faster than that of the hydroxyl ions (10); and during the initial stages of oxide growth in steam and aqueous solutions a considerable fraction of the hydrogen re-

leased is absorbed by the alloy (9). Therefore, equally well the oxygen ions could be extracted from the adsorbed water by the anion vacancy emerging on the zirconia surface and the protons released transported to the intermetallic sites and/or the alloy-oxide interface for reduction.

The model for oxide growth is the same as that proposed by Cox (9) and adapted for oxidation in molten salts (7). Oxygen ions, produced by a dissociation step, are transported along the zirconia crystallite boundaries by diffusion and the protons, transported by surface conduction, are reduced at the intermetallic sites. This latter reaction is analogous to the reduction of NO_2^+ and NO^+ during oxidation in the molten salts. The electronic conductivity of the doped oxide grown on the intermetallics maintains the rest potential at moderately low negative values. When the polarization data obtained in the molten nitrite are compared, the resistance of the oxide on the intermetallics grown in steam is higher than that grown in the molten nitrite. But the ionic conductivity of the zirconia grown in steam is higher than that grown in the nitrite; the compensating effect due to the ionic conductivity leads to faster oxidation in steam compared to that in the molten nitrite.

When the kinetics of oxidation in steam, molten salts, and air are compared the characteristics of the last are seen to be very different from those of the first two. The rate in air is about an order of magnitude less than that in the molten salts at a low weight gain of ≈ 1 mg/dm^2 and is about four times less than those in steam and molten salts at high weight gains up to ≈ 5 mg/dm^2. It is almost linear up to a weight gain of ≈ 2 mg/dm^2. When the air-oxidized sample is immersed in the molten salts, it oxidizes at an increased rate corresponding to the rate of oxidation of a control sample oxidizing in the melts. However, the rate returns to low values, similar to those of a control sample oxidizing in air, when further oxidation is continued in air. Therefore, there is a basic change in the mechanism of oxidation when a sample is transferred from dry air to molten salt and vice versa.

The transport of oxygen ions along crystallite boundaries, is nearly the same in various oxidation media due to nucleation and crystallite growth occurring at the alloy-oxide interface (9). The zirconia crystallites are reported to occupy almost 100% of the oxide volume by the time a thickness of ≈ 0.2 μm is reached. Therefore, major changes in the ionic conductivity of the oxide, imparted by the oxidation medium and associated with crystallite size, impurity incorporation, and surface structures, can be expected to occur during the initial stages of thin film growth. It is observed (*c.f.* Fig. 8) that the ionic conductivity of the air-grown oxide, subsequent to immersions and polarizations in the molten salts, and its variation with the total weight gained are comparable to those of the oxides grown in the molten salts (7). Therefore, the different oxidation behavior observed in dry air and the molten salts is not associated with the oxygen ion conduction in the growing zirconia. The cathodic step in air oxidation is the reduction of oxygen and this reaction has to occur on the zirconia surface near an emerging anion vacancy. The electrons could be transported from the intermetallics by conduction along the p-levels of the chemisorbed oxygen. This surface conduction and/or the reduction of oxygen must be then rate limiting.

Moreover, during oxidation in dry air, conduction and reduction of a cationic species are not involved. Therefore, lowering of the resistance of the alloy-oxide composite may not be as effective as that during oxidation in steam and the molten salts and consequently the rest potential could be highly negative. The rest potential at which the ionic current is equivalent to the rate of oxidation in air can be estimated as ~ -1.6V from the extrapolated anodic plateaus in the polarization curves. Such a highly negative rest potential, combined with a low rate of oxide growth, can be expected to contribute to a bulk electron current through the zirconia. In the initial stages, when the oxide is a few hundred angstroms thick, this might be an emission current, which may become space charge limited with increase in oxide thickness. The contribution from these bulk currents would, however, decrease with increasing weight gain.

Dawson *et al.* reported that the oxidation behavior of chemically polished Zircaloy-2 in oxygen at 573-633 K was complex (11). A change from a near linear to a near parabolic rate is also observed in the present study. Such variations can be interpreted as a reflection of the changes occurring in the electron transport. Initially the rate is linear due to the limited rate of oxygen reduction at the surface determined by the bulk emission current. The rate then decreases due to the buildup of electronic space charge which affects both the ionic and electronic transport and changes again at a higher oxide thickness when the bulk electron current is negligible and localized transport at the intermetallics combined with the surface conduction becomes limiting. When the air-oxidized sample is immersed in the molten salt for polarization the situation is changed completely. The reduction of nitronium and/or nitrosonium ions facilitated by the electron transport at the intermetallics, moves the rest potential to low negative values and any space charge or surface resistance effect on the oxidation rate is minimized; the alloy oxidizes at a rate near to that expected for an oxide of equal thickness in the molten salt.

In their model, Brown and Walton (2) proposed a surface barrier in addition to the growing oxide film barrier for the anodic current. This surface barrier was supposed to control an ionic reaction, not necessarily a rate-determining step, such as dehydroxylation in their experiments. It is seen from the results reported here that the role played by a surface barrier, if it exists, is a very minor one in the oxidation of Zircaloy-2. The interfacial reactions at the oxide-oxidizing medium are all different in different media. But in all media the rate of oxidation is determined by a combination of factors, such as ionic conductivity of the zirconia, electronic conductivity of the oxide on intermetallics, reduction of cationic species in the medium, and the bulk electronic conductivity of zirconia. The surface conduction properties of the zirconia associated with the reduction reactions play a more major role, than a surface barrier, in determining the oxidation of Zircaloy-2. In a similar manner, it cannot be said that either the ion transport or the electron transport is rate controlling (3); because ionic and electronic transport are occurring through different oxide systems, obey different current-voltage relations, and have to be coupled. It can be stated, however, that the anodic half of the oxidation (the oxygen ion transport) is less affected by changes in oxidation medium than the cathodic half. This effect is most evident when oxidation in a conducting medium is compared with that in a nonconducting medium.

Conclusions

Polarization measurements in molten alkali nitrates, nitrites, and their eutectics, on Zircaloy-2 samples oxidized in steam or dry air provide information on the variation of the ionic conductivity of zirconia and the electronic conductivity of the oxide grown on the intermetallics with increasing oxidation. The anodic part of the polarization data is directly relevant to the oxygen ion transport occurring during the oxidation; whereas the cathodic part of the polarization data has no direct correlation to the reduction reactions occurring during the oxidation. Thus, the differences in the oxidation rates calculated from the

polarization and kinetic data arise mainly from the different cathodic reactions involved.

A model for thermal oxide growth at ≤ 1 μm in thickness is proposed, based on the kinetic and polarization data.

1. When oxidizing in steam, the reduction of the protons released is assisted by their surface conduction in the adsorbed water phase on the zirconia surface and the electron transport at the intermetallic sites. Therefore, the rest potential stays at low negative values and the oxidation proceeds at a fast rate comparable to that in the molten salts.

2. In dry air, the oxidation proceeds at a much slower rate than in steam and the molten salts. The electrical conduction properties of the oxides grown in air, however, are similar to those of the oxides grown in the molten salts. Therefore, the low rates of oxidation in air are attributed to a highly negative rest potential on the alloy brought about by a high resistance for the surface conduction of electrons and the absence of a reduction step involving cationic species. The rate of oxidation, initially linear, is controlled by the reduction of oxygen at the surface; then the rate changes due to the buildup of an electronic space charge in the oxide and control by the combination of electron conductivity at the intermetallics and surface conduction.

Acknowledgments

The author wishes to acknowledge the many helpful discussions he had with Dr. B. Cox and the assistance offered by Mr. V. C. Ling in sample preparation.

Manuscript submitted Jan. 5, 1980; revised manuscript received May 20, 1980. This was Paper 63 presented at the Seattle, Washington, Meeting of the Society, May 21-26, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by Atomic Energy of Canada Limited.

High Oxygen Ion Conduction in Sintered Oxides of the Bi_2O_3-Dy_2O_3 System

M. J. Verkerk and A. J. Burggraaf

Department of Inorganic Materials Science, Twente University of Technology, 7500 AE Enschede, The Netherlands

ABSTRACT

The phase diagram of the Bi_2O_3-Dy_2O_3 system was investigated. A monophasic fcc structure was stabilized for samples containing 28.5-50.0 mole percent (m/o) Dy_2O_3. Above and below this concentration range polyphasic regions appear. The fcc phase showed high oxygen ion conduction. The ionic transference number is equal to one for specimens containing 28.5-40.0 m/o Dy_2O_3, whereas an electronic component is introduced at low temperatures for specimens containing 50.0 m/o Dy_2O_3. The conductivity of $(Bi_2O_3)_{0.715}(Dy_2O_3)_{0.285}$ is 0.71 $\Omega^{-1}m^{-1}$ and 14.4 $\Omega^{-1}m^{-1}$ at 773 and 973 K, respectively. Relations were found between the ionic radius, the conductivity, and the minimum concentration of lanthanide necessary to stabilize the fcc phase. It is concluded that the highest ionic conductivity will be found in the system Bi_2O_3-Er_2O_3 or Bi_2O_3-Tm_2O_3. From a study of relations between the activation energy, log σ_o and the composition it is concluded that two conductivity mechanisms play a role.

Recently Harwig investigated the electrical and structural properties of Bi_2O_3 (1-5). At room temperature the monoclinic α-phase is stable and the conductivity is predominantly electronic. On heating to 1002 K the oxide transforms to the face centered cubic (fcc) δ-phase, which is stable up to the melting point at 1097 K. In the δ-phase the electrical conductivity is about 100 $\Omega^{-1}m^{-1}$ and varies little with temperature. The ionic transport number is equal to one (6). On cooling this highly conductive phase may be extended to 923 K, where it transforms into the tetragonal β-phase or to 912 K where it transforms into the body-centered cubic (bcc) γ-phase. These phase transformations are accompanied by sudden volume changes which cause deterioration of the mechanical properties of the material. The conductivity in the β- and γ-phase is mainly ionic and about three orders of magnitude lower than in the δ-phase.

The temperature range at which this material can be used as a solid electrolyte can be extended by substituting Bi_2O_3. The region of highly ionic conductive δ-phase can be extended to room temperature by intro-

Key words: ionic conductor, solid electrolyte, bismuth oxide, lanthanide oxide, phase relations.

duction of 17.5-45 m/o Er_2O_3 (7,8), 25-43 m/o Y_2O_3 (9), 35-50 m/o Gd_2O_3 (10), 25 m/o WO_3 (11), 15-25 m/o Nb_2O_5 and 18-25 m/o Ta_2O_5 (12). The highest ionic conductivity is found in the system Bi_2O_3-Er_2O_3. The conductivity of $[Bi_2O_3]_{0.80}(Er_2O_3)_{0.20}$ is 2.3 and 37 $\Omega^{-1}m^{-1}$ at 773 and 973 K, respectively (7).

Oxygen ion conductors based on bismuth sesquioxide are substantially more conductive than the stabilized zirconias. In the temperature range 773-973 K the conductivity of $(Bi_2O_3)_{0.80}(Er_2O_3)_{0.20}$ is about 50-100 times higher than the conductivity of $(ZrO_2)_{0.915}(Y_2O_3)_{0.085}$.

Because of the relative ease of reduction at higher temperatures (6, 13, 14), the bismuth sesquioxide-based materials are not suitable for fuel cell applications. Their application will be limited to oxygen pumps [*e.g.*, for oxygen-enrichment (15)] or electrolyte for "second generation" oxygen sensors [*e.g.*, the device developed by Heyne (16, 17)]. The "second generation" oxygen sensor is used for automotive control and operates in the lean air/fuel ratio region, *e.g.*, an oxygen-rich exhaust gas (1-10% O_2). The sensor produces a feedback signal to keep the gas mixture fed to the motor oxygen rich. So all the fuel is burned and most pollutants can be removed catalytically (16, 18, 19).

The occurrence of the cubic phase (fcc) in the Bi_2O_3-Dy_2O_3 system is reported for $3Bi_2O_3 \cdot Dy_2O_3$ by Datta and Meehan (20) and for $Bi_2O_3 \cdot Dy_2O_3$ by Nasanova *et al.* (21). The fcc phase in comparable binary compounds exhibits high oxygen ion conduction over a wide temperature range. Therefore, the authors have investigated the phase diagram and the conductivity of the Bi_2O_3-Dy_2O_3 system.

The investigations are a part of our studies on a number of Bi_2O_3-Ln_2O_3 compositions. Phenomenological relations between the ionic radius of the lanthanide, the structure, and the conductivity are given. Some predictions about high ionic conductivity in stabilized Bi_2O_3 are made.

Experimental

Preparation and analysis of the specimens.—Bi_2O_3 (Merck, very pure) and Dy_2O_3 (Serva, 99.9%) were thoroughly mixed and prefired at 1020-1120 K for 16 hr, finely ground and isostatically pressed at about 400 MPa, sintered in air for 45 hr, and cooled down (1/2 K min^{-1}) to room temperature. The sintering temperature was raised as the content of Dy_2O_3 was increased, see Table I. Prefiring and sintering were performed in platinum crucibles.

After the synthesis the composition of the samples was checked with x-ray fluorescense. The accuracy is 0.1% absolute. The specimens were analyzed for small amounts of aluminum and silicon. The procedure is described elsewhere (7, 22). The detection limits of these analyses are 0.005 weight percent (w/o) Al and 0.001 w/o Si.

The crystal structures of the specimens were identified by a Philips PW 1370 diffractometer. Cu $K\alpha$ radiation was used with a Ni filter. The lattice parameters were calculated from diffraction angles in the 60°-120° (2θ) region, obtained at a scanning speed of 1/4° min^{-1} using $Pb(NO_3)_2$ as the internal standard. High temperature x-ray experiments were performed with a Guinier-Simon camera (heating rate: 5 K hr^{-1}). The ceramic structures of polished and thermally etched samples were investigated with the scanning electron microscope (SEM) Type JEOL JSM U3. Differential thermal analysis (DTA) measurements were performed with a du Pont 990 Thermal Analyser, heating rate: 10 or 15 K min^{-1}. The densities of the samples were measured at 298 K by the Archimedes method using mercury.

Table I. Sintering temperature and density

x in $(Bi_2O_3)_{1-x}(Dy_2O_3)_x$	Temperature (K)	Density* (%)
0.05-0.10	1073	
0.15-0.25	1173	
0.28^5-0.35	1273	92
0.40-0.50	1373	94
0.60	1373	

* Density is given as a percentage of the theoretical density based on defect fluorite-type lattice.

Measurement of the ionic conductivity.—The electrical conductivity was measured at a frequency of 10 kHz. The ionic transference number was measured by the emf of an oxygen gas concentration cell. Details of these measurements are described elsewhere (7).

Results

Samples prepared.—The densities of the specimens after sintering were 92-94% of the theoretical density, see Table I. The avrag grain size of the samples is about 30 μm. The ceramic structure of a specimen is shown in Fig. 1. On this photograph it can be seen that the grain growth in this system is very fast even at temperatures of 1273 K. The grain boundaries move so fast that they become curved and pores are isolated within the grains. This implies that higher final densities are difficult to obtain without controlling grain growth.

The color of the specimens was yellow/orange for low percentages of Dy_2O_3 and dark brown for high percentages.

The difference between the calculated composition and the composition measured by x-ray fluorescence was 2.0% absolute or less. Concentrations of silicon and aluminum impurities are lower than 0.002 and 0.03 w/o, respectively.

Structural aspects.—Table II gives a survey of the existing structures if the specimens are subjected to different heat-treatments. In the "quenching" procedure the samples were suddenly removed from the furnace and cooled down to room temperature by natural convection, with the result that the high temperature structure could be retained. Lower temperature phases are occasionally achieved by cooling down very slowly (1/2 K min^{-1}) or by annealing at a suitable temperature.

The sample containing 5 m/o Dy_2O_3 has a tetragonal structure. The high temperature structure is cubic (fcc) as determined by the High Temperature Guinier technique (HTG). The transition temperature is 913 K, see Table III. If this sample is annealed, minor concentrations of other phases appear. This was also

observed in the Bi_2O_3-Er_2O_3 system (7). Possibly the tetragonal solid solution phase is stable at higher temperatures (*i.e.*, between 823-913 K) whereas at lower temperatures the solid solution exists over a narrower range of composition and ultimately only one tetragonal compound exists. It is suggested that this is the case in the Bi_2O_3-Y_2O_3 system (20).

The high temperature structure of the sample containing 10-25 m/o Dy_2O_3 is cubic (fcc). This can be concluded from the quenching experiments and was checked by HTG. The low temperature structure is rhombohedral, as can be seen from the samples cooled down by 1/2 K min^{-1} as well as from the annealing experiments. The annealing experiments indicate that the rhombohedral solid solution is found from about 15 m/o Dy_2O_3 to 25 m/o Dy_2O_3. After annealing for 2000 hr at 880 K the structure of the specimen containing 25 m/o Dy_2O_3 was $\geq$ 95% rhombohedral. Table III shows the transition temperature of the rhombohedral structure to the cubic structure measured by DTA.

The equilibrium monophasic fcc structure was observed at low temperatures for samples containing 28.5-50.0 m/o Dy_2O_3. These results do not agree with the observations of Datta and Meehan (20) who reported the existence of the fcc phase for $3Bi_2O_3 \cdot Dy_2O_3$ at low temperatures. It is very likely that these authors reported the nonequilibrium high temperature structure. Possibly contamination by the porcelain or silica crucibles used for the synthesis of the materials may play a role. The observations of the fcc phase for $Bi_2O_3 \cdot Dy_2O_3$ by Nasonova *et al.* (21) is confirmed.

As shown in Fig. 2 we see that in the whole range of the stabilized fcc phase (28.5-50 m/o Dy_2O_3) and in the range where the high temperature fcc phase can be retained by quenching (10-25 m/o Dy_2O_3) the lattice constant decreases linearly with an increasing Dy_2O_3 content, *i.e.*, Vegard's rule holds.

The specimen containing 60 m/o Dy_2O_3 shows an fcc phase and an unknown phase. Attempts to determine the composition of the two phases with the EDAX unit of the SEM failed because the size of the separate phases was too small compared to that of the analyzed area (0.5-1 μm^2). The deviation of the lattice constant of the fcc phase, see Fig. 2, cannot be explained.

Table III. Transition temperatures measured by DTA in the heating-up direction*

x in $(Bi_2O_3)_{1-x}(Dy_2O_3)_x$	Transition	Temperature (K)
0.05	$\beta \rightarrow \epsilon$	913

0.25†	$\epsilon \rightarrow \delta$	1018

* Measured on samples cooled down by ½ K min^{-1} from sintering temperature.
† Measured on the annealed sample (2000 hr at 880 K).

The theoretical densities can be calculated from the measured lattice constants assuming several defect models and can be compared with the observed densities. These defect models are extensively described and discussed in Ref. (7) and will not be repeated here. It appears that the system Bi_2O_3-Dy_2O_3 shows the same features as reported for Bi_2O_3-Er_2O_3 (7). So we conclude that all cations occupy their normal sites in the fluorite structure and that there are two vacancies in a unit cell, *i.e.*

$$Bi_{4(1-x)}Dy_{4x}O_6\square_2$$

Conductivity of the sintered specimens.—The conductivity of the sintered Bi_2O_3-Dy_2O_3 samples measured in air is shown in Fig. 3 and 4. In Fig. 4 the conductivity of pure Bi_2O_3 [after Takahashi *et al.* (6)] is given as a reference material. Table IV summarizes the values of the activation energies E_a and the pre-exponential terms σ_0 for the Arrhenius plots of the conductivity, while the deviation is given in the 90% reliability interval.

Figure 3 gives the conductivity of the cubic and rhombohedral structures of $(Bi_2O_3)_{0.75}(Dy_2O_3)_{0.25}$. Below 1018 K the cubic phase is unstable but can exist metastable because the transformation is too slow in order to take place during the rapidly performed conductivity measurements, see Table II. For the rhombohedral specimen these is a change in the activation energy at about 780 K. Possibly this may be correlated with a change in the ordering of oxygen in the lattice, as proposed for the cubic samples (see below). At 1010 $\pm$ 15 K there is a sudden increase in the conductivity. According to the HTG experiments this increase is caused by the structural change from the rhombohedral to fcc phase. The transformation temperature corresponds with the DTA data, see Table III. In the Arrhenius plot of the cubic sample

Table IV. Activation energies and pre-exponential terms for the Arrhenius plots of the conductivity

x in $(Bi_2O_3)_{1-x}(Dy_2O_3)_x$	Temperature range (K)	$\log \sigma_0 (\Omega^{-1}m^{-1})$	E_a (kJ mole^{-1})
0.25 (rhom)	600-780	5.3 ± 0.2	97 ± 3
	780-1000	4.4 ± 0.1	85 ± 2
0.25 (cubic)	600-870	7.2 ± 0.2	104 ± 3
	870-1060	5.0 ± 0.2	66 ± 4
0.28[5]	600-870	7.17 ± 0.04	108 ± 1
	870-1140	5.1 ± 0.1	73 ± 3
0.35	600-950	6.33 ± 0.05	101 ± 1
	950-1140	4.8 ± 0.1	73 ± 2
0.40	600-1050	6.34 ± 0.06	107 ± 1
0.45	600-1050	6.4 ± 0.4	112 ± 6
0.50	600-1050	5.9 ± 0.1	109 ± 2
0.60	600-1050	5.1 ± 0.1	112 ± 2

there is a change in the activation energy at about 870 K, this is discussed below.

The structure and the dimensions of the lattices of these phases are very different and the influence on the conductivity is striking. The volume of the rhombohedral and cubic unit cells is 0.123 and 0.166 nm^3, respectively. The cubic lattice is "blown up" compared with the rhombohedral one. Therefore a flat potential profile along the transport path between oxygen ion lattice sites can be expected and rapid transport can occur in the cubic lattice, as suggested for other systems by Huggins (23).

Figure 4 gives the Arrhenius plots of the conductivity of the cubic specimens containing 0.25-0.60 m/o Dy_2O_3. The samples containing 0.25-0.35 m/o Dy_2O_3 show a knee in the Arrhenius plot at about 870-950 K. The changes in the activation energies and the pre-exponential terms are given in Table IV. Present authors (7) correlated this knee to a change in the lattice constant, probably caused by changes in the ordering of oxygen in the lattice. The increase of the lattice constant for $(Bi_2O_3)_{0.80}(Er_2O_3)_{0.20}$ was confirmed by the Simon camera and is in the order of 1.5%. However, for the samples containing Dy_2O_3 no increase in the lattice constant could be measured with HTG. We conclude that the change in activation energy and the change in $\log \sigma_0$ is caused by a minor change in the structure which is not always accompanied by a measurable change in the unit cell volume.

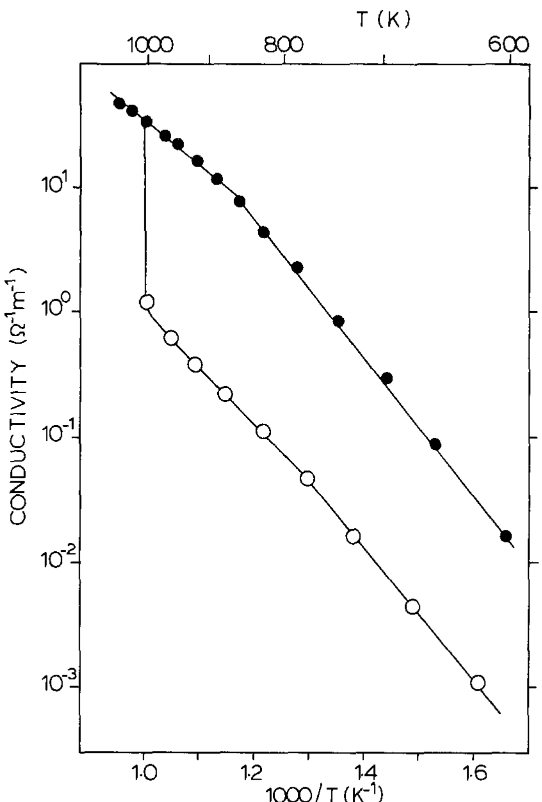

Fig. 3. Conductivity of $(Bi_2O_3)_{0.75}(Dy_2O_3)_{0.25}$ in air. ●, Cubic structure; ○, rhombohedral structure. The specimen with the rhombohedral structure could only be measured in the heating-up direction (see text).

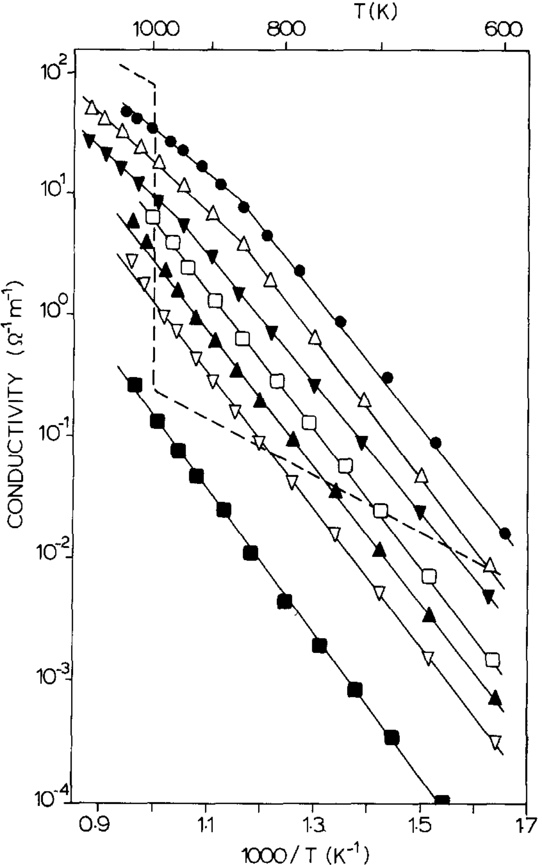

Fig. 4. Conductivity of $(Bi_2O_3)_{1-x}(Dy_2O_3)_x$ in air. ●, $x = 0.25$ (fcc); △, $x = 0.28^5$; ▼, $x = 0.35$; □, $x = 0.40$; ▲, $x = 0.45$; ▽, $x = 0.50$; ■, $x = 0.60$. The broken line represents the conductivity of pure Bi_2O_3 in the heating-up direction.

The best oxygen ionic conductor in this system is found in the material with the composition $(Bi_2O_3)_{0.715}(Dy_2O_3)_{0.285}$. The conductivity at 773 and 973 K is 0.71 and 14.4 $\Omega^{-1}m^{-1}$, respectively. This is about three times lower than the conductivity of $(Bi_2O_3)_{0.80}(Er_2O_3)_{0.20}$ (7) and more than ten times higher than the conductivity of $(ZrO_2)_{0.195}(Y_2O_3)_{0.085}$ at the same temperatures.

The ionic transference number.—The ionic transference number was measured with an oxygen gas concentration cell under the condition of $P'_{O_2} = 0.21$ atm and $P''_{O_2} = 1.00$ atm. The ratio of the measured emf to the theoretical emf is given in Table V.

For $(Bi_2O_3)_{1-x}(Dy_2O_3)_x$ with $x = 0.25$-0.40 the ionic transference number is approximately one, therefore the conductivity in the range 1-100% O_2 can be almost wholly attributed to oxygen ions [this work, (27), (31)]. It may be remembered that the deviation of

Table V. Ratios of the measured emf E to the theoretical value E_0 of the following cell:
O_2 (0.21 atm), Pt | $(Bi_2O_3)_{1-x}(Dy_2O_3)_x$ | Pt, O_2 (1 atm) at different temperatures

x in $(Bi_2O_3)_{1-x}(Dy_2O_3)_x$	E/E_0 823 K	873 K	923 K	973 K	1023 K	1073 K
0.25	—	0.93	0.96	0.97	0.98	0.98
0.28[5]	0.94	1.00	0.98	0.98	0.98	0.98
0.40	0.95	0.97	0.99	1.00	1.01	1.00
0.50	—	0.85	0.99	0.94	0.95	0.95
0.60	0.42	0.47	0.54	0.61	0.69	0.72

the ionic transference number measured by oxygen concentration cells is about 5%. Additional experiments are necessary to determine the (small) contribution of the electronic conductivity. The sample containing 50 m/o Dy_2O_3 had an electronic component at low temperatures ($T < 900$ K). For the sample containing 60 m/o Dy_2O_3 an electronic component was measured for all temperatures. Because the ionic transference number for the monophasic fcc samples coexisting with the second phase is approximately one, the electrical conductivity has to be ascribed to the second phase. In this temperature range and at these oxygen partial pressures pure Dy_2O_3 is an electronic conductor (24). Possibly the unknown phase is Dy_2O_3 rich.

Discussion

The results of this study were combined with literature data of the following systems: Bi_2O_3-Er_2O_3 (7, 8), Bi_2O_3-Y_2O_3 (9), Bi_2O_3-Gd_2O_3 (10), and Bi_2O_3-Yb_2O_3 (25). Our attention is directed to two subjects, first, the optimalization of the conductivity in sintered oxides of the Bi_2O_3-Ln_2O_3 system and, second, some considerations concerning the defect structure.

The optimalization of the conductivity.—The conditions leading to an optimal conductivity of sintered oxides of the Bi_2O_3-Ln_2O_3 system were investigated concerning several aspects. These are, first, the influence of the ionic radius on the conductivity, second, the influence of the composition on the conductivity, and third, the influence of the ionic radius on the minimum substituent concentration necessary to stabilize the fcc phase.

Figure 5 gives the conductivity of bismuth sesquioxide stabilized by several lanthanides as a function of the ionic radius of the substituent. The ionic radii are based on $r({}^{VI}O^{2-}) = 0.140$ nm, coordination number VIII, as given by Shannon and Prewitt (26). The conductivity increases slightly with increasing ionic radius. No precise data about the lattice constants for some of the compositions are known. However, there is a linear relation between the ionic radius of the substituent and the lattice constant, as shown by Cahen (27), and thus there is a linear relation between the conductivity and the lattice constant. There is too little precise data known up till now to analyze this relation further in terms of relationships between the lattice constant and log σ_o respectively E_a.

We propose that it may be ascribed to a change in E_a. Assuming the same defect structure for all substituents at $x = 0.35$ the amount of vacancies is constant, so log σ_o will also be constant. Increasing the ionic radius of the substituent will cause an increase in the lattice constant. This may cause a decrease in the contributions of the local strain components during the passage of oxygen ions through the lattice, which leads to a decrease in the activation energy. This explanation agrees with the observation that the slope of the log σ *vs.* r_{ion} relation at 773 K is larger than that at 973 K. This hypothesis is confirmed in a related system. Kubo and Obayashi (28) showed that in $Ce_{1-x}Ln_xO_{2-x/2}$ for $x = 0.30$ the activation energy decreases with increasing ionic radius of the lanthanide.

In Fig. 6 the oxygen ion conductivity in the Bi_2O_3-Dy_2O_3 system is plotted against the Dy_2O_3 content at different temperatures. The conductivity of $(Bi_2O_3)_{0.80}(Er_2O_3)_{0.20}$ (7) is given as a reference. In the fcc solid solution phase field the conductivity decreases linearly with the composition. For $x = 0.60$ there is a negative deviation from this linear relation. This is due to the second phase. The deviation at $x = 0.25$ is caused by a structural phase transformation. The conductivity of the metastable fcc phase at $x = 0.25$ satisfies this linear relation as shown in Fig. 6. It should be noted that a linear relation between conductivity and concentration holds at temperatures above and below the observed knee in the Arrhenious plot. A linear relation in the fcc solid solution phase field is also found for Bi_2O_3 stabilized with Er_2O_3 (7), Y_2O_3 (9), and Gd_2O_3 (10).

From the Fig. 5 and 6 it is clear that the highest ionic conductivity will be found for large ions and low substituent percentages. As will be shown, these are contradictory requirements. Attention should be paid to the influence of the ionic radius of the Ln^{3+} ion on the minimum substituent concentration ($x_{min.}$) necessary to stabilize the fcc structure at room temperature. The correlation between the ionic radius and $x_{min.}$ is given in Fig. 7. It should be noted that the minimum concentrations given in (9, 10) for Gd_2O_3 and Y_2O_3 may be too low. Present work and (7) show that high temperature structures may be easily retained at low temperatures. So the cooling procedures applied in (9, 10) to determine the phase boundary of the fcc structure may not be sufficient to produce the "equilibrium" phase boundary. Figure 7 shows that there is a minimum in this curve at $r_{ion.} = 0.100$ nm (Er^{3+}). In literature there are no data about $x_{min.}$ for Ln = Tm^{3+} (r_{ion} = 0.009 nm). So it is possible that $x_{min.}$ for Tm^{3+} is somewhat lower than for Er^{3+}.

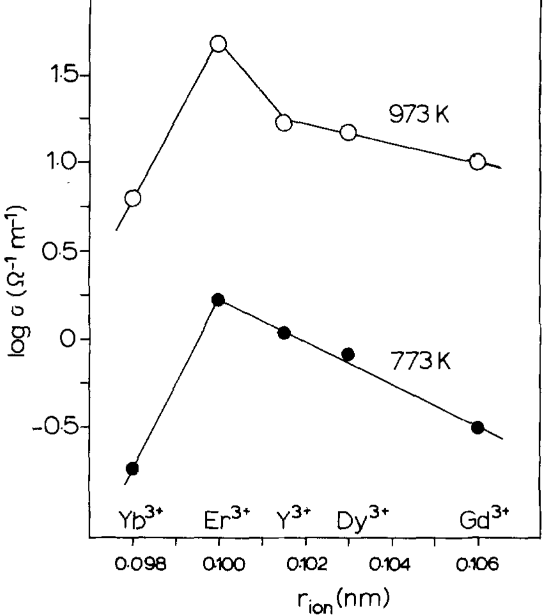

Fig. 8. The conductivity of $(Bi_2O_3)_{1-x}(Ln_2O_3)_x$ for x is the upper boundary of X_{min}. vs. the ionic radius of the substituted Ln^{3+} at 737 K (closed circles) and at 973 K (open circles).

The shape of the curve may be qualitatively explained in the following way. We assume that stabilization of the (very open) high temperature structure occurs at a certain contraction of this structure by the substituent. If the difference between the ionic radii of Bi^{3+} (0.111 nm) and the substituted M^{3+} is large, this will result in a large distortion in the host lattice and a small amount of substituent is necessary for supplying the energy required to stabilize the fcc phase, *i.e.*, for Er^{3+}. Reversely, a small difference between the ionic radii needs a large amount of substituent to supply the energy to stabilize the fcc phase, *i.e.*, for Gd^{3+}. For too large differences between the ionic radii of the Ln^{3+} ion and the Bi^{3+} ion the fcc phase becomes disfavored. At this stage we do not understand the stabilization of the fcc phase at higher concentration of Yb^{3+}, *i.e.*, a substituent with a relatively large difference in ionic radius with respect to Bi^{3+}.

From Fig. 5 we can conclude that the fcc structure will also be stabilized at low temperatures for Ln = Tm (r_{ion} = 0.099 nm), Ln = Ho (r_{ion} = 0.102 nm), Ln = Tb (r_{ion} = 0.104 nm), and possibly for Ln = Sm (r_{ion} = 0.102 nm). The $x_{min.}$ values for these substituents are predicted in this figure.

This discussion allows us to make some predictions about optimalization of the ionic conductivity of Bi_2O_3 stabilized by lanthanides. There are two contradictory tendencies. First, the ionic conductivity increases with increasing ionic radius (Fig. 5). Second, $x_{min.}$ increases with increasing ionic radius (Fig. 7) and a high $x_{min.}$ value results in a low conductivity (Fig. 6). However, the influence of the ionic radius on the conductivity is smaller than the influence of the Ln_2O_3 content. Therefore the optimalization of the conductivity is only possible by lowering $x_{min.}$. Figure 7 shows that there is a minimum in the $x_{min.}$ *vs.* r_{ion} plot at 0.098 nm $< r_{ion} <$ 0.105 nm. The ions Er^{3+} (r_{ion} = 0.100 nm) and Tm^{3+} (r_{ion} = 0.099 nm) fall within this range. The highest conductivity occurs at the lowest $x_{min.}$, as shown in Fig. 8. We conclude that the highest ionic conductivity will be found for Bi_2O_3 stabilized by Er_2O_3 or Tm_2O_3.

If the conductivity above the knee could be stabilized at low temperature, a further optimalization of the conductivity could be achieved. As shown below, the knee is correlated with an ordering process in the oxygen lattice. Therefore it is not very likely that the high temperature conductivity can be stabilized at lower temperatures.

Defect structure.—As pointed out before the knee in the Arrhenius plot cannot simply be ascribed to a change in the lattice constant, but has to be ascribed to a change in the defect structure. At about the same temperature a knee in the Arrhenius plot is reported for Bi_2O_3 stabilized with Er_2O_3 (7), Y_2O_3 (9), and Gd_2O_3 (10), for yttria-stabilized zirconia (29, 30) and for lanthanide-doped ceria (28).

From this work and the results mentioned in literature (7, 9, 10) we searched for relations between the activation energy, log σ_o, and the lanthanide content. For reasons of clarity the data are separately given for temperatures below 820 K and above 900 K. The results are given in Fig. 9 and 10. It appears that there are two different dependences, which can be related to different defect structures.

Above 900 K for the samples showing a knee in the Arrhenius plot the activation energy increases with increasing x whereas log σ_o is independent of x. The values of the activation energy and log σ_o, extrapolated to $x = 0$, come very close to the values of δ-Bi_2O_3. This suggests a disordered oxygen lattice analog to pure δ-Bi_2O_3 (4).

For the samples showing no knee in the Arrhenius plot, it appears that the activation energy is independent of x and log σ_o decreases linearly with increasing x. The same holds below 820 K for the samples showing a knee in the Arrhenius plot. These relations suggest that in this region the composition and therefore the lattice constant have no significant influence on the thermal activated passage of oxygen ions through the lattice, whereas the composition has a strong influence on log σ_o. The hypothesis is put that in this region the oxygen ions are ordered. The concentration of the mobile oxygen ions strongly decreases with increasing lanthanide content.

This hypothesis is supported by neutron diffraction studies at room temperature by the present authors on $(Bi_2O_3)_{0.80}(Er_2O_3)_{0.20}$ which show a peak in the diffuse background, which can be correlated with a short distance ordering of oxygen ions. Further neutron diffraction studies are now being performed and will be correlated with a detailed description of the conductivity mechanism.

Conclusions

High oxygen ion conduction is found in the system Bi_2O_3-Dy_2O_3. The fcc phase can be stabilized by 28.5-50.0 m/o Dy_2O_3. For the samples containing 28.5-40.0

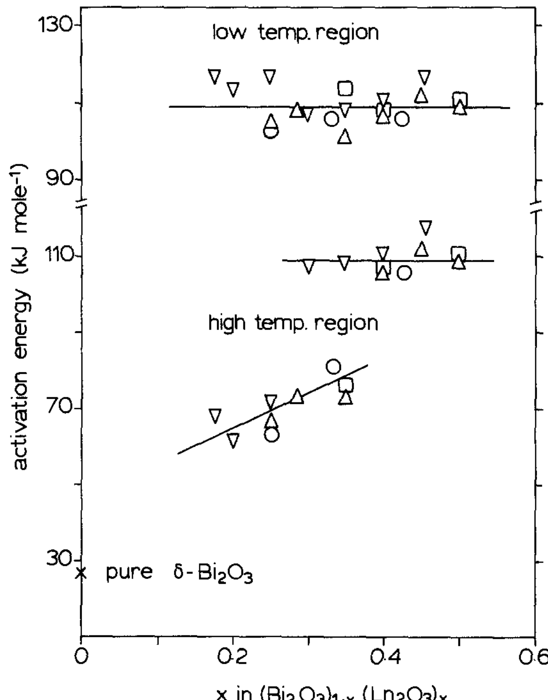

Fig. 9. The activation energy of the conductivity for the low temperature region (<820 K) and for the high temperature region (>900 K) as a function of the composition for several substituents. ○, Ln = Y; □, Ln = Gd; △, Ln = Dy; ▽, Ln = Er.

m/o Dy_2O_3 the ionic transference number is one over the whole temperature range investigated, whereas for the sample containing 50.0 m/o Dy_2O_3 an electronic component is introduced at low temperatures. The conductivity of the most desirable composition in this system, *i.e.*, $(Bi_2O_3)_{0.715}(Dy_2O_3)_{0.285}$, is about three times lower than the conductivity of the best oxygen ion conductor reported for Bi_2O_3-based solid solutions.

It is concluded that the lowest percentage of lanthanide necessary to stabilize the fcc phase is found for Er_2O_3 or Tm_2O_3.

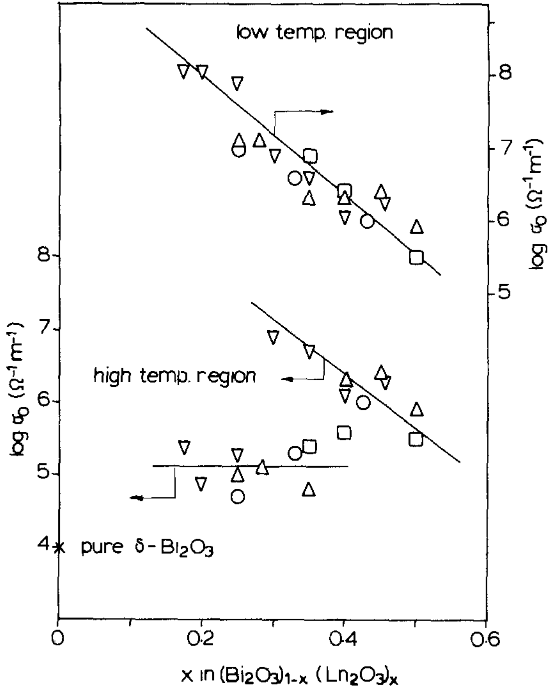

Fig. 10. The log σ_0 of the conductivity for the low temperature region (<820 K) and for the high temperature region (>900 K) as a function of the composition for several substituents. ○, Ln = Y; □, Ln = Gd; △, Ln = Dy; ▽, Ln = Er.

The influence of the ionic radius on the conductivity is smaller than the influence of the lanthanide content. Therefore it is concluded that the highest ionic conductivity based on Bi_2O_3 will be found in the systems Bi_2O_5-Er_2O_3 or Bi_2O_3-Tm_2O_3. The knee in the Arrhenius plot of the conductivity of several specimens is ascribed to a charge in the defect structure.

Acknowledgments

Dr. K. Keizer is thanked for performing some preliminary experiments in this system. We would like to express our appreciation to Mrs. A. van Pelt, Mr. J. Boeysma, and Mr. Th. van Dam for their experimental assistance. Financial assistance from Philips N.V. (Elcoma) is gratefully acknowledged.

Diffusion-Limited Charge Transport at Platinum Electrodes on Doped CeO_2

D. Braunshtein, D. S. Tannhauser,* and I. Riess

Department of Physics, Technion, Israel Institute of Technology, Haifa, Israel

ABSTRACT

We have measured the d-c and a-c properties of platinum paste electrodes on samples of the solid electrolyte $(CeO_2)_{0.9}(Gd_2O_3)_{0.1}$ in the temperature range 700°-900°C and the oxygen pressure range $1 \geqq P_{O_2} \geqq 10^{-4}$ atm. The d-c measurements showed that the current through the system saturated at a value proportional to the oxygen pressure and that the cathode (the electrode where oxygen enters) limits the current. We explain the limitation by a gas diffusion mechanism, which adds a small term to the dynamic resistance of the sample. The dynamic resistance is mainly determined by the resistivity of the electrolyte together with the current constriction at the triple line gas-electrolyte-electrode. A-C measurements gave impedance plots with the shape of a quarter circle, pointing to a diffusion process. We propose as model that part of the oxygen molecules arriving at the triple line is ionized directly and enters the electrolyte, and a second part diffuses as atoms along the interface electrolyte-electrode before being ionized. This model explains the observed quarter circle as well as the impedances measured for $\omega = 0$ and for $\omega = \infty$.

It is well known that electrode impedance plays an important role in the overall impedance of high temperature fuel cells. A large number of papers treat the subject phenomenologically but only a few try to understand the subject in microscopic detail. Some authors measured d-c properties and proposed a detailed model (1-3), other measured also a-c properties but did not analyze the results microscopically (4-7).

In the present paper we report on d-c and a-c properties of platinum electrodes on gadolinia-doped ceria, combined with scanning electron microscope studies of these electrodes. We then present a detailed model for the processes involved.

Very recently two papers by Wang and Nowick (8, 9) reported on a-c and d-c measurements on the same system. We believe that the differences between the results of their work and ours is due to the structure of the electrodes and we shall come back to this in the discussion.

Sample and Electrode Preparation

The starting material for the electrolyte was prepared by coprecipitation of oxalates of cerium and gadolinium and calcination at 1000°C to obtain $(CeO_2)_{0.9}(Gd_2O_3)_{0.1}$. The powder was then pressed at 2000 bar (2×10^8 Nt/m^2) and sintered at 1700°C for 3 hr.

The shape after sintering was a round cylinder 40 mm long and 11 mm across. Pellet-shaped samples about 1 mm thick were cut with a diamond saw from this cylinder. Some additional samples were prepared directly as pellets and sintered under similar conditions. Platinum electrodes were prepared by spreading a thin layer of platinum paste (Engelhard 6082), heating to 900°C at 100°C/hr, and cooling to room temperature in 1 hr. Scanning electron microscope (SEM) pictures confirm that the heating rate is crucial for the electrode resistance: if the rate is too fast (less than a few hours to 900°C) the platinum tends to form separate islands. This was found to increase the impedance of the sample. Figure 1 shows an SEM picture of a Pt-paste electrode heated slowly; it is seen that the platinum grains are connected and do not form separate islands.

The platinum covered surface S_{Pt} equals about 70% of the visual gross electrode area S_E, which is 0.64 cm^2. The cross section of the sample, S_0, is 1.13 cm^2. The typical width of the interconnected platinum islands in Fig. 1 is 2 μm.

We observed also that the surface condition of the sample influences strongly the two-point resistance of the sample. For electrodes prepared on the surface of sintered pellets (the SEM picture of such a surface is shown in Fig. 2) the two-point resistance was a few hundred ohms at 800°C, much higher than the 2.2Ω calculated from the bulk conductivity with the assumption of ideal electrodes (see below). If the surface of the sample was roughened with sandpaper, the

Key words: fuel cell, solid electrolyte, interface impedance.

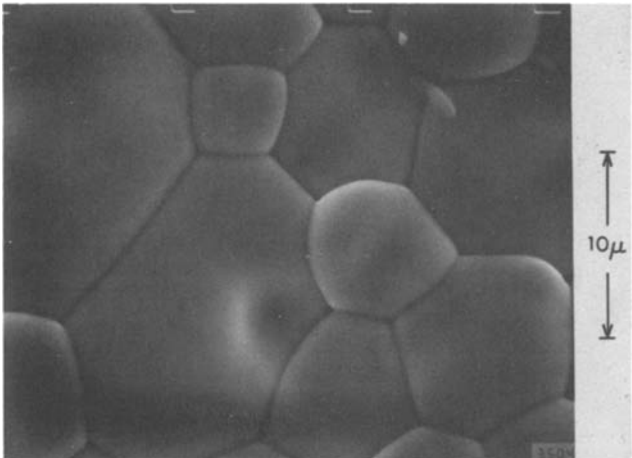

Fig. 2. SEM picture of the surface of a $(CeO_2)_{0.9}(Gd_2O_3)_{0.1}$ sample after sintering.

resistance dropped considerably. The surfaces cut by a diamond saw (see Fig. 3) were naturally rough and gave a two-point resistance of only ~14Ω at 800°C in pure oxygen. Most of the measurements reported in this paper were taken on one sample, 1.4 mm thick, but other samples gave very similar results. It is known that the structure of the platinum electrodes coarsens under heat-treatment (8). Our measurements were taken after the sample had been for a few days at the working temperature; the structure of the electrodes was then presumably coarser than that of the freshly prepared electrode shown in Fig. 1.

Experimental Procedure

The four-point van der Pauw method (10) was used to measure the specific conductivity of the electrolyte. In order to avoid polarization effects the measurements were made with low frequency a.c. (22 Hz).

The sample holder used for two-point measurements has been described previously (11). It permits measurements with two different atmospheres at the two electrodes. *I-V* curves with an external voltage applied were drawn by an X-Y recorder and the dynamic resistance of the system at zero current, $R_o = dV/dI$, was measured from the slope of the curve.

The complex impedance of the system was measured in the frequency range 1 Hz to 50 kHz, using the circuit shown in Fig. 4.

Measurements were performed in the temperature range $700° \leq T \leq 900°C$, and oxygen partial pressure range $10^{-4} \leq P_{O_2} \leq 1$ atm. $Ar-O_2$ mixtures were used to obtain low oxygen pressures, which were measured by a commercial instrument (Thermox I).

Results

D-C measurements.—In Fig. 5 we present *I-V* curves for various oxygen pressures. For the symmetrical cells used the shape of the curves was the same for both current directions, and we observed, in common with other workers (3, 4, 8), a tendency towards current limitation. The limiting current, defined as the value where the *I-V* curve begins to deviate from a straight line, was proportional to the oxygen pressure, as shown in Fig. 6.

The bulk conductivity of the electrolyte was measured and found to be independent of the current. The nonlinear behavior of the system EEE (electrode-electrolyte-electrode) is therefore attributed to the electrodes.

In order to check which electrode limits the current, the *I-V* characteristic of a cell with different atmospheres at the two electrodes was measured (see Fig. 7). In this cell current limitation occurs when oxygen enters the electrolyte from the low oxygen pressure side. Since it is seen from Fig. 5 that in pure oxygen the limiting current is much larger than in an (Ar, O_2) mixture we conclude that the cathode (the electrode where oxygen enters) is responsible for the current limitation. This conclusion was confirmed by measurements on a cell with electrodes differing in size. The ratio of the areas was 2:1, and the limiting current was twice as large when the oxygen entered the sample through the large electrode as in the reverse case. Our conclusion that the cathode causes the current limitation through the sample agrees with that of other workers (1-3).

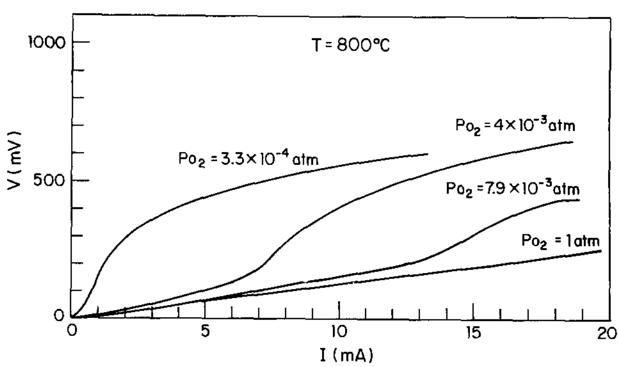

Fig. 5. *I-V* characteristics of a $(CeO_2)_{0.9}(Gd_2O_3)_{0.1}$ sample with Pt-paste electrodes at various oxygen pressures.

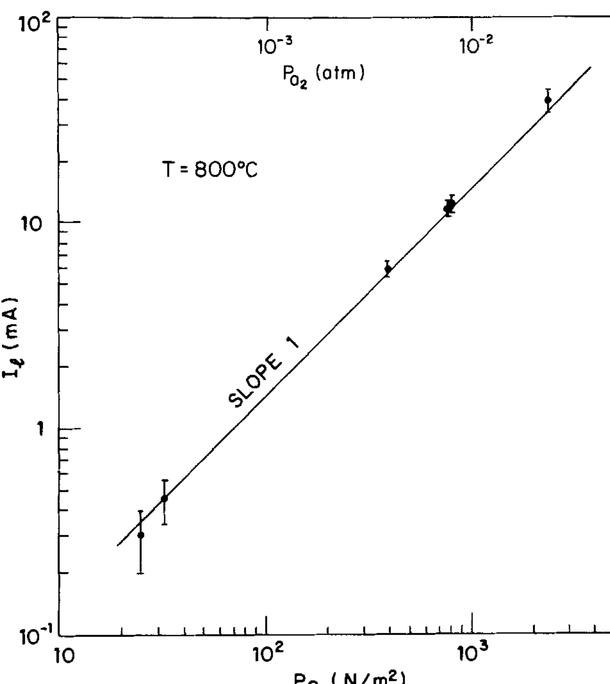

Fig. 6. Limiting current vs. oxygen pressure at 800°C for a $(CeO_2)_{0.9}(Gd_2O_3)_{0.1}$ sample with Pt-paste electrodes.

A-C measurements.—A-C measurements over a fairly wide frequency range were performed in order to get more information about the electrode process. We measured the complex impedance $Z = |Z|e^{j\psi}$ of the system EEE and plotted $|Z|\sin\psi$ *vs.* $|Z|\cos\psi$. In Fig. 8 we present results at different temperatures, the oxygen pressure being 7.9×10^{-3} atm. It is seen that the experimental points fit very well to a quarter circle ($\alpha = 45° \pm 2°$). The deviation of the curve from the quarter circle at the high frequency end of the diagram is caused by the inductance of the connecting wires. This was checked with a dummy sample and has also been observed by Schouler *et al.* (7). Impedance diagrams at different oxygen pressures were found to have the same shape. Figure 9 shows that the shape of the impedance curve did not change even in the presence of d-c bias. These measurements were performed on the asymmetric cell, whose characteristic is shown in Fig. 7. The extrapolation of the impedance curve, with or without d-c bias, to $\omega = 0$ coincides in every case with the resistance measured from the local slope of the *I-V* characteristic.

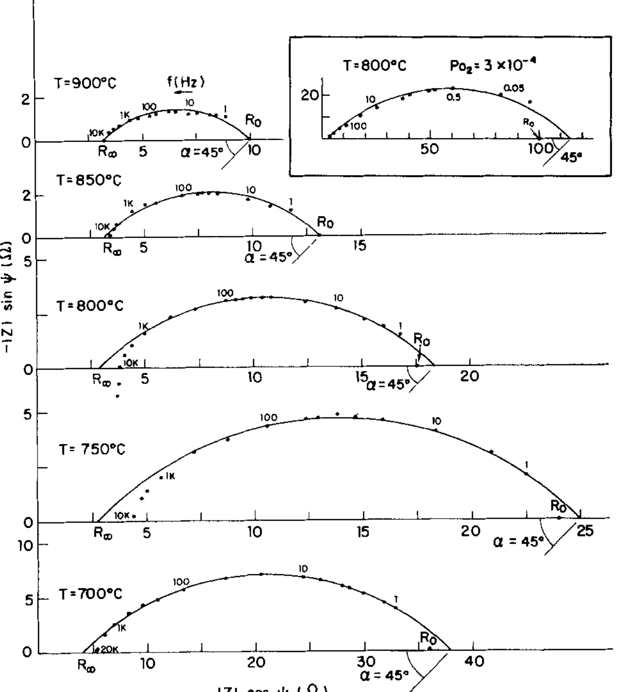

Fig. 8. Complex impedance of a cell $P_{O_2}{}^{I}/Pt/(CeO_2)_{0.9}(Gd_2O_3)_{0.1}$ $Pt/P_{O_2}{}^{II}$ with $P_{O_2}{}^{I} = P_{O_2}{}^{II} = 7.9 \times 10^{-3}$ atm at various temperatures. (Notice that the plot for 700°C has a different scale.) Insert: complex impedance at 3×10^{-4} atm.

Discussion

The novel feature of this work is the clearly-defined quarter circle shape of the complex impedance. We shall however first discuss the d-c results and introduce some concepts which we shall need later.

D-C results.—The fact that the limiting current is proportional to the oxygen pressure indicates that the gas phase is responsible for the current limitation. A similar dependence of $I_l \propto P_{O_2}$ has been observed on ZrO_2 samples by Etsell and Flengas (3) who explained it as diffusion of gaseous oxygen through the pores of the platinum electrode. On the other hand Wang and Nowick (8), who measured on CeO_2 with platinum electrodes, found a limiting current proportional to $P_{O_2}{}^{1/2}$ and therefore to the concentration of adsorbed oxygen atoms.

In common with Etsell and Flengas (3) we shall assume a gas diffusion mechanism. Independent of the details of this mechanism the following equation [1] will connect the voltage V applied to the cell with the current I

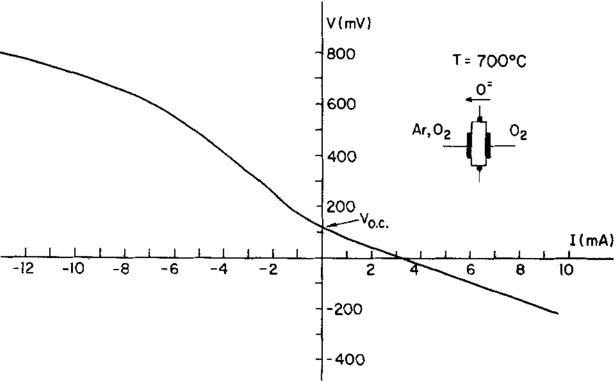

Fig. 7. *I-V* characteristic of the cell: Ar, $O_2(P_{O_2} = 3.3 \times 10^{-3}$ atm$)Pt/(CeO_2)_{0.9}(Gd_2O_3)_{0.1}/Pt/O_2(P_{O_2} = 1$ atm). The inset shows the direction of oxygen ion flow for positive current. The open-circuit voltage $V_{o.c.}$ agrees with the theoretical emf. The sign of V is defined as $V_{O_2} - V_{Ar,O_2}$.

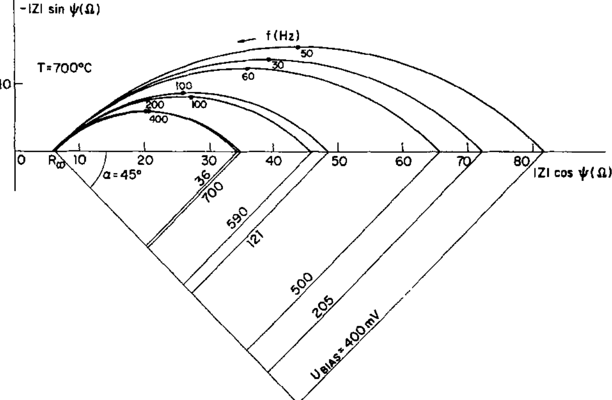

Fig. 9. Complex impedance of a cell $P_{O_2}{}^{I}/Pt/(CeO_2)_{0.9}(Gd_2O_3)_{0.1}/$ $Pt/P_{O_2}{}^{II}$, where $P_{O_2}{}^{I} = 1$ atm, $P_{O_2}{}^{II} = 3.3 \times 10^{-3}$ atm (Ar, O_2), with different d-c bias voltages. The points on the curves correspond to the frequencies shown.

$$V = IR - \frac{kT}{4q} \ln \frac{C_s}{C_o} \quad [1]$$

Here C_s and C_o are volume concentrations of oxygen at the surface of the cell and in the undisturbed atmosphere. R is the resistance of the electrolyte. In Eq. [1] we have assumed that $\overline{t_i}$ (the average ionic transport number in the sample) equals one, and have also neglected the diffusive part of the ionic current (12). These are good approximations for our range of oxygen pressures and our highly doped samples in which the vacancy concentration is practically constant. We have also neglected any concentration gradient of oxygen at the anode.

Since we expect $C_o - C_s$ to be linearly dependent on the current in the form $C_o - C_s = KI$, we can write

$$V = IR - \frac{kT}{4q} \ln \left(1 - \frac{KI}{C_o}\right) \quad [2]$$

and current limitation will occur when the second term diverges. The limiting current will be $I_l = C_o/K$ and since $C_o = P_{O_2}/kT$, we get the observed $I_l \propto P_{O_2}$ behavior. Equation [2] can now be written

$$V = IR - \frac{kT}{4q} \ln \left(1 - \frac{I}{I_l}\right) \quad [3]$$

a form which has been mentioned before in the literature (3). For $I << I_l$ we get the dynamic resistance R_o

$$R_o = \frac{dV}{dI_{I=0}} = R + \frac{kT}{4q} \frac{1}{I_l} \quad [4]$$

i.e., for small currents the diffusion term adds a constant contribution to the overall resistance of the cell.

From the observed values of I_l we calculate the second term in Eq. [4] to be about 4Ω at $P_{O_2} = 4 \times 10^{-3}$ atm and 800°C, and smaller for higher pressures. Since the total measured dynamic resistance R_o is 11Ω at pressures $\geqq 10^{-3}$ atm, we conclude that in this pressure range the major part of R_o is the resistance of the electrolyte. If we assume that the whole platinized area of the electrode determines the current geometry we calculate from Eq. [A-4] of Appendix A, with $S_{Pt} = 0.45$ cm², $S_o = 1.13$ cm², $\sigma = 0.089\ \Omega^{-1}\ cm^{-1}$, and $l = 1.4$ mm, a bulk resistance R_b of 2.2Ω, much smaller than the observed R_o. Let us assume however more realistically that the reaction between free oxygen, electrolyte, and electrons is restricted to a narrow strip along the triple line gas-electrolyte-electrode, the width of the strip being δ and its area S_{TL}. The resistance is then dominated by a constriction effect and will be called R_c. From the SEM picture of the electrode (Fig. 1) we estimate the length of the triple line as $L = 5 \times 10^3$ cm. If we assume that $\delta = 10$Å we get $S_{TL} = \delta L = 5 \times 10^{-4}$ cm². Equation [A-4] of Appendix A gives now $R_c = 23\Omega$, about twice the experimental $R_o = 11\Omega$. The calculated constriction effect, which increases the resistance by a factor ten, depends only logarithmically on the width of the triple line, so that the assumption of $\delta = 10$Å is not critical. The agreement between R_c and R_o can be considered satisfactory in view of the geometrical approximations involved. It is supported by the equal temperature dependence of $1/R_o$ and σ, shown in Fig. 10.

The increase of R_o seen at $P_{O_2} < 10^{-3}$ atm in Fig. 5 can be explained through the inverse dependence of the second term of Eq. [4] on I_l and thus on P_{O_2}. This term becomes dominant at low pressures.

The further rise of current after saturation seen in Fig. 5 is presumably connected to reduction of the electrolyte, as discussed by Casselton for ZrO_2 (13).

We have arrived therefore at the reasonable picture that the oxygen transport goes by gas diffusion to the triple line and from there as ionic current through a resistance determined by constriction effects.

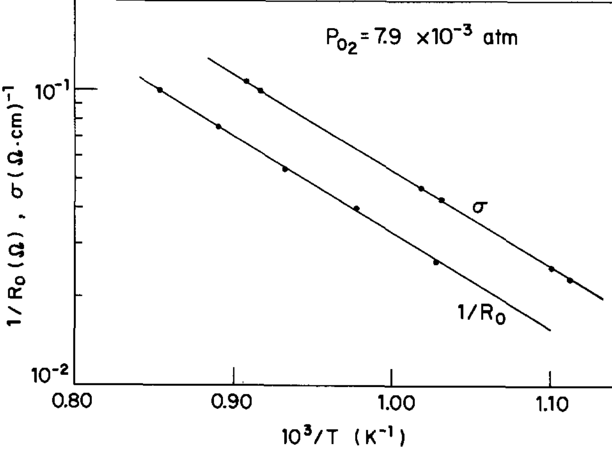

Fig. 10. The dynamic conductance $1/R_o$ together with the bulk conductivity of a $(CeO_2)_{0.9}(Gd_2O_3)_{0.1}$ sample vs. $1/T$ at $P_{O_2} = 7.9 \times 10^{-3}$ atm.

It is interesting to consider a more detailed picture for the diffusion process. If we assume a cylindrical diffusion geometry around the triple line with one-quarter of all directions being allowed, it can easily be shown that I_l is given by

$$\frac{I_l}{P_{O_2}} = \frac{KqD}{kT \ln (\delta/r)} \quad [5]$$

Here D is the gas diffusion coefficient of oxygen, r the distance beyond which $C = C_o$, *i.e.*, the gas is undisturbed by the cell, and K is a constant of order one. Using $D = 0.2 \times 10^{-4}$ m²/sec and $I_l/P_{O_2} = 1.43 \times 10^{-5}$ Am²/N (see Fig. 6) we get $\delta/r = 10^{-6}$. Our assumed $\delta = 10$Å implies therefore $r = 10^{-3}$m which is a reasonable order of magnitude.

We considered also the possibility that the current limitation is caused not by diffusion in the gas phase but by the kinetic limitation of the number of oxygen molecules impinging on the triple line. From such a model one can calculate directly that the width of the triple line involved in the limiting current is 1Å. Since however the mean-free path in air is only 100Å it is unlikely that this is the limiting mechanism.

We saw that the gas diffusion term is a small part of the total dynamic resistance. In a-c measurements this diffusion process would appear as a finite Warburg resistance, which we shall discuss in detail below.

A-C results.—The quarter circle observed in our measurements points mathematically to a diffusive process with a resistive process in parallel (14). The gas diffusion process which we have discussed above cannot serve as explanation because (*i*) there is no conceivable resistive process in parallel with it and (*ii*) the contribution of the diffusion term to the d-c resistance is small, therefore the short-circuiting of the gas diffusion impedance at higher frequencies would change the total impedance by much less than the observed effect. We therefore neglect for the moment the impedance of the gas diffusion process and propose the following model, which uses an interface diffusion process, to explain the results.

The oxygen molecules which arrive from the gas at the triple line are adsorbed and dissociate into two atoms. We now assume that charge is transported through the sample by two parallel modes of transport (see Fig. 11). In one mode the reaction $O + 2e^- + V_O^{\cdot\cdot} \rightarrow O_O$ occurs directly on the triple line, *i.e.*, oxygen ions (transported by oxygen vacancies) penetrate the SE directly from this line. In the second mode the oxygen atoms diffuse along the interface electrode-electrolyte and the above reaction occurs on the interface. Schematically this can be written

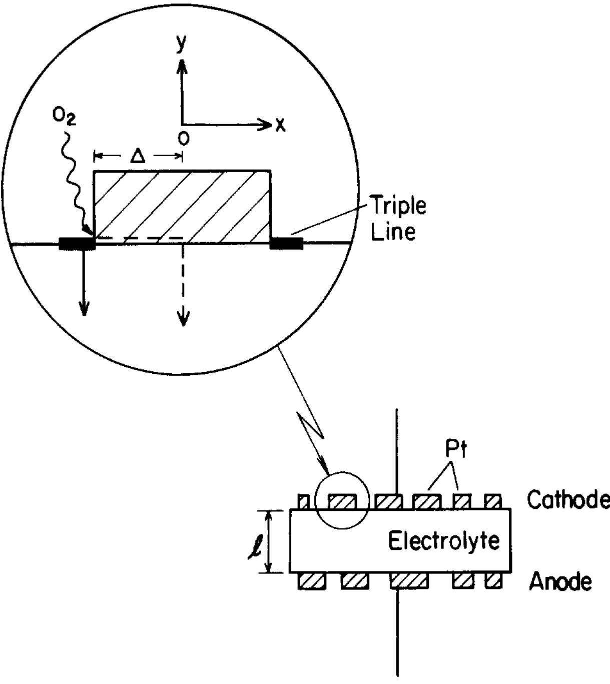

Fig. 11. Schematic cross section of a sample with Pt-paste electrodes. The diffusive mode of oxygen transport from the triple line into the electrolyte is shown by a broken line, the direct penetration mode by a full line.

$$O_2\,(\text{gas}) \rightarrow O_2\,(\text{triple line}) \rightarrow 2\,O\,(\text{triple line})$$

a) $O\,(\text{triple line}) + 2e^- + V_O^{\cdot\cdot} \rightarrow O_O$

b) $O\,(\text{triple line}) \rightarrow O\,(\text{interface}),$

$$O\,(\text{interface}) + 2e^- + V_O^{\cdot\cdot} \rightarrow O_O \quad [6]$$

The diffusion mode is connected with a finite diffusion path length, Δ, of about 1 μm, given by the size of the platinum islands (see Fig. 11), but we shall see that in our system the parameters are such that one can treat Δ as infinite.

In order to calculate the impedance of the diffusion mode we choose the origin $x = 0$ in the middle of a platinum island, as shown in Fig. 11, and assume that oxygen reacts with vacancies only at this point of the interface rather than over the whole area. This idealization makes our model quasi-one-dimensional and therefore more amenable to calculation. We also assume for simplicity that only one electrode contributes to the impedance. It can be shown that the results are essentially the same if both electrodes contribute.

An external voltage is applied between the two electrodes. The interface concentration c_o of oxygen atoms at the triple line c_o is constant; while the interface concentration at $x = 0$ varies with time, $c = c(0,t)$. The applied voltage is connected with the potential difference $\Delta\phi$ in the electrolyte by

$$V = \Delta\phi - \frac{kT}{2q}\ln\frac{c(0,t)}{c_o} \quad [7]$$

which is essentially the same as Eq. [1]. (Here we have assumed that the effective P_{O_2} is proportional to the square of the interface concentration of oxygen atoms). The impedance is therefore

$$Z_D = \frac{V}{I_D} = \frac{\Delta\phi}{I_D} - \frac{kT}{2qI_D}\ln\frac{c(0,t)}{c_o} \quad [8]$$

where I_D is the part of the external current transported by the diffusion mode.

Continuity at $x = 0$ demands that the ionic current flowing from this point into the electrolyte should be the equivalent of the particle current I_a flowing by diffusion along the interface EE and be equal also to I_D

$$I_i = 2qI_a|_{x=0} = I_D \quad [9]$$

The particle current according to Fick's law is

$$I_a = -D_sL\frac{dc}{dx} \quad [10]$$

Here D_s is the surface diffusion coefficient and L the length of the triple line, which defines the cross section of the diffusion path.

We use for the first term of Eq. [8] the bulk resistance R_b of the electrolyte, which was calculated before. This calculation of R_b deviates from the one-dimensional model which we introduced above, but is a more realistic approximation.

To calculate the second term of Eq. [8] we assume that c changes only slightly around the value c_o. This will be valid for small currents

$$c(x,t) = c_o[1 + \epsilon(x,t)]; \quad |\epsilon| << 1 \quad [11]$$

The concentration c obeys the diffusion equation

$$\frac{\partial c}{\partial t} = D_s\frac{\partial^2 c}{\partial x^2} \quad [12]$$

Substitution of [11] into [12] gives

$$\frac{\partial \epsilon}{\partial t} = D_s\frac{\partial^2 \epsilon}{\partial x^2} \quad [13]$$

We are looking for a solution of Eq. [13] of the form

$$\epsilon(x,t) = \epsilon_0 e^{j(\omega t + u'x)} \quad [14]$$

By substitution of [14] into [13] we get for $u'(\omega)$

$$u' = \pm\sqrt{\frac{\omega}{2D_s}}\,(1 - j) \equiv \pm u \quad [15]$$

The general solution of [12] is therefore

$$c = c_o[1 + \epsilon_o' e^{j(\omega t - ux)} + \epsilon_0 e^{j(\omega t + ux)}] \quad [16]$$

and with the boundary condition

$$c(-\Delta,t) = c_o[1 + \epsilon_o' e^{j(\omega t + u\Delta)} + \epsilon_0 e^{j(\omega t - u\Delta)}] = c_o \quad [17]$$

we get

$$\epsilon_o' = -\epsilon_0 e^{-2ju\Delta} \quad [18]$$

From Eq. [16] we obtain

$$\ln\frac{c(0,t)}{c_o} = \ln[1 + (\epsilon_o' + \epsilon_0)e^{j\omega t}] \simeq (\epsilon_o' + \epsilon_0)e^{j\omega t} \quad [19]$$

while the current is given by

$$\frac{I_D}{2q} = I_a|_{x=0} = -D_sL\frac{\partial c}{\partial x}\bigg|_{x=0} = D_sLc_oju(\epsilon_o' - \epsilon_0)e^{j\omega t} \quad [20]$$

We substitute Eq. [15], [19], and [20] into Eq. [8] and get for the impedance of the diffusion mode

$$Z_D = R_b + B\omega^{-1/2}(1 - j)\frac{\epsilon_0 + \epsilon_o'}{\epsilon_0 - \epsilon_o'} \quad [21]$$

where we have defined

$$B \equiv \frac{kT}{4q^2}\frac{1}{c_oL\sqrt{2D_s}} \quad [22]$$

Using [15] and [18] this gives

$$Z_D = R_b + B\omega^{-1/2}(1 - j)\frac{1 - \exp[-\sqrt{2\omega/D_s}(1 + j)\Delta]}{1 + \exp[-\sqrt{2\omega/D_s}(1 + j)\Delta]} = R_b + Z_{Wf}(\text{int}) \quad [23]$$

$Z_W \equiv B\omega^{-1/2}(1 - j)$, known as Warburg impedance, is

the diffusional impedance for an infinite diffusion path (14). Its electrical analog is an infinite transmission line of distributed R-C links. We have therefore called the second term in Eq. [23] $Z_{Wf}(\text{int})$; it is the impedance of the finite interface diffusion path, represented mathematically by a finite transmission line shorted at the end. The frequency dependence of $Z_{Wf}(\text{int})$ is seen in Fig. 13(a), and it is easy to show that $Z_{Wf}^{o}(\text{int}) = B\Delta\sqrt{2/D_s}$. Equation [23] implies that for $\sqrt{\omega/D_s}\Delta >> 1$ $Z_{Wf}(\text{int}) \simeq Z_W$, *i.e.*, the diffusion path length Δ is effectively infinite.

The total impedance of the sample is represented by the equivalent circuit shown in Fig. 12, where we have now added R_c in parallel to Z_D, R_c being again the (real) resistance for the current entering the SE directly through the triple line. $Z_{Wf}(\text{gas})$ represents the gas diffusion process; its frequency dependence should be that of $Z_{Wf}(\text{int})$ and is also given by Fig. 13(a). Since we have seen that its contribution is small compared to R_c even at $\omega = 0$, and since its absolute value decreases for higher frequencies, we will neglect it for the moment in the discussion.

The complex impedance of the circuit of Fig. 12 is shown in Fig. 13 for various values of $R_b/Z_{Wf}^{o}(\text{int})$ and $R_c/Z_{Wf}^{o}(\text{int})$. We see that if and only if

$$Z_{Wf}^{o}(\text{int}) >> R_b, R_c \qquad [24]$$

does the curve, which is given by

$$Z = \left[\frac{1}{R_c} + \frac{1}{R_b + Z_{Wf}(\text{int})}\right]^{-1} \qquad [25]$$

have the experimentally observed shape of a quarter circle. Its end points are then $Z^o = R_c$ and $Z^\infty = R_bR_c/(R_b + R_c)$. We shall show in Appendix B that [24] implies that diffusion can be neglected for $\omega < 4D_s/\Delta^2$. Since for higher frequencies $Z_{Wf}(\text{int}) \simeq Z_W$ it follows that the diffusion path is effectively infinite at any frequency and that $Z_{Wf}(\text{int})$ in Fig. 12 and Eq. [25] can be replaced by Z_W.

The expression $R_bR_c/(R_b + R_c)$ for Z^∞ is formal only because the resistances R_c and R_b shown in the equivalent circuit of Fig. 12 are physically not in parallel. From the suggested model it follows that when $\omega = 0$, diffusion can be neglected, *i.e.*, $Z^o = R_c$, as demanded by Eq. [25]. But when $\omega = \infty$ the active areas of both cathode and anode are S_{Pt}, the surface covered by platinum. Therefore Z^∞ should equal R_b rather than $R_bR_c/(R_b + R_c)$. Since in our case $R_b < R_c$, the difference between the two expressions for Z^∞ is small. The measured values of R_∞ are in good agreement with the calculated R_b (*e.g.*, R_b at 800°C is 2.2Ω, R_∞ is 3Ω) and are also independent of P_{O_2} as required by the fact that σ is independent of P_{O_2} in the range of our measurements. The activation energy of the measured R_∞ is smaller than that of R_b, the discrepancy is probably a result of the approximations involved in our one-dimensional model.

The inequality [24] determines an upper limit for D_s, given by

$$Z_{Wf}^{o}(\text{int}) = B\Delta\sqrt{\frac{2}{D_s}} = \frac{kT\Delta}{4q^2c_oLD_s} >> R_b, R_c \qquad [26]$$

For our samples $R_c > R_b$. We take the measured values of $\Delta = 1$ μm, $L = 5 \times 10^3$ cm, substitute for R_c the measured $R_o = 11\Omega$ and for $c_o \sim 10^{14}$ cm^{-2} (corresponding to a monoatomic layer of oxygen) and obtain that at 800°C $D_s << 10^{-5}$ cm²/sec, which is a reasonable upper limit.

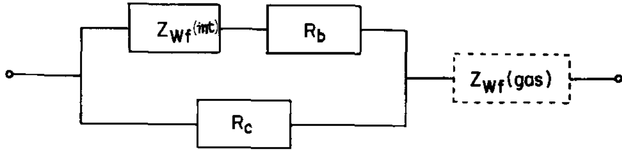

Fig. 12. Equivalent circuit for the model shown in Fig. 11

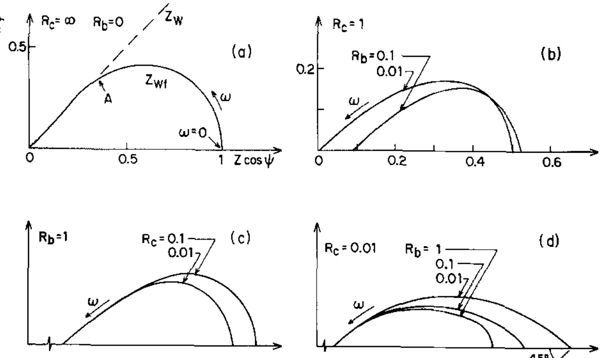

Fig. 13. Complex impedance of the circuit shown in Fig. 12, with various values of R_b and R_c. In all cases Z_{Wf}^{o} (int) = 1. Curve (a) shows Z_{Wf}, the impedance of a finite diffusion path. The curves in (c) and (d) are normalized and shifted to emphasize their shape, their scale is of no significance. Z_{Wf} (gas) is taken as zero.

Figure 13(a) shows incidentally that a finite impedance at $\omega = 0$ can also be explained on the basis of a finite diffusion path without any resistance in parallel, but the shape of the curve would then be very different from the observed quarter circle.

The gas diffusion impedance, $Z_{Wf}(\text{gas})$, which we neglected in the present discussion, can be expected to become more important at lower oxygen pressures. The reason is that the constant B defined by Eq. [22] is proportional to $P_{O_2}^{-1/4}$ for $Z_{Wf}(\text{int})$ (because $c_o \propto P_{O_2}^{1/2}$), while the equivalent constant should be proportional to $P_{O_2}^{-1}$ for $Z_{Wf}(\text{gas})$. Qualitatively we then expect a total impedance given by Eq. [25], *i.e.*, a quarter circle, in series with a curve given by Fig. 13(a). The slope on the left end of the total impedance should stay 45° while that on the right end will be steeper. We found indeed some evidence for such an effect at low P_{O_2}, (See Fig. 8, insert).

Conclusions

We conclude that the limiting current is determined by gas diffusion to the triple line on the cathode side and that the small signal d-c resistance of the system EEE is governed by the constriction resistance associated with the small area of the triple line. This resistance reduces the efficiency of a fuel cell and should be eliminated as far as possible.

The a-c results are successfully explained by an interface diffusion mode of transport of oxygen ions which is in parallel with the above constriction resistance. This model predicts a complex impedance in the shape of a quarter circle and fits very well the experimental data. On the other hand the results of Wang and Nowick (9) did not show such clearly defined quarter circles. They found depression angles up to 26°, rather than the 45° corresponding to a quarter circle. It should be remembered that their experiments were done on freshly prepared platinum electrodes, while we made measurements after the electrodes had been held for a few days at temperature. The length and area of the triple line was therefore larger in their case, while the width of the platinum islands was smaller. These geometrical changes would mainly tend to reduce $Z_{Wf}^{o}(\text{int})$, so that condition [24] may not be fulfilled anymore. We see from Fig. 13 parts (b) and (c) that in this case we could get curves which more or less resemble depressed circles. It seems very likely that diffusion played less of a role in the samples of Wang and Nowick than in ours. These authors do also mention that coarser electrodes lead to diffusion effects.

A very recent article by Franceschetti and Macdonald (15) derives in a much more general form the small signal response for electrode reactions limited by dif-

fusion through the electrode or along the interface electrode-electrolyte. The article is partly based on a diffusion model proposed by Wang (16) which is similar to the model used here, but does not include explicitly the direct penetration mode at the triple line.

APPENDIX A

The Resistance of a Sample with Electrodes of Different Sizes

We would like to derive an analytical formula describing approximately the resistance of a cylindrical sample shown in Fig. 14 which has two electrodes on the two flat surfaces. The electrodes are in the centers of the end planes. The cross section of the sample is S_o and its height l.

For simplicity of calculation we shall assume that the sample is two-dimensional, so that the electrodes become lines of length S_a and S_b. We further approximate the current flow geometry as shown in Fig. 14. Here we have assumed that the current flows in straight lines, that the current density is a function of y only and that the ratio l_a/l_b is such that the current path length is minimized.

The last assumption gives immediately by simple geometrical calculations that

$$l_a = l\frac{S_o - S_a}{2S_o - S_a - S_b} \quad l_b = l\frac{S_o - S_b}{2S_o - S_a - S_b} \quad \text{[A-1]}$$

The resistance of the sample is that of two truncated pyramids with common base. For the upper pyramid we use the following easily derived formula

$$R_a = \frac{l_a}{\sigma}\frac{\ln(S_o/S_a)}{S_o - S_a} \quad \text{[A-2]}$$

so that finally we get for the resistance of the sample

$$R = \frac{l}{\sigma}\frac{\ln(S_o^2/S_aS_b)}{2S_o - S_a - S_b} \quad \text{[A-3]}$$

When $S_a = S_b$ we get

$$R = \frac{l}{\sigma}\frac{\ln(S_o/S_a)}{S_o - S_a} \quad \text{[A-4]}$$

For our samples the electrodes are porous, *i.e.*, made up of many connected small electrodes. We assume in this case that the effective area is the sum of all the small ones.

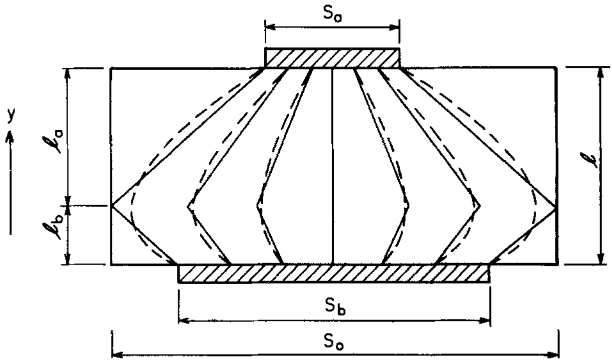

Fig. 14. Approximate distribution of current lines in a cylindrical sample with electrodes differing in size. The dotted lines show the real situation, the full lines are the basis of our approximate calculation and define the truncated pyramids mentioned in the text.

APPENDIX B

Proof That the Condition $Z_{Wf}^o >> R_b, R_c$ Implies That Diffusion Does Not Play a Role for $\omega < 4D_s/\Delta^2$

The impedance diagram for Z_{Wf}, the diffusional impedance in the case of a finite diffusion path, is shown in Fig. 13(a). At the point A $\omega = 4D_s/\Delta^2 \equiv \omega_{cr}$. It is seen from the curve that for $\omega < \omega_{cr}$

$$Z_{Wf} = Z_{Wf}^o\,[1 - \beta + j\gamma]; \quad 0 \leq \beta, \quad \gamma < ½ \quad \text{[B-1]}$$

The total impedance of the equivalent circuit is as before

$$Z = \frac{(Z_{Wf} + R_b)R_c}{Z_{Wf} + R_c + R_b} \quad \text{[B-2]}$$

and it follows from the condition $Z_{Wf}^o >> R_b$, R_c and Eq. [B-1] that $Z \simeq R_c$, *i.e.*, the diffusion mode does not contribute to the impedance for $\omega < \omega_{cr}$.

LIST OF SYMBOLS

B	$kT/(4q^2c_oL\sqrt{2D_s})$
C_o, C_s	concentration of oxygen molecules in the undisturbed gas and at the surface of the sample
c_o, c	concentration of oxygen atoms at the triple line and along the interface EE
D	diffusion coefficient of gaseous oxygen
D_s	diffusion coefficient for oxygen atoms on the interface EE
EE	electrode-electrolyte
EEE	electrode-electrolyte-electrode
I	total electric current
I_a	particle current
I_D	electric current transported by diffusion mode
I_i	ionic current
I_l	limiting current
j	$\sqrt{-1}$
k	Boltzmann constant
l	thickness of sample
L	length of triple line
O_O	$O^=$ ion on a normal lattice site
P_{O_2}	partial pressure of oxygen
q	absolute value of electronic charge
r	thickness of disturbed gas layer
R_o	measured dynamic resistance of system EEE
R_∞	measured resistance for $\omega \to \infty$
R_b	bulk resistance of electrolyte
R_c	constriction resistance
S_o	cross section of sample
S_E	gross area of electrode
S_{Pt}	area of sample covered by platinum
S_{TL}	area of triple line
SE	solid electrolyte
$\bar{t}_i$	average ionic transport number
T	absolute temperature
u	$\sqrt{\omega/2D_s}\,(1 - j)$
V	applied voltage
$V_O^{\cdot\cdot}$	doubly ionized oxygen vacancy
Z	impedance of system EEE
Z^o, Z^∞	impedance at zero and infinite frequency
Z_D	impedance for diffusion mode of transport
Z_W	Warburg impedance
Z_{Wf}(int)	impedance of finite diffusion path along interface
Z_{Wf}(gas)	impedance of finite diffusion path in the gas phase
α	angle between radius of impedance diagram and abscissa
δ	width of triple line
Δ	average length of diffusion path for oxygen along the EE interface
σ	specific conductivity of the electrolyte
ω	angular frequency
ψ	phase of the impedance
$\Delta\phi$	potential difference in the electrolyte

Current Transients and Stress Corrosion Cracking in LiCl-KCl

William H. Smyrl
Sandia Laboratories, Albuquerque, New Mexico 87115

ABSTRACT

The current transients observed during crack propagation in titanium-8 aluminum-1 molydenum-1 vanadium immersed in molten LiCl-KCl have been analyzed. The electrochemical events which cause the transients have been determined. The dominant event during the initial stages of cracking was anodic dissolution from the film-free crack walls. A film was then deposited on the walls which passivated the surface, causing a decrease in current density. The final stage involved thickening of the film. The analysis has revealed that anodic dissolution could not support the very fast crack extension described here (*i.e.*, crack velocities greater than 10^{-3} cm/sec).

The stress corrosion cracking of the titanium alloy Ti-8% Al-1% Mo-1% V has been studied extensively in molten LiCl-KCl (1-3). These studies have shown that minor traces of H_2O (as OH^-), O_2, H_2, and H^-, do not influence cracking and are not acting as critical species. Model calculations have also indicated that minor components (such as OH^-) could not support cracking at the rates observed (up to 1 cm/sec) in the molten eutectic (4). These results were important for demonstrating that hydrogen embrittlement was not operative in this molten salt environment. The simple molten salt environment was important for assessing the importance of other crack extension mechanisms as well, as shown below.

The influence of electrical potential on crack growth rate has been investigated (3). The results and conclusions of that investigation (3) are briefly described here to aid in the introduction of the present study. Cracking was observed to occur at potentials from -1735 mV (the open-circuit potential in the absence of cracking) to -2235 mV (very cathodic conditions). Cracking was retarded by cathodic potentials, *i.e.*, the crack extension was slower at more negative potentials. Investigations at more positive potentials caused gross dissolution of the entire specimen surface which precluded crack length measurements, but cracking did occur at these potentials as well. Increasing the concentration of Ti^{+2} did not change the crack growth rate at any potential. Also, the crack growth rate was too high by several orders of magnitude to be supported by the small anodic current densities observed in the tests. It was concluded that these results would not support an anodic dissolution mechanism. It was found that one could account for the potential dependence by assuming that Cl^- at the metal-solution interface would depend on the potential of the titanium alloy surface and that the crack extension rate was a function of the interfacial concentration of Cl^-. These observations are summarized in Fig. 1. Cracking in the plateau region can be limited by fluid flow, as discussed earlier (5). Cl^--induced cracking is the controlling mechanism down to low crack velocities and anodic potentials, where anodic dissolution becomes important as an extension mechanism.

The tentative assignment of control in these areas was given in (3). The present paper gives results for cracking in the plateau and Cl^- control region, *i.e.*, for velocities between $\sim 10^{-3}$ cm/sec and the plateau velocity and for stress intensities as shown in Fig. 1. Each of the separate curves was measured at a constant potential. The most anodic potential is on the left, with more cathodic potentials progressing to the right. The curves are separated by 100 mV, and the left-most curve was taken at the corrosion potential (*i.e.*, -1735 mV *vs.* 1M Pt^{+2}/Pt), *i.e.*, zero net current to the specimen with no cracking in the pure melt. The potential of the right-most curve was -2235 mV, and the potential of zero charge on Ti for this melt was estimated (3) to be about -2.35V *vs.* 1M Pt^{+2}/Pt. The background current on the specimens in this potential range was small and cathodic, due to the trace quantities of OH^- remaining in the melt. No cracking was observed at low crack velocities, *i.e.*, below 10^{-3} cm/sec, for the four most cathodic potentials shown. That is to say, cracking was never observed to occur below 10^{-3} cm/sec for the most cathodic potentials. Observation at these potentials (*i.e.*, -1935 to -2235 mV) was extended so that cracking at velocities greater than 10^{-7} cm/sec would have been observed, but cracking between 10^{-3} and 10^{-7} cm/sec was not observed. These observations and conclusions serve as a background for the present study.

It has been reported that an anodic current transient accompanies crack extension (2). This current transient has now been investigated as a function of potential, and analyzed, and the results are to be reported here. The investigation was conducted over the poten-

Key words: electrodes, alloy, fused salts.

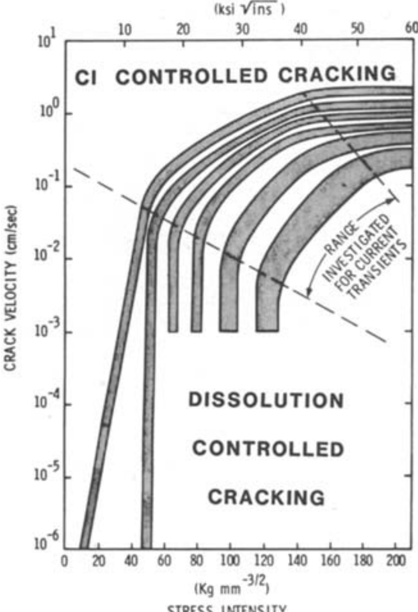

Fig. 1. Processes which control cracking of Ti-8Al-1Mo-1V in molten LiCl-KCl.

tial range of −1.7 to −2.3V *vs.* 1M Pt^{+2}/Pt.[1] The current and crack length were recorded simultaneously, so that the average current density on the crack walls could be calculated as cracking progressed. The analysis of the current density behavior both as a function of time and at different potentials has shown that the current transient was caused by three distinct processes: (*i*) anodic dissolution from film-free crack walls, followed by, (*ii*) nucleation and growth of a passivating film, which leads to, (*iii*) thickening of the film at the later stages of crack growth. The observation that cracking occurs with film-free crack walls implies that the brittle-film mechanism is not important for these molten salt experiments. Anodic dissolution does occur during cracking at some potentials, but is not important for the velocity ranges considered here. The anodic current transients do not support an anodic dissolution controlled cracking mechanism at high velocity.

Experimental

The molten salt, dry box, and electrochemical instrumentation have been discussed previously (3). The DCB specimen has been described as well (1, 4). The material was Ti-8% Al-1% Mo-1% V in a duplex-annealed heat-treatment which produces an $\alpha + \beta$ microstructure, with no precipitated α_2 (6, 7). The texture of the microstructure was such that the preferred cracking plane was oriented in a direction parallel to the rolling direction of the plate material, and specimens were cut from the plate so that the preferred cracking plane was along the length of the specimen. The thickness, *B*, of the specimens was 0.5 cm.

The specimens were stressed to a constant deflection. This resulted in crack extension at high stress intensities (and thus high crack velocities) in the beginning, with cracking at lower stress intensities as the crack propagated. The highest stress intensity was about 60 ksi (in.)$^{1/2}$, and it dropped to less than 10 for cracking at −1735 mV.

Crack extension was videotaped at 60 frames/sec. Frame by frame playback allowed determination of the high initial crack velocity (up to 1 cm/sec) with crack length resolution of <0.5 mm. The crack length data were synchronized with the current transient results as described below and were used in the data analysis.

The block diagram of the experimental arrangement is shown in Fig. 2. The potentiostat controlled the potential of the specimen. Current from the potentiostat was monitored on the Biomation Waveform Recorder. The recorder had an analog-to-digital converter and a 4096 word memory. The dual time-base capability of the recorder was used, whereby an initial fast time base (*A*) was changed to a slower time base (*B*) by a front panel manual push-button. The current was monitored on time base *A* until cracking began and the current rose rapidly, and time base *B* was switched in. This allowed "pre-trigger" information to be preserved. The current transient had a fast rise time and slow decay which was easily resolved with the recorder operation as described.

A pulse was triggered by the manual time base switch on the Biomation and recorded simultaneously on the audio channel of the videotape. This pulse synchronized the crack length and current transient time bases.

Data from the waveform recorder was read out on either a strip-chart recorder or directly into the memory of an HP-9830 calculator.

Results and Discussion

The crack length increased with time [see Ref. (3) for a more complete description], initially at a constant rate (*i.e.*, at a constant "plateau" velocity) and then at a decreasing rate at longer time and longer crack lengths.

A current transient measured on a strip chart recorder is shown in Fig. 3. The background current

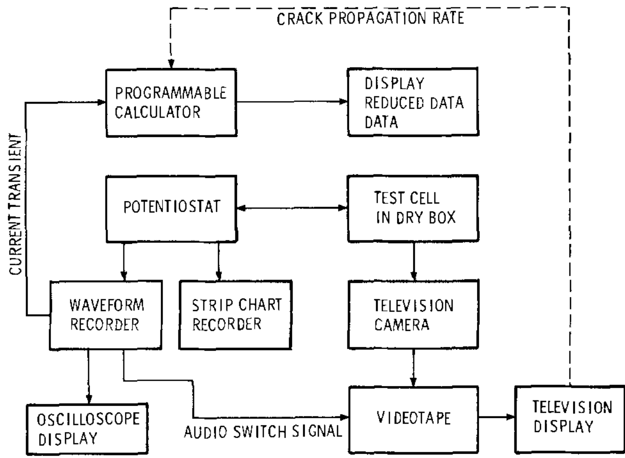

Fig. 2. Block diagram of experimental arrangement for monitoring crack propagation and current transients.

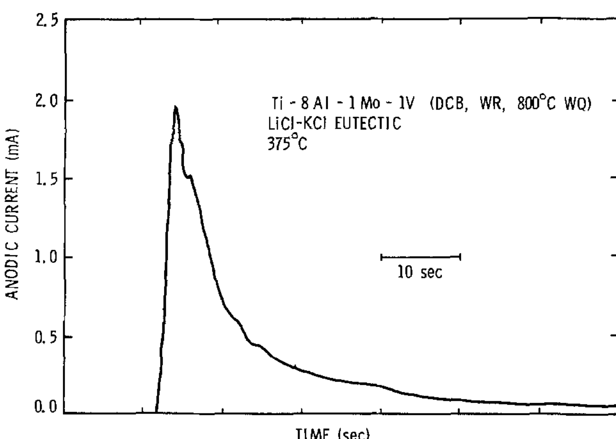

Fig. 3. Current transient measured during crack propagation at −1915 mV *vs.* 1M Pt^{+2}/Pt.

[1] Note: This couple is the standard reference for molten LiCl-KCl [cf. (12)].

before cracking was extremely small and cathodic, and the current transient was anodic. The total anodic charge passed during the cracking event was of the order of 10 mC and was dependent on potential. By synchronizing the time bases for crack length and current, it was possible to associate a particular crack length with a particular current level as shown in Fig. 4. The current in this figure was reconstructed from the Biomation Waveform Recorder data and was smoothed for the purpose of drawing the curve. This clearly revealed that the rising portion of the curve was resolved by using the dual-time base recording mode of the recorder.

The observed cracking and the current transient were always found to begin at the same time, within our resolution. The limit of resolution was in the crack length measurements. Crack length could be resolved to less than 0.5 mm, and for a crack velocity of the order of 1 cm/sec, the time resolution for the onset of cracking was therefore of the order of 0.05 sec. Time resolution for the current transient was always 0.005 sec or better.

Stirring the melt with no crack extension caused a cathodic current transient. Increasing the surface area would also cause a cathodic current transient for a cathodic background current. Therefore, neither stirring nor increasing the surface area could be responsible for the observed anodic current transient during crack propagation.

Since the background current was small, and stirring caused a cathodic transient, it was concluded that the anodic current transient was caused by electrochemical processes within the propagating crack. The average anodic current density from the crack walls was calculated for a typical experiment and is shown in Fig. 5. The crack wall area was calculated as twice the length of the crack multiplied by the specimen thickness. As might be anticipated from Fig. 4, the current density was constant for several seconds of crack life and then decreased at longer times at t^{-1}. This pattern was observed at all potentials, and it appears that an initial dissolution process from the crack wall was modified by the deposition of a passivating film at longer time.

Possible Current Transients

Before any further analysis of the results is discussed, it seems worthwhile to describe the current transients that might be expected for several simple processes. This is not meant to be an exhaustive survey of all possible transients, but rather a description of the transients that could be anticipated for processes that were known or were expected to occur during the tests. This is followed by a more complete analysis of the current density results.

Several current-time curves are shown in Fig. 6 that might be expected if the associated processes were to occur during cracking. In the upper left figure, the current necessary to charge the electrical double layer on the surface for increasing area is shown. This is analogous to the charging current to growing mercury drops, which is well known in polarography (8). Yeager *et al.* (11) have also recently given the relationship for the charging current to an ideally polarizable electrode at constant voltage with changing area as

$$I = VC\frac{dA}{dt}$$

Here, I is the current, V is the (constant) voltage, C is the differential double layer capacitance, and dA/dt is the change of area with time. For a crack propagating through a specimen of constant thickness

$$\frac{dA}{dt} = B\frac{dl}{dt} = B\bar{v}$$

where B is the plate thickness and $\bar{v}$ is the velocity of crack extension. Therefore

$$I = VCB\bar{v}$$

and the current is proportional to the crack velocity. The curve is drawn schematically for a crack length-time dependence as shown in Fig. 4. The initial sharp jump of current (because the velocity jumps from zero to the plateau velocity) would be followed by a level portion (constant velocity) and finally a de-

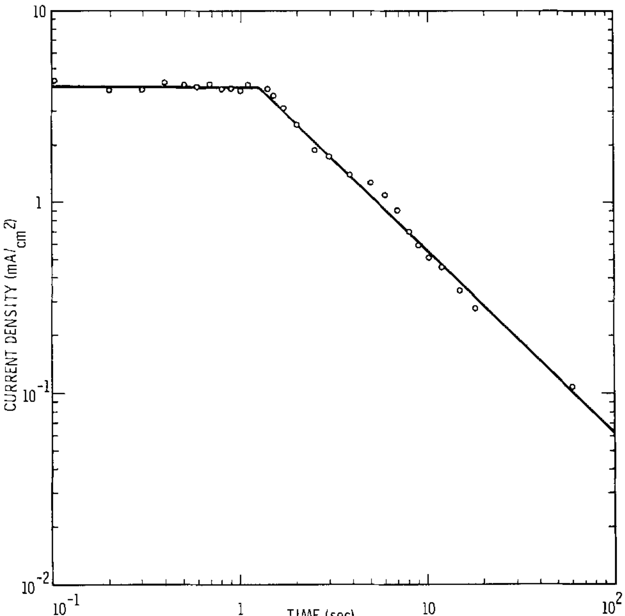

Fig. 5. Time dependence of current density on the crack walls

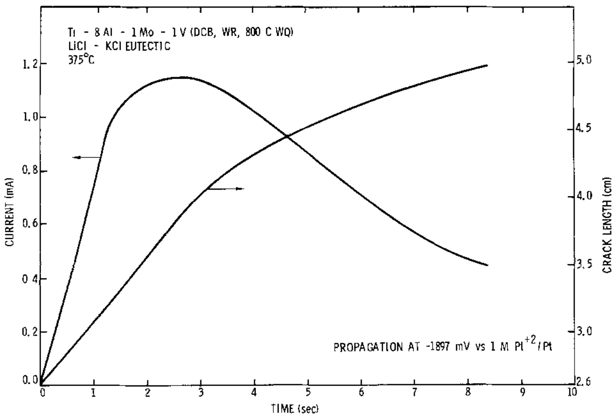

Fig. 4. Current transient and crack length as a function of time

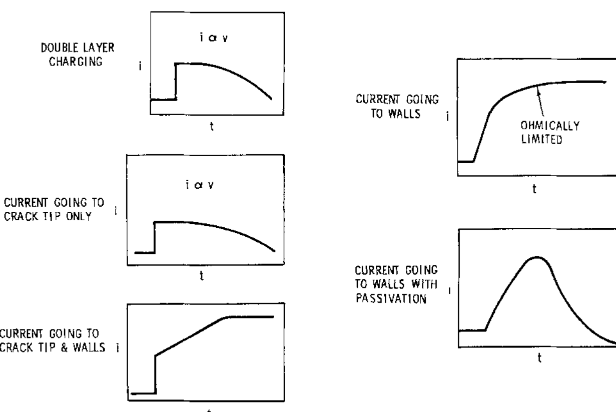

Fig. 6. Current transients expected for various processes

crease with time as the crack velocity decreased. Although this process does occur during cracking, the expected current for double layer charging is smaller than that observed in the anodic transients. For a nominal 25 $\mu F/cm^2$ double layer capacitance, and a rate of change of crack area of 0.5 cm^2/sec (*i.e.*, a velocity of 1 cm/sec multiplied by the 0.5 cm thickness of the specimen), the maximum charging current would be 12.5 μA. This is more than two orders of magnitude lower than the observed current. The predicted initial jump of current from 0 (*i.e.*, background) to 12.5 μA was below the resolution of our measurements. It is concluded that the charging current was a negligible part of the observed current transient, except for the most cathodic potentials as discussed below.

In the middle figure on the left is shown the current transient expected if the anodic current were only from the crack tip and this represented the cause of crack extension. The current would again be proportional to the velocity of cracking as given by the relationship

$$I = n\mathbf{F}\frac{\rho}{M}(B)(W)\bar{v}$$

where n = number equiv./mole for the reaction, taken as 2 in this example, $\mathbf{F}$ = Faraday constant, ρ = density of the metal, M = molecular weight, B = thickness of the specimen, W = width of the crack tip region dissolved, and $\bar{v}$ = crack velocity. If one assumes the properties of metallic titanium, and the width of the zone equal to 1 atomic diameter (*i.e.*, 3×10^{-8} cm for Ti), one calculates the maximum current to be 2.7×10^{-4}A with a current density of 1.8×10^4 A/cm^2. This is about one order of magnitude lower than the observed current. One could increase the current an order of magnitude by increasing W by an order of magnitude and the current density over the dissolution zone, W, would remain constant, *i.e.*, 1.8×10^4 A/cm^2. There would be an initial jump in current to 2.7×10^{-4}A or higher, as the velocity jumps to the constant, plateau velocity of $\sim$1 $\mu m/sec$. The current resolution was about 1%, and a current jump of 2.7×10^{-4}A, or higher, could have been seen easily, but was not. Increasing the zone width, W, would only make the disagreement worse, and decreasing the width below an atomic diameter may not be credible. At any rate, the observed current transient did not match this transient in any way. It is concluded that attributing all the current to crack tip dissolution alone cannot be supported by the experimental data.

If the above process were superimposed on anodic dissolution from the crack walls, the curve on the lower left (Fig. 6) would be expected. The initial current "jump" would be due to the sudden increase in velocity, and the current from the crack tip would be the dominant factor in the total current at first. Current from the crack walls would become increasingly important as the crack grew and could be dominant at long times. The calculation made above of the magnitude of the initial current jump is relevant here as well. The absence of an initial current jump leads to the conclusion that anodic dissolution from the crack tip to cause crack extension was not a significant contribution to the current transient, even if one assumes that other processes were superimposed on it.

At this point in the discussion, it is worthwhile to emphasize what has just been concluded. The absence of an observed current jump at the beginning of cracking means that the crack tip dissolution current was too small to be resolved by our measurements, *i.e.*, lower than 0.02 mA. This is smaller by an order of magnitude than the minimum current which was calculated above for crack propagation due only to anodic dissolution. In addition, the magnitude of the current density (up to 1.8×10^4 A/cm^2 for velocities of 1 cm/sec) for this mechanism is enormous. The largest current densities which can be accounted for in the present investigation (see below) is about 1-10 mA/cm^2. This is a discrepancy of 6-7 orders of magnitude. Large anodic current densities are observed in other electrochemical systems, for example, electrochemical machining, but only at high potentials. The present investigation has been carried out at low potentials (less than 1V anodic of the equilibrium potential), potentials which appear to be too small to give such large current densities. One might alter the dissolution model to allow dissolution from a low density atomic plane, for example, which would lower the total current and the current density. The observed current transient would then be insensitive to such a process and could not be used to give any information about the crack extension (dissolution) mechanism. Nothing more will be said about this or other possible ways of developing a dissolution mechanism which does not conflict with the present current transient results. On the other hand, the point of view is adopted here that the crack tip behaves much as the rest of the crack walls, at least electrochemically, in this molten salt. Dissolution occurs from the tip and walls, but there is no enhancement of current density at the crack tip during the initial stages of crack extension. This is developed below and is shown to be consistent with all the experimental facts. There are no observations in molten LiCl-KCl which are contrary to this point of view. The current transients then do not reveal the mechanism for extension, but are the result of electrochemical reactions on the fresh crack walls which have been created by crack propagation.

Anodic dissolution from the crack walls (and tip) would be expected to give a current transient like that shown on the upper right of Fig. 6. The current would never decrease and would only level off if ohmic resistance became controlling or the crack stopped. The current density would be constant, for a constant potential, independent of crack length or area until the ohmic resistance became dominant. This does not match the observed transient overall, but the initial part of the measured current transient did have the constant current density feature.

Superimposing a passivation phenomena on the anodic dissolution process just discussed would lead to the curve shown on the bottom right (Fig. 6). The current in the beginning would be proportional to area (*i.e.*, constant current density) but this would be modified by nucleation and growth of a passivating film. After the film grew to cover the total area, the current would be governed by transport through the film. This transient most nearly matches that observed and is used as the basis for the remainder of the analysis.

The conclusions which have been reached are: (*i*) the current transient was not caused by double layer charging, and (*ii*) there was no evidence to support anodic dissolution controlled cracking. In fact, the absence of an initial jump in current at the beginning of cracking is strong evidence that anodic dissolution from the crack tip made no major contribution to the current transient and probably did not control crack extension. The current transient can be simply modeled as three processes that are superimposed on one another: region I, anodic dissolution from film-free walls, modified by region II, nucleation and growth of a passivating film patch, followed by region III, increased film thickness. The remainder of the discussion is separated into three parts representing these three different regions of the current transient.

Anodic Dissolution Region (Region I)

The cracking has been investigated as a function of potential, and the associated current transients

recorded. The constant initial current density at the onset of cracking was found to be a function of potential as shown in Fig. 7. There is a break in the curve at a potential of about −2.06V *vs.* 1M Pt^{+2}/Pt. At more negative potentials the measured current was very small as was the total crack growth (although the velocity was still high), and this caused an uncertainty that was as large as the calculated current density. The estimated current density at potentials more negative than −2.06V was about 0.2 mA/cm^2 and is shown because an anodic current was observed. Each point on Fig. 7 was from a complete run, and the scatter of data is the measure of variations of metallurgy from sample to sample.

As noted in the beginning the anodic dissolution of an unstressed Ti electrode, with normal air formed oxide coating, occurs at potentials more positive than about −1735 mV. Li deposition from the melt onto a Ti electrode begins to become significant at −2.750 mV, as determined in the course of this investigation. At potentials between −2750 and −1735 mV, the steady-state current is small, cathodic, and presumably due to the diffusion-limited reduction of residual OH^- impurity. The anodic transients of the present investigation were observed in this very negative potential region. Presumably, the oxide film suppresses any anodic reaction on the unstressed electrode until sufficiently anodic potentials are attained (>1735 mV) to break down the film.

Net anodic dissolution current would be expected from a film-free wall at potentials positive of the equilibrium potential calculated for the concentration of metal ion in the solution. Typical concentrations of Ti^{+2} in salt frozen and removed from the crack was about 10^{-5} molar (3). The reversible potential for Ti/Ti^{+2} for this concentration is −2.07V *vs.* 1M Pt^{+2}/Pt. At potentials more positive than this, net anodic dissolution would occur. At more negative potentials, the current would be due to net reduction of Ti^{+2}, superimposed on double layer charging. The maximum diffusion-limited cathodic current for reduction of Ti^{+2} (10^{-5} molar) would be about 10^{-4} mA/cm^2. The potential of zero charge (pzc) for Ti has been estimated (3) to be about −2.35V *vs.* 1M Pt^{+2}/Pt. At potentials positive of the pzc, the charging current would be anodic and superimposed on the Ti^{+2} reduction current. The charging current density for a propagating crack was estimated above. In the plateau velocity region, the charging current density was calculated to be about 1.25×10^{-5} A/cm^2. Therefore, the charging current in this region can be larger in magnitude than the Ti^{+2} reduction current.

The current density at potentials anodic of the equilibrium potential should be a linear function of the overpotential, *i.e.*,

$$i = \frac{i_o(\alpha_a + \alpha_c)\mathbf{F}}{RT}\eta$$

If α_a and α_c are equal, the linear kinetic range should extend about 50 mV from the equilibrium potential with a slope of

$$\frac{di}{d\eta} = \frac{i_o(\alpha_a + \alpha_c)\mathbf{F}}{RT} \quad (i << i_o)$$

Logarithmic Tafel behavior should be observed at large current densities (*i.e.*, $i >> i_o$). The data in Fig. 7 reveal that *i* *vs.* overpotential has linear behavior, but extends over a larger range than expected. This could be due to experimental uncertainty, but is more likely due to a partial cancellation of the nonlinear current density overpotential behavior at the higher current densities by ohmic effects. The ohmic effects are discussed below.

The linear current density-potential curve was found to yield a value of $(\alpha_a + \alpha_c)i_o$ of 1.18 mA/cm^2

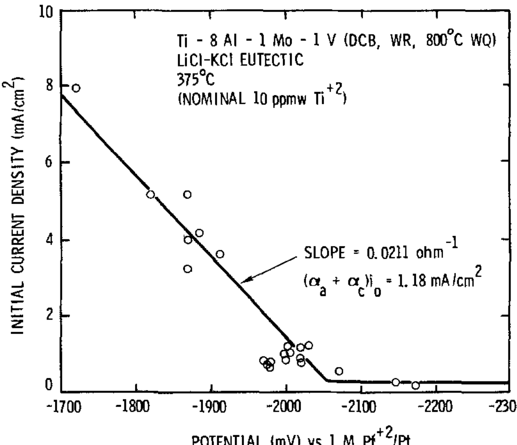

Fig. 7. Initial current density as a function of potential

where α_a and α_c are kinetic transfer coefficients for the anodic and cathodic reactions and i_o is the exchange current density. Assuming α_a and α_c are both 1, the exchange current density corrected to 1M Ti^{+2} was calculated to be 59 A/cm^2. This is somewhat higher than the exchange current densities observed for other divalent metals in LiCl-KCl (7).

The anodic current density in the region negative of −2.07V is larger than the calculated double layer capacitance of 25 $\mu f/cm^2$. In order to make the two comparable, the double layer capacitance would have to be increased by about an order of magnitude to 250 $\mu f/cm^2$. On the other hand, the current density in this region is difficult to measure and could be in error by more than enough to accommodate the model. The transients in this region were quite small, and the total crack extension for an individual test was short and of the order of 4 mm. Both combine to give an error bar that would cover the proposed charging current. There are no other anodic processes that can be identified at this time, for the alloy in the melt, so double layer charging is adopted as a tentative model for the current transient at potentials more negative than −2.07V *vs.* Pt/Pt^{+2}(1M). Of course, it should also occur at more positive potentials but it is obscured by the anodic dissolution reaction in this region.

The model of the rising portion of the current transient (region I) as described above has assumed that the current density is uniformly distributed on the crack walls. This is appropriate for the situation where the current-voltage behavior is dominated by the interfacial electrode kinetics, and it is possible to demonstrate this quantitatively as follows. To estimate the potential and current distributions along the crack, the following model of the crack is adopted: (*i*) the crack is wedge shaped, and has a nominal 1° opening, although the crack angle will be included in the model as a parameter; (*ii*) the potential drop across the crack is negligible as compared to the potential variation down the crack length; and (*iii*) there is a single, anodic dissolution reaction on the crack walls. Figure 8 shows the crack model and the coordinate system used for the calculations. At any instant Laplace's equation for the potential may be written

$$\frac{\partial^2\phi}{\partial r^2} + \frac{1}{r}\frac{\partial\phi}{\partial r} + \frac{1}{r^2}\frac{\partial^2\phi}{\partial\theta^2} = 0$$

On the crack walls it is assumed that there is a single anodic reaction under linear polarization control, *i.e.*

$$i_\theta|_{\theta=\theta_w} = -\frac{(\alpha_a + \alpha_c)\mathbf{F}i_o}{RT}(V - \phi)$$

$$= -\frac{\kappa}{r}\frac{\partial\phi}{\partial\theta}\bigg|_{\theta=\theta_w}$$

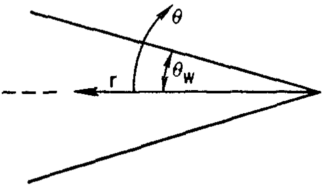

Fig. 8. Coordinate system for a wedge-shaped crack with the origin at the crack tip.

The other boundary condition on i_θ is that there is no current across $\theta = 0$ because of symmetry, *i.e.*

$$i_\theta|_{\theta=0} = 0 = -\frac{\kappa}{r}\frac{\partial\phi}{\partial\theta}\bigg|_{\theta=0}$$

We assume that the predominant variation of potential is radial and that $\partial^2\phi/\partial\theta^2$ may be approximated by

$$\frac{\partial^2\phi}{\partial\theta^2} = \frac{\dfrac{\partial\phi}{\partial\theta}\Big|_{\theta=\theta_W} - \dfrac{\partial\phi}{\partial\theta}\Big|_{\theta=0}}{\theta_W} = \frac{1}{\theta_W}\frac{\partial\phi}{\partial\theta}\bigg|_{\theta=\theta_W}$$

Hence

$$r\frac{\partial^2\phi}{\partial r^2} + \frac{\partial\phi}{\partial r} + \frac{(\alpha_a + \alpha_c)Fi_o}{\theta_W\kappa RT}(V - \phi) = 0$$

is to be solved subject to the boundary conditions $\phi = \phi_l$ at $r = \delta$ (crack length) and $\phi = \phi_o$ at $r = 0$ (crack tip). The solution is shown in Appendix I to be

$$\frac{(\phi_l - \phi)}{(\phi_l - V)} = \left\{1 - \left[\frac{I_o(Z\sqrt{\lambda})}{I_o(\sqrt{\lambda})}\right]\right\}$$

where

$$\lambda = \frac{4(\alpha_a + \alpha_c)F\delta i_o}{\theta_W\kappa RT}$$

$$Z = \left(\frac{r}{\delta}\right)^{1/2}$$

λ is an important parameter in determining the potential and current distributions in the crack. The significance of λ is discussed below.

The potential distribution down the crack is shown in Fig. 9, and Fig. 10 shows the total potential drop in the crack for cracks of different length. It is shown below that the potential drop down the crack is small for the molten salt system studied here and that the current distribution is nearly uniform.

The total current from the crack walls at any instant is found from

$$I_{total} = -2B\int_0^\delta i_\theta|_{\theta=\theta_W}dr$$

$$= \frac{2B\delta(\alpha_a + \alpha_c)i_oF}{RT}\left[\frac{2I_1(\sqrt{\lambda})}{\sqrt{\lambda}I_o(\sqrt{\lambda})}\right](V - \phi_l)$$

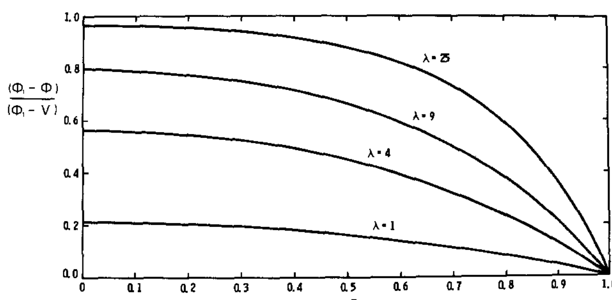

Fig. 9. Potential distribution in a crack for several values of the polarization parameter, λ.

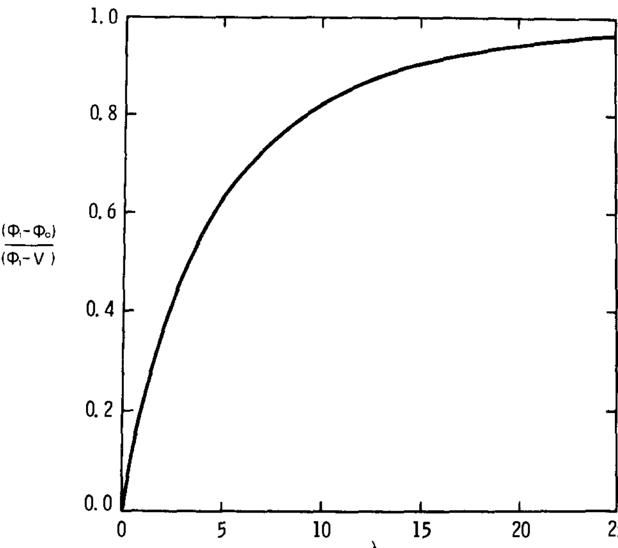

Fig. 10. Potential drop down the crack for cracks of different length.

and for small values of λ

$$I_{total} = 2B\delta(\alpha_a + \alpha_c)\frac{i_oF}{RT}\left[1 - \frac{\lambda}{8}\right](V - \phi_l)$$

As expected, the average current density, $I_{total/2B\delta}$, retains a linear dependence on the applied potential. The slope of the current density-potential curve would be

$$\frac{(\alpha_a + \alpha_c)i_oF}{RT}\left[1 - \frac{\lambda}{8}\right]$$

and was found to be 0.0211 Ω^{-1} cm^{-2} from Fig. 7, assuming $\lambda/8$ was small. This calculation supports the basic idea that current density at the beginning of cracking (Fig. 7) is controlled by dissolution kinetics, with some ohmic contribution. The ohmic contribution causes the current distribution to be nonuniform (*i.e.*, decreasing as the crack tip is approached).

The dimensionless polarization parameter for the crack, λ, measures the relative importance of kinetic *vs.* ohmic influences for the crack environment. Large values of λ are characteristic of ohmic domination and nonuniform current distribution. Small values of λ are appropriate for kinetically controlled dissolution and uniform current distribution down the crack. Factors favoring kinetic control are small exchange current densities, short cracks, large conductivities, and large crack angles. For a typical situation in the present investigation $(\alpha_a + \alpha_c)i_oF/RT = 0.0211$ Ω^{-1} cm^2, $\delta = 0.5$ cm (equal to the specimen thickness), $\kappa = 1.2$ Ω^{-1} cm^{-1}, $\theta_W = 2\pi/360$ (for a 1° crack), $\lambda = 2.0$. The current distribution as a function of λ can be calculated, and from Appendix I

$$\frac{i|_{r=o,\,\theta=\theta_W} - i|_{r=\delta,\,\theta=\theta_W}}{i_{avg}} = \frac{\Delta i}{i_{avg}} = \frac{[I_o(\sqrt{\lambda}) - 1]\sqrt{\lambda}}{2I_1(\sqrt{\lambda})}$$

and for small values of λ

$$\frac{\Delta i}{i_{avg}} = \frac{\lambda}{4} = \frac{(\alpha_a + \alpha_c)i_oF\delta}{RT\kappa\theta_W}$$

Thus, for the calculated value of λ from above

$$\lambda = 2$$

$$\frac{\Delta i}{i_{avg}} = 0.5$$

and the current density will deviate about the average value by approximately 50%. This is not a large effect, and it would be even smaller for cracks of shorter

length. For these same conditions the potential drop down the crack (see also Fig. 10) would be calculated from

$$(\phi_0 - V)I_0(\sqrt{\lambda}) = (\phi_l - V)$$

At the conditions

$$\lambda = 2$$
$$(V - \phi_l) = 50 \text{ mV}$$

then the potential drop is calculated as

$$\phi_0 - \phi_l \cong 17 \text{ mV}$$

The potential drop would be smaller for shorter cracks (see Fig. 10) or larger crack angles.

The model described above is appropriate for cracks whose length is less than the thickness of the specimen. Said another way, the treatment is appropriate for that part of the crack (measuring from the crack tip) which is less than the specimen thickness. At larger lengths, the crack opening is sufficient to cause the current and potential distributions to be rather uniform on the outer crack walls for the molten salt system. The model may be applied to other systems where the walls are film free and a single anodic dissolution occurs on the crack walls.

The model is an instantaneous picture of the electrochemistry within the crack. The time dependence is implicitly included in the dependence of the crack length on time. Separating out the time dependence in this way is legitimate where the relaxation of the current and potential distributions occur on a much faster time scale (10-100 μsec) than the rise time of the current transients (seconds) caused by crack propagation. Since the current and crack length have the same time dependence, the current density would be constant. This correctly models the experimental results.

Film Nucleation and Growth (Region II)

According to the last section, crack propagation would cause the total current to continue to increase and the current density would remain constant until the crack became long enough for ohmic limitations to become important. The current would never decrease unless some other process interfered. The current was observed to decrease in the stress corrosion tests, and it is proposed that it was caused by the deposition of a film which passivated the surface. This section discusses the model of nucleation and growth of the film. The details of the mathematical derivation are in Appendix II.

Vermilyea (9) has discussed a simple model of nucleation and growth of a film. The film patches would "throttle" the anodic dissolution reaction discussed in the previous section. As coverage of the surface approached completion, the total current would have a time dependence given by the passivating reaction. However, the total current would continue to be dominated by the anodic dissolution reaction if the film were insulating and only a small amount of current would go to form the film.

We adopt the approximation that the current to form the film and the current through the film are both much smaller than the current for anodic dissolution from the bare areas of the surface. The total anodic dissolution current density should be a function of time as (see Appendix II)

$$i_t = i_b \exp(-t/\tau)$$

By plotting $-\ln i$ *vs.* t one should obtain a straight line over the time period of nucleation and growth of the film. In Fig. 11 this plot is shown for a typical current transient. Before $t = 1$ sec, there was no appreciable contribution from film growth, probably because the solubility limit had not been exceeded. Dissolution between patches was dominant from $t = 1$ to $t = 2.5$ sec as evidenced by the linear curve. At about 2.5 sec, deviations from the straight line could be observed, and this was interpreted as the region where the small film growth current became appreciable, *i.e.*, as complete coverage of the crack wall was approached.

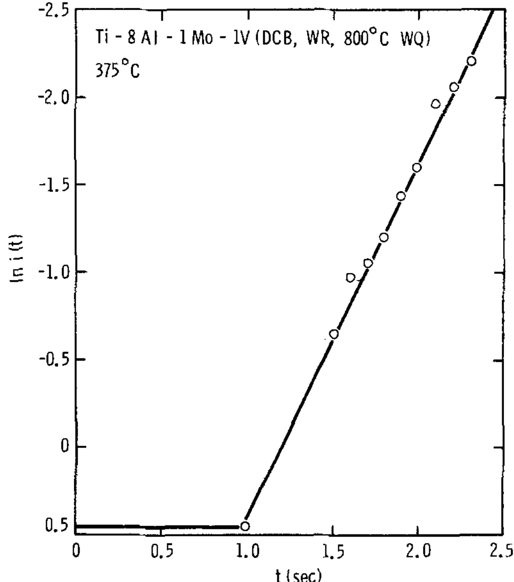

Fig. 11. Drop in current density due to precipitation of passivating layer.

The slope of the curve in Fig. 11 was found to be relatively independent of potential for our tests which were conducted over the range −1750 to −2050 mV (*vs.* 1M Pt^{+2}/Pt). The slope gave a decay constant which varied from 0.38 to 0.71 sec with an average value of 0.59 sec. From Appendix II, the decay constant was shown to be related to the current density, i_b, before nucleation by

$$\tau = ZF\rho\Delta/Mi_b$$

For the initial current density of 5.6 mA/cm² at −1800 mV, for example, the thickness of the film (calculated as TiO) would be

$$\Delta = 2.2 \times 10^{-7} \text{ cm}$$

From the slope of the curve in Fig. 11, the fractional surface coverage may be calculated (see Appendix II), and is shown in Table I. Zero time was taken as $t = 1$ sec on Fig. 11. Therefore the surface approaches complete coverage at times between 1.5 and 2 sec (above 2.5 sec on Fig. 11). This should cause deviations from the linear behavior shown in Fig. 11, as the current in bare areas becomes comparable to the current on the passive areas.

Identification of the film as TiO is somewhat arbitrary because no direct measurements of film properties were made. The solubility of $TiCl_2$ in LiCl-KCl is too high for it to have been precipitated on the surface.[2] There are small quantities of O^{-2} and OH^- in the melt even though the tests were conducted in

[2] Solutions of $TiCl_2$ of over 10^{-3} molar have been made in this laboratory.

Table I

Time (sec)	f
0	0
0.14	0.25
0.35	0.5
0.69	0.75
1.15	0.9
1.5	0.95

a dry box. It is proposed that the impurity level of O^{-2} was sufficient to give precipitation of TiO on the surface. No more definite identification of the film will be attempted until more information has been obtained.

Growth of a Thicker Film (Region III)

The third and final stage of the current transient observed during cracking obeyed a $1/t$ decay as shown in Fig. 12. Curves of current density *vs.* $1/t$ were also linear in this region. The slope varied from 3.1 to 6.3 for different tests, with an average of 4.54×10^{-3} C/cm^2.

The time dependence is consistent with a high field conduction mechanism [see, *e.g.*, Vetter (10)] for thickening of a passive film under potentiostatic conditions. The thickness of the film, Δ, would be expected to have a logarithmic time dependence as (10)

$$\frac{1}{\Delta} = a - b \ln t, \quad \text{with} \quad b = 1/(\beta\Delta\phi)$$

Here, β is the kinetic constant and $\Delta\phi$ is the (constant) potential drop across the film. The slope of the current density *vs.* $1/t$ curve should be approximately

$$\frac{Z\mathbf{F}\rho\beta\Delta\phi}{M}$$

where

$$\beta = \alpha Z\mathbf{F}a/RT$$

and all the symbols have been identified except α = transfer coefficient, taken as 0.5 and a = jump distance [see (10)] = $\sim 3 \times 10^{-8}$ cm. Using the parameters for TiO, the slope was calculated from this expression to be 8×10^{-3} C/cm^2. This is considered to be in adequate agreement with the experimental results which were $3.1\text{-}6.3 \times 10^{-3}$ C/cm^2.

The film thickness in region II was found to be independent of potential. This suggests that the slope of the i *vs.* $1/t$ curve in region III should have an exponential dependence on applied potential, but our data scattered too much to draw any definite conclusions at this point.

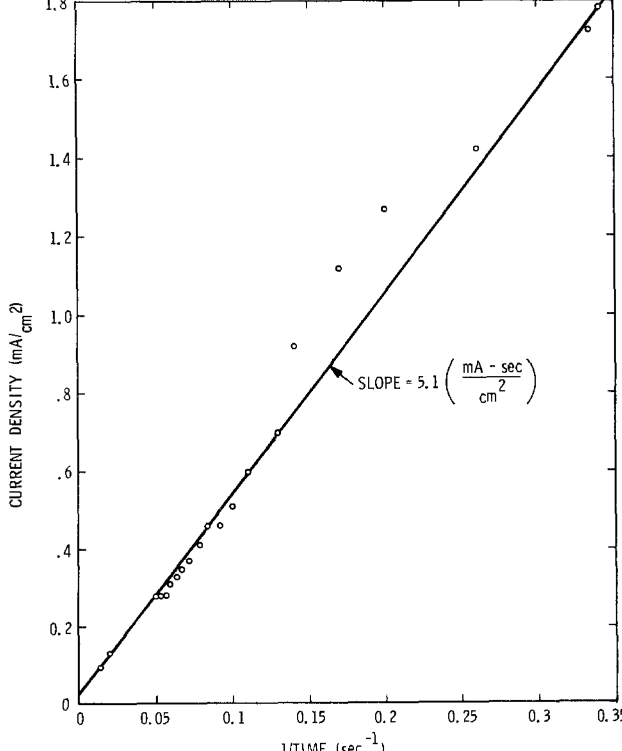

Fig. 12. Decay of current density at long times

Conclusions and Summary

The model which has been presented here accounts for the macroscopic features of the current-time behavior during crack propagation. The anodic dissolution reaction was rather uniformly distributed on the crack walls in the initial stage, and there was no indication that preferential anodic dissolution occurred at the crack tip. The crack walls were free of any film before region II. The film which was nucleated and grown during region II passivated the surface and the current-time behavior reflected the dominant source of current as that which came from the film-free surface. Deviations from this pattern occurred at longer times when the film covered the surface. Current through the film was the dominant source at still longer times where the film grew thicker by a high-field kinetic mechanism.

The dominant effect of potential was in region I. This influence was found to be consistent with linear dissolution kinetics. Data in the other two stages varied enough that the expected potential dependence could not be confirmed.

It is proposed that the events which have been described here occurred along with cracking in this simple environment, but were not responsible for cracking. That is, there has been no necessity to assume anything remarkable about the crack tip. None of the behavior could be ascribed to crack tip events.

Two of the possible mechanisms for crack propagation are eliminated by the model of events adopted here. The anodic dissolution mechanism requires preferential crack tip dissolution in order for a sharp crack to propagate, and none of the observations were consistent with this. In addition, current densities on the order of 10^3-10^5 A/cm^2 would be required to propagate cracks at the velocities observed here, and this seems unreasonable for the low voltage conditions of the tests. A brittle-film mechanism which requires a passivating film on the crack walls appears to be eliminated by the behavior in region I. All the events in region I occurred on film-free walls.

At times longer than those described here (*i.e.*, lower velocities) and at more positive potentials, crack extension could involve anodic dissolution as previously described (3). This may be consistent with the onset of intergranular cracking at low velocities (3). However, current transients have not been measured under such conditions. It should be emphasized that the present treatment is only intended to describe electrochemical events in the crack tip during the initial stages of cracking at high velocities and high stress intensities.

The molten salt environment has made it possible to eliminate from consideration several possible cracking mechanisms. The properties of the eutectic have allowed the separation of controlling parameters, so that each could be studied independently. The simple chemical nature of the environment was the most important property for defining critical processes at the crack tip. The success of the present study suggests that simple environments should be used for other mechanistic studies of stress corrosion cracking. An extension of the present study which is underway is the cracking of stainless steels in molten $AlCl_3$-NaCl. The relative importance of hydrogen embrittlement and Cl^- cracking in the austenitic (*e.g.*, 21-6-9 and 22-13-5) and ferritic (*e.g.*, 430) stainless steels will be determined.

Having eliminated several mechanisms, we have Cl^--induced cracking as a remaining possibility. It is more of an idea than a model and has never been made quantitative. It is simply the idea that adsorption (*e.g.*, Cl^-) onto a surface would weaken substrate lattice bonds so that mechanical failure would occur at reduced stress levels. Many questions about such a process remain unanswered, such as why the crack surface morphology changes from dimpled

(mechanical overload) to brittle cleavage (molten salt stress corrosion cracking) if simple adsorption is the mechanism. These unanswered questions suggest that more study is needed to definitively attribute the cracking to such a mechanism. This is to be the aim of the steel study mentioned above.

In summary, the anodic current transients observed in LiCl-KCl were caused by stress corrosion cracking of titanium-8% aluminum-1% molybdenum-1% vanadium. The transients could be broken into three stages as in Fig. 13. In region I, anodic dissolution occurred from film-free walls by linear kinetics. Nucleation and growth of a film (taken to be TiO here) dominated the behavior in region II. Growth of a thicker film caused the current decay shown in region III. None of these events are responsible for the stress corrosion cracking, but occur on the crack walls exposed by crack extension. The behavior may be consistent with crack extension induced by chloride ion (3).

APPENDIX I

Potential Distribution in a Crack

The potential drop within the crack is to be determined by solving

$$r\frac{d^2\phi}{dr^2}+\frac{d\phi}{dr}-\frac{(\alpha_a+\alpha_c)i_o\mathbf{F}}{RT\kappa\theta_w}[\phi-V]=0$$

Let

$$\theta=\phi-V$$

$$Z=(r/\delta)^{1/2}$$

and this yields

$$\frac{d^2\theta}{dZ^2}+\frac{1}{Z}\frac{d\theta}{dZ}-\frac{4(\alpha_a+\alpha_c)i_o\mathbf{F}\delta}{RT\kappa\theta_w}\theta=0$$

Let

$$\lambda=\frac{4(\alpha_a+\alpha_c)i_o\mathbf{F}\delta}{RT\kappa\theta_w}$$

to obtain

$$\frac{d}{dZ}\left(Z\frac{d\theta}{dZ}\right)-\lambda Z\theta=0$$

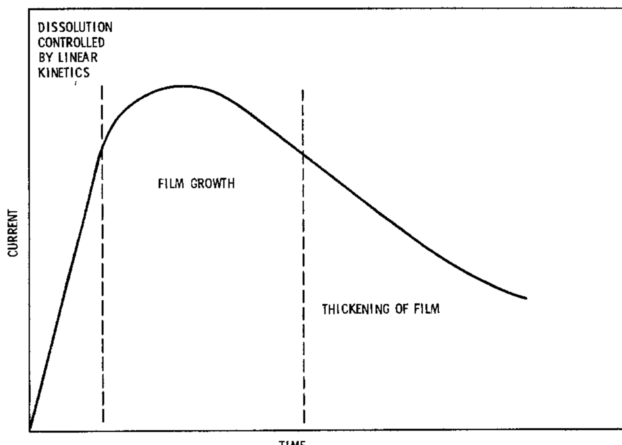

Fig. 13. Summary of processes which occur during a current transient caused by stress corrosion cracking.

The solution may be expressed in terms of Bessel functions as

$$\theta=C_1I_o(Z\sqrt{\lambda})+C_2K_o(Z\sqrt{\lambda})$$

The boundary conditions

$$\theta=\phi_o-V\quad\text{(finite) at } Z=0$$

$$\theta=\phi_l-V\quad\text{at } Z=1$$

gives

$$C_2=0$$

$$C_1=(\phi_o-V)=\frac{(\phi_l-V)}{I_o(\lambda)}$$

and

$$\theta=\phi-V=(\phi_l-V)\frac{I_o(Z\sqrt{\lambda})}{I_o(\sqrt{\lambda})}$$

The total current may be calculated now, and

$$I_{\text{(total current)}}=-2B\int_0^\delta i_\theta|_{\theta=\theta_w}dr$$

$$=\frac{4B(\alpha_a+\alpha_c)i_o\mathbf{F}\delta}{RT}\int_0^1\theta ZdZ$$

$$=\frac{4B(\alpha_a+\alpha_c)i_o\mathbf{F}\delta}{RT\sqrt{\lambda}}\left[\frac{I_1(\sqrt{\lambda})}{I_o(\sqrt{\lambda})}\right](\phi_l-V)$$

As

$$\lambda\to0$$

$$I_1\to\sqrt{\lambda}$$

$$I_o\to1$$

and

$$I_{\text{(total current)}}=\frac{2B(\alpha_a+\alpha_c)i_o\mathbf{F}\delta}{RT}\left[1-\frac{\lambda}{8}\right](V-\phi_l)$$

Current distribution down the crack is nearly uniform for small values of λ as measured by

$$\frac{i|_{\theta=\theta_w,\,r=0}-i|_{\theta=\theta_w,\,r=\delta}}{i_{\text{avg}}}=\frac{(I_o(\sqrt{\lambda})-1)\sqrt{\lambda}}{2I_1(\sqrt{\lambda})}$$

For small values of λ this becomes

$$\frac{i|_{\theta=\theta_w,\,r=0}-i|_{\theta=\theta_w,\,r=\delta}}{i_{\text{avg}}}=\frac{(\alpha_a+\alpha_c)i_o\mathbf{F}\delta}{RT\kappa\theta_w}$$

The above derivation of the potential and current distributions assumed a narrow crack, thick specimen (thickness, B, $>>$ the crack length, δ), and quasi-steady state. These results would thus be applicable at any instant and do not give the time dependence. The current would have the same time dependence as the crack length, and the current density would be independent of time.

APPENDIX II

Nucleation of a Passivating Film

Dissolution of a metal may be throttled by a passivating film that forms on the surface when the solubility of the solid is exceeded. The current density on the free surface will be constant at constant potential. The total current to a given surface area will be composed of the current density to the free surface, plus the current to the edges of passivating patches, plus the current to the surface of the patch to increase its thickness. If we assume that the dominant current is the dissolution current on the film-free surface, that the current to thicken the patches is negligible, and that the current to nucleate and grow a patch is important only to change the area covered by the film, the total current density is

$$i_t=i_b(1-f)$$

Here, f is the fraction of the surface covered by the passivating solid and i_f is the current density to the film-free surface. The time dependence of the total current density will be that of the area fraction f, *i.e.*, i_t will change with time only because f changes.

Once the solubility limit is exceeded and a film begins to precipitate, the rate of deposition of a constant thickness film will cause the fraction of surface covered to change as

$$\frac{df}{dt} = i_t M / Z\mathbf{F}\rho\Delta$$

The first equation may be substituted into the second, and integration yields

$$i_t = i_b \exp(-t/\tau)$$

where the decay constant τ is given by

$$\tau = Z\mathbf{F}\rho\Delta / i_b M$$

and Z = number equiv./mole, taken to be 2 here, $\mathbf{F}$ = Faraday constant, ρ = density of the solid, Δ = thickness of the film, i_b = constant current density to the film-free surface, and M = molecular weight of the film solid.

The surface is half covered at

$$i_t = 0.5\, i_b$$

or

$$t/\tau = 0.693$$

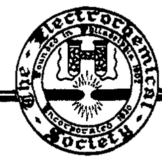
Technical Notes



A Seawater Battery Based upon the Sulfuryl Chloride/Magnesium Couple

K. A. Klinedinst* and F. G. Murphy*

GTE Laboratories, Incorporated, Waltham, Massachusetts 02154

In the continuing search for the optimum energy source for the propulsion of underwater vehicles, the "seawater" battery has established a unique position (1-4). The silver chloride/magnesium couple utilizes seawater as both the electrolyte and the cooling medium for high power applications. One concept to extend the operating life of the seawater battery (while maintaining maximum power density) involves the use of a liquid cathode reactant as in the zinc/chromic acid cell (5-7). In this battery, the stored concentrated chromic acid and sulfuric acid are injected into the incoming seawater as needed.

The use of a liquid oxyhalide cathodic reactant in a seawater battery has recently been suggested (8). This note describes the initial experimental work performed to evaluate the feasibility and potential of seawater batteries containing magnesium or magnesium alloy anodes and liquid oxyhalide cathodic reactants. In this battery, the liquid oxyhalide flows through and is reduced upon an inert porous carbon cathode. The products of the cathodic half-cell reaction along with any unreduced oxyhalide then pass into the seawater electrolyte which flows between the carbon and magnesium electrodes. The consequent acid enrichment of the seawater serves to keep the products of the anodic half-cell reaction in solution.

Experimental

The experimental cell was made almost entirely of PTFE. It consisted of two parts: the body and the cap (as shown in Fig. 1). The body of the cell was made from two pieces of cylindrical PTFE stock joined together to make an L-shaped unit. A hole was drilled

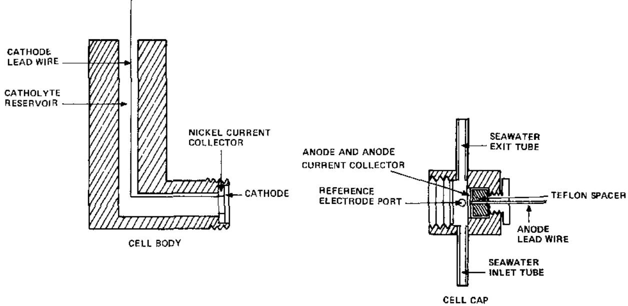


Fig. 1. Experimental cell schematic

* Electrochemical Society Active Member.

Key words: battery, magnesium, seawater, sulfuryl chloride.

through the body to serve as a reservoir for the liquid oxyhalide. A nickel washer (welded to a nickel lead wire) served as the cathode current collector. The porous cathode (a mixture of carbon black and PTFE pressed onto a nickel metal screen) was pressed onto this nickel washer when the cell cap was fastened to the body by means of screw threads machined into the PTFE parts. Thus, during the operation of the cell, the liquid reactant could flow from the reservoir through the porous cathode.

The cell cap was a more complicated assembly. The magnesium or magnesium alloy anode was pressed against a nickel current collector by means of a stainless steel ring. The nickel lead wire (welded to the anode current collector) exited the cell through a hole drilled into a PTFE plug which screwed into the end of the cap. Two stainless steel tubes extended from opposite ends of a cap diameter and were used to transfer the "seawater" (3.5% NaCl dissolved in distilled water) into and out of the cell. (The seawater flowed between the two electrodes in the assembled cell at a rate of about 1 ml/sec.) The Ag/AgCl reference electrode (AgCl electrochemically formed upon the surface of a silver wire) passed into the cell via a third opening in the cap (at right angles to the two stainless steel tubes).

Once the cathode and anode were positioned within the cell body and cap, respectively, the two cell parts were screwed together. However, a thin PTFE washer was placed within the cap just before the parts were joined to insulate the two electrodes from each other. The electrode spacing (about 0.635 mm) was determined by the combined thicknesses of this PTFE washer and the stainless steel ring by which the anode was positioned within the cell cap. The exposed electrode area was 0.8 cm^2.

Once the seawater had begun flowing through the cell, the test was initiated by filling the oxyhalide reservoir. In every experiment, the cell voltage, the anodic half-cell potential, and the cathodic half-cell potential (relative to the Ag/AgCl reference electrode) were simultaneously recorded during each measurement interval by the use of a multichannel recording voltmeter. Two types of measurements were made: current and potential *vs.* time on constant load, and current *vs.* potential under initial discharge conditions. The initial condition performance data were obtained in two ways: either by the application of constant load pulses (in which case the current was calculated from the voltage on load) or by the application of galvanostatic pulses. The half-cell polarization curves were corrected for solution *IR* losses using standard techniques.

Results and Discussion

Of the liquid cathode reactants that have been used in lithium anode cells, sulfuryl chloride (SO_2Cl_2) and thionyl chloride ($SOCl_2$) have yielded the highest cell voltages (9). Therefore, these two compounds were chosen as the liquid oxyhalides to be examined as seawater battery cathode reactants. Both pure magnesium and MTA (a magnesium alloy containing 7% Tl and 5% Al) were considered as possible anode materials.

Initially, seawater cells were assembled with MTA as the anode material and with SO_2Cl_2 and $SOCl_2$ as the cathode reactants. The open-circuit voltages of the MTA/SO_2Cl_2 and MTA/$SOCl_2$ cells were 2.83V and 2.50V, respectively. It was noted that the difference between the two open-circuit voltages (0.33V) is nearly the same as the difference between the open-circuit voltages of the Li/SO_2Cl_2 and Li/$SOCl_2$ cells (0.35V). The two seawater cells were then discharged across constant 100Ω loads resulting in a discharge current density of about 20 mA/cm^2. Again, the MTA/$SOCl_2$ cell voltage was about 0.3V below that of the MTA/SO_2Cl_2 cell, the latter quantity being about 2.3V. Since even lower cell voltages are to be expected with other liquid oxyhalide reactants (*e.g.*, $POCl_3$), SO_2Cl_2 is clearly the preferred cathode reactant for the Mg anode seawater battery.

Then, two seawater cells were assembled with SO_2Cl_2 as the cathode reactant and with pure Mg and MTA as

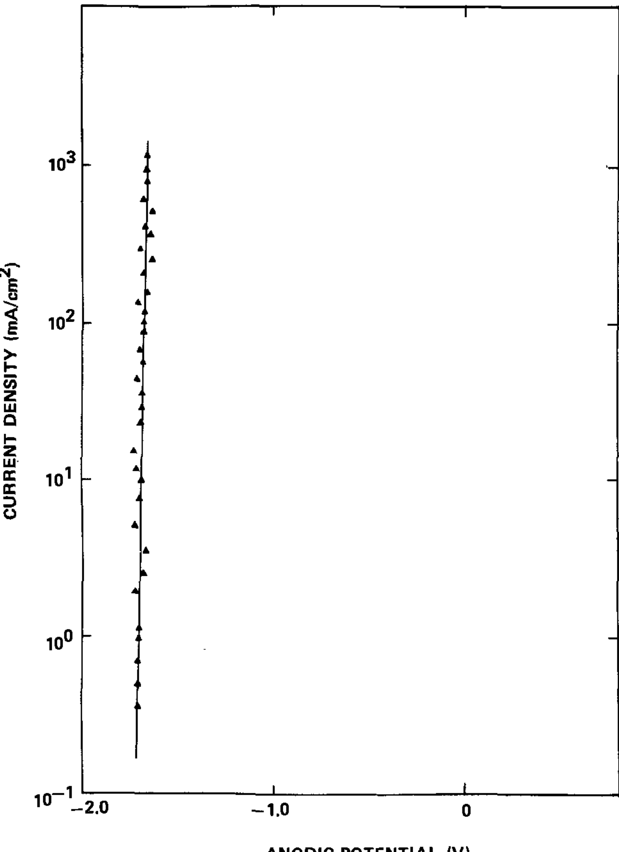

Fig. 2. Anodic polarization curve (vs. Ag/AgCl reference)

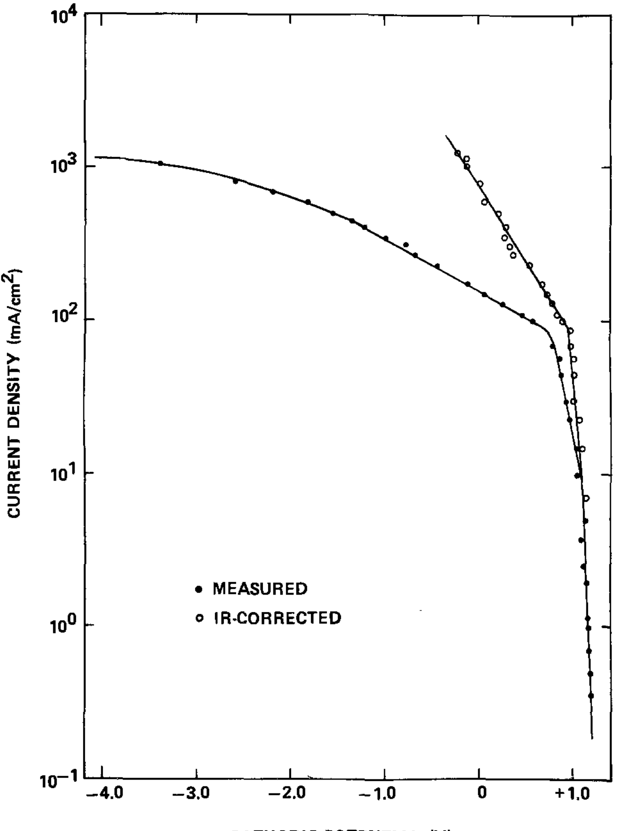

Fig. 3. Cathodic polarization curve (vs. Ag/AgCl reference)

the anode materials. With the pure Mg anode, the open-circuit voltage was about 0.14V below that obtained with the MTA anode. A similar voltage differential was observed when the two cells were discharged across constant 100Ω loads. Therefore, MTA was chosen as the anode material to be used in all of the subsequent experiments.

Initial performance data were then obtained for the MTA/SO_2Cl_2 seawater cell by the application of both the constant load and galvanostatic pulse techniques described above (using the Ag/AgCl reference electrode). The results obtained with the two measurement techniques were essentially identical. Thus, only the results of the galvanostatic pulse measurements will be described here.

The anodic half-cell polarization curve is shown in Fig. 2. (Because of the positioning of the Ag/AgCl reference electrode within the cell cavity, negligible solution *IR* losses were encountered between the anode and the reference electrode.) The data demonstrate that the MTA anode operates with very little polarization. In fact, the anodic potential only decreases by about 50 mV as the current density is raised by over three orders of magnitude.

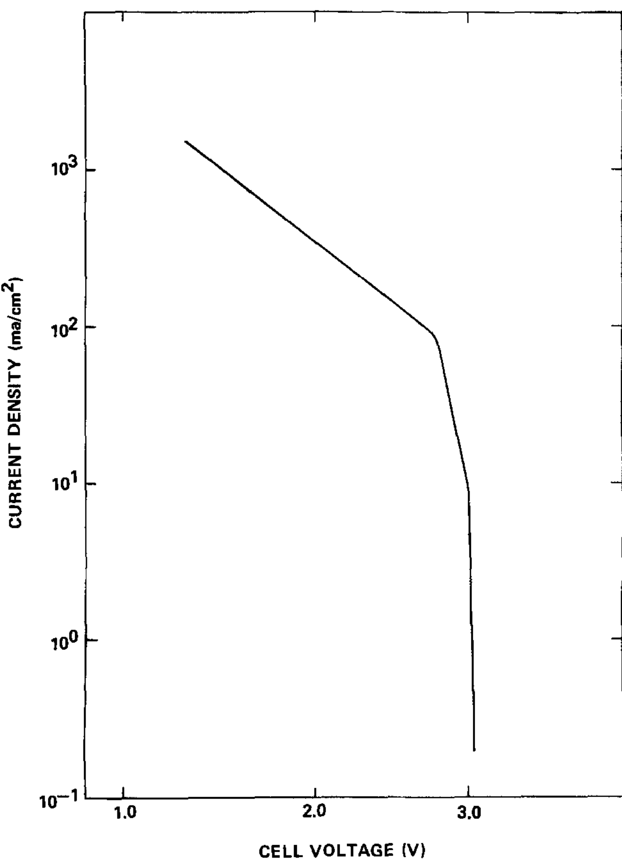

Fig. 4. Cell polarization curve

The measured and *IR*-corrected cathodic half-cell polarization curves are shown in Fig. 3. In contrast to the anodic half-cell results, the SO_2Cl_2 cathode is observed to suffer considerable polarization, particularly at current densities greater than about 100 mA/cm². The *IR*-free full cell polarization curve is shown in Fig. 4.

Summary and Conclusions

The feasibility of a new seawater battery system comprising a magnesium or magnesium alloy anode and a liquid oxyhalide cathodic reactant has been demonstrated experimentally. SO_2Cl_2 has been found to be the preferred cathodic reactant. Tests have shown that the magnesium anode operates with very little polarization, virtually all of the cell polarization occurring at the cathode. Continuing work will seek to identify the process or processes responsible for the observed cathodic polarization.

Heat of Transport of Superionic Conducting Glass $2AgI \cdot Ag_2MoO_4$

Tsutomu Minami, Katsunori Matsuda, and Masami Tanaka

Department of Applied Chemistry, University of Osaka Prefecture, Sakai-Shi, Osaka-Fu 591, Japan

Superionic conductors have attracted attention from the viewpoint of technological applications, such as solid-state batteries (1), electrochromic displays (2), and so on. There are two types in AgI-based superionic conductors; crystalline and glassy ones. The latter ones, or superionic conducting glasses, have several advantages compared to crystalline ones; higher conductivities (3, 4), isotropic properties, and ease of thin film formation.

Key words: heat of transport, superionic conductor, solid electrolyte, glassy electrolyte, ionic transport.

In crystalline superionic conductors the activation energy for conduction, E_σ, is reported to be experimentally equal to the heat of transport, q^*, which is

the anode materials. With the pure Mg anode, the open-circuit voltage was about 0.14V below that obtained with the MTA anode. Heat of Transport of Superionic Conducting Glass $2AgI \cdot Ag_2MoO_4$

Tsutomu Minami, Katsunori Matsuda, and Masami Tanaka

Department of Applied Chemistry, University of Osaka Prefecture, Sakai-Shi, Osaka-Fu 591, Japan

Superionic conductors have attracted attention from the viewpoint of technological applications, such as solid-state batteries (1), electrochromic displays (2), and so on. There are two types in AgI-based superionic conductors; crystalline and glassy ones. The latter ones, or superionic conducting glasses, have several advantages compared to crystalline ones; higher conductivities (3, 4), isotropic properties, and ease of thin film formation.

In crystalline superionic conductors the activation energy for conduction, E_σ, is reported to be experimentally equal to the heat of transport, q^*, which is

Key words: heat of transport, superionic conductor, solid electrolyte, glassy electrolyte, ionic transport.

determined from the temperature dependence of thermoelectric power, and several papers are presented to discuss the ionic transport mechanism of the conductors based on such equality between E_σ and q^* (5-9).

We have found, however, that there is an appreciable difference between E_σ and q^* in superionic conducting glass $2AgI \cdot Ag_2MoO_4$ (mole ratio), which shows the ionic conductivity as high as $4 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$ at room temperature and the transport number of unity of silver ions (3, 10). In the present note q^* of the glass $2AgI \cdot Ag_2MoO_4$ is compared with E_σ reported previously (10). The appreciable difference between these values must give a clue to reveal the transport mechanism in the glass.

The thermoelectric power was measured by using the cell shown in Fig. 1; the cell can schematically be shown as

$$Ag(T)/Ag^+ \text{ ion containing glass}/Ag(T + \Delta T) \quad [I]$$

Chamber 1 in the figure was sunk in a low temperature ethyl alcohol-Dry Ice bath cooled with a cooler (Neslab, Cryocool Model cc-80II) after it was filled with dry nitrogen gas. The temperature of the sample was monitored with the thermocouple 8 and regulated with a PID temperature controller connected to furnace 2 so as to achieve no temperature difference between the top and bottom surfaces of the sample at a given temperature. After keeping the sample at that temperature for at least 30 min, the upper heater 3 was gradually heated with d.c. to generate the temperature gradient in the sample. The thermoelectric voltage ΔV caused by the temperature difference ΔT, smaller than 2 K, was recorded on an X-Y recorder C. The thermoelectric power θ was determined from the slope on the recorder as defined by

$$\Delta V = \theta \cdot \Delta T \quad [1]$$

The sign convention that θ is positive if the hot end shows higher potential is followed in this paper. The impedance of the amplifier A was $10^7 \Omega$ and that of B was higher than $10^{14} \Omega$. The measurements were repeated at least 5 times at each temperature.

The glass preparation technique has been described elsewhere (10). Two types of samples were used for the thermoelectric power measurement, similar to the conductvity measurement: bulk glass and pressed pellet of pulverized glass. The pellet contained voids of about 4.5%.

Figure 2 shows the temperature dependence of θ; circles are for bulk glass and triangles for pellet. A very small difference is observed between bulk and pellet. The thermoelectric power θ was expressed by

$$\theta = -\frac{q^*}{T} + H \quad [2]$$

where q^* is so called the heat of transport of silver ions and H is a constant. The equation of the straight lines was determined by the least squares as

$$\theta(\text{mV/K}) = -(0.067 \pm 0.006)\frac{10^3}{T} - (0.23 \pm 0.02) \quad [3]$$

for bulk glass and

$$\theta(\text{mV/K}) = -(0.059 \pm 0.006)\frac{10^3}{T} - (0.27 \pm 0.02) \quad [4]$$

for pellet.

Table I summarizes q^* and θ_{25} (thermoelectric power at 25°C), together with E_σ and σ_{25} (conductivity at 25°C) for comparison (10). As evident from the table the discrepancy in properties is very small between bulk and pellet, indicating that the bulk diffusion instead of surface or boundary diffusion controls the migration of Ag^+ ions. The value of q^* is appreciably smaller than E_σ, in contrast to the crystalline superionic conductors (5-9). It is also worth noting that q^* of the present glass is very close to that of α-AgI (1.20 kcal/mole) (7). According to Girvin (8, 9) q^* is equal to the static barrier height for ion hopping and the difference between E_σ and q^* is explained in terms of the phonon coupling.

It has been reported that the present glass is composed of Ag^+, I^-, and MoO_4^{2-} ions and some Ag^+ ions show strong partial covalency with oxide ions in MoO_4^{2-} tetrahedra (11). The fact that q^* of the glass is nearly equal to that of α-AgI must imply that Ag^+ ions contributing to the ionic conduction interact electrostatically with I^- ions only and thus a part of Ag^+ ions in glass take part in the ionic conduction; this result is consistent with the deduction given in the pre-

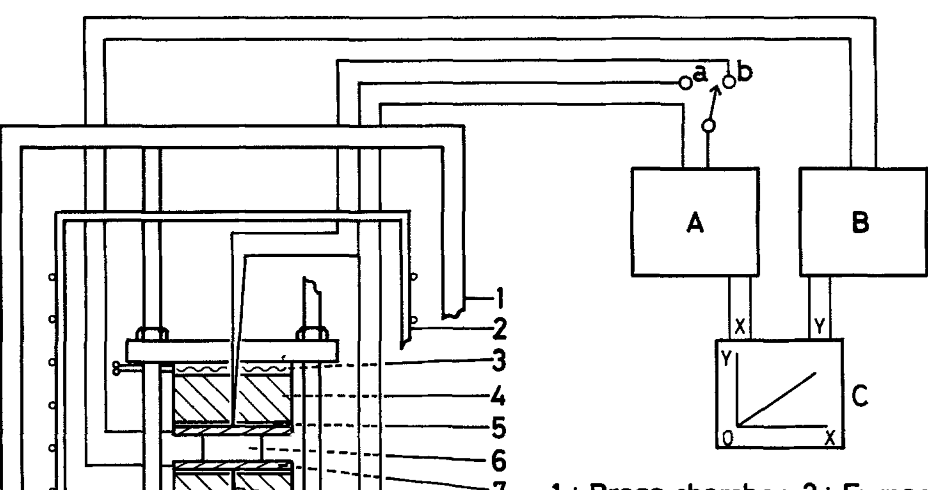

Fig. 1. Schematic diagram of the cell for the measurement of thermoelectric power.

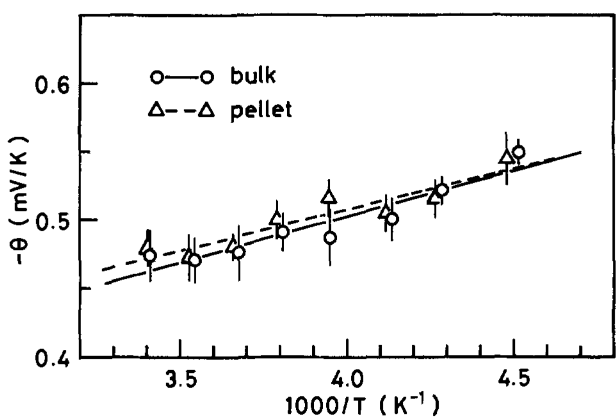

Fig. 2. Temperature dependence of thermoelectric power of glass $2AgI \cdot Ag_2MoO_4$ (mole ratio).

vious paper (10). Much detailed study is under progress on the heat of transport and the ion transport mechanism of superionic conducting glasses, and will be published elsewhere in the future.

Table I. Some parameters for ion transport in superionic conducting glass $2AgI \cdot Ag_2MoO_4$ (mole ratio)

	q^* (kcal/mole)	θ_{25} (mV/K)	E_σ[a] (kcal/mole)	σ_{25}[a] (Ω^{-1} cm^{-1})
Bulk glass	1.6	-0.45_9	5.5	4.0×10^{-3}
Pellet	1.4	-0.46_9	5.7	2.9×10^{-3}

[a] The activation energy for conduction, E_σ, and the conductivity at 25°C, σ_{25} (10). The values of E_σ were determined by $\sigma = \sigma_0 \exp(-E_\sigma/RT)$.

Acceleration of Plasma Etch Rate Caused by Alkaline Residues

T. Makino, H. Nakamura, and M. Asano[1]

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Tokyo 180, Japan

ABSTRACT

Effects of positive resist developer processing on plasma etching characteristics are described. The etch rate of polycrystalline silicon was measured with and without positive resist developer processing using a barrel-type plasma etching system and CF_4 + 5% O_2 as an etching gas. A considerably accelerated etch rate was observed for polycrystalline silicon with residues of positive resist developer. The acceleration is attributed to NaOH residues adhered on the surface, which act as catalytic agents. The residual KOH also accelerates the etch rate of polycrystalline silicon.

Plasma etching has become a promising technique for delineation of patterns in polycrystalline Si (poly-Si), Si_3N_4, and SiO_2 during the manufacture of integrated circuits. Particularly for poly-Si, plasma etching takes the place of a wet process with HF-HNO_3 solution since it is simpler, more economical, and capable of automatic operation. Using CF_4 or CF_4 + O_2 as an etching gas, pressure dependences or rf power dependences of etch rate are widely examined (1-3) in addition to the influence of impurity doping in poly-Si (4). In order to improve the controllability or repeatability, effects of various parameters in the photolithographic process should also be investigated. Zelley has reported (5) that organic residues associated with a negative resist developer sequence can exert a major influence on plasma etch rate and uniformity of Si_3N_4. It is also concluded that the use of a positive resist is the best solution to the problem by avoiding the troublesome residues altogether. However the result was limited to Si_3N_4 and the details of the positive develop process, such as components of the developer, were not clearly described. There are two types of developing solution for positive resist; one is a nonmetal developer and the other contains alkaline metal compounds. The former is inferior in resolution of fine pattern delineation, although it avoids alkaline metal contamination.

This paper describes, for the first time, effects of positive resist developer processing on plasma etching characteristics of boron (B) doped poly-Si. Here an AZ developer was used as a positive resist developer. AZ developer residues result in a considerably faster etch rate than is experienced with virgin wafers and in considerably poorer etch uniformity and repeatability. The enhancement is attributed to NaOH adhered on the poly-Si surface during the photolithographic process, which acts as a catalytic agent. The residual KOH also accelerates the etch rate of poly-Si. In addition, it is found that the etch rate of poly-Si in CF_4 (5% O_2) decreases with B concentration, a result which is contrary to the case of phosphorus doping (4).

Key words: plasma etching, polycrystalline silicon, adhesive alkali, accelerated rates.

Experimental Procedure

The rf plasma unit (IPC-2005T, manufactured by International Plasma Corporation) was used in this study. In this type of apparatus, an aluminum tunnel was inserted into the quartz chamber, so that the etch process consisted of the chemical reaction of neutral free radicals with the wafers. On loading the wafers into the chamber, it was evacuated to 0.01 Torr and then filled with nitrogen to a pressure of 0.5 Torr. RF power (13.56 MHz, 400W) was applied to raise the wafer temperature up to 50°C. The chamber was reevacuated and the etchant gas of CF_4 (5% O_2 as a minor constituent) was introduced, while maintaining at a pressure of 0.5 Torr. RF power of 100W was applied and the plasma was excited for a given time. The temperature of the wafers was 50° $\sim$ 70°C during plasma etching.

Boron-doped poly-Si films were obtained on SiO_2 from an SiH_4-BCl_3-H_2 mixture at 600°C in an air-cooled radiation-heated horizontal reactor. Boron concentrations ranged from $2 \times 10^{19} \sim 3 \times 10^{21}$ cm^{-3}. Here B concentrations were measured using methylene blue colorimetric analysis (6), where the poly-Si films covered with CVD SiO_2 0.1 μm in thickness were entirely oxidized in a wet oxygen ambient followed by dissolution in HF aq. solution. The details of this procedure were described in a previous paper (7).

The etched thickness of poly-Si was measured by two methods; (*i*) Tallysurf measurement using a painted resist as a mask, and (*ii*) reflectometer (Nanospec AFT, manufactured by Nanometrics Incorporated) readings.

As the positive developer process, an AZ developer manufactured by Shipley Company Incorporated was employed. NaOH or KOH solutions were also used in order to investigate etch rate enhancement.

The surface contamination of the poly-Si was measured by x-ray photoelectron spectroscopy (XPS). The photoelectron spectra were obtained with a PHI Model 590 photoelectron spectrometer manufactured by Physical Electronics Industries, Incorporated using MgK_α excitation. The typical residual pressure in this

system was in the 10^{-9} Torr range. In order to obtain depth profiles, Ar sputtering was done with a beam current of 25 mA and a beam voltage of 1 kV, at a pressure of 5×10^{-5} Torr.

Results and Discussion

Intrinsic etch rate of B-doped poly-Si.—First, the etch rate of B-doped poly-Si was measured without photolithographic treatment. Figure 1 shows the etched thickness of B-doped poly-Si *vs.* etch time with B concentration as a parameter, where the poly-Si was etched almost linearly with etch time. It is found that the etch rate decreases with B concentration, from 3200 A/min for undoped to 480 A/min for 3×10^{21} cm^{-3} B-doped poly-Si. The similar decrease of etch rate was also observed in B ion implanted poly-Si. The boron concentration dependence of etch rate is contrary to the P doping case (4) as well as B concentration dependence of growth rate (8).

Impurity dependence of plasma etch rate seems to be correlated to surface potential of poly-Si, as well as impurity dependence of growth rate (9). In the case of poly-Si growth using SiH_4 with B_2H_6 or PH_3 as a dopant gas, the surface potential during the growth is maintained to be positive or negative because of electron deficiency or excessiveness relative to intrinsic silicon, respectively. Naturally a similar surface potential should be maintained during plasma etching. A change in the surface potential affects the adsorption rate of SiH_4 or desorption rate of SiF_4 and/or reaction velocity at the surface. First let us consider the effects of surface potential on adsorption or desorption rate. From a chemical point of view, SiH_4 (SiF_4) gas has the partial ionic Si^+-H^- (9, 11) (Si^+-F^-) bond resulting in making SiH_4 (SiF_4) a molecule with four negative charged hydrogen (fluorine) atoms surrounding a positive charged atom in the center. Therefore it is thought that the enhanced growth rate with B doping is due to positive surface potential which attracts SiH_4 molecules and the reduced growth rate with P doping to negative surface potential. In a case of plasma etching of poly Si, the etching process can be described as follows (2): $Si + 4F \rightarrow SiF_4 \uparrow$. The positive surface potential of B-doped poly-Si is thought to attract and retard the reduction of SiF_4 molecules from the surface, which therefore results in a decrease in plasma etch rate with B concentration.

As for reaction velocity, it is thought that surface potential undoubtedly plays an essential role before decomposition or chemical reaction. A change in the surface potential affects interaction of the reactant F atom with the surface, probably resulting in larger reaction rate.

Effects of developing sequence on etching characteristics.—A long subsequent rinse of wafers with water after development occasionally results in lifting of the resist patterns of IC's. This limits the rinse time and gives rise to residues of the developer on the surface of the wafer.

Etched thickness was measured on the poly-Si which was dipped in an AZ developer and rinsed for 1 min in DI (deionized) water. The results are shown in Fig. 2. Linear relationships between etched thickness and etch time are also observed, as well as for virgin poly-Si. Figure 3 summarizes intrinsic and accelerated etch rate of B-doped poly-Si. Extremely accelerated etch rates are found in the "dipped" poly-Si. Particularly for heavily B-doped specimens, the relative etch rate with and without the developing sequence is very large compared with the undoped one. It is noted that the resist itself, not used in the developing sequence, was not interacting with the plasma to influence etch rate. The accelerated etch rate is independent of B concentration, the result of which will be discussed in the next section in connection with the mechanism. With increasing rinse time in DI water, the enhanced effect is eliminated (Fig. 4). A 10 min rinse brings performance in line with the intrinsic etch rate already established in Fig. 1. That is, the etch rate is actually accelerated by the presence of the residues, with the fainter traces apparently exerting the influence. The uniformity of etch rate appears to be related to the uniformity of distribution of the trace residues.

It is noted that the residues are so insignificant when it comes to conventional wet processing that they exert absolutely no influence whatsoever on the normal etching process, such as HF-HNO_3 solution.

Behavior of alkaline residues during plasma etch.—Since it is known that the AZ developer contains NaOH as a major component, (13), etch rates of poly-Si were measured after dipping NaOH solution with various concentration. Here spinning of wafers

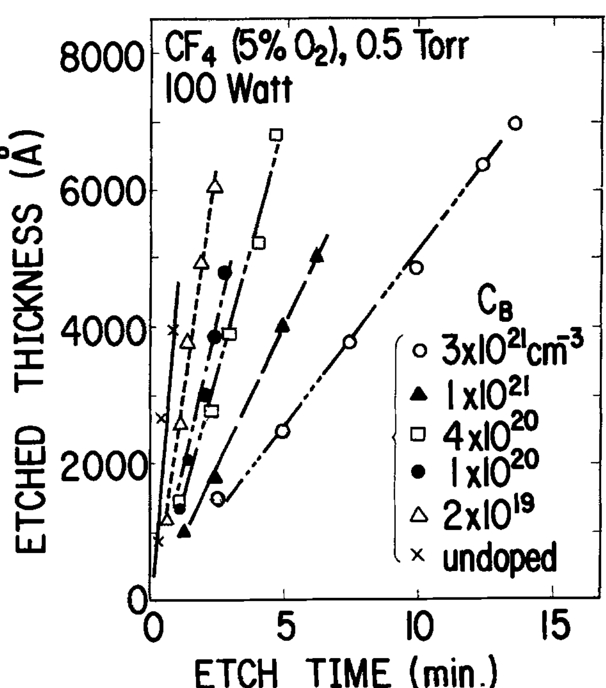

Fig. 1. Etched thickness of poly-Si *vs.* etch time, with B concentration as a parameter.

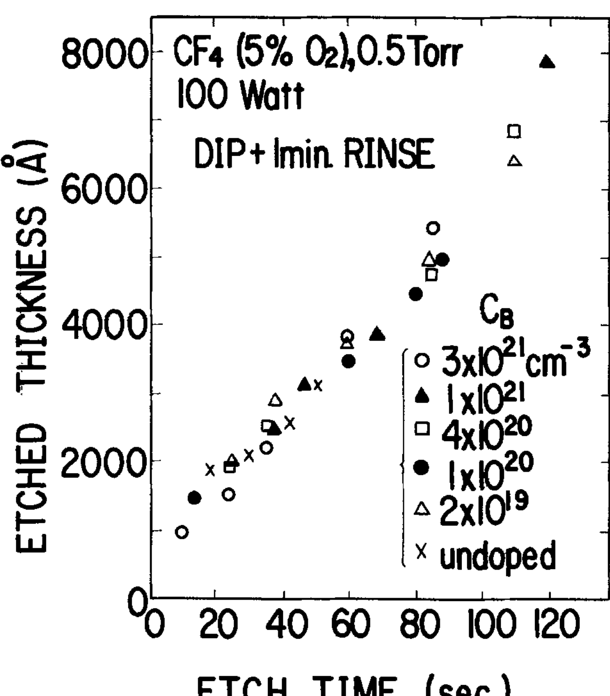

Fig. 2. Etched thickness of dipped poly-Si *vs.* etch time

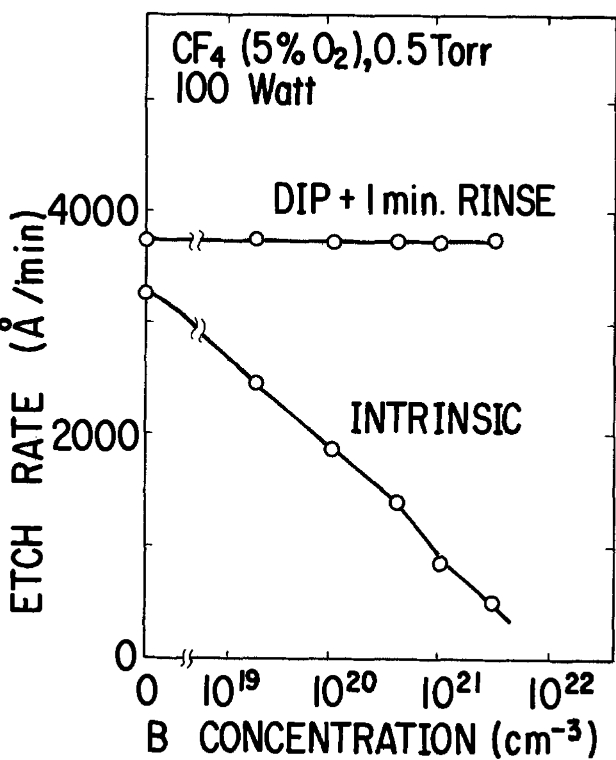

Fig. 3. Intrinsic and accelerated etch rate of poly-Si as a function of B concentration.

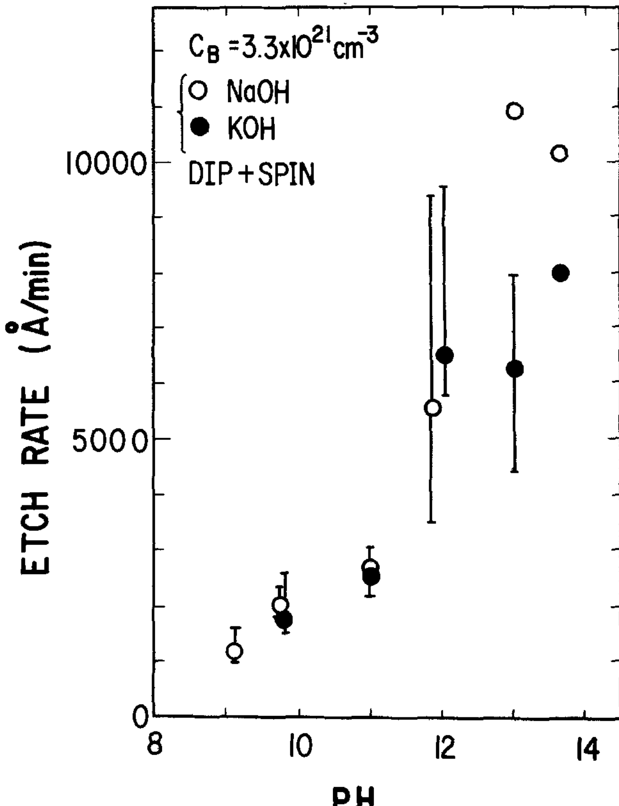

Fig. 5. Dependence of etch rate on *p*H of dipping NaOH or KOH.

followed the dipping. Figure 5 shows the relationships between the etch rate of poly-Si and the *p*H of the NaOH solution. The enhancement of the etch rate was observed with increasing NaOH concentration in the solution. With increasing concentration, the uniformity of etch rate becomes poor, which is related to the poor uniformity of NaOH distribution adhered on the poly-Si surface. A similar enhancement is also observed in the case of "dipping" in KOH solution as shown in Fig. 4. Therefore it can be concluded that alkaline residues such as NaOH or KOH on the poly-Si surface are responsible for enhancement of the etch rate.

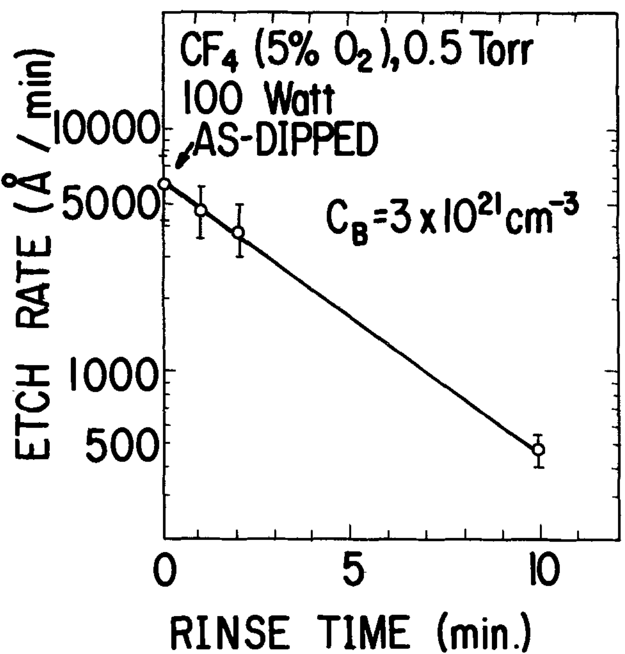

Fig. 4. Dependence of etch rate on rinse time after dipping in an AZ developer.

XPS measurements were done in order to confirm that residual NaOH exists on the poly-Si surface. Figure 6 shows an Na 1s photoelectron spectrum, which is relatively easy to detect, from the poly-Si surface: for

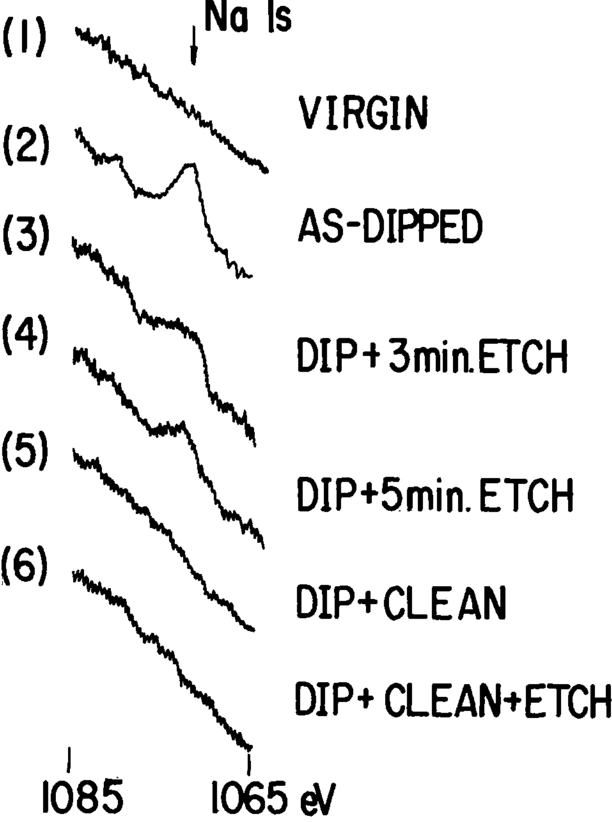

Fig. 6. XPS spectra of poly-Si ($C_B = 3 \times 10^{21}$ cm^{-3}) surface with various treatment.

(1) virgin, (2) as-dipped, (3) dip + 3 min plasma-etched, (4) dip + 5 min plasma-etched, (5) dip + cleaned, and (6) dip + clean + 10 min plasma-etched poly-Si. The dipping was done in NaOH solution with a *p*H of 9.2 followed by spinning. Using an H_2SO_4 + H_2O_2 mixture, the wafers were cleaned after the dipping. Residual Na was observed both for as-dipped and for the 3 and 5 min plasma-etched poly-Si surface, which indicates that NaOH remains on the poly-Si surface even during plasma etching. It is thought that adhered NaOH acts as a catalytic agent to accelerate the etch rate.

The depth profile of adhesive Na is shown in Fig. 7; intensity of Na 1s emission *vs.* sputtering time for the poly-Si, as-dipped, and dip + 3 min plasma-etched poly-Si, where 1 min sputtering corresponds to 10Å sputtering of a single Si wafer. Adhesive Na is near the surface of the as-dipped poly-Si, probably within 50Å estimating from the sputter time. Even for plasma-etched poly-Si, Na exists only near the surface, although it distributes twice as deep as for as-dipped poly-Si. The total amount of Na is almost constant-independent of plasma etch time. Therefore it is confirmed that adhesive alkali acts as a catalytic agent to accelerate etch rate and that the acceleration is not a bulk effect.

It is of interest that the intrinsic etch rate decreases with B concentration and the accelerated etch rate is independent of B concentration, as shown in Fig. 3. A specific mechanism by which the etch rate can be accelerated is as yet not clear, but some general comments can be made. As mentioned before, a decrease in the intrinsic etch rate with B concentration is correlated to a change in the surface potential of B-doped poly-Si. Similarly it is thought that P doping exerts the surface potential negative, which results in an increase in etch rate with P concentration (4). According to these explanations, it seems that the poly-Si surface changes to negative, independent of B concentration owing to excess OH^- species similar to an SiO_2 surface (14, 15) or owing to an electric double layer such as Na^+ OH^- having the negative end towards the vacuum. The negative surface potential allows SiF_4 molecules to desorb easily from the poly-Si surface. Another possibility is that the interaction of the reactant F atom with silicon at the surface is accelerated owing to a change in the surface potential.

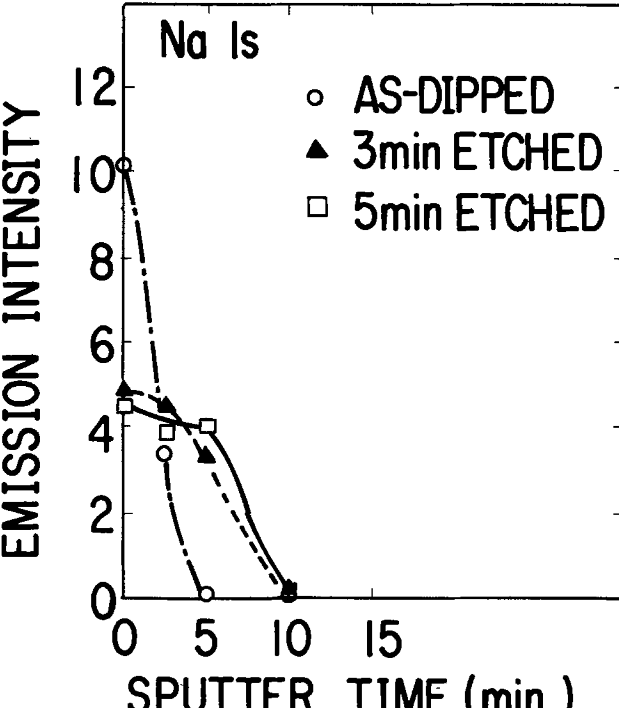

Fig. 7. Depth profile of Na 1s emission intensity

Cleaning in an H_2O_2-H_2SO_4 mixture after the dipping can eliminate both the adhesive alkali and the etch rate enhancement. There are other methods available to clean the surface of wafers. Sufficient rinsing in DI water or a dilute acid dip also can accomplish the elimination of the enhancement, which results in the intrinsic etch rate. Since there is no method available to obtain a uniformly adhered surface, providing a residue-free surface by the method mentioned above is necessary in order to obtain improved uniformity and reproducibility of etch rate from run to run.

Acknowledgment

The authors would like to thank Mr. H. Ikawa for helpful discussions and encouragement during the course of this work. We are indebted to Mr. Y. Watanabe for the XPS measurement.

Studies of the Growth and Oxidation of Metal-Silicides Using Radioactive ^{31}Si as Tracer

R. Pretorius

Southern Universities Nuclear Institute, Faure 7131, South Africa

ABSTRACT

Radioactive ^{31}Si marker experiments show that the metal is the diffusing species during Ni_2Si and Pt_2Si formation, whereas both Pd and Si diffuse during Pd_2Si growth. The formation of $CrSi_2$ on Pd_2Si was also investigated. At low temperatures (480°C) silicon was found to be primarily transported directly from the Si(100) substrate by grain boundary and/or interstitial diffusion through the Pd_2Si layer. At higher temperatures substitutional (vacancy) diffusion of silicon started to be predominant, until at temperatures of about 650°C complete intermixing between radioactive and nonradioactive Si took place between the Pd_2Si and Cr_2Si layers. Tracer studies of the steam oxidation of $CoSi_2$ indicate that silicon diffuses through the $CoSi_2$ layer by a substitutional (vacancy) mechanism during SiO_2 formation. The measured activity profile in the SiO_2 layer shows that growth takes place at the $CoSi_2/SiO_2$ interface and that oxygen is the diffusion species through the SiO_2 layer.

A more comprehensive understanding of the interdiffusion and reaction between components of thin film structures can be obtained by using suitable tracers of the relevant atomic species. Stable or radioactive isotopes are the most suitable for such purposes as their physical and chemical properties are identical to those of the element which is to be traced. The three main questions, which are to be answered in such investigations are, what is the diffusing species, what is its rate of diffusion, and by what mechanism does it diffuse?

A suitable tracer for studying thin film structures used in silicon semiconductor technology, is radioactive ^{31}Si, which can be formed during irradiation of natural silicon in a nuclear reactor, by the reaction $^{30}Si(n, \gamma)^{31}Si$. Although ^{30}Si only has a natural abundance of 3.1 atom percent (a/o) and notwithstanding its low thermal neutron cross section of 0.10 barns, sufficient ^{31}Si radioactivity is formed for its practical use as a tracer. Silicon-31 can be readily measured, as it decays with a half-life of 2.62 hr by the emission of beta-particles (maximum energy = 1.48 MeV) for 99.93% of its disintegrations.

To carry out such tracer experiments, it is necessary to create certain regions in the structure where the silicon atoms are radioactive and other regions where they are not. This can usually be achieved by a proper choice of experimental procedure and conditions during the preparation of the thin film structure. By measuring the position or radioactivity profile of the tracer before and after annealing, information about the diffusing species, as well as the rate and mechanism of diffusion may be obtained.

In this paper a review is given of the use of radioactive ^{31}Si as tracer for studying the formation and oxidation of metal-silicides. Some new results are also reported.

Experimental

Thin film structures were prepared by electron beam evaporation onto single crystal silicon substrates (about 1 cm^2 in size) at pressures of about 5×10^{-7} Torr. Sequential depositions were carried out by using a multiple hearth. Before the evaporation of radioactive silicon, care was taken to first wash it in organic solvents, followed by etching in an $HF:HNO_3$ solution, in order to remove any possible interfering radioactivity due to surface contamination which could have taken place prior to irradiation in the nuclear reactor.

Key words: thin films, diffusion, mechanism, marker.

Samples were annealed in a vacuum tube furnace at pressures below 1×10^{-6} Torr, and for the oxidation studies, heated at temperatures between 800° and 1000°C, in a tube furnace through which steam flowed at atmospheric pressure. The position or activity profile of the radioactive ^{31}Si in the sample, was determined by a combination of chemical or ion beam etching, radioactivity measurement, and Rutherford backscattering.

Results and Discussion

Silicide formation and silicon self-diffusion.—Identification of the dominant diffusing species and its diffusion mechanism is crucial to a fuller understanding of silicide growth. Implanted noble gas markers such as Xe and Ar have been fruitfully used as diffusion markers in thin film studies (1-4), but unfortunately they do have some inherent disadvantages: (*i*) the introduction of foreign atoms into the system could affect the kinetics and mechanism of silicide formation; (*ii*) radiation damage introduced during marker implantation may also influence silicide formation and should first be removed by appropriate annealing; (*iii*) solubility effects could cause dragging of the marker at the interface, thereby giving erroneous results; (*iv*) the choice of marker elements and of silicides which can be studied is restricted because backscattered particles from the marker must be distinguishable from those particles scattered from silicon and metal atoms; and (*v*) the technique only gives information about mass movement past the marker: no information is obtained about the mechanism of the diffusion process. Other approaches to identifying the diffusing species during silicide formation have been the deposition of a thin discontinuous inert metal layer on the silicon surface followed by the deposition of the silicide forming metal (5), measurement of the relative movement of the interface between two different silicide phases (6), and the use of a metal marker having similar physical and chemical properties to that of the metal in the metal-silicide to be studied (7, 8).

We have used radioactive ^{31}Si as a marker for studying Ni_2Si, Pd_2Si, and Pt_2Si formation (9, 10). In this approach a few hundred angstrom of radioactive silicon is first deposited onto the silicon substrate, followed immediately by the deposition of a few thousand angstrom of the metal. When the sample is heated a silicide is first formed with the radioactive silicon. Upon further silicide formation (see Fig. 1) this band of radioactive silicide can move to the

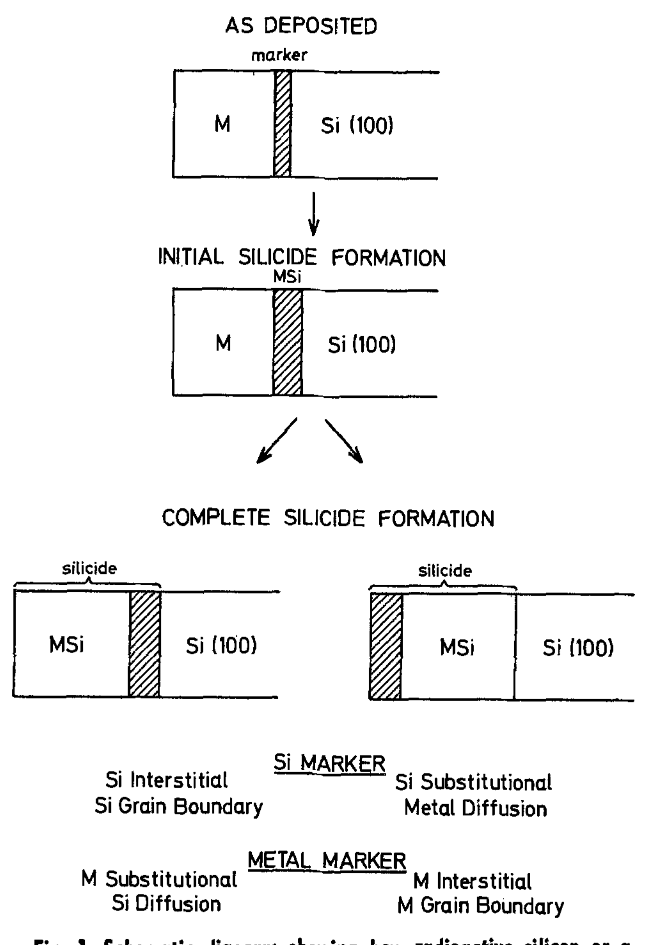

Fig. 1. Schematic diagram showing how radioactive silicon or a radioactive metal marker can be used to determine the diffusing species and mechanism during metal silicide formation.

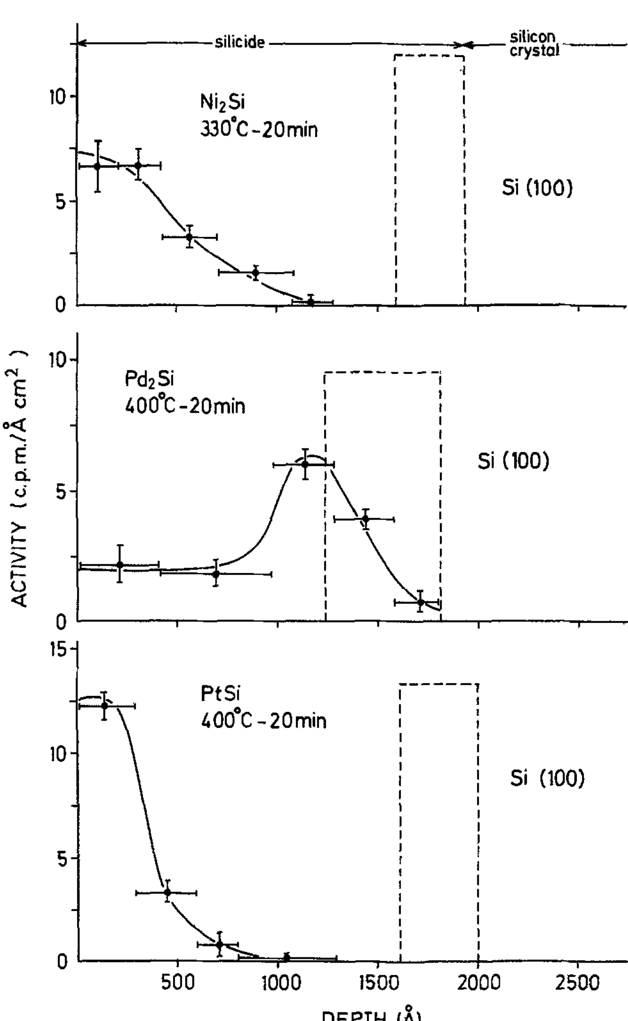

Fig. 2. Silicon-31 activity profiles, measured after complete silicide formation. Calculated activity profile after initial silicide formation is also shown (dashed line). From Ref. (10).

surface of the sample if silicide formation takes place by diffusion of the metal or by silicon substitutional (vacancy) diffusion. However, if the band of radioactive silicide stays at the silicon substrate interface it can be concluded that silicon diffuses by interstitial and/or grain-boundary diffusion. Apart from these two limiting cases the marker could be located somewhere in the middle of the silicide layer, if silicide formation takes place by interstitial or grain boundary diffusion of both the metal and silicon atoms, the exact position depending on the relative diffusion rates of both species. The information obtained when using a stable or radioactive isotope of the metal as marker is also indicated in Fig. 1. It can be seen that a unique answer regarding the identity of the diffusing species and its mechanism of diffusion is obtained when using both metal and silicon markers, the only exception being the case where the silicon marker is at the surface and the metal marker at the silicon/silicide interface. It should also be pointed out that this approach cannot distinguish between grain boundary and interstitial diffusion.

The ^{31}Si activity profiles for Ni_2Si, Pd_2Si, and PtSi formation are given in Fig. 2. The calculated activity profile at the silicon substrate interface immediately after initial silicide formation is also shown (dashed lines). The movement of the activity to the surface of the Ni_2Si and PtSi samples indicates that the metal is the diffusing species or that Si diffuses substitutionally during Ni_2Si formation and first phase formation of Pt_2Si. For Pd_2Si one can deduce that diffusion of both Pd and Si atoms probably occurred during silicide formation in order to obtain a maximum activity somewhere near the middle of the silicide.

It is interesting to note that the activity profiles for PtSi and Ni_2Si are still in a well-defined band, although Ni_2Si shows some broadening. The sharpness of the PtSi and Ni_2Si profiles indicate that the mobility of silicon in these silicides is very low, thereby providing further evidence that the metal is the diffusing element during their formation. It is also interesting to note that the Pd_2Si has an activity tail right to the surface of the sample (Fig. 2). In our discussion of the movement of the initial band of radioactive marker (see Fig. 1) we have only taken into consideration atomic diffusion in solids, by "pure" interstitial or grain boundary diffusion or "pure" substitutional (vacancy) diffusion. There are, however, other diffusion mechanisms, which should also be taken into account (11). We thus believe that not only the general displacement of the initial band of radioactivity is important, but that the whole shape of the activity profile should be considered.

The results we have obtained for Ni_2Si and Pd_2Si formation are consistent with measurements using implanted noble gas markers (1, 2). Our results for Pt_2Si formation do, however, differ from those obtained by other techniques which indicate that both Pt and Si diffuse during silicide formation (6).

If the silicide is heated to still higher temperatures, the mobility of the Si atoms increases and the band of radioactivity (Fig. 3, top) starts to spread out in the silicide due to self-diffusion of the silicon atoms. After heating the sample for 20 min at 570°C the activity for both PtSi and Pd_2Si spreads out completely due to complete mixing of radioactive and nonradioactive silicon atoms (Fig. 3, bottom). By careful measurement of the activity profile as a function of time or temperature, the self-diffusion coefficient and activation coefficients for silicon diffusion in metal-

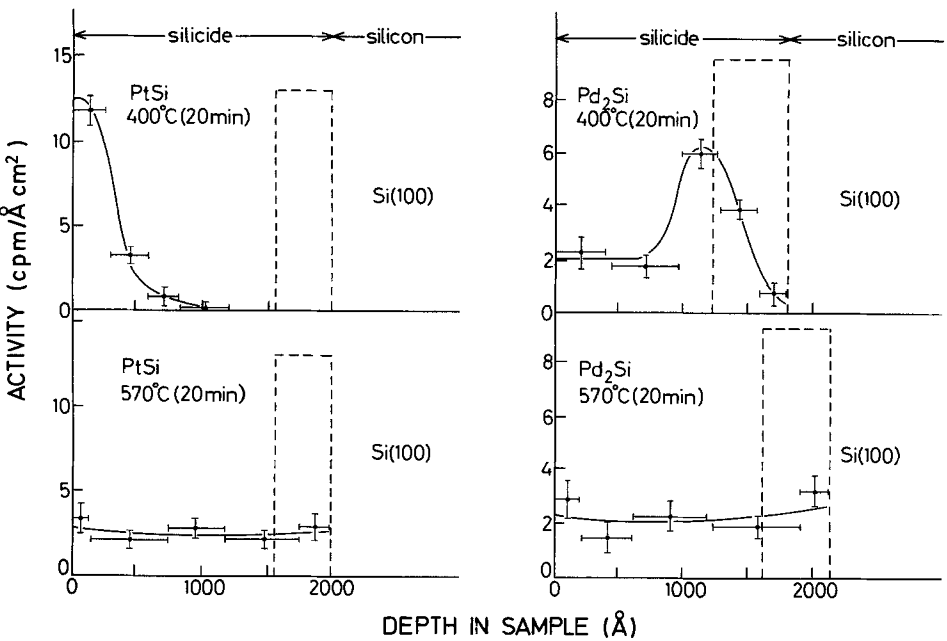

Fig. 3. Activity profiles measured in PtSi and Pd_2Si. Due to the high mobility of silicon in these silicides at 570°C, the radioactive ^{31}Si has spread out and complete mixing between radioactive and nonradioactive silicon has taken place.

silicides can be determined. Such measurements are now in progress.

$CrSi_2$ formation on Pd_2Si.—When $CrSi_2$ is formed on Pd_2Si it is of interest to know whether silicon is supplied for such growth from the silicide layer or directly from the single crystal silicon substrate. We have investigated this problem by using radioactive silicon-31 to mark the Pd_2Si layer. By determining whether radioactive silicon atoms are incorporated into the $CrSi_2$ layer during its growth one can obtain information on the mechanism of the $CrSi_2$ growth.

In Fig. 4, Rutherford backscattering spectra for $CrSi_2$ formation on Pd_2Si are shown. When the as-deposited virgin sample [Fig. 4(a)] is heated at 400°C for 5 min the Pd reacts with the radioactive amorphous silicon above it and with the Si(100) substrate to form Pd_2Si. It can be seen [Fig. 4(b)] that all the radioactive silicon marker is consumed during Pd_2Si formation and that the Cr signal remains unchanged indicating that no $CrSi_2$ forms at this temperature. However, upon heating at higher temperatures, $CrSi_2$ forms on the surface of the sample as can be deduced from the appearance of the silicon signal from $CrSi_2$ at the surface position [Fig. 4(c)]. After complete $CrSi_2$ formation, the $CrSi_2$ surface layer was selectively removed by etching the sample in dilute HF (20%), which attacks $CrSi_2$ but not Pd_2Si or silicon. Because HF forms gaseous SiF_4 with the silicon in $CrSi_2$ the activity in the etchant solution could not be measured and the silicon radioactivity left in the Pd_2Si layer was thus determined by measuring the activity in the sample before and after removal of the $CrSi_2$ layer.

