It is well known that the electrochemical and corrosion behavior of impure aluminum is significantly effected by the presence of Fe-rich, insoluble particles on the metal surface (1-3). When the metal is immersed in an unbuffered aqueous medium of neutral pH, pit growth initiates first at these sites (4). The solution inside the pits appears to be alkaline at the outset (5, 6) owing to high rates of H_2 evolution on the particles. In the presence of an aggressive species like Cl^- in the surrounding medium, a few of these pits may become acidic, while many of the original alkaline pits repassivate (7). However, the Fe-rich particles already exposed continue to function as ideal sites for the cathodic reaction (4). The depolarization of the H_2 evolution reaction is also undesirable due to an increased danger of "cathodic corrosion" (8-10) in various practical applications of the metal (8, 11, 12). Corrosion properties and cathodic behavior of impure aluminum can thus be improved if the surface can be cleaned of these particles.

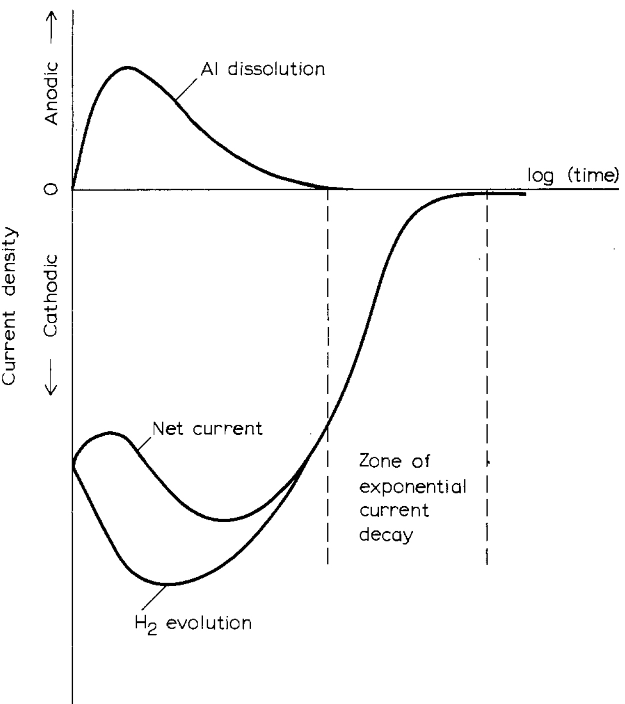

Fig. 1. A schematic representation of net current measured as a function of time under potentiostatic conditions. Postulated trends in the anodic and cathodic current densities are also indicated.

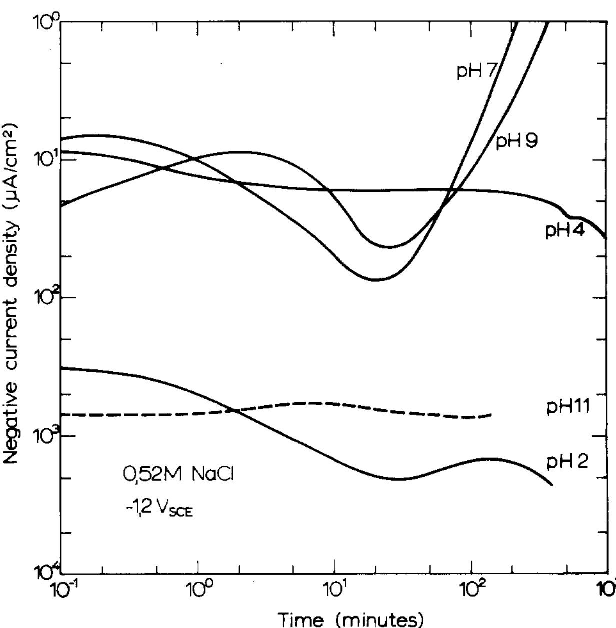

Fig. 2. Typical potentiostatic current-time behavior as a function of bulk pH in unbuffered NaCl solution. The dashed curve is anodic.