In Fig. 5 the percentage of the activity left in the Pd_2Si layer after $CrSi_2$ formation is plotted as a function of $CrSi_2$ (D-value) thickness. From the activity profile in Pd_2Si (Fig. 2) the percentage activity left in the Pd_2Si layer during $CrSi_2$ growth was calculated (see curve A in Fig. 5) for the case in which silicon is supplied by substitutional (vacancy) diffusion through the Pd_2Si layer. During this type of diffusion, the silicon in the Pd_2Si layer is effectively displaced from the bottom upwards by nonradioactive silicon atoms entering from the single crystal silicon substrate, and as would be expected, all the radioactive silicon atoms are displaced from the Pd_2Si layer for $D = 1$. In practice this would happen at a value slightly higher than $D = 1$ owing to the statistical nature of diffusion. Thus silicon atoms supplied from the substrate in effect "push" the radioactive silicon from the Pd_2Si into the growing $CrSi_2$. This would be similar to the mechanism found for silicon diffusion through Pd_2Si during solid-phase epitaxial growth of silicon in the Si(100)/Pd_2Si/Si (amorphous) system (12).

At temperatures higher than about 570°C, the self-diffusion rate of silicon in Pd_2Si is so high that complete intermixing of radioactive and nonradioactive silicon atoms in the Pd_2Si layer takes place within 20 min (see Fig. 3). It is clear that, for $CrSi_2$ formation on Pd_2Si at such temperatures, all the radioactivity in the Pd_2Si layer can never be removed during substitutional diffusion of silicon, regardless of the thickness of the $CrSi_2$ layer. Curve B in Fig. 5 was calcu-

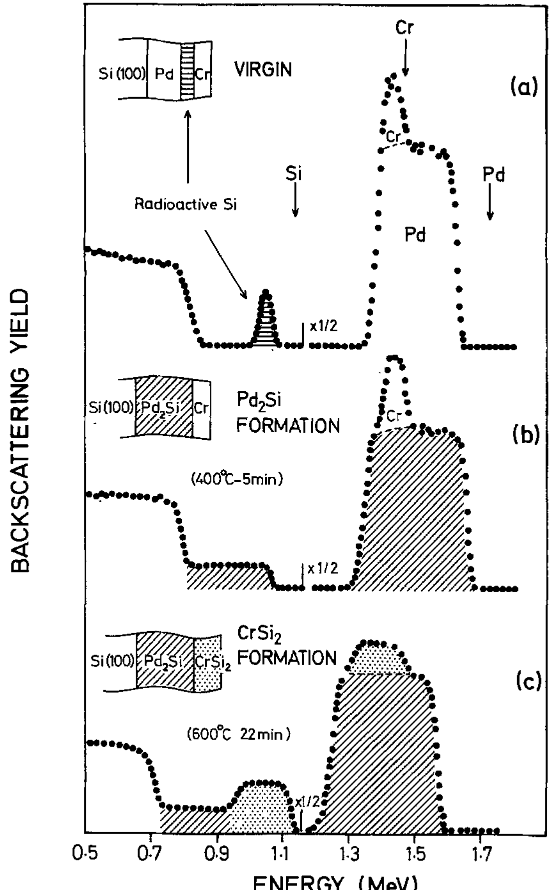

Fig. 4. Rutherford backscattering (2 MeV alpha's) showing $CrSi_2$ growth on Pd_2Si. Vertical arrows indicate energy of alpha particles scattered from surface.

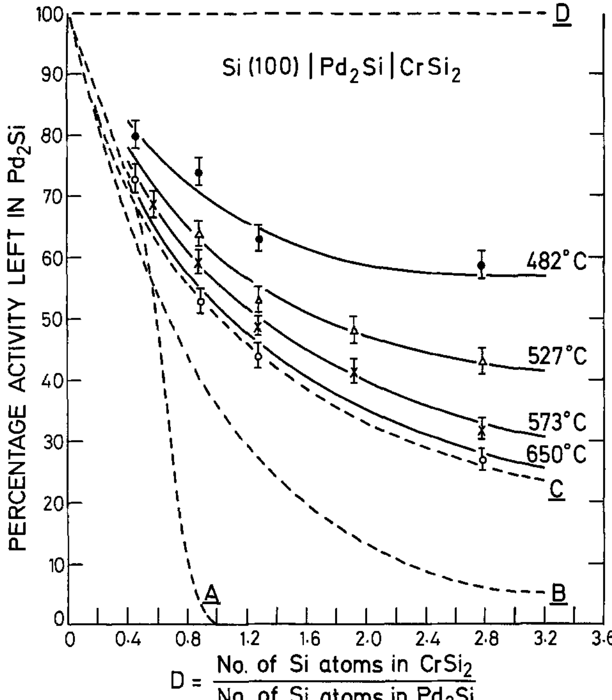

Fig. 5. Percentage ^{31}Si radioactivity left in Pd_2Si layer after $CrSi_2$ formation, as a function of $CrSi_2$ thickness (D-value). A, B, C, and D are calculated curves as described in text.

lated for conditions such that complete equilibrium is immediately obtained between radioactive silicon atoms in the Pd_2Si layer and nonradioactive silicon atoms entering from the single crystal substrate. As the $CrSi_2$ layer grows, the percentage activity in the Pd_2Si layer decreases exponentially with D, and curve B is given by

$$\% \text{ activity} = 100 \exp - D \qquad [1]$$

Curve C is calculated for the case in which silicon self-diffusion is very high in both the Pd_2Si and $CrSi_2$ layers. In this case complete intermixing between radioactive and nonradioactive silicon atoms takes place throughout both silicide layers. The relationship between the percentage activity left in the Pd_2Si layer and D is then given by

$$\% \text{ activity} = 100/(1 + D) \qquad [2]$$

Another possible mechanism of supplying silicon to the growing $CrSi_2$ layer would be by grain boundary or "pure" interstitial (no interaction with Si atoms in the Pd_2Si lattice) diffusion of nonradioactive Si atoms directly from the single crystal substrate. In this case no radioactive silicon atoms will be incorporated into the $CrSi_2$ layer (see curve D in Fig. 5). From Fig. 5 it can be seen that our measurements are located between cases C and D, which indicates that the silicon for $CrSi_2$ growth is being supplied from both the single crystal substrate and the Pd_2Si layer.

The most striking feature of the data is that the supply of silicon for $CrSi_2$ growth comes in part directly from the silicon substrate without interaction or exchange with the silicon atoms in the Pd_2Si layer. For $D = 1$, about 50-75% of the silicon is supplied directly from the silicon substrate without exchange. We believe that grain boundary and/or interstitial diffusion is the most likely mechanism for this supply.

As the $CrSi_2$ formation temperature is increased, the amount of radioactive silicon left in the Pd_2Si layer decreases, showing that there is more exchange between the radioactive silicon and the silicon atoms from the substrate during passage through the silicide layers. It is not possible for the silicide to act as a static lattice; instead the Pd_2Si bonds will be broken and reformed at the temperature of $CrSi_2$ formation. Curves A, B and C in Fig. 5 apply to such a bond-breaking diffusion mechanism. However, in the case of curves B and C, the self-diffusion rate of silicon is much higher than the growth rate of $CrSi_2$.

We conclude, therefore that the silicon is primarily transported directly from the substrate by grain boundary and/or interstitial diffusion. At higher temperatures there is more exchange between this silicon and the radioactive silicon atoms present in the palladium silicide layer, so that in effect, silicon is supplied from both the substrate and the underlying Pd_2Si layer. At still higher temperatures our results begin to indicate a complete intermixing of radioactive and nonradioactive silicon between the $CrSi_2$ and Pd_2Si layers (see curve C in Fig. 5).

The investigation of $CrSi_2$ growth on Pd_2Si and PtSi, by using radioactive ^{31}Si as a marker, is described in greater detail elsewhere (13).

Oxidation of $CoSi_2$.—There is much interest in the oxidation of silicon and metal silicides as the formed SiO_2 layers can act as electrical insulators in thin film semiconductor devices. We have studied the steam oxidation of $CoSi_2$ and have used radioactive ^{31}Si to obtain more information about the oxidation mechanism.

Figure 6 shows the Rutherford backscattering spectra of the as-deposited virgin sample, silicide formation at 800°C for 10 min and the spectrum of the sample after oxidation in steam at 1000°C for 30 min. The thickness of the formed SiO_2 layer was determined in three ways: (*i*) measurement of the width of the oxygen signal; (*ii*) measurement of the width of the step due to silicon in the SiO_2; and (*iii*) determining the shift

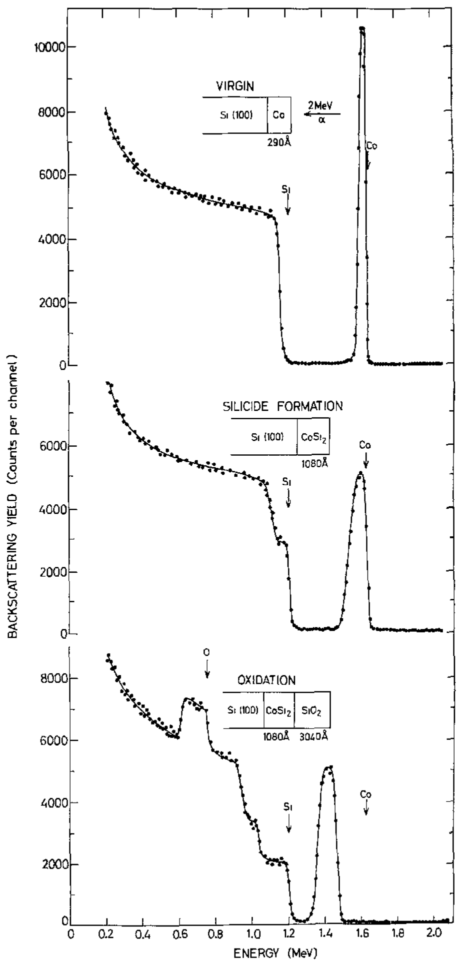

Fig. 6. Backscattering spectra showing $CoSi_2$ formation (800°C) and atmospheric steam oxidation at 1000°C for 30 min.

of the front edge of the Co signal with respect to its surface position. These measurements show that the thickness of the SiO_2 layer is proportional to the square root of time, thereby indicating that the oxidation process is diffusion limited.

Radioactive tracer experiments were carried out in a similar way as that described for the study of $CrSi_2$ growth on Pd_2Si. The $CoSi_2$ was marked with ^{31}Si, by first evaporating a few hundred angstrom of radioactive silicon onto the Si (100) substrate. After silicide formation in a vacuum furnace, oxidation of the $CoSi_2$ took place at 1000°C in steam at atmospheric pressure. Because both $CoSi_2$ and SiO_2 are soluble in HF, rf ion-beam sputtering was used to selectively remove the SiO_2 layer. The percentage ^{31}Si activity left in the $CoSi_2$ layer was determined by measuring the radioactivity in the sample before and after sputtering.

In Fig. 7 the percentage of the activity left in the $CoSi_2$ layer after SiO_2 formation is plotted as a function of SiO_2 (D-value) thickness, where the D value again refers to the ratio of the number of Si atoms in the SiO_2 layer to that in the $CoSi_2$ layer. Curves A, B, C, and D have been theoretically calculated for different modes of silicon transport through the $CoSi_2$ layer, and have the same meaning as previously described, namely: A—substitutional (vacancy) diffusion, B—substitutional (vacancy) diffusion, high self-diffusion of silicon in the $CoSi_2$, low self-diffusion of silicon in SiO_2; C—substitutional (vacancy) diffusion, high self-diffusion in both $CoSi_2$ and SiO_2 layers; D—interstitial and/or grain boundary diffusion of Si through the $CoSi_2$ layer.

It is clear from Fig. 7 that our results at 1000°C approach case B very closely, which is in contrast to the $CrSi_2$ growth on Pd_2Si where curve C is approached at high temperatures.

Activity profiles were also measured in the SiO_2 layer itself. From these results we can see (Fig. 8) that the highest concentration of radioactive ^{31}Si is at the surface of the sample and that the activity decreases exponentially as one moves towards the

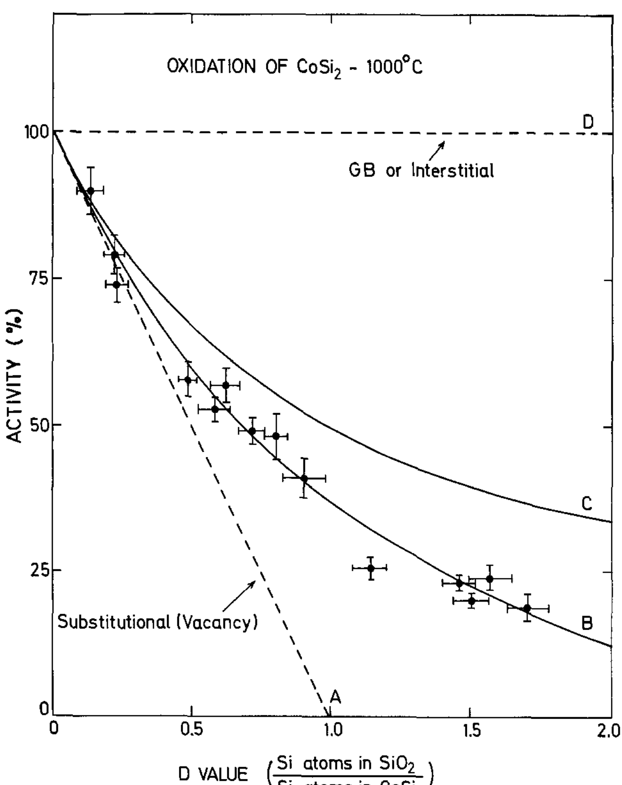

Fig. 7. Percentage ^{31}Si activity left in $CoSi_2$ layer as a function of SiO_2 thickness (D-value). A, B, C, and D are calculated curves for different diffusion mechanisms.

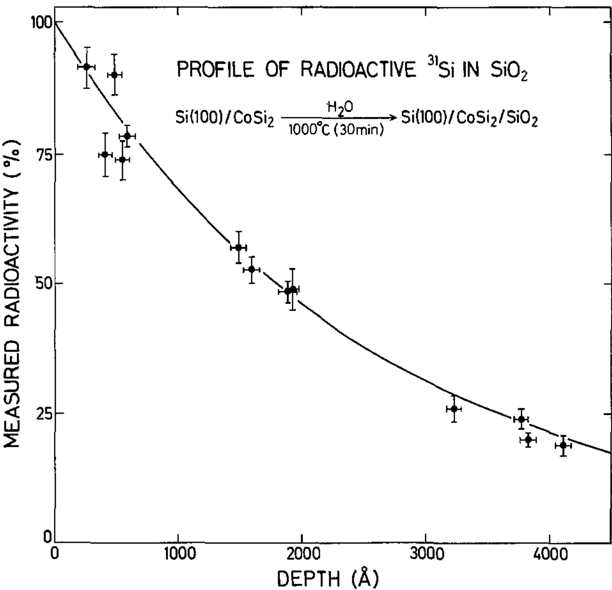

Fig. 8. Radioactivity profile in formed SiO_2 layer on $CoSi_2$. Profile was determined by a combination of ion-beam etching, activity measurement, and Rutherford backscattering.

$CoSi_2/SiO_2$ interface. Such an activity profile can only be obtained if three conditions are fulfilled: (*i*) high silicon self-diffusion at 1000°C in the $CoSi_2$ layer—this has already been proved to be the case (see Fig. 7). (*ii*) Very low silicon self-diffusion in the SiO_2 layer. Once the radioactive silicon originating from the $CoSi_2$ layer is bound to form SiO_2 it becomes completely immobile and its activity concentration gives a record of the activity concentration in the $CoSi_2$ layer at that specific moment. (*iii*) Oxygen is the diffusing species through the growing SiO_2 layer and growth takes place at the $CoSi_2/SiO_2$ interface. If silicon was the diffusing species through the SiO_2 layer, growth would have taken place on the surface of the sample. The highest ^{31}Si concentration would then have been at the $CoSi_2/SiO_2$ interface, decreasing exponentially towards the sample surface.

This work is published in greater detail, elsewhere (14).

Summary and Conclusion

Processes such as silicide formation, silicon self-diffusion, and silicide oxidation usually take place at temperatures well below the melting points of the various components in thin layered structures and thus involve atomic motion in the solid state. We have shown that radioactive ^{31}Si can be successfully used as a tracer to study the motion of silicon in such systems.

Radioactive silicon when used as a marker can give information about the moving species and its mechanism of diffusion during metal-silicide formation. The main disadvantage of the technique is that the radioactive Si is not an immobile marker and only gives a unique answer when silicon is the diffusing species. For silicides where the metal is the moving species a radioactive metal marker should be used, or additional information should be obtained from other marker techniques such as implanted noble gas markers. Also, for silicides which form at high temperature the self-diffusion of silicon in the silicide may be so large that the radioactive silicon marker may spread throughout the silicide layer, thereby losing its usefulness as a marker. The radioactive silicon marker technique does however have the advantage that no foreign atoms are introduced into the system, thereby eliminating erroneous results from interface dragging. Furthermore, it can be applied to all metal silicides and is the only marker technique which can give direct information about the diffusion

mechanism. For Ni_2Si and Pt_2Si formation we have found that the metal is the diffusing species, whereas both Pd and Si diffuse during Pd_2Si formation.

The growth of $CrSi_2$ on Pd_2Si has been studied by marking the silicon atoms in the Pd_2Si layer with radioactive ^{31}Si. At low temperatures (480°C) we find that silicon is primarily transported directly from the Si (100) substrate through the Pd_2Si layer by grain boundary and/or interstitial diffusion. As the temperature at which $CrSi_2$ is formed increases, more exchange occurs between the radioactive silicon atoms in the Pd_2Si layer and the nonradioactive silicon atoms from the substrate, indicating that a substitutional (vacancy) diffusion mechanism of Si through the Pd_2Si starts to dominate. At 650°C our data suggest that complete intermixing of radioactive and nonradioactive silicon takes place between the Pd_2Si and $CrSi_2$ layers.

A similar approach was used to study the steam oxidation of $CoSi_2$ at 1000°C. In this case the silicon atoms in the $CoSi_2$ layer were marked with radioactive ^{31}Si. By using ion-beam sputtering the radioactivity profile in the formed SiO_2 layer could also be measured. These measurements show that silicon is transported through the $CoSi_2$ layer mainly by a substitutional (vacancy) mechanism. Growth was found to take place at the $CoSi_2/SiO_2$ interface by oxygen diffusion through the growing SiO_2 layer. These results also show that the silicon atoms have a very low self-diffusion coefficient in the SiO_2 layer and a very high self-diffusion coefficient in the $CoSi_2$ layer, at 1000°C.

One of the biggest advantages of using radioactive ^{31}Si as a marker is the fact that it has a very convenient half-life of 2.62 hr. Enough radioactivity is available for measurement, for up to 15 hr after the activation of silicon in a nuclear reactor. This is usually long enough to complete most of the experiments of the type described. Because of its relatively short half-life, all the ^{31}Si activity decays almost completely after about 2 days, thereby minimizing the radiation hazards usually associated with the use of radioactive tracers. Also, because of the very low penetration of beta-particles it is easy to shield the ^{31}Si radioactivity thereby further reducing radiation hazards due to exposure. Although ^{31}Si also has a gamma-ray of 1.26 MeV, it is very weak, as it is only emitted for 0.07% of the ^{31}Si disintegrations. The beta-particle (max β^- energy $= 1.48$ MeV) emitted by ^{31}Si can be readily measured with relatively simple and inexpensive beta-counting equipment and because of the very high purity of semiconductor silicon, no interfering activities are found during neutron activation. Interfering activities due to surface contamination do, however, have to be removed after activation.

Radioactive ^{31}Si has nuclear properties which lends itself readily to use as a tracer. When used in conjunction with a depth-sensitive analytical probe such as Rutherford backscattering, much valuable information can be obtained about thin film systems used in silicon semiconductor technology.

Acknowledgments

A large part of the work reported here was carried out during a one year period as a visiting associate at the California Institute of Technology. Special thanks are thus due to my colleagues at Caltech, in particular to S. S. Lau, Z. L. Liau, J. W. Mayer, M.-A. Nicolet, J. O. Olowolafe, and C. Ramiller, who all contributed substantially to the work discussed here. The contribution and assistance of A. Botha and W. Strydom of the Southern Universities Nuclear Institute and C. Comrie of the University of Cape Town is also gratefully acknowledged. The financial assistance obtained from the South African Council for Scientific and Industrial Research and the South African Atomic Energy Board is gratefully acknowledged.

The Detection of Structural Defects in Indium Phosphide by Electrochemical Etching

C. R. Elliott and J. C. Regnault

Post Office Research Centre, Martlesham Heath, Ipswich IP5 7RE, England

ABSTRACT

Two new etching procedures for InP are described; one for damage removal with retention of surface flatness, and the other for high resolution defect delineation. A comparison of the defect etching with transmission x-ray topography is given. Studies of wafers from Sn, S, and Fe-doped InP ingots are reported. The new procedures have revealed a variety of defects.

This paper describes electrochemical replication and defect etching techniques for single crystal n-type and semi-insulating indium phosphide and some results of their application to ingot material. Indium phosphide is assuming increasing importance both as an electronic device material and as a substrate for lattice matched GaInAs and GaInAsP epitaxial layers for optoelectronic devices. In the first case defects in InP will directly affect device performance and in the second case they may also affect the epitaxial growth. A comparison of electrochemical etching with chemical etching and other defect revealing techniques has been given recently (1). Chemical defect etching of InP has been reported in a number of recent publications (2-5). Here we consider the application of an electrochemical etching procedure similar to that of Faktor and Stevenson for GaAs (6); the advantages of which include high resolution, sensitivity to optoelectrically active defects and minimal material removal, the latter making it applicable to submicron layers. The electrolytes used for GaAs are not suitable for InP and for this material new specific procedures had to be developed. The successful outcome of this work is illustrated by the results obtained with ingot material.

Experimental

Single crystal (100) cut slices of InP were obtained from a number of sources and were conventionally polished using solutions of bromine in methanol (7). Residual damage left by the polishing process was removed, prior to defect revealing. This was achieved by continuous electrochemical etching, in the presence of a thick anodic oxide, at constant voltage. The technique is similar to that developed for GaAs by Faktor and Stevenson (6) and extended by the present authors (8). (It was shown that such a process can remove material smoothly, while retaining the initial surface topography).

Removal of about 5 μm of InP left a smooth, damage-free surface. Establishment of a suitable oxide film, about 100 nm thick, is critically dependent upon electrolyte composition. We empirically investigated a number of electrolytes for best results. Dilute phosphoric acid, sodium phosphate solutions from pH 4 to pH 12, 2M potassium hydroxide, ammonium hydroxide pH 11, 1M acetic acid and 1M citric acid were found unsatisfactory. 14M orthophosphoric acid (analytical reagent grade) was found acceptable. Figure 1 is a schematic diagram of the anodization cell. With a constant 40V applied across the cell and rotation of the sample anode at 100 rpm, the steady-state dissolution rate was controlled by varying the bath temperature between 4° and 30°C. When a predetermined amount of material had been removed, the oxide film was dissolved by a short immersion in either 2N hydrochloric or 2N nitric acid.

Key words: anodization, etching, defects, indium phosphide.

The electrochemical defect etching was carried out in similar apparatus, using 0.5N hydrochloric acid. (This medium chemically attacks InP at room temperature, but the rate of attack is 10^{-2} μm/hr, which is insignificant in relation to the duration of the experiment.) The potential of the strongly illuminated anode relative to a saturated calomel electrode was monitored during etching, after initial adjustment to yield a current density of 400 $\mu A/cm^2$. In most cases an average of 0.3 μm of material was removed. The etched specimens were then examined microscopically using Nomarski interference contrast.

Results and Discussion

The variation of current density with electrolyte temperature for etching in the presence of an anodic oxide is shown in Fig. 2. Corresponding material removal rates, determined from weight loss experiments, ranged from 0.5 to 5 μm/hr. Measured faradaic yields averaged nine electrons per unit of formula weight, but were not precisely reproducible. Clearly this yield is not accounted for by simple conversion of InP to oxides, since the highest yield to be expected would be eight, corresponding with the overall reaction $2InP + 16e^+ \rightarrow In_2O_3 + P_2O_5$. Furthermore, the anodic oxide appears to contain lower oxides of phosphorus (it evolves a volatile product with phosphine-like odor on standing at room temperature). The discrepancy is probably due to parasitic electrochemical reactions at the oxide-electrolyte interface, in view of the well-established electronic conductivity of In_2O_3 based

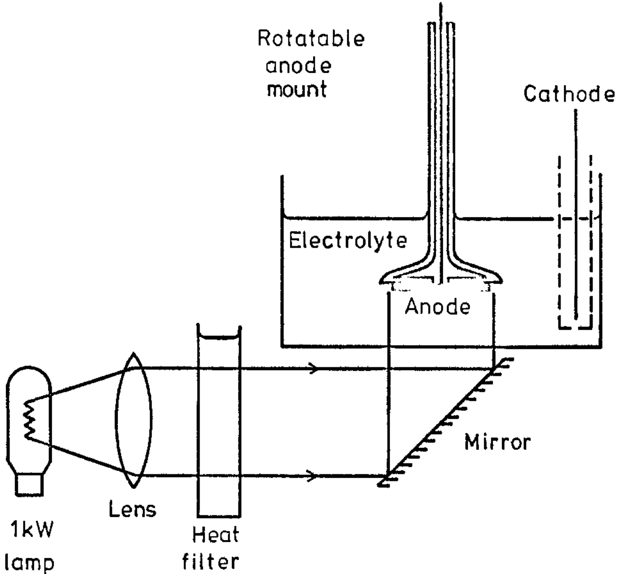

Fig. 1. Anodization cell for n-type semiconductors. The cooling coil for temperature control has been omitted for clarity.

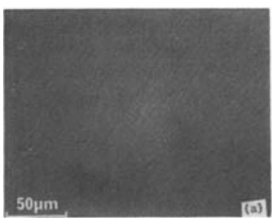
systems (9, 10). No attempts to eliminate or minimize this problem were made in this work, although the accuracy of control of material removal is dependent upon the reproducibility of the faradaic yield.

Interference contrast micrographs of a typical bromine-methanol polished surface before and after anodic removal of 20 μm of material are shown in Fig. 3. Only a small decrease in surface smoothness is apparent after the anodization.

In order to determine the optimum anodic conditions for revealing defects the anodic polarization characteristics of damage-free n-type InP were investigated. Figure 4 shows the variation of anodic (reverse biased) overpotential with current density for two n-type samples in 0.5M hydrochloric acid, under conditions of strong, 0.4 Wcm^{-2}, broadband (tungsten halogen) illumination. Photopotentials of -370 mV were observed with this level of illumination. The conditions chosen for defect-sensitive etching (400 μA cm^{-2}) are two orders of magnitude below the photosaturation current. The corresponding overpotential is close to the range chosen by Faktor and Stevenson (6) for GaAs (250-300 mV anodic). In the latter case the illumination level was lower, so that the photosaturation current was not much greater than the minimum required to give a useful etch rate. Since their photosaturation currents were somewhat dependent upon majority carrier concentration, it was necessary for them to define an anodic overpotential rather than a current density in order to avoid operating in the photosaturation region (where the sensitivity to defects is low).

Figure 5 is a typical interference contrast micrograph taken after anodic removal of approximately ¼ μm of material under defect-sensitive conditions. The material was Czochralski grown, nominally undoped InP and (100) cut. The sharply-defined etch features are raised above the general level of the surface.

Defects delineated show no crystal orientated effects normally associated with the production of etch pits at defects. The very high resolution of the technique can be seen clearly from the series of micrographs in Fig. 6, where the sample was again Czochralski grown and (100) cut, but Sn-doped with a carrier concentration of 3.3 × 10^{18} cm^{-3}. The density of defect clusters is 2 × 10^4 cm^{-2}, the majority of these being of the type shown in Fig. 6(c). Further investigation of Sn-doped InP from two sources showed similar defects in most ingots. Figure 7(a) is a 220 transmission x-ray topograph of similar material, taken with copper radiation. This same area was then electrochemically etched to remove approximately 0.3 μm of material from the surface. Figure 7(b) is an optical micrograph of the etched area. Each of the defect clusters, which appear as white spots in the micrograph, corresponds with a feature (black spot) in the x-ray topograph. This can be confirmed with an overlay prepared from



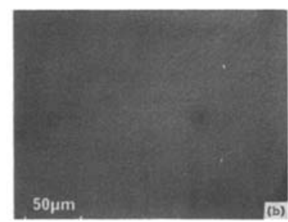


Fig. 3. Nomarski interference contrast micrographs of (a) a typical chemo-mechemically polished InP (100) surface, and (b) the same after removing 20 μm by anodization in H_3PO_4.

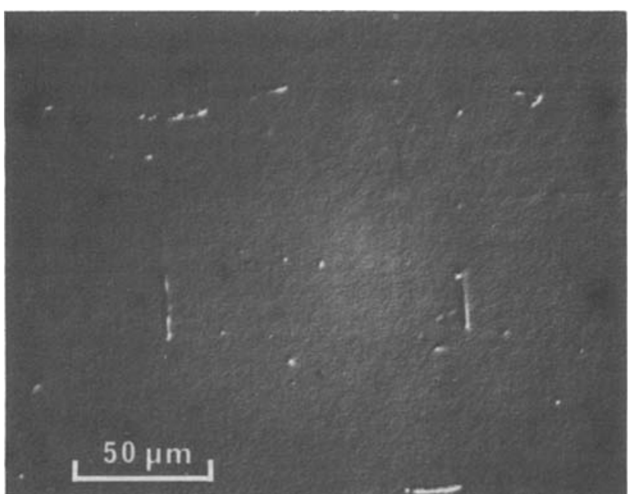

Fig. 5. Nomarski interference contrast micrograph of an InP (100) surface after etching off 0.25 μm of material under defect-sensitive conditions.

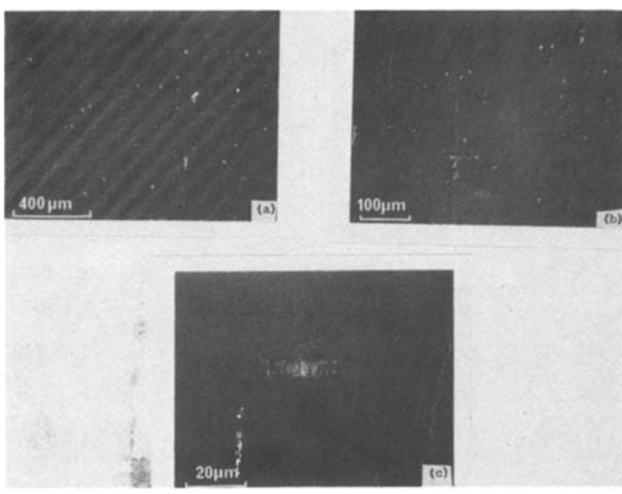

Fig. 6. Nomarski interference contrast micrographs, at increasing magnifications, of an InP (100) surface after defect etching. InP doped with Sn to 3.3 · 10^{18} cm^{-3}.

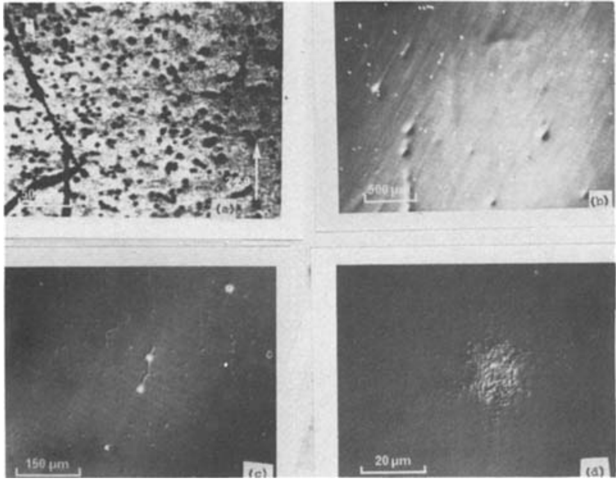

Fig. 7. (a) Transmission x-ray topograph of InP:Sn; (b) surface area of (a) after defect etching; (c) selected area from (b), showing dislocations and defect clusters; (d) single defect cluster.

Fig. 7(b), if allowance is made for the small geometrical distortion of the topograph, due to the Bragg angle used. However, there are six times as many features visible in the topograph as there are on the etched surface. The defect clusters average 20 μm in diameter [Fig. 7(d)] and are approximately sperically symmetrical. This was confirmed by etching a (110) cleavage face perpendicular to (100). Therefore, although the etching only images defects within the 0.3 μm layer removed, it effectively samples a volume of material approaching 40 μm in thickness. As the transmission topograph images defects in the full 200 μm thickness of the sample, a ratio of six to one in the number of defects seen is to be expected. Figures 7(c) and (d) are higher magnification micrographs of a selected area of the same sample. Figure 7(c) shows many defects, the total density being 4 × 10^4 cm^{-2}. The highest magnification Fig. 7(d) shows that the defect clusters extend over an area of 400 μm^2 in the 0.3 μm section taken. Because the very fine detail within the defect cluster is not resolved by optical microscopy a carbon replica of the etched surface was taken. Examination of the replica in a transmission electron microscope showed the cluster to be made up of many small dislocations as can be seen in Fig. 8. Because of the very high x-ray contrast obtained at these defects they are assumed to be associated with precipitates or inclusions. A similar x-ray topograph has been reported recently (11).

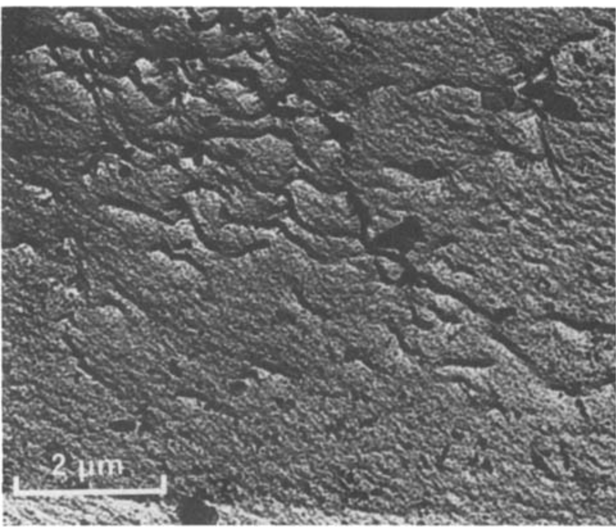

Fig. 8. Transmission electron micrograph of Pt/C shadowed replica taken from the area of Fig. 7(d). Shadowing angle $\tan^{-1} 1/2$.

Some defect etching has been performed on highly sulfur-doped (typically 8 × 10^{18} cm^{-3}) InP. Whereas GaAs of similarly high doping level has been found to contain microdefects (12), the defect etching of complete InP wafers has revealed only growth striations, Fig. 9. The absence of dislocations in this material was confirmed by x-ray transmission topography. We would, however, caution that electrochemical defect etching of such highly doped n-InP has not been attempted previously and that assessment of this material is still incomplete.

Turning to Fe-doped semi-insulating InP, Fig. 10 shows a typical (100) surface after removal of 0.5 μm of material under defect-sensitive conditions. Good defect delineation with high resolution was obtained, as with n-type samples, despite the dark bulk resistivity of the material being $10^9 \Omega$ cm. Detailed studies of semi-insulating semiconductor materials will be reported on in a further paper (13).

Conclusion

Electrochemical etching has been shown to produce sharp delineation of defects in InP, with a large useful range of magnifications spanning the gap between those of x-ray topography and transmission electron microscopy. Good correlation between transmission

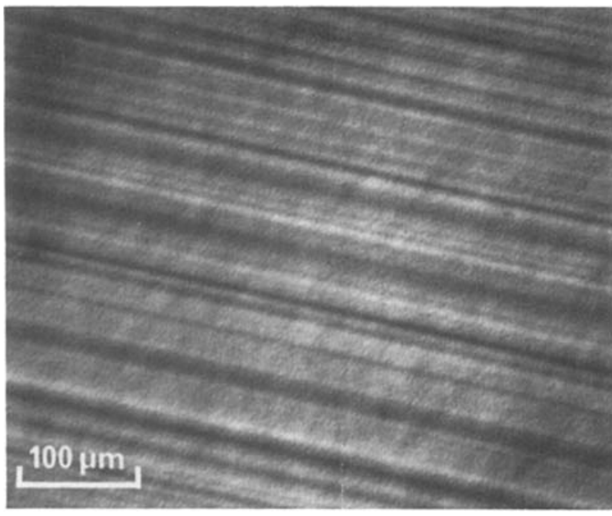

Fig. 9. Nomarski interference contrast micrograph of (100) surface of n^+ InP:S, after defect etching, showing only growth striae.

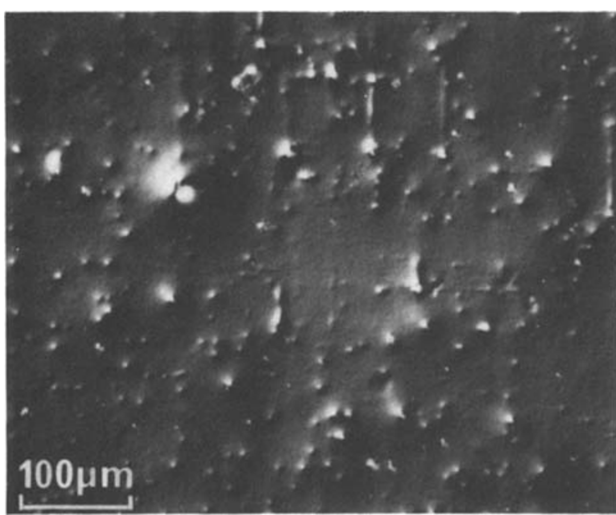

Fig. 10. Nomarski interference contrast micrograph of (100) surface of InP:Fe, after defect etching.

x-ray topography and electrochemical etching was obtained and defect clusters have been shown in great detail. The high sensitivity of the electrochemical etching technique, which only requires a very small amount of material removal, makes the technique ideally suitable for the investigation of defects in thin epitaxial InP layers. As the technique is not restricted to small areas, whole boat-grown or Czochralski-pulled slices may be investigated to carry out defect studies in conjunction with crystal growth.

Anodic thinning, in the presence of an oxide film, may have other applications where damage-free smooth surfaces are required. However, unlike the case of GaAs and GaSb (8) electronic conductivity in the oxide layer gives rise to irrational faradaic yields and precludes the method being used for very precise thinning.

This work is now being extended to cover $Ga_xIn_{1-x}As$ and $Ga_xIn_{1-x}As_yP_{1-y}$ ternary and quaternary alloys.

Acknowledgments

We are grateful to M. M. Faktor for much advice and encouragement, to Mrs. M. A. G. Halliwell for the x-ray topograph, to G. A. Antypass for providing some of the material studied, and for the cooperation of colleagues at the Post Office Research Centre. Acknowledgment is made to the Director of Research of the British Post Office for permission to publish this paper.

A Model for Electrochromic Tungstic Oxide Microstructure and Degradation

Thomas C. Arnoldussen[*,1]

General Motors Research Laboratories, Electronics Department, Warren, Michigan 48090

ABSTRACT

Despite much investigation of the electrochromic (EC) coloration process in WO_3 films, such displays have not yet become commercially viable because of limited useful device life. Device degradation occurs by WO_3 film dissolution on the shelf and erosion during cycling. Water plays a crucial role in both efficient coloring/bleaching and in film degradation. To better understand the degradation process and the role of water, dissolution of EC WO_3 films in aqueous media was studied. The results strongly suggest that EC films formed by evaporation are amorphous molecular solids consisting of trimeric W_3O_9 molecules bound weakly to each other through water-bridge, hydrogen, and van der Waal's bonding. The nature of this microstructure is responsible for the high solubility. Films subjected to ion bombardment show decreased dissolution rates as well as decreased electrochromism and, while amorphous, are believed to have a random network rather than molecular microstructure.

The chief problem to be overcome before electrochromic displays can be commercially viable is the short device life. Degradation of WO_3-acid electrolyte ECD's is associated with film dissolution on the shelf and erosion during cycling. Aqueous acid cells show superior performance from the standpoint of response speed, however, water is a primary culprit in shortening lifetimes through WO_3 dissolution. Nevertheless, Knowles and Hersh have shown (1) that some water must be incorporated in the WO_3 film, even in so-called "aprotic" devices to obtain any electrochromic coloration. Others have studied WO_3 in aprotic solvents but have not systematically analyzed their films for water content as have Knowles and Hersh. The need to better understand the role of water in electrochromism, the interaction of H_2O and WO_3, and the mechanism of ECD degradation have motivated the work presented here. Study of WO_3 dissolution is a proper starting point and provides several key insights into the nature of electrochromic films and the electrochromic process. Others (2, 3) have reported data on dissolution rates of EC WO_3 films in various solvents, but have not related the high observed rates to a detailed physical mechanism or to the nature of the film itself.

Amorphous WO_3 Film Dissolution (Aqueous)

Theoretical.—The thermodynamic equilibrium between crystalline WO_3 and water predicts that WO_3 dissolves by hydrolysis to form normal tungstate ions, WO_4^{2-}, plus $2H^+$. The solubility at 25°C is 1.3×10^{-5} moles/liter in a neutral starting solution and decreases exponentially with decreasing pH. The presence of other species of tungstate ions is negligible. According to this result, a crystalline film 1 cm^2 in area exposed to 1 cm^3 water should saturate the solution after only 4.0 nm of film has dissolved. In an acid environment of pH ~1-2 such as used in EC devices, much less than one molecule-layer would dissolve. By comparison, an EC film which is amorphous and usually deposited by evaporation (0.5-1.0 μm thick) dissolves comparatively fast and completely, even in the small volumes of low pH solutions used in EC devices. We expect the somewhat higher free energy of an amorphous film to drive dissolution more strongly, but unless WO_4^{2-} ions precipitate from solution elsewhere as $WO_3 \cdot nH_2O$ or are converted to metastable polytungstate ions, saturation should ensue and dissolution cease.

Experimental observation during film dissolution indicates no evidence of reprecipitation as WO_3 particles for amorphous films dissolving completely in small volumes of DI water or acid solutions. This strongly suggests that amorphous WO_3 forms polytungstate anions (such as the metatungstate ion which is very stable even in strong acids) (3) upon dissolution. Dissolved WO_3 concentration can reach values far above that expected to produce precipitation. Only many days after a film has been dissolved, or upon extreme concentration of the solution by solvent evaporation, are precipitate particles observed. Crystalline WO_3 dissolves as normal tungstate (WO_4^{2-}) ions according to the hydrolysis reaction

$$WO_3(c) + H_2O \rightleftharpoons 2H^+ + WO_4^{2-}, \quad K_N = 10^{-14.05} \quad [1]$$

Tungstate ions are also known to agglomerate in acid solution to form polymeric anions (4) according to

$$7H^+ + 6WO_4^{2-} \rightleftharpoons HW_6O_{21}^{5-} + 3H_2O, \quad K_{PA} = 10^{53.98} \quad [2]$$

$$14H^+ + 12WO_4^{2-} \rightleftharpoons W_{12}O_{41}^{10-} + 7H_2O, \quad K_{PB} = 10^{110.03} \quad [3]$$

$$18H^+ + 12WO_4^{2-} \rightleftharpoons H_2W_{12}O_{40}^{6-} + 8H_2O, \quad K_M = 10^{132.51} \quad [4]$$

where the polyanions formed in Eq. [2]-[4] are called paratungstate A, paratungstate B, and metatungstate, and the various K's are molar equilibrium constants at 25°C. Pseudo-metatungstate ($HW_6O_{20}^{3-}$) may also be formed. When crystalline WO_3 is allowed to dissolve in an aqueous medium, each of these species can form. The H^+ concentration (C_H) is given by the charge balance

$$(C_H - C^o_H) - (C_{OH} - C^o_{OH}) = 2C_N + 5C_{PA} + 10C_{PB} + 6C_M \quad [5]$$

where the C's denote molar concentrations of the ions noted in Eq. [1]-[4].

C_{OH} is the hydroxyl ion concentration and C^o_H and C^o_{OH} refer to the H^+ and OH^- concentrations of the initial solvent before WO_3 dissolution has occurred. For dissolution in DI water, which is neutral-to-weakly acid, the C_{OH} and C^o_{OH} terms may be ignored. The total molar concentration of dissolved WO_3, C_W, is given by the mass balance

$$C_W = C_N + 6C_{PA} + 12C_{PB} + 12C_M \quad [6]$$

Key words: electrochromic tungstic oxide, dissolution.

Equations [5] and [6] apply regardless of whether the solubility limit has been reached. Equation [5] applies only for dissolution of an oxide, not a tungstate salt, while Eq. [6] pertains to dissolved oxides or salts. The solubility of crystalline WO_3 may be determined using Eq. [5] and [6] in conjunction with the equilibrium mass action relations derived from Eq. [1]-[4]. Doing this, one finds that the solubility of crystalline WO_3 in water is 1.30×10^{-5} moles/liter and the pH attained at saturation is 4.58, corresponding to essentially all the dissolved WO_3 in the form of normal WO_4^{2-} ions. The author verified this pH and solubility experimentally.

A similar quasi-equilibrium analysis for dissolving amorphous WO_3 is unsuitable. This would require (*i*) that the kinetics of reprecipitation elsewhere as crystalline WO_3 be so slow as to be ignored for the time periods of interest, (*ii*) that the detailed mechanism of dissolution be the same as for crystalline WO_3 shown in Eq. [1], and (*iii*) that a dynamic microscopic quasi-equilibrium between the amorphous WO_3 surface and the solution tungstates exists. Experimental observation suggests that condition (*i*) may be met, but there is no evidence to justify assuming that conditions (*ii*) and (*iii*) hold.

Therefore we cannot predict the solubility of an amorphous WO_3 film. In fact, we cannot even say whether quasi-equilibrium solubility is a tenable concept for amorphous WO_3. However, we would expect the solution equilibria expressed by Eq. [2]-[4] to be obeyed regardless of the particular dissolution kinetics and thermodynamics. This permits us to use an indirect approach to investigate amorphous WO_3 dissolution, yet draw some important conclusions.

If we assume various values of dissolved WO_3 concentrations, C_W, then by means of Eq. [2]-[6] we can calculate the pH achieved as a result of dissolution and the distribution of tungsten among the various tungstate and polytungstate species when solution quasi-equilibrium is reached. The result of such a calculation is shown in Fig. 1, showing the quasi-equilibrium curves for pH and tungsten: (free) proton ratio as a function of C_W for dissolution in neutral water. The tungsten: proton ratio is a convenient representation of the distribution of tungsten among the various polytungstate species since this ratio is uniquely determined by the equilibrium distribution. For example, if all the tungsten were in the form of WO_4^{2-} ions, this ratio would be 1:2; if all were in the form of $H_2W_{12}O_{40}^{2-}$, this ratio would be 2:1.

Chemical processes generally do not proceed immediately to equilibrium (particularly true for the reactions considered here). If amorphous WO_3 dissolution proceeds as crystalline WO_3, one WO_3 unit at a time hydrolyzing to form one WO_4^{2-} ion plus two free H^+, we would expect that during and for sometime after dissolution, the pH and $C_W:(C_H - C^o_H)$ ratio would be lower than the values given by the quasi-equilibrium curves of Fig. 1. There would be an excess of lower order species (monomeric ions) and free protons. During equilibration, the excess acidity would induce polymerization of the normal tungstate ions, thereby consuming protons and raising the pH and the $C_W:(C_H - C^o_H)$ ratio. On the other hand, if after dissolving an amorphous film in water we found the measured pH and $C_W:(C_H - C^o_H)$ ratio to fall on the high side of the quasi-equilibrium curves, we would be forced to conclude that the amorphous WO_3 entered solution directly in a polymerized form with equilibration proceeding in the direction of depolymerization.

Experimental

With these theoretical considerations in mind, the following experiment was performed. A 0.70 μm thick WO_3 film was evaporated onto an unheated glass substrate from a Ta boat. The film area was 2.5 cm². This film was placed in 40 ml DI water (pH = 6.15, slight acidity due to dissolved CO_2 presumably) and allowed to dissolve. When dissolution was complete, the pH was measured to be 4.35. This was lower than the 4.58 value predicted and measured for crystalline WO_3. This solution was then titrated back to neutrality while monitoring the pH. A pH = 11.65 NaOH titrant was used. The solution was constantly stirred and 5 min elapsed between each addition of NaOH and the pH measurement. The titration curve is shown in Fig. 2.

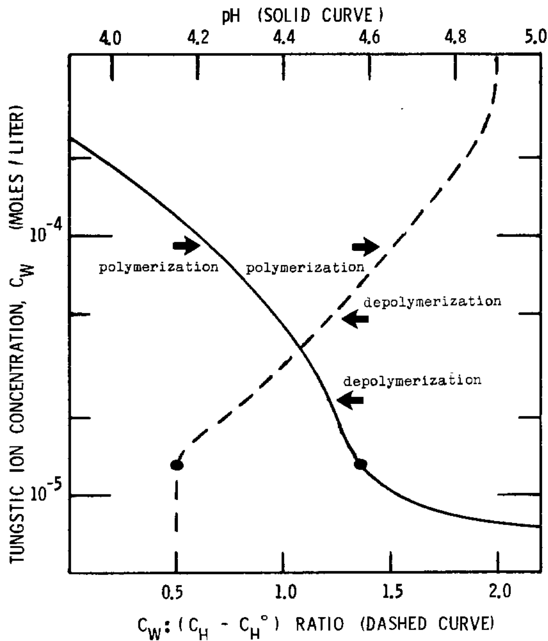

Fig. 1. Calculated quasi-equilibrium curves for pH and tungsten: free proton ratio, assuming various amounts of WO_3 to be dissolved by neutral H_2O. Measured values falling to the left or right of these curves imply equilibration occurs by polymerization or depolymerization, respectively. Dots on lower portions of curves correspond to crystalline WO_3.

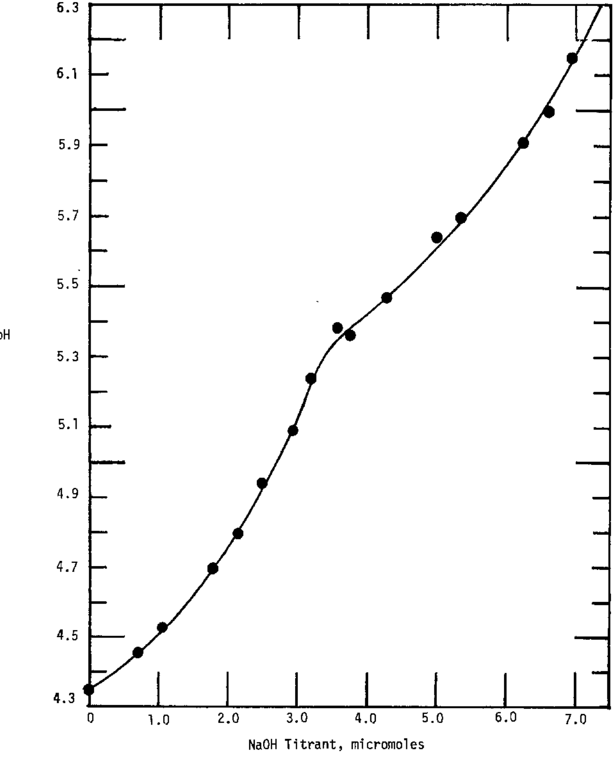

Fig. 2. Titration curve for amorphous WO_3 film dissolved in 40 ml DI water. Film was 2.5 cm² and 0.70 μm thick.

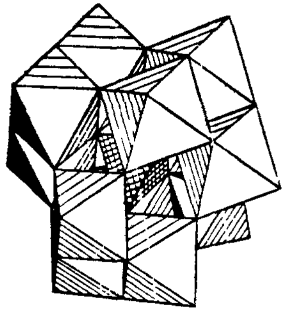
The features of interest here are the initial pH of the dissolved film solution, the quantity of NaOH added to return the pH to that of the DI water (pH = 6.15), and the appearance of a cusp at about 3.4×10^{-6} moles NaOH. From the initial pH = 4.35 of the dissolved film solution and the pH of the starting DI water, we calculate the H^+ concentration due to WO_3 film dissolution is $C_H - C^o_H = 4.40 \times 10^{-5}$ moles/liter. The cusp is characteristic of a depolymerization process induced by raising the pH.

At the point where the pH has been restored to that of the DI water used to dissolve the film, virtually all the WO_3 in solution may be assumed to be in the form of WO_4^{2-} ions and we have essentially a Na_2WO_4 salt solution. The quantity of NaOH needed to reach this point, $C_{Na} = 1.74 \times 10^{-4}$ moles/liter, gives the total concentration of tungsten ions in solution: $C_W = C_{Na}/2 = 8.71 \times 10^{-5}$ moles/liter. The ratio C_W: $(C_H - C^o_H)$ is 1.98:1. This is essentially the ratio (2:1) expected if WO_3 goes into solution from the amorphous film as metatungstate ions, $6H^+ + H_2W_{12}O_{40}^{6-}$. Pseudo-metatungstate, $3H^+ + HW_6O_{20}^{6-}$, could also be the species formed since the tungsten/proton ratio is likewise 2:1.

The important result here is that both the pH and the tungsten: free proton ratio resulting from the dissolution of this amorphous evaporated WO_3 film fall significantly to the high side of the quasi-equilibrium curves shown in Fig. 1. The amount of normal tungstate (WO_4^{2-}) present is less than 3% of that needed to maintain equilibrium with the metatungstate. Clearly, we must infer that the film dissolves not as WO_4^{2-} which subsequently polymerizes, but as 6- or 12-mer ions or as unstable 3-mer ions which quickly form metatungstate or pseudo-metatungstate. Any reactions going on in solution must be in the direction of depolymerization.

The titration results also allow us to calculate the film density from the measured C_W and film thickness and area. We obtain 1.20×10^{22} tungsten ions/cm^3 or 4.62 g/cm^3 assuming stoichiometric WO_3 free of water. Evaporated WO_3 has been reported (5) to contain as much as 0.5 H_2O per WO_3 which would increase the mass density to 4.80 g/cm^3. These values compare with densities ~5 g/cm^3 reported by Randin (2) using another technique.



METATUNGSTATE $6H^+ + H_2W_{12}O_{40}^{6-}$

Fig. 3. (a). Metatungstate ion composed of four tetrahedrally oriented trigonal units sharing corners with two protons in the center cage. Each trigonal unit consists of three edge-sharing WO_6 octahedra (4). (b). Pseudo-metatungstate ion is composed of two trigonal units sharing faces with one proton in the center bi-pyramidal void.

Proposed Structural Model

One clue to understanding the high solubility of evaporated amorphous WO_3 and the peculiar way in which it dissolves directly as polytungstate ions is seen by examining the proposed structures of metatungstate and pseudo-metatungstate ions, shown in Fig. 3. The basic building block of polytungstate ions is a trigonal unit consisting of three edge-sharing WO_3 octahedra. The metatungstate ion (Fig. 3a) is formed by four such trigonal units tetrahedrally coordinated, sharing corners, about a central tetrahedral void containing two trapped protons (3). Similarly, a pseudo-metatungstate ion (Fig. 3b) may be formed by two such trigonal units sharing faces with one proton trapped in the central bi-pyramidal void.

This tendency to form trigonal or trimeric units reappears in numerous WO_3 related substances. Various forms of crystalline tungsten bronzes and solid tungstate salts also contain trigonally oriented octahedra forming low symmetry structures with 3, 5, and 6 member rings. Hashimoto *et al.* have shown that near sublimation temperature WO_3 forms a hexagonal phase (6). And the vapor generated by subliming WO_3 has been shown (7) to consist chiefly of trimeric W_3O_9 molecules as schematically shown in Fig. 4a. Such trigonal clustering may be attributed to formation of delocalized molecular orbitals within the three member ring stabilizing the structure.

The demise of an evaporated amorphous WO_3 film by dissolution as clusters of trigonal units provides one clue to understanding the degradation process. The second important clue is obtained by examining the manner in which such a film is formed during vapor condensation.

As mentioned, the vapor generated by subliming WO_3 consists chiefly of trimeric W_3O_9 molecules illustrated in Fig. 4a. There is also a strong tendency for WO_3 to carry water of hydration, two possible forms of hydrated trimers being shown in Fig. 4b and 4c. When trimeric molecules are deposited at a high rate on low temperature substrates, such as in EC film deposition, it is probable that they remain more or less intact, bonding together weakly through van der Waal's forces or through water-bridge hydrogen bonding. Such phenomena have been observed in evaporation of elemental species such as sulfur and selenium and compounds such as As_2O_3. Evaporating As_2O_3 generates As_4O_6 vapor molecules which upon condensation form the metastable As_4O_6 molecular solid arsenolite (8, 9). Due to the relative stability of molecules exhibiting such associative tendencies, some activation energy is needed to dissociate them into the simplest molecular units before the lower energy network structure can form.

We expect the situation to be similar in EC film deposition, where insufficient thermal activation energy is available to dissociate trimers into monomers

Fig. 4. (a). Schematic representation of W_3O_9 trimeric vapor molecule. (b) and (c). Two possible forms of monohydrated W_3O_9 molecule.

or to break the outer oxygen double bonds which is a precondition to network formation. Moreover, water of hydration, located at outer oxygens of the trimer, will further inhibit W-O-W cross bonding and network formation. Any inter-trimer bonding which does occur is likely to be weakened by lattice distortions inherent in an amorphous structure, while intra-trimer bonding should remain strong and largely unaffected by the disordered arrangement of trimeric units.

The picture that evolves is that an evaporated amorphous WO_3 film, as-deposited, resembles an amorphous molecular solid, rather than an amorphous random network structure, comprised of trimeric units bound weakly to one another such as depicted in Fig. 5. It is easy to imagine that when such a film is placed in an aqueous solution such trimers hydrolyze directly to the trigonal building blocks of polytungstate ions, without forming monomeric WO_4^{2-} ions as an intermediate step. This would account not only for the high solubility of such films, but also for the observation that they dissolve directly as polymeric ions. Trigonal ions carrying high coulombic charge can lower their free energy by agglomerating to form larger clusters of lower charge such as the metatungstate ion. This may occur on the dissolving surface or immediately after entering solution.

Film Restructuring

If evaporated amorphous WO_3 films are molecular solids as proposed then, if by some means one could break double bonds, perhaps even dissociate trimers, rebonding with neighboring molecules could occur to form a lower free energy network structure. Such a film should exhibit a decreased solubility compared to the as-deposited film. Raising the average lattice temperature (energy) by heating, as in recrystallization, is one way of dissociating the trimers. In this case, all the molecules are raised to an activated state simultaneously and can, therefore, undergo a cooperative rearrangement to form a crystalline network with considerable long range order. This would provide no further insight, since we already know that crystalline WO_3 has low solubility.

One can also induce lattice restructuring without crystallization by bombarding the sample with particles of sufficient energy. The activation energy thus provided is absorbed discontinuously in space and time without raising the average lattice temperature significantly. Crystallization would be inhibited because, at any given time, only individual molecules or very

Fig. 5. (a). Representation of EC film as an amorphous molecular solid composed of W_3O_9 trimers bonded together by water-bridge, hydrogen, and van der Waal's bonding. (b). Example of water molecule chain which can form giving rise to high proton mobility by H_3O^+ rotation and porton transfer to adjacent H_2O.

localized regions are in an activated state. Only short range restructuring or relaxation is expected. Amorphous WO_3 films were bombarded by implanting $10^{15}/cm^2$, 70 keV oxygen ions into the film. Primary energy transfer is by ion collisions with the lattice to a depth of 100-150 nm and secondary transfer is by high energy phonon or photon excitation ("thermal spikes") generated by collisions. The incident ion power was $\sim$4 mW/cm^2 and the temperature rise was small, well below the recrystallization temperature of $\sim$345°C (5).

Figure 6 shows an x-ray diffraction pattern obtained by using a rotating nanogram diffraction camera and particles of the bombarded film scraped from the substrate. Only amorphous-like halos are seen. One extends from about 0.24-0.48 nm and another faint halo is centered near 0.18 nm. These correspond to nearest W-W and W-O distances, respectively.

Such bombarded films, despite the implantation of oxygen, were slightly reduced as evidenced by a very slight bluish cast. A several hour postbake in air at 130°C (well below crystallization temperature) was sufficient to reoxidize the films to a transparent yellow. Virgin films used as control samples were given this same baking procedure to guarantee that any differences in film properties were due to the ion bombardment rather than thermal treatment.

As hypothesized, the bombarded films showed over an order of magnitude decrease in dissolution rate in neutral water compared to unbombarded films. They remained more soluble than crystalline WO_3, as might be expected for an amorphous structure. In aqueous acid solutions, bombarded films showed no evidence of significant dissolution even after many weeks in the

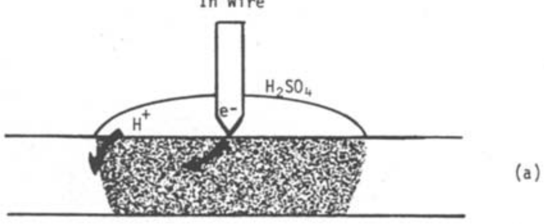

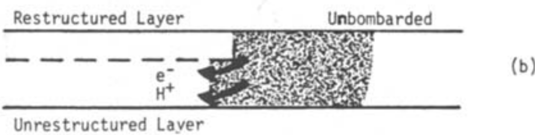

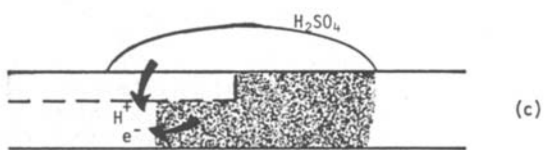

Fig. 7. (a). In wire/H_2SO_4 film coloration technique (10). In dissolves as In^{3+} causing $3e^- + 3H^+$ to be injected into the film. (b). Left portion of film partially restructured (upper layer) by ion bombardment. Right side colored by In/H_2SO_4, rinsed, and dried. Color bleeds slowly into region beneath restructured layer by lateral proton controlled $e^- + H^+$ diffusion. (c). Same as (b) but acid overlaps two regions. Color bleeds rapidly into region beneath restructured layer by lateral electron diffusion plus proton flow through restructured layer.

solvent, whereas virgin films dissolve within one to several days. This dramatic change in solubility is strong evidence of a change in local bonding and microstructure, and it suggests that WO_3 may indeed exist in two distinct amorphous forms: an amorphous molecular solid and an amorphous random network. In addition to the solubility change, ion bombardment produces the additional effect of destroying (or greatly decreasing) the electrochromism.

Electrochromic WO_3 films were also subjected to low energy ion/electron bombardment in an rf glow discharge chamber used for photoresist ashing (~13 Pa O_2, 13.56 MHz, 75W rf power capacitively coupled into a cylindrical chamber 7.6 cm in diameter and 15 cm deep with 50Ω impedance). Again, little heating occurred. Unlike the ion implantation bombardment, the electron/ion energies were only of order 10 eV. Similar decrease in solubility was observed for such low energy bombardment. While it has not been ruled out, chemical oxidation effects are not believed to be responsible for the solubility change. The low energy bombarded films showed no signs of reduction, as did the high energy implanted films (bluish cast), and may in fact have undergone some additional oxidation. Yet both types of bombardment produced the same solubility and colorability change.

Colorability of these bombarded films was checked by the indium wire/H_2SO_4 technique (10). This involves placing an acid droplet on the film and touching an In wire to the surface through the droplet. In dissolves as In^{3+} and the excess electrons on the wire are injected into the film. $3H^+$ are displaced from solution by the In^{3+}, entering the film to neutralize the injected electrons. The coloration spreads from the In contact radially (see Fig. 7a).

In the case of low energy bombardment, the colorability through the surface decreases rapidly during the first 5-10 min of bombardment, but lateral "color bleeding" from an adjacent unbombarded region remains possible until 20-30 min of bombardment have elapsed. This suggests a restructuring process which begins at the upper surface and migrates to the substrate with continued bombardment. (X-ray diffraction was done on 30 min bombarded films.)

In the coloration tests on samples bombarded for 5-10 min, if an unbombarded region is colored up to the boundary with a bombarded region and the sample is rinsed and dried, diffusion of color into the bombarded region is slow (~0.1 mm in ½ hr). If the acid droplet is not removed and overlaps the two regions, color diffusion is rapid (~0.5 mm/sec). These observations are essentially the same as for an unbombarded film, slow color diffusion in the absence and fast diffusion in the presence of an electrolyte. The difference is that an unbombarded film colors by direct contact of the In wire (through an acid) to the film surface, while the bombarded film does not. Moreover, an unbombarded film, so colored, can be bleached thoroughly by heating in air at 135°C for 15-30 min. A bombarded film, colored by bleeding from an unbombarded region, does not bleach even after days of heating in air.

These results may be interpreted as follows. Low energy bombardment restructures the upper portion of the film, leaving the lower portion unchanged (for bombarding times $\lesssim 10$ min). Color bleeds from an unbombarded region into the deeper layer of the bombarded region. In the absence of an electrolyte on the surface, this proceeds by lateral diffusion of electrons and protons from the unbombarded region and is proton diffusion controlled. See Fig. 7b. In the presence of the acid on the surface, the fast color diffusion must be interpreted as lateral diffusion of electrons from the unbombarded region coupled with proton diffusion through the bombarded surface to neutralize the electrons (10). See Fig. 7c. The high speed of color diffusion cannot be explained by lateral proton diffusion.

The inability to color the bombarded region directly by In wire contact, the fast lateral bleeding, and the inability to bleach such a region, once colored by lateral bleeding, implies that the bombarded, restructured layer is still proton permeable, but is blocking to electron transport. The restructuring strengthens the overall bonding (evidenced by decreased solubility) without significantly diminishing the fast proton transport. But it apparently does inhibit electron injection or transport, or induces noncoloring trapping states.

These bombardment studies suggest two important concepts which are worth further investigation: (*i*) It may be proper to speak of not one amorphous state for WO_3, but two: one being closer to a molecular solid, the other a random network. Only the former is electrochromic. (*ii*) Lattice porosity and incorporated H_2O giving high proton mobility may be necessary but insufficient to produce rapid electrochromic response. The electronic states produced by a particular structure are of critical importance to electrochromic response.

Nonaqueous Solvents

It is apparent that EC device shelf degradation in aqueous electrolytes is caused by polytungstate formation. The much lower solubility of EC films in organic solvents may be understood in terms of solvent ionizability, solvent molecule size, and the nature of the solute ion formed. Dissolution is favorable when W-O-W bonds are broken in such a way that the bonds remain saturated. Water is a particularly good solvent because its small size permits it to attack a W-O-W bond and form two saturated W-OH HO-W bonds with a small local distortion of the lattice. Upon going into solution, $(WO_3)_n$ combines with water to form the compact tungstate and polytungstate ion structures. On the other hand, solvents which are not ionizable show little if any action on WO_3 films. Alcohols and glycols with one or more OH radical may ionize to form $R^+ + OH^-$ or $RO^- + H^+$ but are poor solvents for WO_3 films because (*i*) they do not ionize as readily as water, (*ii*) their molecular size is too bulky to penetrate the lattice without severe lattice distortion, and (*iii*) the R^+ and RO^- radicals are too bulky to form compact or complex polytungstate ions in solution. Dissolution in these solvents is likely to be limited to molecular species or simple monomeric ions. Solubility should be low in either case. When an electrolyte, such as H_2SO_4, is added to a nonaqueous solvent, an additional dissolution mechanism may be operative, namely, formation of electrolyte anion-WO_3 complexes. This is further discussed in the next section.

Cycling Degradation

EC device cycling degradation in aqueous and nonaqueous acid electrolytes occurs by an erosion process, probably similar to dissolution, but enhanced by the voltage drive. Film thinning during cycling has been measured by optical interference techniques (2). In aqueous electrolytes, the quiescent dissolution process occurs by polytungstate ion formation and diffusion into the electrolyte. Intuitively, one might expect that it is the nonequilibrium nature of the color/bleach process which leads to cycling degradation. However, nonequilibrium by itself does not imply degradation. A more detailed model is needed. In the literature it has frequently been suggested that cycling degradation may be due to such things as impurities or "irreversible side reactions." Having delineated the nature of quiescent dissolution of electrochromic WO_3 films in the present work, we propose the following intrinsic mechanism of cycling degradation.

In the bleached or moderately colored quiescent state, the electrode potentials are such that the Helmholtz double layer probably has the following structure. The inner layer consists of (*i*) a monolayer of chemisorbed H_2O forming a surface layer of tungstic-oxide-hydroxide which is anionic in nature; (*ii*) just beyond the surface is a layer of predominantly electrolyte anions plus polytungstate anions. The outer layer is chiefly $H_2O + H_3O^+ +$ protons with hydration shells of six or more water molecules. During the coloration cycle, electrolyte and polytungstate anions are driven away from the surface by the applied voltage, while hydrated protons are driven toward it. During this disturbance of the Helmholtz double layer, the depletion of polytungstate anions leads to the removal of tungstic oxide-hydroxide surface molecules to replenish polytungstate anions in the double layer. At the same time, the hydrated protons shed much, if not all, of their water of hydration upon entering the WO_3 surface, leaving an abundance of bond-breaking water molecules in the surface region and inner Helmholtz layer, further promoting dissolution.

While the current carried by the negative tungstate ions leaving the surface may be a small fraction of the proton current, over thousands of cycles it is sufficient to completely erode the film. This voltage-enhanced dissolution would account for the device cycle life decreasing with increased switching speed (higher voltage drive, greater anion depletion, and greater disturbance of the double layer structure) and with increased final point coloration (increased total charge driven per cycle). We expect and, in fact, observe that fast switching to a low contrast state produces more degradation per cycle than slow switching to a high contrast state.

Voltage-enhanced dissolution in nonaqueous electrolytes may occur by one of the following mechanisms. Dissolution by tungstate ion formation requires an oxygen donor species such as H_2O. If there were no dissolved oxygen or trace water in the electrolyte/solvent, and if neither the electrolyte nor solvent dissociate or electrolyze to donate oxygen, tungstate ions cannot form by interaction with the electrolyte. H_2O incorporated in the WO_3 during deposition could, however, contribute to tungstate formation. The $H_2O:WO_3$ ratio can be as high as 1:2 in evaporated films (5) while to form metatungstic acid only 1:3 is needed. Thus, the water incorporated in the film, apparently necessary to achieve high cation mobility (1), may be a self-contained cause of cycling degradation. In addition to this, WO_3 could enter solution by forming a complex with electrolyte anions. Phosphoric acid is known to form complexes with WO_3. To a lesser extent, sulfuric acid may do likewise.

Electrolyte anions are attracted to the surface in the bleached state, and during dynamic bleaching this anion activity is further enhanced. Anions such as SO_4^{2-} may bond to surface molecules forming negative complexes which are swept into solution during coloration. Simple complexes like $[(WO_3)(SO_4^{2-})]^{2-}$ or polymeric complexes like $[(SO_4^{2-}) \cdot (WO_3O_9) \cdot H^+ \cdot (W_3O_9) \cdot (SO_4^{2-})]^{3-}$ could form. Another possibility is a metatungstate isomorph in which SO_6 octahedra are incorporated in place of some WO_3, such as $[H_2^+(WO_3)_8 \cdot (SO_4^{2-})_4]^{6-}$.

Conclusion

Aqueous dissolution and titration results indicate that amorphous WO_3 films (as-deposited) dissolve to form metatungstate or pseudo-metatungstate ions. Moreover, evidence indicates that complex 3-, 6-, or 12-mer ions enter solution directly from the dissolving surface. These results, together with the fact that associative vapor molecules tend to form molecular or semimolecular solids upon condensation, strongly suggest that as-deposited WO_3 films are composed chiefly of trimeric clusters weakly bound to one another. The very open microstructure that would result, along with water-bridge bonds between mole-

cules, can account for the high proton mobilities observed in EC films, but also for the unfortunate rapid dissolution and cycling erosion.

Analysis of evaporated films subjected to oxygen ion bombardment suggests two concepts which may be important to electrochromic development. (*i*) There may exist two distinct amorphous structures, one closer to a molecular solid, the other closer to a random network structure. (*ii*) The restructured (network) film shows decreased colorability, not because it is less permeable to proton flow but because electron injection or transport is inhibited, or noncoloring trapping states are introduced. Further study of bombardment restructuring may provide key information about the effect of microstructure on EC performance.

Cycling erosion can be understood as a natural extension of the dissolution process—voltage enhanced dissolution. Neither impurity side reactions nor any fundamental irreversibility in the proton injection/extraction process need be postulated. In nonaqueous systems, both quiescent dissolution and cycling erosion are slowed because of (*i*) low ionizability and large size of organic molecules such as glycerine and (*ii*) inhibited tungstate ion formation. In these systems, degradation may result from formation of negative complexes with electrolyte anions or from tungstate formation due to H_2O incorporated in the film.

The molecular solid model presented here for electrochromic films may prove to be a fruitful avenue for understanding the nature of coloration in these films. The intervalence transfer model proposed by Crandall and Faughnan (11) may be given physical interpretation by relating phenomenological configuration coordinates to, say, instantaneous configuration of water-bridged W_3O_9 molecules. This would be similar to coloration in charge transfer complexes in solution. Bridging water bonds may be important not only for proton transfer but for electron transfer as well.

SF_6, a Preferable Etchant for Plasma Etching Silicon

K. M. Eisele*

Fraunhofer-Institut für Angewandte Festkörperphysik, D-7800 Freiburg, West Germany

ABSTRACT

SF_6 is a far more selective etchant for silicon than $CF_4 + O_2$ when excited to a plasma discharge. This applies to good advantage in parallel plate reactors where under given conditions of rf power and pressure the etch ratio of silicon to SiO_2 is 30:1 but with CF_4 only 7:1. In contrast to the deposition of carbon in a CF_4 process sulfur has not been found on a silicon surface etched in SF_6. The selectivity of an SF_6 etching process cannot be shifted sufficiently in favor of SiO_2 by adding hydrogen, it can also not be increased much in favor of silicon by adding oxygen. The reaction product is SiF_4. No other silicon compound than SiF_3^+ appeared in the mass spectrum. 1% SF_6 in argon achieves etch rates of more than 100 nm/min with moderate rf energy. SF_6 is also a useful etchant for Si_3N_4 with etch rates of 100 nm/min.

The etching of polysilicon by means of a CF_4 plasma has almost become a standard process in the manufacture of integrated circuits (1). The polysilicon deposited on an SiO_2 layer serves as gate electrode and for interconnections between the active elements, resistors, and bonding pads. The etch rate of a CF_4 + 4% O_2 gas mixture excited to a plasma discharge in a tunnel reactor is selective in favor of silicon over SiO_2 with a ratio of 30:1 (1, 2) so that the SiO_2 is little affected when the time necessary to etch the silicon layer is exceeded by a marginal amount.

Structures of micrometer width are preferably etched in a parallel plate reactor because the anisotropic etching of such a system achieves better definition, less underetching, and better profile control than can be obtained in a tunnel system. Unfortunately, in a parallel plate system the etch ratio Si:SiO_2 is reduced to 7:1 and therefore not any longer sufficiently selective.

This fact has given incentive to look for other etchants. Based on earlier experiences in thermally etching silicon surfaces *in situ* before epitaxial growth with SF_6 (3), this gas seemed suitable for trials in plasma etching (10). SF_6 is not inflammable and not toxic.

* Electrochemical Society Active Member.
Key words: plasma etching, silicon, SF_6, selectivity.

Even in low concentrations it is a powerful etchant for silicon and reacts almost negligibly with SiO_2.

Experimental

The parallel plate reactor consisted of two rectangular water-cooled stainless steel plates with an area of 600 cm^2 spaced 6 cm apart. Either plate could be made cathode by connecting it to an rf-voltage supply while the other plate was grounded or left floating. This configuration permitted to realize any desired bias condition. The etch gas emerged from a diffusor pipe with suitably spaced holes, flowed across the short dimension of the rectangle and was pumped out through a long horizontal slit in the vacuum manifold at the rear (Fig. 1). The gas flow was electronically metered and controlled. The pressure was measured by a special rf protected thermocouple gauge and a capacitive manometer. By optical observation the plasma filled the space between the plates uniformly. A mass spectrometer was connected to a narrow sampling tube. A roots blower and a two stage vane pump permitted vacua of 10^{-3} mbar which could be adjusted to the etching pressure by a diaphragm valve. The etch depth was determined with a stylus at a step on the surface, produced by a photoresist edge during the plasma process.

Anode Coupled Etching

Undiluted SF_6 produced etch rates 10-15 times higher than CF_4 + 4% O_2 under the same conditions of rf-voltage and pressure, (rf = $1000V_{ptp}$, 0.23 mb, 50 sccm SF_6, anode coupled). With reduced rf power we began to systematically dilute the SF_6 with argon. The results are shown in Fig. 2, where for a constant total gas flow of 20 sccm the fraction of SF_6 was decreased down to 1%. Even at this high degree of dilution the etch rate was still at least that of an undiluted CF_4 + O_2 etch. There are also a few etch rates for SiO_2 entered in that graph, all below 0.013 μm/min so that the objective of a high selectivity in favor of silicon over SiO_2 was obtained with a ratio of at least 30:1.

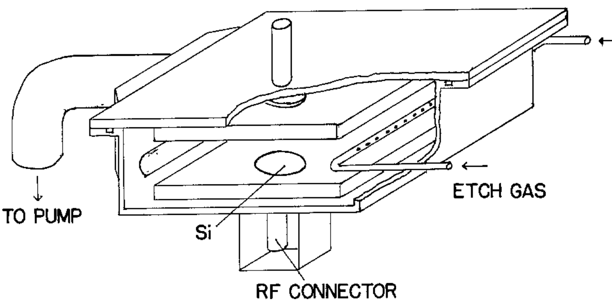

Fig. 1. Etch reactor, showing the gas flow across the electrode

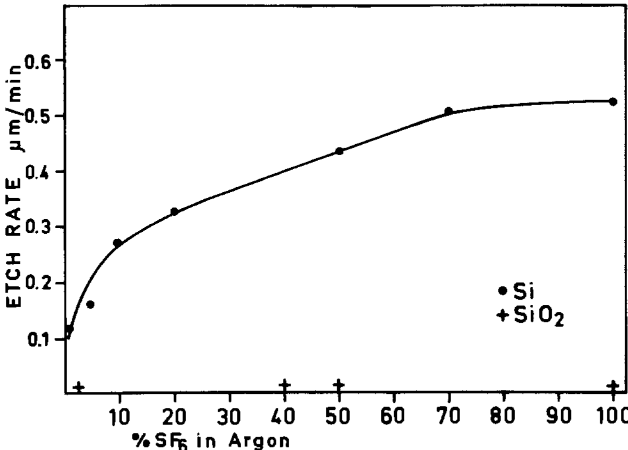

Fig. 2. Etch rate of silicon and SiO_2 in a plasma, anode coupled, when the part of SF_6 in argon increases from 1 to 100% at a total gas flow of 20 sccm. Pressure 0.26 mbar, 0.16 W/cm^2.

In etch processes using CF_4, carbon atoms are set free which may deposit on the silicon surface and impede the attack by the fluorine. This deposition of carbon is suppressed by oxygen which converts it into volatile CO_2 and in consequence raises the etch rate considerably (4, 5). Similarly we expected sulfur to appear on the surface of the silicon in an SF_6 plasma. If this analogy existed between sulfur and carbon a spontaneous increase in etch rate should also obtain in an SF_6 plasma when oxygen is added. Figure 2 shows the result of such an experiment with both SF_6 and CF_4. Oxygen causes a moderate increase in etch rate with SF_6 while with CF_4 the increase is fivefold. We can conclude that if sulfur is on the surface of the silicon, it does not shield against the attack of the fluorine.

The influence of hydrogen added to CF_4 on the etch rate of silicon is a means of steering the selectivity in favor of SiO_2 by suppressing the attack on silicon.

The large amount of fluorine in the SF_6 molecule and the absence of any polymerization moderates the influence of hydrogen to a 10-20% decrease in etch rate. Figure 3 presents this dependence for the smaller percentage of hydrogen where at 20% there seems to be a slight increase. But when the dilution is continued the etch rate will drop faster than with argon, which means it is not just a dilution but a reaction.

It is now obvious that the selectivity of etching only silicon and not SiO_2 is very high and cannot be shifted sufficiently either way by adding oxygen or hydrogen. The selectivity does not depend on the fluorine to sulfur ratio in contrast to CF_4 processes where the F to C ratio is all important (6, 7).

Cathode Coupled Etching

The same measurements were also made in a cathode coupled configuration. Here higher etch rates are achieved because of the more intense activation of the surface by ions. But the same dependence of the etch rate on the admixture of H_2 and O_2 was observed (Fig. 3 and 4). The selectivity is, however, dependent on the pressure. In Fig. 5 the etch rates of Si and SiO_2 are plotted against SF_6 pressure in the reactor. For higher pressure the mean-free path decreases and with it the plasma potential and in consequence the ion bombardment of the surface. This reduces the etch rate of SiO_2 where the activation of the surface by ions is necessary for achieving high etch rates.

The Surface

Occasionally the etched surface was not smooth. On such wafers the etch rate had been unusually high, but also with considerable variations across the wafer. This caused serious difficulties in the earlier stages of the experiments. This effect could be traced to a catalytic action caused by residues from the photoresist

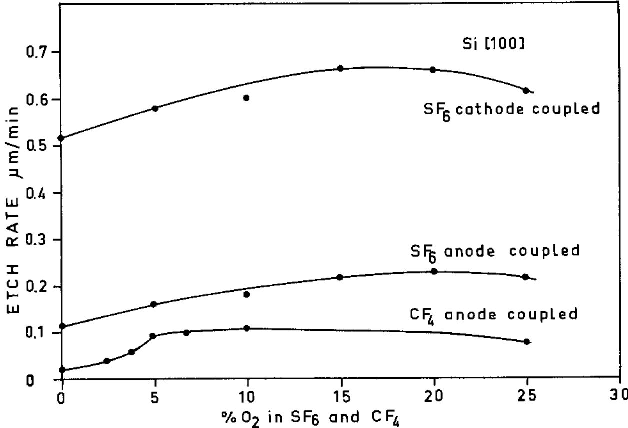

Fig. 3. Etch rate of silicon in SF_6 and CF_4 plasma when oxygen is added. Total gas flow 20 sccm; pressure 0.22 mbar, 0.16 W/cm^2.

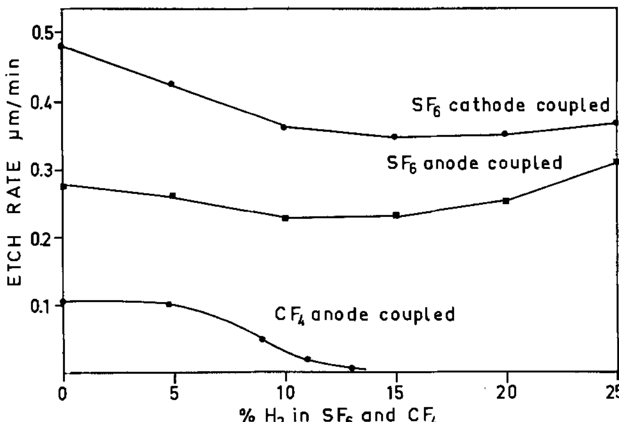

Fig. 4. Etch rate of silicon in SF_6 and CF_4 plasma when hydrogen is added. Total gas flow 20 sccm; pressure 0.22 mbar, 0.16 W/cm^2.

process although the surface appeared clean by inspection even with a microscope. After the wafer was immersed in a 10% HF solution the surface remained perfectly smooth in the process, the etch rate became uniform on a single wafer and from wafer to wafer, but was distinctly less than obtained on wafers that had not been dipped in the HF solution but etched simultaneously. Untreated surfaces sometimes had etched four times deeper than the pretreated ones. This effect was later also found with other etchants, for instance with NF_3. The suspicion is justified that this phenomenon is also present with CF_4, but not easily observed because the etch rates are considerably lower. When SF_6 was used in dilution the overetching was not apparent without special attention.

The crucial question for a semiconductor device application of SF_6 is whether sulfur is deposited on the silicon surface in an SF_6 plasma. XPS analysis was performed on etched and not etched silicon. There was never any sulfur detected. Surprisingly the oxygen and carbon lines increased in intensity on etched samples although no oxygen or carbon containing gas was knowingly admitted to the reactor. Figure 6 shows an XPS spectrum of an SF_6 etched silicon surface. The minimum detectable level of sulfur is 0.07 of a monolayer. Figure 7 shows the energy range around the S2s line, with high resolution.

Mass-Spectroscopic Analysis

When the plasma is switched on without silicon present in the reactor some compounds appear associated with oxygen SO, SOF, SOF_2 which are synthesized in the plasma. When silicon is being etched the only reaction product is SiF_4 observed as SiF_3^+. The height of its mass peak appears at the expense of SF_3^+ which reduces sometimes below that of the SiF_3^+. This close relation between the two mass signals induces speculation about a direct exchange between sulfur and silicon because the SF^+ and SF_2^+ peaks remain

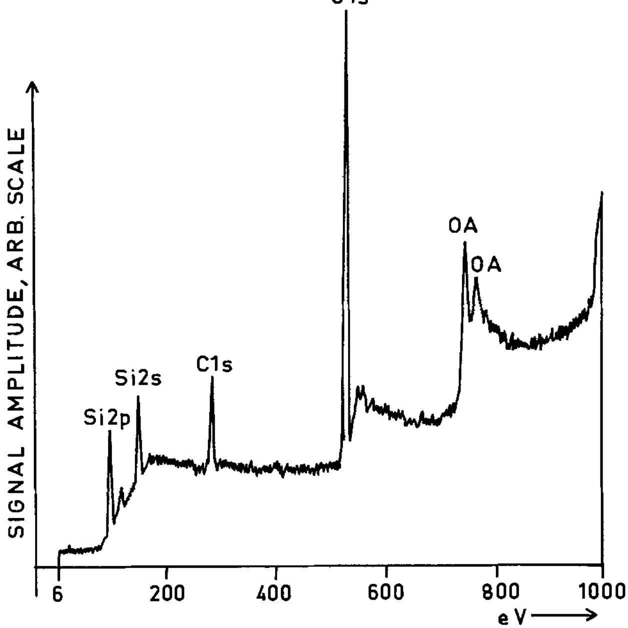

Fig. 6. XPS spectrum of silicon surface etched in SF_6

unchanged. SF_4^+ also reduces, but this peak being much smaller to begin with, its contribution is not as obvious. SF_5^+ seems to change little although it is the largest peak. Recently a mass spectroscopic examination of this process has been published (8) where also an increase in SiF_3 signal concurs with a corresponding decrease in the SF_3 signal. Those measurements were obtained at a much higher power density such as is usually applied in sputter processes. These power levels were not reached in this work here. Therefore, a detailed comparison is not possible.

When the silicon is covered by thermal oxide and is anode coupled then the signal of SiF_3^+ rises barely above the background due to the very low etch rate. Cathode coupled, however, the etch rate is higher and therefore a moderate but distinct signal at 85 amu is recorded. At the same time the sulfuroxyfluorides SO_2F, SO_2F_2, and SOF_3 appear. The peaks of SO_2F and SO_2F_2 can also arise from S_2F and S_2F_2. But as the latter were not present without the SiO_2 in the reactor, only the first assumed identity is acceptable. There are small peaks at 164 and 186 amu which have previously been identified as siliconoxyfluorides $Si_2O_2F_4$ and Si_2OF_6 (9). But these complex compounds have negligible importance in the process.

Because of the absence of carbon, the SF_6 plasma does not have the ambiguity that all mass peaks attributable to silicon could also arise from CO-combinations, because of the same mass, *e.g.*, SiF_2 and COF_2.

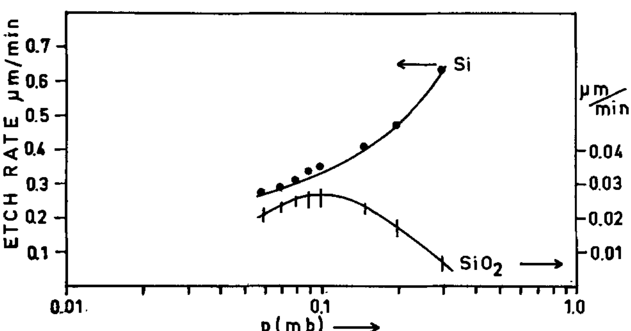

Fig. 5. Etch rate of silicon and SiO_2 in dependence of SF_6 pressure, 0.16 W/cm^2, cathode coupled.

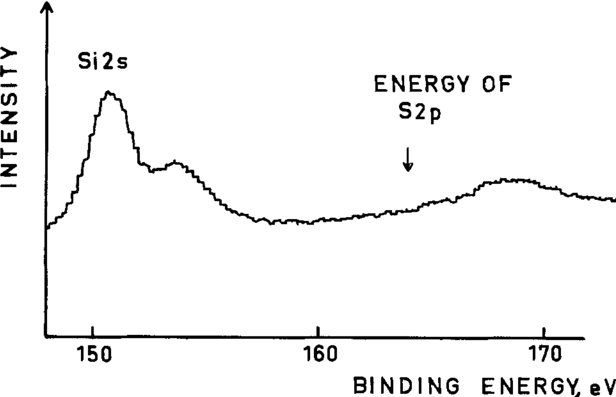

Fig. 7. XPS measurement at the S2s energy level

SF_6 in a Barrel Reactor

Commercially available barrel reactors are in widespread use in the semiconductor industry. Therefore it was considered useful to investigate the etching effect of SF_6 in such a reactor configuration. The etch rates for silicon were higher by a factor 2-3 than previously found with CF_4. At the same time the attack on SiO_2 was immeasurably small. The effects of adding oxygen or hydrogen were the same as in the parallel plate reactor. At more than 50% hydrogen the etch rate falls off considerably as the fluorine is being pumped off as HF. The selectivity in favor of silicon over SiO_2 was 200:1 without aiming for optimum conditions. Exceeding the time in etching a polysilicon structure becomes thus meaningless. Although CF_4 achieves adequate etching in a barrel reactor, the improvement introduced by SF_6 deserves consideration.

The Etching of Silicon Nitride

SF_6 is also a useful etchant for silicon nitride, especially as an alternative when CF_4 does not achieve a good surface. This applies for instance when nitride is used as a passivation layer on already metallized devices and contact holes have to be cut through the nitride. In this case SF_6 leaves a shiny surface suitable for bonding. With 0.2 W/cm^2 rf power density in an anode coupled setup, 0.25 mbar pressure and 20 sccm SF_6 flow, 80-100 nm/min of silicon nitride can be etched. The same conditions but cathode coupled do not achieve an appreciable higher etch rate yet the selectivity with respect to SiO_2 is diminished. Nitride etching is not influenced by small percentages ($<20\%$) of hydrogen added to the SF_6 and also not by oxygen and nitrogen. There is a small increase in etch rate with pressure. In this respect the nitride behaves like the silicon and not like the oxide in Fig. 4. It means that activation of the surface by ion bombardment is not a significant condition for etching nitride.

Conclusion

For plasma etching silicon, SF_6 is a unique etching gas. It requires no oxygen to achieve high etch rates with outstanding selectivity. It is economical and leaves a clean smooth surface with no danger of depositing any layers on the wafer. It should therefore find wide application in the manufacture of semiconductor devices.

Secondary Ion Mass Spectrometric Analysis of Cobalt-Hardened Gold Electroplate Surfaces

Rudolf Schubert

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

In Co-hardened Au electroplate, the Co will diffuse to the surface with time, where it can form an insulating film. It is of interest to know the chemical form of this surface Co on electrical connectors. Secondary ion mass spectrometry is used to distinguish Co, CoO, Co_3O_4, and cobalt hydroxides in less than full monolayer quantities on impure surfaces. This distinction of compounds is made by comparing the positive and negative secondary ion spectra of Au electroplate with standard samples. Both Ar and O_2 are used for the primary beam. Spectra are compared from before and after UHV bakeout. It is shown that electroplated Au samples have different Co compounds on their surface depending upon the sample histories. For Co-hardened Au electroplate heat-treated at 150°C in air, the surface Co is in the form of CoO and Co. When heat-treated at 200°C in air, the surface Co appears to be in the form of a cobalt hydroxide. Numerous other surface species are also identified and discussed.

Cobalt is a component used in many alloys to influence specific properties of these alloys. In the electronics industry, Co is added to electroplating bath solutions to improve the mechanical hardness characteristics of electroplated Au surfaces (1). A side effect of the Co included in the Au electroplate is that, with time and temperature, it diffuses to the surface and can cause high contact resistance upon oxidation in air.

Key words: SIMS, cobalt oxides, hard gold, electrical connectors.

Cobalt metal oxidation has been extensively studied and reviewed (2, 3). Three different oxides form (CoO, Co_3O_4, and Co_2O_3) and are stable under various conditions. Formation is a function of temperature and gas environment except for Co_2O_3, which does not form by dry oxidation (2). The normal oxide formation can be expected to be altered when the Co is in/on a complicated, impure Au electrodeposit. Bulk Au electroplate impurities were first shown to include complicated, organic compounds by wet chemistry (4). The exact nature of these bulk complexes is still uncertain even after sophisticated analyses by Mössbauer spectroscopy (5-7). The majority of the Co is metallically substituted in the matrix (7). However, whatever the nature of these complexes, (β-CoOOH) (6), or $(Co(CN)_6^{-3})$ (7), they will have to disassociate before being able to diffuse to the surface where they are of interest for their electrical contact resistance.

Recently, Auger electron spectroscopy (AES) (8, 9) and x-ray photoelectron spectroscopy (XPS) (10) have been used to evaluate Co diffusion constants in Co-hardened Au electroplate. That work has pointed to a variety of possible surface compounds: CoO, CoOOH, and K_2O. Compounds with C, N, S, Na, and Cl have been neglected although these elements are also present on the surfaces (8, 10).

Secondary ion mass spectrometry (SIMS) used in the static mode is ideal for a qualitative chemical surface analysis (11-14). Static SIMS uses sufficiently low primary ion beam densities ($\sim 10^{11}$ ions/sec-cm^2 $= 16$ nA/cm^2) such that less than 10% of a monolayer of the surface is destroyed through sputtering during an analysis. Chemical analysis is achieved by comparing the unknown spectrum to spectra of standards.

This paper reports on the surface analysis of Co-hardened Au electroplate before and after heat-treatments at $\leq 200°C$ in laboratory air. Standard SIMS spectra of Co foil, CoO, and Co_3O_4 powders were used for comparison. Both positive and negative SIMS spectra are used for analysis. Qualitative interpretation of the Au electroplate spectra indicate varying amounts of hydrocarbons (HC), halogens, alkalies, sulfur, cyanogens, Co, and oxides. The source of these elements and compounds is attributed to the electroplating process.

Apparatus and Sample Preparation

The apparatus in which the SIMS measurements were made is a stainless steel, ion pumped, ultrahigh vacuum system with a 12 in. bell jar. Typically, the system background pressure is 3×10^{-9} Torr before a 225°C, 8 hr bakeout and 1×10^{-10} Torr after a bakeout. A monopole mass spectrometer continuously monitors the background residual gases. Primary residual gases are H_2, CO, H_2O, CH_4, and inert gases. This is typical of an ultrahigh vacuum system. The system and SIMS apparatus have been described and shown in detail previously (15, 16).

Briefly, the SIMS equipment consists of an ion gun, quadrupole mass filter (QMS), and a cylindrical mirror energy prefilter (CMA). The hot filament ion gun is differentially pumped with a liquid nitrogen trapped hydrocarbon oil diffusion pump to reduce the inert gas load on the ion pump when using an Ar ion beam. Other primary ion beams, such as oxygen, can also be generated but with a reduction in filament life. Primary ion beam currents can be varied between 1-400 nA with a beam half-width variable from 300 μm to $\sim$1 cm. The CMA filters out higher energy ($>$10 eV) secondary ions and neutral species. Both positive and negative ion spectra can be measured in the QMS which has an electron multiplier detector. With a 10 nA primary ion beam, typical background counting rates are <1 sec^{-1}.

A pure Co standard (99.9%) was cut ($0.5 \times 1 \times 0.025$ cm) from commercial (MRC Corporation) foil. CoO and Co_3O_4 samples were prepared from commercial (Alfa-Ventron) technical grade powders. X-ray diffraction analysis of the CoO and Co_3O_4 powders showed only CoO and Co_3O_4 lines, respectively. The powders were spread between two pieces of Ag foil which had been previously ultrasonically cleaned in methanol. The sandwich was then compressed to $\sim$100 psi. Excess oxide powder was tapped off after the two foils had been gently separated. Similar Co oxide samples were also made on Sn backed, electroplated soft Au foils to check for substrate effects. Co_2O_3 was not available commercially and since it does not form by dry oxidation (17), it will not be considered in this paper. Immediately prior to insertion in the vacuum system, all samples were ultrasonically cleaned in CH_3OH.

Co-hardened, electroplated Au samples were plated on OFHC Cu to a thickness of 25 microns. A standard commercial (Autronex-CI), citrate buffered, plating solution was used at low current densities. The source of Au and Co was $KAu(CN)_2$ and $CoSO_4$, respectively. Samples similar to these have been described previously (6-8). Cohen *et al.* (7) have shown that bulk impurities are similar over a range of plating currents, Co concentration, and bath age. Co concentration in the films was 0.26 weight percent (w/o) as determined by atomic absorption analysis. Three histories of Au samples were analyzed: (*i*) after plating without a heat-treatment, (*ii*) after 150°C in air for 2000 hr, and (*iii*) after 200°C in air for 120 hr. All samples were ultrasonically cleaned in CH_3OH before the heat-treatment and before vacuum insertion.

Analysis Procedure and Results

Six different types of samples were mounted on a carousel for sequential analysis under the same analysis conditions. Typical sample groupings were Co foil, CoO and Co_3O_4 on Ag foil, and Au sample types (*i*), (*ii*), and (*iii*). Analyses were made before and after bakeout of the vacuum system. All analyses were made such that for an assumed sputtering yield of unity, less than a monolayer of material was sputtered, *i.e.*, the product of ion beam current and analysis time produced an ion dosage of $<10^{15}$ primary ions/cm^2. This insured that when after-UHV-bakeout analyses were made, the original surfaces had not been destroyed by the prebakeout analyses.

Figure 1 shows the positive secondary ion (PSI) spectrum (log relative intensity *vs.* amu) from the pure Co foil sample before the system had been baked

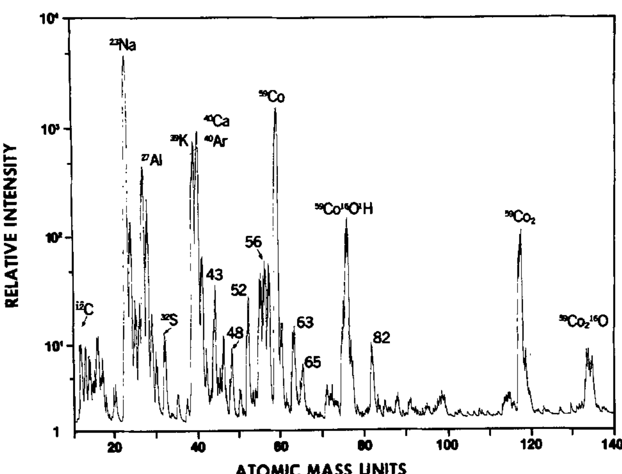

Fig. 1. PSI spectrum of Co metal foil using a 2 keV Ar^+ primary beam of density 1.5×10^{12} sec^{-1} cm^{-2}. The sample has been ultrasonically cleaned in CH_3OH and the system background pressure $= 3 \times 10^{-9}$ Torr. Unlabeled peaks are due primarily to hydrocarbons.

and when it was at a background pressure of 3×10^{-9} Torr. In addition to those impurities labeled, many other peaks are seen and attributed mostly to elemental oxides and to organic surface impurities, *i.e.*, CH_x, C_2H_y, etc. (which are typical of nonvacuum-baked samples which have been exposed to air). In the negative secondary ion (NSI) spectrum, one finds oxides, F, S, Cl and more fragmented organic ions than in the PSI spectrum. The NSI spectrum for Co foil is not shown but is similar to the spectra for the cobalt oxides discussed below. After bakeout of the vacuum system, the Co foil SIMS spectra change considerably. Figure 2 shows a reduction of most impurities in the PSI spectrum. Low mass hydrocarbons increase but high mass ones decrease which is normal for samples that have been through a UHV-bakeout procedure. The mass peaks at amu 113 and 115 increase and are attributed to In diffusing out of the bulk. Also note the substantial reduction of cobalt oxide.

NSI spectra of the two cobalt oxides, CoO and Co_3O_4 pressed into Ag foil samples which have not been baked are shown in Fig. 3 and 4, respectively. The samples show various levels of elemental impurities and hydrocarbons. The primary NSI mass peaks of interest are Co^- at amu 59, CoO^- at 75 amu, and CoO_2^- at 91 amu. The cobalt oxide powder samples pressed into soft Au plated Sn have comparable NSI relative intensities and are not shown. For PSI spectra, the peaks involved in the fragmentation patterns are Co^+ at amu 59, CoO^+ at amu 75, Co_2^+ at amu 118, and Co_2O^+ at amu 134. These spectra are not shown since they are similar to the CoO oxide in the unbaked Co foil shown in Fig. 1 but with more intense oxide peaks. Furthermore, none of the oxides studied showed any significant differences in their PSI fragmentation patterns. Table I lists the normalized relative intensities of fragmentation pattern peaks of both PSI and NSI spectra for the studied cobalt oxides and Co foil after UHV bakeout. Cobalt oxide samples showed no significant differences due to the UHV bakeout with regards to the oxide fragmentation pattern.

PSI and NSI spectra of Co-hardened electroplated Au samples were also recorded. The normalized relative intensities of the relevant Co mass peaks are also listed in Table I. Figure 5 illustrates a typical PSI spectrum of the Co-hardened Au electroplate reference sample (*i*) (no heat-treatment). The PSI and NSI spectra of sample (*iii*) are shown in Fig. 6 and 7, respectively.

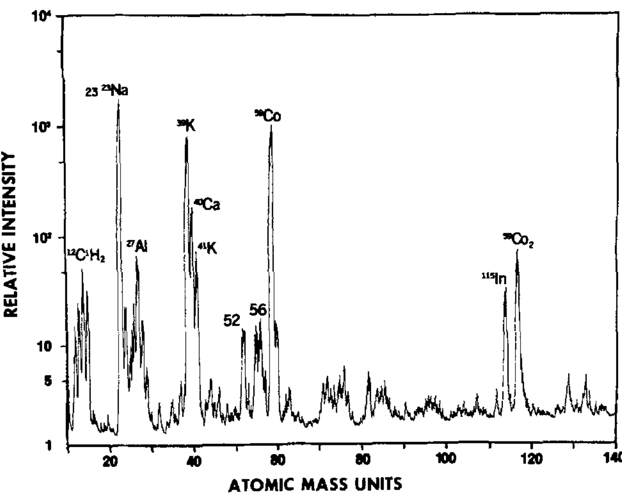

Fig. 2. PSI spectrum similar to Fig. 1 except that the system and sample have been baked in high vacuum at 225°C for 8 hr. Base pressure = 1×10^{-10} Torr. The In is believed to be a bulk impurity which has diffused to the surface during bakeout.

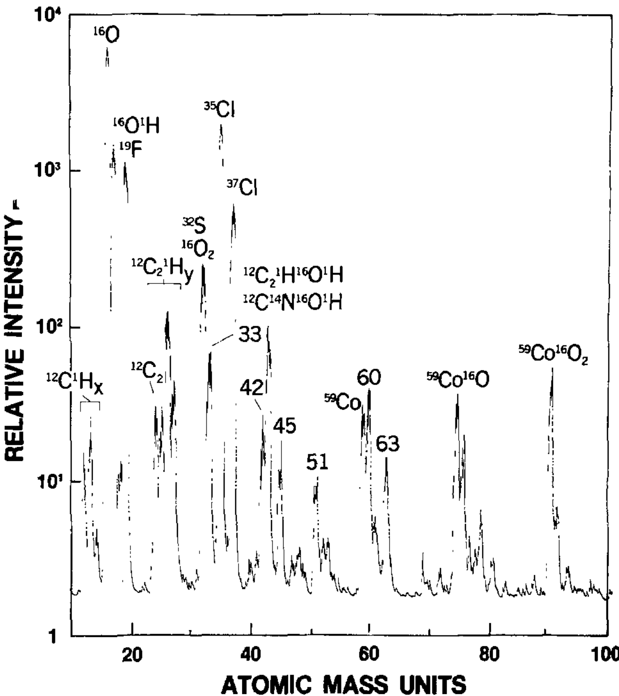

Fig. 3. NSI spectrum of CoO powder pressed onto an Ag foil and ultrasonically cleaned in CH_3OH. The primary Ar^+ beam density is $2 \times 10^{+12}$ sec^{-1} cm^{-2}. The ions at amu 60 and 63 are unrelated to Co.

The primary purpose of this experiment was to determine by SIMS the surface Co oxide compounds in Co-hardened Au electroplated OFHC Cu. As can be seen in the spectra shown in Fig. 6 and 7, the heat-treated Au sample (*iii*) is even more contaminated than the standard powder samples discussed above. Tompkins (8) and Thomas and Sharma (10) using Auger electron spectroscopy and concurrent sputtering, have shown that the surface impurity and oxide layers are only tens of angstroms thick. It has also been shown that cyanide and hydrocarbon complexes extend throughout the Co-hardened, Au plating (6, 7, 23-25). Thus, the surface impurities are not

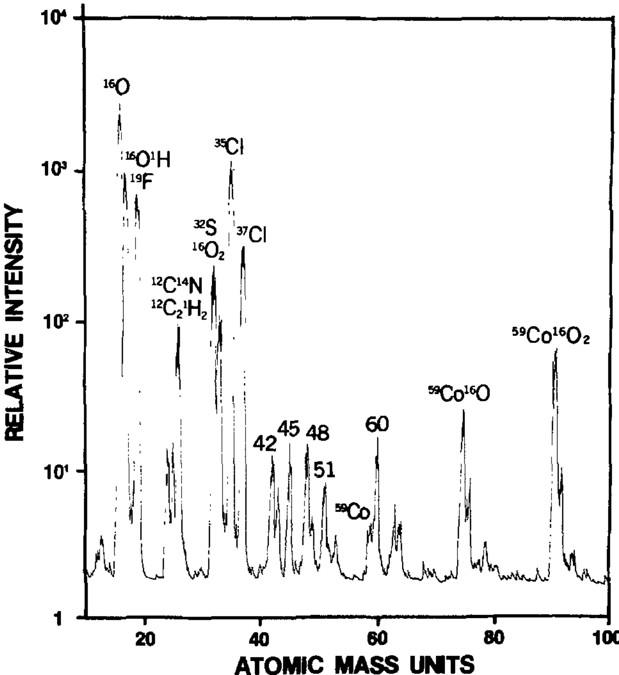

Fig. 4. NSI spectrum of Co_3O_4 recorded with conditions similar to Fig. 3.

* Intensities after UHV bakeout are <10 counts/sec with primary beam densities of ~2×10^{12} Ar^+/(sec-cm²) which precludes listing an accurate fragmentation pattern.

readily cleaned off without also removing the Co oxides of interest. However, from the discussion below it will be indicated that the contamination does not affect the Co oxide fragmentation pattern.

Discussion

It is apparent that the surfaces being analyzed have various impurities on them. It is also well known that electronegative and electropositive elements and compounds dramatically increase or decrease the PSI and NSI yields (16, 18-20), respectively. For example, if one exposes clean Fe-Cr alloys to either CO or C_6H_6, the PSI yield of Fe and Cr increases uniformly by approximately a factor of 100 (21). Oxygen adsorption will increase the PSI yield by >1000, but nonuniformly for the two elements (13). However, the ratio of the fragmentation pattern peaks for a given element does not change [similar results have been reported for Cu and CuO (19) and Si (22)].

In this paper we are concerned with the effects of impurities and oxygen on Co on the Au surface and their effect on the SIMS fragmentation patterns. Comparison of Fig. 1 and 2 show that the PSI Co oxide yield from the Co foil surface has become smaller by more than a factor of 20 due to the surface impurity desorption occurring during bakeout of the vacuum system. Other surface impurities, such as Al and Ca have also been reduced substantially. Indium, at mass 113 and 115, has diffused from the bulk to the surface. Low mass hydrocarbons (HC) have increased while higher mass HC have decreased. After system bakeout CH_4 is a prime residual gas and probably is responsible for a substantial portion of the PSI intensity increases at amu's 12-16. Although Na and K decrease during bakeout, their remaining high PSI intensity is misleading. Both have PSI yields ~100 times higher than Co and both are trace elements in the primary ion beam from the hot filament gun. However, the ratio of $Co^+/Co_2{}^+$ is unchanged at 14.5 after all the surface impurity changes and reductions. One concludes that the fragmentation pattern for Co does not change with surface impurity adsorption.[1]

From Fig. 1 to 4 and Table I it is obvious that Co can be distinguished from cobalt oxides. Distinction of the oxides from one another is not so obvious in the PSI spectra of the powdered samples (not shown) in which only small differences in fragmentation patterns are seen. The smaller peaks, CoO^+ and $CoO_2{}^+$, are essentially equal with a small signal to noise ratio. $^{59}Co^+$ is always the main peak. In the NSI spectra, the fragmentation patterns are unambiguous when comparing the Co^-, CoO^-, and $CoO_2{}^-$ peaks. Thus, from the ratios of $Co^-/CoO_2{}^-$, which are 0.5 and 0.07 for CoO and Co_3O_4, respectively, one can separately identify the two oxides.

The Au electroplated sample which has not been heat-treated in air shows only minimal contamination. One sees the alkalies predominantly, traces of other

[1] As a further check on the effects of oxygen on the fragmentation pattern, a primary O_2 ion beam, as opposed to an Ar ion beam, was also used on all the standard samples. No changes were observed in either the Co metal or oxide fragmentation ratios.

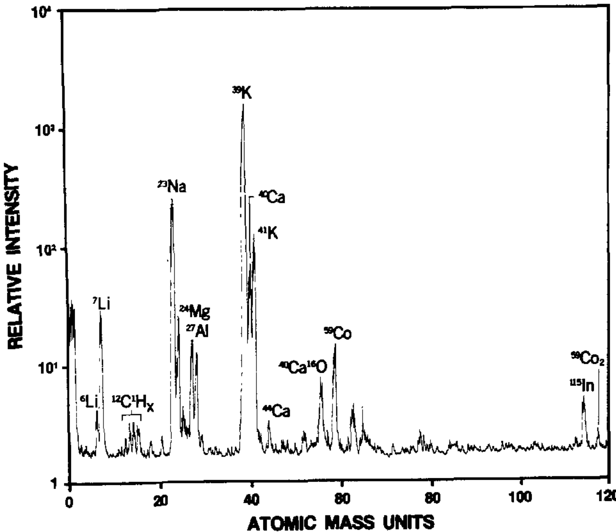

Fig. 5. PSI spectrum of Co-hardened Au electroplated OFHC Cu after UHV bakeout. The sample was inserted directly into the vacuum system following an ultrasonic CH_3OH rinse after plating. Primary Ar^+ beam density was 3×10^{12} sec^{-1} cm^{-2}.

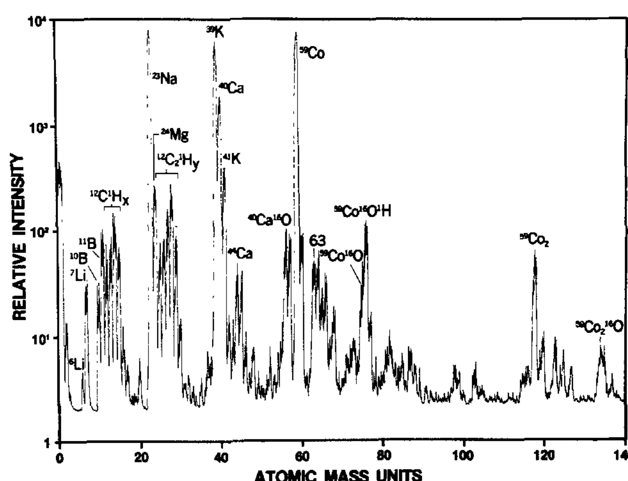

Fig. 6. PSI spectra of a Co-hardened Au electroplated OFHC Cu. After electrodeposition the sample was baked in laboratory air for 120 hr at 200°C, then ultrasonically cleaned in CH_3OH before insertion in the vacuum system. Ar^+ beam density was 3×10^{12} sec^{-1} cm^{-2}. Unlabeled peaks are due primarily to hydrocarbons.

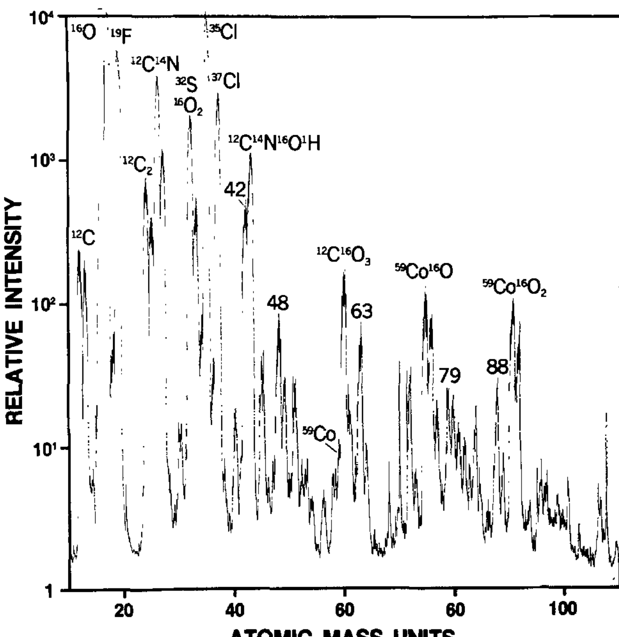

Fig. 7. NSI spectrum of sample shown in Fig. 6. Primary ion beam was similar to the data in Fig. 6.

electropositive elements, and small amounts of Co as shown in Fig. 5. This data was recorded at the same sensitivity level as the data in Fig. 6. If one assumes that the SIMS signal originates from the topmost monolayer of atoms only, then there is less than 1 atomic percent (a/o) of Co and 1 a/o of alkalies present on that surface.

Co-hardened Au electroplate sample (*ii*) data (spectra not shown) can be interpreted, with respect to surface Co, from the data listed in Table I. Taking the NSI contributions at amu 75 (CoO^-) and amu 91 (CoO_2^-) to be due to CoO then the contribution of CoO to the amu 59 (Co^-) signal is 35 units (relative intensity). Assuming equal NSI yields (primary ions in/secondary ions out) for Co and CoO, the calculated value of Co is then $65/(155 + 65)$ or approximately 30 a/o Co with the concurrent value of 70 a/o for CoO. These values are in agreement with Ref. (10). Other surface impurities will be discussed below.

Inspection of both the PSI and NSI data in Table I and Fig. 6 and 7 indicates that the cobalt oxide in the Co-hardened Au electroplate sample (*iii*) is not Co, CoO, Co_3O_4, or a combination thereof. The fragmentation pattern ratios of amu's 59/76 or 59/91 do not fit the standard samples. The ratio of CoO_2^-/CoO_2H^- is 6 and 8.5 for the CoO (Fig. 3) and Co_3O_4 (Fig. 4) standards, respectively. For the unknown this ratio is only 1.5. Similar numbers apply to the CoO^-/$CoOH^-$ ratio. This four to sixfold increase in hydroxide signal implies a proportionantly greater amount of hydroxide than the standard and that it is strongly bonded, since it has survived a UHV bakeout. This is further substantiated by the large O^- and OH^- peaks which are off scale in Fig. 7. Thus, one concludes that the surface Co is really a form of cobalt hydroxide after a 200°C-120 hr heat-treatment in laboratory air. This is in agreement with the work of Leidheiser *et al.* (6), who claimed the bulk Co was complexed as β-CoOOH. Other surface analysis reports on Co-hardened Au electroplate are not in conflict with this conclusion since with AES (8, 10) hydrogen cannot be detected and after the ESCA analysis (10) its presence on the surface was debated.

Hydrocarbons are present in significant amounts on all the samples except the Co foil and unheat-treated Au after UHV bakeout. HC are typically seen at amu's 12-15 (CH_x), amu's 24-27 (C_2H_y), amu's 36-39 (C_3H_z), etc. in both PSI and NSI spectra (11, 21). For the powder samples, HC cannot be eliminated since as one sputters into the "clean" interior of a granule, new exterior surfaces are being exposed from surrounding granules. Figures 6 and 7 show the richest HC spectra. In addition to the labeled HC, it is expected that most of the lower intensity unlabeled peaks are also due to HC. At this point it would be too speculative to attempt an identification due to the myriad possibilities and not having standards available.

Numerous other compounds and complexes are purported to be in the bulk or on the surface of the electroplate depending on which publication one reads and what technique that author used. CN complexes are expected due to the electroplating bath. CN^- is seen at amu 26 in Fig. 7 where it dominates the $C_2H_2^-$ ion. The NSI at amu 42 and 43 are due primarily to CNO^- and $CNOH^-$, respectively. The presence of CoCN complexes on the surface should produce a strong peak at amu 85 in the NSI spectrum. Since a negative amu 85 ion was not observed one concludes that CoCN complexes were not present on the surface. KO and KCN surface complexes also appear doubtful since they appear in neither the PSI nor NSI spectra although the possibility exists that they are only sputtered as neutrals. Thus it appears that large chemically bound complexes are not readily found on the surface of Co-hardened Au electroplate either before or after heat-treatment in air.

Summary

Static SIMS surface analysis has been shown capable of distinguishing Co, CoO, and Co_3O_4 standard samples. The technique has demonstrated that an unheat-treated, Co-hardened Au electroplate surface is relatively clean with predominantly metallic surface impurities of K and Co. For Au electroplate heat-treated at 150°C in laboratory air, the primary surface constituents are CoO, Co, and K. At heat-treatment temperatures of 200°C these surfaces produce complex PSI and NSI spectra and are highly contaminated. A partial listing of contaminants include hydrocarbons, hydroxides, Na, K, Ca, Co, CoOOH, CN, S, and Cl. CoCN, KO, and KCN complexes are believed not to be present on surfaces in substantial quantities.

Manuscript submitted June 9, 1980; revised manuscript received July 31, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

A Review of Depreciative Color Center Phenomena in Lamp Phosphors

John M. Flaherty*

GTE Products Corporation, Lighting Group, Danvers, Massachusetts 01923

ABSTRACT

A review of the role played by color centers in the deterioration of lumen output of lamp phosphors with special attention to the halophosphates is presented. Color center dynamics in halophosphates result in a rapid degradation in phosphor brightness within minutes after the beginning of lamp life. An examination of the extent and rapidity of this effect is reviewed. Unirradiated spectral characteristics of halophosphates are dependent on growth stoichiometry. Radiatively induced spectral absorptions are dependent on the relative intensity of Hg u.v. components and crystal deformation and show thermal and optical bleaching effects. A dynamical model of color centers in halophosphates is extracted from the literature that explains the essential experimental dependencies. Related color center effects in phosphors including defect generation considerations for long-term brightness deterioration are also presented.

The various phenomena which contribute, each in its own degree, to the depreciation in fluorescent lamp performance are often quite complicated. One such phenomenon is due to color center dynamics occurring in the phosphor. A review of the role played by color centers in the deterioration of lumen output of phosphors with special attention to the halophosphates is presented with subsequent generalizations on defect considerations for lamp phosphors.

Ever present in solids are defects. Defects are categorized (1, 2) as point defects and extended defects, the latter considered as sizable aggregates of point defects that together constitute dislocations, voids, or bubbles. Typical examples of point defects are host interstitials or vacancies which are termed intrinsic defects and impurities, an extrinsic defect; a small complex or cluster of these simple defects is also considered a point defect.

Solids whose bonds are predominantly ionic present bandgaps sufficiently wide that these defects and/or their charge modifications often exhibit absorption structure in the u.v., visible, or infrared and are collectively termed "color centers."

High u.v. irradiation may induce new and/or significantly increased color center absorption in the u.v. and visible regions especially. This signals generation, modifications, and interactions of and between defects. Often defect interactions which tend to bring about a diminution of these induced absorptions and their associated defects are initiated by less energetic u.v. and visible radiation as well as thermal treatments. All defects and their interactions occurring in a solid will here be regarded as constituting the defect system of the solid.

The ideal lamp phosphor should absorb and convert all of the u.v. of the lamp discharge to the appropriate visible emission with quantum efficiency of at least unity. In order that all of this visible emission should escape the phosphor layer, the phosphor host lattice must present an energy bandgap sufficiently wide to pass all visible electromagnetic radiation (≥ 3.5 eV). Most phosphors are constituted of a nonfluorescing host lattice into which specific impurities are purposely doped in order to absorb the u.v. of the discharge and emit it as visible radiation. The absorption and emission processes may be accomplished by a single type of impurity in which case it is called an activator or they may be accomplished separately, be unlike impurities whereby an absorber (called the sensitizer) transfers its excitation energy to the emitter (the activator) by some energy transfer process (3). If only the activator or sensitizer, hereafter together constituting the activator system of the solid, is to absorb the u.v. radiation, then the bandgap of the host lattice must pass the u.v. of the discharge additionally. For an Hg discharge this corresponds to a bandgap of ≥ 6.8 eV. The activator system may also be composed, at least in part, of host ions and/or ion complexes. In this case the u.v. is generally absorbed by the host whereby all excitation is ideally transferred to the activator which subsequently emits in the visible.

The defect system can undermine the aforementioned intent of the ideal phosphor, thus lowering its efficiency in essentially three ways as symbolized in Fig. 1. In process 1 the defect system may compete with the activator system for the exciting radiation. Visible absorption caused by defects can reduce activator emission before it is able to escape the phosphor layer in 2. Additionally, entities of the defect system may be intimately connected with or in communication with those of the activator system resulting in a direct nonradiative transfer of excitation energy from the activator system to the defect system. This loss is symbolized by process 3. The relative importance of these

Key words: defects, luminescence, ultraviolet, stoichiometry.

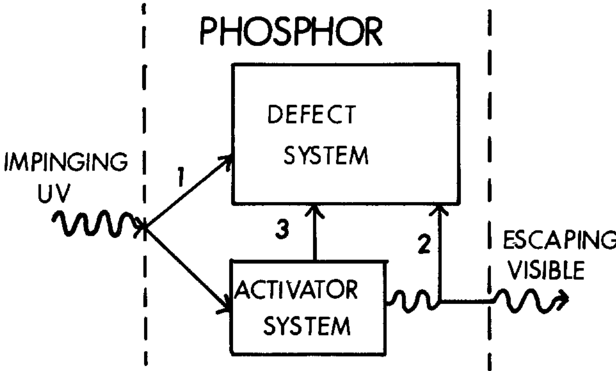

Fig. 1. Schematic of energy loss processes to the defect system of a phosphor.

three loss processes is dependent on the particular phosphor at hand.

Many lamp phosphors show color center absorptions with resulting brightness degradations (4, 5), but none have been analyzed so thoroughly as the halophosphates. Calcium halophosphate, the predominantly used commercial phosphor in fluorescent lamps, shows significant depreciation in brightness under Hg u.v. radiation comprised of the 185 and 254 nm components. A review of the results of the many investigations in the literature on this depreciative effect is of interest for a general understanding of this important phosphor as well as a fruitful example of the typical effects that can occur in other phosphors.

Calcium Halophosphate Depreciation Due to Color Centers

First, the extent and rapidity of this effect will be presented. After a look at the relevant structural aspects of the halophosphates and their probable sites for impurity inclusion, I will examine the experimental results associated with high u.v. radiation correlated with crystal preparation conditions. On the basis of experimental findings, a model of color center dynamics in this phosphor, chosen from the literature, is presented which explains the experimental dependencies and behaviors as well as revealing the deleterious workings of unwanted defects.

General lumen dependencies.—There occurs a rapid deterioration in the lumen output of a halophosphate lamp within ~10 min of lamp life after which time this deterioration onslaught saturates resulting in ~10% lumen loss, 3/4 of which is attributed to overall phosphor efficiency degradation brought on by Hg u.v. irradiation. This lumen loss is depicted in Fig. 2. This short-term depreciation behavior common to various phosphors (5) is generally characterized as exhibiting an initial onslaught of depreciation, the effect of which more or less quickly reaches a saturation level as shown by the dotted line in Fig. 2. This saturation level is defined relatively and more correctly represents

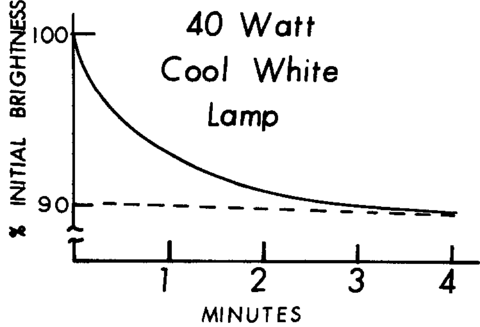

Fig. 2. Typical short-term lumen depreciation of a 40W cool white lamp. Dotted line represents short-term saturation level.

a time domain of a considerably slower depreciation rate.

With regard to the Hg u.v. irradiation of the phosphor, Singleton and Suchow (6) showed that the extent of the depreciation at the saturation level is dependent only on the ratio of the intensity of 185 to 254 nm radiation; the extent being more severe for an increased intensity ratio of the 185 to 254. Moreover, the rate at which the saturation level is attained for a fixed intensity ratio increases with increasing total intensity of radiation.

When the intensity ratio is held fixed the amount of brightness loss is reduced for increased Sb concentration (5, 7). Increasing the concentration of Mn increases the severity of the saturation level (5), but only in the presence of an oxygen-containing atmosphere, otherwise the saturation is independent (7) of Mn concentration. Vrenken *et al.* (8) illustrated the reduction in short term lumen depreciation as the Cd concentration is increased. Figure 3 shows the short-term time dependence of this effect in a 40W cool white lamp. The time dependence of the short-term depreciation can be fitted to a sum of three exponential terms of the same form as in the Butler-Lowry maintenance equation; however, the time constants are, of course, very short. The total short-term depreciation effect is accomplished in ~6 min. Incorporation of nonemitting elements other than Cd can also reduce lumen depreciation (5, 9), but not as effectively as Cd. Cs (10) was found to improve initial brightness as well as maintenance. Apple (11) showed that a halophosphate rapidly quenched from 1150°C will show less short-term lumen loss than one that was slowly cooled.

Short-term brightness loss can be recovered completely after annealing the sample to 500°C (8, 12). Approximately 50% recovery takes place if the sample is irradiated by 254 nm radiation alone (6, 8, 12). Visible radiation is much less effective in the recovery process than the 254 nm radiation (10).

Any defect system model describing the interactions taking place within the phosphor should explain these effects.

Halophosphate structure and dopant sites.—Calcium fluorophosphate forms in the hexagonal fluorapatite structure, space group $C6_3/m$, with two molecules of $Ca_5(PO_4)_3F$ per unit cell (13-15). Figure 4(a) shows the manner in which the crystal is constituted. Each of the large circles in the upper portion represents the group of ions shown below. The plane of the large circles is the mirror plane. These planes are stacked upon each other with the ions in the circle of each successive plane rotated by 60 degrees. The Ca(I) ions are situated between the planes. The dashed rhombus outlines the unit cell containing 42 atoms. The fluorine ions at the center of the circles sit directly above each other as more planes are added on. These fluorine ions follow the direction of the crystal axis and constitute

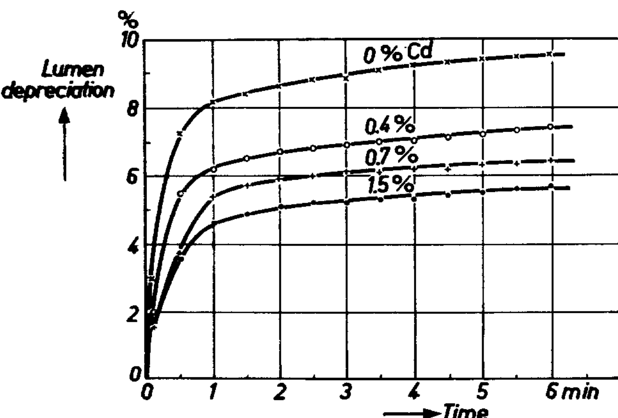

Fig. 3. Lumen depreciation in 40W cool white fluorescent lamps with increasing cadmium percentage as a function of time. After Vrenken *et al.* (8).

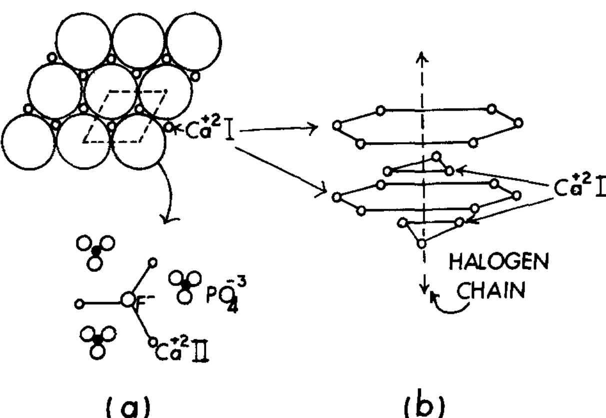

Fig. 4. (a) Diagram of fluorapatite structure. Each circle represents the group of atoms shown below. The circles constitute a plane perpendicular to the c-axis. The CaI ions are behind the plane of the circles and the dashed rhombus outlines the unit cell. (b) Diagram illustrating the orientation of the halogen chain in the apatite structure devoid of phosphorus and oxygen atoms.

by themselves a one-dimensional chain of fluorine ions. The distance between these chains is 9.37Å while the distance between the fluorines of a given chain is 3.44Å. Figure 4(b) illustrates the chain environment devoid of the phosphate groups. The fluorine chain will play a significant role in the defect system in this phosphor.

Calcium enters the lattice as Ca^{2+} (p^6 configuration) in two inequivalent sites labeled Ca(I) and Ca(II) with relative abundance of 2 to 3, respectively. The Ca(II) sites reside at the apexes of an equilateral triangle centered on the fluorine and are in good communication with the chain, whereas the Ca(I) sites are more isolated.

Calcium chlorophosphate (16, 17) is a hexagonal chlorapatite above 212°C but monoclinic below this temperature. The Cl ion (radius = 1.81Å) is larger than the F ion (radius = 1.33Å). This causes a slight expansion of the lattice with the Cl ions displaced slightly above and below the would-be F position. If at least 36% of the halogens in the mixed chlorofluorophosphate are fluorines, then the halophosphate remains at all temperatures in the hexagonal apatite structure (18).

All impurities appear to occupy the calcium sites (19). Sb substitutes in the lattice as Sb^{3+}. Its s^2 configuration, leaving it nonparamagnetic, makes it uncertain as to its occupation position. By charge compensation arguments (20) it is assumed to occupy the Ca(II) site with an oxygen substituting for the neighboring fluorine ion. Dale (21) has some experimental evidence suggesting the substitution of Sb for phosphorus. It will be assumed in this report that Sb resides in the Ca(II) site, however, the model and conclusions would not be substantially altered if Sb actually does substitute for phosphorus.

Manganese goes into the lattice as Mn^{2+} ($3d^5$ configuration). It can occupy either the Ca(I) or Ca(II) sites and several investigations (22-24) have attempted to determine the relative proportionment of manganese among these calcium sites. At very low concentrations Mn preferentially occupies the Ca(II) sites, but as the Mn concentration increases, preference to occupying the Ca(I) sites dominates (25). At normal concentrations (1%) approximately 65% of the Mn resides in the Ca(I) sites which are termed Mn(I). Extensive (20, 23, 25-27) optical and ESR investigations show several modifications to the site symmetry and, therefore, fluorescence characteristic of Mn in Ca(II) sites, likewise termed Mn(II). These modified Mn(II) sites are symbolized as Mn(Cl), Mn(Sb), Mn(IIm) and refer to the Mn ion in the Ca(II) site that is closely neighbored by a Cl ion, Sb ion, and oxygen-vacancy complex, respectively.

Cd goes into the lattice as Cd^{2+}. Since it is essentially the same size as the Ca^{2+} ion, it is assumed to fit into both calcium sites.

Spectral characteristics.—It is the purpose of this section to introduce those spectral properties of halophosphate crystals which are most pertinent to the color center depreciation dynamics addressed in a later section.

Unirradiated characteristics.—The bandedge of halophosphates occurs at wavelengths shorter than 160 nm corresponding to forbidden energy gaps of >8 eV (15). Nevertheless, absorption can occur in the 250 and 185 nm regions of unactivated and unirradiated samples and has prompted several studies (15, 17, 28). Various crystals of fluorapatite were grown (see Fig. 5) with melts of varying degrees from stoichiometry (29). The dependencies of these absorptions on melt conditions relate to their identification with imperfections. The absorption band peaked at 250 nm is attributed (26) to a complex consisting of an oxygen substitution sandwiched by two vacancies along the fluorine chain termed the "X center." The absorption in the 185 nm region is attributed to another defect somewhat similar to, but distinct from, the X center and is termed the "Y center." The strength of the X center absorption present in the crystal is quite strongly dependent on melt conditions (see Fig. 6) An excess in CaF_2 reduces the amount of X centers formed whereas a slight excess of $CaCO_3$ greatly increases X center formation. Obviously, if a low concentration of X centers is desirable in the resulting apatite, the melt should be excess in CaF_2 and deficient in $CaCO_3$.

The amount of overall X band absorption, and therefore the number of X centers, decreases with increasing temperature (29). The X band absorption, though, eventually returns to its initial value when the crystal is brought back to room temperature implying a reformation of X centers. The Y center exhibits the same dependencies as the X center, but to a much smaller degree, suggesting that it is a more stable defect complex than the X center.

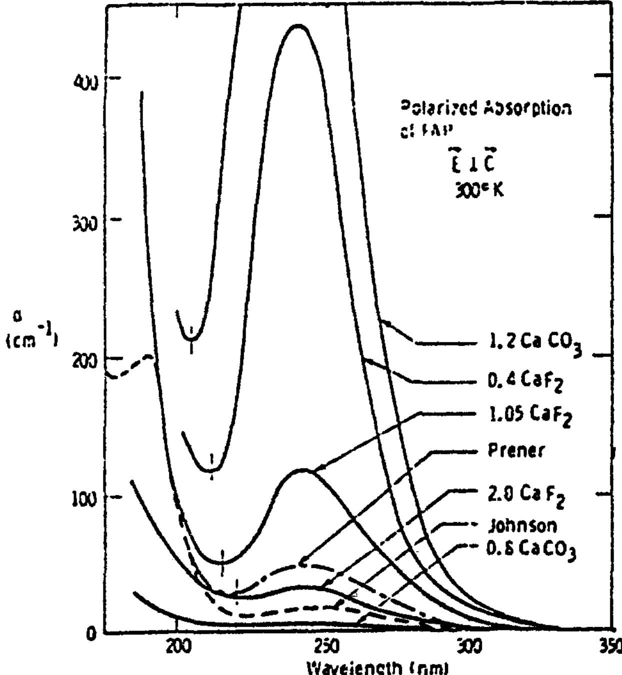

Fig. 5. Absorption of fluorapatite (FAP) in the 185 and 254 nm regions at 300 K. The curves are labeled to indicate the stoichiometry of the melt from which each crystal was grown. 1.2 $CaCO_3$, for instance, means that this melt was stoichiometric except for $CaCO_3$ which was 1.2 times the stoichiometric value. After Warren (29).

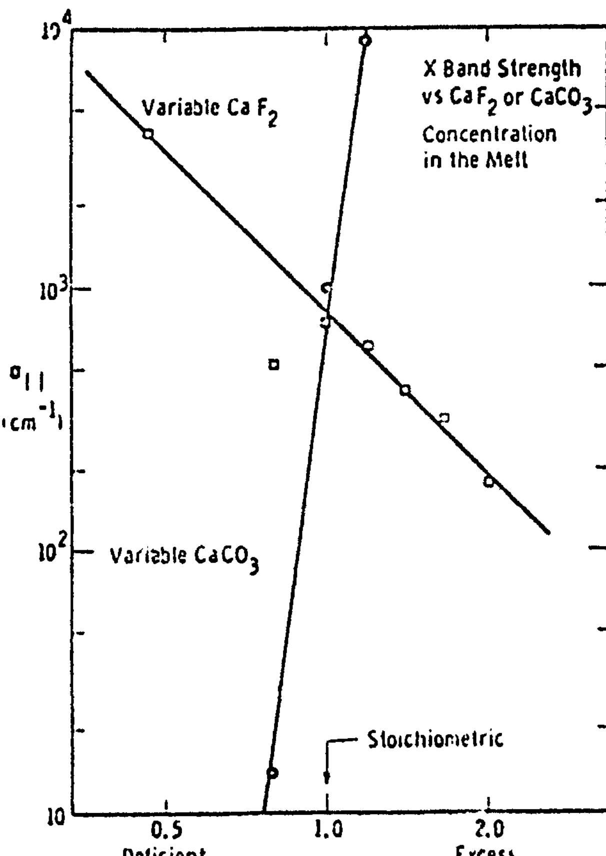

Fig. 6. Dependence of the X band absorption on stoichiometry of the melt. After Warren (29).

The inclusion of Mn and Sb suppresses the X center absorption. Apparently, there occurs a gettering phenomenon whereby some of the oxygen-vacancy complexes are gettered by some Mn(II) sites resulting in a modified Mn site called Mn(IIm).

Figure 7 shows a typical fluorescence spectrum (7) of fluorophosphate doubly activated by Sb and Mn. The absorption spectrum [from Ref. (30)] of Sb in a single crystal of fluorophosphate is presented in Fig. 8. It is important to note for later consideration that the absorption at 185 nm is stronger than at 254 nm. In the presence of an Hg discharge the vast amount of Mn is excited by energy transfer from Sb because of the preponderance of Sb absorption in the region of the Hg emissions and the efficiency of the Sb-Mn transfer process (15, 31).

Cd absorbs below 200 nm. Figure 9 shows a diffuse reflection spectrum of Ca, Cd chlorofluorophosphate for several dopant levels of Cd. Cd does not fluoresce

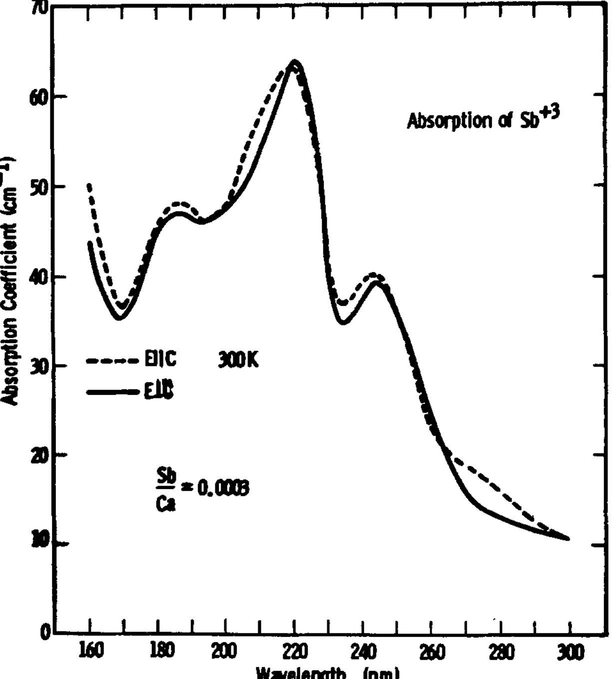

Fig. 8. The absorption of a single crystal of calcium fluorophosphate containing 0.03 atomic percent antimony. After Warren et al. (30).

in the visible and essentially nonradiatively degrades its excitation energy. In phosphate lattices which are heavily doped with Cd or with complete replacement of Ca by Cd, there is efficient Cd to Mn energy transfer occurring. However, it is presumed that in the normal halophosphates employed in lighting, such a transfer process is of negligible contribution.

The incorporation of Cs into the unactivated fluorochlorophosphate actually increases the reflectivity of the host lattice (10). A comparison of the reflectivities of the host matrix, Cs-doped and a standard (no Cd) Sb, Mn-activated halophosphate is presented from Ref. (10) in Fig. 10.

Irradiated halophosphates.—Hg u.v. irradiation induces many absorptions throughout the visible and u.v. as well as a variety of ESR spectra (6, 12, 16, 29, 30, 32-34) in the halophosphates. This coloration occurs in fluoro, chloro, and all proportions of chlorofluorophosphates with only unessential variations in the shapes and peak positions of the induced absorption bands and are therefore associated with defects or color centers common to the halophosphate structure. Mechanical grinding increases the number of defects present in the halophosphate as well as the propensity

After Narita *et al.* (10).

to generate new defects under continued exposure to x-rays (36, 37).

Of specific importance is an induced absorption (29) occurring in the 254 nm region due to the u.v. irradiation of Hg at 185 nm. This induced absorption should be distinguished from the aforementioned "ingrown" X center absorption in the region of 254 nm which can be suppressed by melt conditions and activator inclusions. Narita *et al.* (10) showed that the proclivity of the 185 nm irradiation to induce 254 nm absorption is reduced in proportion to the extent of the absorption introduced at 185 nm by metal additives to the halophosphate.

A measurable decrease in the relative fluorescence and concentration of paramagnetic manganese ions following high u.v. irradiation was found by Skreblyukov *et al.* (38).

Temperature annealing of the u.v. irradiated halophosphate leads to a complete restoration of the concentration of paramagnetic manganese ions, the recovery of phosphor brightness, and to a complete bleaching of all induced absorptions (38). Thermoluminescence however, accompanies the thermal treatment only for activated halophosphate (6) and is composed of the characteristic emissions of Sb^{3+} and Mn^{2+} (38, 40).

Radiational treatment by 254 nm and visible radiation of samples that have been irradiated by 185 nm u.v. shows a bleaching of the induced absorptions (6), especially of the 254 nm induced absorption. However, bleaching with visible light is in no way as effective as 254 nm radiation (10). Radiational bleaching does not bring about the complete recovery of phosphor brightness that a 500°C thermal bleaching affords.

In summarizing the essential radiation dependencies above, it is seen that sample irradiation of 185 nm Hg emission is in part absorbed by a "primitive" defect termed the Y center which is present in the virgin phosphor. Such irradiation induces a defect (color center) absorption in the region of 254 nm which can also bleach out under 254 nm Hg irradiation. The relevant defect absorption locations are presented in Fig. 11. The absorptions are labeled according to Ref. (29, 30). The top of the figure presents regions of absorption in the unactivated and unirradiated halophosphate. Identified are the absorptions due to the X and Y centers which are not induced by high u.v. irradiation, but are ingrown defects. No attempt is made to present the absolute or relative strengths of the absorptions in these figures; only the positions of certain particular absorptions are relevant to the proposed dynamics discussed presently. The middle spectrum presents the general locations of the many absorptions that are induced by high energy irradiation of the unactivated halophosphates. These absorptions are taken from Ref. (12, 14, 29, 30, 32). They were induced by high energy irradiations from 185 nm of Hg, x-rays, and those associated with the tesla coil.

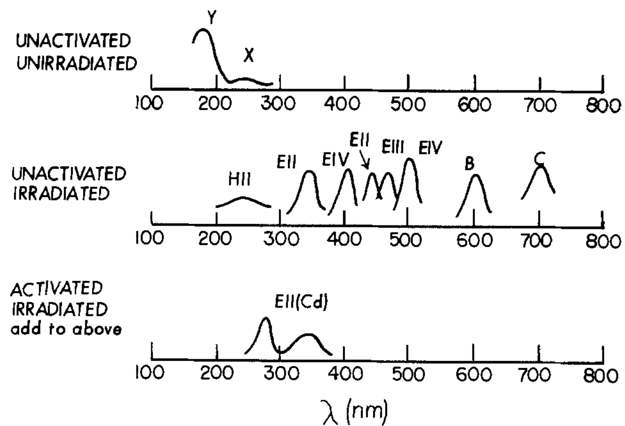

Fig. 11. Schematic of some of the defect absorptions occurring before and after u.v. irradiation in unactivated and activated Ca fluorophosphate. It is the intent here to show only the relevant spectral positions of these color center absorptions and not any absolute or relative (even among the defects) absorption strength.

When the halophosphates are activated by Sb, Mn, and Cd, two new induced absorption bands appear under high u.v. excitation in addition to those that occur in the unactivated phosphor. For clarity, these two bands are shown alone in the lower part of the figure. They are labeled EII(Cd), the reason to be explained in the next section. The induced absorption in the region of 250 nm labeled H(II) should be noticed.

In addition to the spectral evaluation of these absorption bands induced by high u.v. irradiation, extensive electron spin resonance (ESR) investigations were performed (16, 26, 29, 30, 32, 35). There occurred a good amount of ESR spectra that was induced by high u.v. irradiation.

A particular advantage of ESR spectral studies is that the spectra are highly dependent on the symmetry of the entities producing the spectra. As a result, given a particular ESR spectrum, a fairly probable symmetry for the entity can be surmised which is extremely propitious to the identification of the defect responsible for the ESR spectrum.

The various ESR and optical spectra were closely correlated under u.v. irradiation processes and subsequent temperature variations and thermal and radiational bleaching treatments. Through these correlations various defects were identified along with particular dependencies and interactions with other identified defects. The defects are often referred to as "color centers," and it is their specific definition and interactions with which I will be concerned in the next section.

Defect interaction model.—The identification of all the defects are not unique and discrepancies do occur among different papers. All concur, though, that the defects are constituted of vacancies, oxygen substitutions, or combinations thereof along the halogen chain in various charge states. The defect model proposed in this section is taken from Warren (29) and Warren *et al.* (30) since these papers carried through most completely an analysis of the overall phosphor depreciation effects. It was initiated by Piper, Kravitz, and Swank (32).

Identification and definitions of defects in unactivated calcium fluorapatite.—According to conditions associ-

ated with the growth process there will occur to a greater or lesser extent two primitive defects in the fluorapatite lattice. They are (*i*) the oxygen anion substitutions for fluorine anions and (*ii*) fluorine vacancies.

In Fig. 4 it was noted that the fluorine anions constituted one-dimensional chains running along the crystal axis. The two primitive defects occur consequently on the fluorine chain structure. Below is shown a string of blocks symbolizing the fluorine chain. Di-

$F^-|F^-|F^-|F^-|F^-$ FLUORINE CHAIN

$F^-|F^-|O^-|F^-|F^-$ $=(O)^-$ = Oxygen Substitution

$F^-|F^-|\ \ |F^-|F^-$ $=(V)^+$ = Vacancy

rectly underneath this chain is shown two fluorine chains in which a fluorine ion has been replaced by an oxygen anion and a vacancy, respectively. To the right of these chains is the notation used to symbolize the corresponding defect: O for oxygen and V for vacancy. The superscript outside of the parenthesis designates the effective charge associated with the defect relative to the perfect fluorine chain.

Groupings or clusters of these primitive defects can occur. Two defects are symbolized below

$$(O)^- + (V)^+ \rightarrow (OV)^\circ \quad [1]$$

$$(OV)^\circ + (V)^+ \rightarrow (VOV)^+ \quad [2]$$

The $(OV)^\circ$ represents a neutral complex defect formed by the combining of the two, presumably attractive, primitive defects. This defect tends to be fairly stable. The $(VOV)^+$ complex defect is formed as symbolized and is less stable than the $(OV)^\circ$ complex. Apparently, no other clustering affords sufficient stability to be considered to exist leaving only these four defects present in the unirradiated halophosphate crystal.

Table I gives the four defects listed and named along with their absorption characteristic for easy reference.

Defects can reapportionate their relative abundance in accordance with a mass action law if there is sufficient mobility among themselves to afford their interaction. Although the oxygens are considered relatively immobile here, vacancy mobility is sufficient to allow any reapportionment.

To examine this point, it is noted that the equation for Y center formation

$$(O)^- + (V)^+ \underset{k_r^Y}{\overset{k_f^Y}{\rightleftarrows}} (OV)^\circ \quad [3]$$

gives an equilibrium concentration ratio for the defects

$$\frac{[(O)^-]\,[(V)^+]}{[(OV)^\circ]} = K_1 = \frac{k_r^Y}{k_f^Y} \quad [4]$$

Likewise in X center formation, the equation

$$(OV)^\circ + (V)^+ \underset{k_r^X}{\overset{k_f^X}{\rightleftarrows}} (VOV)^+ \quad [5]$$

gives

$$\frac{[(OV)^\circ][(V)^+]}{[(VOV)^+]} = \frac{k_r^X}{k_f^X} = K_2 \quad [6]$$

Table I. Defects in the unirradiated, unactivated halophosphate

Name	Defect	Optical absorption (nm)
Oxygen	$(O)^-$	None
F vacancy	$(V)^+$	None
Y center	$(OV)^\circ$	~185
X center	$(VOV)^+$	~250

which is further converted to

$$\frac{[(O)^-]\,[(V)^+]^2}{[(VOV)^+]} = K = K_1K_2 \quad [7]$$

Equation [7] shows that since $K_2 < 1$ and because of the quadratic dependence in the numerator, high oxygen and vacancy inclusions will cause more than proportionately higher concentrations (dominance) of X centers. Similarly, Eq. [4] shows that Y center concentration should be favored at lower oxygen vacancy concentrations. Such a behavior was elucidated by Warren (29) through monitoring the relative number of u.v. induced defects arising from samples variously prepared to emphasize different concentrations of the primitive defects. This analysis is also in agreement with the reduction of X center absorption under increasing temperature; as temperature is increased, the equilibrium constants K_i increase which favors the reduction of the more complex defects.

Under high u.v. excitation these defects (or centers as they are also called) are converted to "modified centers." The essential modification of the four centers is that they can either (*i*) lose an electron in which case the resulting center is classified as an H center (H implies trapped hole) or (*ii*) gain an electron in which case the resulting defect is classified as an E center (E implying excess electron). The source or sink, as the case may be, for the electrons is simply another defect center. Therefore, under irradiation, defects are swapping electrons resulting in their own modification as well as that of other defects. Many of these modified defects have their own associated absorption bands which clearly have been induced through creation of the modified defects by high u.v. excitations. These modified centers are referred to as "color centers." Some of the H and E centers that occur under high u.v. excitation are listed in Table II along with their construction, evolution, and comments (note: e = electron, h = hole, P = permutation). E and H centers can be destroyed by converting into each other or reverting to one of the four original defects under certain radiations or heating of the crystal (*i.e.*, radiational and thermal bleaching treatments). These processes will be enlarged upon presently.

Defect dynamics in unactivated crystals.—The defect dynamics are initiated by the 185 component of the Hg radiation. Absorption of the 185 nm radiation by the Y center causes it to lose an electron to the conduction band resulting in itself being converted to an H(I) center. This H(I) center may either remain so or with a 50% probability dissociate into an H(II) center and a vacancy which thermally moves off.

The electron that has been freed to the conduction band will be subsequently trapped by a defect located somewhere else in the crystal to produce an excess electron center (an E center). The defects which are available to trap this electron are simply the four centers; a vacancy, an oxygen substitution, an X center, and a Y center. The oxygen center, presenting an effective negative charge, would presumably repel the conduction electron and thus contribute no cross sec-

Table II. Relevant u.v. induced defects*

Name	Defect	Evolution	Comment
	H centers (hole trap)		
H(I)	$= (OV)^+$	$(OV)^\circ$ + h	
H(II)	$= (O)^\circ$	$(O)^-$ + h	absorbs ~250 nm
	E centers (electron trap)		
E(I)	$= (VOV)^\circ$	$(VOV)^+$ + e	
E(II)	$= (V)^\circ$	$(V)^+$ + e	absorbs 360, 450 nm
E(III)	$= (OVV)^\circ$	$P(VOV)^+$ + e	
E(IV)	$= (OV)^-$	$(OV)^\circ$ + e	
B	$= (OVV)^-$	$P(VOV)^+$ + 2e	

* h = hole, e = electron, P = permutation.

tion to the capture. The other three defects can be converted to their respective E centers, namely, E(II), E(I), and E(IV). The relative occurrence of these three trapping processes is a function of the crystal growth conditions according to the mass action argument. E(I) and E(IV) thermally decompose, each to an E(II) center and, respectively, to a Y center and an oxygen substitution afforded by the presumed mobility of the E(II) center.

The action of the 254 nm radiation tends to reverse this resulting E(II) production of the 185 nm radiation through its absorption by the H(II) center which resulted from thermal decomposition of the ionized Y center. Upon this absorption the H(II) center releases a hole to the valence band as it reverts to a simple oxygen substitution. The released hole is then trapped by an E(II) center causing it to revert to a simple vacancy. This is the presumed process of radiational bleaching. The vacancy can combine with the oxygen substitution to become a Y center.

Increased mobility of the E(II) centers under increasing temperatures allows them to annihilate with H(II) centers, thus creating Y centers again. This process accounts for part of the thermal bleaching.

The annihilation processes result in the replenishment of the Y centers which again causes the regeneration of E(II) centers. Obviously, there will exist some steady-state number of E(II) and H(II) centers which will evolve whose number is dependent upon the ratio of 185 to 250 nm radiation penetrating into the phosphor.

Dynamics of activated halophosphates.—The processes just enumerated appear in large measure to be taking place in activated halophosphates. The influence of the dopants does not alter the essential character of the processes, but modifies somewhat the conditions and parameters attendant to the processes. These influences of the dopants Mn^{2+}, Sb^{3+}, Cd^{2+}, and Cs^{+} are summarized below.

The presence of Mn does not decidedly affect the defect dynamics mentioned above. There is some (5, 38, 39) oxidation of Mn but this appears to be minor, most likely a surface effect. Nevertheless, oxidized Mn will reduce brightness and possibly supply electrons to other defect entities.

Sb presents two effects in conjunction with the defect system. First, it absorbs both Hg u.v. components with the 185 nm component more strongly absorbed than the 254. This allows Sb, under increased concentration, to compete more favorably with Y and H(II) absorptions and to cause a reduction of the 185 to 250 nm intensity ratio within the phosphor which favors less H(II) absorption and a lower steady-state number of E(II) and H(II) centers. Second, Sb is believed (30) to moderately trap an E(II) center residing on a neighboring chain. Such a trapped E(II) center may (30) quench an excited Sb through an Sb → E(II) energy transfer process. The fact that Sb emission appears in thermoluminescence (38) may suggest a change in the oxidation state (41) of some Sb due to the interaction with a u.v. induced defect. Nevertheless, a significant loss in Sb excitation energy is presumed degraded by an induced defect interaction. The net result of these effects is that increased Sb concentration should reduce the severity of lumen depreciation consistent with the experimental observations.

Cd also presents two effects similar to those of Sb. First, by its absorption of 185 nm radiation it reduces the ratio of 185 to 254 nm radiation affording a smaller steady-state number of induced color centers to rob Sb excitation energy. Second, it strongly traps an E(II) center [termed EII(Cd)] again reducing the possibility that an E(II) center may directly rob excitation energy from Sb.

Incorporation of Cs rather than Cd in an activated halophosphate system actually increases the initial light output relative to a Cd or non-Cd halophosphate phosphor. This is due to the fact that the presence of Cs increases the transparency at 254 nm of the unactivated halophosphate matrix so that the activator system when incorporated can more efficiently compete for the exciting radiation (10). Cs, however, does not present any absorption in the 185 nm region that would offset induced absorption at 254 nm. In light of this, the smaller brightness depreciation of the Cs containing phosphor compared even to the Cd containing phosphor is surprising and is attributed to a Cs fluxing action in the ignition process to produce a more defect-free phosphor (10). It may also be that the Cs presence inhibits the direct color center interactions with excited Sb that degrade the excitation energy since Cs can reside close to Sb as a charge compensator. Last, the u.v. induced absorption throughout the visible are generally considered of negligible importance in the loss of halophosphate brightness (10, 30).

Figure 12 (analogous to Fig. 1) symbolizes the essential loss processes. As mentioned, process 2 is assumed negligible with perhaps process 3 accounting for the most severe loss, yet it is triggered by the existence of process 1.

The defect dynamics considered so far explain the short-term depreciation in halophosphates in terms of the number density of primitive defects present in the virgin phosphor. The saturation level of the short-term depreciation in Fig. 2, as stated earlier, represents a much slower rate of depreciation. The contribution of color center or defect phenomena to this long-term phosphor depreciation in a lamp environment is not known. Certainly processes which would continually increase the defect number density of the phosphor over the long term would cause a progressive depreciation in lumen output. Such processes will be elaborated upon in the next section.

Other Defect Examples and Considerations of Short- and Long-Term Defect Mechanisms

Defects that can occur in phosphor-type solids in the lamp environment may be delineated into three broad classes:

1. The electronic class: no ionic defects are formed; just the electronic state of existing defects are changed as charge is moved around by photons inducing and bleaching color centers.
2. Photochemical class: new or additional atom or ionic defects are formed by a series of reactions beginning with a photoexcited electron.
3. Diffusional class: new defects are formed under precipitation, aggregation, or evaporation at extended defect locations or through external penetration of the phosphor by impurities.

The first class corresponds to a short-term adjustment of u.v. induced defects to the type and number density of ingrown defects. The latter two classes address the longer term generation and evolution of primitive defects. It is to these generative defects that the induced defects of class I adjust more or less quickly throughout lamp life.

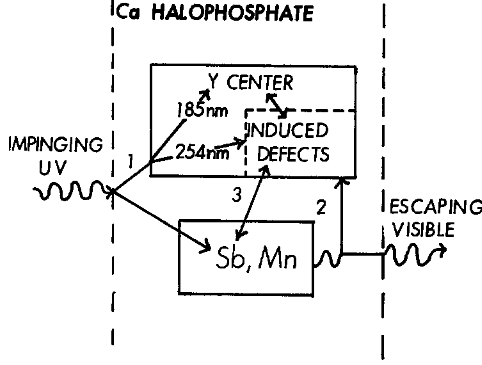

Fig. 12. Schematic of energy loss processes to the defect system of calcium halophosphate.

The ingrown and short-term induced defect dynamics of the halophosphates are a good example of the electronic class phenomena. The color center literature is abundant with other examples of this class. Under no guise of completeness or comprehensive analysis, a look at several other examples in oxidic lattices is of interest as important to lamp phosphors before consideration of generative defect processes of classes 2 and 3.

Reiterating, it can be said that the phosphor depreciation attributed to defect structures arises from (*i*) their possible absorption of u.v. excitation energy, (*ii*) visible absorption, and (*iii*) the fact that their presence can create an energetic environment which can capture and degrade energy from excited entities of the activator system. Impurities and intrinsic host defects are generally intimately connected and the very presence of impurities can necessitate the presence of intrinsic defects. Two major influences on the nature of this connection are growth stoichiometry and charge compensation mechanisms. Some examples of these influences are given below.

The impurities that go into the matrix may be intentional, such as entities of the activator system, or unintentional and undesired. Unwanted doping by transitional metal ions of numerous oxides have been detected and shown to be a promoting factor of color center phenomena as for example, $LiNbO_3$ (42, 43), $CaWO_3$ (44, 45), and Al_2O_3 (46). This is due to oxide lattices often having a high incorporation coefficient for transition metal ions (47, 48). Electron transfer between cation impurities or a cation impurity and a defect is considered (49) to occur most easily with the increased covalency of the oxide compounds. This, along with the easy valence state changes of transition metal ions, can lead to a tendency for multiple interimpurity charge compensation schemes (50, 51). Iron and manganese impurities substituting in trivalent cation positions may compensate as Fe^{3+} and Mn^{3+} or as Fe^{2+}-Mn^{4+} (48, 50) local pairs. In metal vanadates the VO_4^{-3} sublattice may trap an electron forming a VO_4^{-4} complex from easily oxidized impurity cations (52). So those impurity cations which have easily changed oxidation states, including some of the rare earths (53, 54), will afford a high probability of bringing about a variety of induced defects that may interfere with phosphor activation.

It was seen that growth stoichiometry affects defect density in halophosphates. Likewise $CaWO_4$ whose luminescence centers are the WO_4^{-2} complexes must be prepared with an excess of WO_3 due to its volatility. This excess can give rise to WO_3 defect centers in the $CaWO_4$ lattice (55).

The deformation of phosphors under milling can introduce lattice distortions that result in the generation of defects. For the case of halophosphate, the brightness of luminescence decreases by as much as 15%-20% according to the time of grinding which increases the dislocation density from 10^8 to 10^{10} cm^{-2} (36).

Since impurities will be present, charge compensation must occur and, therefore, intrinsic lattice defects are always present. The nature of the lattice, specifically with regard to anion and cation size, will often determine the manner of its natural tendency to charge compensate through intrinsic defect generation. Realization that some natural mechanism may be particularly injurious to efficient operation of an activator system allows possible alternative, less injurious compensation mechanisms to be introduced. As an example, trivalent impurity cations in MgO are charge compensated by positive ion vacancies (56). Such a defect, appearing negative in the lattice, can trap holes causing the lattice to more easily supply possible unwanted reducing electrons to activator entities. Generally it can be said that if something is a hole (electron) trap, it creates a tendency for something else to be an electron (hole) trap. To avoid an activator from gaining or losing an electron in such a tendency-provoking defect environment, a compensating impurity may be introduced that, in a noninjurious way, fully absorbs the effect of the tendency. Easily oxidized impurities are hole traps while those easily reduced are electron traps.

Some activator systems may be particularly sensitive to a specific type of intrinsic defect. An alternative compensation scheme that suppresses the injurious intrinsic defect can restore the efficiency of the activator system. An example of such a circumstance (57) is $SrAl_{12}O_{19}:Eu^{2+}$. In aluminates, inter Eu^{2+} energy transfer under increasing Eu concentration allows the excitation energy to be transported over increasingly larger distances through the lattice before luminescence can occur. The transfer is so good that lattice defects where a nonradiative transfer can occur governs the quantum efficiency even at low Eu concentrations. Strontium aluminate:Eu^{2+} with addition of a small amount of Mg^{2+} ions incorporated at Al^{3+} sites is strongly quenched owing to the creation of oxygen vacancies that offset the reduction of positive charge in the lattice. The oxygen vacancies injurious to Eu^{2+} efficiency can be prevented by adding equal quantities of La^{3+} ions with Mg^{2+} which allows the efficiency of $SrAl_{12}O_{19}:Eu^{2+}$ to be maintained (57).

Bunch (58) showed a Mollwo-Ivey relation between peak color center (oxygen vacancy type) absorption energy and average oxygen ion spacing in several oxides of group II and group III metals. The absorption energy increases as the average oxygen spacing decreases. Such a relation can assist in predicting the deleteriousness of a specific defect according to the approach of the defect's resonance energy with that of an activator's in different oxide host lattices.

Long-term brightness depreciation due to color center phenomena arises from the generative defect processes under the photochemical and diffusional classes. The general conditions promoting such processes are considered now. The strength by which an atom is bound in its position in a solid has a profound effect on the damage that can occur in the solid under radiation. The atoms in ionic solids are bound to their positions by the electrostatic binding energy

$$\text{Electrostatic binding energy} = \frac{A(Ze)^2}{r^2}$$

where the ionic charges are $\pm Ze$, r is the nearest neighbor distance, and A is the Madelung constant ($\sim$1.6-1.8). The electrostatic binding energy for alkali-halides ($Z = 1$) are from 6 to 10 eV whereas that for the alkaline earth oxides ($Z = 2$) is 30 to 40 eV. The higher binding energy of the alkaline earth oxides is of course responsible for the hardness and refractory nature of MgO compared to NaCl, but also for the fact that MgO is quite resistant to radiational damage unlike NaCl. The electronic excitations of alkali halides brought on by u.v. radiation have energies of 5-10 eV, which is sufficient to create defects since the atomic binding energies have the same range. In the alkaline earth oxides, on the other hand, the electronic excitations are still only 5-10 eV and clearly far less able to cause atomic displacements against 30-40 eV binding energies (2).

In the less homogeneous lattices of phosphors the local binding energy is the yardstick by which to measure propensity to radiation damage. Local binding energy will be quite sensitive to the local structure. A phosphor's ability to resist longer term color center depreciation is strongly dependent on its points of weak local structure where defect generating ionic displacements can occur more easily. Displacements can be driven by aggregation processes, gradient diffusions, or through the continual polarization stresses brought on by u.v. maintained induced defects. The last refers to a photochemical process. Typically, under u.v. excitation a self-trapped electron or hole may occur, possibly in response to hole or electron trap impurities. The lattice structure in the region of the

self-trapped entity may be sufficiently weak to give in to the local distortion of the self-trapped entity by local atomic rearrangements resulting in vacancy and/or interstitial creation (59, 60). Tamatani (49) has ascribed the severe and irreversible depreciation of the $K\beta$-Al_2O_3:Eu^{2+} phosphor to permanent defects caused by ion and/or vacancy diffusion instigated by a self-trapped electron. He states that the potassium and oxygen ions are loosely bound in the mirror plane between the spinel layers of aluminum and oxygen ions in the $K\beta$-Al_2O_3 lattice. Loosely bound ions near flaws or extended defects can also be precursors to new defect formation.

Loss of surface fluorine from halophosphates would allow new vacancies to diffuse into the phosphor adding to the defect populations. Last, phosphors that most easily permit Hg ions to diffuse into them should be degraded somewhat by either the direct presence of the Hg or the various other defects that its presence generates.

The processes due to color centers which lead to brightness depreciation in phosphors can be quite subtle and complicated as evidenced by the above examples. The design of phosphors resistant to color center effects will require judicious choice of additives to offset the color center interactions as well as minimizing as much as possible the primitive defects from which color centers are born.

Manuscript submitted May 22, 1980; revised manuscript received Aug. 4, 1980. This was Paper 212 presented at the St. Louis, Missouri, Meeting of the Society, May 11-16, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by GTE Products Corporation.

An Experimental Proof of Radiative Recombination Mechanisms of Electron-Hole Pairs at Activator Ions

Lyuji Ozawa*,[1]

Zenith Radio Corporation, Glenview, Illinois 60025

ABSTRACT

It has been shown that the concentration dependence curve of activator luminescence provides us with a powerful tool in studying cathodoluminescence. The experimental results reveal the excitation mechanisms of activator ions by irradiation of electron beam on phosphor crystals; two excitation mechanisms should be considered: (*i*) direct excitation by incident electrons, including internally generated secondary electrons; and (*ii*) indirect excitation through the mobile electron and holes generated by incident electrons. The experimental results also suggest a possible model that (*iii*) radiative recombination of electron-hole pairs only occurs at the activator ions showing two valences at the ordinary conditions, and (*iv*) the type of radiative recombination process at the activator ions is determined by the type of carrier which is first trapped.

It is generally observed that under ionized radiation, many inorganic crystals emit characteristic luminescence in the visible spectral region (1) caused by the chemical impurities (*i.e.*, activator ions); different crystals exhibit different luminescence efficiencies with the same activator ions. The variation in luminescence efficiencies, however, has been believed to be due to a difference in the probability of energy transfer from radiation-induced carriers of either charge (or excited host lattice) to the activator ions. In this report, we shall try to clarify experimentally these mechanisms of activator ions by incident electrons.

Electron beam irradiation of crystals creates equal amount of electrons and holes (EH's) *i.e.*, radiation-induced carriers, as well as exciting lattice ions in the volume V_d where the incident electrons have penetrated. Hence, there are three possible modes of excitation of activator ions: (*i*) direct excitation by incident electrons, including internally generated secondary electrons; (*ii*) indirect excitation by EH's (*i.e.*, radiative recombination of EH's); and (*ii*) some combination of the two. Even though quite different excitation mechanisms are involved, an ambiguity arises because the activator ions emit the same characteristic luminescence. We, thus, cannot distinguish the difference between the excitation mechanisms from the luminescence spectrum alone. It has recently been shown (2) that the concentration dependence (CD) curve of activator luminescence provides us with a powerful tool for better understanding of the excitation mechanisms of activator ions by incident electrons (10 keV). The type of the excitation mechanisms can be determined from the CD curves. This is explained for the CD curves illustrated in Fig. 1. Before the explanation of the CD curve, however, we must discuss the luminescence intensity measurements on the phosphor crystals.

Luminescence Intensity Measurements

In the study of luminescence intensities from phosphor crystals on the screen, we usually measure time-averaged luminescence intensities $\langle I\rangle$ which are proportional to the number of quanta emitted from the excited activator ions in unit time, on the assumption that each excited activator ion in the crystal emits a photon and returns to ground state. The activator ions are excited as a consequence of the action of the exciting energy carriers to activator ions in the crystals on the screen in unit time. Thus, $\langle I\rangle$ number of photons/sec/volume) from the phosphor crystals on the screen is expressed as a form of the volume integral in unit time. The phosphor screen is usually large *e.g.*, 1 cm^2) compared with the crystal size (*e.g.*, phosphor crystals are usually about 10 μm). In such a screen, the excitation of activator ions only occurs in the crystals in the first layer of the irradiation side because the penetration depth of the incident electrons (10 keV) is about 0.4 μm (3), and EH's are never transferred to other crystals [the crystal is covered with the surface recombination center of EH's (4)]. When the size of electron beam on the screen is kept constant for all measurements (it is usually so), $\langle I\rangle$ is proportional to the number of the excited activator ions in the finite volume V in the crystals arranged in the first layer on the fixed screen area (*i.e.*, cross-sectional area of electron beam) in unit time. Hence, $\langle I\rangle$ is proportional to a result of the volume integral of the action of the exciting energy carriers to activator ions in V and in unit time, which is expressed as

$$\langle I\rangle = k_1 \int_0^t \int_v NJ\, dvdt \qquad [1]$$

where N is the number of activator ions in V, J is the number of exciting energy carriers having entered (or generated) in V, and k_1 is constant. (In contrast, the measurement results of many physical properties are given by a form of the differential; *e.g.*, optical absorption, conductivity, lifetime of the excited state, and others.) For studying $\langle I\rangle$, we must take account of the volume integral, not the differential.

There are two ways of obtaining the solution of Eq. [1]: (*i*) a mathematical solution and (*ii*) a qualitative approach. In this study, we have taken the qualitative approach on the assumption that $\langle I\rangle$ (substantially the number N^* of the excited activator ions per unit time) is proportional to the number of the possible combinations of activator ions and exciting energy carriers in V and in unit time. This study is a first step for increasing the better understanding $\langle I\rangle$ from the phosphor crystals. The results of this study, therefore, will give a macroscopic (instead of microscopic) picture of the excitation mechanisms of activator ions by electron beam irradiation on phosphor crystals.

The chemical analysis usually informs us that the activator ions are uniformly distributed in the crystal, and the activator ions never move out of their positions under the ordinary cathode-ray excitation conditions. For the excitation of activator ions, the activator ions must be visited (or sampled) by the exciting energy

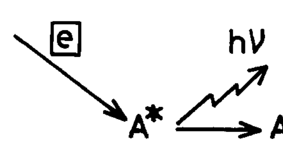
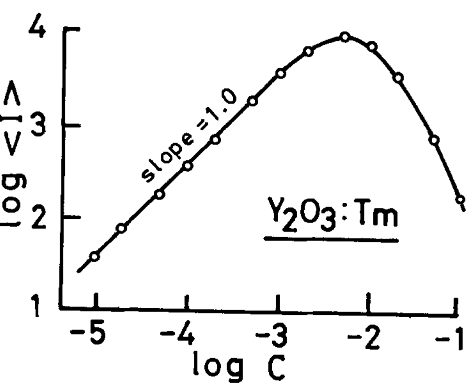
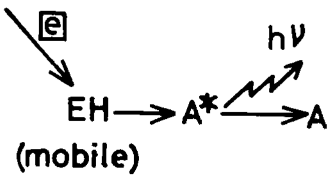
(A) direct excitation





(B) excitation by mobile EH



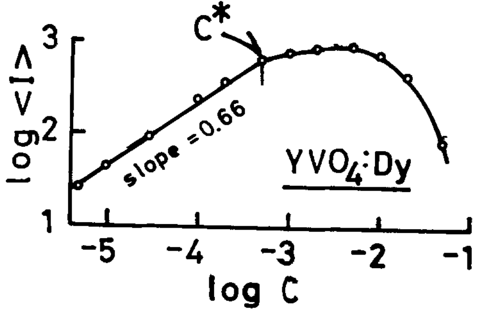


Fig. 1. Difference in concentration dependence curves with types of excitation mechanisms of activator ions by incident electrons. (A) Curve for directly excited activator luminescence which exhibits no crystal size effect and has unity slope. (B) Curve for activator luminescence arising from recombination of mobile carriers; the curve discontinues at C_D* which exhibits crystal size effect due to migration of mobile carriers.

carriers (*e.g.*, photons and/or electrons) which are travelling in the crystal. Consequently, the different travelling mode of the carriers results in the different sampling (*i.e.*, excitation mode) of the activator ions. In order to discuss the CD curve of $<I>$ shown in Fig. 1, thus, we know about the travelling modes of the incident electrons and EH's in the phosphor crystals.

CD Curve for Directly Excited Activator Luminescence

When the crystal is irradiated by electron beam, a large part of the incident electrons penetrate into the crystal and the residuals are ejected from the crystal surface (5) (*i.e.*, backscattered primary electrons due to the elastic scattering with the ions arranged in the surface layers of the crystal). The penetrating electrons lose their energy by elastic and inelastic collisions with the lattice ions along the electron trajectories, generating x-ray, Auger electrons, secondary electrons, electron-hole pairs, and phonons. The electron trajectories in the crystal can be computed by using Monte Carlo technique (6) with single and/or multiple scattering models (7, 8). The profile of the calculated electron trajectories (6-10) are qualitatively confirmed with the observation by Ehrenberg and Frank (11), who have used microphotographs of cathodoluminescence from $CaWO_4$, KI, and plastic. This indicates the incident electrons are randomly scattered (travelling) in the penetration volume. The lattice ions are excited not only by the incident electrons but also by the secondary electrons generated internally. Bohm and Pine (12) proposed a model that the secondary electrons and scattered incident electrons form the electron gas plasma in the crystal, and the lattice ions are excited with the electron-plasmon interaction to produce another secondary electron of the energy smaller than that of the previous one, *i.e.*, the cascade model. Quinn (13) gave an equation to calculate the mean-free path of the plasma electrons in various energies; according to his equation, the mean-free path is about 10Å for 1 keV electrons and about 100Å for 10 keV electrons. Hence, only the secondary electrons generated in the surface volume in depth smaller than the mean-free path can escape from the crystal surface, giving rise to Auger electrons and true secondary electrons which can be collected in front of the crystal; both are now used for studying the surface physics of the crystal. (Auger electrons which are characterized by the elements are used for the identification of the elements in the surface volume and true secondary electrons are used as a signal source in the scanning electron microscope.) The existence of the plasmon in the crystal may be proved by analyzing both the true secondary electrons collected in front of the crystal and the values of the energy loss of the incident electrons in the crystal. Amelio (14) calculated the theoretical distribution of the true secondary electrons, which were in agreement with the experimental results, for Cu metal and Si semiconductor based on the electron-plasmon interaction (dominant) plus electron-electron interaction. Both theory and experiments of the energy loss of the incident electrons show that the values for Si, Ge, ZnS, PbS, SiO_2, MgO, and others are explained by the electron-plasmon interaction (15). These results are probably enough to draw a conclusion that the lattice ions in the crystals are predominantly excited by the electron-plasmon interaction. If the activator ions in the crystal are excited with the plasmons (*i.e.*, incident electrons and internally generated secondary electrons), the excitation of activator ions is limited in the volume where the plasmons are contained. Since the mean-free path of the plasma electrons (less than 100Å) is negligibly small as compared with the penetration depth of the incident electrons (0.4 μm for 10 keV), the volume V for direct excitation of the activator ions by the plasmons is, as a first order, approximated to the volume V_d defined by the penetration depth of the incident electrons and cross-sectional area of the incident electron beam on the screen which is constant for the measurements of $<I>$. The total surface area of the crystals arranged in the first layer on the fixed screen area is not only a constant but is also independent of the crystal size (16). Consequently, V_d is independent of the crystal size of phosphors and is a constant for a given cathode-ray voltage (the crystal size greater than the penetration depth). Since the incident electrons are randomly scattered (travelling) in V_d, it may be said that in some time interval, the plasmons are randomly distributed in V_d, so that the random mixing of activator ions N and the plasmons J in V_d and in unit time can be considered. It follows that the excitation of activator ions by the plasmons is comparable with the random sam-

pling of N by J in V_d and in unit time. If both N and J are large (it is always so), the outcome of the random sampling (corresponding to N^*) in V_d in unit time is proportional to the number of possible combinations of N and J, which is given by

$$N^* = k_2 \frac{N!\,J!}{(N-1)!\,(J-1)!} = k_2 NJ \qquad [2]$$

where k_2 is constant. This leads to a linear dependence of $<I>$ on both N and J. Under the given excitation conditions (*e.g.*, J = constant), $<I>$ is linear with the activator concentration in the range where self-concentration quenching is negligible, and the normalized CD curves of $<I>$ should exhibit no difference due to the crystal size (V_d remains a constant even if the crystal size is changed). Furthermore, the scattering of the plasmons in V_d is possibly independent of the irradiation time of the electron beam at the ordinary conditions of the cathodoluminescence study, so that the CD curve of $<I>$ shows no dependence on the excitation duration (*i.e.*, the pulse width effect). Therefore, if the activator ions are only excited directly by the incident electrons (and internally generated secondary electrons), the normalized CD curves will be the same for pulsed and continuous (d-c) excitations, and the CD curves, plotted on logarithmic basis of the activator luminescence, will have unity slope in the low activator concentration range and exhibit no crystal size effect. This is the case for Tm^{+3} luminescence in Y_2O_3:Tm as shown in Fig. 1(A); the CD curve of Tm^{+3} luminescence exhibits no crystal size effect and no pulse width effect, and the curve has unity slope in the low activator concentration range.

CD Curve for Indirectly Excited Activator Luminescence

The plasma electrons also produce EH's which have the long mean-free path (12). If the activator ions are excited by these EH's (*i.e.*, radiative recombination of EH's at activator ions), the excitation of the activator ions occurs in the effective volume V_e (greater than V_d) in which the EH's are present.

We assume that EH's can move out from the volume in which they are created and disappear by one or more recombination mechanisms (radiative or nonradiative) at the intrinsic and extrinsic recombination centers, which may be host atoms and surface and internal recombination centers, respectively. Since no bandgap luminescence has ever been observed with the phosphor crystals, EH's must disappear at surface and internal recombination centers. It is known empirically that the formation of surface recombination centers depends largely on preparation conditions (4); for crystal prepared under well-controlled conditions (this is true for phosphor crystals), it is assumed that the rate of surface recombination of EH's is constant. Hence the recombination rate of EH's depends solely on the presence of internal recombination centers. There are two types of internal recombination centers to be considered: chemical impurities, including activator ions; and lattice imperfections (*e.g.*, vacancies, dislocations, grain boundaries, and interstitials). It has been shown in our previous work (17) that lattice imperfections do not influence the internal recombination of EH's in Y_2O_3. This is likely to be true for other phosphors. If so, the migration of EH's generally depends on the activator concentration when 99.9999% pure material is used.

We assume that the migration of an EH terminates on the first visit to an unexcited activator ion; the average migration distance L of EH's in the crystal increases as activator concentration decreases. It follows that there are two activator concentration regions in which L is limited by (*i*) crystal size ϕ_M (*i.e.*, $L = \phi_M$) and by (*ii*) activator concentration (*i.e.* $L < \phi_M$). Because the excitation of activator ions by EH's occurs in the crystals arranged in the first layer on the fixed phosphor screen area, the CD curve of $<I>$ should be inflected (*i.e.*, have a discontinuity in the curve) at the activator concentration C^* corresponding to $L = \phi_M$. Therefore, the value of C^* of the CD curve of $<I>$ shows the crystal size effect; the value of C^* decreases as the crystal size increases. In the concentration region below C^*, the effective volume will be limited by the total volume V_ϕ of the crystals involved which is a constant. Under this condition, the number of excited activator ions per unit time will be proportional to the number of EH's created in unit time and also to the number of activator ions N_ϕ in V_ϕ. At concentration greater than C^*, the effective volume is smaller than V_ϕ and decreases as C increases. Therefore, the number of activator ions involved in the excitation is no longer equal to N_ϕ but instead is related to the number of activator ions N_e in the effective volume V_e which shrinks with increasing activator concentration (even as ϕ_M remains constant). Consequently, the CD curve of $<I>$ has two characteristic slopes depending on the activator concentration while the value of C^* depends on crystal size. The experimental CD curves of $<I>$ for many efficient cathodoluminescent phosphors, indeed, have two slopes and the value of C^* exhibits the crystal size effect (3, 17, 18), showing that the activator luminescence arises from the radiative recombination of mobile EH's; however, the interpretation of the experimental value of C^* and the slopes is complicated by the facts that the value of C^* for some phosphors (*e.g.*, Y_2O_2S:Eu) differs greatly with the excitation mode (*e.g.*, d-c and pulse excitations), even if the crystal size is the same. Figure 2 shows the CD curves of Y_2O_2S:Eu ($\phi_M = 3$ μm) under d-c and pulse (2 μsec) electron beam irradiation; the value of C_p^*, for pulse excitation, is 1×10^{-4} whereas the value of C_D^*, for d-c excitation, is 2×10^{-3} (20 times greater). C_D^* depends on crystal size, activator concentration, and excitation intensity, for which the experimental equation can be expressed as

$$C_D^* = \frac{k_3}{\phi_M} \qquad [3]$$

where k_3 is a constant relating to the excitation intensity; k_3 increasing with the excitation intensity. On the other hand, C_p^* does not depend on excitation intensity in the range studied (peak beam density smaller than 10 $\mu A/cm^2$) and can be expressed as

$$C_p^* = \frac{k_4}{\phi_M} \qquad [4]$$

where $k_4 = 3 \times 10^{-8}$ cm. Furthermore, the slopes below the inflection points are unit for pulse excitation

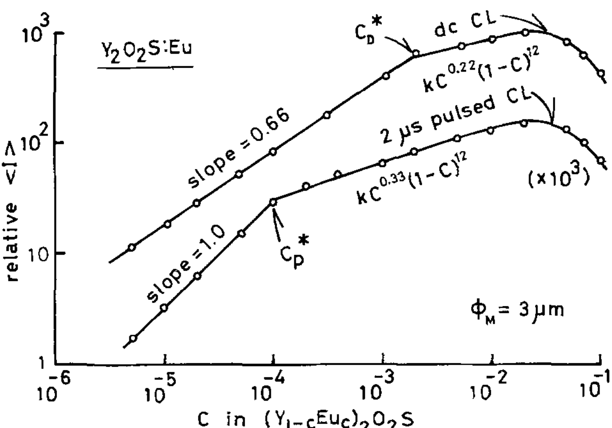

Fig. 2. Concentration dependence curves of Eu^{+3} ($^5D_0$ luminescence) of Y_2O_2S:Eu ($\phi_M = 3$ μm) under irradiation of continuous (d-c) and pulsed electron beam.

and 0.66 (sublinear) for d-c excitation. These results strongly suggest that the excitation of activator ions by EH's is not simply expressed by the random sampling by the EH's, and that the EH's probably do not migrate randomly on cation lattice sites even if there is no externally applied field on the crystals. Further study on the motion of EH's will prove to be an interesting subject.

Although we do not clarify the ambiguities of C_D^*, C_p^*, and slopes of the CD curves in this study, it is sure that under the given d-c excitation conditions, the CD curve of $\langle I \rangle$ certainly has two slopes depending on the activator concentration which the value of C_D^* is changed with the crystal size (2, 18) according to Eq. [3], showing that the activator luminescence arises from the radiative recombination of mobile EH's (the activator ions are not excited directly). Thus, if the activator ions are excited by mobile EH's (*i.e.*, if radiative recombination of mobile EH's occurs at activator ions) the CD of $\langle I \rangle$ under d-c excitation differs significantly from the curve for directly excited activator luminescence; the curve should have two slopes which inflected at C_D^* and the value of C_D^* exhibits a crystal size effect (due to the migration of EH's). This is a case for Dy^{+3} luminescence in YVO_4:Dy as shown in Fig. 1(B).

We use, as a new tool, these distinguishable differences between direct excitation and excitation by mobile EH's seen in the CD curve of cathodoluminescence to study further the excitation mechanisms of the activator ions by incident electrons.

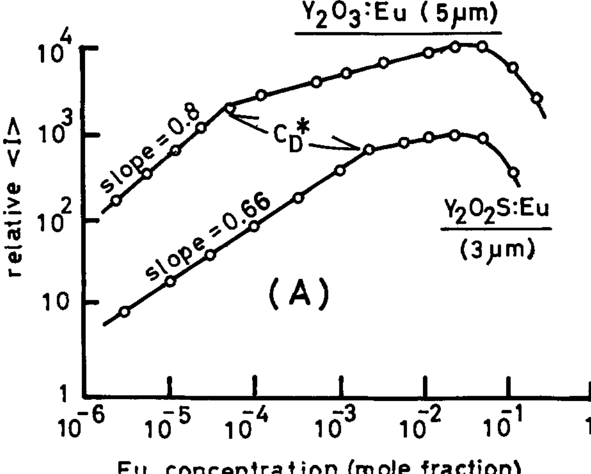
It should be noted that if the concentration quenching mechanisms are involved in the range of C_D^*, the inflection of the CD curves, eventually the crystal size effect, is vague. This is a case of the CD curve of ZnS:Cu (or Ag) and of the $^5D_1$ and $^5D_2$ Eu^{+3} luminescence (19). The inflection point at C_D^* is also vague if the phosphor crystals have a wide distribution in size. We do not use these CD curves in this study.

Results and Discussion

The present study was made with Y_2O_3, YVO_4, and Y_2O_2S crystals activated with eight rare earth elements (Pr, Sm, Eu, Tb, Dy, Ho, Er, and Tm) which emit line luminescence in the visible spectral region (20). The trivalent rare earth (RE^{+3}) activator ions are quite suitable for this purpose for the following reasons: first, each RE^{+3} emits its characteristic, easily identifiable, luminescence spectrum; second, RE^{+3} and Y^{+3} compounds form solid-solution over a wide range; and third, under the ordinary conditions, some RE's show two valences (*e.g.* RE^{+3} and RE^{+2} or Re^{+3} and RE^{+4}) while others exhibit one valence (RE^{+3}).

The results indicate that two modes of excitation of activator ions should be considered for ordinary cathodoluminescence study; direct excitation and indirect excitation through mobile EH's. If the activator ions are excited by the mobile EH's the number of directly excited activator ions is negligibly small as compared with the number of EH's (substantially the number of the activator ions excited by EH's in the crystals). It follows that direct excitation results in weak cathodoluminescence and the radiative recombination of mobile EH's at activator ions results in high efficiency. Thus, we may explain the major difference in efficiency of the same RE^{+3} in different host crystals, as will be described below.

Figure 3(A) shows the CD curves for Eu^{+3} luminescence ($^5D_0 \rightarrow {}^7F_2$) in Y_2O_3:Eu and Y_2O_2S:Eu under the continuous (d-c) irradiation of electron beam (10 keV, 0.2 $\mu A/cm^2$); in both crystals the Eu^{+3} are excited by mobile EH's. In contrast, Fig. 3(B) shows the CD curves for Pr^{+3} luminescence from Y_2O_3:Pr ($^3P_0 \rightarrow {}^3H_6$) (21) and Y_2O_2S:Pr ($^3P_0 \rightarrow {}^3H_4$) (22), respectively; there is a direct excitation of Pr^{+3} in Y_2O_3, and Pr^{+3} is excited by mobile EH's in Y_2O_2S. The results obtained are summarized in Table I. It is inferred that



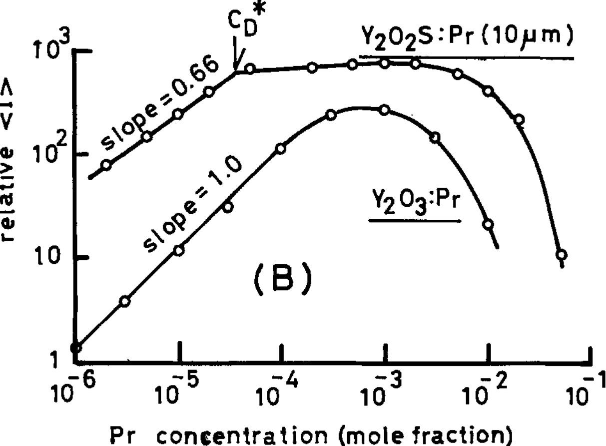


Fig. 3. Concentration dependence curves of Eu^{+3} and Pr^{+3} under continuous irradiation of electron beam. (A) Curve for Y_2O_3:Eu (ϕ_M = 5 μm) and Y_2O_2S:Eu (ϕ_M = 3 μm). (B) Curves for Y_2O_3:Pr and Y_2O_2S:Pr (ϕ_M = 10 μm).

trivalent RE ions which can also be divalent (23) (*i.e.*, Eu, Sm, and Dy) are excited by EH's in Y_2O_3, YVO_4 and Y_2O_2S. The trivalent RE ions which can also be tetravalent (23) (*i.e.*, Tb and Pr) are excited by EH's in Y_2O_2S. The RE ions are not excited by EH's in Y_2O_3 and YVO_4 (they are excited directly); the sulfur ion rather than the crystal structure is probably responsible for their excitation in Y_2O_2S. This is confirmed for Tb in La_2O_3 and La_2O_2S (both host crystals having the same crystal structure, hexagonal with D_{3d}^3 space group). There is direct excitation of Tb^{+3} in La_2O_3 and Tb^{+3} is excited by EH's in La_2O_2S. [These results may explain why Cu (and Ag) activator ions which show two valences (+1 and +2) form the recombination centers for EH's in ZnS, but not in ZnO. It will be interesting to further the experiments on this

Table I. Experimental results on the excitation mechanisms of rare earth activator ions in Y_2O_3, YVO_4, and Y_2O_2S by incident electron beam

point.] RE ions which exhibit only one valence RE^{+3} at the ordinary conditions (*i.e.*, Er, Ho, and Tm) do not form recombination centers (they are excited directly) in the crystals studied. Thus, the recombination of EH's occurs at impurities showing two valences at the ordinary conditions. These results suggest that the recombination of EH's in the rare earth phosphors, which have many direct excitation lines in the spectral region of the energy smaller than the bandgap energy of host crystals, is probably independent of the location of impurity states in the bandgap of the host crystal as has been previously considered (24).

From the above results (Table I), one may propose a model of a recombination mechanism of EH's at activator ions. Using RE ions as an example, we shall explain this model (Fig. 4). In the crystals, the RE ion, which shows the trivalent and divalent traps first as electrons and is converted to RE^{+2}, producing a negatively charged local field. A hole is attracted to this region and is captured by the RE^{+2} to form the excited state of RE^{+3} (RE^{+3*}). The excited RE^{+3*}, after remaining some time in its excited state, emits a photon (luminescence) and returns to the ground state to repeat the excitation process with another EH [Fig. 4(A)]. In the crystal containing sulfur, the RE^{+3}, which shows RE^{+3} and RE^{+4}, can first trap a hole (probably from the sulfur ion), and the RE^{+3} is converted to Re^{+4}, producing a positively charged local field. This RE^{+4} then captures the electron to form RE^{+3*}. The RE^{+3*} returns to the ground state after emitting a photon [Fig. 4(B)]. These models suggest that the type of carrier which is first trapped determines the type of recombination process at the activator ions. The first trapped carrier in Y_2O_3 and YVO_4 crystals is an electron, and in Y_2O_2S crystal, it is either an electron or a hole (depending on the impurities).

As a concluding remark, the usefulness of the concentration dependence curve of the activator luminescence has been demonstrated. Under irradiation of electron beam on phosphor crystals, two excitation mechanisms of the activator ions should be considered; direct excitation by electron beam and the excitation through the mobile electrons and holes generated by incident electrons (*i.e.*, radiative recombination of the electron-hole pairs). The experimental results of the rare earth activators suggest a possible model that the radiative recombination of electron-hole pairs only occurs at the activator ions showing two valences. It should be noted that the results of the concentration dependence curves of the activator cathodoluminescence only give a macroscopic picture and do not allow the drawing of a microscopic picture of the excitation of activator ions, *e.g.*, whether resonance energy transfer and other Auger type process are involved. I feel that the theoretical consideration and further experiments by other techniques are necessary to prove the precise and microscopic picture of the excitation mechanisms of the activator ions by electron-hole pairs. I hope the experimental results of this study may suggest some ideas for the further study.

Effect of Diffusion-Induced Dislocations on Antimony Diffusion into Silicon

Sung Hae Song and Tatsuya Niimi

Department of Electrical Engineering, Keio University, Hiyosh, Yokohama 223, Japan

ABSTRACT

The diffusion of antimony atoms into silicon was performed under the following conditions: diffusion temperatures 1150° and 1050°C, surface concentrations of antimony atom 4.5×10^{19} and $5.0 \times 10^{18}/cm^3$, using antimony-doped oxides as the diffusant source. The distribution of the diffusant in silicon deviated from the well-known erfc curve when the diffusion was carried out for a longer time at the higher diffusion temperature and the higher surface concentration of antimony. In that case, the diffusion coefficient of antimony was determined by the Boltzmann-Matano method. It showed a considerable dependence on the local concentration of antimony and was interpreted in terms of the generation of diffusion-induced dislocations and the excess vacancies introduced from the surface during the diffusion.

Many investigators reported on the anomalous diffusion of phosphorus and boron into silicon, which was observed when the diffusion was carried out from a high concentration source (1-4), and on the effect of diffusion-induced dislocations on their diffusion coefficients (5, 6). It was proposed that these dislocations might explain the anomalous diffusion, because the generation of excess vacancies due to their climbing motion was supposed to be responsible for the marked enhancement of the diffusion and the emitter-push effect (7, 8).

On the other hand, the retardation effect of phosphorus atoms observed when they were diffused into silicon at very high concentration was related to the formation of diffusion-induced dislocations (9, 10). In this case, the effect could be explained by assuming that the excess vacancies generated when phosphorus atoms were diffused would be absorbed by the dislocations (11).

The generation of diffusion-induced dislocations is generally considered due to the stress induced by diffusion, which depends both on the size of a diffused atom and on its concentration (5, 12). As for phosphorus and boron atoms, referred to above, they have smaller atomic radii than silicon.

In this paper, it is reported that antimony, which has a larger atomic radius than silicon, was diffused into silicon using the doped oxide source. Comparing the diffusion coefficient of antimony, which was dependent on its local concentration, with the densities of diffusion-induced dislocations generated, their effect on the diffusion is discussed.

Experimental

Silicon substrates used were (111) oriented p-type single crystal wafers of resistivity 1 ~ 3 Ωcm, mechanically and chemically polished, and had low dislocation densities ($<5 \times 10^2/cm^2$). The wafers were etched in dilute HF solution and then rinsed in deionized water. The condition of the preparation of antimony-doped silicon dioxide deposited on the substrates as a diffusant source and the method of measuring the antimony concentration in the substrates were the same as previously reported (13). The diffusion of antimony into silicon was performed in nitrogen atmosphere under the conditions listed in Table I, in which the data for four typical cases are shown. The diffusion was performed, maintaining the surface concentration of antimony at values indicated in Table I.

The junction depths formed in the substrates were measured by using the interferometer after the substrates were angle-lapped with 2 degrees and then chemically etched with the mixture of 30 cm³ HF and a drop HNO_3. They were also measured by another method using anodic oxidation (13). The junction depths measured by two different methods agreed with

each other. The diffusion-induced dislocations could be observed near the surface of the substrates by repeating the Sirtl etching (14) successively.

Results and Discussion

Figure 1 shows typical concentration profiles of antimony, which were obtained for case I in Table I. They were taken at diffusion time, 0.5, 2.0, and 4.5 hr. The intrinsic carrier concentration n_i in silicon at the diffusion temperature is $2.1 \times 10^{19}/cm^3$, therefore, the local concentration of diffused antimony atoms in the substrate was kept less than the intrinsic carrier concentration during the diffusion. The junction depth corresponds to the three points on the abscissa, where the Sb concentration is equal to the substrate concentration of $1.0 \times 10^{16}/cm^3$. Each of the full lines shows a theoretical erfc curve. These were drawn so as to pass through the two points, one of which was a junction depth on the abscissa and the other, the surface concentration on the ordinate, which were given by the experimental condition. They show a comparatively good agreement with plots by measurements.

The concentration profiles of antimony obtained for case II in Table I turned out, like case I, to agree with erfc curves, so they are omitted from the text.

Figure 2 shows the results obtained for case III in Table I. In the figure, the concentration profiles, corresponding to diffusion time, 0.5, 2.0, and 4.5 hr, are given. Three plots on the abscissa show the junction depths, respectively. They are, in this case, at the concentration $1.0 \times 10^{17}/cm^3$. The profile for a shorter diffusion time (0.5 hr) agreed well with an erfc curve,

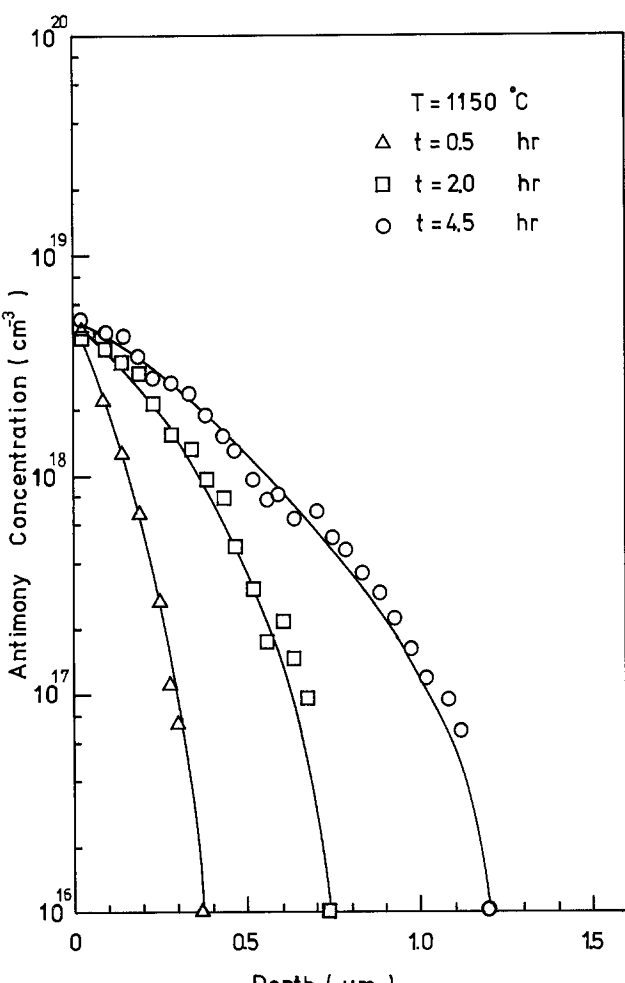

Fig. 1. Profiles of antimony concentration obtained for case I in Table I. Marks △, □, and ○ show the concentrations measured after diffusion was carried out for 0.5, 2.0, and 4.5 hr, respectively. The full lines are theoretical erfc curves drawn as described in the text.

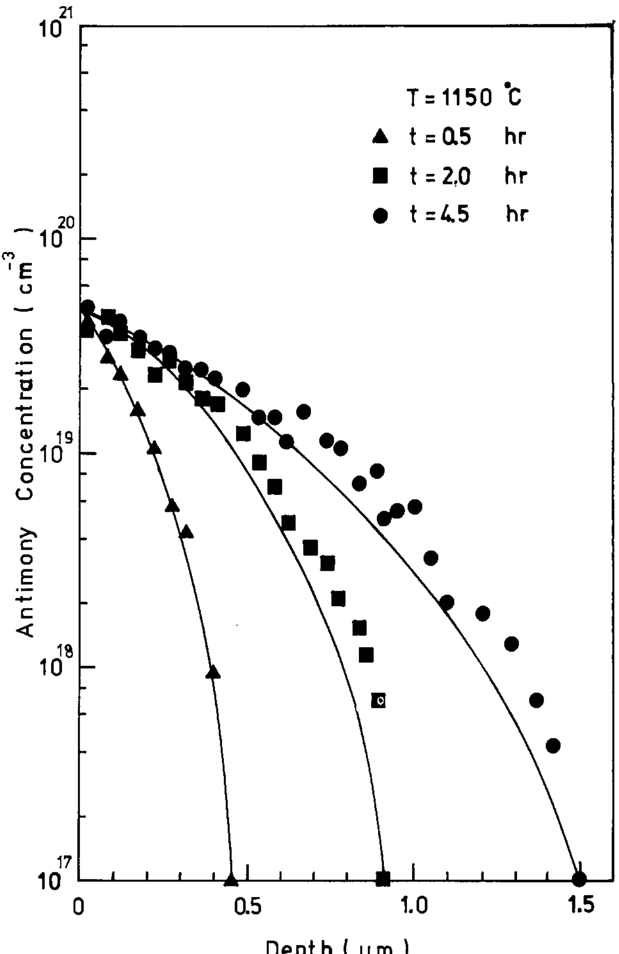

Fig. 2. Profiles of antimony concentration obtained for case III in Table I. Marks ▲, ■, and ● show the concentrations measured for the diffusion times, 0.5, 2.0, and 4.5 hr, respectively. The full lines are theoretical erfc curves drawn as in Fig. 1.

drawn the same way as in Fig. 1, but the profiles for diffusion time longer than 2.0 hr did not.

The concentration profiles obtained for the case IV in Table I had similar characteristics as those given in Fig. 2, showing that the profiles for longer diffusion time deviated from the theoretical curve.

The solid solubility of antimony atoms into silicon, according to Trumbore (15), is $6.0 \times 10^{19}/cm^3$ at the temperature 1150°C and $4.5 \times 10^{19}/cm^3$ at 1050°C. Therefore, the higher surface concentration adopted in this study is roughly equal to the solubility limit of antimony into silicon at the diffusion temperatures.

Figure 3 shows an example of the relationship between diffusion time and dislocation densities generated on the surface of silicon substrates into which antimony was diffused with the condition, case III in Table I. They were measured by counting the number of etch pits on the surface from which the doped oxide had been removed by chemical etching. The vertical spreads of dislocation densities correspond to their measured maximal and minimal values. They have a tendency to be saturated as diffusion time becomes longer. The dislocation densities obtained at diffusion time longer than 4.5 hr could not be determined accurately, because the etch pits were piled up on the wafer. The saturated dislocation densities, $1.0 \sim 3.0 \times 10^9/cm^2$, extended deeply from the surface into about half a distance of the junction depth. The observed results about the generation of diffusion-induced dislocations are listed in Table I, including the above. Whenever dislocations were generated, the concentration profile of diffused antimony atoms deviated from an erfc curve and when dislocations were not generated, the diffusion profile followed an erfc curve. From the results, it is

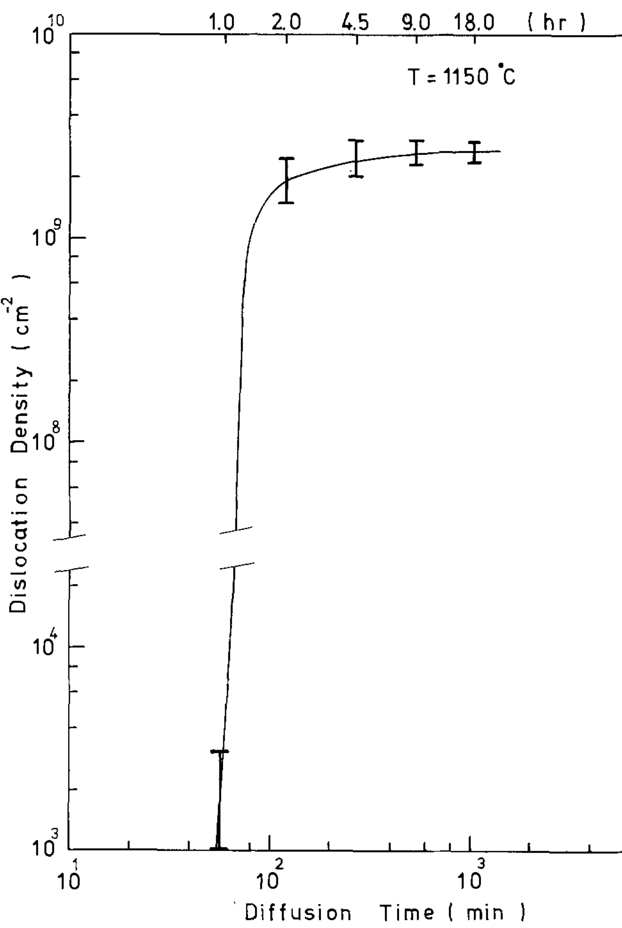

Fig. 3. A relationship between the densities of diffusion-induced dislocations and diffusion time. The diffusion condition is given in case III in Table I.

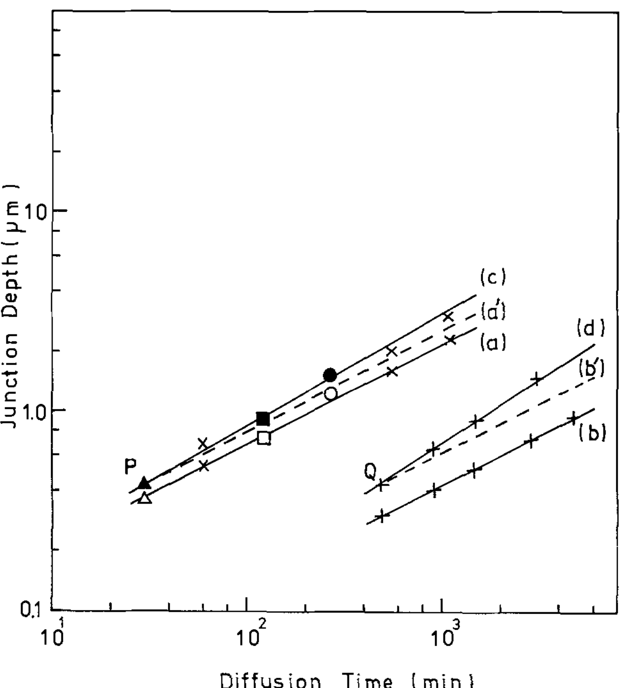

Fig. 4. Relations between the junction depths and the diffusion times. Lines (a), (b), (c), and (d) are drawn, corresponding to the diffusion conditions, case I, II, III, and IV in Table I, respectively.

concluded that the generation of diffusion-induced dislocations depends mainly on the concentration of diffused antimony atoms.

Figure 4 shows the relationship between the measured junction depths and the diffusion times, which were obtained under the diffusion conditions given in Table I. Four lines, labeled (a), (b), (c), and (d), correspond to the diffusion conditions, case I, II, III, and IV in Table I, respectively. Lines (a) and (b) have a slope 1/2, but lines (c) and (d) have a steeper slope than either line (a) or (b). Under the diffusion conditions that lines (c) and (d) were taken, the generation of diffusion-induced dislocations was observed in the substrates after diffusion was carried out, except for the two diffusion conditions labeled P and Q in the figure, where no dislocations were observed. From the slopes of the lines, it is observed that the diffusion represented by line (c) or (d) is enhanced, compared with the case of line (a) or (b). It was reported that the diffusion coefficients of antimony in silicon depended on the surface concentration and that they increased with increased concentration (13). Therefore, if we draw broken lines (a') and (b') parallel to lines (a) and (b) through the points P and Q, the difference between (a') and (a) or the difference between (b') and (b) may be ascribed to the enhancement of diffusion due to the surface concentration of antimony and the difference between (c) and (a') or the difference between (d) and (b'), due to the enhancement of diffusion caused by the generation of diffusion-induced dislocations. It should be noted that the difference between lines (c) and (a') or between lines (d) and (b') increased with increase in diffusion time.

In order to find out a relation between the density of diffusion-induced dislocations and the diffusion coefficient of antimony, the diffusion coefficient was determined from Fig. 1 and 2, where the measured concentration profiles of antimony could be well fitted with an erfc curve, respectively, except the two cases, in which the diffusions were carried out under the conditions, *i.e.*, diffusion temperature 1150°C, surface concentration of antimony 4.5 × $10^{19}/cm^3$, and diffusion time 2.0 and 4.5 hr. When the profile could be well fitted with an erfc curve, a value of the parameter D, which was used to represent the erfc curve, $\mathrm{erfc}(x/\sqrt{Dt})$, was adopted as a diffusion coefficient of antimony. When it could not be, the Boltzmann-Matano method (16) was adopted to determine the diffusion coefficient as a function of local antimony concentrations. To ensure the applicability of the method to the cases stated above, the two profiles in Fig. 2 were transformed to those in Fig. 5, in which the representation of the abscissa was changed from x in Fig. 2 to $x/\sqrt{t}$ in Fig. 5. The two concentration profile curves in Fig. 2 may be considered to be bundled roughly along a broken curve in Fig. 5, showing that the two concentration profile curves in Fig. 2 could be represented by a single parameter of $x/\sqrt{t}$ only. This is considered reasonable because the conditions in the substrates, which would affect the diffusion coefficient, must not be so much different when the two diffusions were carried out. This manifests indirectly the validity of applying the Boltzmann-Matano analysis to the above cases.

The values of the diffusion coefficient of antimony, thus determined, are given in Fig. 6, together with those obtained by the experiments at the diffusion temperature 1050°C. The diffusion conditions and the explanations of symbols used in the figure are summarized in Table II. First, the diffusion coefficient of antimony determined by the experiments, in which the surface concentration of antimony was maintained at 5.0 × $10^{18}/cm^3$ during the diffusion, is described. This is expressed as D_I^H or D_I^L in Table II or in Fig. 6. As is clearly shown in Fig. 6, these were constant over the whole range where antimony atoms were diffused, and irrespective of their local concentration. In this case, the concentration of the diffused atoms was, in all cases, lower than the intrinsic carrier concentration in silicon at the diffusion temperature, 1150° or 1050°C. However,

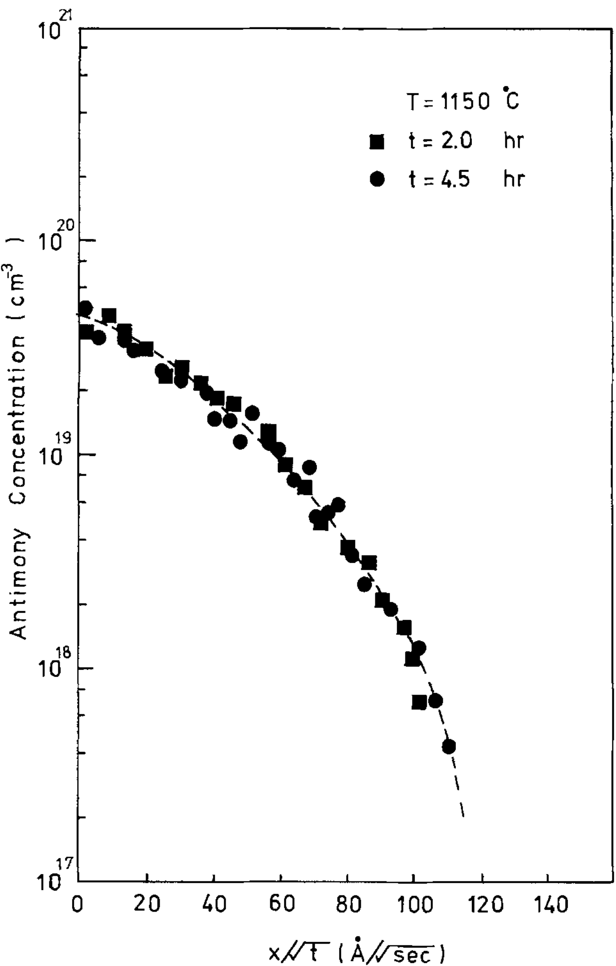

Fig. 5. Concentration profile vs. $x/\sqrt{t}$

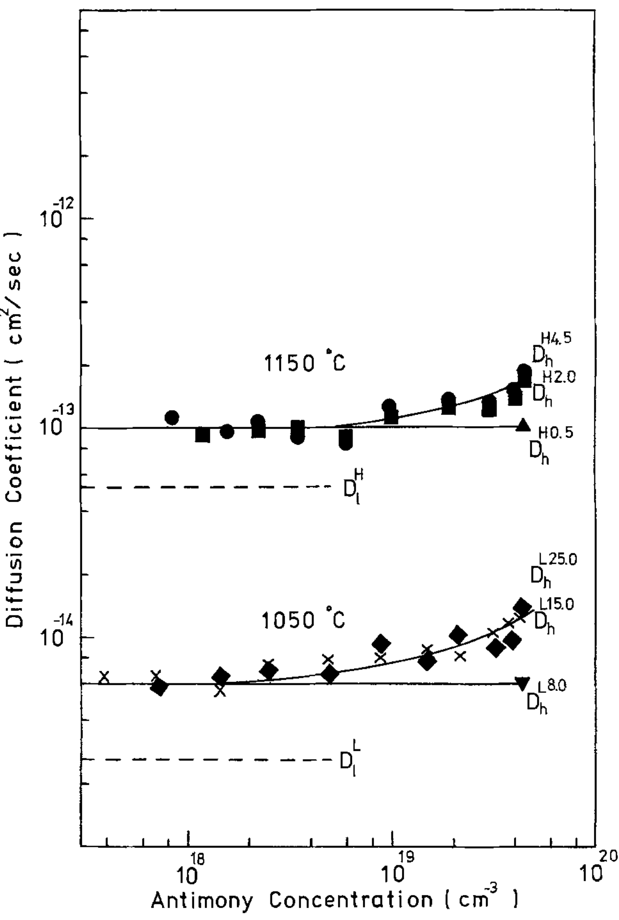

Fig. 6. Diffusion coefficient of antimony vs. local antimony concentration in the substrates. Diffusion conditions and the explanations of the symbols are given in Table II.

the values of D_l^H or D_l^L do not agree with Ghoshtagore's intrinsic diffusion coefficient (2.4×10^{-14} cm²/sec at 1150°C or 2.6×10^{-15} cm²/sec at 1050°C) (17), which was determined by extrapolating his experimental result to the diffusion temperature in the authors' case. This difference must be due to the different methods of diffusion used in the experiments (13).

Next, we will describe the diffusion coefficients determined by the experiments with the higher surface concentration 4.5×10^{19}/cm³. For example, in the case of the diffusion temperature 1150°C, these are shown as $D_h^{H4.5}$, $D_h^{H2.0}$, and $D_h^{H0.5}$ in Fig. 6. These values are always larger than D_l^H over the whole range of antimony concentration examined. Moreover, the difference between $D_h^{H4.5}$ or $D_h^{H2.0}$ and D_l^H can be considered to be divided into two parts, the difference between $D_h^{H0.5}$ and D_l^H and that between $D_h^{H4.5}$ or $D_h^{H2.0}$ and $D_h^{H0.5}$. Though $D_h^{H4.5}$ and $D_h^{H2.0}$ correspond to the diffusion coefficients determined at different diffusion time, 4.5 and 2.0 hr, they could not clearly be discriminated in this experiment. In spite of the determination at the higher surface concentration, $D_h^{H0.5}$ turned out constant over the whole range of antimony concentration, but $D_h^{H4.5}$ and $D_h^{H2.0}$ were constant only in the range of lower concentration, and increased with increase in the concentration.

Next, we will discuss the difference between $D_h^{H0.5}$ and D_l^H. Referring to Tables I and II, it must be pointed out that in the substrates used to determine $D_h^{H0.5}$ or D_l^H, there could be observed no dislocations after the diffusions had been performed. Therefore, we would like to ascribe the difference to the different densities of excess vacancies in the substrates, into which the antimony might be introduced from the surface with the use of the oxide sources containing different densities of diffusant (18, 19). As for the effect of the excess vacancies, the junction depth shown in Fig. 4 must be affected by them and, for example, the difference between lines (a') and (a) may be ascribed to this effect.

Table II. List of diffusion conditions in Fig. 6 and the explanations of the symbols used. Diffusion constants D_l^H and D_l^L obtained under specified conditions were constant, respectively. Also, $D_h^{H0.5}$ and $D_h^{L8.0}$ were constant, but $D_h^{H4.5}$, $D_h^{H2.0}$, $D_h^{L25.0}$, and $D_h^{L15.0}$ were dependent on the local concentration of antimony

Diffusion temperature (°C)	1150 (H)	1050 (L)	1150 (H)	1050 (L)
Surface concentration of antimony (/cm³)	5.0×10^{18} (l)	5.0×10^{18} (l)	4.5×10^{19} (h)	4.5×10^{19} (h)
Diffusion time (hr), mark and symbols	0.5, 1.0, 2.0, 4.5, 9.0, 18.0 } D_l^H	8.0, 15.0, 24.8, 46.5, 77.0 } D_l^L	0.5 ▲ $D_h^{H0.5}$ 1.0 — 2.0 ■ $D_h^{H2.0}$ 4.5 ● $D_h^{H4.5}$ 9.0 — 18.0 —	8.0 ▼ $D_h^{L8.0}$ 15.0 ◆ $D_h^{L15.0}$ 25.0 × $D_h^{L25.0}$ 47.5 —

Next, we will consider the difference between $D_h^{H4.5}$ (or $D_h^{H2.0}$) and $D_h^{H0.5}$. They are nearly the same in the range of the lower concentration of antimony, but become different as the concentration becomes increased. As already shown in Fig. 3, in the substrates which was used for the determination of $D_h^{H4.5}$ (or $D_h^{H2.0}$), the diffusion-induced dislocations were observed after the diffusion had been performed. Then, the difference between $D_h^{H4.5}$ (or $D_h^{H2.0}$) and $D_h^{H0.5}$ may be considered due to the appearance of the diffusion-induced dislocations. Their appearance must enhance the diffusion of antimony. About the enhancement of diffusion due to dislocations, a pipe diffusion model (20) or a dislocation short-circuit model (21) has been proposed.

The same circumstances as stated above may be applied to explain the similar behavior among the diffusion constants, $D_h^{L25.0}$, $D_h^{L15.0}$, and $D_h^{L8.0}$, which were obtained by the experiments with the higher surface concentration at the lower diffusion temperature, listed in Table II.

Moreover, the appearance of diffusion-induced dislocations could be thought to be responsible for the difference between lines (c) and (a') in Fig. 4, referring to the junction depths formed by the diffusion, or the difference between lines (d) and (b'). Some explanations about this point are already given in the previous paragraph.

Conclusion

Antimony atoms were diffused into p-type silicon substrates, using a doped oxide as a diffusant source under the conditions, diffusion temperatures 1150° and 1050°C, and the surface concentrations of antimony 4.5×10^{19} and $5.0 \times 10^{18}/cm^3$.

When the diffusion was performed for a longer diffusion time with the higher surface concentration, a profile representing the concentration of antimony *vs.* diffusion depth might deviate from an erfc curve. In that case, the diffusion coefficient of antimony was determined using the Boltzmann-Matano method, for which the integral was calculated numerically by the computer program. Differences between the diffusion coefficients obtained with the higher and lower surface concentration were analyzed and could be explained qualitatively in terms of diffusion-induced dislocations and the introduction of excess vacancies into the substrate. From the results it has been concluded that the diffusion-induced dislocations will enhance the diffusion of antimony into silicon.

Preparation of Carbon-Free GaAs Surfaces: AES and RHEED Analysis

A. Munoz-Yague, J. Piqueras,[1] and N. Fabre

Laboratoire d'Automatique et d'Analyse des Systèmes du Centre National de la Recherche Scientifique, 31400 Toulouse, France

ABSTRACT

Chemical polishing using an H_2SO_4:H_2O_2:H_2O system and thermal treatments in vacuum to obtain clean GaAs surfaces have been systematically studied for {100} and {111} surfaces. The behavior of these surfaces as far as oxidation and carbon adsorption are concerned has been found to depend on both conductivity type and crystal orientation. The results presented for {100} n- and p-type and semi-insulating material show that it is possible to obtain carbon-free surfaces, covered by a thin oxide layer which protects the semiconductor surface against contamination. A subsequent thermal treatment around 550°C under vacuum permits elimination of the oxide and achieves atomically clean, crystalline and ordered surfaces, which has been confirmed by AES and RHEED analysis.

The preparation of a clean semiconductor surface is among the critical steps in the manufacture of Schottky and ohmic contacts, as well as in epitaxy or photocathode manufacture. The surface should be free of oxides and adsorbed impurities to ensure an intimate contact between the substrate and the deposited layer. The aim of this work is to study a reliable procedure to clean GaAs substrates intended for molecular beam epitaxy.

[1]Permanent address: Laboratorio de Semiconductores, IFES (CSIC-UAM), Cantoblanco, Madrid, Spain.
Key words: semiconductor, etching, oxidation, epitaxy.

The ease in obtaining such a clean surface depends on its chemical activity which is, as is well known, high for most semiconductors. Carbon and other chemical impurities are easily adsorbed from the ambient and the cleaning solvents. Moreover, an unavoidable thin and inhomogeneous oxide layer is formed during or just after the last chemical treatment. In the case of gallium arsenide, if the remaining oxide is etched away with HCl or HF, the surface exhibits a high reactivity and, in addition to the usual C and O contaminants, traces of other impurities such as Cl, S, Ca, N, etc. can be observed (1). Carbon cannot be removed by thermal treatments unless temperatures above 600°C are used (2). This can also be achieved by long time bombardment with argon ions followed by annealing at around 500°C (3). These methods are not appropriate, the first because it requires temperatures above the limit of congruent evaporation of the components, and the second because it involves the creation of a large density of defects. In addition, if the carbon contamination is great enough both treatments lead to faceting of the {100} (2) and $(\bar{1}\bar{1}\bar{1})$ surfaces (3). Moreover, in the case of molecular beam epitaxy, carbon contamination affects both crystal growth and layer morphology, and it should be avoided.

Arsenic and gallium oxides decompose around 370° and 570°C, respectively, (3) which offers a possibility for obtaining a clean GaAs surface under vacuum: indeed, if a thin homogeneous oxide layer could be obtained at the end of the chemical processing, impurity adsorption while pumping down would be avoided and the oxide layer could then be eliminated later on by an appropriate thermal treatment. Surface passivation by chemical etching was pointed out by Cho and Arthur (4) and Cho and Tracy (5), using a $Br:CH_3OH$ solution and deionized water rinsing.

For our purpose, anodic oxidation of GaAs and oxidation by pure oxidants such as H_2O_2 or HNO_3 will not be considered since it is difficult to obtain homogeneous oxide layers of small thickness (~10Å) by these methods and also because thicker oxides are difficult to evaporate. In contrast, chemical treatments with systems such as $Br:CH_3OH$; $H_2SO_4:H_2O_2:H_2O$; $HNO_3:HF$; $HNaO:H_2O_2$ lead to slightly oxidized GaAs surfaces (2, 4, 6, 7).

The results reported up to now only concern <100> oriented semi-insulating Cr-doped (2) and n-type Si-doped (6) GaAs substrates. The results of a systematic study on n-type, p-type, and semi-insulating GaAs substrates oriented in the <100>, [111], and $[\bar{1}\bar{1}\bar{1}]$ directions are detailed here, The polishing solution used is $H_2SO_4:H_2O_2:H_2O$, which appears to be the most suitable etch for surface preparation (2, 6, 7). The analysis was done by Auger electron spectroscopy (AES) and reflected high energy diffraction (RHEED).

Experimental Procedure

The main specifications of the samples used in our study are given in Table I. After mechanochemical polishing, they were degreased in trichloroethylene (boiling), acetone (boiling), ethanol (60°C), and deionized water (60°C). Then, the samples were immersed in HCl in order to remove the remaining inhomogeneous oxide layer and finally etched with an $H_2SO_4:H_2O_2:H_2O$ solution, of different proportions depending on the type and orientation of the sample.

The etching solution was always freshly prepared and stirred in an ultrasonic bath. The violent stirring was introduced in order to ensure a more reproducible oxidizing activity of the solution. The etching was performed at 70°C, and sometimes an additional 30 Klux white light illumination was used.

Just after etch the samples were rinsed and inserted in an ultrahigh vacuum molecular beam epitaxy (MBE) system. The substrate was mounted on an Mo substrate holder that incorporates a heating filament and a thermocouple for temperature measurements; thermal contact between substrate and Mo was ensured by In.

A vacuum interlock system allowed pressures down to 10^{-8} Torr to be reached in 30 min; the pressure limit was 10^{-10} Torr and no hydrocarbon residuals were detected in the mass spectrum obtained with a quadrupole mass spectrometer.

The vacuum chamber was provided with a cylindrical mirror analyzer (CMA), Auger spectrometer (RIBER OPC 105) and a 5 keV glancing angle electron diffraction apparatus. The analyses were made in accordance with the following sequence: RHEED and AES at room temperature, AES during the slow and progressive increase in temperature, and AES and RHEED observation at the final temperature of the thermal treatment.

Table I. Specifications of the GaAs substrates used in this work

Substrate	Face	Dopant	Dopant concentration (cm^{-3})
1	{100}	Te	5.2×10^{17}
2	{100}	Zn	2.2×10^{18}
3	{100}	Cr	$\rho = 10^7\ \Omega \cdot cm$
4	(111) $(\bar{1}\bar{1}\bar{1})$	Sn	5×10^{17}

Experimental Results

No traces of cleaning products or impurities other than C and O were detected, and care was taken to avoid electron-induced adsorption or desorption. The most significant results are given in Tables II and III, in which the proportions of the polishing solution and the conditions of the etch are indicated for faces {100} and {111}, respectively. AES results are presented in the form of peak amplitudes relative to the Ga amplitude. The peaks retained in the $dN(E)/dE$ spectra are:

272 eV	KLL transition for C
510 eV	KLL transition for O
1070 eV	LMM transition for Ga
1228 eV	LMM transition for As

{100} Faces.—After chemical polishing all the samples showed a mirrorlike aspect and only some minor features were observed when contrast microscopy was used. As far as the chemical state of the surface is concerned, the behavior of each conductivity type was different: the oxide coverage for the same polishing solution (3:1:1) was larger for n-type than for p-type, being the lowest for semi-insulating substrates (see Fig. 1). As a general result, it must be pointed out that the carbon contamination increases as the detected oxide coverage decreases. Also it should be mentioned that for a given substrate, an increase in the oxide coverage causes a lowering of the carbon contamination.

In the case of n-type substrates, a carbon-free surface can be prepared with a 3:1:1 solution; to obtain the same result on p-type substrates, the oxidizing activity of the solution has to be increased. A good result was obtained with a 2:1:1 solution. As far as semi-insulating substrates are concerned, the latter ratio was not yet sufficient to avoid carbon adsorption. Nevertheless, a further increase in the concentration of the oxidizing agent results in more difficult control of the etching process and some surface roughness showed up, although the aspect remained mirrorlike. It was found that a 2:1:1 solution under illumination of about 30 Klux was appropriate and led to a carbon-free surface of semi-insulating substrate.

Once these analyses at room temperature were completed, the substrate temperature was increased step by step, and after each one the Auger spectrum was recorded. At about 400°C, a slight reduction of the oxygen peak was observed, probably due to the decomposition of arsenic oxides. To completely remove the oxygen, it was necessary to reach temperatures

Table II. Results obtained for {100} GaAs surfaces

Substrate	GaAs:Te {100}			GaAs:Zn {100}			GaAs:Cr {100}		
Polishing solution H_2SO_4:H_2O_2:H_2O		3:1:1 ~70°C, 1 min			2:1:1 ~ 70°C, 2 min			2:1:1 ~ 70°C, 2 min, illumination

Before heat-treatment	0	1,58	0,91	0	1,41	0,81	0	2,34	0,76
Maximum temperature of the thermal treatment		530°C			583°C			560°C	
After heat-treatment	0	0	0,69	0	0	0,77	0	0	0,74

Table III. Results obtained for $(\overline{1}\overline{1}\overline{1})$ and (111) GaAs surfaces

Substrate	GaAs:Sn $(\overline{1}\overline{1}\overline{1})$			GaAs:Sn (111)		
Polishing solution H_2SO_4:H_2O_2:H_2O		3:1:1 ~ 70°C, 2 min			2:1:1 ~ 70°C, 2 min	
AES	C/Ga	O/Ga	As/Ga	C/Ga	O/Ga	As/Ga
Before heat-treatment	0,18	1,23	1,09	0,11	0,96	0,66
Maximum temperature of the thermal treatment		540°C			530°C	
After heat-treatment	0	0	0,91	0,07	0	0,64

around 550°C, slightly lower than those reported by Laurence *et al.* (2).

Figure 2 shows Auger spectra obtained before and after the thermal treatment. The removal of the oxide layer is rather fast: once the critical temperature is reached the oxygen peak suddenly disappears (see Fig. 3). After overnight storage in the vacuum chamber, at a pressure lower than 10^{-9} Torr no appreciable contamination of the surface was observed. At this point, the surface coverage by any impurity was less than 1% monolayer (detection limit of the CMA). From the chemical point of view, such a surface is

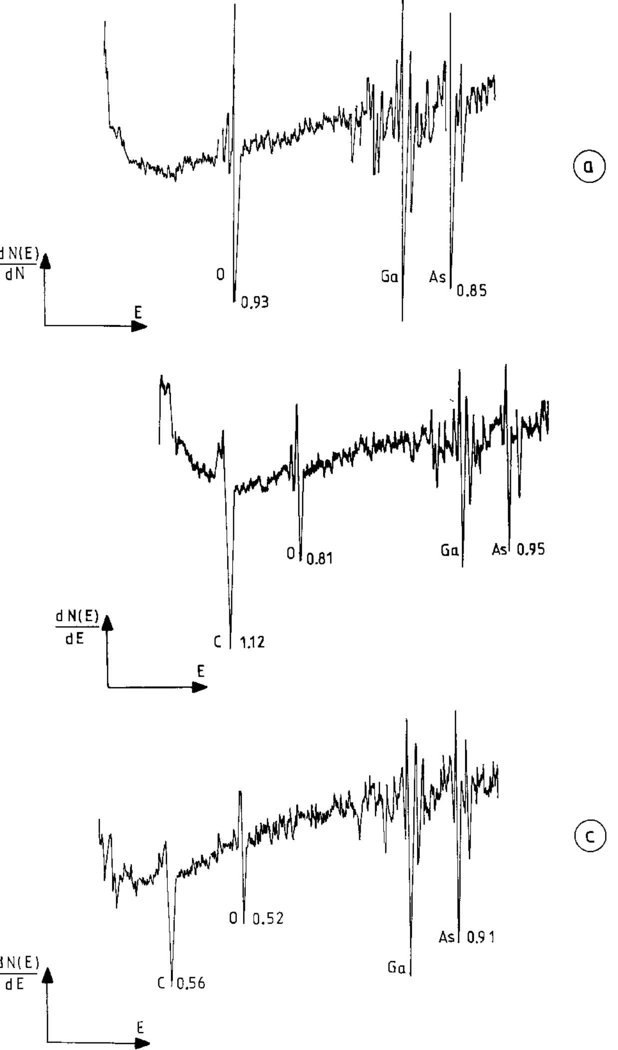

Fig. 1. Auger spectra of {100} GaAs surfaces etched with H_2SO_4:H_2O_2:H_2O (3:1:1) for three different kind of samples: (a) n-type, (b) p-type, and (c) semi-insulating chromium doped.

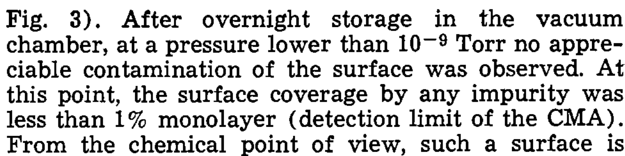

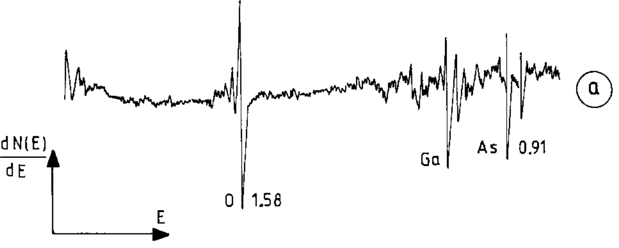

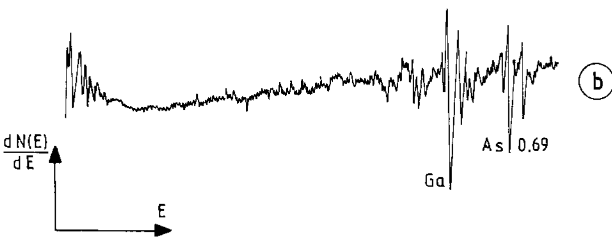

Fig. 2. Auger spectra of {100} n-type GaAs surfaces etched with H_2SO_4:H_2O_2:H_2O (3:1:1) (a) at room temperature and (b) at ~530°C.

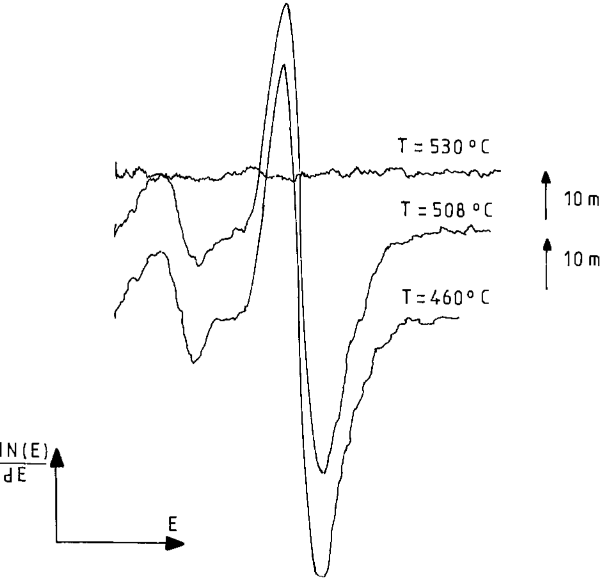

Fig. 3. Oxygen Auger peak obtained at three different temperatures for n-type GaAs {100} surface.

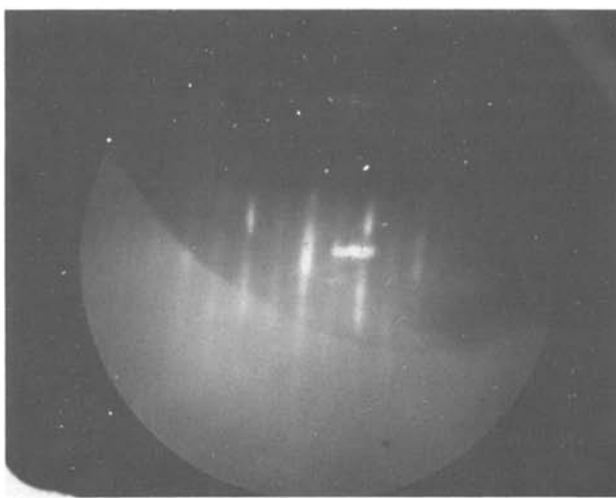
capable of fulfilling the requirements of the different device manufacturing processes mentioned above.

The electron diffraction diagram of the sample before the thermal treatment shows a fairly diffuse spotty pattern because of the presence of an adsorbed layer (see Fig. 4a). At the end of the thermal treatment, the diffraction image consisted of rods showing a weak amplitude modulation. The surface roughness can be estimated to be in the 10^2Å range.



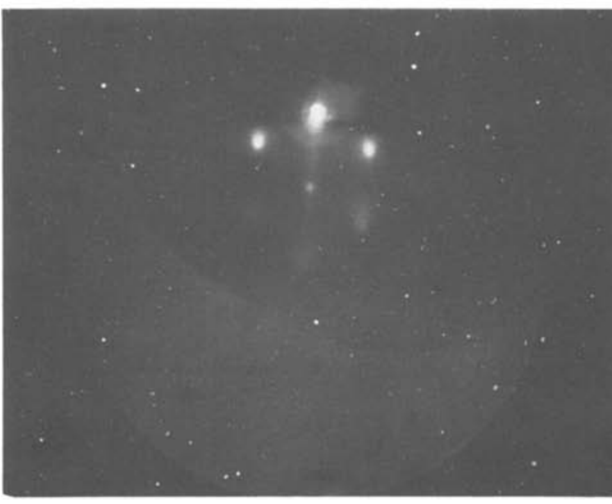


Fig. 4. RHEED diagrams obtained (a, top) at room temperature, (b, center) at the end of thermal treatment with an As flux impinging on the surface, and (c, bottom) at 620°C when after O disappearance a certain amount of C remains at the surface. 5 keV [$\bar{1}$10] azimuth.

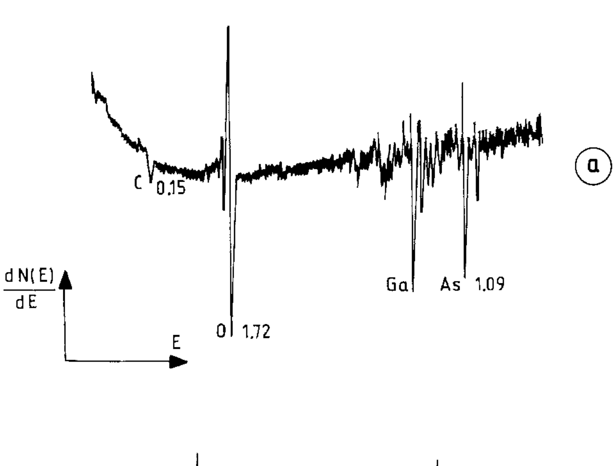
Under As_4 flux (arsenic pressure $\sim 10^{-6}$ Torr) provided by an evaporation cell, the clean surface exhibited surface reconstruction. Figure 4b shows a diagram observed in the [110] azimuth, which corresponds to either the C (2 × 8) or the (2 × 4) surface structures, already observed in molecular beam epitaxy studies.

If, once the oxide layer has been removed a noticeable amount of adsorbed carbon remains on the GaAs surface, a further increase of the temperature would not fully desorb the carbon, and the undesirable result obtained was faceting, as shown in Fig. 4c. The pattern consists of elongated spots tilted with respect to the streak direction of the smooth surface, corresponding to facets which were found to be parallel to the planes (411) by Laurence *et al.* (2).

(111) and ($\bar{1}\bar{1}\bar{1}$) Faces.— As is well known the (111) and ($\bar{1}\bar{1}\bar{1}$) GaAs faces are not equivalent: the [111] direction can be considered to consist of double GaAs layers "weakly" bound between them; one of the faces will be As-rich ($\bar{1}\bar{1}\bar{1}$), and the other will be Ga-rich (111). This fact gives rise to substantial differences between both faces in the mechanochemical as well as in the chemical polishing: the Ga face showed a roughness in the micrometer range while for the As face the final aspect was comparable to that of the {100} substrates.

The best results obtained for these faces are summarized in Table III. The difficulty in obtaining a free carbon surface at the end of the chemical polishing must be noted. Moreover a remarkable difference with {100} surfaces was found: an increase in the relative concentration of the oxidizing agent gave rise to an enhancement of the oxygen peak amplitude, but did not cause an appreciable lowering of the carbon peak amplitude, as illustrated in Fig. 5. This is valid for both faces, even though the As-rich appeared to oxidize more easily than the Ga-rich.

As was the case for {100} surfaces, the oxide removal was obtained around 550°C, but a small quantity of carbon sometimes remained on the surface. An overnight storage in the vacuum chamber at a pressure



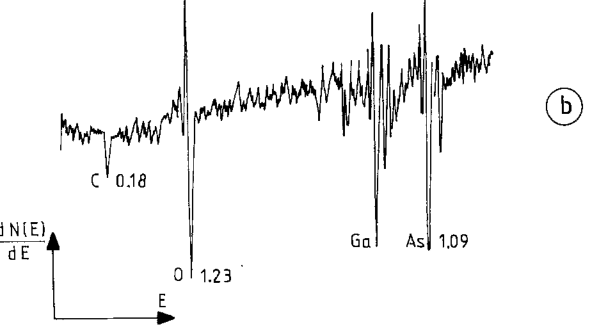


Fig. 5. Auger spectra of ($\bar{1}\bar{1}\bar{1}$) GaAs surfaces prepared with H_2SO_4:H_2O_2:H_2O; (a) 2:1:1 and (b) 3:1:1.

$<5 \cdot 10^{-10}$ Torr gave rise to a significant enhancement of the C and O peaks. The oxygen could again be eliminated by heating, but carbon remained and a further increase in temperature caused the faceting of the surface. In the case of the (111) face, if this situation is not reached, a surface reconstruction can be obtained even in the absence of As or Ga fluxes; Fig. 6 shows the 2× structure observed, which corresponds to a Ga-stabilized surface.

Discussion and Conclusion

It has been found that for {100} surfaces, n-type GaAs is more easily oxidized than p-type or semi-insulating material. This is not surprising if we consider the electrochemical aspects of the oxidation process which involve a loss of electrons from GaAs; indeed, both Ga and As are less electronegative than oxygen (8). This loss may occur via the conduction band in n-type material whereas it would take place via the valence band in p-type samples. Furthermore the electron supply is a diffusion-dominated process; thus it should be expected that the reaction occurs more easily in n-type than in p-type material. According to this, and if we deal with semi-insulating material, the activity of the oxidation process should still be lower. This difficulty was overcome with the aid of the carriers generated by strong illumination.

For n-type GaAs we also observed that as far as ease of oxidation is concerned, the different surfaces can be ordered: $\{100\} > (\bar{1}\bar{1}\bar{1}) > (111)$. The difference between {100} and the last two surfaces can be explained by (*i*) the different configuration of the dangling bonds in the two cases (9, 10), and (*ii*) the higher density of dangling bonds in the {100} case. Also, on the basis of the same atomistic model, $(\bar{1}\bar{1}\bar{1})$ would be more easily oxidized than (111) since in the latter case there are no dangling electrons on the surface Ga atoms. (11).

The carbon contamination after the chemical polishing or after UHV storage was also different for these surfaces: C adsorbed more easily on $(\bar{1}\bar{1}\bar{1})$ and (111) faces than on the {100} face. This could be explained by considering that the (111) face is Ga-rich and that the $(\bar{1}\bar{1}\bar{1})$ surface was probably also partially covered by Ga (the As-stabilized structure was never observed in this study). Then, if Ga exhibits higher chemical activity than As as far as C is concerned, the $(\bar{1}\bar{1}\bar{1})$ and (111) faces will show higher carbon adsorption than {100} faces. This hypothesis is sustained by the fact that the electronegativity difference is higher for the Ga-C bond (0.9 eV) than for the As-C one (0.5 eV) (8).

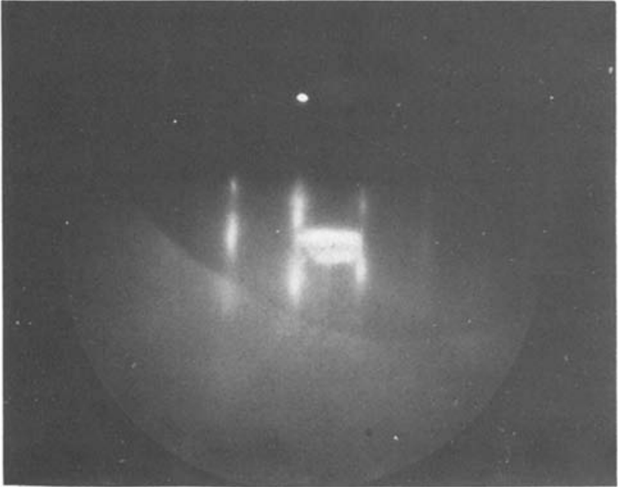

Fig. 6. RHEED diagram of (111) GaAs surface after O and C removal.

In all cases, the removal of the oxide layer was practically instantaneous, in contrast with the values often reported for the duration of thermal treatment (10-30 min). Also, the oxide removal was completed at around 550°C, which implies its being almost entirely Ga_2O_3. This agrees with the mechanism proposed for anodic oxidation and with the experimental observations of Chang *et al.* (1): gallium oxide formation and As pile-up at the GaAs oxide interface. This excess of As was not troublesome in our case because it was removed during thermal treatment; this can be checked in Tables II and III: the As-to-Ga ratio decreases in all cases and, for example, for the {100} cases, it approaches the value reported for the As-stabilized surface (9).

In conclusion, the presented results show that it is possible to prepare by chemical polishing, GaAs surfaces presenting a mirrorlike aspect with no traces of chemical agents and almost completely covered by a thin oxide layer which passivates the semiconductor. This layer can be easily removed by thermal treatment in ultrahigh vacuum giving a C- and O-free GaAs surface of negligible roughness, atomically clean, and ordered. The results obtained show that <100> oriented surfaces should be more suitable for technological applications from the point of view of cleanliness and stability.

Finally, it must be emphasized that the reproducibility of the results of the suggested preparation procedures was checked with good results and that these procedures are now being currently used in our MBE system. Indeed this reproducibility of the result allowed this study to progress, and in almost all the cases treated carbon-free surfaces were obtained by varying the etch proportions.

Growth Mechanisms of Silicon Crystallites Grown on Top of a Metal-Coated Graphite Substrate

W. J. P. van Enckevort and M. W. M. Graef

R.I.M. Laboratory of Solid State Chemistry, Faculty of Science, Catholic University, Toernooiveld, Nijmegen, The Netherlands

ABSTRACT

Microscopic *in situ* observations and *a posteriori* surface topography by means of optical and scanning electron microscopy have been carried out in order to study the growth of large-grain polycrystalline silicon films from the gas phase onto a graphite substrate coated with a liquid layer of tin or aluminum. In the present study, only the initial stages of the process, where crystal growth is governed by vapor-liquid-solid mechanisms, are considered. For the growth of the crystallites in the polycrystalline layers, which occur in two morphological forms, *viz.*, needles and platelets, two different mechanisms could be identified: (*i*) a twin plane reentrant edge (TPRE) mechanism, leading to a fast lengthwise growth of needles and a fast sidewise growth of platelets; and (*ii*) a nucleation mechanism, accounting for a slow thickness growth of the needles and a slow expansion of the platelike crystals. On the upper surfaces of some needles and platelets a capricious surface pattern (always in conjunction with the occurrence of some solidified metal droplets) could be identified, which could be interpreted in terms of a two-dimensional VLS growth mechanism.

The interest in the preparation of photovoltaic silicon solar cells via inexpensive processes has resulted in the publication of a variety of studies dealing with the growth of silicon onto nonsilicon substrates, particularly graphite (1-4). One of the main problems in the chemical vapor deposition (CVD) of silicon onto foreign substrates is the poor crystallinity of the grown layers. It was found that the crystallinity could be enhanced by means of coating the graphite with liquid tin, prior to the deposition of silicon (5). In this CVDOLL process (chemical vapor deposition on liquid layers) the purpose was to grow large-grain polycrystalline silicon layers on top of graphite substrates. The deposition of silicon onto graphite plates, coated with a 10 μm thick molten tin film, resulted in the growth of polycrystalline films having a mean grain size exceeding 100 μm, which is a requirement for satisfactory solar cell operation (typical conditions: 0.75% $SiHCl_3$ and 1.0% HCl in H_2 ambient; surface temperature 1500 K). The formation of large grains is evidently associated with the presence of a liquid film that influences the nucleation and growth of silicon. Although it was assumed that the presence of liquid tin (or, alternatively, liquid aluminum) (*i*) reduces the density of the silicon nuclei, and (*ii*) feeds the growing crystals from a solution of silicon in the solvent (6), a detailed investigation into the nature of this growth process has not yet been carried out.

The purpose of the present studies was to characterize the growth mechanism for the growth of silicon on a liquid-metal coated substrate. This was done by the analysis of the polycrystalline silicon deposits by means of scanning electron microscopy and optical microscopy.

Experimental

Preparation of samples.—The growth process was carried out in a conventional horizontal epitaxial quartz reactor tube, provided with water cooling and rf heating. Trichlorosilane was used as a silicon source, hydrogen chloride as an etching agent, and hydrogen as a carrier gas. The substrates were graphite plates, coated with pyrolytic graphite, and with dimensions $2.0 \times 2.5 \times 0.1$ cm^3, placed on a graphite susceptor.

Key words: polycrystalline silicon, vapor liquid-solid growth, twin plane reentrant edge mechanism.

Tin or aluminum were deposited onto these graphite plates via sublimation *in vacuo* prior to the deposition of silicon. The thickness of the metal layer amounted to 10 μm. The substrate temperature during growth was kept at 1500 K.

The formation of a liquid metal layer was brought about as follows (6): upon melting, the metal contracted to droplets, due to its high surface tension. The surface tension could be reduced by dissolving silicon into the droplets. This was done by an injection of several pulses of 0.75% $SiHCl_3$ in H_2, each one lasting about 10 sec. This caused the droplets to spread out over the graphite, eventually forming a continuous liquid layer.

The growth of silicon on tin-coated graphite was initiated by the continuous addition of 0.75% $SiHCl_3$/1% HCl, which resulted in the formation of silicon needles and platelets. Simultaneously, the tin was evaporated due to the etching activity of HCl. After completion of the evaporation of tin, the growth process continued in a way essentially comparable to conventional CVD of polycrystalline silicon layers [cf., for instance, Ref. (7)].

The growth of silicon on aluminum-coated graphite was carried out by (*i*) dissolving silicon into liquid aluminum [forming a 70 atomic percent (a/o) Si/30 a/o Al liquid mixture at 1500 K], and (*ii*) the removal of aluminum by the addition of HCl to the gas phase, causing silicon needles to grow from a supersaturated solution. This process was described by Graef and Monkowski (8).

For the purpose of this work it was necessary to interrupt the growth process before the evaporation of the liquid metal was completed, since the grain boundaries had not yet developed during this stage, and thus the crystallites could be studied separately.

Observational techniques.—The growth of silicon needles and platelets from solution could be studied *in situ* by means of a binocular microscope placed over an epitaxial reactor tube provided with a quartz window.

A more refined study of these crystallites was performed by means of optical reflection differential interference contrast microscopy in order to reveal low contrast surface patterns. In order to obtain a three-dimensional view at higher magnifications a

scanning electron microscope (SEM) was used. Most of the microscopic observations were carried out on as-grown samples. However, some SEM observations were realized on samples which were etched during 2 hr in a solution 50 volume percent (v/o) concentrated HNO_3/50 v/o H_2O in order to remove residual

droplets of tin or aluminum. This etching was carried out in order to reveal the areas of the silicon crystallites that had been covered by solidified metal. For studying the perfection of the crystals and to reveal stacking faults and twin planes, Sirtl etching (9) was applied.

The Growth of Needles and Platelets

The growth of silicon needles and platelets was observed to be typically associated with the presence of liquid metal droplets on top of the graphite substrate. These crystallites could be studied both during their formation, and *a posteriori*. In order to study the growth mechanism of needles and plates, investigations were made on the morphology of large crystallites that were grown on isolated droplets.

In situ observations.—Figure 1 shows a sequence of micrographs that was made during the deposition of silicon onto tin-coated graphite substrate. It can be observed that the initial growth of needles (*e.g.*, Fig. 1, a and b) and plates (Fig. 1, e and f) proceeds very rapidly, but after a short time, the rapid growth stops, after which the crystallites grow in all directions at a much slower rate. It was estimated that the initial growth rate of the needles lengthwise was more than 60 times larger than the thickness growth rate. The initial expansion velocity of the platelets was of about the same order of magnitude as the needle propagation rate. This observation permits the conclusion that two growth mechanisms are operative: one for the rapid growth and one for the slow growth.

Needle growth.—Characteristics.—The growth of needles is characterized by the following features:

1. The growth of needle-shaped crystallites always starts on the edge of a liquid droplet, and the growth continues in a direction more or less toward the center of the droplet. Figure 2 gives a survey of a group of needles grown from liquid aluminum, whereas Fig. 3 shows silicon needles that were grown from a liquid tin droplet.

2. The upper surfaces of the needles are curved, while the lower ones are in contact with the graphite substrate. For the Sn/Si system the morphology of the needles could be elucidated by the removal of the solidified tin using a 1:1 HNO_3/H_2O etchant, which does not affect the silicon needles and the graphite. Figure 4 shows a typical large needle in the Sn/Si system. The profile of the upper surface is determined by the curvature of the droplet (Fig. 4a and d). This is similar to the way in which the external shape of cylindrical or rectangular crystals is determined by the shape of the meniscus in the case of Czochralski (10) or edge-defined film-fed growth (11). Figure 4b shows that the bottom side of the needle follows the morphology of the graphite substrate.

Both features, *viz.*, the fact that the top surfaces of the needles are determined by the gas-liquid interface and the fact that the bottom surfaces are determined by the substrate, have also been observed clearly in the Si/Al system. Furthermore, it was found that the upper and lower surfaces of the needles are no crystallographic faces in general.

3. The top surfaces of the needles, both in the Si/Sn and in the Si/Al system exhibit a reentrant corner (Fig. 4c and Fig. 5). Associated with a reentrant corner, a group of twin planes running parallel to the needle axis may always be observed (Fig. 4 and 5). These twin planes can be recognized by means of SEM, but particularly by means of differential interference contrast microscopy. The twin planes may be revealed more clearly by slight etching, *e.g.*, by gas phase etching using HCl (Fig. 6a, for Si/Al) or by Sirtl etching (Fig. 6b).

It appears that the needle axis and consequently the twin planes always run parallel to one of the sides of the stacking fault triangles that were created by the deposition of epitaxial silicon layers onto the needles (12) (Fig. 6b). This indicates that the twin lines always run parallel to a {111} plane. Also, the twin planes are virtually always parallel to the lateral faces of the needles. These faces constitute {111} planes, being the only stable F-face for the growth

Schematic representation of the characteristic features of needle growth.

of silicon from the metal melt (13). Hence it can be concluded that the twinning is of the type {111} normal twin (the twin axis <111> is normal to the {111} composition plane). This type of twinning is the most common one that occurs in the diamond lattice (14) (Fig. 7).

The growth mechanism that accounts for the generation of steps at a twin plane reentrant edge (TPRE) has been extensively studied both theoretically (15-17) and experimentally (18-21) for germanium, silicon, and diamond. The easy nucleation at a reentrant corner explains the high growth rate of the needles; Bennett and Longini (18) have been able to grow germanium crystals at a rate of 15 cm/min using TPRE growth.

The rate-determining step in this VLS mechanism is unknown in the present case; it is possible that the growth is limited by surface kinetics, volume diffusion, or heat transport.

It was shown by Wagner (19) and by Hamilton and Seidensticker (15) that at least two twin planes are required for a continued reentrant edge growth mechanism. As a matter of fact, on virtually all needles two or more twin planes could be discerned; the separation was sometimes less than 0.5 μm.

Growth history of the needles.—The growth process of the silicon needles can be summarized as follows (cf. Fig. 8):

1. The growth starts in the vicinity of the edges of the liquid droplets. Some of the microcrystals (having a size of a few microns) that are formed contain two or more parallel {111} twins. If these twins are directed toward the liquid, the formation of needles will start (Fig. 8a).

2. Needle growth (Fig. 8b): the TPRE-defined needle growth takes place at a very high rate (roughly 1000 μm/sec) and stops suddenly. In the Si/Al system the needle growth is stopped only by collision against other needles (cf. Fig. 2), but in the Si/Sn system, the needle growth often stops without an evident reason (this might be due to poisoning of the reentrant corner, or exhaustion of the solution due to the poor solubility of Si in Sn, 2 a/o at 1500 K). In principle, the needle size in the Al/Si system is unlimited (needles having a length up to 10 mm have been grown); the top and bottom surfaces are deter-

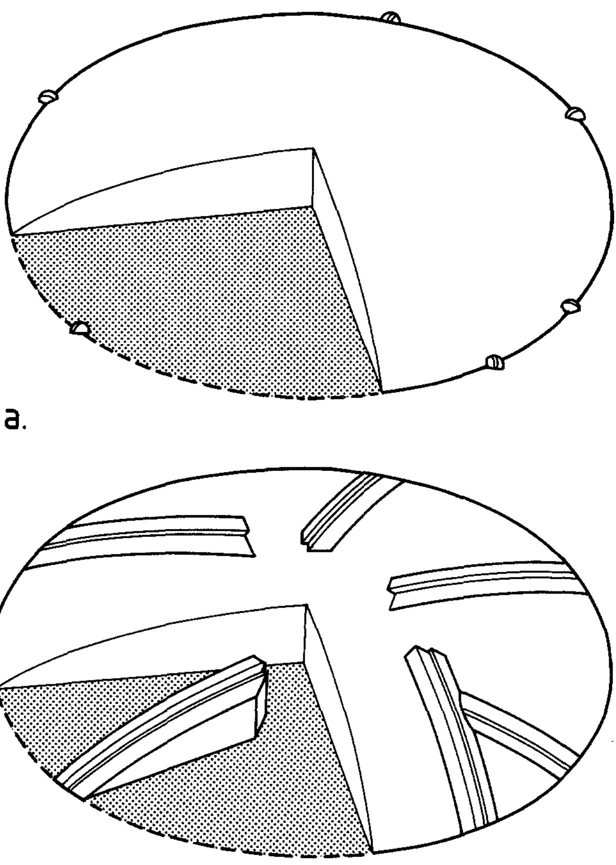

Fig. 8. Growth history of silicon needles. a. Nucleation on the edges of a droplet. b. Needle growth by a TPRE growth mechanism, followed by two-dimensional nucleation.

mined by the shape of the aluminum liquid and by the substrate, respectively.

3. Thickness growth: subsequently, the growth of the needles in the directions perpendicular to the silicon-liquid interfaces starts. Here, the growth rate is less than 1/60 of the TPRE growth. From this sharp decrease in growth rate, it can be concluded that for the thickness growth, the surface kinetics constitute the rate-determining step in the process. Very probably, this growth process is determined by a nucleation mechanism. This is indicated by the fact that the TPRE mechanism only occurs if no spiral growth mechanism is operative (17). It is well known that VLS growth can result in the formation of highly perfect crystals (22, 23). The defects that were revealed by Sirtl etchant were typically twins, stacking faults, and many points defects (the latter were presumably created due to tin inclusions, or after growth).

Only in a few cases dislocations or dislocation arrays (which might have been formed during cooling) have been found. The relatively low dislocation density is in agreement with the assumed nucleation mechanism.

Platelet growth.—Characteristics.—The growth of platelets is characterized by the following features:

1. The platelets usually originate in the liquid metal (homogeneous nucleation; Fig. 1e and f) and subsequently grow rapidly over the liquid surface via a VLS mechanism. In some cases platelets were observed to originate from the edge of a droplet (Fig. 9). Platelet growth was found to occur only in the Si/Sn system, and not in the Si/Al system.
2. The platelets always exhibit a hexagonal shape (Fig. 1f and Fig. 9), so it can be concluded that the top and bottom surfaces are usually {111} crystal faces. However, since the curved surface of the liquid determines the upper surface of the platelet (analogous to the morphology of needles), this surface can be slightly curved. The bottoms of the platelets are usually not in contact with the substrate; in some cases a movement of platelets over the liquid surface has been observed.
3. Sirtl etching and surface topography did not reveal any twinning lines (intersection lines of a twin plane with a crystal face) on the upper surfaces of the platelets originating from a central point to the corners. Careful observation, however, revealed the presence of twinning lines and associated reentrant corners on the narrow side faces of the {111} plates (Fig. 10). These lines were parallel to the {111} surface.

This indicates that the growth of platelets is governed by two or more twin planes parallel to the {111} surface. Thus, the growth of platelets proceeds via the TPRE mechanism that is also responsible for the growth of needles, as described by Faust and John (20) and Wagner (19). The growth mechanism has been pictured schematically in Fig. 10b.

Growth history of the platelets.—The growth process of the platelets can be summarized as follows (Fig. 11):

1. Probably, homogeneous nucleation in the liquid metal is responsible for the formation of platelets. Alternatively, nucleation may be initiated at the liquid-vapor interface (which might be explained by the existence of a concentration gradient in the liquid metal). Nucleation at the liquid metal-substrate interface is improbable, since after etching of the solidified metal no traces of silicon on the graphite could be detected. In some cases heterogeneous nucleation on the graphite on the edge of a droplet caused the formation of platelets; in this case the twin planes run parallel to the liquid surface.

In the case of homogeneous nucleation inside the liquid, a microcrystal migrates to the liquid surface (due to its small density compared with that of tin), where the platelet adjusts itself to the surface (*i.e.*, the twin planes become directed parallel to the surface). Any other geometry will result in the growth of needles.

2. Subsequently, a rapid lateral growth of the platelets takes place. Since the curvature of the droplet determines the curvature of the crystal top surface, the platelet will be slightly bent. As a consequence of this bending, after some time the twin planes will come out at the top surface instead of at the side facets, and lose contact with the liquid (Fig. 11b). Then, the growth rate decreases suddenly (Fig. 1f). On the upper surface of some platelets twin lines have indeed been found, running parallel to the edges.
3. If there are no twinning lines left on the side faces of the platelets (and consequently the reentrant corners are no longer operative), the subsequent growth continues via a nucleation mechanism. This is the slow growth (about 1/60 times the TPRE growth rate) that has been observed after the rapid growth

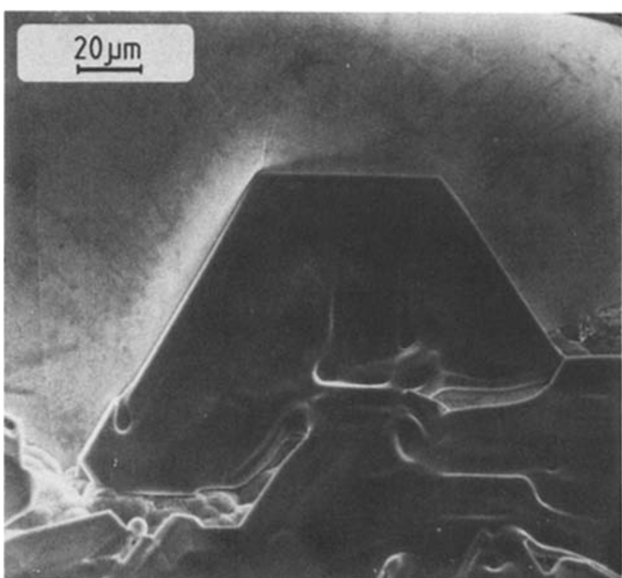

Fig. 9. Silicon platelet, nucleated on the edge of a tin droplet (SEM micrograph).

(Fig. 1g and h). The arguments for the assumption that this growth is governed by a nucleation mechanism, and that the surface process is the rate-determining step, are similar to the reasons given for the growth via nucleation for needles.

Two-dimensional VLS Growth

In some cases it was observed that some small tin droplets remained present on the top surfaces of the needles and platelets. Here the crystal surface always exhibited a very complicated pattern in which these few isolated tin droplets could be detected (see Fig. 12a). These patterns can be understood in terms of a two-dimensional VLS growth mechanism and are similar to the ones that have been observed on ice by Kobayashi (24) (however, in the present case there is no repeatable process for the formation of multiple terraces) and on $CuGaS_2$ by van Enckevort *et al.* (25). This two-dimensional VLS growth mechanism for the advancement of a macrostep has been outlined schematically in Fig. 12b. The growth of such a step is governed by the presence of a liquid tin front, which accelerates the process via a VLS mechanism. The observed solidified tin droplets are the remnants of these liquid "frills" at the edges of the macrosteps.

Conclusions

Silicon crystallites that resulted from the isothermal growth of silicon by means of chemical vapor deposition onto a graphite substrate coated with a liquid metal have been analyzed. It was found that the initial growth of the crystallites proceeds via a VLS mechanism. Two stages in this growth process could be discerned:

1. A rapid growth of needles and platelets according to the twin plane reentrant corner (TPRE) mechanism: the twin planes that are responsible for this mechanism run parallel to the needle axis in the case of needles and parallel to the surface in the case of platelets. There is no essential difference between the growth of needles and platelets. The distinction in morphology is determined by geometrical factors.

2. A slow growth via a nucleation mechanism: in the case of needles this process is observed as the thickness growth perpendicular to the needle axis. In the case of platelets it is observed as a slow lateral growth of the platelets if the twinning lines are no longer in contact with the liquid. Crystallites without twin planes have not been observed. This is caused by the overgrowth of these slow-growing clusters by crystallites possessing two or more parallel twin planes. Two-dimensional VLS growth has been observed on the upper surfaces of needles and platelets. The velocity of macrosteps appeared to be influenced considerably by the presence of a liquid metal frill at the step front. From the fact that even for higher supersaturations growth of the {111} faces of silicon and germanium from the melt or metallic solution is strongly accelerated by the occurrence of a TPRE mechanism as compared to two-dimensional nucleation, it can be concluded that the standard temperature θ [for definition of θ, see Ref. (26) and (27)] of these systems is far below the roughening transition point as was determined by Monte Carlo simulation (27). In a forthcoming paper (28), in which a comparison will be made between the Monte Carlo simulation results and growth experiments of {111} Si and Ge from the liquid phase, special attention will be paid to the relation between the parameters, which rule the simulations (such as θ), and experimentally known values. A closer investigation into the thermodynamic and kinetic phenomena that are associated with the described growth process may lead to an augmented knowledge of the growth of thin large-grain polycrystalline silicon layers onto nonsilicon substrates, and enable the preparation of inexpensive materials for photovoltaic solar cell fabrication.

Boron Autodoping during Silicon Liquid Phase Epitaxy

B. Jayant Baliga

General Electric Company, Corporate Research and Development, Schenectady, New York 12345

ABSTRACT

The occurrence of boron autodoping phenomena during the growth of silicon layers from the liquid phase (tin melt) is described. Autodoping has been observed to occur in this epitaxial growth process whenever meltback of the substrate occurs prior to epitaxial growth. Measurements of lateral autodoping show that the boron injected into the melt due to substrate meltback is rapidly dispersed in the melt. However, by preventing meltback with supersaturation of the melt prior to the introduction of the substrate into the melt, autodoping can be eliminated, thus allowing the achievement of abrupt doping profiles between the substrate and the epitaxial layer, and also allowing the fabrication of closely spaced, buried, boron-diffused regions for device applications.

Many silicon devices, such as bipolar integrated circuits, microwave IMPATT and PIN diodes, high speed varactors, and high frequency discrete transistors, require the growth of epitaxial layers on heavily-doped substrates with an abrupt transition in the doping between the substrate and the epitaxial layer. The silicon layers have conventionally been grown by vapor phase epitaxial growth techniques. In this process, two phenomena that prevent the achievement of an abrupt interface are the out-diffusion of the dopant from the substrate into the epitaxial layer during the high temperature epitaxial growth, and autodoping effects. In general, autodoping can be defined as the transport of dopants from the substrate into the epitaxial layer via the gas phase. Since autodoping degrades the abruptness in the transition between the doping of the substrate and the epitaxial layer and also increases the background doping concentration in the epitaxial layers, many studies have been conducted in order to minimize autodoping effects during silicon vapor phase epitaxial growth (1-4). These studies have shown that autodoping during vapor phase epitaxial growth arises primarily from (*i*) dopant outgassing into the vapor phase prior to the commencement of epitaxial growth, (*ii*) dopant evaporation from the back surface of the wafer during epitaxial growth, and (*iii*) dopant introduction into the gas phase due to substrate etching by halides during epitaxial growth. Based upon these mechanisms reduction in the autodoping during vapor phase epitaxy has been achieved by (*i*) lowering the epitaxial growth temperature, (*ii*) sealing the back surface

Key words: silicon epitaxy, autodoping, liquid phase epitaxy, meltback.

of the substrates with silicon dioxide, silicon nitride, or polycrystalline silicon, (*iii*) performing the epitaxial growth in the absence of halides by using silane as the source, and (*iv*) lowering the pressure in the reactor during epitaxial growth so as to reduce the partial pressure of the dopant impurities during deposition. In addition, two step epitaxial growth procedures have been developed to reduce autodoping effects (2, 3). Although all of these techniques have been successful in reducing the autodoping, they have not been able to eliminate the problem altogether. This is particularly noticeable when epitaxial growth is conducted over localized diffusions of dopants into the substrates, as is necessary, for example, during the fabrication of integrated circuits. In this case, autodoping causes the lateral transport of the dopant from the diffused area which results in severe distortion of the geometry of the diffused buried layer (5). Further, in the case of devices requiring closely spaced diffused buried layers such as field-controlled devices (6, 7), lateral autodoping can result in the formation of a connecting layer which prevents the desired isolation between these buried regions. The fabrication of these devices by vapor phase epitaxy, consequently, requires compensation of the autodoping by the addition of dopants in the gas phase. This approach is difficult to pursue in practice because of the need to achieve low epitaxial doping concentrations in the presence of strong autodoping effects.

This paper discusses autodoping phenomena observed during the growth of silicon layers by using liquid phase epitaxy. It is demonstrated here that autodoping effects can be completely eliminated by performing the epitaxial growth from the liquid phase. However, autodoping can occur even during silicon liquid phase epitaxial growth if care is not taken to prevent substrate meltback prior to epitaxial growth. In addition, the results of lateral autodoping studies are reported here for the case of boron-diffused regions in n-type silicon substrates. On the basis of these studies, growth conditions have been established which allow the fabrication of closely spaced boron diffused fingers buried under an n-type epitaxial layer. This new epitaxial growth technology has allowed the fabrication of high voltage field-controlled thyristors (8).

Epitaxial Growth Technique

The silicon epitaxial growth technique utilized in this study was based upon using liquid tin as the medium for the epitaxial growth. Tin was chosen as the solvent for the silicon because it is an element that lies in the fourth column of the periodic table of elements. Thus, the incorporation of the tin in the epitaxial layers was not expected to introduce either shallow dopant levels or deep lying recombination levels in the silicon energy gap. This has been confirmed by the fact that, although more than 10^{19} atoms per cm^3 of tin have been detected in the epitaxial layers by electron microprobe analysis, layers could be grown with n-type background doping levels between 5×10^{15} and 1×10^{16} per cm^3 with high minority carrier recombination lifetimes (greater than 10 μsec). In addition, the solubility of silicon in tin at relatively low temperatures (900°-950°C) is sufficient for the growth of even thick (50-100 micron) epitaxial layers.

The growth of the epitaxial layers was conducted in a hydrogen ambient by using the dipping technique. Studies of the growth of epitaxial layers conducted under slow cooling, as well as steady-state conditions using supersaturation, have demonstrated the capability for growing specular films with growth rates in the range of 0.1-1 micron per minute (9-11). In order to grow n-type epitaxial layers, the tin melt was first saturated with 100 Ω-cm, phosphorus-doped silicon wafers. The saturation was conducted while periodically monitoring the weight of the saturation wafers and was terminated when no further loss in the weight of the saturation wafers could be detected. In order to study the influence of both undersaturation and supersaturation, epitaxial growths were conducted on substrates which were introduced into the melt at temperatures above and below the saturation temperature. In each case, the epitaxial growth was induced by reducing the temperature of the furnace at controlled cooling rates ranging from 0.1° to 7°C/min. After epitaxial growth, the substrates were withdrawn from the melt and any excess tin attached to them was removed in aqua regia.

Autodoping Experiments

Heavily-doped substrates.—The first set of autodoping experiments were conducted with 0.01 Ω-cm, boron-doped, (111) ±½° oriented silicon wafers. Epitaxial layers were grown on these substrates with the melt undersaturated and supersaturated by 5°C prior to the introduction of the substrates into the melt. The doping profile in the epitaxial layer was then measured by using the ASR100 spreading resistance measurement system. The profiles are shown in Fig. 1. It can be seen that when the melt is undersaturated, a p-type interface layer with a graded doping concentration profile is observed at the interface between the epitaxial layer and the substrate. The nature of this doping profile has been analyzed and the p-type layer shown to arise from meltback of the substrate prior to epitaxial growth (12). If the melt is undersaturated when the substrate is introduced into it, part of the substrate is dissolved and the boron in that portion of the substrate is injected into the melt. This boron is subsequently incorporated into the epitaxial layer forming an exponentially graded p-type interface. This phenomena is, thus, similar to the autodoping observed in the case of vapor phase epitaxy and leads to a nonabrupt doping profile at the interface between the epitaxial layer and the substrate. In contrast, when the melt is supersaturated prior to the introduction of the substrate into the melt, no meltback can occur and an abrupt doping transition is observed at the interface between the epitaxial layer and the substrate as shown in Fig. 1b. Consequently, these experiments show that although autodoping can occur during silicon liquid phase epitaxy, it can be completely suppressed by supersaturation of the melt prior to the introduction of the substrates into the melt.

Boron-diffused substrates.—As stated in the introduction, one of the problems encountered during vapor phase epitaxy is the occurrence of lateral autodoping effects. This has been found to be particularly severe in the case of boron diffusions in n-type silicon substrates. Experiments were, therefore, conducted to study lateral autodoping effects during liquid phase epitaxy. For these experiments, boron diffusions were performed over a portion of 40 Ω-cm, phosphorus-doped silicon wafers using thermally grown silicon dioxide as a mask. After stripping the oxide on the wafer surface, n-type epitaxial layers were grown with an undersaturation of 5°C to determine the extent of the lateral autodoping. As illustrated in Fig. 2, if the boron injected into the melt due to meltback is localized to the diffused region, the lateral autodoping should be limited to a portion close to the diffused region. In contrast, if the boron injected into the melt is rapidly dispersed, the lateral autodoping should extend across the entire surface of the wafer.

To measure the lateral autodoping, spreading resistance measurements were made at the diffused portion of the wafer and at various distances from the edge of the diffused region as illustrated in Fig. 3 and 4. In the case shown in Fig. 3, only a part of the diffused layer was etched away by meltback as can be seen in the profile taken at the diffused region. The profiles taken at various distances from the edge of

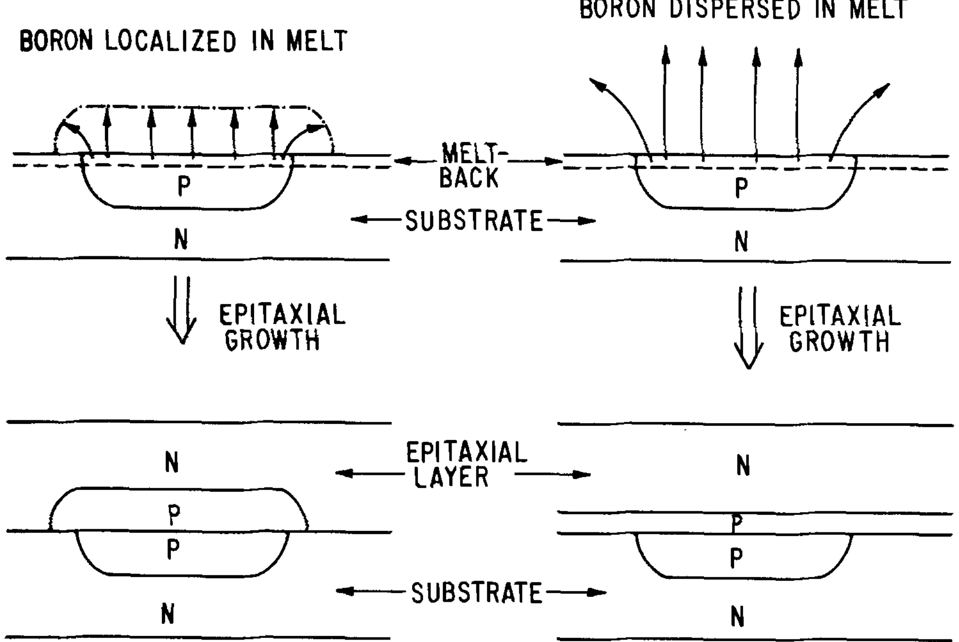

Fig. 2. Schematic illustration of lateral autodoping which occurs when the boron injected into the melt due to meltback is localized or dispersed in the melt.

the diffused region are also shown in Fig. 3. It can be seen that a p-type layer is observed at all distances from the edge of the diffused layer. (The maximum distance from the edge of the diffused region that was profiled was 1 in.) This p-type layer has the same peak doping concentration and width at all the profiled locations within the limits of experimental error. From this observation it can be concluded that the boron injected into the melt must be rapidly dispersed throughout the melt during epitaxial growth. Another example of this can be seen in Fig. 4. In this case, the meltback was sufficient to completely dissolve the boron diffused region prior to epitaxial growth. As a result the p-type layer formed at the interface between the substrate and the epitaxial layer has the same doping profile and

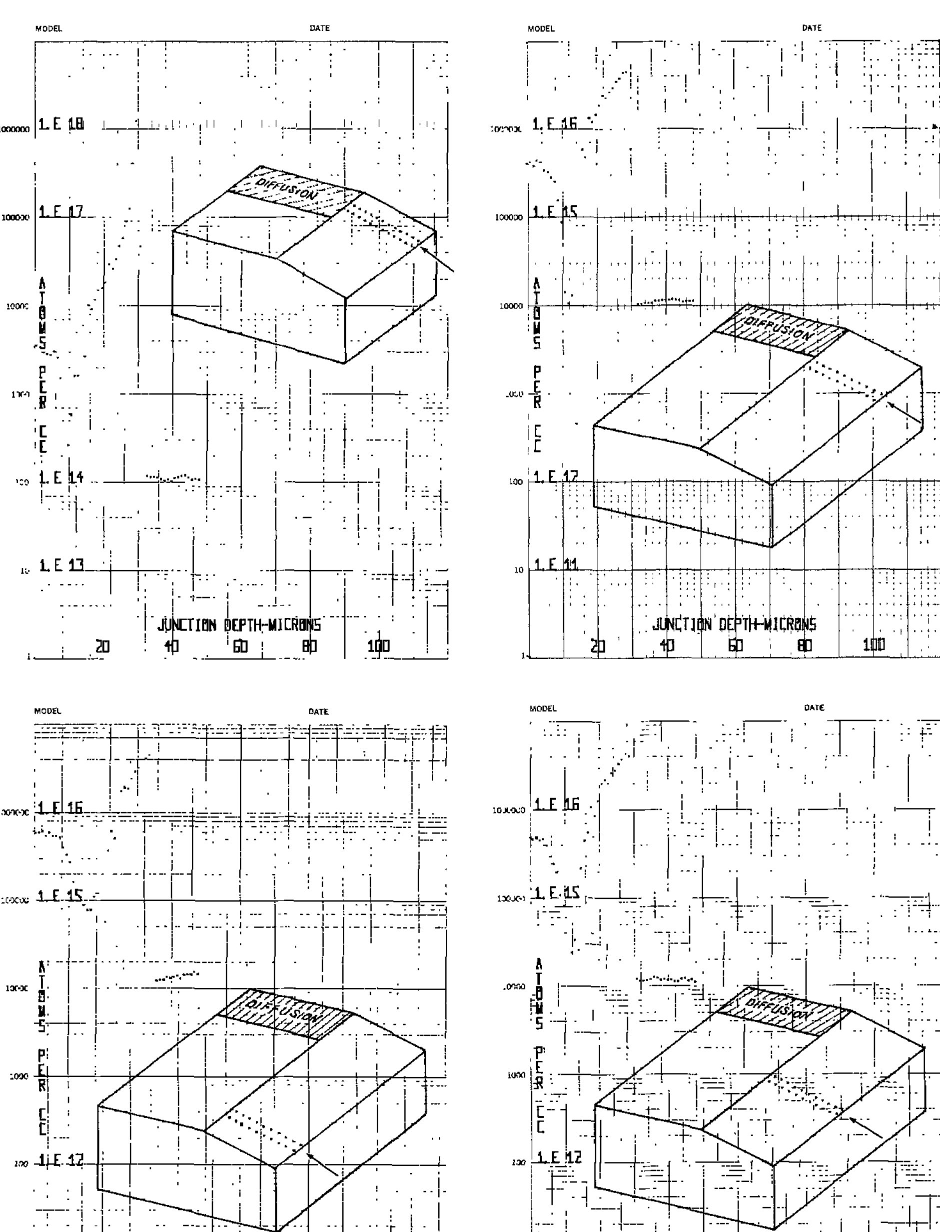

Fig. 3. Impurity distribution profiles taken at four locations on a wafer with boron diffusion at one end and an epitaxial layer grown with partial meltback of the diffused region prior to epitaxial growth.

thickness across the entire wafer. The results of these lateral autodoping studies, thus, indicate that to prevent lateral autodoping it is imperative to prevent meltback of the substrate prior to epitaxial growth by careful supersaturation of the melt.

Conclusions

Autodoping phenomena during silicon liquid phase epitaxy have been studied for the cases of boron-doped substrates and boron diffused layers in n-type substrates. It has been determined that autodoping can also occur during silicon liquid phase epitaxy if any meltback of the substrate occurs prior to epitaxial growth. In the case of localized boron diffused regions, it has been found that the lateral autodoping extends uniformly across the entire wafer surface indicating that the boron injected into the melt from the diffused regions due to meltback is rapidly dispersed throughout the melt. It can, therefore, be concluded that in order to eliminate autodoping during silicon liquid phase epitaxy it is essential to prevent any meltback of the substrate by supersaturation of the melt prior to the introduction of the substrate. With supersaturation of the melt, the liquid phase epitaxial growth technique is capable of completely eliminating boron autodoping effects. This has allowed the fabrication of epitaxial layers with abrupt doping transitions between the epitaxial layer and heavily-doped substrates, and the fabrication of closely spaced, buried, boron diffusion regions in n-type substrates (13).

Resolution Limits of PMMA Resist for Exposure with 50 kV Electrons

Alec N. Broers

IBM, T. J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

An electron beam with a diameter below 1 nm has been used to measure the resolution of PMMA. Test patterns are written in 30 nm thick PMMA layers coated onto 60 nm thick Si_3N_4 membrane substrates. Both lateral scattering of electrons in the resist and backscattering from the substrate are negligible for these samples. Preliminary results obtained with 50 kV electrons are presented in this paper. The test patterns contain nominal linewidths down to 4.4 nm. The exposure distribution is determined by measuring the exposure dose needed to open up lines with widths smaller than the width of the distribution. Samples are examined in the scanning transmission microscope mode using the same beam used to write the patterns. The width [standard deviation (σ) assuming a normal distribution] of the exposure distribution has been measured to be between 11 and 14 nm. This spread function makes it possible to resolve lines on 45 nm centers in these very thin resist layers. Spreading is assumed to be set by straggling of low energy secondary electrons into the resist although effects that may be attributable to the finite molecular size of the PMMA have also been observed. It is pointed out that thin film substrates are not essential to obtain linewidths of 50 nm. Resolution and contrast on thick substrates are discussed and compared with the resolution and contrast obtainable with light optical systems.

Since the original publication of Haller, Hatzakis, and Srinivasen (1), polymethyl methacrylate (PMMA) has been used as the standard resist for high resolution electron beam fabrication. The exposure dosage for PMMA (5×10^{-5}-2×10^{-4} C/cm^2) is too high for many semiconductor direct exposure applications, but, to the extent that it has been measured, its resolution is unsurpassed by other resists. Operational devices with dimensions of 0.15 μm (2) and metal structures as small as 60 nm (3) have been fabricated on bulk substrates (substrates thick compared to the electron penetration distance), and 25 nm lines have been resolved on substrates thin compared to the electron penetration distance (4). In addition to PMMA's use with electron beams, exposure with 4.5 nm x-rays has yielded features of 17.5 nm (5) and exposure with ions has produced linewidths below 100 nm (6).

The resolution that can be obtained in an electron resist layer is usually determined by lateral scattering of electrons in the resist layer and by electron backscattering from the underlying substrate. In order to measure the resolution in the absence of significant electron scattering we have used 50 kV electrons to expose very thin ($\sim$30 nm) layers of PMMA supported on thin ($\sim$60 nm) Si_3N_4 membrane substrates. Under these conditions, resolution becomes effectively limited only by the basic physical processes involved in breaking the bonds in the methacrylate polymer. The probability that lateral scattering of electrons will be significant can be estimated from the theoretical and experimental data of Misell (7), if it is assumed that scattering in PMMA is similar to that in carbon. Such an estimation shows that in passing through a 50 nm thick carbon film, less than 1% of 50 kV electrons will be scattered through angles equal to or exceeding the convergence angle of the electron beam (10^{-2} radian). Lateral scattering effects in a 30 nm thick PMMA layer should therefore be negligible. Backscattering from the Si_3N_4 substrate can be estimated by calculating the probability of Rutherford scattering events through angles greater than 90°. Data presented by Wells (8) indicate that there is only a 10^{-3} probability that a 50 kV electron will be backscattered from a 60 nm thick film of atomic number 12. Therefore, backscattering from the Si_3N_4 substrate should also be negligible.

The minimum energy required to break bonds in PMMA can be estimated to be 5 eV from the wavelength of the "softest" u.v. radiation capable of exposing the resist (9). With electrons, it is proposed that exposure is effected predominantly by low energy secondary electrons because the cross section of these electrons for bond scission will be very much greater than the cross section of the high energy primaries. The secondaries can be excited at a distance from the path of the high energy primaries and they can travel further into the resist before their energy is fully dissipated. The overall distance the secondaries travel blurs the pattern and determines the ultimate resolution of the resist exposure process. Measurements of the secondary electron yield from thin dielectric layers indicate that the range of low energy secondary electrons in dielectrics is several tens of nanometers (10). The measurements on PMMA presented here in general confirm this deduction.

Sample Preparation

The membrane substrates were fabricated by selectively etching holes through the silicon of Si_3N_4 coated silicon wafers. An anisotropic silicon etch was used to etch the holes (11). The etch stops at the Si-Si_3N_4 interface and leaves the Si_3N_4 membrane covering the holes. The holes were generally about 100×100 μm. We used 30 and 60 nm thick membranes, however, the 30 nm membranes were generally too fragile to be practicable; almost half of them broke during processing. Because no loss in resolution was observed with the 60 nm membranes (this is expected from electron backscattering data), they were used for most experiments. Very few cases of breakage were encountered with the thicker membranes.

After window fabrication, the silicon wafers were diced into chips 2.6×1 mm. For electron beam exposure and subsequent examination in the scanning transmission electron microscopy (STEM) mode, the chips were mounted in a sample holder designed for standard 3 mm diam electron microscope grids. Each chip contained two windows.

Resist was coated onto the membrane substrates using a conventional spin-coater. The samples were held with a vacuum chuck designed to avoid the application of atmospheric pressure across the membranes. Very dilute resist (1:50, 2010 PMMA:chlorobenzene) and relatively slow spinning rates (2000-3000 rpm) were used to produce resist layers with thicknesses between 30 and 100 nm. As discussed below precise measurement of resist thickness was made from STEM images of the developed samples after shadowing the samples with a thin layer of metal. Resist thickness was uniform to better than 10 nm over the window areas. Resist layers were baked at 160°C for 1 hr to remove residual solvent.

In order to provide detail on the sample for focusing, a 5 nm thick PdAu layer was vapor deposited onto the underneath of the membrane. Structure in this layer provided high contrast in the bright field STEM image and made it easy to determine that the beam diameter was less than 1 nm. The number of primaries backscattered from this layer is less than 1 in 500 (8), and few low energy secondaries formed at the PdAu/Si_3N_4 interface will penetrate the Si_3N_4 membrane to the resist. The PdAu layer should therefore have little effect on resist exposure.

Image spreading due to the finite angular width of the beam was about 2 nm (resist thickness 30 nm, substrate thickness 60 nm, beam half-angle 10^{-2} radian) assuming that the beam was focused accurately on the bottom of the Si_3N_4 membrane. The AuPd layer had sufficient conductivity to avoid sample charging during exposure.

Exposure

Patterns were written in an STEM (12) with an electron beam diameter of less than 1 nm. The patterns were written under the control of a flying spot scanner. The exact nominal exposed linewidths were measured from the video signal produced by the STEM bright field detector. The linewidth is given by the width of the "beam-on" pulses on the video signal. This method eliminated any errors that might have arisen due to the finite resolution of the flying spot scanner. In practice the linewidths scaled very closely with the actual mask dimensions.

Beam current was measured using a Faraday cup located below the sample. Beam current had to be kept at a level of about 2×10^{-12}A because of the small area of the pattern and the relatively slow scan rate of the STEM system (minimum frame time of 10 sec). The pattern was typically 2.5×2.5 μm for a minimum nominal linewidth of about 2.5 nm.

Before each pattern was exposed, the beam was offset to an area adjacent to the exposed area and the beam focused on the PdAu layer underneath the membrane. The sample was mechanically moved approximately 20 μm between exposure sites. The vertical accuracy of the sample stage was such that adjustment of focus after movement was unnecessary in the majority of cases.

Samples were developed for about 50 sec with the standard PMMA developer; one part methyl isobutyl ketone to three parts of isopyl alcohol. Our measurements indicated that the developer dissolved the unexposed resist at a rate of about 25 nm/min so the initial resist thickness was approximately 20 nm thicker than that measured for the developed patterns.

After development, 5 nm of AuPd was vapor deposited onto the top of the resist at an incidence angle of 45°. This metal layer clearly outlined the resist pattern, and the shadow length was an accurate measure of the resist thickness.

Determination of Exposure Distribution

The test pattern used in these experiments is shown in Fig. 1. The pattern was written at a size that yielded a minimum nominal linewidth of 4.4 nm.

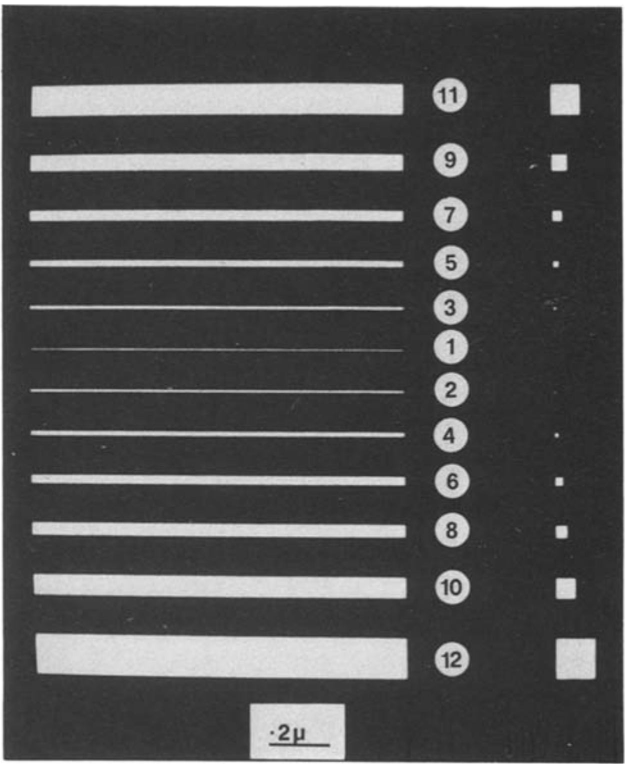

Fig. 1. Pattern used to evaluate exposure distribution in PMMA. Nominal linewidths in the exposed patterns were as follows: 1, 4.4 nm; 2, 7.5 nm; 3, 11 nm; 4, 14 nm; 5, 20 nm; 6, 26 nm; 7, 33 nm; 8, 38 nm; 9, 53 nm; 10, 62 nm; 11, 96 nm; 12, 120 nm.

The broadest line was about 120 nm wide. Eleven different exposure times were used for each experimental run. The shortest time gave an exposure dose which was below that needed to open up the largest shapes. The longest time was such that the resist developed through in the site of the narrowest line.

If the exposure distribution is Gaussian, then using the "reciprocity principle" of Chang (13), the exposure dose (Q_w) received at the center of an infinitely long rectangle of width w can be shown to be given by

$$Q_w = Q_o \operatorname{erf}(w/2\sigma)$$

where Q_o is the exposure dosage in the center of an infinitely large shape and σ is the standard deviation of the distribution.

Figure 2 is a bright field STEM micrograph of the test pattern exposed at a dose slightly greater than that needed to open large shapes. The standard deviation (σ) of the exposure distribution was calculated from patterns of this type exposed at progressively greater doses. σ was calculated from the nominal linewidth (w) of the narrowest line that had developed through to the substrate, and the ratio of the exposure dosage for the given test exposure to the exposure dosage needed to develop through to the substrate in the sites of the large shapes (Q_w/Q_o). If the distribution is truly Gaussian, then the same σ will be found for each of the test exposures. In practice, this was not the case. Heavier exposures, in which narrower lines had developed through to the substrate, in general yielded σ values higher than those deduced from lower exposure doses. In a series of five separate experiments, the average values of σ varied from 11 to 14 nm. The resist thickness was about 30 nm. The fractional exposures received for different linewidths are plotted in Fig. 3. The fractional exposure was determined from the exposure times needed to open up different linewidths. For example, it took about five times longer to open the 5 nm nominal linewidth line than it did to open the large shapes. Figure 3 also

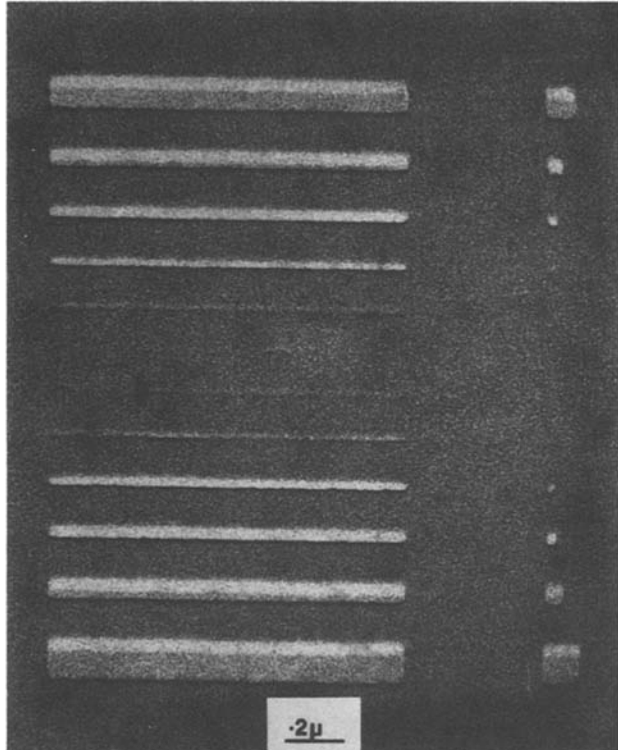

Fig. 2. Bright field STEM micrograph of test pattern exposed at a level slightly greater than that necessary to open up shapes that are large, compared to the width of the exposure distribution. Narrowest line that has opened up in this case is 20 nm wide. Electron beam used to write the pattern was smaller than that used to obtain this micrograph. Detail resolved in the AuPd coatings at higher magnification shows that the beam diameter is less than 1 nm. Sample is shadowed at 45° with AuPd to reveal resist thickness.

shows the fractional exposure that would be obtained with a resist with a Gaussian distribution ($\sigma = 12.5$ nm). An additional experiment in which identical exposures were made on three different resist thicknesses (50, 80, and 100 nm) showed that, as expected from electron scattering data, there was no significant dependence on resist thickness for thicknesses below 100 nm.

The narrowest line that opened up at the dose required to open up the large shapes ($\sim 3 \times 10^{-4}$ C/cm^2) was between 20 and 25 nm wide (line 5 and line 6). In practice the developed lines were close to their nominal width. As the exposure dose was increased to open the narrower lines, the linewidth of the wider lines increased. The rate of increase can also be used to estimate the σ of the spread function in the resist, however, this will not be discussed here.

If exposure is due to low energy secondary electrons alone, and the excitation of secondaries is isotropic and random, it would appear reasonable for the distribution to be Gaussian. The deviation observed could be the result of a dependence of development rate on linewidth. Development may be slower for narrower lines because the lines become comparable in size to the molecular size of the PMMA and slow the development process.

If the exposure distribution is Gaussian, then the ratio of the exposure dose received at the center of a line (Q_l) to the exposure dose received at the center of a space (Q_s) for an array of infinitely long parallel lines with equal linewidth and spacing is given by

$$\frac{Q_l}{Q_s} = \frac{\operatorname{erf} S/4 + \sum_{n=1}^{n=m} [\operatorname{erf}(4n+1)S/4 - \operatorname{erf}(4n-1)S/4]}{\sum_{n=1}^{n=m} [\operatorname{erf}(4n-1)S/4 - \operatorname{erf}(4n-3)S/4]}$$

where s is the center to center spacing between the lines, and m = the number of lines taken in account on either side of the line under consideration. It is also useful to define what we shall call the resist contrast function (RCF), K, where

$$K = \frac{Q_l - Q_s}{Q_l + Q_s}$$

This definition is similar to that of the modulation transfer function (MTF) for an optical system except that for the optical case the pattern distribution is generally assumed to be sinusoidal rather than the square wave we have assumed for the electron beam resist case. Figure 4 shows the RCF for a resist that exhibits a Gaussian exposure distribution. For a thin substrate, 60% contrast ($K = 0.6$) corresponds to a spatial frequency (ν) of 0.28 σ^{-1}. If it is assumed that the distribution for PMMA is Gaussian and that σ = 12.5 nm, then 60% contrast is obtained for $\nu = 0.28 \div 12 \times 10^{-7} = 2.24 \times 10^5$ lines/cm (44.6 nm center to center spacing). As already discussed, it is assumed that the electron beam diameter is zero and that lateral electron scattering in the resist is negligible.

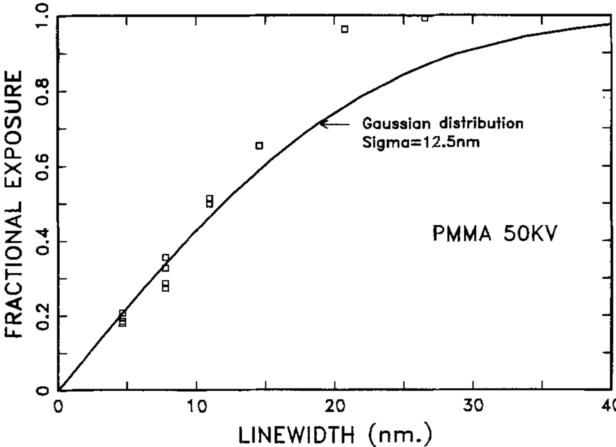

Fig. 3. Fractional exposure received at the center of isolated lines of various widths for PMMA exposed on a thin substrate with 50 kV electrons. Curve shows case for a Gaussian exposure distribution with $\sigma = 12.5$ nm.

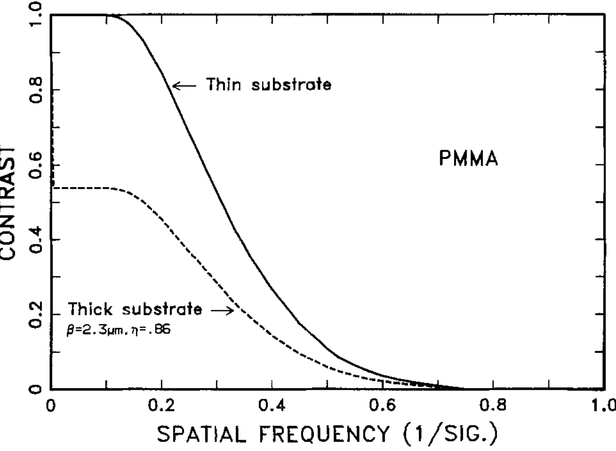

Fig. 4. Resist contrast function (RCF) for a resist with a Gaussian exposure distribution. Thick substrate curve assumes that the width of the backscattered distribution >> that of the resist exposure distribution, and that the total backscattered exposure contribution is 0.86 times that of the incoming beam.

60% is the order of contrast normally required for adequate definition in a developed resist pattern. Broers, Harper, and Molzen (4) reported a minimum center to center spacing of 50 nm for a 110 nm thick PMMA layer on top of a 20 nm layer of AuPd on an Si_3N_4 membrane. This is in good agreement with the results reported here. The RCF for a thick substrate shown in Fig. 4 is discussed in the next section.

Resolution with Thick Substrates and with Optical Systems

On thick substrates, both backscattered and primary electrons produce secondaries and contribute to resist exposure. It has been found that exposure by the backscattered electrons can be approximated by a Gaussian distribution with a standard deviation of several microns. The total exposure contribution of the backscattered electrons is approximately equal to that of the primary electrons. Several workers have modeled and measured the parameters associated with backscattering from targets of different materials and thicknesses [*e.g.*, Ref. (14-18)]. We shall assume that for silicon, the standard deviation of the distribution is 2.3 μm, and the total exposure due to backscattered electrons is 0.86 times that of the primaries (19). According to these parameters, the backscattered contribution to an isolated line 25 nm wide on a silicon substrate is 0.86 Q_o erf (0.025/4.6) $=$ 0.004 Q_o where Q_o is the incident dosage. The contribution is, therefore, so small that it can be ignored. This is the case for an isolated shape that is very small compared to the area from which backscattered electrons re-emerge from the sample. For an array of such shapes that covers an area that approaches, or is greater than, the area from which the backscattered electrons emerge, then backscattering becomes significant and gives rise to the well-known proximity effect (13). The dotted curve in Fig. 4 shows what happens to the RCF in this case. In the example shown, it is assumed that $\sigma_{\text{backscattered}} = 184 \times \sigma_{\text{resist}}$ ($\sigma_{\text{backscattered}} = 2.3$ μm, $\sigma_{\text{resist}} = 12.5$ nm), and that the total backscattered contribution is η times the contribution of the primary beam, where $\eta = 0.86$ (silicon substrate). The maximum contrast is 0.54 under these conditions.

Figure 5 shows the resist contrast functions for PMMA plotted against linewidth. Again it is assumed that the pattern consists of an infinite array of equal lines and spaces. The contrast for a light optical system with a numerical aperture (NA) $=$ 0.41 and operating wavelength (λ) $=$ 405 nm is also shown. The dotted version of the optical curve shows the contrast for a square-wave target (20) rather than a sinusoidal target. Several observations can be made from Fig. 5:

1. For electron beam (50 kV) exposure of PMMA on a thin substrate, 60% contrast is obtained for a linewidth of 22.3 nm.

2. For the thick silicon substrate, the electron beam RCF for PMMA is essentially flat from 50 nm to 2 μm, meaning that it should be no more difficult to produce 50 nm lines and spaces than it is to produce 2 μm lines and spaces. As before, this assumes that resolution is not limited by the electron optical system or by lateral electron scattering in the resist (*i. e.*, the resist must be very thin). Proximity correction will probably have to be used in most cases. The algorithms used for computing proximity corrections will depend on the ratio of the size of the pattern elements to the width of the backscattered distribution. For very small pattern features, proximity correction may be easier because it may be possible to treat the backscattered contribution as a uniform background. For intermediate dimensions, it may be adequate to use the average exposed area in regions surrounding each pattern element, rather than to take individual pattern elements, and even partial elements, into account as is done for 1 μm dimensions.

3. On the thick silicon substrate, 54% contrast is reached for a linewidth of 50 nm, whereas on the thin substrate, 54% contrast is reached at 20 nm. In other words, minimum lines 2.5 times smaller should be obtained on the thin substrate.

4. The 0.41 NA optical system has higher contrast than the electron beam on a thick substrate for linewidths above about 0.5 μm. At 1.25 μm linewidth, the contrast of the optical system is 85% compared to 54% for the electron beam. It is important to realize, however, that the exposure transition at the boundary between a line and a space can be sharper for the electron beam case than it is for an optical system even when the nominal contrast is lower. This is illustrated in Fig. 6 which simply compares the exposure profiles of four lines and three spaces for an optical system with 85% contrast, and for an ideal electron beam system with 54% contrast.

All of the preceding discussion relates to the contrast obtained for an infinite array of lines and spaces. When the total pattern area is small compared to the area from which the backscattered electrons emerge, resolution on bulk substrates should be as good as that on thin membranes. This is the case for

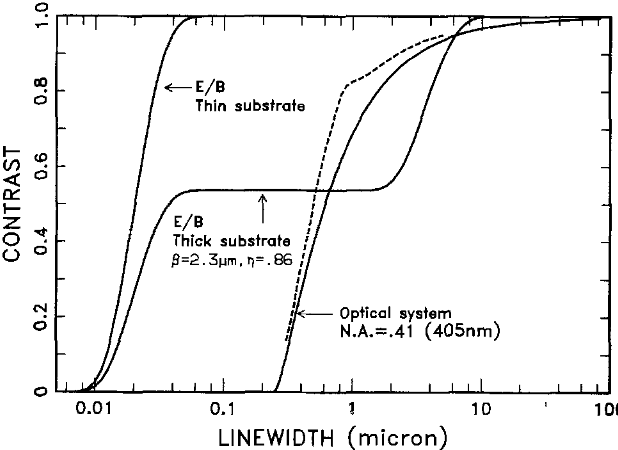

Fig. 5. Contrast *vs.* linewidth for electron beam exposure of thin PMMA on a thin substrate, electron beam exposure of thin PMMA on a thick silicon substrate and for an optical system with NA $=$ 0.41 and λ $=$ 405 nm (dotted curve shows contrast for optical system when target has a square wave distribution). Contrast is calculated for an infinite array of equal lines and spaces.

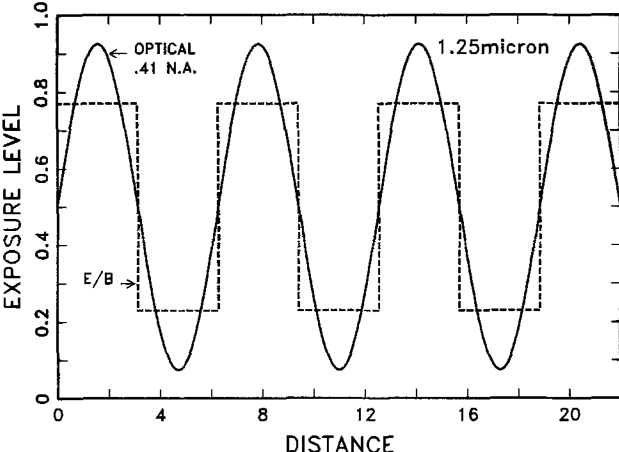

Fig. 6. Exposure distribution for an ideal electron beam system exposing thin resist on a thick substrate (contrast 54%), compared to exposure distribution for an optical system with 85% contrast. In the electron beam case, the transition between line and space is sharp, but there is an overall background exposure due to the backscattered electrons.

several of the experimental structures and devices built to date, for example, nanobridges (21) and SQUIDS (22). These devices were fabricated using contamination resist and thin substrates, however it would seem quite possible to make them using PMMA on thick substrates. In support of this, lines of 40 nm have recently been produced on a thick substrate using a high contrast double layer resist process (23).

A significant practical disadvantage of samples on bulk substrates is that they have to be examined in the conventional surface SEM with relatively low contrast and resolution. When the samples are on thin membranes, they can be examined by transmission electron microscopy with much higher contrast and resolution. This is particularly important for structures smaller than about 20 nm in size where we have had difficulty with the SEM in examining resist patterns, in knowing whether samples were completely etched, or even in knowing whether the films from which the structures were fabricated were continuous.

Subthreshold Degradation in MNOS Technology

P. K. Chaudhari[1]

IBM Corporation, Poughkeepsie, New York 12602

ABSTRACT

A film of Si_3N_4 deposited on thermally grown SiO_2 was studied to determine the subthreshold voltage stability. Long-term reliability results have indicated the presence of more than one mechanism causing the subthreshold degradation. The two mechanisms are identified as electron tunneling and lateral migration of the ions along the surface of the device. The relevant experimental results have confirmed the sources of these mechanisms to be: (*i*) polyoxide-nitride interface for electrons, and (*ii*) metal-nitride interface and/or a cavity at the edge of the device gate for ions.

A major instability and hence reliability concern in an insulated-gate field effect transistor (IGFET) technology is the threshold voltage shift. Many of the current applications of MOS and related devices depend critically upon current flowing in the device in the normally off or subthreshold region of operation. As the gate-to-source voltage is reduced below the conventional threshold voltage, channel current does not suddenly drop to zero. Rather it diminishes approximately exponentially with decreasing gate voltage, making I_D-V_G characteristics very sensitive to any small variations in the gate voltage. Therefore a slight departure in the subthreshold region of I_D-V_G behavior will be a serious reliability concern for the design circuitry, with stringent low current restrictions (low picoampere range) such as dynamic memory arrays. For several years, Si_3N_4 films have been the subject of extensive studies. The objectives of these studies were to eliminate the instabilities of MOS devices due to contamination of Na ions (1) and to enhance gate reliability. Recently DeSimone *et al.* of IBM (2) announced a dynamic memory using MNOS FET technology. It has been found that MNOS structures exhibited a new type of instability, electronic in origin (3), causing a conventional threshold shift (4). However, nothing has been reported about the subthresh-

Key words: oxide-nitride dielectric, MNOS FET, subthreshold leakage mechanism.

old degradation of these MNOS FET devices. Therefore MIS structures consisting of a film of Si_3N_4 deposited on thermally grown SiO_2 were studied to determine the subthreshold voltage stability. In this paper, we first describe the fabrication of MNOS FET devices and provide details of measurements. Then the results of the subthreshold voltage degradation are analyzed with the development of a physical model. Next, consistent with the experimental results, the sources of the degradation mechanism are discussed, followed by concluding remarks.

Experimental

A number of experimental MNOS FET devices were fabricated using p-type 1-2 Ω cm silicon wafers. The first step in the process is the deposition of arsenosilicate glass film, which acts as a dopant for the source and drain regions. The first masking operation defines a window in this initial oxide for source and drain formation. After the diffusion of arsenic from this glass film to form source and drain regions, the film is stripped off and gate oxide is grown immediately after cleaning. Immediately following thermal oxidation, silicon nitride is deposited on SiO_2 by decomposition of silane in ammonia. The physical and electrical properties of Si_3N_4 films have been found to vary with the deposition conditions such as NH_3/SiH_4 ratio and the deposition temperature. As the Si_3N_4 film is a part of the gate dielectric in this study, the requirement was to have the lowest electrical conductivity films and high dielectric constant. Such an ideal insulator film was obtained when Si_3N_4 was chemically deposited at 925°C using a ratio of NH_3/SiH_4 of 150:1 by volume, with H_2 as a carrier gas. The deposition rate was approximately 10 nm/min. The dielectric constant of the film was 7.0 and the etch rate in 5:1 buffered etch was 6 nm/min at 50°C. Transmission electron microscopic examination did not reveal any evidence of crystallinity and were found to be essentially amorphous. Si_3N_4 films thus fabricated were used in this study. In order to make an n-channel technology practical for dynamic storage applications, a field shield can be used to prevent high leakage due to depletion or inversion of the p-type silicon wafer (5). Therefore, the p-type polysilicon layer was chemically vapor-deposited on top of SiO_2 and Si_3N_4 dual dielectric. The oxide-nitride insulator forms the gate dielectric and the insulator which separates the field shield from the substrate. The field shield is then removed from the gate region and is oxidized in steam at 1050°C to reduce the possibility of shorting between the field shield and the gate. The thickness of the polyoxide is about 300 nm. After opening the contact holes through this polyoxide and cleaning the gate region, metal gate is deposited and is subtractively etched. The final process is the postmetal anneal in forming gas at 400°C for 20 min to minimize the surface states at the Si/SiO_2 interface. Conventional photolithography was used throughout the fabrication. A cross section of the device thus fabricated is shown in Fig. 1. The high frequency (1 MHz) MNOS C-V technique was used to measure the maximum capacitance, C_{max}, with a control wafer. The equivalent gate dielectric thickness, t_{eq}, was determined from

$$t_{eq} = t_{ox} + \frac{t_n \epsilon_{ox}}{\epsilon_n} = \epsilon_{ox}\epsilon_0 A_c / C_{max} \quad [1]$$

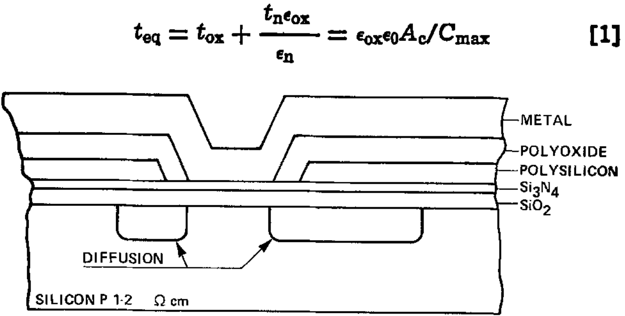

Fig. 1. MNOS FET device process profile

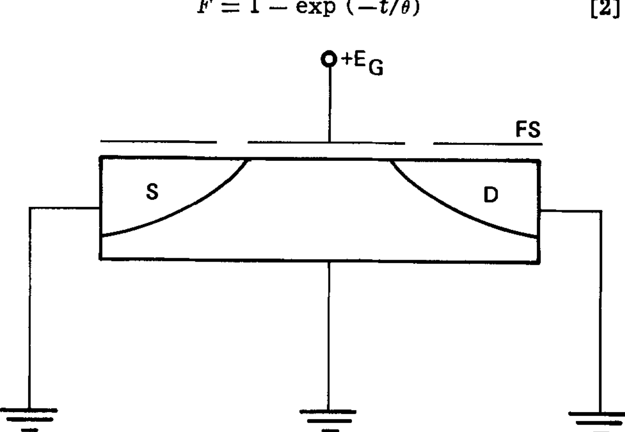
where t_{ox} is the oxide thickness, t_n is the nitride thickness, ϵ_{ox} and ϵ_n are the dielectric constants of the oxide and nitride, respectively, and A_c is the capacitor area. The equivalent dielectric thickness, t_{eq}, was 45 ± 3 nm. Mobile ion contamination, checked with a control wafer by the high temperature quasistatic technique (6), was found to be consistently less than 5×10^{10} cm^{-2}.

The aging experiments were performed in the following manner. Devices were stress aged in standard configuration, as shown in Fig. 2, at various voltages and temperatures. Forty to 70 devices were stressed in each stress cell. After a given period at elevated temperature, the devices were cooled to room temperature with the bias applied, subthreshold voltage readouts (I_D-V_G at $V_s = -0.5$V) were taken using automatic tester. A typical I_D-V_G relationship at time zero (*i.e.*, before the device is stress aged) is shown in Fig. 3. As expected, the device turns off as the gate voltage is decreased. The device design specification in this region generally calls for a slope of ≤ 80-90 mV per decade at room ambient. On stressing, the I_D-V_G relationship for a device susceptible to the subthreshold leakage is also shown in Fig. 3, now the slope in the subthreshold region >> 80-90 mV/decade. Clearly this is not acceptable behavior, as the device is no longer an enhancement device. Therefore, the value of the stress voltage threshold at which the subthreshold begins to appear is important and should be high enough so that over the lifetime of the device there is no significant parasitic leakage. For the purpose of analysis of the results of this parasitic leakage (or subthreshold voltage shift), a failure criterion used was when the value of I_D measured at $V_G = 0.5V < 350$ Pa. For subthreshold degradation characterization, another suitable criterion used was a value ΔV_{eff} measured at $I_D = 50$ nA.

Results and Discussion

Using the failure criteria mentioned above, Fig. 4 shows a typical behavior of failure F, due to subthreshold degradation, as a function of time plotted on a linear scale. The curve is seen to follow an exponential law quite well, which can be described as

$$F = 1 - \exp(-t/\theta) \quad [2]$$



STRESS MATRIX

FIELD V/CM / TEMP →	85°C	125°C	165°C
2.44 x 10^6		X	
3.11 x 10^6		X	
3.80 x 10^6	X	X	X

X = SAMPLES

Fig. 2. Standard stress configuration for subthreshold stability

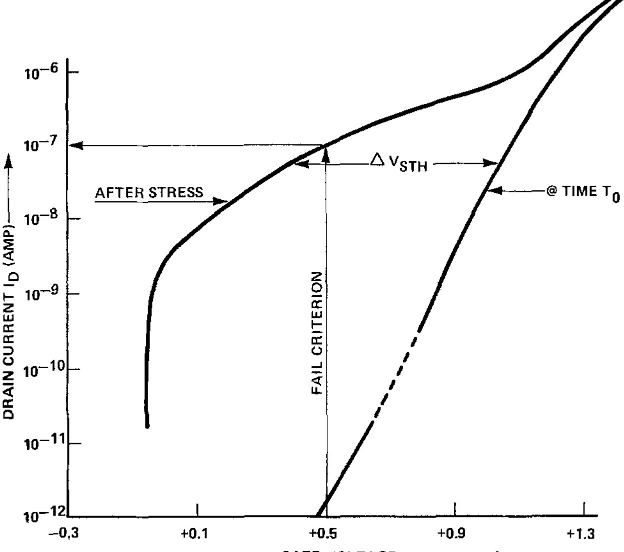


Fig. 3. Typical plot of subthreshold characteristics for MNOS FET.

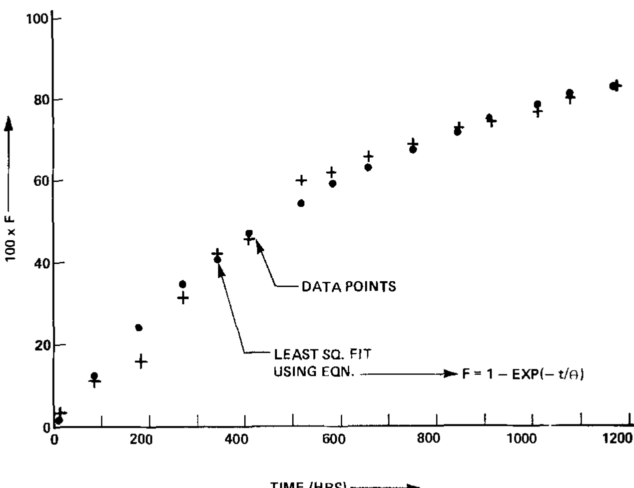

Fig. 4. Subthreshold degradation failure, *F*, as a function of stress time (standard stress at 85°C, 3.5 × 10^6 V/cm).

where t is the time to fail and θ is the mean time to fail (MTTF → θ), a function of stress field and temperature. Functional dependence of θ on stress field E is shown in Fig. 5.

The curves A and B in Fig. 5 represent the results accumulated at two different time periods. The curve B does indicate the improvement over the curve A. The only difference in these curves is that the polyox deposition temperature was 50°C higher in the curve B than in the curve A device process. However, it is evident that the mechanism causing the subthreshold degradation remains the same in both cases. The improvement due to higher polyox temperature (*i.e.*, higher field for the onset of subthreshold leakage) is consistent with the proposed mechanism to be discussed below. From Fig. 5, the following salient features of the subthreshold failure characteristics are observed.

1. At fields > 3.5 × 10^6 V/cm, $\theta - E$ behavior is very sensitive to the stress field and does not follow the linear relationship, as is evident in the field range of $2.5 \times 10^6 < E < 3.5 \times 10^6$ V/cm. This behavior is more clearly demonstrated with the combined short-term and long-term stress data shown in Fig. 6.

2. At low fields < 2.5 10^6 V/cm, the trend seems to indicate that the mechanism causing the failure is either minimal or insignificant. This point is elaborated later.

Physical Model

From Fig. 5 and 6, it is evident that the experimental data at high fields is below the linear region, *i.e.*, θ tends to be small in going from region II to region I. Therefore, this observed behavior is successfully explained if the degradation mechanism is assumed to consist of two mechanisms as discussed below.

Region I.—Electronic and ionic, with electronic component dominant. In this region the presence of electronic component is positively demonstrated with the fact that the subthreshold degradation is seen to exist at liquid nitrogen (LN_2) temperature as shown in Fig. 7. Ionic drift cannot be possible at such a low temperature. Now the tunneling is well characterized by the current-field relationship, given by

$$I_{STH} \sim CE^2 \exp - B/E \quad [3]$$

where C and B are constants. Subthreshold leakage behavior observed in region I obeys this law very well, as shown in Fig. 8. Therefore the results lead to the conclusion that the subthreshold at high fields (*i.e.*, in

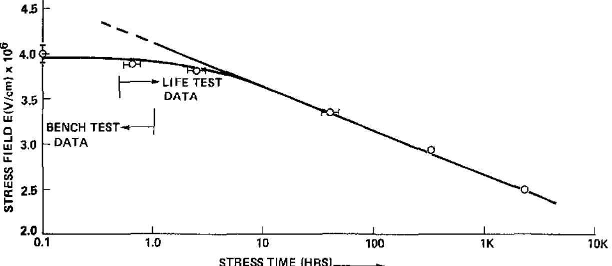

Fig. 6. Subthreshold failure characteristics time to fail as a function of stress field (standard stress of 120°C).

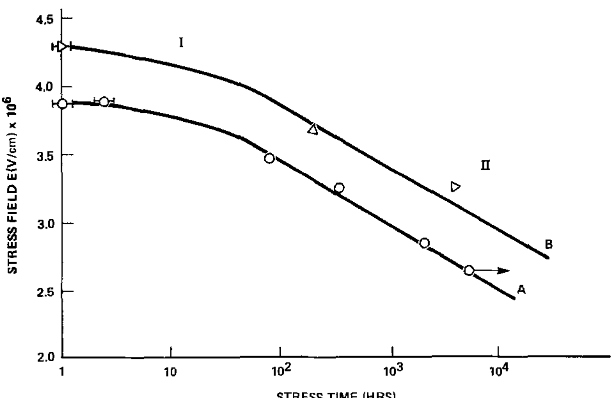

Fig. 5. Subthreshold failure characteristics mean time to fail vs. stress voltage.

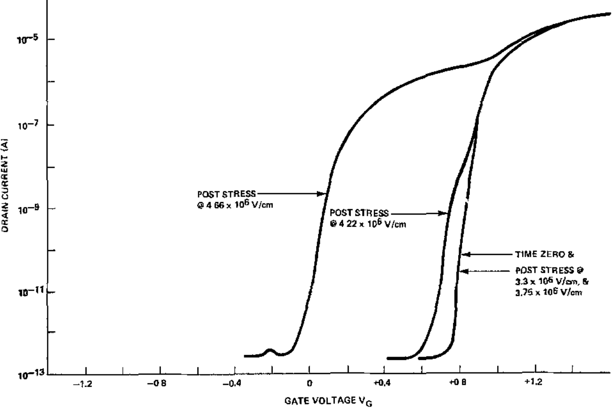

Fig. 7. Subthreshold leakage characteristics as a function of field (standard stress at LN_2).

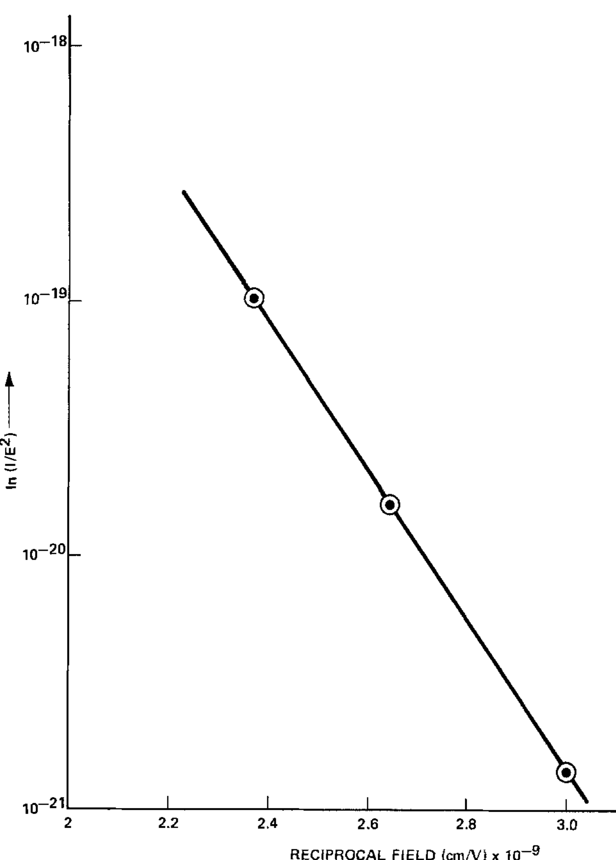

Fig. 8. Subthreshold leakage current, I_{STH}, as a function of stress field (standard stress at LN_2).

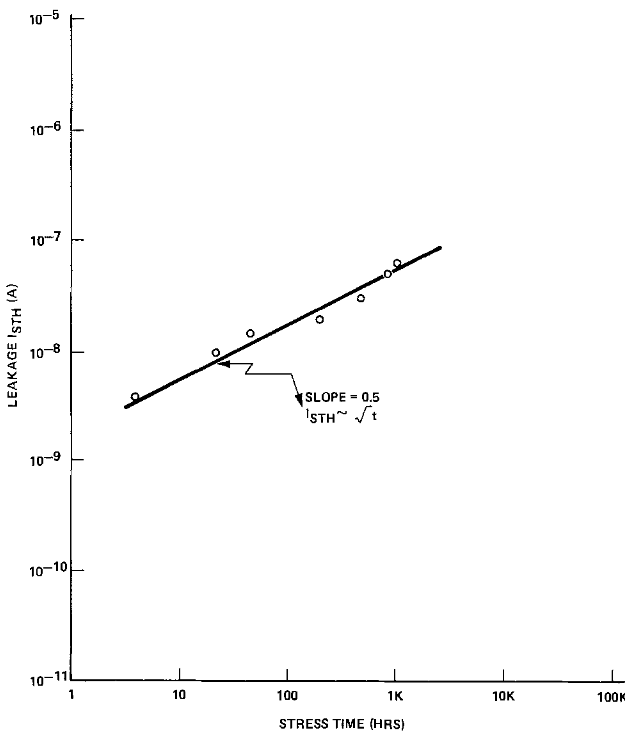

Fig. 9. Subthreshold leakage current, I_{STH}, as a function of stress time (standard stress at 165°C/2.66 × 10^6 V/cm, I_{STH} measured at V_G = 0.5V).

region I) is largely due to electron tunneling and ion drift, to be described below.

Region II.—Ionic drift. The field required for tunneling is generally 4-5 × 10^6 V/cm. Hence, as the field becomes low (*i.e.*, < 4 × 10^6 V/cm), a phenomenon other than electronic injection must be present. That phenomenon, the ionic drift, will now be established. There are two key characteristic features of the ionic drift-related instability (ΔV_{STH}).

1. $\Delta V_{STH} \sim t^{1/4} \exp - H/KT$, where t is the stress time, H is the activation energy, K is the Boltzmann constant, and T is the temperature in degrees Kelvin.

2. ΔV_{STH} recovers completely if the devices are shorted at stress temperature or are subjected to a negative bias-temperature stress aging.

Data shown in Fig. 9 and 10 does indeed confirm the characteristic features 1 and 2 observed in MNOS FET devices. These results clearly support the fact that the ionic drift most probably is the dominant mechanism for the subthreshold degradation in region II. Absence of electronic mechanism is also evidenced from the data of Fig. 9 and 10. The presence of ionic component in region I should not be ruled out, due to the field and temperature dependence. However, because of the exponential nature of the field dependence, the tunneling and hence electronic component would be dominant.

Sources of Subthreshold Degradation

From the practical point of view, the knowledge of the sources of origin causing the subthreshold degradation is of vital importance. Hence, with the help of the experimental facts, we will establish the sources of this problem mechanism.

Electron injection source.—Open-gated MNOS device consists of exposed nitride around the gate sides, with polyox-nitride interface absent under the gate region. Under positive bias stressing, these devices show no subthreshold degradation at LN_2, as shown in Fig. 11, while the devices having polyox-nitride interface under the gate region show subthreshold degradation at LN_2 as discussed above in reference to Fig. 7. Electron injection from the thermal oxide-nitride interface cannot be possible as it contradicts the charge transport. Furthermore, thermal ox-nitride structures subjected to poly and polyox process cycles show instability, while the same samples not subjected to poly and polyox process were found to be quite stable. These observations clearly support the proposition that the

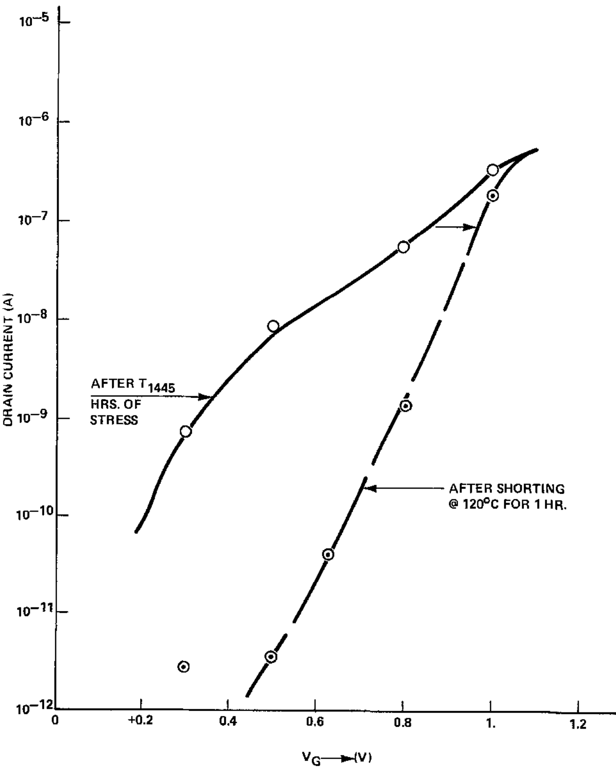

Fig. 10. Effect of baking on subthreshold shift (standard stress at 120°C/3.4 × 10^6 V/cm).

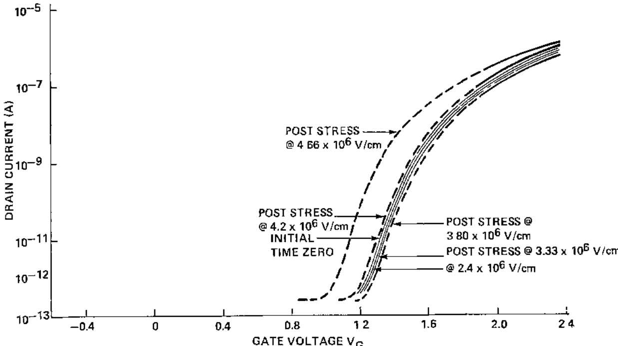

Fig. 11. Subthreshold leakage behavior at LN_2, open-gated MNOS FET device (standard stress).

seat of the electrons which cause subthreshold degradation via tunneling under high lateral field as discussed below is the interface between the polyox and nitride under the gate region. Data of Fig. 5 is consistent with this proposition, because polyox deposition at high temperature improves polyox-interface integrity. Therefore, curve B requires higher field for the onset of the subthreshold degradation.

Ionic drift source.—It is shown above that the ionic drift also causes the subthreshold degradation. Two-dimensional analysis indicates that the field at the edge of the device is the same within 50 nm along the horizontal and vertical directions (7). As the Si_3N_4 acts as a barrier to the ionic motion in the vertical direction, ionic drift will cause a subthreshold degradation only if we assume a lateral motion of these ions in the presence of a lateral field. Snow *et al.* (8) reported a $\sim t^{1/2}$ dependence for the Na^+ transport through thermally grown SiO_2 films, deliberately contaminated in aqueous NaCl solutions. This time dependence can be attributed also to temperature-field induced emission of ions from trapping centers located near the metal-nitride interface at the edge of the gate. The field dependence of the ion transport process is also consistent with a trapping model (low field end of Fig. 5). Such a transport process is thermally activated with an activation energy found in the present case $\sim 0.45 \pm 0.05$ (see Fig. 12). The value obtained in the linear region of Fig. 5 was $\sim 0.55 \pm 0.05$, which agrees quite well with this bench data. This value is about the same for hydrogen (proton) ions in SiO_2 (9). The activation

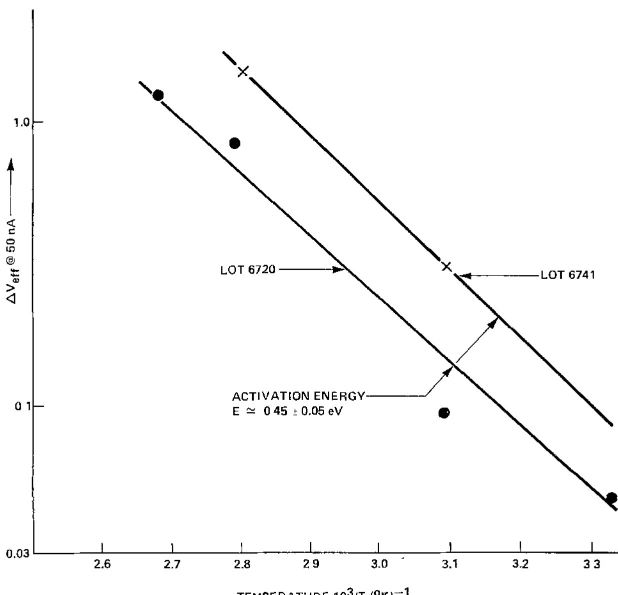

Fig. 12. Subthreshold shift as a function of reciprocal of temperature (standard stress at 3.1 × 10^6 V/cm for 10 min).

energy for Na^+ in SiO_2 is about 1.0 eV (8, 10, 11). The mobile ion contamination in the lots studied here was consistently less than 5 × 10^{10} cm^{-2}, which cannot explain the degree of degradation observed. Therefore the charges causing the subthreshold degradation are most likely hydrogen ions (protons). The source of these ions is presumably the traps N-H, Si-H which are invariably present in chemically vapor-deposited Si_3N_4 films (12, 13). However, if there is any cavity or void left during poly and polyox processing, contamination like photoresist residue, wet chemicals, or moisture remaining during gate cleaning prior to metallization could be trapped, thereby causing a severe subthreshold degradation. Physical analysis has indeed confirmed the presence of a void in the polyox edge.

The deterministic evidence of the ionic source in the presence of such a fault region is clearly established when a lift-off process is used for gate metallurgy. Results of subthreshold degradation using lift-off and no-lift-off processed devices are shown in Fig. 13. The data clearly demonstrate that the source of the ions is the contamination trapped at the polyox corner at the metal-nitride edge of the gate region and/or the trapped ions at the metal-nitride interface. It was often found that certain lots showed subthreshold degradation, while physical analysis did not detect the presence of a void. In such a case, the trapped ions at the metal-nitride interface (*i.e.*, N-H, Si-H traps) is the only source that can explain the subthreshold degradation.

Thus, consistent with the analysis of the results, the subthreshold degradation is correctly described by a two-mechanism model as shown schematically in Fig. 14, *i.e.*, the accumulation of the positive charge at the edge of the metal gate which images into silicon to create an inversion and thus causing the subthreshold

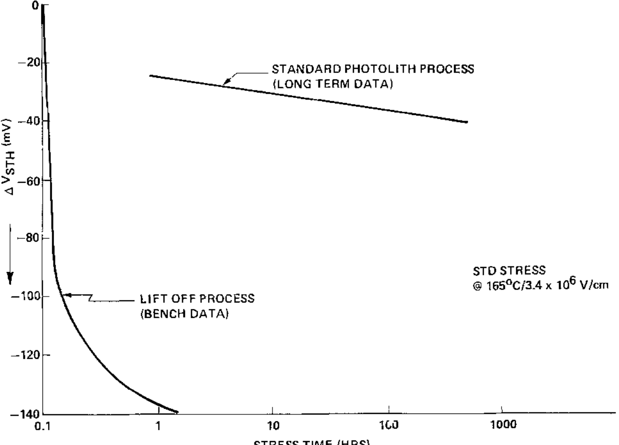

Fig. 13. Subthreshold degradation lift-off vs. standard photolith process.

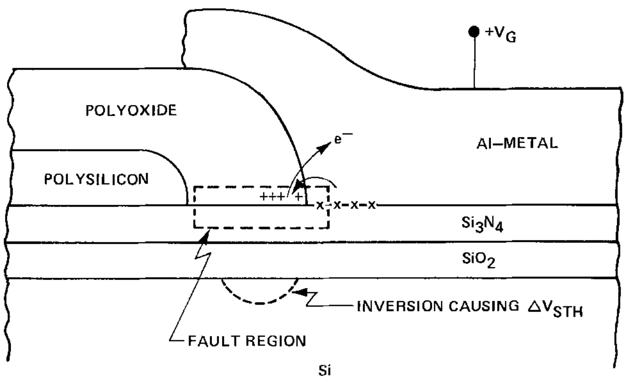

Fig. 14. Schematic showing the subthreshold degradation mechanism model.

leakage to occur by way of enhancement in the drain current. The accumulation of this positive charge is due to the surface ion migration away from the edge of the metal gate into the polyox-nitride interface and the electron tunneling from the polyox-nitride interface into the metal gate, especially at high fields of $\geqq 3.5 \times 10^6$ V/cm. The mechanisms occur because of the presence of lateral field.

Conclusion

Long-term and short-term reliability data for subthreshold degradation of MNOS FET devices is analyzed. Consistent with the results, a two-mechanism model is shown to correctly describe the observed subthreshold degradation. These two mechanisms are identified as electron tunneling and surface ion migration in the presence of a lateral field. Electron injection is shown to occur from the polyox-nitride interface under the edge of the device, while the source of the ions is found to be wet chemicals, moisture trapped at the polyox edge, and/or ions trapped at the metal-nitride interface.

Suppression of Mobile Ion Related Instability in Mo-Gate MOS Structures

Tadatoshi Nozaki and Hidekazu Okabayashi

Nippon Electric Company, Limited, Central Research Laboratories, Miyazaki, Takatsu-ku, Kawasaki, Japan

ABSTRACT

Electrical instability in Mo-gate devices, caused by the presence of mobile ions, has been successfully prevented by depositing phosphosilicate glass (PSG) film on Mo-gate metal and carrying out high temperature annealing after PSG film deposition. It is concluded that mobile ions were gettered into PSG film along the perimeter of Mo-gate metal after lateral diffusion of mobile ions at the metal-oxide interface. The rate-limiting step was PSG film gettering reaction, which was expressed by a first-order reaction. Reaction velocity constant activation energy was 1.3 ~ 1.6 eV. Mo-gate MOSFET's, having good stability in short term BT stressing, were fabricated with satisfactory reproducibility.

Recently, applications of Mo film as a gate material in MOSLSI's have been reported (1-4). Mo film offers several advantages as a gate material in comparison with conventional poly-Si. Mo film has about 100 times lower resistivity, compared with poly-Si, and has smaller grain size resulting in easiness in fine pattern formation. Therefore, high speed and high density MOSLSI's are promising.

In Mo-gate MOS devices, however, it is not easy to establish stable characteristics for the metal-oxide interface, especially in suppression of mobile ion related instability. The Mo-gate fabrication process, including preevaporation step before Mo film deposition and washing wafers in H_3PO_4 solution, was reported as a method of obtaining mobile ion contamination-free devices (5). However, this process is rather complex.

Key words: molybdenum, MOSFET, mobile ion, gettering, phosphosilicate glass.

Recently, the effect of annealing in H_2/N_2 mixture gas on mobile ion contamination reduction was reported (4). However, details of this effect are not well known. MNOS structure was used to stabilize threshold voltage (2), since silicon nitride film has a blocking effect against mobile ions. Mo-gate structures with gate oxide having a passivation effect, such as phosphorus-diffused gate oxide (6) or HCl oxidized gate oxide (7, 8), will be considered. However, in these structures, it is difficult to reproducibly form a thin gate oxide film a few hundred Angstrom thick while maintaining good reliability at the metal-oxide interface and maintaining the passivation effect. Mo/poly-Si layered structure gate was investigated (9) in order to obtain the same stable gate-oxide interface properties as a poly-Si gate.

During this work, the new procedure for mobile ion gettering in Mo-gate MOS devices was developed. It was found that high temperature annealing after PSG

film deposition on Mo-gate metal had a pronounced effect on reduction in mobile ion related instability. The mechanism of this PSG annealing effect was examined with changing annealing time and temperature using MOS diodes having different areas. Mo-gate MOSFET's fabricated with the PSG annealing process were evaluated by positive BT stressing test.

Experimental

Mo-gate MOS structures were made using thermally grown 400Å thick silicon dioxide film and 3000Å thick sputtered Mo film on p-type silicon substrates of 2 ~ 3 Ωcm resistivity. In the case of diodes, the Mo film was annealed at temperatures ranging between 800° and 1100°C before overcoating film deposition on Mo-gate metal. In the case of FET, the Mo film was annealed at 1000°C in order to ensure flatband voltage saturated value (5) and implanted As atom electrical activation to form source and drain region. Mo film annealing was accomplished in nitrogen atmosphere without any Mo film surface oxidation. CVD SiO_2 or PSG film was used as an overcoating film on Mo-gate metal. After SiO_2 or PSG film deposition, high temperature annealing in nitrogen atmosphere was carried out for almost all devices, in order to examine the effect of the high temperature annealing on mobile ion related flatband or threshold voltage instability.

BT stress tests were made in order to examine mobile ion related instability of flatband voltage. Gate bias was mainly 2 or 4V. Temperature and time were 200°C and 30 min, respectively. Flatband voltage was measured by high frequency C-V method.

Results and Discussion

PSG annealing effect on flatband voltage instability under positive BT stressing.—A large amount of flatband voltage (V_{FB}) shift in the negative direction was observed for Mo-gate MOS diodes under positive BT stressing. Figure 1 shows the amount of V_{FB} shift ($|\Delta V_{FB}|$) for diodes fabricated with changing Mo film annealing temperature at 800°, 900°, 1000°, and 1100°C. Almost constant 2 ~ 4 $V|\Delta V_{FB}|$ values were observed. V_{FB} recovers to its initial value, if the diode is heated with zero or negative bias after positive BT stressing. These large V_{FB} shifts may be due to mobile ion migration from the metal-oxide interface to the silicon-oxide interface, as was reported by Yanagawa *et al.* (5). Considering negligibly small V_{FB} shift under negative BT stressing, mobile ion density was estimated from these $|\Delta V_{FB}|$ values to be approximately 1 ~ 3 × 10^{12} cm^{-2}.

It was found that a large amount of V_{FB} shift could be avoided by depositing PSG film on Mo-gate metal and carrying out high temperature annealing after PSG film deposition. Figure 2 shows the results of positive BT stress tests on diodes having PSG overcoating film with different phosphorus content, together with the results of diodes having SiO_2 overcoating film. High temperature annealing at 1000°C for 10 or 30 min was carried out after PSG or SiO_2 overcoating film deposition for all devices, except one. SiO_2 overcoating film shows no stabilization effect, even though high temperature annealing at 1000°C was carried out. In the case of annealing for 10 min, poor stabilization effect was observed for PSG film with about 1 weight percent (w/o) phosphorus content. However, good stabilization effect was obtained for more than 2 w/o phosphorus content, showing minimum $|\Delta V_{FB}|$ constant value for higher phosphorus content. When annealing was carried out for 30 min, good stabilization effect was obtained, even for PSG film with about 1 w/o phosphorus content, and V_{FB} shift was negligibly small for more than 2 w/o phosphorus content. In the experiments described hereafter, PSG film with about 4 w/o phosphorus content was used. Diodes fabricated with PSG annealing at 1000°C for 10 min had 0.03 ~ 0.1V V_{FB} shift, which corresponds to 2 ~ 5 × 10^{10} cm^{-2} mobile ion density. In the case of annealing for 30 min, the remaining V_{FB} shift was less than 0.01V, corresponding to less than 5 × 10^{9} cm^{-2} mobile ion density. However, these remaining V_{FB} shifts were found to be dependent on diode area, as described in the next section. In this section, circular diode with 180 μm radius was used.

PSG annealing effect was found to be quite sensitive to annealing temperature. Figure 3 shows the results of positive BT stress tests on diodes fabricated with annealing at 800°, 900°, and 1000°C for 10 min. 1 ~ 2 × 10^{12} cm^{-2} mobile ion density was observed for annealing at 800°C, which is almost the same as that of diodes fabricated without PSG annealing. PSG annealing effect was observed for annealing at 900°C and good stabilization effect was obtained, as in the results in Fig. 2, for annealing at 1000°C.

Mechanism of mobile ion related instability suppression by PSG annealing.—Although the mobile ion contaminant is not definite at present, sodium may be responsible, as in the paper reported by Yanagawa *et al.* (5), where the coincidence of activation energy of V_{FB} change in the Mo-gate structures measured by BT stressing with that of sodium ions was reported. Kerr *et al.* (6) reported Al-gate MOS device stabilization by forming a phosphosilicate layer on the gate

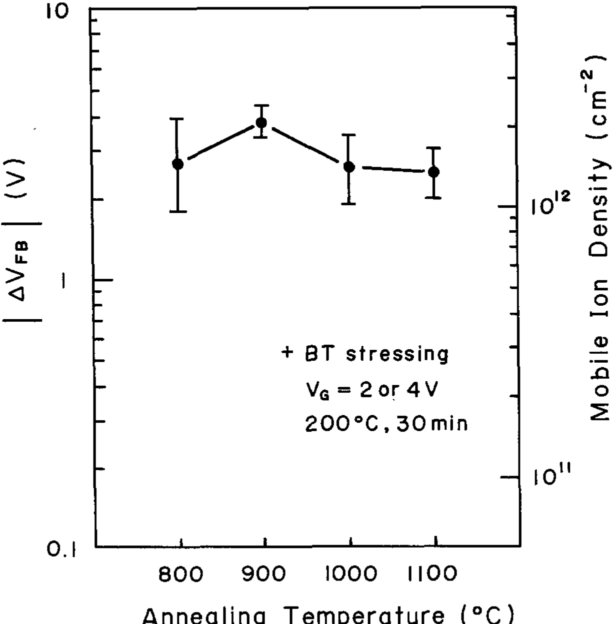

Fig. 1. $|\Delta V_{FB}|$ **and mobile ion density vs. Mo film annealing temperature for diodes fabricated without PSG annealing.**

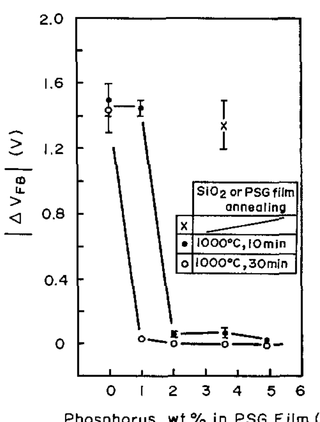

Fig. 2. $|\Delta V_{FB}|$ **vs. phosphorus w/o in PSG film for diodes fabricated with and without annealing.**

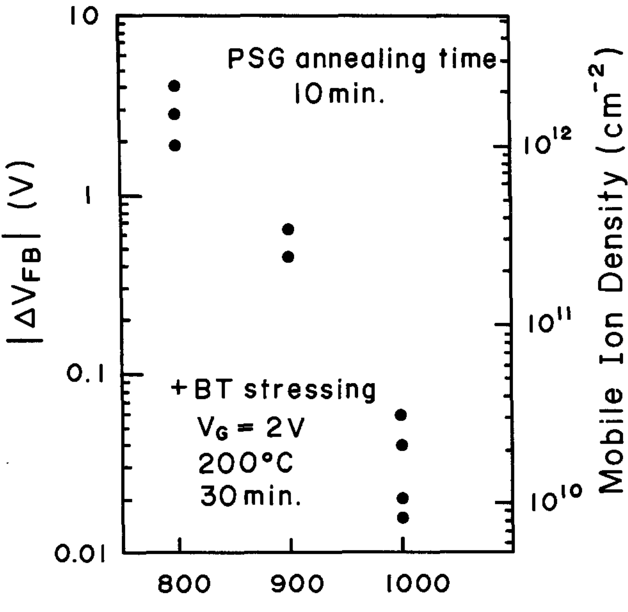

Fig. 3. $|\Delta V_{FB}|$ and mobile ion density vs. PSG annealing temperature.

oxide surface prior to metallization. Yon *et al.* (10) reported sodium ion accumulation in a phosphosilicate layer formed by phosphorus diffusion into a gate oxide film, which was heavily contaminated with NaCl. Considering these studies, the present results suggest that sodium ions are gettered during high temperature annealing into PSG overcoating film or gettered into a phosphosilicate layer, which might be formed on a gate oxide layer resulted from phosphorus diffusion from PSG overcoating film, since SiO_2 overcoating film showed no stabilization effect, as shown in Fig. 2.

Figure 4 shows the results of positive BT stressing on three kinds of diodes having different areas. The sodium ion contamination level was almost the same for these three kinds of diodes fabricated without PSG annealing. However, diode area dependence of PSG annealing stabilization effect was observed, as in the results in Fig. 4. Some amount of sodium ion density remained for the diode having the largest area, in contrast to negligible sodium ion density for the other two diodes.

PSG film gettering of sodium ions after sodium ion diffusion through Mo-gate metal or phosphorus diffusion into Mo-gate metal from PSG film, resulting in the formation of a phosphosilicate layer at the metal-oxide interface, can be ruled out for the mechanism of PSG annealing stabilization effect, because of difficulty in explaining the diode area dependence of this effect. Therefore, it is adequate to consider lateral diffusion of phosphorus or sodium ions.

As mentioned in the previous section, V_{FB} shift was negligibly small for diodes having 180 μm radius after PSG annealing at 1000°C for 30 min. If a phosphosilicate layer is formed by the phosphorus lateral diffusion, diffusion length will be the same diode radius order of 180 μm. Thus, the phosphorus lateral diffusion coefficient is estimated to be about 2×10^{-7} cm^2/sec, which is approximately 10^{10} larger than phosphorus diffusion coefficient in bulk SiO_2 (11). This value is anomalously large, even though the enhancement of phosphorus diffusion at the metal-oxide interface occurs. Therefore, phosphorus lateral diffusion need not be taken into consideration and PSG film gettering along the perimeter of Mo-gate metal after sodium lateral diffusion can be considered as a mechanism. In this case, a considerable rate-limiting step is sodium ion lateral diffusion or PSG film gettering reaction of sodium ion. As shown in Fig. 3, for diodes having 180 μm radius, PSG film stabilization effect was not observed for PSG annealing at 800°C for 10 min. For this PSG annealing condition sodium diffusion length is estimated to be about 1000 μm using sodium diffusion coefficient of about 2×10^{-5} cm^2/sec at 800°C, which was extrapolated from the diffusion coefficient at temperatures lower than 300°C (12, 13), assuming 1.4 eV (12-14) as an activation energy. This diffusion length is much larger than the 180 μm diode radius. Thus, the PSG film gettering reaction is considered to be a rate-limiting step.

Figure 5 shows the PSG annealing time dependence of $|\Delta V_{FB}|$ with changing PSG annealing temperature from 800° to 1100°C for square diodes with 880 μm sides.

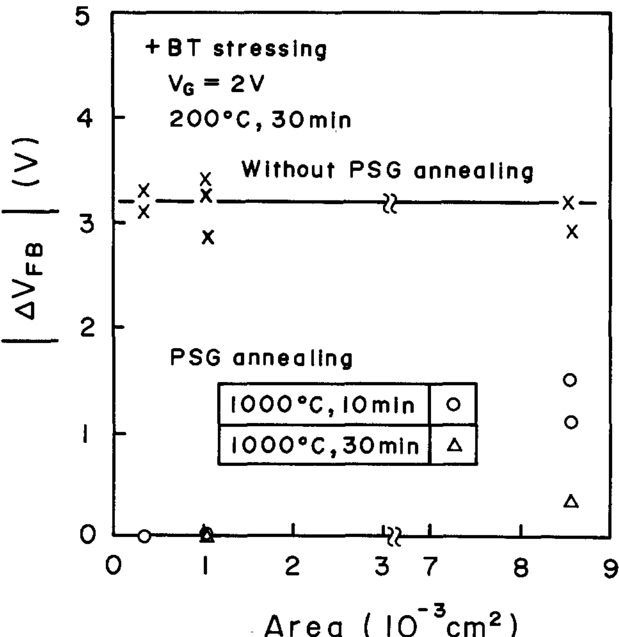

Fig. 4. BT stressing results on three kinds of diodes having different areas.

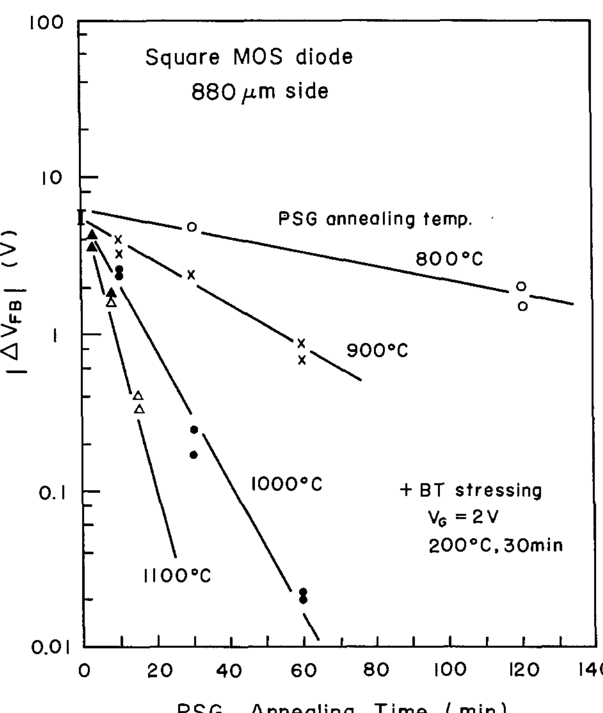

Fig. 5. $|\Delta V_{FB}|$ vs. PSG annealing time with PSG annealing temperature ranging from 800° to 1100°C.

Mobile ion density N decreases exponentially with PSG annealing time, as in the behavior of $|\Delta V_{FB}|$, since $N = C_0 \cdot |\Delta V_{FB}|/q$, where q is an electronic charge and C_0 is a gate-oxide capacitance per unit area. Thus, PSG gettering reaction is expressed to be a first-order reaction, such as

$$-dN/dt \propto N \quad [1]$$

As mentioned before, PSG film gettering reaction takes place only along the perimeter of Mo-gate metal. Therefore, Eq. [1] must be modified to

$$-dN/dt = kNL/A \quad [2]$$

where A, L, and k are diode area, perimeter, and reaction velocity constant, respectively. From Eq. [2], N can be expressed as the following equation

$$N = N_0 \exp(-kLt/A) \quad [3]$$

where N_0 is mobile ion density for diodes fabricated without PSG annealing. It is clear, from Eq. [3], that N at fixed PSG annealing condition increases with increasing diode area, since L/A is, for example, proportional to $(\text{radius})^{-1}$ for circular diodes. Equation [3] is rewritten as

$$[\ln(N_0/N)]^{-1} = r/(2kt) \quad [4]$$

for circular diodes with radius r. This relationship agrees with experimental results, which are shown in Fig. 6.

The reaction velocity constant at each PSG annealing temperature was obtained from the slope of the straight lines in Fig. 5 for square MOS diodes. For circular MOS diodes, reaction velocity constant was obtained from the slope of the straight lines in Fig. 6 and also from results similar to that in Fig. 5. The resultant reaction velocity constant plot as a function of $1/T$ is shown in Fig. 7. In obtaining the reaction velocity constant, a geometric perimeter was used. However, the effective perimeter, where PSG film gettering of sodium ions takes place, is considered to be smaller than geometric perimeter for square diodes. This leads to larger reaction velocity constant than that in Fig. 7 for square diodes. 1.3 ~ 1.6 eV activation energy was obtained for PSG film gettering reaction.

Short term positive BT stressing to MOSFET fabricated with PSG annealing.—Figure 8 shows the results of short term positive BT stress tests with from 2 to 16V gate voltage for FET's fabricated with PSG annealing process. In the case of FET, PSG annealing at 1000°C for 10 min was enough to prevent mobile ion related threshold voltage instability, since gate area is very small, as compared with diodes. It is clear in Fig. 8 that FET's fabricated in several lots show good stability in threshold voltage.

Summary

Mo-gate MOS devices fabrication process was investigated to suppress mobile ion related instability. By performing high temperature annealing after PSG film deposition on Mo-gate metal, mobile ion related instability has been successfully suppressed. The newly developed mobile ion gettering technology is expected to play an important role in fabrication of stable Mo-gate MOS devices in large scale production. A detailed summary of this study is as follows.

1. In order to ensure suppression of mobile ion related instability, PSG annealing temperature at 1000°C and phosphorus content of more than 2 w/o in PSG film were needed.

2. PSG film gettering reaction of mobile ions occurs along the perimeter of Mo-gate metal after lateral diffusion of mobile ions at the metal-oxide interface.

3. Rate-limiting step was PSG film gettering reaction, which was expressed by a first-order reaction.

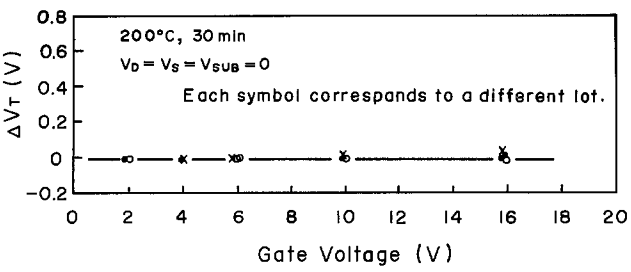

Fig. 8. Threshold voltage shifts (ΔV_T) vs. gate voltage in positive BT stressing.

Activation energy of reaction velocity constant was found to be 1.3 ~ 1.6 eV.

4. Mo-gate MOSFET's, having good stability in short term BT stressing, were fabricated with satisfactory reproducibility.

Silicon by Sodium Reduction of Silicon Tetrafluoride

A. Sanjurjo,* L. Nanis,* K. Sancier, R. Bartlett, and V. Kapur*

SRI International, Menlo Park, California 94025

ABSTRACT

High purity silicon can be prepared from the reaction of Na with SiF_4 to form Si and NaF. The SiF_4 is obtained from inexpensive H_2SiF_6 by precipitation and decomposition of Na_2SiF_6. Concentrations of B and P are each in the 0.1 ppm wt range in the product Si, separated from NaF by aqueous leaching.

Silicon is an important material in modern semiconductor technology and is finding increased use in solar cells for the photovoltaic generation of electricity. Each application presents special requirements for the purity of the silicon. Certain elements (Ti, Zr, Mo, V, Cr, Fe) have been found to be detrimental to the operation of silicon solar cells by acting as recombination traps when present in concentrations of as little as 0.01-1 ppba (1, 2). Low cost silicon of high purity is needed to foster the continued development of solar photovoltaic systems. With today's technology, approximately 20% of the total cost for the manufacture of a solar cell is ascribed to the silicon material produced by the conventional hydrogen reduction of chlorosilanes. It has been estimated (3) that the cost of silicon must be reduced from its present level of at least $70/kg to about $14/kg (in 1980 dollars) to achieve acceptance for use in solar photovoltaic panels. We have developed a process that offers a pathway to an industrial method that satisfies this cost requirement. The starting material is fluosilicic acid, H_2SiF_6, a low cost waste by-product of the phosphate fertilizer industry (4). SiF_4 gas is prepared from H_2SiF_6 and is reacted with sodium metal to produce a mixed reaction product consisting of Si and NaF. Aqueous leaching is used to separate NaF from granular Si.

The SiF_4-Na Process

The overall process consists of three major steps: step 1, precipitation of Na_2SiF_6, followed by SiF_4 generation; step 2, Na reduction of SiF_4; and step 3, separation of Si from the Si-NaF mixture. A flow diagram of the process steps is shown in Fig. 1. The sequence of reactions is described below.

Generation of SiF_4 (step 1).—Fluosilicic acid (H_2SiF_6) of commercial grade [23 weight percent (w/o)] was used directly as received without purification or special treatment. Sodium fluosilicate, Na_2SiF_6, was precipitated by adding solid sodium fluoride directly to the as-received H_2SiF_6. The mixture was stirred overnight at room temperature in a polypropylene tank. The supernatant liquid, containing mostly HF and some H_2SiF_6, was decanted, and the Na_2SiF_6 precipitate was filtered on a plastic Buchner funnel. The fluosilicate was washed with cold distilled water to remove HF and H_2SiF_6 and dried in an oven at 200°C. A minimum yield of 92% was obtained for 1 kg batches of pure Na_2SiF_6 as determined by x-ray diffraction. The product Na_2SiF_6 is a nonhygroscopic white powder that is very stable at room temperature and thus provides an excellent means for storing the silicon source before it is decomposed to SiF_4.

As SiF_4 is needed, the Na_2SiF_6 can be thermally decomposed (Fig. 1) at 650°C in a graphite-lined, gas-tight stainless steel retort. In separate experiments, it was determined that SiF_4 gas at a pressure of 0.4 atm is in equilibrium at 650°C with solid Na_2SiF_6 and NaF. Accordingly, gaseous SiF_4 evolved at 650°C was condensed as a white solid in a storage cylinder cooled by liquid nitrogen, attached to the retort. The SiF_4 gas was allowed to expand by warming of the storage cylinder

Key words: silicon, solar cells, sodium, silicon tetrafluoride.

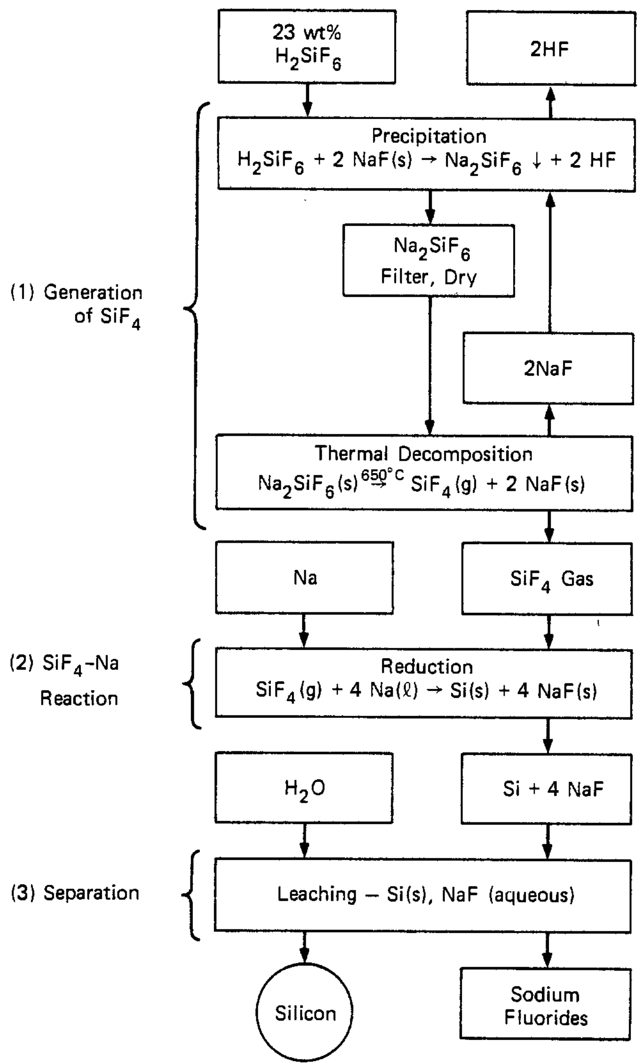

Fig. 1. Three-step method for silicon production

to room temperature and was fed into the reactor as needed. SiF_4 gas prepared in this manner was determined by mass spectrometric analysis to be more pure than commercial grade SiF_4, as shown in Table I. Ions formed from the sample gas were identified from the observed mass numbers, isotopic distribution, and threshold appearance potentials. The detection limit was better than 0.005%. Positively identified gaseous impurities are listed in Table I; no metallic impurities were detected. Peaks corresponding to B compounds, such as BF_3, were specially checked, but none were found.

Although the SiF_4 produced from H_2SiF_6 had less impurity, the commercial grade SiF_4 was also used for experimental convenience. The possible presence of metallic impurities in commercial SiF_4 was determined by bubbling the gas through high purity H_2O and heating the resulting slurry with an excess of HF to drive off Si as SiF_4. The final clear solution was then analyzed by plasma emission spectroscopy (PES). The

Table I. Mass spectrometric analysis of SiF_4

Ion	SiF_4 prepared at SRI from H_2SiF_6 (%)	SiF_4 commercial (%)
SiF_3^+	96.9	93.6
$Si_2OF_6^+$	3.04	4.24
$SiOF_2^+$	—	1.79
CCl_3^+	—	0.159
$SO_2F_2^+$	0.076	0.098
$Si_2O_2F_4^+$	—	0.081
SO_2^+	—	0.035

results are listed in Table II, together with PES analysis of the waste by-product H_2SiF_6 and the NaF used to precipitate Na_2SiF_6 (step 1, Fig. 1). Comparison of the first two columns of Table II with column three shows that the concentrations of some elements, *e.g.*, Li, B, V, Mn, Co, K, and Cu, were unchanged by precipitation of Na_2SiF_6, whereas the elements Mg, Ca, Al, P, As, and Mo were diminished by a factor of 5-10. Some elements were concentrated into the Na_2SiF_6, namely Cr, Fe, and Ni. The fourth column in Table II is representative of the impurity content to be found in SiF_4 gas prepared on a commercial scale. The low content of P is of special significance for both semiconductor and solar cell applications. Elements known to reduce solar cell efficiency (V, Cr, Fe, Mo) are uniformly low in commercial grade SiF_4. Only Mn, As, and Al are of comparable concentrations in both Na_2SiF_6 and SiF_4 at the 1 ppm or less level.

SiF_4-Na reaction (step 2).—The central operation of the pure Si process (step 2, Fig. 1) is the reduction of SiF_4 by Na according to the reaction

$$SiF_4(g) + 4Na(l) \rightarrow Si(s) + 4NaF(s) \qquad [1]$$

Although this reaction is thermodynamically favored at room temperature ($\Delta G°_{298\,K} = -146$ kcal/mole Si), it has been found experimentally that Na has to be heated to about 150°C before any appreciable reaction can be observed. Once the reacting has been initiated, the released heat ($\Delta H°_{298\,K} = -164$ kcal/mole Si) raises the temperature of the reaction Na, which in turn increases the reaction rate. Under adiabatic conditions, a temperature of 2200 K is predicted for reaction [1] with the stoichiometric quantities of SiF_4 and Na. In practical reactors, rapid consumption of gaseous SiF_4 produces a pressure decrease. The kinetic behavior of reaction [1] is complex because of the interplay of several factors, *e.g.*, pressure of SiF_4, vaporization of Na, local temperature, porosity of two solid products, and transport of SiF_4 and Na vapor through the product crust that forms on the liquid Na.

Although only preliminary studies have been made of the kinetics, the general features of reaction [1] have been surveyed. In a series of experiments to estimate reaction temperatures, 5g of Na were loaded in a Ni crucible (3 cm ID, 4 cm high) and heated in SiF_4 initially at 1 atm pressure. The Na surface tarnished at around 130°C, with the formation of a thin brown film. As the temperature increased, the color of the surface film gradually changed from light brown to brown and finally to almost black. The SiF_4-Na reaction became rapid at 160° ± 10°C and liberated a large amount of heat, as indicated by a sudden rise in re-

action temperature. As shown in Fig. 2, the pressure in the reactor typically decreased slightly until the temperature increased sharply, with an associated rapid decrease in SiF_4 pressure. The reaction lasts for several seconds only. For SiF_4 pressures below 0.3 atm, the reaction mass was observed to glow at a dull red heat. For higher pressure, a characteristic flame was observed. The shortest reaction time (20 sec) and the highest temperatures (about 1400°C) were obtained when the initial pressure of SiF_4 was around 1 atm. In addition, complete consumption of Na was obtained for 1 atm SiF_4. When scale-up of this reaction was attempted by loading larger amounts of Na, it was found that as the depth of the Na pool increased, the amount of Na remaining unreacted also increased. The product formed a crust on top of the Na surface, building a diffusion barrier for the reactants. As the barrier thickness increased, the reaction slowed and eventually stopped.

On the basis of preliminary studies of the parameters that affect reaction [1], a system was developed that is capable of producing Si at the rate of 0.5 kg/hr in a batch mode. The reactor is shown schematically in Fig. 3. The upper section of the Na dispenser is coated internally with epoxy resin on all Pyrex glass surfaces that may contact Na.

Sodium chips were prepared by feeding 225g blocks of sodium (6 cm diam rod, cut longitudinally) into a food processor using a blanket of argon to minimize contact with atmospheric oxygen and moisture. While Na chips were being introduced into the top of the storage chamber of the dispenser (2 kg capacity), dry argon flowed up through the chamber. The Na chips were transferred from the storage chamber to the reactor by means of a horizontal "hoe" mechanism. Downward flow of Na chips in the storage chamber was aided by agitation of the vertical rod.

The lower section of the reactor was made of Inconel (20 cm diam, 90 cm high) and was fitted with a sheet nickel liner (18 cm diam, 60 cm high) and an inner liner of sheet Grafoil (18 cm diam, 90 cm high). The outside of the Inconel reactor was wrapped with four sets of heavy duty electrical heating tapes (rated for use to 800°C), which were covered with Kaowool insulation (1.3 cm thick). The top of the Inconel reactor and the flanges that connect to the Pyrex Na dispensing section were water cooled.

In operating the reactor, the system was first evacuated, then filled with SiF_4 gas to a pressure of about 1 atm. Reaction was initiated as soon as Na chips were dropped to the bottom of the reactor, which was preheated to 400°C. Reaction was sustained by manually adding Na chips at a rate sufficient to maintain a given SiF_4 flow rate, as indicated by an electronic flowmeter. The maximum flow rate used was 380 liters SiF_4/hr, corresponding to an addition rate of about 1.4 kg Na/hr and a production rate of 0.5 kg Si/hr. During the operation of the Inconel reactor, the temperature of the reactor walls in the region of the reaction products rose to 600°-650°C, as indicated by external thermocouples. The temperature of the nickel liner reached the melting temperature of NaF (998°C), indicated by molten NaF observed on the outside of the nickel liner near seams as the reaction zone progressed upward.

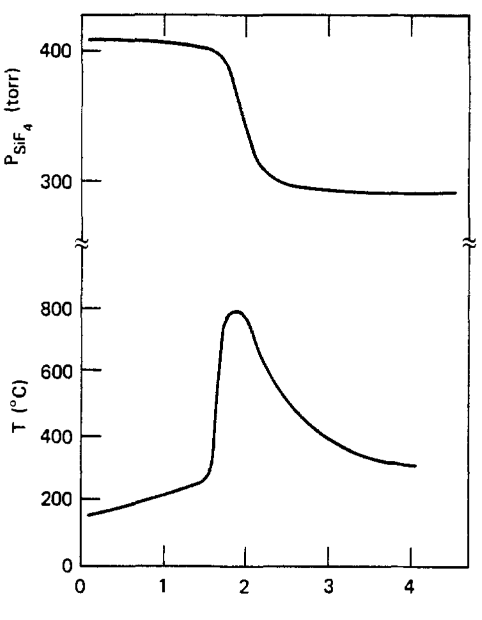

Fig. 2. SiF_4-Na reaction: pressure and temperature profiles

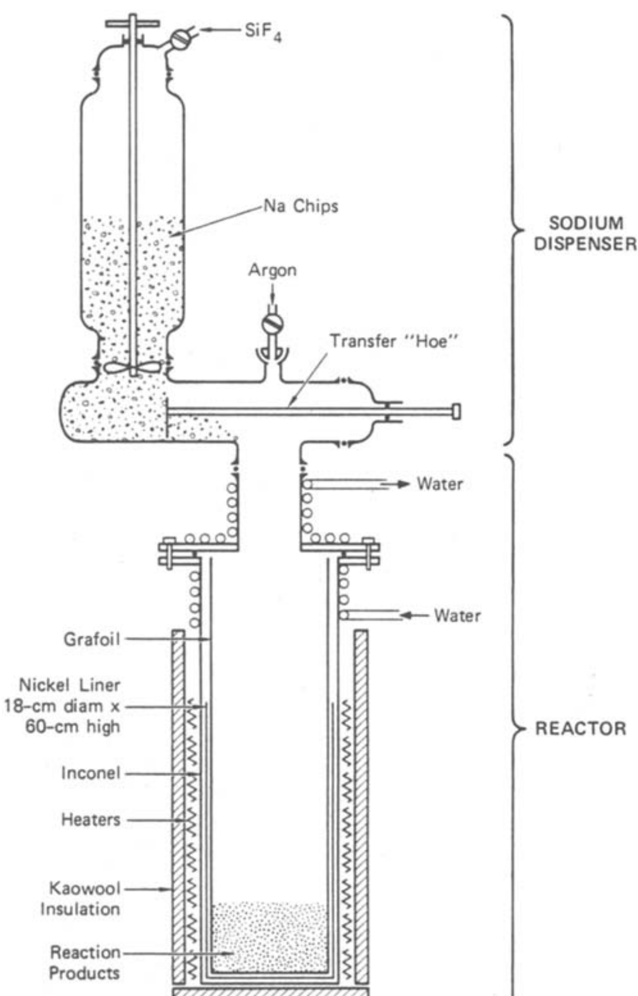

Fig. 3. Schematic of 18 cm diam Inconel reactor

After each SiF_4-Na run was completed, the reaction products completely occupied the cylindrical space inside the Ni-Grafoil liner. The reaction products were pulverized with plastic equipment, and routine checks were made for the presence of unreacted Na by acid titration. An important parameter regulating the rate and extent of the reaction is the surface-to-volume ratio of the Na feed. For the 18 cm diam Inconel reactor, no unreacted Na was observed in the reaction products even for the highest Na addition rate used (1.4 kg/hr) when the Na chips had a surface to volume ratio of about 20 cm^{-1}.

The relative amounts of Si, NaF, and Na_2SiF_6 were conveniently determined by x-ray diffraction using standard mixtures. The weight fraction of Na_2SiF_6 was determined from the ratio of the peak intensities of Na_2SiF_6 and KCl reference additive. The method is rapid and accurate to about ± 5%. The presence of Na_2SiF_6 was also cross-checked by thermogravimetry.

The presence of Na_2SiF_6 in the reaction product mixture is an indication of possible side reaction according to

$$SiF_4 + 2NaF \rightarrow Na_2SiF_6 \quad [2]$$

which is the reverse of the decomposition reaction used for SiF_4 generation in step 1 (Fig. 1) of the overall process.

When the reactor walls are kept above 600°C, the formation of by-product Na_2SiF_6 was less than 2 w/o.

Separation (step 3).—The reaction product obtained by the SiF_4-Na reaction [1] is a porous, brown mass. This intimate mixture of NaF and Si is readily separated by aqueous leaching. The Si product obtained after leaching is a brown crystalline powder with particle sizes ranging from submicrometers up to 150 μm. Some of the various morphological forms observed in this powder are shown in Fig. 4. Leaching is performed using 1.0*N* HCl in a polypropylene container, although other acids such as H_2SO_4, CH_3COOH, and HF are equally effective. The acid normality can vary in the range 0.1-1.0*N* without affecting the leaching process, which may be monitored by measuring the F^- and Na^+ concentrations in the leachant using ion selective electrodes. When the F^- concentration is about 10^{-5} mole/liter, leaching is stopped. The acidification of the leach solution is a precautionary measure to prevent increase in local *p*H due to reaction of H_2O with Na, which could, in turn, result in Si loss by oxidation according to the reaction

$$Si + 2H_2O \rightarrow SiO_2 + 2H_2 \quad [3]$$

It has been determined (6) experimentally that during leaching in 1*N* acid, Si can be oxidized at an initial rate of 15 weight percent per hour. The rate of oxidation increases with increased F^- ion concentration in solutions with *p*H in the range of −0.8 to 10. The contact time may be minimized by using forced filtration, which yields a 98% complete recovery of Si. Differences in leaching rate due to particle size of the products, temperature of the leaching bath, and amount of stirring were found to be important only during the first minutes of leaching.

Purity of Silicon

Several analytical methods have been used to characterize the very low levels of impurity elements in the silicon leached from the products of SiF_4-Na reaction [1]. Generally, each of the methods is used at the limit of resolution for several elements. For comparison, a reference sample of high purity Si was analyzed in a similar manner to provide a check of spurious readings caused by sample preparation, background effects, and instrumental limitations. The reference material was commercial polycrystalline semiconductor grade Si with resistivity greater than 1×10^5 Ω cm.

In Table III, the uncertainty in the methods of emission spectroscopy and spark source mass spectrometry has been taken into account by selecting representative average concentrations based on several analyses. A range is indicated for (Fe, Cr, and Cu) where wide variations occur because of its importance, phosphorous was also determined by a wet chemical colorimetric method (5).

Discussion

The process sequence shown in Fig. 1 was selected because of the inherent simplicity of the steps and their independent and combined suitability for scale-up. Some purification occurs during precipitation (step 1, Fig. 1) for Mg, Ca, Al, P, and As due to the high solubility of their fluosilicates and fluosalts. Some concentration takes place for Cr, Fe, and Ni, and this effect

may be due to coprecipitation of these elements as fluorides since their fluosilicates are very soluble. From Table II, it is clear that most of the purification is accomplished as a result of the thermal decomposition in step 1 (Fig. 1). Most transition metal fluorides are very stable condensed phases at 650°C, the temperature of decomposition in step 1 (Fig. 1) and, therefore, will stay in the solid. In addition, volatile fluorides formed during the decomposition of fluosalts such as Na_2TiF_6 and Na_2ZrF_6 will condense upon cooling of the SiF_4 gas stream from step 1. The condensed material is then removed from the gas mainstream by in-line fume particle filtration. Mass spectrometry did not detect the presence of any metallic or dopant impurity (Table I) in either the SRI produced gas or in the commercial SiF_4 gas. The analysis done on the SiF_4 by passing the gas through high purity water was based on the hypothesis that fluoride impurities should be hydrolyzed and/or trapped in the SiO_2 formed. The results listed in Table II show that the level of metal impurities in the resulting SiO_2 is so low that, for practical purposes, the SiF_4 can be considered free of metallic impurities.

The Na feed, reactor materials, and possible contamination of the product during handling remain as possible sources of impurities in the Si.

The impurities in Na can be divided roughly into three types according to their tendency to react with SiF_4, as classified by the free energy of reaction. The first type of impurity includes aluminum and elements from the groups IA, IIA, and IIIB. The free energy of reaction of SiF_4 with these impurities ranges from -100 to -200 kcal/mole SiF_4 at room temperature and from -50 to -100 kcal/mole SiF_4 at 1500 K. It is expected, therefore, that even when these impurities are present at the ppm level, they will react with the SiF_4 to form the corresponding fluorides. Subsequently, the fluorides will be dissolved preferentially in the NaF phase. The second type of impurity includes transition metals such as Mo, W, Fe, Co, Ni, and Cu, and the elements P, As, and Sb. These elements exhibit positive free energies of reaction in excess of 100 kcal/mole SiF_4 and are not expected to react with SiF_4. However it is an experimental fact that the silicon resulting from the SiF_4-Na reaction contains amounts of Fe, Ni, and Cr in proportion to the concentration of these elements in the Na feed. The mechanism by which these metals are transferred to the silicon has not yet been studied. In any case, the concentration of Fe, Cr, Ni, and also Ti can be decreased by a factor of about 10^4-10^6 for single-pass directional solidification or the Czochralski crystal-pulling procedures used presently for solar cell manufacture. At the resulting levels, these elements would not be detrimental to solar cell performance (1). Boron represents a third type of impurity. The free energy of reaction of this element with SiF_4 is positive but small (5-20 kcal/mole SiF_4 for temperatures up to 1500 K); therefore, some partial reaction can be expected and B will be distributed between the NaF and Si phases. It is noted that the levels of the dopant elements, B, P, and As in SRI silicon are the same as in the semiconductor silicon used as reference. Since it is convenient to have dopant levels as low as possible to permit flexibility in subsequent doping procedures for semiconductor and solar cell applications, the low B and P content (Table III) of Si produced by the SRI process is of advantage. The possibility of contamination from the reactor materials was minimized by the use of Ni and Grafoil liners (Fig. 3) that completely contained the reaction products and avoided contact or impurity transfer with the reactor walls. The Ni liner served merely as a mechanical retainer for the Grafoil sheet and did not contact the solid mixed reaction product. Both Ni and Inconel were selected for use in the reactor (Fig. 3) because of their stability in the presence of fluoride compounds.

Contamination during handling was, after the Na feed, probably the second most important source of impurity pick up. Airborne dust could have contacted the products either during their removal from the reactor or during sampling. Furthermore, although electronic grade acid and deionized water were used for leaching the NaF, the large volume of liquid used could have contributed to the accumulation of impurity in the silicon. Finally, although the purity of the silicon produced by the SiF_4-Na reaction is appropriate for solar cell manufacture, it is expected that by prepurification of the commercial grade Na used and by avoiding contamination during handling, semiconductor grade silicon could be produced.

Conclusion

We have shown experimentally that high purity Si can be prepared as a powder using the inexpensive starting materials H_2SiF_6 and Na. Favorable thermodynamics of the reduction step, easily controlled kinetics, and abundant availability of inexpensive starting materials make this method attractive. Of special interest for semiconductor applications are the low concentrations of B and P impurities in the product Si. The Si produced by the SiF_4-Na reaction, if purified further by directional solidification, should be a low cost material suitable for the manufacture of solar cells.

ABSTRACT

After an exhaustive reevaluation of the contact printing processes, photoresist sticking to the photomask surface is identified as the principal cause of patterning defects and a preventive measure is developed. This process, called surface conversion for antisticking (SURCAS), facilitates a reduction in defect density by about one-fourth compared to conventional contact printing. This technique opens the way for improvement of current LSI fabrication, and moreover should be useful in ultrafine pattern lithography down to 1 μm in the near future.

Photolithographic technology has been successively improved and has dominantly contributed to an increase in LSI packing density by almost a factor of two every year over the last decade. On the other hand, it has also been shown (1, 2) that low device yield is mainly due to patterning defects formed in photolithography. Presently, LSI's with lines and spacings of 3 μm or less are just going into commercial production. When positive photoresists, instead of negative ones, are used in combination with a contact printer, it seems rather easy to delineate 1 μm fine patterns. However, patterning defects due to fragility of the base resin itself have appeared as the most serious problem. Therefore, a new technique to reduce patterning defects is urgently needed to fully utilize the high resolution of positive photoresists for LSI fabrication. In the last several years, great progress has been made by using a 1:1 projection aligner in yield improvement. Still, its resolution limit is recognized to be about 2 μm.

In this work, the contact printing process is reexamined in detail focusing on patterning defects. The investigation has revealed that sticking of photoresist pieces on photomask surfaces is the dominant contributor. This photomask to photoresist adhesion phenomenon is analyzed based on the dry adhesion mechanism reported earlier (3). And finally, a novel technique to effectively prevent sticking, i.e., surface conversion for antisticking (SURCAS), is developed.

Theoretical Treatment

It has become a matter of common knowledge that photoresist to substrate adhesion is improved by surface conversion of substrate wafers with organic compounds such as HMDS.[1]

Our experiments revealed an inconsistent phenomenon; when the same conversion treatment is applied to a photomask surface, photoresist to photomask adhesion is drastically weakened. This inconsistency is solved by two different adhesion mechanisms, dry and wet adhesion (3).

Key words: photolithography, contact printing, patterning defects, adhesion, surface conversion.

[1] Hexamethyldisilazane: $(CH_3)_3SiNHSi(CH_3)_3$

Since there is no liquid in the contact printing process, adhesion in photomask-photoresist-substrate system is analyzed according to the dry adhesion mechanism as outlined below. Adhesion between two materials, i.e., photomask to photoresist and photoresist to substrate wafer, is evaluated by dispersion interaction as follows

$$W_{a(MR)} = 2(\gamma_M{}^d\gamma_R{}^d) \quad [1]$$

$$W_{a(MR)} = 2(\gamma_R{}^d\gamma_S{}^d) \quad [2]$$

where the suffixes M, R, and S denote the photomask, photoresist, and substrate wafer respectively, W_a is the work of adhesion indicating the affinity between two materials denoted by suffixes, and γ^d is the dispersion component of surface free energy. Since adhesion increases with W_a, the photoresist will stick to the photomask rather than the substrate when

$$W_{a(MR)} > W_{a(RS)} \quad [3]$$

Substituting formulas [1] and [2] into [3] produces

$$\gamma_M{}^d > \gamma_S{}^d \quad [4]$$

Consequently, to prevent the photoresist sticking, $\gamma_M{}^d$ must be smaller than $\gamma_S{}^d$.

The values of γ^d were evaluated for various materials commonly used in the semiconductor industry, as shown in Fig. 1. The most important point is that a conventional chromium mask washed with organic solvents shows a higher γ^d value than any other substrate material. Thus, photoresist sticking can be expected with the above consideration. On the other hand, γ^d of the SURCAS mask is the lowest, indicating a low adherence to photoresist.

Experimental

Wafer inspection.—Two series of wafer inspection tests were carried out with each object. The first series was to classify the patterning defects in conventional processes. The second was for yield comparison with and without SURCAS. In the first series, 20 wafers, each including 80 chips of 9 mm^2 die, are processed

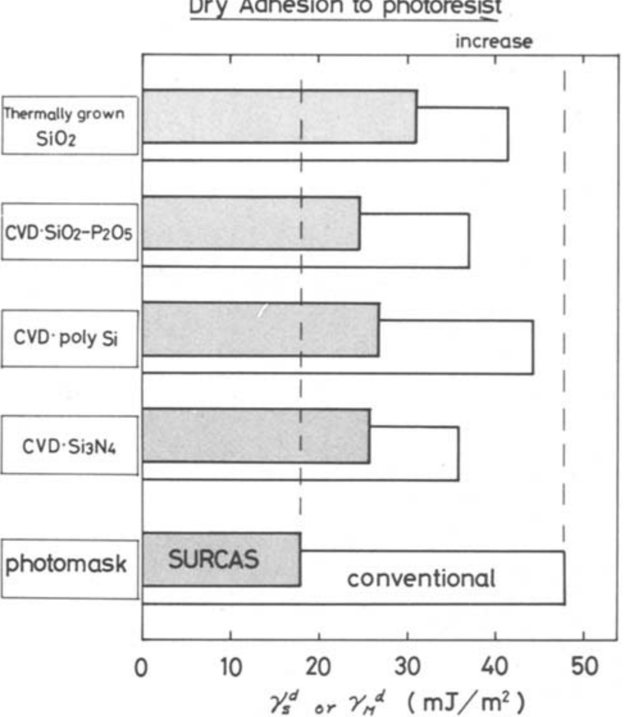

Fig. 1. Measured γ^d values for various substrate materials and photomask. Clear and shaded column of each material indicate surfaces before and after conversion treatment, respectively.

under standard MOS fabrication, including six lithography steps. A positive photoresist Shipley's AZ1350J, chromium hard surface mask, and Cobilt's contact printer AF 2800H were used. Wafers were inspected just after the four lithography steps by optical microscope. In normal inspection, 100× magnification is sufficient and, when needed, 1000× magnification permits detection of defects as small as 0.5 micron. For yield comparison 15 and 30 mm² dies were examined in the second series. Wafers were processed under same conditions except for photomask pretreatments.

Surface conversion.—As reported earlier (4), an SiO_2 surface is converted into hydrophobic nature through the following reaction with HMDS

$$2SiOH + (CH_3)_3SiNHSi(CH_3)_3 \rightleftharpoons 2SiOSi(CH_3)_3 + NH_3 \quad [5]$$

where SiOH denotes surface silanol group on SiO_2 film. Since HMDS reactivity with SiO_2 surface is extremely high compared to the alcohols, the above reaction is completed by exposing the SiO_2 to HMDS vapor at about 100°C for several minutes. Furthermore, at our laboratory, more effective conversion agents were found. These are silane derivatives with the following fluorocarbon chain

$$(CF_3)_2CFO(CH_2)_3Si(CH_3)Cl_2$$

Heptafluoroisopropoxypropylmethyldichlorosilane (7F-silane in abbreviation)

$$CF_3(CH_2)_2Si(CH_3)Cl_2$$

Trifluoropropylmethyldichlorosilane (3F- silane in abbreviation). These F-silane compounds were also so reactive that the SiO_2 surface could be converted by exposure to their vapors.

Characterization of converted surface.—As mentioned, photomask-photoresist and photoresist-substrate adhesion can be accurately evaluated by the dispersion component of their surface free energy γ^d. This parameter was controlled through the surface conversion technique and estimated by measuring the contact angle of iodomethylene, CH_2I_2, according to Fowkes' theory (5). Contact angles were measured by the sessile drop method using a goniomicroscope.

Dry adhesion test.—The procedure of the dry adhesion test is illustrated in Fig. 2. Silicon wafers of 3 in. diam were oxidized in steam oxygen at 1100°C to 1 μm thickness. Then, various surface conversion treatments were applied to control the $\gamma_S{}^d$ of SiO_2. The SiO_2 film was selectively etched to form 900 islands of 1 mm² die throughout the wafer by conventional photolithography. After the photoresist was removed, other photoresist patterns, 32 μm square and 1 μm thick, were formed. At the same time, photomasks were also prepared through various hydrophobic conversions. Then, the wafer and the photomask were pressed on to each other using a contact printer for 5 min. After removal of the photomask, the wafer was inspected to count the number of removed photoresist patterns, *i.e.*, N^{dry}, under an optical microscope. In this work, N^{dry} counting was restricted to the tops of SiO_2 islands where it is considered better.

Results and Discussion

Classification of patterning defects.—Although wafer inspection with an optical microscope is painstaking work, it is nevertheless one of the most effective ways of classifying and determining the cause of patterning defects. In this report, inspected defects were divided into the following five categories according to shape, color, clarity, or opaqueness, etc. Elemental analyses by microprobe were also helpful in some cases.

Dust.—Despite stringent efforts to minimize dust, it remains as one of the main defect components. Some typical examples of dusts detected in this work are as follows: stainless steel dust from the planetary hot plates of chemical vapor deposition apparatus; hillocks and clusters formed in vacuum evaporation of metal films; some clear pieces from plastic wafer cassettes used in the rotary dryer; and so-called dust from ambient, oven, mask aligner etc.

Sticking.—Photoresist pieces stick on the photomask surface. A birds-eye view of a photomask surface pro-

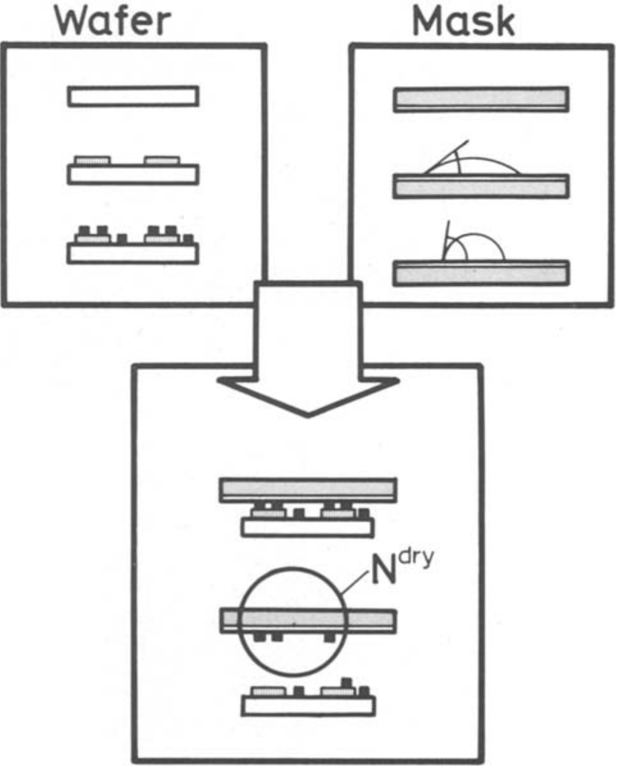

Fig. 2. Procedure of dry adhesion test

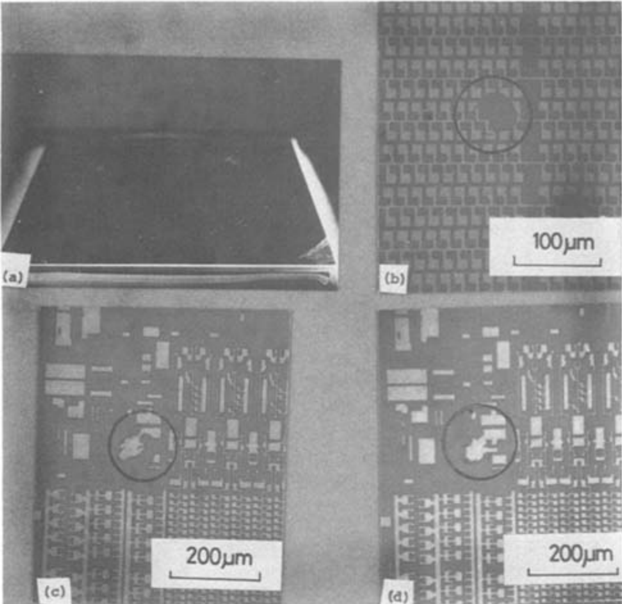

Fig. 3. Typical examples of inspected patterning defects. (a) Photoresist pieces stuck to photomask surface; (b) sticking results as patterning defect on the wafer where photoresist is stripped off; (c) and (d) stuck photoresist pieces interrupt exposure resulting in photoresist residues of similar shape at similar locations on different two wafers.

cessed with eight wafers using contact printer is shown in Fig. 3(a). In this photograph, a nonpatterned mask plate is used to expose the stuck photoresist pieces in the inclined light. These stuck photoresist pieces result in wafer defects such as shown in Fig. 3(b).

Exposure interruption.—The stuck photoresist pieces cause other kinds of patterning defects on the wafer as shown in Fig. 3(c) and (d). Two wafers, which were successively processed, are shown with similar resist patterns formed at similar locations on both wafers. These patterns are due to exposure interruption by the stuck photoresist pieces.

Mask defects.—Even when chromium hard surface mask are used, damage to the photomask is inevitable because soda-lime glass hardness is less than that of Si or Si_3N_4. Mask defects will also interrupt exposure and result in defects similar to those mentioned above.

Others.—Patterning defects not classified into the preceding four categories and those thought to be the result of special accidents are included in this category, *e.g.*, mechanical damage due to handling, patterning faults due to droplets of developer.

Patterning defects are distributed among the five causes as summarized in Table I. As mentioned above, since exposure interruption originates from sticking, it

Table I. Classification of inspected patterning defects

Category	Lithography steps 1	2	3	4	Total share (%)
(1) dust	1	5	10	8	27
(2) sticking	15	7	7	1	22
(3) exposure interruption	4	12	5	3	27
(4) mask defect	4	0	0	7	12
(5) others	4	3	1	2	11

can be seen as causing up to 50% of patterning defects in conventional contact prints. This conclusion leads us to the development of SURCAS to prevent photoresist sticking.

Results of dry adhesion test.—One example of a wafer put through the dry adhesion test is demonstrated in Fig. 4. Photoresist patterns of 32 µm square on a wafer before (a) and after (b) contact with photomask. In these photographs, 1 mm white squares and letters (R and r) are delineated in SiO_2 film of 1 µm thickness, the remaining part is Si substrate. Obviously, the photoresist patterns on the SiO_2 islands are favorably diminished, in this case 80%, whereas almost all patterns stay on the portion of the wafer outside the islands. The SiO_2 islands seem to serve our purpose by making photomask-wafer contact better at this address. However, after examining all addresses on the wafer, it is seen that N^{dry} tends to disperse, and in extreme cases no pattern was removed from the island. This fact indicates that the wafer comes in contact with photomask in a different manner from point to point. Though the contact printer is not a sufficient apparatus from the standpoint of a modeling experiment, it was adequate to relate our modeling concept to practical production processes. Considering those experimental difficulties, at least 70 addresses were examined and average value was taken as N^{dry} for each wafer. The relationship between the sticking frequency, N^{dry} in percent and the dry adhesion factor f^{dry} is shown in Fig. 5. This factor is defined as the ratio of the work adhesion mentioned above

$$f^{dry} = W_{a(MR)}/W_{a(RS)} = (\gamma_M{}^d/\gamma_S{}^d)^{1/2} \quad [6]$$

From the definition, photoresist patterns are expected to stick to the photomask when f^{dry} exceeds unity. This premise is completely confirmed by the results shown in Fig. 5. Here, the negative photoresist OMR 83, the commercial product of Tokyo Ohka, was also tested in addition to positive AZ1350J. The fact that the above results fit for both polymers, poly(*cis*-isoprene) and phenol-novolak, respectively, indicates the broad applicability of our adhesion model.

Yield comparison with and without SURCAS.—Accumulated defect densities are plotted against the number of photolithographic steps in Fig. 6. Two series of wafer inspection results on 30 and 15 mm^2 dies are shown as circles and squares, respectively.

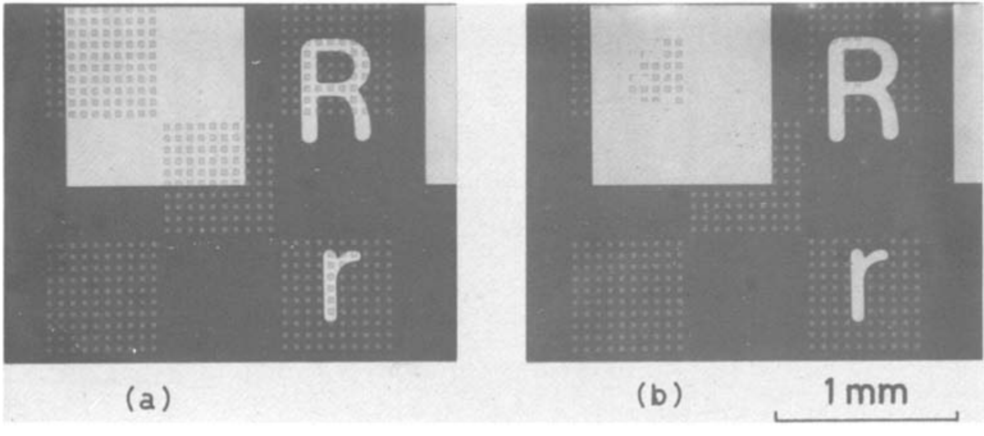

Fig. 4. Photoresist patterns on a wafer before (a) and after (b) contact with photomask. White squares and letters are delineated in SiO_2 film of 1 µm thickness, the remaining part is Si substrate.