In recent papers (7, 10, 13, 14), we investigated the electrochemical behavior of impure aluminum in 3% (0.52M) NaCl solutions. When a constant potential within the passive range is applied to the metal, the net current typically exhibits the trend shown schematically in Fig. 1. In a mathematical sense, the current increases slightly at the outset, then decreases to a minimum, and finally decays to a steady-state level close to zero. This behavior is attributed to the following sequence of events. Immediately after the potential is applied, the film breaks at sites where Fe-rich particles are found, leading to H_2 evolution as well as Al dissolution. The local alkalinization of the solution at these sites makes possible a growth of pits as long as the alkalinity is sustained. The pits repassivate once the cathodic particles either dissolve or repassivate, as the solubility of the oxide film is exceeded locally due to Al dissolution (10). The present work provides additional electrochemical and metallographic data to support the suggested mechanism.

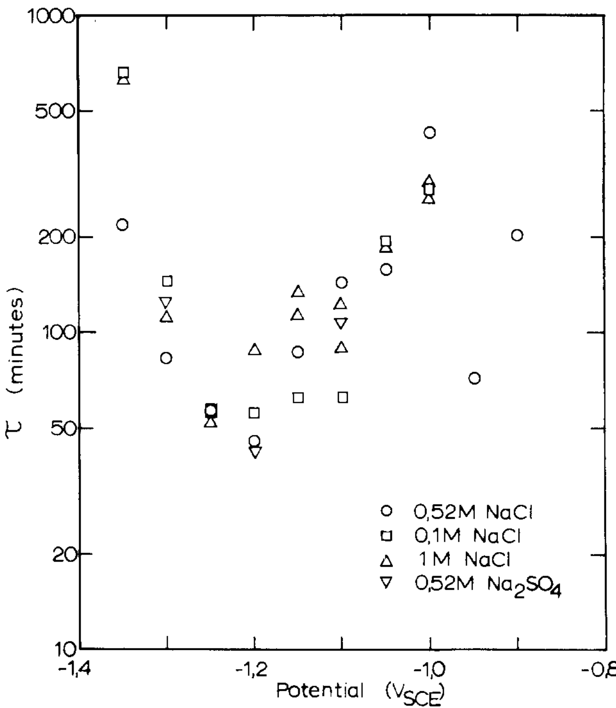

Fig. 3. The time constant for repassivation as a function of applied potential in unbuffered solutions of nearly neutral pH in the bulk (pH range 6-8).

Experimental

The aluminum contains approximately 0.3% Fe and 0.1% Si and corresponds to the specification AA1050A.[2] The specimens were machined from extruded rods, covered with "Sevriton" acrylic resin (tooth enamel) on the cylindical surface, and cast in epoxy to expose a circular area 1 cm in diameter. The resin forms a tight, crevice-free seal around the edge (13). The specimens were polished through 1 μm alumina. The electrolytic solutions consisted of different concentrations of NaCl and Na_2SO_4 in distilled water maintained at 25°C. The solution pH was adjusted to the desired value and maintained at that value during a polarization test by adding HCl, H_2SO_4, or NaOH depending

on the pH desired and test solution employed. Additional experimental details for the electrochemical studies were reported earlier (10). The specimen surfaces were analyzed by SEM and EDAX.