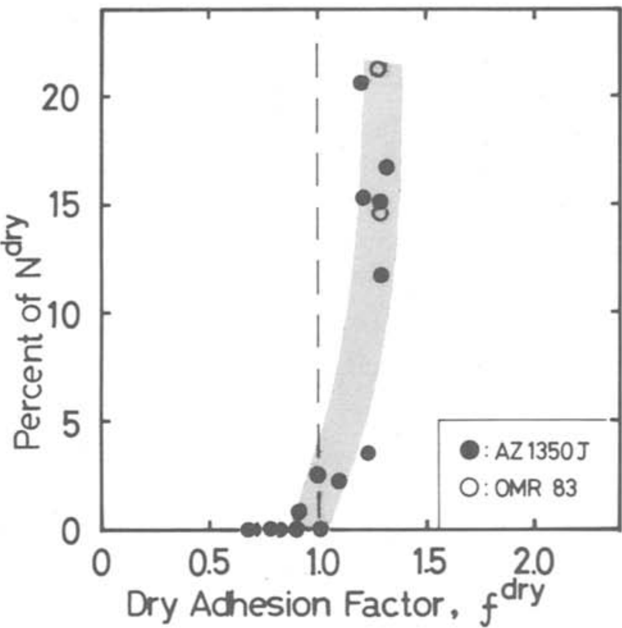

Fig. 5. Relationships between the number of stuck photoresist patterns, N^{dry} in percent, and dry adhesion factor f^{dry}.

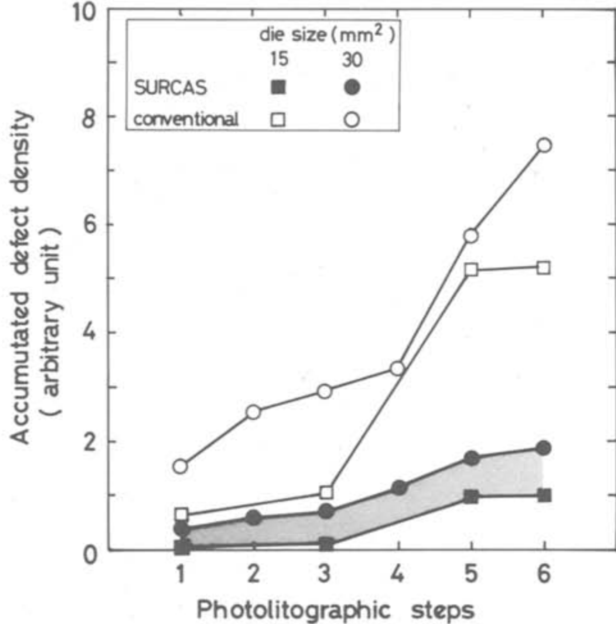

Fig. 6. Yield comparison with and without SURCAS inspected on 30 and 15 mm^2 dies.

The black and white symbols correspond to processes with and without SURCAS. Every defect density is normalized by die area for comparison.

A dramatic improvement in reducing defect density, almost to one-fourth at the final stage, is clearly apparent from this figure. In this wafer inspection, photoresist sticking is principally observed on the tops of the substrate steps" as expected from the results of the dry adhesion test. It is also noteworthy that the remarkable increase during lithography steps 4 and 5 is mainly caused by dust introduced in the chemical vapor deposition process. Considering that patterning defects are affected by the various factors, dispersion in the inspected data within the same process is not unexpected.

The utility of contact printing using a positive photoresist combined with the SURCAS mask is demonstrated. The process enables delineation of ultrafine pattern down to 1 μm at fairly low defect densities. Dust remains as main contributor to patterning defects.

Acknowledgments

The authors would like to express their appreciation to Kikuo Douta, Masahiko Tsujita, and Michie Morita for their assistance in wafer inspection. They are also deeply appreciative to Dr. Ichiro Miwa for his encouragement throughout this work.

Heavy Ion Nuclear Tracks—An Emerging Technology

R. Spohr

Gesellschaft für Schwerionenforschung mbH, D-6100 Darmstadt 11, Germany

ABSTRACT

Nuclear tracks are a logical extrapolation of the principles of cloud and bubble chamber onto solids. Besides their well-known application in particle detection, in solids a completely new aspect arises, the generation of extremely fine permanent tracks, which can be transformed into open channels. Nuclear tracks are therefore a unique single-particle structuring tool. Applications comprise (*i*) single hole membranes for particle counting and sizing, (*ii*) manufacture of microfilters with very uniform hole sizes, (*iii*) modification of magneto-optic materials for application in display memories, and (*iv*) micromachining of surfaces.

One measure for the rapid pace of technological advancement is the steady refinement of our machining tools. If we extrapolate the existing trend from mechanical machining to particle beam scribing, a single particle technique appears as the ultimate approach for the shaping and machining of solid surfaces. The nuclear track technique (1) is actually such a tool, now at the verge of being applied in practice. In contrast to photon and electron lithography, in which only the interaction of many particles is capable of generating a permanent material change, in the track process the information on number, nuclear charge, energy, and direction of single particles is maintained. Nuclear tracks are thus capable to produce holes of uniform size, length, and angle of inclination. Beyond the production of discrete holes, the technique in a more general sense can be applied for the shaping of almost any material, either directly or using replica techniques.

One necessary requirement for a systematic study of nuclear tracks as a single-particle microstructuring tool has been the advent of powerful heavy ion accelerators. Such a facility is the accelerator UNILAC (2) at GSI Darmstadt. At GSI nuclear tracks can be generated with defined beam isotope, areal dose, range, and angle of incidence in virtually any material (3). In the following, four starting points for a practical utilization of tracks in technology are described.

Single Hole Membranes

In medical diagnostics the characterization and sorting of single living cells steadily gains in importance. This field is now established under the name "flow cytometry and sorting." Its goal of identifying individual cells is achieved using a capillary that reduces the observed volume to a fine cylinder containing only one cell at a time. The passage of a cell through this cylinder is registered either optically or electrically. Up to now, cell counters and sorters with capillaries down to about 10 μm have been used, whereby typical values, however, ranged around 100 μm.

In 1977, it became possible for the first time to generate at will a single nuclear track at a specified site of an elsewhere completely virgin solid body (4). This method for convenient production of single hole membranes developed at GSI works as follows.

The ion beam is defocused to a width, so that on the average only very few particles pass through a small beam-defining aperture per second. Once an ion has passed the aperture it penetrates through the track-sensitive virgin foil and is registered in an electronic particle detector. As soon as it is registered, the accelerator beam is shut off. Through etching of the foil a single hole is obtained which corresponds to the passage of exactly one single particle (*cf.* Fig. 1). Using a target inlet system for rapid replacement of the irradiated foil by a virgin foil, in this way a considerable number of single hole membranes for test purposes has been generated at GSI.

The nuclear track technique enables the manufacture of channels as small as 10 nm and as large as 100 μm in diameter, controlled by the time of development. Foils more than 100 μm thick have been perforated up to now at GSI. The actual shape of the etched channel is defined by the sensitivity of the material, given by the ratio of track etching to general (bulk) etching v_t/v_g at a given specific energy loss $\Delta E/\Delta x$ of the penetrating ion. Track etching v_t can be more than thousand times faster than general etching v_g. This enables the manufacture of almost cylindrical cones which for prolonged etching transform into cylinders.

In blood rheology single hole membranes of 5 μm hole diam have been successfully applied for rigidity measurements of individual red blood cells (approximate diameter 8 μm) (4-6). Observed parameter is the passage time of the red blood cell, defined by the plastic deformation of the cell membrane from an oblate to a prolate shape. At present, GSI is the only facility capable of manufacturing single hole membranes with diameters smaller than 10 μm in membranes of sufficient thickness. This unique single particle application clarifies the concept of the nuclear track technique as a single-particle structuring tool.

Microfilters

Conventional filter materials as fibrous felts or open-porous foams are defined in their properties by several

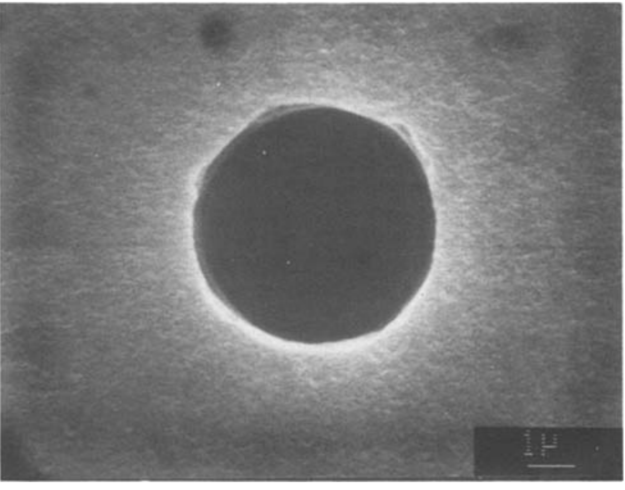

Fig. 1. Single hole for use in single hole cell counting apparatus (4-6). Hole diameter 5.0 μm, hole length 45 μm. Material: 50 μm thick Hostaphan BN 50 (Kalle, Wiesbaden, FRG). Key words: heavy ions, nuclear tracks, lithography, microfilters.

parameters, which are from each other dependent, parameters as temperature, concentration of various ingredients, and environmental factors. Particles suspended in the liquid are following intricate paths within the filter and finally are retained in the volume of the filter. The filter transmission function is broad and not well suited for classification of microscopic particles.

In contrast hereto, nuclear track filters (Fig. 2) are determined by very few parameters, which are practically independent from each other and can be precisely adapted to the required transmission properties of the filter (7): (*i*) each individual ion generates exactly one nuclear track, therefore, it is easy to adjust the throughput conductivity of the filter which is proportional to the number of holes; (*ii*) hole diameter increases linearly with the time of development, therefore, it is easy to adapt the hole size to the actual critical particle size; and finally, (*iii*) hole length corresponds to the thickness of the irradiated foil. Therefore, the total filter selectivity corresponds directly to the selectivity of the single hole.

Due to the statistical distribution of the original nuclear tracks on the filter surface, multiple holes of larger cross section occur. This leads to a mutual dependence of two of the originally independent parameters: hole size and areal density of tracks. The influence of multiple holes on filter properties has been investigated in computer simulation using square holes (8) and compared with image analysis of etched nuclear tracks in mica (9). An upper limit for the transmission of particles of given size is given by the "areal transmission function" T_s (Fig. 3). Only at very high "nominal porosity" P (defined as the product of areal track density, N, and single hole area, S_1), uncommon to conventional filters, the influence of multiple holes on transmission properties becomes important. For thick filters this influence can be minimized using irradiations under different angles.

Nuclear track filters using fission fragments from a nuclear reactor have been available since 1972.[1] This has been the first example of a commercial use of single atomic particles as a structuring tool. At GSI, heavy ions up to ten times the range of fission fragments are available at present, making possible nuclear track filters with a hundredfold increased mechanical strength. In addition, the applied ion beam technology enables the manufacture of almost parallel hole arrays (*cf.* Fig. 2).

Magneto-Optic Garnets

Iron garnets are a group of materials that were originally conceived and developed for use in bubble memories, where high domain wall mobility is a prerequisite. More recently, Philips Research Laboratory in Hamburg became interested in applying the same group of materials as an optical storage. In order to avoid cross-talk between neighboring storage cells, the magneto-optically active iron garnet film was subdivided into a regular array of discrete islands, each island representing a logical "1" or a "0", depending on its magnetization.

Another way to obtain a stable optical memory from the original high mobility garnet material was opened by heavy ion irradiation of an otherwise unstructured iron garnet film. Thereby, nuclear tracks act as very efficient pinning centers (Fig. 4), drastically reducing the originally high domain wall mobility by more than

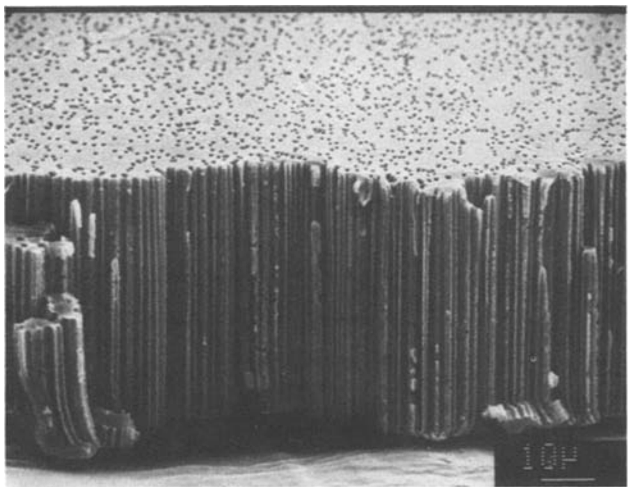

Fig. 2. Nuclear track filter manufactured with high energy heavy ions. Hole diameter 0.7 µm, hole length 49 µm. Material: 50 µm thick Hostaphan BN 50 (Kalle, Wiesbaden, FRG). Irradiation: 1.6×10^7 cm^{-2} ^{136}Xe ions of 4.7 MeV/nucleon. Development: 42 hr 99% 1n NaOH + 1% Tickopur R33 (Brinkmann Instrumentenbau GmbH, Mannheim, FRG) at 40°C. Observation: scanning electron microscope.

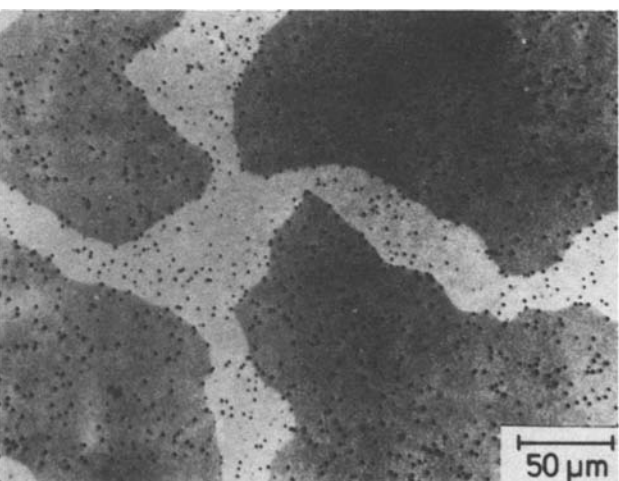

Fig. 4. Pinning of magnetic domain walls by etched nuclear tracks. Material: epitaxial $(Gd, Bi)_3(Fe,Ga)_5O_{12}$ garnet film. Irradiation: 3×10^6 cm^{-2} Xe ions of 1.4 MeV/nucleon. Development: 3 hr 1/3 HNO_3 + 1/3 CH_3COOH + 1/3 H_2O at 80°C. Observation: light microscope, Faraday contrast using polarized light.

a factor 100 (10-14). The pinning effect resides in the interaction of magnetically deactivated latent tracks with the domain walls, whereby each trapping process dissipates wall energy in the form of heat. Thus, on the average, the coercitivity of domain wall movement is increased. Irradiated films can therefore carry much finer domain pattern than virgin films. Information densities of several hundred kilobits per cm^2 have been achieved up to now. An important aspect of such a modified magneto-optic storage material is that, due to the high optical contrast, memory and display can be realized in one and the same device. This reduces unnecessary shuffling back and forth of information between memory and display in a computer application.

Heavy Ion Lithography

In solid-state technology more and more components have to be compressed onto smaller and smaller areas. Maintaining simultaneously critical cross sections of conductors becomes a major problem in planar technology using light, u.v., x-rays, or electrons. Thereby, high lateral resolution is no longer a sufficient condition. Much more stress has to be placed on obtaining better control over depth profiling. Great efforts are undertaken, using, *e.g.*, multiple layers of materials, to enlarge the planar technology concept into depth. However, any further progress will depend very essentially on the capability of the applied technique to generate a laterally well-defined activated zone that extends down to the desired depth.

For this purpose, heavy ion nuclear tracks appear to be an almost ideally suited tool (15, 16). In contrast to other techniques using photons or electrons, heavy particles possess a momentum and energy concentration that is several orders of magnitude higher. Only heavy particles are subject to a quasi-continuous energy loss on their trajectory and thus, come to a hold at a nicely defined depth. Range straggling of individual heavy ions can be of the order of only a few percent. In contrast hereto, for photons and electrons an equivalent term for "range" can only be defined rather arbitrarily as a gross property of many particles, via the exponential law of extinction. Every individual heavy ion thus creates a submicron size pencil of sensitized resist along its path, that can be used as a resolution element. The diameter of the latent track is around 10 nm which can be considered as the ultimate resolution limit (present experimental resolution limit is around 50 nm). Individual particle beam scribing may attain this ultimate limit in the future.

At GSI, a shadow casting technique (15, 16) has been developed, using low energy heavy ions from a 300 kV accelerator. Figure 5 shows the obtained deep structures with steep edges and a smooth bottom. Negligible mask scattering is observed in this micrograph. Also, due to the much smaller radiation damage in metals (higher atomic mobility) it should be possible to make many replicas of one metal mask in this way. Sputtering thereby should be a negligible effect, due to the small dose accumulated over many exposures. In the case of Fig. 5 the resist layer was thicker than the ion range. Even prolonged etching showed no measurable influence on structuring depth in this experiment. This proves the capability of the applied technique to sensitize a defined volume down to a well-defined depth. Depth resolution of the order of a few percent should be possible. In many cases a more precise definition may be achieved by termination of the etch attack, in a track or etch insensitive buried layer or substrate.

Application of heavy particles to lithography has another inherent advantage over x-rays and electrons. Due to the very high specific energy loss of heavy ions in solid matter (often more than 10 keV/nm) not only conventional resist materials can be sensitized but equally well an almost unlimited number of different materials. For example, the resist coating step in silicon technology can be replaced by a much simpler oxidizing step leading to a "resist" (passivation) layer of much better defined thickness. Even pure silicon can be track-sensitized using heavy ion irradiation and transforming the inscribed information into structure during a later selective etching process (Fig. 6). In this case, however, range and lateral resolution are dominated by nuclear stopping, yielding a quite rough bottom of the etched troughs due to multiple scattering and recoils atoms.

A final virtue of heavy ions as a structuring tool in comparison to x-ray sources resides in the existence of very bright ion sources. Parallel heavy ion beams of high intensity can be achieved using conventional ion optical systems. Heavy ion lithography can be directly applied to small accelerators and low energy implanters. At 1 mA beam current a sample throughput of 1 m^2/sec can be achieved.

Auger Electron Spectroscopic Study of Oxidation of Zirconium

Gopala N. Krishnan, Bernard J. Wood, and Daniel Cubicciotti*,[1]

SRI International, Menlo Park, California 94025

ABSTRACT

The uptake of oxygen on the surface of an intially clean zirconium crystal was observed by means of Auger electron spectroscopy (AES). This technique permitted measurement of both rate of growth of surface oxygen and the chemical state of the oxygen. Experiments were performed in the temperature range 773-1008 K with oxygen pressures from 1.9×10^{-4} to 7.2×10^{-3} Pa. Under these conditions, the rate of diffusion of oxygen into the metal bulk becomes significant and determines the extent of the chemisorption regime. At the higher temperatures, the chemisorption regime extends to long exposure periods, whereas at the lower temperature, an oxide is rapidly formed. The observed linear rate of oxygen uptake after the appearance of the surface oxide may be caused by oxygen diffusing through an oxide layer of constant thickness and subsequently dissolving in the bulk metal underneath. This oxide layer is estimated to be about 1 nm thick.

In recent studies (1-3) of the reaction of zirconium with oxygen at low pressures (10^{-4}-10^{-1} Pa)[2] and at elevated temperatures ($T > 775$ K), it was demonstrated that the oxygen uptake rate follows a linear rate law for a substantial length of time. After extended periods of exposure, especially at higher pressures, when there has been ample opportunity for the formation of an oxide scale layer, oxygen uptake can be described by a parabolic rate law. Previous investigators have hypothesized that, in the linear rate regime, oxygen uptake is controlled either by arrival rate of oxygen molecules to the surface or by diffusion of oxygen adspecies through a "thin layer" of oxide on the surface (2). However, no quantitative information is available on the nature of the rate of formation, or the thickness of such an oxide layer. Auger electron spectroscopy (AES) was used to characterize the initial stages of oxidation of zirconium under clean surface, ultrahigh vacuum conditions. For applications where the oxygen gettering quality of zirconium is of interest, the results of this study will permit one to define the conditions of temperature and oxygen pressure that favor bulk dissolution of oxygen in contrast to oxide film (scale) formation.

Experimental Program

Approach.—The use of AES to study initial stages of gas-metal interactions has been well documented (4). In this technique, the emission of Auger electrons is stimulated by the bombardment of the specimen with a high energy (3 kV) electron beam. The emitted Auger electrons are energy analyzed to provide a spectrum of peaks whose positions on the energy scale identify the elemental components on the specimen surface. AES is a highly surface-selective analytical technique because of the limited escape depths of Auger electrons. For electron energies ranging from 50 to 500 eV, the range of interest in this study, the escape depth of electrons varies between 0.5 to 1 nm (5), which is equivalent to two to four atomic layers; hence, components in the bulk metal below this depth will not be detected by AES.

The concentration of a particular elemental component in the near-surface atomic layers of a specimen determines the amplitudes of the peaks in its Auger spectrum. But the proportionality factor relating concentration to peak amplitude, frequently referred to as the Auger yield, is a complex quantity that cannot be precisely evaluated from first principles (4). However,

changes in concentration of a component can be followed with good precision by measuring the growth or decay of an Auger peak. Thus, we observed the adsorption of oxygen on the zirconium surface by measuring the amplitude of the oxygen Auger peak at 510 eV.

Apparatus and materials.—All experiments were conducted in an ultrahigh vacuum system capable of attaining 10^{-8} Pa base pressure. The AES analyses were performed with a Varian cylindrical mirror analyzer with an integral electron gun. The incident electron beam was ~100 μm in diameter at the specimen, and it was normally operated at 3000 eV and 5 μA. The total pressure in the system was measured with an ionization gauge, and the partial pressures of gaseous components were determined with a quadrupole mass spectrometer. A rastered, 3 keV argon gun was used to clean the specimen surface. The arrangement of the various components with respect to the specimen is shown in Fig. 1.

Measurements were made on a "Marz grade" zirconium crystal, containing ~100 ppm oxygen impurity obtained from Materials Research Corporation. This specimen was a disk, spark cut from a 0.63 cm diam rod that was nominally a single crystal. However, x-ray diffraction and metallographic observations revealed that the rod consisted of several large grains. After sequential mechanical and chemical polishing, seven large grains could be delineated on the face of the 1 mm thick specimen; thus, the average diameter of each grain was about 250 times greater than the AES electron beam diameter. To avoid problems associated with grain boundary impurities of oxygen transport the AES beam was focused onto the center of a large grain. The specimen was heated by radiation from a tungsten filament situated beneath it (Fig. 1), and the average temperature was measured with an iron-constantan thermocouple spot-welded to the edge of the disk.

Oxygen (Linde UHP grade, 99.99% O_2) was admitted to the vacuum chamber through a calibrated stainless steel capillary tube (75 cm long by 0.017 cm ID). The mass flow rate of gas into the chamber could be precisely controlled and measured, independent of the pressure in the chamber, by adjusting the oxygen pressure at the upstream end of the capillary tube. The downstream (outlet) end of the capillary tube pointed at the specimen surface from a distance of about 0.2 cm. On the basis of mass spectroscopic measurements of mass flux as a function of radial distance from the center line of the capillary tube, it was estimated that about 70% of the gas molecules emanating from the tube impinged on the specimen surface.

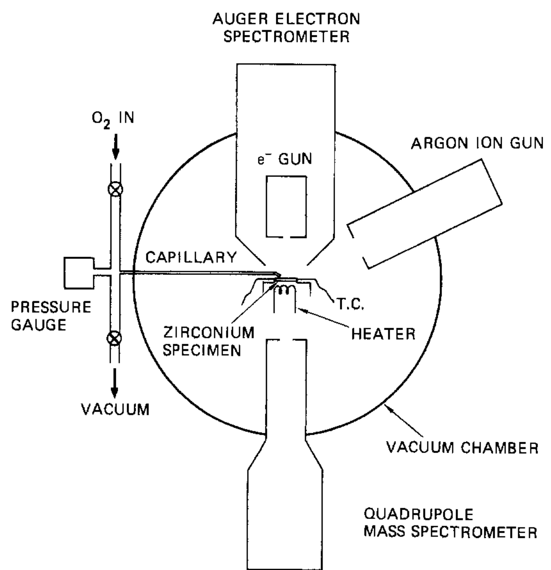

Fig. 1. Schematic diagram of apparatus

Procedure.—The only detectable impurity on the zirconium crystal surface following cleaning by argon ion bombardment at 1000 K was a trace of oxygen. In the vacuum chamber at 10^{-7} Pa, the surface of the specimen remained clean indefinitely at temperatures above 900 K. At lower temperatures, oxygen accumulated on the surface. The observed rate of accumulation was too fast to be due to adsorption from the gaseous environment in the vacuum chamber ($P_{O_2} \approx 10^{-9}$ Pa); hence, it was concluded that dissolved oxygen diffused from the bulk to the surface while the crystal was cooling.

Due to the relatively massive size of the crystal and its poor thermal contact with any heat sink, the specimen could not be quenched from a high temperature to give an oxygen-free surface at temperatures less than 750 K. Consequently, oxygen uptake rate measurements on the zirconium crystal were made only at temperature in the range 750-1050 K.

After the specimens were cleaned by Argon ion bombardment at 1000 K, the temperature was shifted to the desired level for the experiment by adjusting the power input to the heater. When the specimen temperature became stable (typically within 120 sec), the capillary inlet valve was opened enough to establish a steady flow of oxygen at a desired level. An equivalent, average, steady-state pressure, P_{O_2}, of oxygen at the specimen surface was calculated from the known mass flow rate, $\dot{m}$, of oxygen through the capillary tube using the following equation derived from the kinetic theory of gases (6)

$$\alpha \dot{m}/A = P_{O_2}\bar{c}/4RT$$

where $\bar{c}$ is the mean molecular velocity at the gas temperature, T, R is the gas constant, A is the exposed geometric surface area of the specimen, and α is the fraction of incoming molecules that strike the specimen. Oxygen flux distribution as a function of lateral position of a specimen with respect to the nozzle was measured with the mass spectrometer using a movable aperture. From this measurement the fraction, α, was found to be 0.7 for our specimen geometry. Specimen temperatures and oxygen pressures used in these experiments are summarized in Table I.

Auger spectra over the energy range 60-560 eV were recorded every 30 sec on an oscillographic chart recorder (Beckman Dynograph, Type RS). Rate data were obtained from this chart by measuring the AES peak height as a function of elapsed time. At longer intervals, the Auger spectrum of the specimen surface was recorded more slowly in order to obtain higher resolution of the Auger peaks.

Results

Auger spectra.—The observed peaks in our experimental study are associated with particular Auger transitions (7) as shown in Table II. Figure 2 is a representative sequence of Auger spectra obtained during exposure of a specimen to oxygen at a constant temperature. Besides the obvious increase in the oxygen peak (510 eV) height, there are other features to be noted. The three zirconium peaks that involve valence band electrons (127, 147, and 175 eV) decrease in amplitude with increasing oxygen coverage. At some point during oxygen exposure, a new zirconium Auger peak appears and begins to grow in height. This peak

† No line shift was observed for the oxygen lines.

can be interpreted as a 7 eV shift to lower energy of the 147 eV peak. Similar shifts appear for the 175 and 127 eV peaks. Such peak shifts are indicative of a change in the chemical state of the zirconium atoms in the specimen surface region. Similar Auger peak shifts during oxide formation have been reported in the case of nickel (8), silicon (9), molybdenum (10), iron (11), and aluminum (12).

In contrast to this behavior, the Auger peaks (92 and 117 eV) arising exclusively from core level transitions are less profoundly affected by oxygen uptake. These peaks exhibit a modest shift of about 4 eV during oxide formation. This smaller shift attests to the fact that the core level electrons are less affected than the valence level electrons by the chemical environment.

More interestingly, the amplitudes of the core level Auger transition peaks (92 and 117 eV) do not change appreciably during oxygen uptake. In fact, within the precision of our experimental measurements, the 92 eV peak showed little change during the entire range of oxygen coverage studied in this investigation. This insensitivity of the zirconium core level peaks to the presence of oxygen was confirmed by obtaining an Auger spectrum of ZrO_2. In the oxide, the peaks involving valence band electrons are attenuated considerably relative to the peaks involving core levels only. Thus the ratio of $Zr(M_5N_1N_{2,3})/Zr(M_4N_{2,3}N_{4,5})$ is 0.17 in the pure metal and $\sim$ 1 in the oxide.

Surface oxygen growth.—Figure 3 illustrates the surface oxygen coverage on Zr crystal as a function of oxygen exposure. Note that the surface coverage at 933 K is independent of oxygen pressure when the coverage is plotted as a function of oxygen exposure. Since exposure is defined as the product of oxygen pressure and exposure time, the above observation indicates that the surface coverage is linearly proportional to the oxygen pressure.

The variation in surface oxygen coverage on the zirconium specimens is displayed as a function of oxygen exposure and of temperature in Fig. 3. The abscissa of Fig. 3 is expanded in Fig. 4 to resolve the shape of

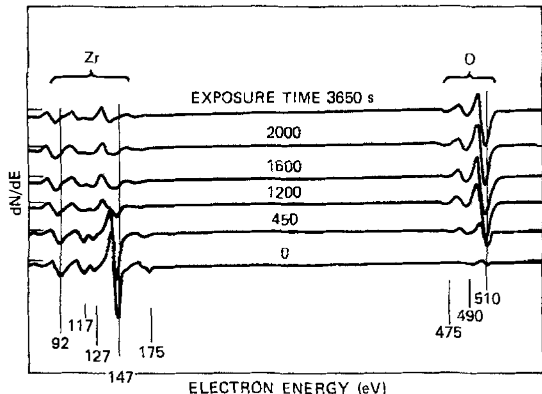

Fig. 2. Changes in Auger spectra of zirconium crystal during exposure to oxygen. $T_{Zr} = 963$ K. $P_{O_2} = 2.5 \times 10^{-3}$ Pa.

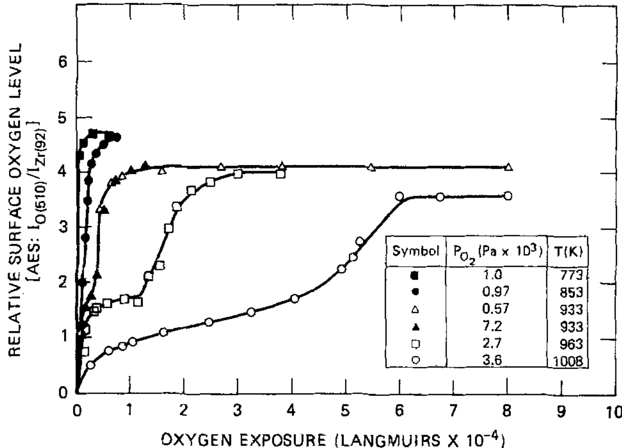

Fig. 3. Oxygen uptake on zirconium crystal as a function of temperature and oxygen exposure. (1 Langmuir $= 1.33 \times 10^{-4}$ Pa · sec.)

the curves at small values of exposure. Since the Zr (92 eV) peak height is shown to be insensitive to the presence of oxygen, we have used it as a normalizing factor to compensate for changes in incident electron beam current, electron multiplier gain, and the like.

The surface oxygen uptake curves indicate four distinct sequential stages in the accumulation of oxygen on the zirconium surface: stage 1, an initial period of rapid oxygen accumulation; stage 2, a region of slow increase in oxygen level; stage 3, a second period of further rapid oxygen accumulation; and stage 4, a constant coverage region. The rate at which oxygen accumulates on the surface decreases with increasing temperatures during stages 1 and 3. Stage 2, the slow growth regime, appears to be of negligible duration at 773 K but extends to longer exposure periods at higher temperatures. The final steady-state level of surface coverage attained on the crystal specimen in stage 4 reaches a lower value as the temperature of the specimen increases.

During stage 3, energy shifts in the zirconium AES peaks are observed, indicating the beginning of chemical changes on the surface. As mentioned earlier, these peak shifts are likely due to the formation and growth of a condensed phase of a zirconium oxide. Hence, the uptake of oxygen by a zirconium surface appears to be a sequential process in which initial chemisorption is followed by nucleation and growth

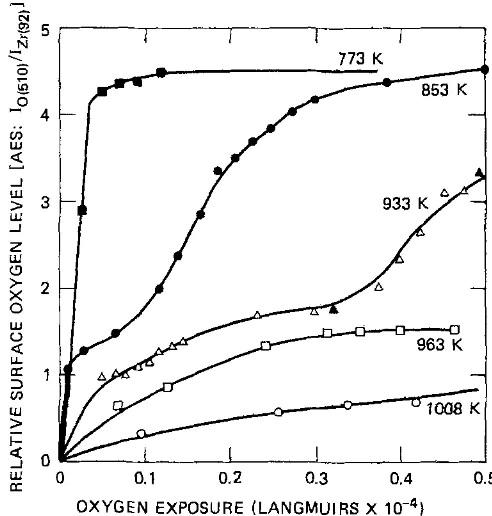

Fig. 4. Oxygen uptake on zirconium crystal as a function of temperature and oxygen exposure, expanded scale. See legend in Fig. 3 for symbols.

of an oxide phase. The experimental curves indicate that formation of the oxide phase is favored by lower temperatures and by higher oxygen pressures. Conversely, the chemisorption regime is extended at higher temperatures and at lower oxygen pressures.

Mass spectrometric measurements.—The residual oxygen partial pressure in the specimen chamber was monitored concurrently with the AES measurements. Entering oxygen molecules that do not adsorb or react irreversibly on the zirconium specimen surface are pumped out of the chamber. Thus a mass balance in oxygen is described by the following equation

$$r_{Zr} = \dot{m} - SP_{O_2}$$

where $\dot{m}$ is the mass flow rate of oxygen into the chamber through the capillary tube, r_{Zr} is the rate of oxygen uptake by the zirconium specimen, and S is the pumping speed of the vacuum system for oxygen. In our experiments, $\dot{m}$ is calculated from the observed pressure at the inlet of the capillary tube, the measured conductance of the tube, and P_{O_2}, which is monitored by the mass spectrometer. Thus, if S is known, values for r_{Zr} can be calculated. Pumping speed was evaluated by measuring the steady-state oxygen partial pressure in the chamber with the zirconium specimen absent, over a range of values of $\dot{m}$. The pumping speed was found to vary from 600 liters sec^{-1} at $\dot{m} = 2.7 \times 10^{-2}$ Pa liters sec^{-1} to 900 liters sec^{-1} at $\dot{m} = 4 \times 10^{-3}$ Pa liters sec^{-1}. The precision of this measurement was relatively poor because S exhibited some dependence on the chamber pressure and also on the immediate history of the system (it increased, for example, when titanium was freshly deposited in the sublimation pump). However, over most of the range of pressure variation observed in one kinetic experiment, the pumping speed was found to be reasonably constant (±25%).

The curves shown in Fig. 5 illustrate the change in oxygen pressure that occurs during exposure of the zirconium specimen to a constant flux of the gas. The scale on the abscissa in Fig. 5 is identical to that in Fig. 3, so that changes in P_{O_2} can be compared directly with the amount of oxygen observed on the crystal surface by AES. The oxygen partial pressure in the chamber increases monotonically with increasing exposure until it reaches a steady-state value (Fig. 5). There is no discontinuity in the rate of increase of oxygen pressure corresponding to the first plateau in the rate of growth of oxygen on the zirconium surface (compare the respective curves in Fig. 3 and 5). This observation, that r_{Zr} exhibits a finite value in a region where the oxygen surface coverage is nearly constant, indicates that oxygen must be diffusing into the crystal as rapidly as it chemisorbs. At longer exposures, both surface coverage and P_{O_2} become constant. Based on the estimated values of S and the measured values of P_{O_2}, oxygen is still diffusing into the zirconium crystal but at a much lower rate. The steady-state rate of oxygen uptake was estimated to vary from $0.7 \pm 0.3 \times 10^{20}$ molec cm^{-2} sec^{-1} $Torr^{-1}$ at 930 K to $1.6 \pm 0.3 \times 10^{20}$ molec cm^{-2} sec^{-1} $Torr^{-1}$ at 1050 K with an apparent activation energy of $+9 \pm 4$ kcal $mole^{-1}$. It is this regime, undoubtedly, in which the linear oxygen uptake rates were observed by Nagasaka *et al.* (1). Where the experimental conditions overlap, our values of oxygen uptake rates are about an order of magnitude greater than these reported by these investigations. However, within the precision of our measurements and of the estimate of our pumping speed, this agreement is reasonable.

Dissolution of surface oxide.—After a steady-state P_{O_2} and a constant surface coverage are attained, interruption of the supply of oxygen to the crystal causes the surface oxygen level to gradually decrease. During this surface decay, the oxygen partial pressure in the chamber does not increase, an indication that the surface oxygen is disappearing by diffusion into the bulk of the crystal. The decrease in the normalized surface oxygen AES peak height is plotted as a function of time in Fig. 6. It is evident that the rate of diminution in surface oxygen depends on the temperature and on the previous oxygen exposure. After an initial rapid loss of surface oxygen, subsequent loss rates are very slow; that is, approximately 8 hr at 963 K were required to attain a nearly zero oxygen coverage. Note that the extent of surface oxygen coverage attained after the initial rapid loss appears to correspond to the steady-state chemisorption level (stage 2) observed during oxygen exposure. In view of the great affinity of Zr (bulk) for oxygen, the longevity of this oxygen adstate is remarkable.

Discussion

The oxygen surface accumulation is a function of oxygen exposure. The rate decreases with increasing temperature. However, the total rate of oxygen uptake calculated from the mass spectrometric data indicates that the total rate increases at higher temperature. The disparate behavior between AES and mass spectrometric data is due to the diffusion of oxygen into the bulk of the zirconium crystal. Zirconium metal can dissolve up to 28.6 atomic percent of oxygen, and the rate of diffusion of oxygen in zirconium metal becomes significant above 773 K (13). The initial rate

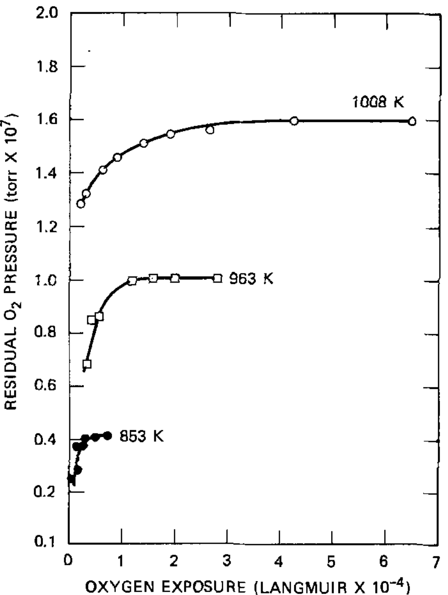

Fig. 5. Variation of P_{O_2} as a function of oxygen exposure at various temperatures.

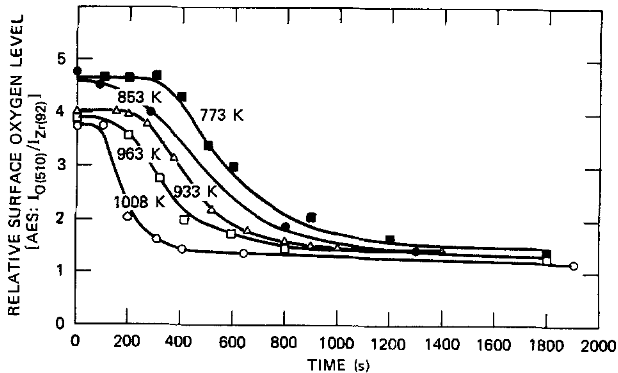

Fig. 6. Dissolution of surface oxygen at various temperatures

of surface coverage as measured by AES is plotted against inverse temperature in Fig. 7, and a negative activation energy of -44 kcal $mole^{-1}$ is obtained. Indeed, this value is identical but opposite in sign to the activation energy reported for the diffusion of oxygen in zirconium metal (13). The total uptake of oxygen includes both surface accumulation and dissolution in the bulk. Thus, as the temperature increases, the rate of dissolution also increases thereby decreasing the surface coverage at any given oxygen exposure.

Since the rate of diffusion is proportional to the concentration gradient between the surface and the bulk, the diffusive flux would be low at the start of the exposure while oxygen accumulates on the surface. As the coverage increases, the amount of surface oxygen is determined by the dynamic competition between the adsorption rate of oxygen on the surface and by the rate of diffusion of oxygen into the bulk of the crystal. As the surface sites become filled with oxygen, the surface accumulation rate decreases and the total uptake rate is then determined essentially by the rate of diffusion into the crystal.

As the concentration of oxygen in the surface layers reaches a critical value, the AES oxygen peak height begins to increase. During this growth period (stage 3) the zirconium Auger peaks shift to lower energy indicating the formation of a condensed oxide layer. The characteristic shape of the kinetic curves (coverage *vs.* exposure) and the Auger energy shifts, taken together, give strong support to the hypothesis that in this region an oxide layer nucleates and grows. At this stage, the oxygen uptake rate is governed by the rate of the oxide growth and by the rate of diffusion of oxygen into the bulk.

When the surface is covered with the oxide layer, the oxygen uptake rate becomes limited by the diffusion of oxygen through the oxide into the metal. The rate of diffusion of oxygen in the oxide is significantly lower than in the metal (14), and thus the oxygen uptake rate decreases. In this region (stage 4) both the surface coverage as measured by AES and the uptake rate as calculated from oxygen partial pressure is constant. Even though the precision of the total oxygen uptake measurement is poor in this study, it is clear that the oxide layer is dynamic and that a steady-state condition exists between the oxygen arrival rate from the gas phase and the rate of diffusion into the crystal. In the absence of gaseous oxygen, the oxide layer dissolves into the metal.

The conditions of temperature and oxygen pressure used in this study overlap those used by Nagasaka *et al.* (1). Under these conditions an oxide layer would be formed in less than a few minutes. The reported linear oxygen uptake rate at higher exposure suggests that the oxide layer has a nearly constant thickness with steady-state diffusion of oxygen through the oxide governing the rate of oxygen uptake. Similar considerations apply to the data reported by Dechamps and Lehr (2). Indeed the existence of a thin oxide layer was postulated earlier by Dechamps and Lehr (2). The present AES study confirms the existence of such an oxide layer and permits us to determine its thickness.

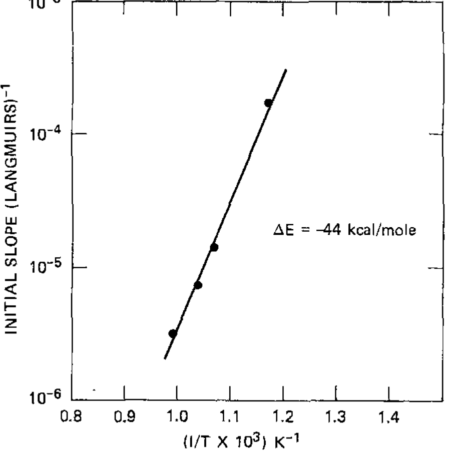

Fig. 7. Variation of initial rate with temperature

At the highest coverage of oxygen recorded in this study the Auger peaks corresponding to metallic zirconium are still evident in the spectra, suggesting that the thickness of the oxide layer is approximately 1 nm (10Å), the escape depth of Auger electrons with a kinetic energy of 150 eV. The AES oxygen peak height attained during the final steady-state condition decreases with increasing temperature (Fig. 3); thus, the thickness of the oxide layer could become even smaller as the temperature increases.

According to Nagasaka *et al.* (2), the activation energy associated with the linear oxygen uptake rate is about 10 kcal $mole^{-1}$, and our results tend to agree with that value. However, this value is rather small in comparison to the activation energy of 56 kcal $mole^{-1}$ reported for diffusion of oxygen in zirconium oxide (14). This discrepancy may be due to the nature of the oxide layer formed initially on the metal under the conditions employed. In fact, the activation energy for oxygen diffusion in oxide scales formed on metallic zirconium is substantially lower ($\sim$29 kcal $mole^{-1}$) (14). The initial oxide layer may have a high defect concentration and, according to Kofstad (15), the oxide may be a p-conductor, a mixed ionic/electronic conductor, or an n-conductor, depending on the stoichiometry and the impurity level. The studies conducted by Bradhurst *et al.* (16) and by Lightstone and Pemsler (17) have shown that the rate of ionic transport in the oxide is appreciable and that the growth of the oxide layer is controlled by the rate of transport of electronic defects. The transport of electrons have a rather low activation energy of 2-3 kcal $mole^{-1}$. In a mixed kinetic regime in which ionic and electronic transport controls the oxygen diffusion, the activation energy required may be comparable to the observed value.

An alternative scheme to explain the observed activation energy involves the adsorption of oxygen on the oxide surface and subsequent diffusion. The rate of adsorption decreases with increasing temperature while the rate of diffusion increases. Thus in a mixed kinetic regime, the combined effect of these two rates will result in a modest apparent activation energy as observed.

Conclusions

The initial stage of oxidation of a clean zirconium surface proceeds first as a chemisorption process followed by nucleation and growth of an oxide layer. At temperatures above 773 K, the rate of diffusion of oxygen into the bulk becomes significant and governs the extent of the chemisorption regime. At higher temperatures, the chemisorption regime extends to long exposure periods, whereas at low temperatures, an oxide is formed rapidly. The observed linear rate of oxygen uptake after the appearance of the surface oxide may be due to diffusion of oxygen through an oxide layer of constant thickness. This oxide layer formed at very low oxygen pressures is estimated to be approximately 1 nm thick.

Thermodynamics of Vaporization of ZrI_4 in the Univariant Region: Zirconium Monoiodide/Zirconium

Daniel Cubicciotti* and K. H. Lau

SRI International, Menlo Park, California 94025

ABSTRACT

The pressures of gaseous ZrI_4 over solid zirconium iodides in the composition range ZrI to Zr were measured by a torsion-effusion method. A univariant region was observed between solids of composition $ZrI_{1.05}$ and Zr for which the pressure of gaseous ZrI_4 was represented by the equation

$$\text{Log}_{10} P(\text{atm}) = (12.83 \pm 0.1) - (13{,}200 \pm 100)/T$$

These results extend literature information on the thermodynamics of vaporization in the ZrI_4/Zr region of the Zr-I system.

The chemistry of the zirconium-iodine system is intimately involved in the mechanism of iodine-induced stress corrosion cracking of zirconium alloys (1, 2). We have been investigating the thermodynamics to improve understanding of the chemistry of the system. The thermodynamic properties of the gaseous zirconium iodides are reported in Ref. (3). We have studied the vaporization of gaseous ZrI_4 from the solids to evaluate the thermodynamic properties of the solid phases. The vapor pressure of pure, solid ZrI_4 is given in Ref. (4). In a recent paper (5), the partial pressures of gaseous ZrI_4 in equilibrium with substoichiometric solid zirconium iodides in the composition range $ZrI_{2.4}$ to $ZrI_{1.0}$ were determined by the torsion-effusion method. This technique requires no knowledge of vapor composition to evaluate total vapor pressure. Simultaneous mass loss and effusion rate measurements confirmed that the vapor contained only gaseous ZrI_4, and the measurements gave average molecular weight values within experimental error of the value of ZrI_4 gas. A univariant region was found between the solids $ZrI_{1.9}$ and $ZrI_{1.3}$, and the equilibrium pressures of gaseous ZrI_4 were derived. Between $ZrI_{1.3}$ and $ZrI_{1.0}$ the vapor pressure decreased as effusion proceeded at constant temperature, indicating that a single phase solid solution region existed in this range.

The part of the zirconium-iodine system most relevant to the stress corrosion cracking problem is the region that includes zirconium metal. In this paper we report the vaporization of ZrI_4 from the two-solid-phase region that involves zirconium metal and the lowest iodide, approximately ZrI.

The principle of the method we used is described in Ref. (5). A sample of solid zirconium iodide (of composition approximately $ZrI_{1.2}$) was heated in a torsion-effusion gravimetric system so that gaseous ZrI_4 was released. The pressure of the gas was measured from the torque of the cell. The composition of the solid was monitored through its weight change. As ZrI_4 evaporated, the average composition of the residual solid changed, becoming richer in zirconium. The results are given below.

* Electrochemical Society Active Member.

Key words: sublimation, free energy, inorganic, pressure.

Experimental Materials

The $ZrI_{1.2}$ samples loaded in the graphite effusion cells were prepared as follows: the starting material was $ZrI_{2.4}$ prepared as described earlier (5). A weighed amount of $ZrI_{2.4}$ was loaded in a graphite crucible and sealed under high vacuum into a 20 cm long by 1.6 cm diam fused silica tube. The tube was placed in a two-zone tilted furnace. The lower 8 cm of the tube containing the sample was heated to 425°C. The upper 4 cm was kept at 140°C so that ZrI_4 vaporized from the sample condensed there, thereby maintaining a ZrI_4 vapor pressure of about 2×10^{-7} atm. The tube was heated in this temperature gradient for three weeks and was then transferred to a dry box under an atmosphere of argon. The tube was cracked in the center and a lump of reddish brown ZrI_4 product was collected from the upper end and weighed to obtain an estimate of the composition of the solid residue. The sample in the graphite crucible was a black, granular material.

Two samples were prepared; part of each was used for chemical and x-ray diffraction analyses. The rest was loaded into the effusion cells, one sample into cell A, the other into cell B. Titration with silver ion to an iodide electrode end point showed the composition of the starting material was $ZrI_{1.2\pm0.1}$ for cell A and $ZrI_{1.1\pm0.1}$ for cell B. These starting compositions were in good agreement with the total mass lost by the cells in the vaporization study, during which all the iodide was evaporated from the cell (see below). Table I gives the lines observed in a powder pattern taken on a portion of the sample placed in cell A. We believe the pattern represents the phase ZrI but the stoichiometry may differ somewhat.

Vapor Pressure Measurement

Vapor pressures were measured by the torsion-effusion method. The apparatus, the sample loading procedures, and other details of this method were described in our earlier publications (4, 5). Two series of vapor pressure measurements were made with graphite effusion cells labeled cell A (0.047 cm orifice diameter) and cell B (0.0803 cm orifice diameter). These are the same two cells used in our earlier work (4, 5) and described in detail there (3).

Results

The results of the measurements are listed in Table II. The data are presented in the chronological order in which they were obtained. The pressure (column 2) was calculated from the measured angular displacement of the torsion effusion cell at each temperature. The molecular weight of the effusing gas (column 3) was calculated from the pressure and the rate of mass loss of the cell. The composition of the solid (column 4) was calculated from the initial sample weight and the total mass loss incurred by the sample, assuming the vapor lost was gaseous ZrI_4. The last column of the table, P_{obs}/P_{calc}, gives the ratio of the measured pressure divided by the pressure calculated from one of the equations that represents the univariant region for the given cell, namely, Eq. [1] or [2] below.

The molecular weights observed (column 3) were in the range 579-637, which is within the experimental error of the method for ZrI_4 gas—namely, 599. Vapor in equilibrium with zirconium metal under these conditions can be shown to contain essentially ZrI_4, with only traces of lower valent gas (3). Thus the gas was presumed to be pure ZrI_4 in all these measurements.

* Obtained with a 2 in. diam camera and CuKα radiation.

The pressures observed for cell A over the range of composition of the solid in the cell of $ZrI_{1.07}$ to $ZrI_{0.57}$ could be represented, within ±3%, by a single equation independent of composition, as follows

$$\log_{10} P(\text{atm}) = (12.26 \pm 0.10) - (13{,}080 \pm 80)/T \quad (745\text{-}980\ \text{K}) \quad [1]$$

The pressures observed for cell B over the composition range $ZrI_{1.05}$ to $ZrI_{0.65}$ could also be represented by an equation independent of composition, as follows

$$\log_{10} P(\text{atm}) = (11.75 \pm 0.11) - (13{,}010 \pm 90)/T \quad (730\text{-}722\ \text{K}) \quad [2]$$

The uncertainty given in each equation is a standard deviation derived in a least squares treatment. The data are shown graphically in Fig. 1.

As part of our investigation (5) of ZrI_4 pressure in the solid composition range $ZrI_{2.4}$ to $ZrI_{1.3}$ we made some preliminary measurements at lower stoichiometries. Those measurements showed evidence for univariant behavior at compositions below about ZrI. Because of the small amount of sample remaining in the cells at compositions below ZrI (since the initial composition was $ZrI_{2.4}$), we were not sure of the reliability of the results and did not publish them at that time. The pressures observed in those experiments were found to be in good accord with the present data measured on samples of initial composition $ZrI_{1.2}$. The values found as part of the Ref. (5) measurements were as follows for cell A

$$\log_{10} P(\text{atm}) = (11.92 \pm 0.4) - (12{,}850 \pm 290)/T \quad (740\text{-}780\ \text{K}) \quad [3]$$

These values in cell A were observed over the range of compositions of $ZrI_{0.97}$ to $ZrI_{0.89}$. At lower stoichiometries the measured pressures were smaller. For cell B the results were represented by

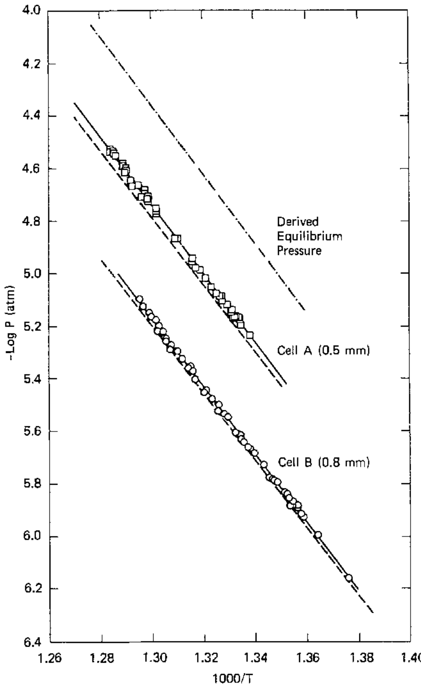

Fig. 1. Vapor pressures of ZrI_4 in the univariant region of the system between ZrI and Zr. Data points represent values from Table II and solid lines are least squares equations [1] and [2]. Dashed lines are results obtained earlier and work represented by Eq. [3] and [4]. Dot-dash line gives equilibrium pressures obtained by extrapolation to zero orifice area.

$$\log_{10} P(\text{atm}) = (11.38 \pm 0.2) - (12{,}750 \pm 130)/T \quad (740\text{-}780\text{ K}) \quad [4]$$

These values in cell B were observed over the composition range $ZrI_{0.96}$ to $ZrI_{0.53}$. At lower stoichiometries the pressures were smaller than Eq. [4]. These results are shown in Fig. 1 as dashed lines. The values of Eq. [3] (cell A) are about 10% smaller than Eq. [1], and those of Eq. [4] (cell B) are about 6% smaller than Eq. [2]. The data represented by Eq. [3] and [4] were considered to be less accurate than those of Eq. [1] and [2] and so were not used further.

The differences between the values obtained in cell A and cell B were assumed to be due to the usual influence of effusion orifice size on apparent calculated pressure. The effect of orifice size on the measured pressure was treated by the Whitman-Motzfeldt method (4), which indicates that the reciprocal of measured pressure is expected to vary linearly with effective orifice area. For the cells used in the present work the effective orifice areas were 0.125 mm² for cell A and 0.478 mm² for cell B. The equilibrium pressures derived by extrapolation of the reciprocals of the pressures measured in cells A and B *vs.* their effective orifice areas are represented by the dot-dash line in Fig. 1. An equation representing those equilibrium pressures for the univariant composition region of the present work is

$$\log_{10} P_{eq}(\text{atm}) = (12.83 \pm 0.1) - (13{,}200 \pm 100)/T \quad (720\text{-}790\text{ K}) \quad [5]$$

When the composition of the solid dropped below $ZrI_{0.57}$ in cell A and $ZrI_{0.65}$ in cell B, the measured pressures fell below the values anticipated from Eq. [1] and [2], respectively. That effect can be noted from the values given in the last column of Table II, which represents the ratios of the measured pressures (of ZrI_4) divided by the values calculated from Eq. [1] or [2], respectively, for cell A or B. The ratios are shown graphically as a function of composition in Fig. 2. The solid remaining in cell A after the series of pressure measurements reported in Table II was analyzed and found to correspond to an I/Zr ratio of 0.003. An x-ray powder diffraction pattern of that material showed only lines corresponding to alpha zirconium.

The ratios in Fig. 2 depart from unity in a fairly smooth fashion. We interpret this behavior to indicate that no new phase was being formed, and that the deviation from unity resulted from depletion of the

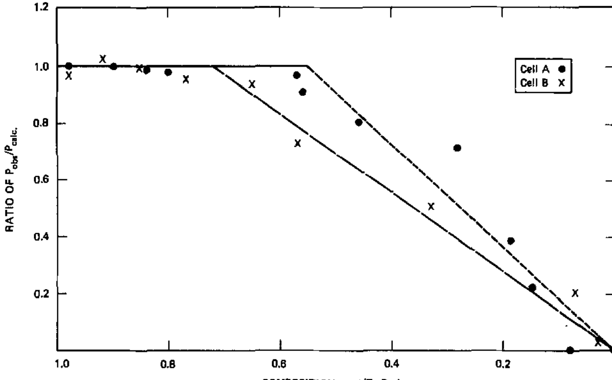

Fig. 2. Ratio of measured pressure to value calculated from Eq. [1] (for cell A) or Eq. [2] (for cell B) as a function of composition of solid remaining in cell. Dots and crosses represent cell A and cell B data, respectively.

samples in the cells. The fact that the cell B ratios fell off at lower I/Zr stoichiometries was in keeping with that interpretation.

To corroborate the above result, a sample of $ZrI_{2.4}$ in a graphite crucible was heated for 45 days at 475°C in a sealed glass bulb with one end of the bulb maintained at about 50°C. During the heating period, ZrI_4 vaporized from the sample and condensed in the cold end of the bulb. The sample remaining in the crucible was analyzed and found to be $ZrI_{0.1}$. An x-ray powder pattern of that material showed lines mainly corresponding to alpha zirconium. The remaining lines were the same as the x-ray pattern for ZrI given in Table I, and the overall intensity was about one-tenth that of the alpha zirconium pattern. That result indicates that the equilibrium phases present for the overall composition $ZrI_{0.1}$ were ZrI and alpha Zr.

The upper composition limit for the univariant region corresponding to the pressures given in Eq. [5] was evaluated as follows. In Ref. (5) there was evidence for a new univariant region starting between I/Zr = 1.03 and 0.96 [see Table III of Ref. (5)]. The present results (Table II) indicate that the univariant region extends to I/Zr of about 1.05. (We do not understand why for cell A the observed pressures were smaller than the univariant values for I/Zr greater than 1.05. We presume that was due to some kinetic phenomenon in the cell—possibly some surface barrier on the sample which later was disrupted.) Therefore, the chemical reaction corresponding to the pressures of Eq. [5] is

$$3.8\, ZrI_{1.05}(s) = ZrI_4(g) + 2.8\, Zr(s) \quad [6]$$

The enthalpy change derived from Eq. [5] for reaction [6] is 60.4 ± 0.5 kcal/mole.

Figure 3 indicates our assessment of the vaporization thermodynamics for the zirconium iodides; the assessment combines our earlier results with the present data. Zirconium tetraiodide is the predominant vapor species, and the partial pressure of ZrI_4 as a function of composition of the solid is shown in the upper curve. The horizontal segments of the curve correspond to univariant regions, that is, regions in which two solids exist in equilibrium with the vapor (ZrI_4). The nonhorizontal portions represent regions of solid solution that have approximately the stoichiometries of the tetriodide, triiodide, diiodide, monoiodide, and are also indicated on the diagram. The enthalpies of vaporiza-

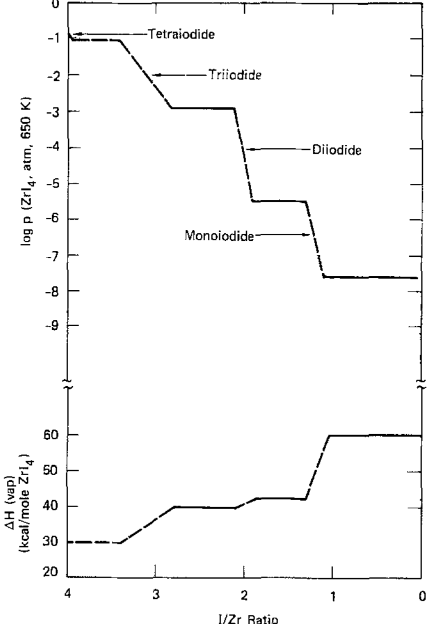

Fig. 3. Thermodynamics of vaporization as a function of composition in the Zr-I system. Upper curve, pressure of ZrI_4 at 650 K; lower curve, enthalpies of vaporization reactions per mole of ZrI_4. Dashed lines indicate regions of estimated data.

tion per mole of ZrI_4 gas are presented in the lower curve of Fig. 3. The enthalpies of vaporization became greater the smaller the I/Zr ratio of the solid, which indicates that the removal of ZrI_4 from the solid becomes energetically more difficult as the composition decreases in iodide.

ABSTRACT

The response of TiO_2 and $SrTiO_3$ photoelectrodes to subband gap light has been explored as a function of numerous variables, including intensity and wavelength of light, applied potential, temperature, and electrolyte composition. The photoresponse is shown to be linear with light intensity, to depend on the square root of the applied potential, to occur only for $h\nu \gtrsim 2.2$ eV, and to be independent of temperature and electrolyte composition. These results suggest a bulk excitation process involving impurity and defect-related states in the gaps of these semiconductors. A qualitative model is presented to account for the main features of this excitation process and to provide a basis for suggesting future experiments.

The development of the photoelectrochemical, energy conversion field (1) has proceeded to the point where details of the charge transfer process at the semiconductor-electrolyte interface are now of considerable interest (2). In particular, the role that surface states might play in this process has received considerable attention. Unfortunately, evidence for the importance of surface states has been primarily of an indirect nature. In an attempt to obtain more direct evidence for surface states several groups have explored the excitation of photoelectrodes by subband gap light (3). Some of these results have been presented as evidence for surface states in TiO_2 (4-5).

In this paper we present evidence of a subband gap excitation process for TiO_2 and $SrTiO_3$ which involves bulk rather than surface states. It is shown that the potential dependence of the photoresponse defines the nature of the excitation process and will allow a distinction between bulk and surface states. A model is presented which describes this excitation process and explains the dependence of the photoresponse on the wavelength of the light and its intensity.

Experimental Results

Measurements of the subband gap photoresponse were made using a conventional three electrode electrochemical cell where the TiO_2 or $SrTiO_3$ was the working electrode and a saturated calomel electrode (SCE) was the reference electrode. A platinum foil was used as the counterelectrode. The potential was controlled using a potentiostat patterned after a previously published design (6). The electrolytes were prepared using commercial reagents. The samples were cut from a boule obtained from Materials Research Company, polished using ¼ μm diamond paste, and reduced in hydrogen under various conditions as indicated in the figure captions. Contact was made using In-Ga alloy.

The light source was an Oriel 1000W xenon lamp with a single pass SPEX monochromator which provided about 1 mW/cm^2 incident on the sample. The light was chopped using a PAR Model 191 chopper at 5 Hz and then passed through a filter to remove stray light components. This filtering is of crucial importance since the subband gap response we are looking for is orders of magnitude smaller than the above-bandgap response. Thus a small amount of stray u.v. light can give an erroneous response. The best filter was a Pyrex glass plate combined with an unreduced, 2 mm thick slice of the semiconductor being studied. The efficiency of this filter was checked by looking for a photoresponse above the bandedge. Since the observed response was significantly less than the observed subband gap response we can be confident that the filtering was adequate. Erroneous signals due to stray u.v. light were observed without this filtering.

The signal was detected using a PAR lock-in amplifier on the output of the potentiostat. Typical results for TiO_2 and $SrTiO_3$ are shown in Fig. 1 and 2, respectively. These spectra are not corrected for light intensity and thus they show structure around 470 nm which is due to structure in the lamp spectrum. In a sense, this is very useful since it proves that the photoresponse is due to excitation by subband gap light. While these spectra were taken using chopped light, the photocurrent was also observed using d-c techniques to insure that the a-c measurements did not represent a transient phenomenon such as a-c photoconductivity. These spectra come from a steady-state phenomenon and have the same sign as the photocurrent observed

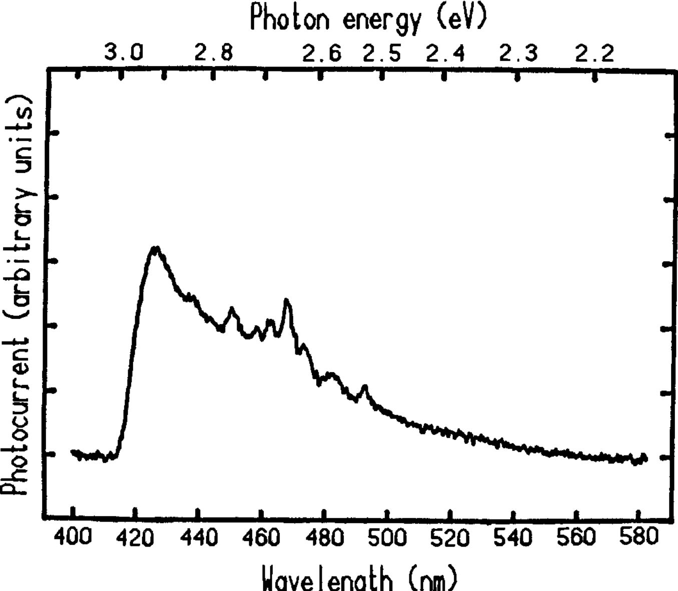

Fig. 1. The subband gap photoresponse of a TiO_2 sample in 1M KOH and at 0V (SCE). The sample was cut ⊥ to the C-axis and reduced at 700°C for 30 min in a 10% H_2-90% N_2 atmosphere. The cutoff at short wavelengths is due to the optical filter cutting of the light source.

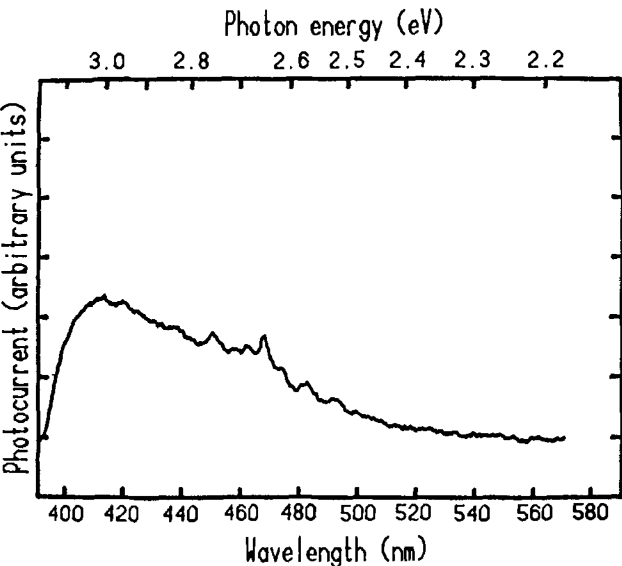

Fig. 2. The subband gap photoresponse of an $SrTiO_3$ sample in 1M KOH and at −0.14V (SCE). The sample was reduced in vacuum at 800°C for 2 hr. The cutoff at short wavelengths is due to the optical filter cutting of the light source.

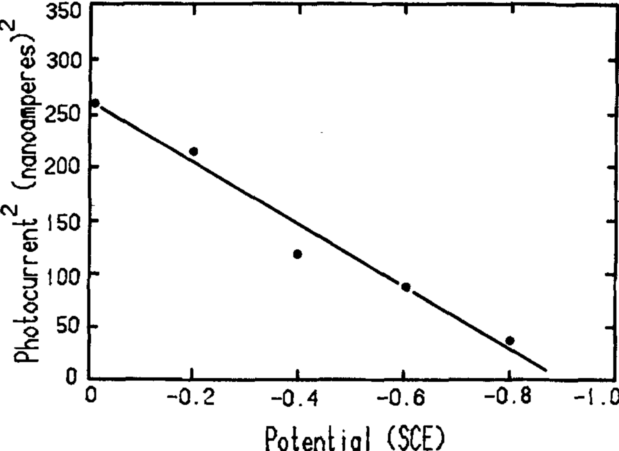

Fig. 3. The potential dependence of the subband gap photoresponse of TiO_2 in 1M KOH and for $h\nu = 2.95$ eV. Note that the photocurrent disappears at the flatband potential.

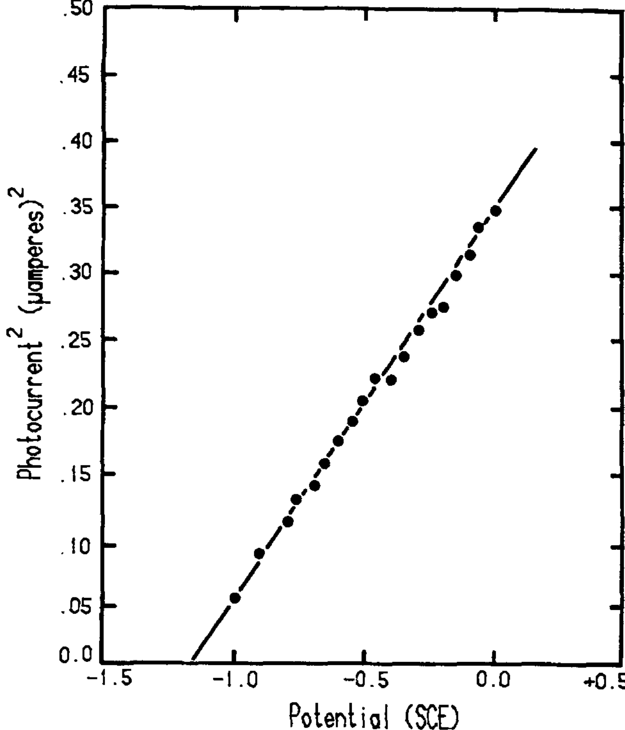

Fig. 4. The potential dependence of the subband gap photoresponse of $SrTiO_3$ in 1M KOH using the 4880Å (2.54 eV) argon ion laser line at 100 mW intensity. Note that the photocurrent disappears at the flatband potential.

with above-bandgap illumination (*i.e.*, these are anodic photocurrents). Typical quantum efficiencies for this subband gap excitation process are $\lesssim 10^{-5}$.

Note that these photocurrents occur under anodic bias which is the normal operating potential range for photoanodes in a photoelectrochemical cell. This is to be contrasted with the subband gap response observed in TiO_2 at cathodic bias (5) and subsequently explained as a photothermal effect (7). We have explored the potential behavior and the results are shown in Fig. 3 and 4 for TiO_2 and $SrTiO_3$, respectively. The behavior is identical to that observed for illumination just above the bandgap. This is the first hint that perhaps what we are observing arises from a "bulk" process rather than from excitation of surface states.

Another useful parameter to vary in exploring this subband gap photoresponse is the intensity of incident light. These results are shown for TiO_2 using our normal light source and neutral density filters in Fig. 5. Within experimental error the photocurrent depends linearly on light intensity. To explore the behavior at higher light intensities, the 4880Å line of an argon ion laser was used. The results for $SrTiO_3$ are shown on a log-log plot in Fig. 6. The relationship is linear over three orders of magnitude and has not saturated at power densities of 200 mW/cm².

Several other variables were also explored for their possible effect on the subband gap photoresponse. In addition to the data shown which was taken in 1M KOH, other electrolytes were tried which spanned the complete range of *p*H from strong acid to strong base. No significant effect of electrolyte was noted other than changes in the potential dependence due to the shifting flatband potential. The electrolytes were saturated with various gases including O_2, N_2, and Ar. However, no changes in the subband gap photoresponse were observed. The temperature of the electrochemical cell was raised 30°C above ambient temperature but no effect on the photoresponse was observed.

These results then pose the problem as to the origin of the subband gap photoresponse, whether it is a bulk or surface effect, and the mechanism for this process.

Discussion

The important clue to the nature of the subband gap photoresponse comes from the potential behavior. Figures 3 and 4 show that the square of the photocurrent depends linearly on potential and extrapolates to zero at the flatband potential. Analysis of the response of the Schottky junction at the semiconductor-electrolyte interface has shown that the photocurrent density due to above-bandgap illumination may be expressed as (8)

$$J' = e\phi_o \left[1 - \frac{e^{-\alpha W}}{1 + \alpha L} \right] \quad [1]$$

where e is the electronic charge, ϕ_o is the incident photon flux, α is the optical absorption coefficient, W is the depletion layer thickness, and L is the minority carrier diffusion length. For subband gap illumination the absorption coefficient is small, thus $\alpha W << 1$ and $\alpha L << 1$. We also know that for a lightly reduced electrode such as we are using in these experiments $W >> L$. Then we may expand the exponential and ignore the diffusion term so that

$$J \simeq e\phi_o \alpha W \quad [2]$$

Thus the photocurrent is linearly related to depletion

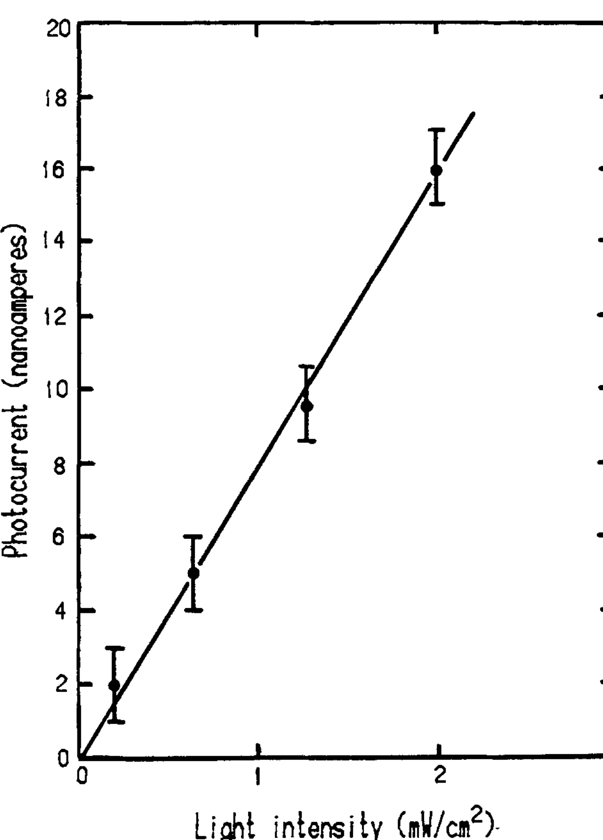

Fig. 5. The linear relationship between incident light intensity and subband gap photocurrent for TiO_2 in 1M KOH at 0V (SCE) just below the bandedge (2.95 eV).

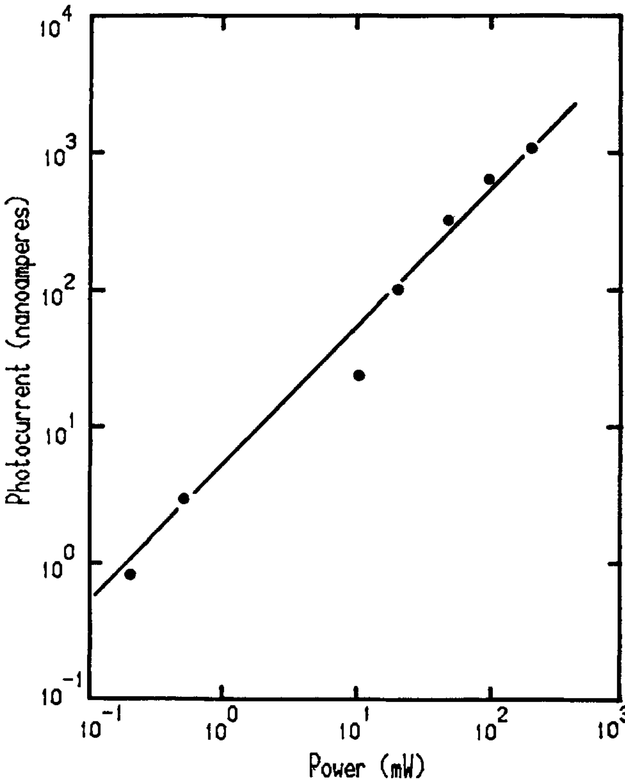

Fig. 6. The linear relationship shown on a log-log plot between incident light intensity and subband gap photocurrent for $SrTiO_3$ in 1M KOH at 0V (SCE) measured using the 4880Å (2.54 eV) line of an argon ion laser. The solid line shows linear behavior over three orders of magnitude and to power densities larger than 200 mW/cm^2.

layer thickness. Since (8)

$$W = W_0(V - V_{FB})^{1/2} \quad [3]$$

where V is the applied potential, V_{FB} is the flatband potential, and W_0 is a constant depending on the properties of the semiconductor, we expect that, for a bulk process which occurs uniformly throughout the depletion layer region, the square of the photocurrent should depend linearly on applied potential and extrapolate to zero at the flatband potential. While this relationship is usually not obeyed at small band bending (9, 10), this is exactly what we observe. We believe that the use of an I^2 *vs.* V plot and the relatively high noise level obscures this region of expected deviation. This result shows that the observed subband gap response is a bulk phenomenon occurring throughout the depletion layer. For surface state excitation we would not expect this square root dependence on applied potential. Thus the potential dependence of the photocurrent is a means of distinguishing between bulk excitation processes and surface state excitation processes.

The next question to address is the nature of the bulk excitation process and whether a consistent model can be constructed which will explain the dependence of the photoresponse on wavelength and intensity of light. Since the photocurrent is a d-c effect, the subband gap response probably involves a two-step process such as shown in Fig. 7. This seems to be necessary, since it is difficult to envision sufficient impurity level conduction to sustain the relatively large photocurrents observed with laser illumination without seeing saturation effects. The other possibility would be a two-step process in which one of the steps is a thermally assisted process. Again it is unlikely that the linear relationship between photocurrent and light intensity shown in Fig. 6 would be possible under these conditions. In addition we observed no dependence of the photocurrent on temperature. Thus we believe that the excitation mechanism is a two-step process where both steps are photoexcitations and the intermediate state is an impurity or defect-related midgap state.

For a two-photon excitation process where there is no real intermediate state, there would be a quadratic dependence of the photocurrent on light intensity. However, for a two-photon process with a real intermediate state the effective transition rate W_{eff} can be shown using simple rate equations (11) to be

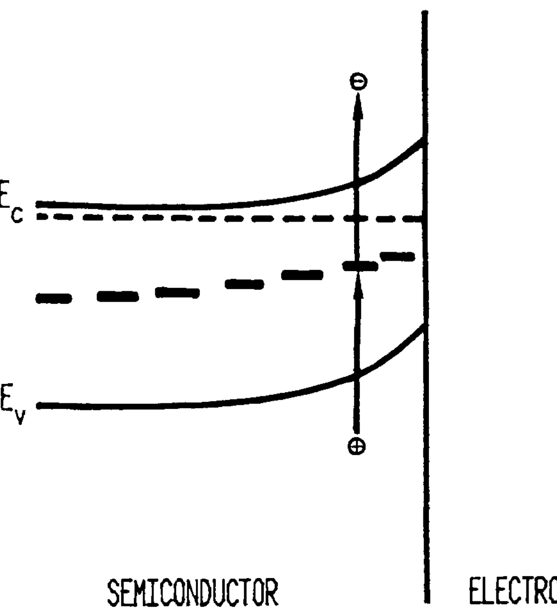

Fig. 7. The two-step excitation process envisioned for the subband gap photoresponse of TiO_2 and $SrTiO_3$. Depending on the particular example there may be a distribution of midgap states.

$$W_{eff} = \frac{W_{12}W_{23}}{W_{12} + W_{23}} \quad [4]$$

where W_{12} is the transition rate from valence band to intermediate state and W_{23} is the transition rate from the intermediate state to the conduction band. Since both W_{12} and W_{23} depend linearly on light intensity, W_{eff} will also depend linearly on light intensity. This simple picture of course ignores spontaneous relaxation of the photoexcited electrons (W_{21}). This seems justified since it explains the linear dependence of photocurrent on light intensity.

The spectral dependence of the subband gap response is somewhat more difficult to explain than the intensity dependence, since many factors such as transition matrix elements and the energy distribution of the intermediate states are not known. Thus we are going to assume a plausible, simplified model to explore the general features of the behavior that is to be expected. Following arguments made for discussing optical absorption in semiconductors (12), we assume parabolic conduction and valence bands and that the transition matrix element is independent of photon energy. Furthermore, since the interband transitions in the materials of interest are known to be indirect (13), we will assume that the momentum k is not conserved. Then we are making primarily density of states arguments as to the spectral dependence of the photoexcitation process. The effective transition rate is then given by

$$W_{eff}(h\nu) = \int_{-(h\nu-Eg/2)}^{(h\nu-Eg/2)} f(x)\, W_{eff}(x, h\nu)\, dx \quad [5]$$

where x is the energy of the intermediate state shown in Fig. 7 measured from the center of the gap and $f(x)$ is the energy distribution of these midgap states. The limits of the integral insure that energy is conserved in the photoexcitation process. The individual transition rates in this two-step process may be written

$$W_{12} = M_{12}\,(h\nu - Eg/2 - x)^{1/2} \quad [6]$$

and

$$W_{23} = M_{23}\,(h\nu - Eg/2 + x)^{1/2} \quad [7]$$

where M_{12} and M_{23} are constants which include the transition matrix elements, and other factors independent of x and $h\nu$. If we use the full expression for the effective transition rate, Eq. [3], then the integral, while simple to evaluate numerically, will not clearly display the qualitative features of the model. Thus we again simplify by assuming $W_{12} << W_{23}$. Since $M_{12} \simeq M_{23}$, this assumption is reasonable if the dominant midgap states are closer to the conduction band than the valence band. Then the frequency dependent factor determines the important rate constant and Eq. [4] becomes

$$W_{eff}(h\nu) \simeq M_{12} \int_{-(h\nu-Eg/2)}^{(h\nu-Eg/2)} f(x)\,(h\nu - Eg/2 - x)^{1/2} dx \quad [8]$$

Consistent with the above approximation we will assume a uniform continuum of midgap states extending to an energy E_o below the conduction bandedge. This limits the integral in Eq. [7] so that we have

$$W_{eff}(h\nu) \simeq M_{12} \int_{(Eg/2-E_o)}^{(h\nu-Eg/2)} (h\nu - Eg/2 - x)^{1/2} dx \quad [9]$$

Or the effective transition rate in this greatly simplified model is given by

$$W_{eff}(h\nu) \simeq \frac{2}{3} M_{12}[h\nu - (Eg - E_o)]^{3/2} \quad [10]$$

Thus we expect that the quantum efficiency to the 2/3 power should be linear in photon energy and the intercept, $(Eg - E_o)$, defines the edge of the bulk defect state distribution. In the other extreme, where a continuum of midgap states extend from the valence band to an energy E_o above the valence band, $W_{12} >> W_{23}$. Integrating in this limit yields the same expression for W_{eff} except that M_{12} is replaced by M_{23} in Eq. [10]. A single dominant discrete state in the gap of energy E_o would give

$$W_{eff}(h\nu) \simeq [h\nu - (Eg - E_o)]^{1/2} \quad [11]$$

a square root dependence on photon energy. Naturally more complex distributions of intermediate states $f(x)$ would result in other forms for the effective transition rate $W_{eff}(h\nu)$.

While the model presented is overly simplified, it is instructive to compare it with the data we have for TiO_2 and $SrTiO_3$. Figures 8 and 9 show a plot of the quantum efficiency to the 2/3 power *vs.* photon energy for TiO_2 and $SrTiO_3$, respectively. The rather good linear dependence exhibited by the data suggests that the model with a continuum of midgap states extending E_o from a bandedge is not an unreasonable description of the data. While there is no *a priori* reason to assume that the midgap states extend down from the conduction band rather than up from the valence band, a distribution of defect-related shallow traps have been observed to extend ~0.8 eV below the conduction bandedge (14) in TiO_2. The 0.8 eV agrees rather well with the intercept shown in Fig. 8. The similarity in physical and chemical properties of TiO_2 and $SrTiO_3$ suggests

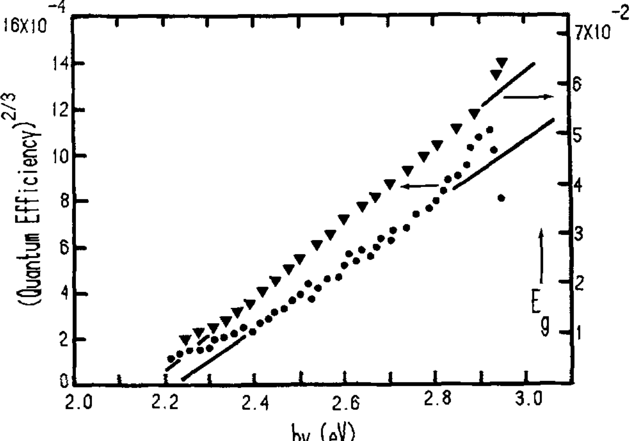

Fig. 8. Quantum efficiency to the 2/3 power *vs.* photon energy for TiO_2. The dots are for the undoped TiO_2 data shown in Fig. 1, while the triangles are Cr-doped TiO_2 data taken from Ref. (12). The straight line behavior is expected for the model discussed in the text.

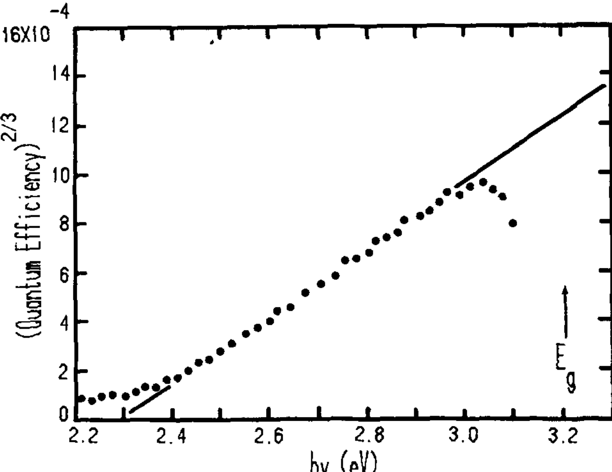

Fig. 9. Quantum efficiency to the 2/3 power *vs.* photon energy for the $SrTiO_3$ data shown in Fig. 2. The straight line behavior is expected for the model discussed in the text.

that a similar behavior for $SrTiO_3$ is not unreasonable. The tailing of the data exhibited below 2.4 eV is due to the noise level and poor baseline location. The peak around 2.9 eV in TiO_2 could come from a nonuniform distribution of states in the gap. This is an area that needs further exploration.

The model described above is unfortunately not unique. The same photon energy dependence can be obtained by assuming the two-step model with a single discrete intermediate state at an energy E_o from a bandedge and that each transition is a forbidden direct transition (12). This model would lead to the same 3/2 power dependence of W_{eff} on photon energy. However, the known distribution of midgap states (14) tends to favor our initial model for interpretation of the data.

Intentional doping of TiO_2 to extend the photoresponse to energies below E_g has been explored and found to show some promise (15). However, the mechanism for this effect has not been defined. In Fig. 8 we show the extended photoresponse of Cr-doped TiO_2 (15) plotted as the quantum efficiency to the 2/3 power. The striking linear dependence and the similar intercept for this much stronger subband gap response suggests a similarity in mechanism for the Cr-doped TiO_2 and the ostensibly undoped samples. Since the intercept does not seem to correlate with the position of the Cr acceptor levels in TiO_2 (15), we would like to propose another interpretation of this data. Substitutional doping of TiO_2 with Cr requires the generation of charge compensating defects. We suggest that these defects are the same defects responsible for the subband gap response in both the Cr-doped and undoped samples of TiO_2. Furthermore, the two-step model described in this paper is applicable to both kinds of samples. This interpretation would explain the spectral dependence of the data, both the power law and the intercept, and also remove the requirement for significant impurity band conduction in these samples.

Conclusions

The results of this paper clearly show that subband gap excitation of semiconducting photoelectrodes is possible by a bulk mechanism. This bulk excitation process may be distinguished from surface state excitation by the dependence of the photoresponse on electrode potential. A linear dependence of the photocurrent squared on potential with an intercept at the flatband potential, implies a uniform excitation process throughout the depletion layer, *i.e.*, a bulk process. The simplified model presented, involving transitions to states in the gap, is capable of explaining qualitatively the dependence of the photocurrent on light intensity and wavelength. However, our lack of knowledge about the distribution of midgap states puts the model on a very tentative footing. A brief examination of the extended spectral response in Cr-doped TiO_2 suggests that the same model is applicable in these samples. It is proposed that the relevant midgap states arise from charge compensating defects generated by the Cr doping process.

These results in both the Cr-doped and undoped TiO_2 samples suggest further doping experiments with impurities which produce known states in the TiO_2 bandgap. Such experiments are necessary to test the validity of the proposed model and to explore some of the detailed aspects such as type of transition and the validity of the assumptions of the model.

Technical Notes

Surface Stability Studies on Some CRT Phosphors

S. Sinharoy, A. S. Manocha, and F. M. Ryan*

Westinghouse R&D Center, Pittsburgh, Pennsylvania 15235

Recently developed techniques of surface analysis (1-3), such as Auger electron spectroscopy (AES), electron spectroscopy for chemical analysis (ESCA), secondary ion mass spectrometry (SIMS), and ion scattering spectroscopy (ISS) etc., have found widespread application in the electronic, chemical, and metallurgical industries. The purpose of the present study was to demonstrate the usefulness of one of these techniques, namely ESCA, in the study of surface composition of phosphors, as well as the chemical stability of these phosphors under ion bombardment. This chemical stability is of particular interest in applications where phosphors are subjected to ion impact such as in plasma discharge displays.

ESCA was chosen in preference to the other common techniques mentioned above for the following reasons: (*i*) the primary excitation in ESCA is caused by soft x-rays rather than electrons or ions, thereby providing a nondestructive analytical tool for sensitive surfaces; (*ii*) surface charging effects are not as severe as in the other techniques and can be corrected very easily, thus providing a distinct advantage in the analysis of samples that are electrically nonconducting; (*iii*) it is a surface sensitive (~50Å) technique, and it provides information about the elemental composition (down to a level of 0.1 atomic percent) at the surface. Although the other techniques are slightly more surface sensitive and some of them (SIMS, ISS) can detect elements present to a much lower level, ESCA provides information over a larger sampling area of the surface. This is an advantage for the type of studies reported here. (*iv*) It provides information about the chemical bonding states of the elements detected on the surface. In this respect, the other techniques are not nearly as efficient.

There are also some disadvantages inherent in the ESCA technique. For example, (*i*) data acquisition process is very slow and (*ii*) meaningful data cannot be acquired simultaneously while the sample surface is being sputter-etched with inert gas ions.

In this particular case, the advantages of using ESCA far outweighed the disadvantages, mainly because of the nature of the samples and the type of information desired.

Experimental

Eight different types of CRT phosphor in powder form were obtained from various commercial sources for analysis. The phosphor types were the following: (*i*) YOE red, Y_2O_3:Eu; (*ii*) red YVO_4:Eu; (*iii*) $Y(VO_4)_{1/2}(PO_4)_{1/2}$:$Eu^{+3}$; (*iv*) $CaWO_4$:Pb; (*v*) Y_2O_2S:Eu^{+3}; (*vi*) P-22 green, ZnCdS: (Ag); (*vii*) P-22 blue, ZnS: (Ag); and (*viii*) P-22 red, CdS: (Ag).

ESCA analysis of the phosphor samples were performed in a GCA-McPherson/36 photoelectron spectrometer, using a magnesium anode as the source of primary x-rays (1253.6 eV). Some of the powders were analyzed in the form of pellets and the others on indium foil. In the latter case, the larger crystals were ground in a wig-l-bug, the powder sprinkled between two indium foils and pressed to 1 ton/in.² for 1 min. The samples were mounted on a carousel sample holder. The pressure in the experimental chamber was in the low 10^{-9} Torr range. The chamber was equipped with an ion gun for sputter etching of the samples. The sputter rate was estimated to be approximately 5 Å/min. By alternating argon ion sputtering with ESCA measurements, it was possible to determine the composition and chemical state as a function of depth in each sample.

Results

Two types of spectra were plotted for each of the phosphor samples. The first was a 1000 eV "survey scan" to identify the various elements present on the surface. The second type consisted of high resolution spectra of lines corresponding to core level transitions of elements of interest. Both types of spectra were plotted before sputtering, and after various stages of sputtering. All binding energy values reported in this paper have been corrected for charging effects following the procedure of Wagner *et al.* (4), by making the carbon 1s line due to the adventitious hydrocarbon contaminant appear at 284.6 eV. The 1000 eV survey scans of all the phosphors show the presence of the common hydrocarbon and oxygen contaminants from the atmosphere. No special mention of these two contaminants will be made in the following. The results obtained in the various phosphors are presented and discussed below.

Y_2O_3:Eu.—A survey scan of this phosphor, shown in Fig. 1, reveals the presence of silicon as the only contaminant detected on the surface. The activator (Eu) concentration was below the level of detection of the spectrometer. High resolution spectra of the Y3d and O1s lines of the as-received and sputter-etched surfaces are shown in Fig. 2. It is clear that with the progress of sputtering, the impurity oxygen de-

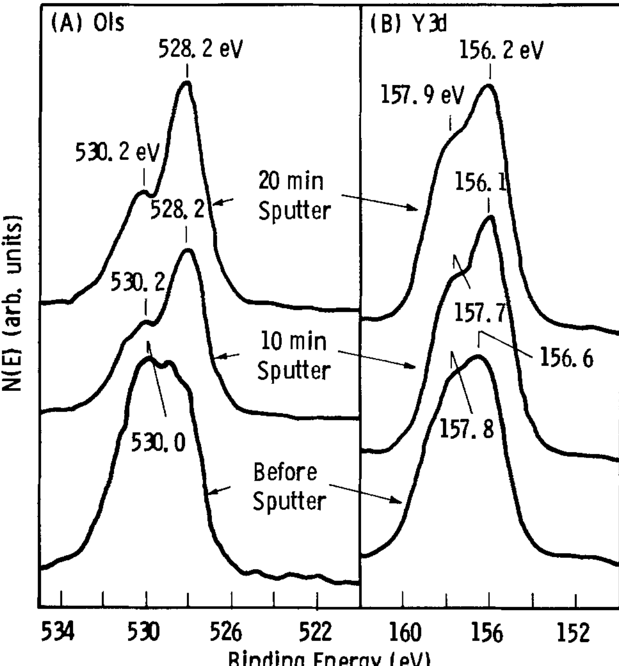

Fig. 2. High resolution O1s and Y3d lines of Y_2O_3:Eu as received, after 10 min sputter and after 20 min sputter.

creases, resulting in the gradual decrease of the 530.1 eV component of the O1s line, and a slight improvement in the resolution of $Y3d_{5/2}$ and $Y3d_{3/2}$ peaks. There were no significant changes in the peak positions after 20 min of sputtering, indicating that Y_2O_3:Eu is quite stable chemically under argon ion bombardment.

YVO_4:Eu.—Silicon was again the only contaminant detected on the phosphor surface. The high resolution spectra of the $Y3d_{5/2,3/2}$, O1s, and $V2p_{3/2}$ lines after various periods of sputtering are shown in Fig. 3. The most significant change was observed in the $V2p_{3/2}$ peak which shifted gradually to lower binding energies after 10 and 20 min sputtering. The binding energy shift, which was accompanied by a gradual broadening of the peak, was 1.9 eV after 20 min sputtering. The shift to lower binding energies is indicative of the transformation of vanadium to a lower oxidation state (4). However, the broadening would indicate that the transformation is not complete after 20 min sputtering.

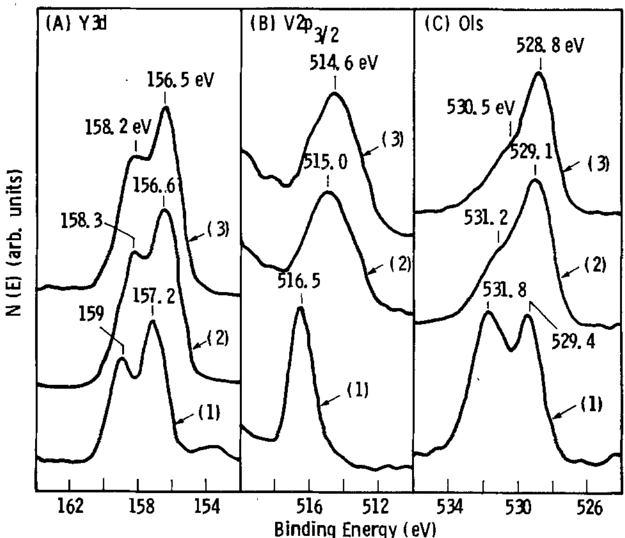

Fig. 3. High resolution Y3d, O1s, and $V2p_{3/2}$ lines of YVO_4:Eu; curve (1) as received, curve (2) after 10 min sputter, and curve (3) after 20 min sputter.

Vanadium is thus present in a mixed oxidation state after 20 min of ion bombardment, the transformation being of the form $V^V \rightarrow V^V + V^{IV}$, the likely reduction process being $YV^VO_4 \rightarrow Y_2V_2^{IV}O_7$. The $Y3d_{5/2}$ and O1s peaks showed much smaller shifts in the B.E. after 20 min of argon ion bombardment. The binding energy 528.8 eV of O1s must be representative of oxygen in VO_4^{3-} and $V_2O_7^{6-}$ states.

$Y(VO_4)_{1/2}(PO_4)_{1/2}$:$Eu^{+3}$.—The survey spectrum of this phosphor did not indicate the presence of any impurities on the surface. The behavior under argon ion bombardment was quite similar to that of the vanadate phosphor. This is illustrated in Fig. 4, where the high resolution spectra of $Y3d_{5/2,3/2}$, P2p, O1s, and $V2p_{3/2}$ lines of $Y(VO_4)_{1/2}(PO_4)_{1/2}$ have been plotted after various periods of sputtering. Both the P2p and $V2p_{3/2}$ peaks undergo a gradual shift in the binding energy to lower energies, accompanied by a broadening of the peaks. As in the case of the vanadate phosphor, the shifts can be attributed to transformation of phosphorus and vanadium to lower oxidation states, the broadening being due to the presence of mixed oxidation states. As can be seen from Fig. 4, the trend towards reduction to lower oxidation states was continuing after 20 min argon ion bombardment. This is evidenced by the appearance of a new shoulder at 131.8 eV in case of P2p and continuing development of the shoulder at 514.3 eV in case of the $V2p_{3/2}$ peak.

$CaWO_4$:Pb.—The survey spectrum of this phosphor, shown in Fig. 5, reveals the presence of a significant

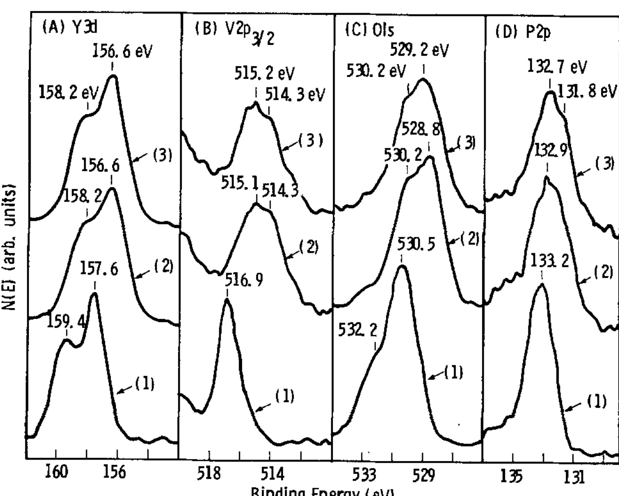

Fig. 4. High resolution Y3d, O1s, $V2p_{3/2}$, and P2p lines of $Y(VO_4)_{1/2}(PO_4)_{1/2}$:$Eu^{+3}$. Curve (1) as received, curve (2) after 10 min sputter, and curve (3) after 20 min sputter.

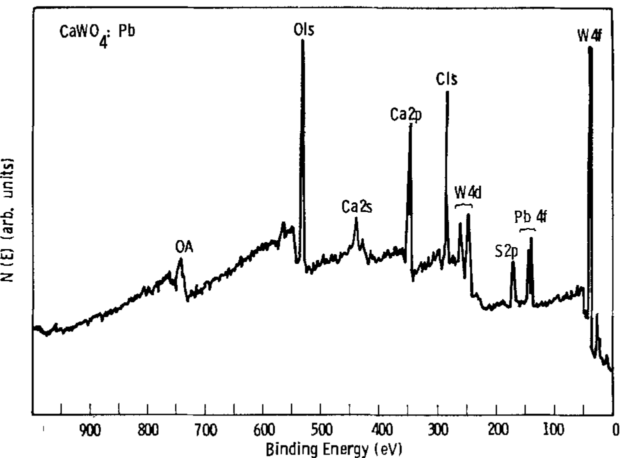

Fig. 5. Survey scan of $CaWO_4$:Pb

amount of lead on the surface, suggesting an enhancement of activator concentration at the surface region. The lead was present in the form of PbO[4]. There was also a significant amount of sulfur contaminant at the surface. After 10 min of argon ion bombardment, the Pb concentration fell below the level of detection. High resolution spectra of the $W4f_{7/2,5/2}$, $Ca2p_{3/2}$, and O1s photoelectron transitions are shown in Fig. 6. Notice the splitting of the W4f peak, indicating partial reduction of the tungsten in $CaWO_4$ to metallic tungsten (4). The small shift accompanied by some broadening of the $Ca2p_{3/2}$ peak indicates (4) the conversion of $CaWO_4$ to a mixture of CaO and $CaWO_4$. The partial reduction of $CaWO_4$ to W and CaO under argon ion bombardment might have taken place through intermediate metastable $CaWO_3$.

The sulfide phosphors (ZnCdS:Ag, ZnS:Ag, CdS:Ag, and $Y_2O_2S:Eu^{+3}$).—A small amount of silicon contaminant in the form of SiO_2 was detected in all sulfide phosphors studied. The activator amount was below the level of detection. The binding energies and widths of the S2p, $Cd3d_{5/2}$, and $Y3d_{5/2}$ photoelectron peaks and the zinc Auger peak of these phosphors remained unchanged after up to 20 min of argon ion bombardment, attesting to their chemical stability. The spectra corresponding to S2p, $Cd3d_{5/2}$, and zinc Auger lines from ZnCdS, ZnS, and CdS phosphors are shown in Fig. 7. In case of Y_2O_2S (Fig. 8), the $Y3d_{5/2}$ peak appeared in an altered form because of interference with the S2p photoelectron peak. Sulfur in this phosphor had to be detected on the basis of the S2s photoelectron peak, which had a much lower intensity compared to the S2p peak. A measurement of the peak heights corresponding to the main elements in all the sulfide phosphors yielded information about the relative abundance of sulfur at various depths from the surface after sputtering. An examination of the results listed in Table I reveals that ZnCdS and CdS are deficient in sulfur at the surface, relative to the bulk down to about 100Å. In case of ZnS and Y_2O_2S, the reverse appeared to be true. The reason for choosing the zinc Auger peak in preference to a photoelectron peak in the results discussed above is the fact that for zinc, the Auger line is known (5) to be more sensitive to changes in the chemical environment.

Discussion

On the basis of the ESCA results presented in the previous section, the following conclusions can be made for the phosphors studied.

(*i*) Silicon is the principal surface contaminant in most of the phophors examined. Probable sources of the silicon contamination are from the quartz used during preparation or from the "silicizing" used with some commercial phosphors. There was a significant amount of sulfur in the tungstate phosphor studied.

(*ii*) The calcium tungstate has a higher concentration of the activator (Pb) at the surface, compared to the bulk. The activator concentration in all the other phosphors (including the bulk activator concentration in calcium tungstate) is below the level of detection by ESCA. Migration of lead to the surface has also been observed (6) in glasses, where trace levels of Pb appear as percent levels on the surface.

(*iii*) The vanadate, vanadate-phosphate, and the tungstate phosphors reduce to lower oxidation states as a result of ion bombardment, whereas the oxide and the sulfide phosphors are chemically stable under ion bombardment for a limited time (up to 20 min). We have not studied the long-term stability of these phosphors under ion bombardment.

The present study deals with argon ions of 10 keV energy. These ions are normally used for sputter etchings and their advantage lies in penetrating the entire sampling depth. Smaller ions and electrons of the same energy are expected to have less damaging effects. Knowledge about the nature of the target material is very essential, *e.g.*, SiO_2 powder shows (7) higher stability than SiO_2 films obtained on oxidation of silicon wafers.

Table I. Relative change in sulfur content at various depths from the surface in the sulfide phosphors

Phosphor	ZnS			ZnCdS			CdS		Y_2O_2S (Sample 1)		Y_2O_2S (Sample 2)	
Sputter time (min)	0	2	13	0	10	20	0	10	0	10	0	10
ESCA peak height ratio S2p/ZnA	0.55	0.51	0.50	0.64	0.69	0.79	1.31	2.17	—	—	—	—
ESCA peak height ratio S2p/Cd$3d_{5/2}$	—	—	—	0.38	0.49	0.54	0.19	0.24	—	—	—	—
ESCA peak height ratio S2s/Y$3d_{5/2}$	—	—	—	—	—	—	—	—	0.07	0.03	0.07	0.03

Often times, reduction of a higher oxide to the elemental stage requires large amounts of energy, *e.g.*, W in tungstate to the metallic state. In such cases, reduction proceeds via intermediate, stable or metastable states. The extent to which the different states may appear is a function of the fate of the released species. For instance the released species may recombine with the reduced species. In an extreme case, Storp and Holm (7) observed the formation of nitrates on reduction of nitrites.

Also, carbonates easily decompose under argon ions. In a closed system they may act as a source of oxygen for oxidation and carbon for reduction. The extent of reduction and the amount of various species as observed in our studies is therefore only a small step in understanding the nature of various processes that may be occurring in real systems. Our studies do however indicate that under similar conditions, the oxides and sulfides of the materials studied here are more stable towards ion-induced damage than the vanadates, phosphates and tungstates.

(*iv*) ZnCdS and CdS phosphors were found to be sulfur deficient at the surface compared to a depth of about 100Å from the surface. The reverse is true for ZnS and Y_2O_2S phosphors.

In this study we have shown that the surface composition of these phosphors can differ greatly from the bulk. This difference extends only a small distance into the bulk (~100Å) so that it comprises less than 1% of the phosphor particle volume and its presence cannot be inferred from bulk analysis. ESCA studies, coupled with ion sputtering, have proven to be ideally suited for studying such surface layers.

Summary

There are two significant results that we have obtained from these studies. One is that many phosphors lack chemical stability under ion impact, making them unlikely candidates for ion excited phosphor display panels. The second result is that many commercially important cathode ray phosphors possess an outer layer of differing composition. One can speculate that the presence of this outer layer may play an important role in the functioning of the phosphor, particularly at high current densities. The saturation and loss of efficiency of cathode-ray phosphors at high current densities can be caused by diffusion of excitation energy to the surface of the phosphor where nonradiative recombination can occur. The presence of a second phase region, extending in an appreciable distance from the surface, will certainly affect this process. It is conceivable that this outer layer could tend to repel diffusing electron or holes away from the surface by means of a charge layer or by an increase in the bandgap energy near the surface. Further ESCA studies, coupled with saturation and efficiency measurements, should be capable of determining if such processes do indeed exist.

Manuscript received July 16, 1980. This was Paper 214 presented at the St. Louis, Missouri, Meeting of the Society, May 11-16, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Luminescence in the $SrO-Li_2O-P_2O_5$:Mn, Ce System

A. Wachtel*

Westinghouse R&D Center, Pittsburgh, Pennsylvania 15235

Koelmans and Cox (1) reported the luminescence of (Sr, M)$_3$ $(PO_4)_2$:Sn^{2+} where M is an ion such as Mg, Ca, Zn, Cd, Al which promotes the formation of the $\beta Ca_3(PO)_2$ structure in $Sr_3(PO_4)_2$. They also have shown that the Mn emission in $\beta Sr_3(PO_4)_2$:Mn, Sn^{2+} is relatively narrow and centered near 615 nm. Kroeger (2) sensitized $Ca_3(PO_4)_2$:Mn and $Sr_3(PO_4)_2$:Mn with Ce^{3+} and Froelich (3) charge-compensated Ce^{3+} in (Ca, Sr)$_3$ $(PO_4)_2$:Mn, Ce with Li or Na.

During attempts to find an inexpensive replacement for Y_2O_3:Eu^{3+} in "Ultralume" (red + green + blue emitting) fluorescent lamps, recent studies in this laboratory concerned Mn + Ce activated compositions along the $Sr_3(PO_4)_2$-Li_3PO_4 join. A small amount of Al (~ 0.09 Al per 2P) as well as the usual small excess of P_2O_5 was also found advantageous.

Phosphors were prepared by firing the mixed phosphates, carbonates, or oxides in air for 1 hr, followed by NH_3 for 2 hr. Firing temperatures depended on the composition and the oxidation state of the activators. It was interesting to note that for maximum red fluorescence intensity, the temperature had to be chosen so as to obtain hard rather than friable products. In optimized compositions firing temperatures ty-

Key words: inorganic, visible, fluorescence.

pically ranged from 820° to 850°C. 254 nm excited fluorescence was measured through filters to isolate the red (Mn^{2+}) and u.v. (Ce^{3+}) bands and are reported in arbitrary units which are not comparable with each other.

The total Li content of the compositions between $M_3^{2+}(PO_4)_2$ and Li_3PO_4 included the charge compensation scheme $2Sr^{2+} = M^{3+} + Li^+$ so that a small amount of the Li remained part of the M^{2+} component. Compositions along the join therefore contained

$$Sr = 3 - Mn - 2(Ce + Al) - x$$

$$Li = (Ce + Al) + 2x$$

where $0 \leq x \leq 3 - Mn - 2M^{3+}$.

Figure 1 shows the relative fluorescence of phosphors as a function of x. It can be seen that between $x = 0.5$ and 1 ($SrLiPO_4$), both emissions, *i.e.*, overall efficiency, decrease. Below $x = 0.5$ and above $x = 1$, Ce^{3+} emission increases while the Mn^{2+} emission decreases (energy transfer decreases); no independent measurements of overall efficiency were taken. It is clear, however, that maximum red fluorescence obtains approximately midway between the ideal compositions $Sr_3(PO_4)_2$ and $SrLiPO_4$.

X-ray powder diffraction analyses of phosphor powders with $x = 0$, 0.533, and 1 showed no significant differences, despite the fact that $Sr_3(PO_4)_2$ and $SrLiPO_4$ (4) have different structures. In all cases, reflections due to α and $\beta Sr_3(PO_4)_2$ (the latter predominating) were found. (Lines due to $SrLiPO_4$ as well as several weaker lines which could not be indexed were also noted.) Table I shows the data obtained for $x = 0.533$ where the lines assigned to $\beta Sr_3(PO_4)_2$ are based on published analyses of (Ca, Sr)$_3(PO_4)_2$ with allowances made for lattice contraction due to Mn, Al, and Li. The complexity of the pattern is consistent with earlier observations by Koelmans and Cox (1). They stated that $Sr_3(PO_4)_2$ containing additives which promote the $\beta Ca_3(PO_4)_2$ modification, displays a highly distorted structures if fired at high temperatures. Annealing at 600°C for 1 hr which caused a 10% reduction in fluorescence intensity had no effect on the pattern, neither did washing in dilute HCl which dissolves most of the Li_3PO_4 without significant change in fluorescence.

Figure 2 shows luminescence as a function of Mn and Ce. As one may expect, energy transfer from Ce to Mn increases rapidly with Mn concentration up to the optimum, after which it levels off. Measurements of quantum efficiency for compositions with $x = 0.53$, Mn = 0.17, and Ce = 0.08-0.935 range between 0.8 and 1.0. However, absorption of 254 nm is relatively

Notes: α = similar to α $Sr_3(PO_4)_2$—hexagonal—but with contracted lattice. β = based on β (Sr, Ca)$_3$ $(PO_4)_2$ (6) data but with contracted lattice. $SrLiPO_4$ = see Ref. (4). Additional lines were found only in rare instances.

weak and does not exceed 0.9 even for 5-30 μm particles which were freed of fines by DTPA[1] washing and elutriation.

Figure 3 shows the emission and reflectance spectra of an optimized phosphor. The Mn emission band shows a half-width of 72 nm and its shape and position is identical to that of β(Sr, Al)$_2(PO_4)_2$:Mn, Sn^{2+}. Its intensity is about 1.3 times as high, but in contrast to the Sn-sensitized species, the Ce^{3+} has a greater tendency to oxidize on heating in air. The SPD is also the same at least between $x = 0$ and 1. In this connection, it should be noted that essentially the same Mn emission is reported for $SrLiPO_4$:Mn, Cu^+ (4) and β(Sr, Al)$_3(PO_4)_2$:Mn, Cu^+ (5). Thus, we cannot distinguish the presence of $SrLiPO_4$ in our phos-

[1] Diethylenetriaminepentaacetic acid diammonium salt.

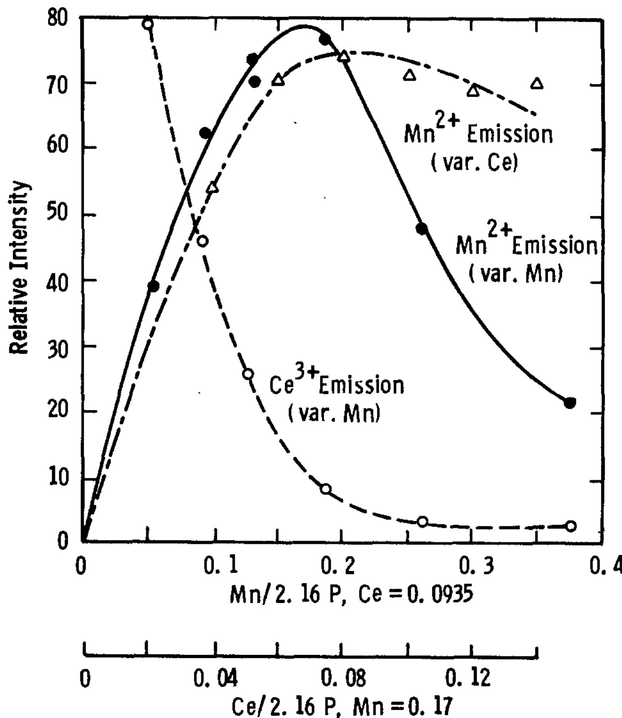

Fig. 2. 254 nm excited fluorescence of $Sr_{2.094-y}Mn_yCe_{0.0935}Al_{0.0935}Li_{1.253}P_{2.16}O_{8.4}$ (upper abscissa) and of $Sr_{2.11-2z}Mn_{0.17}Ce_zAl_{0.0935}Li_{1.16+z}P_{2.16}O_{8.4}$ (lower abscissa).

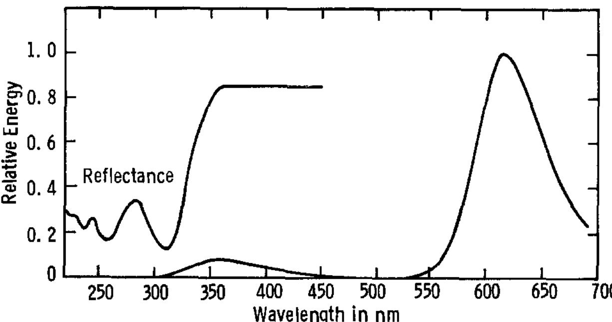

Fig. 3. Reflectance and 254 nm excited emission of $Sr_{1.923}Mn_{0.17}Ce_{0.0935}Al_{0.0935}Li_{1.253}P_{2.16}O_{8.4}$.

phors from $\beta Sr_3(PO_4)_2$ on the basis of emission spectra.

Unfortunately, our x-ray patterns give no additional information concerning the presence of $SrLiPO_4$. The patterns vary little over this composition range despite the fact that one might expect to see an increase of intensity of lines due to $SrLiPO_4$ as the proportion of Li_3PO_4 in the mixture is increased. In particular the second strongest line of the compound $SrLiPO_4$, $d = 2.501Å$, is missing from the pattern, and other lines which can be attributed to $SrLiPO_4$ lie close to lines for α and $\beta Sr_3(PO_4)_2$ (Table I). Several unindexed lines also remain in the pattern. Thus we cannot distinguish from our data whether Li_3PO_4 (*i*) enters a glassy phase during firing which cannot be detected by x-ray diffraction, (*ii*) enters into an unidentified phase which produces the unindexed lines in our pattern, or (*iii*) the reaction between Li_3PO_4 and $Sr_3(PO_4)_2$ proceeds so slowly that no significant amount of $SrLiPO_4$ formed during the firing process we used.

The important finding of the present study is the observation that there exists a multi-phase mixture along the $\beta Sr_3(PO_4)_2$-$SrLiPO_4$ join in which Mn fluorescence is sensitized by Ce^{3+} more efficiently than at either end, and also more efficiently than by Sn^{2+}. Based on present data, we feel that the present phosphor consists of $\beta Sr_3(PO_4)_2$:Ce^{3+}, Mn^{2+} and contains Li-bearing phases which act as fluxes.

Suppression of Thermal Damage in InP Substrates in InGaAs Vapor Phase Epitaxy

Yoshiharu Yamauchi and Nobuhiko Susa

Nippon Telegraph and Telephone Public Corporation,
Musashino Electrical Communication Laboratory, Musashino-shi, Tokyo, 180, Japan

Photodiodes made from III-V compound semiconductors have been studied to cover the 1-1.7 μm wavelength region, where silica fibers have low material dispersion (1) and low loss characteristics (2). InGaAs crystal lattice-matched to InP is a suitable material, having sensitivity over this whole wavelength region. Low carrier density semiconductor crystals are desired in order to obtain uniform and reliable avalanche multiplication (3-5). In nonavalanche photodiodes, low carrier concentration is also favorable to low reverse bias voltage operation with low dark current (6) and small capacitance (7-9). Low diode capacitance is also beneficial for high speed response. Vapor phase epitaxy (VPE) is beneficial in obtaining a low carrier density layer. Low carrier concentration and high mobility InGaAs layers (10) can be grown without as much difficulty as the long time In melt heat-treatment (7, 11) encountered in liquid-phase epitaxy (LPE).

In growing high quality InGaAs or InGaAsP layers by VPE, it is important to start crystal growth after material gas flow reaches steady state (10, 12-14). The authors have devised a quartz slide boat for this purpose (10). Thermal damage to the InP substrates caused by high phosphorus vapor pressure is suppressed by introducing PH_3 (15) or Ar (16) gas into the ambient H_2 gas. In LPE, the damaged surface is etched off by the In melt before growth (17). It has been reported that, in InGaAsP VPE growth, PH_3 gas flowing over the InP substrate is also effective in preventing substrate damage while waiting to establish steady-state gas flow (12-14). The PH_3 gas, however, affects the growth of InGaAs and InGaAsP with low P composition, resulting in lattice mismatch. Experimental results are reported in this letter to the effect that InP thermal damage and the PH_3 contamination in InGaAs layer can be suppressed in the VPE process by using the substrate holder with sliding cover (10).

Key words: photodiode, VPE, crystal.

The substrate holder made of quartz is shown in Fig. 1. The space to contain the substrate is small, only 25 × 25 × 1 mm^3, in order to minimize PH_3 gas contamination. Substrates are initially covered with a quartz sliding plate until steady-state gas flow is attained. The cover is slid off to expose the substrate surface for InGaAs deposition. The crystal growth equipment has been reported previously (10, 18).

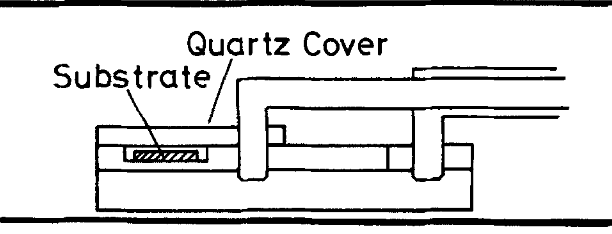

Fig. 1. Schematic view of substrate holder and cover

The InP substrate is mounted on the holder and is inserted into a reaction tube. In a palladium-purified hydrogen atmosphere, the substrate is heated to 730°C. Hydrogen chloride gas, which is obtained by the thermal decomposition of $AsCl_3$ at 850°C, flows over In and Ga melts. The H_2 carrier gas flow rates passing through $AsCl_3$ bubblers (16°C for In and 0°C for Ga) are 150 and 55 cm^3/min for the In and Ga melts, respectively. The 4% AsH_3/H_2 gas has a flow rate of 50 cm^3/min. Steady-state gas flow is obtained in about 30 min. InGaAs crystal growth is started by opening the holder cover and exposing the substrate surface to the gas flow.

In order to study the effect of the ambient gas on substrate surface quality, InP crystal heat-treatment experiments were carried out. Substrates mounted in the holder were exposed to temperature of 730°C for 1 hr, which is longer than the time required to establish steady-state gas flow in typical crystal growth procedure. Effects of the sliding cover and PH_3 gas content in hydrogen gas were studied, as shown in the left column in Fig. 2. Iron-doped InP substrates oriented, along (100) and (111)B were etched with 2.5% bromine methanol. Hydrogen gas flowing at 400 cm^3/min rate was used as the ambient gas. In addition, 5% PH_3 gas mixed with H_2 was introduced to the ambient. The PH_3 gas partial pressure was kept at 1×10^{-2} atmosphere pressure, which is higher than the PH_3 equilibrium pressure over In-P liquidus (19). Gas flow rates were measured with mass flow controllers. The substrate mounted in the holder with sliding cover was inserted into the furnace at room temperature and hydrogen ambient gas was flowed for purge. The temperature was then raised to 730°C in about 10 min.

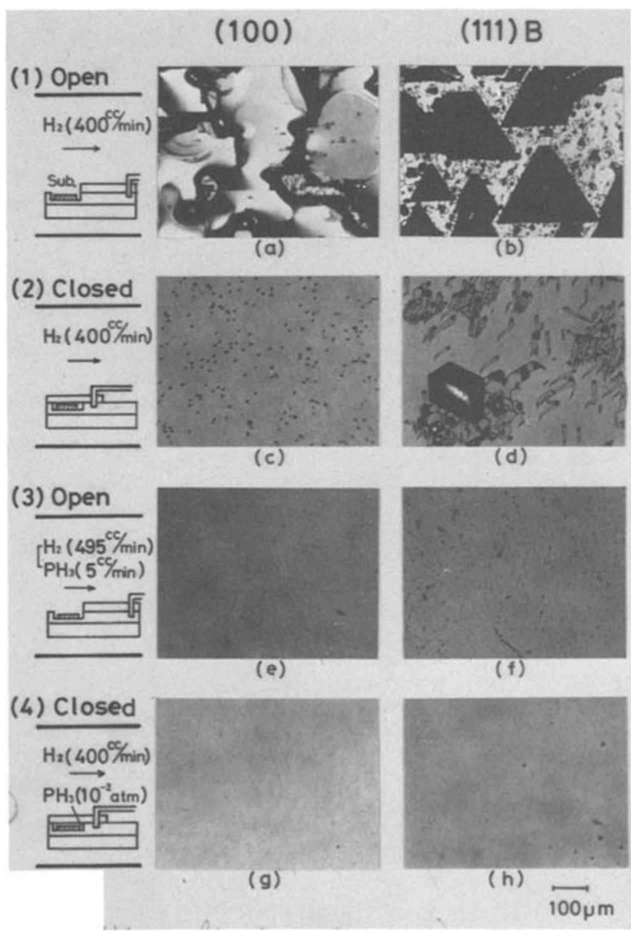

Fig. 2. Phase-contrast photomicrographs of the (100) and (111)B InP surfaces after exposure to various ambient gases at 730°C.

When samples were exposed to the high temperature with the cover opened, as shown in Fig. 2(1), the (100) and (111)B surfaces suffered by severe thermal damage and In droplets appeared, as shown in Fig. 2(a) and (b). Tadpole shapes were observed on the (111)B faces, as previously reported (20), and triangular etching patterns, reported on (111)A face (20), were simultaneously found on the (111)B faces. When the sliding cover is closed, as shown in Fig. 2(2), the substrates shown in Fig. 2(c) and (d) were not as seriously damaged, as those shown in Fig. 2(a) and (b). This is because the phosphorus partial pressure established by initial evaporation suppresses further decomposition. These results show that the cover on the holder effectively seals the substrate. When the ambient gas contains PH_3, as shown in Fig. 2(3), thermal deterioration is not present, as shown in Fig. 2(e) and (f). The undesired deposition shown in Fig. 2(f), however, was sometimes observed, probably due to Ga, In, and/or AsH_3 used for InGaAs growth. In Fig. 2(4), H_2 and PH_3 gas mixture flows at room temperature and the holder cover is closed. The ambient gas is then switched to pure H_2. The substrate cell, in which PH_3 gas is sealed, is then heated to 730°C for 1 hr. The substrates after this heat-treatment show no thermal damage, as shown in Fig. 2(g) and (h). This treatment is useful in preventing the deposition shown in Fig. 2(f), as well as in preventing thermal damage. Similar experiments were carried out by using sulfur-doped InP substrates, yielding the same results as in Fig. 2.

InGaAs crystal growth was carried out after the steady-state gas flow was established. The substrate is in the H_2 and PH_3 ambient delivered in Fig. 2(4) and is then exposed to the stationary gas flow. Crystal thickness of 2.5 μm is obtained after 20 min growth. The layer was studied by electron probe microanalysis (EPMA) and Auger analysis, whose phosphorus detection limits are 1×10^{19} and 1×10^{20} cm^{-3}, respectively. No traces of phosphorus atoms were detected, to the 10^{19} cm^{-3} concentration accuracy, on the InGaAs surface by the EPMA method. Auger measurements of a 3° angle polished sample are shown in Fig. 3. The acceleration voltage was 10 kV and the electron probe diameter less than 1 μm. The P concentration profile de-

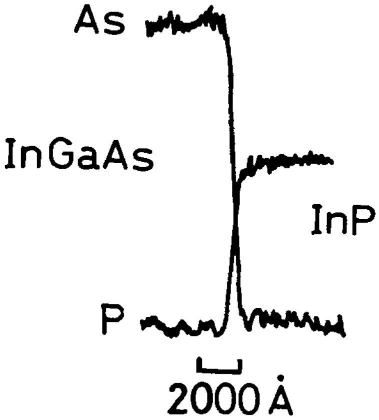

Fig. 3. Composition profile of InGaAs/InP layer by Auger analysis

creases rapidly in the InGaAs layer, and no PH_3 contamination in the layer was observed in this analysis either.

The double crystal x-ray diffraction rocking curve for this layer is shown in Fig. 4. The lines correspond to (400) plane reflection of the Cu-Kα1 line in InP and InGaAs. The InGaAs layer has a lattice constant slightly larger than that of InP due to the deviation of Ga and In compositions from the matching condition, not because of phosphorus atom contamination. Lattice mismatch $\Delta a/a$ is 0.002. Full widths at half maximum for the InGaAs layer and the InP substrate are 45 and 30 sec, respectively. The small shoulder, noted at the small lattice constant side tail of the InGaAs line, seems to be caused by gas composition fluctuation during the growth process, or residual PH_3 gas contained in the substrate holder cell, which causes a shift to a smaller lattice constant (21). Since the Auger measurement showed no trace of phosphorus in the InGaAs layer, and the holder cell size is only 0.63 cm^3, the effect of PH_3 contamination is considered to be small.

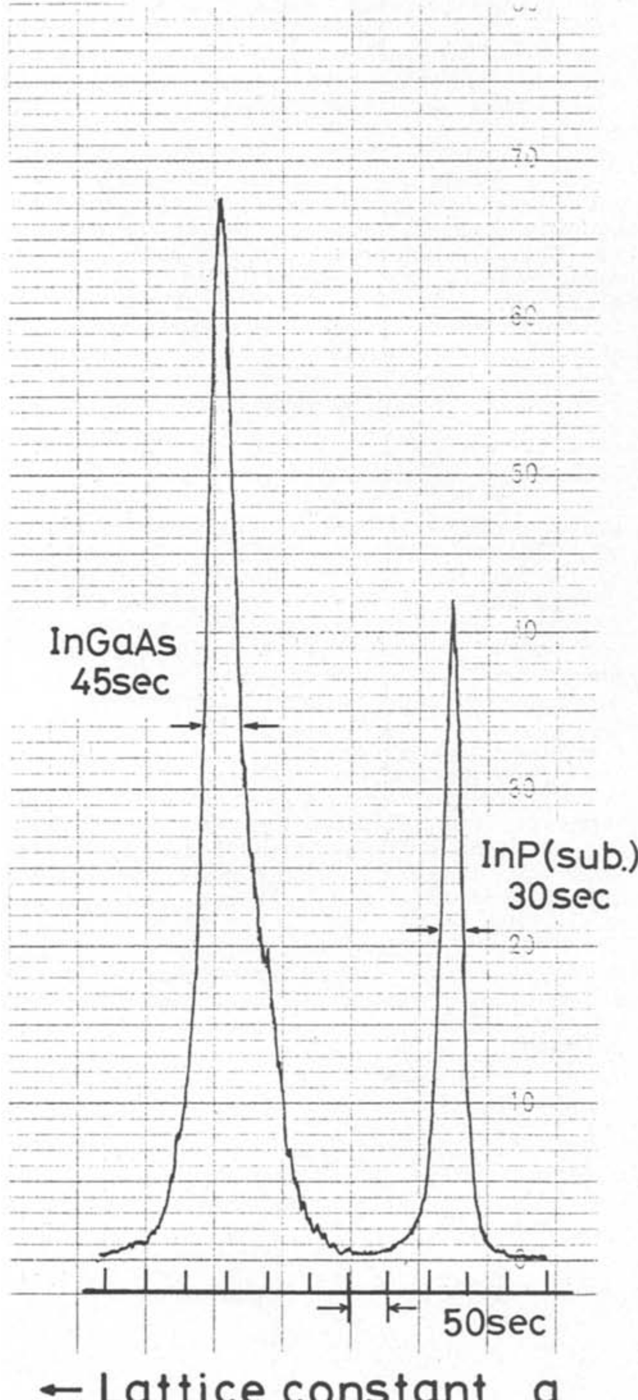

Fig. 4. X-ray double crystal rocking curve of InGaAs/InP layer

In conclusion, the (100) and (111)B InP substrate thermal damage can be suppressed at 730°C by using a substrate holder with a sliding cover filled with PH_3 gas in InGaAs VPE. The holder is confirmed to be useful to minimize the PH_3 contamination in the VPE InGaAs growth by EPMA, Auger analysis, and double crystal x-ray rocking curve.

Acknowledgment

The authors would like to thank Dr. T. Kimura and Dr. H. Kanbe for encouragement and useful discussions, and H. Takaoka for Auger analysis measurement.

Addition Rule for Patterned and Nonpatterned Hardenings in Dichromated-PVA Coatings

W. H. Fonger

RCA Laboratories, Princeton, New Jersey 08540

Dichromated-PVA photoresist is used to make phosphor and black-matrix dot or line patterns in color television picture tubes. The details of this application are reviewed in Morrell *et al.* (1); see especially Sections 3.1.1, 5.1, 5.2.1, 5.3.5, and 5.5. The photochemistry of dichromated colloids, including PVA, is reviewed in Chapter 2 of Kosar (2). Both books give many references.

The hardenings (PVA cross-linkings) of dichromated PVA coatings are often the combined result of patterned and nonpatterned hardenings. Patterned hardenings arise from light exposures through masks. Nonpatterned hardenings arise from flood exposures or from coating dark hardenings (no light). We address the measurement of both hardening components for PVA clear-resist coatings. The analysis is handled in the approximation that all hardenings (PVA cross-linkings) increase linearly in time and that the transition to threshold hardening, the hardening level that just resists development, is very sharp.

The clear-resist case occurs for the black-matrix deposition (1). However, we are concerned here more with the general study of coating light and dark hardening, and envisioned experimental conditions are much more variable than in matrix deposition. The exposure light can be directed toward or through the glass substrate; the pattern mask can be q-spaced or contact; the pattern can have any desired shape; mask and flood exposures can utilize different wavelengths, etc. We generally consider fairly thin coatings so that the photohardening is not very graded from coating top to bottom. However, the only real requirement is that a point of threshold hardening can be properly read and rated for exposure, and it is possible to work with some hardening grading through the coating.

The simplest case is where the patterned hardening is digitalized in a large-area step or checkerboard pattern, as illustrated in Fig. 1. The numbers in the checkerboard squares give the units of patterned exposure time. The hatched area shows the portion of the coating that survived development. In the case illustrated, 9-10 units of patterned exposure time were needed to give threshold hardening. Calling this patterned exposure time t_p and the time for nonpatterned hardening t_n, the equation (addition rule) describing coating hardening at the hardening threshold is

$$\frac{t_p}{\tau_p} + \frac{t_n}{\tau_n} = 1 \qquad [1]$$

where τ_p is the time for threshold patterned hardening for no nonpatterned hardening, and τ_n is the time for threshold nonpatterned hardening for no patterned hardening. The constants τ_p, τ_n are characteristic constants of the coating.

To measure the coating times τ_p, τ_n experimentally, one needs two coatings 1, 2 with different applied nonpatterned hardening times t_{n1}, t_{n2}, and, therefore, different observed patterned exposure times t_{p1}, t_{p2} to bring the coating to threshold hardening. Using the addition rule [1], one then has two linear equations in the two unknowns $1/\tau_p$, $1/\tau_n$

$$\frac{t_{p1}}{\tau_p} + \frac{t_{n1}}{\tau_n} = 1, \qquad \frac{t_{p2}}{\tau_p} + \frac{t_{n2}}{\tau_n} = 1 \qquad [2]$$

which can be solved for these unknowns.

For the more complicated case of dot (or line) exposures using a television shadowmask, the patterned hardening is a continuously decreasing function of the dot-diameter coordinate D (or of the line-width co-

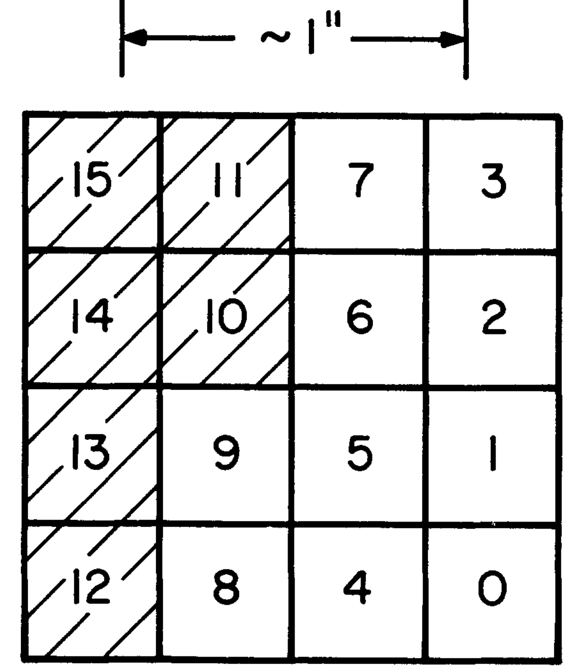

Fig. 1. Checkerboard pattern for light exposures. The integer in each square gives the units of exposure time.

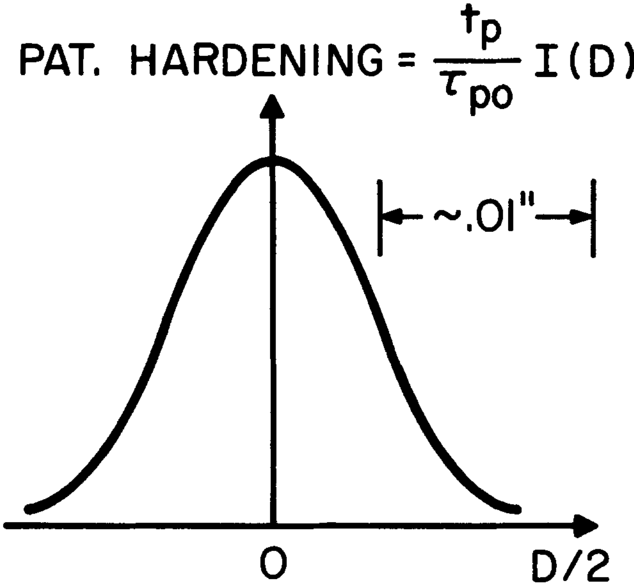

Fig. 2. Profile of patterned hardening beyond each mask hole. *I(D)* is the normalized light shape function.

Key words: dichromated PVA, TV-screen deposition, photohardening.

ordinate W) due to the light penumbra developed between the mask and coating. See Fig. 2. In this figure, t_p is the mask-exposure time, the coating constant τ_{po} is the mask-exposure time needed to harden dots of some arbitrary standard diameter D_o with no nonpatterned hardening, and $I(D)$ is the shape function of the patterned light intensity at the coating, normalized to unity at $D = D_o$.

For combined shadowmask and nonpatterned hardenings, the addition rule analogous to Eq. [1] is

$$\frac{t_p}{\tau_{po}} I(D) + \frac{t_n}{\tau_n} = 1 \qquad [3]$$

where t_n and τ_n have the same meanings as in Eq. [1], and D is the developed-dot diameter.

If a resist with negligible nonpatterned hardening ($t_n/\tau_n << 1$) is available, the light shape function $I(D)$ *vs.* D can be measured experimentally using Eq. [3] which then reduces to

$$I(D) = \frac{\tau_{po}}{t_p(D)} \qquad [4]$$

Here $t_p(D)$ is the measured mask-exposure time for dots of diameter D. We assume hereafter that the shape function $I(D)$ has been measured and is known.

The constants τ_{po}, τ_n of an "unknown" coating can be determined using Eq. [3]. One uses two coatings with different nonpatterned hardening times t_{n1}, t_{n2} and superimposed mask-exposure times t_{p1}, t_{p2} which give developed dots of observed diameters D_1, D_2, respectively. One then has the two linear equations

$$\frac{t_{p1}}{\tau_{po}} I(D_1) + \frac{t_{n1}}{\tau_n} = 1, \quad \frac{t_{p2}}{\tau_{po}} I(D_2) + \frac{t_{n2}}{\tau_n} = 1 \qquad [5]$$

which can be solved for the unknowns $1/\tau_{po}$, $1/\tau_n$.

We have used the methods underlying Eq. [1] and [3] to obtain the characteristic constants of unknown coatings. The method using Eq. [1] is simpler because it avoids both the light shape function $I(D)$ and microscope measurements.

The addition rules [1] and [3] will handle any case of combined light and dark hardening. Two special cases of rule [3] are of interest. We consider first the case where the nonpatterned hardening time t_n is held constant while the mask-exposure time t_p is varied. Equation [3] can then be written

$$\frac{t_p(D)}{\tau_{po}} = \frac{\alpha}{I(D)} \qquad [6]$$

where α is the constant $\alpha = 1 - t_n/\tau_n$. Equation [6] shows that $t_p(D)$ is inversely proportional to the light shape function $I(D)$, just as it was in the Eq. [4] case for no nonpatterned hardening. That is, the function t_p *vs.* D (mask-exposure time *vs.* developed dot diameter) has the same shape with or without a superimposed constant nonpatterned hardening.

Figure 3 shows a measured example of this case. The measured shapes $t_p(D)$ are seen to be the same for no nonpatterned hardening and for a nonpatterned hardening for which t_n/τ_n was approximately 2/3. In this example, the nonpatterned hardening was provided by Hg 436 mμ floodlight. This light is weakly absorbed in dichromated-PVA coatings and gave uniform nonpatterned hardening *vs.* coating depth. The mask exposures used Hg 365 mμ light. The dot mask had 3 out of every 4 of its mask holes blocked so that the period between mask holes was double the normal size. Dot diameters up to 60 mils could therefore be used before adjacent dots overlapped.

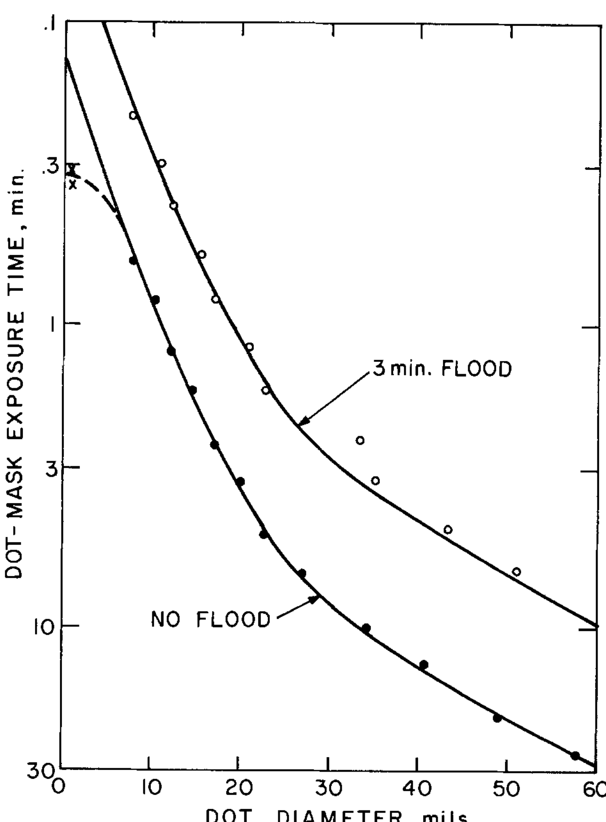

Fig. 3. Dot-mask exposure time *vs.* dot diameter with and without a superimposed flood exposure. This plot is drawn in the form $1/t_p$ *vs.* D which directly portrays the shape function $I(D)$.

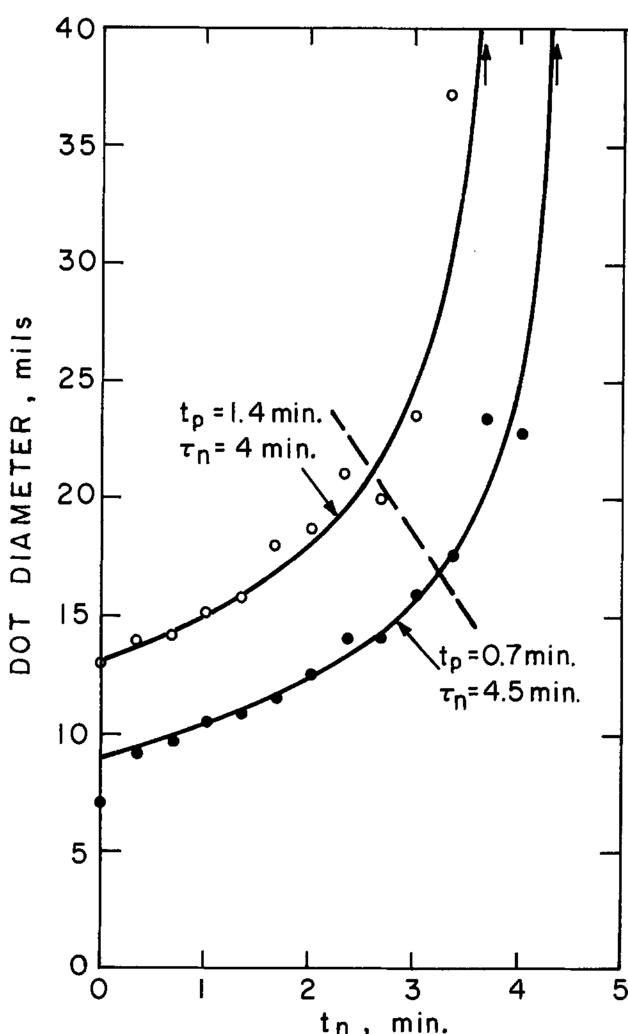

Fig. 4. Dot sizes when a variable flood exposure t_n was superimposed on fixed dot-mask exposures t_p. The curves through the data points were calculated from the shape function $I(D)$ in Fig. 3.

Figure 3 was purposely drawn in the form $1/t_p$ *vs.* D to directly portray the light shape function $I(D)$. This plot is in contrast to the more normal plot of D *vs.* t_p which displays the growth of dot diameter D with increasing mask-exposure time.

We consider finally the case where the mask-exposure time t_p is held constant while the nonpatterned hardening time t_n is varied. Equation [3] is then usefully written in the form

$$I(D) = \frac{\tau_{po}}{t_p}\left(1 - \frac{t_n}{\tau_n}\right) \quad [7]$$

We assume that τ_{po}, τ_n, and the shape function $I(D)$ are known, t_p is given, and t_n is varied. As t_n is varied, the right-hand side of Eq. [7] gives the numerical value of $I(D)$, and, from the known shape-function I *vs.* D, the expected dot diameter D can then be read off.

Figure 4 shows examples of measured (data points) and calculated (smooth curves) dot diameters D *vs.* the nonpatterned hardening time t_n. The exposure mask was the same dot mask used for the Fig. 3 measurements, and the shape function $I(D)$ used in the calculations is that shown in Fig. 3. All data in Fig. 4 were taken on two coatings. One was mask-exposed with Hg 365 mμ light with $t_p = 0.7$ min, the other with $t_p = 1.4$ min. The various nonpatterned hardening times t_n were obtained by superimposing on the dot exposures flood exposures with Hg 436 mμ light in a large-area checkerboard pattern. The flood-exposure times in the various checkerboard squares provided the various t_n abscissa values in the figure.

As $t_n \to \tau_n$, the developed dot diameter increases catastrophically, and the coating becomes undevelopable. This region (to the upper right of the dashed curve in Fig. 4) is readily recognized in practice and avoided. In the region to the lower left of the dashed line, the developed dots look innocently as if no nonpatterned hardening occurred. However, the coating photosensitivity to mask exposures would be seriously overestimated if the underlying nonpatterned hardening were ignored. In practice, underlying nonpatterned hardenings come from flood exposures and from coating dark hardenings.

Since the catastrophic increase of dot diameter with t_n is so sensitive to τ_n, the two τ_n values in Fig. 4 (4 and 4.5 min) were separately chosen empirically for best fit of the theory to the data points.

Damage-Free Polishing of Polycrystalline Silicon

B. L. Sopori, T. Nilsson, and M. McClure

Motorola Incorporated, Semiconductor Group, Phoenix, Arizona 85008

Recently there has been considerable interest in using polycrystalline silicon for solar cells. Although cells of about 10% efficiency can be fabricated on polycrystalline silicon substrates, it is expected that higher efficiencies can be obtained if some of the grain-boundary effects, which limit the cell performance, are well understood and, thereby, subject to moderation. Much of this investigative work to study photovoltaic mechanisms at grain boundaries involves electro-optical techniques. For this purpose, it is necessary to polish the surface of a polycrystalline silicon sample such that surface damage and profile variations, in particular at the grain boundaries, can be minimized. This paper reports a polishing technique which yields a damage-free polished surface with grain-to-grain surface height variation, δ, less than 0.05 μm. A method for monitoring surface damage due to polishing in order to optimize the polishing conditions is also described.

The problems associated with polishing polycrystalline silicon can be generalized as follows: (*i*) both chemical and mechanical (using fine grit) polishing result in steps at the grain boundaries due to different removal rates for various grain orientations; (*ii*) mechanical polishing results in surface damage giving rise to a high surface recombination velocity (which has deleterious effects on solar cell performance and complicates the interpretation of measurement data); (*iii*) chemical polishing/etching generally causes "grooving" at the grain boundaries due to the fact that the etch rate at grain boundaries is often higher than that of the grains. From these considerations it is clear that polishing to minimize surface damage and δ requires a sequence of mechanical polish followed by chemical/mechanical polish. The chemical/mechanical polishing should be done just long enough to remove the surface damage from mechanical polishing. We have tried several mechanical and chemical/mechanical polishing procedures and describe the one that gave best results.

Key words: polycrystalline, grain boundaries, surface photovoltage, Nalcoag.

Procedure and Results

Polycrystalline silicon samples that were polished had sawn and etched surfaces. These wafers have considerable surface roughness and their grain structure is clearly visible, as is shown in Fig. 1. Various grains show up due to variations in reflectivity caused by changing grain inclination with respect to the incident light. Wafers were first lapped with alumina powder (typical grit size $\sim$ 30 μm) using a felt pad[1] for about 30 min. The lapped sample exhibits a grayish appearance and no grains are visible under normal visual inspection. A heavy surface damage was evidenced by a lack of surface photovoltage signal due to high surface recombination velocity (1).

Samples were then polished with oil-based diamond (typical grit size $\sim$ 2 μm) while gradually reducing pressure from 5 to 2 psi and maintained at this value for 2 min. Diamond polishing removed much of the lapping damage, there is still residual surface stress

[1] A laboratory-type machine with single spindle and rocking arm was used for all polishing steps.

Fig. 1. Photograph of a polycrystalline wafer before polishing. Size: 2.5 × 2.5 cm².

which must be removed. This is done by a chemical/mechanical polish using Nalcoag slurry, Type 2350.[2]

To optimize polishing conditions, as discussed earlier, surface photovoltage technique has been used to monitor the degree of surface damage based on the fact that the surface voltage signal developed across the sample is a function of surface recombination velocity (1).

Reduction in surface damage by chemical/mechanical polishing was compared by polishing the samples for short intervals of time and measuring its photovoltage. Light intensity and the gap between top electrode and sample surface were held constant throughout all measurements. Variation of photo-signal at 10 sec intervals of polishing time is shown in Fig. 2. The solid circles show this signal variation. The decreased signal after 60 sec of polish was felt to be caused by insufficient flow of Nalcoag during polishing since repeating the experiment on another wafer yielded the signal value shown by the triangle. Saturation of signal occurs after about 60 sec of polishing, implying the surface to be free from damage.

[2] Nalcoag is a colloidal silica slurry manufactured by Nalco Chemical Company.

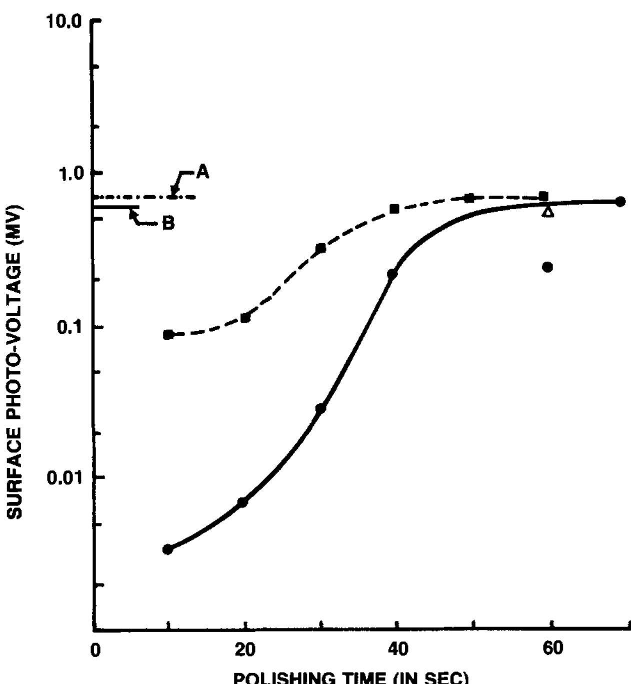

Fig. 2. Amplitude of SPV signal vs. polishing time for Wacker Silso polycrystalline silicon. Constant light intensity and optical beam size ($\lambda = 1.0$ μm).

In order to compare (qualitatively) the residual surface damage after lapping and diamond polishing with that of diamond polishing alone, the above sample (after Nalcoag polish) was given a diamond polish followed by repolishing with Nalcoag for 10 sec intervals and remeasuring the SPV signal. These data are shown by squares in Fig. 2. Residual damage from diamond polishing alone was much less than when the sample was lapped prior to diamond polish. Furthermore, the signal saturation occurred after only 40 sec of total polishing time. The two lines A and B in Fig. 2 indicate the signal levels obtained from two samples which were first Nalcoag polished and then etched using two different etchants. Since these samples were not mechanically polished, these signal levels correspond to damage-free surfaces lending support that the saturation signal level implies a damage-free surface.

The procedure was used to polish polycrystalline silicon wafers to a smoothness, δ_{max}, of less than 0.05 μm with negligible (or no) surface damage. This is clearly seen from Fig. 3 which is a surface profile trace of a polished Wacker polycrystalline silicon wafer. A Nomarski photograph of a part of the polished surface is given in Fig. 4. Although the photographed region has many grain boundaries, only a few are visible in Fig. 4. A Dektak trace (accompanying the photograph) across the most prominent grain shows the height variation to be 0.03 μm. An interference photograph of a part of the surface, taken under sodium light (λ = 0.513 μm) is shown in Fig. 5.

The polishing procedure described above was established following several variations in mechanical and chemical/mechanical polishing sequences. Table I summarizes some essential features of these. It should be emphasized that procedures a, b, and c in Table I, lead to a steady-state grain-to-grain height variation (*i.e.*, δ does not change if the polishing is continued past

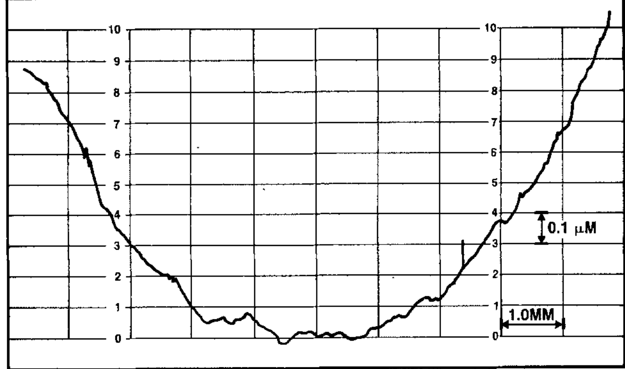

Fig. 3. Dektak trace of the surface profile of a polished Wacker polycrystalline silicon sample.

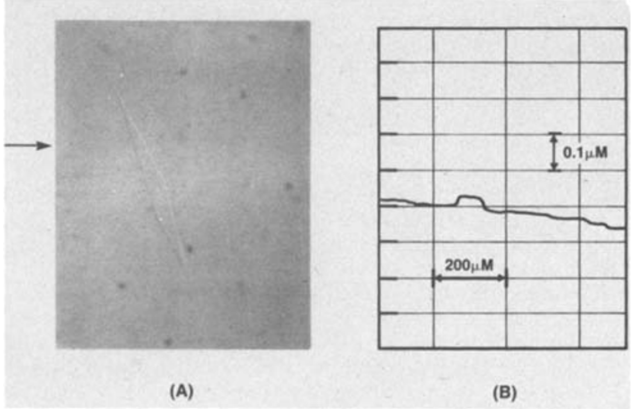

Fig. 4. (A) Nomarski photograph of a polished wafer, magnification = 50. (B) Dektak trace across the prominent grain (along the arrow in A).

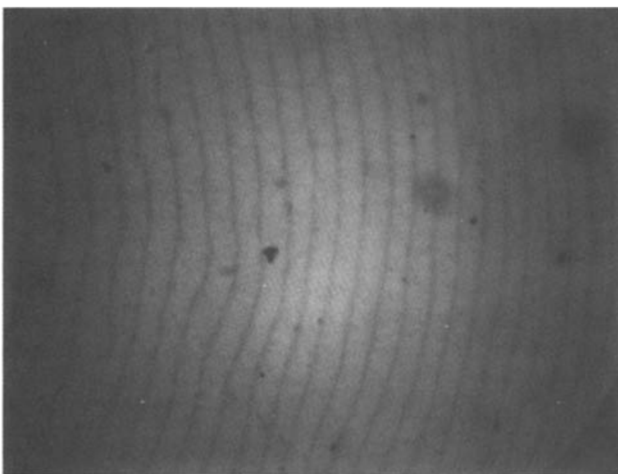

Fig. 5. Interferogram of a polished section of a polycrystalline silicon wafer.

an initial period of rapid variation). Results of chemically polishing the samples in two different etchants are also given in Table I for comparison. These etchants are often used for silicon surface preparation.

We have also found Nalcoag polishing to be a very attractive technique for wafer thinning. Figure 7 shows a plot of thickness removed *vs.* polishing time for two pressures. It is seen that removal rates are comparable

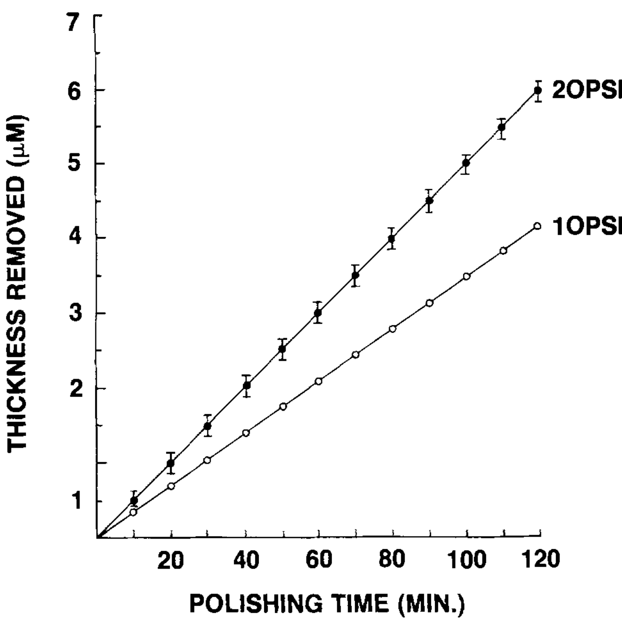

Fig. 7. Plot of thickness removed *vs.* polishing time during Nalcoag thinning.

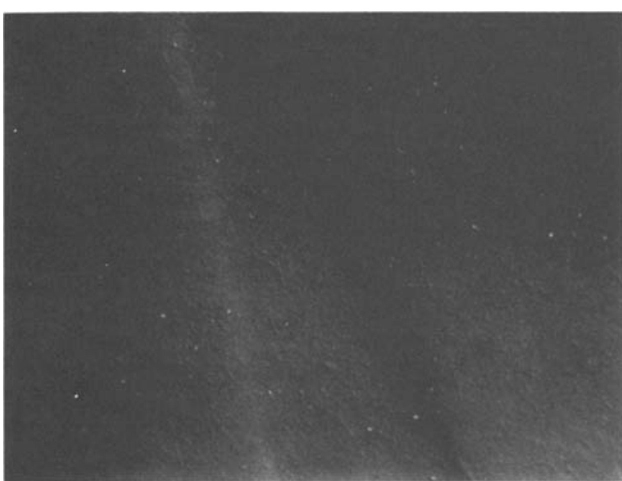
to that of lapping. In addition, Nalcoag polishing allows better control for these wafers. Using Nalcoag thinning and the polishing techniques described in this paper we have been able to parallel polish RTR silicon ribbons down to a thickness of 28.1 μm for the measurement of absorption coefficients at wavelengths down to 0.7 μm (2).

Applications

The polishing of polycrystalline silicon is necessary for a variety of important electrical and optical characterization techniques. Some of these are: (*i*) focused laser scanning to determine local variations in photoresponse and to evaluate some effects of grain boundaries; (*ii*) material thinning and polishing for measurement of optical constants such as reflection and absorption coefficients, and to determine microscopic stresses by infrared birefringence; (*iii*) planar defect characterization for delineating various types of defects using chemical etchants; (*iv*) angle lapping for a variety of characterizations such as variation of defects in the bulk, junction depth measurements (at and away from grain boundaries), and a variety of other measurements (*e.g.*, potential probing) which require signal pick-off from the surface.

Summary

The Nalcoag polishing technique for polycrystalline silicon resulted in a grain-to-grain surface height variation of $\delta < 0.05$ μm. The slope of the surface profile at grain boundaries is very gentle, and no "grooving" at grain boundaries has been observed. These properties are very important for probing grain boundaries, electrically and/or optically, along the sample surface. SPV monitoring showed the extent of surface damage to be minimal. This polishing/monitor technique has also facilitated other evaluation methods such as measurement of absorption coefficient for wavelengths near the bandedge, spectroscopic measurements of impurities like oxygen, and defect delineation by chemical etching.



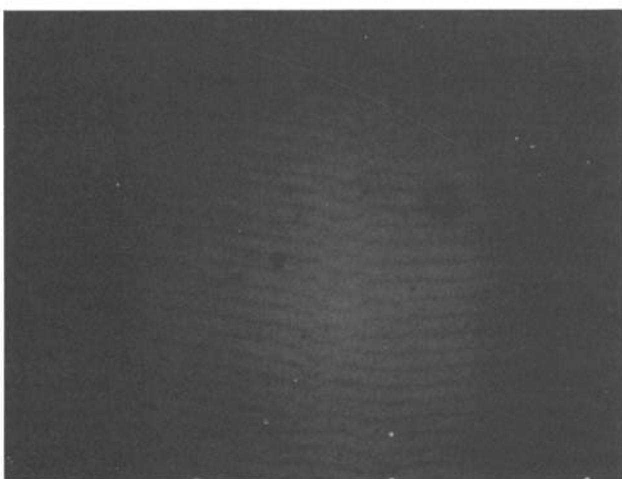


Fig. 6. (a, top) Nomarski photograph of a grain shows that damage introduced by lapping (as pits) is not completely removed by a chem mech polish for 4 min. A gentle tamer at the grain boundary is clearly seen. Magnification 400×. (b, bottom) Low magnification (10×) interference pattern of the grain in Fig. 6(a).

Acknowledgments

The Influence of Promoter Elements in Acidic Sulfate Solutions on Hydrogen Absorption in Titanium

Z. A. Foroulis*

Exxon Research and Engineering Company, Florham Park, New Jersey 07932

It is well known that certain elements, particularly those of Group VA and VIA of the periodic table, can markedly increase the entry of hydrogen into iron and carbon steel during cathodic polarization. Elements which produce this effect are known in the literature (1, 2) as "promoters." Several papers have been published in the literature dealing with the influence of promoter elements on the rate of hydrogen absorption in iron and carbon steel (3-6). However, information on the role of these elements on the rate of hydrogen absorption in titanium is not available. This brief communication presents experimental data which show that promoter elements such as P, As, S and Sb have a rather pronounced effect on the rate of hydrogen absorption in titanium in acidic sulfate solutions under conditions of cathodic polarization.

EXPERIMENTAL

The material used in this study was commercially pure titanium (ASTM B265-72 Grade 2) of the following analysis (0.025% C, 0.06% Fe, 0.021% N, 0.005% H, 0.15% O_2). The titanium electrodes were small rectangulars with dimensions 1 x 1 x 0.3 cm. All sides of the electrodes were exposed in the test solution. The electrode assembly in which only glass and teflon, besides the electrode, came in contact with the electrolyte, as well as the cell design, were similar to those described previously (7). Constant current for the cathodic charging experiments was drawn from a constant voltage power source through a variable resistance. The electrode surface was polished with 6/0 emery paper, rinsed with toluene and acetone and pickled with HF (14% HF) to remove the air formed oxide film. No measurable hydrogen absorption was detected as a result of surface etching. The test solution was 0.1 N H_2SO_4 (pH = 1.2) with and without the addition of equal molar concentrations (3.1×10^{-3} M/l) of sulfur, phosphorous, arsenic and antimony which were added in the test solution as Na_2S, $Na_4P_2O_7$, $NaAsO_2$ and potassium antimony tartrate $K(SbO)\ C_4H_4O_6$ respectively. Charging solutions were prepared from distilled water and reagent grade chemicals. The cathodic charging experiments were carried out at 10 ma/cm^2 for 24 hours at 93°C. After cathodic charging, the hydrogen content of the titanium electrodes was determined by the hot extraction method at 1400°C (8). Several electrodes, after charging were also polished metallographically in cross section, etched with an HF-HNO_3-lactic acid reagent (9) and the morphology of the hydride layer was examined with an optical microscope.

RESULTS AND DISCUSSION

The Ti-H system forms an interesting contrast to the well known Fe-H system in at least two respects. First, in the Fe-H system, the affinity between metal and hydrogen is only slight; they form no chemical compounds and the hydrogen dissolves in the metal in comparatively small concentrations. In the titanium-hydrogen system, on the other hand, the mutual affinity is great, a chemical compound, titanium hydride (TiH_2) is formed and the hydrogen dissolves in the metal in relatively large quantities.

The second major difference between titanium and iron is that titanium in air or when immersed in most aqueous solutions at open circuit potential forms a stable "passive" film which is probably a thin TiO_2 film (10-11). This oxide film, when present, may act as a barrier to hydrogen pickup.

To eliminate the presence of an oxide surface film on titanium during the cathodic hydrogen charging experiments, the titanium electrodes, after pickling with HF to remove the air-formed oxide film, were kept in an inert

* Electrochemical Society Active Member.

Key Words: Hydrogen Absorption, Titanium, Promoter Elements.

atmosphere and immediately upon immersion in test solution were cathodically polarized at 10 ma/cm^2 while the charging solution was maintained at 93°C. The test solutions were acidic sulfate solutions pH = 1.2 with and without equal molar concentration of the promoter elements. During cathodic charging

Table I. Potential of Titanium Electrode Cathodically Polarized at 10 ma/cm^2 at 93°C in 0.1 N H_2SO_4

Solution	Potential V (SCE)
0.1 N H_2SO_4	-0.93
0.1 N H_2SO_4 + 3.1 x 10^{-3} M/l Na_2S	-1.12
0.1 N H_2SO_4 + 3.1 x 10^{-3} M/l $Na_4P_2O_7$	-1.15
0.1 N H_2SO_4 + 3.1 x 10^{-3} M/l $NaAsO_2$	-1.0
0.1 N H_2SO_4 + 3.1 x 10^{-3} M/l K(SbO) $C_4H_4O_6$	-0.92

at 10 ma/cm^2, the electrochemical potential of titanium as shown in the table was in the range of -0.9 to -1.15 V (SCE). In this potential region in acidic sulfate solutions (pH = 1.2), titanium oxides are not stable thermodynamically (12). It is, therefore, reasonable to assume that during the cathodic charging experiments, the bare titanium metal surface was exposed in the test electrolyte.

Figure 1 shows the titanium hydride (TiH_2) layer formed in titanium cathodically polarized at 10 ma/cm^2 for 24 hours in 0.1 N H_2SO_4 (pH = 1.2), at 93°C. This is typical of the morphology of the titanium hydride layer produced by cathodic charging in acidic sulfate solutions with and without the addition of the promoter elements. After prolonged exposure, diffusion of hydrogen and formation of titanium hydride thin plates far deep into the metal structure were also detectable. The effect of different promoter elements on the rate of hydrogen absorption in titanium cathodically polarized at 10 ma/cm^2 at 93°C is shown in Figure 2. The promoter elements were added as Na_2S, $Na_4P_2O_7$, $NaAsO_2$, and $K(SbO)C_4H_4O_6$. These compounds were complete soluble and had no effect on the pH of the 0.1 N H_2SO_4 solution.

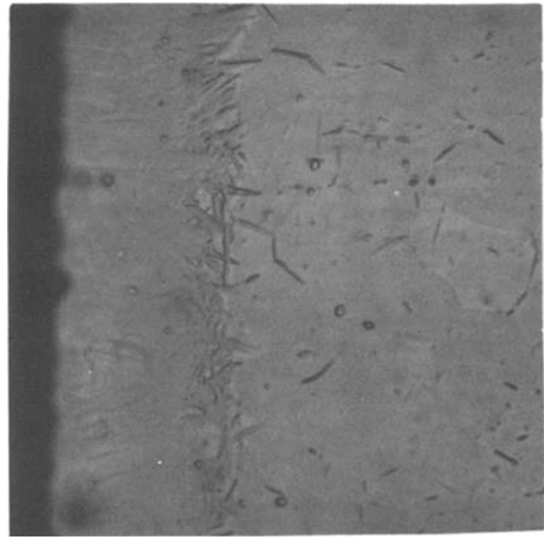

Figure 1. Morphology of Titanium Hydride Formed in Titanium Cathodically Polarized at 10 ma/cm^2 in 0.1 N H_2SO_4, 93°C.

The nature of the ionic species containing the promoter element which are present in the solution are likely to be $SO_4^{=}$, SH^-, $P_2O_7^{4-}$, AsO_2^- and SbO_2^- respectively. The data shown in Figure 2 demonstrate the pronounced effect of SH^-, $P_2O_7^{4-}$ and to a lesser extent of AsO_2^- on the rate of hydrogen absorption in titanium cathodically polarized at 10 ma/cm^2, 93°C in 0.1 N H_2SO_4. The effect of K(SbO) $C_4H_4O_6$ (which is likely to produce SbO_2^- in solution) on the hydrogen absorption rate was not as pronounced.

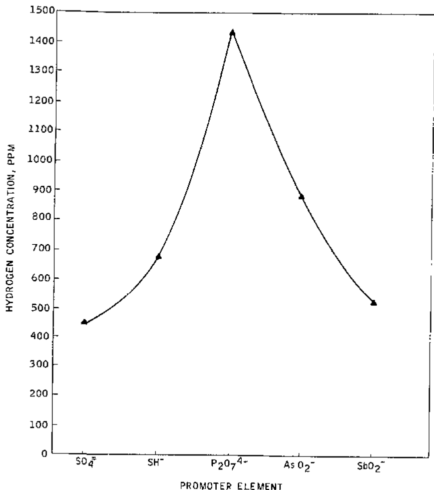

Figure 2. The Effect of Promoter Elements on Hydrogen Absorption in Titanium Cathodically Polarized at 10 ma/cm^2 in 0.1 N H_2SO_4 (pH = 1.2), 93°C.

As indicated previously, it is reasonable to assume that during the cathodic charging experiments, the bare titanium metal surface was exposed in the electrolytic solution. It is also reasonable to assume that the promoter element containing compounds exert their influence on increasing the rate of hydrogen uptake, by adsorbing on the titanium metal surface. However, the molecular species containing the promoter element which adsorb on the metal surface and the mechanism of their action in enhancing the rate of hydrogen absorption is not known. It is possible that the adsorbed promoter species increase the Ti-H bond on the metal surface and this increases the coverage of adsorbed atomic hydrogen which thereby increases the permeation rate. Other explanations such as formation of hydride of the promoter element during polarization as an essential process of hydrogen entry in titanium must also be considered. Additional work in this area is clearly required before a definitive mechanistic explanation of the role of promoter elements on hydrogen absorption in titanium can be advanced.

Semiconductor Electrodes

XXXV. Slurry Electrodes Based on Semiconductor Powder Suspensions

Wendell W. Dunn, Yosihiro Aikawa, and Allen J. Bard***

Department of Chemistry, University of Texas at Austin, Austin, Texas 78712

Irradiated suspensions of semiconductor powders, e.g., TiO_2, have been employed in such heterogeneous photo processes as the oxidation of cyanide, the decomposition of carboxylic acids, and the deposition of metals. Details about these and other reactions are given in recent reviews (1-3). The mechanism proposed for these processes is based on the formation of an electron-hole (e^-h^+) pair at the particle surface upon absorption of light of energy greater than the semiconductor band-gap. The particle then behaves as a short-circuited cell with both oxidation and reduction taking place at the particle surface. Recent measurements of the electrophoretic mobility of TiO_2 powder have demonstrated that in solution, the surface charge on the particle under illumination is more negative than that measured in the dark (4). Moreover, this negative charge persists for at least 10-15 minutes after the irradiation stops. These results suggest that when the holes are scavenged by an oxidation process, electron density builds up on the particle surface. We report here that this excess charge can be collected on an inert electrode to produce an anodic current flow. Thus, semiconductor powder suspensions (e.g., TiO_2, WO_3, CdS) can behave as electrodes ("slurry electrodes") in the same manner as the single crystal and polycrystalline semiconductor materials currently being investigated. Measurements involving such slurry electrodes are of use not only for the characterization of the powders but may also have practical applications in photoelectrochemical cells.

In a typical experiment, a suspension of n-TiO_2 particles in 0.02 M HCl was deaerated for 24 hours prior to measurements. A Pt foil (area ∿ 3 cm^2), polished with Al_2O_3 and cleaned in boiling HNO_3, was used as the collector electrode. Electrochemical measurements were conducted in a Pyrex H-cell, with the compartments separated by a fine-porosity glass frit. One compartment contained the deaerated TiO_2 suspension while the other compartment contained a Pt counter electrode and 0.02 M HCl with a low oxygen concentration to support a current flow. A 2500 W xenon lamp, operated at 1600 W, was used for illumination. A Pyrex water bath approximately 15 cm in diameter was placed in front of the electrochemical cell to remove IR radiation.

A negligible current flowed between the two half-cells in the dark under short circuit conditions. When the TiO_2 suspension was irradiated, a cathodic current transient appeared; the current quickly became anodic and finally attained a steady anodic current

*Electrochemical Society *Active, **Student Member. Key words: photoelectricity, photoanode, solar energy.

level (Fig. 1b). When the light beam was interrupted, an anodic transient appeared and the anodic current decayed to zero. In a control experiment in the absence of the suspension under otherwise identical conditions, only very small current responses appeared under illumination (Fig. 1a). The behavior of the TiO_2 suspension can be interpreted based on the model for photoprocesses at the particle surface (Fig. 2). The photoproduced hole rapidly forms a hydroxl radical that reacts in a following reaction to produce oxygen (5). In the absence of oxidants in solution, electrons accumulate at the powder surface. While proton reduction is a possible process, this reaction is apparently slow at an uncatalyzed TiO_2 surface. The direction of current flow depends upon the relative rates of electron transfer between the collector electrode and the particle. Initially a cathodic current, probably representing reduction of OH•, is observed. However the accumulation of electrons and the subsequent reaction of •OH leads to a net anodic current. A quantitative treatment of the model of Fig. 2, to be described elsewhere, leads to current-time (i-t) curves resembling the experimental ones. Evidence in favor of such a model is the finding that addition of oxygen to the suspension quenches the anodic photocurrent, and produces only a brief cathodic transient and a small cathodic steady state current, since the photogenerated electrons react with O_2. Similarly the anodic current with platinized TiO_2 is much smaller, because Pt catalyzes the proton reduction reaction. Finally the addition of acetate causes a decrease or elimination of the cathodic transient and an increase in the anodic current, because the preferential oxidation of acetate at the powder produces methyl radical which undergoes a very rapid reaction (6), so that electron transfer to this species does not occur.

Similar behavior is observed with other semiconductor powders. The i-t curves with WO_3 powder in sulfate solutions (pH 1.8) are similar to those of TiO_2 (Fig. 1c). For a CdS suspension in a sulfate medium, however, no cathodic transient is observed and the current rises in an anodic direction and then decays to a steady value (Fig. 1d). In this case the photogenerated holes lead to decomposition of the semiconductor

$$CdS + 2h^+ \rightarrow Cd^{2+} + S \qquad [1]$$

and the sulfur so produced is not reducible. The addition of Na_2SO_3 (10^{-5} $\underline{M}$) which retards this decomposition reaction (8) caused no significant change in the photoresponse.

Electrochemical studies of semiconductor slurries in the dark and under illumination appear promising. The determination of photocurrent as a function of the wavelength of the irradiating light can provide information about the band gap energy and, perhaps the existence of energy levels within the gap, with the powder immersed in the reaction medium. Moreover the effect of solution conditions on the photoresponse can provide information about relative reaction rates at the particle surface. Although the magnitudes of the photocurrents generated with the slurry electrodes are small compared to single crystal and some polycrystalline film electrodes under similar irradiation intensities, they may find some practical application. They are potentially very inexpensive and easy to construct and replace. Regenerative (photovoltaic) and storage (photoelectrosynthetic) cells employing slurry electrodes are possible and are currently under investigation in this laboratory.

Edge Acuity Improvement by Spectral Filtration in the Deep U.V.

A. W. McCullough

The Perkin-Elmer Corporation, Norwalk, Connecticut 06856

It has previously been shown that shorter wavelength exposure can increase the modulation transfer function[1] and consequently the effective resolution[2] of a projection mask aligner. This paper addresses the issue of edge acuity under these conditions.

A F/3 projection mask aligner was modified for exposure in the 275 nm to 325 nm region and used to expose one micron of Shipley AZ-2400 resist with standard processing conditions. The silicon substrate had 720 nm of wet grown oxide on it.

Figure 1a shows scanning electron micrographs of 1.5 micron features, of a mask of nominally equal lines and spaces, with two conditions of partial coherence (S). The edge acuity, that is the measured angle of the resist with respect to the substrate, is $\Theta = 48^\circ$ for $S = 0.86$ and $\Theta = 53^\circ$ for $S = 0.52$. In both cases the angle is too small for adequate linewidth control.

A high pass filter was used to reduce the exposure bandwidth to the range 300 nm to 325 nm. The motivation is illustrated in Figure 2 which shows the transmission of one micron of unexposed AZ-2400 resist as a function of wavelength. The strong absorption below 300 nm is characteristic of the Novalac resin contained in most commercial positive resists. Also shown is the bandwidth of the exposure tool and the transmission of the UBK-7 glass that was used as the filter.

It can be seen that there is considerable actinic light at shorter wavelengths than the resist absorption edge. Most of this light is absorbed in the resist leading to loss of resist thickness and poor edge acuity. The UBK-7 filter obviates this effect. The results using this high-pass filter are shown in Figure 1b. Here $\Theta = 57^\circ$ for $S = 0.86$ and $\Theta = 70^\circ$ for $S = 0.52$. These results are a notable improvement and indicate good lithographic performance. Additional experiments were performed with a filter consisting of AZ-2400 on a quartz plate. The results were similar but the organic coating deteriorated rapidly under the intense UV exposure.

Exposure times were 20 sec without the high-pass filter and 30 sec with UBK-7. Experiments are in progress to optimize the filter in order to minimize the increase in exposure time. Different resists may require their own matched filter for optimum results. Similar experiments conducted in the near UV (350 nm to 440 nm range) showed an insignificant improvement in the slope angle as the exposure bandwidth was changed within this range. This would be expected because the Novalac resin has very low absorbtion in this range and the absorbtion of the photo active compound does not exhibit such large variations in this range as does the resin in the 280 to 320 nm range.

Zn Diffusion in GaAlAsSb and GaSb

R. Chin and H. D. Law

Rockwell International/Electronics Research Center, Thousand Oaks, California 91360

The demonstration of both optical sources (1) and detectors (2,3) in the GaAlAsSb-GaSb system at long wavelength ($1.0\ \mu m<\lambda<1.8\ \mu m$) has stimulated further interest in this particular alloy system for optical communication purposes. For numerous optical devices in other III-V alloy systems, Zn diffusions have shown to be invaluable for device fabrication. In heterojunction structures, it is requisite that the diffusion rate of the impurity (Zn) be known for the different composition materials comprising the heterostructure. If the p-n junction must be placed within a narrow region such as the active region of a double heterojunction laser, this information is indispensable.

In this article, we describe the diffusion rate for GaAlAsSb and GaSb. In addition, the effect of antimony overpressure upon the regularity (planar p-n junction) of the p-n junction is shown to be important.

The GaSb material of this work is doped at $3\text{-}5 \times 10^{17}\ cm^{-3}$ with Te, while the $Ga_{1-x}Al_xAs_{1-y}Sb_y$ ($x \sim 0.3$; $y \sim 0.97$) is doped at $6\text{-}8 \times 10^{16}\ cm^{-3}$ also with Te. Lattice matching of the GaAlAsSb epitaxial layer is aided by the addition of a small amount of arsenic. Since this amount of arsenic in the solid is minor, the GaAlAsSb will hereafter be referred to as GaAlSb. Although the doping of the GaSb and GaAlSb differs by a small amount, from other work (5) the gradient of the impurity is extremely large at the p-n junction. Therefore, the difference in doping will not lead to any appreciable error in comparisons of diffusion rate between the two materials. The diffusions of this work were performed at a temperature of 520°C. Although this temperature is low relative to zinc diffusions carried out in other III-V systems (e.g., GaAlAs-GaAs), it is still high for the antimonide system given that GaSb melts at approximately 712°C. The diffusion source consisted of Zn in Ga at 7 atomic percent. This is similar to the type of source used by Rezek et al. (4). The samples were sealed in an ampoule evacuated to $\sim 10^{-6}$ torr. A small amount of pure antimony was also placed in the ampoule prior to seal off. This resulted in planar junctions which were not possible otherwise under the same conditions. A typical diffusion into GaAlSb is shown in Fig. 1. The p-n junction location in the GaSb and GaAlSb as well as the heterojunction between the GaAlSb and GaSb were revealed in cross section with a $H_2O:KOH:K_3Fe(CN)_6$ 20:1:1 etch. The junction depth was ascertained with a Nomarski contrast optical microscope.

The p-n junction depths as a function of the square root of diffusion time for the $Ga_{0.7}Al_{0.3}Sb$ and GaSb are shown in Fig. 2. As is evident in the figure, the diffusion rate for the aluminum bearing alloy is approximately >1.6 times higher than for the GaSb. It is expected that the difference between diffusion rates of the two materials would be more pronounced as the diffusion temperature is increased for a given diffusion time (6). In addition, a break in the diffusion depth vs. time curve occurs at a depth of approximately one micron for both the GaAlSb and GaSb. A similar effect has been observed in GaP (7). This was attributed to the introduction of dislocations. The dislocations affect either the substitutional to interstitial impurity ratio or change the diffusion coefficients (D_i; D_s), depending on the nature of the dislocations. The same effect is probably operative in the antimonide compounds. The net result is to enhance the diffusion rate. This is shown by the greater slope after a diffusion depth of $\sim 1\ \mu m$ is exceeded. The higher rate of diffusion of zinc in the ternary over that of the binary is similar to that found for all Ga-Al compounds with an As or P anion. The diffusion concentration profile is not expected to follow a complementary error distribution owing to the concentration dependence of the distribution coefficient.

In conclusion, it has been found that Zn diffusion in GaAlSb-GaSb system is similar to other Ga-Al compounds with other anions such as As or P. In addition, much lower diffusion temperatures are required in this lower bandgap material. It has also been found that an antimony overpressure results in more planar p-n junctions.

Electrochemical Inactivation of Marine Bacteria

H. P. Dhar and J. O'M. Bockris*

Department of Chemistry, Texas A&M University, College Station, Texas 77843

and D. H. Lewis

Department of Veterinary Microbiology, Texas A&M University, College Station, Texas 77843

Previous methods used to control microbial fouling have had limited success (1,2, 3,4). One approach involved electrochemical evolution of Cl_2 in the bulk of the solution (4). Power requirements and Cl_2 concentrations of this method are, however, impractically large. Other electrochemical approaches have involved the cathodic evolution of H_2, which, although partially successful, causes the region near the interface to become alkaline and encourages the development of other deposits (5,6).

The present report concerns the bactericidal properties of H_2O_2, which is formed from dissolved O_2 present in an electrolyte at low power densities on the metal surface. Direct observations of bacterial activity of Vibrio Anguillarum, a marine species of bacteria were made in a cell constructed of transparent conducting SnO_2 glass, using dark field and phase contrast microscopic techniques. The cell used involved a transparent Nafion cationic membrane #425 to separate the anode and cathode compartments. The dimensions of each compartment were 3 cm X 2 cm X 0.02 cm. 400X magnification (3.10^{-6} m depth of field) allowed observation of the cathode surface, while eliminating transfer of anodically produced Cl_2. In addition to direct observations, assessment of bacterial viability was made by diluting and culturing aliquots from each compartment (7).

The current-density/potential relation for the reaction

$$O_2 + 2H^+ + 2e \rightarrow H_2O_2$$

revealed that H_2O_2 formation would occur in 30°/∘∘ NaCl at approximately -0.3 V on the Normal Hydrogen Electrode (NHE) scale at a current density of around 100 mA m^{-2}.

*Electrochemical Society Active Member

Key Words: Microbial fouling, hydrogen peroxide, tin oxide glass

Trivial calculation shows that, at 10% current efficiency of the experimentally obtained value of $5.\ 10^{-6}$ amp cm^{-2}, the region of 0.02 cm near the surface has an H_2O_2 concentration of around $5.\ 10^{-6}$ mole l^{-1}. Bacterial viability as a function of H_2O_2 concentrations was determined in separate experiments. The results are presented in Table I.

TABLE I: VIABILITY OF VIBRIO ANGUILLARUM AT VARIOUS H_2O_2 CONCENTRATIONS

H_2O_2 Concentration (mole l^{-1})	Bacteria Concentration (number/ml)
10^{-8}	10^3
10^{-7}	3.10^2
10^{-6}	10^1
10^{-5}	4
10^{-4}	1
10^{-3}	1

It can be seen that a concentration $5.\ 10^{-6}$ mole l^{-1} of H_2O_2 would reduce the bacterial concentration about 33 times. The electrode surface itself would be likely, therefore, to be toxic to Vibrio Anguillarum.

The pH of the electrolyte used would have been near 7 before any effects of electrolysis. A change of pH near the electrode would be due to the concentration of H^+ ions near the cathode which combine with O_2 to produce H_2O_2. Taking 1% current efficiency for the production of H_2O_2, the concentration of H^+ ions near 0.02 cm of the electrode was calculated (Ficks Law) to be $4.\ 10^{-7}$ mole l^{-1}. Thus, a pH range of 6 to 7 is expected near the cathode and such a range is not unfavorable for bacterial existence (8).

A potentiostat was used to bring the SnO_2 cathode to the H_2O_2-producing potential, and after introduction of bacteria at about 10^7 ml^{-1} in the cell the following direct assessments of the bacterial viability were made: (i) Some change in the motility

of the bacteria was observed immediately, upon achieving this potential and (ii) After five minutes, approximately half the observed bacteria ceased movement; after ten minutes no movement was observable. The data presented in Figure 1 represents bacterial viability as a function of time during the production of H_2O_2 in the cathode and Cl_2 in the anode compartments, as determined by the serial dilution counting method (7). In the visual experiments above, orders of magnitude more bacteria were used than in those where bacteria were counted by the serial dilution technique (7). The half life values of approximately one minute in the anode compartment and two minutes in the cathode compartment (Fig. 1) suggests that H_2O_2 is less bactericidal than Cl_2. However, the H_2O_2 arises at a surface relatively cathodic and hence, less likely to corrode than one evolving Cl_2.

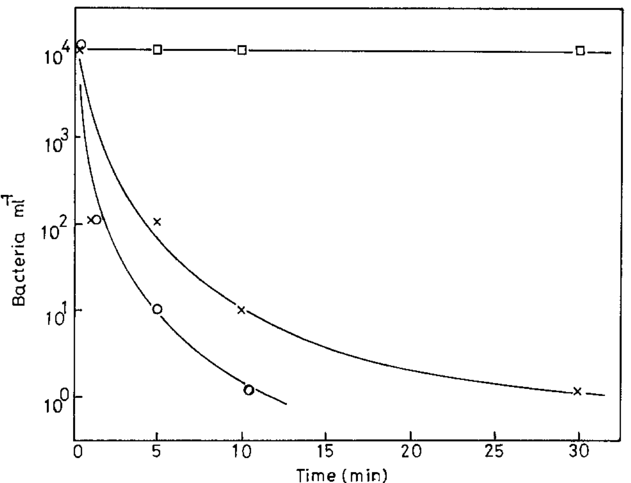

Fig. 1. Bacteria concentration v. time of experiment. □ , blank, no potential being applied; × and ○ , cathode and anode compartment results, respectively. Thickness of each compartment, 0.02 cm. Cathode potential -0.36V (NHE); cell potential 1.95V; current density 5.10^{-2} amp m^{-2}.

The bacterial concentrations presented in Figure 1 refer to those in the cathode and anode compartments. To obtain results more relevant to the conditions near the surface, four cells were fabricated so that distances between the plates were varied. Figure 2 presents data of bacterial viability (number of bacteria still living) versus time after applying potentials appropriate for the formation of H_2O_2 on the cathode in each of these cells.

At a constant time, the number of bacteria in the cell decreases with decreasing cell thickness indicating that in a thinner cell, bacteria come into contact with a higher concentration of H_2O_2, and thus die quicker than would have been possible in a thicker cell.

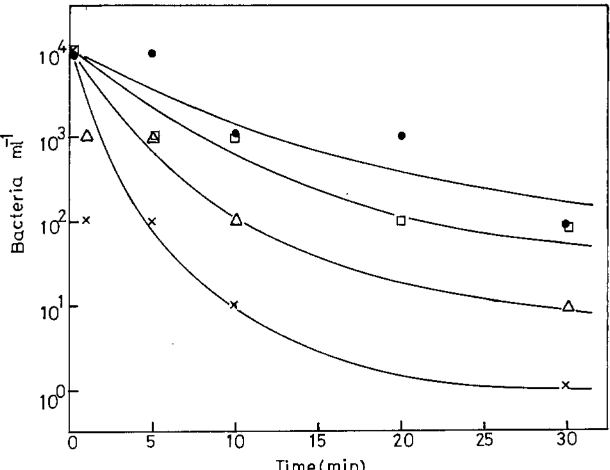

Fig. 2. Bacteria concentration v. time of experiment in cells of varying thickness: 0.15 cm (●), 0.09 cm (□), 0.06 cm (△), and 0.02 cm (X). Cathode potential -0.36 V (NHE). Current density 5.10^{-2} amp m^{-2}.

The bacterial half life revealed by reading from Figure 2 as a function of cell thickness yields data presented in Figure 3. The extrapolated zero thickness value from Figure 3 gives half life value of 30 ± 3 seconds near the electrode surface. This value was obtained through least square analysis of the data. The half life value should not be identified with concentration of bacteria on the surface.

The relevance of the present work to technological situations arises from the small power used and the possibility that device development to intermittent application of the H_2O_2 potential formation range would suffice to reduce greatly the growth of bacterial layers.

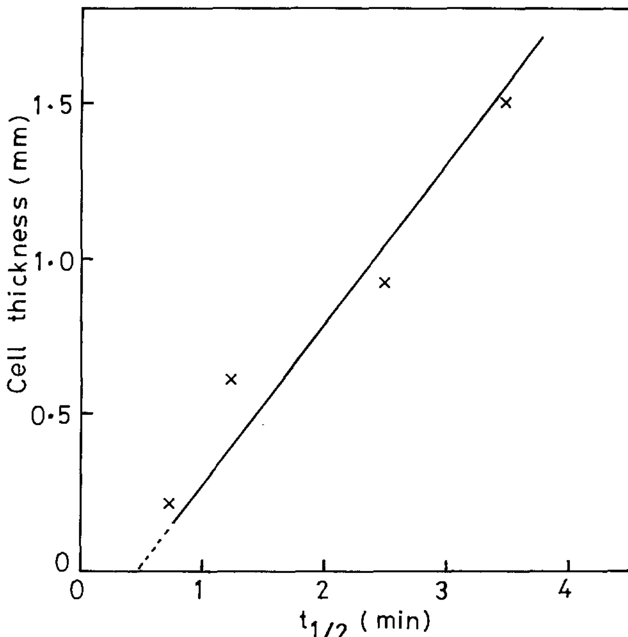

Fig. 3. Cell thickness v. half lifetime of bacteria.

Conductivities in Thionyl Chloride

Mark Salomon*

U.S. Army Electronics Technology and Devices Laboratory (ERADCOM), Power Sources Division, Fort Monmouth, New Jersey 07703

ABSTRACT

Conductivity measurements in thionyl chloride are reported for dilute solutions of $AlCl_3$, $LiAlCl_4$, and the tetrapropylammonium (Pr_4N) salts Pr_4NCl, Pr_4NClO_4, Pr_4NAlCl_4. The data for electrolyte solutions having concentrations in the range of ~0.01 to 1×10^{-5} mole dm^{-3} were fitted empirically to an equation of the Fuoss-Hsia type. In all cases except for $AlCl_3$ ion pair formation was found to be extensive. $AlCl_3$ solutions in thionyl chloride appear to be complex possibly owing to the formation of complex species such as Al_2Cl_6 and $Al_2Cl_7^-$. The effect of ionic strength on the solubility of LiCl is discussed.

In addition to the interesting general solvent properties of thionyl chloride (1), this solvent has received considerable attention as a cathode depolarizer in primary lithium batteries (2, 3). A number of important physico-chemical properties of electrolytic solutions have been reported (1, 4) including the conductivities of $LiAlCl_4$ solutions (4). In the present paper, the conductivities of dilute solutions (between 0.01 and 1×10^{-5} mole dm^{-3}) of various salts including $LiAlCl_4$ are reported and analyzed in accordance with an ion pairing model. The dielectric constants and densities of the pure solvent over a small temperature range are also reported.

Experimental

Chemicals.—Purified $LiAlCl_4$ was supplied by W. K. Behl of this laboratory and was purified as described previously (3). Fluka purris $AlCl_3$ was sublimed in vacuum and transferred to a dry box while under vacuum. Tetrapropylammonium perchlorate (Pr_4NClO_4) was recrystallized from distilled water, and Pr_4NCl was precipitated from an acetone/ether mixture: both salts were dried in a vacuum at 60°C and stored in the dry box. AR grade LiCl was dried at 110°C and stored in the dry box. Tetrapropylammonium tetrachloroaluminate, Pr_4NAlCl_4, was prepared in the dry box by mixing stoichiometric quantities of $AlCl_3$ and Pr_4NCl followed by addition of the solvent. $SOCl_2$ (MC/B best grade) was refluxed with P_2O_5 at room temperature for 24-48 hr before distillation: the middle 2/3 of the colorless distillate was retained for use. A Vacuum Atmospheres Corporation dry box with an argon atmosphere was used in this work.

Dielectric constant measurements.—The static dielectric constants at 15°, 25°, and 35°C were measured by the comparison method (5). The cell, which utilized Type 304 stainless steel, consisted of concentric steel electrodes threaded onto a Teflon base which also formed part of a water jacket. The cell capacitances were measured at 1 MHz by a substitution method with a General Radio 1606-B bridge and 722-D and 1422-ME precision capacitors. The cell constants were determined from measurements with air, benzene, and tetrahydrofuran. The cell was filled with $SOCl_2$ in the dry box, sealed with a Teflon stopper, and removed to the laboratory for capacitance measurements at 15°, 25°, and 35° ± 0.1°C.

Conductivity measurements.—These measurements were carried out at 25° ± 0.03°C (uncalibrated thermometer) at 1 kHz using a General Radio 1608-A impedance bridge. Yellow Springs Instrument Company Type 3402 conductivity cells were modified to permit sealing with a 10/20 ST Pyrex stopper, and to permit immersion in a thermostated water bath. Smooth Pt electrodes were used, and the two cells modified for this work had cell constants of the order of 0.1 cm^{-1}. The cell constants were determined with dilute KCl solutions. All solutions were prepared in the dry box at room temperature (22°-26°C), the cells filled and sealed, and removed into the laboratory for the measurements. Solutions were prepared on a volume basis, and corrections to 25°C were made utilizing results from dilatometric measurements on the pure solvent, and in several cases for dilute salt solutions. The error in concentration using solvent densities rather than solution densities is negligible. The major factors influencing the accuracies of the conductivities were the weighing of salts in the dry box (±0.04%) and the determination of final volumes (±0.2%): the accuracy in the reported concentrations is therefore ±0.3%. Due to the use of smooth Pt electrodes and associated instrumentation, the overall accuracy in the molar conductivities is no better than ±3%.

Results and Data Analyses

The static dielectric constants at 15°, 25°, and 35°C are, respectively, 9.65, 9.23, and 8.77D. These results were fitted by least squares to the following smoothing equation

$$\epsilon/D = -3.88 + 3903/(T/K) \qquad [1]$$

For the densities of pure $SOCl_2$, dilatometric measurements at 15°, 20°, 25°, and 35°C were fitted by least squares to the following smoothing equation

$$d/\mathrm{kg}\ m^{-3} = 1.6284 - 0.00191(t - 25) \qquad [2]$$

* Electrochemical Society Active Member.

Key words: battery, conductance, dissociation, solubility.

The experimental conductivity data for $LiAlCl_4$, $AlCl_3$, Pr_4NClO_4, Pr_4NCl, Pr_4NAlCl_4 (Λ) were calculated from the electrolytic conductivities, κ, after correcting for the solvent conductance: at 25°C the electrolytic conductivity of the solvent is $\kappa(SOCl_2) = 5 \times 10^{-9}$ S cm^{-1} (6). The conductivity data were analyzed using the following equation (7)

$$\Lambda = \Lambda^{\infty} - S(\alpha c)^{1/2} + E(\alpha c)\ln(\alpha c) + J_1(\alpha c) + J_2(\alpha c)^{3/2} - \Lambda\alpha c y_{\pm}^2/(K^{\circ}_{D} y_n) \quad [3]$$

The Onsager and Fuoss-Onsager constants S and E were calculated using the present value for the dielectric constant of $SOCl_2$ and a value of 0.626 cp for the viscosity at 25°C (6). The remaining terms in Eq. [3] are defined as follows: α is the degree of dissociation of the neutral ion pair; c is the total molar concentration of the salt; Λ^{∞} is the molar conductivity at infinite dilution; $y_{\pm}$ is the mean molar activity coefficient and y_n is the activity coefficient for the neutral ion pair; J_1 and J_2 are constants which were evaluated empirically by least squares; and K°_{D} is the dissociation constant for the ion pair defined by

$$K^{\circ}_{D} = \alpha^2 c y_{\pm}^2/[(1-\alpha)y_n] \quad [4]$$

Initial attempts to evaluate activity coefficients by emf measurements on cells without transport failed. In spite of reports (1b) that metals such as Ag, Ni, Mo respond thermodynamically to Cl^-, attempts to utilize these electrodes in various combinations, and in combinations with Li and Ag, AgCl electrodes, lead to irreproducible results. The mean molar activity coefficients were therefore calculated from the Davies equation (8)

$$\log y_{\pm} = -AI^{1/2}/[1 + I^{1/2}] + 0.3AI \quad [5]$$

where I is the ionic strength,[1] and A is the Debye-Hückel factor. At the present time the only justification for the use of Eq. [5] for $SOCl_2$ solutions is that the Davies equation has previously been successfully used in aprotic solvents of varying dielectric constants (9, 10). Since $SOCl_2$ has a low dielectric constant, it is anticipated that salting out coefficients would be significantly more important than in aqueous solutions, and in the present calculations, it is assumed that the activity coefficient for the neutral ion pair is given by

$$\log y_n = 0.3AI \quad [6]$$

For the concentrations employed in the present study, the y_n values as calculated from this equation are close to unity and have a small effect on the magnitudes of K°_{D} and Λ^{∞}. Equation [6] was incorporated into the present calculations.

Equation [3] was solved by evaluating J_1 and J_2 by least squares (11). Both K°_{D} and Λ^{∞} were varied until the error σ_{Λ} was minimized. σ_{Λ} is defined by

$$\sigma_{\Lambda} = \{\Sigma(\Lambda_{obs} - \Lambda_{calc})^2/(N-3)\}^{1/2} \quad [7]$$

where N is the number of data points in each experiment. The results are summarized in Table VI, and the associated results for α and y have been included in Tables I-V. Two, or three at the most, data points for concentrations of the order of 0.1 mole dm^{-3} are not reported in the tables. The reason these points were omitted from the present analyses is that their inclusion gave rise to abnormally large σ_{Λ} values which is undoubtedly due to the formation of triple ions according to (4, 6)

$$MX + X^- = MX_2^- \quad [8a]$$

$$MX + M^+ = M_2X^+ \quad [8b]$$

The conductivity data for the binary $AlCl_3$-$SOCl_2$ system could not be analyzed by the present method, and the possible reasons for this are discussed below.

[1] For 1:1 electrolytes, $I = \alpha c$.

An attempt was also made to evaluate the solubility of LiCl, c_{satd}, in the pure solvent. The solubility is given by

$$c_{satd} = [LiCl]_{sln} + [Li^+] \quad [9a]$$

and in terms of equilibrium constants

$$c_{satd} = K^{\circ}_{s0}/(K^{\circ}_{D} y_n) + (K^{\circ}_{s0})^{1/2}/y_{\pm} \quad [9b]$$

where K°_{s0} is the thermodynamic solubility product constant for LiCl. $[Li^+]$ can be calculated from the electrolytic conductivity of a saturated LiCl solution, and c_{satd} is obtained from Eq. [9b]. $SOCl_2$ was saturated with LiCl in the dry box at 22°-26°C for 72 hr with occasional shaking. Storage of these solutions for more than 7 days results in slight decomposition which is indicated by the appearance of a light green color. The conductivity cell containing excess solid LiCl was filled in the dry box, removed to the laboratory, and

Table VI.* Results of analyses based on Eq. [3]

Salt	J_1	$-J_2$	$\Lambda^\infty(\sigma)$	$10^5K^o_D(\sigma)$	σ_Λ
$LiAlCl_4$	7.649×10^4	3.531×10^5	75.5 (1.7)	3.0 (0.1)	0.28

* All data are for 25°C. Λ^∞ units are S cm^2 mole^{-1}, and K^o_D units are mole dm^{-3}.

placed in the water bath at about 33°C for 10 min. Reducing the temperature to 25°C and measuring the conductivity gave an electrolytic conductivity for the solution of $\kappa(\text{sln}) = 1.65 \times 10^{-7}$ S cm^{-1}: correcting for the electrolytic conductivity of the solvent, $\kappa(\text{LiCl}) = 1.60 \times 10^{-7}$ S cm^{-1}. The concentration of dissociated LiCl, c' (note $c' = [Li^+]$), was calculated from the Onsager equation

$$1000\kappa(\text{LiCl})/c' = [\Lambda^\infty - S(c')^{1/2}]/[1 + y_\pm^2c'/(K^o_D y_n)] \quad [10]$$

$\Lambda^\infty(\text{LiCl})$ is obtained from the data in Table VI, *i.e.*, $\Lambda^\infty(\text{LiCl}) = \Lambda^\infty(LiAlCl_4) + \Lambda^\infty(Pr_4NCl) - \Lambda^\infty(Pr_4NAlCl_4) = 85.1$ S cm^2 mole^{-1}. Since at high dilutions α values are generally quite large (*i.e.*, $\simeq$ 0.9), K^o_D is rather insensitive to the final c_{satd} and it is found that c_{satd} is almost constant (within experimental error) from $K^o_D = 0.1$ to 1×10^{-5} mole dm^{-3}. Values of $K^o_D = 1 \times 10^{-6}$ mole dm^{-3} or smaller results in significantly increasing c_{satd} values. In light of the smallest K^o_D value of 3×10^{-5} mole dm^{-3} for $LiAlCl_4$ found in the present work, and the value of $K^o_D = 1 \times 10^{-5}$ mole dm^{-3} for $(CH_3)_4NOC_6H_2(NO_2)_3$ (picrate) reported by Beronius and Brändström (15) in water saturated methylene chloride ($\epsilon = 9.53D$), the present assumed value of $K^o_D(\text{LiCl}) = 1 \times 10^{-5}$ in $SOCl_2$ seems a reasonable lower estimate. Solving for c' by an iterative method, the following are obtained (note $K^o_{s0} = (\alpha c_{satd} y_\pm)^2$)

$$c_{satd} = 2.2 \times 10^{-6} \text{ mole dm}^{-3} \text{ and}$$

$$K^o_{s0} = 3.3 \times 10^{-12} \text{ mole}^2 \text{ dm}^{-12}$$

Discussion and Conclusions

The data in Table VI demonstrate that the salts studied are all highly associated. The only other study on ion association by conductivity methods is that of Venkatasetty and Ebner (4) in which values of $\Lambda^\infty = 16.5$ S cm^2 mole^{-1} and $K^o_D = 1.61 \times 10^{-3}$ mole dm^{-3} were reported. They analyzed conductivity data from a simplified form of the Fuoss-Shedlovsky equation (12), and neglected to include activity coefficients. These authors also report $K_3/\Lambda_3{}^\infty = 1.21 \times 10^{-3}$ dm^3 S^{-1} cm^{-2}. By means of Walden's rule, $\Lambda_3{}^\infty$ for the triple ion can be estimated from $\Lambda^\infty(LiAlCl_4)/3$: using the present value for $\Lambda^\infty(LiAlCl_4)$, the molar conductivity for the triple ions given in Eq. [8] at infinite dilution is 25.8 S cm^2 mole^{-1} which gives a value of 0.03 mole^{-1} dm^3 for the triple ion formation constant K_3. Since the conductivity data of Venkatasetty and Ebner appear (only graphical data are given in their paper) similar to the present data, the differences in our results for Λ^∞ and K^o_D must be due to the method of treament of the data. For $K_D < 10^{-3}$, the Fuoss-Shedlovsky plots become insensitive to Λ^∞, and the K_D values are even more uncertain (7, 13). In addition, the neglect of activity coefficients is not justified (the Debye-Hückel "A" factor = 12.64 mole$^{-1/2}$ dm$^{3/2}$ at 25°C). The major problem encountered in the present work involves the estimation of activity coefficients. In a previous study (11), it was found that the empirical solution of Eq. [3] using Eq. [4]-[6] can reproduce previously published Λ^∞ and K^o_D values for K^o_D ranging from 1 to 1×10^{-5} mole dm^{-3}, and in solvents having dielectric constants ranging from 78.3D (water) to 9.53D (83 mass% p-dioxane in water). Generally, the analysis of the conductivity equation [3] by more elaborate methods (7) employs the following relation for the activity coefficients

$$\log y_\pm = -A(\alpha c)^{1/2}/[1 + BR(\alpha c)^{1/2}] \quad [11]$$

The activity coefficients listed in Tables I-V can be reproduced by Eq. [11] by taking values of the ion association distance, R, around 0.4 nm. However if R is equated (14) to the Bjerrum critical distance q ($q = z^2e^2/(2\epsilon kT) = 3.0$ nm for 1:1 electrolytes in $SOCl_2$ at 25°C), then the calculated activity coefficients differ significantly from those given in Tables I-V, *e.g.*, for concentrations of the order of 0.01 mole dm^{-3}, Eq. [11] results in $y_\pm$ values about twice as great as those calculated from Eq. [5], and this difference decreases to around 10% at concentrations of the order of 1×10^{-4} mole dm^{-3}.

The analysis of the conductivity data for $AlCl_3$ solutions in terms of the simple dissolution reaction

$$AlCl_3 + SOCl_2 = SOCl^+ + AlCl_4^- \qquad K^o_D = (SOCl^+)(AlCl_4^-) \quad [12]$$

was not successful, *i.e.*, σ_Λ values were generally large and insensitive to values of K^o_D. This inability to fit the data to this simple dissolution mechanism is attributed to both the experimental error and to the probability that dissolution is more complex and involves such species as Al_2Cl_6, $Al_2Cl_7^-$, etc.

The solubility of LiCl in $SOCl_2$ plays an important role in the stability of lithium-$SOCl_2$ primary batteries (2). The solubility for the binary system is described by Eq. [9b], and in the presence of an excess of "neutral" electrolyte, *i.e.*, one which does not yield Cl^- or Li^+ ions, the solubility is given to a good approximation by

$$c_{satd} = (K^o_{s0})^{1/2}/y_\pm \quad [13]$$

Equation [13] demonstrates the need for reliable activity coefficient data at high concentrations of the neutral salt. For example if Eq. [5] is used to approximate $y_\pm$ at higher concentrations, the solubility of LiCl reaches a maximum of 0.005 mole dm^{-3} at ionic strengths of around 0.4-0.5 mole dm^{-3}: this is three orders of magnitude greater than the solubility in the binary system. In solutions containing a large excess of a salt which yields a common ion, say $LiAlCl_4$, the solubility of LiCl is given approximately by

$$c_{satd} = K^o_{s0}/\{y_\pm^2[Li^+]\} \quad [14]$$

In highly concentrated $LiAlCl_4$ solutions, say 1.5 mole dm^{-3}, c_{satd} will still be significantly larger than it would be in the pure binary system because $[Li^+]$ will be small as the major species in solution are the ion pair and the triplet Li_2Cl^+. Taking $K_3 \simeq 0.03$ mole^{-1} dm^3, the concentration of Li_2Cl^+ is about 0.3 mole dm^{-3}, and by Eq. [14], the solubility of LiCl should increase significantly.

Effect of Discharge Current Density on Structure of the Lead Negative Plate

C. P. Wales, S. M. Caulder,[1] and A. C. Simon[1]

Naval Research Laboratory, Washington, DC 20375

ABSTRACT

To help understand how the high current demands of an electric vehicle might affect the electrode microstructure and performance of lead-acid batteries, experiments were run wherein commercial negative plates were given 26 cycles of deep discharge at current densities of either 18, 125, 500, or 2000 A/m^2. Sections of the plates were removed after cycles 1, 6, 16, and 26 and carefully examined by light and electron microscopy, image analysis, and surface area analysis to determine how the electrode active material composition and structure changed with cycling at the different current densities. Electrochemical performance was monitored by measuring plate capacity and electrode potential as a function of current density and number of cycles. The size of the $PbSO_4$ crystals in the discharged plates decreased roughly in correspondence to the decrease in plate capacity produced by the increasing current densities. This suggests passivation as the cause for loss of capacity, since passivation is accepted as becoming more critical as $PbSO_4$ crystal size decreases. The shapes of the electrode polarization curves indicate, however, that limited electrolyte diffusion rates and lessened contact of active material crystals, the result of the porosity that develops with cycling, may also be acting to reduce plate capacity.

The present revival of interest in electric vehicles has raised questions as to the effect that the power demands of such vehicles would have on the microstructure of the lead-acid battery. Since electric vehicle applications will at times require high discharge rates, it was of interest to determine what differences in microstructure are produced by different rates of discharge.

As a first stage of this investigation the effect of different rates of discharge on the negative electrode was investigated. The microstructure of the negative plate of the lead-acid battery has been studied by a number of investigators but little effort has been made to determine the effect that various discharge currents have on the microstructure. Hughel and Hammer examined the structure of the constituents used in plates, and the active material structure before formation and after completing the forming charge (1). Hattori *et al.* examined a small area of the surface of a miniature negative plate (2). The surface of their formed plate contained smooth particles about the size shown by Hughel and Hammer (1) and also included some dendritic clumps of platelets. After a discharge and recharge these platelets aggregated into larger clumps. Pierson *et al.* showed that the surface of a negative plate was not typical of the bulk of the active material in the interior (3). Since Hattori *et al.* examined only the plate surface, this may explain why they found no differences between plates with and without expanders (2), while others reported that expanders have a strong effect on structure (1, 3-5). Weininger (6) found a greatly different structure for a formed negative plate than has been generally reported.

Negative plates require an expander for satisfactory life. When no additives are present the lead forms into large single crystals during the initial charge (4). These large particles cannot be completely converted to $PbSO_4$ during discharge, and result in a plate having low cycle life (5). The presence of lignin, an expander often added to the negative plate together with $BaSO_4$, yields a formed plate containing smaller and less complex dendritic Pb crystals than would be obtained without lignin (3, 4). Plates with both lignin and $BaSO_4$ give a much improved cycle life, and the lead forms into small rod-like particles that have a greatly increased surface area (4, 5).

In the present work commercial plates were cycled using four low to very high discharge rates. The struc-

tural changes that occurred in the active material were studied mainly with the scanning electron microscope and with the light microscope, aided by an image analyzer.

Experimental

The negative and positive plates in this work were commercial plates of the type used in automotive batteries. The negative plates contained expander. The grids contained a Pb alloy with a 4% Sb content. The negative plates were 144 × 122 × 1.4 mm, not including the tabs. The active material had not been formed. Before a negative plate was put in use, seven equal areas were outlined by removing some of the active material pellets to expose the grid members surrounding these seven areas. This treatment facilitated later removal of seven samples of equal size from a cycled wet plate. About 48.5g of unformed active material remained after removing the pellets. This was 64% of the amount originally present. Later, when a sample was to be taken, it was easy to cut the bare grid members and remove a sample without unduly disturbing the remaining active material.

Each cell contained one of these negative plates, two positive plates, a polyethylene separator between each positive and the negative, and an Hg/Hg_2SO_4 reference electrode. There was no pressure on the plates. Two pieces of sheet plastic were placed parallel to the plates, filling most of the empty space inside the cell case. Removal of the plastic allowed easy withdrawal and replacement of the negative plate. The cell contained 410-420 ml of electrolyte. The cell potential, the potential between the reference electrode and the negative plate, and the current were recorded using a strip chart recorder.

The two positive plates had a much greater capacity than the negative plate and were formed separately. Instead of using fresh positive plates for each cell, often a cell contained used positive plates taken from an earlier cell; no difference in negative plate behavior was observed. Negative plates form better in a more concentrated acid than the dilute H_2SO_4 often used for positive plates (7-9). The negative plates were formed in 1.200 sp gr H_2SO_4 at 40 A/m^2 apparent area (both sides) for 20 hr at room temperature. At the end of the forming charge the acid was adjusted to about 1.255 sp gr. The specific gravity at the end of charge was maintained at 1.250-1.260 during the cycling, except for one cell that was cycled in 1.190 sp gr H_2SO_4.

Discharge currents were chosen to give negative plate current densities of 18, 125, 500, or 2000 A/m^2 apparent area. Discharges at these four rates lasted approximately 20 hr, 2.5 hr, 0.5 hr, and 5 min, respectively, using final cell potentials of 1.8, 1.75, 1.5, and 1.0V. All discharges of a particular negative plate were done at the same current density to see the effect of repeated use of that discharge rate. Currents were lowered after each sample was removed, so that current densities remained constant on the negative plate. Capacity discharges were done at cycles 1-6, 16, and 26. All other discharges were ended after removing 80% of negative plate capacity, with capacity taken to be the value obtained in the most recent complete discharge. The cycling was done at room temperature (19°-25°C).

The negative plates were charged at a current density of 31.25 A/m^2 for all cycles except the forming charge. Charges were ended about 1 hr after the negative plate potential dropped sharply and strong gassing began.

Samples cut from the negative plates were washed in distilled water which was boiled and cooled immediately before use to exclude dissolved CO_2 or O_2. This was especially necessary for samples removed from formed plates, where the Pb is very reactive. After 1-2 hr of washing, the samples were dried for about 1 hr under a slow flow of argon in a vacuum dessicator maintained at 100°-110°C.

The negative active material was examined by several methods. Direct examination of the fractured cross sections was made using an AMR Model 1000 scanning electron microscope. Portions of plates were impregnated with plastic, cut into cross sections, polished, and examined by optical microscopy. The approximate proportions of Pb, $PbSO_4$, and void space in representative cross sections were determined at 1350× or 2700× magnification using an Imanco Quantimet 720 image analyzer. The BET surface area of the active material was determined using a Micromeritics Model 2205 surface area analyzer. The active material was broken into pieces smaller than 5 mm to fit into the sample tube of the analyzer and was degassed 40 min at 200°C. Degassing temperature was not critical, with 150° and 250°C giving the same results as 200°C.

Results and Discussion

The capacity of the negative plates slowly declined with cycling (Fig. 1). Corrections for loss of active materials when a sample was cut from a plate are included in Fig. 1. These corrections assumed that the capacities of all samples were equal, but this was only approximately true since all active material pellets did not have exactly the same size. Therefore, the removal of samples at cycles 1, 6, and 16 could cause some error in the capacities calculated for the following cycles. This may be the cause of some vertical displacements of values in Fig. 1. The capacity decline averaged 0.7% per cycle for discharges at 125-2000 A/m^2, and 0.3% per cycle at 18 A/m^2.

The effect of discharge rate and cycling on the negative plate potential is shown in Fig. 2. Polarization of the active material increased when current density was increased. This was indicated by the lowered potential during the first half of a discharge, and by a decrease in the amount of discharge that was obtained before potential began to fall rapidly. Discharges between cycles 1 and 26 gave potentials intermediate between those shown in Fig. 2. Potentials during the main part of a discharge were relatively constant in the early cycles, but discharge potentials tended to decline continually after a negative plate had been cycled repeatedly.

The structure of the active material varied according to the cycling treatment used. The following descriptions refer to the active material in fractured cross sections of negative plates. It was noted that the structure of the surface of a plate was often not representative of the bulk of the active material. This agreed with the results of Pierson *et al.* (3).

Formed plates.—Most of the active material consisted of small Pb particles 2-5 μm in size at the end of the forming charge (Fig. 3). The particles resembled un-

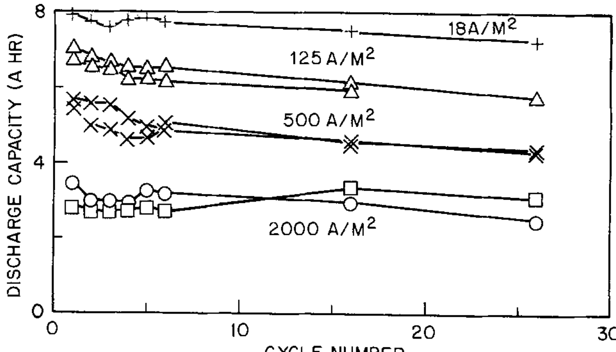

Fig. 1. The results of capacity discharges of negative plates. Discharge rates are given on the curves. Discharges in 1.190 sp gr H_2SO_4 at 2000 A/m^2 are shown by the squares. All other discharges were done in 1.260 sp gr H_2SO_4.

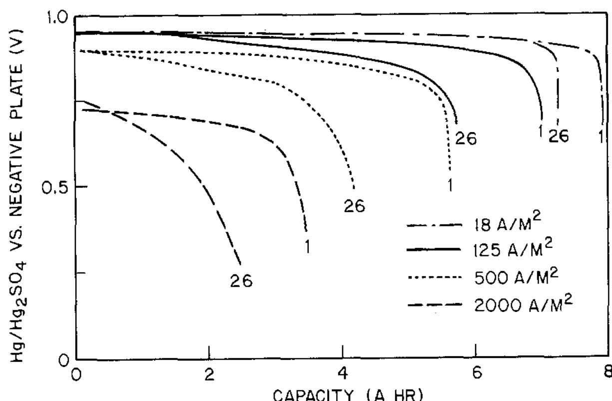

Fig. 2. Discharge potentials measured between the Hg/Hg_2SO_4 reference electrode and the negative plate. Potentials are shown for cycles 1 and 26 at four rates of discharge. The discharge current density used for the negative plate at cycle 1 was repeated in all subsequent cycles.

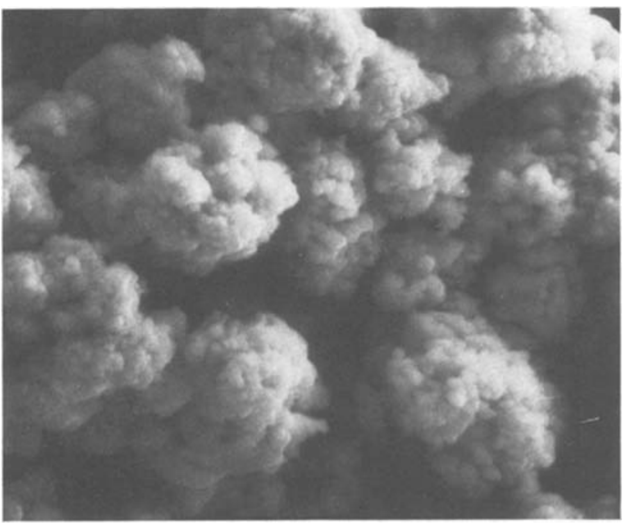

Fig. 3. Lead particles in the negative active material at the end of the forming charge. Magnification 5000×.

even clumps of small, irregular spheres. This shape was believed to result from dendritic growth, but the expander in the active material inhibited Pb from growing in the usual dendritic branches (3, 4). The active material also contained some $PbSO_4$ crystals and small amounts of symmetric clumps of short needles, believed to be Pb. The needle-like crystals were only found at the end of the forming charge. These crystals may be related to platelets reported to have been found among smooth Pb particles in negative plates after the forming charge. These platelets subsequently dissolved preferentially during discharge (2).

Hughel and Hammer (1) showed a negative plate at the end of the forming charge. Their formed plates consisted of particles that were smoother and about half the size of those shown in Fig. 3. The structural difference may result from differences in the manufacturing process or formation conditions.

Discharges at 18 A/m².—At the end of cycle 1 discharge at 18 A/m^2, the 20 hr rate, most of the active material consisted of $PbSO_4$ crystals about 2-7 μm in size, although many particles fell outside this range. The $PbSO_4$ resembled that present after one discharge at 125 A/m^2 (Fig. 4), except the particles were about 1 μm larger when using 18 A/m^2. Discharged plates showed only a slow change in structure with cycling. Large $PbSO_4$ crystals were found more frequently as the cycling progressed. At cycle 26 over half of the active material consisted of crystals in the 3-8 μm

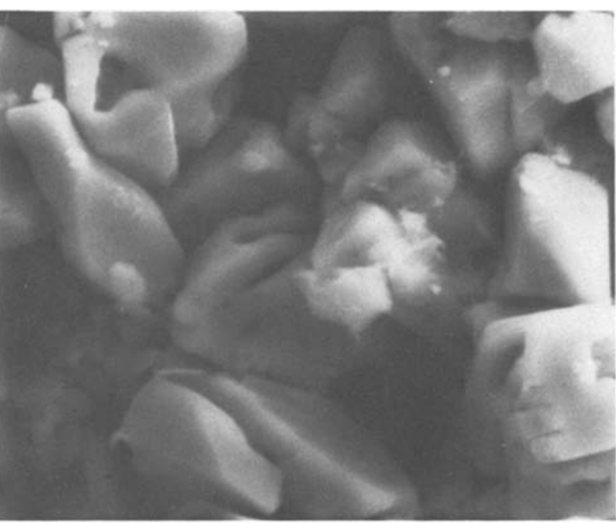

Fig. 4. Crystals of $PbSO_4$ in the negative plate at the end of cycle 1 discharge at 125 A/m^2, the 2.5 hr rate. Magnification 5000×.

range, although many crystals had grown to 10-20 μm and some were only 0.5-2 μm. The Pb in a charged plate was never completely converted to $PbSO_4$ during a discharge. The quantity of Pb present at the end of a discharge increased with cycling.

Discharges at 125 A/m².—Most $PbSO_4$ crystals were about 2-5 μm in size after cycle 1 discharge at 125 A/m^2, the 2.5 hr rate (Fig. 4), although many particles were as small as 1 μm or as large as 7 μm. The $PbSO_4$ crystals often contained holes. It was again found that crystal size slowly increased with cycling. At cycle 26 the $PbSO_4$ crystals were up to 10-15 μm in size, although many still were 2-5 μm. The structure shown in Fig. 4 is much the same as given by Weininger (6) after a negative plate had been given 163 cycles at 60 A/m^2.

Discharges at 500 A/m².—In general, a typical $PbSO_4$ particle was only half as large when it developed at 500 A/m^2, the 0.5 hr rate, as it was at 125 A/m^2. The most common $PbSO_4$ crystal size fell in the range 0.5-3 μm at cycles 1, 6, and 16, although the amount of $PbSO_4$ having a size greater than this gradually increased. Many particles up to 5 μm were present at cycle 16.

A large number of small Pb particles remained at the end of these discharges, with their size generally under 1 μm. Optical microscopy of the polished cross sections of a plate indicated that a higher proportion of Pb remained at the end of a discharge than one would assume judging only by the results of scanning electron microscopy. Much of the Pb was surrounded by $PbSO_4$ and was not visible when broken pieces of a plate were examined by SEM. The cross sections also gave a better idea of the way that porosity increased with cycling.

Discharges at 2000 A/m².—Most $PbSO_4$ crystals in the negative active material were between 0.4 and 2 μm after one discharge at 2000 A/m^2, the 5 min rate (Fig. 5). Some crystals were as small as 0.2 μm or as large as 4 μm. These crystals that were produced at 2000 A/m^2 were noticeably smaller than those that developed at 500 A/m^2, and much smaller than those that developed at 18 or 125 A/m^2 (Fig. 4). Average $PbSO_4$ crystal size tended to increase as the plate was cycled. Crystals in the 2-5 μm size range had become common at cycle 16, although most $PbSO_4$ crystals were still smaller than 2 μm. A large proportion of the active material was still in the charged form of metallic Pb at the end of a discharge at 2000 A/m^2, since this

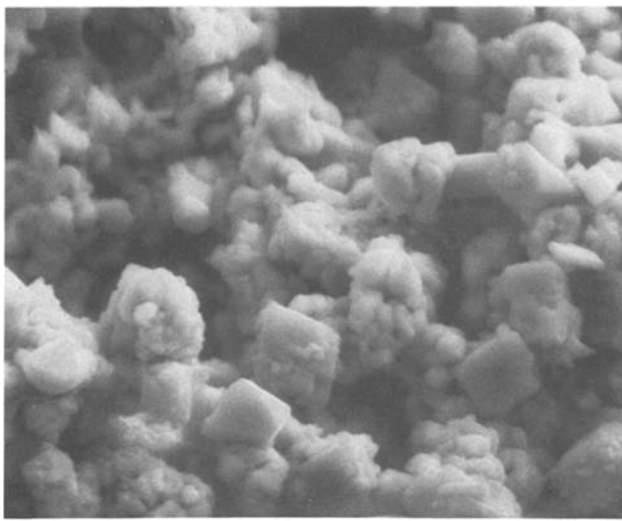

Fig. 5. Crystals of $PbSO_4$ at the end of cycle 1 discharge at 2000 A/m², the 5 min rate. Compare with Fig. 4 to see the effect of discharge rate. Magnification 5000×.

rate gave much less discharge capacity than the other discharge rates.

Charged plates.—The type of irregular Pb surface present after the forming charge (Fig. 3) was never found in cycled active material. After the first discharge, all subsequent charges gave Pb particles that were smoother than those obtained in the forming charge. Typical Pb particles after cycle 6 charge were 1-3 μm in size when the active material had been discharged at 18-500 A/m². These particles were quite irregular in shape, with surface features rounded rather than angular, and they often contained hollows or caves. As cycling continued there was no great change in the appearance of the charged active material, although when using discharges of 18 or 125 A/m² the size of the Pb clumps had increased to 1-4 μm at the end of cycle 27 charge and the surface was a little smoother (Fig. 6).

The Pb often contained holes of 0.2-1 μm diam, corresponding to the holes found in some $PbSO_4$ particles at the end of discharges. Although the Pb did not usually take the angular shapes of $PbSO_4$ crystals, it did keep enough of the shape that a large hole in a $PbSO_4$ crystal could be maintained. Lead particles with angular shapes were found most often when using 18 A/m² as the discharge rate, the rate producing the largest $PbSO_4$ crystals. The electrolyte space between particles gradually increased as the plate was cycled and became thicker or expanded.

Fig. 6. Lead particles at the end of cycle 27 charge of a negative plate always discharged at 125 A/m². Magnification 5000×.

When all discharges were done at 2000 A/m², much of the Pb in the charged active material consisted of irregular clumps of small, rounded particles (Fig. 7). The small size of the Pb was the result of the particles developing from small $PbSO_4$ crystals such as those shown in Fig. 5. As the cycling continued, there was some tendency for these Pb clumps to grow together and become a little smoother.

Scattered crystals of $PbSO_4$ were often found among the Pb in a charged plate. In some places large patches of $PbSO_4$ remained. The amount of $PbSO_4$ in the charged plates increased with cycling. The size of typical $PbSO_4$ crystals remaining at the end of cycle 27 charge was 5-10 μm for a plate always discharged at 125 A/m² and 7-15 μm for a plate always discharged at 18 A/m². The disappearance of most of the smaller $PbSO_4$ crystals during a charge indicates that these are more easily reduced to Pb than are the large crystals.

Acid concentration.—All results reported up to this point were with H_2SO_4 that was about 1.260 sp gr at the end of a charge. Since the test cells contained excess electrolyte, acid concentration did not decrease as greatly during discharges as it does in cells having the usual configuration. The results in the test cell could differ greatly from results in a typical lead-acid battery if a lower acid concentration at the end of a discharge has a strong effect on morphology.

In order to see the effect of a more dilute acid, one negative plate was cycled in 1.190 sp gr H_2SO_4 using 2000 A/m² as the discharge current. This is the approximate acid concentration for an automotive starting battery that is half discharged and would be closer to the average concentration in a typical battery during discharge. When the results in 1.190 sp gr were compared to the results in 1.260 sp gr, there was no significant difference in the appearance or size of $PbSO_4$ at the end of discharges nor of Pb at the end of charges. Thus the change in acid concentration did not have a strong effect on morphology and the results in the test cell were comparable to results in a typical lead-acid battery. The most noticeable effect was that discharge capacity in the first six cycles was a little lower in 1.190 H_2SO_4 (Fig. 1). This capacity difference may not be significant, since Fig. 1 shows that two plates cycled in 1.260 H_2SO_4 could give as much variation. According to the results of Gillibrand and Lomax (10) capacity should increase as H_2SO_4 concentration decreases.

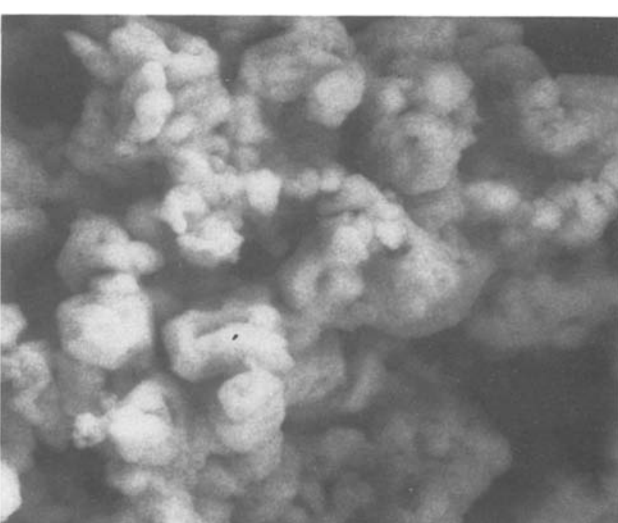

Fig. 7. Lead particles at the end of cycle 16 charge. This negative plate was always discharged at 2000 A/m². Compare with Fig. 6 to see how discharge rate affects structure of charged active material. Magnification 5000×.

Surface area.—The active material had too low a surface area to give high reproducibility with the Micromeritics surface area analyzer. Table I gives results from cycled negative active material. Most values in Table I are averages of four measurements. Repeated measurements of the same sample often varied by as much as 10% from the average of these measurements. Five to nine measurements were made of the few samples with the highest variation. At least 16 measurements were made before reporting a value below 0.1 m^2/g. Since measurement accuracy decreased greatly as surface area decreased, values reported in Table I as being under 0.1 m^2/g should only be regarded as an indication that surface area was low.

The results in the top half of Table I show that surface area of discharged negative active material increased as discharge current density increased. This agrees with the results of microscopic examination given above where the average crystal size of $PbSO_4$ decreased as current density increased (see Fig. 4 and 5). No significant change in surface area was detected after repeated cycling at any of these rates.

The unformed negative active material had a surface area of 0.82 m^2/g. Surface area dropped to 0.23 m^2/g at the end of the forming charge at 40 A/m^2 in 1.200 sp gr H_2SO_4. Although the four discharge rates produced different surface areas, these differences became somewhat obscured by the time a charge had been completed, since all recharges were made using the same 31.25 A/m^2 current density. The low surface area produced by discharges at 18 or 125 A/m^2 resulted in a low surface area for charges that followed these rates (Table I). The sample taken at cycle 16 charge when all discharges were done at 125 A/m^2 apparently was not representative of the active material. The value of 0.39 m^2/g was unacceptably large compared to all other samples of charged plates. None of the other recharged samples had surface areas quite as large as the 0.23 m^2/g observed after the forming charge. This agrees with the observation given above that a recharged plate contained smoother Pb particles than had been obtained in the forming charge.

The values for surface area reported in the literature seem to depend somewhat on the measurement method. A dye adsorption method gave 0.3 m^2/g for a charged negative (11). The BET method gave 0.3-0.5 m^2/g in a study of the effect of several expanders, and surface area decreased a little with cycling (12). Other work found that the BET surface area remained fairly constant at values between 0.3 and 0.4 m^2/g during the life of a battery (13). A radioactive method of measuring surface area agreed there was little change with cycling but gave much lower values, reporting a gradual decrease from 0.06 m^2/g at cycle 10 to 0.05 m^2/g at cycle 100 (14). The present work confirmed that surface area did not change appreciably with cycling, but found values a little lower than those usually reported.

Porosity.—As the negative plates were cycled an increasing number of large voids appeared in the active material and the plates gradually expanded. At the end of cycling the plates were about 30-50% thicker than the original size. Since the active material softened considerably during the cycling, it gradually became easier for active material to be deformed by the hydrogen bubbles that formed during a charge (5). Expansion of the negative plates would have been more limited if the plates had been under some pressure, as usually occurs in a tightly packed cell case, and fewer large voids would have formed.

The image analyzer was used to determine porosity of the negative active material. The values given in Table II are averages of 15-25 measurements of void space made during a continuous series of adjoining views at 1350× magnification in steps about 0.086 mm wide extending from one surface of a plate to the opposite surface. The number of views increased as a plate gradually became thicker when cycled. Areas were chosen that did not include the large voids that had developed. Porosity increased as the plate expanded, since the amount of active material per unit of volume decreased.

Although the two plates that were examined at the end of forming charges (Table II, cycle 1) had been treated similarly, the active material of one gave 43% and the other 48% porosity. This suggests that the difference between porosity of the various charged plates may be partly due to differences in the original plates, as well as being an effect of discharge current density.

Discharged plates showed less porosity than charged plates. This was caused by the $PbSO_4$ that formed during a discharge occupying a larger volume than the Pb in a charged plate. Since more $PbSO_4$ formed during the slower discharges, porosity of discharged active material decreased as discharge current decreased.

Active material composition.—The image analyzer was used to obtain values for composition of the negative active material. A magnification of 2700× was used after discharges at 2000 A/m^2 because of the large number of small particles present. Magnification was 1350× for discharges at all other rates. The composition values shown in Fig. 8 are averages of 15-35 measurements made in a continuous series from one surface to the other. Different areas of a plate usually showed large variations in composition. Therefore, the values in Fig. 8 could differ by several percent if the measurements had been made in different areas.

Another source of uncertainty was caused by the shades of lightness or darkness of the three phases (Pb, $PbSO_4$, and void spaces) in the active material not differing sufficiently. One could not choose thresholds between these shades and be certain that the image analyzer would detect all of one phase while not detecting any part of another phase. Although the absolute values were uncertain, the trends in Fig. 8 were believed to be significant since the same threshold settings were used for a series of samples, and all results should be biased in the same direction.

The amount of $PbSO_4$ that formed during a discharge decreased as current density increased (Fig. 8), since discharges gave decreasing capacity at higher currents. Figure 8 also shows that the amount of $PbSO_4$ present in a discharged plate decreased slowly with cycling.

Table I. BET specific surface areas of the negative active material, given in m^2/g. Values under 0.1 are dubious

Condition	Discharge rate (A/m^2)	Cycle 1	Cycle 6	Cycle 16	Cycle 26
Discharged	18	0.02	0.11	0.03	0.00

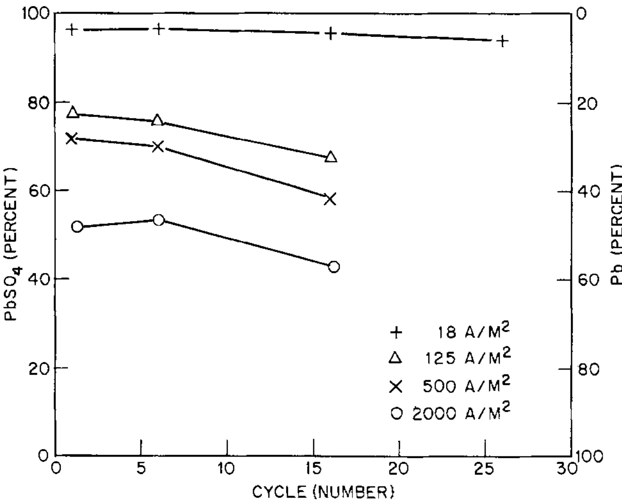

Fig. 8. Composition of negative active material at the end of discharges at 18, 125, 500, or 2000 A/m². The plates were recharged at 31.25 A/m². Composition was measured with an image analyzer.

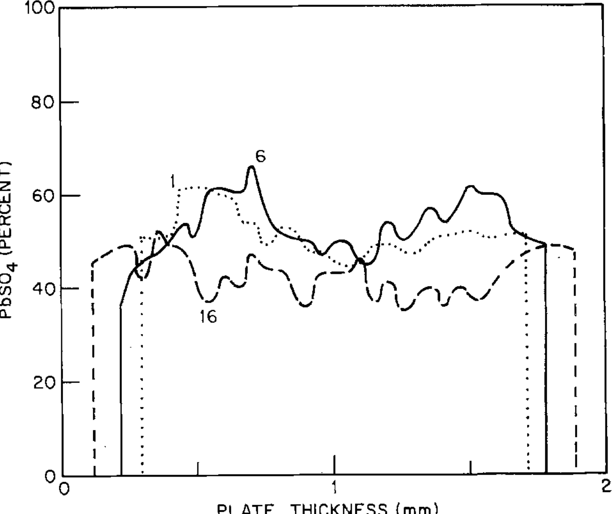

Fig. 9. Distribution of $PbSO_4$ at cycles 1, 6, and 16 in a negative plate that was always discharged at 2000 A/m². The plates are centered at 1 mm on the thickness scale.

The opposite effect occurred in charged plates. At the end of the forming charge (cycle 1) the active material was close to 100% Pb. Samples of active material examined after cycle 26 charge contained 1-10% $PbSO_4$. These changes in charged and discharged plates that occur with cycling may be caused by a gradual worsening of contact within the active material, isolating some active material from the electrochemical reactions. A gradual decrease in surface area could also bring about similar changes but surface area did not change with cycling (Table I).

Although random areas of high or low $PbSO_4$ concentration were common in the active material, there was no significant difference between the average of $PbSO_4$ concentrations measured in areas near the surface and average concentration in the center of plates discharged at 18-500 A/m². This agrees with the results of Panesar and Portscher, who reported an even distribution of $PbSO_4$ after discharges at 15-300 A/m² for negative plates 1.5 mm thick (15). Their plates were approximately the same thickness as the plates in the present work.

Measurements made at the end of cycle 1 and 6 discharges at 2000 A/m² indicated that the $PbSO_4$ concentration was usually a little higher near the plate surfaces than it was near the center. Figure 9 shows the smoothed results of 28-35 consecutive measurements in steps 43×10^{-6}m wide extending from one plate surface to the other surface. A rapid discharge does not allow sufficient time for much additional H_2SO_4 to diffuse into the plate interior after depletion of acid that was present when the discharge began. As the plate gradually expanded with cycling more acid became available in the interior, and an increased $PbSO_4$ concentration near the surface was less evident. Measurements at cycle 16 showed a fairly random distribution of $PbSO_4$ with little difference between plate surface and center. Panesar and Portscher measured $PbSO_4$ distribution after a discharge at 1800 A/m² (15). Their results show the center of a plate having only about 55% as much $PbSO_4$ as the surface areas, a much greater difference than the small variations shown in Fig. 9. Whether or not $PbSO_4$ is highly concentrated at the surfaces after a rapid discharge is probably greatly affected by plate structure. Variation among plates of different manufacturers is to be expected.

Summary and Conclusions

It is commonly accepted that passivation is increased as the size of the crystals forming the passivating barrier decreases. In the present case the change in capacity roughly corresponds to the change in crystal size of the lead sulfate in the range of current densities studied (Fig. 1). The fact that the lead sulfate was evenly distributed from surface to center of the electrode (Fig. 9) also suggests that passivation rather than diffusion might have been the limiting factor in determining the available capacity.

On the other hand, the effects noted on the negative plate potential with increasing current density indicate that the diffusion rate was a factor. While the knee in the polarization curve might be indicative of passivation, the change in the initial portion of the curve at different current densities must be the result of limiting diffusion rates (Fig. 2). The change in the polarization curve between the 1st and 26th cycles indicates the introduction of another resistive factor, probably reduced contact areas between the crystals as a result of the repeated cycling.

Reduced contact area would also appear to be a logical consequence of the increased porosity noted as cycling progressed. This increased porosity was probably a result of using a lignin derivative and $BaSO_4$ in the formulation of the commercial plates that were used. This expander material also prevented an increased size differential for the lead sulfate crystals at the different current densities employed.

Cobalt and Nickel Cations as Corrosion Inhibitors for Galvanized Steel

Henry Leidheiser, Jr.* and Ichiro Suzuki[1]

Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015

ABSTRACT

Gravimetric measurements on galvanized steel and cathodic polarization curves indicate that corrosion of zinc in 3% NaCl is inhibited by a low concentration of cobalt ions in solution or by simple predipping of the zinc in 0.05 or 0.1M solutions of $CoCl_2$. Corrosion inhibition is also obtained when zinc is predipped in a nickel acetate solution and nickel ions are present in the NaCl solution. The corrosion inhibition is attributed to the introduction of electron traps (cobalt or nickel atoms) in the oxide on the surface of zinc which lead to inhibition of the cathodic reaction, $H_2O + \frac{1}{2} O_2 + 2e^- = 2\, OH^-$. When the concentration of elemental cobalt or nickel in or on the oxide becomes too great, the cathodic reaction, $2H^+ + 2e^- = H_2$, is catalyzed and corrosion activation occurs.

Galvanized steel (a coating of zinc on a steel substrate) is a very effective corrosion protective system under atmospheric exposure conditions. The zinc corrodes at a relatively low rate and it provides galvanic protection to the steel substrate at points where the steel is exposed. Longer system lifetimes would be possible if the zinc corroded at a lower rate under those conditions where the steel was not exposed. It has been pointed out previously (1) that greater system lifetimes should be possible if the oxide film on the surface of the zinc could be made a less effective catalyst for the cathodic reaction, $H_2O + \frac{1}{2} O_2 + 2e^- = 2\, OH^-$ The purpose of the present study was to seek effective inhibitors for the cathodic reaction on zinc. The experiments have been very successful and this article outlines the inhibiting properties of cobalt and nickel cations and gives a tentative interpretation of the corrosion inhibiting mechanism.

Attention was focused on cobalt and nickel ions as inhibitors on the basis of a preliminary screening using zinc cathodic polarization curves obtained in aerated 3% NaCl solution to which various cations were added. The decision to focus initially on cobalt was reinforced by the fact that a recently introduced commercial electrogalvanized steel contains a small concentration of cobalt and the claim has been made that the corrosion rate was greatly decreased (2, 3). Cobalt and nickel species are also constituents in proprietory commercial pretreatment baths used for developing corrosion resistance at the paint/metal interface. A parallel study of the chemical state of cobalt in electrogalvanized steel (4) provided additional background and incentive for the present study. The addition of nickel to electrogalvanized steel is also claimed to reduce the corrosion rate of zinc (5-9).

Key words: corrosion, inhibition, cobalt, nickel, galvanized steel.

Experimental Procedure

Corrosion rate measurements were carried out on the galvanized steel samples described in Table I. All of the reported measurements made with cobalt and nickel ions were carried out with sample L-6 since there was available a large supply of this material. The thickness of the zinc coating was also great enough that the chances of exposing the steel substrate during polishing were less. Another advantage of the L-6 samples was the 70% (0001) orientation, a representative value for many lots of hot-dipped galvanized steel. Orientation determinations were made by the method previously described by Kim and Leidheiser (11). A sufficient number of experiments was carried out with different samples of galvanized steel to be confident that the results apply generally, although the degree of the corrosion inhibition may be a function of the composition of the zinc coating. No specific experiments to explore this variable were conducted.

The majority of cathodic polarization curves was determined on single crystals of 99.999% pure zinc cut to expose the (0001) plane. The zinc crystals were ob-

Q-3	60%	20	490	1.1
T-22	50%	21	570	2.9

tained from Prof. Robert Pond of Johns Hopkins University in the form of cylindrical rods and were cut in the form of disks with surfaces parallel to the (0001) plane.

The galvanized steel samples used in the corrosion experiments were smoothed with No. 400 and No. 600 emery papers, followed by high-gloss polishing with alumina powders of 1 and 0.6 μm size. One side of the galvanized steel and all edges were covered with a vinyl adhesive tape and the exposed zinc was 20 cm^2 in area. Two samples were exposed to 200 ml of liquid in each reaction vessel. The panels were placed horizontally on the bottom of the vessel such that the liquid was 4.5 cm in depth. At the conclusion of the experiment, the panels were carefully abraded with a soft brush to remove any adhering corrosion product.

The polarization curves were determined on mechanically polished zinc single crystals. They were polished in much the same manner as the galvanized steel samples except that the final polishing step used diamond powder in place of the alumina. The crystals were mounted in an epoxy resin manufactured by the Woodhill Permatex Company and were used in the mounted condition.

Cathodic polarization curves were determined by manually increasing the potential at a rate of 20 mV/min. The counterelectrode was graphite and the cell was constructed with a fritted glass membrane in order to separate the solution and the cathode from any oxygen generated at the anode.

In some of the experiments, the zinc samples were preimmersed in solutions of cobalt chloride or nickel acetate. After immersion in the cobalt or nickel ion solutions, the zinc was heated at 80° for approximately 2 hr before immersion in the sodium chloride test medium. The effects of cobalt and nickel apparently were not dependent upon this heat-treatment since similar results were obtained on zinc that was simply dried in air before immersion in the sodium chloride test solution. The *p*H's of the cobalt and nickel ion solutions were as follows: $CoCl_2$ solutions: 1M, 4.0; 0.5M, 4.35; 0.1M, 4.65; 0.05M, 5.05; 0.01M, 5.60; Ni acetate solutions: 0.5M, 6.05; 0.1M, 6.70; 0.05M, 6.80; 0.01M, 6.70; 0.005M, 6.45.

Experimental Results

The corrosion rates of many different samples of galvanized steel were determined in 3% sodium chloride and 3% sodium sulfate solutions under the standard procedure described. Representative data are summarized in Table II. It will be noted that the corrosion rates of the 10 different samples were approximately the same, averaging 0.34 mg/cm^2/day in the 3% NaCl and 0.28 mg/cm^2/day in the 3% Na_2SO_4. Typical cathodic polarization curves for a zinc single crystal in the absence and presence of stirring are given in Fig. 1 and a comparison of polarization curves obtained in aerated and deaerated solutions is given in Fig. 2. The method of generating the polarization curves in the aerated and deaerated solutions was slightly different in that the aerated curve was obtained in a quiescent

solution and the deaerated curve was obtained in a solution which was slightly agitated by the passage of a stream of nitrogen through a porous thimble. This difference in procedure probably accounts for the higher current density at the more negative potentials in the case of the curves obtained in the deaerated solutions. As described in more detail later, these data suggest that the rate-controlling step in the corrosion of zinc under these conditions is the cathodic reaction, $H_2O + \frac{1}{2} O_2 + 2e^- = 2\,OH^-$. The rate of corrosion of galvanized steel samples in deaerated solutions of 3% NaCl was 0.01 mg/cm^2/day indicating that a small fraction (about 3%) of the total corrosion was a consequence of the alternate cathodic reaction, $2H^+ + 2e^- = H_2$.

A survey was made of the effect of various ions added to the NaCl solution on the corrosion rate of galvanized steel using both gravimetric measurements and cathodic polarization curves. The ions that were surveyed included barium, cadmium, cobalt, lead, manganese, nickel, tin, and strontium. As a result of this survey, cobalt and nickel were selected for intensive study. The experiments with cobalt and nickel will be described separately because of the slightly different approaches used.

Cobalt ions as inhibitors.—Cathodic polarization curves are given in Fig. 3 for zinc single crystal samples that were dipped in various concentrations of $CoCl_2$ solution for 30 sec, washed in a stream of water, dried in air at 80°C for approximately 2 hr, and the polarization curve then determined in 3% sodium chloride solution. It will be noted that the cathodic current was significantly lower at potentials of −1.06 to −1.2V

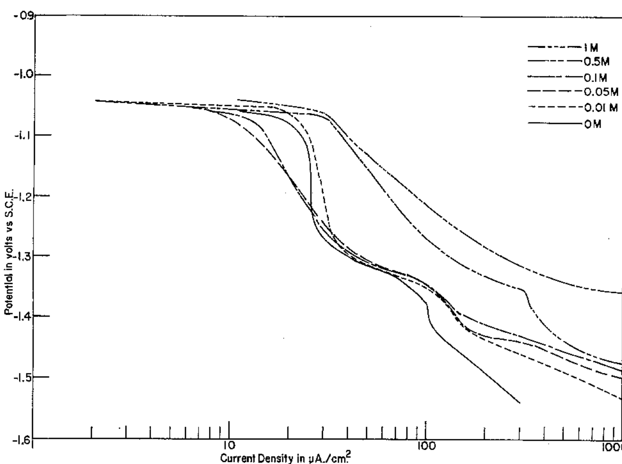

Fig. 3. Cathodic polarization curves for zinc single crystals immersed in 3% NaCl solution. Zinc samples were immersed for 30 sec in cobalt chloride solutions prior to determining the polarization curves. See text for details.

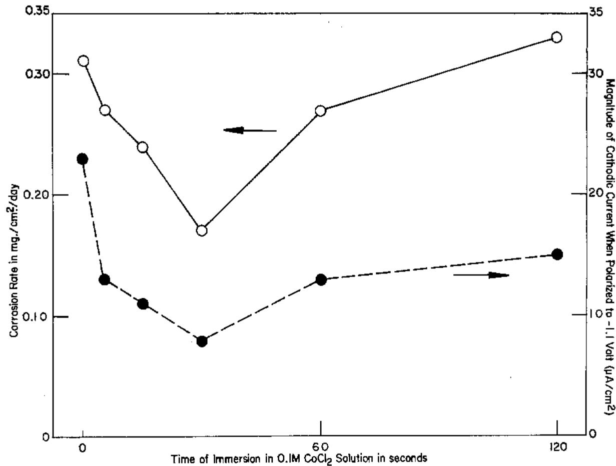

Fig. 5. The corrosion of galvanized steel (solid curve) and cathodic polarization current at −1.10V *vs.* SCE of zinc single crystal (dashed curve) after dipping in 0.1M $CoCl_2$ solution for different times prior to immersion in 3% NaCl solution. Note similarity in shape of curves.

for the samples that were dipped in 0.05M and 0.1M $CoCl_2$ solutions prior to obtaining the cathodic polarization curve. At potentials more negative than −1.3V the cathodic current was greater than the blank for all the $CoCl_2$ concentrations from 0.01 to 1M.

Figure 4 summarizes corrosion rate data for galvanized steel and gives the cathodic current at −1.10V for zinc single crystal samples that were predipped in cobalt chloride solutions. The gravimetric data and the cathodic polarization current data are complementary and indicate that a low corrosion rate is obtained when zinc is predipped in solutions of 0.05 and 0.1M $CoCl_2$ prior to immersion in the NaCl solution. Figure 5 gives corrosion rate and cathodic polarization current data for zinc materials predipped in 0.1M $CoCl_2$ for various periods of time before immersion in the 3% NaCl. As seen in Fig. 5 the two types of data give parallel results and the optimum time of predipping in the $CoCl_2$ solution is 30 sec.

The results of a series of experiments carried out in deaerated 3% NaCl are given in Fig. 6, where it will be noted that the corrosion rate and cathodic corrosion current at −1.15V increase with increase in concentration of $CoCl_2$ in the solution in which the zinc samples are predipped. At the two higher concentrations, 0.5 and 1.0M, the surface exhibited blackening that suggested the formation of metallic cobalt on the surface. No blackening was observed at the lower $CoCl_2$ concentrations. Cathodic polarization curves obtained in deaerated solution are summarized in Fig. 7.

A few experiments were also carried out in which galvanized steel was exposed to 3% NaCl solution which contained additions of $CoCl_2$ such that the Co^{++} ion concentration was in the range of 10^{-5} to 10^{-2}M. In these experiments there was no predipping of the zinc in Co^{++}-containing solutions; the cobalt was present only in the corrosion test medium. Results of these experiments are summarized in Fig. 8 where it will be noted that slight corrosion inhibition was obtained at 10^{-5} and 10^{-4}M concentrations of Co^{++} and strong activation of corrosion was obtained at 10^{-3} and 10^{-2}M concentrations of Co^{++}. At the higher concentrations a black coating, which appeared to be finely divided metallic cobalt, formed on the surface.

Samples of zinc dipped for 30 sec in cobalt chloride solutions of 0.01, 0.05, 0.1, 0.5, and 1.0M were examined by x-ray photoelectron spectroscopy (XPS). Elemental cobalt is characterized by two peaks representing binding energies of 778 and 793 eV whereas CoO is characterized by 4 peaks with binding energies of 780.0 and 795.5 eV plus two satellite peaks at 787 and 804 eV. In all cases the predominant spectrum of the unsputtered surface was that characteristic of a cobalt

oxide, probably CoO (12). Sputtering of the superficial oxide resulted in the formation of a spectrum consisting of both ionic cobalt and elemental cobalt (13). Examples of the spectra are shown in Fig. 9 and 10. Figure 9A is a spectrum of the sample dipped in 0.05M $CoCl_2$. The two major peaks ($2p_{3/2}$ and $2p_{1/2}$) approximate those characteristic of CoO and the two minor peaks are the so-called "shake-out" satellite peaks. After sputtering away the surface layer, the spectrum shows elemental cobalt as a major component and ionic cobalt as a second component (Fig. 9B). In the case of the most concentrated solution, the major component is elemental cobalt after sputtering etching but ionic cobalt can also be seen (Fig. 10B). After a

Top spectrum (A) is before sputterng and bottom spectrum (B) is after superficial sputtering. Note the increase in intensity of the elemental cobalt peaks at 778 and 793 eV after sputtering.

second sputtering, the ionic cobalt decreased to a very low level and the total spectrum was largely due to elemental cobalt as seen in Fig. 10C.

Qualitative information concerning the amount of cobalt present on the surface of zinc after exposure to cobalt chloride solutions was obtained using Auger spectroscopy. The spectra were obtained over an energy range of 0-1200 eV and the ratios of the amounts of zinc, cobalt, and oxygen in the surface region were obtained approximately from measurements of peak-to-peak values. Data for oxygen/cobalt ratios are given in Fig. 11 and data for zinc/cobalt ratios are given in Fig. 12 as a function of the cobalt chloride concentration in the pretreatment solution. These data along with the XPS data of the type shown in Fig. 9 and 10 indicate that the cobalt concentration in the zinc oxide increased with increasing cobalt concentration in the pretreatment solution. The oxygen/cobalt ratio and the zinc/cobalt ratio also both decrease with increase in the cobalt concentration in the pretreatment solution.

Nickel ions as inhibitors.—Experiments similar to those carried out with cobalt were executed with nickel ions. Galvanized steel panels were dipped in solutions of nickel acetate ranging in concentration from 0.005 to 0.5M for 60 sec, the surface was washed in a stream of water, the panels were heated at 80°C for 1-2 hr, and they were then immersed in 3% NaCl solution open to the air for 24 hr. The data, summarized in Table III, indicate that there was no significant corrosion inhibition at any concentration and slight corrosion activation at an Ni^{++} ion concentration of 0.5M. These results were very puzzling in view of the fact that the cathodic polarization curves, shown in Fig. 13, suggested that corrosion inhibition of the same order of magnitude as with cobalt was to be expected. The major difference between corrosion rates determined gravimetrically and those estimated qualitatively from the cathodic polarization curves is the time of exposure of the sample to the corrosive medium. The polarization curve data were obtained on samples that were exposed to the test medium, at the low overvoltages, for less than 1 hr, while the gravimetric measurements were obtained on samples exposed for 24 hr or more. When this fact was recognized, it suggested that the nickel was probably rapidly leached out of the oxide

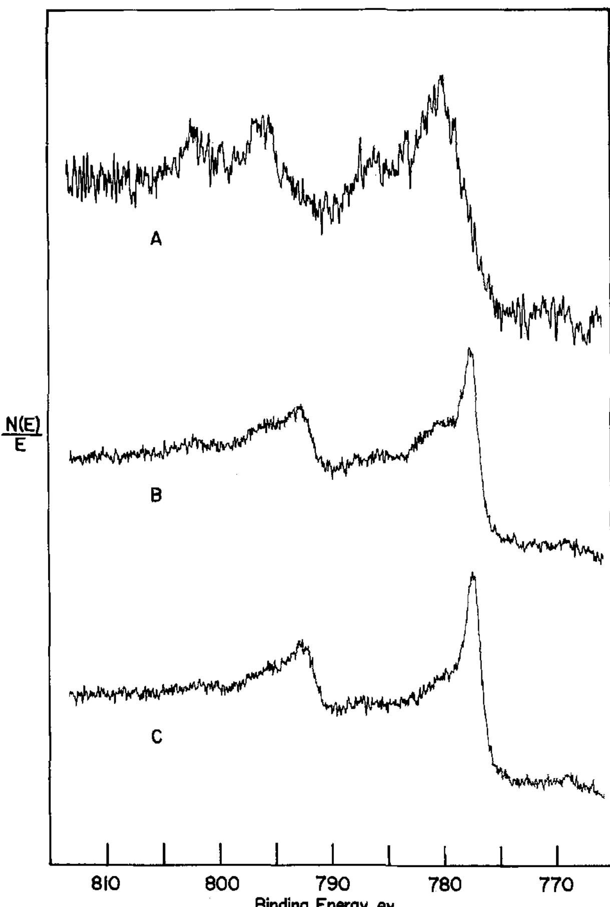

Fig. 10. XPS spectra of zinc single crystal that had been dipped in 1M $CoCl_2$ for 30 sec and dried at 80°C. coating on the zinc. The following experiments were then performed.

The galvanized steel panels were dipped in 0.01M nickel acetate solution for 15 sec, washed in a stream of water, dried in a warm air stream, and weighed. They were then immersed in 3% NaCl solution containing nickel ion concentrations of 0.0001, 0.0005, and 0.001M and exposed for 24 hr. Results are summarized in Table IV. It is apparent that good corrosion inhibition was obtained in the case of predipping in the nickel acetate solution and exposing to the 3% NaCl solution which contained 0.0005M Ni^{++}.

Discussion

The major experimental facts resulting from this study may be summarized as follows.

1. Predipping zinc in solutions of cobalt salts of the proper concentration for 15-60 sec results in a lower corrosion rate in 3% sodium chloride solution. The corrosion inhibiting effects last for a minimum of 2 days.

2. Cobalt ions at low concentrations are corrosion inhibitors for zinc in 3% NaCl.

3. Cathodic polarization curves of zinc previously exposed to low concentrations of cobalt or nickel ions indicate inhibition at low cathodic overvoltages and activation at high cathodic overvoltages.

4. Predipping zinc in concentrated solutions of cobalt chloride leads to corrosion activation in both aearated and deaerated solutions of NaCl.

Ni^{++} ion concentration in NaCl solution	Corrosion rate during 24 hr exposure
0	0.33 mg/cm²/day
0.0001	0.16
0.0005	0.026
0.001	0.23

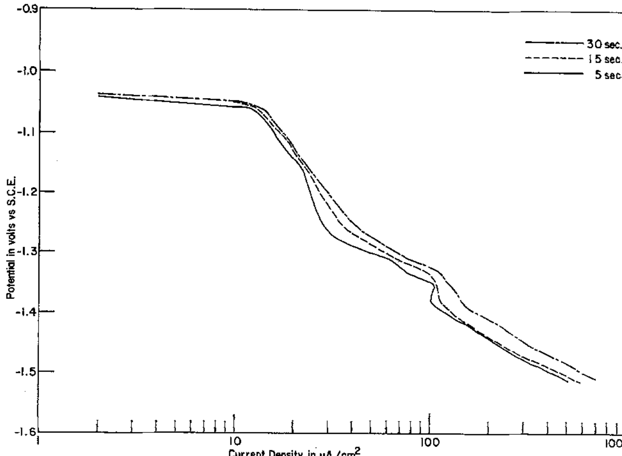

Fig. 13. Cathodic polarization curves for galvanized steel samples immersed in 0.05M nickel acetate solutions for 5, 15, and 30 sec before polarization in 3% NaCl solutions.

5. Dipping zinc into 1.0M $CoCl_2$ solution leads to a significant amount of elemental cobalt on the surface. Dipping zinc into 0.05M $CoCl_2$ solution leads to the formation of minor amounts of cobalt in both the ionic and elemental form.

6. Predipping zinc in solutions of nickel acetate does not result in long-term corrosion inhibition.

7. Predipping zinc in solutions of nickel acetate, followed by immersion in NaCl solutions containing low concentrations of nickel ions, leads to a high degree of corrosion inhibition.

It is the purpose of the remarks that follow to explain these results.

The majority of the experiments reported herein were carried out in 3% sodium chloride solution and it must be recognized that the conclusions made herein apply to this electrolyte. However, sodium chloride is utilized as a test medium in many accelerated tests and there is a body of practical experience that suggests that the behavior of materials in a sodium chloride environment can be generalized to apply to many types of atmospheric exposure. It is believed that the conclusions drawn below should apply in many different environments.

Experiments reported previously (1) have shown that an oxide (or hydrated oxide) coating forms on zinc when immersed in sodium chloride solution open to the air. This oxide coating becomes approximately 50Å thick after 1-2 min immersion and develops a steady-state film thickness of the order of 75-150Å in about 5 min. The oxide is reducible as shown by a reduction peak at approximately −1.3V. The exact values obtained for the rate of growth of the oxide, the steady-state film thickness, and the potential at which the reduction peak occurs are all a function of particular lots of galvanized steel.

Predipping galvanized steel in an aqueous solution containing cobalt ions results in the incorporation of cobalt in, or on, the oxide which is present on the surface of the zinc. The chemical nature of the cobalt was ascertained from the XPS spectra. All samples that had been predipped in cobalt chloride solutions exhibited a spectrum characteristic of CoO. Superficial sputtering caused the majority of the ionic spectrum to disappear in the case of samples dipped in the more concentrated solutions. Presumably the CoO spectrum was largely a consequence of reaction of the metallic cobalt with air during the period between removal from the $CoCl_2$ solution and insertion into the spectrometer. In the case of samples immersed in the lower concentration solutions, such as 0.05M $CoCl_2$, the spectrum after sputtering was characteristic of a mixture of divalent cobalt and elemental cobalt, as shown for example in Fig. 9. The concentration of cobalt at the surface was relatively low as indicated by the noisy nature of the spectrum.

It is concluded that predipping of the zinc in solutions containing high concentrations of Co^{++} (0.5 and 1.0M) leads to the formation of a large amount of elemental cobalt on the surface. This conclusion from the XPS studies is in agreement with the data shown in Fig. 3 and 4 where the surface is very active for the cathodic reaction. At the lower concentrations of Co^{++} in the pretreatment solutions, it appears that the cobalt is present in or on the surface of the zinc oxide in both the elemental and ionic form. This conclusion must be considered tentative since the analytical procedure itself may cause valence changes in the cobalt on the surface.

The corrosion rate data summarized in Table II, the large effect of stirring on the current density of the plateau in the cathodic polarization curve, and the negligible rate of corrosion of zinc in deaerated NaCl all lead to the conclusion that the cathodic reaction in aerated solutions includes oxygen and is in all probability

$$H_2O + \tfrac{1}{2} O_2 + 2e^- = 2\,OH^-$$

This reaction is the dominant cathodic reaction, but the corrosion rate in deaerated solution (Fig. 6) suggests that the competing cathodic reaction, $2H^+ + 2e^- = H_2$, accounts for approximately 3% of the total cathodic reaction. Although no study was undertaken, it is likely that the relative ratio of these two cathodic reactions is a function of the impurity content and perhaps crystallographic nature of the zinc.

The surface of a typical galvanized steel is a very effective catalyst for the water-oxygen reaction under the conditions used in these experiments and the rate is determined by concentration polarization, either the rate at which oxygen reaches the surface or the rate at which the OH^- ions can diffuse away from the surface. This conclusion is borne out by the fact that stirring has a great effect on the cathodic polarization curve (Fig. 1) and that the corrosion rates of a number of galvanized steel samples were approximately the same as shown by the data in Table II. It thus appears that the corrosion rate of galvanized steel is limited by a diffusion process in the aqueous phase and is not limited by the availability of electrons for the cathodic reaction.

The proposed mechanism for corrosion inhibition by cobalt ions will now be given. It is suggested that during the predipping process in cobalt chloride solution, the oxide (or hydrated oxide) film on zinc grows by the mechanism outlined schematically in Fig. 14. The anodic reaction, $Zn - 2e^- = Zn^{++}$, occurs at the zinc/oxide interface and the cathodic reaction, $H_2O + \tfrac{1}{2} O_2 + 2e^- = 2\,OH^-$, occurs at the oxide/solution interface. The oxide thickness at the surface of the zinc reaches a steady-state value determined by the balance between the rate of formation of the oxide (or hydrated oxide) and the rate of dissolution of the oxide in the medium. So long as the concentration of zinc in the chloride solution does not exceed the solubility limit, there is no precipitation of hydroxide and the oxide maintains a steady-state thickness of the order of 100Å. It is through this oxide that the corro-

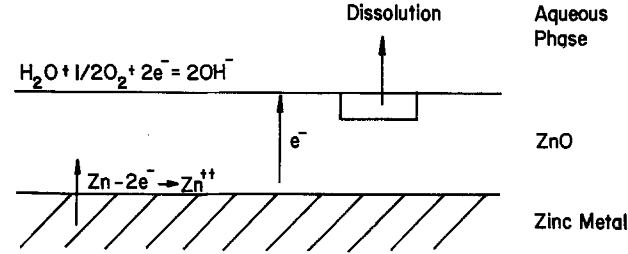

Fig. 14. Schematic representation of the corrosion of zinc in NaCl solution through an oxide film on the surface.

sion process occurs and it is on the surface of the oxide that the cathodic reaction occurs. When the solubility limit of the zinc corrosion product is exceeded, a dynamic process develops in which the corrosion product precipitates at one site and dissolves at another site. The precipitate which forms on the zinc surface may act as a diffusion barrier for species in solution, but presumably it plays no significant role in controlling reactions that occur through the compact oxide present on the zinc surface.

When the zinc samples are dipped in the cobalt chloride solutions, it is proposed that a portion of the total cathodic current that occurs may be represented by the reaction, $Co^{++} + 2e^- = Co$, and that uncharged cobalt atoms are incorporated in the oxide. It is also probable that a certain amount of ionic exchange occurs and that cobalt ions are also incorporated into the oxide by this mechanism. Some of these ionic species may later be converted to elemental cobalt during the corrosion process ($Zn - 2e^- = Zn^{++}$) as the companion cathodic reaction, Co^{++} (in oxide) $+ 2e^- =$ Co(in oxide). This latter reaction is viewed as the electron trapping reaction. In the presence of a sufficient number of trapping sites, the anodic reaction ($Zn = Zn^{++} + 2e^-$) is inhibited because of an excess of Zn^{++} ions in the oxide. Cobalt, at the proper concentration in the zinc oxide lattice, thus reduces the flux of electrons through the oxide to supply charges for the cathodic reaction. At high cobalt concentrations in or on the surface of the oxide, the elemental cobalt aggregates sufficiently to form metallic cobalt in contact with metallic zinc which then serves as an effective catalyst for the competing cathodic reaction, $2H^+ + 2e^- = H_2$.

The fact that the corrosion inhibitive effects are long-lived in the case of cobalt is probably because the equilibrium, Co^{++} (in zinc oxide lattice) $+ 2e^- \rightleftharpoons Co^o$ (in zinc oxide lattice), is shifted strongly to the right such that there are few cobalt ions available to enter the aqueous phase. Cobalt remains in the zinc oxide lattice during the corrosion reaction and it continues to serve as an electron trap. The reaction

$$Co^{++}\text{(in aqueous phase)} \rightleftharpoons Co^{++}\text{(in zinc oxide lattice)}$$

is also shifted very strongly to the right. The net effect is that cobalt atoms remain in the zinc oxide lattice and are not leached out during the corrosion process.

The situation with nickel is different from that of cobalt in that the cathodic polarization curve (taken immediately after immersion in the test electrolyte) indicates corrosion inhibition and the weight loss measurements indicate no significant inhibition. The strong inhibition under those conditions where the zinc is predipped in the nickel acetate solution and the sodium chloride solution contains a low concentration of nickel ions, suggests that the equilibrium

$$Ni^o\text{(in zinc oxide lattice)} \rightleftharpoons Ni^{++}\text{(in zinc oxide lattice)} \rightleftharpoons Ni^{++}\text{(in aqueous phase)}$$

is shifted sufficiently to the right that the nickel ions are leached from the oxide during the corrosion reaction.

Support for the greater stability of Co^{++} ions in the zinc oxide lattice than Ni^{++} ions is found in the relative solubilities of the hydroxides in water. Cobalt hydroxide [$Co(OH)_2$] is soluble to the extent of 0.00032 g/liter in cold water, whereas nickel hydroxide [$Ni(OH)_2$] is 40 times more soluble with a solubility under similar conditions of 0.013 g/liter (14). The solubility data are for water solutions, whereas the corrosion experiments were carried out in 3% NaCl solution, so it is not known if the same relative solubilities apply in the chloride medium.

The cathodic polarization curves shown in Fig. 3 are consistent with all other observations made during the study. Samples dipped in a solution 0.01M in Co^{++} yielded a polarization curve at potentials more positive than −1.35V very similar to that of the blank. Samples dipped in solutions 0.05M and 0.1M in Co^{++} showed lower cathodic currents than the blank at potentials slightly negative to the rest potential and higher cathodic currents at potentials more negative than −1.35V. The higher cathodic currents at potentials more negative than −1.35V are developed because the oxide film is reduced at this potential and the cobalt present in the oxide remains on the surface of the zinc in the metallic form. The greater catalytic activity of cobalt, as compared to zinc, for the hydrogen evolution reaction results in a higher cathodic current. At potentials more negative than −1.35V the cathodic current increases with increase in concentration of the cobalt chloride solution in which the predipping occurred. Samples dipped in 0.5M and 1.0M $CoCl_2$ gave higher cathodic currents over the entire range of potentials, a result consistent with the fact that the reaction

$$Zn^o + Co^{++} = Zn^{++} + Co^o$$

occurred to such an extent that large amounts of metallic cobalt were present on the zinc surface after predipping. The blackened appearance of the surface and the XPS data support this conclusion.

An alternate explanation of the corrosion inhibition by cobalt and nickel ions which must be considered is the following. Let us assume that the zinc oxide is an excellent catalyst for the cathodic reaction, $H_2O + \frac{1}{2} O_2 + 2e^- = 2\,OH^-$, and metallic cobalt is a good catalyst for the cathodic reaction, $2H^+ = 2e^- = H_2$. The cathodic activity of the surface is then the total of (*i*) the activity for the hydroxyl generation reaction times the surface area fraction of zinc oxide exposed and (*ii*) the activity for the hydrogen evolution reaction times the surface area fraction of metallic cobalt exposed. If the polarization curves for these two reactions on these two different substrates are greatly different, it might be reasonably expected that the measured polarization curve would have a range of shapes such as those shown in Fig. 3 depending upon the relative area ratios. We discard this alternate explanation for the following reasons.

1. It is not likely that alloying zinc with cobalt at concentrations of the order of 0.2% would lead to corrosion inhibition as has been proven experimentally (2). If the cobalt was active as a catalyst, it would be expected to concentrate at the surface of the zinc as corrosion occurred and the corrosion reaction would be activated after a time, rather than deactivated.

2. Nickel is rapidly leached from the oxide film and it is hard to conceive that sufficient nickel would remain on the zinc surface in the metallic form to provide corrosion inhibition by the alternate explanation in the case of zinc-nickel alloys, which have been shown by others (5-9) to have corrosion protective properties.

3. The data for deaerated solutions summarized in Fig. 6 indicate that metallic cobalt only becomes a significant catalyst for the hydrogen evolution reaction in the case of dipping in solutions of 0.5 and 1.0M $CoCl_2$. Thus, significant amounts of cobalt are required on the surface before the hydrogen evolution reaction is vigorously catalyzed.

A simple calculation indicates that corrosion inhibition by cobalt results from the presence of very few cobalt atoms. The Auger data summarized in Fig. 12 indicate that the cobalt concentration on the surface of a sample dipped in 0.05M $CoCl_2$ solution is not great relative to that of zinc. The surface appearance gives no indication of metallic cobalt. If we assume that the oxide layer is of the order of 30 atom layers in thickness and that there are approximately 10^{15} metallic atoms per cm^2 per layer, the total number of metal atoms in or on the oxide would be of the order of 12×10^{17} metallic atoms for 40 cm^2 area (2 samples of 20 cm^2 each). If half of the metal atoms are cobalt, there are 6×10^{17} cobalt atoms.

The least soluble cobalt species in the sodium chloride solution would be expected to be $Co(OH)_2$ or $Co(OH)_3$, the solubility of both of which is given as 0.00032 g/liter since in aearated solution the stable species in the case of high-surface-area hydroxide would be expected to be the trivalent form. For a liquid volume of 200 cm^3, as used in these experiments, the total number of soluble cobalt ions can be calculated to be 6×10^{17} ions.

Although these numbers are very crude, they do show that only a limited number of cobalt atoms would be expected to exist on the surface of zinc in NaCl solution under conditions where the zinc was predipped in a solution of 0.01M $CoCl_2$. Since the zinc oxide is continually being generated by the corrosion reaction, it is extremely unlikely that metallic cobalt could occupy a significant fraction of the surface during the 24 or 48 hr duration of the corrosion experiment.

The suggested interpretation of the corrosion inhibition by cobalt and nickel opens up an entirely new approach to corrosion control for galvanized steel. Any means whereby the catalytic activity of the surface oxide on zinc can be poisoned for the cathodic reactions offers hope for reducing the corrosion rate of zinc. The ideal poison would be one that is effective against both the water-oxygen reaction and the hydrogen evolution reaction. Such poisons might be electron traps within the oxide, as hypothesized for cobalt and nickel, or they might be trapping sites developed by adsorption of a species from the solution.

A recent survey (15) has described the various ways in which metallic cations may serve as corrosion inhibitors. The present study, which has shown the inhibition of zinc corrosion by cobalt and nickel, bears some resemblance to the effect of cobalt on the corrosion of lead anodes in sulfuric acid (16). Both types of corrosion inhibition apparently result because the metal cation enters an oxide film on the surface of the metal and changes its electrical properties. The inhibition of anodic lead corrosion by cobalt is accompanied by a reduction in the overvoltage for the oxygen evolution reaction on lead (17). Cobalt appears to play its role by entering the PbO_2 film on the surface of lead and increasing the predominance of the anodic reaction, $2\,OH^- = H_2O + \frac{1}{2}\,O_2 + 2e^-$, over the undesirable reaction, $Pb - 2e^- = Pb^{++}$.

Redox Potential Measurements in High Temperature Aqueous Systems

Digby D. Macdonald,*[1] **Arthur C. Scott, and Paul Wentrcek**

SRI International, Materials Research Laboratory, Menlo Park, California 94025

ABSTRACT

Redox potential measurements on platinum and Type 304 stainless steel in equilibrium (H_2 or O_2) and nonequilibrium ($H_2 + O_2$) boric acid/lithium hydroxide solutions at 275°C are reported. For equilibrium systems containing hydrogen, good agreement was obtained between the measured potentials on platinum and calculated equilibrium potentials for pH (275°C) = 5.49, 5.60, and 8.02. For highly basic systems (0.1m LiOH), however, the observed potentials tended to be more positive than the calculated values; the difference was probably due to trace amounts of oxygen remaining in the system. In oxygenated equilibrium systems, good agreement was found between the observed and calculated potentials for the 0.1m LiOH solution for $[O_2] \leq 7$ ppm, but the observed potentials tended to be less positive than the calculated values for more acidic solutions and for lower oxygen concentrations. Steady-state measurement on nonequilibrium ($H_2 + O_2$) boric acid solutions at 275°C showed that the redox potential on platinum becomes more negative as the ratio $[H_2]/[O_2]$ increases. Transient studies on nonequilibrium ($H_2 + O_2$) boric acid solution revealed that the redox potential can vary over a wide range on cycling the relative concentrations of oxygen and hydrogen. The experimental findings are interpreted in terms of mixed potential model from which numerical simulations have reproduced the essential features of the data.

Considerable interest has arisen in recent years on the properties of high temperature aqueous solutions (100°-300°C) because of their use as heat transport media in many power generating systems. For example, extensive work on the electrochemical behavior of metals and alloys in this hostile environment has been reported over the last decade (1), particularly with reference to corrosion processes. Ion hydrolysis and acid/base dissociation phenomena have also been studied (2-7) using concentration cells for precise acidity measurements at temperatures as high as 300°C. Also, considerable progress has been made in the development of a reliable pH electrode for the long-term monitoring of high temperature aqueous systems (8-13). Some of this latter work (13) is part of a more extensive effort in this laboratory to develop electrochemical probes for monitoring the chemical properties of aqueous heat transport systems in electrical energy producing facilities.

Because corrosion processes and many oxide dissolution phenomena involve a change in oxidation state of one or more components, it is necessary, from a purely thermodynamic viewpoint, to specify or control the redox state if the chemistry of the system is to be fully understood. In practical power generating systems this normally involves the continuous or periodic injection of reducing agents (*e.g.*, H_2, N_2H_4) or oxidizing agents (*e.g.*, O_2, H_2O_2) into the high temperature environment. However, the effective control of the redox state of a system requires a means for the continuous monitoring of the redox potential. Experimental studies aimed at developing suitable probes have been reported (14). However, the theoretical basis for the redox potential is not well established and the relationship between the measured potential and the composition of the system is poorly understood.

In this study, we report redox potential measurements carried out on platinum and Type 304 stainless steel electrodes in boric acid/lithium hydroxide solutions at a temperature of 275°C (548 K). The potential measurements were made in systems containing oxygen, hydrogen, and nonequilibrium mixtures of these components. A theoretical analysis of the redox potential is presented and used to interpret the experimental data.

Experimental

Apparatus.—The high temperature recirculating loop used for these studies is described elsewhere (15). Briefly, boric acid/lithium hydroxide buffer solutions were pumped from a reservoir through a preheater and into the measurement cell using a positive displacement diaphragm pump. The exiting solution was heat-exchanged with the input, cooled in a second heat exchanger, and then discharged back to the reservoir via a pressure control valve. The pressure in the circuit was set at 75.3 kPa (1100 psig) to maintain a single (liquid) phase within the loop. Both the preheater and the measurement cell were thermostatted with electrical heaters and controllers. Adjustment of these heaters permitted the cell temperature to be controlled to within ± 2 K at temperatures as high as 548 K (275°C). The solution flow rate could be varied between 0 and 5 ml sec^{-1} by changing the stroke of the pump. Because the volume of the loop (excluding the reservoir) was 2.5 liters, the time required to completely replace the solution is estimated to be 2-3 hr for the flow rate (1 ml sec^{-1}) employed here. The reservoir contained facilities for continuously sparging the solution with oxygen, hydrogen, or mixtures of these gases. Gas concentrations in the solution were computed using the appropriate Henry's law coefficient. The calculated oxygen concentration was confirmed (± 10%) by direct measurement using a dissolved oxygen analyzer (Delta Scientific Model 2210).

Details of the measurement cell used in this work are given in Fig. 1. The main body of the cell was machined from Type 316 stainless steel, and contained ports for the entrance and exit of the solution, a CONAX lead-through for the platinum and Type 304 stainless steel bead electrodes (~ 2 mm diam), and the reference electrode. The bead electrodes were always placed in the same, reproducible, position with respect to both the fluid stream and the reference electrode liquid junction. Reproducible placement with respect to the fluid flow was considered to be necessary, because theory predicts (see Discussion) that the redox

potential will be a function of the mass transfer coefficients for the various electroactive components in the system.

A major problem in any study of this kind is choosing a suitable reference electrode against which the potential of the indicator electrode can be measured. The problems encountered with the traditional internal reference electrodes have been reviewed by Macdonald (16). In this work, we employed a pressure balanced external reference electrode of the type recently described by Macdonald, Scott, and Wentreek (17). The design of this reference electrode is shown in Fig. 2; details of the construction and operation of the electrode are given in the original publication (17). Briefly, the external Ag/AgCl electrode was calibrated against an identical internal electrode in various KCl solutions ranging in concentration from 0.005 mole kg^{-1} to 0.505 mole kg^{-1}. Thermodynamic analyses then permitted evaluation of the correction parameters, $\Delta E_{SHE}(T) - \Delta E_{obs}(T)$, where $\Delta E_{obs}(T)$ is the observed potential of the bead electrode against the external reference electrode, and $\Delta E_{SHE}(T)$ is the corresponding potential *vs.* the hypothetical standard hydrogen electrode (SHE) at the system temperature. Analysis of the reference electrode with an internal KCl solution of concentration 0.102 mole kg^{-1} showed that the correction term for $T = 275°C$ is $-0.001V$ (17). Therefore, within the precision of the measurements ($\pm$ 5 mV), the observed potentials at 275° $\pm$ 2°C can be assumed to refer to the thermodynamically well-defined standard hydrogen electrode scale.

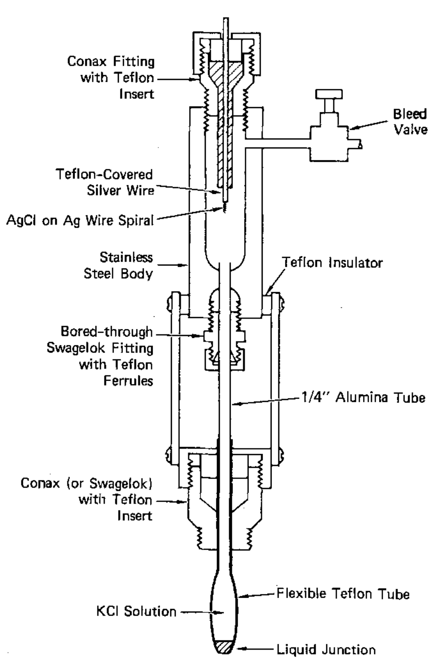

Fig. 2. Reference electrode assembly

Method.—After assembly of the apparatus, the system was pressurized to 75.3 kPa (1100 psig), and the reservoir purged of oxygen using high purity nitrogen for at least 10 hr while the solution was circulated around the high pressure loop. The temperature was then increased to 275° $\pm$ 2°C by adjusting the inputs to both the preheater and the cell heater. Once the cell temperature was stable, the reservoir was sparged with the desired gas or mixture of gases. The redox potential was then measured using a battery-powered electrometer with input impedance $> 10^{14}\Omega$. The electrometer output was connected to a strip-chart recorder for continuous monitoring of the potential.

Three sets of experiments were carried out: (*i*) equilibrium studies using oxygenated and hydrogenated solutions separately, (*ii*) nonequilibrium studies in which the solution was sparged with mixtures of hydrogen and oxygen and the potential recorded until a steady-state response was obtained, and (*iii*) transient experiments in which the system was cycled between oxygenated and hydrogenated states. The experiments were carried out in various boric acid and boric acid/lithium hydroxide solutions. The *p*H of each solution at 275°C was calculated as described previously (13).

Results and Discussion

Equilibrium studies.—Typical plots of the potential of a platinum electrode *vs.* the concentration of hydrogen and oxygen in solution as a function of *p*H are shown in Fig. 3 and 4, respectively. The equilibrium potentials also plotted in these figures were calculated from the composition of the solution assuming that the potential-determining reactions for the hydrogenated and oxygenated systems are

$$2H^+ + 2e^- \leftrightarrows H_2,$$

$$E_{H^+/H_2} = -(2.303RT/2F) \log p_{H_2} - (2.303RT/F)pH \quad [1]$$

and

$$O_2 + 4H^+ + 4e^- \leftrightarrows 2H_2O,$$

$$E_{O_2/H_2O} = E^\circ + (2.303RT/4F) \log P_{O_2} - (2.303RT/F)pH \quad [2]$$

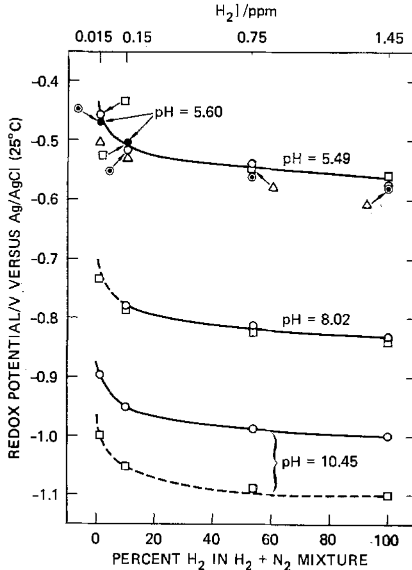

Fig. 3. Equilibrium potential at 275°C *vs.* concentration of hydrogen in 0.1m boric acid (*p*H = 5.49), 0.01m boric acid (*p*H = 5.60), 0.01m boric acid + 0.001m LiOH (*p*H = 8.02), and 0.1m LiOH (*p*H = 10.45). Data points: ○—Pt, experimental. △—Type 304 stainless steel. □—calculated (*p*H = 5.49, 8.02, 10.45). ⊙—*p*H = 5.60, for the reaction $2H^+ + 2e^- = H_2$.

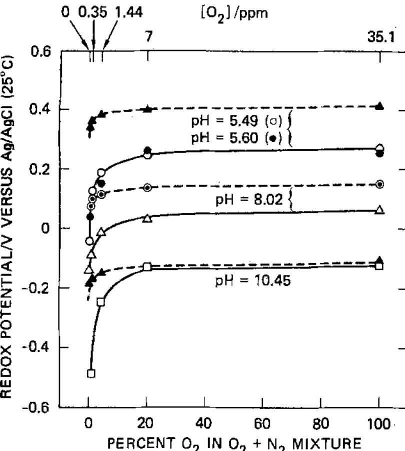

Fig. 4. Equilibrium potential at 275°C vs. concentration of oxygen for a platinum electrode in boric acid/LiOH buffer solutions (see Fig. 3 for compositions). Data points: ○, ●, △, □—experimental. ▲—calculated for the reaction $O_2 + 4H^+ + 4e^- = 2H_2O$.

Hypothetical partial pressures of hydrogen and oxygen in the high temperature zone can be calculated from the known concentrations of these solutes in the reservoir at 25°C and the Henry's law coefficients at 275°C. For a solute concentration in the reservoir at 25°C of x parts per million (ppm), the equivalent partial pressure at the operating temperature is

$$p_i = x_i/1000\, M_i B_{275,i} \quad (i = H_2, O_2) \qquad [3]$$

where M_i is the solute molecular weight and $B_{275,i}$ is the Henry's law coefficient at 275°C (18). Substitution of Eq. [3] into Eq. [1] and [2] therefore yields

$$E_{H^+/H_2} = 0.0408 - 0.0544 \log x - 0.10875\, pH \qquad [4]$$

$$E_{O_2/H_2O} = 0.9857 + 0.272 \log x - 0.10875\, pH \qquad [5]$$

The data plotted in Fig. 3 show that for hydrogenated systems the observed redox potential for platinum and Type 304 stainless steel ($pH = 5.49$ only) is in excellent agreement with the calculated values for the three lowest pH values (5.49, 5.60, 8.02). However, the experimental data at the highest pH (10.45) do not agree with the theoretical values; the experimental values are approximately 100 mV more positive than the potentials calculated using Eq. [4]. Conversely, experimental and theoretical data plotted in Fig. 4 for the oxygenated systems show reasonable agreement at the highest pH, particularly for high oxygen concentration ($[O_2] \geqq 7$ ppm), but progressively poorer agreement is found as the acidity of the solution increases. At low oxygen concentrations the observed potentials tend to be less positive than the calculated values by an amount that increases with decreasing concentration.

The generally good agreement found between the observed and calculated data for the three most acidic hydrogenated systems illustrates the precision that can be obtained in potential measurements using external pressure balanced reference electrodes. For this reason we do not believe that the discrepancy between experiment and theory found in the most highly basic solution ($pH = 10.45$) is due to a malfunction of the reference electrode. Nor do we believe that it is due to any uncertainty in the calculated pH, even though the association constant for Li^+ and OH^- is not well established, particularly at elevated temperatures. If a significant error in the calculated pH did exist, it is unlikely that close agreement would have been found between the calculated and observed potentials for oxygenated systems at $pH = 10.45$ and $[O_2] \geqq 7$ ppm (Fig. 4). The discrepancy between the calculated and experimental data at high pH in the hydrogen-containing solutions presumably arises from kinetic factors and/or more probably from contamination of the system with other electroactive species, particularly oxygen.

The generally poor agreement found between the observed and calculated potentials for oxygenated solutions at low oxygen concentrations and pH is not surprising in view of previous work on the oxygen electrode reaction. For example, Hoare (19) points out that in oxygenated systems platinum is not inert and the metal surface reacts with the environment to form platinum oxides. The observed potential may therefore refer to a mixed potential which arises from the simultaneous operation of anodic (*e.g.*, Pt oxidation) and cathodic (oxygen reduction) reactions at the surface. This theory predicts that the observed potential will be less positive than the equilibrium potential for the oxygen electrode, as observed. Also, the observed potential should lie closest to the equilibrium potential for that partial process with the highest exchange current density; that is, closest to the equilibrium potential for the most reversible reaction. The data plotted in Fig. 4 show that progressively better agreement between the theoretical and observed potentials is obtained as the pH increases from 5.49 to 10.45. This behavior indicates that the oxygen electrode reaction becomes more reversible compared with the anodic reaction on platinum as the pH increases.

Steady-state nonequilibrium studies.—Many industrial systems that utilize high temperature aqueous solutions operate under nonequilibrium conditions as far as the oxygen and hydrogen contents of the fluid are concerned. For example, in Boiling Water (Nuclear) Reactors (BWR's), nonequilibrium concentrations of oxygen and hydrogen are produced in-core due to the radiolysis of water. These nonequilibrium concentrations persist into out-of-core areas, so that any realistic study of the redox potential in this environment must consider kinetic as well as equilibrium factors.

Typical steady-state redox potentials observed on platinum in nonequilibrium high temperature (275°C) boric acid/lithium hydroxide solutions are summarized in Fig. 5 as a function of the relative amounts of oxygen and hydrogen in the fluid. At all pH values, the redox potential becomes more negative as the ratio

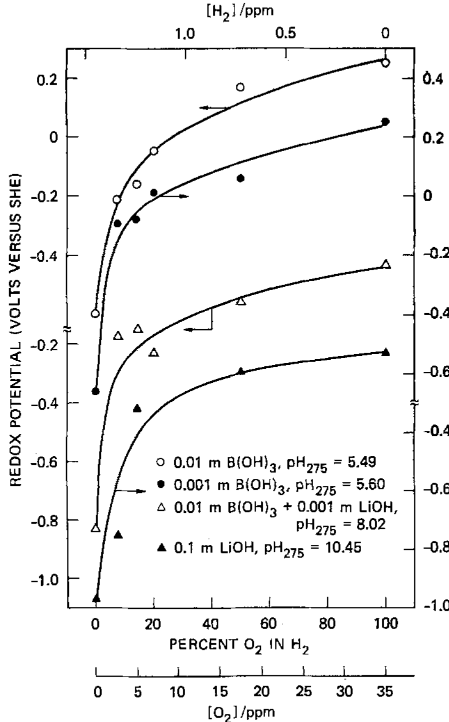

Fig. 5. Steady-state redox potentials for platinum as a function of composition for nonequilibrium systems containing oxygen and hydrogen at 275°C.

$[H_2]/[O_2]$ increases. However, the data were not sufficiently reproducible or stable, particularly at the highest pH, to ascertain the composition dependence of the redox potential quantitatively.

The poor reproducibility of these data could be due to reaction of the electroactive components (O_2, H_2) in the high temperature zone, so that the actual concentrations sensed by the redox probe are considerably lower than those established in the reservoir and hence those used for the plotting of Fig. 5. A more probable explanation is that the system is inherently unstable for kinetic reasons over the composition range of interest due to the approximate equality of the limiting currents for the oxidation of hydrogen and the reduction of oxygen. This latter explanation is supported by the theoretical work described later in this paper.

Transient experiments.—The most important application of redox potentiometry in industrial systems is expected to be for the monitoring of aggressive environments such as aqueous solutions at elevated temperatures. Few industrial systems operate in a steady state; for example, the levels of both oxygen and hydrogen in BWR heat transport circuits vary with the power output of the core, temperature, and with time upon start-up and shut-down. Accordingly, considerable interest exists in defining the redox potential response under transient conditions in which the relative concentrations of hydrogen and oxygen are cycled over a wide range. In the present work these transient experiments were carried out using platinum redox probes only. Also, the concentration of hydrogen in solution in the high temperature (275°C) zone was monitored continuously using the palladium resistance probe that is described in another publication (20).

A typical plot of redox potential *vs.* time for an experiment in which the reservoir was sparged cyclically with various mixtures of hydrogen and oxygen is shown as the lower curve in Fig. 6. Also plotted in this figure (upper curve) is the output of the palladium resistance hydrogen monitor. This output is proportional to the resistance of a palladium wire sensing element and has been processed to compensate for small temperature fluctuations in the experimental apparatus. Since the monitor output is nearly linear with hydrogen concentration, the value for V_c may be taken as an approximate measure of the hydrogen content of the high temperature aqueous solution (0-1.45 ppm).

Prior to recording the segment of data shown in Fig. 6, the system had been exposed to 100% hydrogen for 22 hr. Injection of 9% O_2 in H_2 caused the redox potential to increase rapidly to a maximum after 2-3 hr. This response time corresponds to the estimated mass transfer time of the loop, and it is not considered to be an indication of the performance of the probe itself.

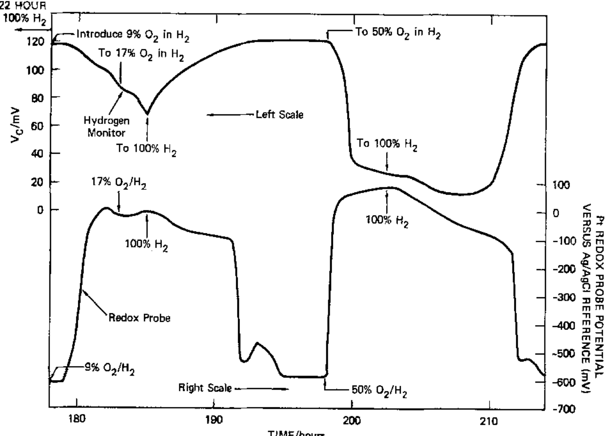

Fig. 6. Response of hydrogen monitor (upper curve) and redox probe (lower curve) to hydrogen and oxygen in 0.1m boric acid at 275°C.

Injection of a slightly higher oxygen level (17% O_2 in H_2) causes a further small upward response in the redox potential. Subsequently, injection of 100% hydrogen into the system caused the potential at first to shift slowly in the negative direction, followed by a rapid change to a value that is close to the equilibrium value for the H^+/H_2 reaction. A similar reponse is observed during the second cycle.

Comparison of the two curves in Fig. 6 shows clearly that the transient response of the redox probe is closely associated with the relative concentrations of hydrogen and oxygen in the fluid. For example, good coincidence is observed between the increase in hydrogen concentration (decrease in $[O_2]$) and the shift in the redox potential to more negative values. Similarly, the decrease in the hydrogen concentration (increasing $[O_2]$) is in excellent fidelity with the rapid rise in the redox potential.

In many experiments, a small maximum was observed in the redox potential on sparging the solution with hydrogen after prior exposure to oxygen. It is probable that this maximum arises from the reduction of surface platinum oxide phases. We consider this to be indirect evidence in support of the mixed potential hypothesis for the discrepancy between the observed and calculated potentials for the oxygen electrode reaction in this environment.

Mixed potential model.—The close correspondence between the redox potential and composition suggests that the electrochemistry of the system may be modeled using mixed potential theory.

In the mixed potential model developed here, we assume that the electrochemical reactions involved occur uniformly across the active surface, that each reaction may involve varying degrees of charge and mass transfer control, and that each reaction is characterized by a set of parameters which include the exchange current density, transfer coefficients, equilibrium potential, and limiting currents for the forward and reverse directions. In this analysis, we limit the model to two simultaneous electrochemical reactions of the type

$$R_k \rightleftarrows O_k + n_k e \quad [6]$$

where R and O are reduced and oxidized species, respectively, and $k = 1, 2$. Consideration of both charge transfer and mass transfer shows (21) that the generalized current-voltage expression for reaction [6] can be written in the form

$$i_k = i_{o,k} \left\{ \left(\frac{i_{l,f,k} - i_k}{i_{l,f,k}} \right) \exp\,(a_k \eta_k) - \left(\frac{i_{l,r,k} - i_k}{i_{l,r,k}} \right) \exp\,(-\,b_k \eta_k) \right\} \quad [7]$$

where $i_{o,k}$ is the exchange current density

$$i_{o,k} = i^{\circ}{}_{o,k}\,(C_{O,k}{}^b)^{\alpha_k}(C_{R,k}{}^b)^{\beta_k} \quad [8]$$

$i^{\circ}{}_{o,k}$ is the standard exchange current density, $C_{O,k}{}^b$ and $C_{R,k}{}^b$ are the bulk solution concentrations of O_k and R_k, respectively, and α_k and β_k are the transfer coefficients for the forward and reverse directions. The constants a_k and b_k are equal to $\alpha_k n\mathbf{F}/RT$ and $\beta_k n\mathbf{F}/RT$, respectively. The limiting currents for the forward and reverse reactions are designated by $i_{l,f,k}$ and $i_{l,r,k}$; the latter quantity being negative.

Rearrangement of Eq. [7] yields an expression for the current i_k

$$i_k = \omega_k\{\exp\,[a_k(E - E_{e,k})] - \exp\,[-b_k(E - E_{e,k})]\}/\{x_k + y_k \exp\,[a_k(E - E_{e,k})] - z_k \exp\,[-b_k(E - E_{e,k})]\} \quad [9]$$

where

$$\omega_k = i_{o,k} i_{l,f,k} i_{l,r,k} \quad [10]$$

$$x_k = i_{l,f,k} i_{l,r,k} \quad [11]$$

$$y_k = i_{o,k} i_{l,r,k} \quad [12]$$

$$z_k = i_{o,k} i_{l,f,k} \quad [13]$$

and $E_{e,k}$ is the equilibrium potential for reaction [6] under the prevailing conditions

$$E_{e,k} = E^\circ_{e,k} - \frac{RT}{n_k F} \ln \left\{ \frac{\gamma_{R,k} C_{R,k}{}^b}{\gamma_{O,k} C_{O,k}{}^b} \right\} \quad [14]$$

$E^\circ_{e,k}$ is the standard potential, and $\gamma_{R,k}$ and $\gamma_{O,k}$ are activity coefficients for the reduced and oxidized species, respectively.

For an electrically isolated surface upon which $k = 1, 2, \ldots, n$ reactions of type [6] are taking place, the mixed potential, E_m, is determined by the zero total current condition

$$Y(E) = \sum_{k=1}^{h} i_k \cdot A_k = 0 \quad [15]$$

where A_k is the local area on which the kth reaction occurs. In this analysis we have invoked the uniform accessibility condition so that $A_{electrode} = A_k$ and Eq. [15] therefore reduces to

$$Y(E) = \sum_{k=1}^{h} i_k = 0 \quad [16]$$

The more general expression, Eq. [15], permits galvanic effects to be taken into account. In both cases, the problem reduces to one of finding a value for the potential which satisfies the zero total current condition as expressed by Eq. [15] or [16].

The solution to Eq. [16] is most easily determined using the Newton-Raphson iterative technique. In this method, an improved approximation for the mixed or redox potential, $E_{m,j}$, is obtained from

$$E_{m,j} = E_{m,j-1} - Y(E_{m,j-1})/Y'(E_{m,j-1}) \quad [17]$$

where j is the iteration number, and Y' is the first derivative of Eq. [16] with respect to potential. The iteration is continued until the desired level of precision is obtained. Alternatively, E_m may be estimated directly by plotting the current function $Y(E)$ *vs.* potential; E_m being that potential at which $Y(E) = 0$. Both methods have been used in this study.

Because the experimental work reported in this paper was restricted to systems containing oxygen and hydrogen only, the two following reactions are considered in this analysis

$$\tfrac{1}{2} H_2 = H^+ + e^- \quad [18]$$

$$2H_2O = O_2 + 4H^+ + 4e^- \quad [19]$$

Both reactions are written in the oxidation sense to emphasize that the forward (anodic) current is considered to be positive, whereas the reverse (cathodic) current is negative. No attempt was made to include the oxidation of platinum in the analysis, since insufficient data are available on the thermodynamic and kinetic parameters involved.

After an extensive search of the literature it was evident that few data are available for the kinetic parameters for reactions [18] and [19] at 275°C. Accordingly, no particular attempt was made in this study to reproduce the experimental data. Instead, the redox potential was calculated for a range of environmental and kinetic parameters so that trends in the experimental data could be identified. The input data for the numercial simulations are summarized below and in Tables I and II.

As noted above, insufficient data are available in the literature for α, β, and i°_o for the two reactions of interest. For the H^+/H_2 reaction we have adopted values of $\alpha = 0.43$, $\beta = 1$, $i^\circ_o = 4 \times 10^7$ A cm^{-2}; and for the O_2/H_2O reactions values of $\alpha = 0.375$, $\beta = 0.125$, and $i^\circ_o = 0.2 \times 10^{-3}$ A cm^{-2} were assumed. The transfer coefficients are among those listed by Bockris and Reddy (22) for these two reactions under ambient conditions. The i°_o values yield exchange current densities (i_o) for the H^+/H_2 and O_2/H_2O reactions at pH = 5 and for $[H_2] = 2.2 \times 10^{-7}$ mole cm^{-3} and $[O_2] = 3.1 \times 10^{-10}$ mole cm^{-3} of 0.8×10^{-3} A cm^{-2} and 0.12×10^{-6} A cm^{-2}, respectively. These values are typical of those expected for these reactions under the conditions of interest. Limiting current for the two reactions

$$i_l = nFDC/\delta \quad [20]$$

where δ is the diffusion layer thickness, were calculated

assuming that $D_{H_2} = D_{O_2} = 5 \times 10^{-5}$ cm² sec⁻¹, $D_{H^+} = 5 \times 10^{-4}$ cm² sec⁻¹, and $\delta = 10^{-2}$ cm.

Four sets of numerical simulations were carried out (Table III), each intended to determine the response of the redox potential to systematic variations in a single system parameter. The variables of interest include: pH (set A), $[H_2]$ – low $[O_2]$ (set B), $[H_2]$ – high $[O_2]$ (set C), and $[O_2]$ – low $[H_2]$ (set D). Set A is divided into three subsets; A(1) – high $[H_2]$, low $[O_2]$; A(2) – low $[H_2]$, high $[O_2]$; and A(3) – med $[H_2]$, med $[O_2]$. Appropriate nuclear technologies to which these cases and sets B, C, and D refer are also indicated in Table III. Typical current-voltage curves for the simultaneous oxidation of hydrogen and the reduction of oxygen at an inert electrode are shown in Fig. 7. The total current ($I = i_1 + i_2$) is also plotted, and the intercept at which $I = 0$ defines the mixed potential (E_m) for the system. In the case shown, the mixed potential is dominated by the hydrogen electrode reaction with the reduction of oxygen being under mass transfer control.

The effect of pH on the calculated redox potential for the three subsets A(1), A(2), and A(3) is shown in Fig. 8. The redox potentials for low $[H_2]$ – $[O_2]$ [A(2)] and med $[H_2]$ – med $[O_2]$ [A(3)] are predicted to exhibit the same pH dependencies as the equilibrium potential. For the first case (A(1), high $[H_2]$ – low $[O_2]$) a small deviation from the equilibrium potential pH dependence is predicted; the deviation is, however, small (10 mV) over the five pH units considered in the simulation.

The predicted variation of redox potential, E_m, with the relative concentrations of hydrogen and oxygen in solution is shown in Fig. 9 for cases B, C, and D listed in Table III. The equilibrium potentials for the hydrogen and oxygen electrode reactions for all three cases are also plotted for comparison. For case B, in which $[H_2] >> [O_2]$, the redox potential behavior is dominated by the hydrogen electrode reaction and the dependence of E_m on composition closely follows that for the equilibrium potential $E_{e,1}$. These calculations suggest that, under typical operating conditions for PWR primary coolant circuits, redox potential measurements, at least on platinum, will be of little value for indicating the presence of small nonequilibrium concentrations of oxygen in the fluid. However, the assumption of a higher oxygen concentration (1.0 ppm *vs.* 0.001 ppm) yields curve C, which exhibits a sharp transition from a response that is dominated by the oxygen electrode reaction for low $[H_2]/[O_2]$ ratios to one that is determined by the hydrogen electrode reaction for hydrogen-rich systems. A similar behavior is predicted for case D (low $[H_2]$-varying $[O_2]$) which was intended to simulate start-up and operating conditions in BWR's. Indig and co-workers (14) have observed large redox potential swings on start-up and shut-down of an operating boiling water reactor apparently due to large changes in oxygen concentration, in agreement with the predictions reported here.

The origin of the sudden shift in the redox potential on changing the composition of the system can be seen by examining the data plotted in Fig. 7. Because both

reactions exhibit mass transfer control over most of the potential region between $E_{e,1}$ and $E_{e,2}$, it is evident that if $i_{l,f,1} > i_{l,r,2}$ then $E_m \rightarrow E_{e,1}$; that is, the redox response is dominated by the hydrogen electrode reaction. On the other hand, for $i_{l,f,1} << i_{l,r,2}$, $E_m \rightarrow E_{e,2}$, and the redox potential tends to mimic the oxygen electrode behavior. In the intermediate region where $I_{l,f,1} \approx i_{l,r,2}$ the system is unstable in that a small change in either of the limiting currents (and hence concentration) will cause a large shift in potential.

Because the sparging of a dissolved gas from a fluid is expected to be a first-order kinetic process, then to a first approximation it is expected that log $\{[H_2]/[O_2]\}$ will be roughly proportional to time. Accordingly, it is expected that the form of the experimental redox potential *vs.* time curve (Fig. 6) will show qualitative similarities to the calculated curves plotted in Fig. 9. Comparison of the two sets of data shows that this is indeed the case. For example, theory predicts (Fig. 9) that sparging of a hydrogen-containing system with oxygen will cause the redox potential to first increase rapidly with time, followed by a more gradual change towards the equilibrium potential for the oxygen electrode reaction. On the other hand, sparging of an oxygenated solution with hydrogen is expected to have the reverse effect; a relatively slow change with time is first predicted for E_m, followed by a sharp drop to the equilibrium potential for the hydrogen electrode reaction, as observed.

Finally it is of interest to compare (semiquantitatively) the observed redox potentials with the calculated values. In carrying out this comparison, we have adjusted the potential scales for the experimental data at $pH = 5.49$ and 8.02 to $pH = 7$ by subtracting and adding, respectively, the amount $(2.303\ RT/\mathbf{F})\Delta pH$ to the experimental values. The experimental conditions under which the steady-state redox potential measurements were made most closely correspond to those for case C, Table III. In spite of the considerable scatter in the experimental data, reasonable agreement between theory and experiment is observed.

Summary and Conclusions

Redox potential measurements in boric acid/lithium hydroxide solutions at 275°C in the presence of equilibrium and nonequilibrium amounts of oxygen and hydrogen have shown that:

1. Platinum adopts the equilibrium potential for the hydrogen electrode reaction in hydrogen-containing solutions of pH 5.49-8.02. In a more basic solution (0.1m LiOH), the observed potentials were less negative than those predicted from theory, probably due to contamination by oxygen.

2. In oxygenated solutions, the observed potential of a platinum electrode was found to be in good agreement with the predicted equilibrium value only in the highly basic solution (0.1m LiOH), and then only for $[O_2] \geqq 7$ ppm. Under all other conditions, the observed potentials were less positive than the predicted values.

3. In steady-state, nonequilibrium systems containing both hydrogen and oxygen, the redox potential becomes more negative as the ratio $[H_2]/[O_2]$ increases.

4. Transient studies on nonequilibrium systems showed that the redox potential swings over a wide range on cyclically sparging the solution with oxygen and hydrogen. Comparison of the redox probe response with that for a hydrogen monitor revealed a high fidelity between the observed potential and the concentration of hydrogen in solution.

5. Extensive numerical simulations of the redox potential for nonequilibrium oxygen- and hydrogen-containing solutions have shown that the observed data can be understood using a mixed potential model which assumes that the potential-determining reactions are the simultaneous oxidation of hydrogen and reduction of oxygen at the electrode surface.

Reaction Model for Iron Dissolution Studied by Electrode Impedance

I. Experimental Results and Reaction Model

Michel Keddam, Oscar Rosa Mattos, and Hisasi Takenouti

Groupe de Recherche No. 4 du CNRS "Physique des Liquides et Electrochimie," associé à l'Université Pierre et Marie Curie, 75230 Paris Cedex 05, France

ABSTRACT

Steady-state polarization curves and electrode impedances were measured during the dissolution of iron in 1M Na_2SO_4 solution acidified by the addition of 1M H_2SO_4. These experiments were performed within very wide pH (0-5), current density (up to 0.1 A · cm^{-2}), and frequency (10^{-3}-10^5 Hz) ranges. Three time constants, in addition to the high-frequency capacitive loop attributed to the double layer capacity and the charge transfer resistance, were observed before the onset of the passivation process. The experimental results were quantitatively interpreted by computer simulation on the basis of a reaction model including three dissolution paths. At low current densities, the dissolution path, which can be related to the consecutive mechanism, controls the overall rate. At higher current densities, a self-catalytic path, implying a ferrous intermediate, determines the overall current. Another self-catalytic path, with monovalent iron, plays an important role in the electrode impedance and the prepassivation process although its contribution to the current is not prevalent at any pH.

Bonhoeffer and co-workers strove to establish the mechanism of iron dissolution in acidic medium and proposed, for the first time, reaction models implying reaction intermediate species (1-4). According to Heusler, the dissolution of iron takes place in two steps coupled by monovalent iron (model I) (4)

Model I

$$Fe + OH^- \rightleftharpoons (FeOH)_{ad} + e^- \quad [I-1]$$

$$Fe + (FeOH)_{ad} + OH^- \rightarrow (FeOH)_{ad} + (FeOH)^+_{sol} + 2e^- \quad [I-2]$$

The subscripts "ad" and "sol" indicate, respectively, the species adsorbed at the electrode surface and that dissolved in the solution bulk. $(FeOH)^+_{sol}$ decomposes in the solution bulk into hydrated Fe^{2+} and OH^-. The reaction step [I-2] does not consume the intermediate species $(FeOH)_{ad}$; thus at steady state, step [I-1] remains in equilibrium.. This reaction mechanism was proposed in order to interpret the following three experimental observations: (*i*) The slope of the steady-state polarization curve, usually called Tafel slope, $d(\log J)/dE$, is equal to 0.03V. (*ii*) The transient Tafel slope obtained from the maximum potential E_{tr} following the stepwise current change, $d(\log J)/dE_{tr}$, is equal to 0.06V. (*iii*) The reaction order with respect to OH^- ion concentration, $d(\log J)/dpH$, is equal to two.

A few years later, Bockris and co-workers (5-7) repeated the experiments made by Heusler and found somewhat different results, namely, (*i*) The steady-state Tafel slope is equal to 0.04V. (*ii*) The reaction order with respect to OH^- concentration is equal to unity.

Key words: adsorption, metals, passivity.

They examined several reaction models, including model I and proposed the reaction model constituted by two consecutive steps (5)

Model II

$$Fe + OH^- \rightleftharpoons (FeOH)_{ad} \quad [II-1]$$

$$(FeOH)_{ad} \rightarrow (FeOH)^+_{sol} \quad [II-2]$$

Step [II-2] is considered slow and limits the overall reaction rate whereas the first step is in pseudo-equilibrium. The occurrence of a pseudo-equilibrium reaction implies an electrode potential close to its thermodynamic equilibrium potential and its reaction rate very fast compared to that of step [II-2]. Bockris and co-workers considered these situations satisfied by the open-circuit corrosion potential (6).

In both cases, similar hypotheses were considered in order to transcribe the reaction models into mathematical expressions.

1. The reaction rate of the elementary step K_i follows the Tafel law

$$K_i = K_{0,i} \exp\left(\frac{z\alpha_i \mathbf{F} E}{RT}\right) \quad [1]$$

where $K_{0,i}$ is the reaction rate at $E = 0$ determined with respect to the equilibrium potential or to any reference electrode, z the number of electrons implied in the elementary step, α_i the transfer coefficient corresponding to the fraction of energy supplied by the electrical field in forward reaction. For the inverse reaction, $\alpha_{-i} = 1 - \alpha_i$. **F**, R, and T have their usual meaning.

2. α is considered to be equal to 0.5.
3. All reactions occur on the whole surface area.

Since then, much work has been done to verify these two reaction mechanisms (8-11). The steady-state Tafel slope is, very often, found to be equal or close to 0.04V, thus model II is, nowadays, generally considered as confirmed. However, in certain cases, the Tafel slope was very different from the two previous values and was measured between 0.029 and 0.1V (12-14). Later on, when the measurements were extended to potential values far from the corrosion potential, near which earlier work was constrained, more complicated behaviors were found. Lorenz and coworkers (15-18) investigated iron dissolution up to the onset of the passivation process in weakly acidified sulfate media (pH 4-5). They proposed the reaction model implying two dissolution paths and trivalent passivation species which can be represented schematically by

Model III

$$\begin{array}{ccccc} & & Fe(II)_{sol} & & \\ & K_2 \nearrow & K_4\uparrow & & \\ Fe \underset{K_{-1}}{\overset{K_1}{\rightleftarrows}} Fe(I)_{ad} & \underset{K_{-3}}{\overset{K_3}{\rightleftarrows}} & Fe(II)_{ad} & \underset{K_{-5}}{\overset{K_5}{\rightleftarrows}} & Fe(III)_{ad} \end{array}$$

where the K_4 reaction can be written explicitly by

$$Fe(II)_{ad} + Fe \overset{K_4}{\rightarrow} Fe(II)_{sol} + Fe(I)_{ad} + e^-$$

The dissolution path through the K_2 reaction is identical to that of model II. The reactions relating to K_1/K_{-1} and to K_3/K_{-3} are in pseudoequilibrium and thus they are very fast compared to K_2 and K_4 reactions over the whole potential range considered. Using hypotheses 1 and 2 given above and introducing instead of 3 the surface coverage by intermediate species which follows the Langmuir-type isotherm, they succeeded in simulating by computer the experimental steady-state polarization curves.

It is now generally accepted that elucidating an intricate reaction mechanism by means of steady-state techniques alone is an extremely difficult task. Selective criteria for mechanisms have to be elaborated on the basis of Tafel slopes by using highly questionable and strongly restrictive assumptions. In fact, the steady-state approach provides too little information in comparison with the complexity of the process under investigation.

In our Laboratory, the electrode kinetics study based on electrode impedance measurements over a very wide frequency range (typically 10^{-3}-10^5 Hz) has been developed and applied to dissolution-passivation processes as well as to electrodeposition of various metals (19-24). Epelboin and Keddam (25) showed experimentally that the electrode impedance, measured between 10^{-2} and 10^4 Hz during iron dissolution in acidic sulfate media, reveals an inductive behavior. By means of the rotating disk electrode and correction of the ohmic drop due to solution resistance, the measurements were spread over a wide range of current densities compared to earlier works. The electrode impedance was calculated on the basis of model II according to the formalism developed by Gerischer and Mehl (26) for the hydrogen evolution reaction. It was found that both steady-state polarization curves and electrode impedance measurements could only be interpreted by assuming a large degree of irreversibility of the first step and also values of α_1 and α_2 different from 0.5.

Later, the electrode impedance was measured at even higher current densities and more accurately than in earlier experiments. The electrode impedance revealed two inductive loops. These new results were interpreted by introducing into model II a parallel dissolution path (27), different from model III

Model IV

$$\begin{array}{ccccc} & & Fe^*(I)_{ad} & & \\ & & K_3\uparrow\downarrow K_{-3} & \searrow K_4 & \\ Fe & \overset{K_1}{\rightarrow} & Fe(I)_{ad} & \overset{K_2}{\rightarrow} & Fe(II)_{sol} \end{array}$$

The K_4 reaction is such that

$$Fe^*(I)_{ad} + Fe \overset{K_4}{\rightarrow} Fe(II)_{sol} + Fe^*(I)_{ad} + 2e^-$$

Although, according to Bechet *et al.* (27) the K_4 reaction is under the influence of sulfate anions, this reaction path can be related to model I. In fact, $Fe^*(I)_{ad}$ is the dissolution intermediate species and, at the same time, plays a catalytic role in this reaction. We call this kind of reaction a "self-catalytic reaction."

Recently, with very careful experiments, it was found that the impedance diagrams reveal three inductive loops under certain experimental conditions (28). The presence of three time constants in addition to the high-frequency capacitive loop were also found by Schweikert (29).

The aim of this paper is twofold: first, to present the results of electrode impedance measurements performed within a wide range of experimental conditions: pH (0-5), current density up to 0.1 A · cm^{-2}, and full frequency range, and second, to describe a reaction model which interprets quantitatively these experimental results. In Part II of this paper, the hypotheses used to transcribe the reaction models into mathematical expressions are examined in detail. Since experimental results showed three time constants in addition to the high-frequency capacitive loop, it is supposed that there are three adsorbed species. Forty different reaction schemes were established as the whole set of prospective models. In Part II, the reason for which only one reaction scheme was retained will be shown.

Experimental and Numerical Procedures

The experimental conditions were described elsewhere (28). The current is practically free of mass transfer effects in the range of current densities examined in this work.

Based on the reaction model and using the hypotheses described below, the mathematical expressions were established. Then by setting the numerical value of the kinetic constants, the steady-state polarization curve was numerically simulated. Some parameters were very sensitive for this calculation, but many of them were not. Once the calculated polarization curve was considered sufficiently close to the experimental curve, the electrode impedance was calculated about various steady-state polarization points. The kinetic parameters were modified manually after each calculation, up to the run which gives results in sufficiently good agreement with the experimental results. No fitting program for adjusting kinetic parameters was used. It is found that double precision (64 bits) was necessary for the calculation of the electrode impedance, although the mathematical expressions were simplified as far as possible. During the simulation calculation, it was found very difficult to establish other sets of kinetic parameters, and the rate constants change reasonably with the solution pH, but it is not possible to ascertain that the values given in the results were the only possible set.

Experimental Results and Discussion

Steady-state polarization curves.—In Fig. 1, the steady-state polarization curves obtained for different pH's are shown. The points on these curves indicate the polarization condition at which the electrode impedance measurements were performed, *i.e.*, during the measurements which last *ca.* 1.5 hr, the current remains constant except a few percent variation. In the following, only some will be shown which illustrate typi-

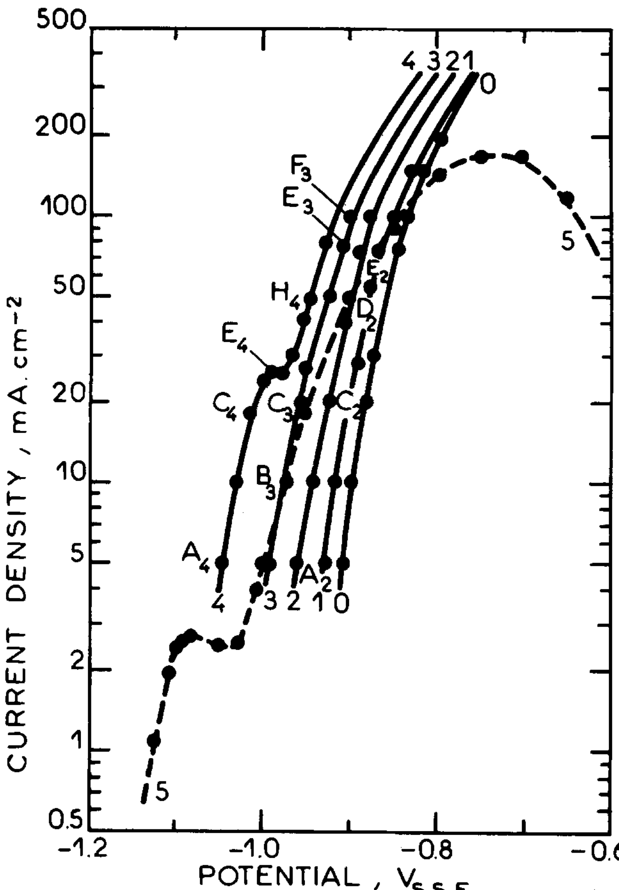

Fig. 1. Steady-state polarization curves; Fe (Johnson-Motthey) disk electrode; diameter = 3 mm; rotation speed = 1600 rev · mn^{-1}; mixture in various proportion of 1M Na_2SO_4 and 1M H_2SO_4; 25° ± 0.2°C; deoxygenated by Ar. Solution pH: curve 0, pH = 0; curve 1, pH = 1.0; curve 2, pH = 2.0; curve 3, pH = 2.6; curve 4, pH = 4.0; and curve 5, pH = 5.0. The electrolyte resistance for the actual electrode (3 mm in diameter) was: pH 0, 4.3Ω; pH 1, 14Ω; pH 2, 15Ω; pH 2.6, 15Ω; pH 4, 16Ω; pH 5, 17Ω.

cal features of the impedance diagram and its change with potential and pH. On this figure, it can be seen that the dissolution current is greater for a given potential when the solution pH increases except for the pH 5 solution. In low pH solutions, the curves bend at high current densities in agreement with our previous results (25, 27). The experimental reaction order with respect to OH^- concentration is *ca.* 0.7 in the low current density range and *ca.* 0.3 in the high current density range when the potential E is measured against an SSE (Hg, Hg_2SO_4 sat. K_2SO_4) reference electrode. It is worth noting that the potential difference between SSE and SCE (KCl saturated calomel electrode) reference electrodes depends on the solution pH. The experiments were performed with SSE and all results are referred to this electrode.

The curve obtained in the pH 5 solution showed two current maxima. The current maximum located at a less anodic potential ($E = -1.09V$) will be called maximum I and the domain preceding this maximum will be called the active dissolution domain and that corresponding to subsequent current decrease up to the current minimum will be called the prepassivation domain. The further current increase corresponds to the prepassive dissolution and finally beyond current maximum II ($E = -0.75V$) the passivation process sets in. These labelings (30) were used for the sake of simplicity. Similar results were reported for weakly acidic media (15-18), but in contrast to (29), two maxima were obtained in the steady-state polarization curve. Two current maxima for the polarization curve of iron dissolution were also reported in different acid media (18, 31, 32).

A current arrest observed in the pH 4 solution near −1.0V is, as will be shown more clearly by the impedance measurements, closely related to the prepassivation process observed in the pH 5 solution. It can be seen that the shoulder current corresponding to maximum I for the pH 5 solutions is about ten times greater. No current arrest or shoulder is observed in the polarization curves obtained in a more acidic solution (pH ≦ 3). In these solutions, the current maximum is limited by convective diffusion (not shown in Fig. 1) and the limiting current is proportional to the square root of the rotation speed of the disk electrode. The transition from activity to passivity occurs by a steep current change under a voltage regulation (33, 34).

Electrode impedance.—Figure 2 shows the impedance diagrams obtained for the pH 0 solution at various polarization points: hydrogen evolution domain (K), open-circuit corrosion potential (A_0), and anodic dissolution (B_0-F_0). The steady-state conditions at which the impedance measurements were performed are marked by the corresponding letter in the polarization curve given on the same figure.

The diagram K was measured at the potential 0.06V cathodic to the open-circuit corrosion potential and shows only one capacitive loop. For pure iron, almost the entire surface is covered by adsorbed hydrogen, which is probably the reason why the relaxation of this coverage cannot be seen by the impedance (23). The electrode remained practically undamaged and retained its bright appearance after a 24 hr immersion at this potential. Besides, the inductive loop relating to dissolution was not seen, *i.e.*, the hydrogen adsorption hinders considerably the metal dissolution process. It was also noticed that the steady-state current was reached only after a 20 hr polarization at constant potential, indicating that interaction between iron and hydrogen is a very slow process. This slow current change was observed in the cathodic domain and at potentials very slightly anodic to the open-circuit corrosion potential. These observations were interpreted by the blocking nature of a strongly bonded adsorbed hydrogen (35). In the anodic range for instance $J > 2$ mA · cm^{-2} in the pH 0 solution, where no blocking nature of hydrogen is observed, the current reaches a steady state within 10 min.

At the open-circuit corrosion potential, the surface coverage by hydrogen is still close to unity for pure iron. This is the reason why diagram A_0 shows only one inductive loop. The desorption of hydrogen occurs

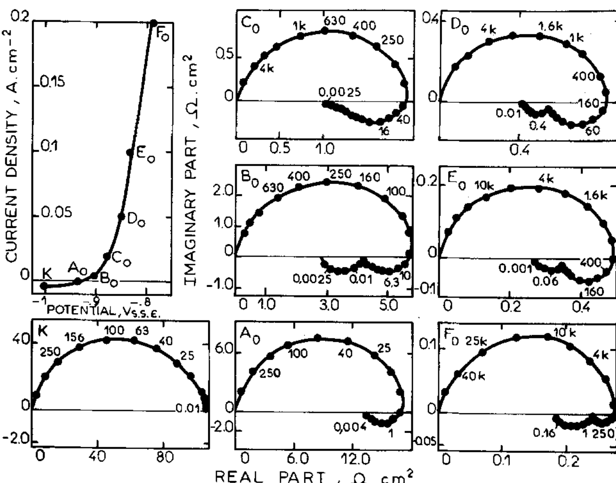

Fig. 2. Impedance diagrams in pH 0 solution. Polarization points about which the impedance was measured are marked on the polarization curve by corresponding letter. Parameter is frequency in Hz.

at potentials considerably anodic to the open-circuit corrosion potential. This slow process can be seen in the hysteresis cycle exhibited by the polarization curves when measured by the voltage sweep method (23). During the potential-increasing sweep, the hydrogen desorption cannot reach its steady state and the metal dissolution takes place on a smaller surface area than its steady-state value. Hydrogen desorption will be complete only at high anodic potentials. During the reverse sweep, the hydrogen coverage becomes significant only when the electrode potential becomes very cathodic and iron dissolution takes place over almost the entire surface area. When certain organic inhibitors, such as an acetylenic alcohol, is added to the electrolyte, the hysteresis loop is enlarged (36). On the other hand, the steady-state plot does not show the hysteresis and the current value is independent of the direction of voltage sweep. In the impedance diagram, the adsorption-desorption of hydrogen is detected by the inductive loop in the lowest frequency domain as shown in diagrams B_0 and C_0 (36, 37).

Thus the Tafel slope determined at low current densities is under the influence of both the iron dissolution process and the adsorption-desorption of hydrogen. In this range, the potential-decreasing sweep gives roughly the Tafel slope related only to the dissolution process on an hydrogen-free surface and values close to 0.06V. The Tafel slope can also be roughly evaluated by the R_p' value corresponding to the extrapolation toward the low frequency limit of the higher-frequency inductive loop, *i.e.*, at a frequency high enough to have a constant hydrogen coverage. If, locally, the polarization curve follows the Tafel law whose slope is B, the product of R_p' times the current J gives

$$B = \ln 10 \times R_p' \cdot J \qquad [2]$$

Diagrams B_0 and C_0 give the B value close to 0.06V. This dynamic value can be related to the transient Tafel slope determined by Heusler (4).

It can be concluded that low values of the Tafel slope (0.03-0.04V) observed in the low current density range arise clearly from a potential-dependent hydrogen coverage and must not be used for mechanistic purposes and particularly as a proof for a first step at equilibrium. This result illustrates the advantage of a-c techniques compared to steady-state experiments for discriminating between various contributions in the electrode process.

At high current densities (diagrams D_0, E_0, and F_0), two inductive loops can also be observed in impedance diagrams in agreement with our previous measurements (27). The origin of the lower-frequency loop is different from that observed at low current densities, which is no longer detected at current densities greater than 0.02 A · cm^{-2}. At higher current densities, no hydrogen adsorption takes place. It can also be remarked that the characteristic frequency, corresponding to the top of the low-frequency inductive loop, is ten to one hundred times greater than that observed by the relaxation of hydrogen coverage. The lower-frequency inductive loop is actually related to the iron dissolution process.

Impedance diagrams plotted in the pH 1 solution were very similar to those measured in the pH 0 solution. It can nevertheless be remarked that the characteristic frequencies of two inductive loops decrease for a given current density as the pH increases. In Fig. 3, the impedance diagrams relating to the pH 2 solution are shown. Diagrams A_2 and C_2 are very close to those observed in strongly acidic media though similar diagrams were observed at current densities about ten times greater compared to those in the pH 0 solution. On the other hand, at higher current densities (diagrams D_2 and E_2) three inductive loops can clearly be seen. None of them originates in the adsorption-desorption of hydrogen; thus they are all to be attributed to

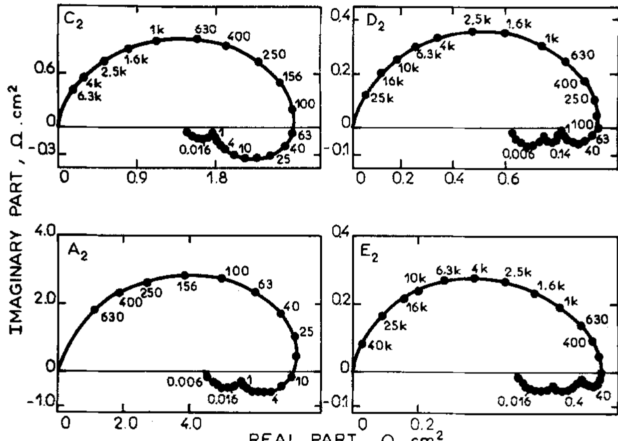

Fig. 3. Impedance diagrams in pH 2 solution. Polarization points marked on curve 2 in Fig. 1.

the iron dissolution process. The presence of three time constants is reported by (29) even in a strongly acid medium.

Again, in the pH 2.6 solution (Fig. 4), and with the experimental conditions examined here, only two time constants, in addition to the high-frequency capacitive loop, can be seen. If the characteristic frequencies are compared to those of the pH 2 solution, the relaxation process corresponding to the lowest and highest frequencies in the pH 2 solution are visible in the pH 2.6 solution. The comparison of diagrams C_3 and E_3 reveals that the lower-frequency inductive loop (diagram C_3) transforms into a capacitive loop when the anodic potential increases. The diameter of this capacitive loop becomes considerably greater when the potential becomes further anodic (diagram F_3).

In Fig. 5, the impedance diagrams relative to the pH 4 solution are shown. Diagrams A_4 and C_4 are very similar to diagrams C_3 and E_3, respectively. The transformation of the lower-frequency inductive loop into the capacitive one takes place at lower current density when the solution pH increases. In the pH 4 solution, the shoulder on the polarization curve was observed. Diagram E_4 is obtained at a potential very close to this shoulder potential. The low-frequency capacitive branch shows a very high value of the zero-frequency limit of the electrode impedance corresponding to the slope of the polarization curve almost parallel to the voltage axis. In the potential range more anodic to this shoulder, three time constants, in addition to that related to the high-frequency capacitive loop, are revealed by two capacitive and one inductive loops, as seen in diagram H_4.

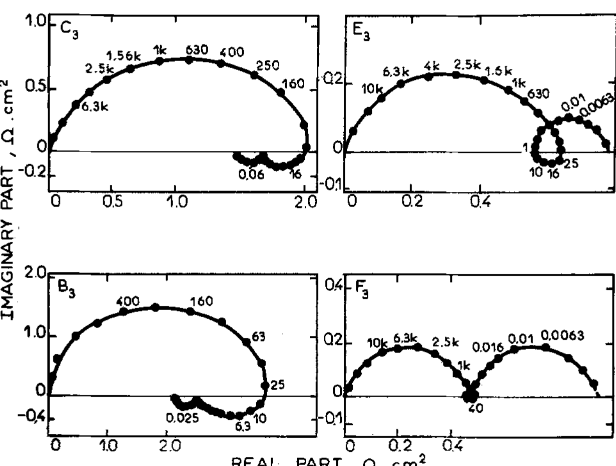

Fig. 4. Impedance diagrams in pH 2.6 solution. Polarization points marked on curve 3 in Fig. 1.

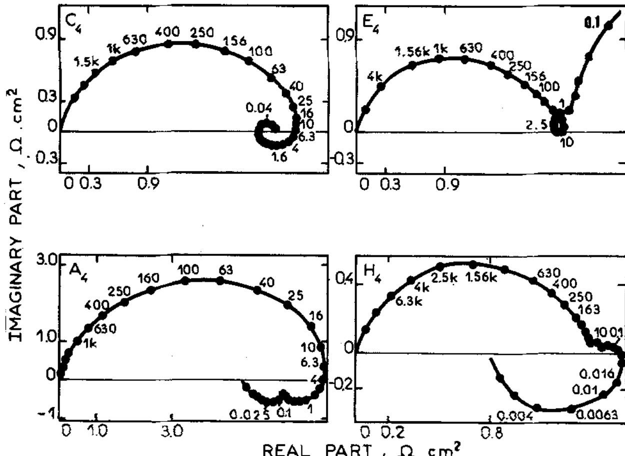

Fig. 5. Impedance diagrams in pH 4 solution. Polarization points marked on curve 4 in Fig. 1.

The impedance diagrams obtained in the pH 5 solution are shown in Fig. 6. Diagram D_5 is obtained in the active dissolution domain. This diagram is very similar to those observed in a more acidic solution. The low-frequency capacitive loop observed in diagram D_5 is directly related to the prepassivation process as indicated in diagram E_5. From these results, it can be corroborated that the current shoulder observed in the pH 4 solution is actually related to the prepassivation process because the low-frequency capacitive branch of diagram E_4 is compared to the capacitive branch leading to the negative polarization resistance (limit of the zero frequency of the electrode impedance which is equal to the slope of the steady-state polarization curve). Diagram F_5, obtained in the polarization corresponding to the prepassive dissolution domain, is very similar to diagram H_4 (Fig. 5) obtained at the potential more anodic to the current shoulder. A relatively large capacitive loop observed in diagram F_3 (Fig. 4) in the pH 2.6 solution may indicate that the transition to prepassive dissolution is taking place at rather high current density ($J > 0.1$ A · cm^{-2}) even in this solution, without showing any current maximum or current shoulder. Diagrams H_4 and F_5 show also that the capacitive loop leading to the prepassivation process transforms again into the inductive loop when the polarization points are reached in the prepassive dissolution domain. Since the passivation process can only appear as a capacitive loop (38), this transformation seems to indicate that the species leading to the prepassivation process progressively vanishes in the prepassive dissolution range. This observation was found later to be very crucial for the choice of the reaction model (see Part II).

When the potential becomes very anodic, $E \simeq -0.95$V, all relaxation phenomena disappear in the impedance diagram and only one capacitive loop at the high-frequency range was observed. At a more anodic potential, approaching maximum II, two time constants, in addition to the high-frequency capacitive loop, are again observed. One of them reveals itself as a capacitive loop and is related to the passivation process as can be seen on diagrams H_5 and I_5.

The high-frequency capacitive loop is attributed to the double layer capacity in parallel with the charge-transfer resistance R_t. The product of R_t times the d-c current J indicates the change of the reaction path as will be shown later. In fact, the $R_t \cdot J$ value, which is close to 0.04V in the active dissolution domain, increases with the electrode potential and reaches about 0.08V in the prepassive dissolution domain. The increase of the $R_t \cdot J$ value is observed even in the pH 0 solution, which actually indicates that the change of dissolution paths is also taking place in a strongly acidic solution even though the steady-state polarization curve hardly reveals any such phenomenon.

It seems useful to summarize the main experimental results:

1. Impedance diagrams of iron dissolution reveal, under certain experimental conditions, three time constants in addition to that related to the double layer capacity-charge transfer resistance before the onset of the passivation process.

2. In pH 2 solution, these three time constants are revealed by three inductive loops.

3. They are all clearly observed at the beginning of the prepassive dissolution domain. Under other conditions, with the iron specimen used here, only two time constants were observed clearly.

4. The prepassivation process, clearly observed in the pH 5 solution, can be seen as a current shoulder in the pH 4 solution. Only the impedance measurements performed at relatively high current densities (diagram F_3 in Fig. 4) indicate the existence of this process in the pH 2.6 solution.

5. The species leading to the prepassivation process seems to decrease its surface coverage again when the polarization potential attains the prepassive dissolution domain.

6. The current density at which the change of dissolution paths occurs depends on the solution pH. The more acidic the solution, the greater the current density at which this change takes place.

7. The measurements of the $R_t \cdot J$ value show the change of the reaction paths even in a very acidic solution. The steady-state polarization curve hardly reveals such a change.

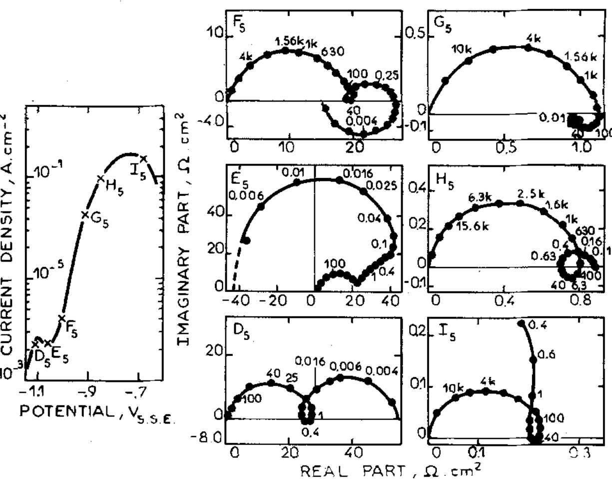

Fig. 6. Impedance diagrams in pH 5 solution. Polarization points marked on curve a.

Results of Calculation

Reaction model.—As will be shown in Part II, among all of the schematic configurations of reaction paths implying three intermediate species, only one model is able to interpret the set of experimental results

Model V

$$
\begin{array}{ccccc}
 & Fe^*(I)_{ad} & & & \\
 & K_3\uparrow\downarrow K_{-3} & & \searrow K_4 & \\
Fe \xrightarrow{K_1} & Fe(I)_{ad} & \xrightarrow{K_2} & & Fe(II)_{sol} \\
 & & K_5 \searrow\nwarrow K_{-5} & & \uparrow K_6 \\
 & & & & Fe^*(II)_{ad} \\
 & & & & K_7\downarrow\uparrow K_{-7} \\
 & & & & Fe(II)_{ad}
\end{array}
$$

K_4 reaction:

$$Fe^*(I)_{ad} + Fe \xrightarrow{K_4} Fe^*(I)_{ad} + Fe(II)_{sol} + 2e^-$$

K_6 reaction:

$$Fe^*(II)_{ad} + Fe \xrightarrow{K_6} Fe^*(II)_{ad} + Fe(II)_{sol} + 2e^-$$

As can be seen, this reaction model stems from model III by introducing a third dissolution path. The reactions relating to K_4 and to K_6 are both self-catalytic and no consumption of $Fe^*(I)_{ad}$ and $Fe^*(II)_{ad}$ takes place. The reason for such a process is explained in detail in Part II, but essentially this assumption allows one to make the time constant of the corresponding relaxation process independent of the d-c current flux. The passivation process, K_7/K_{-7} path, forms a bivalent passivation species. In fact, the formation of the Fe(III) passive species becomes significant only at potentials very close to the Flade potential, and the main part of the current decrease in the passivation process is due to the Fe(II) coverage (39). In this paper, nevertheless, the main interest is focused on the iron dissolution process. In the model examined in Part II, the passivation process accounted for by the K_7/K_{-7} path will be omitted since we are interested only in the mechanism of iron dissolution. However in the pH 5 solution, this passivation can no longer be ignored. It can also be seen that the reaction scheme includes three dissolution paths, K_2, K_4, and K_6. The K_1 reaction is considered to be irreversible according to our previous investigations (25, 27, 37). The reactions relating K_3/K_{-3}, K_5/K_{-5}, and K_7/K_{-7} are reversible but not necessarily in pseudo-equilibrium, *i.e.*, the reaction rate of these reactions is not necessarily very high compared to others (see Part II). Neither the role of OH^- ion is *a priori* considered nor the chemical nature of the intermediate species. Conclusions will be drawn only from the pH dependence of the kinetic parameters as they result from the numerical simulation.

Equation setup.—The reaction scheme given above will be transcribed into the series of mathematical expressions using a certain number of hypotheses. They are identical to those used in previous works and are summarized in the following:

1. The elementary steps obey the Tafel law.
2. The Tafel coefficient α is any value between 0 and 1 and is independent of potential.
3. The intermediate species occupies the fraction θ of the electrode surface and the adsorption-desorption follows the Langmuir-type isotherm law. θ_1 indicates the fraction of the surface covered by $Fe(I)_{ad}$, θ_2 by $Fe^*(I)_{ad}$, θ_3 by $Fe^*(II)_{ad}$, and θ_4 by the passivating species $Fe(II)_{ad}$. No overlapping of these coverages is considered thus $\theta_1 + \theta_2 + \theta_3 + \theta_4 < 1$. The so-called chemical reaction step, implying no electron transfer, may be potential dependent (see Part II).

Based on these hypotheses, the charge balance gives the current flowing through the electrode interface

$$\frac{J}{\mathbf{F}} = K_1\Sigma + (K_2 + K_5)\theta_1 + 2K_4\theta_2 + (2K_6 - K_{-5})\theta_3 \quad [3]$$

where $\Sigma = 1 - \theta_1 - \theta_2 - \theta_3 - \theta_4$, K is the potential-dependent parameter, and θ is the potential- and time-dependent parameter. Since J is expressed in $A \cdot cm^{-2}$, K implies implicitly the concentration expressed in $mole \cdot cm^{-2}$. The mass balance of the adsorbed species allows one to express the time dependence of θ through differential equations

$$\beta_1 \frac{d\theta_1}{dt} = K_1\Sigma - (K_2 + K_3 + K_5)\theta_1 + K_{-3}\theta_2 + K_{-5}\theta_3 \quad [4]$$

$$\beta_2 \frac{d\theta_2}{dt} = K_3\theta_1 - K_{-3}\theta_2 \quad [5]$$

$$\beta_3 \frac{d\theta_3}{dt} = K_5\theta_1 - (K_{-5} + K_7)\theta_3 + K_{-7}\theta_4 \quad [6]$$

$$\beta_4 \frac{d\theta_4}{dt} = K_7\theta_3 - K_{-7}\theta_4 \quad [7]$$

β is the constant linking the fraction of the surface θ and the surface concentration of adsorbed species expressed in $mole \cdot cm^{-2}$. β_i values are considered to be equal to 10^{-8} $(mole \cdot cm^{-2})$ which corresponds to about one monolayer for the case of one intermediate bonding to one surface metal atom. K_4 and K_6 do not intervene in the mass balance because the related reactions neither produce nor consume the intermediate species.

Steady state.—The steady state is characterized by the constancy of the surface coverage with time, *i.e.*, $d\theta/dt = 0$. Putting this condition into Eq. [4]-[7], the steady-state value of θ can be calculated

$$\bar{\theta}_1 = \frac{K_1K_{-3}K_{-5}K_{-7}}{D}; \quad \bar{\theta}_2 = \frac{K_1K_3K_{-5}K_{-7}}{D}; \quad \bar{\theta}_3 = \frac{K_1K_{-3}K_5K_{-7}}{D}$$

and

$$\bar{\theta}_4 = \frac{K_1K_{-3}K_5K_7}{D}$$

where

$$D = K_1K_{-3}K_5K_7 + [K_1\{K_3K_{-5} + K_{-3}(K_5 + K_{-5})\} + K_2K_{-3}K_{-5}]K_{-7} \quad [8]$$

By using the steady-state expressions of Eq. [4]-[7], the steady-state current can be expressed by

$$\frac{\bar{J}}{\mathbf{F}} = 2(K_2\bar{\theta}_1 + K_4\bar{\theta}_2 + K_6\bar{\theta}_3) \quad [9]$$

The steady-state polarization curve thus can be computer simulated according to Eq. [8] and [9] with suitable values of $K_{0,i}$ and b_i $(=\alpha_i\mathbf{F}/RT)$.

Faradaic impedance.—The electrode impedance is defined by perturbing the electrode interface with a small signal. About the d-c potential $\bar{E}$, a sine wave potential change δE of small amplitude $|\delta E|$ will be superimposed. If its frequency is f(Hz), its angular frequency ω is equal to $2\pi f$, then

$$\delta E = |\delta E| \exp(j\omega t), \qquad j = \sqrt{-1}$$

This potential change prompts the variation of J, (δJ), of the same frequency about its steady-state value $\bar{J}$. The faradic impedance Z_F can be calculated by the Taylor expansion of Eq. [3] limited to the first order

$$\frac{1}{Z_F} = \frac{1}{R_t} - \mathbf{F}\left\{(K_1 - K_2 - K_5)\frac{d\theta_1}{dE} + (K_1 - 2K_4)\frac{d\theta_2}{dE} + (K_1 + K_{-5} - 2K_6)\frac{d\theta_3}{dE} + K_1\frac{d\theta_4}{dE}\right\}$$

where

$$\frac{1}{R_t} = \mathbf{F}[(b_1 + b_2)K_2\bar{\theta}_1 + 2b_4K_4\bar{\theta}_2 + \{(b_5 + b_{-5})K_{-5} + 2b_6K_6\}\bar{\theta}_3] \quad [10]$$

R_t is the charge-transfer resistance corresponding to the high-frequency limit of the faradaic impedance at which θ can no longer follow the potential change, *i.e.*, $d\theta/dE = 0$. If K_{-5} is small, the charge transfer resistance is closely correlated to the steady-state current given in Eq. [9]. In other words, if one of the reaction paths is very fast compared to others, for instance $K_2\theta_1$,

the product of R_t by the current $\bar{J}$ is constant, for instance equal to $2/(b_1 + b_2)$ (25). When there is a change in the reaction path, for instance to the K_4 path, the $R_t \cdot \bar{J}$ value approaches $1/b_4$ continuously. The change of the $R_t \cdot J$ value corresponds thus to the change of reaction path.

Z_F can be calculated if $d\theta/dE$ is determined, which contains implicitly the relaxation of θ due to the potential perturbation. This term can be derived from Eq. [4]-[7]. With a sine wave potential change, θ changes also in a sine wave of the same frequency. Thus $d\delta\theta/dt = j\omega\delta\theta$ and then

$$X_1 = Z_1 \frac{d\theta_1}{dE} + (K_1 - K_{-3}) \frac{d\theta_2}{dE} + (K_1 - K_{-5}) \frac{d\theta_3}{dE} + K_1 \frac{d\theta_4}{dE}$$

where

$$X_1 = (b_1 - b_2) K_2 \bar{\theta_1} - (b_3 + b_{-3}) K_{-3} \bar{\theta_2} - (b_5 + b_{-5}) K_{-5} \bar{\theta_3}$$

$$Z_1 = K_1 + K_2 + K_3 + K_5 + j\omega\beta_1 \quad [11]$$

$$X_2 = -K_3 \frac{d\theta_1}{dE} + Z_2 \frac{d\theta_2}{dE}$$

where

$$X_2 = (b_3 + b_{-3}) K_{-3} \bar{\theta_2}$$

and

$$Z_2 = K_{-3} + j\omega\beta_2 \quad [12]$$

$$X_3 = -K_5 \frac{d\theta_1}{dE} + Z_3 \frac{d\theta_3}{dE} - K_{-7} \frac{d\theta_4}{dE}$$

where

$$X_3 = \{(b_5 + b_{-5}) K_{-5} + (b_5 - b_7) K_7\} \bar{\theta_3} - (b_5 + b_{-7}) K_{-7} \bar{\theta_4}$$

and

$$Z_3 = K_{-5} + K_7 + j\omega\beta_3 \quad [13]$$

$$X_4 = -K_7 \frac{d\theta_3}{dE} + Z_4 \frac{d\theta_4}{dE}$$

where

$$X_4 = (b_7 + b_{-7}) K_{-7} \bar{\theta_4}$$

and

$$Z_4 = K_{-7} + j\omega\beta_4 \quad [14]$$

Once $K_{0,i}$ and b_i are determined, Eq. [11]-[14] allow calculation of $d\theta_i/dE$, and substituting these values into Eq. [10], the faradaic impedance is obtained. Setting the double layer capacitance C_{dl} in parallel with Z_F, the electrode impedance is numerically simulated. The value of C_{dl} is considered to be equal to 100 $\mu F \cdot cm^{-2}$ independent of the electrode potential, though a slight dependency was observed experimentally.

Calculation results.—Since in the pH 5 solution, the prepassivation process was clearly observed and also since the impedance diagrams were plotted throughout the polarization curve, the experimental results from

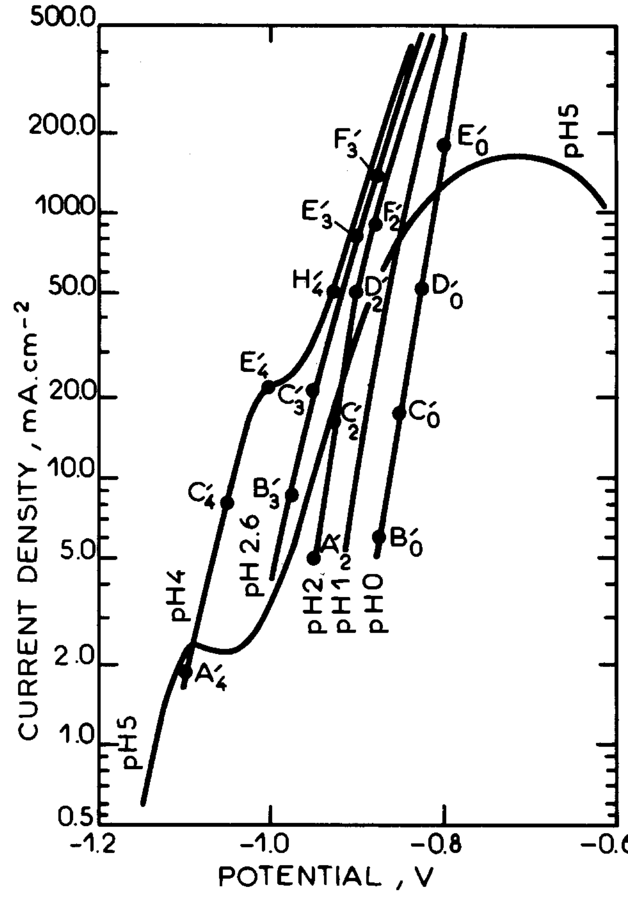

Fig. 7. Simulated polarization curves; rate constants are shown in Tables I and II. Corresponding solution pH is marked near the curve.

this solution are first numerically simulated. The kinetic constants that gave satisfactory results are shown in Table I.

The results relative to other pH solutions are also computer simulated. To perform this, one attempts to reproduce the experimental results by keeping the b_i value independent of pH and by modifying the least number of $K_{0,i}$ values. We tried to change the rate constant $K_{0,i}$ monotonically with respect to the solution pH. The reaction order for each process is not introduced *a priori*. The $K_{0,i}$ values used for the simulation calculation are summarized in Table II.

The results of the simulation calculation of the steady-state polarization curves are shown in Fig. 7. The simulated impedance diagrams for the solutions of different pH are shown in Fig. 8-12. These figures will be compared to the experimental results shown in Fig. 1-6. The steady-state polarization curves obtained by the simulation calculation are similar to the experimental curves, except the bending observed experimentally at high current densities is ignored in simulation curves. This is the price to be paid for better agreement of the impedance diagrams. The model reflects

well the increase of the $R_t \cdot J$ value with electrode potential. Thus model V interprets suitably the numerous results obtained over wide *p*H and current-density ranges.

The parameters shown in Table II are sensitive to *p*H change, but their change deviates somewhat from a linear law. The rate constants are dependent not only on the solution *p*H but also on impurities and crystal imperfections. This may be the reason for the observed scatter. The reaction order "n" was calculated for each rate constant accompanied with correlation coefficient r ($= n\sqrt{\sigma_{pH}2/\sigma_{K_0}2}$) by the least mean squares method. An integral number for the reaction order was not found. At the moment, the reason for a nonintegral reaction order has not been elucidated, although it is rather commonly encountered in heterogeneous kinetics. In this particular case, the OH^- concentration change covers such a wide range, 10^5, that a change in

the chemical nature of the intermediate cannot be excluded. The determination of the fine structure of reactions and intermediates remains beyond the scope of the present work. The reaction steps considered may not, strictly speaking, be related to the true elementary steps, but are introduced as possible overall steps sensitive to the electrode impedance.

Figure 13 shows the contribution of each dissolution path to the overall current, calculated for the *p*H 5 so-

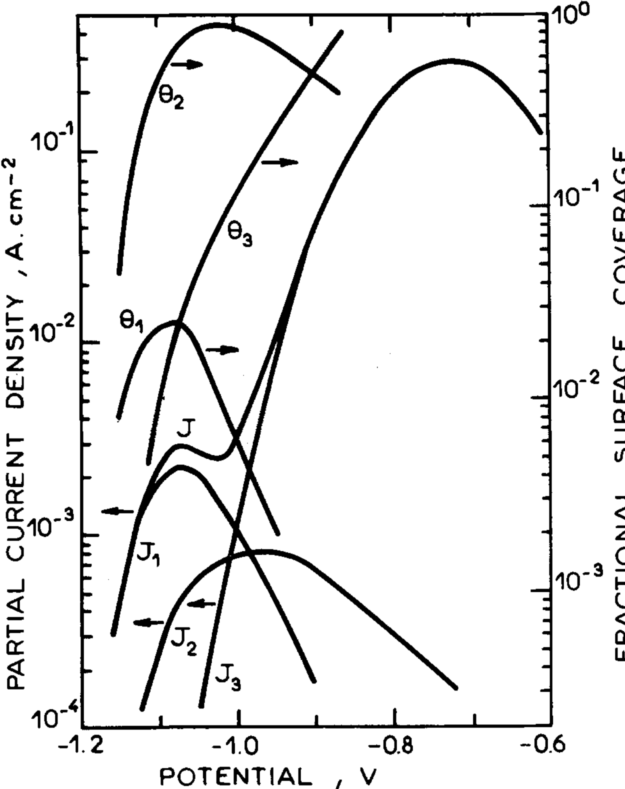

Fig. 13. Contribution of partial currents for the overall current J. Simulation calculation for the pH 5 solution. J_1 the current through K_2 reaction, J_2 and J_3 are, respectively, the current through K_4 and K_6 reaction. Change of surface coverage with respect to potential. θ_1 is the fractional surface coverage by $Fe(I)_{ad}$, θ_2 by $Fe^*(I)_{ad}$, and θ_3 by $Fe^*(II)_{ad}$.

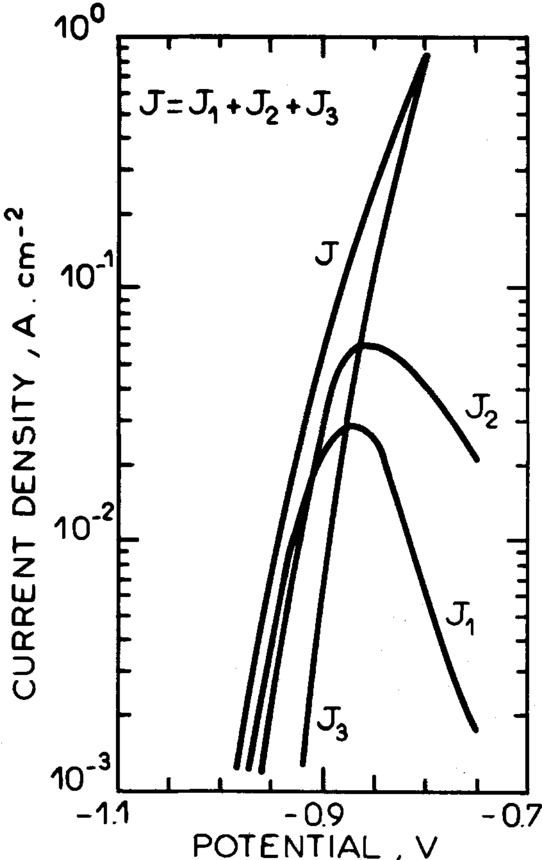

Fig. 14. Contribution of partial current for the overall current. Simulation calculation for pH 2 solution. J_1, J_2, and J_3 see Fig. 13.

lution. It can be seen that at very low anodic potential in the active dissolution domain, the metal dissolves through the K_2 reaction path (J_1). On the other hand, prepassive dissolution is almost entirely limited by the K_6 dissolution path (J_3). In this way, the model proposed by Lorenz *et al.* (15-18) is verified in the corresponding pH medium. However, the decrease of θ_1, consequently the prepassivation process, is due to the increase of θ_2, the surface coverage by $Fe^*(I)_{ad}$. The current minimum is coincident to the maximum of θ_2 which will be gradually replaced by $Fe^*(II)_{ad}$ coverage. The dissolution through K_4 reaction (J_2) contributes to the current minimum not too much pronounced in agreement with the experiments.

Figure 14 shows the contribution of different dissolution paths on the overall current for the pH 2 solution. It can be seen that the K_2 dissolution path controls in the low current density domain, whereas the K_6 dissolution path determines the overall current at high current densities. The K_4 dissolution path is the fastest process within the narrow domain in which three inductive loops were clearly observed. The comparison of Fig. 13 and 14 shows that the contribution of J_1, J_2, and J_3 with respect to the potential is relatively similar and the approach of J_1 and J_3 curves is the main cause for not observing maximum I.

In models III and IV, the influence of sulfate ion concentration is suggested, respectively, in the K_5/K_{-5} and in the K_4 reaction. In this paper, the overall sulfate concentration was kept constant and the effect of HSO_4^- and SO_4^{2-} was not examined.

Conclusion

The experimental results covering a very wide range of current density, solution pH value, and frequency allowed the establishment of the reaction model of iron dissolution in acidic sulfate media. The simulation calculations are performed by computer for the reaction model implying three dissolution paths using several hypotheses previously used in this Laboratory. Three intermediate species, corresponding to three dissolution paths, are revealed under capacitive or inductive loops. The calculated impedances correspond well to those obtained by experiment. The pH dependence of the different reactions are examined on the basis of the experimental results. The model proposed here is limited to the current density range where mass transfer does not affect the reaction rate.

Acknowledgment

This paper in two parts is dedicated to the memory of the late Dr. I. Epelboin who died during the last stages of this work. This paper constitutes a part of O.R.M.'s Thesis to be submitted to the Université Pierre et Marie Curie.

Manuscript submitted July 16, 1980; revised manuscript received Sept. 19, 1980. This was Paper 262 presented at the Los Angeles, California, Meeting of the Society, Oct. 14-19, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by the Centre National de la Recherche Scientifique (CNRS).

Reaction Model for Iron Dissolution Studied by Electrode Impedance

II. Determination of the Reaction Model

Michel Keddam, Oscar Rosa Mattos, and Hisasi Takenouti

Groupe de Recherche No. 4 du CNRS "Physique des Liquides et Electrochimie," associé à l'Université Pierre et Marie Curie, 75230 Paris Cedex 05, France

ABSTRACT

The electrode impedance determined experimentally shows a certain number of time constants as capacitive or inductive features. These impedances arise from various processes occurring at or near the electrode interface, such as charge transfer, adsorption-desorption of reaction intermediate species, changes of the roughness factor, changes of the number of active sites or of volume concentration in the vicinity of the electrode, etc. The origins of impedances are examined on the basis of experimental results given in Part I. Then, hypotheses describing reaction rates, such as the Tafel law, reaction reversibility, and the adsorption isotherm law, are analyzed in order to translate reasonably the reaction models into mathematical expressions. With hypotheses retained, it is concluded that the experimental results should be interpreted by a model including three adsorbed reaction intermediate species. Forty possible reaction schemes, as the complete set of prospective models, were written and examined according to both steady-state polarization curves and electrode impedances. The appearance of two current maxima implies at least two dissolution paths in the reaction models and allowed us to eliminate 10 of the 40 reaction schemes. On the other hand, the appearance of inductive impedance was found to constitute a very selective criterion. Only one model, given in Part I, was found to simulate suitably the whole set of experimental results.

In Part I (1), the experimental results of the steady-state polarization curves and the electrode impedance measurements performed over wide ranges of pH and current density were shown. These results were interpreted quantitatively on the basis of the reaction model. In this paper, the reasons for which this model

Key words: capacitance, electrode kinetics, inductance, surface relaxation, transfer coefficient.

is selected from 40, corresponding to the complete set of possible prospective reaction schemes, is described. But first, critical examinations are made of various hypotheses by which reaction models are translated into mathematical expressions. When the electrode kinetics are analyzed by a crude method, even with unduly restrictive hypotheses, the results are interpreted on the basis of a model. For instance, a steady-state polarization curve indicates only the overall reaction rate which depends on the slowest reaction path for a series process or on the fastest reaction path for a parallel process. Thus the hypotheses regarding other processes may have little influence on a calculated polarization curve. On the other hand, with hypotheses that allow too much flexibility in mathematical expressions, numerous models may explain the same results.

The electrode impedance contains varied information, in particular, on intermediate reaction steps. Even if they cannot sensitively affect the overall reaction rate, their contribution cannot, very often, be neglected in the electrode impedance. Since many impedance diagrams are plotted along with steady-state polarization curves, the number of results that should be taken into consideration for comparison of the models and experiments increases considerably. Furthermore, as was shown elsewhere (2), the electrode impedance behaves as an inductance or as a capacitance according to rather well-determined analytical conditions. With hypotheses that restrict the possibility of quantitative exploitation of any tested model, satisfactory agreements between experimental results and those drawn from a model become difficult or impossible to realize. It can also be noticed that the experimental conditions at which the iron dissolution was performed in this study are unusually wide: the H^+ concentration was spread over five orders of magnitude and the current densities changed by more than two orders. More realistic hypotheses have to be taken into consideration.

Examinations of Hypotheses

Origins of the electrode impedance.—The different origins of the electrode impedance were examined with mathematical models by Grahame (3). But in all of these models, the electrode impedance appears only as a capacitive feature. It can also be noticed that the transcription of a reaction model into a set of mathematic expressions is not very easy with the formalism used in this paper. In 1955, Gerischer and Mehl (4) established that the relaxation of surface coverage by an adsorbed intermediate species is able to cause a capacitive as well as an inductive faradaic impedance. This formalism was used by Epelboin and Keddam (5) to interpret quantitatively the results of impedance measurements during iron dissolution in acidic sulfate media.

Since then, the electrode impedance of various electrochemical interfaces of greater complexity during anodic as well as cathodic processes were largely interpreted on the basis of this concept. However, this is not the only possible origin of the electrode impedance: it is well known that mass transport, if it intervenes in the overall reaction rate, contributes to the electrode impedance (6). In passivity, the growth of the oxide film gives rise to a capacitive or inductive impedance (7). But the experiments on iron dissolution examined in this paper were performed under such conditions that these processes did not need to be taken into account.

If the electrode surface area is dependent on potential and on time through the roughness factor or the number of active sites N^*, these phenomena interfere in the electrode kinetics and will appear in the electrode impedance. Bignold and Fleischmann (8) also discussed origins of the time constant observed during iron dissolution, and they considered the pit-shaped relaxation: when iron dissolves, conical pits are formed on the surface. The number of pits is determined by the number of dislocations and thus constant, but the pit form is potential dependent. In other words, the roughness factor is considered as a time and potential-dependent parameter. By considering the overlapping of conical pits, they concluded that the relaxation time constant is reciprocally proportional to the current.

In the case of electrodeposition, the short period current transient was interpreted by the formation of crystal nuclei and their growth (9, 10). But this model cannot describe the steady state and the related impedance since no equation of mass balance is proposed for the time dependence of N^*. This type of model was reformulated, very recently, in our Laboratory, (11) for successfully describing the electrodeposition of silver in order to express the impedance as a step-line propagation of the crystallite. Lorenz and Schweikert (12) considered the potential and time dependence of the number of active sites without any physicochemical model. The expression of dN^*/dt in the case of dissolution cannot be compared to the formation of crystal nuclei; thus calling it negative deposition does not resolve the problem physically.

The time constants observed in the electrode impedance, whatever their origin, are interpreted by the relaxation phenomenon of "sites." If these sites are metal atoms bonded with a chemical species and if they are taking part in the reaction, the adsorption of intermediate species is inferred. The relaxation time constant is thus dependent on the chemistry of the interface. If these sites are specific points on the metal surface, in particular crystallographic imperfections, the active sites may be considered. The relaxation time constants will be essentially determined by the metal specimen itself. Heusler used successively both concepts for the same iron electrode (13-15). Numerous observations concerning the influence of potential, of solution pH, and of the addition of alloying elements such as Cr (16), indicate that the change of chemical nature of the parameter determines the time constants observed in the electrode impedance. Thus, it can be reasonably assumed that, in the case of iron dissolution, the origin of the time constants, except that related to the high-frequency capacitive loop, is due to the relaxation of surface coverages by reaction intermediate species. Since this relaxation rate is essentially dependent on the formation and the consumption of intermediate species, the hypotheses which will be used to express reaction rates in mathematical form have to be examined in detail. The main hypotheses concern the potential dependence and reversibility of the reaction rate and an adsorption isotherm law. These three points are examined in this order in the following.

Potential dependence of reaction rate.—It is generally admitted that the reaction rate follows with respect to the potential the so called Tafel law (17, 18)

$$K = K_0 \exp\left(\frac{z\alpha \mathbf{F}}{RT} E\right) \quad [1]$$

The value of α has been found to be 0.5 for the hydrogen evolution reaction on various metals (19), and this value is widely assumed to be valid for any other electrochemical process. However, from the view point of theory, α may have any value between 0 and 1 (20, 21) and may be potential dependent (22, 23).

Though the potential range considered in this work is very wide, the Tafel law (α = constant) can be considered as a reasonably restrictive approximation.

When the solution pH is changed, the chemical nature of intermediate species may be modified. Thus α could be considered to be pH dependent especially when a very wide range of pH is investigated.

Reversibility of reaction.—In early works on iron dissolution, the electrode kinetics were examined in the potential range near its thermodynamic equilibrium

potential (24-26). Notice that the model proposed in (24) concerns both dissolution and electrodeposition of iron. This model (model II) is recalled here

$$\mathrm{Fe} + \mathrm{OH}^- \underset{K_{-1}}{\overset{K_1}{\rightleftarrows}} (\mathrm{FeOH})_{\mathrm{ad}} + e^- \quad \text{[II-1]}$$

$$(\mathrm{FeOH})_{\mathrm{ad}} \xrightarrow{K_2} (\mathrm{FeOH})^+ + e^- \quad \text{[II-2]}$$

Step [II-1] is considered to be in pseudo-equilibrium, *i.e.*, the reaction is reversible and very fast compared to step [II-2]. Thus, $K_{-1} >> K_2$. This situation is assumed to be realized in the region of the open-circuit corrosion potential (25).

There is no doubt that at the equilibrium potential all steps are in equilibrium. However, when the electrode potential is removed from this potential, the reaction becomes irreversible. This has been disregarded in previous works (27-30). At the onset of the passivation process, the difference from the equilibrium potential reaches *ca.* 1V. Considering that pseudo-equilibrium is maintained for such an overpotential seems unrealistic. The maximum current observed in this solution is limited by mass transfer even at the rotation speed of the disk electrode equal to 6000 rev · mn^{-1}, and was 2.6 A · cm^{-2}. If a pseudo-equilibrium were assumed for an intermediate step, its exchange current density would be greater than a few tens of A · cm^{-2}. This value is far greater than that known for any fast system of Red-Ox reaction (31).

Let us examine now the consequence of a pseudo-equilibrium reaction on the electrode impedance. Model II is used as an example. Considering that the Langmuir-type isotherm law is valid (32) (see the following paragraph), the charge balance due to model II can be written by

$$\frac{J}{\mathbf{F}} = (1-\theta)K_1 - (K_{-1} - K_2)\theta \quad [2]$$

The Taylor expansion of Eq. [2] limited to the first-order term leads to the expression for the faradaic impedance Z_F

$$\frac{1}{Z_F} = \frac{dJ}{dE} = \frac{1}{R_t} - \mathbf{F}(K_1 + K_{-1} - K_2)\frac{d\theta}{dE} \quad [3]$$

R_t is the charge transfer resistance corresponding to $(\partial J/\partial E)_\theta$, *i.e.*, the resistance value when any θ change is frozen, and can be calculated by

$$\frac{1}{R_t} = \left\{ (b_1 + b_2) + (b_1 + b_{-1})\frac{K_{-1}}{K_2} \right\} \frac{\bar{J}}{2} \quad [4]$$

The pseudo-equilibrium for the first step corresponds to $K_{-1} >> K_2$, thus $(K_1 + K_{-1} - K_2) > 0$. Since θ is a potential increasing function, $d\theta/dE > 0$, Z_F appears always as capacitive (2) and a so-called "pseudo-capacitance" is observed (25). The capacitance value depends on θ. The pseudo-capacitance is maximum at $\theta = 0.5$ and has the value of *ca.* 10 mF for $\beta = 10^{-8}$ (mole · cm^{-2}). For $\theta = 0.1$, the capacitance is equal to 3 mF for the same β value.

Experimentally, such a high capacitive value is not obtained in the high-frequency capacitive loop if the metal is of sufficient purity and the surface remains bright during the dissolution. Furthermore, if the high-frequency capacitive loop includes the pseudo-capacitance, two time constants should be seen. Experimentally, though, the high-frequency capacitive loop cannot be represented by a true *R-C* circuit and a frequency distribution can be observed (5). None of the results allowed us to ascertain the presence of two distinct time constants.

If the first step is irreversible, K_{-1} is very small and Eq. [4] leads to

$$R_t \cdot J = \frac{2}{b_1 + b_2} \quad (K_{-1} << K_2) \quad [5]$$

Thus the $R_t \cdot J$ value is independent of current. The minimum value of $R_t \cdot J$ can be calculated when $\alpha_1 = \alpha_2 = 1$ and is equal to 0.026V. Experimentally, the diameter of the high-frequency loop multiplied by the current yields a value close to 0.04V and remains constant up to medium current densities (5, 33). Thus the diameter of this loop may reasonably be attributed to the transfer resistance. The parallel capacitance, determined at the top of the loop, is *ca.* 100 μF · cm^{-2} and may reasonably be considered as the double layer capacitance. The high-frequency capacitive loop is thus considered to be due to the transfer resistance and the double layer capacitance.

Adsorption isotherm.—The simplest adsorption isotherm at appreciable θ values is the Langmuir type. The reaction rate K is assumed independent of θ, thus the rates of formation or of consumption k of a species concerned can be written by

$$k = k_i(1-\theta) \quad \text{or} \quad k_- = k_{-i}\theta \quad [6]$$

Strictly speaking, Eq. [6] is considered valid for $\theta <$ 0.2 or $\theta > 0.8$ and a more elaborate isotherm might be taken into consideration at intermediate θ values. It may be expected that by using a more elaborate isotherm, complicated results can be interpreted on the basis of simple models, at least for steady-state polarization curves (34, 35). No matter how elaborate is the isotherm, it does not give rise to an additional time constant. The number of processes to be considered is determined by experiment. On the other hand, mathematical resolution of the model becomes difficult and increases the number of parameters to be adjusted. Therefore, as a first approximation, the Langmuir-type isotherm is assumed. Since this isotherm is a rather crude model, it may affect a fine quantitative analysis (36). If the experiments cannot be simulated suitably, other isotherm will be considered.

The hypotheses which are used in this work are summarized in the following:

1. The high frequency capacitive loop is due to the double layer capacity and the transfer resistance.
2. The time constants observed in addition to hypothesis 1 are due to the surface coverage relaxation of reaction intermediate species.
3. The elementary steps obey the Tafel law. Tafel coefficient b values between 0 and $38.4\mathrm{V}^{-1}$ correspond to α values equal to 0 and 1, respectively, for a one-electron transfer.
4. The adsorption-desorption of intermediate species follows the Langmuir-type isotherm.
5. The reaction may be reversible but not necessarily in pseudo-equilibrium.

Criteria for Model Determination

Tafel slope measurements constitute one of the main criteria for the determination of the reaction mechanism. For instance, Lorenz *et al.* (37) found that the Tafel slope changed from 0.04 to 0.03V when the iron specimen was subjected to a severe mechanical deformation. This variation was interpreted by the change of the reaction model from model II to model I. However, with the hypotheses retained in this paper, such a consideration is no longer possible.

According to the hypotheses given above and assuming that the first step of model II is irreversible, model I has a Tafel slope smaller than 0.06V and model II greater than this value. On the polarization curves shown in Fig. 1 of Part I, it is seen that the Tafel slope, in the current density range where most work has been performed, is significantly smaller than 0.06V. This is true even when the current density is determined from weight loss measurements and no contribution of cathodic current is included (38). This result

may be interpreted in favor of model I. However, the impedance diagram B_0 (see Fig. 2 in Part I) shows clearly two inductive loops, which is in contradiction with model I. Both models I and II predict only one time constant corresponding to the relaxation of $(FeOH)_{ad}$. As was shown in Part I, the lower frequency inductive loop is due to the relaxation of surface coverage by hydrogen. The Tafel slope without the influence of hydrogen coverage is close to 0.06V, but this measurement cannot be used as the criterion for determination of the reaction model. The model will be examined in terms of both the polarization curves and the impedance diagrams obtained at various potentials.

Analysis of Models Including Two Intermediates

Since three time constants in addition to the high-frequency capacitive loop due to the double layer are observed in impedance diagrams, the iron dissolution model has to include at least three intermediate species. Before discussing the three-intermediate reaction model, it seems useful to examine two reaction models proposed in the literature. One was proposed by Lorenz *et al.* (27-30) on the basis of polarization curves obtained in weakly acidic media:

Model III

$$Fe \underset{K_{-1}}{\overset{K_1}{\rightleftarrows}} Fe(I)_{ad} \overset{K_2}{\rightarrow} Fe(II)_{sol} \qquad \theta_1 \text{ for } Fe(I)_{ad}$$

$$Fe(I)_{ad} \underset{K_{-3}}{\overset{K_3}{\rightleftarrows}} Fe(II)_{ad} \overset{K_4}{\uparrow} Fe(II)_{sol} \qquad \theta_2 \text{ for } Fe(II)_{ad}$$

K_4 reaction: $Fe(II)_{ad} + Fe \overset{K_4}{\rightarrow} Fe(II)_{sol} + Fe(I)_{ad} + e^-$

The other model was proposed by Bechet *et al.* (33) on the basis of steady-state polarization curves and impedance measurements in strongly to mildly acidic media:

Model IV

$$Fe \overset{K_1}{\rightarrow} Fe(I)_{ad} \overset{K_2}{\rightarrow} Fe(II)_{sol} \qquad \theta_1 \text{ for } Fe(I)_{ad}$$

$$Fe(I)_{ad} \underset{K_{-3}}{\overset{K}{\downarrow\uparrow}} Fe^*(I)_{ad} \overset{K_4}{\nearrow} Fe(II)_{sol} \qquad \theta_2 \text{ for } Fe^*(I)_{ad}$$

K_4 reaction: $Fe^*(I) + Fe \overset{K_4}{\rightarrow} Fe(II)_{sol} + Fe^*(I)_{ad} + 2e^-$

These two models are relatively similar and both have two dissolution paths. The K_2 dissolution path can be related to model II. The main difference between these two models are:

1. The K_1 reaction is considered to be in pseudo-equilibrium in model III and irreversible in model IV. Model III explains the 0.04V Tafel slope according to hypotheses discarded in this work.

2. In the K_4 reaction, both models imply the participation of an adjacent Fe, but model IV is a self-catalytic process and produces two electrons. On the other hand, model III is a noncatalytic and monoelectronic process. The two-electron transfer reaction is less likely to occur from the viewpoint of theoretical physical chemistry but seems intimately related to a catalytic reaction (13).

3. The intermediate species for the K_4 dissolution path is bivalent in model III and monovalent in model IV. Thus their formation implies one electron in model III and no electron transfer in model IV. This difference appears in the electrode impedance, as seen below.

Using the expressions of charge and mass balances, the steady-state current can be expressed by the same equation for both models

$$\bar{J} = 2\mathbf{F}(K_2\bar{\theta}_1 + K_4\bar{\theta}_2) \qquad [7]$$

On the other hand, the expressions for the faradaic impedance Z_F differ for the two models. For model III

$$\frac{1}{Z_F} = \frac{1}{R_t} - \mathbf{F}\left\{(K_1 + K_{-1} - K_2 - K_3)\frac{d\theta_1}{dE} + (K_1 + K_{-3} - K_4)\frac{d\theta_2}{dE}\right\} \qquad [8]$$

where

$$\frac{1}{R_t} = \mathbf{F}\{(b_1 + b_{-1})K_{-1}\bar{\theta}_1 + (b_1 + b_2)K_2\bar{\theta}_1 + (b_3 + b_{-3})K_{-3}\bar{\theta}_2 + (b_3 + b_4)K_4\bar{\theta}_2\} \qquad [9]$$

and for model IV

$$\frac{1}{Z_F} = \frac{1}{R_t} - \mathbf{F}\left\{(K_1 - K_2)\frac{d\theta_1}{dE} + (K_1 - 2K_4)\frac{d\theta_2}{dE}\right\} \qquad [10]$$

where

$$\frac{1}{R_t} = \mathbf{F}\{(b_1 + b_2)K_2\bar{\theta}_1 + 2b_4K_4\bar{\theta}_2\} \qquad [11]$$

Comparing Eq. [7] and [11], it can be seen for model IV that the product of R_t times $\bar{J}$ is equal to $2/(b_1 + b_2)$ when the metal dissolves through the K_2 path ($K_2\theta_1 >> K_4\theta_2$) and equals $1/b_4$ through the K_4 path. The change of the $R_t \cdot \bar{J}$ value indicates thus the change of dissolution path. Besides, if $(b_1 + b_2) > 2b_4$, the increase of the $R_t \cdot \bar{J}$ value, observed experimentally (33), can be explained in the reaction model. On the other hand, in model III (Eq. [9]), even if the K_1/K_{-1} reaction is considered to be irreversible, the change of the $R_t \cdot \bar{J}$ value is not so simply related to the change of the reaction path. At relatively low anodic potentials, both $d\theta_1/dE$ and $d\theta_2/dE$ may be positive in both models. If the terms related to these values in Eq. [8] and [10] are negative, the faradaic impedance may appear as two inductive loops (2). In other words, if the pseudo-equilibrium reaction (K_1/K_{-1}) is no longer retained, model III can also explain, under certain conditions, the appearance of inductive faradaic impedance.

Models Including Three Adsorbed Intermediates

An Fe(III) species does not intervene in the dissolution range (29) and appears only at potentials close to the Flade potential (39). Therefore, the three reaction intermediates that will be taken into consideration are mono- or bivalent species. The dissolution process through model II is kept in all reaction schemes according to the examination of models and of hypotheses made above. The first step [II-1] may be reversible, but as was shown in our previous works (5, 33) the contribution of the backward reaction is negligibly small. For the sake of simplicity, different models are examined assuming a nonreversible first step. Introducing the slow backward reaction in the first step does not essentially change the results. It was found during preliminary work that no fundamental difference can be detected between models in which intermediate species are directly formed from the metal atom and those involving branching from Fe(I). This latter case was retained because it leads to simpler mathematical expressions. According to schematic forms, reaction schemes can be divided into three groups. Reaction schemes differ from one another by interactions between intermediate species, and consequently the expressions for charge and mass balance are different for each reaction scheme. But each elementary step is not explicit and may be written in many ways. Though a self-catalytic reaction intervenes in the expression of mass balance, this type of reaction is also considered.

Table I shows the reaction schemes in which all intermediate species are monovalent. Eight different

schemes can be constructed. If the two intermediate species formed from Fe(I) are both bivalent, they are classified in group 2. Sixteen different schemes were considered and are given in Table II. The last group is formed by two monovalent and one bivalent intermediate species. Sixteen schemes can also be written, as seen in Table III. It must be emphasized that these models are restricted to a minimal degree of complexity with respect to the data of impedance measurements.

Comparison of Models and Experiments

The selected models have to describe, using the hypotheses retained above, the maximum number of experimental results given in Part I. It is found that a certain number of prospective models can be ruled out by examining their mathematical structure analytically, without making a numerical simulation.

Analytical Examination of Models

Polarization curve having two current maxima.—In the pH 5 solution, the steady-state polarization curve exhibited two current maxima. As was shown in (29) and in agreement with Bech-Nielsen (35), such a curve can only be explained by reaction models including at least two dissolution paths. Thus 10 models having only one dissolution path were eliminated from the models shown in Tables I-III (marked "A").

Three inductive loops.—Three inductive loops were observed simultaneously in certain diagrams in mildly acidic solution and with medium current densities (dia-

grams D_2 and E_2 in Fig. 3 of Part I). Similar considerations to that for models including two intermediate species can be made here. From the expression of the charge balance, the electrode impedance can be written in general form such that

$$\frac{1}{Z_F} = \frac{1}{R_t} - \mathbf{F}\left(p\frac{d\theta_1}{dE} + q\frac{d\theta_2}{dE} + r\frac{d\theta_3}{dE} \right) \quad [12]$$

$d\theta/dE$ will be positive in the low potential range where most of the electrode surface is bare and the increase of θ_i is not disturbed by other coverages. In order that three inductive loops be observed, p, q, and r must be negative (2). The charge balance of the remaining schemes was written down and the Taylor expansion limited to first order was made. It is found that an inductive impedance can only appear when an intermediate species dissolves as $Fe(II)_{sol}$ (18). Models that cannot show three inductive loops simultaneously are marked by B on Tables I-III.

Impedance diagrams E_5 and F_5 (see Fig. 6 in Part I).—These diagrams showed the peculiar nature of the species intervening in the prepassivation process. In fact, the capacitive loop observed in diagram E_5 at the lowest frequency range transforms into an inductive loop near the current minimum. A process giving rise to this loop has appeared as an inductive loop at potentials less anodic to maximum I as seen in diagrams A_4 and C_4 (Fig. 5 of Part I). This change from an inductive to a capacitive loop cannot be interpreted by the change of sign in q or r in Eq. [13], $d\theta_1/dE$ being attributed to the inductive loop observed at the highest frequency range. The change from a capacitive to an inductive loop near the current minimum may be interpreted by the change of sign in $d\theta_2/dE$ or $d\theta_3/dE$. That is to say, a species which leads to the prepassivation process by an increase of the surface coverage decreases when the prepassive dissolution process sets in. On the other hand, the capacitive loop observed at about 0.4 Hz remains capacitive. Therefore, relationships such as $(d\theta_2/dE) \times (d\theta_3/dE) < 0$ will be satisfied in the prepassivation dissolution domain.

With the steady-state relationship, the following relation can be written for schemes 1-D, 1-H, 2-D, and 2-P

$$\theta_2 = \frac{K_3K_{-7}}{K_{-3}K_7}\bar{\theta}_3 = \bar{\theta}_3 K \cdot \exp\{(b_3 + b_{-3} - b_7 - b_{-7})E\} \quad [13]$$

Step i is marked in schemes 1-H and 2-P. Thus the product $\theta_2 \cdot \theta_3$ is a monotonic function with respect to the potential and $(d\theta_2/dE) \times (d\theta_3/dE) > 0$. These models cannot illustrate the change of the diagram shapes such as from E_5 to F_5. These reaction schemes are marked by "C" in Table I-III.

Examination of these three points allowed us to eliminate analytically 32 schemes from 40. The remaining eight schemes will be examined by numerical simulation.

Simulation Calculation

Reaction scheme 3-P corresponds to the general form of group 3. The other schemes can be discussed by considering certain reaction rates to be equal to zero. Let us recall scheme 3-P

$$\begin{array}{lllll} & K_1 & K_2 & & \\ Fe \rightarrow & Fe(I)_{ad} & \rightarrow & Fe(II)_{sol} & \theta_1 : Fe(I)_{ad} \\ & & K_5 & & \\ & & K_4 & & \\ & & & \uparrow K_6 & \\ & K_3\downarrow\uparrow K_{-3} & & & \theta_2 : Fe^*(I)_{ad} \\ & & K_{-5} & & \\ & & K_7 & & \\ & Fe^*(I)_{ad} & \rightleftarrows & Fe^*(II)_{ad} & \theta_3 : Fe^*(II)_{ad} \\ & & K_{-7} & & \end{array}$$

For K_6 reaction, two different cases are considered: for case 1 as proposed in (29)

$$Fe^*(II)_{ad} + Fe \xrightarrow{K_6} Fe(I)_{ad} + Fe(II)_{sol} + e^-$$

and for case 2 as a self-catalytic reaction

$$Fe^*(II)_{ad} + Fe \xrightarrow{K_6} Fe^*(II)_{ad} + Fe(II)_{sol} + 2e^-$$

Although two cases were also considered for the K_4 reaction, only the case of a self-catalytic reaction is given here for the sake of simplicity

$$Fe^*(I)_{ad} + Fe \xrightarrow{K_4} Fe^*(I)_{ad} + Fe(II)_{sol} + 2e^-$$

The expression for the charge balance can be written as

$$\frac{J}{\mathbf{F}} = K_1\Sigma + (K_2 + K_5)\theta_1 + (2K_4 + K_7)\theta_2 - \{K_{-5} + K_{-7} - (2-\rho)K_6\}\theta_3 \quad [14]$$

where $\rho = 1$ for case 1 and $\rho = 0$ for case 2 in reaction K_6.

From expressions for the mass balance of these three intermediate species, the steady-state values of the surface coverage can be calculated and one obtains

$$\frac{\bar{J}}{\mathbf{F}} = 2(K_2\bar{\theta}_1 + K_4\bar{\theta}_2 + K_6\bar{\theta}_3) \quad [15]$$

The electrode impedance can be expressed from Eq. [14]

$$\frac{1}{Z_F} = \frac{1}{R_t} - \mathbf{F}\left\{(K_1 - K_2 - K_5)\frac{d\theta_1}{dE} + (K_1 - 2K_4 - K_7)\frac{d\theta_2}{dE} + (K_1 + K_{-5} + K_{-7} - (2-\rho)K_6)\frac{d\theta_3}{dE}\right\}$$

where

$$\frac{1}{R_t} = \mathbf{F}\{(b_1 + b_2)K_2\bar{\theta}_1 + b_5K_5\bar{\theta}_1 + (2b_4K_4 + b_7K_7)\bar{\theta}_2 + (b_{-5}K_{-5} + (2-\rho)b_6K_6 + b_{-7}K_{-7})\bar{\theta}_3\} \quad [16]$$

$d\theta/dE$ can be derived from the mass balance expression

$$X_1 = Z_1\frac{d\theta_1}{dE} + (K_1 - K_{-3})\frac{d\theta_2}{dE} + (K_1 - K_{-5} - \rho K_6)\frac{d\theta_3}{dE}$$

$$X_1 = \{(b_1 - b_2)K_2 - b_3K_3 - b_5K_5\}\bar{\theta}_1 - b_{-3}K_{-3}\bar{\theta}_2 - (b_{-5}K_{-5} - \rho b_6K_6)\bar{\theta}_3$$

$$Z_1 = K_1 + K_2 + K_3 + K_5 + j\omega\beta_1 \quad [17]$$

$$X_2 = -K_3\frac{d\theta_1}{dE} + Z_2\frac{d\theta_2}{dE} - K_{-7}\frac{d\theta_3}{dE}$$

$$X_2 = \{(b_3 + b_{-3})K_{-3} + (b_3 - b_7)K_7\}\bar{\theta}_2 - (b_7 + b_{-7})K_{-7}\bar{\theta}_3$$

$$Z_2 = K_{-3} + K_7 + j\omega\beta_2 \quad [18]$$

$$X_3 = -K_5\frac{d\theta_1}{dE} - K_7\frac{d\theta_2}{dE} + Z_3\frac{d\theta_3}{dE}$$

$$X_3 = (-b_5 + b_7)K_7\bar{\theta}_2 + \{(b_5 + b_{-5})K_{-5} + (b_5 + b_{-7})K_{-7} + \rho(b_5 - b_6)K_6\}\bar{\theta}_3$$

$$Z_3 = K_{-5} + K_{-7} + \rho K_6 + j\omega\beta_3 \quad [19]$$

Equations [17]-[19] allow one to calculate the $d\theta/dE$ values for three intermediate species. By introducing these values into Eq. [16], the faradaic impedance can be obtained.

Model 3-P includes ten rate constants K_i, and since K_i is expressed by two potential-independent parameters, $K_{o,i}$ (mole·cm^{-2}·sec^{-1}) and b_i (V^{-1}), 20 parameters will be adjusted for the simulation calculation. The β values are considered to be equal to 10^{-8} (mole·cm^{-2}) (5), corresponding to one intermediate species bonded to one metal atom of the electrode surface. Impedance diagrams were calculated by considering that the overall impedance Z contains the contribution of the double layer capacitance in parallel with the faradaic impedance Z_F

$$\frac{1}{Z} = \frac{1}{Z_F} + j\omega C_{dl}; \quad C_{dl} = 10^{-4}\ (\mathbf{F}\cdot\text{cm}^{-2}) \quad [20]$$

As an example, Fig. 1 shows the steady-state polarization curves calculated on the basis of scheme 3-G, *i.e.*, $K_4 = K_5 = K_{-5} = 0$. This example was calculated with $\rho = 1$. The agreement between the experimental and the calculated curves is very satisfactory. When the dissolution is determined by the K_6 path, the overall reaction rate is controlled by the smallest of K_3, K_6, and K_7. Thus the bending of curves at high current densities was easily simulated.

On the other hand, the electrode impedance is somewhat difficult to simulate with the reaction corresponding to $\rho = 1$ both in shape and in frequency. The time constants τ of the relaxation phenomena are determined by expressions of Z_i. Since $\tau = 1/\omega$, one obtains from Eq. [17]-[19]

$$\frac{1}{\tau_1} = \frac{K_1 + K_2 + K_3 + K_5}{\beta_1}; \quad \frac{1}{\tau_2} = \frac{K_{-3} + K_7}{\beta_2}; \quad \frac{1}{\tau_3} = \frac{\rho K_6 + K_{-7}}{\beta_3} \quad [21]$$

For the $Fe^*(II)_{ad}$ relaxation, the following relationship can be derived

$$\frac{1}{\tau_3} > \frac{K_6}{\beta_3} = \frac{\bar{J}}{2\mathbf{F}\beta_3\bar{\theta}_3} = \frac{\bar{J}}{2\cdot 10^{-3}\cdot\bar{\theta}_3} > \frac{\bar{J}}{2\cdot 10^{-3}} \quad [22]$$

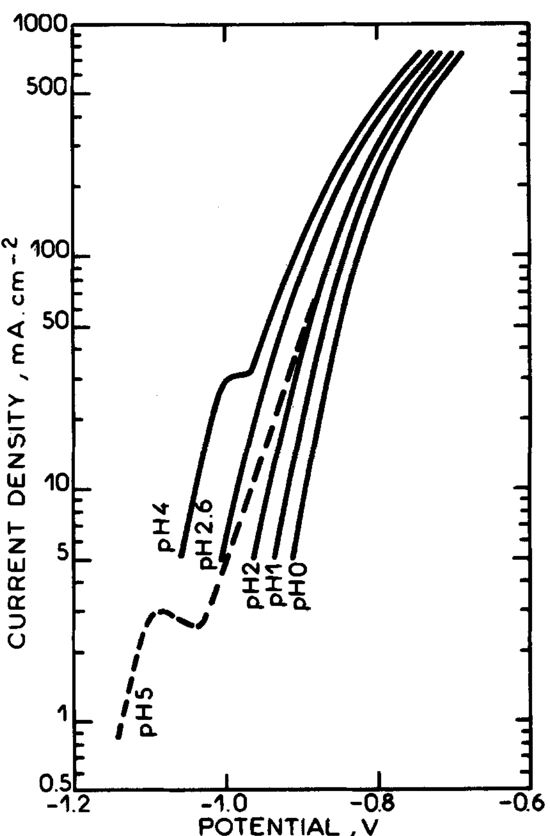

Fig. 1. Simulated polarization curves for various *pH* values according to reaction scheme 3-G. The K_6 reaction is nonself-catalytic. Reaction rates for the *pH* 5, solution are: $K_1^* = 4\cdot 10^{10}\exp(38.4E)$; $K_2 = 8\cdot 10^{-4}\exp(7E)$; $K_3^* = 1\cdot 10^{7}\exp(29E)$; $K_{-3} = 1.5\ 10^{-8}$; $K_6^* = 2.3\ 10^{2}\exp(23E)$; $K_7 = 1.4\exp(16.4E)$; and $K_{-7} = 8.4\ 10^{-18}\exp(22E)$. * indicates the *pH* dependent parameter.

Equation [22] shows that the relaxation time constant τ_3 is smaller than $(2 \cdot 10^{-3})/\bar{J}$, *i.e.*, the characteristic frequency in Hz for this relaxation process (top of the loop) is greater than $\bar{J}/(1.2 \cdot 10^{-2})$. With the experimental current $\bar{J}$, the calculated characteristic frequency is too high compared to that observed experimentally. Strictly speaking, this characteristic frequency is related to the electrode admittance and a slight difference is expected when using the impedance diagrams. If the self-catalytic reaction ($\rho = 0$) is considered, $\tau_3 = \beta_3/K_{-7}$. The current and the relaxation time constants are separated and the simulation calculation may show satisfactory results. This consideration is also true for the K_4 reaction. In fact, as mentioned above, this process was considered self-catalytic for the sake of simplicity in Eq. [14]-[19]. If the K_4 reaction were written for instance as

$$Fe^*(I)_{ad} + Fe \xrightarrow{K_4} Fe(I)_{ad} + Fe(II)_{sol} + 2e^-$$

the same analysis as the $Fe^*(II)_{ad}$ relaxation shows that this reaction yields too small relaxation time constants compared to the experimental results if satisfactory polarization curves are simulated. However, with a self-catalytic reaction, the overall reaction rate is no longer limited by the slowest step in a series reaction, $K_3 - K_7 - K_6$, and the simulated polarization curves no longer bend at high current densities.

In Fig. 2, the impedance diagrams calculated at the foot of the prepassive dissolution domain are shown. The impedance at the lowest frequency range is capacitive instead of inductive (cf. diagram F_5). If steady-state polarization curves and other impedance diagrams were suitably simulated, this loop will remain capacitive even when numerical parameters are changed. This was found also true for models 2-H, 2-L, 3-G, 3-H, 3-L, 3-O, and 3-P. Only scheme 3-D allowed simulating the whole set of experimental results, except the bending of polarization curves at high current densities. It was impossible for us to rule out these seven models analytically. Nevertheless, it can be remarked that scheme 3-D is the only model having no direct interaction between two intermediate species $Fe^*(I)_{ad}$ and $Fe^*(II)_{ad}$. The results of numerical simulation and the value of parameters were given in Part I.

As was stated previously, the reaction steps considered in the model are of a minimal degree of complexity to interpret the experimental results obtained in this work. For instance, a two-electron transfer process is likely to take place through at least two steps. However if one of the steps is fast and reversible, the time constant cannot be observed experimentally. Furthermore, if the surface coverage by our intermediate species is small, the pseudocapacitance may be of the same order of magnitude or smaller than the double layer capacity. Therefore no experimental proof for this first step can be obtained by impedance measurements.

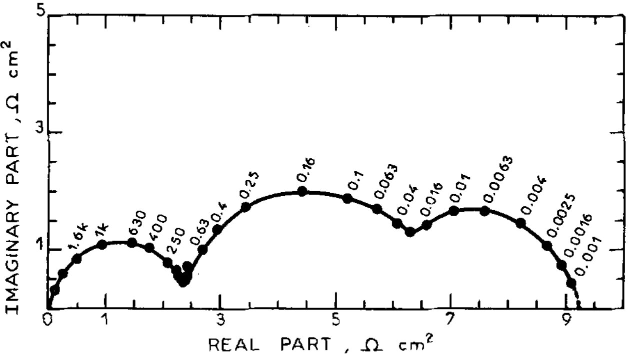

Fig. 2. Simulated impedance diagram. $E = -1.0V$ and $J = 4$ mA $\cdot$ cm^{-2} in the prepassive dissolution domain in pH 5 solution. Reaction scheme 3-G, the K_6 reaction being self-catalytic. The reaction rates are equal to those given in Fig. 1 $\beta_i = 1 \cdot 10^{-8}$ mole $\cdot$ cm^{-2} and $C_{dl} = 1 \cdot 10^{-4}$ F $\cdot$ cm^{-2}.

The reaction steps given for the K_6 path are an example of the simplest expression but different from the K_2 path. What we can verify by experiment is the reaction scheme and not the individual chemical steps. In particular, only the introduction of a self-catalytic process allows the separation of time constant and current flow.

In the simulation calculation, it was found that even the simulation of the steady-state curve needs the potential dependence of the so-called chemical process. Sato and co-worker (40) assumed that the dissolution of metal hydroxide is potential dependent and that $\alpha_+ + \alpha_-$ is equal to unity. On the other hand, if the reaction occurs through multiple steps and the rate-determining step is different for the forward and for the backward processes, $\alpha_+ + \alpha_-$ is no longer unity (41).

From the 40 schemes examined, ten were eliminated by steady-state polarization curves (A), 18 by the impossibility of interpreting three inductive loops (B), and 11 schemes were eliminated because they cannot predict diagrams such as H_4 and F_5. Since the ten models eliminated by polarization curves also cannot explain three inductive loops, the usefulness of electrode impedances for comparison of models and experiment is clearly demonstrated. Only one model covering wide experimental conditions is retained using reasonable hypotheses.

Bending of the polarization curves at high current densities was not simulated with the reaction model selected. This may be interpreted in different ways: another process begins to occur, the Langmuir adsorption isotherm is no longer valid, or the Tafel law is no longer valid. Since impedance diagrams cannot be plotted with sufficient accuracy at these current densities, it is not possible to examine these assumptions at present.

Conclusion

Fundamental hypotheses of electrode kinetics allowing transcription of the reaction models into mathematical expressions were critically examined. The experimental impedance diagrams showed one high-frequency capacitive arc and three time constant at lower frequencies appearing as inductive or capacitive loops. They are attributed in the models, respectively, to the double layer capacitance in parallel with the transfer resistance and to the relaxation of three reaction intermediates.

Provided that the dissolution mechanism through two consecutive steps implying adsorbed Fe(I) remains valid, two adsorbed intermediate species could be introduced. Then, 40 different reaction schemes were constructed as the complete set of prospective combinations. It is worth noting that, since individual reactions can be differentiated in reaction schemes, a fairly large number of models must be tested. The examination of steady-state polarization curves allowed us to rule out only ten schemes. On the other hand, the analysis of impedance enabled us to select only one reaction model. The procedure developed in this work may be applied to other electrochemical interfaces.