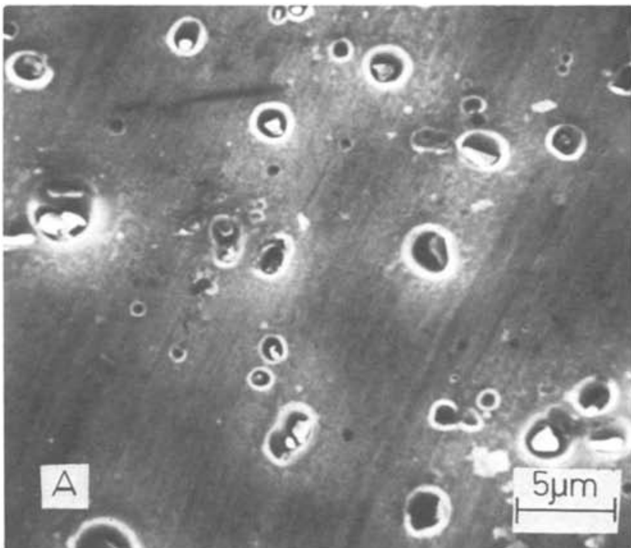
Results and Discussion

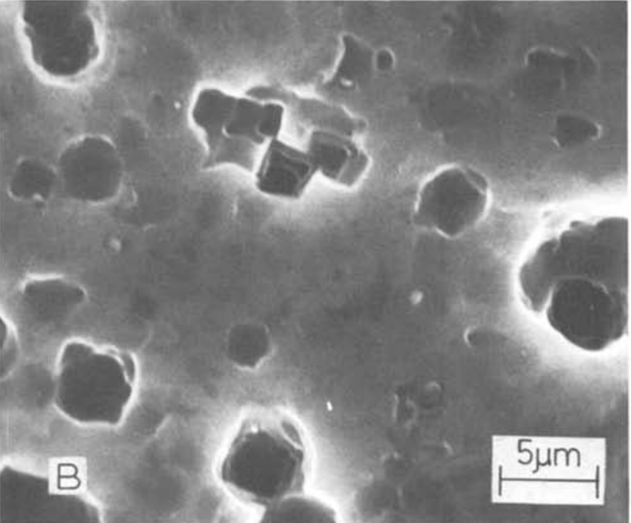
The discussion is based mainly on experimental data obtained in NaCl solutions. A few runs carried out in Na_2SO_4 solutions, even if not shown in detail, gave similar results in terms of polarization behavior and surface morphology. Thus, the anion (Cl^- or $SO_4^=$ in this case) does not have an appreciable effect on the observed phenomena. The present results confirm the earlier finding (10) that the repassivation of active areas under potentiostatic conditions results in an exponential decay of net current as indicated in Fig. 1. This behavior was observed also in other work investigating repassivation of active aluminum during either anodic or cathodic polarization (3, 15, 16). The current-time trend shown in Fig. 1 is typical for polarization of impure aluminum in unbuffered aqueous solutions of neutral pH. In acidic or basic solutions, the oxide film cannot stifle cathodic or anodic reactions at the metal surface. The current is therefore controlled by H_2 evolution or Al dissolution kinetics (Fig. 2). In buffered solutions of nearly neutral pH, the initiation of alkaline pits within the passive potential range can largely be eliminated (14).

The exponential part of these current-decay data can be utilized to obtain repassivation rates. A plot of ln $(i_\infty - i)$ *vs.* time yields straight lines, where i_∞ is a steady-state current density recorded at long times (after an exposure period of the order of 10^3 min depending on the applied potential) (10). The reciprocal slopes of the lines give a "time constant for repassivation," τ. These τ values are fairly reproducible at a given applied potential regardless of stirring conditions and anion concentration. A plot of τ as a function of applied potential, as measured in different aqueous media, is given in Fig. 3. Regardless of the type of solution used, the time constant exhibits a minimum at about -1.2 V_{SCE} for the present batch of specimens, indicating that the active sites on the metal repassivate most rapidly at this potential.

Micrographs of specimen surfaces polarized at -1.2 V_{SCE} for various lengths of time are shown in Fig. 4. The pits initiate at Fe-rich sites as indicated earlier; the particles can be observed as bright spots (Fig. 4A and B) during the earlier stages of polarization. After about 40 min (Fig. 4C), only a few pits still retain particles. After the current decays to a steady-state value, virtually none of the pits retain any particles (Fig. 4D). Figure 5 demonstrates at a higher magnification typical pits during earlier and later stages of polarization. Absence of particles in the pits at later stages was also confirmed by EDAX analyses of interiors of pits. A few exceptions were, however, observed; large occluded pits sometimes trap particles on the bottom even after lengthy periods of polarization (Fig. 5C).

Micrographs of pits grown by polarization for 24 hr at potentials different than -1.2 V_{SCE} are shown in Fig. 6. At more positive potentials, *e.g.*, -0.8 and -0.9 V_{SCE}, the particles are not always removed from the surface. Passivation also occurs by film formation on the particles. Most particles fall out or dissolve at potentials less than or equal to about -1.0 V_{SCE}. This occurs superficially and without exposing fresh particles from the substrate at potentials more positive than -1.3 V_{SCE}. At -1.3 V_{SCE} and below, the alkaline pits become quite large, thereby exposing new particles as they grow. These particles can again be observed as white flecks inside pits (Fig. 6E-G). These large, occluded pits give way to closely packed, shallow hemispherical pits at -1.38 V_{SCE} and below. This type of morphology is characteristic of an aluminum surface





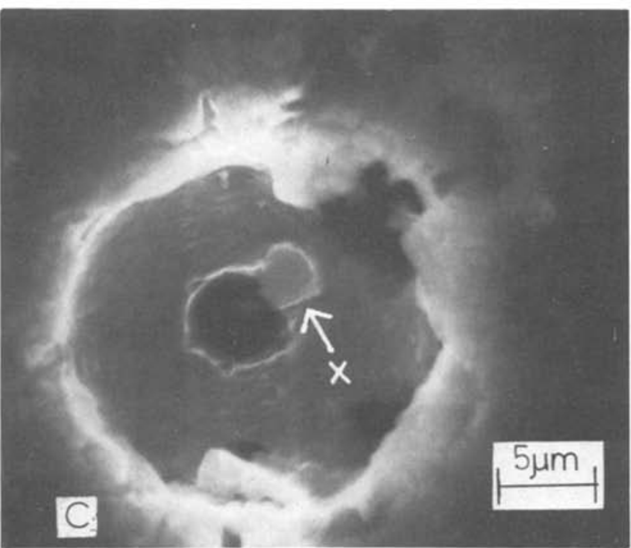


Fig. 5. Examples of pits observed at -1.2 V_{SCE} in 0.52M NaCl corresponding to (A) early stages of polarization when particles can still be observed as bright areas inside the pits and (B) later stage of polarization when pits are free of particles. (C) A large pit with an Fe-rich particle entrained at its bottom (marked X). The dark circular area in the middle is a smaller diameter pit grown inside the larger one.

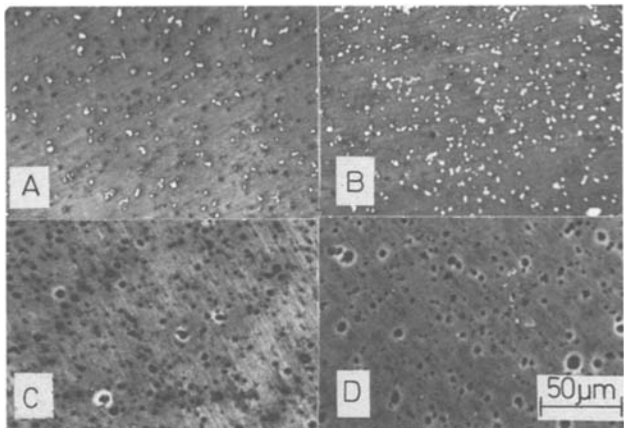
uniformly etched in alkaline media. Fe-rich particles are also visible on an etched surface (Fig. 6H). These