LIST OF SYMBOLS

- ad — subscript for adsorbed species
- B — Tafel slope (V)
- b — Tafel coefficient $(\ln 10)/B$ (V^{-1})
- C_{dl} — double layer capacitance ($\mathbf{F} \cdot cm^{-2}$)
- C — capacitance ($\mathbf{F}$)
- E — electrode potential (V)
- $\mathbf{F}$ — Faraday constant (A·sec)
- J — current density ($A \cdot cm^{-2}$)
- $\bar{J}$ — steady-state value of J ($A \cdot cm^{-2}$)
- K_i — forward reaction rate for step i ($mole \cdot sec^{-1}$)
- K_{-i} — backward reaction rate for step i ($mole \cdot sec^{-1}$)
- N^* — number of active sites
- R — gas constant ($J \cdot deg^{-1}$)
- R_t — charge transfer resistance (Ω)
- sol — subscript for species in solution bulk
- T — absolute temperature (deg)
- Z — overall electrode impedance (Ω)
- Z_F — faradaic impedance for unit surface ($\Omega \cdot cm^2$)
- α — transfer coefficient
- β — constant linking θ and surface concentration ($mole \cdot cm^{-2}$)
- θ — fractional surface coverage
- $\bar{\theta}$ — steady-state value of θ
- Σ — fractional bare surface area, $1 - \Sigma\theta_i$
- τ — relaxation time constant (sec)
- ω — angular frequency ($rad \cdot sec^{-1}$)

IBM Corporation, General Products Division, San Jose, California 95193

ABSTRACT

The corrosion rate of copper in laboratory tests is shown to be a sensitive function of relative humidity, sulfur dioxide, hydrogen sulfide, ozone, hydrogen chloride, and chlorine concentrations. Observed indoor corrosion rates obey log normal statistics over the field population of this study. Also, the observed indoor rates correlate reasonably well with the measured reduced sulfur concentrations (H_2S, S_8). The corrosion rate of silver is shown not to be humidity dependent. Hydrogen sulfide, ozone, chlorine, and hydrogen chloride concentrations substantially influence its corrosion rate. The observed indoor rates obey log normal statistics and correlate well with the reduced sulfur gas concentration. In contrast to copper, where indoor rates are 1% of outdoor values, silver often corrodes faster indoors than outdoors. Its sensitivity to sulfur gases and insensitivity to relative humidity is proposed as a plausible explanation for these findings. It is proposed that metallic silver is stable in polluted acidic atmospheric environments and therefore is the dominant surface species while Cu_2O is present on the surface of copper. The thermochemistry and kinetics of these two surfaces will control the stability of silver and copper, respectively, in the presence of pollutants.

Copper and silver are important functional materials. They are widely used in industrial, commercial, and home environments. Found in their native state approximately 6000 years ago, they are considered noble metals. Corrosion of both copper and silver, a common problem, can be aesthetically beautiful and frustratingly complex.

Atmospheric corrosion of copper has been studied extensively. Reviews by Leidheiser (1) and Rozenfeld (2), among others (3-5), provide the reader with a historical perspective. The majority of these studies focused attention on outdoor urban corrosion. The atmospheric corrosion process is more complex than high temperature oxidation, where theories exist that explain reasonably well the observed rates (6). No such theory exists for atmospheric corrosion, although attempts have been made to correlate observed outdoor rates to sulfate and relative humidity levels (7). Water vapor, sulfur dioxide, and hydrogen sulfide have been shown to influence the rate of copper corrosion (8-10).

Silver has been cited as a classical example of a material that decays by a diffusion-controlled process at either the atmosphere-product interface or in the corrosion product itself (11). Its propensity to tarnish is well recognized by scientists and homemakers alike. Sulfur gases are the dominant reactive pollutants (10, 12); however, some reference is given to humidity and chlorine-containing gases as accelerators of corrosion (13, 14).

The purpose of this paper is to add to the understanding of both copper and silver atmospheric corrosion, with particular emphasis given to the corrosion response in indoor environments. We develop the quantitative rate dependence on relative humidity and pollutant concentrations in synthetic laboratory environments that are not grossly accelerated. The results of an indoor test site program in the United States are also presented and compared to published indoor and outdoor data. The observed rates are correlated to pollutant and relative humidity measurements made concurrently. This paper is the last in a series that has addressed cobalt corrosion (15), nickel corrosion (16), the role of water in atmospheric corrosion (17), and indoor atmospheric corrosion (18).

Experiment

Copper and silver coupons, both greater than 99.999% pure, were exposed to either laboratory synthesized test environments or indoor field test sites. The total corroding area was 12.9 cm^2. The samples were generally cleaned by a sequence of hot xylene, isopropanol, and deionized water immersions. As-received metals corroded at the same rate as the cleaned samples; therefore, the above procedure was not found to be critical, but good practice. The coupon weight increase to the nearest microgram was measured as a function of time in either the laboratory or field environments.

The weighing accuracy for the laboratory test samples was ± 0.16 $\mu g/cm^2$. This resulted in a 16% weighing error for the lowest total weight changes measured, 1 $\mu g/cm^2$, and a 0.03% error for the highest weight changes measured. The weighing accuracy for the field samples was ± 0.39 $\mu g/cm^2$. This was equivalent to a 16% error in the lowest weight changes recorded and 0.3% in the highest weight changes.

The laboratory tests were performed in chamber environments synthesized from purified humid air containing predetermined trace quantities of sulfur dioxide (SO_2), nitrogen dioxide (NO_2), hydrogen sulfide (H_2S), chlorine (Cl_2), hydrogen chloride (HCl), ammonia (NH_3), and ozone (O_3).

Figure 1 is a schematic of one of the laboratory test systems used in this study. In this particular example, two chambers run simultaneously from the same cylinder tank farm and analytic equipment, one for general humidity variation and the other for pollutant variations.

The purity of the compressed-air supply was found to be very important to insure reproducibility of the corrosion rate results. Purification was accomplished by a reverse coalescent filter in series with activated charcoal and particle filters. These filters removed oil mist, pollutants and oil vapors, and residual particles, respectively. This combination allowed comparatively high flow rates, 50-500 liters/min, while maintaining the background inorganic pollutant concentrations equal to or less than 0.9 $\mu g/m^3$ for SO_2, 0.1 $\mu g/m^3$ for NO_2, 0.006 $\mu g/m^3$ for H_2S (S_8), 0.05 $\mu g/m^3$ for Cl_2 (HCl), 0.1 $\mu g/m^3$ for NH_3, and 1 $\mu g/m^3$ for O_3. The most common problems we encountered in cleaning the air were high concentrations of NO_x, O_3, and oil vapors passing through the filter system. The first two are typically high in our local urban California environment; the oil vapor comes from the compressor.

The purified air was proportioned so that some would pass over a thermostatically controlled kettle containing deionized water for humidification. Humid-

ity control could be maintained at ±3% (25°C) up to 80% relative humidity. The relative humidity was routinely measured by the dew point method (19); however, the wet and dry bulb technique was used as a cross check. This was necessary because the laboratory environments would slowly condense species such as sulfuric acid on the gold reflecting surface and yield incorrect humidity values.

Pollutants were added to the dry (<5% RH) purified air by one of three methods: permeation tubes (20), rotameters from 0.1% by volume pollutant in a high purity N_2 cylinder, and porous plug flowmeters (21) from 1% by volume pollutant in high purity N_2 cylinders. All three methods were acceptable for short-term tests of the order of two weeks, but the porous plug flowmeters were the most reliable over long periods and not restricted to certain pollutants. Rotameters required constant attention. Reliable permeation tubes are only available for a limited number of pollutants. SO_2, H_2S, and Cl_2 permeation tubes were found satisfactory for our short-term tests. Our objective was to control pollutants to ±10% of the desired concentration.

The pollutant-containing dry air was premixed with the humid air before entry into the chambers. The construction materials of the gas-handling system downstream from the metering valves was Pyrex glass, Plexiglas, and Teflon. These materials eliminated system failures due to corrosion and minimized adsorption losses of the pollutants that are common to other construction materials. The atmospheric exchange rate varied from 3/min for the larger chambers to 6/min for the smaller chambers.

The dependence of corrosion rate on pollutant concentration was measured in special multiple compartment Plexiglas chambers that permitted up to five different concentrations by serial addition of the pollutant being studied (Fig. 1). All other pollutants and relative humidity were fixed at the input levels. This proved a very efficient and simple way to obtain significant quantities of data. This technique minimized problems associated with chamber reproducibility.

The pollutant concentrations were measured near the samples by the techniques summarized in Table I. The acidic chlorine gases, HCl, and Cl_2, as well as H_2S, could not be measured continuously because of the low concentrations. Integrating methods were developed for these gases. The actual choice of inorganic pollutants for this study was based on either reported problems associated with the pollutant or its presence at high levels in urban atmospheres. Graedel and Schwartz have reviewed both pollutants and problems (29). The pollutant concentrations in the laboratory tests were chosen to be similar to urban levels but at the 99%-99.9% upper end of the distribution function. Table I summarizes the rationale for pollutant selection and typical ranges in indoor and outdoor environments.

The field site tests were performed in specially designed flow control modules that pulled the ambient

Table I. Inorganic pollutants used in this study, typical indoor and outdoor ranges, analytic methods, and rationale for selection

Pollutant gas	Typical outdoor range ($\mu g/m^3$) (18, 29)	Typical indoor range ($\mu g/m^3$) (18)	Analytic methods	Rationale for selection
SO_2	3-185	1-40	Flame photometric, (continuous) (22), West Gaeke (23) (periodic)	Major pollutant, known to attack many metals. Forms acidic surface
NO_2	20-160	3-60	Chemiluminescence, (continuous) (24), Saltzman (periodic) (25)	Major pollutant, known to attack Co, Ni, and Fe (18)
H_2S	1-36	0.2-1	Lead acetate tape sampler with prefilter (periodic) (26)	Stress corrosion accelerator, known to attack Cu and Ag
O_3	10-90	7-65	Chemiluminescence (continuous) (27)	Major pollutant, degrades polymers and accelerates oxidation of H_2S, NO_2, and SO_2
HCl	0.3-5	0.08-0.3	O-tolidine densitometry (periodic), $AgNO_3$ titration (periodic)	Destabilizes passive films by lattice impregnation and acid dissolution
Cl_2	Less than 5% of HCl levels except where local Cl_2 source exists	0.004-0.015	Same as above	Same as above
NH_3	6-12	10-150	Chemiluminescence (continuous) (28)	Major pollutant, forms complexes with Cu and Ag, forms basic surface

indoor air over the samples at 2.5 m/sec parallel to the surface. The location and characteristics of the eight indoor test sites in this study are given in Table II. Samples were returned after 6, 12, and 18 month exposure and reweighed after removing benzene soluble organic deposits. These organic deposits generally were only 10%-20% of the inorganic weight gain; however, for a few samples they were comparable. Pollutant and humidity measurements were concurrently measured at six of the eight sites. This data has been summarized previously, as has the high resolution x-ray photoelectron spectroscopic analysis of the corrosion product on the samples returned after 18 months (18).

Results and Discussion

Relative humidity.—The corrosion rate, r, dependence on relative humidity, RH, for both copper and silver in two complex test environments are shown in Fig. 2. Pollutant concentrations in these tests are listed in Table III. The rates are the initial linear rate constants. These were chosen because the total weights are more representative of the field measurements. These rates will generally overestimate the amount of weight increase for long test times; however, the same general dependence on atmospheric variables will be observed. Figure 3 shows representative weight gain *vs.* time curves at various relative humidities for copper.

The difference between copper and silver is remarkable. The corrosion rate of copper is strongly dependent on relative humidity. The approximate equation relating rate and relative humidity is $r = 0.042 \exp 4.6\text{RH}$ for environment A with a correlation coefficient equal to 0.97. Environment B results in a rate that is more sensitive to RH. These results are generally in agreement with the work of Vernon (8) and others (1-5) at higher pollutant concentrations. Corrosion rates could be measured over the entire range of RH's studied. There was no "critical humidity" in an absolute sense. At high SO_2 concentrations or in SO_2 environments only, where equilibrium with sulfate surface products

or condensed sulfuric acid controls the amount of adsorbed water, the idea of a critical humidity may be useful. For complex environments, care must be taken in using the critical humidity concept without a precise understanding of the corrosion products. The atmospheric corrosion mechanism for copper is electrochemical with the water-pollutant chemistry providing the medium for ionic mobility and surface product dissolution. There are many surface reactions that are thermodynamically favorable for copper oxidation.

Silver, unlike copper, shows no significant rate dependence on relative humidity, $r = 0.37 \exp 0.13\text{RH}$, in these complex environments. This is evidence that aqueous electrochemical intermediates have different roles in the mechanism of silver and copper corrosion.

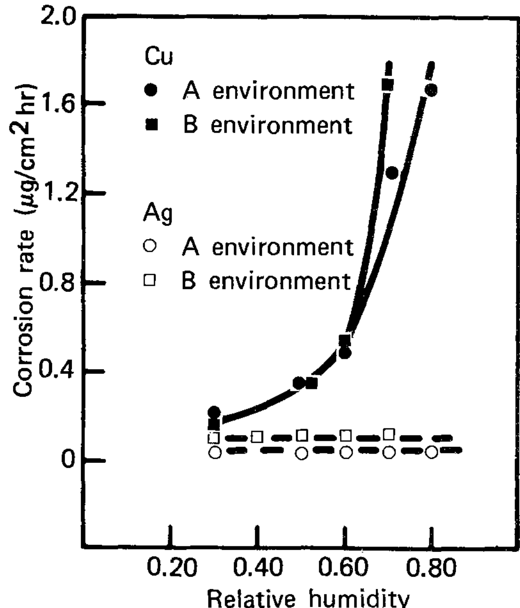

Fig. 2. Corrosion rate of copper and silver vs. relative humidity in two test environments.

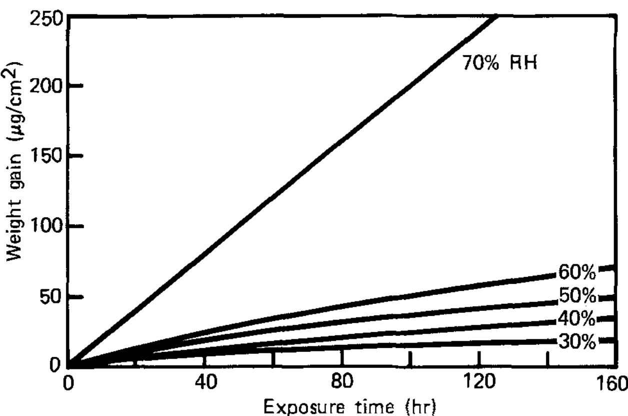

Fig. 3. Weight gain vs. environment B test exposure time for copper at various percentage relative humidities.

Direct chemical attack of silver metal by sulfur or H_2S is a plausible explanation of the observed results. We use the lack of a rate dependence on relative humidity to explain the similarity between its indoor and outdoor corrosion rates. These results contradict reported silver corrosion rate models that assume a relative humidity dependence (13-14).

Pollutants.—A series of tests was performed at 70% RH (25.0°C) with a single pollutant as the controlled variable either in the absence of other pollutants or with other pollutants present. The purpose of the tests was at minimum to yield engineering information about each pollutant and hopefully some insight into mechanisms. A summary of the rate data at various pollutant concentrations is given in Table IV for both metals. We will discuss each pollutant and its influence on the corrosion rate.

Sulfur dioxide.—Sulfur dioxide is a common pollutant produced by fossil fuel combustion. It has been studied from both a health and corrosion point of view. A great deal of effort and money has been expended to reduce its urban concentration. It is readily soluble in water and reacts with it to form sulfurous acid. Further oxidation yields sulfuric acid. The mean outdoor urban site SO_2 concentration was 17.6 $\mu g/cm^3$ for 840 monitoring stations reported by the U.S. Environmental Protection Agency in 1975 (30). Significantly higher values can be experienced on the average at a few sites or for short periods of time at any given site. The mean indoor concentration of SO_2 is 12.2 $\mu g/m^3$ (18). The reader is referred to reviews on the atmospheric chemistry of SO_2 for background information (31).

Sulfur dioxide is known to increase the rate of copper corrosion at higher RH's (8). The mechanism is still an issue. Vernon (8), as well as the authors (15, 16), propose that SO_2 influences the local anodic pH sufficiently to cause increased oxide dissolution and, hence, an increase in corrosion rate. Sulfurous acid would be the dominant acid species on the surface because it is simply formed by reacting with one water molecule. Rozenfeld has proposed that SO_2 enhances the rate by depolarizing the cathodic region of the surface (2).

The equilibrium of gaseous SO_2 with liquid water and sulfurous acid yields a pH between 3 and 4 for the partial pressures in this study. The condensate of test environment A had a $pH = 3.75$. If sulfuric acid was the resultant product, which is thermodynamically favorable, the pH would be extremely low and very corrosive. Some metals do indeed catalyze the formation of sulfuric acid (32).

The copper and silver corrosion rate dependence on SO_2 partial pressure is shown in Fig. 4. The rate was measured in environments containing SO_2 as the only pollutant and in environments containing the background levels of environment A in Table III. The rates measured under these two conditions are labeled S and M, respectively. The rates, r, were fit to an equation of the form $r = AC^n$ where A and n are constants and C is the pollutant concentration.

Table IV. Summary of copper and silver corrosion rates, in $\mu g/cm^2$ hr, at various pollutant concentrations. C is the pollutant concentration in $\mu g/cm^3$, while Cu and Ag are used to identify the rates for copper and silver, respectively. n and A are the coefficients in the expression $r = AC^n$ for each pollutant. C.C. is the correlation coefficient which represents the quality of the data fit to the analytic expression.

* The reference background environment was A in Table III.
** No other pollutants were present.
† HCl gas was present at 1.46 $\mu g/m^3$.
‡ SO_2 gas was present at 47 $\mu g/m^3$.

For copper, the exponent for both environments was close to 0.35. The correlation coefficients were equal to or greater than 0.99. A value of ± 1 is a perfect fit while zero indicates no correlation. In this case, the equation is an excellent approximation of the data. If we assume, as we have proposed earlier (15, 16), that SO_2 controls the surface pH and, hence, oxide stability (dissolution) by the reaction

$$SO_2 + H_2O\ (ad) = H_2SO_3\ (surface)$$

$$= H^+ + HSO_3^-\ (surface)$$

then we would expect $n = 0.5$. For Co and Ni, this is the case; however, for Cu the reaction is more complex. It is clearly less sensitive to SO_2 concentration changes. One possible explanation is that copper catalyzes the formation of sulfuric acid

$$SO_2\ (g) + H_2O\ (ad) + 1/2\ O_2\ (g) = H_2SO_4\ (surface)$$

$$= 2H^+ + SO_4^=\ (surface)$$

which is a much stronger acid; $pK_{H_2SO_4} = -3, +1.9$ and $pK_{H_2SO_3} = 1.8, 7.2$ The equilibrium concentration of hydrogen ions from the above equation is

$$[H^+] = P_{SO_2}{}^{1/3} P_{O_2}{}^{1/6} a_{H_2O}{}^{1/3} K^{1/3}$$

At fixed P_{O_2} and a_{H_2O}, the rate will depend on $P_{SO_2}{}^{0.33}$ if we assume that the corrosion rate is linear in the concentration of hydrogen ions (33). Even if the surface were saturated in $CuSO_4$, the $SO_4^=$ concentration would not suppress the ionization of H_2SO_4 significantly and the $P_{SO_2}{}^{0.33}$ dependence would be predicted. This clearly implies that the dissolution rate of a surface oxide, such as Cu_2O, controls the overall copper corrosion rate.

Silver showed comparative insensitivity to SO_2. In the complex environment $n = 0.015$ while in the simple SO_2 environment $n = 0.16$. Reaction of silver with SO_2 to form concurrently sulfide and oxide is not thermodynamically favorable, $\Delta G° = +57$ kcal/mole. The production of a sulfate is, however, feasible, $\Delta G° = -4$ kcal/mole. The rationalization of the magnitude of n is not clear. The observation that silver corrosion is insensitive to SO_2 is consistent with its resistance to dilute sulfuric acid. Copper will corrode forming Cu^{++} in dilute sulfuric acid that contains oxygen. It is also important to note that for both metals, the more complex environment showed significantly higher rates at a fixed SO_2 concentration. This demonstrates that other pollutants act either synergistically or individually to enhance the rates, a fact that is repeatedly demonstrated in the remaining sections of this paper.

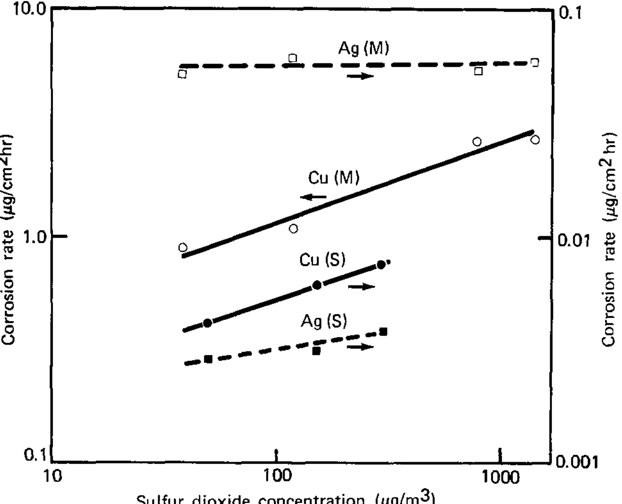

Fig. 4. Corrosion rate of copper and silver vs. sulfur dioxide concentration (70% RH, $T = 25°C$). Arrows indicate appropriate scale. S and M refer to SO_2 only and the more complex reference environment A (Table III), respectively.

It is interesting to compare this behavior of the metals in atmospheric corrosion with their chemistry in bulk aqueous solutions. In neutral air-saturated solutions, the surface of copper will be covered with a layer of Cu_2O with a comparatively thin CuO layer at the solution interface. Silver will be immune from corrosion in this neutral environment.

If SO_2 is introduced, the pH will fall. The CuO will dissolve exposing Cu_2O. This compound will remain comparatively stable and protect copper until the pH reaches 3-4 where significant dissolution will begin. In the presence of other atmospheric species which complex Cu^+ or form compounds, such as CuCl, the protection is less good kinetically. In the case of silver, the metal is thermodynamically stable with respect to Ag^+ at lower pH. Presentation of a sulfiding species at the Ag surface will result in sulfidation. Attack by chloride-containing species and complexing agent can also be facilitated by the presence of metallic silver. The difference in the surface of the two metals due to the different solubility of the oxides will profoundly affect the kinetics of metal oxidation and of the depolarization reaction which is probably oxygen reduction.

Hydrogen sulfide.—Hydrogen sulfide is produced by fossil fuel combustion, vegetation decay, and geological activity. It is slightly soluble in water and forms a weak acid. It causes sulfiding of both copper and silver in the presence of oxygen. It can be oxidized by species like O_2 and Cl_2 to free sulfur, a reactive form of sulfur. Typical H_2S concentrations in urban areas are 1 μg/m³ (18); however, significantly higher concentrations have been reported in some urban areas where local sources such as paper mills exist (8, 29, 34). Indoor concentrations are not significantly less than outdoor levels.

Figure 5 shows the copper and silver corrosion rates *vs.* the H_2S partial pressure in three different reference conditions: M, the complex environment A in Table III, S, the H_2S pollutant only environment, and HCl, an environment with HCl at 1.46 μg/m³. The corrosion rates of both metals are significantly influenced by the H_2S partial pressure. Copper exhibits a monotonic increase in rate when going from a simple to a complex environment. The values of n are 0.9, 0.4, and 0.3 for the S, HCl, and M environments, respectively. The

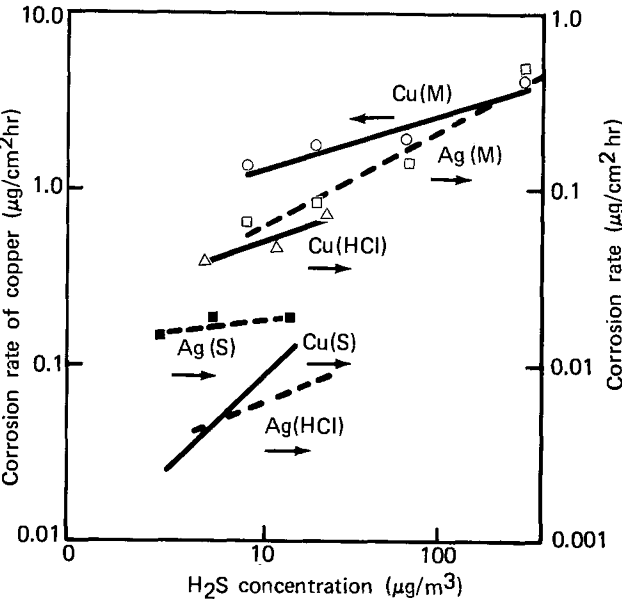

Fig. 5. Corrosion rate of copper and silver vs. hydrogen sulfide concentration. M is the multipollutant environment A, S is the single pollutant environment, HCl is the environment with the HCl concentration fixed at 1.45 μg/m³ with no other pollutants except H_2S. The arrows identify the appropriate scales (RH = 70%, $T = 25°C$).

mechanism of corrosion must change significantly as indicated by these comparatively large changes in n. The rate dependence in the simple environment can be explained by a controlling surface process such as diffusion of H_2S to the surface or oxidation of H_2S by O_2 to a reactive sulfur species accompanied by a rapid diffusion process in the developing corrosion product. Either of these rate-controlling processes results in a linear dependence of surface active concentration on H_2S. This states that $n = 1$ which is close to the observed value of 0.9. The corrosion product in the polluted H_2S environment is Cu_2S and adds plausibility to a simple sulfiding process. Application of Wagner's model (35) will not explain the sulfiding rate dependence on H_2S. It would yield a less sensitive dependence on H_2S.

The more complex test environment, M, results in a less sensitive function of rate on H_2S concentration $n = 0.3$. The corrosion products are more complex consisting of hydroxide, oxide, sulfate, and chloride combinations with little, if any, sulfide. Hydrogen sulfide must then enhance the rate of corrosion by a far more complex process. In an independent experiment a strong positive synergism of H_2S (1335 $\mu g/m^3$) and SO_2 (2980 $\mu g/m^3$) was demonstrated on the rate of copper corrosion with a resultant $CuSO_4 \cdot 5H_2O$ product. No sulfides were detected. The H_2S may catalyze the oxidation of copper followed by rapid sulfurous acid attack. These are purely speculative mechanisms and more detailed experiments are needed to test the hypothesis.

Silver, in contrast to copper, shows the lowest corrosion in the HCl-containing reference environment, followed by the simple H_2S and complex reference conditions. The presence of an AgCl surface product may inhibit sulfidation. The exponent n for silver is 0.14, 0.4, and 0.55 for the S, HCl, and M environments, respectively. The corrosion product in environment A (M) at the highest H_2S level tested, 328 $\mu g/m^3$, as measured by XPS was Ag_2S with trace quantities of hydroxide and sulfate. Chlorides were detected, in addition to the above products, when this environment had H_2S at the lower concentration of 20 $\mu g/m^3$.

The mechanism of silver sulfidation in the H_2S environment is different than copper. It would be tempting to propose that the Wagner model fits the data. This is, however, not the case, because, first, the kinetics were linear at each H_2S concentration as shown in Fig. 6 and, second, a simple defect diffusion model would predict $n = 0.25$ if the equilibrium concentration of cation vacancies controlled the rate.

Acidic chlorine gases.—The acidic chlorine gases considered in this study are HCl and Cl_2. These are produced in urban environments by fossil fuel combustion, synthetic product incineration, purification of water, and salt spray interaction with secondary photochemical pollutants. Typical levels in urban environments range from 0.1 to 5 $\mu g/m^3$, although very little data has been published (29). Hydrogen chloride is estimated to be the dominant acidic chlorine gas in the environment (36). HCl is highly soluble in water. The presence of Cl^- is a known accelerator of electrochemical corrosion for many materials. The pH of a solution in equilibrium with 4 $\mu g/m^3$ of HCl gas is approximately 1. This is a typical concentration for our test and at the upper bound of observed values in urban environments. The equilibrium pH for 4 $\mu g/m^3$ of Cl_2 is 5.

Figure 7 summarizes the silver and copper corrosion-rate dependence on Cl_2 in a mixed reference environment, and singly polluted environments containing either HCl or Cl_2. Copper rates increase significantly with an increase in HCl and Cl_2 partial pressures in the single polluted environments. The rate depends on the 0.63 power of the pollutant pressure. In the complex environment M, little influence is observed. The presence of a high concentration of SO_2 and H_2S may dominate the process. Clearly, SO_2 will result in a much lower surface pH and mask the influence of Cl_2. Silver is most sensitive to Cl_2 alone, showing an exponent in the rate dependence on P_{Cl} of 1.01. The other two environments had an exponent equal to 0.17.

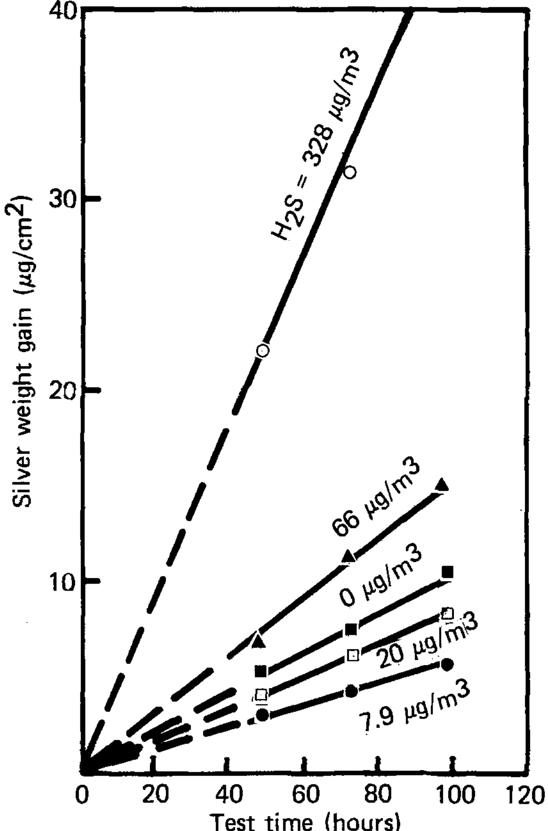

Fig. 6. Weight gain of silver vs. test time for various H_2S concentrations in environment A (Table III).

Nitrogen dioxide.—Nitrogen dioxide is a secondary pollutant of photochemical smog and is also produced in combustion processes. It is typically found at a concentration of 44 $\mu g/m^3$ in urban centers (37). Its direct or acidic contribution to corrosion problems has not been reported; however, nitrate particles formed in the

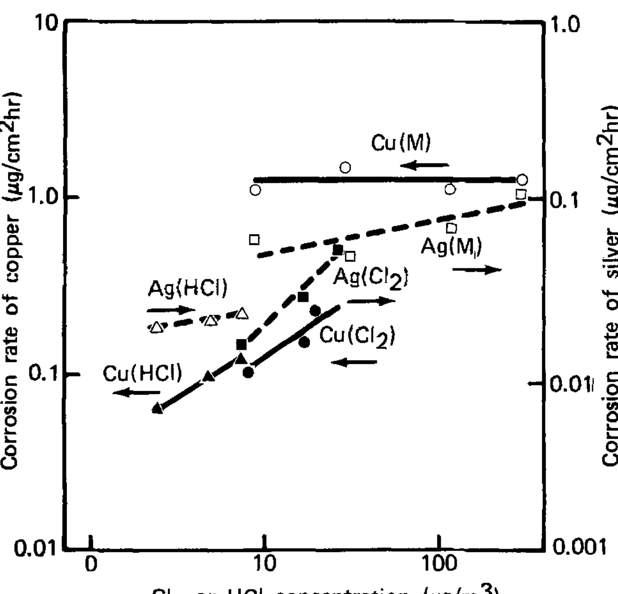

Fig. 7. Corrosion rate of copper and silver vs. Cl_2 or HCl concentrations. M, environment A (Table III) with variable Cl_2, Cl_2 is the single pollutant in the environment, HCl is the single pollutant in the environment. The arrows identify the appropriate scale (RH = 70%, T = 25°C).

atmosphere have caused electric contact failures (38). Nitrogen dioxide is a precursor to nitrous and nitric acid, but the kinetics are slow.

Neither copper nor silver corrosion rate was significantly affected by an increase of NO_2 levels in the test environment A over the concentration range 0-1316 $\mu g/m^3$.

Ozone.—Ozone, O_3, is produced in photochemical processes as well as by natural and anthropogenic electrical discharges. Urban concentrations are generally in the range of 10-115 $\mu g/m^3$ (39). It is well recognized that ozone attacks carbon double bonds and degrades rubber. The influence of ozone on metals has not been well documented. It may directly influence the rate of oxidation; however, pure oxygen oxidation is not generally considered a problem in urban materials corrosion.

The corrosion rate dependence of copper and silver on ozone partial pressure in the multipolluted environment A is shown in Fig. 8. The corrosion of both metals is significantly influenced by ozone. This may be explained for silver as an increased oxidation of H_2S to form sulfur which reacts readily with Ag. Recall that silver corrosion is very sensitive to H_2S. For copper, ozone may, in addition to the above mechanism, enhance oxidation of SO_2 to SO_3, followed by the formation of sulfuric acid on the copper surface, a reactive acid in the presence of oxygen.

Photoelectron spectroscopy of the high level O_3 corroded silver surface shows equal amounts of both sulfate and sulfide which supports the argument that the O_3 can enhance the oxidation of SO_2.

Ammonia.—Ammonia is produced by decaying vegetation, as well as by many anthropogenic sources. It is found at typical levels of 6-12 $\mu g/m^3$ in urban areas (40). Ammonia complexes of copper and silver are common. This ability to complex may cause significant acceleration in the corrosion of these metals. The *p*H of aqueous solutions in equilibrium with the NH_3 partial pressures in this study are very basic.

Figure 8 shows copper and silver corrosion rates *vs.* ammonia concentration in the complex multipolluted environment. The rate of copper corrosion is inhibited while silver shows a significant weight increase. The NH_3 must act to increase the *p*H on copper surfaces rather than accelerate the dissolution rate by complex formation. Analysis of the white corrosion product on silver showed ammonium chloride with significant quantities of silver. Silver was a good catalyst for the ammonia and chlorine reaction to form solid NH_4Cl. This is a thermodynamically favorable reaction at the chamber conditions where NH_3 was present. For example, at 9 $\mu g/m^3$ of HCl, the NH_3 vapor pressure in equilibrium with NH_4Cl (s) is 16 $\mu g/m^3$. At pressures higher than this, we expect NH_4Cl precipitation. Table IV indicates that for an NH_3 concentration between 6 and 35 $\mu g/m^3$ the NH_4Cl precipitation begins in good agreement with the above calculations.

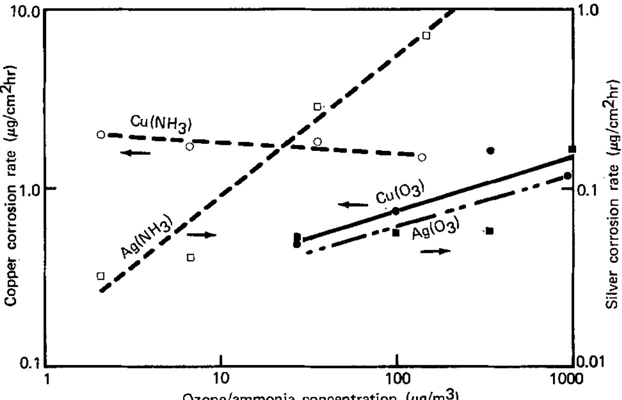

Fig. 8. Copper and silver corrosion rate vs. ozone and ammonia concentrations (RH = 70%, T = 25°C, reference environment A).

Indoor corrosion.—Extensive work has been directed to understand the magnitude and mechanism of copper corrosion in outdoor urban and marine environments. The American Society for Testing Materials has coordinated much of the work on the North American Continent and summarized the researchers' work in a multitude of publications (41-45). Guttman and Sereda have made an attempt to correlate observed rates with atmospheric parameters (7). Sulfur dioxide (sulfate particles) and water vapor (time of wetness) were the most important parameters; however, the correlation was not great. The outdoor corrosion of silver is not well documented but is recognized as a problem.

The indoor corrosion of materials has received less attention, because in most applications it is an insignificant problem. This is not, however, the case for the electronics industry. The integrity of microconductors, contacts, cables, semiconductors, and memories is an integral and important consideration for reliability in indoor environments. We will compare the indoor corrosion rates of copper and silver with the extensive outdoor data. Furthermore, we will correlate the observed indoor rates to a given pollutant, reduced sulfur.

Table V summarizes the indoor copper rates in this study (the first eight sites), other reported indoor rates, and outdoor rates. The rates are reported as weight gain per square centimeter per hour. We had in some cases to convert the other researchers' rates, obtained by cathodic reduction or weight loss measurements, to weight gain by either use of the reported products or by an estimate of the products. Table VI is a similar summary for silver.

All of the indoor data were used to fit to a log normal distribution function over the 35 sites for copper and 25 sites for silver. The statistical summary is given in Table VII. This includes the rate at various cumulative percentages of the population, the standard geometric deviation, correlation coefficient, and sample size. A similar analysis is reported for the outdoor data in Table VII.

Examination of these results demonstrates that the log normal distribution is a good fit of the data. Also, copper is shown to corrode indoors at approximately 0.01 the rate outdoors, while silver corrodes more rapidly indoors than outdoors by a factor of two or three. We propose that silver's comparative insensitivity to relative humidity accounts for the similarity in indoor and outdoor rates. The presence of indoor sources of H_2S and S_8 may account for the higher indoor levels. The corrosion rate of copper shows a much more pronounced humidity dependence and, hence, upper extremes of outdoor humidity will cause it to corrode significantly faster than indoors.

The pollutant measurements, as well as the relative humidity for six of the eight indoor sites in this study, have been summarized in a previous report (18). The reduced sulfur concentration, which consists of the sum of H_2S and free sulfur, was the best indicator of the indoor environmental severity toward both copper and silver. For example, if we combine our copper data with that of Vernon (8), the resulting rate in $\mu g/cm^2hr$ *vs.* reduced sulfur concentration in $\mu g/m^3$ is

$$r = 0.00211\,[S_x] + 0.00054$$

with a correlation coefficient equal to 0.995. Figure 9 shows the results. For silver the equation is

$$r = 0.00423\,[S_x]^{0.33}$$

with a correlation coefficient equal to 0.91. Both of these equations must be regarded as empirical fits. Examination of the laboratory data would clearly indicate that many pollutants are operative and circumstances may occur that make reduced sulfur an insignificant pollutant.

Summary

Copper corrosion rate is shown to be a sensitive function of relative humidity in a complex test environment, while silver is insensitive. The rate of copper corrosion is influenced by SO_2, H_2S, Cl_2, HCl, and O_3 concentrations. Silver's rate depends on H_2S, Cl_2, HCl, and O_3 concentrations. The indoor corrosion rates of both metals are comparable and fit log normal statistics over the population size studied. Silver corrodes faster indoors than outdoors, while copper cor-

Inclusions in Electroplated Additive-Free Hard Gold

S. Nakahara* and Y. Okinaka*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Hard gold deposits plated from an additive-free phosphate bath have been analyzed for codeposited inclusions using transmission electron microscopy. Electron diffraction analyses of residues obtained from aqua regia dissolution of the gold deposits and those collected from the surface of thermally aged deposits showed that these residues consist of aurous cyanide (AuCN). These results and other electrochemical evidences suggest that AuCN is codeposited in additive-free hard gold, bringing about a grain refining effect and the resulting increase in hardness.

Hard gold deposits for electronics applications are generally electroplated from baths containing $KAu(CN)_2$, a citrate or phosphate buffer, and a hardening agent such as a cobalt salt. Recently, it was found that the inclusion of cobalt in the gold at concentrations above a certain limit may cause the formation of a highly resistive, cobalt-containing surface film (CoO) when the gold is aged at moderately high temperatures (~150°C) (1). As a practical solution to this

* Electrochemical Society Active Member.

Key words: electrodeposition, transmission electron microscopy, electron diffraction.

problem it has been suggested to replace the cobalt-hardened gold (CoHG) with an additive-free hard gold (AFHG) for certain applications (2).

The plating of AFHG was first described by Reinheimer (3), who obtained hard gold deposits by operating at low temperatures (~25°C) the conventional citrate or phosphate bath which normally yields soft gold at elevated temperatures (~70°C). He also observed that the increase in hardness with decreasing plating temperature is accompanied by a corresponding increase in carbon content of the deposit. Subsequently, we carried out a transmission electron microscope (TEM) study of various hard gold deposits (4), and found that AFHG contains a high density of small nonmetallic objects. The present study was undertaken to identify these inclusions and to obtain an understanding of the mechanism of codeposition and the role that the codeposited material might play in determining the structure and properties of AFHG. It is shown that AFHG contains aurous cyanide (AuCN), which is known to form a polymeric structure with infinite linear chains (5, 6). This finding is consistent with the recently proposed mechanism of cathodic gold deposition from $Au(CN)_2^-$, which involves the formation of AuCN as an adsorbed intermediate (7-11).

Experimental

Plating procedure.—The AFHG deposits examined in this work were plated from a phosphate bath with the following composition: $KAu(CN)_2$ 44 g/liter, KH_2PO_4 100 g/liter, KOH 28 g/liter, pH 7.0. The plating was carried out at 40°C using the previously described experimental setup (12) involving a stainless steel rotating cylinder cathode and a concentric anode. The cathode, 2 cm in diameter and 2.1 cm in height, was tightly wrapped with a substrate, which was a sheet of copper, 2.1 × 6.5 × 0.005 cm, coated with a thin flash of gold strike. The anode was made of titanium, and it was coated with an active layer consisting of RuO_2 and TiO_2 (12). The inner diameter of the anode measured 2.9 cm. The cathode was rotated at 3600 rpm to obtain a turbulent flow condition which allowed high speed plating at a current density of 250 mA/cm^2 (12).

Specimen preparation.—The copper substrate was first dissolved off the gold deposit (~25 μm) in 1:1 HNO_3. TEM specimens for direct observation of inclusions were prepared by electropolishing the gold in a mixture of 25 ml ethyl alcohol, 25 ml glycerin, and 50 ml concentrated HCl (4).

The residue obtained upon dissolution of the AFHG deposit in aqua regia was collected on a TEM specimen grid after thorough washing in distilled water. In this procedure the aqua regia had to be replaced by distilled water immediately after complete dissolution of the gold because the residue dissolved rather rapidly in aqua regia. It was noted that the amount of this residue was considerably less than that obtained from a CoHG deposit. The latter was first discovered by Munier (13) and called "polymer," which more recently was identified as cobaltous cyanocobaltate, $Co_3[Co(CN)_6]_2 \cdot xH_2O$ (14). This "polymer" is stable in aqua regia unlike the residue from the AFHG.

The surface residue formed on a thermally aged (150°C, 1 week) AFHG deposit was collected on a small piece of knife edge using the scraping technique described previously (15). The knife edge was directly mounted on a specimen holder for TEM observation.

Transmission electron microscopy.—TEM micrographs were taken with a JEM-200 electron microscope operated at 200 kV. The defocus imaging technique (16) was used for direct observation of nonmetallic inclusions in gold deposits.

Experimental Results

Direct observation.—A TEM micrograph of an AFHG film taken in the under-focused condition [Δf (defocus distance) = −3.9 μm] is shown in Fig. 1. Nonmetallic objects are seen in this micrograph mostly as small white circles surrounded by black rings (marked by white arrows), while some are seen with an opposite contrast as black circles surrounded by white rings (marked by black arrows). These small image features result from phase contrast, and therefore these objects are sometimes called "phase objects" (17). It can be easily shown from the previously described image analysis based upon geometric optics (18) that the black circles in Fig. 1 are due to objects situated on the specimen surfaces, whereas the white circles are images resulting from objects located inside the specimen. As shown previously (19), the image size measured from under-focused micrographs closely corresponds to the true size of phase objects in the range of about 20-50Å. The micrograph of Fig. 1 shows that approximately 80% of the phase objects measure 20-55Å in diameter, the remainder measuring up to 200Å. The population density was ~1 × 10^{17}/cm^3, and the volume ratio was estimated to be 1.3 to 1.9%, assuming the phase objects to be spherical and taking measurements in the regions of thicknesses ranging from 500 to 750Å. A close examination of the micrograph shows that the phase objects are located both within the grains and at grain boundaries. In spite of the presence of these phase objects, the electron diffraction pattern obtained with the gold film did not show any detectable diffraction lines other than those due to gold metal.

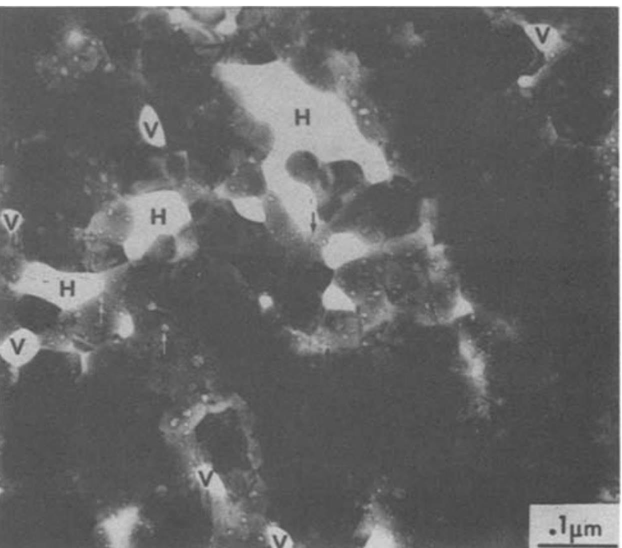

Fig. 1. TEM micrograph of electropolished AFHG, showing nonmetallic objects (black and white arrows), voids (denoted by a symbol V), and holes (marked by H). White arrows indicate inclusions inside the deposit, whereas black arrows show objects lying on the surface. The micrograph was taken in slightly underfocused condition in order to reveal the images of inclusions.

It is also seen from Fig. 1 that the size of gold grains ranges from ~250 to 750Å, which is somewhat larger than that of a typical CoHG (225-275Å) (4) but considerably smaller than the grain size of soft gold deposits [typically 1-2 μm (20)]. Generally, when TEM specimens are prepared by electrothinning, holes surrounded by thin tapered edges are produced. The large holes denoted by H in Fig. 1 are seen to have this feature. On the other hand, the small faceted holes denoted by V are not surrounded by such tapered edges, and their size and shape resemble those of individual grains. Based on these observations, it may be assumed that these small holes are voids produced during film growth. The significance of this assumption will be discussed in a later section.

Residue from aqua regia dissolution.—A TEM micrograph obtained with the residue from aqua regia dissolution is shown in Fig. 2a, and the corresponding electron diffraction pattern in Fig. 2b. It is seen that the residue consists of extremely small crystals (25-

30Å) with poor crystallinity. The analysis of the diffraction pattern shows that the material is AuCN (Table I). It was noted that this material is stable to electron beam irradiation as opposed to the similar aqua regia residue obtained from a cobalt-hardened gold, which was observed to decompose in a few seconds in the electron microscope.

Surface residue.—Figures 3a and 3b show a TEM micrograph obtained with the residue collected from the surface of a thermally aged (150°C, 1 week) deposit and the corresponding electron diffraction pattern. The residue is seen as well-developed needle-shaped crystals 100-300Å thick. No such residue was obtained from the surface of as-deposited gold. The analysis of the diffraction pattern also showed that the crystals are AuCN (Table I). The relatively large discrepancy for the largest d-spacing is attributed to an experimental error.

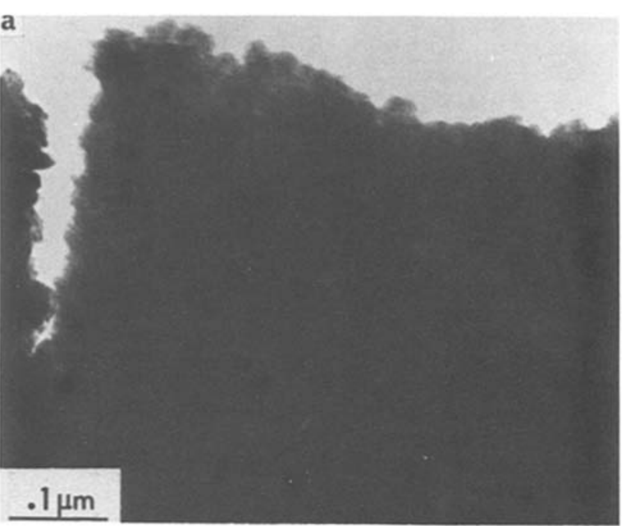

Fig. 2. Structure of aqua regia residue from AFHG. The image of the residue (a) and its electron diffraction pattern (b). Note details around edges in (a).

Discussion

Existence of AuCN in deposits.—Reinheimer (3) studied the carbon inclusion in gold deposits plated from additive-free baths as a function of various plating parameters. He unequivocally showed that the carbon results from the inclusion of a cathodically formed product, and considered these compounds as the most likely source of carbon: KCN, AuCN, $KAu(CN)_2$, and HCN. For cobalt-hardened gold deposits, Raub, Knödler, and Lendvay (21) also considered the possibility of the inclusion of AuCN among other compounds as a source of carbon. Subsequently, Cohen, West, and Antler (22) made a Mössbauer spectroscopic study of cobalt-hardened gold, and reported that the deposit contained no detectable AuCN, $KAu(CN)_2$, or $KAu(CN)_4$. The detection limit for AuCN by this technique was ~2 mole percent (m/o) of the total Au. The analysis of AFHG plated under the conditions of the present experiment showed the presence of 0.055 weight percent (w/o) of carbon (2), which corresponds to 0.90 m/o as AuCN if all of the carbon is assumed to be present in this form. Thus, Mössbauer spectroscopy would not detect the AuCN in AFHG. Based on these considerations in conjunction with the results of analysis of aqua regia residue and surface residue, it is postulated that AuCN is codeposited in AFHG.

Mechanism of AuCN codeposition.—The mechanism of gold deposition from $Au(CN)_2^-$ has been studied by many investigators in recent years. All agree that a chemical step precedes the charge transfer step but disagree in detailed description of the chemical step. Harrison and Thompson (8), using a potentiostatic linear sweep technique, found that the reduction of $Au(CN)_2^-$ to be first order in cyanide, and proposed that AuCN is the reducible species

$$Au(CN)_2^- \rightleftarrows AuCN + CN^- \quad [1]$$

$$AuCN + e^- \rightarrow Au + CN^- \text{ (slow)} \quad [2]$$

Beltowska-Brzezinska and Dutkiewicz (9) determined the dependence of exchange current on con-

centrations and arrived at the same conclusion as above. MacArthur (7) carried out a cyclic voltammetric study and found evidence for the adsorption of AuCN intermediate at low overpotentials. Eisenmann (10) concluded from his kinetic studies of the deposition systems of soft as well as hard gold that the reaction proceeds via a common mechanism involving adsorption equilibria preceding and following the electron transfer step

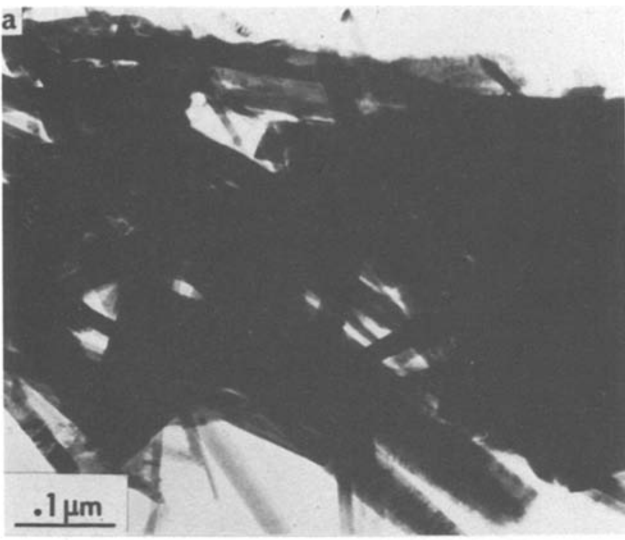
$$Au(CN)_2 \rightleftarrows AuCN_{ad} + CN^- \quad [3]$$

$$AuCN_{ad} + e^- \rightleftarrows (Au^\circ CN)_{ad}^- \quad [4]$$

$$(Au^\circ CN)_{ad}^- \rightleftarrows Au \text{ (lattice)} + CN^- \quad [5]$$

McIntyre and Peck (11) observed a distinct cathodic prewave in their potential scan experiment, which they consider may be attributed to the reduction of an insoluble film of AuCN. These mechanistic evidences are consistent with our experimental results indicating that AuCN is incorporated in the gold deposit.

It was found by Reinheimer (3) that the carbon content of AFHG is strongly temperature dependent, and soft gold plated at 70°C contains only ~0.001 w/o C as compared to ~0.055 w/o for AFHG. From this result it is clear that soft gold contains essentially no AuCN. A TEM observation of soft gold also did not show any evidence of nonmetallic inclusions (19). This result can be understood if the adsorption of AuCN is involved because the coverage by an adsorbed species decreases exponentially as temperature is increased through an adsorption isotherm (23).



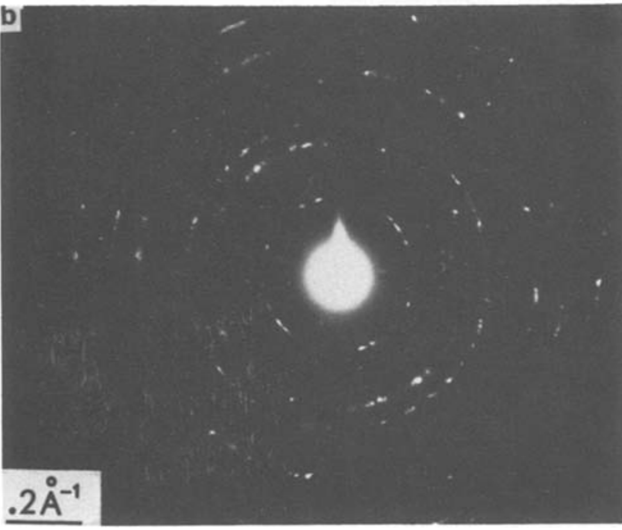


Fig. 3. Structure of surface residue obtained from thermally aged AFHG. The image of the surface residue (a) and its electron diffraction pattern (b).

AuCN as phase object.—As stated in the preceding section, the volume occupied by the phase object in the specimen amounts to 1.3-1.9%. If it is assumed that these objects are AuCN with a bulk density of 7.12 g/cm^3, the carbon content of the specimen corresponding to the AuCN can be calculated to be 0.032 $\pm$ 0.006 w/o. Thus, under these assumptions the phase object accounts for approximately 50-70% of total carbon content (0.055 w/o). It appears that two or more sources of carbon exist in AFHG; a similar conclusion has been reached recently for CoHG (14).