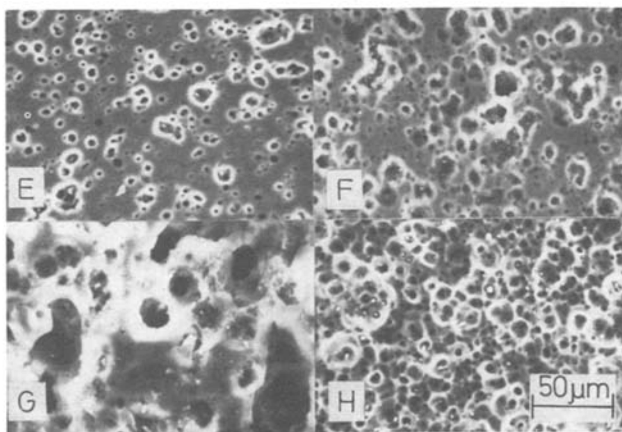


Fig. 6. Pit morphology on specimens polarized for 24 hr in 0.52M NaCl solutions. (A) −0.8V, (B) −0.9V, (C) −1.0V, (D) −1.1V, (E) −1.3V, (F) −1.35V, (G)−1.37V, (H) −1.38V. All potentials are with respect to SCE.

results explain the cause of slower repassivation rates at the more negative and more positive extremes of the passive potential range. For the present specimens, −1.2 V_{SCE} happens to be the potential where the particles are removed most rapidly without exposing new ones from underneath.

Qualitative analyses of the particles by EDAX and Auger electron spectroscopy indicate that they contain mainly Al and Fe; Si was detected in some of the particles by EDAX. It is well known that the secondary phases existing in commercial-purity aluminum are predominantly Al_3Fe and α-AlFeSi (1). These phases are reported to behave in a similar way electrochemically (17). They are known to be much better cathodes than the Al matrix. In addition, Al_3Fe exhibits active-passive dissolution kinetics in alkaline media (18, 19). The potential range for active dissolution corresponds roughly to the range of present interest, where the particles are efficiently removed from the metal surface. Thus, the present results throw more light on the cathodic behavior of impure aluminum reported earlier (10) and suggest a possible, low current-density method of cleaning the metal surface of Fe-rich particles. A more common method, which effectively removes the secondary-phase particles and which, in addition, improves the esthetic looks of the surface, is electropolishing in ethanol-$HClO_4$ solutions (20).

Investigation of Photoelectrochemical Corrosion of Semiconductors

II. Kinetic Analysis of Corrosion-Competition Reactions on n-GaAs

K. W. Frese, Jr.,* M. J. Madou, and S. R. Morrison

SRI International, Menlo Park, California 94025

ABSTRACT

The model of photoelectrochemical corrosion-stabilization of semiconductors has been extended. Detailed expressions for rate constants are given including capture cross sections and energy levels for hole capture. It is concluded from analysis of experimental data that the first hole in the rate-limiting step is captured at an energy level slightly above the valence band-edge. Analysis of stabilization efficiency *vs.* pH gave a value of 0.72 eV for the rearrangement energy of [Fe(II) EDTA]$^{=}$.

In this paper we further develop our corrosion-stabilization model (1) for semiconductors in contact with electrolytes. The theory attempts to describe the competition between photocorrosion and the photoinduced redox reactions of the stabilizing agent. Without loss of generality we discuss the case of an n-type material such as n-GaAs in contact with an aqueous electrolyte.

In the earlier study (1) of the simple stabilization/light intensity relationship, developed independently by Gomes *et al.* (2) and ourselves, we were able to identify the most probable reaction mechanism. However, from this simple experiment, important details such as the energy levels involved could not be determined. Thus we have obtained new experimental data, showing the dependence of stabilization on the energy level of the ion in solution and on the *p*H of the solution for systems selected for their simple behavior. These data are analyzed with the help of a more detailed development of the theory.

The more detailed development given here, such as expressions for corrosion rate constants including activation energy for hole capture and use of the fluctuating energy level model for the redox electrolyte, has provided new insights into the corrosion-competition process. We have been able to determine the characteristic rearrangement energy, λ, of the reducing agent and estimate energy levels for hole capture at surface on back bonds. The use of Eq. [19] below allows a nearly complete separation of the kinetics of corrosion from that of the stabilization process.