The structure of AuCN is known to be polymeric with infinite linear chains arranged in parallel (5, 6)

```

As noted previously, the size of AuCN crystallites in the aqua regia residue was 25-30Å while the majority of phase objects measured 25-50Å. This similarity in size suggests that the phase objects are, in fact, AuCN crystallites, and they coagulate to form the residue upon dissolution of gold in aqua regia. From the known lattice constants (hexagonal, a = 3.40Å, c = 5.09Å) (6) it can be estimated that each crystallite consists of 5-10 unit cells. The observation of the needle-shaped crystals on the surface of thermally aged deposit shows that the small crystallites segregate on the surface to grow in the direction of c-axis upon heating.

It has been found that the density of AFHG determined by the gravimetric method using a specific gravity bottle is equal to 17.40 $\pm$ 0.10 g/cm^3, as compared to 19.3 g/cm^3 for pure bulk gold (2). A simple calculation using the volume percent of the phase object and the density of AuCN shows that the incorporation of AuCN as the phase object accounts for a decrease in density from 19.3 g/cm^3 only to 19.1 g/cm^3. It appears that the considerably lower density observed is due to the presence of voids. This interpretation is based on the following measurements and calculations. A TEM micrograph taken at a low magnification (20,000$\times$) yielded $\sim$1 $\times$ 10^{15}/cm^3 for the population density of voids and 300-650Å for the range of void diameter. Using these values and estimated film thicknesses (750-1000Å), the ratio of the volume occupied by the voids to the film volume can be calculated as 8-14%. These values yield film densities ranging from 16.3 to 17.4 g/cm^3 in good agreement with the observed density.[1]

Role of AuCN.—Hard gold electrodeposits are generally obtained by the addition of small amounts of metal ions such as Co^{2+} or Ni^{2+}. These ions are known to codeposit with gold in at least two different forms, cyano-complex and substitutional alloy (14, 25, 26). The increased hardness is primarily due to the grain refining effect (27) which is brought about by the codeposited cyano-complex (4, 14). Similarly, the codeposited AuCN appears to play the role of a grain refining agent for AFHG either by promoting the nucleation of gold or by inhibiting the growth of gold grains or both.

As was described in a previous communication, the contact resistance stability on thermal aging of AFHG is superior to that of CoHG (2). However, a small increase in contact resistance was found to occur upon heating AFHG at >100°C. The results described indicate that this increase is due to the surface segregation of AuCN at elevated temperatures.

Summary and Conclusion

A transmission electron microscope study of electroplated additive-free hard gold indicated that AuCN is codeposited as an impurity. Electrochemical evidences found in the literature suggest that this compound, which is formed as an adsorbed intermediate during the reduction of $Au(CN)_2^-$, is incorporated in the gold deposit. The amount of AuCN estimated from the volume density of phase objects observed by TEM shows that about 50-70% of the total carbon found by chemical analysis of AFHG can be accounted for by AuCN. The AuCN appears to be present in AFHG as crystallites, each consisting of 5-10 unit cells, within gold grains as well as at grain boundaries. The incorporation of AuCN can explain the decreased grain size, increased hardness, and small contact resistance instability of additive-free hard gold.

Manuscript submitted April 17, 1980; revised manuscript received Aug. 8, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by Bell Laboratories.

[1] The density of CoHG is also known to be low (17.3-17.8 g/cm^3) (24). A TEM examination of this type of gold showed that voids similar to individual grains in size and shape ($\sim$250Å) are distributed randomly. As in the case of AFHG, the volume of these voids appears to account for the decreased density of CoHG.

Cyanoaurate(III) Formation and Its Effect on Current Efficiency in Gold Plating

Y. Okinaka* and C. Wolowodiuk

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The cyanoaurate(III) ion has been found to form and accumulate in acidic or neutral gold plating baths containing cyanoaurate(I) as the source of gold. This trivalent gold species brings about a decrease in plating current efficiency because its reduction to gold metal requires three faradays per mole, whereas only one faraday is consumed to reduce one mole of Au(I). The accumulation of Au(III) should therefore be minimized to produce gold deposits with a thickness unaffected by bath age. This paper describes various methods for achieving this objective, which include the use of the so-called "dimensionally stable anode" and a techniqe of chemically reducing Au(III) to Au(I).

Thickness control in gold plating has become increasingly important in recent years because of the necessity for saving gold by plating only a minimal thickness required for specific applications. Since deposit thickness is directly proportional to plating current efficiency, it is important to have knowledge of factors affecting the latter. It is recognized that the current efficiency of both soft and hard gold plating from acidic or neutral cyanoaurate(I) baths tends to decrease with increasing extent of bath use, and generally extrinsic contaminants are believed to be responsible for the efficiency deterioration.

During the course of our recent work to develop a polarographic method for analyzing gold plating solutions (1), significant amounts of cyanoaurate(III) ions, $Au(CN)_4^-$, were found in extensively used production baths. It has been established that this species is produced as a result of a reaction at the anode, generally platinum or platinized titanium, and that it is, at least partly, responsible for the decrease in plating current efficiency because of the greater quantity of electricity required to reduce Au(III) than Au(I).

In the present work, the relationship between current efficiency, Au(III) content, and bath age has been studied, and methods for minimizing the formation and accumulation of Au(III) have been investigated.

Experimental

Plating Solutions

Results obtained with two different types of plating solutions are described in this paper: a conventional cobalt-containing hard gold bath (denoted as CoHG) and a high speed, additive-free hard gold bath (AFHG) (2). Make-up compositions and optimum operating conditions of these baths are listed in Table I. During the bath aging experiments, the plating solutions were analyzed for total gold and Au(III) and for Co^{2+} using, respectively, the polarographic and colorimetric methods described previously (1), and the total gold and cobalt concentrations were maintained within approximately ±10% by periodic addition of appropriate salts. The pH was kept constant within ±0.1 unit by adding citric phosphoric acids for CoHG and AFHG baths, respectively.

Apparatus

CoHG.—A jacketed glass plating cell containing 300 ml of the CoHG plating solution was used. A rigid flat anode (platinum unless noted otherwise) measuring 3.8 × 3.8 cm was placed vertically at the center of the cell, and two copper sheets with the same dimensions plated

Table I. Bath compositions and operating conditions

Ion	Form of salt added	CoHG	AFHG
$Au(CN)_2^-$	$KAu(CN)_2$	8.2 g/liter as Au	30 g/liter as Au
Co^{2+}	$CoSO_4$	100 ppm as Co	—
Citrate	$K_3C_6H_5O_7 \cdot H_2O$ and $C_6H_8O_7 \cdot H_2O$	0.52M	—
Phosphate	KH_2PO_4 and KOH	—	1.23M
	Condition

	Temp.	32°C	40°C
	Current	10 mA/cm²	250 mA/cm²
	Agitation	Mild	Vigorous

with strike gold were immersed on both sides of the anode with cathode-to-anode separation of about 3.2 cm. The solution temperature was maintained at 32°C by circulating constant-temperature water. Mild agitation was provided with a magnetic stirrer.

AFHG.—A rotating cylinder electrode system with a stationary, concentric cylindrical anode (Fig. 1) was used to plate AFHG at high speed. The substrate was a sheet of copper, 2.1 × 6.5 × 0.005 cm, coated with a thin flash of gold strike. It tightly wrapped the stainless steel portion of the rotating cathode as illustrated in Fig. 1. The ends of the substrate were folded into the vertical narrow groove, and a small Teflon key made to fit snugly into the groove was inserted to hold the substrate securely in place. The rotating cathode was fabricated by first attaching a short piece of stainless steel rod (1 cm in radius and 2.1 cm in height) to a rotating disk electrode core purchased from Pine Instruments Company, Grove City, Pennsylvania (Cat. No. DT-101-AA), followed by potting in epoxy resin and machining. This cathode design allowed quick, easy installation and removal of the substrate. The cylindrical anode had an inner radius of 1.46 cm, and was placed on a Teflon support in a glass plating cell. The volume of the plating solution was 1 liter. The solution temperature was maintained at 40°C by circulating it with a pump through an external heat exchanger.

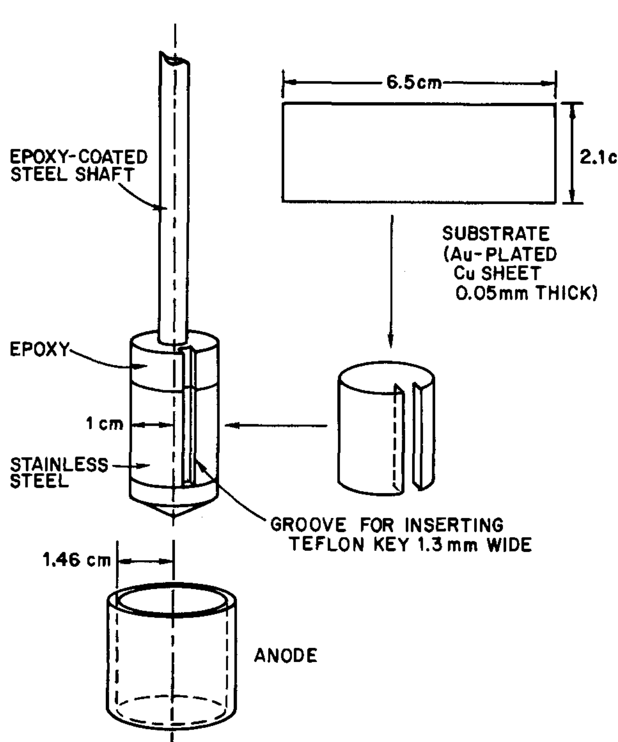

Fig. 1. Rotating cylinder electrode with demountable film substrate.

The cathode was rotated at 3600 rpm, which was well above the critical speed (822 ppm)[1] necessary to obtain turbulent flow. This high rotation speed was necessary to obtain hard, bright deposits at the plating rate (typically a minimum of 2.54 μm in 16 sec) required for practical high speed plating, for example, in continuous strip plating of electrical connector terminals.

Experimental Results

Current Efficiency, Bath Age, and Au(III) Content

CoHG.—Many actual production baths, including both citrate-based and organophosphonate-based baths, were analyzed for Au(III) and found to contain up to 25% of total gold in the form of Au(III). In the laboratory aging experiment carried out at 300 mA (~10 mA/cm² at both anode and cathode) with the apparatus described in the preceding section, the rate of accumulation of Au(III) was quite slow; for example, after ten bath turnovers[2] the Au(III) content was only about 5% of the total gold. In order to facilitate the study of the effect of Au(III) content on plating current efficiency, it was necessary to age the bath under accelerated conditions. It was found that Au(III) accumulates much more rapidly if plating is performed with a high initial gold concentration without cobalt present and the solution is subsequently heated (see Discussion section). Thus, a citrate buffer containing $KAu(CN)_2$ only (20.5 g/liter as Au) was first electrolyzed continuously at 32°C and 300 mA for 3 hr, and then the solution was heated at 60°C for 1 hr. The analysis of the resulting solution showed that the total gold concentration decreased to 8 g/liter, and that the Au(III) content amounted to 24% of the total gold. CoHG baths containing different amounts of Au(III) were prepared by diluting the above solution with the citrate buffer and adjusting the concentrations of total gold and cobalt to 8.2 g/liter and 100 ppm by adding $KAu(CN)_2$ and $CoSO_4$, respectively. Plating current efficiencies of these baths were measured at the cathode current density of 10 mA/cm² at 32°C with mild agitation. The results are shown in Table II. A significant decrease in plating current efficiency is seen with increasing Au(III) content. The "calculated efficiency" was obtained by multiplying the initial current efficiency observed in the absence of Au(III) by the theoretical fraction of initial current efficiency, which was calculated by taking account of the difference in number of electrons involved in reducing Au(I) and Au(III)

Fraction of initial current efficiency

$$= \frac{[Au(I)] + [Au(III)]}{[Au(I)] + 3[Au(III)]} = \frac{1}{1 + 2x} \quad [1]$$

where x is the Au(III) content of the bath expressed by

$$x = \frac{[Au(III)]}{[Au(I)] + [Au(III)]} \quad [2]$$

[1] For this electrode system the critical Reynolds number at which the transition from laminar to turbulent flow occurs is given by (3) $Re(crit.) = (r_o - r_i)r_i\omega\nu^{-1} = 3960$, where r_o is the inner radius of the anode, r_i the radius of the rotating cylinder electrode, ω the angular rotation speed, and ν the kinematic viscosity. With $r_o = 1.46$ cm, $r_i = 1.00$ cm, $\nu = 10^{-2}$ cm² · sec⁻¹, the above Re(crit.) value can be achieved when $\omega = 86.1$ rad/sec = 822 rpm.

[2] A bath turnover is defined as completed when the amount of gold initially present has been plated out and this amount of gold replenished.

Table II. Effect of Au(III) on plating current efficiency of CoHG bath (10 mA/cm², 32°C)

Au(III)/total Au, %	Current efficiency, %	
	Observed	Calculated
0	40.0	(40.0)
6.1	34.5	35.7
10.7	32.1	32.9
24.0	29.8	27.0

The good agreement between the observed and calculated efficiencies implies that the decrease in current efficiency brought about by Au(III) can indeed be accounted for by the greater number of electrons required to reduce Au(III) than Au(I).

AFHG.—In the high speed AFHG system the Au(III) buildup and accompanying current efficiency deterioration occurs more rapidly as the bath is aged. Results obtained with the platinum anode are represented by curves 1 and 1 in Fig. 2, in which changes in current efficiency and Au(III) content are plotted against the total weight of gold plated out from 1 liter of the plating solution and the number of bath turnovers. The cathodic current density used in this experiment was in the range of 230-300 mA/cm^2, while the corresponding current density at the platinum anode was 150-200 mA/cm^2. It is seen that the initial efficiency of greater than 90% decreased to only about 50% after four bath turnovers, during which the Au(III) content of the bath increased to almost 25%.[3]

From the results obtained with both CoHG and AFHG baths, it is clear that if plating current efficiency is desired to be maintained on the level of 90% of the initial efficiency, Au(III) content should not be allowed to exceed about 5% of total gold. In the case of CoHG this Au(III) level was reached after about 10 bath turnovers, whereas for AFHG it took only two-thirds of a turnover. Although the rate of Au(III) accumulation is likely to be controllable to some extent, for example, by increasing the anode area to decrease the anodic current density, it is clearly desirable to establish a method to compensate for the Au(III) effect, or to minimize or eliminate the formation and accumulation of Au(III).

Methods of Controlling Deposit Thickness

Adjustment of plating parameters.—The most obvious method of maintaining the deposit thickness constant with changing current efficiency is to adjust either the plating current or the plating time. A general relationship between current efficiency and Au(III) content can be calculated as already explained for CoHG (Table II). Figure 3 shows this relationship, where the ordinate is the fraction of initial current efficiency, or the ratio of current efficiency at a given Au(III) content to that in its absence. The curve was calculated from Eq. [1], and the points are experimental. The agreement is considered to be fair. This relationship is valid for both CoHG and AFHG baths (and for any other gold plating baths), and can be used for adjusting plating current or time based on the results of total gold and Au(III) analyses.

This approach is simple but suffers from certain limitations. For example, the current adjustment method results in a continuous increase in current density at the anode, which in turn is expected to accelerate the accumulation of Au(III) and hence the plating efficiency deterioration. The method relying on the adjustment of plating time is applicable to batch plating, but not to continuous strip plating in which the substrate travels at a fixed speed.

Use of other anodes.—It was found that the Au(III) accumulation and accompanying current efficiency deterioration can be decreased significantly by replacing the platinum anode with an anode of the type often called "dimensionally stable anode" (DSA®), which is now widely used for chlorine production (4). This electrode, which is made typically by coating a titanium metal base with a mixture of RuO_2 and TiO_2, has anodic overvoltages considerably lower than platinum does for the evolution of chlorine (4) as well as oxygen (5). The initial study was carried out with CoHG bath using a RuO_2/TiO_2 anode obtained from Magneto-Chemie B.V., Schiedam, The Netherlands. During eleven bath turnovers, no detectable amount (<0.2%) of Au(III) was found, whereas with paltinum 5.4% of Au(III) was found at the conclusion of the experiment performed under identical conditions. It was noted in these experiments that the yellow discoloration usually observed with CoHG baths operated with platinum anodes was much less intense for the solution aged with the RuO_2/TiO_2 anode. This appears to indicate that citrate ions are more stable at this anode.

The anode used with high speed AFHG bath was prepared using the procedure described by Janssen *et al.* (6). The results of the aging experiment carried out with this anode in AFHG bath are compared in Fig. 2 (curves 2 and 2′) with those obtained with other anodes. The Au(III) concentration never exceeded

[3] Theoretically, the minimum efficiency achievable should correspond to 33.3% of the initial efficiency, which should occur when all Au(I) is converted into Au(III), *i.e.*, when $x = 1$ in Eq. [1].

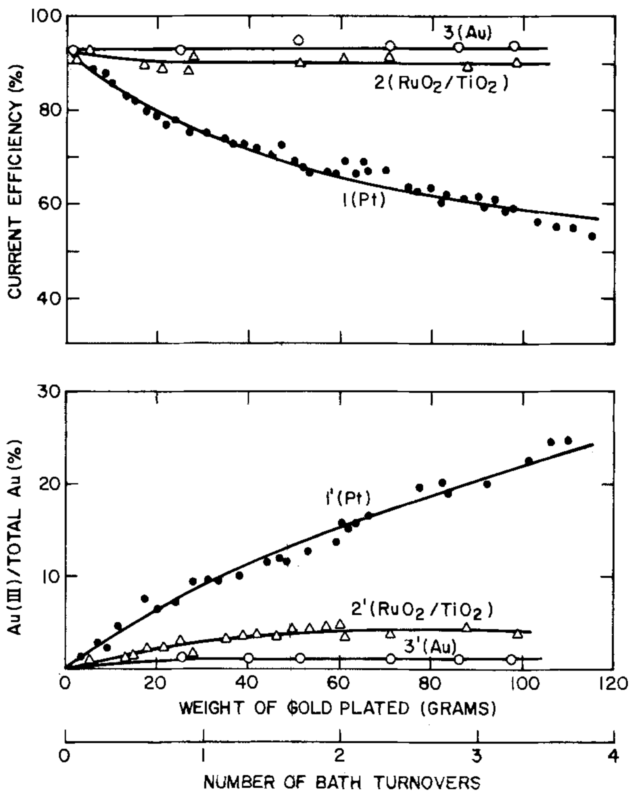

Fig. 2. Variation of plating efficiency and Au(III) content with bath age (AFHG bath). (Curves 1, 1′: Pt anode; curves 2, 2′: RuO_2/TiO_2 anode; curves 3, 3′: Au anode.)

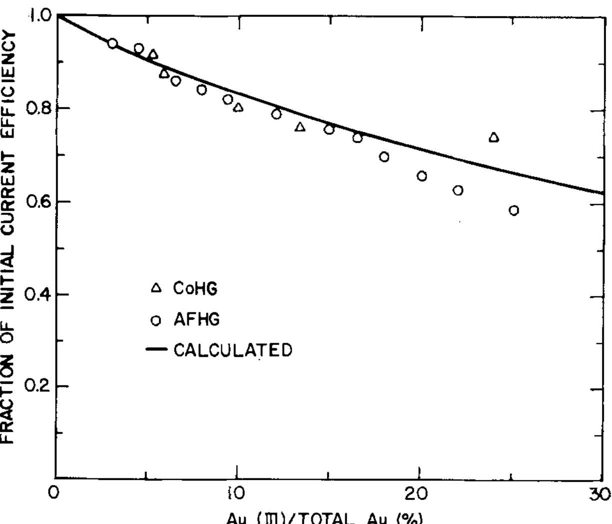

Fig. 3. Relationship between fraction of initial current efficiency and Au(III) content. (Points are experimental, line is calculated.)

~5% of total gold, and the efficiency remained greater than 89% (as compared to the initial efficiency of 93%) over the period of four bath turnovers. It is recognized that "dimensionally stable anodes" have a limited life as does platinized titanium depending on electrolysis conditions, coating composition, and the method of preparation. Results of our investigation concerning the life of anodes under the conditions of gold plating will be described elsewhere (7).

It was found that a gold anode also brings about the same beneficial effect. The level of Au(III) accumulation was even lower than that observed with the RuO_2/TiO_2 anode, and the current efficiency remained essentially unchanged at the initial level (curves 3 and 3', Fig. 2). The reason why the gold anode works is that gold dissolves preferentially over the oxidation of Au(I) to Au(III). Under the conditions of high speed plating, the concentration of free cyanide becomes quite high because of its rapid formation at the cathode. It was actually found that the gold anode loses its weight quite rapidly. Under our experimental conditions the rate of anode dissolution was such that a 0.38 mm (0.015 in.) thick anode would not last more than 100 hr of continuous plating. For this reason, a gold anode is not likely to be practical.

Chemical reduction.—Many common reducing agents are capable of reducing cyanoaurate(III) to cyanoaurate(I), but for the present application it is important to choose one which does not leave undesirable reaction products after treatment. Hydrazine was selected here for this reason (see Discussion section).

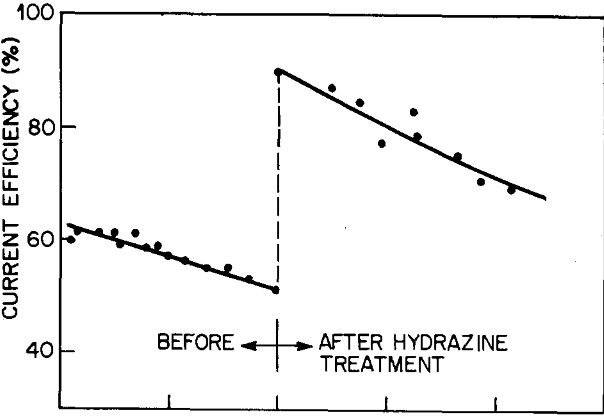
A CoHG bath, 100 ml, containing 20% of total gold in the form of Au(III) was treated with 0.25 ml of 85% hydrazine hydrate ($N_2H_4 \cdot H_2O$) at 75°C for 4 hr. Then, additional 0.25 ml of hydrazine was added, and heating was continued for 4 more hours. This treatment reduced about 90% of the Au(III) to Au(I). The initial current efficiency of this bath was 29%, which improved to 40% upon hydrazine treatment. No apparent difference was noted on the deposits from the hydrazine-treated bath and from the fresh bath. The addition of large excess hydrazine, *e.g.*, 2 ml, greatly accelerated the reaction; however, the plating done after this treatment yielded discolored deposits.

The AFHG bath aged with platinum anode was also treated with hydrazine and the aging experiment continued. The hydrazine treatment-plating cycle was repeated several times under various treatment conditions. An optimum set of conditions found was to add about an equimolar amount of hydrazine hydrate and heat the bath at 75°-80°C for 1-3 hr depending on Au(III) content of the bath. When the Au(III) content was high (>15%), it was necessary to repeat the treatment in order to bring it down to <2%. The decrease in Au(III) concentration upon hydrazine treatment and the accompanying recovery of current efficiency are illustrated in Fig. 4.

Active carbon treatment.—Carbon treatment is conventionally carried out for removing organic contaminants. It was found that this treatment also removes Au(III) effectively. Active carbon (Darco Red Label), 0.25g, was added in 10 ml of a CoHG bath containing 14% of total gold in the form of Au(III), and the mixture heated at 90°C for 30 min. This treatment removed approximately 80% of the Au(III). However, about 29% of Au(I) was also lost. The loss of gold by carbon treatment is generally known, and for this reason this purification procedure should preferably be avoided. It is also known that carbon treatment does bring about a recovery of plating current efficiency. The experimental result described above shows that it is, at least partly, due to the removal of Au(III).

Discussion

Mechanism of Au(III) formation.—No detailed study has been carried out to establish the mechanism of the formation of $Au(CN)_4^-$. However, the following experimental observations should be noted: (*i*) A laboratory-aged CoHG bath was analyzed for $Au(CN)_4^-$ by the polarographic method immediately after termination of electrolysis for 3 hr at 32°C and after heating in boiling water for 1 hr. The height of the Au(III) wave found after heating was nearly twice that observed before heating. (This post-heating effect was used for the accelerated aging described in the Experimental section.) It was also noted that the wave height increased significantly when a freshly electrolyzed CoHG bath was allowed to stand overnight at room temperature. (*ii*) Electrolysis of a fresh CoHG bath was carried out in an H-type cell in which cathode and anode compartments are separated by a sintered glass disk. A platinum sheet was used as the anode, while the cathode was a copper sheet. After electrolysis, the solution in each compartment was analyzed polarographically. Only the solution in the anode compartment showed the presence of Au(III). These two experimental results indicate that $Au(CN)_4^-$ forms as a result of a slow homogeneous chemical reaction involving an intermediate species produced at the anode. The identity of this intermediate has not been established.



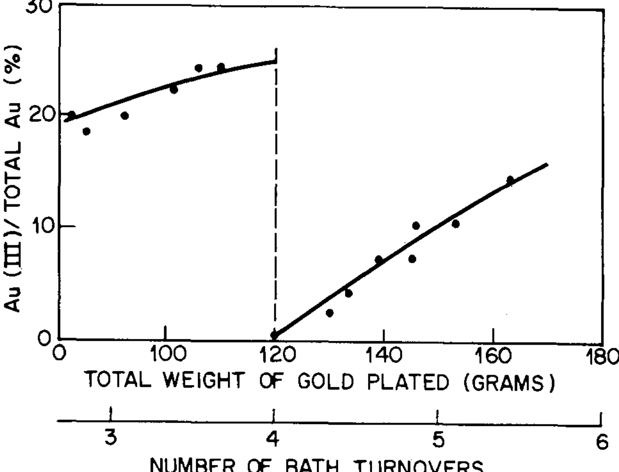


Fig. 4. Recovery of plating current efficiency and Au(III) content upon hydrazine treatment of aged AFHG bath.

Effect of anode material.—In order to obtain some insight into the mechanism of the effect of anode material on Au(III) formation, polarization measurements were made at 32°C for CoHG bath as well as for the citrate buffer without gold and cobalt present. Results obtained with platinum and RuO_2/TiO_2 anodes are compared in Fig. 5. In both solutions potentials were higher in the plating solution than in the buffer. It is also seen that the potential ranges for the RuO_2/TiO_2 anode are about 0.5V lower than those for platinum in both solutions over the entire current range investigated. Quali-

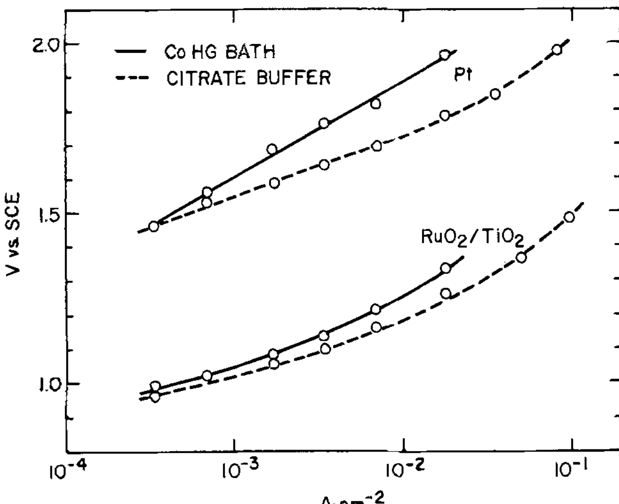

Fig. 5. Polarization curves for Pt and RuO_2/TiO_2 anodes in CoHG bath and in pH 4 citrate buffer at 32°C.

tatively, these results are expected from the known polarization behavior in strongly acidic solutions (8, 9). Because of the lack of identity of the reaction intermediate, no mechanistic interpretation can be offered for the observed anode effect on Au(III) formation. However, it is of interest to compare the potential ranges for the two electrodes with the equilibrium potential of the Au(III)/Au(I) couple

$$Au(CN)_4^- + 2e^- = Au(CN)_2^- + 2CN^-; \quad E_1° = +0.90V \quad [3]$$

Since the standard potential $E_1°$ was not found in the literature, it was calculated from the following values

$$Au(CN)_2^- + e^- = Au + 2CN^-; \quad E_2° = -0.60V\ (10) \quad [4]$$

$$Au^{3+} + 3e^- = Au; \quad E_3° = +1.50V\ (10) \quad [5]$$

$$Au^{3+} + 4CN^- = Au(CN)_4^-; \quad K = 10^{56}\ (11) \quad [6]$$

Furthermore, using $K = 1.62 \times 10^9$ (12) for the stability constant of HCN, the equilibrium potential for a typical plating solution with pH = 4 containing 0.04M $Au(CN)_2^-$, 0.0004M $Au(CN)_4^-$ [1% of Au(I)], and 0.01M free cyanide (a typical concentration of HCN plus CN^-) was calculated from $E_1°$ to be equal to +1.26V (or +1.02V *vs.* SCE). An increase in the ratio of Au(III) to Au(I) by a factor of 10 (to 10%) shifts the potential by 0.03V in the positive direction. Comparison of these equilibrium potentials with the polarization curves in Fig. 5 shows that the oxidation of $Au(CN)_2^-$ to $Au(CN)_4^-$ is possible at both platinum and RuO_2/TiO_2 at practical current densities (>10^{-2} A/cm^2). The faster accumulation of Au(III) observed with the platinum anode may be anticipated from the higher potential at this anode. A further discussion of this subject will be given in a subsequent paper dealing with the behavior of various other anode materials (7).

The oxygen evolution at ruthenium metal was found to take place at potentials which are lower by additional 0.1-0.2V than at the RuO_2/TiO_2 anode. An experiment with a ruthenium-plated platinum electrode showed, however, that ruthenium metal dissolves significantly at current densities greater than ~30 mA/cm^2.

Reaction with hydrazine.—The reaction between hydrazine and Au(III) accompanies the evolution of colorless gas. From this fact and a comparison of $E°$ values for the $Au(CN)_4^-/Au(CN)_2^-$ couple (reaction [3]) and various half-reactions of hydrazine (10), the overall reaction is likely to be either or both of the following two reactions

$$2Au(CN)_4^- + N_2H_5^+ = 2Au(CN)_2^- + N_2\uparrow + 4HCN + H^+ \quad [7]$$

$$3Au(CN)_4^- + N_2H_5^+ + H_2O = 3Au(CN)_2^- + N_2O\uparrow + 6HCN + H^+ \quad [8]$$

where $N_2H_5^+$ is the protonated form of hydrazine which is predominant in the pH range under consideration [$N_2H_5^+ = N_2H_4 + H^+$, $K = 1.02 \times 10^{-8}$ (10)]. By using relevant thermodynamic data (10), the $\Delta G°$ values for reactions [7] and [8] have been calculated to be −154 and −138 kcal, respectively. The very large values reflect the combined effect of the strong oxidizing power of $Au(CN)_4^-$ and the large numbers of electrons involved in these reactions (4 for [7] and 6 for [8]).

In order to obtain insight into the mechanism of these reactions, a kinetic study was carried out by following the disappearance of Au(III) after the addition of large excess hydrazine. The conventional first-order plot shown in Fig. 6 was obtained at 40°, 50°, and 60°C with an AFHG bath containing a total gold concentration of 30.5 g/liter (0.155M) and an initial Au(III) content of 13.9% (0.0215M). Concentrated hydrazine (85% $N_2H_4 \cdot H_2O$) was added to make the initial concentration equal to 0.215M. It is seen that the linear relationship holds only after about 7 min. A similar set of curves was obtained at 60°C with three different hydrazine concentrations as shown in Fig. 7. The slopes of these curves are approximately proportional to hydrazine concentration. Higher order analyses did not yield consistent results at different temperatures and hydrazine concentrations. Thus, the initial deviation from linearity appears to indicate the presence of some mechanistic complications which become less significant with increasing reaction time. For the linear range, the above results lead to the conclusion that the overall reaction consists of multiple steps including a rate-determining step which is first order with respect to both

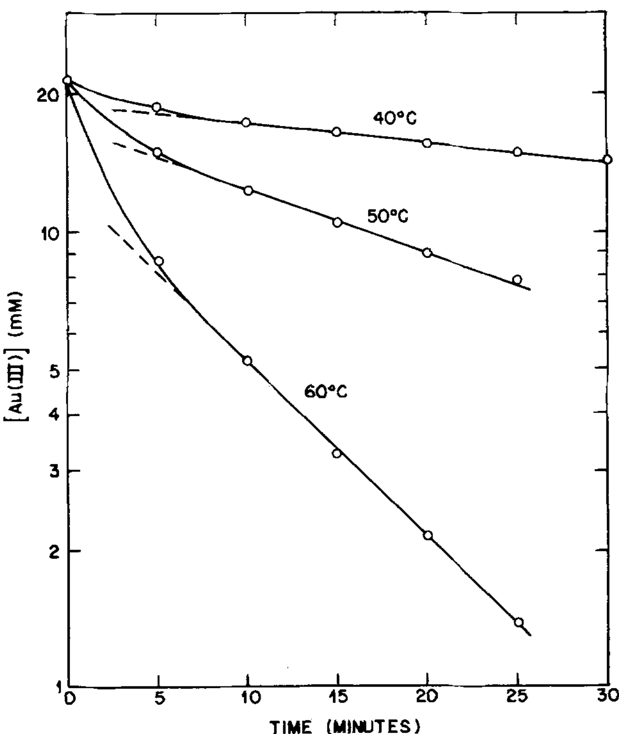

Fig. 6. Semi-logarithmic plot of Au(III) concentration against time after addition of excess hydrazine at different temperatures. (AFHG bath; total Au, 0.155M; initial Au(III), 0.0215M; hydrazine, 0.215M).

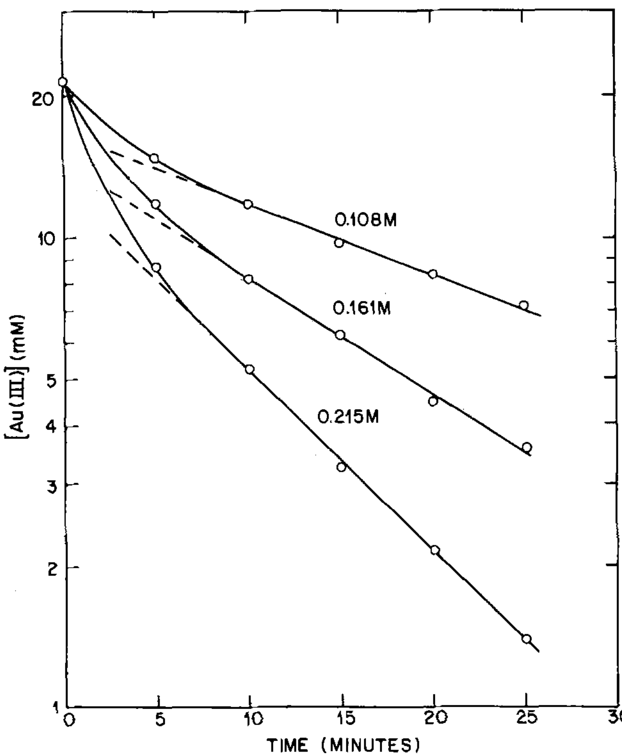

Fig. 7. Semi-logarithmic plot of Au(III) concentration against time after addition of different amounts of hydrazine at 60°C. (Same bath as for Fig. 6.)

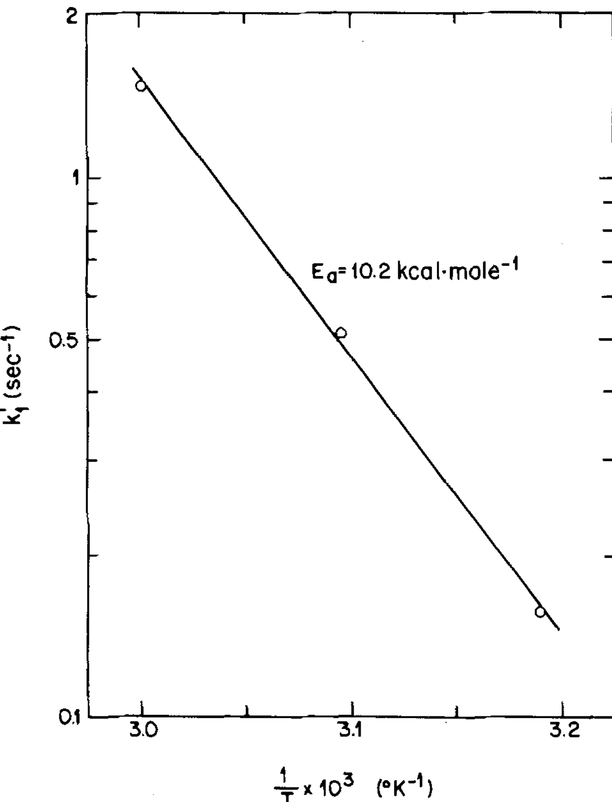

Fig. 8. Arrhenius plot derived from Fig. 6

Au(III) and hydrazine. It is likely then that hydroxylamine is formed as an intermediate

$$Au(CN)_4^- + N_2H_5^+ + H^+ + 2H_2O \xrightarrow{k_1} Au(CN)_2^- + 2NH_3OH^+ + 2HCN \quad [9]$$

This reaction is followed by

$$Au(CN)_4^- + 2NH_3OH^+ \xrightarrow{k_2} Au(CN)_2^- + N_2 + 2HCN + 2H_2O + 2H^+ \quad [10]$$

and/or

$$2Au(CN)_4^- + 2NH_3OH^+ \xrightarrow{k_3} 2Au(CN)_2^- + N_2O + 4HCN + H_2O + 2H^+ \quad [11]$$

This type of reaction sequence is known to be encountered fairly often [*e.g.*, "consecutive, competitive second-order reaction" (13)], and it can be shown readily that under the conditions of constant $[H^+]$ (buffer), constant $[N_2H_5^+]$ (large excess), and $k_1 << k_2$ and/or k_3, the reaction becomes first order with respect to $[Au(CN)_4^-]$. The last condition has been verified experimentally; namely, the disappearance rate of Au(III) observed with hydroxylamine (added as hydrochloride) as the reducing agent was at least an order of magnitude faster than that found with hydrazine.[4] The Arrhenius plot shown in Fig. 8 was obtained for the pseudo first-order rate constants calculated from the slope of linear portion of the curves in Fig. 6. The activation energy was found to be equal to 10.2 kcal mole^{-1}.

Finally, it should be noted that hydrazine has been described in the literature as an additive for gold plating baths. It is said to harden electroplated gold (14) presumably due to its influence on grain size (15). In addition, Winters (16) showed that hydrazine acts as an "oxygen scavenger" and increases the current efficiency of soft gold plating. Presumably, a similar effect is expected for hard gold plating, but the discoloration of deposits by excess hydrazine noted previously precludes its use for this purpose.

[4] Hydroxylamine would be preferred to hydrazine for this reason. However, the former is available only in the form of salts, such as hydrochloride or sulfate, which would introduce unwanted anions into the bath.

Summary and Conclusions

1. Cyanoaurate(III) ions form and accumulate in acidic or neutral gold plating baths with platinum anodes as the baths are aged. The accumulation of the Au(III) species leads to a significant decrease in plating current efficiency.

2. Methods based on adjusting plating current or time to maintain a constant deposit thickness with steadily decreasing plating efficiency are not always applicable. As a simple and more general approach, it is recommended to replace the platinum anode with a low polarization anode such as the so-called "dimensionally stable anode." Although this electrode does not completely prevent the formation of Au(III), it is possible to maintain the Au(III) concentration at a level low enough to obtain a current efficiency greater than 90% of the initial level.

3. Hydrazine is useful for reducing Au(III) to Au(I) without forming undesirable reaction by-products.

4. Treatment with active carbon removes the Au(III) species, but this method suffers from the disadvantage that significant amounts of Au(I) are also removed.

Finally, it should be remembered that the current efficiency of hard gold plating is influenced by many other variables besides Au(III). Concentrations of Au(I), Co^{2+}, *p*H, temperature, agitation conditions, and impurities all affect the current efficiency. Therefore, it is important to control these variables as well as Au(III) concentration in order to maintain a stable current efficiency and to produce a constant deposit thickness.

Acknowledgment

We are grateful to A. Heller for his advice in obtaining the initial sample of RuO_2-based dimensionally stable anode from Magneto-Chemie B.V., and to B. Miller for supplying the ruthenium-plated platinum electrode.

Steady-State Characteristics of Oxygen Concentration Cell Sensors Subjected to Nonequilibrium Gas Mixtures

J. E. Anderson and Y. B. Graves

Ford Motor Company, Chemistry Department, Research Staff, Dearborn, Michigan 48121

ABSTRACT

Oxygen sensors, based on membrane concentration cells, are to be used in a feedback control system on automobiles. For proper control function, the sensors should develop voltages corresponding to equilibrium oxygen partial pressures in engine exhaust, even when substantial deviations from chemical equilibrium actually exist in the bulk exhaust stream. This is accomplished through use of catalytic electrodes that are supposed to equilibrate local oxygen concentrations at the membrane surface and measure the emf developed across the concentration cell. This paper explores physicochemical factors influencing the emf across concentration cell oxygen sensors in the presence of surface reactions that are not necessarily in chemical equilibrium. Specifically, we report an isothermal kinetic analysis linking emf to (*i*) mass transfer between the bulk gas and boundary layers; (*ii*) adsorption, desorption, and chemical reaction on the catalyst/electrode surface. With nonequilibrium bulk gas mixtures, our analysis indicates that cell emf corresponds to equilibrium oxygen partial pressures when two restrictions are met: (*i*) mass transfer between bulk gas and surface boundary layers is slow relative to the rate of surface reactions; (*ii*) the reactant gases have identical mass transfer coefficients. Experimental studies of ZrO_2 oxygen sensors with platinum catalyst/electrodes are also reported. Voltage/composition curves for O_2/alkane systems deviate substantially from those calculated for chemical equilibrium. This reflects a relatively poor platinum catalytic efficiency for alkane oxidation. Following recent work by Takeuchi *et al.*, a "mass transfer shift" of voltage/composition curves was observed at 600°C with the O_2/H_2 and the O_2/D_2 systems. This result, which follows from our kinetic analysis, reflects the substantially different mass transfer coefficients of the reactant gases. In a second set of experiments, gas mixtures were equilibrated chemically before reaching the sensor by passing them over a secondary platinum catalyst. Stoichiometric voltage/composition curves were obtained under these conditions.

Oxygen sensors are being developed for engine control systems on automobiles (1-3). The basic concept involves sensing oxygen partial pressures in engine exhaust, then using this information to control the air-to-fuel ratio entering the engine. In this way, engine efficiency is optimized while exhaust emissions are controlled.

Sensors based on oxygen concentration cells have been extensively investigated for this control operation.

Key words: solid electrolyte, gas electrode, control systems, kinetics.

These devices employ a solid-state oxygen-ion conducting electrolyte separating (*i*) an oxygen reference gas (air) from (*ii*) a gas of unknown oxygen concentration (engine exhaust). Sensor operation is based on the Nernst equation

$$\Delta V = -\left(\frac{RT}{4F}\right) \ln (P_{O_2}/P_{O_2}') \quad [1]$$

which relates the emf across the electrolyte, ΔV, to oxygen partial pressures in the two gases, P_{O_2} and P_{O_2}'. The most commonly used sensor consists of a Y_2O_3-doped ZrO_2 electrolyte with platinum electrodes on both surfaces.

Control system strategy is based on sensing an oxygen partial pressure corresponding to chemical equilibrium in the exhaust stream. Meaningful air-to-fuel adjustments can then be made. It is well known, however, that the oxygen partial pressure in engine exhaust does not correspond to chemical equilibrium. Oxygen is present as one component of a nonequilibrium gas mixture containing products of incomplete combustion. Other important components include CO, CO_2, H_2, H_2O, NO, NO_2, N_2, and a variety of hydrocarbons and hydrocarbon derivatives.

Sensor electrodes are made from catalytic metals in order to circumvent this difficulty. The electrodes serve two functions. First, they catalyze oxidation reactions and equilibrate local oxygen concentrations; second, they monitor the emf developed across the concentration cell.

The present research explores physicochemical factors influencing sensor emf in the presence of nonequilibrium gas mixtures. Specifically, we develop an isothermal kinetic analysis linking sensor emf to the processes of mass transport, adsorption, desorption, and chemical reaction. Experimental studies relating sensor voltage to catalytic efficiency are also reported.

There has been relatively little previous research directed at the emf across concentration cells in the presence of nonequilibrium gas mixtures. Fleming (4, 5) presented an analysis where oxygen and carbon monoxide are assumed to be in chemical equilibrium at a fictive temperature that characterizes surface catalytic efficiency. Fleming's work does not treat surface boundary layers. Later, Takeuchi *et al.* (6) showed experimentally that boundary phenomena are crucial in producing sensor voltages corresponding to oxygen equilibrium in the bulk gas. This important finding is amplified and extended in the present work through kinetic analysis and experimental results. Etsell and Flengas (7) published definitive studies of ZrO_2 sensors in the presence of equilibrium oxygen partial pressures. Questions of gas adsorption and surface reactions on ZrO_2 oxygen fuel cells have also been explored (8). Haaland (9) has recently reported studies of O_2 sensors with noncatalytic surface electrodes.

The oxygen-ion conducting electrolyte (*e.g.*, ZrO_2) plays a passive role in the present analysis: all internal electrochemical processes are idealized and cell emf becomes a convenient monitor of the surface processes that are the primary focus of the present work. This oversimplification both contrasts and complements simplifications made in previous studies of similar cells, where nonelectrochemical surface processes are idealized and internal electrochemistry is examined (8) Clearly, the experimental situation lies somewhere between these extreme views.

Kinetic Analysis

This analysis concerns the cell configuration shown in Fig. 1. We consider three regions on each side of an oxygen-ion conducting electrolyte: (*i*) a bulk gas region; (*ii*) a gaseous boundary layer; and (*iii*) the electrode/catalyst surface. Kinetic expressions, given below, describe both chemical reaction on the electrode/catalyst surface and mass transfer between adjacent regions.

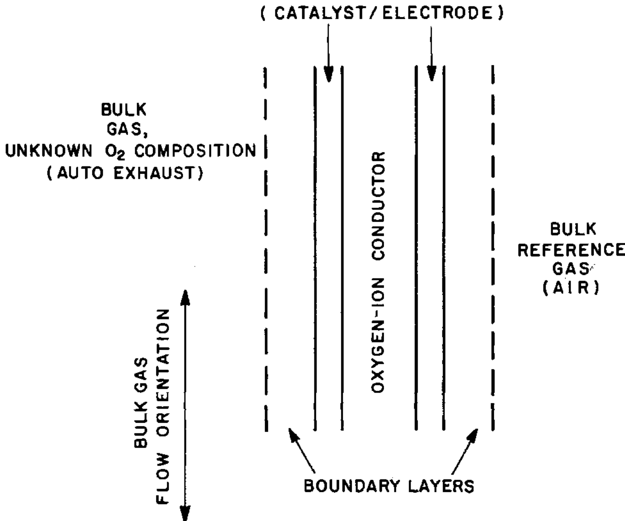

Fig. 1. Schematic drawing of oxygen concentration cell sensor showing the regions considered in the kinetic model: bulk gas region; gaseous boundary layer; electrode/catalyst surface.

The analysis is framed in terms of the reaction $O_2 + 2CO \rightleftarrows 2CO_2$, which is of primary importance in sensor/exhaust applications. The same physical principles are, *mutatis mutandis*, directly applicable to other surface reactions.

Six coupled, nonlinear differential equations are involved:

Surface reactions

$$d\theta_A/dt = -2k_2\theta_A^2 + 2k_A A_1 \theta_v^2 - k_R\theta_A\theta_B + k_D\theta_C\theta_v \quad [2]$$

$$d\theta_B/dt = -k_4\theta_B + k_B B_1\theta_v - k_R\theta_A\theta_B + k_D\theta_C\theta_v \quad [3]$$

$$d\theta_C/dt = -k_6\theta_C + k_C C_1\theta_v + k_R\theta_A\theta_B - k_D\theta_C\theta_v \quad [4]$$

Boundary layer reactions

$$dA_1/dt = -k_1(A_1 - A_g) - k_A A_1\theta_v^2 + k_2\theta_A^2 \quad [5]$$

$$dB_1/dt = -k_3(B_1 - B_g) - k_B B_1\theta_v + k_4\theta_B \quad [6]$$

$$dC_1/dt = -k_5(C_1 - C_g) - k_C C_1\theta_v + k_6\theta_C \quad [7]$$

The following variables appear in Eq. [2]-[7]: A_1, B_1, and C_1 are the partial pressures of O_2, CO, and CO_2 in the boundary layer; θ_A, θ_B, and θ_C are the fractional surface coverages of atomic oxygen, CO, and CO_2, respectively; θ_v, the fractional surface coverage of vacancies, is related to the others by $\theta_A + \theta_B + \theta_C + \theta_v = 1$. Rate constants k_1, k_3, and k_5 describe mass transfer of O_2, CO, and CO_2 between the bulk gas and the boundary layer. k_A, k_B, and k_C describe adsorption of these gases from the boundary layer onto the catalyst surface. k_2, k_4, and k_6 characterize the corresponding desorption processes. k_R is the rate constant for the surface reaction $\theta_A + \theta_B \rightarrow \theta_C + \theta_v$; k_D is the rate constant for the reverse of this surface reaction. Input parameters are the partial pressures of O_2, CO, and CO_2 in the bulk gas region; they are denoted A_g, B_g, and C_g.

The above expressions describe isothermal Langmuir-type adsorption/desorption kinetics (10). The oxygen-carbon monoxide reaction is assumed to occur exclusively on the catalyst/electrode surface via the Langmuir-Hinshelwood mechanism. This kinetic scheme is admittedly arbitrary. Simplifications have been introduced including an assumption of isothermal conditions. It should be noted that many particulars of carbon monoxide surface oxidation at atmospheric gas pressures remain unresolved despite extensive study (10-14). Although arbitrary and simplified for the present purpose, the kinetics described in Eq. [2]-[7] are in qualitative agreement with existing experimental observations.

The various rate constants are related to K_{eq}, the equilibrium constant for the O_2-CO-CO_2 system, by

$$K_{eq} = \frac{(O_2)^{1/2}(CO)}{(CO_2)} = \frac{k_4 k_C k_D}{k_6 k_B k_R}\sqrt{\frac{k_2}{k_A}} \quad [8]$$

Equation [8] is readily obtained by applying detailed balance constraints to all adsorption/desorption processes and to the surface reaction.

K_{eq} is of order 10^{-10} atm$^{1/2}$ or less for the O_2-CO-CO_2 system at temperatures below 1000 K (15). The back reaction, $2CO_2 \rightarrow 2CO + O_2$, is often neglected in catalytic studies for this reason. It must be included here if one is to compute proper limiting voltages when the bulk gas is rich in CO; *i.e.*, when the bulk gas contains less than a stochiometric amount of oxygen.

Cell EMF and Surface Concentrations

This section relates cell emf to surface concentrations on the catalyst/electrodes. It presumes that surface concentrations are determined by adsorption, desorption, and chemical reaction between un-ionized species; *i.e.*, that cell emf is a convenient measure of surface concentrations governed by nonelectrochemical processes. Following Etsell and Flengas (8), two potential-determining reactions are considered

$$\theta_A + h^{+2} + 2e \underset{k_8}{\overset{k_7}{\rightleftarrows}} A_s + \theta_v \quad [9a]$$

$$\theta_C + h^{+2} + 2e \underset{k_{10}}{\overset{k_9}{\rightleftarrows}} A_s + \theta_B \quad [9b]$$

In the above equations, h^{+2} and A_s are surface concentrations of doubly charged oxygen ion vacancies and of oxygen atoms in the electrolyte. Under steady-state conditions with no external current, reaction rate theory gives

$$(k_7\theta_A + k_9\theta_C)h^{+2}e^{-\mathbf{F}\phi/RT} = (k_8\theta_v + k_{10}\theta_B)A_s e^{\mathbf{F}\phi/RT} \quad [10a]$$

or

$$\frac{2\mathbf{F}\phi}{RT} = \ln\left\{\frac{k_7}{k_8}\left(\frac{(\theta_A/\theta_v) + (k_9/k_7)(\theta_C/\theta_v)}{1 + (k_{10}/k_8)(\theta_B/\theta_v)}\right)\frac{h^{+2}}{A_s}\right\} \quad [10b]$$

for the emf difference between electrolyte and an electrode exposed to O_2, CO, and CO_2. The reference electrode is exposed to air, and similar arguments lead to

$$\frac{2\mathbf{F}\phi'}{RT} = \ln\left\{\left(\frac{k_7}{k_8}\right)\left(\frac{\theta_A}{\theta_v}\right)'\left(\frac{h^{+2}}{A_s}\right)\right\} \quad [11]$$

since N_2 adsorption is vanishingly small. Making the usual assumption that (h^{+2}/A_s) is uniform across the electrolyte, the cell emf becomes

$$\Delta V = -\frac{RT}{2\mathbf{F}}\ln\left\{\left(\frac{(\theta_A/\theta_v) + (k_9/k_7)(\theta_c/\theta_v)}{1 + (k_{10}/k_8)(\theta_B/\theta_v)}\right)\left(\frac{\theta_v}{\theta_A}\right)'\right\} \quad [12a]$$

This reduces to

$$\Delta V = -\frac{RT}{2\mathbf{F}}\ln\{(\theta_A/\theta_v)(\theta_v/\theta_A)'\} \quad [12b]$$

for the case of an oxygen concentration cell with no external CO or CO_2. Equation [12b] is readily obtained from Eq. [1] for this case by application of Langmuir statistics. Note that strongly adsorbed nonreactive gases have no effect on ΔV. Such gases strongly reduce absolute values of θ_A and θ_v but not the (θ_A/θ_v) ratio under Langmuir adsorption/desorption statistics.

The mixed potential governed by Eq. [9a] and [9b] is reflected in the terms (k_9/k_7) (θ_c/θ_v) and (k_{10}/k_8) (θ_B/θ_v). Both terms are set equal to zero in the numerical results presented in the next section. This simplification does not change qualitative conclusions to be drawn from the analysis in any substantial way, and it would be easy to include these terms in the analysis if we knew what their relative magnitude was experimentally. Clearly neglecting these terms has largest quantitative effect when excess CO is present.

We now rewrite Eq. [2]-[4] for steady-state conditions in terms of three new variables $\gamma_A \equiv (\theta_A/\theta_v)$, $\gamma_B \equiv (\theta_B/\theta_v)$, and $\gamma_c \equiv (\theta_C/\theta_v)$

$$2(k_A A_1 - k_2\gamma_A^2) - k_R\gamma_A\gamma_B + k_D\gamma_C = 0 \quad [13]$$

$$S(k_B B_1 - k_4\gamma_B) - k_R\gamma_A\gamma_B + k_D\gamma_C = 0 \quad [14]$$

$$S(k_c C_1 - k_6\gamma_C) + k_R\gamma_A\gamma_B - k_D\gamma_C = 0 \quad [15]$$

where

$$S \equiv (1 + \gamma_A + \gamma_A + \gamma_c) \quad [16]$$

Addition of Eq. [12] and Eq. [15], etc. gives (in the same notation)

$$A_1 = A_g - (k_R\gamma_A\gamma_B - k_D\gamma_C)/(2k_1S^2) \quad [17]$$

$$B_1 = B_g - (k_R\gamma_A\gamma_B - k_D\gamma_c)/(k_3S^2) \quad [18]$$

$$C_1 = C_g + (k_R\gamma_A\gamma_B - k_D\gamma_c)/(k_5S^2) \quad [19]$$

The simultaneous Eq. [13]-[19] can be solved numerically with specified input partial pressures while varying rate constants for adsorption, desorption, mass transfer, and chemical reaction. We used a two-dimensional version of Newton's method with γ_A and $(\gamma_B + \gamma_C)$ as parameters. The six variables are then determined by combinations of Eq. [13]-[19]. Concentration cell voltages are obtained from Eq. [12] once γ_A is known. Assuming that no oxygen reactions occur on the reference side of the cell, $\gamma_A' = (A_g' k_A/k_2)^{1/2}$.

Numerical Results

Figures 2-5 show calculated cell voltage, ΔV, plotted as a function of $(O_2/CO) = A_g/B_g$, the ratio of partial pressures in the bulk gas region. In all cases, bulk gas compositions do not correspond to chemical equilibrium. The parameters $T = 600°C$, $A_g' = 2 \times 10^4$ Pa (0.2 atm), $K_{eq} = 5 \times 10^{-13}$ atm$^{1/2}$ were used in generating the numerical results (15).

The data presented in Fig. 2-3 presume rapid mass transfer between the bulk gas and boundary layer, such that $A_1 \simeq A_g$, $B_1 \simeq B_g$, $C_1 \simeq C_g$. The influence of bulk

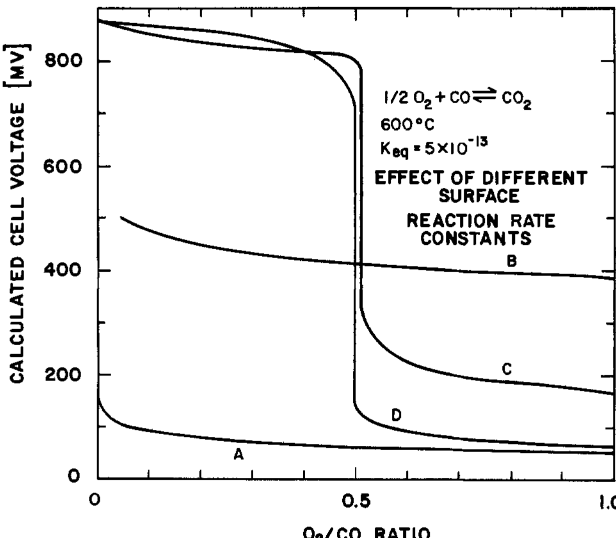

Fig. 2. Calculated cell voltage vs. bulk gas O_2/CO ratio with $B_g = 0.1$. Rapid mass transfer assumed, such that $A_1 \simeq A_g$, $B_1 \simeq B_g$, $C_1 \simeq C_g$. Rate constants are $k_a = k_B = 100$, $k_c = 0.1$, $k_2 = k_4 = 0.001$, $k_6 = 1000$. In curve A, $k_R = 0.00001 = 5k_D$. In curve B, $k_B = 1 = 5k_D$. In curve C, $k_R = 1000 = 5k_D$. Curve D corresponds to chemical equilibrium. Similar trends, from curve A toward curve D, are seen with other input parameters as the surface reaction rate is increased.

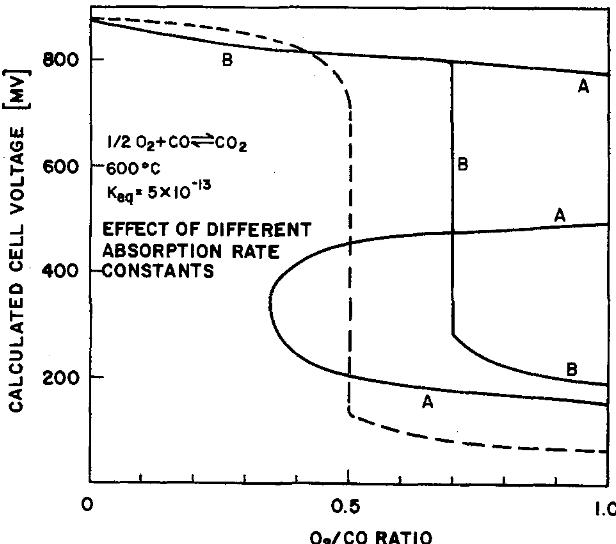

Fig. 3. Calculated cell voltage vs. bulk gas O_2/CO ratio with $B_g = 0.1$. Rapid mass transfer assumed. Rate constants are $k_R = 1000 = 5k_D$, $k_c = 0.1$, $k_6 = 1000$, $k_2 = k_4 = 0.001$. In curve A, $k_A = 1.5k_B = 150$. In curve B, $k_A = 0.75k_B = 75$. Dashed line shows equilibrium curve.

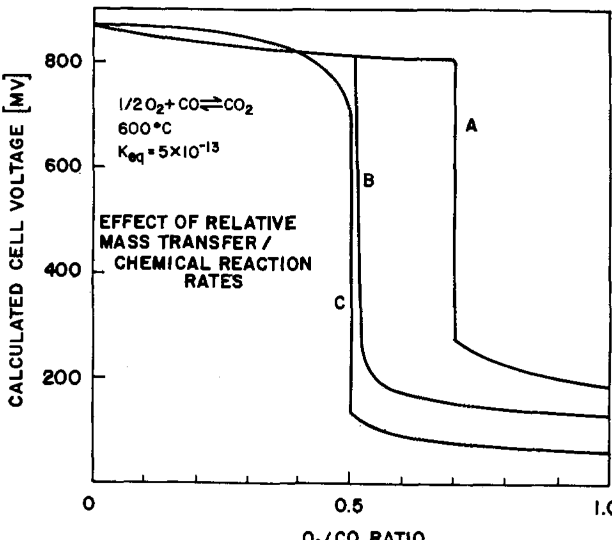

Fig. 4. Calculated cell voltage vs. bulk gas O_2/CO ratio with $B_g = 0.1$. Rate constants are $k_R = 5k_D = 1000$, $k_c = 0.1$, $k_6 = 1000$, $k_2 = k_4 = 0.001$, $k_A = 0.75k_B$. Curve A corresponds to fast mass transfer: $k_1 = k_3 = k_5 = 10^6$; curve B, to an intermediate mass transfer rate: $k_1 = k_3 = k_5 = 1$; curve C to slow mass transfer: $k_1 = k_3 = k_5 = 1 \times 10^{-4}$.

gas/boundary layer mass transfer rates is illustrated in Fig. 4-5.

Adsorption of oxygen and carbon monoxide, from the boundary layer onto the catalyst surface, is presumed to occur at identical rates in the data presented in Fig. 2; *e.g.*, $k_A = k_B$. Curves A-C, where the surface reaction is presumed to occur at progressively faster rates, are to be compared with curve D, which corresponds to each bulk gas composition at chemical equilibrium. Curve A assumes a surface where both gases are adsorbed but no reaction occurs ($k_R = k_D = 0$). An enormous change in equilibrium oxygen partial pressure, caused by the chemical reaction, produces the voltage step at stoichiometry in the equilibrium curve D. If no reaction occurs, as assumed here, the voltage-composition curve A corresponds to an oxygen concentration cell. Curve B assumes a reaction rate constant k_R comparable to adsorption/desorption rate constants. The limiting voltage at high A_g/B_g ratio corresponds to

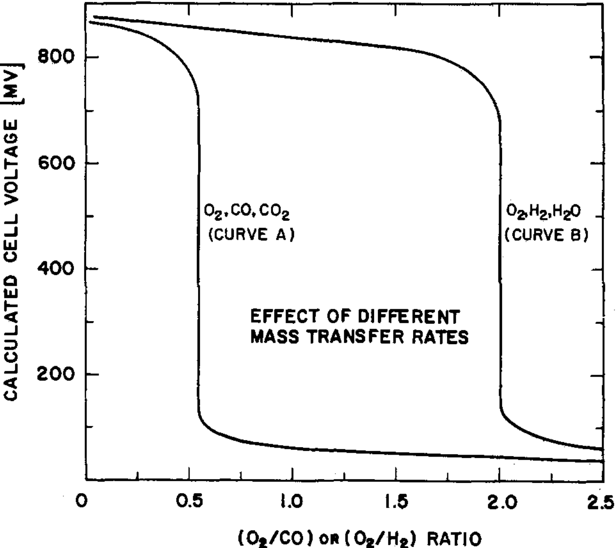

Fig. 5. Calculated cell voltage vs. bulk gas O_2/CO and O_2/H_2 ratios. Bulk CO and H_2 values of 0.1 atm assumed. Slow mass transfer in both curves. In curve A (for CO), $k_1 = 0.94k_3 = 1.17k_5$. In curve B (for H_2), $k_1 = 0.25k_3 = 0.75k_5$.

$$\gamma_A = \left(\frac{2k_Ak_4}{k_Bk_R}\right)\left(\frac{A_g}{B_g}\right) \quad [20]$$

which follows from $\gamma_B \simeq (k_BB_g/k_4)$, $2k_AA_g \simeq k_R\gamma_A\gamma_B$. Note that these voltages extend beyond the voltage limits calculated for (*i*) no chemical reaction and (*ii*) chemical equilibrium. This result cannot be interpreted by quasi-equilibrium concentration cell arguments, since these arguments require oxygen partial pressures between A_g (no reaction) and (A_g − 0.5 B_g) (complete irreversible reaction). This situation is caused by the rate of surface reaction being competitive with the rate of oxygen desorption: together these processes generate smaller (θ_A/θ_v) values than those resulting from adsorption/desorption alone.

Figure 2, curve C assumes a surface reaction rate faster than the rates of CO/O_2 adsorption/desorption. This situation best approximates equilibrium behavior, curve D. Deviations between Fig. 2, curve C and curve D persist both above and below stoichiometry.

Figure 3 illustrates the role of relative gas adsorption rates in a situation where the rate of surface reaction is faster than either adsorption process. Here voltage-composition curves shift along the (A_g/B_g) axis such that the voltage step occurs where $A_g = 0.5 (K_B/K_A)B_g$. This result was obtained previously by Fleming (5) from consideration of a different kinetic model.

Our numerical calculations frequently produced two steady-state solutions for one set of input parameters; *e.g.*, Fig. 3, curve A. One of these solutions corresponds to high fractional surface coverage by oxygen; the other, to high surface coverage by carbon monoxide. Multiple steady states are well known in both experimental and theoretical studies of surface CO oxidation. They result from autoinhibitory features of Langmuir-Hinshelwood kinetics. The reader is referred to a recent review by Sheintuch and Schmitz (16) for a discussion of this phenomenon.

The numerical data presented thus far assume rapid mass transfer between bulk gas and boundary layers. Even with this restriction, there are seven adjustable rate constants. With judicious selection of relative k values, it is possible to produce a variety of voltage-composition curves in addition to those illustrated in Fig. 2-3. This serves to illustrate an important result: When the bulk gases are not in chemical equilibrium, there is no reason to expect oxygen concentration cell emf to reflect equilibrium oxygen partial pressures.

It turns out, however, that isothermal concentration cell emf corresponds to equilibrium oxygen partial pressures in a nonequilibrium bulk gas mixture when two conditions are met: (*i*) bulk gas/boundary layer mass transfer is slow, and (*ii*) the reactant gases have identical mass transfer rates.

Figure 4 contains some of the most important results of this analysis. Curve A is identical to Fig. 3, curve B, corresponding to rapid mass transfer with dissimilar adsorption rates. Note that the voltage step is shifted from stoichiometry. Figure 4, curves B and C assume progressively slower mass transfer. With slow mass transfer, (*i*) voltage-composition curves approach those calculated for chemical equilibrium of the bulk gases, and (*ii*) calculated gas partial pressures in the boundary layer match chemical equilibrium values for each bulk gas composition. This is a general result, independent of relative rates of adsorption, desorption, and surface reaction.

Figure 5 illustrates another important point. It demonstrates that voltage-composition curves shift under slow mass transfer conditions when the reactant gases have different mass transfer coefficients. Under isothermal/isobaric conditions, kinetic theory (Graham's law) predicts that mass transfer coefficients vary as $M^{-1/2}$, where M is the gas molecular weight. Similar variations of mass transfer coefficients in gas mixtures have been derived (17). CO and O_2 have approximately equal molecular weights, and mass transfer differences are expected to be slight under slow mass transfer conditions. On the other hand. Graham's law argues for a large effect in the H_2-O_2-H_2O system. This is shown in Fig. 5, curve B.

Finally, it should be noted that boundary layer partial pressures can be approximated by chemical equilibrium under slow mass transfer conditions; *e.g.*

$$(A_1)^{1/2}(B_1) = K_{eq}(C_1) \qquad [21]$$

Mass balance constraints require $2k_1(A_g - A_1) = k_3(B_1 - B_g) = -k_5(C_1 - C_g)$. Together, these relations lead to a cubic equation for A_1. The corresponding γ_A and ΔV can be obtained from $\gamma_A = (A_1k_A/k_2)^{1/2}$, that is, by assuming the surface reactions are in dynamic equilibrium.

Experimental

Our experimental apparatus consisted of a gas flow system passing through a tube furnace. The homemade concentration cell sensor contained platinum electrodes on the inner and outer surfaces of an 8% Y_2O_3-doped ZrO_2 tube. The external electrode, in contact with nonequilibrium gas mixtures, was sputtered onto the closed tube tip and had a geometric surface area of approximately 0.25 cm². The inner electrode was in contact with air. Thin platinum wires connected the electrodes to a high-impedance voltmeter. Gas mixtures were prepared using Matheson Series 8240 Mass Flow Controllers. A thermocouple attached to the inner air/electrode surface measured cell temperature. Tests with a thermocouple mounted on the outer surface indicated a temperature difference less than 10°C.

Figure 6 compares experimental voltage/composition curves for gas mixtures in N_2. The λ scale is used as the abscissa, where λ is defined as the experimental O_2/reactant mole ratio divided by the corresponding mole ratio at stoichiometry. The experimental voltage step in the O_2/CO system occurs at $\lambda = 1$, as anticipated for two reactant gases with a mass ratio of 0.875 in contact with an efficient catalyst surface. These results are independent of flow rates past the sensor surface ranging between 130 and 520 cm/sec. The voltage steps in the O_2/H_2 and the O_2/D_2 systems are shifted from $\lambda = 1$ in the direction predicted by mass transport analysis when the reactant gases differ by 16 and 8 in mass, respectively. Since H_2 and D_2 have virtually identical reaction characteristics, the difference between the O_2/H_2 and the O_2/D_2 voltage/composition curves is unambiguous experimental evidence for a mass transfer shift. Similar shifts were reported previously by Takeuchi *et al.* (6), who found voltage steps at $\lambda = 4$ and $\lambda = 2$ for the $O_2/H_2/N_2$ and the $O_2/D_2/N_2$ systems at 400°C. The earlier data is in total agreement with mass transfer concepts. Our experiments indicate a less dramatic shift; *e.g.*, to $\lambda = 2.2$ for O_2/H_2. The magnitude of the shift is sensitive to the flow rate past the sensor. Consequently, we feel that variations in sensor design and fabrication, rather than temperature effects, are responsible for differences between the present results and those of Takeuchi.

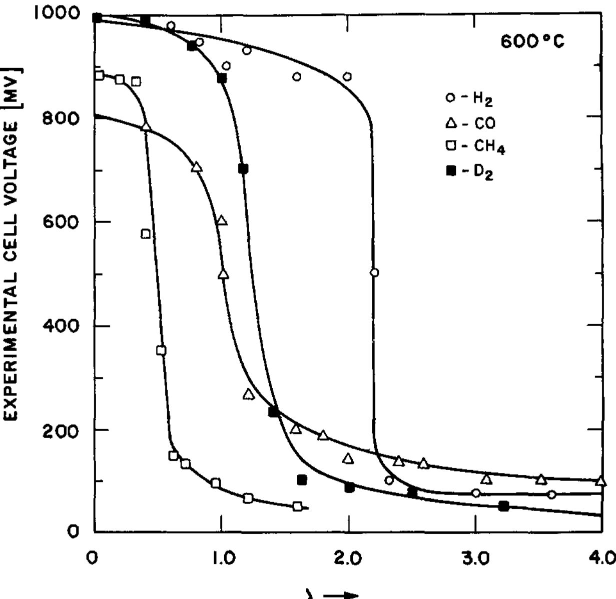

Fig. 6. Experimental cell voltage *vs.* λ, the ratio of reactant gas partial pressures. H_2, D_2, CO, and CH_4 partial pressures maintained at 0.02 atm and O_2 partial pressure varied.

The voltage step in the O_2/CH_4 system occurs near $\lambda = 0.5$. This is typical of experimental results (not shown) on other O_2/alkane systems (O_2/C_2H_6, O_2/C_3H_8, O_2/C_4H_{10}) and reflects the relative inefficiency of alkane oxidation over platinum catalysts (18). Some experiments with reactant gas mixtures containing both CO and CH_4 were performed. The voltage step moves systematically from that found in the O_2/CH_4 system to that found in the O_2/CO system as the CO/CH_4 ratio is increased.

In other experiments, a secondary catalyst was used to equilibrate gas mixtures before they reached the sensor. High surface area platinum supported on Al_2O_3 was used at an operating temperature of approximately 600°C. A three-way stopcock routed the gas flow to the sensor by either of two alternate paths: one path passed over the secondary catalyst; the other led directly to the sensor. Using this arrangement, we were able to explore the effects of gas pre-equilibration under highly controlled experimental conditions. Typical results are shown in Fig. 7. Voltage steps that occur either above or below stoichiometry with unequilibrated gas mixtures occur at $\lambda = 1$ after passing over the secondary catalyst. As expected, stoichiometric behavior can be modified if high flow rates are used and the catalyst no longer has sufficient time to equilibrate the gas mixtures.

Discussion

The main results of the present analysis include (*i*) relating concentration cell emf to catalyst/electrode surface concentrations under nonequilibrium conditions; (*ii*) expressing a catalytic analysis in terms of cell emf; and (*iii*) using the results of this analysis to assess the influence of mass transport, adsorption, desorption, and surface reaction upon sensor emf. Many conclusions drawn from this analysis appear in the

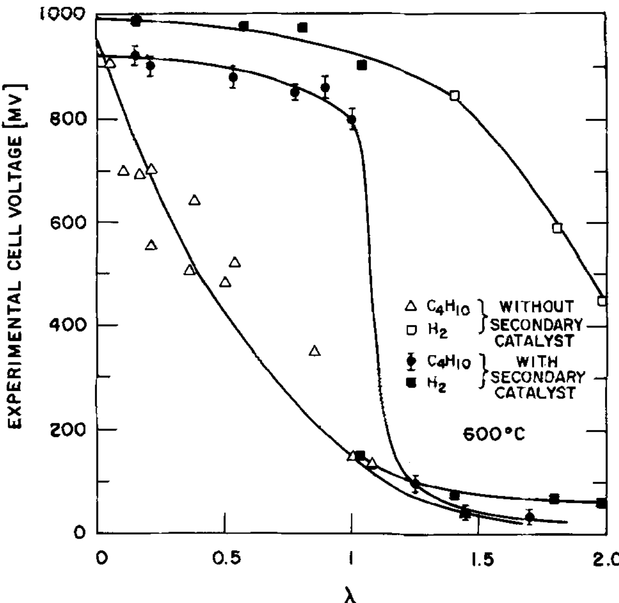

Fig. 7. Experimental cell voltage vs. λ, the ratio of reactant gas partial pressures. Deviations of the voltage step from stochiometry are observed without pre-equilibration over a secondary catalyst. Pre-equilibration produces a transition at stoichiometry.

catalyst literature; previously they have not been expressed in terms of emf across a concentration cell.

It would appear that an ideal steady-state oxygen concentration cell sensor has a mass transfer rate much smaller than the rate of surface reaction; *i.e.*, it has a small Thiele modulus (19). It is well known that heterogeneous catalysts typically exhibit small Thiele moduli at high temperatures; this follows directly from the higher activation energies for chemical reactions relative to the activation energy for mass transfer. The converse of this argument implies some lower temperature where mass transfer rates and surface reaction rates become comparable: this temperature varies with the catalyst, gas concentrations, and the reaction involved. This may explain experimental observations that concentration cell sensors operate best at high temperatures ($T > 500°C$) where mass transfer is expected to be rate limiting. Internal electrochemical factors, such as electrode polarization and high electrolyte impedance, also influence low temperature sensor behavior (20). These factors lie beyond the scope of the present research.

At constant temperature, it is possible to move from mass transport limited kinetics to reaction limited kinetics by decreasing the concentration of the reactants, since the effective Thiele modulus is concentration dependent. This conclusion, which follows directly from the concentration dependence of the chemical reaction rate, may produce nonideal sensor characteristics at low reactant gas concentrations.

Criteria for an ideal sensor are modified when dynamic response characteristics are considered. With a small Thiele modulus, the sensor response rate to a change in bulk gas composition is proportional to the mass transfer rate. Consequently, an ideal steady-state cell with a slow mass transfer rate may be impractical because of poor response characteristics.

Pre-equilibration of gas mixtures before they reach the sensor is a useful way to circumvent difficulties connected with relative kinetic/mass transfer rates. Indeed, secondary catalysts are commonly used for this purpose in commercial laboratory instruments. It is to to be noted, however, that pre-equilibration is not always feasible when large gas volumes and high flow rates are involved.

It is reasonable to inquire how strongly the conclusions of the present analysis depend on specifics in the assumed kinetic scheme. The most important model-dependent element involves use of Langmuir-Hinshelwood kinetics. This mechanism is known to produce multiple steady-state solutions for surface concentrations with certain choices of input parameters. There is some experimental evidence that multiple steady states occur on the surface of oxygen sensors; notably the experiments of Hetrick and Logothetis (21) on ZrO_2 and TiO_2, and the studies of Dauchot and Van Cakenberghe (22) on Schottky diodes. Multiple steady states provide a convenient explanation of experimental observations of voltage hysteresis in response to bulk gas composition changes, but this remains a subject for further study. Alternate reaction mechanisms (*e.g.*, Eley-Rideal kinetics) also predict that slow mass transfer is necessary to produce quasi-equilibrium oxygen partial pressures in the boundary layer.

Ideal concentration cell sensors produce a sharp voltage step at stoichiometry in O_2/reactant gas mixtures. Frequently, experimental (nonideal) sensors exhibit a broadened voltage transition that occurs over a range of compositions near stoichiometry (c.f. the data for the O_2/C_4H_{10} system in Fig. 7). As noted by Fleming (5), there is strong experimental evidence that the broadened transition is related to loss of catalytic activity by the sensor. Our analysis predicts some broadening of the voltage step at stoichiometry when (*i*) surface adsorption/desorption rates are much faster than mass transport rates, and (*ii*) mass transport rates are faster than surface reaction rates. However, calculated voltage transitions are sharper than those seen experimentally.

Turning to the experimental results, observation of a "mass transfer shift" in the O_2/H_2 and O_2/D_2 systems is of considerable interest. Under isothermal/isobaric conditions, it should occur even with extremely high activity catalytic surfaces and displace cell voltage from chemical equilibrium values. Explanation of this finding by the kinetic theory of gases involves independent diffusive transport of components in a gas mixture. As Jackson (23) points out, independent transport arguments cannot be extended indefinitely since they lead to pressure differences in the system that are relieved by convective processes that couple the transport of all component gases. Convective transport is augmented in the present case by thermal gradients between the bulk gas and boundary layer that are produced by exothermal chemical reactions. Our experiments confirm earlier results of Takeuchi *et al.* (6) that "mass transfer shifts" exist. However, our data suggest that the magnitude of the shifts is less extensive than those indicated by Takeuchi's experiments and by simple theory.

Finally, it should be noted that one must use caution in drawing parallels between (*i*) sensor characteristics with respect to pairs of reactants in a flow system (*e.g.*, O_2/CO or O_2/H_2), and (*ii*) sensor behavior relative to the plethora of chemical species present in engine exhaust. While identical physicochemical principles hold in both cases, the varied interactions present in multicomponent systems can severely modify experimental results.

Acknowledgments

We are grateful to M. Bettman, R. H. Hammerle, R. E. Hetrick, J. W. Kress, J. T. Kummer, E. M. Logothetis, N. Otto, and H. Wroblowa for fruitful discussions of both the experimental and analytical results reported in this paper.

Manuscript submitted July 1, 1980; revised manuscript received Aug. 22, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by the Ford Motor Company.

Surface Changes during A.C. Etching of Aluminum

Christopher K. Dyer[1] **and Robert S. Alwitt**

United Chemi-Con, Incorporated, 3000 Dundee Road, Northbrook, Illinois 60062

ABSTRACT

Electrochemical etching of Al with alternating current produces a high density of cubic etch pits covered with a film of oxide or hydroxide. Micrographs of the metal and film structures are presented and a model is proposed to explain the observations. Calculations demonstrate the feasibility of film deposition from acid solution when a high cathodic current density is applied. A critical feature is that the high aluminum salt concentration near the metal surface hinders proton mobility.

Electrochemical etching with alternating current is used to obtain a high surface area on Al foil for electrolytic capacitor electrodes and also to obtain a roughened surface suitable for aluminum lithographic plates. A-c etching is characterized by a uniform depth of roughened metal and by the presence of a film of oxide or hydroxide within this etched layer. This film is presumed to deposit because of the increase in local pH caused by the cathodic half-cycle (1). The tunnel structures that dominate the appearance of Al etched with direct current in chloride solutions at high temperature (2, 3) are not seen with a-c etching.

Although a-c etching has been used commercially for over 25 years it has not been discussed in the scientific literature except for a recent paper which presented evidence for the deposited film (1). The present work shows the appearance and development of the etch structure and accompanying film under a limited set of experimental conditions. Calculations demonstrate the feasibility of film deposition from acid solution when a high cathodic current density (C.D.) is applied.

Experimental

99.99% Al foil was mounted and masked on a glass slide with epoxy resin (Shell 828 plus TETA). After the resin on the specimen had been cured at 65°C, the specimen was immersed in 1*N* NaOH at room temperature for 10 min and then thoroughly washed with distilled water. Etching was done with 5 Hz sinusoidal current supplied from a potentiostat operating in the galvanostatic mode and coupled to a signal generator. The specimen was immersed in 1M HCl at 60°C and an rms current of 700 mA/cm^2 was applied, using graphite counterelectrodes, for a time calculated to give an anodic charge up to 25 C/cm^2.

After a-c etching, the specimen was immediately removed from the cell, washed in distilled water, and dried with methanol. Some specimens had no further treatment so only the film deposited during etching was on the surface. With other specimens, an anodic oxide film was grown in 40% ammonium pentaborate in ethylene glycol at room temperature. Then the etched area was cut from the specimen, peeled from the epoxy resin backing, and the Al metal was dissolved in warm 10% Br_2/methanol. The remaining oxide flakes, after sputter-coating with gold, were examined in a scanning electron microscope.

Results and Interpretation

The "Etch film."—When an a-c etched foil is immersed in Br_2/MeOH a fragile film remains after all the metal has been dissolved. This shall be called the "etch film." The film is probably a hydroxide, possibly in combination with amorphous oxide, since the film loses weight upon heating but shows no crystalline structure by electron diffraction. The etch film is obviously insoluble in 1M HCl at 60°C during the time of an experiment (15 sec) and was still present after much longer etches (10 min). An orthoganol view of

[1] Present address: Bell Laboratories, Murray Hill, New Jersey 07974.

Key words: films, capacitor, diffusion, dissolution.

this film from the etchant side (Fig. 1) shows many interconnected cubic pits. Figures 1 and 2 show cubic "shadows" under the outer film surface, some of which are aligned with uncovered pits. This suggests that the outer film was undercut, presumably by dissolution of metal, and in some places the outer film separated from the surface while in other places it remained as a "cap." A view from the side of the flake in Fig. 3 shows the structure of the film from the metal side (in the lower two-thirds of the field of view) as well as the etchant side (top one-third of the field). It is seen that the etch film replicates the interior of the cubic pits on the metal surface. The thickness of the etch film seems to vary from place to place; in Fig. 2 where the film has broken and peeled back it is less than 50 nm.

Etch film + anodic oxide.—Figures 4 and 5 show the oxide after a 5 C/cm^2 etch charge followed by anodization to 100V. From Fig. 5 it is possible to deduce the method by which an additional pit grows onto an existing cubic pit. In the lower half of Fig. 5 are two views of a double cube structure, one above the other, with walls approximately 150 nm thick (the anodic film) and an internal ledge which is much thinner. This ledge was presumably not in contact with metal during anodization since it is much less than 150 nm thick. It is probably the remains of an etch film that covered the base of the upper cube before the start of dissolution that formed the lower pit.

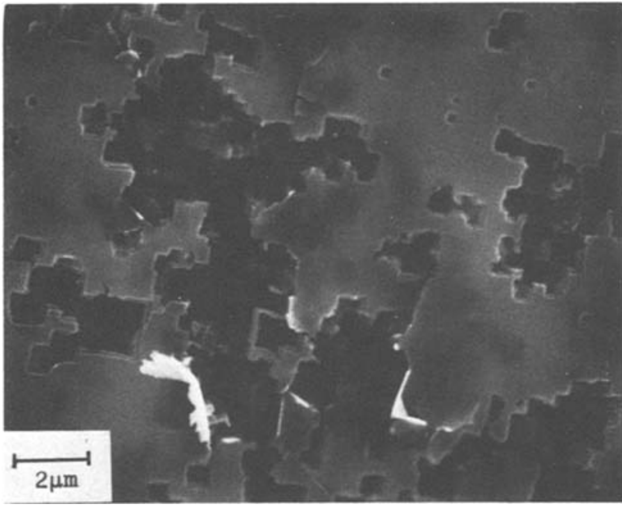

Fig. 1. Etch film from etchant side (not anodized). Conditions: 5 C/cm^2, 5 Hz (0° tilt).

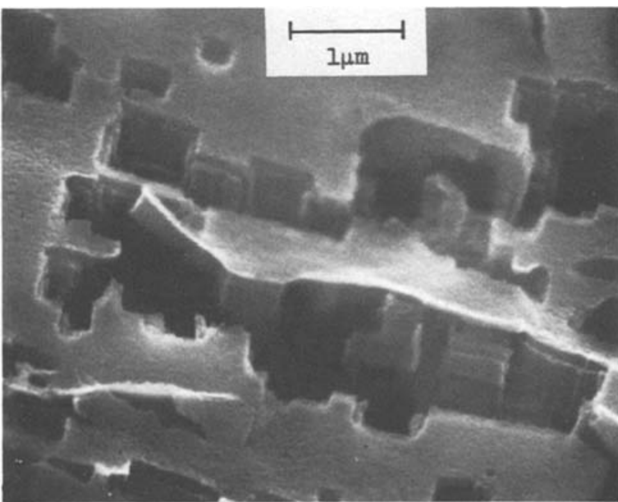

Fig. 2. As Fig. 1 but 60° tilt

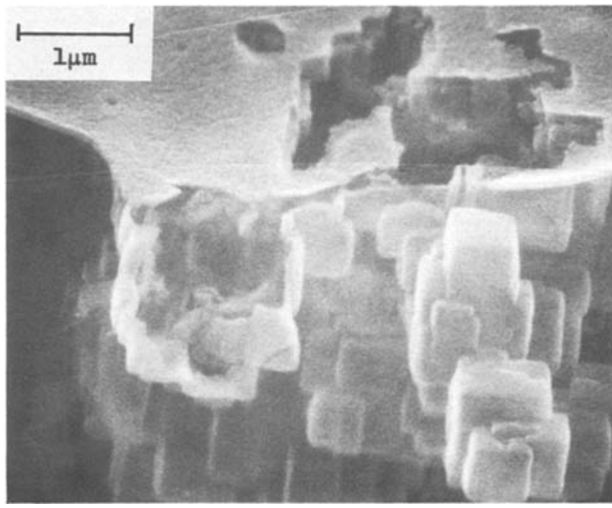

Fig. 3. Etch film showing pit shape from metal side and original surface (not anodized). Same conditions as Fig. 1 (60° tilt).

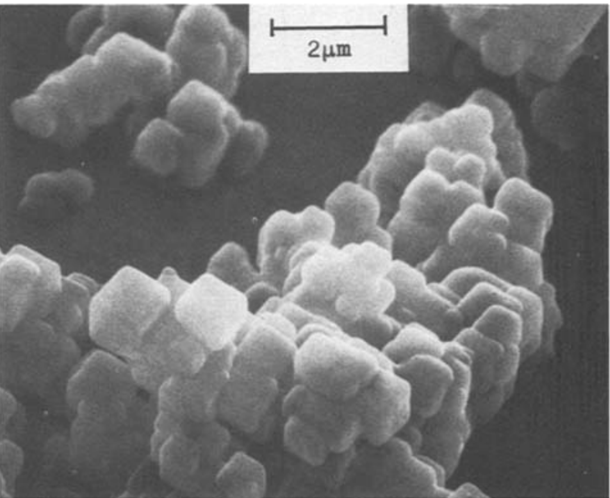

Fig. 4. View from metal side after anodization to 100V. Same conditions as Fig. 1 (45° tilt).

A sequence that could give rise to the observed double cube morphology is shown schematically in Fig. 6. A single cubic etch pit is shown with walls covered by an etch film that deposited during the cathodic half-cycle immediately following pit formation. At the pit base, a second pit initiates at a weak point in the etch film followed by orthogonal expansion underneath the film. The new pit undercuts the preexisting etch film and grows until the end of the anodic half-cycle. During the next cathodic half-cycle this metal

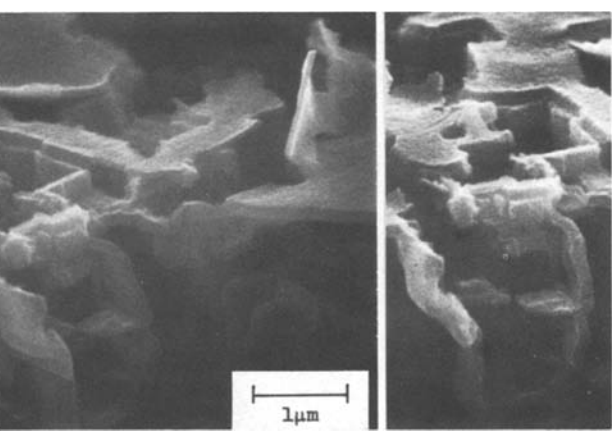

Fig. 5. As Fig. 4 but 60° tilt, different views

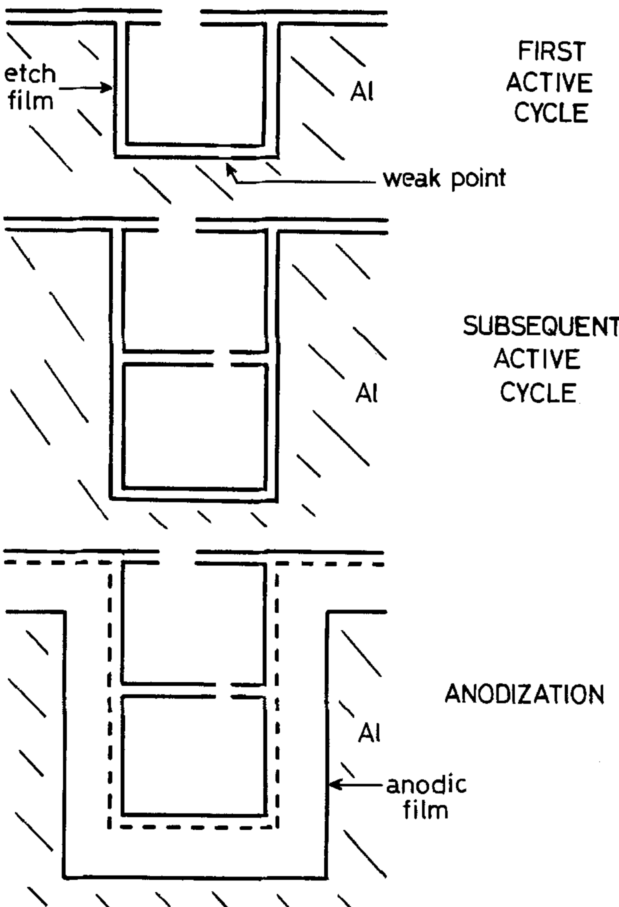

Fig. 6. Schematic diagram of cube-by-cube pit propagation

surface becomes covered with etch film, thus completing the sequence. Repeated sequences of this kind involving weak points in the etch film on different pit faces would give rise to multidirectional cube-by-cube pit propagation (Fig. 4).

The effect of frequency supports the idea that each cubic etch pit is formed during only one anodic half-cycle. Figure 7 shows smaller etch cubes formed at 10 Hz than at 5 Hz. The rms C.D. was the same in both cases but the charge per cycle at 5 Hz was twice that at 10 Hz.

The above model of pit propagation seems to apply also to the larger merged cube structures seen in Fig. 4 since random sections through these structures show an internal network of walls and ledges. Figures 8 and 9 are sections through an etch film + 150V anodic film after a 10 C/cm^2 etch. At the lower right of these micrographs (particularly Fig. 9) is the anodically formed portion of the film which must have been in contact with metal since it is now ~200 nm thick. Elsewhere are seen much thinner films in cubic relationships to each other which are most probably undercut etch film.

Further evidence in support of the model of cube by cube pit propagation in each anodic half-cycle comes from an etch done at two frequencies. A foil was etched for 5 C/cm^2 at 5 Hz and then for 1 C/cm^2 at 20 or 100 Hz. The replicas, from the metal side, are shown in Fig. 10. Application of a small charge at the higher frequency produced small additional cubes characteristic of the higher frequency and therefore independent of the previous etch morphology. The results were not affected by the time on open circuit between the low and higher frequency etches which was varied between 10^{-3} and 200 sec. A second etch at higher frequency is therefore a useful tool in identifying places where further pits can propagate, presumably at weak points in the etch film of the "mother cube." From the patterns of small cubes observed, weak points did not seem to be concentrated at edges or between "mother cubes" (Fig. 10b) and often there were clusters of small cubes (Fig. 10c) which indicated that nucleation and propagation continued preferentially on the freshly activated surfaces.

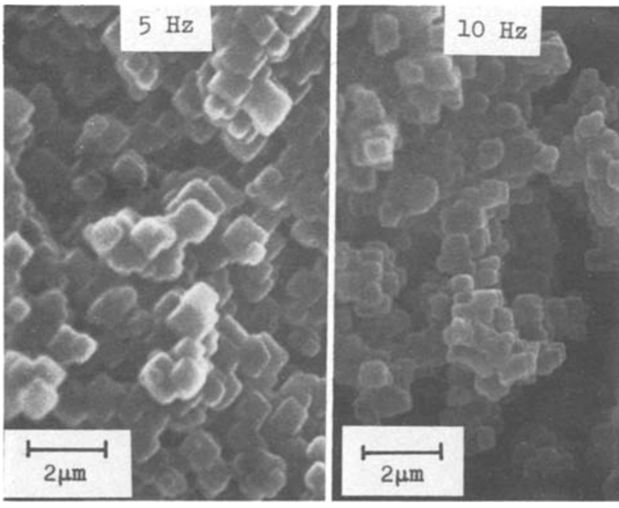

Fig. 7. Structure after 5 Hz (left) and 10 Hz (right) etch; both at 400 mA/cm^2, 25 C/cm^2. Anodization to 100V, metal side (0° tilt).

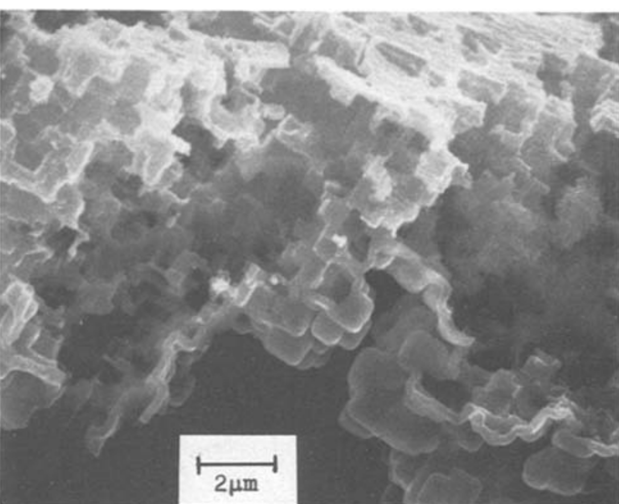

Fig. 8. Film section after 10 C/cm^2, 5 Hz etch then 150V anodization.

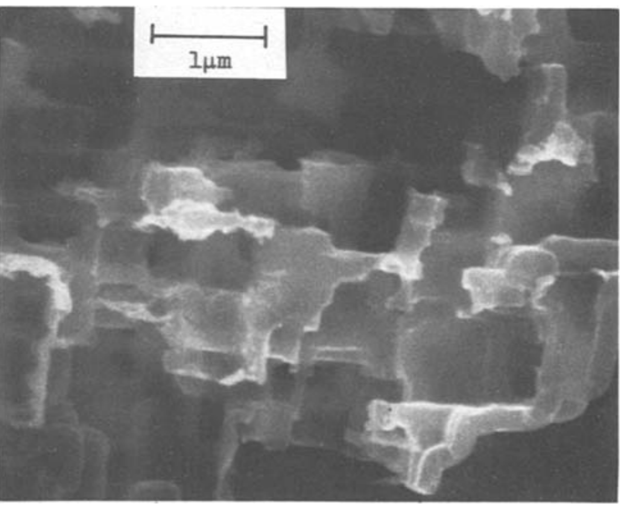

Fig. 9. As Fig. 8, higher magnification

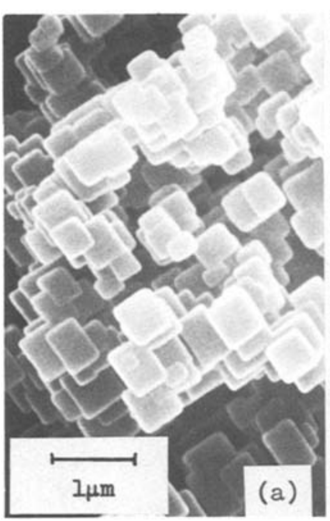

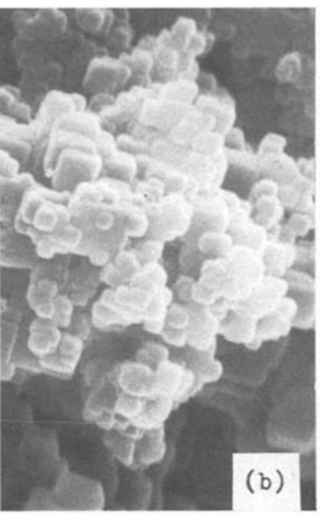

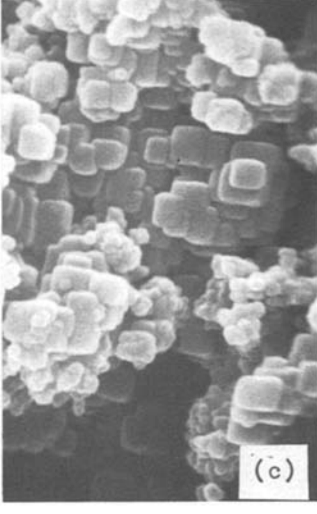

Fig. 10. Appearance of 2-frequency etch. (a) 5 Hz, 5 C/cm², (b) 5 Hz, 5 C/cm² + 20 Hz, 1 C/cm², (c) 5 Hz, 5 C/cm² + 100 Hz, 1 C/cm². Anodized to 60V, metal side. All at same magnification.

Typical values from the micrographs of cube side length (s) are plotted as a function of frequency in Fig. 11. For the conditions used in these experiments, it is found that $s \propto f^{-1/2}$.

Discussion

The formation of aluminum oxide in 1M HCl solution is unexpected, but the hydrogen evolution reaction during the cathodic half-cycle will certainly raise the pH close to the metal surface and, if the local Al^{3+} concentration is high enough, a precipitate might form. For example, at room temperature the pH of a saturated $AlCl_3$ solution is about 0.15 and increasing the pH to above 3 causes some $Al(OH)_3$ to precipitate. It must be determined if it is reasonable that such a pH increase could occur at the conditions used in these experiments, and if there is sufficient time during the cathodic half-cycle for film deposition.

Although a steady-state alternating current is applied to the electrode, the anodic and cathodic processes occur only on fresh surfaces at new positions for each cycle. To obtain an estimate of the time dependence of the pH increase we must consider only the time interval for a single cathodic half-cycle. The situation during the cathodic half-cycle can be approximated by a planar electrode to which is diffusing a species (H^+) which reacts and disappears at the electrode surface at some time t. This problem has been considered at length by Bockris and Reddy (4) for a variety of conditions. The diffusion is described by Fick's second law

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} \quad [1]$$

where C is the hydrogen ion concentration. If C_o is the bulk concentration, suitable initial and boundary conditions are $C(t = 0) = C_o$, $C(x \rightarrow \infty) = C_o$ at $t > 0$ where x is the distance from the surface. The rate of disappearance of H^+ is given by the periodic flux, $J = J_{max} \sin \omega t$, for the time interval $0 < t < \pi/\omega$. From the solution for a similar problem [p. 327 in (4)] we can directly give the solution for C_s, the time dependent surface concentration of H^+

$$\frac{C_s}{C_o} = 1 - \frac{J_{max}}{C_o(D\omega)^{1/2}} \sin\left(\omega t - \frac{\pi}{4}\right) \quad [2]$$

This shows that the surface concentration also varies sinusoidally, but lags the flux by a $\pi/4$ phase difference. This lag increases the response time for the change in surface pH.

The pH at which aluminum hydroxide deposition can occur depends on the local Al^{3+} concentration, but it must rise to at least pH 3. For the limiting case of deposition occurring when $C_s/C_o \rightarrow 0$, a sufficient condition for deposition is

$$J_{max}/C_o(D\omega)^{1/2} \geq 1 \quad [3]$$

since the value of the sine term in Eq. [2] is no greater than unity.

To obtain a value for J_{max} requires an estimate of the specific C.D. during the cathodic half-cycle, which can be obtained from an estimate of the cathodic area. According to our model, the cathodic area is simply the surfaces of the freshly generated etch cubes from the previous anodic half-cycle. It is assumed that all etch cubes grow at the same rate and without impingement over the full anodic half-cycle, thus producing equal size cubes with side s. There will be created n cubes/cm²-cycle, each with a surface area of $5s^2$. We make use of the following relations

$$\text{charge/cm}^2\text{-half-cycle} = q = 2\sqrt{2}I/\omega \quad [4]$$

$$n = q/\text{charge-cube} = \frac{2\sqrt{2}M}{\mathbf{F}\rho} - \frac{I}{s^3\omega} \quad [5]$$

$$i = I/5s^2n = \frac{\mathbf{F}\rho}{10\sqrt{2}M} \cdot s\omega \quad [6]$$

$$J_{max} = \sqrt{2}i/\mathbf{F} = \frac{\rho}{10M} \cdot s\omega \quad [7]$$

In these equations I = nominal rms C.D., i = specific rms C.D., M = eq. wt., ρ = density of Al, $\mathbf{F}$ = Faraday.

Taking the results of 5 Hz, 0.7 A/cm² as an example, from the micrographs we estimate $s = 0.5$ μm. Using Eq. [5]-[7], $n = 2 \times 10^7$ cubes/cm², $i = 3$ A/cm², and $J_{max} = 5 \times 10^{-5}$ eq./cm²-sec.

With this value of J_{max} and $C_o = 10^{-3}$ eq./cm³, Eq. [3] sets an upper limit for D at 8×10^{-5} cm²/sec. If H^+ diffuses more rapidly than this, C_s will remain high enough so that precipitation cannot occur during the cathodic half-cycle. This value of D, at 60°C, is lower than reported values for protons in dilute solution, where transport occurs by a hopping mechanism. In these experiments the solutions are not dilute and the same mechanism for proton diffusion may not prevail. This must be examined in order to arrive at an estimate of D_{H^+} in the etch pit.

The apparent diffusion coefficient of H^+ ions has been measured by polarography in supporting electrolytes of chloride salts at salt concentrations up to 3M (5). The value of D decreases with increasing [salt]/[acid] ratio and depends on the cation of the supporting electrolyte. In LiCl solutions the dependence on salt concentration is much stronger than in KCl or RbCl solutions. This difference is due to Li^+ ions being more strongly solvated than K^+ or Rb^+ ions, so that at high salt concentration more water molecules are immobilized by the Li^+ ions and not suitably oriented

Table I.

C_{salt} (M)	$D_{H^+} \times 10^5$ cm²/sec (25°C) K+	Rb+	Li+	Al3+

2.0	7.5	—	5.3	—
Hydration number	1.1	1.1	3.2	16

to contribute to proton conduction by the Grotthus hopping mechanism.

The "hydration number" is the effective number of water molecules attached to the ion as it moves through the solution. Hydration numbers calculated from the effect of solute on dielectric constant provide a measure of "irrotational binding" of water molecules to the ion (6). The ion hydration numbers calculated from the static dielectric constant (6) are listed in Table I, along with values of D_{H^+} determined polarographically for 10^{-2}M HCl at several chloride salt concentrations (5). Stastny and Strafelda (5) extrapolated to a D_{H^+} value of 3×10^{-5} cm²/sec in 2M LiCl at very low HCl concentration, only one-third the value found in the absence of the salt.

A comparison of hydration numbers indicates that in $AlCl_3$ solutions five times as many water molecules would be immobilized as in LiCl solutions of the same molarity. The $AlCl_3$ content in the etch pits at the end of the anodic half-cycle is probably at least 1-2M. In 1M $AlCl_3$ 30% of the water molecules would be immobilized. Under these conditions proton hopping could only occur to a very limited extent and H^+ diffusion would be mostly by conventional transport processes in the same manner as other ionic species. Thus, at 25°C the value of D_{H^+} would be expected to be close to 2×10^{-5} cm²/sec. The diffusion coefficient would be about 3×10^{-5} cm²/sec at 60°C and using this value in Eq. [2], with the previously determined values for the other parameters, gives $t_o = 5 \times 10^{-2}$ sec, where $t = t_o$ when $C_s/C_o = 0$. Thus, t_o is about 50% of the cathodic half-cycle time (t_c).

Since we observe $s \propto \omega^{-1/2}$ (see Fig. 11), it follows from Eq. [7] that $J_{max} \propto \omega^{1/2}$ and inspection of Eq. [2] shows that the pH increase occurs over a time interval such that ωt_o = constant. Because of this relationship, over the range 5-100 Hz the calculated t_o remains at a constant fraction of the cathodic half-cycle time, $0.5t_c$. Because of the observed dependence of s on ω the calculated number of cubes per cycle increases with frequency. Since n depends on weak points in the etch film, this suggests that frequency influences the nature of the deposited etch film, making it more defective when the time for precipitation is shortened. Figure 10c indicates preferential pitting of 100 Hz cube walls.

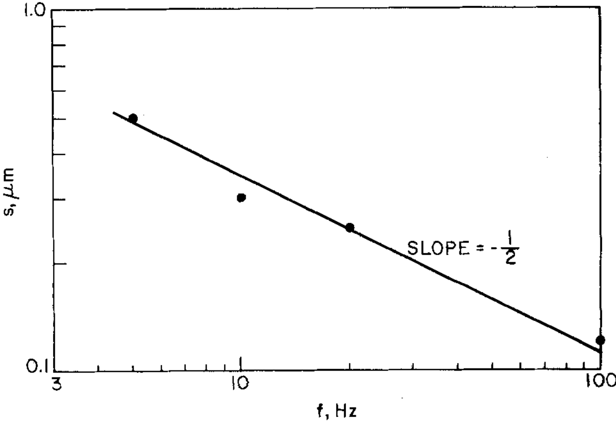

Fig. 11. Frequency dependence of cube side length

The total time for film deposition is the sum of the times for pH increase and for $Al(OH)_3$ precipitation. This latter time interval can be estimated by solving Eq. [1] for Al ion diffusion to the hydroxide surface. C is now the aluminum ion concentration which we assume is uniform within the etch pit at the end of the pH increase. The initial condition and first boundary condition are then the same as used before: C ($t = 0$) $= C_o$ and C ($x \rightarrow \infty$) $= C_o$, $t > 0$. When precipitation starts, the Al ion concentration at the surface drops to its saturation concentration at the surface pH. This will be more than an order of magnitude smaller than the bulk concentration so the second boundary condition is chosen as C ($x = 0$) $= 0$, $t > 0$. This is a problem in unsteady diffusion analogous to the unsteady heat conduction problem of finding the temperature profile or total heat flux in a body initially at uniform temperature when one surface has an abrupt temperature change [*e.g.*, see Ref. (7)]. The flux at the surface is

$$N \Big|_{x=0} = -D_{Al} \frac{\partial C}{\partial x} \Big|_{x=0} = \left(\frac{D_{Al}}{\pi t} \right)^{1/2} C_o \quad [8]$$

Integrating the flux from $t = 0$ to $t = t$ gives the total amount of Al deposited as $Al(OH)_3$

$$M_{Al} = \int_0^t C_o \left(\frac{D_{Al}}{\pi t} \right)^{1/2} dt = 2C_o \left(\frac{D_{Al} t}{\pi} \right)^{1/2} \quad [9]$$

Hence

$$t = \frac{\pi}{D_{Al}} \left(\frac{M_{Al}}{2C_o} \right)^2 \quad [10]$$

The thickest films were ~ 50 nm thick so assuming a composition of $Al(OH)_3$ with a density of 2.5 g/cm³ gives $M_{Al} \sim 2 \times 10^{-7}$ moles/cm². With $C_o = 2 \times 10^{-3}$ moles/cm³ and $D_{Al} = 3 \times 10^{-5}$ cm²/sec, Eq. [10] gives the time for precipitation as $t = 3 \times 10^{-4}$ sec. At the highest frequency examined, 100 Hz, this is only 6% of the half-cycle time, much less than the time required for pH adjustment.

Thus, pH adjustment is the critical step in the deposition process. Although at 60°C the diffusion of H^+ is slow enough to permit film deposition, at some higher temperature D_{H^+} could become large enough to preclude deposition. No SEM observations were made of surfaces etched at elevated temperatures, but some data on the weight of etch film supports the importance of temperature. Specimens were etched in 1*N* HCl at 50 Hz, 400 mA/cm², 30 C/cm², and the weight of etch film was determined by difference after stripping the oxide in 5% H_3PO_4-2% CrO_3 at 85°C. These average weights are given in Table II. The last column is an estimate of the specific area per square centimeter of projected area based on capacitance values of 20V anodic oxide films. The sharp decrease in surface area that accompanies the absence of etch film is further evidence of the key role of that film.

The inner surface (metal side) of the etch film is quite smooth compared with the outer surface (Fig. 2 and 3). It seems remarkable that a precipitated film could pack densely enough to replicate the surface, but another example of this is the deposition of pseudoboehmite (8, 9) during the reaction of Al with hot water. The replicating etch film is precipitated, and not anodically grown, as evidenced by a cell voltage in the anodic half-cycle of only 6V, most of which is due to polarization at the two electrodes and the electrolyte resistance.

Another interesting feature of the etch film is that it formed over the whole of the original unpitted sur-

Table II.

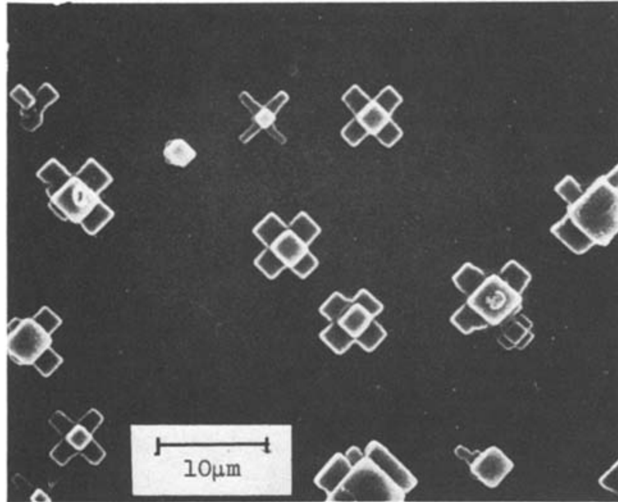

Fig. 12. 1 sec d-c etch at 1 A/cm^2 in 1M NaCl at 65°C

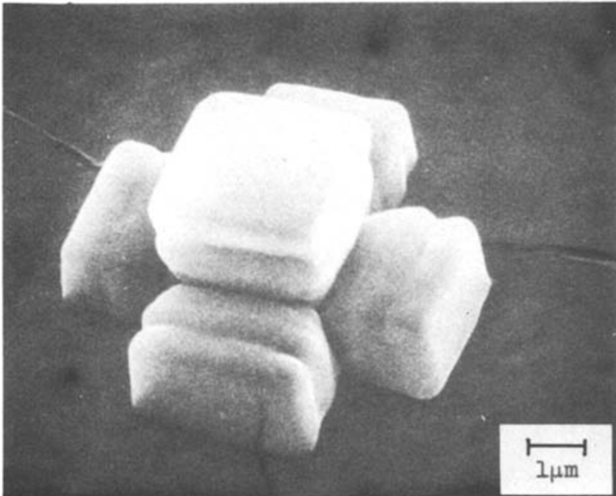

Fig. 13. 1 sec d-c etch at 1 A/cm^2 in 3M NaCl at 65°C

face (Fig. 1 and 2), so it appears that in the very earliest stages of the a-c etch uniform anodic dissolution and precipitation occurred before there was local attack with pit formation. This "pre-pitting" stage was not studied but initial uniform precipitation may not be a general feature of a-c etching. The specific C.D. would be close to the nominal value so Eq. [3] would predict film formation only at low frequencies or low acid concentrations.

Although d-c etching of Al in acid or neutral chloride solutions produces a tunnel structure and no etch film, in the earliest stages of d-c etching, like a-c etching, a cube etch structure is formed (Fig. 12 and 13). The d-c etch in Fig. 12 and 13 corresponds to a single square-wave anodic half-cycle at 0.5 Hz, with no cathodic half-cycle. Although, like the a-c etch, a single cubic pit is formed first (Fig. 12) subsequent cubes seem to form only by propagation outward of the whole of each face of the first cube (Fig. 13) and not in the random way observed for a-c etching, where new cubes propagate from different points on the cube faces. This difference is consistent with the presence during a-c etching of a protective etch film containing weak points.

Experimental Verification of a Simplified Model for Porous Electrode Electrochemical Reactors

Gilbert M. Brown and Franz A. Posey*

Oak Ridge National Laboratory, Chemistry Division, Oak Ridge, Tennessee 37830

ABSTRACT

A simplified, one-dimensional, macroscopic model for porous electrode reactors with forced convection was experimentally verified. The mass-transfer-limited reduction of ferricyanide ions was studied using porous graphite electrodes in a cell configuration having an upstream counterelectrode. Impedance characteristics of the electrode-electrolyte system were measured by the transient potentiostatic step method. An expression for the potential difference between upstream and downstream ends of an operating reactor was obtained based on the simplified macroscopic model. An experimental method was also developed for determining the efficiency of porous electrode systems from the variation of this potential difference with solution flow rate. In further work, new equations were derived that allow optimum linear flow rate and electrode length to be predicted for a porous electrode reactor operating at any desired efficiency. Predictions of a straight-pore model of porous electrodes are compared with those of the macroscopic model.

There has been a great deal of interest in recent years in the use of flow-through porous electrodes for the removal of metal ions and for other industrial electrochemical processes. Flow-through porous electrodes can provide a very large surface area per unit volume and also allow intimate contact of the electrode surface with the process stream. The minimum requirements for the scale-up of porous electrode electrochemical reactors to industrial demands are a knowledge of the collection efficiency (CE) for a single pass through the reactor and the potential drop in the solution-filled pores ($\Delta\phi_S$). The macroscopic model of porous electrode systems has been extensively developed, particularly by the groups of Newman and Alkire (1-4). Recent review articles (5, 6) have outlined the progress to date, although relatively few experimental tests of theoretical predictions have been made.

In this paper a simplified macroscopic model for the mass-transfer-limited reaction of a single species in a flow-through porous electrode reactor is considered for the case of a counterelectrode upstream of the porous electrode. The theoretical equations are presented in terms of the variables which are directly and conveniently measured by experiment. Detailed experimental tests of the model have been conducted, utilizing the reduction of $Fe(CN)_6^{3-}$ at a commercially available porous graphite electrode material. Experimental procedures for evaluating the efficiency of porous electrodes are established. In this respect, our treatment resembles the semi-phenomenological treatment of Sioda (7-13). Equations have been derived to allow optimization of the electrode length and flow rate for a porous electrode at any desired efficiency, where the potential drop in solution and the concentration of the electroactive substance are variables.

The straight pore model (14) has not been developed as extensively as the macroscopic model. The former model differs from the latter in some detail, and the former will be briefly sketched out in an appendix. These two models will be compared, leading to the conclusion that the macroscopic model is preferred.

Theoretical

The porous electrodes to be treated in this work consist of a conducting matrix with electrolyte solution penetrating the void spaces of the electrode material. The conductivity of the matrix will be assumed to be significantly higher than that of the solution-filled pores, so that any potential difference between the upstream and downstream faces of an operating porous electrode reactor will be attributed to the finite conductivity of the electrolyte phase. The macroscopic model treats the average properties of the electrode without a detailed description of the geometry of the pores. The porous electrode is assumed to be isotropic, and it is characterized by its porosity (void fraction, ϵ) and surface area per unit volume (a). The electrode configuration to be treated is the case of an upstream counterelectrode, with potentiostatic control of the front or upstream face of the porous electrode with respect to a reference electrode. A schematic diagram of a (hypothetical) pore is shown in Fig. 1 with the defined coordinate system and conventions for directions of (total) current flow from the electrode, superficial current density in the solution phase, superficial linear flow rate, and reactant flux at the interface between the pore wall and the solution (the convention of a positive anodic current is followed). The model is made one-dimensional by assuming that all quantities between the positions x and $x + dx$ in the electrode, which has the cross-sectional area A, are constant in any direction perpendicular to the flow. The distance from the front face of the electrode (x) is thus the only spatial variable; the total length of the electrode is denoted by L.

A simplified macroscopic model for the mass-transfer-limited reaction of a single species will be outlined, and this treatment follows closely the theoretical developments which have been presented in

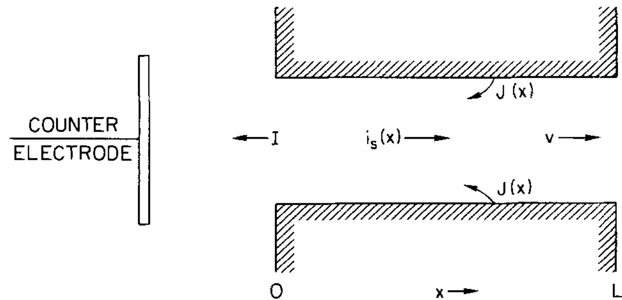

Fig. 1. Schematic diagram of idealized pore showing coordinate system and conventions for directions of total current (I), superficial current density in the solution phase ($i_S(x)$), superficial linear flow rate (v), and interfacial reactant flux ($J(x)$).

* Electrochemical Society Active Member.

Key words: current, convection, mass transport.

recent publications (1-6). The superficial current density in solution [$i_s(x)$, current per unit area of matrix plus pores] in the region between x and $x + dx$ varies according to the equation

$$\frac{di_s(x)}{dx} = n\mathbf{F}aJ(x) \quad [1]$$

where n is the electron number of the interfacial reaction, $\mathbf{F}$ is Faraday's constant, and $J(x)$ is the flux of the reactant normal to the electrode surface. The local flux of reactant at the interface is related to the concentration of the reactant in solution by the equation

$$J(x) = k_m[C_o(x) - C(x)] \quad [2]$$

In Eq. [2], k_m is an average mass-transfer coefficient which is independent of position within the electrode, $C(x)$ is the position-dependent concentration of the reactant within the bulk of a pore, and $C_o(x)$ is the concentration at the pore wall. The treatment below (Eq. [6] ff.) applies to mass-transfer-limited electrochemical reactors in which the local overpotential is sufficient to drive the surface concentration, $C_o(x)$, essentially to zero. Generally, however, the potential in solution, $\phi_s(x)$, is described by Ohm's law within the pores, according to

$$i_s(x) = -\sigma_{eff}\frac{d\phi_s(x)}{dx} \quad [3]$$

where σ_{eff} is the effective conductivity of the solution phase. From Eq. [3] it follows that

$$\frac{di_s(x)}{dx} = -\sigma_{eff}\frac{d^2\phi_s(x)}{dx^2} = n\mathbf{F}aJ(x) \quad [4]$$

The continuity or mass-balance equation within the porous electrode is

$$\frac{d[\epsilon C(x)]}{dt} = aJ(x) - v\frac{dC(x)}{dx} + D'\frac{d^2C(x)}{dx^2} \quad [5]$$

where v is superficial linear flow rate and D' is a diffusion coefficient (includes ϵ). The third term on the right side of Eq. [5] accounts for mass transfer within the porous electrode by diffusion and axial dispersion. The electrode material to be considered in this study has a moderately high surface area. At low flow rates the effects of diffusion become important, but at these flow rates the reactant is essentially completely consumed. At high flow rates the contribution to mass transport from diffusion is insignificant compared to that from forced convection. The transition from essentially complete conversion to significantly less than complete conversion occurs at a relatively high flow rate for the electrode material used in this study. Furthermore, the minimum Péclet number ~10 for the lowest flow rates used, so that the influence of axial dispersion on the apparent mass-transfer coefficient (6) is expected to be small over the range of flow rates of interest here. The diffusional term will therefore be omitted. Under steady-state conditions $d[\epsilon C(x)]/dt = 0$ and a solution of the resulting differential equation for $C(x)$, using the boundary condition $C(0) = C_b$, where C_b is the concentration of the electroactive species upstream of the porous electrode, is given by

$$C(x) = C_b \exp\left(-\frac{ak_m x}{v}\right) \quad [6]$$

Substitution of Eq. [2] (with $C_o(x) = 0$) and [6] into Eq. [1], followed by solution of the resulting differential equation with the boundary condition $i_s(L) = 0$, gives the result

$$i_s(x) = n\mathbf{F}vC_b\left[\exp\left(-\frac{ak_m x}{v}\right) - \exp\left(-\frac{ak_m L}{v}\right)\right] \quad [7]$$

for a cathodic process. The total current from the reactor (I) appears at $x = 0$ (cf. Fig. 1), and by use of the definitions $I = -i_s(0)A$ and $U = vA$, where U is volume flow rate, it follows from Eq. [7] that

$$I = -n\mathbf{F}UC_b\left[1 - \exp\left(-\frac{ak_m AL}{U}\right)\right] \quad [8]$$

for a cathodic process.

An explicit expression for the mass-transfer coefficient was derived by Wilson and Geonkoplis (15, 16) for a packed bed of spherical particles. Trainham and Newman (1) have proposed a different proportionality coefficient, and their recommendation has been followed, so that the mass-transfer coefficient is given by Eq. [9]

$$k_m = \frac{0.2574a^{2/3}D^{2/3}U^{1/3}}{\epsilon(1-\epsilon)^{2/3}A^{1/3}} \quad [9]$$

By combination of Eq. [8] and [9], an explicit expression for the current from a porous electrode reactor is therefore

$$I = -nFUC_b\left[1 - \exp\left(-\frac{0.2574a^{5/3}D^{2/3}A^{2/3}L}{\epsilon(1-\epsilon)^{2/3}U^{2/3}}\right)\right] \quad [10]$$

for a cathodic process. With long electrodes and/or low flow rates, Eq. [10] reduces to

$$I_{max} = -nFUC_b \quad [11]$$

which is Faraday's law for the maximum current from the reactor. The collection efficiency (CE) is defined by the relation

$$(CE) = \frac{I}{I_{max}} = 1 - \exp\left(-\frac{ak_m AL}{U}\right) \quad [12]$$

Use of (CE) or an analogous quantity as a measure of the efficiency of a porous electrode reactor was introduced by Gurevich and Bagotsky (17), Austin, Palasi, and Klimpel (18), and Sioda (19). Measurement of the total current from a porous electrode reactor as a function of flow rate is a convenient means of determining an important operating parameter of the reactor. Equation [10] can be rearranged, with use of Eq. [11], to

$$\ln\left[1 - \frac{I}{I_{max}}\right] = -\frac{P}{U^{2/3}} \quad [13]$$

where P is a constant for a given reactor length which is equal to

$$P = \frac{0.2574\,a^{5/3}D^{2/3}A^{2/3}L}{\epsilon(1-\epsilon)^{2/3}} \quad [14]$$

Determination of an experimental value for P from the slope of a plot of $\ln[1 - I/I_{max}]$ *vs.* $U^{-2/3}$ thus provides the necessary information to calculate the (CE) of a reactor at any flow rate. This type of plot was employed by Coeuret (20) and by Gaunand, Hutin, and Coeuret (21). It is easily recognized that the effective reaction depth (x_o) within the porous electrode (*i.e.*, the depth at which the reactant concentration is decreased by a factor of $1/e$) is given by

$$x_o = |C_b/C'(0)| = \frac{v}{ak_m} = \frac{U^{2/3}L}{P} \quad [15]$$

where the primed quantity denotes differentiation with respect to x. This definition of x_o was also used by Gurevich and Bagotsky (17) and by Newman and Tiedemann (5).

An expression for the potential in the solution phase is obtained by substituting Eq. [7] into Eq. [3]

$$\frac{d\phi_s(x)}{dx} = -\frac{nFUC_b}{\sigma_{eff}}\left[\exp\left(-\frac{ak_m x}{v}\right) - \exp\left(-\frac{ak_m L}{v}\right)\right] \quad [16]$$

Integration of Eq. [16] between the limits $x = 0$ and $x = L$ gives an equation for the potential difference between the upstream and downstream faces of the porous electrode

$$\frac{[\phi_s(0) - \phi_s(L)]}{nFvC_b} = \frac{1}{\sigma_{eff}}\left\{\left(\frac{v}{ak_m}\right)\left[1 - \exp\left(-\frac{ak_m L}{v}\right)\right] - L\exp\left(-\frac{ak_m L}{v}\right)\right\} \quad [17]$$

This equation can also be obtained by setting D' (*cf.* Eq. [5]) equal to zero in an equation presented by Trainham and Newman (1). Equation [17] may be rewritten in terms of the volume flow rate and the maximum current from the reactor to give

$$\frac{|\Delta\phi_s|}{|I_{max}|} = R_s\left\{\left(\frac{U}{ak_m AL}\right)\left[1 - \exp\left(-\frac{ak_m AL}{U}\right)\right] - \exp\left(-\frac{ak_m AL}{U}\right)\right\} \quad [18]$$

where $\Delta\phi_s = \phi_s(0) - \phi_s(L)$, and the resistance of the solution-filled pores is given by

$$R_s = \frac{L}{\sigma_{eff} A} \quad [19]$$

Various versions of Eq. [17] and [18] may be found in the works of Sioda (8, 9, 13), Bennion and Newman (22), and Gaunand, Hutin, and Coeuret (21).

Introduction of Eq. [9] for k_m into Eq. [18], with use of Eq. [14] for the parameter P, leads to the alternative form

$$\frac{|\Delta\phi_s|}{|I_{max}|} = R_s\left\{\left(\frac{U^{2/3}}{P}\right)\left[1 - \exp\left(-\frac{P}{U^{2/3}}\right)\right] - \exp\left(-\frac{P}{U^{2/3}}\right)\right\} \quad [20]$$

At high flow rates the collection efficiency (CE) is small and Eq. [20] reduces to

$$\frac{|\Delta\phi_s|}{|I_{max}|} \sim \frac{R_s}{2}\cdot\frac{P}{U^{2/3}} \quad [21]$$

On the other hand, at flow rates where (CE) $\sim$ 1, Eq. [20] reduces to

$$\frac{|\Delta\phi_s|}{|I_{max}|} \sim R_s\cdot\frac{U^{2/3}}{P} \quad [22]$$

Equation [22] shows that a knowledge of the resistive impedance of the solution (R_s) together with information on the influence of flow rate upon the potential difference $\Delta\phi_s$, in the region where (CE) $\sim$ 1, will permit the parameter P to be calculated. By this means it is possible subsequently to calculate the flow-rate-dependent (CE) of the electrode at any flow rate by use of the relation

$$(CE) = 1 - \exp(-P/U^{2/3}) \quad [23]$$

which follows from Eq. [9], [12], and [14].

It is clear from the behavior of Eq. [21] and [22] with flow rate (U) that a plot of $|\Delta\phi_s|/|I_{max}|$ *vs.* $U^{2/3}$ will possess a maximum. Upon setting the derivative of the right side of Eq. [20] with respect to $U^{2/3}$ equal to zero, it follows that the maximum in the plot occurs when

$$\frac{P}{U^{2/3}} - \ln\left[1 + \left(\frac{P}{U^{2/3}}\right) + \left(\frac{P}{U^{2/3}}\right)^2\right] = 0 \quad [24]$$

Numerical solution of Eq. [24] leads to the relation

$$P = 1.793\, U_{max}^{2/3} \quad [25]$$

where U_{max} is the flow rate at which the maximum in the plot of $|\Delta\phi_s|/|I_{max}|$ *vs.* $U^{2/3}$ occurs. Furthermore, the value of $|\Delta\phi_s|/|I_{max}|$ at the maximum in the plot may also be used to obtain an independent estimate of R_s according to

$$R_s = 3.351\left(\frac{|\Delta\phi_s|}{|I_{max}|}\right)_{max} \quad [26]$$

Consequently, all information needed for the rational design of porous electrode reactors of this type may be obtained from observations on the effect of flow rate upon the potential difference between the upstream and downstream faces of the reactor.

Experimental

Apparatus.—Porous electrodes were machined from a block of UCAR grade 45 porous graphite (23). A long cylinder (1.2 cm diam) was covered with heat-shrinkable polyolefin tubing. Individual electrode elements 0.25, 0.5, 1.0, and 2.0 cm in length were cut from this cylinder, thus ensuring uniform cross-sectional area and relatively homogeneous samples. The manufacturer specifies an average pore diameter of $\sim$ 60 μm and a nominal porosity of 0.48 for the porous graphite used in this study. The latter value represents both the micro- and macro-porosity of the material. As noted elsewhere (6), in a flow-through porous electrode it is the interfacial area which is accessible to the flow that is relevant. Consequently, we will use a value of 0.4 for the porosity accessible to flow, a value appropriate for random packing of spherical particles, as suggested by Newman and Tiedemann (6) and by the extensive measurements of Alkire *et al.* (24) The cylindrical electrodes were mounted in a Kel-F and Pyrex glass cell arrangement shown schematically in Fig. 2. This cell configuration is similar to that employed by Posey and Palko (25). The reference electrode (SCE) was located upstream of the porous electrode in a separate compartment containing the test solution which was bridged into the cell by the pointed capillary shown in Fig. 2. The tip of the reference electrode capillary terminated close to (< 1 mm) the upstream end of the porous electrode. The counterelectrode (spectroscopic grade carbon rod) was also located upstream of the porous electrode in a compartment separated from the flowing stream by a glass frit; this arrangement prevented contamination of the test solution by counterelectrode reaction products. The potential of the front or upstream face of the porous electrode was controlled by a Princeton Applied Research Corporation Model 173D potentiostat with Model 176 current-to-voltage converter. Electrical contact to the porous graphite electrode was made by press fitting an 18-

gauge Pt wire, sealed in glass with ~ 1 mm exposed, to the downstream face of the electrode. Forced flow of solution (deoxygenated by sparging with argon) through the porous electrode was controlled with a Sage Instruments Model 375 peristaltic pump. The average volume flow rate was measured by noting the time required for collection of a known volume of the effluent.

Steady-state and transient current measurements were made in the conventional manner. The potential difference between the upstream and downstream faces of the porous electrode was measured by use of a second, downstream reference electrode (SCE). A battery-operated Keithley Model 602 electrometer, referenced to the ground of the PARC Model 173D potentiostat, served as a buffer amplifier for the downstream reference electrode. Steady-state measurements of the potential difference in solution between the upstream and downstream faces of the porous electrode ($\Delta\phi_s$) were measured from the differential voltage of the PARC Model 173D electrometer output and the Keithley Model 602 unity-gain output on a digital voltmeter. Transient measurements of $\Delta\phi_s$ were determined from photographs of the trace of a Tektronix Model 5115 storage oscilloscope. A Tektronix Model 5A19N differential amplifier plug-in unit was used to measure the voltage difference from the two electrometer outputs.

Procedure.—Solutions were prepared from reagent grade chemicals. Laboratory distilled water was further purified by passage through a Milli-Q purification system (Millipore Corporation) producing water with a conductivity of $\leq 8 \times 10^{-8}\ \Omega^{-1}\ \text{cm}^{-1}$. All measurements were made in an electrolyte containing 1.0*M* KCl and 0.01*M* $Na_2B_4O_7$ (borax buffer, pH ~ 9). Solutions of $K_3Fe(CN)_6$ were analyzed by coulometric methods. All solutions were degassed with a stream of argon before being pumped into the porous electrode apparatus. Observed values of the limiting current and of $\Delta\phi_s$ were considered to correspond to steady states after 3-4 electrode volumes of solution flow. The $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple has an apparent "half-wave potential" at low flow rates and currents ($\Delta\phi_s <$ 10 mV) of +0.22V *vs.* SCE. Steady-state measurements were made with the entire electrode maintained at potentials no more positive than ~ 0V *vs.* SCE. The lowest concentration of $Fe(CN)_6^{3-}$ employed in this study (~ $5 \times 10^{-4}M$) was dictated by a desire to make the residual current insignificant with respect to the Faradaic current. The highest flow rate (~ 0.7 $\text{cm}^3\ \text{sec}^{-1}$) was limited by the potential drop in the solution-filled pores and the necessity of keeping the entire electrode in the limiting-current region. At potentials of the upstream (controlled-potential) face more negative than −0.30V *vs.* SCE, the background current became too large to be neglected.

The impedance characteristics (C_T and R_s, *cf.* below) of the porous electrodes were measured by the potential step method (26) in the 1.0*M* KCl + 0.01*M* $Na_2B_4O_7$ electrolyte. A 50 or 100 mV potential step was applied to the upstream face of the porous electrode in the potential range +0.25 to +0.10V *vs.* SCE. The transient current data were analyzed as described below. All measurements were carried out at room temperature (23° ± 2°C).

Results and Discussion

Determination of electrode impedance characteristics.—Theoretical aspects of the transient response of porous electrodes to a potential step have been discussed elsewhere (14, 26). The theory applies to charging of the double layer in the absence of a significant contribution to the current from Faradaic reactions, and it provides a convenient means of determining the effective resistance of a solution-filled porous electrode, a parameter that is needed for analysis or prediction of the behavior of a porous electrode reactor. Although the transient current response to a potential step was derived by Posey and Morozumi (26), the plotting method used by Johnson and Newman (27) and by Tiedemann and Newman (28) is especially advantageous. In this method $I(t)\sqrt{t}$ is plotted against $\sqrt{t}$, where $I(t)$ is the total current at time t. Analysis shows that, for negligible resistance between the reference electrode and the upstream end of the porous electrode, this plot is described by

$$I(t)\sqrt{t} = \frac{2\eta_o\sqrt{\tau}}{R_s}\left\{\sqrt{\frac{t}{\tau}}\sum_{k=0}^{\infty}\exp\left[-(k+1/2)^2\pi^2 t/\tau\right]\right\} \quad [27]$$

where η_o is the change in the potential of the upstream end of the porous electrode, R_s (resistance of solution in pores of electrode) is given by Eq. [19], and $\tau = R_sC_T$ is a time constant. The total capacity of the porous electrode is given by

$$C_T = acAL \quad [28]$$

where c is the differential capacity per unit area and other quantities are defined above. For $t << \tau$, Eq. [27] reduces to

$$\lim_{t\to 0}[I(t)\sqrt{t}] = \frac{\eta_o}{\sqrt{\pi}}\cdot\frac{\sqrt{\tau}}{R_s} \sim [I(t)\sqrt{t}]_{\max} \quad [29]$$

This result follows also from the equation of de Levie (14) for potentiostatic charging of the double layer of a semi-infinite porous electrode. In practice, as noted by Tiedemann and Newman (28), the quantity $I(t)\sqrt{t}$ cannot approach a constant at arbitrarily short times because of the finite resistance in the solution between the porous electrode and the reference electrode and any resistance associated with the leads and current collector. Instead a plateau or maximum is observed in the plot of $I(t)\sqrt{t}$ *vs.* $\sqrt{t}$. A plot of this type for a porous electrode with L = 0.25 cm is shown in Fig. 3; in this case of course no $Fe(CN)_6^{3-}$ was present in the solution phase. The solid line in Fig. 3 follows Eq. [27]. The data points, taken from a photograph of the oscilloscope trace, lie below the line predicted by Eq.

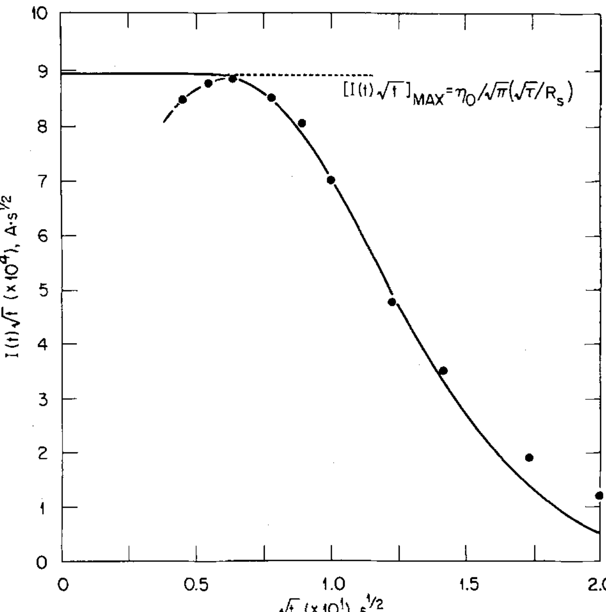

Fig. 3. Plot of $I(t)\sqrt{t}$ vs. $\sqrt{t}$ for potential step. $|\eta_o|$ = 0.10V (+0.25 to +0.15V vs. SCE); L = 0.25 cm.

[27] or [29] at short times (*cf.* dashed line in Fig. 3) because of the resistive factor noted above.

If the resistance between the reference electrode and the porous electrode is not excessive (28), the value of the maximum or plateau observed in a plot like Fig. 3 will be a good measure of the quotient $\sqrt{\tau}/R_s$, as implied in Eq. [29] (*cf.* dotted line in Fig. 3). Furthermore, this type of plot may also be used to estimate τ from the data observed at times when the electrode capacity begins to saturate and $I(t)\sqrt{t}$ begins to decrease. Most of the data shown in Fig. 3 correspond to this case. It follows from Eq. [27] and [29] that the ratio of values of $I(t)\sqrt{t}$ to the maximum or plateau value is given by

$$\frac{[I(t)\sqrt{t}]}{[I(t)\sqrt{t}]_{max}} = 2\sqrt{\pi}\left\{\sqrt{\frac{t}{\tau}}\sum_{k=0}^{\infty}\exp\left[-(k+1/2)^2\pi^2 t/\tau\right]\right\} \quad [30]$$

Consequently each value of this ratio corresponds to a unique value of t/τ, so that use of Eq. [30] with any particular value of the ratio and the corresponding time leads to an estimate of τ. Values of the ratio defined by Eq. [30] along with corresponding values of t/τ are given in Table I.

Any number of estimates of τ may be obtained from a transient like that shown in Fig. 3. Obviously, consistency among separate estimates lends confidence to the procedure, but some deviation can be expected in practice because of the difficulty of removing traces of electroactive substances (*e.g.*, dissolved oxygen) from the base electrolyte. The positive deviation of the data points in Fig. 3 for $\sqrt{t} > 0.15$ may be attributed to this cause.

Combination of values of $\sqrt{\tau}/R_s$ obtained by use of Eq. [29] with values of τ obtained by use of Eq. [30] leads to separate values of R_s and C_T for the four electrode lengths used in this study, and the results are shown in Fig. 4. As predicted by Eq. [19] and [28], both R_s and C_T are observed to depend linearly upon the length of the electrode. The lines in Fig. 4 are least-squares fits of the data forced through the origin. Use of Eq. [19] with the resistance data of Fig. 4 leads to $\sigma_{eff} = 2.1 \times 10^{-2}\ \Omega^{-1}\ cm^{-1}$. The deviation of this value from the bulk conductivity of 1.0*M* KCl ($\sigma_o = 0.11\ \Omega^{-1}\ cm^{-1}$ at 25°C) may be rationalized by use of the Bruggeman equation (29)

$$\sigma_{eff} = \sigma_o \epsilon^{3/2} \quad [31]$$

where σ_o is the bulk conductivity of the continuous liquid phase and ϵ is void fraction, as discussed by De La Rue and Tobias (30) and by Meredith and Tobias (31). For $\epsilon = 0.4$ and $\sigma_o = 0.11\ \Omega^{-1}\ cm^{-1}$, an estimate of $\sigma_{eff} \sim 2.8 \times 10^{-2}\ \Omega^{-1}\ cm^{-1}$ is obtained from Eq. [31]. This estimate is probably as consistent as can be expected with the quantity estimated from the data in Fig. 4 considering the uncertainty in ϵ and

in the strict applicability of Eq. [31] to the present situation.

Use of Eq. [28] with the capacity data of Fig. 4 leads to $ca = 1.7 \times 10^{-2}$ F cm^{-3} for the double layer capacity per unit volume of the electrode material used here. Estimation of the area-to-volume ratio (a) from these data requires a knowledge of the differential capacity per unit area (c). Bauer, Spritzer, and Elving (32) observed approximately 50 μF cm^{-2} for the differential capacity of polished pyrolytic graphite in 0.5*M* KCl. More recently, Randin and Yeager (33) observed large differential capacities ($\sim$ 100 μF cm^{-2}) for the edge orientation of stress-annealed pyrolytic graphite as determined by a-c measurements (1000 Hz), and even larger values could be estimated from voltammetry. A value of c greater than that observed for pyrolytic graphite in 0.5*M* KCl (32) seems reasonable since the material of this study is probably much more inhomogeneous than pyrolytic graphite, and it is known that surface roughness by itself plays a significant role in measurements of differential capacity by both a-c and pulse techniques, as shown by de Levie (34). If a value of c $\sim$ 100 μF cm^{-2} is assumed, then it follows that a $\sim$ 1.7 $\times$ 10^2 cm^{-1}. This value of a agrees well with that ($\sim$ 1.6 $\times$ 10^2 cm^{-1}) estimated from values of P determined from the variation of I or $\Delta\phi_s$ with U, as shown below. And in addition, microscopic examination of the individual grains comprising the porous electrode shows that the average particle diameter (D_p) is approximately 200 μm. This value of D_p together with use of the well-known engineering formula $a = 6(1 - \epsilon)/D_p$ leads to the estimate $a \sim 1.8 \times 10^2$ cm^{-1}, in good agreement with the other estimates of a.

It was noted previously (26) that the ratio of the matrix resistance (R_m) to the solution resistance (R_s) may be estimated from observations on the transient response of a porous electrode to a potential step by use of the relation

$$\frac{R_m}{R_s} = \frac{\eta(L,0)}{\eta_o} \quad [32]$$

In Eq. [32] $\eta(L,0)$ is the sudden change in the potential of the downstream end of the porous electrode when the potential of the upstream end is changed by η_o. For all electrode samples used in this work we

found that $R_m \leq 0.03\ R_s$, in agreement with published data on matrix conductivity (23). This measurement also proved to be a convenient means of determining whether or not a good electrical contact had been obtained between the platinum contact rod and the porous graphite electrode.

Mass-transfer-limited current.—The simplified treatment of the macroscopic model predicts a linear relationship between current and flow rate (*cf.* Eq. [10] and [11]) in the flow regime in which (*CE*) is very near to unity. This is the observed relationship, as shown by the dashed line (unity slope) in the log-log plot of current *vs.* flow rate in Fig. 5. This type of plot has also been used by Sioda (7, 10, 19, 35-37), Alkire and Gracon (3), and Alkire and Ng (4). For short electrodes and/or high flow rates, Eq. [10] approaches the asymptotic limit of Eq. [33]. The flow rate required

$$I = -\frac{0.2574nFC_b a^{5/3}A^{2/3}D^{2/3}U^{1/3}L}{\epsilon(1-\epsilon)^{2/3}} \qquad [33]$$

to observe this limit could not be achieved in these measurements before the potential drop in the pores becomes excessive, but the limit is being approached in Fig. 5 (these data were obtained on an electrode with $L = 0.25$ cm). The limiting behavior predicted by Eq. [33] has been observed in other studies of porous electrode systems (4, 38).

Equation [13] predicts that a plot of ln $[1 - I/I_{max}]$ *vs.* $U^{-2/3}$ will be linear with a zero intercept. Similar plots have been employed by Coeuret (20) and by Gaunand, Hutin, and Coeuret (21). Experimental data from three independent series of measurements carried out with different electrodes for which $L = 0.25$ cm are shown in Fig. 6. A linear regression analysis of these data leads to a slope of −0.48 with a correlation coefficient of 0.95 (*cf.* dashed line in Fig. 6). The intercept (+0.06) is sufficiently small to force a zero intercept. When analyzed in this manner the slope is −0.44 ± 0.05, and this corresponds to the solid line in Fig. 6. These results show that, within experimental error, the data are described well by Eq. [13]. As noted in Eq. [15], the quantity $U^{2/3}L/P$ is the flow-rate-dependent effective reaction depth. Thus the parameter *P*, determined from the slope of the plot of Fig. 6, is an important experimental parameter which may be used to calculate (*CE*) for a given electrode material, electrode length, and flow rate. The solid line in Fig. 5 was calculated using $I = I_{max} \cdot (CE)$ with Eq. [23] and a value of *P* determined by the procedure of Fig. 6; the agreement between calculated and experimental results is excellent. An analogous treatment of

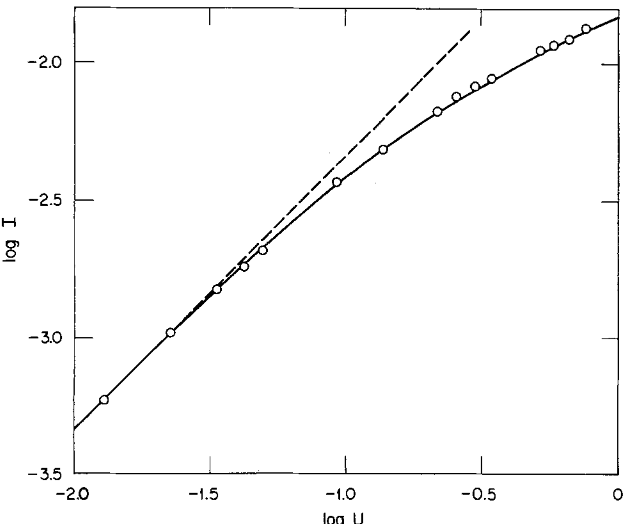

Fig. 5. Reduction of $4.8 \times 10^{-4}M$ $Fe(CN)_6^{3-}$ in porous graphite electrode; $L = 0.25$ cm.

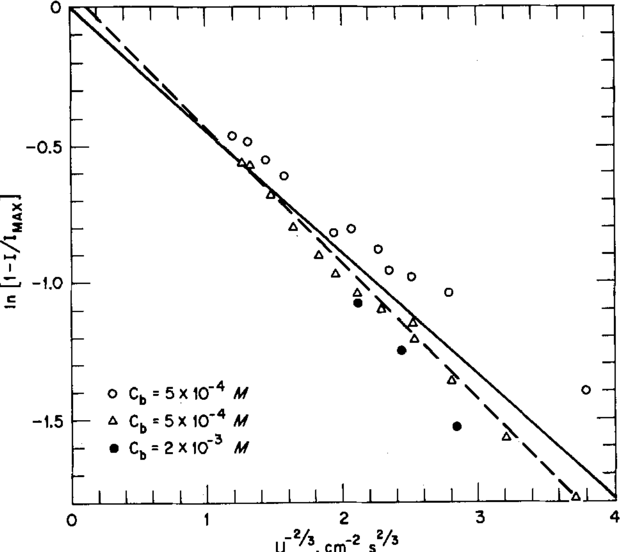

Fig. 6. Reduction of $Fe(CN)_6^{3-}$ in porous graphite electrode; 1.0*M* KCl + 0.01*M* $Na_2B_4O_7$, $A = 1.13$ cm², $L = 0.25$ cm.

data obtained with electrodes for which $L = 0.50$ cm led to $P = 1.0$. We were unable to achieve a high enough flow rate to observe that (*CE*) was significantly less than unity for electrodes with $L = 1.0$ and 2.0 cm, while maintaining the entire electrode in the potential region of mass transfer control. The method of data analysis used in this work is analogous to the double logarithmic plots used by Sioda (7, 10, 11, 36, 39, 40). Our treatment emphasizes determination of the parameter *P* whereas Sioda was interested in the power dependence of the limiting current on the flow rate.

The predictions of the simplified model may be compared with those of the more extended model of Trainham and Newman (1), which includes effects of axial diffusion and dispersion and of a simultaneous side reaction. Upon neglect of these factors their expression for the current reduces to Eq. [8]. Substitution of the appropriate parameters to describe the electrode material and conditions of this study into the expression of Trainham and Newman (1) shows that the current predicted by the extended model differs from that of Eq. [10] by less than 5%. This is taken to be evidence that the diffusional flux, at least to a first approximation, is an insignificant mode of mass transport for these electrodes and flow rates.

Potential drop in solution-filled porous electrodes.—It is important to develop a relationship for $|\Delta\phi_s| = |\phi_s(0) - \phi_s(L)|$ as a function of flow rate which will allow the parameters needed for design of a porous electrode reactor to be determined. Furthermore, as noted above, this potential difference itself is one of the important criteria that must be satisfied for optimum design of a porous electrode reactor.

The theoretical expression for the potential difference in solution is given by Eq. [20], which suggests use of a plot of $|\Delta\phi_s|/|I_{max}|$ *vs.* $U^{2/3}$. Plots of experimental data for three different electrode lengths are shown in Fig. 7 and 8. In the flow regime where (*CE*) is near unity, the experimental data are described by Eq. [22]. The dashed lines in Fig. 7 and 8 are in good agreement with this relation. Consequently, it is possible to estimate a value of *P* from data of this type by use of a value of R_s obtained from analysis of the current transient of a porous electrode to a potential step, as noted above.

In all cases investigated, the experimental data points at the lowest flow rates did not follow the prediction of Eq. [22] as well as might have been desired. This positive deviation (*cf.* Fig. 8) cannot be accounted for by the simple model used in this analysis. How-

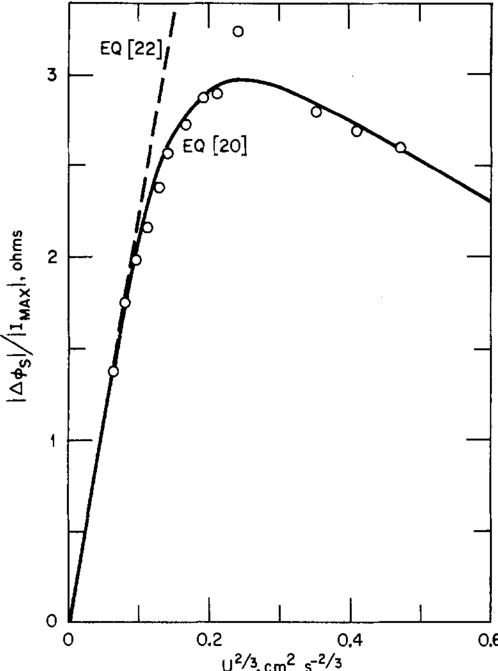

Fig. 7. Plot of $|\Delta\phi_s|/|I_{max}|$ vs. $U^{2/3}$ for $L = 0.25$ cm. Solid line: Eq. [20] with $P = 0.45$ cm^2 sec$^{-2/3}$, $R_s = 10\Omega$; dashed line: Eq. [22].

ever, it is probably related to diffusion effects at the upstream face of the electrode. At low flow rates, all of the reactant is consumed near the upstream face of the electrode, *i.e.*, the effective reaction depth is a very small percentage of the reactor length (*cf.* Eq. [15]). And even for $U = 0$ a finite current can be expected due to diffusion (and possible natural convection) of the reactant to the upstream face of the electrode (6), a process that is not treated here. In any event, this problem will not be serious in determination of the parameters needed for design of porous electrode reactors, and in addition one consideration for optimization of reactor design is to maximize the effective reaction depth, as described below.

At flow rates where (CE) is appreciably less than unity, it is clear from **Eq. [20]** that a plot of $|\Delta\phi_s|/|I_{max}|$ *vs.* $U^{2/3}$ will possess a maximum (*cf.* Eq. [21] and [22]). This is illustrated by the data in Fig. 7. As noted above (*cf.* Eq. [25]), the parameter P may be calculated from the value of U at which the maximum occurs. In addition, the resistance of the solution within the porous electrode (R_s) may be calculated from the maximum value of $|\Delta\phi_s|/|I_{max}|$ by use of Eq. [26]. Thus, under favorable conditions, two important parameters needed for design of a porous electrode reactor may be determined by measurement of the flow rate dependence of $\Delta\phi_s$. Unfortunately the maximum in a plot of $|\Delta\phi_s|/|I_{max}|$ *vs.* $U^{2/3}$ is rather broad, and the difficulty of precise determination of its location may limit the usefulness of this method to some extent.

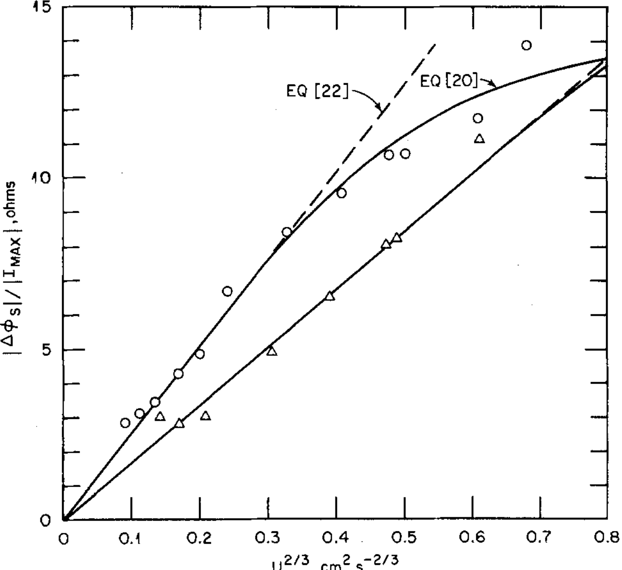

Fig. 8. Plot of $|\Delta\phi_s|/|I_{max}|$ vs. $U^{2/3}$ for $L = 1.0$ and 2.0 cm. Circles: $L = 1.0$ cm, $P = 1.8$ cm^2 sec$^{-2/3}$, $R_s = 46\Omega$; solid line: Eq. [20]; dashed line: Eq. [22]. Triangles: $L = 2.0$ cm, $P = 4.8$ cm^2 sec$^{-2/3}$, $R_s = 81\Omega$; solid line: Eq. [20]; dashed line: Eq. [22].

Sioda (8, 40) and Gaunand, Hutin, and Coeuret (21) have also investigated the potential difference between the upstream and downstream faces of a porous electrode reactor. Sioda (8, 40) chose to plot the ratio $|\Delta\phi_s|/|I|$ as a complex function of (CE) which can be obtained by rearrangement of Eq. [17], [18], or [20]. A similar plot was used by Gaunand, Hutin, and Coeuret (21). These plots only allowed a determination of the effective conductivity of the solution (σ_{eff}). The method of data analysis suggested above allows not only R_s, and thus σ_{eff} (*cf.* Eq. [19]), but also the important parameter P to be determined.

Values of the parameter P were calculated from both potential drop and current measurements for electrodes with $L = 0.25$ and 0.50 cm. Based upon current measurements, as discussed above, the calculated values of P were 0.44 and 1.05 cm^2 sec$^{-2/3}$. The values based upon measurements of $\Delta\phi_s$ were 0.45 and 0.90 cm^2 sec$^{-2/3}$, respectively. This good agreement between two measuring techniques also extends to determinations of R_s. Use of the maximum values of $|\Delta\phi_s|/|I_{max}|$ for the 0.25 and 0.50 cm electrodes leads to $R_s = 10$ and 29Ω, respectively, in good agreement with the values estimated for the same electrodes by analysis of the current response to a potential step (*cf.* Fig. 4).

The good agreement of experimental data with theoretical predictions of the macroscopic model is taken to be evidence that Eq. [20] (or Eq. [17]) accurately describes the potential difference between the upstream and downstream faces of a porous electrode. Furthermore, the agreement between parameters calculated from current measurements and from potential measurements indicates the self-consistency of the macroscopic model. We were unable to use a flow rate high enough to observe a (CE) significantly different from unity for $L = 1.0$ and 2.0 cm without encountering excessively large $\Delta\phi_s$, so that P could not be estimated by use of Eq. [25] in these cases. However, P could be calculated for these cases by use of Eq. [22] and values of R_s estimated from the current response to a potential step (*cf.* Fig. 4). The values of P obtained in this manner were 1.8 and 4.8 cm^2 sec$^{-2/3}$ for $L = 1.0$ and 2.0 cm, respectively.

The parameter P is predicted by the macroscopic model to be a linear function of reactor length (*cf.* Eq. [14]). Values of P determined by the methods described above are shown plotted as a function of L in Fig. 9. The data for $L = 0.25$, 0.50, and 1.0 cm show within experimental error a linear dependence upon L. From the slope of the line in Fig. 9, with use of $D = 7.63 \times 10^{-6}$ cm^2 sec^{-1} for the diffusivity of $Fe(CN)_6^{3-}$ in 1*M* KCl (41), it can be calculated that $a \sim 1.6 \times 10^2$ cm^{-1}. As noted above, this value of a agrees well with that estimated from the average particle diameter and also with the value estimated from the total capacity of the electrodes. The value of P for the electrode with $L = 2.0$ cm deviates markedly from the line that describes the other data in Fig. 9. The cause for this deviation is not known.

Comparison of macroscopic and straight pore models.—The two models that describe mass transport to the pore walls of a porous electrode differ not only in the

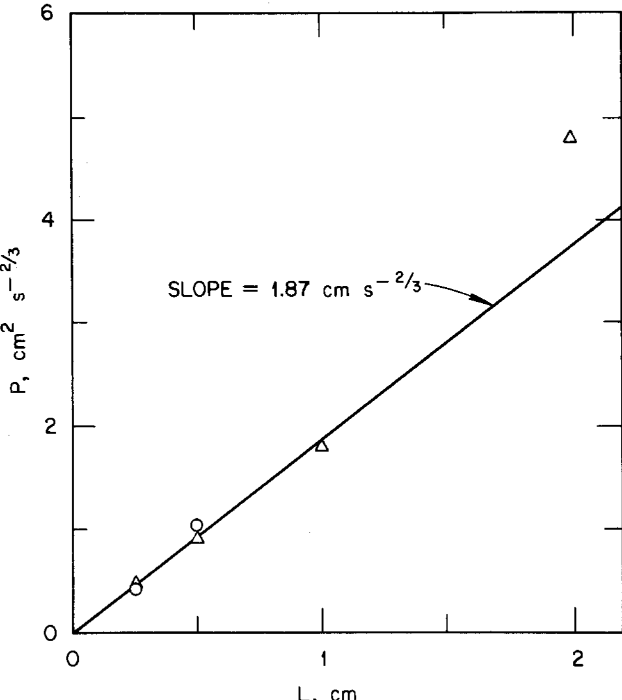

Fig. 9. Plot of the parameter *P* as a function of *L*. Circles: current measurements; triangles: potential measurements.

geometric description of the pores but also in the hydrodynamic description of flow. The straight pore model assumes that fully developed laminar flow takes place within the pores whereas the macroscopic model is based upon an average mass transfer coefficient which is independent of position. Theoretical predictions of total current (and thus collection efficiency) and potential difference based on the straight pore model are outlined briefly in the Appendix. It was shown above that the macroscopic model agrees well with experimental data. The two models are compared below using, as far as possible, the same parameters to describe the porous electrode system.

A plot of (CE) *vs.* log U for an electrode with $L = 0.25$ cm is shown in Fig. 10, which contains two different sets of experimental data on reduction of $Fe(CN)_6^{3-}$. Plots of this type were used by Sioda (10, 42), Wroblowa and Razumney (43), Alkire and Gracon (3), and Alkire and Gould (44). The macroscopic model was fit to the data using Eq. [23] and the appropriate value of P from Fig. 9. The straight pore model was fit by choosing a value of the constant a^2DAL/ϵ in Eq. [A-5] such that the two models coincide at high flow rates (*cf.* Eq. [33] and [A-7]). Numerically the two models differ somewhat in the flow region from essentially complete conversion to $\sim$ 50% conversion. Although the macroscopic model seems to fit these data a little better than the straight pore model, the scatter in the data precludes a clear distinction. An asymptotic solution valid at high flow rates (*cf.* Eq. [A-7]) is also shown in Fig. 10; this was obtained from the Lévêque solution to the mass transport problem (*cf.* Appendix) for $(CE) \sim 0$.

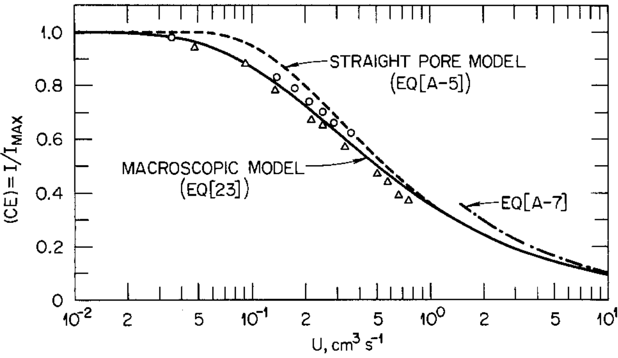

Fig. 10. Comparison of macroscopic and straight pore models: collection efficiency as a function of flow rate. Reduction of $5 \times 10^{-4}M$ $Fe(CN)_6^{3-}$; $L = 0.25$ cm. Macroscopic model: $P = 0.44$ cm^2 sec$^{-2/3}$. Straight pore model: $a^2 D A L/8\epsilon = 3.85 \times 10^{-2}$ cm^3 sec^{-1}.

Consideration of the potential difference between the upstream and downstream faces of a porous electrode $(\Delta\phi_s)$ provides a clear distinction between the two models. Figure 11 is a plot of log $|\Delta\phi_s|/|I_{max}|R_s$ *vs.* log U for the two models using the same parameters as in Fig. 10. At low flow rates where (CE) is near unity the quantity $|\Delta\phi_s|/I_{max}|$ varies directly with U for the straight pore model while for the macroscopic model this quantity varies with $U^{2/3}$, as may be seen by comparison of Eq. [22] and [A-8]. This same difference in dependence upon U is also exhibited by the effective reaction depth (*cf.* Eq. [15]). In addition the macroscopic model agrees well numerically with experimental data over the entire region of the maximum in Fig. 11. Although some improvement in fit with the straight pore model could be achieved by adjustment of the physical constants, the shape of the maximum predicted by this model for the log-log plot of Fig. 11 would not allow the close fit observed for the macroscopic model over a wide range of flow rates. From a mathematical standpoint the straight pore model is more complicated than the simplified macroscopic model (*cf.* Appendix). Consequently, use of the macroscopic model is preferable for analysis and design of porous electrode systems both for its convenience and because of its consistency with experimental results. However, there are electrode configurations for which the straight pore model might be a better approximation. Such an electrode consists of a bundle of parallel wires with longitudinal solution flow, a configuration which is similar to the brush electrode of de Levie (45).

Design considerations for porous electrode reactors.—The fundamental relationships needed to design a porous electrode electrochemical reactor are provided by Eq. [7] or [12] and [17]. Perhaps the most commonly used design criterion for a practical reactor arises as

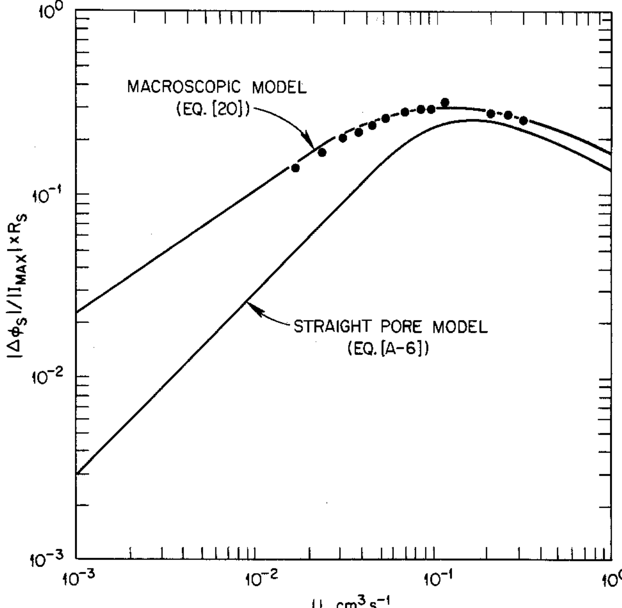

Fig. 11. Comparison of macroscopic and straight pore models: normalized potential drop as a function of flow rate. Reduction of $1.93 \times 10^{-3}M$ $Fe(CN)_6)^{3-}$; $L = 0.25$ cm. Macroscopic model: $P = 0.44$ cm^2 sec$^{-2/3}$. Straight pore model: $a^2 D A L/8\epsilon = 3.85 \times 10^{-2}$ cm^3 sec^{-1}.

a result of a desire to keep the flow rate sufficiently low so that (CE) is near unity, and thus the reaction will be completed in a single pass. Equations [12] and [17], written in terms of superficial current density $(i_s(0))$ and superficial linear flow rate (v), become

$$(CE) = \frac{i_s(0)}{nFvC_b} = 1 - \exp\left(-\frac{ak_mL}{v}\right) \quad [34]$$

$$\frac{\Delta\phi_s}{nFvC_b} = \frac{L}{\sigma_{eff}} \left\{\left(\frac{v}{ak_mL}\right)\left[1 - \exp\left(-\frac{ak_mL}{v}\right)\right] - \exp\left(-\frac{ak_mL}{v}\right)\right\} \quad [35]$$

The average mass transfer coefficient (k_m), written in terms of superficial linear flow rate, becomes (cf. Eq. [9])

$$k_m = \frac{0.2574}{\epsilon(1-\epsilon)^{2/3}}(aD)^{2/3}v^{1/3} \quad [36]$$

Equations [34] and [35] may be solved simultaneously, with use of Eq. [36], to give optimum values of v and L for any desired value of (CE) as a function of $\Delta\phi_s$, C_b, and the physical parameters that describe the electrode-electrolyte system.

It is convenient to introduce the parameter Q, defined by

$$Q = -\ln[1 - (CE)] = ak_mL/v = P/U^{2/3} \quad [37]$$

as a measure of the desired current or collection efficiency. Use of Q in Eq. [34] and [35] and solution for v and L lead to the following relations

$$v = 4.53 \times 10^{-4} \frac{(\sigma_{eff})^{3/5}aD^{2/5}}{\epsilon^{3/5}(1-\epsilon)^{2/5}}\left(\frac{\Delta\phi_s}{nC_b}\right)^{3/5} \frac{1}{[1-(1+Q)\exp(-Q)]^{3/5}} \quad [38]$$

$$L = 2.29 \times 10^{-2} \frac{(\sigma_{eff}^{2/5}\epsilon^{3/5}(1-\epsilon)^{2/5}}{aD^{2/5}}\left(\frac{\Delta\phi_s}{nC_b}\right)^{2/5} \frac{Q}{[1-(1+Q)\exp(-Q)]^{2/5}} \quad [39]$$

The required cross-sectional area of the reactor (A) may be calculated from the total volume flow rate (U) and the relation $A = U/v$. It is clear from Eq. [38] and [39] that the optimum reactor length and flow rate will depend on the allowable potential difference between the upstream and downstream faces of the electrode $(\Delta\phi_s)$ and on the concentration of the electroactive species (C_b). The other quantities in Eq. [38] and [39] describe the properties of the electrode and the electrolyte and the desired (CE). Bennion and Newman (22) and Newman and Tiedemann (5) discuss alternative relations that could be used for design and optimization of porous electrodes operating under limiting current conditions for $(CE) \sim 1$. Many other design considerations and a graphical method for estimation of v and L for situations where k_m differs from Eq. [9] or [36] are reviewed by Newman and Tiedemann (6).

These design equations can be used to estimate the appropriate physical size, linear flow rate, and cross-sectional area required for a typical industrial application. Two limiting cases are: (*i*) removal of trace metal ions from a flowing stream by electrodeposition, and (*ii*) electrosynthesis of a species soluble in aqueous solution. The properties of the porous graphite electrode material used in this study may be taken as fairly typical for many applications of interest. It has a relatively large average pore diameter ($\sim 60\ \mu m$) to minimize pumping costs, and yet it retains a relatively large specific surface area ($> 10^2\ cm^{-1}$). Typical values which can be assigned to a, D, ϵ, and σ_{eff} are $1.7 \times 10^2\ cm^{-1}$, $1 \times 10^{-5}\ cm^2\ sec^{-1}$, 0.4, and 0.05 $\Omega^{-1}\ cm^{-1}$, respectively. In addition, it will be assumed that an electrode assembly will be required to process $4.38 \times 10^2\ cm^3\ sec^{-1}$ (10,000 gal/day) to be economically feasible. In both cases it will be assumed that a potential difference of 0.5V is allowable between the upstream and downstream faces of the electrode and that $(CE) = 0.99$ so that $Q = 4.605$.

The reduction of Hg(II) in chlor-alkali process streams to Hg° at a concentration of approximately $2.5 \times 10^{-4}M$ ($\sim$ 50 ppm) is an application which has been considered previously (25). The optimum electrode length and linear flow rate, calculated from Eq. [38] and [39], are 2.3 cm and 1.1 cm sec^{-1}, respectively. Consequently the required volume flow rate demands use of a cross-sectional area $A \sim 400\ cm^2$. Thus a compact porous electrode device is capable of treating a large volume of liquid in applications of this type.

On the other hand, use of a porous electrode reactor for electrosynthesis, where a moderately high concentration of the electroactive substance is desirable, appears to be relatively inappropriate with the present configuration. For example, one might consider a redox process for which $nC_b = 0.5M$. It can be estimated from Eq. [38] and [39] that $L \sim 0.14$ cm and $v \sim 1.8 \times 10^{-2}$ cm sec^{-1} for this application. Consequently the required cross-sectional area would be $A \sim 2.5 \times 10^4\ cm^2$, so that the physical dimensions of the reactor would need to be approximately 1.5m on a side by ~1.5 mm thick. These dimensions appear to be unrealistic for a practical device. However, a porous electrode cell might find application in electrosynthesis as a "polishing" device following prior treatment by a conventional flat plate electrochemical cell.

Conclusions and Summary

Equations have been derived, based upon a simplified macroscopic model, which allow optimum design parameters to be estimated for porous electrode reactors operating at any desired efficiency. The model has been verified experimentally by measurements of the limiting current and the potential difference between upstream and downstream faces of an operating reactor as a function of flow rate for a reaction under pure mass transfer control. Various methods are discussed for determining the efficiency and other parameters of a porous electrode reactor. A new method of data analysis has been proposed that is based entirely on measurements of the potential difference between upstream and downstream faces of a porous electrode. Based on the properties of the electrode material used in this study, the relative merits of the macroscopic model and the straight pore model have been compared. In addition, two typical industrial applications have been examined to delineate situations in which the use of a porous electrode reactor may be feasible.

APPENDIX

Straight pore model of porous electrodes.—The straight pore model assumes that the electrode consists

of a number of identical, straight, nonintersecting, cylindrical pores running the entire length of a conducting matrix (*i.e.*, a bundle of capillaries). The problem involves accounting for the current from a single pore, and then multiplying by the total number of pores to obtain the total current. Current-potential relationships for a single pore in the absence of forced convection were reviewed by de Levie (14). An approximate solution for the mass-transfer limited current with forced convection was obtained by Posey and Nelson (38) by piecing together the asymptotic solutions for high flow rate and for low flow rate within a tubular electrode. The number of pores (N) was taken to be the cross-sectional area of voids divided by the cross-sectional area of a single pore, *i.e.*, $N = \epsilon A/\pi R^2$, where R is pore radius.

More recently, Newman (46) has published an exact solution to the problem of mass transfer to the interior wall of a tube from a stream with fully developed laminar flow (the Graetz problem). The solution neglects axial diffusion as a mode of mass transport; this assumption is analogous to that used above in derivation of the simplified macroscopic model. The treatment should be valid for relatively long, narrow pores which can be thought of as constituting the porous electrodes of this study (radius $\sim 3 \times 10^{-3}$ cm; length $\geqq 2.5 \times 10^{-1}$ cm). For the case of the limiting current (zero reactant concentration at wall), Newman presents an expression for the average concentration of reactant, $C_m(x)$, at the position x (*cf.* Eq. [6])

$$C_m(x) = C_b \sum_{k=1}^{\infty} M_k \exp(-\lambda_k^2 \pi D x/2 U_i) \quad \text{[A-1]}$$

In this equation M_k and λ_k are the coefficients and eigenvalues for the solution of this Sturm-Liouville problem in convective diffusion, U_i is the volume flow rate in the i^{th} tube or capillary, and other quantities are defined above. The first ten values of M_k and λ_k have been evaluated and tabulated by Newman (46). It follows that the (limiting) current from a single tube (I_i) of length L for a cathodic process is given by (*cf.* Eq. [8])

$$I_i = -n \mathbf{F} U_i C_b \left[1 - \sum_{k=1}^{\infty} M_k \exp(-\lambda_k^2 \pi D L/2 U_i) \right] \quad \text{[A-2]}$$

The average current density in the solution phase for a single tube, $i_{s,i}(x)$, is given by (*cf.* Eq. [7] and [16])

$$i_{s,i}(x) = \frac{n \mathbf{F} U_i C_b}{\pi R^2} \sum_{k=1}^{\infty} M_k [\exp(-\lambda_k^2 \pi D x/2 U_i) - \exp(-\lambda_k^2 \pi D L/2 U_i)] = -\sigma_0 \frac{d \phi_s(x)}{dx} \quad \text{[A-3]}$$

In Eq. [A-3] $\phi_s(x)$ is the average potential in the solution phase at the point x and σ_0 is the bulk conductivity of the solution as above. Equation [A-3] transforms into Eq. [A-2] when $x = 0$ since $\Sigma M_k = 1$ (46). Integration of Eq. [A-3] leads to an expression for the potential drop between upstream and downstream ends of the tube, $\Delta\phi_s = [\phi_s(0) - \phi_s(L)]$ (*cf.* Eq. [17])

$$\Delta\phi_s = \frac{n \mathbf{F} U_i C_b}{\sigma_0 \pi R^2} \sum_{k=1}^{\infty} M_k \left\{ \frac{2 U_i}{\lambda_k^2 \pi D} [1 - \exp(-\lambda_k^2 \pi D L/2U_i)] - L \exp(-\lambda_k^2 \pi D L/2U_i) \right\} \quad \text{[A-4]}$$

These relations may be put into forms that resemble the corresponding equations of the simplified macroscopic model. The flow rate for a single pore is related to the total flow rate by $U_i = U/N$, where $N = \epsilon A/\pi R^2$ as above. The total current (I) is simply $I = N I_i$, the area-to-volume ratio (a) for a bundle of cylindrical capillaries is given by $a = 2\epsilon/R$, and the resistance of the solution is $R_s = L/\sigma_0 \epsilon A$. Then the total (limiting) current for the electrode is given by (*cf.* Eq. [10])

$$I = -n \mathbf{F} U C_b \left[1 - \sum_{k=1}^{\infty} M_k \exp(-\lambda_k^2 a^2 D A L/8 \epsilon U) \right] \quad \text{[A-5]}$$

And finally the potential drop is described by (*cf.* Eq. [20])

$$\frac{|\Delta\phi_s|}{|I_{max}|} = R_s \sum_{k=1}^{\infty} M_k \left\{ \frac{8\epsilon U}{\lambda_k^2 a^2 DAL} [1 - \exp(-\lambda_k^2 a^2 DAL/8\epsilon U)] - \exp(-\lambda_k^2 a^2 DAL/8\epsilon U) \right\} \quad \text{[A-6]}$$

For low flow rates the current approaches the asymptotic limit $I_{max} = -n \mathbf{F} U C_b$ (*cf.* Eq. [11]). For high flow rates $C_m(x) \sim C_b$ at all x and an asymptotic form for the current may be obtained from the Lévêque solution (46-48)

$$I \sim -1.017\, n \mathbf{F} C_b (a^2 D A L/\epsilon)^{2/3} U^{1/3} \quad \text{[A-7]}$$

Equation [A-7] is seen to be analogous to Eq. [33]. The potential drop at low flow rates is given approximately by

$$\frac{|\Delta\phi_s|}{|I_{max}|} \sim 0.917 R_s (\epsilon U/a^2 D A L) \quad \text{[A-8]}$$

which may be compared with Eq. [22]. On the other hand, at high flow rates, the potential drop is described approximately by the relation

$$\frac{|\Delta\phi_s|}{|I_{max}|} \sim 0.407 R_s (a^2 D A L/\epsilon U)^{2/3} \quad \text{[A-9]}$$

which was obtained from the Lévêque solution by the procedure used to derive Eq. [A-4]. Predictions of these relations for the behavior of the straight pore model are compared above with the predictions of the simplified macroscopic model.

LIST OF SYMBOLS

a	specific interfacial area, cm^{-1}
A	cross-sectional area of electrode (matrix + solution), cm^2
c	differential capacity per unit area, F cm^{-2}
C_b	concentration of electroactive species upstream of porous electrode, moles cm^{-3}
$C(x)$	concentration of reactant in bulk of pore at the position x, moles cm^{-3}
$C_m(x)$	average reactant concentration in straight pore at the position x (*cf.* Appendix), moles cm^{-3}
$C_o(x)$	concentration of reactant at pore wall at the position x, moles cm^{-3}
C_T	total differential capacity of porous electrode (*cf.* Eq. [28]), F
(CE)	$= I/I_{max}$, collection efficiency (*cf.* Eq. [12])
D	diffusivity of electroactive species, cm^2 sec^{-1}
D'	diffusion coefficient (*cf.* Eq. [5]), cm^2 sec^{-1}

Copper Recovery Using a Tumbled-Bed Electrochemical Reactor

Richard P. Tison

General Motors Research Laboratories, Electrochemistry Department, Warren, Michigan 48090

ABSTRACT

A tumbled-bed electrochemical reactor was described and shown to function well in reclaiming copper from a dilute acid copper system. A sound electrodeposit was obtained routinely and may be conducive to a stable and low maintenance industrial application. Graphs which approximately represent operating cost-capital cost trends have been presented and suggested as useful for future work in developing and comparing alternative waste treatment techniques.

Process waste waters generated at various manufacturing facilities often cause a twofold problem. They may have a toxic effect on the environment and their disposal causes a loss of much valuable material, not only in dissolved solids but in process water also. Waste treatment methods in current use often (*i*) detoxify inadequately, (*ii*) detoxify but generate undesirable by-products, creating a new waste disposal problem, or (*iii*) detoxify without materials recovery or water recycle. Current developments concerning both environmental considerations and the growing scarcity of natural resources provide an increasingly strong impetus for the development of more effective yet economical waste treatment technologies.

Electrochemical methods of treatment offer an intriguing alternative to conventional chemical methods in that waste waters may be treated without adding additional chemicals. Also, metals may be recovered in the metallic form, relatively pure and salable.

For dilute metal-bearing waste waters, three-dimensional conductive-bed electrodes are often considered, to provide extended surface area. The intention is to enhance the small electrochemical reaction rates anticipated with low metal ion concentrations. Descriptions of several types of bed electrodes may be found in the literature, including the packed bed (1-3), dynamic packed bed (4), fluidized bed (1, 5, 6), and vibrated bed (7, 8).

In this work we describe a tumbled-bed electrode, which is an adaptation of conventional barrel plating technology. By this technique a tumbling motion is imparted to a bed of conductive particles contained in a rotating barrel. A tumbled particulate-bed electrode has been described in a patent issued to McCoy *et al.* (9). While he suggested its use in electrowinning or refining processes, his application was in a battery. Inoue also used a tumbled-bed electrode, but his application was electrochemically deburring metal workpieces (10). Oehr (11) described the use of a barrel plater for waste treatment. He used the tumbled bed as an anode for cyanide oxidation. Kammel *et al.* (12) electroplated metals from dilute waste water by the employment of a tumbled-bed cathode. Their work was described in patent form, however, and little performance data was made available.

This present work describes the effectiveness for waste water treatment of a tumbled-bed electrochemical reactor. Copper recovery from a dilute acid copper system was used as the test case and serves as a representative of a number of toxic heavy metal waste waters which constitute a major waste handling problem.

Experimental

Apparatus and procedure.—The tumbled-bed electrochemical reactor concept is shown in Fig. 1. The actual unit used in this work is shown in Fig. 2. It was made by reworking a commercially available miniature portable barrel plater. While one of the best geometries for industrial application of this concept may well involve an "open" rotating cylinder submerged in the waste water being treated in a fashion similar to conventional barrel plating, this initial work made use of an "internalized" design to facilitate controlled flow-through for single- and multiple-pass characterization studies. Thus, the porous cylinder was replaced by a sealed acrylic cylinder, 127 × 140 mm ID. Four acrylic blocks, 4 × 4 × 127 mm, were cemented to the interior walls, equally spaced around the periphery and parallel to the axis of rotation, to aid bed movement. All plumbing and electrical connections were made through two axial end-plate holes, as shown, and included a 3.1 mm diam lead (Pb) wire extending slightly below the axis as anode, two lead ball danglers, approximately 11 mm diam, which provided electrical feeds to the cathode bed, and solution inflow and outflow tubes. The cathode bed consisted of steel spheres, 4.5 mm diam, plated with 18 μm copper. The cylinder was loaded with 3.05 kg of copper-plated steel spheres

which took up approximately 35% of the cylinder's volume.

Simulated acid copper waste water was made up of various concentrations of reagent grade copper sulfate in 1M sulfuric acid using distilled water. This simulated waste water was then used without further purification. For multiple-pass studies, test solutions were pumped through the system using a tubing pump according to the scheme illustrated in Fig. 3. For once-through studies, spent solutions were returned to a second reservoir. All work was performed at room temperature and at a cylinder rotation speed of 9 rpm.

All runs were potentiostated via a saturated calomel reference electrode communicating with the inlet tube to the reactor. Copper concentrations were determined by use of a commercial cupric specific ion electrode calibrated daily by an atomic absorption spectrometer analysis of several samples withdrawn during each run. Current, overall voltage, and specific ion electrode potential were continuously recorded.

Polarization studies were obtained during single-pass runs by the "steady-state" method. For each multiple-pass run, a fresh 5 liter volume was continuously recirculated at constant cathode potential until all copper was depleted. Initial copper concentrations were approximately 1400 ppm. Each recirculatory run thus provided reactor performance data for a given potential over a range of concentration. Flow-through rates were also held constant at 550 ml/min except where otherwise specified. This rate corresponds to 58 turnovers/hr based on an experimentally determined 0.57 liter liquid capacity of the loaded cylinder. Approximately 3 hr per run were required to deplete the copper content in the waste water.

Calculations.—Data from the recirculatory runs were processed by a computer program which fit appropriate calibration equations to the cupric specific ion electrode data, and provided tabulations and plots of input data as well as several derived indices of reactor performance (see Appendix).

Reproducibility and sources of error.—As a test of reproducibility, one particular multiple-pass depletion run was performed three times. Experimental values for overall current efficiency, electrical energy yield, and volumetric reaction rate for each run over the range 300-10 ppm copper were calculated and compared. The maximum deviation from average of any of these performance indexes over the three runs was 15%.

After the reactor work was completed, a reanalysis of solution samples by atomic absorption was undertaken for iron. The analyses showed that iron had slowly built up in the recirculation solutions and may have affected reactor performance. Final iron concentrations ranged from 81 ppm for the most rapid run (4 hr) to 177 ppm for the slowest runs (8 hr). This iron contamination apparently came from discontinuities in the copper plating on the steel spheres. These spheres were subsequently replaced by solid copper shot for further work (not yet reported). In the present work, however, an assessment of available data suggested that the iron dissolution was coupled partially with hydrogen evolution and partially with copper removal from the solution (cementation). Based on solution analyses, calculations indicate that the copper removal rates reported herein are only 3-7% larger in magnitude than would have occurred in the absence of the cementation effect.

Results and Discussion

Single-pass performance.—The flow of waste water through a reactor once-only for treatment is often advantageous as it is well suited to high production rates and involves minimum pumping requirements.

Polarization studies.—Figure 4 shows polarization curves for the tumbled-bed electrochemical reactor under single-pass conditions. It may be noted that each copper deposition curve exhibited an inflection but not a plateau before becoming obscured by the secondary hydrogen evolution reaction which dominated at large cathode polarizations. The absence of a mass transfer limiting current plateau sometimes associated with a "fast" electrochemical reaction such as this may be accounted for by several factors but perhaps the most significant is the following.

An increasing rather than constant (limiting) copper deposition current can result from a significant *IR* potential drop through the solution within the bed electrode causing the cathode reaction within the bed to be operating over a wide range of potential. Thus, as larger and larger negative potentials were applied to the cathode, more and more remote regions of this bed electrode would become active with a resultant increase in current, as was obtained experimentally. Unfortunately, this situation also eventually forces the most accessible areas of the bed electrode to potentials sufficiently negative to evolve hydrogen as well as deposit copper. Thus, performance of this reactor could be improved by suitable design changes to minimize these variations, *e.g.*, a thinner bed (in the direction of current flow), additional counterelectrodes at

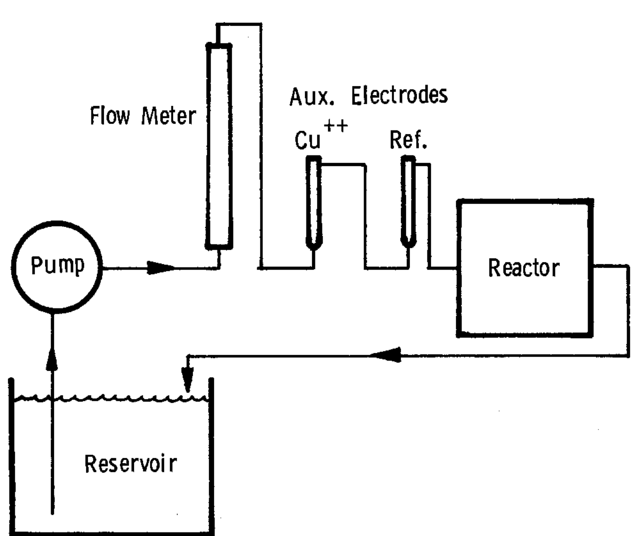

Fig. 3. Schematic diagram of the experimental system

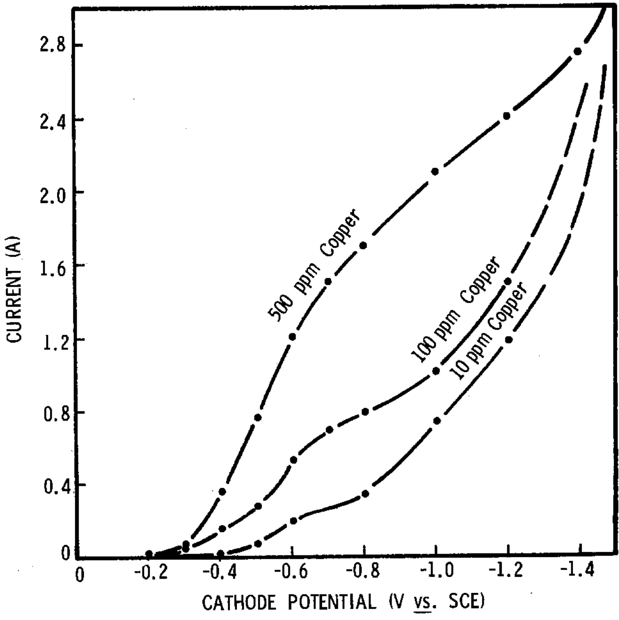

Fig. 4. Polarization studies of a tumbled-bed electrochemical reactor. Solution feed rate was 74 ml/min.

suitable positions throughout or surrounding the bed, greater solution conductivity, or greater bed porosity.

Effect of potential.—The effect of cathode potential on reactor performance may be seen in Fig. 5. Percent recovery increases with increasing cathode polarization. This increase is expected, especially since remote regions of the cathode bed apparently become productive at large polarizations as discussed earlier. Extreme polarizations contributed primarily to increased hydrogen gassing which tended to occur at the bed surface and therefore did not contribute greatly to increased rates of recovery.

Electrical energy yield and current efficiency, on the other hand, decrease with increasing cathode polarization. This is largely due to the increasing proportion of current and electrical energy being consumed by the hydrogen evolution side reaction, which becomes more prominent at large cathode polarizations. Obviously in selecting operating conditions for a practical application, a tradeoff must be made between operating costs and completeness of recovery in a single pass.

Effect of flow-through rate.—The influence of solution feed rate on a reactor performance is shown in Fig. 6. Percent recovery is enhanced by lower flow-through rates as would be expected due to the longer solution residence time involved. In this work, as much as 99.4% recovery was obtained. Again, improved performance in terms of percent recovery was obtained at the expense of higher operating costs as reflected by the electrical energy yield and current efficiency data. These performance indexes improve with higher flow rates and thus demonstrate one of the advantages of an alternate method of reactor operation which is described next.

Recirculatory performance.—A second method by which waste waters may be treated electrochemically is to allow the waste water to be recirculated through the reactor until satisfactory results are obtained. Recirculation involves greater pumping requirements, but the multiple pass and higher feed rates practical by this method often provide enhanced mass transport, more uniform concentrations throughout the reactor, and other inherent operational advantages, thus sometimes providing improved overall electrochemical performance.

Multiple-pass purification.—The gradual depletion of copper by recirculating a volume of waste water through the tumbled-bed electrochemical reactor is shown in Fig. 7. It is noted that decreased cathode potentials increase the speed of purification down to −1.2V, below which the rate of purification did not significantly change. (The test run at −0.6V proceeded so slowly that after 24 hr the starting concentration was reduced only slightly, and the run was terminated.)

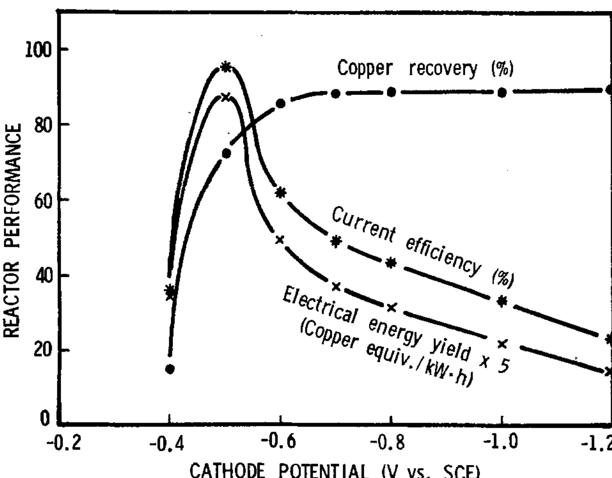

Fig. 5. Effect of cathode potential on single-pass reactor performance. Test solution contained 100 ppm copper. Solution feed rate was 74 ml/min.

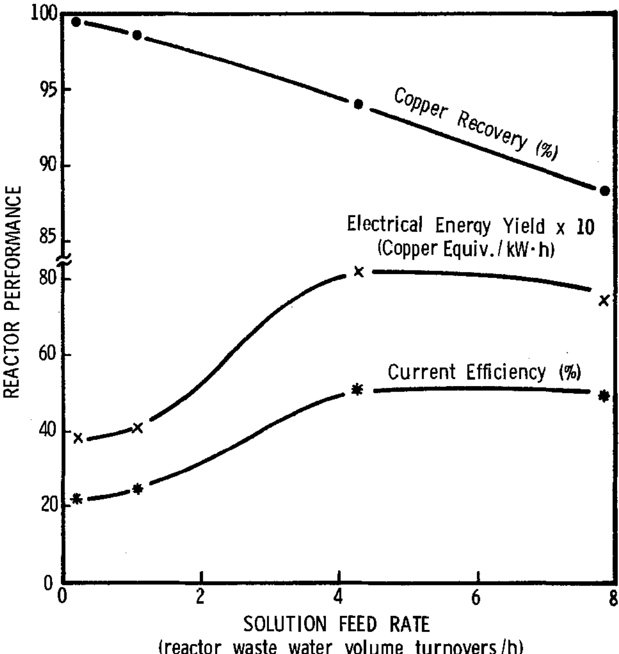

Fig. 6. Effect of feed rate on single-pass reactor performance. Test solution contained 100 ppm copper. Cathode potential was −0.7V.

Effect of potential.—Figure 8 shows trends in electrochemical performance over a range of cathode potentials. Volumetric reaction rate is seen to increase with increasing cathode polarization while electric energy yield and current efficiency decrease. Thus, in a manner similar to single-pass operation, tradeoffs between the performance indexes are seen to occur.

Effect of concentration.—Figure 9 provides a typical example of reactor performance over a range of inlet concentrations. The large falloff in performance with decreasing copper concentration is noted, and expected from theoretical considerations.

Lowest electrical energy yields and current efficiencies were observed when treating waste waters of lowest copper content. This is largely because nonproductive electrochemical reactions occur at the cathode as

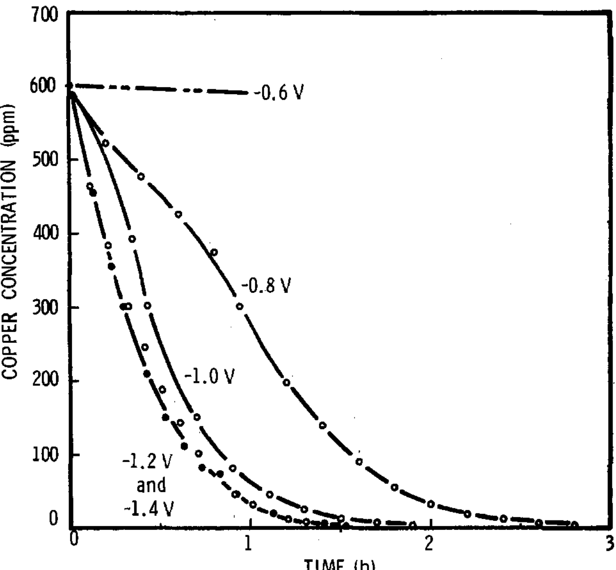

Fig. 7. Multiple-pass purification of acid copper waste waters with the tumbled bed. Five liters of solution were used for each run and recirculated at 58 turnovers/hr. Cathode potentials are listed.

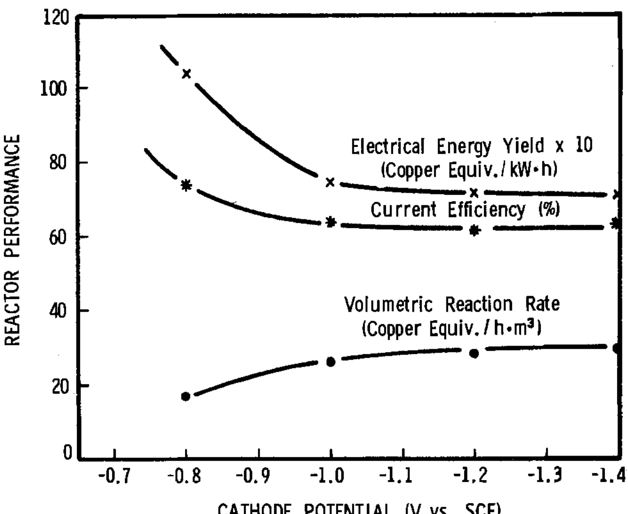

Fig. 8. Effect of cathode potential on multiple-pass reactor performance. Incoming solution contained 100 ppm copper. Rate of recirculation was 58 turnovers/hr.

well as copper deposition. These reactions likely include the reduction of dissolved oxygen as well as hydrogen ions, as the waste waters used in this work were not pretreated to remove dissolved oxygen, nor were the waste waters being treated kept isolated from the oxygen-generating anode. The resulting background current reduces both current efficiency and electrical energy yield during recovery efforts. This drain on performance becomes more significant at lower copper concentrations, where the copper deposition current is less, because the background current from these other reactions then makes up a larger fraction of the total current. This explains the observed trend.

Smaller reaction rates were also observed as copper concentrations decreased. A decrease in copper concentration in the bulk solution causes a decrease in the concentration gradient that can develop across the cathode boundary layer. This produces a decrease in diffusional transport of copper to the cathode surface which, in turn, results in a decrease in the limiting rate of the copper deposition reaction. For this reason, the diffusion-limiting rate for metal deposition from dilute solutions would be expected to be approximately proportional to concentration. This dependency was very much in evidence over the three-decade concentration range investigated in this work (Fig. 9).

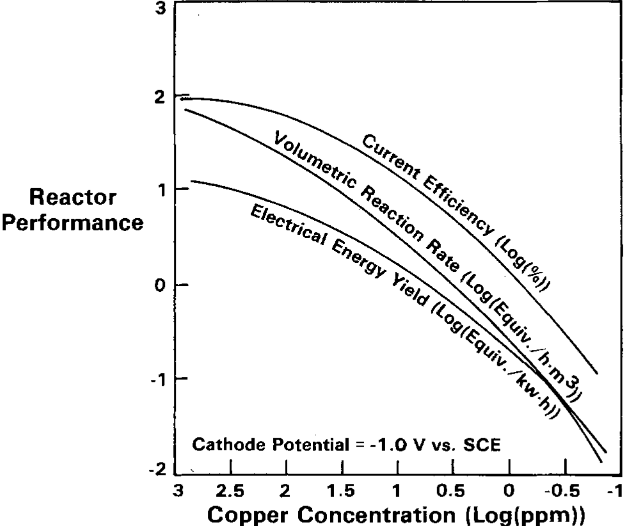

Fig. 9. Effect of copper concentration on multiple-pass reactor performance. Rate of recirculation was 58 turnovers/hr.

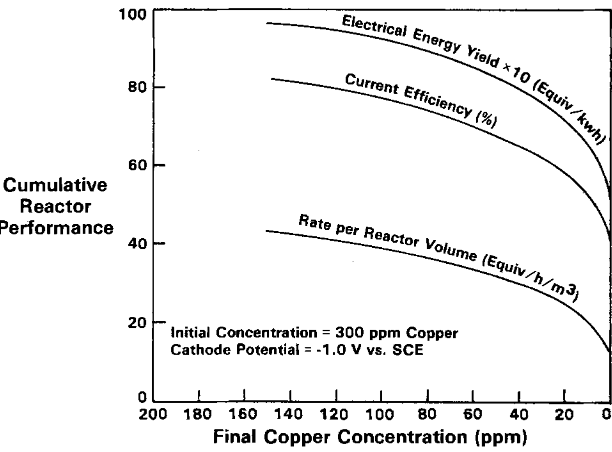

Fig. 10. Effect of degree of purification desired on overall reactor performance. Rate of recirculation was 58 turnovers/hr.

Overall reactor performance.—Resulting reactor performance during recirculatory operation will depend, of course, on the degree of purification one wishes to obtain. Figure 10 provides a typical example of how overall performance depends on the final concentration desired, when starting with a waste water containing 300 ppm copper. As shown in the plot, overall performance decreases as lower final concentrations are attained, with performance rapidly deteriorating below approximately 10 ppm as absolute purity is approached.

Method for making performance comparisons.—During this work the need for a procedure by which different modifications of the tumbled-bed reactor or alternate reactors could be compared on a sound economic basis became evident. An all-embracing, completely accurate assessment would be a formidable undertaking, not generally prudent at early stages of research and development efforts such as in this present work. We rather construct a useful approximation, selecting two appropriate engineering quantities, one that reflects operating costs and one that reflects capital costs. Drawing from available experimental performance data (in this study the family of constant potential plots, of which Fig. 9 is one example), these quantities are then plotted against each other, as in Fig. 11. In

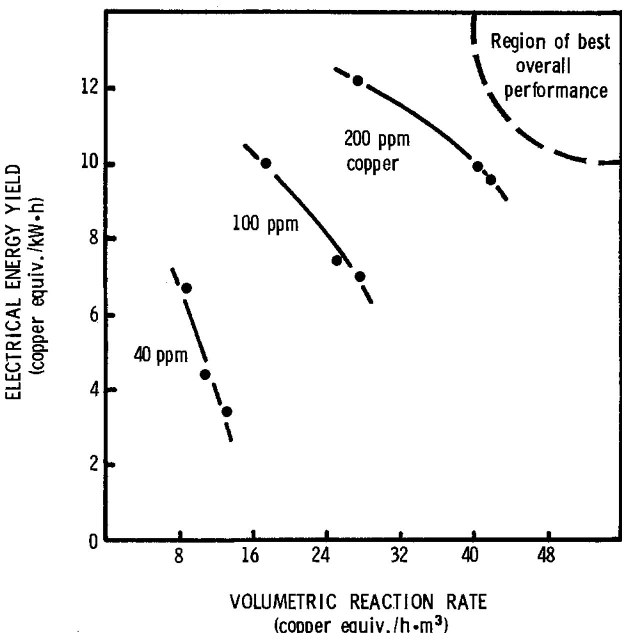

Fig. 11. Performance summary of the tumbled bed during multiple-pass operation. Concentrations of copper in the waste waters being treated are indicated. Rate of recirculation was 58 turnovers/hr.

this figure electrical energy yield (metal equiv./kW · hr) may be thought of as reflecting operating costs of the tumbled-bed electrochemical reactor as electrolytic power requirements have been considered a very substantial proportion of total operating costs in electrolytic processing of metals in aqueous solution (16-18). In a similar manner, volumetric reaction rate (metal equiv./m^3 · hr) may be thought of as reflecting capital costs which are generally related to reactor size and capacity (6, 14, 19, 20).

In applying and refining this assessment formalism, engineering quantities which indicate operating cost and capital cost trends must be judiciously selected based on the particular electrochemical reactors involved.

Referring to Fig. 11, the tumbled-bed is seen to be characterized by a gradual tradeoff relationship between electrical energy yield and volumetric reaction rate. Total performance improves with increasing copper concentrations in the waste water. While this type of plot was used in this present work to compare the tumbled-bed at different copper concentrations, it could also be used in a similar manner to compare different versions of the tumbled bed, or other similar reactors, with each other.

Deposit characteristics.—Figure 12 shows typical cathode bed surfaces from the tumbled-bed reactor after several runs. Cathode bed surfaces from a packed-bed electrochemical reactor studied in this laboratory are also shown for purposes of comparison. The packed-bed results were obtained using cathode bed material identical to that in the tumbled-bed and after having treated similar waste water solutions under similar conditions. After even a short-term test, deposits on the packed-bed were rough and unevenly distributed. Particularly, nonuniform deposits were obtained on circular areas (see Fig. 12) where the packed-bed particles were either in contact with each other or with the walls of the containing vessel.

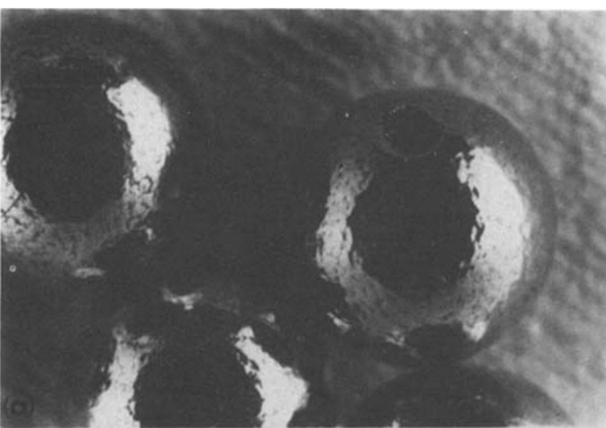

Fig. 12. Typical cathode bed surfaces from (a) a tumbled-bed electrochemical reactor and (b) a packed-bed electrochemical reactor after operation under similar conditions.

One particularly pleasing observation made throughout this work with the tumbled-bed was that resulting deposits of reclaimed copper were smooth, bright, compact, adherent, and uniformly distributed over the entire cathode bed particle surfaces. (The only roughness observed was the "orange peel" texture initially present on the sphere surfaces.) This kind of deposit was obtained after extended operation, even under extreme operating conditions, such as during the simultaneous evolution of considerable hydrogen.

These contrasting deposit qualities are apparently the result of the impinging, burnishing, and redistributing action of the tumbling and cascading bed particles against each other and with the solution. This type of deposit would tend to eliminate certain problems reported with packed-bed electrochemical reactors (8, 13, 14) such as changes on the cathode surfaces with time, making optimum reactor control more difficult, electrical shorting by dendritic deposits, and interparticle bridging and nonuniformly distributed deposits, causing premature plugging of the cathode bed and premature regeneration requirements. Therefore, the tumbled-bed could presumably translate into a relatively simple, reliable, and low maintenance system for practical applications. Considering the purification of a typical plating rinse waste water containing 200 ppm copper, calculations show that even the small tumbled-bed reactor used in this investigation could handle 4300 liters (1100 gal.) of waste water before reaching a deposit loading of only 25% of the original bed particle volume.

Acknowledgment

The author is grateful to Russell A. Foust, Jr. for providing the computer program, Earl E. Williams for constructing the tumbled-bed reactor, and to Robert F. Paluch for analyzing the samples.

Reduction of Benzene and Related Compounds in Aqueous Solution and Undivided Cells

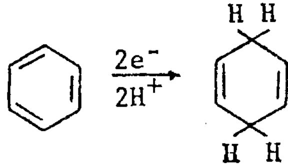
J. P. Coleman and J. H. Wagenknecht*

Monsanto Company, Corporate Research & Development Staff, St. Louis, Missouri 63166

ABSTRACT

Benzene and other aromatic compounds may be reduced to the 1,4-dihydroderivatives in an undivided cell using a dispersion of hydrocarbon and aqueous quaternary ammonium hydroxide. At optimum conditions benzene is converted to 1,4-cyclohexadiene at 90% selectivity with nearly quantitative current efficiency. A continuous reaction scheme for the benzene reduction is described.

The cathodic reduction of benzene to 1,4-cyclohexadiene (**I**), as an extension of the Birch (1) reaction, has been known for a long time. This reaction has been demonstrated in liquid ammonia (2)



I

amines (3-6), amides (7-8), ethers (9-17), and aqueous solution (18) with varying current efficiencies. All of the systems previously demonstrated have one or more features which make them unattractive as commercial processes.

The most substantial recent advance in this area was revealed in a patent (18) to Asahi Chemical Company and described the cathodic reduction of benzene and other aromatics in an aqueous emulsion with a quaternary ammonium salt as supporting electrolyte in a divided cell. We have substantiated their claims of high current efficiency and selectivity and later discovered conditions which allow this reaction to be carried out in an undivided cell. It is that study which led to a simplified method for synthesis of dihydroaromatics and an improved process for 1,4-cyclohexadiene that is described in this paper.

Experimental

The aromatic compounds that were reduced were reagent grade obtained commercially and used as received. Quaternary ammonium hydroxides were obtained from Southwestern Analytical Chemicals, Incorporated, Fisher Scientific Company, or Monsanto Chemical Intermediates Company.

NMR spectra were obtained with a Varian T-60 NMR spectrometer. Mass spectra were obtained on a Varian MAT CH7A mass spectrometer. GC analyses (benzene reduction products) were obtained using a 6 ft × 1/8 in. column packed with Carbowax 400 on Chromosorb P at 80°C isothermal. GC peak integration was performed by an Autolab System IVB integrator. A Lambda LP-412A-FM (up to 1A) or Sorensen DCR80-6B constant current/voltage power supply was used for the electrolyses.

Pure 1,4-cyclohexadiene used as a GC standard was obtained by distillation of several combined electrolysis products through a 3 ft heated, jacketed column packed with glass helices. A mixture of 50 ml benzene, 25 ml cyclohexene, 214 ml 1,4-cyclohexadiene, and 17 ml high boilers was distilled to give 140 ml of 99% purity 1,4-cyclohexadiene, bp 89°C. [The literature (19) reports 85.6°C, possibly low owing to the presence of benzene.) Figure 1 shows a plot of distillate composition *vs.* temperature for the early part of that distillation.

Batch reactions.—A large number of small batch reactions was carried out in the cell shown in Fig. 2 to examine the effects of variables. The cell was a 100 ml jacketed resin flask. When Hg was used as the cathode, 20 ml were added (20 cm^2 surface) and electrical contact was achieved via a Teflon tape-insulated copper wire. Mounted close to the Hg pool was a glass paddle stirrer. Good stirring was necessary to keep the aqueous and organic phases well mixed. The anode (steel tubing, Ni wire, metal plate, etc.) was mounted just above the stirrer paddles. The temperature was maintained by circulating water through the jacket from a temperature-controlled reservoir. A condenser was mounted on the cell, but some hydrocarbon was still carried away with the evolving O_2 and H_2. The cell was generally filled with 50 ml of aqueous quaternary am-

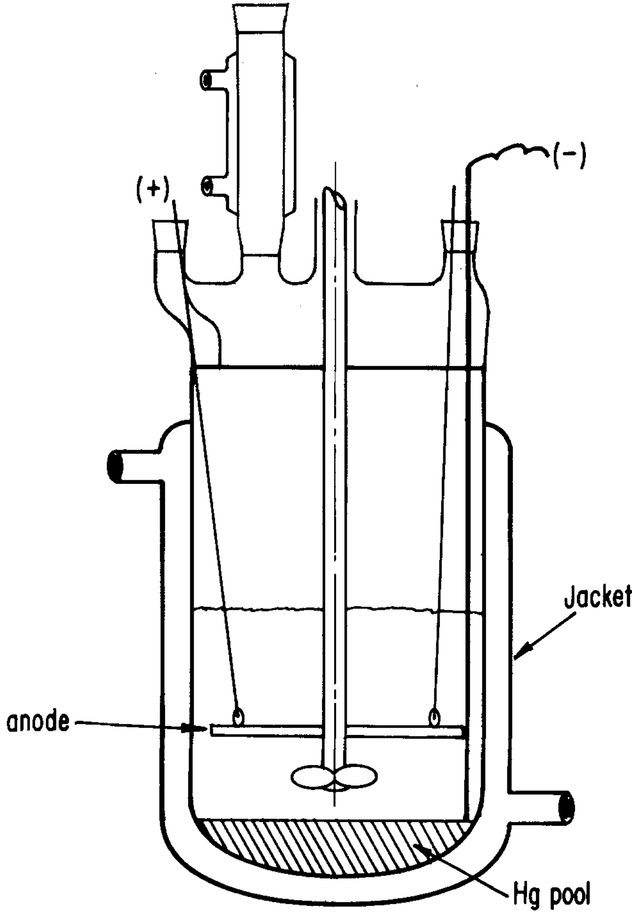

Fig. 2. Batch reaction cell

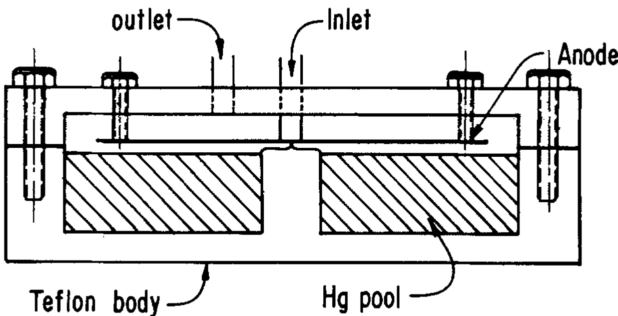

Fig. 3. Flow cell

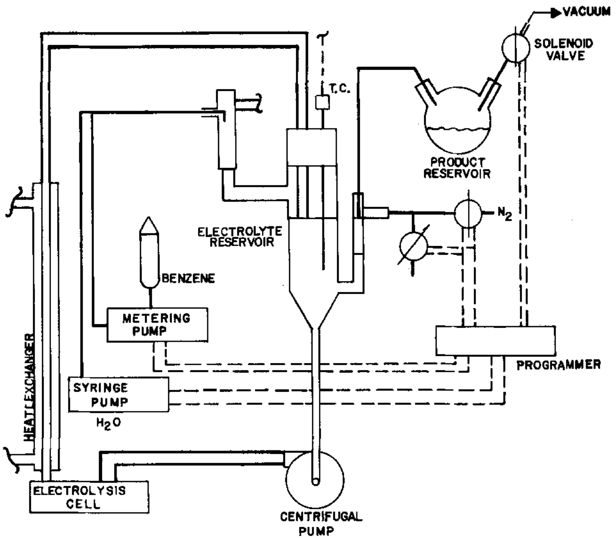

Fig. 4. Continuous electrolysis scheme

monium hydroxide solution and 10 ml benzene (or other substrate).

Continuous electrolysis.—The cell apparatus is shown in Fig. 3 and 4. The system was filled with 150 ml 20% $Bu_4N^+OH^-$ and 25 ml benzene. The cell contained 135 ml Hg with a surface area of 80 cm^2. The center post in the cell as 1.2 cm in diameter and the Hg pool 10 cm in diameter. The electrode gap was 4 mm. The solution was circulated through the system at about 2 liters/min with a centrifugal pump (Micro Pump Model 10-40-316). The temperature of the solution was held at 60°C via a heat exchanger. The electrolysis was started with a constant current of 2A requiring about 5V. The condenser above the electrolyte was cooled to 5°C with solvent circulated through a refrigerated bath (Neslab PCB-2). An Eagle Signal repeat-cycle timer was used to operate the reagent addition and sample recovery system. The system operated on a 1 hr cycle in which first a sample was removed and then 2 ml benzene and 1 ml of water were pumped into the solution.

Sample removal occurred as follows: under normal operation the N_2 valve was open and the vacuum valve and N_2 sidearm valve were closed. A small flow of N_2 kept the sidearm of the electrolysis reservoir empty. At the beginning of the sample period, the N_2 valve closed and the N_2 sidearm valve opened to the atmosphere. Electrolyte solution filled the side arm, and, since there was no agitation due to high flow rate, the organic phase formed a layer at the top. After 2 min, the vacuum valve opened and the organic layer was drawn into the product reservoir until the level fell below the end of the retrieval tube. After a few seconds, the vacuum and N_2 sidearm valves closed and the N_2 valve opened to resume normal operation. In this manner 48 ml of benzene were added to the system each day. An average of 30 ml of organic material were

recovered each day; the remainder was lost, presumably by evaporation and migration through walls of the polyethylene tubing used for solution lines. Analysis of the daily product sample gave the following results

Days of operation	% cyclohexene	% 1,4-cyclohexadiene	% benzene
1	8.2	60.6	31.2
2	8.7	62.5	28.6
3	8.8	61.5	29.5
4	9.0	60.4	30.6
7	8.5	55.1	36.4

Assuming equivalent loss of all three components of the organic phase, the electrolysis operated at 38% current efficiency. That is less than obtained in batch-cell operation and may be due to less than optimum transport at the cathode because of improper cell-flow characteristics or contamination of the Hg surface by impurities in the system.

Electrolysis of toluene.—Into the cell shown in Fig. 2 was placed 25% aqueous tetrabutylammonium hydroxide solution and toluene (20g). The cathode was the mercury pool and the anode was a coil of 1/8 in. OD stainless steel tubing, 8 in. long, parallel to the pool and *ca.* 2 cm above it.

The solution was maintained at 60°C with vigorous stirring and electrolyzed at 1.0A for 20 hr.

The organic layer (15.82g) was separated and GC analysis showed

CH_3 isomers — 12% (area %)

CH_3 — 74%

CH_3 — 14%

Structures were confirmed by NMR and GC-mass spectrometry.

Assuming equal loss of all three components, this represents current efficiencies of 43% to diene and 14% to methylcyclohexenes.

Electrolysis of p-*xylene.*—*p*-Xylene (20g) was reduced in the same way as toluene at 1.0A for 20.5 hr.

GC analysis of the product (14.25g) showed

CH_3 CH_3 — 68% (area %)

dimethylcyclohexenes — 13%

CH_3 CH_3 — 19%

Assuming equal losses, this represents 34% current efficiency to diene and 12% to cyclohexenes.

4-Phenylbutyric acid electrolysis.—4-Phenylbutyric acid (8.4g, 0.05 mole) was dissolved in 28% aqueous tributylethylammonium hydroxide solution (41g) and stripped on the rotary evaporator to leave a yellow oil. More 28% tributylethylammonium hydroxide solution (60 ml) was added and the homogeneous solution electrolyzed in the same way as *p*-xylene at 1.0A for 3 hr The solution was cooled, filtered (to remove mercury), and acidified with concentrated HCl. The product was extracted into ether (2 × 100 ml) which was washed, dried ($MgSO_4$), and stripped to leave a yellow oil (7.65g).

A sample was silylated with "Regisil" and analyzed by GC (SP 2100, 140°) which showed 33% conversion to 4-(2,5-dihydrophenyl) butyric acid (current efficiency = 30%). Identification confirmed by NMR and GC-MS.

Electrolysis of biphenyl.—In a 1 liter jacketed resin pot fitted with overhead stirring, Hg pool cathode (95 cm^2) and O_2-evolving DSA (TIR-2000, Diamond-Shamrock) (56 cm^2) were placed 500 ml 10% $Bu_4N^+OH^-$ and 100g biphenyl. Hot water (60°C) was circulated through the jacket. A constant current of 4A was passed through the cell for 17 hr. The oil was removed from the cell, cooled to 0°C and filtered, giving 30g filtrate. The solid and 50g more biphenyl were added to the cell and the electrolysis continued for 33 hr. The cell was allowed to cool overnight after which some biphenyl had crystallized and precipitated to the bottom of the cell. The oil layer was removed, cooled to 0°C, and more biphenyl crystallized. The mixture was filtered, giving 50g of oil. The solid, 50g of fresh biphenyl and 54 ml water were returned to the cell and the electrolysis continued overnight. Another 50g of biphenyl were added and the electrolysis continued another day. The oil was then removed, cooled, and filtered, giving 69g of oil.

The first two oil samples were combined, mixed with 100 ml H_2O, and acidified with HCl. The oil was separated and dried over $MgSO_4$ and filtered, giving 74g of dry oil. The oil was distilled on a 3 ft glass helices-packed column at 0.2 mm Hg. A forecut of 2 ml was taken before the temperature reached 55°, then, 56g of material were collected. The distillate was redistilled on a spinning-band column at 2 mm Hg. After a small forecut, 36g were collected, boiling at 73°C. The distillate was analyzed by GC-mass spectroscopy and found to contain 21% phenylcyclohexane, 35% phenylcyclohexenes, 41% 1-phenyl-1,4-cyclohexadiene, and only a trace of biphenyl. The distillation pot contained more than 50% biphenyl.

Electrolysis of naphthalene.—In a 1 liter jacketed resin pot arranged as for the biphenyl reduction above were added 500 ml 15% $Bu_4N^+OH^-$ and 100g naphthalene. The cell was maintained at 80°C. The electrolysis was run for three days at 4A. The oil was removed, cooled to 0°C, and filtered. The filtrate was washed with water and dried over $MgSO_4$, giving 60 ml of dry oil. This was distilled on a spinning-band column at 4 mm. A small forecut was obtained and, then, 25g were collected at 75°C. GC analysis indicated it contained 16% 1,4,5,8-tetrahydronaphthalene, 16% naphthalene, and unidentified components. The pot from the distillation was treated with decolorizing carbon and filtered, giving 25g of oil containing 22% 1,4,5,8-tetrahydronaphthalene, 45% 1,4-dihydronaphthalene, 17% naphthalene, and unidentified components.

Results and Discussion

The reduction of benzene to 1,4-cyclohexadiene was studied in detail to optimize the yield and current efficiency. The goal of the study was to define conditions for a commercial process in an undivided cell in aqueous solution.

Initial studies were carried out in an undivided cell with a mercury cathode, quaternary ammonium ion (Bu_3EtN^+), and benzene-water emulsions based on results of Asahi Chemical Company (18). In addition, the hydroxide form of the quaternary ammonium salt was used both to stabilize the steel (inexpensive) anode and to increase the hydrogen overpotential of

the cathode. It was found that the solution must be warm to obtain reasonable current efficiencies (Fig. 5). The warm (60°C) solution did give good current efficiencies even when most of the benzene had been converted to products (Fig. 6).

It was desirable from the standpoint of commercial cell design to have a solid cathode for this reaction, but none of the solid electrodes examined gave substantial current efficiencies for benzene reduction. Those cathode materials studied include glassy carbon, 75% Pb amalgam, 25% Cd amalgam, 3% Na amalgam (solid), Al, Wood's metal, Hg-coated Cu, Cd, Cu, Pb, and carbon.

In studies to examine alternative anodes for this reaction we were surprised to find that Pt and carbon anodes very efficiently converted 1,4-cyclohexadiene to benzene. An example is shown in Fig. 7. In that experiment a normal electrolysis in the cell shown in Fig. 2 was carried out for 4 hr using a steel anode. During that time about 20% of the benzene was converted to 1,4-cyclohexadiene. After 4 hr, the steel anode was replaced by a Pt anode after which the total conversion with time actually decreased, indicating that more benzene was being formed than consumed.

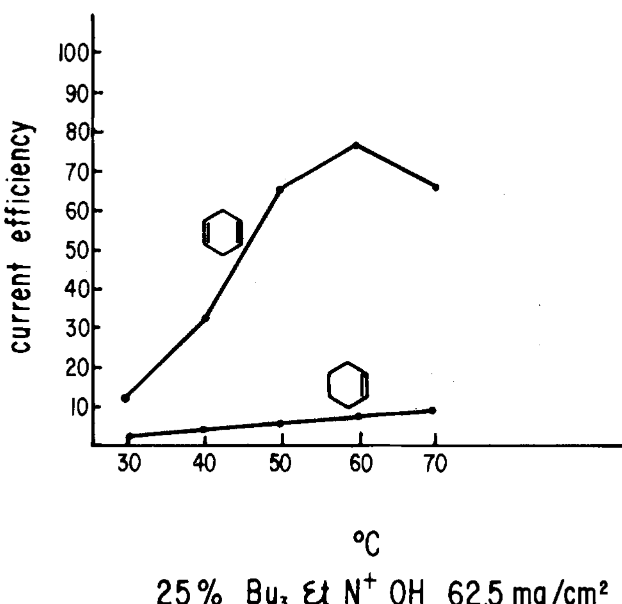

Fig. 5. Current efficiency for 1,4-cyclohexadiene formation vs. temperature.

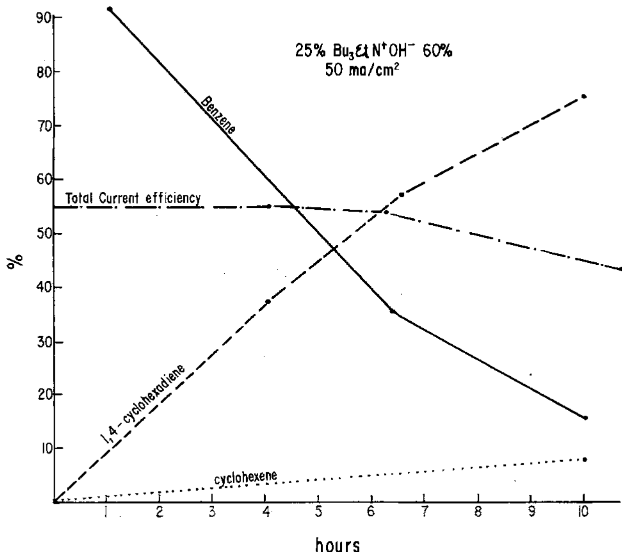

Fig. 6. Composition of the organic phase (and total current efficiency) vs. time.

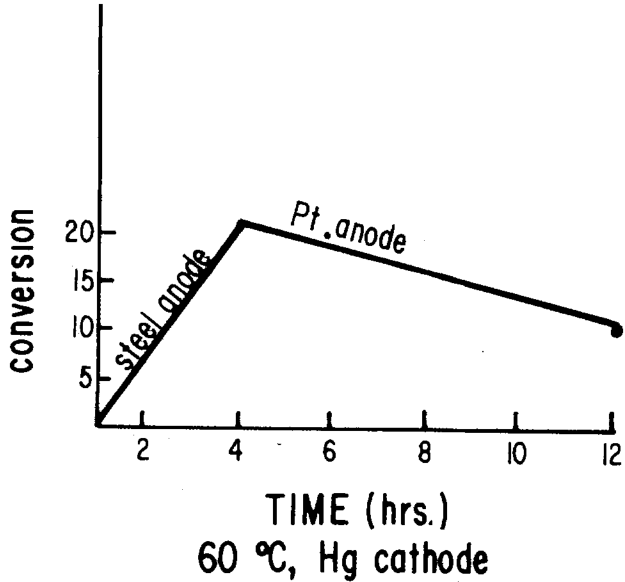

Fig. 7. Conversion of benzene to 1,4-cyclohexadiene with time using a steel and then Pt anode.

Ni and steel anodes were stable as long as the pH remained high (pH 13-14); however, lower pH led to anode corrosion. The O_2-evolving DSA (TIR-2000) seems to be the best anode for the reaction although no long-term (weeks) lifetime studies were carried out.

In a survey of the effect of various quaternary ammonium ions on the current efficiency of the reaction it was found that under certain conditions $Bu_4N^+OH^-$ gave nearly quantitative current efficiencies for benzene reduction. A comparison of $Bu_4N^+OH^-$ and $Bu_3EtN^+OH^-$ is shown in Fig. 8. Good current efficiencies (>50%) could also be obtained using $Pr_4N^+OH^-$; however, $Bu_3MeN^+OH^-$ gave poor results (30% C.E.) and only traces of benzene reduction products were formed if $Et_4N^+OH^-$ or $Me_4N^+OH^-$ were used.

The concentration of quaternary ammonium hydroxide necessary for high current efficiency is surprisingly low. Even 2% $Bu_4N^+OH^-$ gives quite high (>90%) current efficiencies at low conversions; however, that drops off significantly as more benzene is converted to products (Fig. 9). With 20-25% $Bu_4N^+OH^-$ the current efficiency for benzene reduction is maintained at >90% even at 75% conversion.

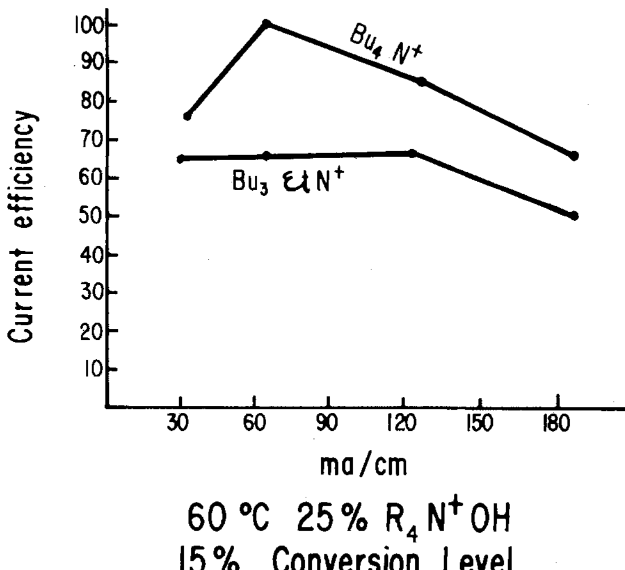

Fig. 8. Current efficiency for benzene reduction at varying current densities.

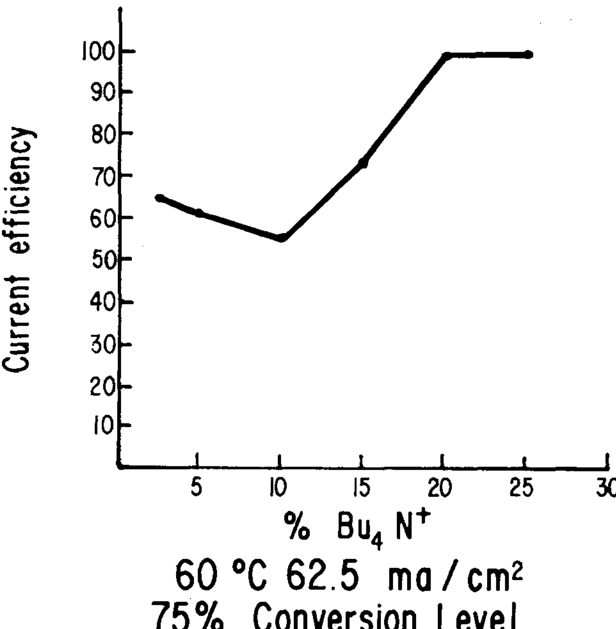

Fig. 9. Total current efficiency vs. Bu_4N^+ concentration after 75% of the benzene is consumed.

Although the main aim of this study was to define a process for 1,4-cyclohexadiene production, a few other aromatic compounds were also examined but not optimized. Toluene and p-xylene give the expected dihydro-derivatives using these reaction conditions (see Experimental section). As a totally soluble substrate, 4-phenylbutyric acid was reduced to 4-(2,5-dihydrophenyl)butyric acid. Biphenyl gave a low yield of the 1,4-dihydro-derivative, whereas naphthalene was reduced predominantly to a mixture of 1,4-dihydronaphthalene and 1,4,5,8-tetrahydronaphthalene. The last two examples were carried out with sufficient heat to maintain the hydrocarbon in the molten state.

It is interesting to speculate about the first electron-transfer step to benzene in this reaction. The data suggest that the hydrocarbon is actually dissolved in the aqueous phase since the water-soluble example (4-phenylbutyrate) was reduced as well as toluene which is similar but not very soluble in the aqueous phase. If aqueous phase solubility is required, as suggested by the poor results obtained using small (Me_4N^+, Et_4N^+) quaternary ammonium ions, it is surprising that 2% $Bu_4N^+OH^-$ gives such good current efficiencies. However, with low $Bu_4N^+OH^-$ concentrations the current efficiency decreases as conversion increases, suggesting that benzene is extracted from the aqueous phase into the organic (predominantly, 1,4-cyclohexadiene) phase.

It may be that the aromatic substrate is dissolved in the predominantly organic layer of quaternary ammonium ions at the cathode surface, and it is irrelevant whether the organic molecules come from aqueous or organic phase in a well-stirred solution.

Direct electron transfer from cathode to benzene, toluene, or xylene seems unlikely in view of the large potential required for that step. Also, one would expect reduction at other high overvoltage cathode materials, such as lead and cadmium.

A mediated reduction involving reduced quaternary ammonium ion seems unlikely because one would expect to find large quantities of by-product amines and none were detected. Another mediated reduction scheme involves quaternary ammonium amalgam (20) which could transfer an electron to the aromatic hydrocarbon to initiate the reduction. In some reactions colloidal Hg is formed in the reaction which would be consistent with amalgam formation, separation from the cathode, and subsequent oxidation (by benzene). Another argument for an amalgam mediated reduction is that only Hg gives significant current efficiencies for benzene reduction.

It is possible that solvated electrons are formed at or near the cathode surface and it is the solvated electrons that reduce the aromatic compound. The reactions appear very similar to those in which solvated electrons are, in fact, present (Na in NH_3).

Further work is required to answer the mechanistic questions.

To more nearly approximate a commercial process for the reduction of benzene to 1,4-cyclohexadiene it was necessary to devise a continuous reaction scheme involving a flow-through cell. Early attempts at construction of a flow cell having an Hg pool cathode led to rapid loss of Hg from the cell at quite low flow rates. Eventually, a cell was built (Fig. 3) which allowed a reasonable flow between anode and cathode without significant Hg loss from the cell.

In the cell shown in Fig. 3 the solution enters the center tube, flows radially out between cathode and anode, around and then behind the anode, and eventually out the exit port. Hg that separates from the cathode is carried up behind the anode where the solution velocity slows, allowing the Hg to drop to the back of the anode. The Hg droplets combine on the back surface of the anode and eventually drop back into the cathode.

This cell in combination with the components shown in Fig. 4 formed a continuous reaction system which operated for at least a week without interruption or operator interference (except to fill and empty reservoirs). A description of the system is given in the Experimental section.

Electron Transfer Reactions at Passive Tin Electrodes

S. Kapusta* and N. Hackerman**

Chemistry Department, Rice University, Houston, Texas 77001

ABSTRACT

The kinetics of charge transfer between passive tin electrodes and solutions of $K_3Fe(CN)_6$-$K_4Fe(CN)_6$ have been studied in the *p*H range 7.5-10.0 and the temperature range 1°-50°C. The results have been analyzed on the basis of the quantum theories of electron transfer at oxide covered metal electrodes, and semi-quantitative agreement between theory and experiment was found. The electrochemical behavior of passive tin ranges from almost metallic, for very thin films, to that typical of n-type semiconductors, for thick films. Exchange current densities are, in all cases, much smaller than those measured on bare metal electrodes.

In a series of papers (1-3) we recently characterized the kinetics of growth and the semiconducting properties of passive films anodically grown on tin in borate buffer solutions. Both the thickness and the electronic properties of these films were found to be functions of the growing potential. A sharp distinction was seen between films grown at low potentials (below 1.7V *vs.* saturated calomel electrode), called thin films, and those grown at higher potentials. In both cases they were nonstoichiometric, having n-type conductivity due to an excess of tin cations. Measured flatband potentials were -0.25 and $+0.5$V at $pH = 8.4$ for thin and thick films, respectively. In both cases a dependence of -64 mV/*p*H was observed.

Donor concentrations could not be determined due to the frequency dispersion of the capacity data. However, using a value of $\epsilon = 10$ for the dielectric constant (*i.e.*, that corresponding to SnO_2), and the results obtained at high frequencies, the estimated donor concentrations ranged between 1×10^{19} and $1 \times 10^{21}/cm^3$, depending on the growing potential. The bandgap of these films could not be determined from optical measurements, because of the existence of an indirect transition at 2.55 eV. The bandgap is expected to be close to that of bulk SnO_2 (*i.e.*, 3.7 eV).

The kinetics of charge transfer across these films should reflect their semiconducting properties. It is well established that the rates of redox reactions at oxide covered metal electrodes are slower than at bare metal electrodes. The decrease in the rate constant depends strongly on film thickness, composition, and type of conductivity, as well as on the relative position of the rest potential of the redox couple and the flatband potential (4-8). According to the quantum mechanical theories of electron transfer (9-11) the main effect of very thin films (about 1 nm thick) is to increase the tunneling distance between the metal and the electrolyte (12). The tunnel probability decreases exponentially with the thickness of the barrier, and under normal conditions so does the exchange current (13).

For thicker films (several nm), on the other hand, direct tunneling from the metal cannot make a significant contribution to the overall current and these electrodes are expected to behave as semiconductor electrodes, with participation of electronic states inside the oxide in the electron transfer reactions. The boundary between both mechanisms (*i.e.*, direct tunneling from the metal and tunneling from states in the film) will depend on the electronic characteristics of both the film and the redox couple.

Although several studies of the electrochemical behavior of SnO_2 have been published [*e.g.*, (14-17)], only one of them was concerned with the semiconducting properties of passive tin (17). The kinetics of the $Fe(CN)_6^{4/3-}$ redox couple was found to be slower than on Pt under similar conditions, although no blocking of the oxidation reaction was observed as was the case for SnO_2 samples. The authors concluded that the thickness of the passive film (3 nm) was too low to show typical semiconductor behavior. More recently (18) passive tin was reported to be a very bad catalyst of the oxygen electroreduction reaction in alkaline solutions. The intrinsic complexity of this reaction, however, does not allow one to draw any conclusions on the rate of single electron transfer steps.

In the present work, we report on the kinetics of the $K_3Fe(CN)_6$-$K_4Fe(CN)_6$ redox couple on passive tin electrodes in borate buffer solutions in the *p*H range 7.5-10.0, and for different thickness of the passive film. The results are analyzed on the basis of the quantum theories of charge transfer at oxide covered metal electrodes.

Key words: passive tin, quantum theory, electron tunneling.

Experimental

Details of electrode preparation and film growth are given elsewhere (1-3). The redox system used was $K_3Fe(CN)_6$-$K_4Fe(CN)_6$ dissolved in 0.2M borate buffer solutions of *p*H between 7.5 and 10.0. Films were grown for 16 hr at constant potential in pure borate buffer solutions, which were then replaced by deaerated redox solutions under nitrogen pressure. Solutions were continually deoxygenated by a stream of purified nitrogen. The temperature was maintained within 0.2°C of the chosen value (23°C unless otherwise stated) by means of a water thermostat.

Polarization curves were measured under steady-state conditions using a rotating disk electrode technique to eliminate diffusion effects by extrapolation to infinite rotation speed. Other details of the experimental setup have been given (1). Previous results indicate that the film thickness does not change (within $\pm$ 1%) during potentiostatic polarization for up to 1 hr at potentials lying between the growing potential and that of massive oxide reduction (about -1.0V *vs.* saturated calomel electrode). These conditions were satisfied during polarization measurements.

Since in many cases extrapolation of the anodic and cathodic Tafel regions to the redox potential yielded two different values of the exchange current density, i_o, a linear polarization technique within $\pm$ 5 mV of the rest potential was used to determine i_o (19). When no difference between the anodic and cathodic extrapolated values was observed, i_o measured by linear polarization agreed with this single value.

All potentials are referred to the saturated calomel electrode (SCE) at the working temperature. All currents are expressed in terms of the projected electrode area (1 cm^2) without consideration for any roughness factor, estimated at about 2.

Results

The redox potential is rapidly established on passive tin electrodes, reaching a constant value equal to that measured on Pt ($\pm$ 1 mV) within 5 min after intro-

duction of the redox couple, for thin films, and within 1 hr for thick films. This behavior is usually observed on passive metal electrodes. Both types of films show a Nernstian behavior over at least 2 orders of concentration of the reduced and oxidized species (0.1-0.0025M). The redox potential does not depend appreciably on the redox couple concentration over that same range.

Steady-state current readings were obtained within 5 min (typically 30 sec) after imposing a potential step. These relatively slow transients can be attributed to a redistribution of charges in the film, since, as mentioned earlier, no changes in film thickness (determined by the cathodic reduction charge, Q_c) were observed. At least 5 different rotation speeds were used (between 600 and 3000 rpm) in order to extrapolate to infinite rotation speed.

Figure 1 shows typical polarization curves measured on tin electrodes passivated for 16 hr at 1.0, 1.4, 1.6, 1.8, 2.0, and 2.1V, after 1 hr of immersion in the redox electrolyte. Film thicknesses are expressed in terms of the reduction charge Q_c. A linear relationship between Q_c and film thickness d can be assumed. Considering a uniform film, we estimated that $Q_c = 2.4$ mC/cm^2 corresponds to $d = 2.5$ nm, and $Q_c = 20$ mC/cm^2 to $d = 22$ nm. Reflectometric results confirm both this estimate and the above assumption.

The exchange current density decreases continually with Q_c (*i.e.*, d) over the whole range of growing potentials here considered, as is evident from the results in Fig. 2. The decrease in log i_o is approximately linear with Q_c for thin films, although it tends to a constant value for thick films. In all cases i_o are much smaller than those measured on Pt under similar conditions *i.e.*, about 0.1 A/cm^2. As mentioned in the introduction, this result is expected on most passive electrodes, especially being n-type semiconductors.

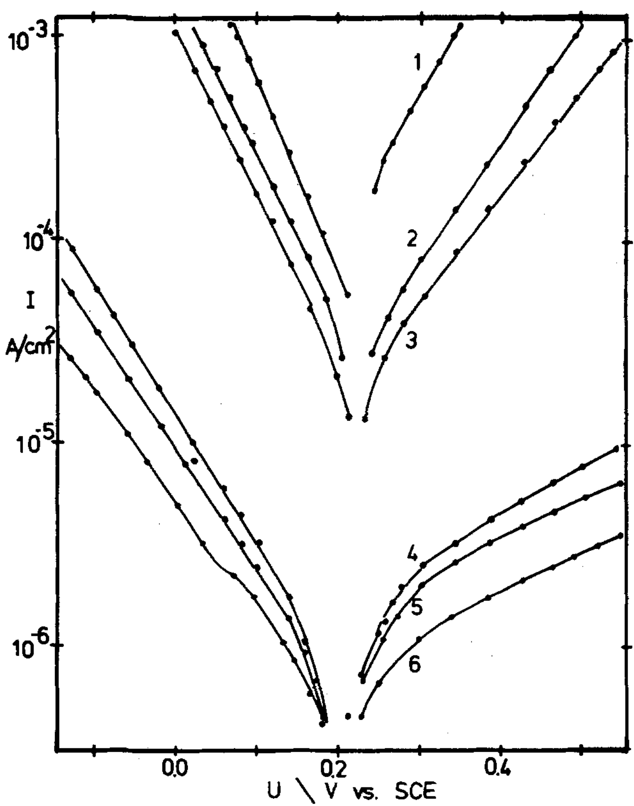

Fig. 1. Steady-state anodic and cathodic polarization curves measured on tin electrodes passivated for 16 hr at the following potentials: curve 1, 1.0V, Q_c = 2.0 mC/cm^2; curve 2, 1.4V, Q_c = 2.3 mC/cm^2; curve 3, 1.6V, Q_c = 2.5 mC/cm^2; curve 4, 1.8V, Q_c = 20 mC/cm^2; curve 5, 2.0V, Q_c = 35 mC/cm^2; curve 6, 2.1V, Q_c = 55 mC/cm^2. pH = 9.1. T = 23°C. Redox potential, U_r = 0.21V vs. SCE. Redox couple concentration = 0.05M.

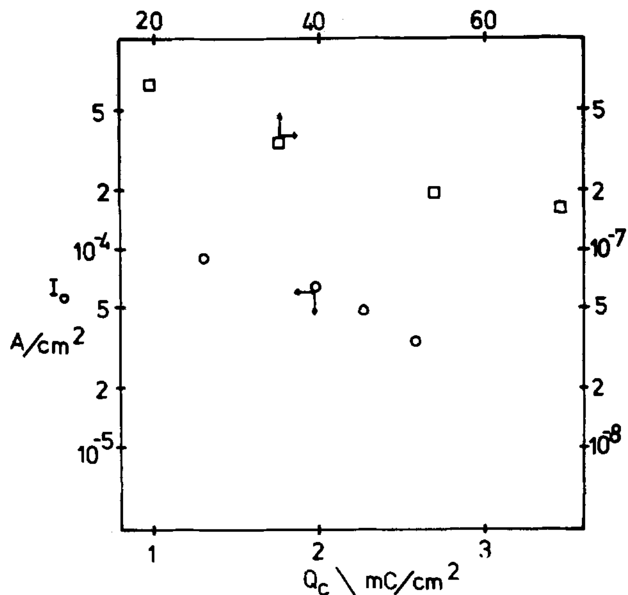

Fig. 2. Dependence of the exchange current density, i_o, on cathodic reduction charge, Q_c, for thin (○) and thick (□) films. Same conditions as in Fig. 1.

Transfer coefficients for the cathodic Tafel regions, α_c, are close to 0.5 for thin films, and between 0.4 and 0.45 for thick films. Anodic transfer coefficients, α_a, on the other hand, decrease continually with Q_c, having a value of 0.45 for films grown at 1.0V (Q_c = 2.0 mC/cm^2) but only 0.2 for films grown at 2.1V (Q_c = 65 mC/cm^2). The blocking of the oxidation reaction is typical of n-type semiconductors, and these results reflect the increasing semiconducting properties of thicker films.

Extrapolation of the anodic and cathodic Tafel regions to the redox potential yields a single i_o value for thin films, equal to that measured by linear polarization. For thick films, on the other hand, two different i_o values are obtained from cathodic and anodic extrapolation. As a rule, i_o anodic is larger than i_o cathodic, although their relative magnitude depends on the pH value. A similar behavior has been reported for passive iron (20).

Figure 3 shows the Arrhenius plots obtained for two of the films in Fig. 1, *i.e.*, those grown at 1.0 and 1.8V. The good linearity of the results indicates that activation energies are independent of temperature in the range here considered. Anodic and cathodic transfer coefficients were also found to be independent of tem-

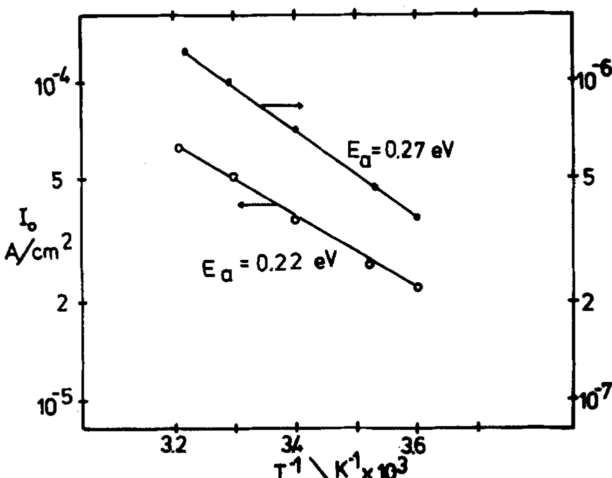

Fig. 3. Arrhenius plots of the exchange current density measured on films grown at 1.0V, Q_c = 2.0 mC/cm^2 (lower line) and at 1.8V, Q_c = 20 mC/cm^2 (upper line). Other conditions as in Fig. 1.

perature. Values of E_a ranging from 0.2 eV for films grown at 0.8V to 0.3 eV for films grown at 2.1V have been measured. The corresponding values are 0.19 eV on Au (21) and 0.17 eV on Pt (22). There is therefore a systematic dependence of E_a on Q_c, although no quantitative relationship could be derived.

Both the shape of the polarization curves and the values of the exchange currents measured on thick films depend on the solution pH, as is apparent from the results shown in Fig. 4. A small shoulder develops in the cathodic branch at the highest pH values and at potentials near the redox potential. The reaction order with respect to pH, defined as

$$\delta \log i_o / \delta \text{ pH}$$

is close to 0.5. The dependence of the exchange currents measured on thin films was much smaller, with a reaction order near zero.

Figure 5 shows the dependence of the exchange current measured on a thick film grown at 1.8V (Q_c = 20 mC/cm²) on the concentration of the redox couple. The reaction order is 1, as is also the case for thin films. For bare metal electrodes, the reaction order should be equal to the sum of the anodic and cathodic transfer coefficients. For this same electrode, $\alpha_a + \alpha_c = 0.7$. This result should again be attributed to the semiconducting properties of the film.

Discussion

Only the general concepts of the quantum theory of charge transfer in condensed media are given below, as far as they are needed in order to explain the experimental results.

Electron transfer proceeds by tunneling between occupied and unoccupied states of equal energy in the electrode and in the electrolyte. The transfer reaction is considered much faster than the thermal oscillations of the heavy particles. In the electrolyte the electronic states are localized at the reduced and oxidized species. The energy depends on the configuration of the re-

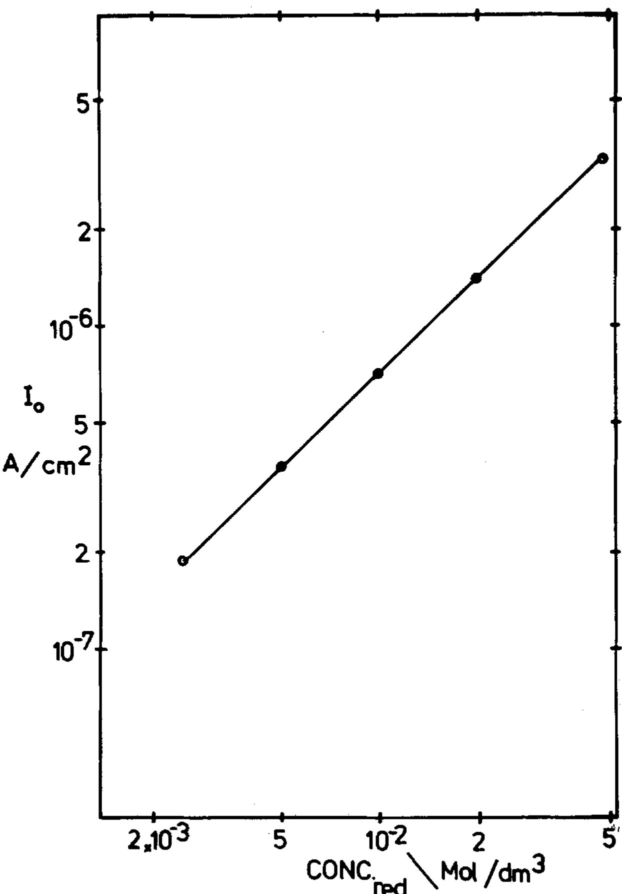

Fig. 5. Redox couple concentration dependence of the exchange current density measured on a film grown at 1.8V for 16 hr. Other conditions similar to those in Fig. 1. Note small change in ratio of reduced to oxidized form alters the quantities on the abscissa very slightly.

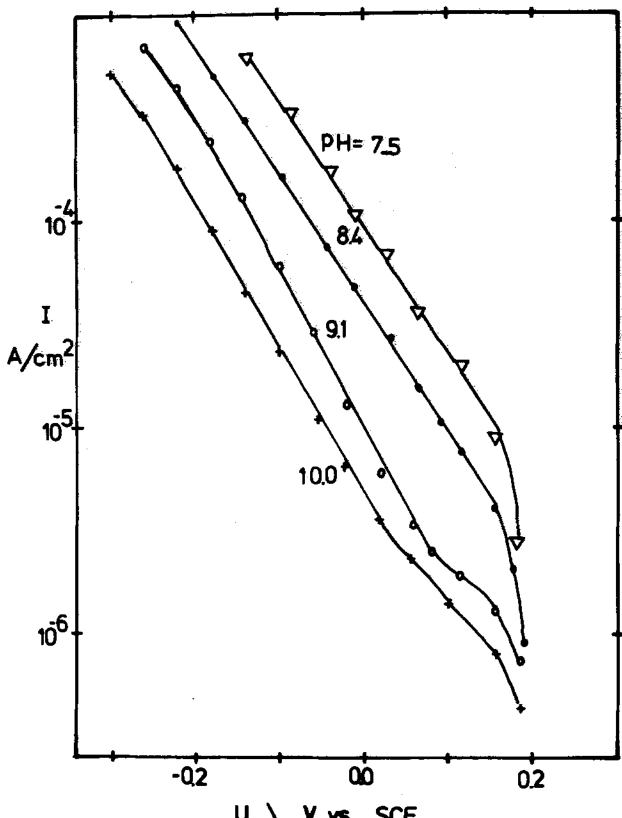

Fig. 4. pH dependence of the cathodic branch of the polarization curve, for a film grown at 1.9V for 16 hr, Q_c = 30 mC/cm². Redox couple concentration = 0.05M. Temperature = 23°C.

active complex. Thermal fluctuations produce a Gaussian distribution around the most probable state. Assuming for simplicity that the width of this Gaussian distribution is the same for the reduced and oxidized species, the Fermi energy $E_{F,el}$ at which occupied and empty states in the electrolyte have equal probability differs from the energy of the most probable state by a common reorganization energy, λ. The density of states function in the electrolyte is usually described by (14)

$$D_r = \exp - (E - E_{F,el} + \lambda)^2/4kT\lambda \quad [1]$$

$$D_o = \exp - (E - E_{F,el} - \lambda)^2/4kT\lambda \quad [2]$$

for the reduced and oxidized states, respectively. Here E is the energy.

The rates of electrochemical reactions are proportional to the total flux of reactive complex to the electrode, Zc_r; to the tunneling probability, T; and to the probability, $\rho(1 - f)$, of finding unoccupied electronic states in the electrode and D_r, of finding occupied states in the electrolyte, for the anodic current, and vice versa for the cathodic current

$$J^+ (E) = F Z C_r \rho(1 - f) D_r T \quad [3]$$

$$J^- (E) = F Z C_o \rho(f) D_o T \quad [4]$$

where fluxes are given as the product of a velocity, Z, and the concentration, C. The measured current density can be written as the normalized integral of [3] and [4] at any energy level

$$J = 1/E_o \times \left[\int_0^\infty J^+ (E)\, dE - \int_0^\infty J^- (E)\, dE \right] \quad [5]$$

Here E_o is the normalization constant.

In a metal electrode the probability of finding occupied states can be described by Fermi's distribution function

$$f(E) = [1 + \exp - (E - E_F)/kT]^{-1} \quad [6]$$

where E_F is the Fermi level of the metal. The probability of finding unoccupied states is then $1 - f(E)$. The maximum of $J(E)$ occurs at the Fermi level even under irreversible conditions, when

$$e\eta = E_{F,el} - E_F \quad [7]$$

η being the overvoltage. For $\eta << 2\lambda/e$ straight Tafel lines having transfer coefficients close to 0.5 are expected. The tunneling probability is high on bare metal electrodes ($T_o \simeq 1$), independent of electrode potential. This probability decreases from T_o to T if a film separates the metal from the electrolyte. The energy barrier assumes a trapezoidal shape due to the electric field inside the film. Therefore, T is usually given as

$$T = T_o \exp[-4\pi d (2m^* \Delta E_b)^{1/2}/h] \quad [8]$$

Here d is the film thickness, m^* is the effective mass of the tunneling electrons, h is Planck's constant, and ΔE_b is the average barrier height. T decreases exponentially with d (11), as shown in Fig. 2. An order of magnitude for the barrier height can be calculated using the results of Fig. 2 for thin films, and an estimated value of 0.5 for m^*. The result (*i.e.*, 0.2 eV) is reasonable for these type of films. Therefore, the experimental results obtained on thin films can be explained considering direct tunneling of electrons from the metal and through the oxide layer.

As the film thickens an additional current density due to electron exchange with electronic states in the oxide becomes important. For very thick films the current due to direct electron exchange with the metal becomes negligible, and electron transfer to and from the oxide predominates. The thickness at which the transition from one process to the other takes place will depend on the semiconducting properties of the film and on the nature of the redox couple. Assuming that the valence band does not significantly contribute to the observed C.D. (*i.e.*, wide bandgap), electron tunneling proceeds to and from states in the conduction band below the surface. Both the height of the barrier and the tunneling distance depend on band bending and therefore on electrode potential and solution pH.

The tunneling probability can now be expressed as

$$T = T_o \exp\{-8\pi/3h\, [m^* (E_c^s - E_c^b)]^{1/2}\}\, x \quad [9]$$

and the tunneling distance, x, as

$$x = (2/e)(\epsilon\, \epsilon_o/2N_d)^{1/2}\, [(E_c^s - E_c^b)^{1/2} - (E - E_c^b)^{1/2}] \quad [10]$$

where e is the electron charge, E_c^s and E_c^b are the energy of the conduction band of the oxide at the surface and in the bulk, respectively; N_d is the donor concentration; ϵ_o is the permittivity of free space, and ϵ the dielectric constant of the film.

The total overvoltage, η, is composed of changes in the electrical potential inside the film, η_s, and in the Helmholtz layer, η_h.

$$\eta = \eta_s + \eta_h \quad [11]$$

It is therefore necessary to calculate η_s for any value of η. This is usually done following the procedure outlined in Ref. (6). The final expression for the current density is

$$j = j' \int_{E_c^b}^{E_c^s} \frac{\exp\{-r(E_c^s - E)^{1/2}[(E_c^s - E_c^b)^{1/2} - (E - E_c^b)^{1/2}]\}}{1 + \exp\{-(E - E_F)/kT\}} \exp\left\{-\frac{(E - E_{F,el} + \lambda)^2}{4kT\lambda}\right\} dE$$
$$- j' \int_{E_c^b}^{E_c^s} \frac{\exp\{-r(E_c^s - E)^{1/2}[(E_c^s - E_c^b)^{1/2} - (E - E_c^b)^{1/2}]\}}{1 + \exp\{+(E - E_F)/kT\}} \exp\left\{-\frac{(E - E_{F,el} - \lambda)^2}{4kT\lambda}\right\} dE \quad [12]$$

where

$$r = (16\pi/3he)(m^* \epsilon_o \epsilon/N_d)^{1/2} \quad [13]$$

and J' is a constant containing all energy independent factors. The integration must be performed numerically, choosing an upper limit equal or greater than E_c^s.

Several assumptions are implicit in this derivation: (*i*) The contribution of electrons having a nonvanishing momentum parallel to the reaction interface has been neglected. In this way the 3-dimensional barrier could be approximated by a triangular cross-section barrier. (*ii*) The WKB-factor (Eq. [9]) is a good approximation to the tunneling probability only far from the flatband potential. (*iii*) Equation [10] does not consider the location of the donor level below the conduction band. For anodic films this level lies several tenths of eV below E_c and results in partial donor dissociation. This effect could however be partially compensated during calculation of η_s, and by the choice of E_F.

Schmickler (21) used an exact expression of the Poisson-Boltzmann equation in order to calculate the shape of the space charge barrier, *i.e.*, $x(E)$. Although he considered E_c^b fixed and assumed that E_c^s changed with overvoltage η, the opposite convention seems more convenient, since E_c^s is usually fixed by external conditions (*i.e.*, solution pH). Therefore (24)

$$x = L_d \int_v^{v_s} du/\mathbf{F}(u) \quad [14]$$

where

$$v(x) = [E_c^b - E(x)]/kT \quad [15]$$

$$v_s = v(0) \quad [16]$$

$$\mathbf{F}(v) = \sqrt{2}\, \{(1 - g)(e^v - v - 1) + \ln[1 + (e^v - 1)g] - vg\}^{1/2} \quad [17]$$

$$g = [1 + \exp(E_d/kT)]^{-1} \quad [18]$$

E_d is the energy of the donor level with respect to the bottom of the conduction band in the bulk, E_c^b, and L_d is called the Debye length and is equal to $(2/e)(\epsilon\, \epsilon_o/2N_d)^{1/2}$.

The final expression of the C.D. is found introducing [14] instead of [10] for the tunneling distance. It is also possible to simplify this integral by noting that, from [14]

$$d\, E_c(x)/dx = -(kT/L_d)\mathbf{F}(v) \quad [19]$$

It is not therefore necessary to calculate explicitly $x(E)$. The C.D. is then expressed as

$$j = j' \int_{E_c^b}^{E_c^s} \frac{\exp\left\{-\int_{x_1}^{x_2} [E_c(x) - E]^{1/2} dx\right\}}{1 + \exp[-(E - E_f)/kT]} \cdot \exp\left[\frac{-(E - E_{f,el} + E_\lambda)^2}{4kTE_\lambda}\right] dE \quad [20]$$
$$- j' \int_{E_c^b}^{E_c^s} \frac{\exp\left\{-\int_{x_1}^{x_2} [E_c(x) - E)]^{1/2} dx\right\}}{1 + \exp[+(E - E_f)/kT]} \cdot \exp\left[\frac{-(E - E_{f,el} - E_\lambda)^2}{4kTE_\lambda}\right] dE$$

Equation [20] must be numerically integrated in order to obtain theoretical $J(E)$ curves. This can be done by substituting the integration terms by experimentally accessible quantities. Introducing the integration variable $y = E - E_c^b$, and calling U_r' the redox potential with respect to the flatband potential, *i.e.*, $U'_r = U_r - U_{FB}$, then

$$E_c{}^s - E_c{}^b = e(U'_r + \eta)$$
$$E - E_{F,el} = e(y - \eta + E_d/2) \quad [21]$$
$$E_c{}^s - E = e(U'_r + \eta - y)$$
$$E - E_F = e(y + E_d/2)$$

Absolute values of J cannot be obtained because J' is unknown. Reliable values of N_d, U_{FB}, and ϵ for thick films on tin are also undetermined (2, 3). Therefore, an indirect approach was used, and the best values of these parameters were estimated from fitting of theoretical curves to the experimental results. Using $m^* = 0.5$ (2) and $\lambda = 1.2$ eV (25), the polarization curves shown in Fig. 6 and 7 have been obtained with the parameters indicated. A change of 60 mV/pH in U_{FB} was assumed (2).

The values of the film parameters obtained from the fitting procedure, *i.e.*, $U_{FB} = -0.25$V; $E_d = -0.5$ eV with respect to the conduction band; $\epsilon = 10$; and the range of N_d between 1.1×10^{20} and 3.3×10^{19}/cm^3, coincide fairly well with those given in the introduction for thin films. This result indicates that the differences observed in the electrical and photoelectrochemical properties between thin and thick films are not intrinsic, but can be attributed to the presence of discontinuities in the film or recombination centers, as postulated before (2, 3).

In any case the similarities between the theoretical calculations and the experimental results are mostly qualitative. Theory for instance predicts a stronger potential dependence of the cathodic branch of the polarization curves and weaker for the anodic branch. At the same time, the experimentally measured pH dependence of the current density is smaller than expected. The increase in activation energy with film thickness (*i.e.*, decrease in donor concentration) can be at best explained only qualitatively. According to Schmickler (23) the maximum of the current distribution among the different electronic states is shifted towards higher values of the electronic energy with

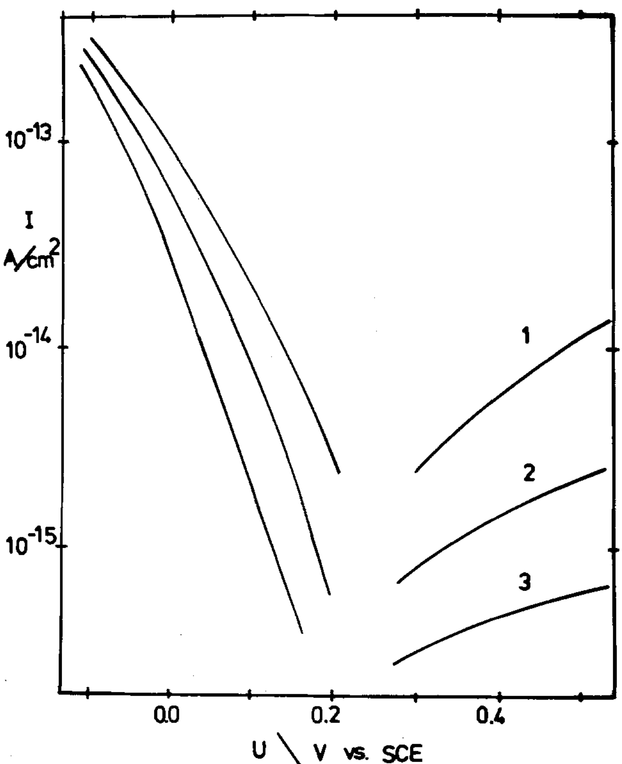

Fig. 6. Anodic and cathodic polarization curves calculated by numerical integration of Eq. [20], using the following parameters: pH $= 9.1$; $\epsilon = 10$; $U_{FB} = -0.25$V; $U_r = 0.21$V; $E_d = 0.5$ eV below the conduction band; $E_F = 0.25$ eV below the conduction band; and $N_d = 1 \times 10^{20}$; 2.5×10^{19}; 3.3×10^{19}/cm^3.

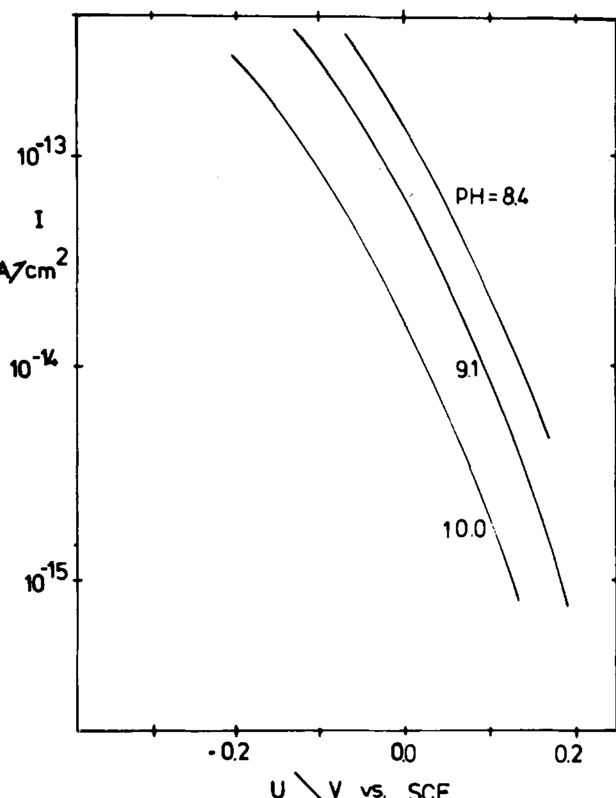

Fig. 7. Cathodic polarization curves calculated by numerical integration of Eq. [20], using the same parameters as in curve 2 in Fig. 6, and a change in U_{FB} of 60 mV/pH.

increasing Debye length, *i.e.*, decreasing donor concentration, for thick films, and with increasing thickness for thin films where direct tunneling from the metal still makes an appreciable contribution. These effects are observed (Fig. 3), although a quantitative correlation with theory is not possible.

The differences in the i_o values obtained by extrapolation of the anodic and cathodic Tafel regions for thick films is inconsistent with the present model. A possible explanation for this behavior is a resonance tunneling mechanism (23, 26) involving localized states within the bandgap of the film. The location of this resonance level, E_r, can in principle be determined from the difference between anodic, $i_o{}^a$, and cathodic, $i_o{}^c$, values of the exchange current density. Alternatively, it can also be determined from the increase in the activation energy of the redox reaction on passive electrodes with respect to bare metal electrodes (26). Defining

$$\Delta = kt\ (\ln i_o{}^c - i_o{}^a) \quad [22]$$

then

$$|\Delta| = |E_r|/kT \quad [23]$$

On the other hand, the activation energy measured on passive electrodes is

$$E_a = E_a{}^o + e\eta_{FB}/2 + |E_r|/2 \quad [24]$$

where $E_a{}^o$ is the activation energy measured on bare metal electrodes, and η_{FB} the overvoltage at the flatband potential.

Using the results shown in Fig. 1 for films grown at 2.0V to calculate Δ, and a value of $E_a = 0.28$ eV for this same film, values of $E_r = 0.15$ to 0.2 eV below the conduction band have been calculated using Eq. [23] and [24], respectively. Further evidence for this resonance tunneling mechanism could not be obtained from the experimental results.

The contribution of other electron conduction mechanisms cannot be ruled out considering the above mentioned differences between theory and experiments. The effects of cracks in the passive film, or the presence of recombination centers or surface states, previ-

ously proposed to explain anomalous behavior of thick films, cannot be estimated from the present results.

Conclusions

The kinetics of charge transfer at passive tin electrodes can be explained on a semi-quantitative basis using the quantum mechanical theories developed for oxide covered metal electrodes. On thin films the main contribution to the measured current density arises from direct electron exchange between the metal and the redox electrolyte. The effect of the film is to increase the tunneling distance of electrons. Therefore, the exchange current decreases exponentially with film thickness. The activation energy increases continually from the value measured on Pt (0.17 eV), although a quantitative correlation, for instance between the increase in E_a and the barrier height, could not be obtained.

The behavior of thick films is similar to that of n-type semiconductor electrodes. Since in this case the direct tunneling contribution should be negligibly small, electronic states in the oxide participate in the exchange reaction and provide the main contribution to the total current. The effect of film thickness in this case is only secondary, and can be related to a decrease in the donor concentration. The activation energy also decreases with film thickness, although this can be attributed to an increase in the Debye length with decreasing donor concentration.

The experimental results, however, show some differences from the theoretical predictions, both in the magnitude of the anodic and cathodic Tafel slopes and in the pH dependence of the exchange current. At the same time, extrapolation of the anodic and cathodic Tafel regions to the rest potential yields different values of the exchange current. This later effect could be caused by a resonance tunneling phenomenon, involving localized states within the bandgap of the oxide. No conclusive evidence for this process was obtained.

The parameters describing the semiconducting properties of the thick films (*i.e.*, U_{FB}, N_d, and ϵ) obtained from fitting the theoretically calculated polarization curves to the experimental results coincide fairly well with those estimated for thin films. This indicates that the difference between both types of films might be due only to the presence of imperfections in the thick films. The effect of these imperfections (*e.g.*, cracks, recombination centers, or surface states) on the electrical and photoelectrochemical response of the electrodes has already been shown. Their participation in electron transfer reactions, however, is difficult to estimate.

ABSTRACT

The oxidation of perylene (PeH) in aprotic melts containing primarily $SbCl_3$ was studied spectroelectrochemically. In molten $SbCl_3$ containing 0.038m CsCl at 100°C, PeH is oxidized at 0.26V relative to the $SbCl_3$/Sb, saturated CsCl reference electrode to form a stable solution of the radical cation $PeH^{+\cdot}$. The optical absorption spectrum (500-900 nm) of this cation has five maxima with the highest at 545 nm ($\epsilon = 4.2 \times 10^4$). In molten $SbCl_3$ containing 0.079m $AlCl_3$ at 100°C PeH is spontaneously oxidized to $PeH^{+\cdot}$ by reduction of $SbCl_3$. In this melt electrochemical oxidation of $PeH^{+\cdot}$ to form the dication PeH^{2+} at 100°C occurs at 0.97V relative to the $SbCl_3$/Sb, saturated CsCl reference electrode. The optical absorption spectrum (400-800 nm) of PeH^{2+} consists of two overlapping bands with a peak at 533 nm ($\epsilon = 3.7 \times 10^4$).

Polycyclic aromatic hydrocarbons ArH are often soluble (1) in molten $SbCl_3$[5] and can be oxidized chemically or electrochemically to form their radical cations $ArH^{+\cdot}$ (5-7). Many of these cations are quite stable in $SbCl_3$, in spite of the elevated temperature, and some have been characterized by electron spin resonance (ESR) spectra at high resolution (8, 9). For three arenes, perylene PeH, 9,10-diphenylanthracene, and coronene, electrochemical studies (6) indicated that the radical cation in $SbCl_3$ could be oxidized further to form what was presumed to be the arene dication ArH^{2+}, and the visible absorption spectrum of the presumed perylene dication PeH^{2+} was subsequently published. However this absorption spectrum is quite different from that for PeH^{2+} prepared in superacid media, where the cation has been identified by its proton NMR spectrum (11, 12).

As part of a study of arene cations in molten $SbCl_3$ we have developed an electrochemical cell in which potentiometric, coulometric, and spectrometric methods may be used in concert to generate and characterize species formed by arene oxidation. The present paper describes the application of this cell to a clarification of the species formed by the oxidation of perylene and its radical cation.

Experimental

Materials.—Antimony(III) chloride (from three vendors, viz.: Ultrapure grade from Ventron Alfa Products; 99.0% min. from Mallinckrodt; and 99.0% min. from Matheson, Coleman, and Bell) was further purified by sublimation, distillation, and when very high purity material was needed, by repeated zone refining.

Aluminum chloride was made by reacting 99.9999% Al metal with semiconductor-grade HCl according to a procedure previously described (13). Potassium chloride and cesium chloride (both Suprapur grade, E. Merck, Darmstadt) were further purified by purging the molten salts with HCl(g) and then Ar.

Antimony metal (99.99%, Bradley Mining Company) was vacuum cast into 3 mm diam single crystals that were drilled and threaded to serve as electrodes.

[5] mp, 73°C (2); bp, 223°C (3); crit. pt., 521°C (4).

Perylene (99+%, Gold Label from Aldrich Chemical Company) was either used without purification or, for purposes of spectrometric measurements, was recrystallized from toluene.

Instrumentation.—Differential pulse polarography and cyclic voltammetry experiments were performed with a Princeton Applied Research Model 174A Polarographic Analyzer, and coulometric measurements with a Model 173 Potentiostat/Galvanostat equipped with a Model 179 Digital Coulometer. A Hewlett-Packard Model 7045A X-Y recorder was used for data display.

Absorption spectra were measured with a Tektronix Model J20 silicon-vidicon rapid-scan spectrometer controlled by a Digital Equipment Corporation PDP-8/I minicomputer. A detailed description of the spectrophotometer and computerized data sampling and processing has been published (14). A Heath Company Model EU-701-50 tungsten/deuterium source served as the light source.

A resistance furnace made from Pyrex tubing and Ni/Cr heating wire was used. In order to minimize convection in the optical cell during the experiments, a thermal gradient kept the lower end of the cell at a temperature 2°-5°C lower than the rest. The furnace temperature was controlled by a Leeds and Northrup Series 80 3-action D.A.T. Controller in connection with a calibrated AZAR module and a Speedomax H recorder. During spectrometric measurements a furnace was used that had side arms to allow the light beam to pass.

Electro-optical cell.—The electrolytic cell (Fig. 1a) was made of Pyrex glass with a silica spectrometric cell fused to the lower end. Electrodes were inserted through threaded glass joints equipped with Teflon bushings and FETFE O-ring seals (Ace Glass). There was room for six joints on top of each cell, one central and five others spaced around it. Not all are shown in Fig. 1a. The usual electrode arrangement consisted of two working electrodes, one counterelectrode, one reference electrode, and one optical electrode. The sixth joint was used for evacuation of the cell. The temperature of the electrolyte was monitored with a thermocouple placed in a well fused to the top of the cell.

The working electrodes were made either of vitreous carbon (supplied by IMC Industry Group) or Pt wire, whereas the counterelectrode was fabricated from Pt foil. Electrode wires were sealed with vacuum-tight, standard tungsten/Pyrex seals. In most experiments

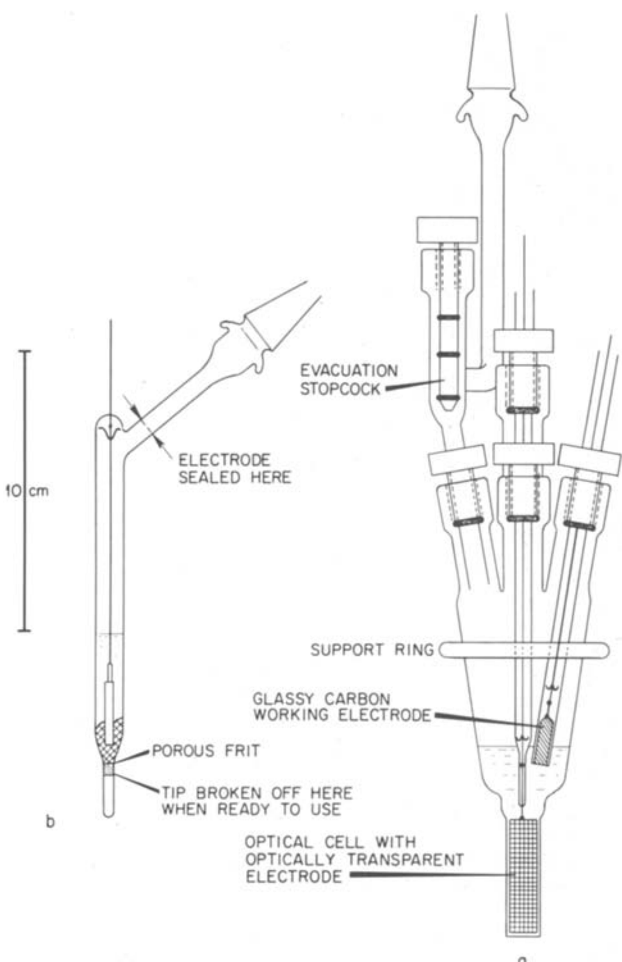

Fig. 1. (a) Electro-optical cell. Only two electrodes and an evacuation stopcock are shown for clarity. (b) Reference electrode.

the cell contained both a glassy carbon and a Pt working electrode.

Optically transmitting electrodes (OTE), which also were used in coulometric measurements, were made either from reticulated vitreous carbon (RVC, a glassy carbon foam from Fluorocarbon Company) or from Pt-wire screen. The RVC material was sliced into thin plates which fitted into the optical cells (1-2 cm path length). The characteristics of the vitreous carbon OTE have previously been described (15).

Reference electrode.—The reference electrode (Fig. 1b) was built to fit the bushings on top of the cell. The active electrode was a rod of Sb metal that was drilled and threaded on one end. At Pt pin, screwed into this end, provided good electrical contact. Electrical contact with the main electrolyte was through a porous alumina frit (Radiometer Copenhagen). As shown in Fig. 1b, this frit was sealed into a small, closed tube so that the electrode could be sealed under vacuum after it was filled with the salt. Then, the salt was melted and allowed to soak the frit so that when it resolidified, it formed a gas-tight plug. The closed tube over the frit was broken off just prior to first usage and thereafter the electrode could be used repeatedly.

The electrolyte in the Sb(III)/Sb reference electrode was $SbCl_3$ saturated with solid $Cs_3Sb_2Cl_9$ present in excess. This compound is the equilibrium solid phase when excess CsCl is added to molten $SbCl_3$ at temperatures within the range of interest here, 70°-200°C (16). We prepared $Cs_3Sb_2Cl_9$ by fusing stoichiometric amounts of $SbCl_3$ and CsCl together in a thick-walled silica ampul. The alternative procedure of trying to equilibrate solid CsCl with molten $SbCl_3$ was unsatisfactory because the rate at which CsCl reacted to form the equilibrium compound was very slow even at temperatures near the melting point of $Cs_3Sb_2Cl_9$. The electrode described here is designated $SbCl_3$/Sb, sat. CsCl.

Note that the corresponding electrodes made with KCl or RbCl would not be satisfactory over the temperature range of interest here because in the KCl-$SbCl_3$ system the solid phase in equilibrium with molten $SbCl_3$ changes from $KSbCl_4$ to $K_3Sb_2Cl_6$ at 110°C (17) while in the RbCl-$SbCl_3$ system a similar change occurs at 125°C (18). Phase diagrams are not available for the LiCl-$SbCl_3$ and NaCl-$SbCl_3$ systems.

Experimental procedure.—All inorganic salts were handled in an Ar-atmosphere glove box with H_2O and O_2 content kept constantly below 1 ppm. Perylene was weighed on a microbalance outside the glove box since it was neither hygroscopic nor air sensitive.

The cell was evacuated prior to each experiment and closed off by means of a bakeable, Teflon high-vacuum valve. Fusion of the electrolyte took place in the furnace. When all of the electrolyte was molten, it was necessary to expel liquid from the optical electrode compartment and refill from the main body of liquid several times in order to ensure complete mixing. Liquid cannot be poured out of the optical electrode compartment because the narrow space is filled with electrode grid and holds liquid like a sponge. Therefore, liquid was expelled by vapors of electrolyte boiled in the compartment with a hot-air gun.

Concentration units.—Molal concentrations (m) used here are calculated as moles of solute per kilogram of $SbCl_3$.

Results and Discussion

Solvent characterization.—Prior studies (6, 19-22) of the chemical and electrochemical properties of molten $SbCl_3$ that relate to the present investigation are summarized by the following, widely used model.[6] $SbCl_3$, a molecular liquid, is assumed to be slightly ionized

$$SbCl_3 \rightleftarrows SbCl_2^+ + Cl^- \quad [1]$$

where $SbCl_2^+$ is a Lewis acid and Cl^- is a base.

Aluminum chloride is a very strong Cl^- acceptor and reacts with $SbCl_3$

$$AlCl_3 + SbCl_3 \rightarrow AlCl_4^- + SbCl_2^+ \quad [2]$$

where $AlCl_4^-$ in $SbCl_3$ is neither a Cl^- donor nor acceptor. Alkali metal chlorides MCl, on the other hand, separate into their constituent ions, M^+ and Cl^-, and are strong Cl^- donors. When MCl and $AlCl_3$ are both present, neutralization, the reverse of Eq. [1], occurs leaving M^+ and $AlCl_4^-$ as spectator ions. We shall refer to a melt as neutral if $[Cl^-] = [SbCl_2^+]$, as basic if $[Cl^-] > [SbCl_2^+]$, and as acidic if $[Cl^-] < [SbCl_2^+]$.

Typical background cyclic voltammograms obtained in our research at a glassy carbon electrode at 100°C are shown in Fig. 2. The curve in Fig. 2a is for 0.038m CsCl (~0.1M), a basic melt, while Fig. 2b is the background sweep for 0.077m $AlCl_3$ (~0.1M), an acidic melt. The available potential range is quite close to that which Bauer and co-workers (7) reported for the $SbCl_3$-KCl and $SbCl_3$-$AlCl_3$ systems at 99°C with a Sb(III)/Sb, sat. KCl reference electrode.

The lower potential limit corresponds to the reduction of $SbCl_3$ to the metal

$$SbCl_3 + 3e = Sb + 3Cl^- \quad [3]$$

while the upper limit corresponds to oxidation to the pentachloride (6)

$$SbCl_3 + 2Cl^- = SbCl_5 + 2e \quad [4]$$

[6] There is evidence (23, 24) that the structural entities responsible for Lewis acid-base chemistry in $SbCl_3$ melts are more complex than those postulated in this model. Nevertheless, the model is quite useful for purposes of correlating many important facts about the acid-base chemistry and at present there is no better model available.

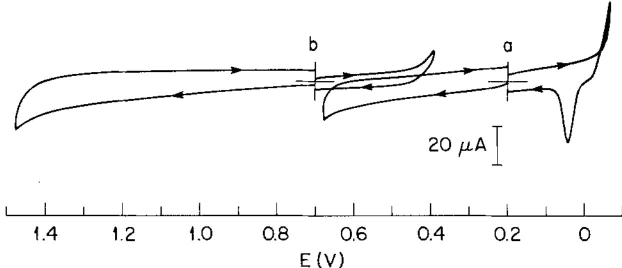

Fig. 2. Background cyclic voltammograms at a glassy carbon working electrode at 100°C. Sweep rate was 200 mV sec^{-1}. Electrode area was 0.071 cm^2. Melts were (a) 0.038m CsCl in $SbCl_3$ and (b) 0.077m $AlCl_3$ in $SbCl_3$.

Because of the role of Cl^- in these reactions, the solvent becomes more oxidizing and also more difficult to oxidize as the system progresses from basic to acidic. It is conventional to measure relative acidity in chloride melts in terms of $pCl = -\log [Cl^-]$. Thus, the potentials of the couples Sb(III)/Sb and Sb(V)/Sb(III) increase with increasing pCl.

In our work both Pt and glassy carbon working electrodes were used, but glassy carbon was found to be the most suitable. The available potential range with a Pt electrode was considerably smaller (~0.2V) because the reduction of $SbCl_3$ to antimony metal took place at a more positive potential than the theoretical value, probably because of Sb-Pt alloy formation (25) at the electrode.

The curves in Fig. 2 are smooth and featureless except for a peak that is caused by reoxidation of reduced antimony metal near the cathodic potential limit in the basic melt (Fig. 2a). Deposition of Sb on the glassy carbon surface took place at a small overpotential. This can be seen from the loop the curve makes and crosses itself; the stripping of Sb metal took place at a more anodic potential than that at which it was deposited.

Electrochemical oxidation of perylene.—Typical cyclic voltammograms of 1.60×10^{-3}m perylene in $SbCl_3$ are shown in Fig. 3. Here Fig. 3a was obtained in the basic 0.038m CsCl melt while Fig. 3b shows voltammograms of perylene in the acidic 0.079m $AlCl_3$ melt. All curves were obtained at 100°C at a glassy carbon working electrode. Sweep rates were 20, 50, 100, and 200 mV sec^{-1}, respectively.

There is one well-defined oxidation wave for each solution with an equally well-defined reduction wave on the return sweep. The separation between the two oxidation waves is 0.72V, which is close to that observed by Bauer and co-workers (7) in $SbCl_3$-KCl and $SbCl_3$-$AlCl_3$ melts. As we shall demonstrate below with spectroscopic and additional electrochemical data, the neutral perylene molecule is stable in the basic melt and the oxidation wave is due to the formation of the perylene radical cation $PeH^{+\cdot}$ thus

$$PeH = PeH^{+\cdot} + e \quad [5]$$

In the acidic melt perylene is chemically oxidized to form a stable solution of $PeH^{+\cdot}$ in the following way (9)

$$3PeH + 3SbCl_2^+ = 3PeH^{+\cdot} + Sb + 2SbCl_3 \quad [6]$$

For this system the oxidation wave represents the oxidation of $PeH^{+\cdot}$ to the perylene dication PeH^{2+} thus

$$PeH^{+\cdot} = PeH^{2+} + e \quad [7]$$

In both the basic and acidic melts the perylene concentration was nearly equal but the two waves were not completely similar, as illustrated for the highest scan-rates in Fig. 3. Both the height and the slope of the oxidation wave in the acidic melt have somewhat lower values than in the basic solvent. By using Nicholson's (26, 27) method (with correction for the charging current) we found that within experimental error the cathodic to anodic current ratios were unity in the basic system whereas a tendency toward lower ratios with decreasing scan rates was found in the acidic melt (Table I). This might indicate that there is a slow follow-up reaction in the acidic melt which makes less PeH^{2+} available for reduction at slow scan rates.

The half-wave potentials, $E_{1/2}$, were calculated from the anodic half-peak potentials

$$E_{1/2} = E_{p/2} + 1.09\ RT/nF \quad [8]$$

under the assumption that charge transfer is a one-electron reversible process. The results are listed in Table I.

Differential pulse polarograms obtained in the same melts are shown in Fig. 4. We found two well-defined, symmetric peaks that correspond to the formation of the radical cation, shown in Fig. 4a, and the dication, shown in Fig. 4b. A shoulder obtained at low anodic potential in Fig. 4b was probably due to the oxidation of a minor impurity.

The relation between the peak potential, E_p, for differential pulse polarography and the half-wave potential may be expressed as (28)

$$E_{1/2} = E_p + \Delta E/2 \quad [9]$$

where ΔE is the pulse amplitude. By using a small pulse amplitude, $\Delta E \leq 10$ mV, the correction term was reduced until it approached the uncertainty with which the peak potential could be read from the graph. The half-wave potentials derived from Eq. [9] are 0.26 and 0.97V for the oxidation to $PeH^{+\cdot}$ and PeH^{2+}, respectively. The values correspond to those calculated from cyclic voltammetry (Table I).

The use of platinum working electrodes gave identical peak potentials, but side reactions appeared to take

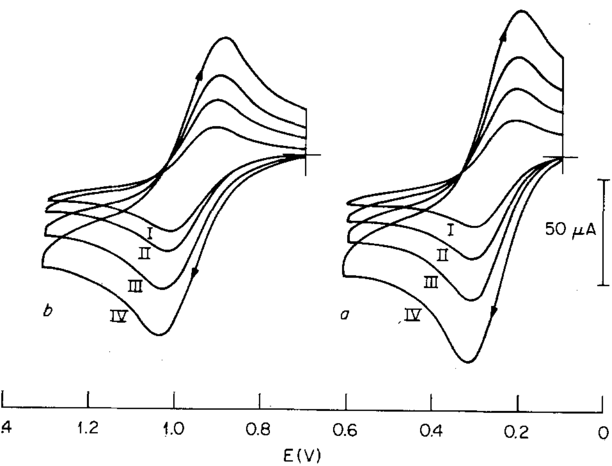

Fig. 3. Cyclic voltammograms at a glassy carbon working electrode in 1.60×10^{-3}m perylene at 100°C. Sweep rates were (I) 20 mV sec^{-1}, (II) 50 mV sec^{-1}, (III) 100 mV sec^{-1}, and (IV) 200 mV sec^{-1}. Electrode area was 0.071 cm^2. Solvents were (a) 0.038m CsCl in $SbCl_3$ and (b) 0.079m $AlCl_3$ in $SbCl_3$.

* i_{pc} and i_{pa} are cathodic and anodic peak currents, respectively.

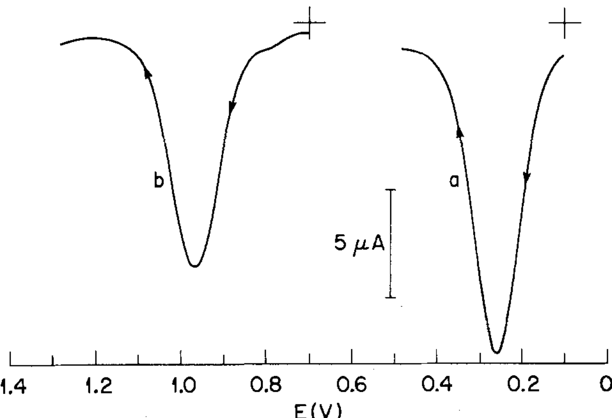

Fig. 4. Differential pulse polarogram at a glassy carbon working electrode in 1.60 × 10^{-3}m perylene at 100°C. Sweep rate was 2 mV sec^{-1} and pulse amplitude was 10 mV. Electrode area was 0.071 cm^2. Solvents were (a) 0.038m CsCl in $SbCl_3$ and (b) 0.079m $AlCl_3$ in $SbCl_3$.

place more readily on the metal surface and often resulted in additional oxidation waves. Also platinum electrodes were not as durable as those made of glassy carbon. We found it difficult to avoid a small amount of alloying by Sb that decreased the reproducibility of the electrodes upon reuse. This effect was probably due to surface defects that resulted from oxidation of Sb during cleaning.

Thin-layer coulometry.—An exhaustive electrolysis of the substrate in the optical cell may easily be carried out provided that mass transport due to convection between the electrolysis compartment and the bulk melt is eliminated or made very small. Figure 5a shows a coulogram obtained when 355 μliters of $SbCl_3$ containing 7.75 × 10^{-4}m perylene and 0.38m (~1M) KCl was electrolyzed at a Pt screen electrode. The potential was switched from +0.10 to +0.50V followed by switching back to +0.10V after ~1900 sec elapsed time as shown in Fig. 5a, where the curve gives the net charge Q added to the system. When electrolysis started, there was a rapid increase in Q. Then, after about 1400 sec, Q leveled off as the current went to zero. This showed that all perylene in the electrolysis chamber had been oxidized to its radical cation. When the potential was switched back to +0.1V the reverse reaction occurred

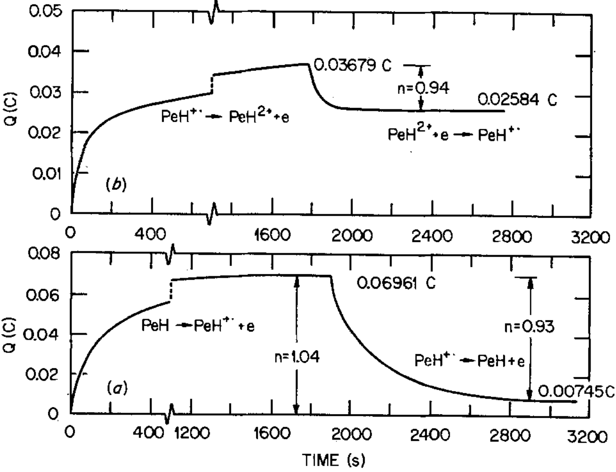

Fig. 5. (a) Thin layer coulogram of 7.75 × 10^{-4}m perylene in 0.38m KCl at 100°C. Potential was switched from +0.10 to +0.50V at start of curve and back to +0.10V after ~1900 sec. Electrolyte volume was 355 μliters. Electrode was Pt screen. (b) Thin-layer coulogram of 1.37 × 10^{-4}m perylene in 0.76m $AlCl_3$ at 125°C. Potential was switched from +0.69 to +1.15V at start of curve and back to +0.69V after ~1800 sec. Electrolyte volume was 380 μliters. Electrode was glassy carbon.

in which the radical cations were reduced to neutral molecules at the electrode. As the current flowed in the opposite direction, Q decreased and finally reached a steady, nonzero value. This value is due to both the diffusion of radical cations out of the cell during electrolysis and to their decomposition into nonreducible species. The formal number of electrons n for the oxidation step was 1.04 and for the reverse reduction was 0.93.

The reason for substituting KCl for CsCl in the coulometric study was the following: a fairly substantial electrolyte concentration was necessary in order to keep the conductivity high enough to allow electrolysis to take place throughout the optical cell rather than just near the top of the cell. Our procedure was to begin with a basic melt and make various measurements including coulometry, then add a known excess of $AlCl_3$ and again make various measurements, this time on an acidic solution. When this was done with CsCl at the concentration level necessary for good conductivity, subsequent addition of excess $AlCl_3$ caused precipitation of solid $CsAlCl_4$. This trouble was not encountered with KCl. We note that in going from CsCl solutions to KCl solutions the oxidation potential of perylene was shifted by only 30 mV, from 0.26V in 0.038m CsCl to 0.29V in 0.38m KCl at 100°C.

As previously discussed the second oxidation step to form the dication (Eq. [7]) appeared to be followed by a reaction on the electrode. Electrolysis of 380 μliters of 1.37 × 10^{-4}m perylene in an acidic melt containing 0.76m $AlCl_3$ gave no horizontal plateau within ~1800 sec that would have been indicative of an exhaustive electrolysis (Fig. 5b). (This electrolysis was done at a glassy carbon electrode at +1.15V and 125°C.) On the contrary, the net charge added to the system at this time showed a much larger Q than the theoretical quantity for a one-electron oxidation according to Eq. [7].

When the potential was switched back to +0.69V an exhaustive reduction of the generated dication took place and the charge Q corresponded to the formal number of 0.94 electrons for the reduction step.

The oxidation potential of the Sb(V)/Sb(III) couple is close to the applied potential in this acidic melt and only the presence of a considerable overpotential (5, 6) made it possible to extend the electrochemical window to the value shown in Fig. 2. Therefore, the excess charge consumed during the oxidation process was most probably due to an irreversible reaction involving Sb(V).

Absorption spectra of perylene cations.—Figure 6 shows absorption spectra of perylene radical cations recorded during electrolysis of a solution containing 5.83 × 10^{-5}m perylene and 0.38m KCl at a Pt screen electrode at 100°C. Spectrum I is the background prior to electrolysis and the other spectra display successive increases in radical cation concentration for successively longer electrolysis times up to 600 sec. The ϵ values for $PeH^{+\cdot}$ in the basic melt (Table II) were calculated from the known concentrations of the substrate based on the assumption of complete oxidation to PeH^+ after 600 sec. These radical cation spectra have five absorption bands in the range 500-900 nm. As shown in Table II the wavelengths and molar absorptivity of the band maxima agree well with prior measurements of the perylene radical cation spectrum in molten $SbCl_3$ (10, 29) and in other solvents (30, 31).

The spectra in Fig. 6 increase in intensity in a mathematically monotonous way at all wavelengths and thus give no evidence for the formation of more than one species. However, when electrolysis was carried beyond 600 sec, new bands appeared at wavelengths longer than 740 nm while the intense radical cation band at 546 nm decreased in intensity and its peak shifted toward longer wavelengths. The shift in existing bands and the appearance of new ones are probably due to the formation of arenium ions and condensation products as have been observed (34, 35) when other

* Electrochemically oxidized.

arenes were chemically oxidized in $SbCl_3$-$AlCl_3$ melts. However, in the case of $PeH^{+\cdot}$ these follow-up reactions were much slower than those previously reported, a result that probably depends in part on the low concentration of $PeH^{+\cdot}$ in our experiments as well as the relatively high stability of $PeH^{+\cdot}$

According to prior investigations (6, 7, 9) perylene is chemically oxidized in acidic melts by the reaction given in Eq. [6]. Accordingly, when we prepared a melt containing 6.38 × 10^{-5}m perylene and 0.77m $AlCl_3$ in $SbCl_3$, the absorption spectrum prior to electrolysis was that of $PeH^{+\cdot}$ as shown in Fig. 7a. The molar absorptivities of the band maxima of this chemically generated $PeH^{+\cdot}$ (Table II) are quite close to those we obtained for electrolytically generated $PeH^{+\cdot}$. This fact provides independent evidence that electrolysis after 600 sec was virtually complete.

When the acidic melt was electrochemically oxidized until absorption due to $PeH^{+\cdot}$ was gone, we obtained the spectrum shown in Fig. 7b. This spectrum was recorded after an electrolysis time of 600 sec at an anodic potential of +1.30V. Similar results were obtained at a glassy carbon optical electrode, and repeated oxidation-reduction-oxidation of the perylene ions showed no significant change in absorption values for PeH^{2+} after its formation was completed. Upon monitoring the spectrum of the electrogenerated dication over a period of 900 sec (open cell circuit), we found no significant decay. These results from the spectroscopic and coulometric experiments in the acidic melt do not appear to be fully consistent with the cyclic voltammetric results. This discrepancy might, however, be due to the different concentrations of perylene in these experiments, which differ by about one order of magnitude. An optimal substrate concentration for cyclic voltammetry is too high for spectroscopic work in a 1 mm optical cell because of the very high absorptivity of the perylene cation.

Table III. Spectral characteristics of the perylene dication in various solvents

* Electrochemically oxidized.

The molar absorptivity value given in Table III is calculated on the basis of a total conversion to PeH^{2+} in the electrode compartment.

The spectrum of the species shown in Fig. 7b is quite different from that which Bauer and co-workers (10) reported for the dication formed by electrolysis of $PeH^{+\cdot}$ in $SbCl_3$-$AlCl_3$, but it is quite similar to that previously reported for PeH^{2+} in superacid media (11, 12) where its identity was established by proton-NMR spectroscopy (11). We believe that Bauer and co-workers did prepare PeH^{2+} because the $E_{1/2}$ value they found agrees with ours, but this dication must have subsequently reacted prior to the time the spectrum was measured. It is interesting that the spectrum they reported as being that of PeH^{2+} is, in fact, rather like that of the perylenium ion, PeH_2^+ (32, 33), which,

as we noted above, is also a likely product of the downstream reactions of $PeH^{+\cdot}$.

Conductance Studies in Amide-Water Mixtures

V. Lithium and Cesium Bromides in Formamide-Water Mixtures at 25°C

Lal Bahadur and M. V. Ramanamurti

Department of Chemistry, Banaras Hindu University, Varanasi 221005, India

ABSTRACT

Conductance data for lithium and cesium bromides in formamide-water mixtures ($88 \leq D \leq 111$; $0.89 \leq \eta \leq 3.29$ cp) are reported at 25°C in the concentration range 0.01-0.10*N*. Solvent properties like density, viscosity, and dielectric constant are also reported at the same temperature. The conductance data have been analyzed by the Fuoss (1978) equation. Viscosities of the solvent mixtures show a slight negative deviation from ideal behavior without showing any maximum or minimum in the solvent composition-viscosity curve, indicating overall slightly less structured solvent mixtures than that expected from ideal behavior. The limiting equivalent conductance for each of the salts decreases with the increase of formamide content in the solvent mixtures over the whole range of the solvent composition, but the variation is not such that it can give a constant value for the Walden product. In any given solvent mixture $\Lambda_0(CsBr) > \Lambda_0(LiBr)$. Both electrolytes were found to be practically completely ionized ($K_A < 4.0$) in all solvent mixtures studied. Although, a wide range of values of the distance parameter R was found to be acceptable for both the salts in each solvent mixture for fit to $\sigma \leq 1.1\ \sigma_{min.}$, best values ($\sigma = \sigma_{min.}$) of R derived for CsBr were found to be almost constant (2.18 ± 0.19Å) in all solvent mixtures while no systematic trend was observed for LiBr.

In the first paper (1) of this series of investigations, the conductance data for Et_4NBr and Bu_4NBr in formamide-water mixtures were reported. In this communication little attention was paid to the variation of Walden product with solvent composition because Walden product was almost constant up to 50 mole percent (m/o) formamide in a solvent mixture. But later studies (2-4) in aqueous binary mixtures of other amides (DMF and DMA) showed quite systematic variation of the Walden product with a maximum at a solvent composition around 10 m/o amide for simple (2) as well as tetraalkylammonium salts (3, 4). Keeping these observations in view, previous results in formamide-water mixtures (1) were reconsidered and it was interesting to note that if $\Lambda_0\eta$ values for Et_4NBr and Bu_4NBr in pure water (5) [$\Lambda_0\eta$ (Et_4NBr) = 0.986; $\Lambda_0\eta$ (Bu_4NBr) = 0.868] and in pure formamide (6) [$\Lambda_0\eta$ (Et_4NBr) = 0.931; $\Lambda_0\eta$ (Bu_4NBr = 0.790] are incorporated in our results, a maximum in the Walden product becomes obvious at solvent composition around 70 m/o formamide for both the salts (Fig. 1). Since the existence of a maximum in the Walden product for tetraalkylammonium salts in DMA-water mixtures (3, 4) could successfully be attributed to hydrophobic dehydration of tetraalkylammonium ions due to presence of cosolvent (DMA), Fig. 1 clearly indicates that hydrophobic dehydration of Et_4N^+ and Bu_4N^+ by cosolvent (formamide) becomes effective only in the solvent composition region sufficiently rich in formamide, not in the water-rich region as was found in the case of disubstituted amide (DMA)-water mixtures (3, 4). Somsen and co-workers (7-9) also arrived at a similar conclusion in the case of formamide-water mixtures on the basis of their studies on enthalpies of tetraalkylammonium bromides in various amide-water mixtures. They observed that the presence of formamide reduces the ability of hydrophobic ions to promote the hydrogen-bonded structure in aqueous formamide containing more than 30 m/o formamide.

In view of these observations it was of interest to study a few simple salts also in formamide-water mixtures with particular attention to the trend of the Walden product with change in solvent composition. The present paper deals with the conductance data for LiBr and CsBr in formamide-water mixtures at 25°C along with the properties (density, viscosity, and dielectric constant) of the solvent mixtures.

Key words: lithium bromide, cesium bromide, formamide-water mixture, conductance, Walden product.

Experimental

Water, KCl, and formamide used in present work were purified as described earlier (1). LiBr (E. Merck) and CsBr (L. R., Hopkin and Williams, London) were recrystallized from conductivity water and dried in a vacuum desiccator.

All experimental techniques and procedures for the measurements of viscosities and densities of the solvent mixtures and conductance of electrolyte solutions have been described earlier in detail (2).

Results and Discussion

Densities, viscosities, and dielectric constants of the solvent mixtures (formamide-water) at 25°C are re-

* Values taken from the literature [Ref. (10)].

ported in Table I. Dielectric constant data incorporated in this table have been taken from the literature (10). Equivalent conductance, Λ, of electrolyte solutions is given in Table II as a function of concentration, c, for both the electrolytes in solvent mixtures of different compositions.

For a given set of conductance data (c_j, Λ_j; $j = 1, n$), the three adjustable parameters Λ_0, K_A, and R were derived by solving the following three equations by successive approximations

$$\Lambda = \nu[\Lambda_0(1 + RX) + EL] \quad [1]$$

$$\nu = 1 - K_A c \nu^2 f^2 \quad [2]$$

$$\ln f = -\beta\kappa/2(1 + \kappa R) \quad [3]$$

Here R is cosphere diameter (11) and RX and EL are the relaxation and hydrodynamic terms, respectively. Other terms have their usual meanings. Expressions used for RX and EL were the same as those derived by Fuoss (12). Computational methods adopted here for the analysis of the conductance data were the same as those suggested by Fuoss and co-workers (11), and computer programs of Fuoss (1975) equations were used after the relevant portions of these programs corresponding to the expressions for RX and EL terms were modified according to new expressions (12) used for these two terms. Detailed description of the method of analysis has been given in our previous communication (3). Various parameters thus derived from the conductance data are summarized in Table III. Here it should be noted that Eq. [1] and [2] are the same as the Fuoss (1975) equation (11) except for the use of new expressions for RX and EL derived by Fuoss himself in his modified version (12) of the conductance-concentration relation. The introduction of the term α, as suggested by Fuoss (12), and consequently the replacement of ν by $[1 - \alpha(1 - \nu)]$ in Eq. [1] and K_A by $K_R/(1 - \alpha)$ in Eq. [2] seem to be redundant. Hence, these were avoided in our previous publications (3, 4) also. The reason for this is as follows: Fuoss in his recent publication (12) modified his previous equation (11) for the conductance-concentration relation in two ways. His first modification was the change in certain boundary conditions in the derivation of the expressions for the relaxation and hydrodynamic terms. This change resulted in different values of the coefficients of interpolation formulas for RX and EL as compared to the previous one (11). This change has been incorporated by us while using the equations for the analysis of the conductance data of present and previous studies (3, 4) also. His second modification was regarding ion pairs. According to this, all the ions for which center-to-center distance r is in the range $a \leq r \leq R$ are designated as diffusion pairs, with concentration $c(1 - \nu)$. All these ion pairs were considered as nonconducting in Fuoss' previous treatment (11), but in his recent publication (12) these diffusion pairs are divided into two subsets, dipolar pairs and virtual dipoles. It has been argued that only a fraction α of diffusion pairs [*i.e.*, $c\alpha(1 - \nu)$] diffuse to contact to form nonconducting dipolar pairs (contact pairs, $r = a$), the rest of the diffusion pairs (virtual dipoles) taking part in conductance in addition to free ions. Thus, a fraction $[1 - \alpha(1 - \nu)]$ of the total ionic concentration takes part in conductance instead of ν as in previous treatment (11). The introduction of this new term α, therefore, resulted in the replacement of ν by $[1 - \alpha(1 - \nu)]$ in Eq. [1] and K_A by $K_R/(1 - \alpha)$ in Eq. [2]. But in our opinion, all of the ion pairs, if they are at all considered as paired, should be taken as nonconducting, otherwise if they are conducting there is no reason why they should be accounted as paired ions so far as conductance property is concerned. In addition to this, the distance parameter R introduced in the Fuoss (1975) equation is by definition "the average radius of the spheres containing partner ion for paired ions" and these ions are excluded from the population of free ions taking part in conductance. Since, this R value is derived from the experimentally observed

* $X_{(range)}$ ($X = K_A$ or R) corresponds to $\sigma \leq 1.1\ \sigma_{min.}$ while others are best-fit values corresponding to $\sigma = \sigma_{min.}$.

values of conductance, it is obvious that this R includes only nonconducting ion pairs. Due to these reservations, the changes due to introduction of the term α have not been incorporated in Eq. [1] and [2] in the present work as well as in previous publications (3, 4).

The viscosity variation with composition of the solvent mixtures is represented in Fig. 2. As is clear from the figure, viscosity of this binary mixture increases monotonically with the increase of formamide content in the solvent mixture. No minimum or maximum was observed in the viscosity indicating total absence of structural enhancement of either of the components by the presence of the other in this binary mixture. However, the viscosity curve is slightly concave upward indicating a small negative deviation from the ideal behavior, contrary to dialkylated amide-water mixtures which show positive deviations (2-4). A similar difference between formamide-water and disubstituted amide-water mixtures has been observed in respect to other properties such as molar excess heat capacities (13); dielectric constants (10), and reorientational correlation times of the constituent molecules (14) of these binary mixtures. This negative deviation in viscosity of formamide-water mixtures shows the structure-breaking effect, although to a very small extent, of either of the components on the other one of

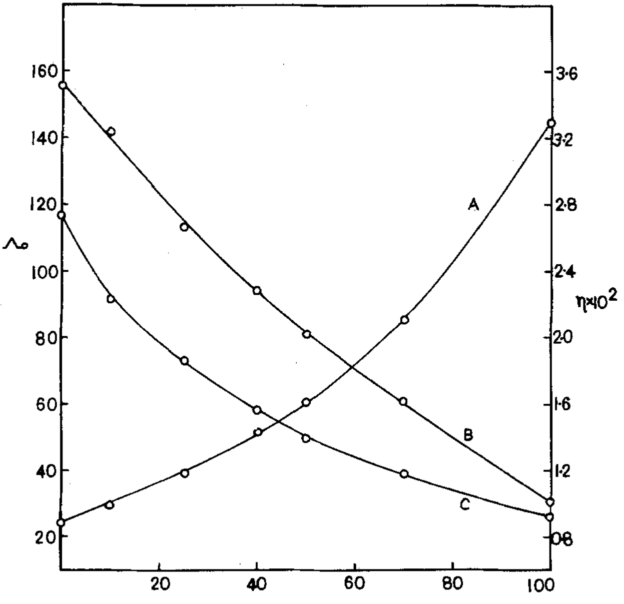

Fig. 2. Variation of viscosity of the solvent, η, and limiting equivalent conductance, Λ_0, with composition of the solvent mixtures. A— ; B—Λ_0(CsBr); C—Λ_0(LiBr).

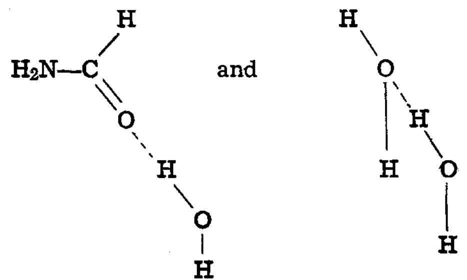
the solvent mixtures. Rohdewal and Moldner (10) proposed loose association between formamide and water molecules because according to their conclusion there is an association between amide and water molecules in general and the sign of the deviation depends on the strength of the hydrogen bond and ordering of the solvent dipoles. Rupley (15) has suggested that formamide molecules disrupt the structure of water, which was corroborated subsequently by Hinton and Ladner (16) on the basis of NMR shifts of water protons with increasing amount of formamide. Visser and Somsen (13) observed negative molar excess heat capacities for different solvent composition of this binary mixture, which indicated the structure-breaking effect of formamide on water.

In the light of these conclusions drawn by previous workers, coupled with the consideration of the present findings, it can be concluded that formamide molecules have a distinct influence on breaking the structure of water primarily, followed by the individual water molecules getting loosely associated with formamide molecules through hydrogen bonding, resulting in an overall slightly less structured solvent than that expected from an ideal behavior. Hydrogen bond energies in the case of



are almost the same (17). This may be one of the reasons for higher compatibility of the two solvents.

The variation of limiting equivalent conductance, Λ_0, with solvent composition for each of the salts studied is shown in Fig. 2. Values of Λ_0 for these salts in pure water (18) and in pure formamide (19) were taken from literature. As can be seen from Fig. 2, the limiting equivalent conductance decreases with the corresponding increase in the viscosity of the solvent mixture, but variation is not such that it can give a constant value of the Walden product, $\Lambda_0\eta$. In any given solvent mixture Λ_0(CsBr) > Λ_0(LiBr), which can be attributed to the structure-forming effect of cations (Br^- being common anion). The predominant structure-breaking effect of Cs^+ is well known and this leads to greater mobility of Cs^+. Correspondingly Li^+, having a high surface charge density, is highly structure forming, thus resulting in less mobility.

For both the alkali bromides, the Walden product does not show constancy with the change in solvent composition (Fig. 3) showing appreciable ion-solvent interactions. The curve showing the variation of $\Lambda_0\eta$ with solvent composition is slightly concave downward for CsBr while it is concave upward (passing through a minimum) for LiBr. This difference is expected because Li^+ is a strong structure former while Cs^+ is a strong structure breaker. The trend in $\Lambda_0\eta$ with the increase of formamide content in the solvent mixture shows that ions are preferentially solvated with formamide resulting in smaller ionic mobility than that expected due to change in the solvent viscosity. In the water-rich solvent composition region this preferential solvation is more pronounced in the case of LiBr, resulting in a more sudden decrease in Walden product, than in the case of CsBr for which $\Lambda_0\eta$ decreases slightly. This is possibly because of the stronger structure-forming effect of Li^+ than Cs^+. Now if we look into the trend in the formamide-rich region, the variations of $\Lambda_0\eta$ for these two salts are opposite to each other. $\Lambda_0\eta$ decreases in case of CsBr whereas it slightly increases for LiBr. This indicates that preferential solvation of CsBr with formamide is effective in the same direction with the increase of formamide content in solvent mixture right up to pure formamide and the sudden decrease in the highly formamide-rich region is possibly due to formamide molecules being larger than those of water. The ion solvated with formamide molecules will result in a larger mobile entity giving less mobility than the same ion solvated by even the same number of water molecules. In the case of LiBr the slight increase in $\Lambda_0\eta$ in the formamide-rich region (beyond 50 m/o formamide) after passing through a minimum clearly indicates that the mode of solvation in this case is different from that in the case of CsBr. In the light of Hemmes proposition (20) the minimum in $\Lambda_0\eta$ for LiBr indicates the existence of more than one type of solvated complex. However, it seems difficult to decide the actual modes of solvation in water-rich and formamide-rich solvent regions responsible for the reverse trend observed in $\Lambda_0\eta$ in these two regions. In addition to this, the free volume available between solvent molecules due to discrete structure of the solvent as proposed by Aprano and Fuoss (21) may be effective in the case of Li^+ because of its smaller size in comparison to the solvent molecules and may be an additional factor for the nonconstancy of $\Lambda_0\eta$.

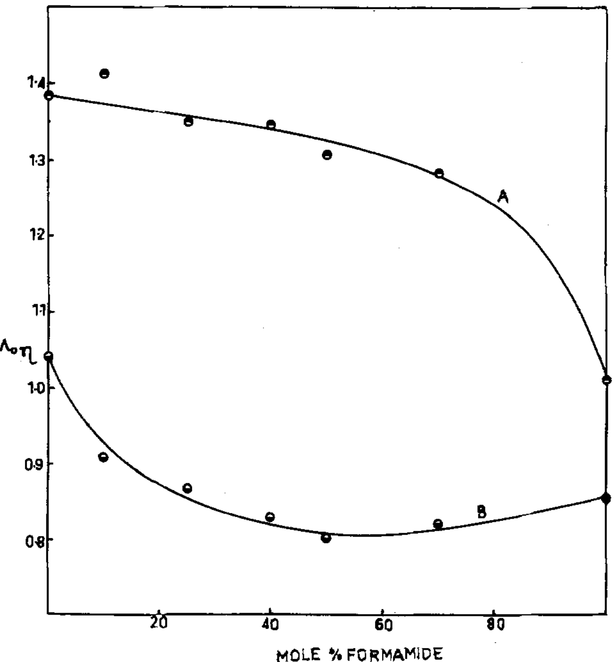


Fig. 3. Variaton of Walden product with composition of the solvent mixtures. A, CsBr; B, LiBr.

While going through the literature, it was found that various reasons have been proposed from time to time to explain the variation of Walden product with the composition of mixed polar solvents. Attempts have been made by many workers to give the mathematical treatment to these physical reasons for the nonconstancy of Walden product, but no one has succeeded in establishing a single satisfactory relation between Walden product and solvent properties of mixed solvents which could explain quantitatively the observation made for the various types of systems. Zwanzig in his recent treatment (22) gave a relatively more accurate expression; however, this expression also could account only for the variation of Walden product with solvent composition, but fails to account for maximum and/or minimum in Walden product. The latest attempt claimed to be an improved version of Zwanzig's treatment (22) has been made by Hubbard and Onsager (23), but this treatment was still within the framework of continuum mechanics which has already been questioned (21). Furthermore, the Hubbard-Onsager equation was tested by Evans *et al.* (24) and some inconsistencies and marked deviations from experimental data have been shown, particularly for smaller ions for which theory was expected to be more accurate. Keeping all these in view, it can be concluded that specific ion-solvent interactions, which are rather difficult to account for theoretically, play an important role resulting in the variation of Walden product, and without giving due consideration to this effect it seems difficult to derive a theoretical expression to explain the observations successfully.

It can be seen from Table III that in all cases the association constants are almost negligible ($K_A < 4.0$) which shows that both salts are completely ionized practically in all the solvent mixtures studied. This is according to expectation because of the high dielectric constants of the solvent mixtures. It is general practice that if $K_A < 10$, numerical values of K_A are not taken seriously and electrolyte is considered to be completely ionized practically. However, recently Aprano *et al.* (25) attempted to find out the physical significance, rather than the mathematical parameter only, of an association constant even if it is less than 10, but could not arrive at any useful conclusion. Variation of R with reciprocal of the dielectric constant of the solvent mixtures is shown in Fig. 4. Dotted lines represent the variation of Bjerrum distance $\beta/2$. Perpendicular lines in this plot show the range of R values corresponding to $\sigma \leq 1.1\sigma_{min.}$ (a realistic estimate which can reproduce the data within $1.1\sigma_{min.}$) and circles correspond to the best values ($\sigma = \sigma_{min.}$). It can be seen from Fig. 4 that the best-fit R values in the case of CsBr are almost constant (2.18 ± 0.19Å) throughout the solvent compositions, whereas no systematic trend was observed for LiBr. In spite of being unambiguously best values, these are too small in the case of CsBr to be physically meaningful. Since R is the measure of the extent of the influence of ionic charge in the solvent and consequently the extent of ionic association, R and K_A values are expected to decrease with the increase of dielectric constant of the solvent mixtures up to a certain limit where ionic association is almost negligible ($K \simeq 0$) and R attains a minimum value. Beyond this dielectric constant of the solvent mixtures, no further decrease in R is expected with the increase of dielectric constant. On this basis, it can be said that in solvent mixtures of sufficiently high dielectric constants (lowest being ~88) studied in present work, small as well as almost constant values of R are expected throughout the solvent compositions. This expected constancy in R is supported by present results for CsBr as well as for tetraalkylammonium bromides studied previously (1) in the same solvent mixtures. Thus, the trend in R is in accordance with the expectation. However, the values of R, at least for CsBr, are

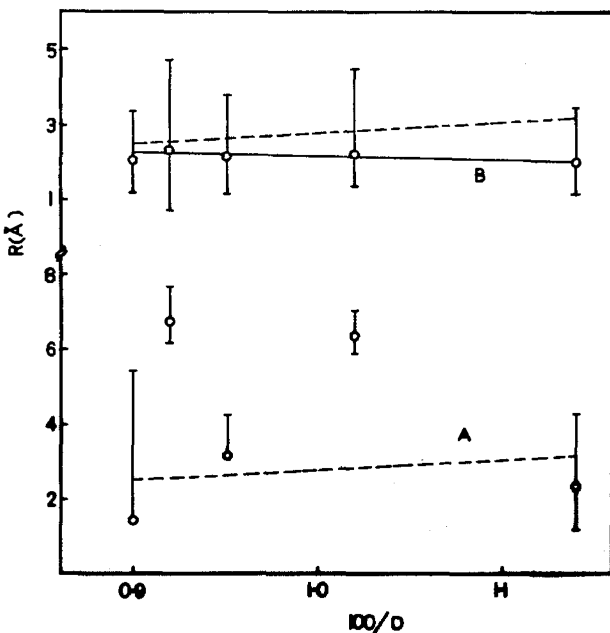

Fig. 4. Variation of pairing radius R with reciprocal of the dielectric constant of the solvent mixtures. A, LiBr; B, CsBr. Dotted lines represent $\beta/2$.

unreasonably small. Even in extreme case, the values of R should never be less than the lower limit, the sum of the crystallographic radii of the constituent ions of the electrolyte (3.64Å for CsBr). Thus best-fit R values for CsBr are hardly acceptable. This makes it necessary to look for an alternative. From Fig. 4 and Table III, it is clear that wide ranges of R values can reproduce data equally well (within $1.1\sigma_{min.}$) so any value in that range can be accepted. Similar wide ranges of acceptable R values have been observed in our previous studies (3, 4) also. But this leads to another difficulty in assigning any definite value of R for a particular system, thus making it difficult to draw any definite conclusion on the basis of these R values. Also, wide ranges of acceptable R values observed in present as well as in previous works (3, 4) clearly indicate the insensitivity of goodness of fit to the parameter R of the model. The same has been noticed by Fuoss (12) also. Although, it has been mentioned in the paper by Fuoss (12) that data in dioxane-water mixtures for some electrolytes have been analyzed by Fuoss (1978) equation, but the variation of R with dielectric constant of the solvent mixture has not been given. No other papers we have come across analyzed the data by the same equation. So due to lack of literature data, it is not possible to make any correlation with our results and same is the reason for not being able to come to any definite conclusion at this stage about R values derived by using Fuoss (1978) equation.

Acknowledgments

The authors are indebted to Professor R. M. Fuoss of Yale University, U.S.A., for invaluable help in making his computer programs available and to the computer center, Delhi University, for help in analyzing the data on an IBM 360 Computer. The authors' sincere thanks are due to Professor B. M. Shukla, Head, Department of Chemistry, Banaras Hindu University, for providing necessary facilities. Grateful thanks are also due to C.S.I.R., Government of India for granting a Junior Research Fellowship to one of the authors (Lal Bahadur) during this work.

Manuscript submitted Feb. 11, 1980; revised manuscript received *ca.* Aug. 8, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Technical Notes

The Application of Nb_2O_5 as a Cathode in Nonaqueous Lithium Cells

Benjamin Reichman* and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

Materials that undergo intercalation or topochemical reactions with Li have been investigated actively in recent years as candidates for cathodes in nonaqueous cells (1-3). The desired properties for such materials include good conductivity, a high free energy of reaction with Li, and minimal structural change on reaction leading to the possibility of repeated charging and discharging of the electrodes without permanent changes or decomposition. Intercalation involves the interstitial introduction of Li into the host compound, such as with the layered compound TiS_2 (4, 5). The reaction of most other materials with Li is topochemical and involves larger structural modifications. For example, topochemical reactions occur with some transition metal oxides such as V_2O_5 (4, 6, 7), the layered MoO_3 (4, 8-11), TiO_2 (4, 7, 12), WO_3 (13, 14), and MnO_2 (9). We recently found that Li reacts with Nb_2O_5, and that upon electrochemical reduction of Nb_2O_5 films on Nb metal in acetonitrile solutions containing $LiClO_4$, a dark blue color appeared on the electrode surface (15). The blue color could be bleached upon oxidation and could be cycled repeatedly, thus suggesting possible application to electrochromic display devices (15). Similar experiments have been performed with sputtered and chemically vapor deposited Nb_2O_5 (16). We report here preliminary electrochemical studies of the cells $Li/LiClO_4$ (1M), propylene carbonate $(PC)/Nb_2O_5$. Measurements of the cell voltage as well as the stoichiometry of the $Li\text{-}Nb_2O_5$ reaction provided thermodynamic information about the reaction. The behavior of the system upon charging and discharging was also investigated.

Experimental

The Nb_2O_5 electrode was prepared by heating Nb metal to 550°C in air. By this treatment a white layer of Nb_2O_5 formed on the Nb metal. The amount of oxide was determined by weighing the sample before and after the thermal oxidation process. The electrical contact was made with a Cu wire attached with silver epoxy cement to the Nb substrate. The Li anode was Li wire of ~3 mm diam. The electrodes were assembled in a sealed cell which contained 1M $LiClO_4$ in propylene carbonate (PC) solution in a glove box under an He atmosphere. All electrochemical measurements were carried out with the cell in the glove box. The $LiClO_4$ PC solution was prepared in the glove box from $LiClO_4 \cdot H_2O$ (AR grade, G. F. Smith Company) which had been dried at 110°C under vacuum for three days. The PC was allowed to stand for four days over molecular sieves (4Å) and then was distilled twice under vacuum onto molecular sieves; the fraction collected at 65°C (vacuum 0.4 Torr) was used. The PC was then degassed by three freeze-pump-thaw cycles and was stored in the glove box over molecular sieves. The cell was discharged (see Eq. [1]) across a constant external

$$x\text{Li} + \text{Nb}_2\text{O}_5 \underset{\text{chg.}}{\overset{\text{dischg.}}{\rightleftarrows}} \text{Li}_x\text{Nb}_2\text{O}_5 \quad [1]$$

load resistance and its voltage was measured with a recorder through a voltage-follower circuit; the current was measured via a current-to-voltage converter to a recorder. The cell voltage as a function of x (where x is the Li/Nb_2O_5 mole ratio) was measured on discharge as follows: the cell was slowly discharged across a constant external load resistance (10 kΩ) and x was determined by integration of the current. The discharge process was interrupted at different stages and the open-circuit voltage was measured after the system reached equilibrium (several hours to one day). The cell was charged at constant current (0.1 mA) with a Princeton Applied Research (PAR) potentiostat, Model 173. The x-ray powder diffraction pattern was obtained with a Phillips Norelco x-ray diffractometer using Cu Kα radiation.

Results and Discussion

The open-circuit voltage of a cell composed of an Nb_2O_5 (cathode) and Li (anode) as a function of x is shown in Fig. 1(a). The molar free energy, ΔG, involved in the cell reaction is also shown in the figure. The initial open-circuit voltage of the cell, 2.8V, was constant for at least two weeks to within ± 0.02V as was the cell voltage for other x values. The calculated emf for the reaction

$$2\text{Li} + \text{Nb}_2\text{O}_5 \rightarrow \text{Li}_2\text{O} + \text{Nb}_2\text{O}_4 \quad [2]$$

is only 1.37V (based on the known values of $\Delta G°$ for Li_2O (−133.8 kcal/mole), Nb_2O_5 (−426.4 kcal/mole), and Nb_2O_4 (−355.8 kcal/mole) (17, 18). This is lower than the open-circuit voltage measured in any of the Li/Nb_2O_5 cells constructed. Thus the cell reaction is more probably the topochemical reaction of Eq. [1], as was suggested for V_2O_5, MoO_3, and TiO_2 (4, 8, 11, 12).

Upon increasing x, the cell voltage decreased at lower x values, but when x attained the value of ~0.4 it remained almost constant at ~1.7V until $x \sim 1.5$. The constant cell voltage suggests equilibrium between two phases in this region. Prior to this region only a single phase of nonstoichiometric $Li_xNb_2O_5$ exists as indicated by the decrease of the voltage with increase in x. The equilibrium existing between two different phases in the cathode material is also reflected in the discharge curve under load shown in Fig. 1(b). Again a sharp decrease in cell voltage is observed in the region of lower x values. The cell voltage then remains almost constant until the sharp decrease when x reaches 1.5. The sharp drop at $x \sim 1.5$ is probably caused by a sudden decrease in the diffusion coefficient of Li in the cathode material (1). For this experiment 0.02g Nb_2O_5 electrode material was used [in the form of a thin film (20)]. The time scale is indicated in the upper axis

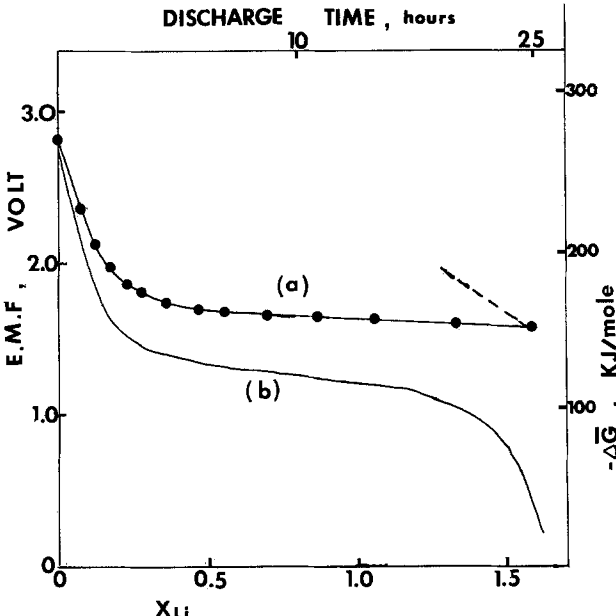

Fig. 1. Voltage of the cell Li/1M $LiClO_4$, propylene carbonate/Nb_2O_5 as a function of x (moles Li discharged/mole Nb_2O_5): (a) open-circuit values during discharge of Nb_2O_5 (●) and recharge of $Li_xNb_2O_5$ (- - - - -). The ΔG values related to these experiments are shown on the right ordinate; (b) cell voltages during discharge across a load resistance of 10 kΩ. 0.02g Nb_2O_5 formed on Nb by air oxidation was used in this experiment. The upper abscissa of the figure is the discharge time.

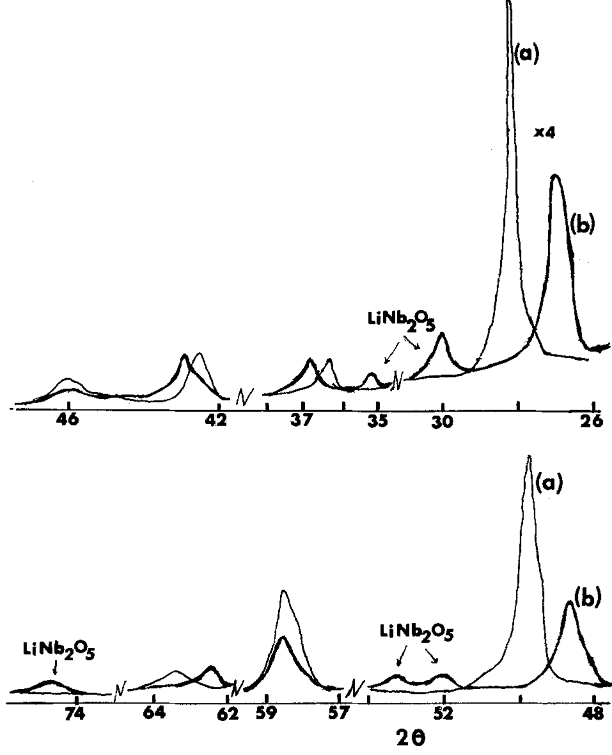

Fig. 2. X-ray diffraction pattern of (a) Nb_2O_5 electrode before discharge and (b) cathode material after complete discharge.

of Fig. 1; note that about 25 hr was required to complete the discharge at this load. Since saturation occurs only after reaction with ~1.5 equivalent of Li, the capacity of the Li/Nb_2O_5 cell is high (0.15 A-hr/g) and its theoretical energy density based on the initial open circuit (2.8V) is ~500 W-hr/kg; the more practical energy density based on the discharge curve shown in Fig. 1(b) is ~230 W-hr/kg. Values of x higher than 1.0 have also been found for other oxides like MoO_3 (7, 10) ($x = 1.5$), V_2O_5 (4, 7) ($x = 2$), and WO_{3-y} (14) ($x = 1.5$). The fact that a new phase of $Li_xNb_2O_5$ is formed when the value of x increased over ~0.4 was also suggested by the x-ray diffraction patterns shown in Fig. 2. The x-ray pattern of the cathode material after charging to saturation ($x =$ 1.6) [Fig. 2(b)] is different from that taken with the fresh electrode material [Fig. 2(a)]. The pattern of Fig. 2(a) is similar to the known one for Nb_2O_5 (19). Some of the x-ray peaks in the diffraction pattern of fresh cathode material are shifted with respect to those of the electrode material after complete discharge. Moreover some new peaks appear in the x-ray pattern of the discharged electrode. The peaks which appear at 28.2°, 63.4°, and 49.7° (Nb_2O_5 peaks) shift by about 1° to lower diffraction angles in the discharged electrode while the peaks at 36.3° and 42.5° (Nb_2O_5) in Fig. 2(a) are shifted by about 1.5° towards lower angles in 2(b). New peaks appear at 30°, 35°, 52°, 53°, 74.8°, and 78°. The shift in some diffraction angles of the original Nb_2O_5 can probably be attributed to some distortion in the structure of the Nb_2O_5 lattice as more Li is inserted into the lattice to form the nonstoichiometric $Li_xNb_2O_5$, as is observed for Li_xTiS_2 (4). The new peaks which appear in Fig. 2(b) indicate formation of different phase, *e.g.*, $LiNb_2O_5$, which is the phase in equilibrium with the Nb_2O_5. This compound is formed during the discharge of the cell in the region where the cell voltage plateau occurs.

Experiments were also carried out to study the reversibility of the cell. Upon charging the cell after complete discharge, only about 20% of the charge could be recovered; decomposition of the solvent started to take place at a charging voltage of ~ 5V (applied charging current, 0.1 mA). The cell voltages (open circuit) as a function of x, measured during charging (broken line in Fig. 1) were different than those obtained during discharge. Upon further discharge-charge cycles the charge recovered in the charging cycles decreased further from cycle to cycle. The capacity lost is probably caused by the very low rate of oxidation of the $LiNb_2O_5$ phase which was formed during the discharge. Because of this low rate (high energy of activation for oxidation), higher voltages are needed for the charging process at reasonable current densities. However, the oxidation of the solvent itself occurs at voltages lower than that required to complete the oxidation of the electrode so that a loss of capacity is observed. This mechanism for capacity loss was clearly addressed by Wittingham (4) and others, and it usually occurs in cases where a new phase is formed during the discharge process. The oxidation of this phase probably involves a high activation energy and is very difficult to accomplish without decomposition of the solvent. This is in contrast to the highly reversible layered dichalcogenide cathodes, *e.g.*, TiS_2 and others (1, 4), where no phase transition occurs during the discharge and where only a single nonstoichiometric compound Li_xTiS_2 is formed with only a slight change in the lattice structure. Note that in our experiments with Nb_2O_5 no attempt was made to optimize the properties of the active material. It has been previously shown that slight changes in the crystal structure, crystallite size, and method of preparation of cathode material can often improve significantly the cell performance, both in terms of capacity and reversibility (3, 12) as was found, for example, with V_6O_{13} (4, 21).

Conclusion

Li can be introduced in a topochemical reaction into Nb_2O_5. Preliminary experiments show that a cell based on this reaction has a high open-circuit voltage (2.8V) and energy density. The reaction of the cell involves a phase transition in the cathode material, so that the cell voltage shows a plateau during discharge at ~ 1.7V. Only about 20% of the capacity can

be recovered upon recharge, however, and this poor reversibility of the cell will prevent its use as a secondary one. However, different methods of material preparation may lead to changes in the lattice structure of the cathode material to make it a more open one, which can accommodate Li ions and improve the cell reversibility.

Transport of Oxidant in Molten Na_2SO_4 in O_2-SO_2-SO_3 Environments

David A. Shores* and W. C. Fang,[1]**

General Electric Research and Development Center, Schenectady, New York 12301

In the Na_2SO_4-induced hot corrosion of superalloys the main corrosion products are oxides and, to a lesser extent, sulfides. On susceptible alloys a small amount of salt can produce a relatively large quantity of corrosion products, demonstrating that the salt, for the most part, is not consumed by the corrosion reaction. Rather, oxidant is supplied by the gas phase. Thus, an important step in the overall hot corrosion reaction is the transport of oxidant through a layer of liquid salt. A knowledge of transport rates is needed to decide whether gradients of oxidants will exist in the salt film for a particular set of conditions. Oxidant gradients are a key part of the early theory of hot corrosion fluxing developed by Goebel and Pettit (1), and also of the recent theory of Rapp and Goto (2), that proposes a negative gradient of solubility of corrosion products as a criterion of sustained attack. The purpose of the present work was to identify which species would provide the predominant flux of oxidant through molten Na_2SO_4 in O_2-SO_2-SO_3 environments and to measure its diffusivity.

Transport rates of oxidant through Na_2SO_4 have been determined from the limiting cathodic current densities observed in polarization experiments. A three-electrode cell, shown schematically in Fig. 1, has been used with Pt (or Au) foil for the working and counter-electrodes and an Ag wire dipping into an Na_2SO_4 melt contained in a mullite tube as the reference electrode (3). The Pt or Au foils were cemented (Aremco 552 cement) to the bottom of the crucible. The thickness of the salt was determined from the geometry of the cell, the amount of salt added, and the density of liquid Na_2SO_4 at temperature. Cathodic polarization runs were carried out with high purity Na_2SO_4 (99.999%) at 896°C with a scan rate of 0.33 mV/sec. Several runs

Key words: corrosion, alloy, salts.

were carried out in O_2 + 0.15% (SO_2 + SO_3) with salt thicknesses ranging from 0.022 to 0.24 cm. In addition, for a given salt thickness limiting currents were determined as a function of $P_{SO_3} + P_{O_2} \simeq 1.0$ atm and as a function of $P_{SO_3} + P_{O_2}$ at $P_{SO_2} \simeq 1.0$ atm. Because gas phase O_2-SO_2-SO_3 reactions are known to be slow, a Pt catalyst was placed in the gas inlet tube (shown in Fig. 1) to insure equilibration.

The shape of the polarization curves obtained from these experiments was typical of concentration polarization. The limiting current density increased as the thickness of the salt layer decreased. A plot of the limiting current density *vs.* 1/(thickness) in O_2 + 0.15% (SO_2 + SO_3), as shown in Fig. 2, yielded a straight line, but with some scatter owing to the uncertainty in the determination of the salt thickness.

To help identify the predominant reduction reaction in an O_2-rich environment containing small amounts of SO_2 + SO_3, a series of polarization runs at a given salt thickness was carried out in which the gaseous environment was varied. As shown in Fig. 3 the limiting current densities were found to increase linearly with increasing $P_{SO_3} + P_{SO_2}$ at constant P_{O_2} ($\simeq$1.0 atm). These data indicate that in the presence of SO_3 the reduction of O_2 is not the predominant reaction. In another series of runs with P_{SO_2} held constant at ~1.0 atm the limiting current densities were found to increase linearly with $P_{SO_3} + P_{O_2}$ (Fig. 4). Thus, in the presence of SO_3 the reduction of SO_2 may also be ruled out as a predominant reaction. By this process of elimination the reduction of SO_3, or as will be shown below, the reduction of a soluble species whose concentration is proportional to P_{SO_3} is proposed as the predominant reaction. Extrapolation of the limiting current data from Fig. 3 and 4 to $P_{SO_3} + P_{SO_2} = 0$ or $P_{SO_3} + P_{O_2} = 0$ yielded residual current densities that have been interpreted as due to the reduction of O_2 and SO_2, respectively.

The limiting current density data have been further analyzed to obtain diffusion coefficients with the use of the well-known equation

$$D = i_l\delta/n\mathbf{F}C \quad [1]$$

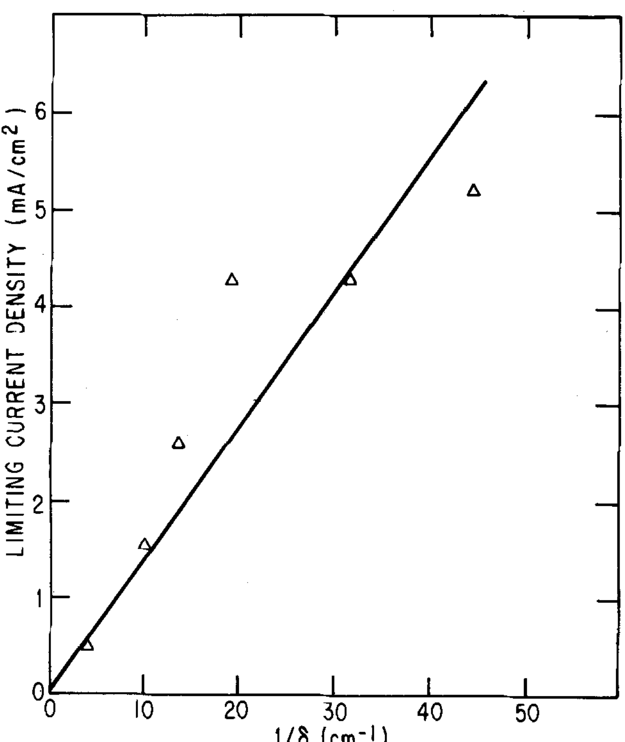

Fig. 2. Plot of limiting reduction current densities as a function of the reciprocal of the salt film thickness in O_2 + 0.15%(SO_2 + SO_3) at 896°C.

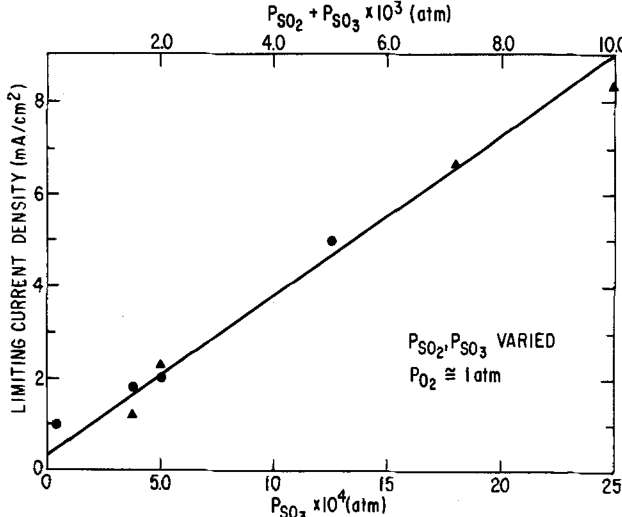

Fig. 3. Plot of limiting current densities as a function of P_{SO_3} from duplicate experiments with $P_{O_2} \simeq 1$ atm at 896°C with a salt thickness of 0.08 cm.

where i_l is the limiting current density, δ is the diffusion distance, n is the number of equivalents/mole, $\mathbf{F}$ is the Faraday constant, and C is the bulk concentration of the diffusing species. For most liquids diffusion coefficients lie in the range 10^{-4} cm²/sec. Inman (4) has quoted a value of $D_{SO_3} = 2 \times 10^{-4}$ cm²/sec in a chloride melt at 750°C. Although many reduction reactions in Na_2SO_4 are conceivable, it has been possible to eliminate some by showing that an unreasonable value of D would be required for the experimental data to be consistent with the above equation. Clearly, Na^+ and SO_4^{2-} are not being reduced under the present experimental conditions, because one would expect limiting current densities to be very high and not to be significantly influenced by the gas composition. In Table I are listed several reactions for the reduction of minority species. The solubilities of O_2 and SO_2 were obtained from the measurements of Andresen (5). The solubility of gaseous SO_3 is unknown, but it is unlikely to exceed that of SO_2 on the basis of its molecular diameter. The solubilities of Na_2SO_3, $Na_2S_2O_7$, Na_2O_2, and NaO_2 were calculated from thermodynamic stability data assuming ideal solution behavior (6-9).

Table I shows that in an O_2 + 0.15% (SO_2 + SO_3) environment the reduction of $\underline{SO_3}$, $\underline{SO_2}$, SO_3^{2-}, O_2^{2-}, and O^{2-} can be ruled out as requiring unreasonably large values of D to be consistent with the experimental data.[2] On the other hand, the reduction of pyrosulfate ion provided a reasonable consistency with the experimental data. The concentration of pyrosulfate ions is proportional to P_{SO_3}. The reaction listed in Table I for the reduction of pyrosulfate ions is preferred over

$$S_2O_7^{2-} + 6e^- = SO_4^{2-} + \tfrac{1}{2}\,\underline{S_2} + 3\,O^{2-} \quad [2]$$

on the grounds that dissolved S_2 (g) is an unlikely reaction product, since its solubility in Na_2SO_4 is expected to be extremely low. The reactions

$$S_2O_7^{2-} + 4e^- = 2\underline{SO_2} + 3\,O^{2-} \quad [3]$$

and

$$S_2O_7^{2-} + 2e^- = SO_4^{2-} + \underline{SO_2} + O^{2-} \quad [4]$$

also were rejected because the rates of these reactions would be limited by the rate of removal of the $\underline{SO_2}$ product, if P_{SO_2} cannot exceed 1 atm at the reduction site. That SO_2 removal is not rate controlling in our experiments is demonstrated by the data in Fig. 3.

[2] The underlining implies dissolved gaseous species.

Table I. Diffusivities calculated from limiting reduction current densities in Na_2SO_4 in O_2-0.15%(SO_2 + SO_3)

Reaction	$i_l \cdot \delta$* (A/cm)	C (mole/cm³)	D (cm²/sec)
$O_2 + 4e^- = 2\ O^{2-}$	2.40×10^{-5}**	1.84×10^{-7}	3.38×10^{-4}
$\overline{SO_2} + 6e^- = S^{2-} + 2\ O^{2-}$	1.11×10^{-4}	1.20×10^{-9}	0.16
$\overline{SO_3} + 2e^- = \underline{SO_2} + O^{2-}$	1.11×10^{-4}	$<3.88 \times 10^{-10}$	>1.48
$\overline{S_2O_7{}^{2-}} + 8e^- = \overline{SO_4{}^{2-}} + S^{2-} + 3\ O^{2-}$	1.11×10^{-4}	6.88×10^{-7}	2.09×10^{-4}
$SO_3{}^{2-} + 6e^- = S^{2-} + 3\ O^{2-}$	1.11×10^{-4}	4.9×10^{-12}	39
$O_2{}^- + 3e^- = 2\ O^{2-}$	1.11×10^{-4}	$\sim 1 \times 10^{-11}$	33
$O_2{}^{2-} + 2e^- = 2\ O^{2-}$	1.11×10^{-4}	$\sim 4 \times 10^{-17}$	1.4×10^7

* The value of $i_l \cdot \delta$ was obtained from the slope of the curve in Fig. 2.
** The proportion of i_l due to oxygen reduction was estimated from Fig. 3 as the ratio of i_l at $P_{SO_3} = 0$ to i_l at $P_{SO_3} = 3.66 \times 10^{-4}$.

That is, upon increasing P_{SO_2} in the gas the $\overline{SO_2}$ concentration gradient across the salt would decrease or, at the low P_{SO_2} levels in Fig. 3, remain essentially unchanged. Hence, if diffusion of $\overline{SO_2}$ away from the electrode were rate controlling, $\overline{i_l}$ would have decreased or remained essentially constant. In fact, i_l increased as P_{SO_2} (and P_{SO_3}) increased.

The reduction of dissolved O_2 also yielded a reasonable value of D based on the value of i_l extrapolated to $P_{SO_3+SO_2} = 0$, $P_{O_2} = 1$ atm ($D_{O_2} = 3.4 \times 10^{-4}$ cm²/sec). (Measurements in pure $\overline{O_2}$ were not consistent with these data. Since the salt is unbuffered in O_2 alone, its acidity, and hence the concentrations of minority species, can change radically during cathodic polarization experiments.) Similarly, a reasonable value of D_{SO_2} was obtained from i_l at $P_{SO_3+O_2} = 0$, $P_{SO_2} = 1$ atm from Fig. 4 ($D_{\overline{SO_2}} \simeq 1.6 \times 10^{-4}$ cm²/sec). The slopes of the curves in Fig. 3 and 4 also were found to be self-consistent. That is, $\delta(di_l/dP_{SO_3})$, obtained by differentiating Eq. [1] with respect to i_l and C and taking $C \propto P_{SO_3}$, had about the same value for the data in Fig. 3 as in Fig. 4.

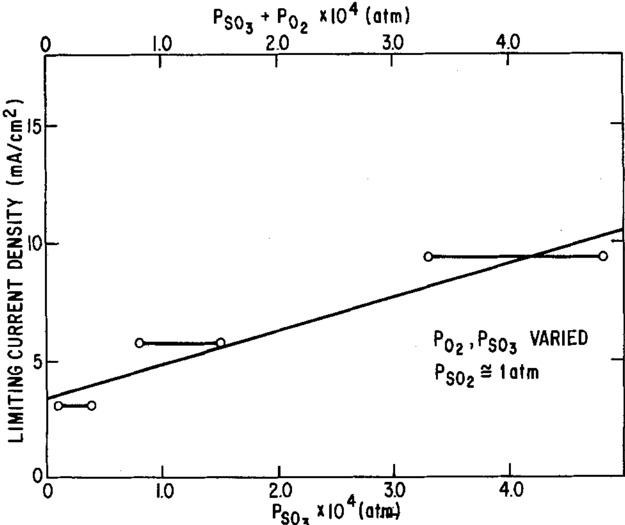

Fig. 4. Plot of limiting current densities as a function of P_{SO_3} with $P_{SO_2} \simeq 1$ atm at 896°C with a salt thickness of 0.019 cm.

It is proposed that diffusion of pyrosulfate ion provides the predominant flux of oxidant through Na_2SO_4 in O_2-rich environments containing more than a few hundred ppm of SO_3. The diffusivity of $S_2O_7{}^{2-}$ has been estimated here as 2.1×10^{-4} cm²/sec at 896°C. Dissolved O_2 and SO_2 can also supply oxidant, but their contributions are limited by their very low solubilities in Na_2SO_4. The actual contribution of each species will depend, of course, on the composition of the gas mixture. It is estimated that in O_2 + 0.15% (SO_2 + SO_3) the reduction of $\overline{O_2}$ accounts for about 18% of the current and $\underline{SO_2}$ for 0.1%.

Generalization of the Boltzmann-Matano Method?

C. van Opdorp

Philips Research Laboratories, Eindhoven, The Netherlands

In a recent paper dealing with the diffusion of Cd in InAs, Kolodny and Shappir (1) presented a generalization of the Boltzmann-Matano (BM) method. The original, well-known method provides a means of evaluating an unknown dependence of a diffusion coefficient D on the concentration C of the diffusant from an experimentally determined concentration *vs.* depth (c-x) profile. The original method applies only if D is a function of C exclusively. In the generalization of Ref. (1), D is allowed to be an arbitrary function of C, x, and t.

In this paper it will be shown that the mentioned generalization of the BM method is incorrect. We restrict our critique of the paper of Ref. (1) to this confusing claim of generalization. In the same paper the authors have generated theoretical concentration profiles resembling the experimentally observed profiles by substituting a hypothetical dependence of D on C and x into Fick's second law. In principle this alternative heuristic approach of finding $D(C,x)$ is correct and basically independent of the validity of the BM generalization. The merits of this heuristic approach for the case in question lie outside the scope of the present paper.

The BM Method and the Impossibility of Generalization

Suppose one has a semi-infinite continuum into which diffusion of some species is performed subject to the conditions that the initial concentration in the continuum is everywhere equal to zero and at its surface the concentration is kept fixed at a constant value. Assume further that D is a function of C. Under these conditions the BM method provides a means of evaluating $D(C)$ from an experimentally determined C-x profile (2). The value of D at $C = C_1$ follows from the profile determined at $t = t_1$ by applying the formula (2)

$$D(C_1) = \frac{-1}{2t_1} \frac{\int_0^{C_1} x dC}{[dC/dx]_{C=C_1}} \qquad [1]$$

The method applies only if D is a function of C exclusively. Experimentally one can verify whether this condition is fulfilled by checking invariance of the profile of C when plotted *vs.* $x/\sqrt{t}$ for different values of the diffusion time t; strictly speaking, this check should be performed for all values of x and t (3).

In the generalization of Ref. (1), D is allowed to be an arbitrary function of C, x, and t. The value of D at any given point (C_1, x_1, t_1) of this three-dimensional space was claimed to follow from an expression actually identical to the right-hand side of Eq. [1]

$$D(C_1, x_1, t_1) = -\frac{1}{2t_1} \frac{\int_0^{C_1} x dC}{[dC/dx]_{C=C_1}} \qquad [2]$$

where again $C\ (x, t_1)$ is a known profile at time t_1.

No derivation was presented for Eq. [2]. Actually generalization is impossible. This becomes evident if one follows the steps made in deriving the original BM formula of Eq. [1] (2). The essential step in deriving this equation consists of investigating the possibility of transforming the partial differential equation describing the diffusion process (*i.e.*, Fick's second law) to an ordinary differential equation. For this, one has to investigate the possibility of applying the Boltzmann transformation, *i.e.*, substitution of a single independent variable $\eta \equiv x/\sqrt{t}$ for the two variables x and t. If this can actually be accomplished, the resulting second-order ordinary differential equation is exact, *i.e.*, a first integral is obtainable by immediate integration (4). After that, rearrangement of this integral and reintroduction of x and t yield directly Eq. [1].

The crucial, obvious point in this whole procedure is that application of the Boltzmann transformation is indeed possible provided D is a function of C exclusively, whereas this is not possible if D is an arbitrary function of C, x, and t. This fact prohibits any generalization of the BM method as suggested in Ref. (1). Thus it is essentially impossible to reconstruct the field of local D values in the three-dimensional C-x-t space from applying Eq. [2] to (even an infinite set of) C-x profiles measured for different values of t.

A very simple example may serve to illustrate the serious consequences of improper application of the generalized expression given by Eq. [2]. Let D be a function of t only, *viz.* $D = D_o$ (constant) for $t \leq t_o$, and $D = 0$ for $t > t_o$. The resulting C-x profiles at different values t_1 for diffusion under the mentioned initial and boundary conditions are given by $C = C_o$ erfc $(x/\sqrt{D_o t_1})$ for $t \leq t_o$. For longer diffusion times the profile completely stagnates, so that $C = C_o$ erfc $(x/\sqrt{D_o t_o})$ for all $t_1 > t_o$. Application of Eq. [2] to the profiles for $t_1 \leq t_o$ and any value of C_1 yields the correct value $D(t_1 \leq t_o) = D_o$. Application to the profile(s) for $t_1 > t_o$, however, for any value of C_1 yields $D(t_1 > t_o) = D_o t_o/t_1$ instead of the correct value $D(t_1 > t_o) = 0$.

Conclusion

Generalization of the Boltzmann-Matano method for evaluating a diffusion coefficient which depends not only on the concentration of the diffusant, but also on depth and time explicitly is impossible. Application of the incorrect generalized method of Ref. (1) may yield results which are seriously erroneous.

High Precision Computer Controlled Electrocapillary Measurements

David M. Mohilner* and Takashi Kakiuchi[1]

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523

In preparation for an investigation of the temperature dependence of organic electrosorption in order to test a recently proposed theory (1), it was decided to try to improve the precision of our computer controlled capillary electrometer (2) over the precision we had already obtained (3) in 1976. The reason for attempting further improvement in precision is because it is known (4-6) that the temperature coefficient of interfacial tension is quite low. We have succeeded in improving the instrument so that it is now capable of measuring the interfacial tension with 95% confidence limits of ± 0.02 dyne cm^{-1}. The purpose of this note is to describe how this improvement was accomplished.

Experimental

14-bit A/D converter and new pressure transducer.—The previous best precision (3) of ± 0.1 dyne cm^{-1} represented a relative precision of about 1 part in 4000. This was approximately the same as the precision of the 12-bit A/D converter which was being used. We thought it was possible that an improvement might be made if we interfaced an A/D converter with more bits to the PDP-8/I computer which controls the electrocapillary measurements. Therefore we interfaced an Analog Devices ADC-1131K 14-bit A/D to the computer. Because the computer is only a 12-bit machine special hardware and software provisions were necessary. The hardware provision was an interface which can strobe the eleven most significant bits (plus sign) into the high order 12-bit mantissa word of the floating accumulator and the three least significant bits into the lower order mantissa word.[2] The software provision was to add a new routine to the vendor supplied floating point package to enable the computer to float a 14-bit number. This new routine, DFLOAT, was modeled on the vendor supplied FLOAT routine which floats an 11-bit number (plus sign) in the high order mantissa word of the floating accumulator. The only problems in adding the routine DFLOAT to the floating point package were caused by the necessary movement of several other floating routines within the code in order to collect the two or three spare words on each page of the package together onto one page so that there would be space for DFLOAT.[3]

The Lion pressure transducer which had been used previously was also replaced by a much more stable transducer based on a temperature compensated, unbonded, fully active strain gauge bridge, manufactured by Gould Incorporated, Measurements Systems Division, Oxnard, California. The new transducer system consists of a Model PL131TC transducer, a CON2 pressure adapter, a DC12 electrical disconnect, and a Model SC1105 power supply with bridge amplifier. In order to achieve even better stability the Gould bridge amplifier in the SC1105 was replaced with an Analog Devices Model 606M instrumentation amplifier which is connected to the analog input of the 14-bit A/D converter.

We found that with the 14-bit A/D converter and the new pressure transducer the precision of a measurement of the interfacial tension was improved. However it was not improved as much as would have been expected, *i.e.*, 1 part in 16,000 which is the uncertainty of the least significant bit of a 14-bit A/D. We found that it was necessary to make several additional changes in the instrument to correct for sources of scatter in the data which had not been noticeable at the previous lower precision.

Improvement of the potential control.—On monitoring the long term reproducibility of the electrode potential with an accurate digital voltmeter (Fluke 8300A) it was found that there was a measurable scatter of tenths of a millivolt which could account for some of the scatter of the interfacial tension, especially at potentials far from the electrocapillary maximum. It was found that this scatter of electrode potential was due partly to the reproducibility of the 12-bit D/A converter which supplied the voltage signal to the potentiostat and partly to the stability of the operational amplifiers which were being used as the control amplifier and voltage follower in the potentiostat. The 12-bit D/A converter was replaced with an Analog Devices DAC-12QM ultrahigh stability 12-bit D/A. The control amplifier on the potentiostat was replaced with an Analog Devices Model 234L low noise-wideband chopper stabilized amplifier which has an extremely low drift (0.1 $\mu V/°C$ and 1 pA/°C). The voltage follower was replaced with an Analog Devices Model AD517L amplifier which is a laser trimmed precision IC amplifier which is recommended for ultrahigh stability as a unity gain voltage follower. These changes in the potential control circuitry have greatly improved the long term reproducibility of the electrode potential. The standard deviation of the drift of emf over a period of two months is now only about 0.1 mV.

Vibration control.—After the modifications just mentioned were introduced there still remained some scatter in the measurements. This scatter was traced to building vibrations. Therefore a Newport Research Corporation vibration free table was purchased (Research table top, Model RS-46-8 with support system Part No. XLB2A-24) and the cell was mounted on it. This last modification removed most of the remaining scatter from the data.

Mercury head.—At this stage the single most inaccurate part of the measurement remaining was the determination of the head of mercury which was read with a cathetometer calibrated to 0.01 mm. In order to minimize the frequency of necessary cathetometer readings the mercury reservoir which had an area of about 20 cm^2 was replaced with a much larger one having an area of 180 cm^2. With this new reservoir it is now only necessary to read the head of mercury once every 2600 measurements of interfacial tensions. This means that one reading of the head of mercury remains valid for about ten 60 point electrocapillary curves, each of which is measured in triplicate.

Results and Discussion

After the modifications in the instrument described above had been installed, a critical test was performed to determine the 95% confidence limits of a triplicate

[3] A listing of the modified floating point package will be supplied on request.

measurement of the interfacial tension at any electrode potential. This test was performed by measuring three times a 49 point electrocapillary curve for a 0.1M NaCl aqueous solution at 25°C. For each of these three measurements, a freshly prepared solution was used. Each of these electrocapillary curves was measured in triplicate. An Ag/AgCl reference electrode in the same solution was employed.[4]

In order to determine whether the precision of the measurements was independent of electrode potential, a statistical test for homogeneity of variance was performed. The variances at each emf were calculated for the three electrocapillary curves, *i.e.*, nine measurements of the interfacial tension at each emf, and arranged in order of emf. Because the means at the different values of electrode potential are different, a generalized likelihood-ratio test is interactable (7). However, the theory of runs can be used to test the hypothesis that the observations have been drawn at random from a single population (8). We implemented a test for homogeneity of variance based on the theory of runs using the formulas for probability given (9) by Swed and Eisenhart. The result of this test was that indeed the variances at all of the different values of emf belonged to a single population. Therefore it was statistically permissible to pool the variance for all values of emf. The pooled variance was $3.96(10)^{-4}$ dyne^2 cm^{-2} and the pooled standard deviation was $1.96(10)^{-2}$ dyne cm^{-1}. Therefore, using the t-table, the 95% confidence limits for any triplicate measurement of the interfacial tension is 0.02 dyne cm^{-1} which represents a fivefold improvement in the precision of the instrument.

Figure 1 shows a typical triplicate measurement for an electrocapillary curve as recorded by the on-line plotter of the computer controlled capillary electrometer. It can be seen from this figure that the scatter of data with this improved instrument is smaller than the pen width on the plot. An idea of how much the instrument has been improved over the original version can be obtained by comparing this figure with Fig. 11 of Ref. (2).

Acknowledgment

This work was supported by the National Science Foundation under Grant No. CHE76-83432. Acknowledgment is also made to the donors of the Petroleum Research Fund, administered by the American Chemical Society for partial support of this research. This work constitutes a portion of the research in a collaborative international program on thermodynamic studies of the inner part of the electrical double layer supported in part by the North Atlantic Treaty Organization (NATO). We express our gratitude to the late Professor Patricia R. Mohilner, Department of Computer Science, Colorado State University who wrote the computer programs used in this study. We also thank Professor Paul W. Mielke, Department of Statistics and Professor Elliot R. Bernstein, Department of Chemistry, Colorado State University, for advice on the statistical analysis and on the selection of a vibration-free table.

[4] It was found that the glass sodium ion electrode which we had employed in our previous measurements (3) was not stable enough for use with the new level of precision.

Metallographic Aspects of the Corrosion of a Preoxidized Co-30 Cr Alloy in an H_2-H_2O-H_2S Atmosphere at 900°C

P. J. Hunt and K. N. Strafford

Newcastle upon Tyne Polytechnic, Newcastle upon Tyne NE1 8ST, England

ABSTRACT

The reaction at 900°C between preoxidized Co-30 Cr alloy samples and an H_2-H_2O-H_2S gas mixture has been studied from a metallographic viewpoint to allow comparison with the morphology and composition of the corrosion products formed on an unoxidized Co-30 Cr alloy exposed under the same test parameters. Preoxidation was carried out in an H_2-H_2O gas mixture in the temperature range 850°-1000°C. This binary gas mixture generated an oxidizing potential of between 3.5×10^{-21} atm (3.5×10^{-19} kN/m^2) to 1.8×10^{-18} atm (1.8×10^{-16} kN/m^2) resulting in the exclusive formation of a Cr_2O_3 layer on the alloy. On exposure at 900°C to the low oxidizing (2×10^{-19} atm, 2×10^{-17} kN/m^2) and high sulfidizing ((1×10^{-4} atm, 1×10^{-2} kN/m^2) potentials generated in the ternary H_2-H_2O-H_2S gas, both oxide and sulfide species were formed. Samples which had been preoxidized at 850°C generally exhibited the formation of mainly Cr-sulfide rich regions above the preformed Cr_2O_3 scale: only isolated regions displayed the existence of thick mounds of a Co-rich sulfide. Samples preoxidized at 1000°C however yielded a greater density of rapidly growing Co-sulfide nodules on the surface of the alloy. Irrespective of the preoxidation temperature, subsurface oxidation and sulfidation additionally occurred. The alloy which had undergone no pretreatment developed a sulfide layer over the alloy surface, but in certain areas a continuous Cr_2O_3 layer formed beneath this exterior sulfide scale.

The current generation of commercially available heat-resistant stainless steels and cobalt and nickel base superalloys rely, for environmental protection, on the selective oxidation of chromium and/or aluminum to form a dense, compact, and adherent exterior oxide layer. However such conventional alloys were developed primarily for operation under highly oxidizing conditions such as those normally generated in power plants and gas turbine engines. In coal gasification or combustion process plants the metallic components are exposed at high temperatures to atmospheres of comparatively low oxygen and high sulfur activity. An analysis of the raw gas from a typical gasification step indicates oxygen and sulfur partial pressure of the order of 10^{-16} atm (10^{-14} kN/m^2) and 10^{-5} atm (10^{-3} kN/m^2), respectively (1).

Under certain conditions of operation the current generation of heat-resistant alloys are unable to form a protective oxide at the alloy-gas interface and unacceptably high rates of material degradation are observed (1, 2). Alternatively an oxide may form which is unable to prevent penetration of the oxide by sulfur and the subsequent formation of subsurface sulfides. In laboratory controlled experiments in sulfurous environments subsurface sulfidation has been regarded as a precursor of an accelerated rate of corrosion (3, 4).

Preliminary results from the first stage of a comprehensive investigation into the intrinsic capacity of preformed Cr_2O_3 oxide scales exposed to low oxidizing and high sulfidizing potentials to prevent severe sulfidation of the underlying metallic components have already been reported (5). It was observed that samples of the Co-30 Cr alloy which had been preoxidized at 850°C displayed an incubation period before exhibiting an accelerated rate of attack, whereas alloy samples preoxidized at 1000°C corroded at an approximately linear rate from an early stage of the reaction. Irrespective of the preoxidation exposure time, samples preoxidized in the H_2-H_2O gas mixture at 850°C had gained only about 1 mg/cm^2 after 40 hr service at 900°C in the oxidizing-sulfidizing gas mixture whereas specimens preoxidized at 1000°C exhibited weight gains of approximately one order of magnitude greater (see Fig. 1). However, due to the accelerating form of the kinetics displayed by the alloy samples preoxidized at 850°C, these differences in reaction rates between preoxidized samples had narrowed considerably by the end of the various experimental runs. Unoxidized samples also corroded at an approximately linear rate when exposed to the H_2-H_2O-H_2S environment at 900°C. However, the preoxidized samples always corroded at a slower rate than the samples which had undergone no pretreatment. This paper describes the morphologies and compositions of the reaction products associated with these observed kinetic differences.

Experimental

The apparatus and experimental method associated with the exposure of the Co-30 Cr alloy in the equi-

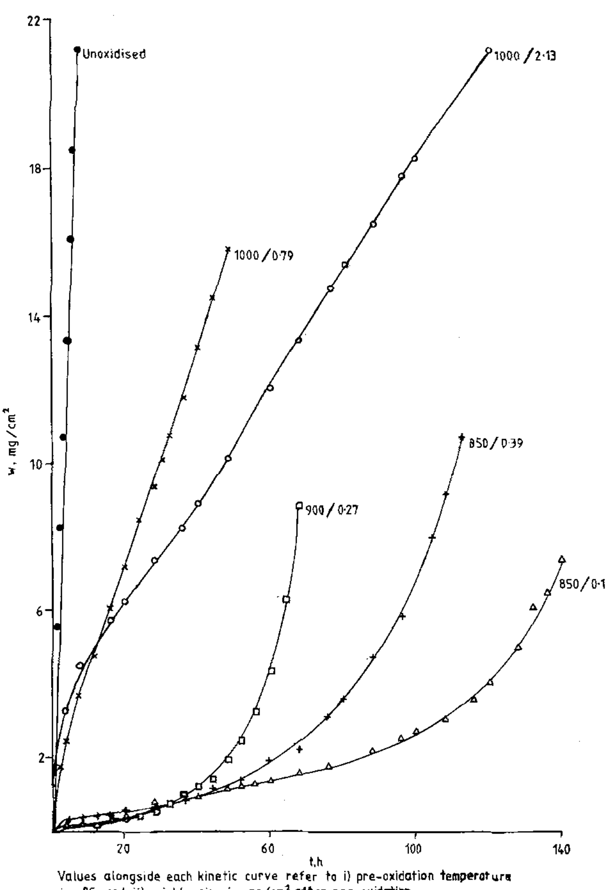

Fig. 1. The weight gain, as a function of exposure time, observed during the corrosion of various preoxidized samples of a Co-30 Cr alloy in an H_2-H_2O-H_2S atmosphere at 900°C.

librated H_2-H_2O-H_2S environment at 900°C have been described in detail elsewhere (5). The dimensions of a typical specimen were approximately 8 × 6 × 0.7 mm resulting in a surface area and weight of about 1.1 cm² and 200 mg, respectively. The preoxidation experiments were carried out in an H_2-H_2O gas mixture generated by bubbling hydrogen gas through dreschel bottles containing water maintained at 20°C. The main feature of this pretreatment assembly was a traveling furnace controlled by time clocks. After exposure periods of 24.33 to 290.33 hr, the oxidized samples were removed from the assembly and reweighed on a Stanton Balance, Model MCl, capable of reading to ± 0.02 mg.

A continuous corrosion monitoring technique was adopted with experiments undertaken in the H_2-H_2O-H_2S gas mixture. The balance/recorder arrangement was capable of reading changes in weight to ± 0.005 mg. In order to exclude corrosive gases from the balance a standard liquid seal technique was employed (5). The corroded samples, on removal from the test environment, were embedded in Scandiplast thermosetting resin and polished to a 1 μm finish prior to metallographic and energy dispersive x-ray analyses. Full details of the techniques of preparation and analysis have been given in another recent publication (6).

Results

In this section, the binary designations "CoS" and "CrS" are used as a convenient shorthand and are not intended to indicate a stoichiometric composition.

Co-30 Cr exposed to H_2-H_2O-H_2S environment: no preoxidation routine.—The exterior corrosion layer was of uneven thickness and, over parts of the alloy surface, was composed of mounds which were sometimes several hundred micrometers thick. It was clear from the globular appearance of the scale formed on the alloy after exposure to the oxygen-sulfur environment at 900°C that in certain areas the reaction product had partially fused so that extreme softening or plastic flow of the mounds had occurred.

Figures 2a-c shows the S, Cr, and Co elemental traces across a severely corroded area. The corrosion product is structured into two distinct layers. The outer layer contained some cracks and large pores. However, it was more compact than the inner layer which contained numerous small pores and extended to the forefront of the subsurface degradation. Figures 2a-c show that the outer region of the outer layer was Co-sulfide, whereas the inner region of this layer was Cr-sulfide with some Co in solid solution. Cr-sulfide was also the predominant phase in the porous inner layer. No oxide was observed in regions which had undergone the most severe attack.

Over those areas of the Co-30 Cr alloy which had suffered less intensive corrosion than the areas described above, the external corrosion layer was also composed of sulfide phases (see Fig. 2d-f). This thin and irregular layer was principally Cr-sulfide containing some Co and in places the Cr-sulfide was surmounted by Co-sulfide regions, which displayed a lamellar structure characteristic of a eutectic phase mixture (Fig. 2g) At certain areas a Cr_2O_3 layer formed under the sulfide. Thus Fig. 2e and the region overlaid by a flag on Fig. 2g, h provide evidence for the existence of an apparently compact, though underlying, ragged oxide layer. At the forefront of the internal

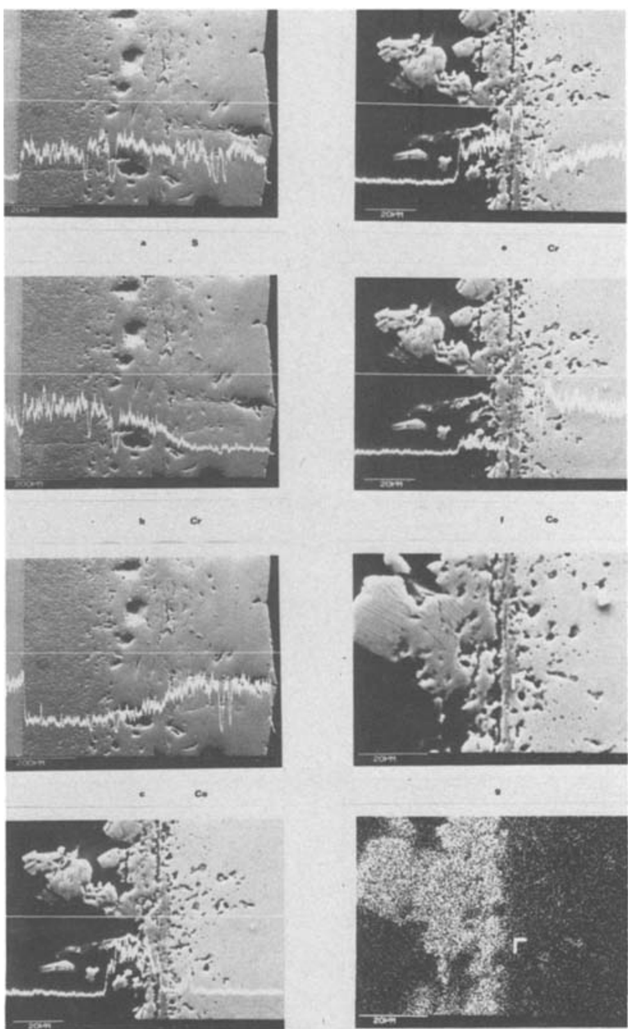

Fig. 2. Morphological features of corrosion relating to the exposure of a Co-30 Cr alloy for 7 hr in an H_2-H_2O-H_2S atmosphere at 900°C—electron and x-ray images, as indicated.

attack scattered and isolated Cr-sulfide particles were observed.

Cr-30 Cr exposed to the H_2-H_2O-H_2S environment: preoxidized at 1000°C.—The preoxidation treatment was carried out for either 24.33 or 290.33 hr. After either treatment, some samples showed scale exfoliation. In order to minimize this problem the specimens were cooled slowly prior to removal from the preoxidation furnace. Only samples showing no exfoliation when examined at 120× were used in the subsequent experiments in the oxygen-sulfur environment at 900°C. The rupture of the scale in small flakes occurred mainly at edges and to a lesser degree elsewhere (see Fig. 3a). All specimens displaying such spallation were excluded from the subsequent oxidation-sulfidation studies.

After exposure in the ternary environment mounds of a silver coloration had formed over parts of the alloy surface and these mounds had again been partially fused. These mounds of corrosion formed in a random distribution over much of the surface of the specimens but were definitely most thick and densely located along specimen edges and in areas neighboring the specimen suspension hole. In Fig. 3b an SEM photomicrograph shows a typical section of the corrosion products. It must be pointed out, however, that the mound shown in this figure had formed from an area of the specimen surface located adjacent to the oxide layer displayed. This applies also to Fig. 3c: here the mounds were composed of two morphologically distinct phases. Small Cr-sulfide mounds (Fig. 3d-f) were surmounted by areas principally rich in Co-sulfide. However there was also probably a degree of elemental interdistribution between the two mounds.

Fig. 3. (a) Electron image of the oxide formed on the surface of a Co-30 Cr alloy after exposure for 290.33 hr in an H_2-H_2O atmosphere at 1000°C; (b-f) morphological features of corrosion relating to the exposure for 120 hr of a preoxidized Co-30 Cr alloy in an H_2-H_2O-H_2S atmosphere at 900°C—electron and x-ray images, as indicated; preoxidation conditions as above at (a).

The preformed oxide was exclusively Cr_2O_3 (Fig. 3e). Although compact and dense it had become detached from the underlying substrate and in places small cracks had appeared (Fig. 3b, c). In areas of the substrate adjacent to the oxide-alloy interface Cr_2O_3 oxide formation had occurred in localized regions with a degree of oxy-sulfide formation near the internal oxide-substrate boundaries. Again Cr-sulfide was the main internal corrosion product present as small clusters deep (> 100 μm) into the alloy.

The small grain size of the oxide formed after preoxidation for 24.33 hr at 1000°C is shown in Fig. 4a. After exposure of these preoxidized samples to the ternary gas environment the corrosion products displayed the same general morphological and compositional aspects as described above. Thus, as shown in Fig. 4b, f, and g internal sulfidation was again evident.

Whereas the mound shown in Fig. 4b was composed of both Co-sulfide and Cr-sulfide (see Fig. 4c-e), Fig. 4f and g show mounds composed primarily of Cr-sulfide and Co-sulfide, respectively. It is of interest to compare the loss of integrity of the oxide when the outer sulfide mound was principally rich in Co. Figure 4g shows a segmented Cr-oxide layer whereas in Fig. 4f the Cr-sulfide mound has grown above an apparently compact and dense chromia layer.

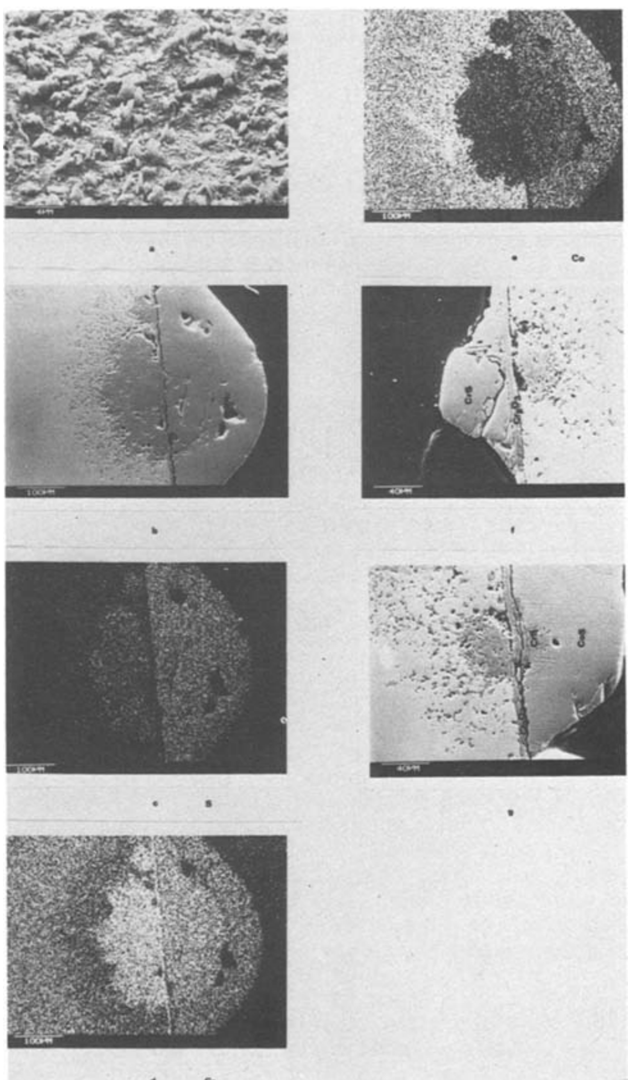

Fig. 4. (a) Electron image of the oxide formed on the surface of a Co-30 Cr alloy after exposure for 24.33 hr in an H_2-H_2O atmosphere at 1000°C; (b-g) morphological features of corrosion relating to the exposure for 48 hr of a preoxidized Co-30 Cr alloy in an H_2-H_2O-H_2S atmosphere at 900°C—electron and x-ray images, as indicated; preoxidation conditions as above at (a).

Co-30 Cr exposed to the H_2-H_2O-H_2S environment: preoxidized at 850°C.—After preoxidation at 850°C the oxide formed on the surface of the Co-based binary alloy appeared to be completely adherent. Nevertheless as with samples preoxidized at 1000°C, the surface oxide on each alloy specimen was examined prior to exposure in the H_2-H_2O-H_2S gas assembly as described earlier. Energy dispersive x-ray analyses, carried out on sections of the oxide formed during the preoxidation treatment showed that the oxide was exclusively Cr_2O_3. The topography and grain size of the chromia layer is shown in Fig. 5a.

After exposure in the H_2-H_2O-H_2S environment at 900°C the surface of the preoxidized alloy was, in places, covered with nodules similar in composition, morphology, and location to those described in the preceding section relating to samples preoxidized at 1000°C. Thus the high temperature degradation was not uniformly distributed over the alloy surface. In Fig. 5b a Cr_2O_3 scale, which had become separated from the underlying substrate and beneath which Cr-sulfide particles had formed, was the only surface corrosion product, whereas in Fig. 5c a Cr-sulfide phase had formed above the thin ballooned Cr_2O_3 layer. In this figure subsurface Cr-sulfidation is again noticeable and it is worthwhile mentioning that this internal degradation was evident below the Cr_2O_3 exterior layer even if this oxide had not been surmounted by a sulfide mound (Fig. 5b).

Other areas of the surface displayed more extensive sulfide corrosion products but apart from the relatively thick surface mounds most other corrosion products were lean in Co, being principally Cr-rich. Figures 6a-c show the formation of a compact Cr-sulfide mound. It is also apparent that the major part of the Cr_2O_3 layer beneath this sulfide mound is also compact. Co is again absent from both the internal and external corrosion species (Fig. 6d).

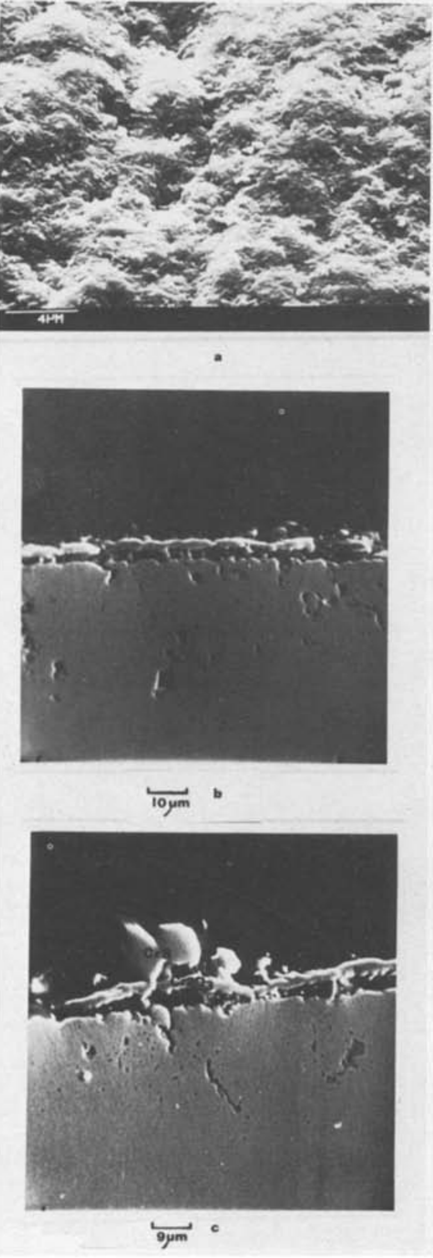

Fig. 5. (a) Electron images of the oxide formed on the surface of a Co-30 Cr alloy after exposure for 290.33 hr in an H_2-H_2O atmosphere at 850°C; (b, c) electron images of corrosion features relating to the exposure for 113 hr of a preoxidized Co-30 Cr alloy in an H_2-H_2O-H_2S atmosphere at 900°C; preoxidation exposure conditions as above at (a).

Discussion

The oxidizing potentials generated in the mixed and equilibrated H_2-H_2O environment at 850° and 1000°C were 3.5×10^{-21} atm (3.5×10^{-19} kN/m²) and 1.8×10^{-18} atm (1.8×10^{-16} kN/cm²), respectively. From a consideration of the Cr-O-S and Co-O-S phase stability diagrams set out in Fig. 7 it is clear that Cr_2O_3 would be expected to be the only stable phase to be formed on the surface of the alloy specimens. This was indeed verified by SEM and energy dispersive x-ray studies (see, for example, Fig. 3e). Thus the experiments carried out using preoxidized alloy samples gave information concerning the intrinsic capacity of preformed Cr_2O_3 layers to withstand severe material degradation when operating in a potentially aggressive oxygen-sulfur environment at 900°C. The oxygen and sulfur chemical potentials generated in the H_2-H_2O-H_2S atmosphere at this temperature were 2×10^{-19} atm (2×10^{-17} kN/m²) and 1×10^{-4} atm (1×10^{-2} kN/m²), respectively. This composition is represented by the symbol + in Fig. 7, where it can be seen that the stable phases to be formed on the surface of the Co-Cr alloy should be Cr_2O_3 and a Co-sulfide.

However from Fig. 2 it is seen that both Co and Cr-sulfides formed on the surface of the bare alloy in the ternary gas atmosphere and that, although Cr_2O_3 did indeed form, its location was always beneath an externally formed sulfide network (see Fig. 2e, g). Thus it would appear that the stable phases to be formed on the surface of the bare Co-30 Cr alloy were Cr-sulfide and Co-sulfide. The phase stability diagram shown in Fig. 7 has been constructed on the basis that the activities of the metal, oxide, and sulfide are unity. This results in the most restricted field of stability for each condensed phase (1). A decreased activity of sulfide (or oxide) reaction product enlarges the sulfide (or oxide) phase stability field. The fact that the Cr-sulfide contained some Co (see Fig. 2e and 2f) would result in the oxide-sulfide transition line marked ab on Fig. 7 moving to the right. This must, presumably, have been sufficient to ensure that the gas atmosphere would form Co and Cr-sulfide reaction products.

The partially fused nature of the surface corrosion product over certain areas of the alloy specimen after exposure in the oxygen-sulfur atmosphere can be accounted for by the formation of the Co-Co_4S_3 eutectic which forms at $\simeq$ 880°C (7). Thus in Fig. 2g and 4g a lamellar structure characteristic of a eutectic phase mixture is clearly evident. On metallographically scrutinizing these lamellae it was possible to discern that these Co-sulfide regions contained some metallic cobalt, formed as a result of the eutectoid reaction

$$Co_4S_3 \rightleftharpoons Co + Co_9S_8$$

which occurs at $\simeq$ 790°C (7).

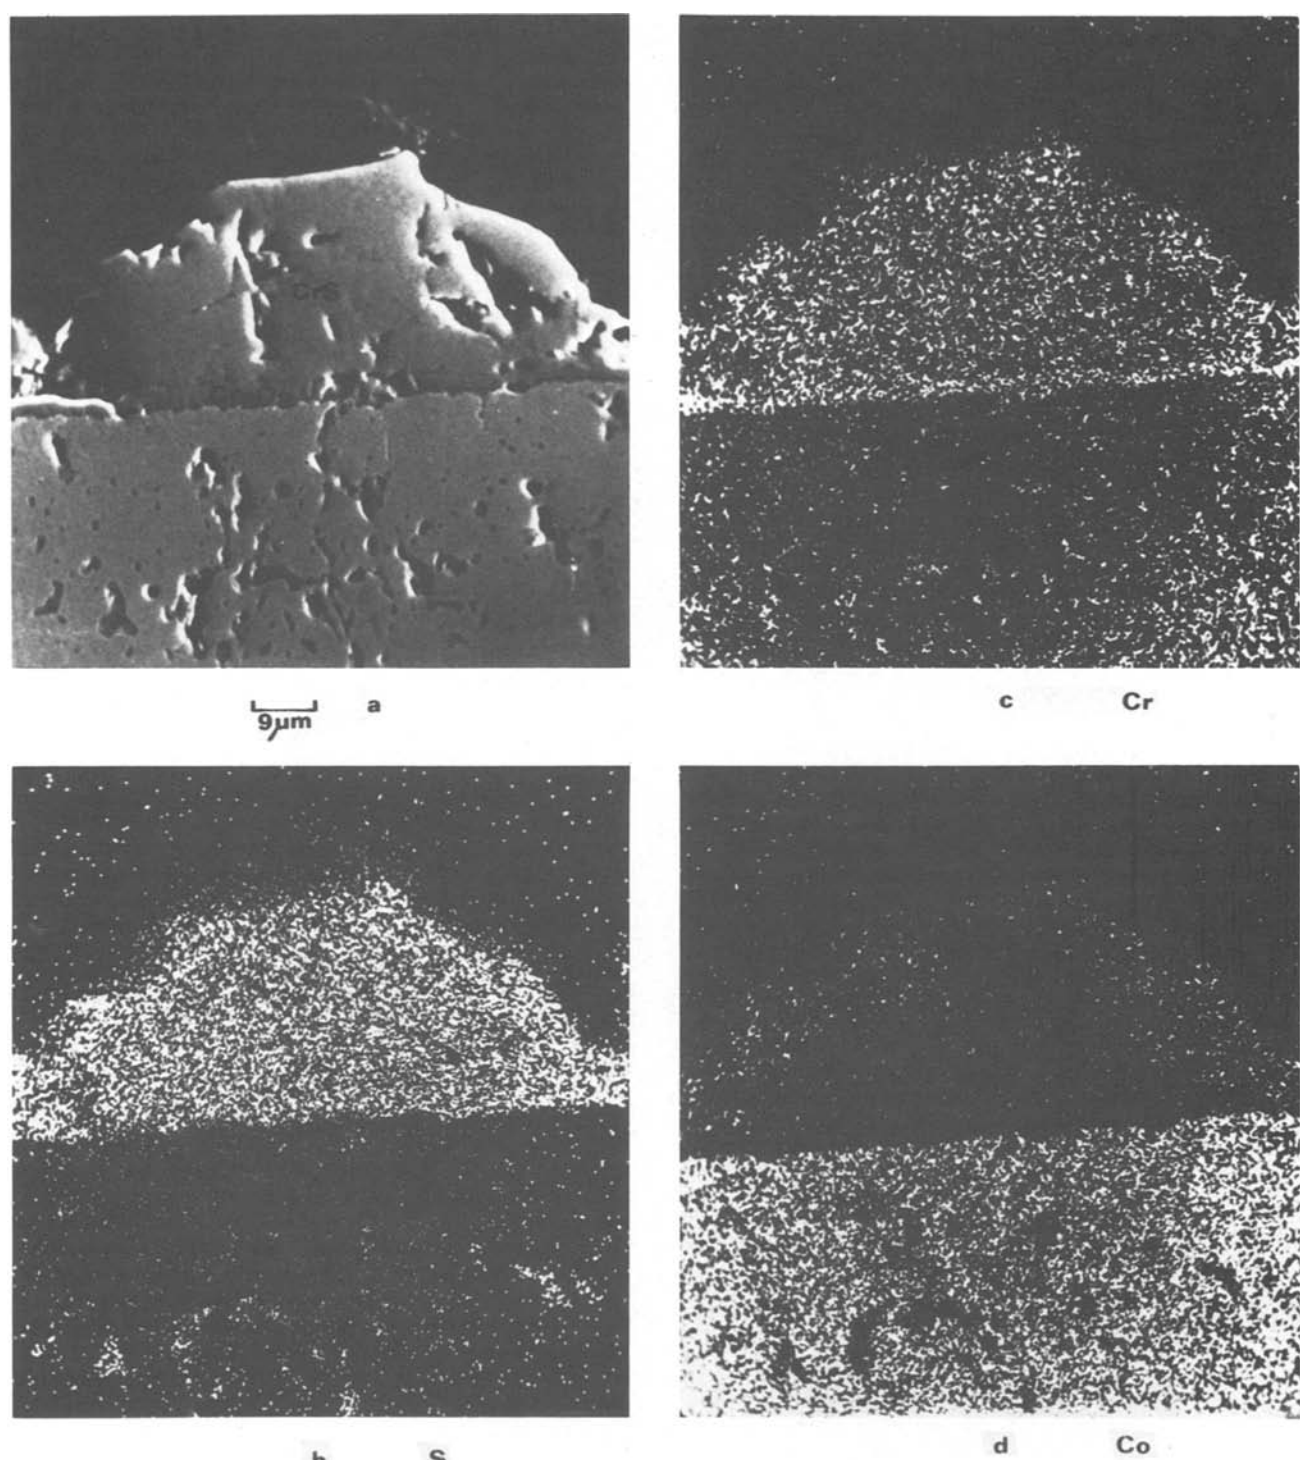

Fig. 6. Morphological features of corroson relating to the exposure for 113 hr of a preoxidized Co-30 Cr alloy in an H_2-H_2O-H_2S atmosphere at 900°C—electron and x-ray images as indicated; preoxidation conditions—290.33 hr in an H_2-H_2O atmosphere at 850°C.

On the Co-30 Cr alloy specimens which had been exposed to the ternary environment without any prior preoxidation routine, the corrosion product was mainly composed of sulfide, with a Cr_2O_3 subsurface layer being formed beneath this sulfide layer over certain areas (see Fig. 2d). Subsurface oxidation, as a phenomenological event, is akin to subsurface sulfidation occurring in a high oxidizing-low sulfidizing environment of which numerous examples have been reported in the literature (6). It was apparent that the external sulfide layer was relatively thin ($\simeq$ 30 μm) if there was an underlying compact Cr_2O_3 layer, in comparison with the thick ($\simeq$ 600 μm) layer formed when there had been no discernable oxide layer formation. Thus it must be concluded that the existence of a basal barrier oxide layer restricted the outward diffusion of Co and Cr ions resulting in a thinner exterior sulfide layer.

Where there had been no discernable oxide formation, the morphology and composition of the external corrosion layer were similar to those reported in studies of the sulfidation of Co-Cr alloys (8, 9). Thus, in a solely sulfidizing environment, and irrespective of the exposure temperature, Biegun *et al.* (8) found that Co-based alloys containing approximately 30% Cr formed a multiphased scale with the outer layer consisting of a pure sulfide of the base metal and the inner layer composed of Cr-sulfide containing Co. It is also worthwhile noting that the irregular nature of the high temperature corrosive attack experienced by

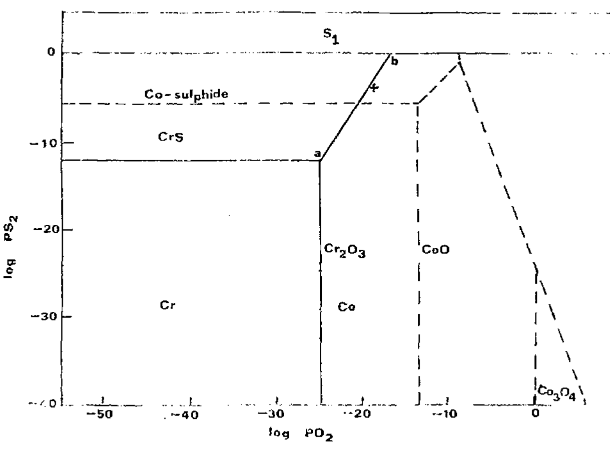

Fig. 7. Phase stability diagrams of the Cr-O-S and Co-O-S systems at 900°C (1173 K). All pO_2 and pS_2 values are in atmospheres.

this binary alloy after high temperature service in the oxygen-sulfur gas atmosphere has also been reported as a feature of the operation of Fe (1, 2, 10), Ni-(1), and Co(1)-based metallic materials in low oxygen-high sulfur activity atmospheres.

The observation that localized oxide exfoliation had occurred on the surface of certain alloy samples during cooling from the preoxidation temperature of 1000°C (but not 850°C) was indicative of the generation of severe internal stresses in the Cr_2O_3 scales. This is in agreement with the reported findings of Caplan *et al.* (11). Although it is reported in the literature that the scales formed after the high temperature oxidation of Co-(25-35%)Cr alloys almost invariably spall on cooling due to a phase change in the underlying alloy, it appears from this present work that the formation of relatively thin Cr_2O_3 oxide layers produced after preoxidation at 850°C may not result in a phase transformation. Thus the reduced Cr depletion associated with a thinner oxide layer may not have resulted in the formation of the fcc phase, which transforms to an hcp phase between 850°-700°C (7).

From the curves shown in Fig. 1, it is evident that preoxidation of the Co-30 Cr alloy conferred additional protection upon the alloy when exposed to the oxidizing-sulfidizing environment at 900°C. This effect of preoxidation is in agreement with the reported results of other independent investigators (2, 12). The observation of the formation of both Co and Cr-sulfides above the oxide barrier (which can be regarded as a marker) indicates that both Co and Cr were transported across the Cr_2O_3 layer. Perkins (1) has presented evidence for the outward diffusion of Fe, Mn, and Co ions across chromic oxide scales operating in atmospheres simulating typical coal gasification conditions. Thus, if Co ions can diffuse, via suitable short-circuit paths, to the surface of the Cr_2O_3 scale the formation of Co-sulfide will occur if the activity of Co is above the critical level required.

The alloy samples exposed to the O_2-S_2 environment after preoxidation at 850°C exhibited accelerated corrosion kinetics after an incubation period. However even during the incubation period before the establishment of a manifestly accelerated rate of corrosion there was a small increase of weight indicative of some sulfide formation on the external surface at certain specific sites. Nevertheless the majority of the oxide surface was not surmounted by sulfide corrosion products at the end of the exposure period (compare Fig. 5b with 6a). The variable location of the external corrosion products tends to suggest that certain areas of the Cr_2O_3 oxide were more susceptible to outward cation transport.

Conclusions

A preformed layer of Cr_2O_3 improved the corrosion resistance of a Co-30 Cr alloy in an H_2-H_2O-H_2S atmosphere at 900°C. This beneficial effect, however, lasted for a limited period only.

Sulfide corrosion products then formed above the preformed Cr_2O_3 layer even though this oxide had been grown in a sulfur-free low oxidizing environment.

ABSTRACT

We have studied the experimental growth rate of boron obtained by pyrolysis of BBr_3 under reduced pressure. Results are interpreted assuming that BBr_3 is adsorbed with dissociation on the boron surface, with no activation energy. Boron combines with the underlying lattice. Bromine is chemisorbed in the form of atoms. Bromine may either desorb in atomic form, or it may recombine and desorb in a molecular form or in the form of a bromide. The growth rate is a function of temperature and of surface coverage, hence of pressure. There is a good fit between the experimental results and the theoretical calculations. The deposition yield depends on the BBr_3 flow rate and on the pumping speed in the reactor.

Preparation of elementary boron by chemical vapor deposition has been frequently discussed, because this method allows one to obtain a very high purity product. Usually, boron halides (BCl_3 or BBr_3) are reduced by hydrogen at atmospheric pressure. Therefore, it is possible to prepare boron in large amounts in different allotropic forms, depending on the deposition temperature (1). However it is hard to make homogeneous deposits on pieces of complex shape by this process. On the other hand, coatings made under reduced pressure show a remarkable uniformity. This has induced us to study conditions of deposition by pyrolysis of BBr_3 under low pressure.

Thermodynamic Approximation

Although a chemical vapor deposition reactor, in particular a cold-wall reactor, does not behave like a system in thermodynamic equilibrium, we may assume that near the substrate there is a zone where chemical species are in thermodynamic equilibrium. The deposition field may then be computed. The boron-bromine system has been studied with a method of calculation based on minimization of the free energy of the system, taking material balance into account (2, 3).

The problem is easy to solve because only two elements are interacting. The number of possible species in the system is also limited. They are: Br_2, Br, B, <B>, BBr_3, BBr_2, BBr. Thermodynamic values necessary for the calculation are given in JANAF tables (4). At high temperature, all species are gaseous with the exception of boron.

We have plotted in Fig. 1 molar concentrations of products in equilibrium at different temperatures for one mole of gaseous BBr_3 at a total pressure of 7.7×10^{-2} Torr. Clearly, decomposition of BBr_3 occurs under reduced pressure, leading to the formation of solid boron.

At higher temperatures (*i.e.* > 1600 K) formation of boron is restricted by the formation of BBr. Nevertheless, the transformation yield of BBr_3 into elementary boron may exceed 95%.

One can also observe that the amounts of molecular bromine and of BBr_2 remain small and that gaseous boron may be neglected.

Experimental Study

The experimental study has been done in a cold-wall reactor (Fig. 2). The reaction chamber is a quartz tube 40 mm in diameter and 300 mm long. A BBr_3 evaporator made of Pyrex is immersed in an ice and water bath. A needle-valve allows one to regulate BBr_3 flow which is measured by a ball flowmeter.

In the reactor, a rotary pump maintains a pressure of about 1×10^{-2} Torr. The unreacted BBr_3 vapors and by-products of the deposition reaction are condensed in a liquid nitrogen trap located between the pump and the reactor. The substrate is a graphite cylinder, 16 mm in diameter and 8 mm thick and rf heated. It is possible to hang the substrate on the beam of an automatic microbalance ,and the variation of weight may be followed continuously. Forces acting on the sample are: its weight, the electromagnetic force due to the induced currents from the magnetic field of the coil, and the upward thrust of the gaseous flow.

Archimedes's force on the sample can be neglected. The resultant of these three forces can be compensated by the re-equilibration force of the balance.

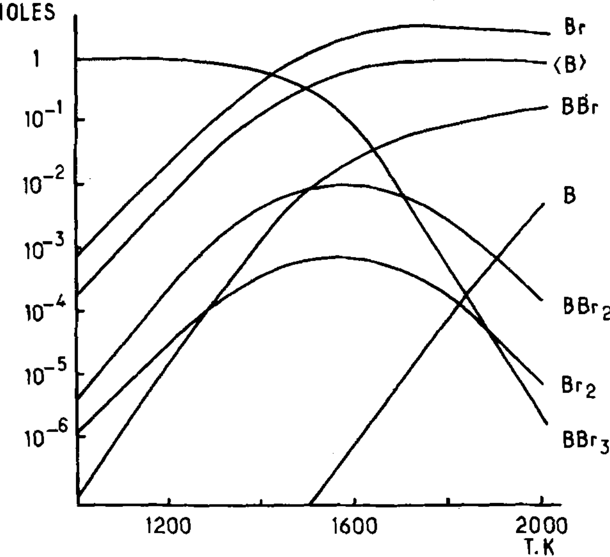

Fig. 1. Calculated compositions *vs.* temperature. Initial concentration: 1 mole of BBr_3; $P = 7.6 \cdot 10^{-2}$ Torr.

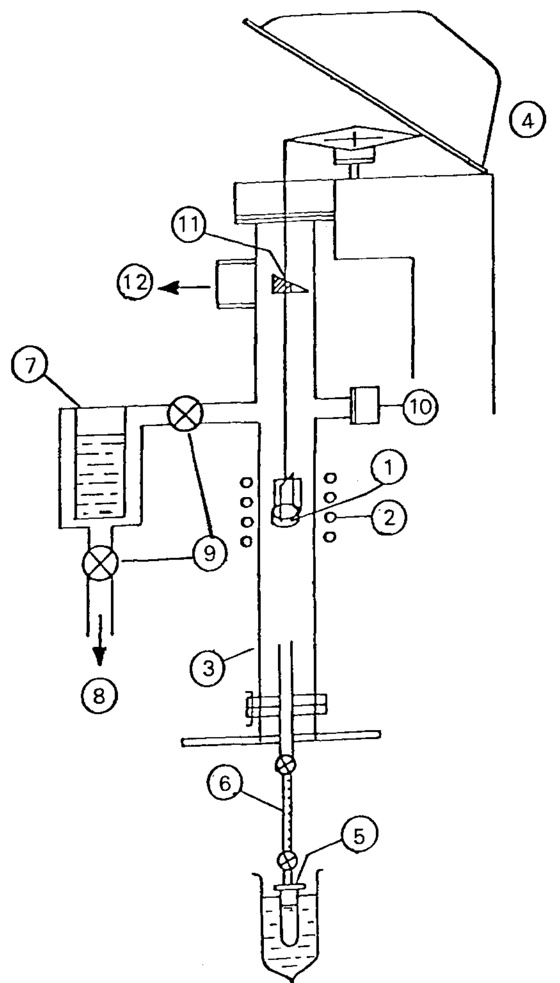

Fig. 2. CVD apparatus. 1, Sample; 2, induction coil; 3, silica tube; 4, balance; 5, BBr_3 evaporator; 6, flowmeter; 7, liquid nitrogen trap; 8, vacuum pump; 9, valve; 10, pressure sensor; 11, prism; 12, pyrometer.

The variation of this force will correspond to the variation of the weight of the sample assuming that other forces are constant. That is the case only if the temperature of the sample T, the gaseous flow Q, and the pressure P are constant. Thus, various experimental parameters must be varied stepwise. When all parameters are fixed, we obtain a record of the weight variation of the sample as a function of time. A derivative of this function gives the growth rate on a sample of a given area.

Since the deposit is thin, we may consider that the deposition area is constant. Series of runs with samples of various dimensions show that growth rate is proportional to the deposition area, all other parameters being equal. We can express the growth rate Vd as a function of weight change per unit area and per unit time. In practice, it is expressed in mg $\times$ cm^{-2} $\times$ hr^{-1}.

When substrate temperature, pressure, and flow of BBr_3 are constant, the increase in weight of the sample is a linear function of time. Therefore, growth rate is constant from the beginning of the deposition on graphite, whereas in the case of boron deposition on metallic substrates (Nb, Ta, W) a boronization of the underlying metal occurs (5), and the curve of weight increase *vs.* time is no longer linear but parabolic. We will only study boron deposition on a boron substrate; *i.e.*, on a graphite cylinder previously covered with a boron layer, and we will not study the formation of the initial layers.

Keeping the pressure and BBr_3 flow constant, the substrate temperature was varied stepwise, and we obtained a series of straight line data that represents weight gain *vs.* time. The slopes of these gave growth rates Vd at the corresponding temperatures.

First, the growth rate increases with substrate temperature T up to about 1700 K, beyond which it becomes quite steady.

We studied at constant temperature the growth rate *vs.* the pressure in the reactor and BBr_3 flow. Pressure can be varied without any significant change in the BBr_3 flow by varying the pumping speed of the gas, because the pressure in the evaporator (19 Torr) is higher than in the reactor ($P < 1 \cdot 10^{-1}$ Torr). On the other hand, if the BBr_3 flow is changed, the pumping speed must be modified in order to have a constant pressure in the reactor.

For fixed substrate temperature and BBr_3 flow, the growth rate increases *vs.* the pressure. For $T > 1700$ K the growth rate is proportional to the pressure (Fig. 3).

For fixed temperature and pressure, the growth rate is not dependent on the BBr_3 flow (Fig. 4). We deduce from these experimental results that the growth rate is only a function of the substrate temperature and the pressure in the reactor

$$Vd = f(T, P)$$

Only the β rhombohedral form of solid boron was obtained.

Interpretation

A kinetic model has been proposed to explain oxygenated (or halogenated) molecule-transition metal interactions (6). We have applied this model to the pyrolysis of BBr_3 at low pressure on a boron substrate.

The main assumptions of this model are as follows: (*i*) Adsorption of BBr_3 on the boron substrate is dissociative and nonactivated. Boron combines with the underlying lattice. Bromine is chemisorbed as atoms and may be desorbed in atomic or molecular form, or as boron bromide after reacting with boron surface atoms. (*ii*) Chemisorbed bromine is mobile at reaction temperatures. (*iii*) BBr_3 may not react with the adsorbed species (Eley-Rideal mechanism is excluded).

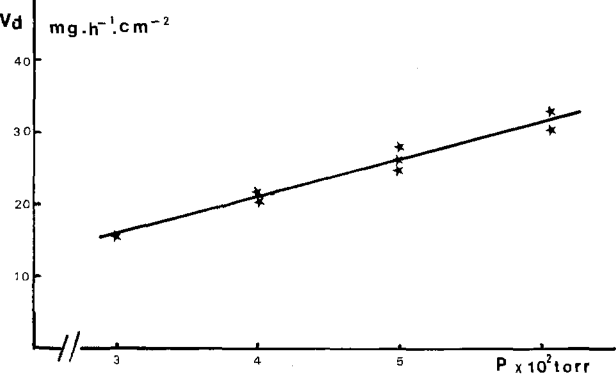

Fig. 3. Experimental growth rate vs. pressure. $T = 1720$ K; $Q_{BBr_3} = 4.18$ g $\cdot$ hr^{-1}.

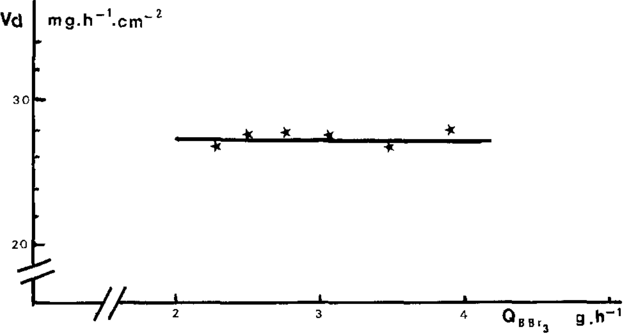

Fig. 4. Experimental growth rate vs. BBr_3 flow. $T = 1720$ K; $P = 5 \times 10^{-2}$ Torr.

The deposition mechanism can be described by the following reactions

$$BBr_3 + 2B \rightarrow 3(B - Br)_{ads} \quad [1]$$

$$(B - Br)_{ads} \rightarrow B + Br \quad [2]$$

$$2(B - Br)_{ads} \rightarrow 2B + Br_2 \quad [3]$$

$$(B - Br)_{ads} \rightarrow BBr \quad [4]$$

$$2(B - Br)_{ads} \rightarrow B + BBr_2 \quad [5]$$

$$3(B - Br)_{ads} \rightarrow 2B + BBr_3 \quad [6]$$

Reactions [2] and [3], combined with reaction [1], lead to boron deposition, while reactions [4] and [5] involve boron attack. Reaction [6] induces neither deposit nor attack.

The flux of BBr_3 molecules which are adsorbed on the surface is

$$Z_{ads} = P_{BBr_3} \cdot (2\pi \cdot m_{BBr_3} \cdot kT_g)^{-1/2} \cdot b(\theta) \quad [I]$$

P_{BBr_3} is BBr_3 pressure in the reactor, T_g is the gas temperature (which is the wall temperature of the reactor, *i.e.*, T_g is about 300 K), m_{BBr_3} is molecular weight of BBr_3, and K is Boltzmann's constant. $b(\theta)$ represents the adsorption sticking probability which depends on the surface coverage θ of bromine.

Various desorption fluxes are

$$Z_{Br} = \nu_{Br} n_s \theta \exp\left(-\frac{\chi(\theta)}{RT}\right)$$

$$Z_{Br_2} = \nu_{Br_2} n_s^2 \theta^2 \exp\left(-\frac{2\chi(\theta) - D_{Br_2}}{RT}\right)$$

$$Z_{BBr} = \nu_{BBr} n_s \theta \exp\left(-\frac{\chi(\theta) + L_B - D_{BBr}}{RT}\right) \quad [II]$$

$$Z_{BBr_2} = \nu_{BBr_2} n_s^2 \theta^2 \exp\left(-\frac{2\chi(\theta) + L_B - D_{BBr_2}}{RT}\right)$$

$$Z_{BBr_3} = \nu_{BBr_3} n_s^3 \theta^3 \exp\left(-\frac{3\chi(\theta) + L_B - D_{BBr_3}}{RT}\right)$$

where ν represents pre-exponential factors, n_s the number of possible adsorption sites per area unit, $\chi(\theta)$ the heat of chemisorption of bromine atoms, L_B the heat of sublimation of boron, D_{Br_2} the heat of dissociation of molecular bromine, D_{BBr}, D_{BBr_2}, D_{BBr_3} the heats of dissociation of BBr, BBr_2, BBr_3 into gaseous boron and bromine atoms at the substrate temperature T.

Under steady-state conditions, the material balance is

$$3Z_{ads} = Z_{Br} + 2Z_{Br_2} + Z_{BBr} + 2Z_{BBr_2} + 3Z_{BBr_3} \quad [III]$$

If Z_B is the flux of boron atoms deposited ($Z_B > 0$ corresponding to deposition of boron), the boron balance will be

$$Z_{ads} = Z_B + Z_{BBr_3} + Z_{BBr_2} + Z_{BBr} \quad [IV]$$

and

$$Z_B = 1/3\, Z_{Br} + 2/3\, Z_{Br_2} - 2/3\, Z_{BBr} - 1/3\, Z_{BBr_2} \quad [V]$$

Therefore boron's growth rate is not expressed in a simple form. Nevertheless, the previous thermodynamic study allows us to make several simplifications: (*i*) the BBr_2 and Br_2 fluxes are negligible in the entire range of temperature studied, (*ii*) at temperature $T > 1600$ K, the BBr_3 desorption flux is also negligible, and (*iii*) further, near $T = 1800$ K, the BBr flux is less than 10% of the Br flux; in this range Eq. [IV] just becomes

$$Z_{ads} = Z_B \quad [VI]$$

Experimental results and Eq. [I] allow us to calculate the sticking probability $b(\theta)$ of BBr_3.

At very high temperature the growth rate approaches a constant value which means, as has been shown previously (6) and as we will confirm later, that surface coverage is small. So Eq. [I] and [VI] allow us to calculate easily the value of b for $\theta = 0$. The value we find is

$$b(\theta = 0) = 0.08$$

The other parameters ν and χ cannot be determined easily. Therefore, we have proceeded to an optimization by the Rosenbrock method (7).

Equation [III] combined with Eq. [II] allows us to determine θ by successive approximations, then we calculate Z_{Br} and Z_{BBr}. Equation [V] then leads to a value for the growth rate for every experimental point. We have used the following thermodynamic data (4): $L_B = 132.8$ kcal/mole, $D_{BBr} = 103.5$ kcal/mole, $D_{BBr_3} = 258$ kcal/mole, and the value of $b(\theta = 0) = 0.08$ previously determined. The theoretical expression for $b(\theta)$ being unknown, we have used a cubic law $b(\theta) = b(\theta = 0)(1 - \theta)^3$ because it is necessary to have three superficial sites free to adsorb BBr_3.

Optimization of other parameters (θ and χ) has led to the following results: (*i*) the BBr_3 desorption flux is important only for the low temperature ($T \lesssim 1400$ K) range in which the experimental results are not very accurate, so it has not been possible to determine ν_{BBr_3}, (*ii*) the binding energy is independent of the surface coverage within the precision of the experiment. We have found that $\chi(\theta) = \chi(\theta = 0) = 65$ kcal/mole, and (*iii*) the order of magnitude of the pre-exponential factors are reasonable, $\nu_{Br} = 10^{28}$ and $\nu_{BBr} = 9 \times 10^{28}$.

Using all these values, we have calculated the curves of Fig. 5 and compared these curves with experimental data; the agreement is satisfactory. Nevertheless it should be observed that the number of optimized parameters is large and the only experimental result is the deposition rate. Hence it is not possible to obtain a set of parameters with good precision. To increase the accuracy, one would have to measure directly the Br, BBr, and BBr_3 fluxes and to determine their kinetic parameters.

Deposition Yield

We notice that the above interpretation of the experimental results does not need the BBr_3 flux through the reactor at any moment. The growth rate Vd will be determined only by the temperature of the substrate and the surface coverage, *i.e.*, by the pressure.

In practice it is important to know the deposition yield Rd, *i.e.*, the ratio of the boron deposited to the amount injected into the reactor in the form of BBr_3

$$Rd = (Vd \times S \times 250.5)/(Q_{BBr_3} \times 10.82)$$

where Q_{BBr_3} is the BBr_3 flow rate, S the deposition

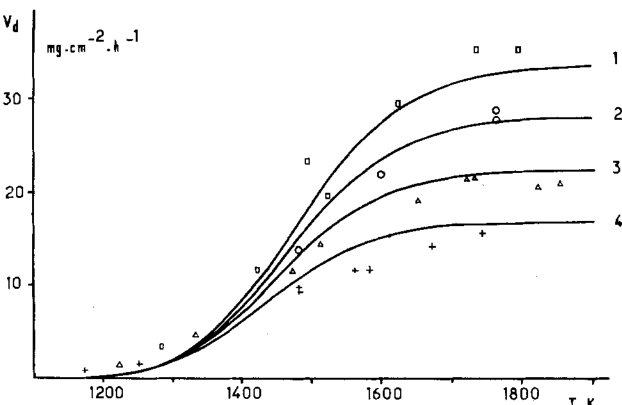

Fig. 5. Growth rate vs. substrate temperature. Experimental results: □, $P = 6 \times 10^{-2}$ Torr; ○, $P = 5 \times 10^{-2}$ Torr; △, $P = 4 \times 10^{-2}$ Torr; +, $P = 3 \times 10^{-2}$ Torr. Calculated curves ($b(\theta = 0) = 0.08$): curve 1, $P = 6 \times 10^{-2}$ Torr; curve 2, $P = 5 \times 10^{-2}$ Torr; curve 3, $P = 4 \times 10^{-2}$ Torr; curve 4, $P = 3 \times 10^{-2}$ Torr.

area, and Vd the deposition rate. If Q_{BBr_3} is held constant, the yield Rd will increase with Vd or S. When the temperature is optimal Vd will increase with the pressure, *i.e.*, with decreasing pumping speed. Rd will increase when the sticking probability increases.

It should be noticed that if Vd or S increase too much, Rd could be higher than 1, which is impossible. In this case, there is a consumption of BBr_3 greater than the flow and the steady-state conditions are no longer established. The BBr_3 partial pressure in the reactor will decrease until a new steady state is established. Then yield becomes maximum for these new conditions. We have obtained a yield $Rd = 0.89$ with an 8 cm^2 deposition area heated at $T = 1630$ K, a 3.32 g/hr BBr_3 flow rate, and an initial total pressure of 1×10^{-1} Torr. The growth rate was equal to 16 mg/hr/cm^2, which corresponds to a BBr_3 partial pressure of 3×10^{-2} Torr.

Conclusion

The kinetic model previously published (6) has been extended to BBr_3 pyrolysis at low pressure on a hot surface. We have determined the parameters determining the boron growth rate; these are the temperature and the surface coverage, therefore also the BBr_3 pressure. The reactor yield depends essentially on the BBr_3 flow and on the pumping speed that should be optimized as a function of deposition area.

A Negative-Working Plasma-Developed Photoresist

Gary N. Taylor,* Thomas M. Wolf, and Michael R. Goldrick

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Plasma-developed negative photoresists with good sensitivity and at least 1 μm resolution have been developed by the addition of quinone sensitizers such as phenanthrenequinone to a plasma-developed x-ray resist comprised of poly(2,3-dichloro-1-propyl acrylate) and N-vinyl carbazole. The sensitivity is optimum in the 290-350 nm range. Locking of the carbazole by cationic polymerization is presumably accomplished via cation radical intermediates produced upon quenching N-vinyl carbazole excited states with quinones that are excellent electron acceptors.

In a recent report (1) Taylor and Wolf described materials and a technique whereby patterns could be developed in negative x-ray resist by dry development using an oxygen plasma. An essential feature of this technique was the differential removal rates of resist in the imaged and nonimaged areas which allowed the shallow relief image obtained after fixing to be further enhanced to practically usable film thicknesses upon plasma development. The essential compositional elements which optimized sensitivity were found to be (*i*) an x-ray absorbing host polymer having a high removal rate in an oxygen plasma as best exemplified by poly(2,3-dichloro-1-propyl acrylate) DCPA and (*ii*) a moderately volatile aromatic monomer that is readily polymerized by ionizing radiation as best exemplified by N-vinyl carbazole NVC. Using an 81:19 mixture by weight of DCPA and NVC, submicrometer patterns were obtained upon exposure with low doses (4.5 mJ/cm^2) of $Pd_{L\alpha}$ x-rays at the 4.37Å wavelength.

When these results were obtained it intrigued us as to whether such resists could be made sensitive to u.v. and visible radiation and thus be of use in more conventional photolithographic printing of high resolution negative resist patterns needed for VLSI device fabrication. The recent announcement by Motorola of a dry-developed photoresist (2) whose detailed structure was not given and a patent pertaining to this result (3) prompts us to report results obtained with monomer-polymer mixtures containing sensitizers which render them sensitive to u.v. and visible radiation.

Experimental

Poly(2,3-dichloro-1-propyl acrylate) was prepared as previously described (4). Its molecular parameters were $\overline{M}_w = 2.45 \times 10^6$ g/mole, $P = \overline{M}_w/\overline{M}_n = 2.69$, $[\eta] = 1.95$ dl/g in ethyl acetate at 30°C. N-vinyl carbazole and hydroquinone dimethacrylate were used as received from Polysciences Incorporated and Monomer Polymer Labs, respectively. Sensitizers were obtained from Aldrich Chemical Company except for Irgacure 651 which was obtained from Ciba-Geigy Corporation. Wafers were coated by spinning from chlorobenzene solutions that had been filtered thru 0.45 μm pore membrane filters. These solutions were prepared by sequential dissolution of the polymer, monomer, and sensitizer, respectively, in the chlorobenzene.

Samples were exposed on a Kasper Model 2001 contact printer having standard optics. The mask and wafer were flushed with nitrogen in proximity prior to contact. Additional samples were exposed on a

Perkin Elmer Model 120 projection printer and a Perkin Elmer Model 111 projection printer with the optics modified for exposure at 3100Å. After exposure the monomer not locked into the host polymer by irradiation was removed by treatment for 1 hr at 80°C and 0.1 Torr pressure. This afforded a relief image having greater thickness in the exposed regions but less than the initial thickness. Development was accomplished by treatment with an O_2 plasma in a Model 2005T-1813-SCA plasma etcher manufactured by the International Plasma Division of Dionics Incorporated. Operational parameters were: power = 100W, pressure = 0.55 Torr, and starting temperature = 35°C. Treatment was continued until the unexposed areas were completely removed. Sensitivity curves were obtained from step tablet and discrete exposures. Exposures using the step tablet always resulted in lower normalized film thickness through chrome areas of increasing optical density compared to discrete exposures of the equivalent dose. This indicated. that the sensitivity curves were flux dependent. Final evaluations were consequently conducted using discrete exposures of full wafers.

U.V. spectra were measured on a Cary 17 U.V.-visible spectrometer. Film thicknesses were measured on a Nanometrics, Incorporated Model 10-0174 Nano-Spec automatic film thickness gauge.

Results and Discussion

Two approaches were taken to try to sensitize the plasma-developed negative x-ray resists to u.v.-visible radiation. The first was use of sensitizers which generate radical species that initiate polymerization of acrylic and styrenic monomers thus locking them in the irradiated regions. The second approach was generation of cation radical intermediates by quenching suitable monomer or sensitizer excited states with either donor or acceptor quenchers. Best results were obtained with N-vinyl carbazole, a very good electron donor which is itself efficiently polymerized by cation radical species. These methods were recently reviewed by Ledwith and co-workers in 1974 (5) and 1975 (6), respectively.

Five sensitizers were evaluated using DCPA as the host polymer and hydroquinone dimethacrylate as the polymerizable monomer. The sensitizers were 2,3-diphenylindenone (1), acenaphthenequinone (2), peri-naphthenone (3), phenanthrenequinone (4), and Irgacure 651 (5). The first

1 2 3

4 5

four have moderate absorption in the u.v. and visible regions with ϵ ranging from 1000 to 5000 liters $mole^{-1}$ cm^{-1} while Irgacure 651 is weakly absorbing at 3130 and 3660Å (ϵ = 150 and 100 liters $mole^{-1}$ cm^{-1} at these wavelengths, respectively). Using approximately 2.5 weight percent (w/o) of sensitizers 1-4 and 5.4 w/o of sensitizer 5 the results summarized in Table I were obtained using 1 μm initial thickness films exposed for 4 min through a chrome step tablet mask. The least absorbing sensitizer, Irgacure 651, proved to be the most efficient sensitizer. Upon absorption of light it affords free radical species which initiate the polymerization of acrylic monomers very efficiently. The two quinones, phenanthrenequinone and acenaphthenequinone were almost as effective as the Irgacure. Presumably, these sensitizers form free radical species by photoreduction of the reactive α-diketone groups to give a hemiketal radical by hydrogen abstraction presumably from the host polymer molecule. Monomer polymerization then ensues. The two eneones, perinaphthenone and 2,3-diphenylindenone, were less sensitive. The latter is very insensitive but highly absorbing. It may not undergo the facile photoreduction thought to provide initiating radical species because its lowest triplet state may be a π-π^* state rather than an n-π^* state which is more prone to undergo hydrogen abstraction (7). All of the combinations shown in Table I are less sensitive than the Kodak 747 negative photoresist which requires about 1 sec of exposure time.

The resolution of the resist mixtures listed in Table I was not optimized for the smallest features on the step tablet and mask because other formulations containing DCPA and N-vinyl carbazole offered improved sensitivity. Results for these materials are summarized in Table II. Typical sensitivity curves are given in Fig. 1. Two additional quinone sensitizers were studied. These were 1,5-diaminoanthroquinone (6) and 1,2-naphthoquinone (7).

6 7

All sensitizers resulted in highly sensitive negative resist materials with sensitivity comparable to that of conventional wet-developed negative resists and better than that of novolac-based positive photoresists. Phenanthrenequinone and acenaphthenequinone were the most efficient sensitizers. The photolocking mechanism which we suggest is outlined below (in Scheme 1) where Q represents the sensitizer quinone, N represents N-vinylcarbazole, and P represents polymerized N-vinylcarbazole. We believe that quenching of $^1N^*$ by the quinone is the dominant means of generating the radical cation which we feel is responsible for efficient polymerization of N. A less efficient means of generating $N.^+$ is by quenching $^3Q^*$ with N. We presume this may be a less efficient process because the absorption of the quinone is much less than that of the N-vinylcarbazole in the short wavelength region. This is best visualized in the absorption spectra of various DCPA, NVC, and phenanthrenequinone films shown in Fig. 2. For example, at 334 nm and for 1 μm thick films DCPA-NVC has OD = 0.53 compared to OD = 0.08 for DCPA-PQ. Here DCPA/NVC and DCPA/PQ values are 4.26 and 37.5, respectively. Thus, the quinones may not be sensitizers in the classical sense (reactions [10]-[12]) but probably sensitize primarily by quenching N-vinylcarbazole excited states.

[b] Thickness obtained as previously described in Table I.
[c] $D^{0.20}$ is the dose required to give a normalized thickness of 0.20 after plasma development.
[d] γ, the contrast, is explained in Table I.

$$P.^{+} \rightarrow P \quad [14]$$

Except for the perinaphthenone and 1,2-naphthoquinone sensitizers these resists have very low contrast. Similar results were obtained for the compositions containing hydroquinone dimethacrylate except when 2,3-diphenylindenone was used as the sensitizer. However, we find, as Taylor and Wolf observed for the plasma-developed x-ray resists (1), that resolution is independent of the exposure dose. This results from the differential nature of the plasma development process in which the exposed regions are removed more slowly than the unexposed regions.

Since acenaphthenequinone is relatively insoluble in the DCPA-NVC mixture, we did not choose to try to optimize its effectiveness. Note in Fig. 1 that at exposure times greater than 7 sec and less than 30 sec acenaphthenequinone is a more effective sensitizer and thus could have offered the advantage of greater final thickness. Instead we chose to optimize formulations containing phenanthrenequinone sensitizer. Thus we studied the influence of composition, exposure conditions, and exposure mode on resist properties.

The data presented in Tables III and IV summarize the results of compositional changes in the DCPA-NVC-PQ formulation. Unfortunately, these results were obtained without flushing the wafer with a high enough flow of nitrogen (standard machine conditions were used) prior to contacting the mask and wafer. This allows residual dissolved oxygen to remain in the film and leads to higher contrast because the low dose exposures are quenched by O_2 to a greater extent than the high dose exposures. However, relative comparisons appear valid and two trends are evident. The first denoted by Table III is that excess sensitizer appears to act as a quencher. In these experiments the DCPA/NVC ratio was held constant at 4.29 while the sensitizer concentration was varied. Nearly optimum sensitivity was found at the intermediate 2.6 w/o concentration.

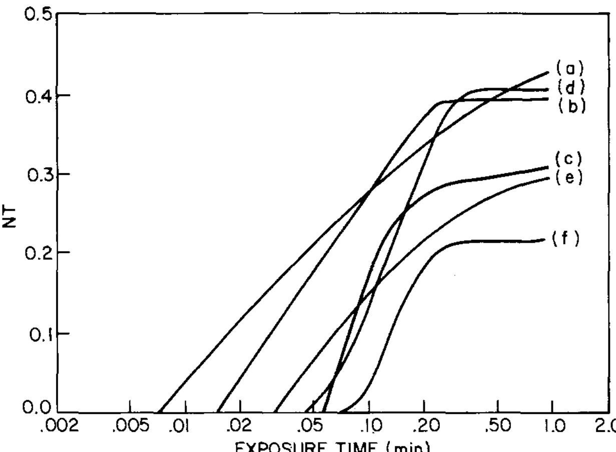

Fig. 1. Sensitivity curves for step tablet exposures of mixtures containing 78.9 parts DCPA, 18.4 parts N-vinyl carbazole, and 2.6 parts of the following sensitizers: curve (a), phenanthrenequinone; curve (b), acenaphthenequinone; curve (c), Irgacure 651; curve (d), perinapthenone; curve (e), 1,5-diaminoanthroquinone; curve (f), 1,2-naphthoquinone. NT = normalized thickness.

Table III. Effect of sensitizer concentration on DCPA-NVC-PQ plasma-developed photoresist

w/o DCPA	w/o NVC	w/o PQ	$D^{0.20}$ (sec)	γ
79.8	18.6	1.5	14	0.42
78.9	18.4	2.6	9	0.66
76.9	17.9	5.1	14	0.59

Table IV. Effect of monomer concentration on DCPA-NVC-PQ plasma-developed photoresist

w/o DCPA	w/o NVC	w/o PQ	$D^{0.20}$ (sec)	γ
73.2	24.4	2 .4	19	0.61
78.9	18.4	2.6	9	0.66
85.7	11.4	2.9	15	0.38

A second observation is that unlike the DCPA-NVC x-ray resist where sensitivity increased with increasing w/o NVC (1), the photosensitized samples show optimum sensitivity at an intermediate NVC concentration. This is indicated by comparing the results of the experiments listed in Table IV conducted at approximately 2.5 w/o sensitizer. From these results plotted as $D^{0.20}$ *vs.* w/o NVC and phenanthrenequinone, the composition for optimum sensitivity is predicted to contain approximately 80.0 w/o DCPA, 16.5 w/o NVC, and 3.5 w/o phenanthrenequinone.

The influence of exposure conditions has been mentioned in the previous section. A sufficient nitrogen flow is required to get reproducible results and to minimize exposure time. Comparison of adequate and inadequate nitrogen flushing of the mask-wafer sandwich prior to contact is presented in Fig. 3 which shows one sensitivity curve for each of these pretreatment conditions. Presumably, the residual oxygen in the inadequately flushed film b inhibits NVC polymerization at the lowest doses thus offering the advantage of higher contrast but adding the disadvantage of irreproducibility. We believe that failure to obtain short exposure times using the Perkin Elmer Model 120 printer with output primarily at 366, 405, and 435 nm is due to overwhelming O_2 quenching in the air atmosphere. The DCPA-PQ mixture is weakly absorbing at these wavelengths and moderately absorbing at 303, 313, and 334 nm where only weak lamp output is available. Short 23 sec exposure times have been obtained using the Perkin Elmer Micralign 111 with optics and filters modified to optimize exposure at the 303, 313, and 334 nm wavelengths. With these operating conditions the absorbed flux is apparently high enough to completely react all the O_2 present in the film as well as that which diffuses into the film during exposure.

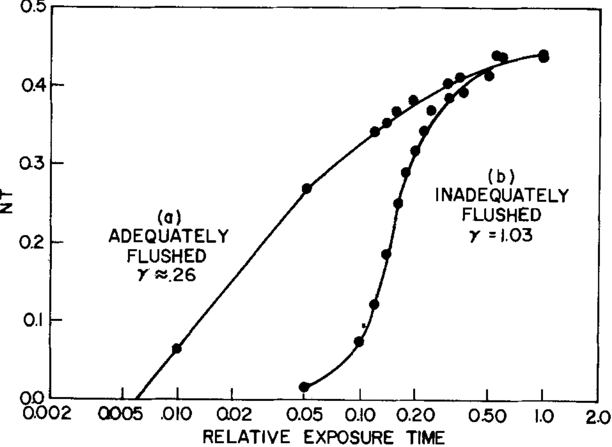

Fig. 3. Sensitivity curves for DCPA-NVC-PQ resist exposed with curve (a) adequate N_2 flushing; curve (b), inadequate N_2 flushing. NT = normalized thickness.

Exposure mode is another factor which affects resist response. We mentioned previously that step tablet exposures made the resist appear less sensitive than it was when discrete exposures were conducted. This effect is best demonstrated by the sensitivity curves shown in Fig. 4. The resist was a 78.9, 18.4, and 2.6 part mixture by weight of DCPA, NVC, and phenanthrenequinone. For a constant normalized thickness of 0.2 the step tablet exposures gave varying exposure times of 4.7, 2.7, and 2.0 sec for total exposure times of 60, 30, and 15 sec, respectively. If discrete exposures were used, then for large features having > 10 μm minimum dimensions, sensitivity curve a in Fig. 5 was obtained. Note that the contrast for this curve is 0.45, a much higher value than that for the 60 sec curve in Fig. 4 where $\gamma = 0.10$. Thus, to get a true sensitivity curve for these materials, discrete exposures must be used. Relative sensitivity data can be obtained from step tablet exposures. However, when resolution is the primary concern the discrete method must be used. Also included in Fig. 5 are sensitivity curves for Kodak 747 negative resist and Hunt HPR-204 positive resist. Both exhibit much higher contrast than the plasma-developed resist and require exposure times of 1.0 and 6.5 sec, respectively.

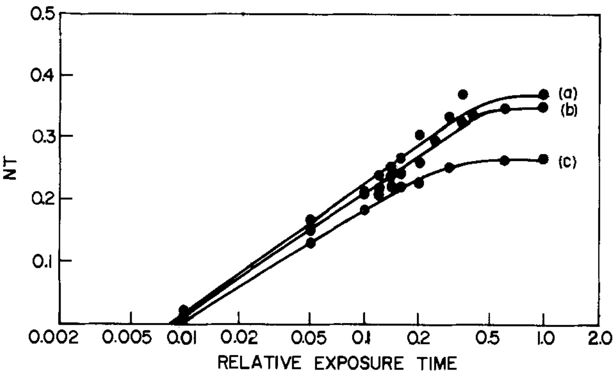

Fig. 4. Sensitivity curves for step tablet exposures of DCPA-NVC-PQ resist exposed for curve (a), 60 sec; curve (b), 30 sec; curve (c), 15 sec.

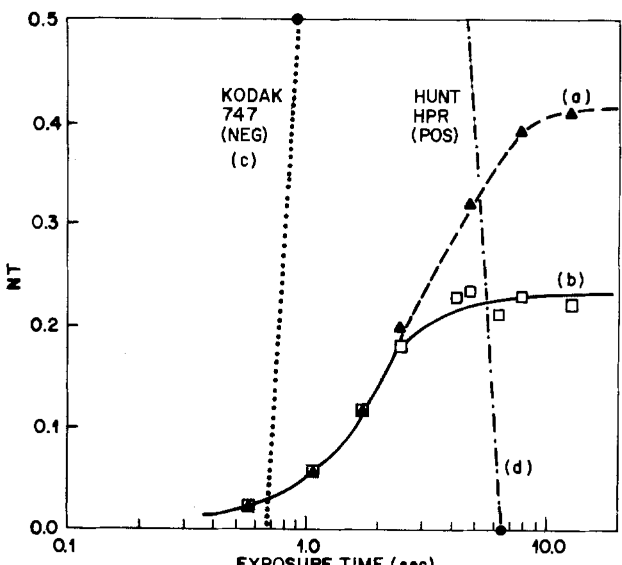

Fig. 5. Sensitivity curves for discrete exposures of DCPA-NVC-PQ resist showing the dependence on feature size: curve (a) features > 10 μm; curve (b), features ≥ 1 μm. Curves (c) and (d) are for Kodak 747 negative resist and HPR-204 positive resist. The dark spots indicate the doses required for high resolution features.

The curves in Fig. 5 also reveal another important phenomenon. Curve (a) is the curve obtained when the thicknesses are measured for large features with minimum dimensions greater than 10 μm. Unexposed regions contiguous to such regions have no residual resist remaining. However unexposed features having a minimum dimension <10 μm are not completely cleared. The smallest features exhibit the worst deviations. If the smallest features on the mask (~1 μm) are completely cleared, another sensitivity curve is obtained, curve (b) in Fig. 5. All features with dimensions ≥1.0 μm are well resolved for each point on curve (b). We believe the differences are due to diffraction effects even though the mask and wafer are presumably in contact. Exposures of a bowed wafer having proximity and contact exposures show even worse final resist thickness variations where the resist and mask are out of contact.

The effect on resolution by exposing for an exposure time longer than about 3 sec and plasma developing until only the large unexposed areas are cleared is shown in Fig. 6. The patterns were made by exposing for 10 sec (Fig. 6A) to give a 0.40 μm final thickness film, and 3 sec (Fig. 6B) to give a 0.21 μm final thickness film. Note that the image quality in 6A is fuzzy and that considerable resist remains in the 1 μm lines and spaces and the 2 μm contact windows which exhibit the worst diffraction effects. In Fig. 6B the features are much sharper and resolution appears to be about 1 μm.

Better examples of the resolution of the plasma-developed photoresist are presented in Fig. 7. Here the 1 μm lines and spaces (Fig. 7a), the 2 μm contact windows (Fig. 7b), the isolated fine lines (Fig. 7c), and the isolated fine gaps (Fig. 7d) are all resolved at a final thickness of 0.24 μm. The exposure time was 3 sec. High resolution patterns also were obtained on the modified Perkin Elmer at a 23 sec exposure time on the aperture 4 setting. Figure 8 shows examples of some of the patterns obtained. Exposure conditions and mask resolution were not optimum in these experiments. Better results might be obtained with more experimentation. Final resist thicknesses were 0.25 μm.

Like the plasma-developed x-ray resist (1), the plasma-developed photoresist can only be used with trilevel processing (8) since flat surfaces are required. The DCPA-NVC-PQ mixture is quite resistant to conditions (CHF_3 reactive ion etching) used to etch the SiO_2 layer in the trilevel process (8). Typically,

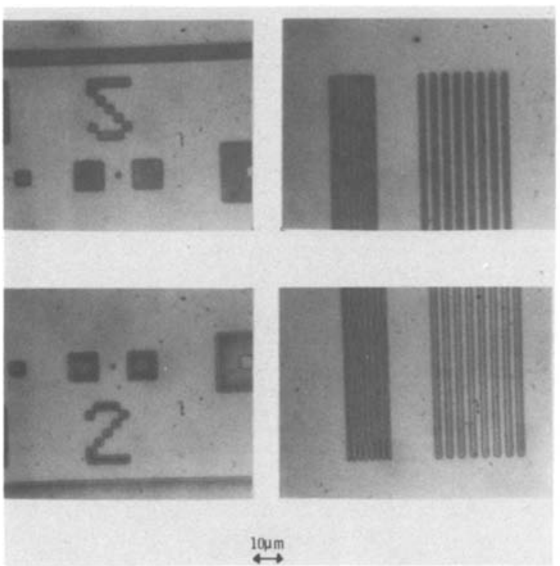

Fig. 6. Photomicrographs of contact exposures of 1 and 2 μm windows (left) and 1 and 2 μm lines and spaces in the DCPA-NVC-PQ resist exposed for (a) 10 sec, 0.40 μm thickness; (b) 3 sec, 0.21 μm thickness.

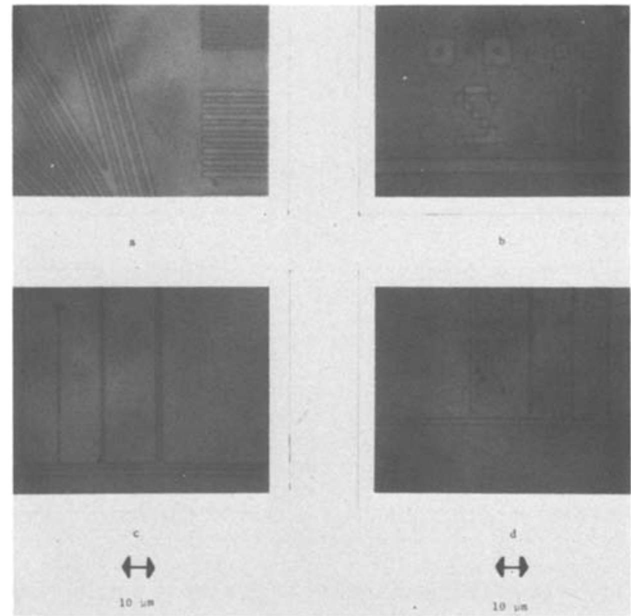

Fig. 7. Photomicrographs of 0.24 μm thick patterns in DCPA-NVC-PQ resist contact exposed for 3 sec (a) 1 and 2 μm lines and spaces and 2 μm oblique lines, (b) 1 and 2 μm windows, (c) 0.5, 1.0, and 2.0 μm isolated lines, (d) 0.5, 1.0, and 2.0 μm isolated gaps.

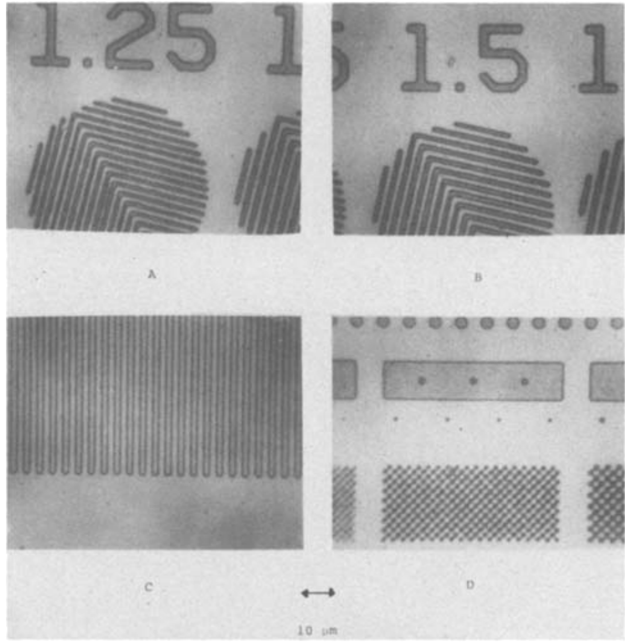

Fig. 8. Photomicrographs of 0.25 μm thick patterns in DCPA-NVC-PQ resist obtained by exposure with the Perkin Elmer 111 projection printer with optics modified for exposure at 3100Å. (A) 1.25 μm oblique lines, (B) 1.50 μm oblique lines, (C) 2 μm lines and spaces, (D) 1.25 μm contact windows. 1.0 μm and smaller features were not resolved. Exposure time was 23 sec.

200-300A are lost when 1200A of SiO_2 is removed by the RIE process.

Conclusions

The plasma-developed x-ray resist consisting of poly(2,3-dichloro-1-propyl acrylate) (15) and N-vinyl carbazole (16) has been sensitized to u.v. radiation by the addition

— $(CH_2—CH)_n$— C=O O CH_2 CH Cl CH_2 Cl

15

16

of quinone sensitizers. The most efficient sensitizer is phenanthrenequinone. The optimum composition contains 80.0 w/o DCPA, 16.5 w/o NVC, and 3.5 w/o phenanthrenequinone. With it 1 μm features can be printed in 0.23 μm final resist thickness with about one-half the exposure time required for HPR-204 positive photoresist. The resist is compatible with and can only be used with trilevel processing. It is sensitive primarily to the 3000-3400Å radiation of the u.v. spectrum. Resolution is sensitive to diffraction indicating a low modulation transfer function for this type of resist. However, high resolution features can still be obtained because of the differential development of exposed and unexposed regions during O_2 plasma processing.

Presently, this resist class offers no significant advantages over commercially available positive photoresists. Resolution is in fact probably somewhat higher for the latter. However, the resolution of plasma-developed photoresists is better than that of presently available negative photoresists. This is not a significant advantage since most high resolution photolithography is adequately accomplished using positive photoresists. The main advantages mentioned for the Motorola version (3) of the plasma-developed photoresist are that it is more cost effective and eliminates the need for the use of large volumes of potentially hazardous wet chemicals to develop and remove the resist patterns. These are important advantages. While plasma development avoids the use of wet chemicals, it does, however, require extensive capital investment in vacuum and plasma processing equipment which also must be safely exhausted. Throughput is less with presently available plasma processing units and uniformity of development can be a problem. In our opinion the foremost reasons for using plasma-developed resists are to obtain enhanced resolution and sensitivity. This makes such negative resists very attractive for x-ray lithography where resolution of highly sensitive resists is limited by swelling during development to about 1 μm. Similar advantages are not as significant in photolithography at conventional wavelengths with the materials we have studied.

Edge Profiles in the Plasma Etching of Polycrystalline Silicon

A. C. Adams* and C. D. Capio

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Five gas mixtures for plasma etching polycrystalline silicon films have been compared with emphasis on the edge profiles and the linewidth loss. The two isotropic etches, CF_4-O_2 and 1:1 C_2F_6-CF_3Cl produce edge profiles that follow an arc of a circle and have line width losses that are nearly twice the thickness of polycrystalline silicon etched. In contrast the anisotropic etches, C_2F_6-Cl_2 and 4:1 C_2F_6-CF_3Cl produce profiles that are nearly vertical and have line width losses that are dependent on the etch rate of the photoresist mask. Samples etched in CF_3Cl have circular profiles and have linewidth losses that are initially very small but increase rapidly as the samples are overetched. Measurements of the resist erosion rate indicate that the photoresist mask etches isotropically in C_2F_6-Cl_2 even though the polycrystalline silicon is etching anisotropically. Of the five etches examined, C_2F_6-Cl_2 is superior for etching very fine features.

Several processes for the plasma etching of polycrystalline silicon have been reported (1-5). The various etches differ in the degree of etching anisotropy, the etching selectivity over SiO_2, the loss in feature size, and the sensitivity to loading effects. These effects become increasingly important in new device technologies where gate oxides are very thin (300-500Å) and where submicron features must be etched. In addition, several papers discussing mechanisms of plasma etching have been published (6-11). It appears that the relative roles of ionic and neutral etching species and their relative lifetimes are important factors affecting the degree of etching anisotropy and the selectivity of various etchants (2, 12-15).

* Electrochemical Society Active Member.
Key words: etching, films, photoresist.

However, detailed comparisons of different plasma etching processes are not available. In this paper we report the etching of undoped and phosphorus-doped polycrystalline silicon with five different plasma etches, and compare the edge profiles and the losses in feature size.

Experimental

Samples are etched in a parallel-plate, radial-flow reactor that has been described previously (1). The etching conditions are summarized in Table I. Samples are prepared using standard processing techniques. The polycrystalline silicon (1.2 μm thick) is deposited at reduced pressure by decomposing silane at 640°C. The substrates are thermally oxidized silicon (0.4 μm of SiO_2 on 75 mm diam wafers). The polycrystalline silicon is doped with phosphorus subsequent to deposition using phosphorus tribromide at 1000°C for 25 min. The resistivity after doping is 1×10^{-3} Ω-cm. The samples are baked (180°C, 45 min) and an adhesive layer of HMDS (hexamethyldisiloxane) is applied, followed by 1 μm of positive resist (HPR-204). The samples are then baked at 100°C for 20 min; the photoresist is exposed and developed; and, the samples given a final bake at 90°C for 30 min. Thick polycrystalline silicon (1.2 μm instead of the usual 0.3-0.5 μm) is used to improve the accuracies of the linewidth and the edge profile measurements. The underlying oxide is 0.4 μm thick (instead of 300-1000Å) to eliminate the possibility of etching through the oxide when samples are overetched for long times.

Edge profiles are measured by SEM cross sections at magnifications of 7000-12000× after cleaving the samples with the resist intact. Etch rates are determined by measuring the step height with a Taylor-Hobson Talystep after removal of the photoresist. The etch rates have been checked using unpatterned wafers in separate experiments. Linewidths are measured for six features on each sample (the nominal feature sizes are 2, 3, 4, 5, 10, and 20 μm); each feature is measured at five places on the sample. The measurements are made optically at 1000× before plasma etching (to determine the feature sizes in the resist) and after etching (with the resist removed). The loss in linewidth is taken as the difference between the measurements. Etch times are chosen so samples are etched for approximately 25, 50, 75, 100, 125, 150, 200, and 300% of completion. Samples are etched singly, and loading effects have not been investigated. The CF_4-O_2 mixture is known to have large loading effects and the etch rate decreases as the area of etched material increases (9, 16). Loading effects for the four Cl containing etches are very small, and the use of single wafers should not affect the results (2, 3).

The process variables (power, pressure, and gas composition) have been previously adjusted for each of the gas mixtures to give optimum etching of the polycrystalline silicon. The five gas mixtures are compared using these optimum conditions (actual etching conditions) rather than trying to maintain constant process variables for all five gas mixtures. Independent experiments show that variations in the pressure and power over the range indicated in Table I have almost no effect on the edge profiles, although the etch rates and sensitivities are affected.

The procedure for each sample is as follows: (*i*) the linewidths in the photoresist pattern are measured; (*ii*) the sample is etched; (*iii*) the sample is cleaved and examined by SEM to determine the edge profile; (*iv*) the photoresist is removed and the step height measured to determine the etch rate; and, (*v*) the linewidths in the etched pattern are measured and the line width losses calculated by difference.

Results

Etch rates.—The measured etch rates for P-doped and undoped polycrystalline silicon, for silicon dioxide, and for photoresist (HPR-204) are listed in Table II. The selectivities (the ratio of etch rates) are also given. The etch rates for silicon dioxide and for photoresist have been measured in separate experiments using unpatterned samples. The agreement between the measured rates in Table II and reported rates is good (2, 3). The selectivities over silicon dioxide are probably adequate for all five etches, especially if end-point detection is used to monitor the etching. The selectivity over photoresist is also adequate except for the C_2F_6-CF_3Cl mixtures where the high resist etch rate contributes to the loss in feature size. This is a disadvantage when very fine features are being etched.

Edge profiles.—Edge profiles obtained from SEM cross sections at approximately 7000× are shown in Fig. 1 as a function of the amount of material etched. The profiles are shown with the resist still over the polycrystalline silicon. Representative SEM photographs are given in Fig. 2. The profiles in Fig. 1 and 2 show P-doped polycrystalline silicon; almost identical profiles are obtained for the undoped material. The profiles obtained with CF_4-O_2 and with 1:1 C_2F_6-CF_3Cl indicate nearly isotropic etching; the profiles follow an arc of a circle with a radius nearly proportional to the etch time (17). In contrast, the profiles obtained with C_2F_6-Cl_2 and 4:1 C_2F_6-CF_3Cl are nearly vertical with only a slight curvature at the bottom. As the etching proceeds a slight reverse taper develops for both gases. The profiles for these etching gases have a slight undercut at the resist edge. This undercut remains nearly constant as etching proceeds even though the resist is being etched away from the edges. A profile for 200% etching (100% overetch) is not shown in Fig. 1 for the 4:1 C_2F_6-CF_3Cl gas because the photoresist is completely removed during the long etch time. The profile obtained from CF_3Cl follows a circular arc but the undercut is not as great as expected for isotropic etching; the etching in the vertical direction is greater than the lateral etching.

There are other features apparent in the profiles in Fig. 1. The relatively rapid etching of the photoresist with the C_2F_6-CF_3Cl mixtures is indicated by the decrease in the resist thickness. Etching of the oxide is apparent for C_2F_6-Cl_2 and both C_2F_6-CF_3Cl etches. This is expected since these gases have the lowest selectivity over silicon dioxide.

Table I. Etching conditions

Etchant	Type	Gas composition	Power W	Pressure Torr
C_2F_6-Cl_2	Anisotropic	8% Cl_2	350	0.35
C_2F_6-CF_3Cl 1:1	Isotropic	50% CF_3Cl	550	0.40
C_2F_6-CF_3Cl 4:1	Anisotropic	19% CF_3Cl	550	0.40
CF_3Cl	Intermediate	100% CF_3Cl	200	0.35
CF_4-O_2	Isotropic	8% O_2	100	0.35

Electrode spacing: 3.1 cm
Total gas flow: 200 sccm
Wafer temperature: 25°-30°C
Electrode area: 1250 cm²

Table II. Etch rates and selectivities

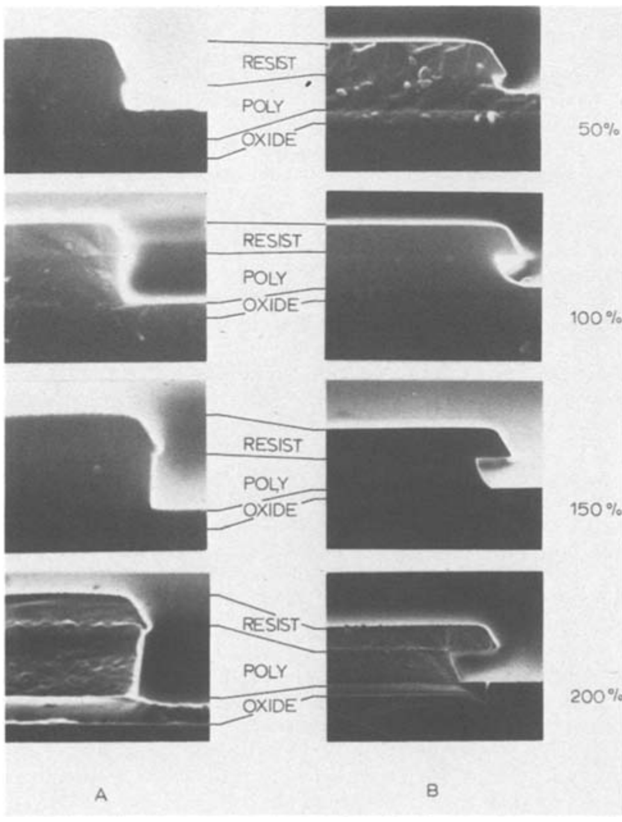

Fig. 2. SEM cross sections at different stages of etching for P-doped polycrystalline silicon etched with: (A) C_2F_6-Cl_2, (B) CF_4-O_2.

A detailed model for anisotropic etching has been proposed (2). The anisotropy results from ion bombardment enhanced reactions of adsorbed species on the horizontal surfaces, with recombination of the etching species predominating on the vertical walls. Based on this model, the difference in edge profiles for the two C_2F_6-CF_3Cl mixtures is caused mainly by differences in the rate of recombination. Sputtering is thought to have little or no contribution to the overall etch rate. This has been checked by using an argon plasma at the powers and pressures listed in Table I. No etching is observed; the detection limit is about 3 Å/min.

The edge profiles shown in Fig. 1 and 2 have been duplicated in other planar etchers (ranging in size from 35 to 61 cm diam). However, the results do not apply to tunnel etchers, where the anisotropic etches, C_2F_6-Cl_2 and 4:1 C_2F_6-CF_3Cl, have very slow etch rates, appear to etch isotropically, and do not etch reproducibly.

Linewidth loss.—The average loss in linewidth is shown as a function of the etching time (expressed as the amount of polycrystalline silicon that would have been etched) for each of the five gases in Fig. 3-7. The linewidth loss is independent of the feature size. The thickness etched is the actual amount for samples etched to less than completion (1.2 μm), and is calculated for greater times. The solid points are for undoped polycrystalline silicon; the open points are for P-doped samples. The dashed line is calculated for completely isotropic etching so the linewidth loss is twice the thickness of polycrystalline silicon etched. The solid lines are calculated for anisotropic etching of the polycrystalline silicon (etching only in the vertical direction with no component in the horizontal direction) assuming that the loss in linewidth is due entirely to erosion of the photoresist pattern (lateral etching of the photoresist). For this model, the slopes of the solid lines are given by $2E/R_p$, where E is the resist erosion rate and R_p is the etch rate of the polycrystalline silicon. For the calculated solid lines in Fig. 3-7, the resist erosion rate is assumed to be equal to the etch rate of the photoresist (given in Table II). A more exact discussion of resist erosion is given in the next section.

The calculated lines give good agreement for the anisotropic etches, C_2F_6-Cl_2 and 4:1 C_2F_6-CF_3Cl (Fig. 3 and 4), and also for the two isotropic etches, 1:1 C_2F_6-CF_3Cl and CF_4-O_2 (Fig. 6 and 7). The linewidth losses for samples etched with CF_3Cl are intermediate between the two lines (Fig. 5). For this case, the linewidth loss is best described by assuming anisotropic etching until completion (at 1.2 μm) followed by isotropic etching. Although this model gives a good description of the linewidth loss data, it is not sup-

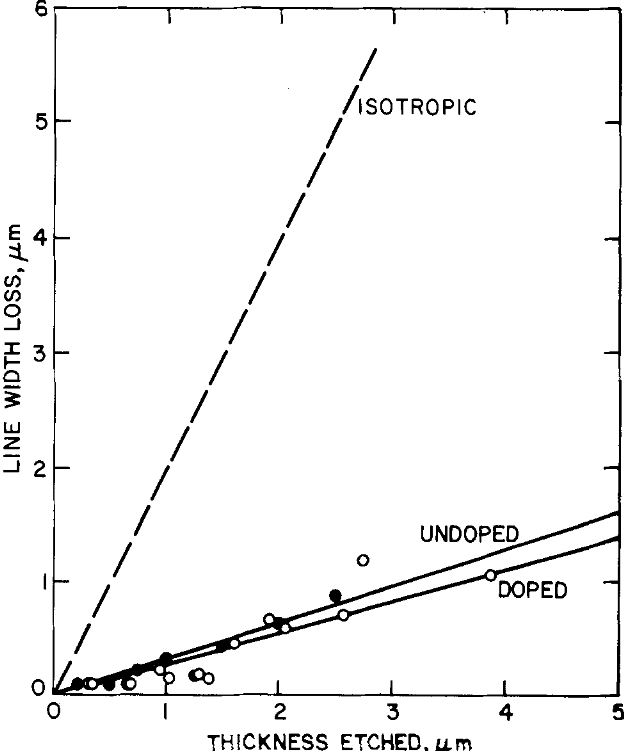

Fig. 3. Average linewidth loss vs. the thickness of silicon etched with C_2F_6-Cl_2.

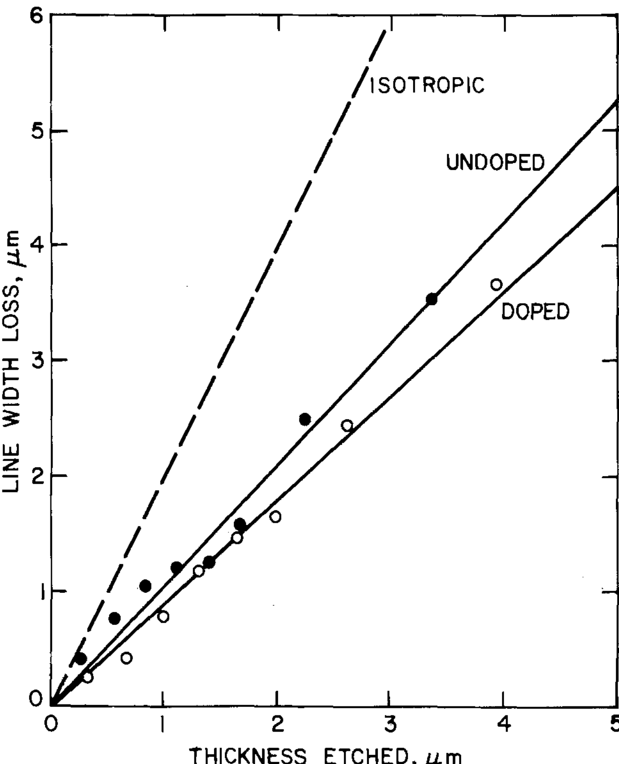

Fig. 4. Average linewidth loss vs. the thickness of silicon etched with 4:1 C_2F_6-CF_3Cl.

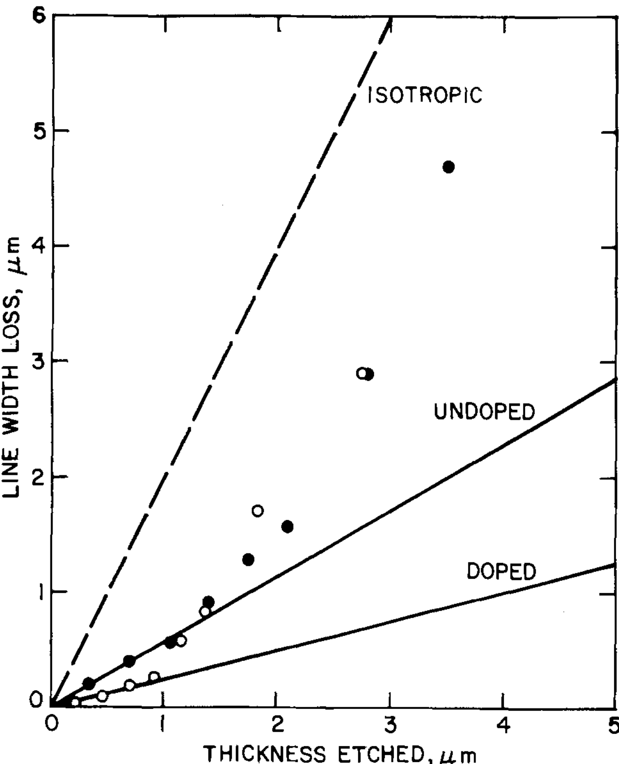

Fig. 5. Average linewidth loss vs. the thickness of silicon etched with CF_3Cl.

ported by the edge profiles shown in Fig. 1. In general, the loss in line width increases in the order: C_2F_6-Cl_2 $<$ CF_3Cl $<$ 4:1 C_2F_6-CF_3Cl $<$ 1:1 C_2F_6-CF_3Cl $<$ CF_4-O_2.

The data in Fig. 3-7 show the loss in linewidth for samples with the same thickness of polycrystalline silicon but etched for different times. The losses in linewidth for samples of different thicknesses (0.35, 0.60, and 1.2 μm) of polycrystalline silicon with all the samples given a 25% overetch have been measured and compared with results calculated from Fig. 3-7. The agreement is good. The linewidth loss for 4:1 C_2F_6-CF_3Cl is relatively large in spite of its being anisotropic because the photoresist is etching rapidly in this plasma.

A negative undercut (an increase in feature size) has been reported for silicon etched in a CF_4 plasma (18). The negative undercut decreases as etching

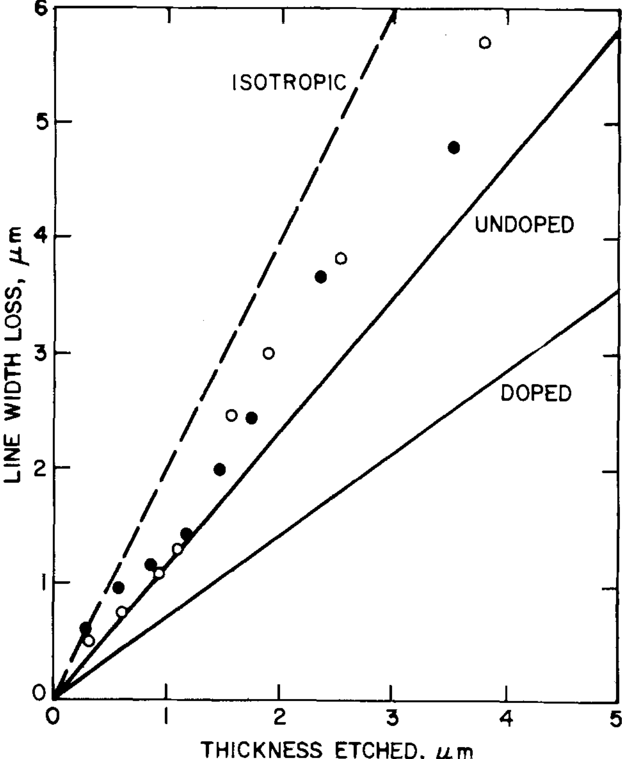

Fig. 6. Average linewidth loss vs. the thickness of silicon etched with 1:1 C_2F_6-CF_3Cl.

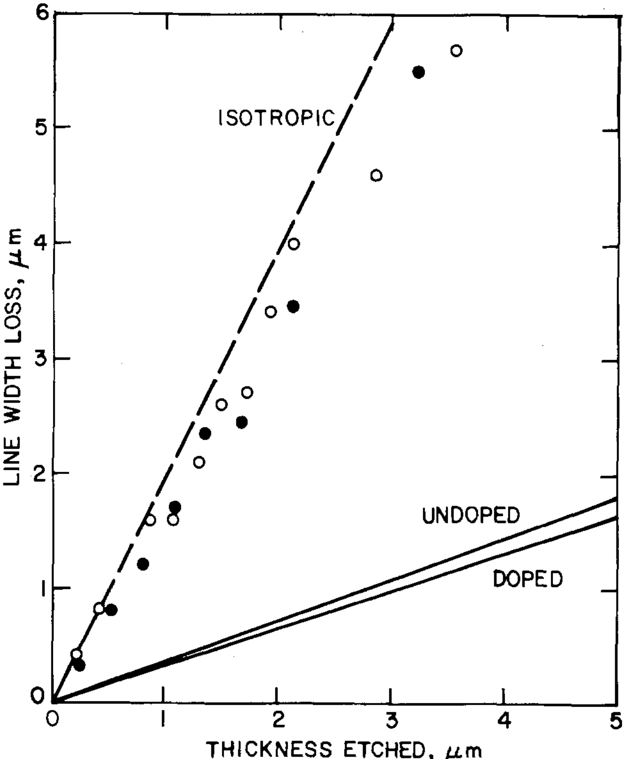

Fig. 7. Average linewidth loss vs. the thickness of silicon etched with CF_4-O_2.

proceeds and eventually becomes positive (a decrease in feature size is a positive undercut). The overall effect gives an initial increase in feature size followed by a decrease or loss in size. This effect has not been observed for any of the five etchants. However, this phenomenon may explain the nonlinear loss in linewidth observed with CF_3Cl. The etching in this plasma may be nearly isotropic (as indicated by the edge profiles) but may be initially inhibited near the photoresist (as observed for the negative undercut) (18). The combined effect produces a small loss in linewidth during the initial etching followed by a more rapid loss as etching proceeds, as observed in Fig. 5.

Resist erosion.—Lateral etching of the photoresist pattern (resist erosion) depends on the angle made by the photoresist and on the nature of the photoresist etching (isotropic or anisotropic). For anisotropic etching of the photoresist (etching only in the vertical direction), the rate of resist erosion, E, is given by $R/\tan\theta$ where R is the etch rate of the photoresist and θ is the angle made by the photoresist edge. For isotropic etching of the photoresist (etching normal to the photoresist surface), the erosion rate is equal to $R/\sin\theta$. The rate of resist erosion divided by the resist etch rate is plotted in Fig. 8 as a function of the angle made by the resist profile. If the photoresist profile is vertical ($\theta = 90°$), the erosion is zero for anisotropic etching of the resist and is equal to the resist etch rate for isotropic etching. As the angle decreases from 90°, the erosion increases until at small angles the erosion is nearly the same for both isotropic and anisotropic etching.

Experimental data showing resist erosion in a C_2F_6-Cl_2 plasma for three angles are also shown in Fig. 8. The angle is varied by using different bake temperatures after the photoresist is developed (the bake temperatures are 90°, 140°, and 210°C for angles of 60°, 45°, and 25°). The angles are measured from SEM cross sections. The rate of erosion is calculated from the slopes when the average linewidth loss is plotted against the thickness of polycrystalline silicon etched (Fig. 3). As already stated the slope is $2E/R_p$. This assumes that resist erosion is the only mechanism for the loss in linewidth. The solid point in Fig. 8 is obtained by measuring the resist erosion from the SEM cross sections. Although the data are not conclusive, there is an indication that the photoresist is etching isotropically in the C_2F_6-Cl_2 plasma, even though the polycrystalline silicon is etching anisotropically.

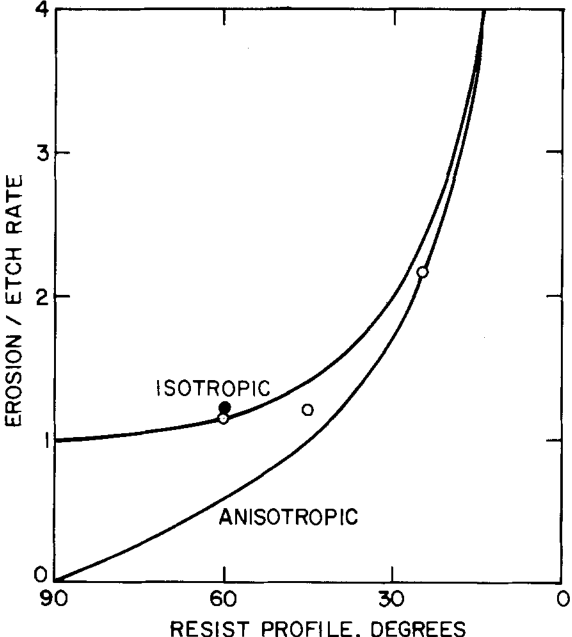

Fig. 8. The ratio of resist erosion to resist etch rate for different edge angles.

Summary and Conclusions

Five different plasma etches for etching polycrystalline silicon have been compared. The loss in linewidth increases in the order C_2F_6-Cl_2 < CF_3Cl < 4:1 C_2F_6-CF_3Cl < 1:1 C_2F_6-CF_3Cl < CF_4-O_2. Examination of edge profiles as a function of etch time confirm that the C_2F_6-Cl_2 and 4:1 C_2F_6-CF_3Cl etches are nearly anisotropic, and that the 1:1 C_2F_6-CF_3Cl and CF_4-O_2 etches are nearly isotropic. Samples etched in CF_3Cl have profiles that appear to follow a circular arc but the lateral etching is less than expected for isotropic etching. As expected, the isotropic etches have a linewidth loss that is approximately twice the thickness of the polycrystalline silicon etched. In contrast, the linewidth loss for the anisotropic etches is determined by the erosion rate of the resist pattern. Samples etched in a CF_3Cl plasma have linewidth losses that are intermediate between isotropic and anisotropic etching. Initially the linewidth loss is small, but increases rapidly after samples are etched to completion. This nonlinear behavior of the linewidth loss may be related to the recently reported phenomenon of negative undercut (18). Of the five etches examined, C_2F_6-Cl_2 is superior for etching very fine feature sizes. Samples etched with this gas mixture have nearly vertical profiles and have very small losses in feature size.

Acknowledgments

The authors would like to thank J. E. McNulty for the step height measurements and for much of the plasma etching; E. I. Povilonis for help in processing the samples; and H. J. Levinstein, C. J. Mogab, and S. Broydo for many discussions.

Manuscript submitted March 13, 1980; revised manuscript received Aug. 19, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by Bell Laboratories.

Progress in the Development of Solid-State Sulfate Detectors for Sulfur Oxides

M. Gauthier,* R. Bellemare, and A. Bélanger*

Institut de recherche d'Hydro-Québec (IREQ), Varennes, Québec, J0L 2P0, Canada

ABSTRACT

The purpose of this article is to describe and analyze the performance of four different reference electrodes adapted for use in solid-state sulfate detectors for sulfur oxides: an electrode in which a calibrated gas circulates, an Ag/Ag^+ electrode, an oxygen electrode using air as a reference and, finally, a thermal-decomposition type of electrode using an MSO_4-MO couple. The article also contains a description of a quartz detector for hot-gas analysis of SO_2-SO_3 mixtures and shows how the fact of replacing the platinum at the electrode by a less catalytic metal such as gold can lead to the specific detection of SO_3 in the presence of SO_2.

Previous work at IREQ has already shown that gaseous oxides, the major pollutants resulting from fossil-fuel combustion, can be measured potentiometrically using electrolytes containing oxyanions (1-3). Efforts so far have focused on the detection of the sulfur oxides SO_2 and SO_3. The reaction taking place at the triple-contact electrode SO_3 (g), O_2 (g), $Pt/SO_4^=$ has been shown to correspond to the half-cell

$$SO_3 + 1/2\,O_2 + 2e^- \rightleftarrows SO_4^= \quad [1]$$

Furthermore, with platinum, it has been observed that equilibrium is achieved rapidly between SO_2, O_2, and SO_3 in the vicinity of the electrode. The emf of the total sulfur oxide detector is given by the following equation

$$E = C_1 + \frac{RT}{2F}\ln(p_{SO_2})_{in.} + \frac{RT}{2F}\ln pO_2 - \frac{RT}{2F}\ln(K + (pO_2)^{1/2} \quad [2]$$

Two earlier papers (1, 2) presented the derivation of this equation and the symbols used, and described how in certain cases the emf expression can be made independent of the oxygen partial pressure. It was concluded from this that a total sulfur oxide detector is just as efficient for atmospheric-pollutant monitoring as for stack-gas analysis, where the oxygen partial pressure is not a constant.

The aim of this paper is to describe the latest improvements to the gas-circulation device developed at IREQ for the detection of atmospheric sulfur oxide pollutants. In view of the advantages this new detector offers for stack-gas analysis and the control of desulfurization processes, research efforts are still focusing on sulfur oxides. The results of various tests are presented in two sections, one related to the development of stable reference electrodes, the other to the study of gas-circulation electrodes operating both in equilibrium and in nonequilibrium conditions. In fact, the work reported in section two represents a first step towards the adaptation of the detector for hot-gas analysis of SO_2 and SO_3 mixtures and for the selective detection of SO_3 in the presence of SO_2.

Experimental

The preparation of the gas mixtures and the method of sintering the solid electrolytes were described in previous papers (1, 2) and remarks here will therefore be limited to pointing out that the K_2SO_4 electrolyte (mp 1063°C) is sufficiently plastic at the operating temperature of the detector to ensure a hermetic seal of the various atmospheres in the device. The test setup used to study the SO_2-air mixtures is an alumina and stainless steel apparatus sealed with an organic resin, which was described in a previous publication (1). The photograph in Fig. 1 shows a two-compartment alumina cell together with details of the tip of the alumina tube and the platinum electrodes in contact with the potassium sulfate pellet. Adaptation of this type of detector for hot-gas analysis (SO_2 and SO_3) has led to the development of a quartz device based on an SiO_2 tube, Type 204, 6.5 mm OD, with 2-mm bores from General Electric, Willoughby, Ohio. The gas inlet and outlet, welded to the tube, are made of Pyrex glass and terminated in ball-and-socket joints lightly coated with silicon grease and

gastight at 350°C. The platinum wire of the electrode in the gas outlet is welded with a special glass to ensure a good seal. With this setup the reference electrode must always be placed on the other side of the solid electrolyte. Figure 2 presents a schematic diagram of the quartz detector, equipped here with a thermal-decomposition type of reference electrode to be described later, while Fig. 3 shows the detector in its dismantled state on the right along with a simplified version on the left. In this simplified version, the wire forming the metal-electrolyte interface can be placed in position or removed freely, thus allowing replacement of the electrode metal during a test; small Viton O-ring joints are used in the gas outlet for adjusting the position of the wire of the gas-circulation electrode.

In all the tests described here, the gas is drawn by suction from the sample bag to the detector by means of a diaphragm pump. Care is taken to ensure that the pressure in the detector is close to atmospheric pressure; the flow rate is regulated by a control valve placed between the pump and the detector.

When SO_2 has to be converted into SO_3 upstream of the detector, an external catalyst is used consisting of 10 cm^3 of granular alumina platinized by the decomposition of chloroplatinic acid. Since the working temperature of the catalyst is 402°C, the gas feedthroughs connecting it to the detector are insulated and maintained at 350°C to avoid the risk of condensation of SO_3 or H_2SO_4.

If a catalyst is used inside the apparatus near the measuring electrode, several platinized alumina tubes 0.85 mm OD and 2.5 cm long are placed in the gas inlet as shown in Fig. 2. An alternative method of establishing the platinum-electrolyte contact, which is particularly favorable to equilibrium of the gas constituent, is to use a platinum felt formed by compressing and annealing a mesh screen of platinum wire 0.08 mm OD, as illustrated in Fig. 1 and 4. In this method, complete equilibrium of the constituent gases (O_2, SO_2, and SO_3) is achieved, since only the small fraction of the gas that diffuses into the platinum felt escapes towards the electrode surface.

Results and Discussion

Study of the reference electrodes.—Four types of reference electrode were studied in terms of their stability over a number of weeks in comparison with a conventional gas-circulation electrode. This measuring electrode was fed with SO_2-in-air mixtures that were equilibrated in terms of SO_2 to SO_3 conversion by precatalyzing the mixture just before the gas reached the electrode.

The first reference electrode studied was the gas-circulation type identical to the measuring electrode. In fact, the detectors originally developed for the measurement of gaseous oxides were concentration cells of the type

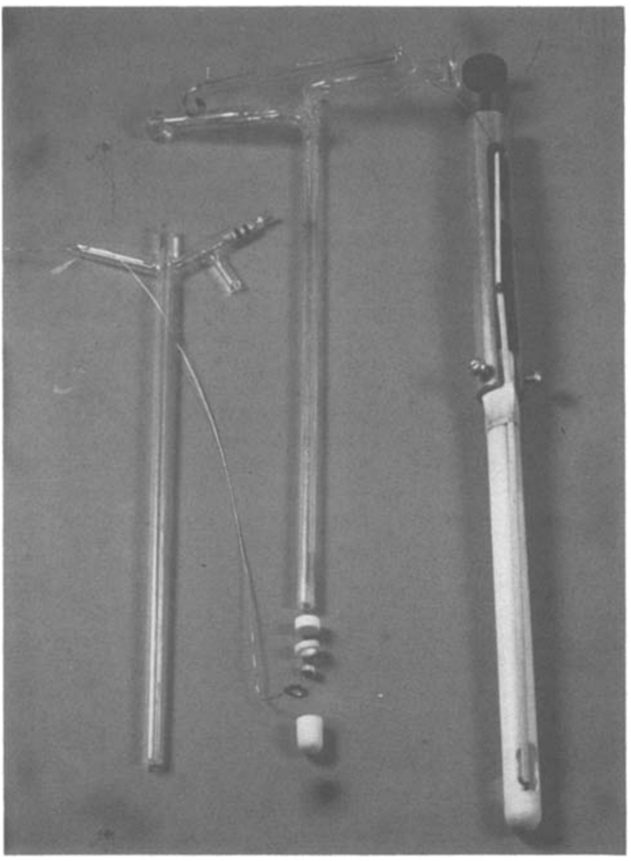

Fig. 3. Photograph of a quartz detector in the dismantled state (right). On the left is a simplified version of the quartz device in which small O-rings are provided to enable the electrode metal to be replaced during a test.

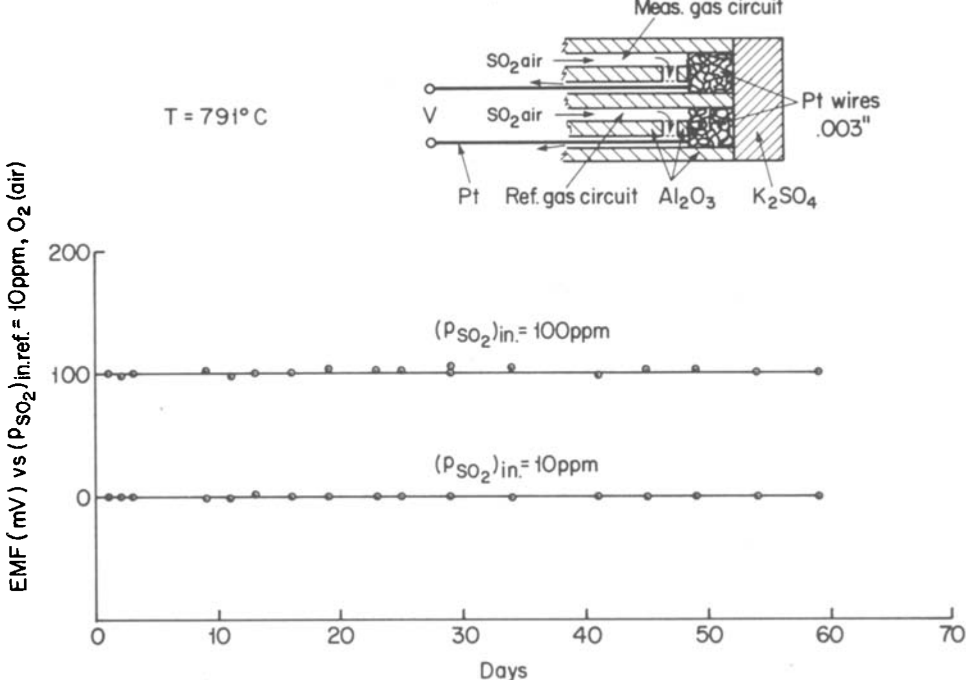

Fig. 4. Gas-circulation reference electrode: construction details of the electrodes and test results obtained over 60 days with $(p_{SO_2})_{in.ref.} = 10$ ppm in air.

$$\text{Pt}, SO_3, O_2(\text{air})/K_2SO_4/O_2(\text{air}), SO_3', \text{Pt} \quad [3]$$

where one of the two gases circulating at the electrodes was of known composition. The emf of this type of detector, used in air, is given by the simplified Nernst equation, as shown in our previous work (1)

$$E = \frac{RT}{2F} \ln\left(\frac{p_{SO_2 \text{ in.}}}{p_{SO_2 \text{ in. ref}}}\right) \quad [4]$$

The gas-circulation reference electrode seems very reliable and highly reproducible but it is cumbersome to use in a practical detector for pollutants, since it requires an external calibration source which periodically needs renewing. Despite this drawback, a study was made of its stability *vs.* time and it then served as a source of comparison for the other three reference electrodes. Every day for 60 days the reference gas, 10 ppm SO_2 in air, was first passed over the two electrodes simultaneously to check that the signal was at zero; a second gas, 100 ppm SO_2 in air, was then passed over the measuring electrode. The alumina test setup is illustrated in Fig. 1 with details of the electrodes provided in Fig. 4. The test results reported in the same Fig. 4 show that the 10 ppm signal offers excellent stability (± 1 mV) whereas for 100 ppm of SO_2 in air the signal fluctuates somewhat (± 6 mV) because of the poor reproducibility of the gas-mixture preparation method.

The second reference electrode studied was the Ag/Ag^+ type. Since Ag_2SO_4 is soluble in K_2SO_4 around the 0.01 mole fraction (1), this electrode can be adapted for solid oxyanions and is commonly used in aqueous or fused mediums. The emf of an SO_2 detector operating in air, for example, is expressed as follows

$$E = \text{Const.} - \frac{RT}{2F} \ln a_{Ag_2SO_4} + \frac{RT}{2F} \ln (p_{SO_2})_{\text{in.}} \quad [5]$$

The validity of this emf expression was established experimentally in an earlier work (1). A study of the stability *vs.* time of a detector corresponding to the following cell

$$Ag^\circ/Ag_2SO_4 \ (0.01 \text{ mole fraction in } K_2SO_4)/ /K_2SO_4/SO_3, O_2(\text{air}) \text{ Pt} \quad [6]$$

was conducted over a period of 53 days. The emf variations are plotted in Fig. 5 along with detailed uses of the different electrodes tested, namely, two silver and one platinum. Two distinct types of behavior were observed in the signal (V_1) *vs.* time. The first was a rapid increase in potential during the first two days, which may be traced to a decrease in the silver ion activity at the silver electrode in contact with the solid solution. Since the potential (V_2) of the silver electrode in contact with pure K_2SO_4 simultaneously reflects an increase in silver ion activity, it was concluded that this is due to the rapid diffusion of silver ions through the entire electrolyte. Chemical analysis subsequently confirmed this. The second type of behavior was observed a few days later when the emf (V_1) began slowly but steadily to decrease. This may be attributed to the gradual formation of silver oxide as a solid solution in K_2SO_4 at the silver electrode in the presence of air, an explanation which was validated by a second test using a cell where the electrolyte was pure K_2SO_4 covered on its external face with metallic silver powder in contact with air (Fig. 6). The behavior of the signal reflects the presence of increasing silver ion activity over 48 days (Fig. 6). At the end of the test, the cationic fraction of the silver ions was determined by atomic absorption as 6.2×10^{-3}. Pure silver oxide alone is thermodynamically unstable under these conditions (4) but, as a solution in K_2SO_4, the predictable activity of Ag_2O in equilibrium with air would be 8.8×10^{-3}.

These results were in fairly good agreement with the atomic-absorption analysis after 48 days and were confirmed qualitatively by another independent test. Two pure K_2SO_4 pellets in the presence of powdered silver were kept for 14 days in an oven at 750°C, in air. Atomic-absorption analysis indicated silver ion concentrations of 1.2 and 1.1×10^{-3} cat. fract. in accordance with the silver oxide formation suggested by previous tests.

Finally, a third test with the silver electrode is described in Fig. 7 using the following type of cell

$$Ag^\circ/Ag_2SO_4 \ (0.01 \text{ mole fraction in } K_2SO_4)/SO_3, O_2(\text{air}), \text{Pt} \quad [7]$$

where the metallic silver was completely cut off from the ambient air. A silver rod, 0.5 mm OD, fusion-sealed in an alumina pellet, was protected from the air on one side by the K_2SO_4 electrolyte and, on the other, by a piece of annealed-platinum foil; pressure was then applied to press all these components one against the

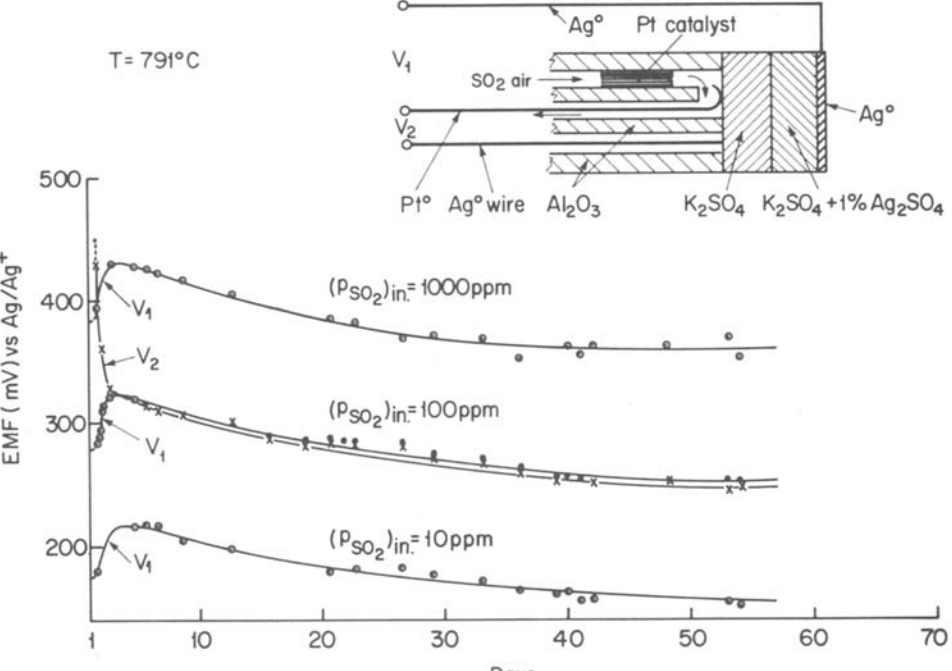

Fig. 5. Ag/Ag+ reference electrode: construction details of the electrodes and test results obtained over 53 days at the measuring electrode with $(p_{SO_2})_{in.}$ = 10, 100, and 1000 ppm.

other. It was observed that the emf did not decrease as during the previous tests, but in fact rose slightly and seemed to stabilize after 30 days. This arrangement therefore seems to be an effective way of preventing the formation of Ag_2O, although the initial increase in emf remains difficult to explain. Silver sulfate is relatively stable in air and its equilibrium partial pressure of SO_3 in air at 800°C is in the order of 80 ppm (5); however, in solution at 0.01 mole fraction in K_2SO_4, its equilibrium partial pressure would be below the ppm level if activity should equal the mole fraction. This apparent stability of the solid solution Ag_2SO_4-K_2SO_4 was confirmed by the emf observed experimentally and it therefore cannot explain the initial rise in the emf, which could actually be due to losses by vaporization of Ag_2SO_4.

The silver electrode thus appears fairly stable in time, providing that certain precautions are taken, but its use should be limited to the analysis of gases relatively rich in oxygen because of the constant presence of Ag^+ ions at the platinum measuring electrode resulting from the rapid diffusion of the ions in the electrolyte. In order to illustrate this, tests were conducted on the performance of a detector with an Ag/Ag^+ reference electrode at 750°C. No reduction of silver ions occurred when the oxygen content of a gas containing 100 ppm of SO_2 was reduced to $p_{O_2} = 5 \times 10^{-4}$ atm. On the other hand, if an inert gas such as purified argon passed through the detector, the voltage dropped to zero and the detector did not resume its normal performance until it had operated for several minutes in air in the presence of sulfur oxide. This may be explained by the silver ion reduction near the electrode and the ensuing oxidation of the silver metal when the atmosphere becomes an oxidizing agent again. The Ag/Ag^+ reference electrode should therefore never be used for other than the measurement of pollutants in ambient air.

A number of tests were performed in an attempt to use air as the reference gas with the juxtaposition of

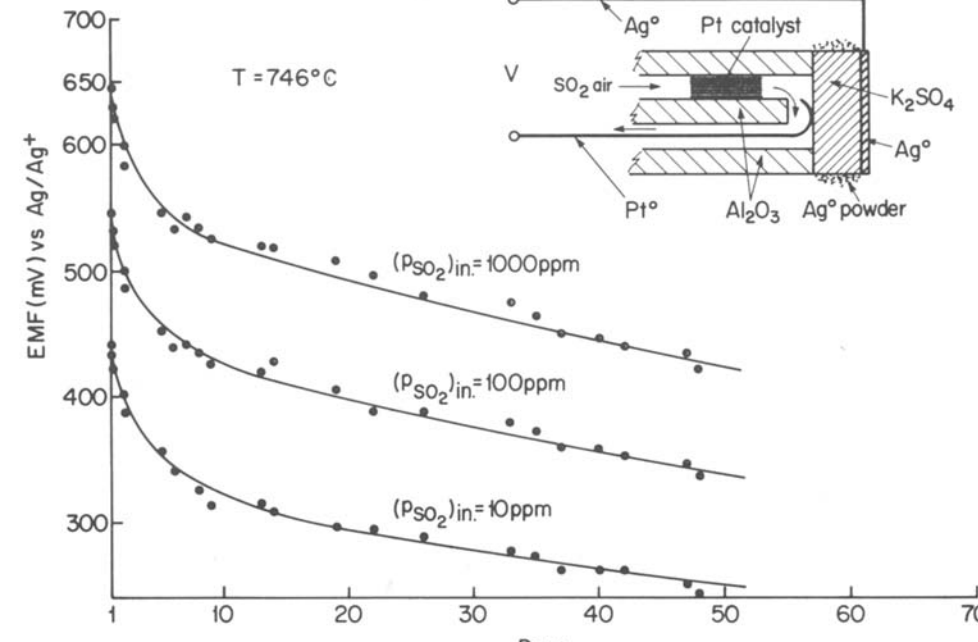

Fig. 6. Emf variations measured between a gas-circulation electrode and a silver plate in contact with pure K_2SO_4.

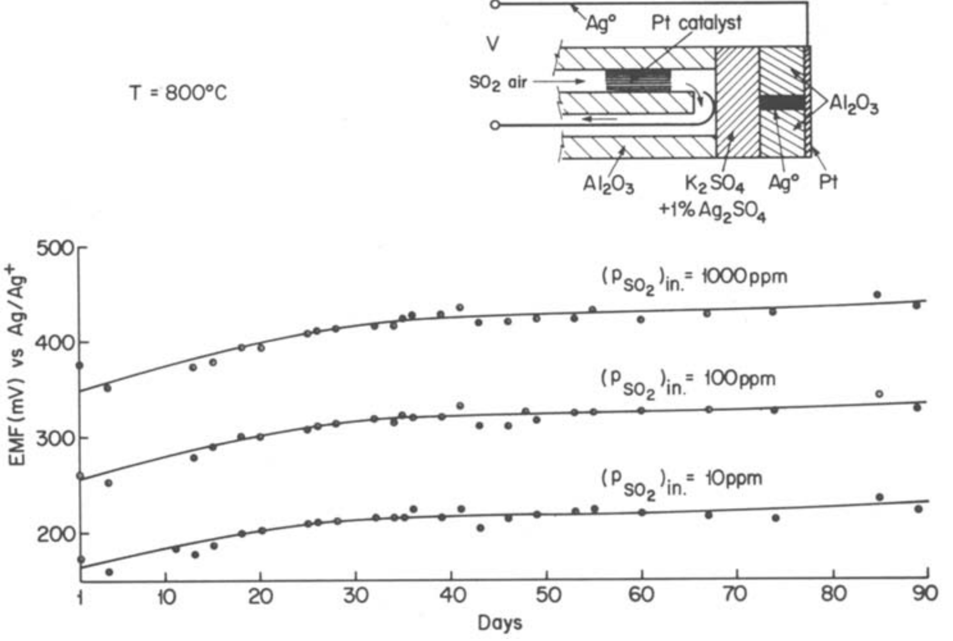

Fig. 7. Ag/Ag$^+$ reference electrode in which the silver metal is protected from the ambient air.

two solid electrolytes, K_2SO_4 and ZrO_2-CaO. The following cell was used

$$\text{Pt, } O_2(\text{air})/ZrO_2\text{-CaO}//K_2SO_4/SO_3,\ O_2(\text{air}),\ \text{Pt} \quad [8]$$

The resulting emf expression can be expressed as

$$E = \text{Const.} + \frac{RT}{2\mathbf{F}} \ln (p_{SO_2})_{\text{in.}}$$

where the constant includes the oxygen pressure $(-RT/4\mathbf{F} \ln(p_{O_2})_{\text{ref}})$ of the reference electrode and the sulfate-zirconia junction potential, which is considered a constant.

The atmosphere surrounding the junction between the two solid electrolytes was sealed off from the ambient air by a gold O-ring as may be seen in Fig. 8. The emf signals observed experimentally over a period of 74 days are reported on the same figure. After the first few days the signals reached a constant value, the unmistakable shift observed after one month being the result of an uncontrolled variation in the oven temperature. An earlier duration test performed without controlling the atmosphere at the junction showed erratic emf fluctuations. This observation is in accordance with other studies performed at IREQ which have indicated that the sulfate-zirconia junction may involve an equilibrium such as

$$O^{=}_{ZrO_2\text{-CaO}} + 2K_{K_2SO_4}{}^{+} + SO_3(g) \rightleftarrows K_2SO_4 \quad [10]$$

which depends on the composition of the gas phase (6).

Except for the unexpected variations in the detector temperature in the duration test, this type of reference electrode shows satisfactory results. However, the need to control the atmosphere at the junction calls for apparatus which, for the moment, is fairly complex to build.

The fourth type of reference electrode studied is somewhat similar to certain metal-oxide couples (*e.g.*, Ni-NiO, Pd-PdO) developed as reference systems for stabilized zirconia-oxygen detectors (7, 8). A pow-

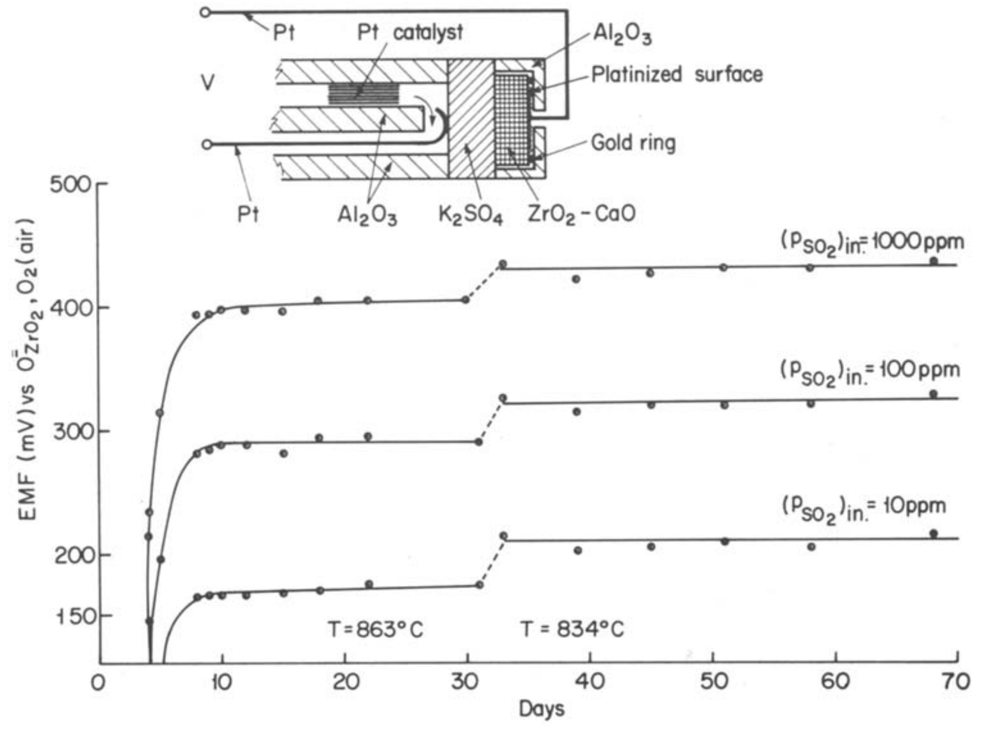

Fig. 8. Air reference electrode made by placing K_2SO_4 in contact with calcia-stabilized zirconia: construction details and results over 70 days.

dered metallic sulfate, which shows relatively thermal stability in air, is mixed with its oxide in order to fix a low sulfur oxide partial pressure at the detector operating temperature. The first system studied was $MgSO_4$-MgO. The chemical equilibrium reaction of this system was

$$MgSO_4(s) \rightleftarrows MgO(s) + SO_3(g) \quad [11]$$

with $K_2 = (p_{SO_3})$ as the equilibrium constant.

The whole electrochemical cell involved in the detector may be described as

$$Pt, MgO\text{-}MgSO_4, O_2(air)/K_2SO_4/SO_3, O_2(air), Pt \quad [12]$$

In air, the sulfur trioxide in equilibrium with the solid mixture $MgSO_4$-MgO is constant. If, in addition, the equilibrium between SO_3, SO_2, and O_2 is considered to be achieved rapidly, the emf corresponding to the electrochemical cell described above is expressed as

$$E = \frac{RT}{2F} \ln \frac{(p_{SO_2})\ in.}{K_2(1 + K/(0.21)^{1/2})}$$

The experimental setup corresponding to this electrochemical cell is shown chematically in Fig. 2 and 9. For this experiment the $MgSO_4$-MgO mixture is placed in an alumina crucible open to the atmosphere through a small-diameter hole (0.05 mm), to ensure a constant total pressure of 1 atm. The electrode contact is obtained using a small alumina ring wound with platinum in contact with the K_2SO_4 pellet and inserted in another alumina ring which prevents direct contact of the electrode with ambient air (see details in the photograph in Fig. 3).

The results obtained over a three month period illustrate the stability of this type of reference electrode. The emf values observed experimentally (Fig. 9) are 30 mV higher than those calculated from the equilibrium constants culled from the literature (9). This was attributed to a temperature gradient between the inner crucible and the oven where the temperature reading was taken. Incidentally, the results of preliminary studies on the possibility of adapting these electrochemical cells for metallurgical applications (10) are in good accordance with calculated values for $MgSO_4$-MgO ($\simeq$2 mV) with the temperature measured inside the crucible as illustrated in Fig. 2.

The slight drift observed in the emf over 90 days ($\simeq$23 mV) is largely explained by the temperature coefficient $(dE/dT)_{725°C} = 1.5$ mV/°C and by the difference in temperature between initial and final measurements of 721° and 730°C, respectively. Moreover, x-ray examination before and after the test revealed no apparent modification of the sulfate-oxide mixture.

Another solid sulfate-oxide mixture, $MnSO_4$-Mn_2O_3, was studied at the lower temperature of 714°C using an experimental setup identical to the magnesium system. The results are presented in Fig. 10. The short lifespan of this system is probably due to a high sulfur oxide pressure ($\simeq 10^{-3}$ atm). Furthermore, x-ray examination failed to indicate the presence of $MnSO_4$ at the end of the test. Hence this system appears better suited for lower detector operating temperatures whereas the magnesium mixture can operate at up to 900°C. Stringent control of the temperature guarantees the reliability and reproducibility of this thermal-decomposition type of electrode over extended periods of time. In addition, the reference-electrode potential could be adjusted by selecting the appropriate operating temperature and sulfate-oxide mixture. The use of a closed crucible to contain the powder mixture will eventually improve the lifespan of this promising type of reference electrode.

Study of the gas-circulation electrodes in equilibrium and nonequilibrium conditions.—Previous studies on sulfur oxide detectors have revealed that the active species at the electrode is SO_3 not SO_2, and that the use of platinum for the metal electrode generally results in equilibrium between SO_2, O_2, and SO_3, at least in the vicinity of the triple contact between the electrolyte, the metal, and the gas phase. One of the conclusions of recent work is that a platinum precatalyst is required in the gas inlet just before the electrode. The two types of precatalyst used for this purpose were described in the experimental section. Recourse to these catalysts resulted in close agreement between calculated and experimental values, as illustrated by the upper curve of Fig. 1. In previous work without a precatalyst, an increasing discrepancy was found between calculated and experimental values towards higher sulfur oxide concentrations as may be seen in Fig. 4 of Ref. (1). When equilibrium of the gas constituents prevails at the electrode, the sulfate-based detector can be used quite successfully for measuring either SO_2 or SO_3 or the two together ($SO_2 + SO_3$) when both oxides are present simultaneously.

In combustion-gas analysis, the sulfur oxide is mostly SO_2, although occasionally a small percentage of the highly corrosive SO_3 is also observed. Consequently, a search was undertaken for an electrode metal that

would not catalyze the equilibration of SO_2 with SO_3 so that SO_3 could be detected selectively. The quartz device with the removable electrode illustrated in Fig. 3 was used to test various metals in the same experimental conditions to assess their performance as electrode materials. For this purpose, the SO_2-in-air mixtures were first passed over a precatalyst placed in the vicinity of the electrode. As shown in Fig. 11, all the metals tested were electrochemically active in accordance with Eq. [1] except for iridium (not represented), which is erratic in its performance. A second test, reported on the same figure, was carried out by removing the precatalyst from the gas inlet to study the catalytic performance of these metals. For the same SO_2-in-air mixtures, palladium has a catalytic performance similar to that of platinum; however, gold and rhodium show very little response to the SO_2 content. Thus, there seems to be a possibility of optimizing certain experimental parameters-temperature, gas flow rate, geometry, etc., in order to measure SO_3 selectively in the presence of SO_2.

The last test to be described was performed with a quartz device adapted to the analysis of hot SO_3-bearing mixtures. The quartz gas-circulation circuit was identical to that shown in Fig. 2 except that the precatalyst was removed and an electrically insulated gold wire was used along with the platinum wire of the gas-circulation electrode. The aim of this test was to compare the two electrodes in the same conditions when the detector was supplied first with SO_2-in-air-mixtures, then with hot SO_3-in-air mixtures. The latter were prepared on an external catalyst, described in the experimental section, that converts most of the SO_2 into SO_3 ($\simeq$99% at equilibrium at 402°C). As illustrated in Fig. 12, on platinum, the gas mixtures were at equilibrium at the electrode and the results are therefore identical, whether the gases entering the detector are SO_2-in-air or SO_3-in-air mixtures. On gold, the low catalytic activity of the metal was confirmed with the SO_2-in-air mixtures, particularly at high concentrations. On the other hand, with SO_3-in-air mixtures, the electrode responds to the proportion of SO_3 defined by the external catalyst at 402°C, at least when concentrations are high. To prevent the SO_3 from returning to equilibrium conditions as observed in Fig. 12, especially at low concentrations, the gas flow rate was increased to 200 cm³/min, which avoided a drop to the equilibrium potentials observed on platinum. However, the external catalyst then seemed unable to ensure complete conversion of SO_2 into SO_3 and, although the curve is parallel to the curve predicted for SO_3 alone, it remains below it. Based on these preliminary tests, it was concluded that the quartz detector may be successfully adapted to hot-gas analysis and appears most interesting for the selective detection of SO_3, especially when gold is used at the electrode.

Since the preparation of this paper, more thorough studies of the specific determination of SO_3 in the presence of SO_2 have been undertaken by other researchers at IREQ which confirm the present results (11).

Conclusion

In this work, four types of reference electrodes were developed and compared with regard to their stability *vs.* time. Of these, the gas-circulation electrode seems to

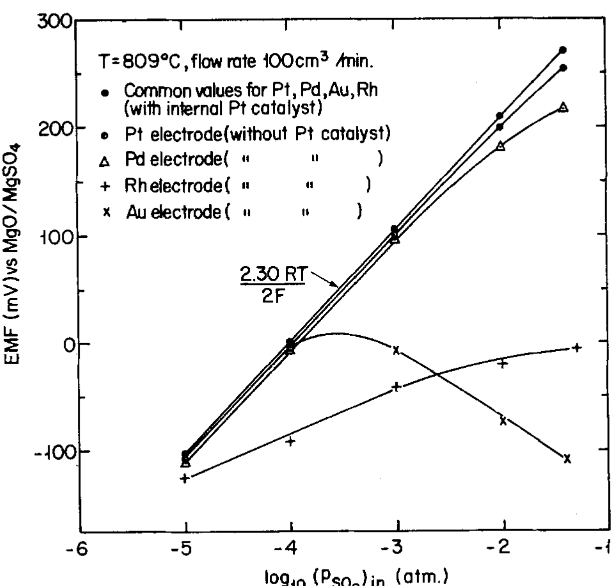

Fig. 11. Electrochemical and catalytic activities of four metal electrodes when several SO_2-in-air mixtures are precatalyzed in the gas inlet of the detector before reaching the electrode; the results of the same test repeated after removal of the precatalyst are also given in this figure.

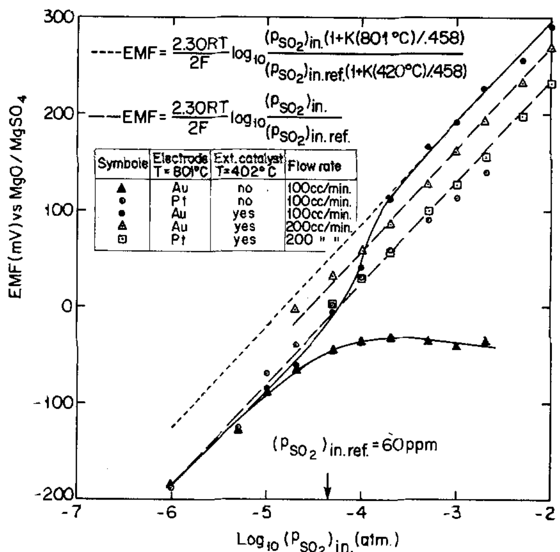

Fig. 12. Relative catalytic activities of Au and Pt electrodes with SO_2-in-air and hot SO_3-in-air gas mixtures; the dashed lines are the calculated values for complete nonequilibrium and complete equilibrium at the gas-circulation electrode, with the reference always considered to be at equilibrium at 801°C.

be the most stable and the most reliable, although in practice it is awkward and expensive to operate. The Ag/Ag^+ electrode, on the contrary, is easy to set up experimentally despite the fact that silver must be protected from air in order to maintain emf stability *vs.* time; in addition, the rapid diffusion of silver ions through the electrolyte precludes the use of these electrodes for the analysis of oxygen-lean gases. The air reference electrode with a sulfate/stabilized-zirconia junction provides satisfactory results but its elaborate experimental setup presents a drawback. Finally, the reference electrode based on the thermal decomposition of solid sulfate-oxide mixtures has a highly reproducible signal that is stable with respect to time, although the temperature needs to be particularly well controlled; its potential can be adjusted as required by selecting an appropriate sulfate-oxide system and temperature. This fourth type of electrode is still under investigation.

An attempt was also made, by adding a precatalyst upstream of the measuring electrode, to optimize the equilibrium of the reacting species at the electrode when cell is to be used as a total sulfur oxide detector. Finally, demonstration of the weak catalytic activity of gold and rhodium with respect to the conversion of SO_2 to SO_3 led to the development of a quartz detector suitable for hot-gas analysis, which should eventually permit the selective measurement of SO_3 in the presence of SO_2.

Optical and Auger Microanalyses of Solder Adhesion Failures in Printed Circuit Boards

K. Kumar and A. Moscaritolo

The Charles Stark Draper Laboratory, Incorporated, Cambridge, Massachusetts 02139

ABSTRACT

Printed circuit boards used in electrical systems have shown solder separation from the copper wiring network with prolonged use at about 325 K (120°-130°F). Optical and Auger microanalyses of boards that have shown such failures have revealed the existence of discrete oxide particles in the form of an oxide layer at the separated interface. High temperature accelerated aging tests have shown that the time-dependent accumulation of the oxide particles at this interface results from rejection of the oxygen out of the reacted zone and into the intermetallic-matrix boundary with the continued growth of (low Pb-containing) Cu_xSn_y intermetallic compounds. (These compounds are formed as a consequence of the chemical reaction that occurs between the Pb-Sn solder and the underlying copper circuit.) Increased thermal activation leads to increased growth of the intermetallics, and this results in more oxygen exclusion from the reacted zone into the interface region (giving rise to a time-dependent accumulation of the oxide particles at this boundary). Eventually, these particles inhibit the solid-state diffusion reaction between copper and the Cu_xSn_y intermetallics and lead to the observed separation of the solder from the underlying copper. Experiments performed in this study have shown that the oxygen (giving rise to oxide-particle accumulation at the interface) is distributed throughout the bulk of the copper plating. Organic addition agents, codeposited with the copper during the formation of the copper wiring network, are probably acting as a source for the observed oxygen.

Printed circuit boards are used extensively in the electronics industry as components of larger electrical assemblies. The printed circuit consists of a wiring network which is produced using a combination of photolithographic and plating and laminating techniques. Both electroless and electrodeposition procedures are used to fabricate these circuits. A layer of a preselected Pb-Sn solder composition is electrodeposited on top of the copper network. To achieve proper wetting of the copper by the solder material, a post-deposition fusion procedure is used. In one process, this consists of heating the entire assembly to about 480 K (410°F) for close to 15 sec. This results in phase segregation within the solder material and in chemical reaction between the solder and the copper circuit, thereby enhancing the integrity of the completed circuit through increased solder adhesion (due to the chemical forces that result from the solder-copper reaction).

A few of the printed circuit boards used in electronic systems at about 325 K (120°-130°F) have shown severe degradation of solder adhesion with prolonged use. This time-temperature dependence of solder layer separation in some of the printed circuits has been known to exist by the circuit industry for a reasonably long time (1). Past attempts at identifying the causes of these failures have met with only limited success (1-3). Our own experience with the use of these boards has shown that circuits obtained in 1977 from vendor A did not display solder adhesion failures. In contrast, samples procured from another vendor (B) in 1978 almost consistently showed this type of deterioration. In most instances, solder adhesion degradation was found to reach a level whereby the solder could be easily removed from the copper surface with a fine-edged X-acto blade with a minimum of effort. A detailed study was consequently initiated at this Laboratory to determine the causes of the observed dewetting of the solder. It was hoped that, as a result of such an investigation, further use of these materials could be qualified and also a determination made as to whether newer (1979) material procured from vendor B could be used for future applications. Such an evaluation was deemed desirable in view of the manufacturer's claim that suitable modifications had been made in the processing procedures to produce a 1979-designated product that was superior to the 1978-designated product. This paper illustrates the nature of the problem and identifies the mechanism by which the observed solder separation has most probably occurred.

Key words: oxide, intermetallics, solder separation, mechanism.

Experimental Procedure

Representative samples were mounted (with the copper-solder interface slightly inclined to the plane of polishing) at room temperature in a resin-containing cast and polished for metallographic examination. The selected angular tilt of the copper-solder assembly allowed amplification of the solder-copper interface, upon polishing, by a factor of ten. The samples were photographed, using optical microscopy, and analyzed using a Physical Electronics Auger system in the as-polished condition. The heat-treatments that were performed on several of the selected samples are described in detail in the next section.

Results and Discussions

The different features observed in microstructures which are typical of those observed in failed samples are shown in Fig. 1. As one traverses the solder-copper interface from the solder side to the copper side (that is from left to right), several layers are observed. The observed layers correspond to a two-phase solder region which contains a high concentration of the Pb-rich phase, two Cu_xSn_y intermetallic compounds (containing very low levels of Pb), and a region with a high concentration of oxide particles located between the Cu_3Sn intermetallic and the copper. The two intermetallic phases, Cu_3Sn and Cu_6Sn_5, observed in this study have earlier been reported elsewhere (1). These correspond to the near-equilibrium phases predicted by the binary Cu-Sn phase diagram (4) indicating that the role of Pb in this ternary system is minimal. An Auger line scan for Pb (shown in Fig. 1), however, in-

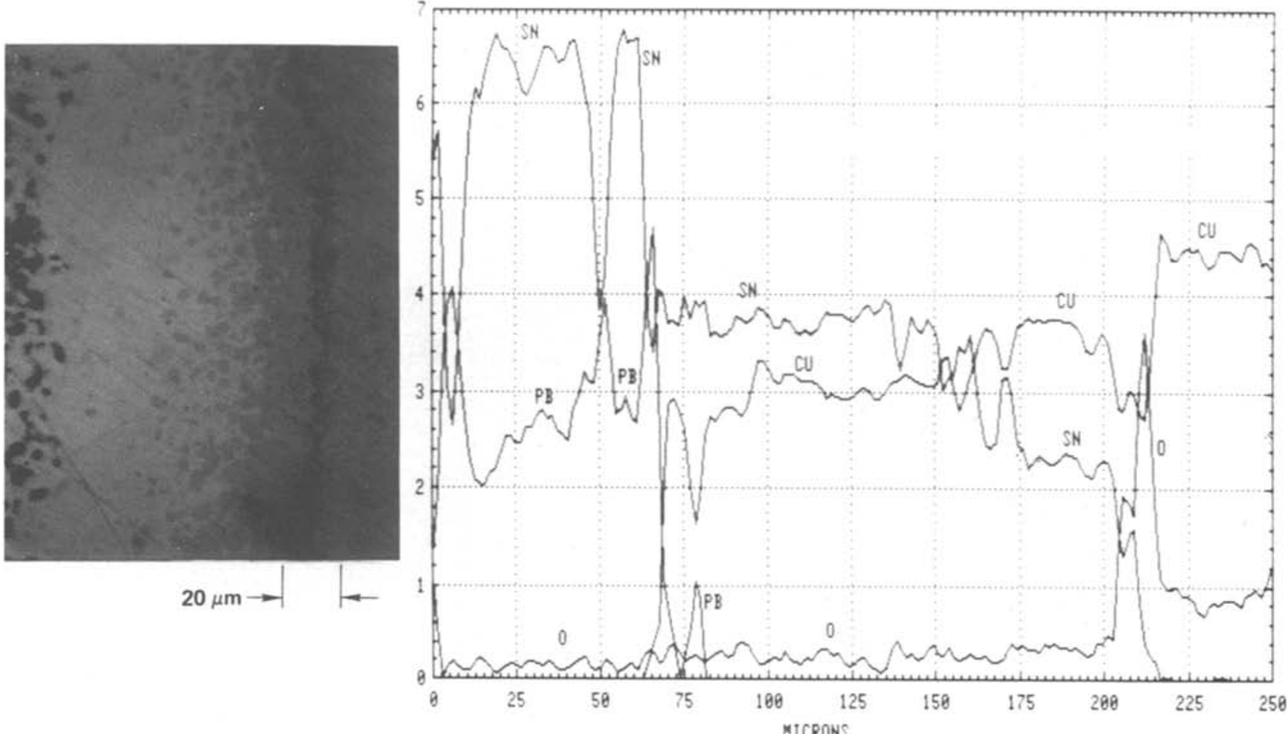

Fig. 1. Typical Cu-solder interface region in failed board. Photograph shows two Cu_xSn_y intermetallics and oxide presence at Cu-Cu_3Sn boundary. Auger line scans were made across the entire interface region.

dicates that a small amount of Pb does exist in these phases, possibly in solid solution. [Details on Auger spectroscopy and interpretation of spectra can be obtained from Ref. (5).] All of the main features can be easily identified on the Auger line scans (also contained in Fig. 1) that were obtained on this sample. The strong intensity of the oxygen signal at the Cu_3Sn-Cu boundary (in the Auger scan) clearly shows that the particles observed are indeed an oxygen-containing species that have collected at this interface. The presence of a two-phase zone with a high concentration of the Pb-rich phase (observed on the solder side of the micrograph as dark precipitates) was a direct consequence of the formation of the (low Pb-containing) Cu-Sn intermetallic compounds between the solder material and the copper network. Formation of these intermetallics resulted in an exclusion of Pb from the reacted regions leading to an enrichment (in Pb) of the solder material close to the solder-Cu_6Sn_5 boundary. An Auger survey showed that the only elements which were consistently present in the several samples that were examined (in detectable quantities) were Cu, Pb, Sn, O, and C, all of which were expected.

Because of the known differences in the performance of the 1977 and 1978 circuit boards, typical samples representative of those years and one sample, designated as a 1979 product, were selected for further examination. Figure 2 shows the microstructure observed for the as-received condition of these circuit boards. The reacted zone was found to be considerably smaller in the 1977 sample compared to the 1978 and 1979 samples. This also accounted for the near absence of the Pb-rich zone in the 1977 sample in contrast to the 1978 and 1979 samples where its existence was clearly observed. Larger reaction zones mean more overall exclusion of Pb from the reacted area. One, therefore, expected an intense concentration of the Pb-rich phase at the solder-intermetallic boundary in the 1978 and 1979 samples in agreement with the observations. The differences in the extent of the reaction observed in samples obtained from the two vendors was partly explained by the differences in the solder-fusion procedures used by these vendors. Whereas vendor A uses an infrared lamp to cause improved wetting of the copper by the solder, vendor B uses an oil bath in which the entire assembly is immersed. It is possible that the circuits are subjected to more thermal activation by oil immersion than is the case when they are exposed to infrared radiation. Differences in thermal activation can explain the differences in the extent of the reaction that was observed. The microstructures shown in Fig. 2 were found to be substantially free of the oxide layer that is known to exist at the copper-Cu_3Sn boundary in boards where separation of the solder is known to have occurred. It may be noted, however, that a few oxide particles were nevertheless found to be attached to the copper surface in the 1979 sample even in this condition.

Since the degradation in the solder-to-copper adhesion has been observed to be dependent on both time and temperature, samples of as-received boards were subjected to elevated temperature aging treatments in air (so as to accelerate the kinetics of the microstructure changes that are induced during actual service at lower temperatures). Effects related to sample-to-sample variations were avoided by sectioning the as-received boards in two, such that the as-received state of the individual boards could be examined on one piece while the other piece could be examined after it had been subjected to the desired heat-treatment. The microstructures observed for each of the as-received samples corresponded very closely to those shown in Fig. 2. The heat-treatment temperature was chosen as 438 K (165°C) and the samples were examined after 4, 75, and 264 hr of exposure. A gradual development of the oxygen-containing species, with increasing time, was observed in the 1978 and 1979 samples in contrast to the 1977 sample where none was observed. The sample microstructures obtained after the 264 hr treatment on these three samples are shown in Fig. 3. It is clear that the condition observed for the 1978 and 1979 type samples is most undesirable, since it ultimately results in solder separation from the copper network. That such a direct relationship exists between development of the oxygen-containing particles and degradation of solder adhesion was verified

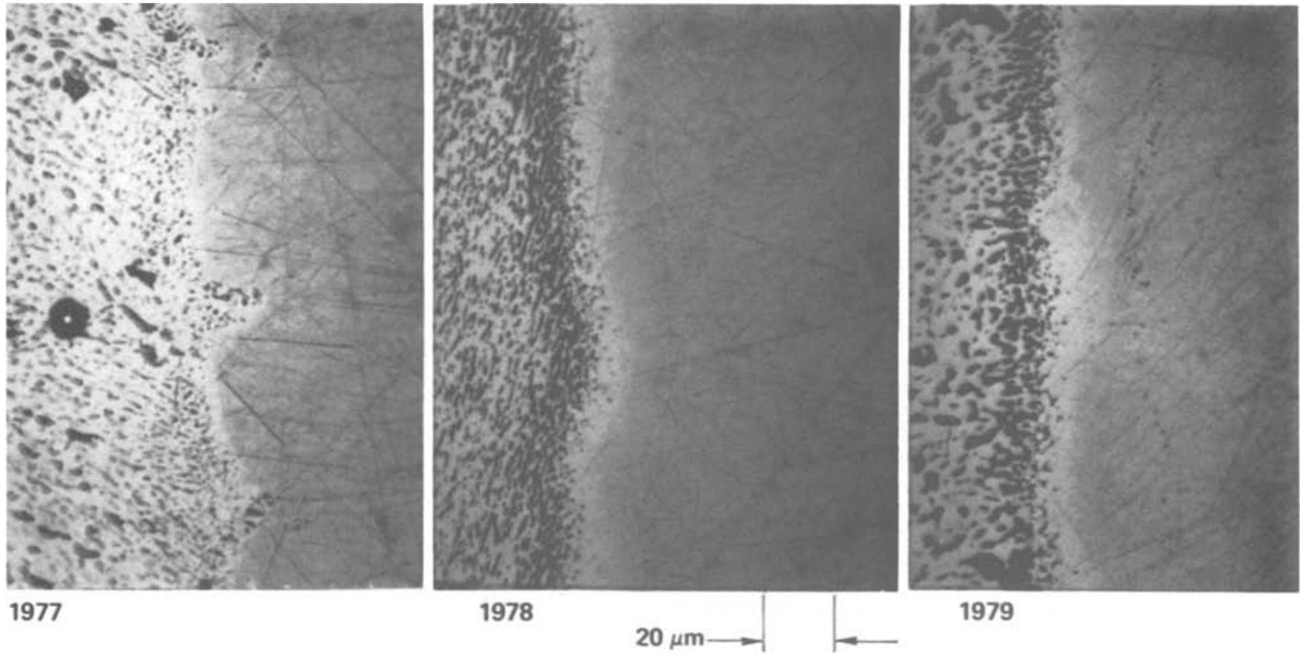

Fig. 2. As-received microstructures of 1977, 1978, and 1979 boards. Extremely narrow reaction zone with little enrichment of the Pb-rich phase in the neighboring solder region is observed in the 1977 sample compared to the 1978 and 1979 samples.

in separate experiments. These consisted of soldering individual wire leads to the printed wiring network prior to the 438 K treatment. After the thermal exposure the leads were pulled at known increasing loads until they separated from the circuit board. The decreasing value of load required to cause separation, and the increase in the amount of copper observed after separation (with increase in total thermal exposure), were considered a direct measure of the degradation in solder adhesion. It was determined that these correlated well with the accompanying changes in microstructure which showed a clear development of the oxygen-containing species in samples produced by vendor B.

Figure 4 contains an oxygen-line scan which was made across the copper-to-solder interface region in the 1978, 264 hr heat-treated sample. Unlike other line scans that were made on similarly heat-treated samples, this one showed strong oxygen peaks on both sides of the Cu_xSn_y intermetallics; that is, at the Cu-Cu_3Sn interface, and also at the (Pb-Sn solder)-Cu_6Sn_5 interface. Also, within the intermetallics themselves, a lower level of oxygen was detected than that which was found to exist in both the copper plating as well as in the Pb-Sn solder deposit. This observation clearly showed that the intermetallics rejected oxygen on both sides, as they grew, and this accumulated as oxides at both of the intermetallic-matrix interfaces. Oxide accumulation at the solder-Cu_6Sn_5 boundary could be a contributing factor to fractures at this interface that appeared in observations made earlier on similar metallic systems (2). The reasonably high level of oxygen in the solder area (of Fig. 4) was found to exist mostly as an oxide of Sn (as was interpreted from the close

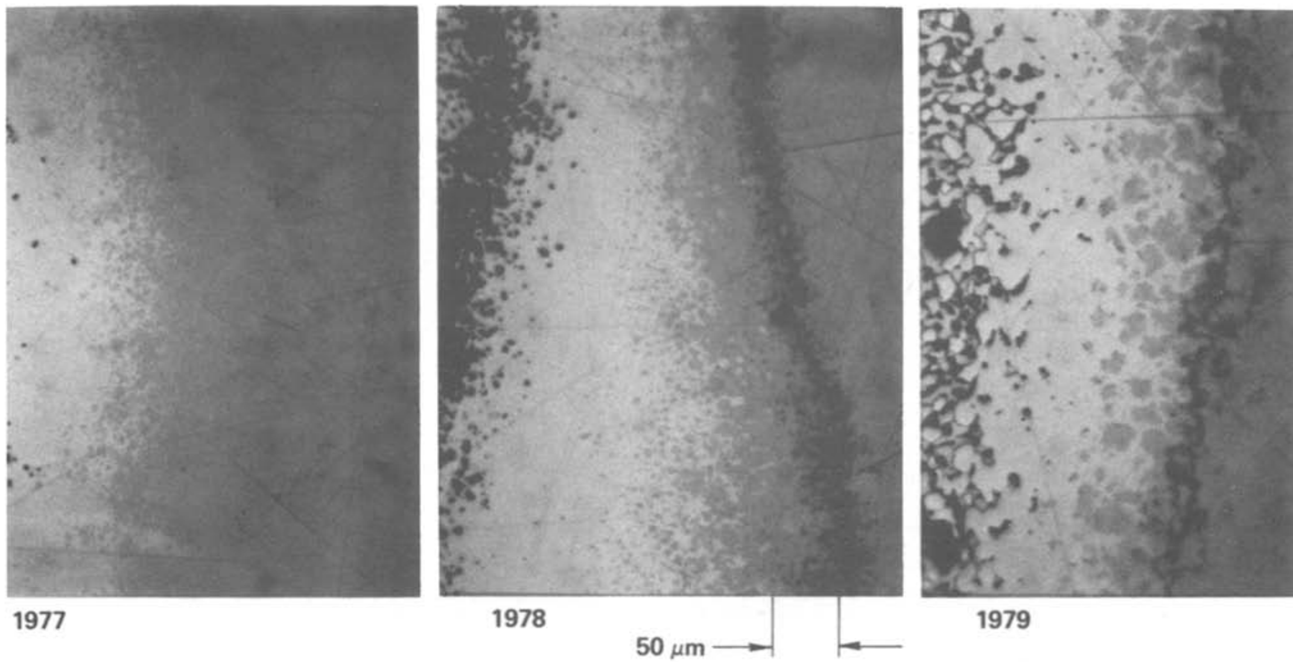

Fig. 3. Microstructures after 165°C, 264 hr air heat-treatment. Severe oxidation observed at Cu-Cu_3Sn boundary in 1978 and 1979 samples. None observed in 1977 sample.

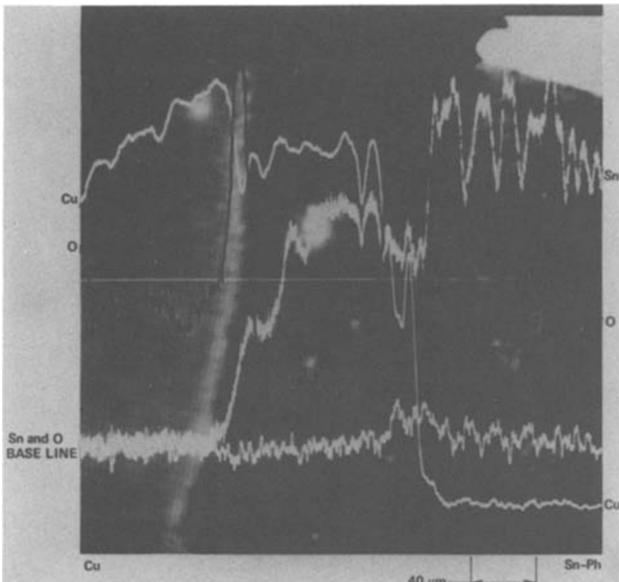

Fig. 4. Auger line scans across interface region in 1978 165°C, 264 hr air heat-treated sample. Oxygen peaks observed on both matrix-intermetallic interfaces.

correspondence between the Sn and the O Auger line scans in the solder region). A low level of oxygen within the intermetallics and the accumulation of an oxygen-containing species at the intermetallic-matrix boundaries clearly implies that oxygen present inside the solder will not migrate to the $Cu-Cu_3Sn$ boundary and lead to the observed degradation of the adhesion at that interface. The source of oxygen must, therefore, be located on the copper side of the reacted assembly. The two sources that could conceivably give rise to the time-temperature accumulation of the oxide in failed samples are the environment (because all of the aging occurs in air) and the copper plating. If the oxygen contribution is from the copper plating, then the source of oxygen must be distributed reasonably uniformly throughout the thickness of the deposit. Surface oxidation of the copper plating, prior to solder deposition, cannot, by itself, account for the time-temperature dependence of oxide development at the interface. If surface oxidation of the copper were the dominant contributor of the observed oxygen, the density of the oxide particles would not have significantly changed with increase in reaction time. The oxide particle concentration at the intermetallic-matrix interface, in such a circumstance, would have either remained constant (after all of the available oxygen was used up to form oxides in the very initial stages of the reaction), or even decreased because the intermetallics do show a finite, albeit low, oxygen solubility. Most of the oxygen contribution to the development of the oxide must, therefore, have originated either from the aging environment or from the bulk of the copper plating.

In order to further isolate the source of the oxygen (which leads to ultimate separation of the solder) an additional experiment was performed as part of this study. Sectioned samples, similar to those treated earlier in air, were obtained from the circuit boards and subjected to a 240 hr heat-treatment at 438 K (165°C) in an argon atmosphere. Figure 5 shows the microstructures that were obtained on the argon-treated samples. As with the air heat-treatments, formation of the oxide layer at the $Cu-Cu_3Sn$ interface was observed in both the 1978 and the 1979 samples whereas none was observed in the 1977 sample. Development of the oxide layer from heat-treatment in an inert atmosphere clearly showed that the source of oxygen was located within the copper plating. Organic addition agents, codeposited with the copper during the plating process, are believed to be the contributing source for the oxygen which is detected at the interface (6). This view is indirectly supported by the observation that the 1977 sample (where the copper was deposited in a pyrophosphate bath) did not show development of the oxide, whereas the 1978 and 1979 samples (where copper deposition was performed in a copper sulfate bath) showed extensive oxide formation at the $Cu-Cu_3Sn$ interface. The irregularly shaped, jagged $Cu-Cu_3Sn$ interface observed for the 1977 sample in Fig. 2 is indicative of copper deposition with limited use of leveling (addition) agents. This contrasts sharply with the smooth matrix-intermetallic interfaces observed for the 1978 and 1979 samples which clearly suggest a greater role for the leveling agents in the copper sulfate bath. The reduced level of irregularity at the $Cu-Cu_3Sn$ interface for the 1977 samples in Fig. 3 and 5 was believed to be related to effects resulting from extended high temperature ther-

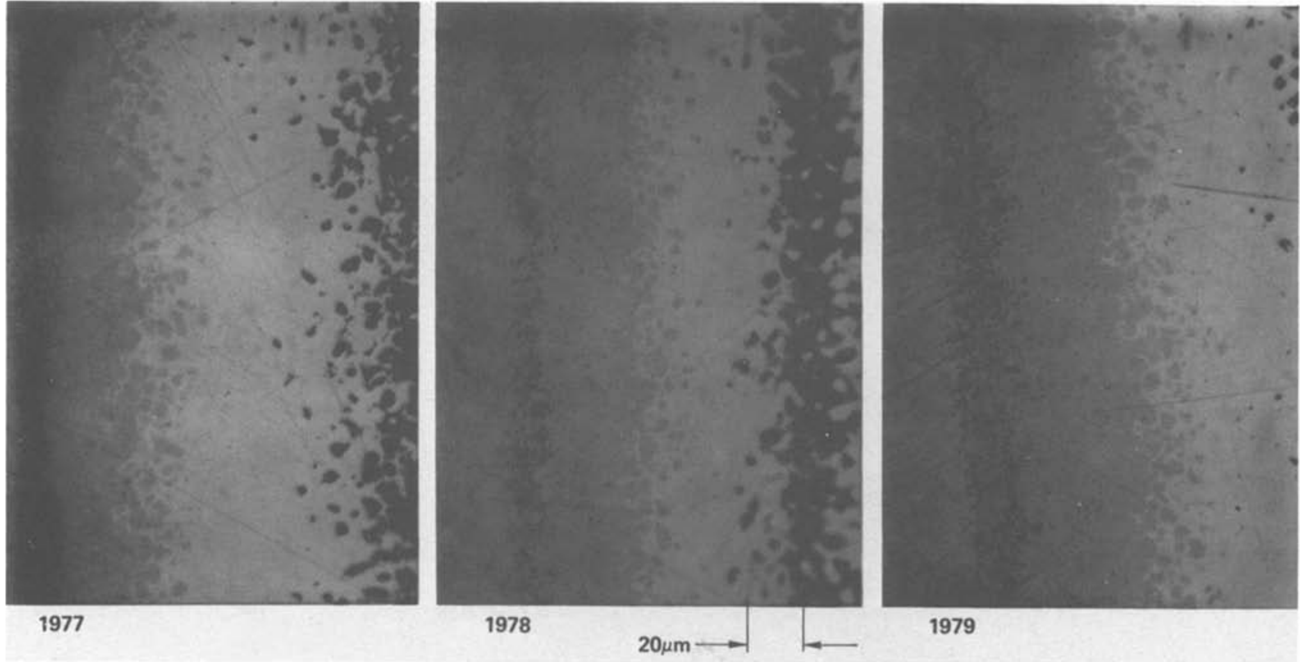

Fig. 5. Microstructures after 165°C, 240 hr argon heat-treatment. Oxide development similar to that observed in Fig. 3

mal exposure of the samples. It is possible that the treatments that were used resulted in decomposition of the organic addition agents and this may have permitted the development of a smoother Cu-Cu_3Sn interface with continued growth of the intermetallics. A bulk composition analysis, using Auger instrumentation, of the copper layer in the 1977, 1978, and 1979 samples indicated oxygen and carbon levels of about 3 to 5 atomic percent in the as-received condition for the 1978 and 1979 samples and an undetectable level of oxygen for the 1977 sample in agreement with the above interpretation of observed data. Carbon was not detected in the 1977 sample. All of this supported the view that organic addition agents might well be the source of the observed oxygen. These analyses were performed at a depth of about 1000Å to reflect actual bulk composition. (Depth profiles of the copper showed that the composition values stabilized after penetration by the Auger beam of a few hundred angstroms of thickness from the surface.) Examination of the composition after the 264 hr treatment in air (also at a depth of 1000Å) showed a much lower level of oxygen and almost no carbon in the 1978 and 1979 samples suggesting possible migration of these elements from regions close to the interface to the reacted zone under the influence of thermal activation.

Considerations such as solder composition, carbon contamination of the interface, and quality of the copper, can all, conceivably, to some extent, be expected to influence the rate of degradation of solder adhesion. Investigations at this Laboratory, however, suggest that the degradation mechanism itself will not be significantly altered by these several variations. The role of solder composition will be limited mainly to influencing the kinetics of growth of the various compounds and, therefore, to the accumulation rate of the oxygen-containing species. A detailed kinetics study showing the activation energy variations, for the several compounds, with changes in solder composition, is the subject of a separate publication (7). As for carbon contamination of the interface, this is expected to manifest itself in a manner similar to that observed for oxygen in this study. It may be noted, however, that even though almost equal amounts of carbon and oxygen were detected for the bulk composition of the as-received 1978 and 1979 boards, the distribution of these elements in the interface region was markedly different. Whereas oxygen was found to exist over the entire interface, where the oxygen-containing particles were distributed, high concentrations of carbon were detected only in a few discrete locations. This indicated that while carbon was also being rejected from the reaction zones in a manner similar to the oxygen (accounting for the observed buildup in concentration) its role in the observed degradation was minimal, albeit finite. The role of quality of the copper, however, is somewhat more complex. In addition to solder separation occurring from buildup of occluded impurities, such as those discussed in this paper, microstructural details, in particular the grain size, can be expected to also influence the rate of solder separation. The kinetics of growth of the several compounds can be expected to be dependent on grain size variations especially if this is the slow stage in the overall growth process.

Conclusions

This study shows that every effort should be made to eliminate the source of oxygen in the copper plating to avoid solder-adhesion failures in printed circuit boards. There is reason to suspect that organic addition agents that are codeposited with copper are acting as sources of the observed oxygen. The oxygen accumulates as discrete oxide particles at the matrix-intermetallic boundaries because of oxygen exclusion from the reacted zone with the continued growth of the intermetallics. Increase in oxide-particle concentration leads to solder separation, possibly through inhibition of the solid-state diffusion reaction across the Cu-Cu_3Sn interface even while the diffusion reactions at the Cu_3Sn-Cu_6Sn_5 and the Cu_6Sn_5-(Pb-Sn) solder interfaces continue to proceed.

Self-Aligned Aluminum Gate MOSFET's Fabricated by Laser Anneal

ABSTRACT

Self-aligned aluminum gate MOSFET's have been fabricated by applying laser anneal technology. The threshold voltage and surface electron mobility were similar to the conventional silicon gate MOSFET's. But the low resistivity of gate and interconnection electrodes by aluminum is advantageous for high switching speed MOSLSI.

Most of the gate electrodes for self-aligned MOSFET's have been fabricated with silicon gate (1), molybdenum gate (2), molybdenum-silicide gate, and the other refractory metal gates. Silicon and refractory metal gates are advantageous because high temperature processes can be utilized after these gate materials are deposited and patterned. Aluminum gates have traditionally been fabricated after all high temperature processes are completed because of the low melting point of aluminum (660°C). Aluminum gates like Mo gates have low resistivity (3×10^{-6} Ω-cm compared to 6×10^{-6} Ω-cm for Mo) which is advantageous for high speed MOSLSI circuits. Silicon gate has, on the other hand, a much higher resistivity (10^{-3} Ω-cm). It is therefore desirable to develop self-aligned aluminum gate MOSFET's. In this paper, experimental results are reported for self-aligned aluminum gate SOS MOSFET's fabricated by laser anneal technology (3).

Figure 1 shows the fabrication sequence for self-aligned aluminum gate SOS MOSFET's by laser anneal technology. The wafers used in this study have 0.3 μm thickness undoped (100) single crystal films which are epitaxially grown on $(1\bar{1}02)$ single crystal sapphire substrates. The silicon layer was first patterned to define silicon islands in a conventional manner. The patterning was accomplished with KOH anisotropic etching. Then a 100 nm gate oxide was grown by dry oxidation at 1050°C. Next, a 300 nm aluminum layer was deposited by vacuum evaporation. The aluminum layer was patterned, using H_3PO_4-HAc-H_2O solution etching, to form the gate electrodes and its connections. Phosphorus ion implantation was then applied to form the source and drain junctions, at the energy of 160 keV with a dose of 2.5×10^{15} cm^{-2} and 80 keV with a dose of 2.5×10^{15} cm^{-2}. The next step was laser anneal on the top surface of the wafer to activate the ion implanted silicon layer. For the laser anneal, a 2 kHz pulsed and second harmonic generated YAG laser ($\lambda = 0.503$ μm) was used in an X-Y scanning system. The laser spot size was 100 μm$^{\phi}$, the scan rate was 20 mm/sec, and the step size was 30 μm. The laser output power was chosen about 100 mW, so that the silicon layer was heated just below its melting point. In this step, the aluminum gate electrode was not melted by laser anneal in spite of its low melting point, because of its high reflectance of the laser light. In this step, the aluminum gates act as masks for source-drain ion implantations and laser anneal and perform self-aligned aluminum gate formation.

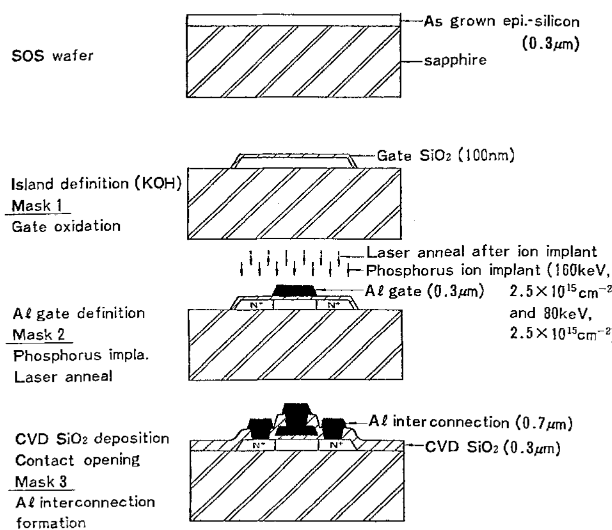

Fig. 1. Fabrication sequence for self-aligned aluminum gate MOSFET by laser anneal technology.

In the subsequent steps, silicon dioxide was chemically vapor deposited, and windows for the source, drain, and gate contacts were patterned and etched. Aluminum was deposited again over the entire surface which was patterned and etched to define the second interconnection plane. The final step was a 30 min sinter in H_2 at 450°C for minimizing the surface state densities to 5×10^{10} cm^{-2} at the Si-SiO_2 interface and for performing the Si-Al contact alloy.

Devices with channel length of 2 to 40 μm were fabricated: the channel widths were 80 and 20 μm. A photograph of the self-aligned aluminum gate SOS MOSFET is shown in Fig. 2. The source-drain *I-V* characteristics of the device are shown in Fig. 3. The threshold voltage is −0.7V showing depletion mode operation, and surface electron mobility is 350 cm²/V·sec at $V_o = 0.1^-$, $V_G = 2$V. These characteristics are similar to the conventional n-channel silicon gate SOS MOSFET's at nondoped 0.3 μm thick silicon layer. When an enhancement mode device is needed, it is possible to control the threshold voltage by applying the channel ion implantation and laser anneal to the silicon layer before the aluminum gate formation. Self-aligned aluminum gate MOSFET's technology is also useful for not only SOS MOSFET's but also bulk silicon MOSFET's.

The advantages of the self-aligned aluminum gate MOSFET's with laser anneal technology are: (*i*) low resistivity of gate and interconnection electrode by aluminum results in fabrication of high switching speed MOSLSI, and (*ii*) very low temperature process, except for thermal oxidation step, results in elimination of wafer warpage and minimum lateral

ABSTRACT

Microtwinning in silicon-on-sapphire (SOS) has been examined by a new technique. A crystallographic contrast on the sample surface is observed with a scanning electron microscope in the backscattered electron mode when a very bright source and a high pass energy filter is used. A modified Stereoscan MKIIa SEM with a field emission gun and an energy filter for backscattered electrons with a 200 eV window for a 45 kV primary beam has been used to study defect content in epitaxial SOS. Silicon layers thicknesses in the range of 0.1-1 μm were analyzed with a spatial resolution of 100Å.

This paper is concerned with an improved method for observing crystal defect content, it allows the determination of defect content in the surface region of thick samples without chemical etching or ion milling. We use an SEM in a special mode. The spatial resolution in the present experiments is 100Å. The depth explored beneath the surface is around 1000Å, so for a typical value of silicon epitaxial film thickness of (0.6 μm), we can obtain a defect content profile if we sequentially observe layers of varying thicknesses.

We briefly present here the fundamental of this technique and a description of the microscope used. We also discuss the results obtained for varying silicon film thicknesses in the range of 0.1-1 μm.

SEM Electron Channeling

A scanning electron microscope operating in the backscattered mode is sensitive to the relative orientation of the crystal with regard to the incident beam. A defect near the surface causes local bend of crystallographic planes and thus a local change in the backscattering current is observed. The anomalous absorption effect associated with Bragg reflection explains the contrasts observed (1).

Electron channeling patterns.—When a flat single crystal sample is observed at low magnification, bands

of contrast similar to Kikuchi lines in electron diffraction patterns are obtained. The symmetry of the pattern and its evolution when the specimen is tilted or rotated can be used to determine the crystallographic orientation of the sample. The origin of this contrast is explained qualitatively in Fig. 1.

When the electron probe scans the sample surface, the incident electron beam crosses the Bragg position for different sets of lattice planes. An anomalous electron absorption at Bragg angle θ_B produces variations in the backscattered electron current and consequently a contrast is obtained. A very flat surface is required to avoid a topographic contribution to contrast.

Crystal defect imaging.—At high magnification the variation of probe incidence angle can be neglected. When the incident beam is at the Bragg position for a set of lattice planes, a local bend of these planes, due to a crystal defect near the surface, produces an image contrast as shown in Fig. 2.

Required experimental conditions.—Crystal defect imaging needs a good compromise among the experimental parameters such as probe size, beam divergency, and electron beam current (1, 2). The probe size d must be smaller than the region where the lattice planes are perturbed. The divergency of the incident beam α must be smaller than the angular spread of the bent lattice planes. Thus it is necessary to work with a low illumination angle. In order to reveal the contrast pattern over the background noise the beam current I must be as high as possible.

These three parameters are related to the electron source brightness B by the equation

$$B = \frac{0.4I}{d^2\alpha^2}$$

Therefore a high brightness electron source is required (3). Patterns of reasonable contrast within standard exposure times are obtained with $B \simeq 10^8$ A/cm^2 sec. Thus a field emission gun is needed.

For samples giving a weak contrast it is necessary to eliminate the influence of beam fluctuations on video signal electronically. Crystallographic contrast imaging being sensitive to crystal orientation, a goniometer stage has to be used. We use a high pass energy filter to collect the backscattered electrons which have lost ~100 eV energy so as to get a pattern of high contrast.

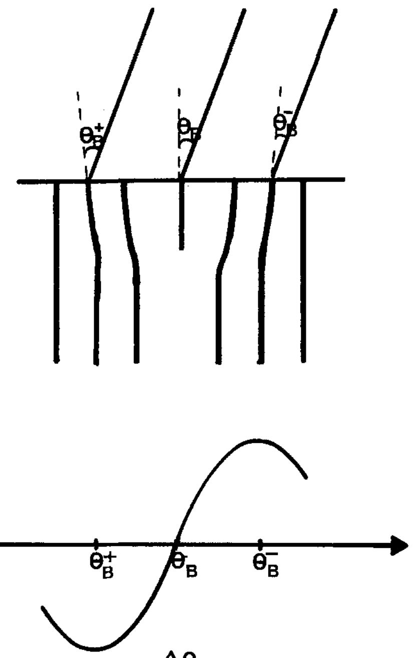

Fig. 2. Crystal defect imaging. At high magnification, a local bend of lattice planes produces an imaging contrast.

Experimental Arrangement

A schematic diagram of the microscope is shown in Fig. 3. The SEM is a Cambridge Stereoscan MKIIa with several modifications (4).

A field emission gun (5) differentially pumped (less than 10^{-10} Torr near the tip, 10^{-8} Torr in the intermediate chamber, and 10^{-5} Torr in the column) has been set up. Field emission instability is eliminated by an electronic attachment which divides the video signal by a signal proportional to the incident beam current (6).