Theory

In a previous paper (1) we presented a general kinetic model of semiconductor corrosion and used it to describe the photoelectrochemical corrosion of the A-B type semiconductor GaAs. The model included the competitive reaction of the stabilizing agent, *e.g.*, Fe(II) EDTA. The following steps were postulated in the corrosion-competition mechanism

$$>A{:}B< h^+ \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} >A{\cdot}B< \qquad [1]$$

$$>A{\cdot}B< + h^+ \xrightarrow{k_2} >A + B< \qquad [2]$$

$$R + h^+ \xrightarrow{k_3} O_x^+ \qquad [3]$$

$$R + A{\cdot}B \xrightarrow{k_4} O_x^+ + A{:}B \qquad [4]$$

In the corrosion mechanism attention is focused on a single electron pair bond, A:B. A hole generated behind the surface row of atoms migrates to the surface and is captured by the surface bond. The surface bonds are between surface Ga or As atoms and the underlying lattice. This surface ($2e^-$) bond, SB, or back-bond, is considered to be a surface state designated E_{SB}. When the first electron is removed or equivalently the first hole captured we have the radical-like ($1e^-$) surface state A·B which we designate E_{SR} (3). We emphasize that E_{SB} and E_{SR} are the surface state energies of the hole when captured. These active surface bonds are between atoms that certainly have bonds to other foreign atoms such as oxygen, hydrogen, or possibly to metal atoms such as gold or ruthenium (4). Therefore the energy levels E_{SB} and E_{SR} will be influenced by other ligands attached to the surface atoms.

Figure 1 shows a diagram of the energy levels in the corrosion model along with the different current paths. The currents j_1 and j_{-1} are the rate of capture and emission of holes between the valence band and the surface bond, E_{SB}. The energy levels of the surface bonds or back-bonds on the clean, relaxed (110) GaAs surface are known (5) to be below the valence bandedge. For this reason in Fig. 1, we tentatively place the energy level, E_{SB}, several hundred meV below the valence bandedge to include the case when the

* Electrochemical Society Active Member.

Key words: photoelectrochemical corrosion, corrosion-competition reactions, rearrangement energies, n-GaAs.

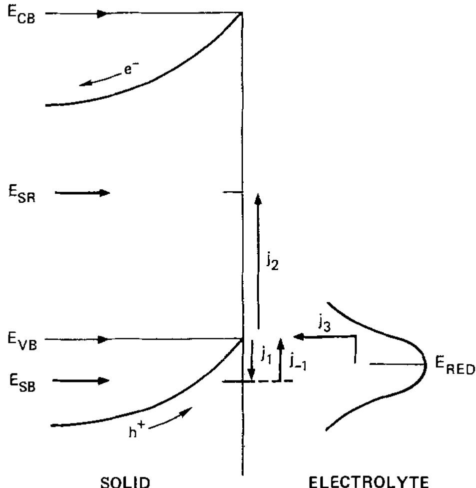

Fig. 1. Energy level diagram of an illuminated n-type wide gap semiconductor under depletion layer conditions. The energy levels and currents associated with each step in the corrosion-stabilization mechanism (Eq. [1]-[3]) are shown. For simplicity the reducing agent captures holes in the energy range E_{VB} to $E_{VB} - 2kT$. E_{SB} and E_{SR} denote surface state energy levels for holes.

first hole capture is activated. Later in the discussion we will estimate ($E_{VB} - E_{SB}$) from experiment. The current, j_2, represents the irreversible hole capture by the surface state E_{SR} which is represented by the one-electron species, A·B. We assume this hole capture is irreversible because the energy of the unpaired electron is expected to be much higher (weaker bond) than the energy of a paired valence electron, and so the expected energy level, E_{SR}, can be expected to be in the midgap region.

We ignore hole capture by excitation of an electron from E_{SR} to E_{CB}. While the process may be important for Ge (6) the results of Ref. (1) (where corrosion is shown to be second order in hole concentration) suggest it is a minor effect for wide gap materials such as GaAs.

Finally j_3 and j_4 represent the rate of competitive hole capture by the stabilizing (reducing) agent in solution. We believe (1, 2) step [3] in the mechanism (hole capture from the valence bandedge) dominates (1) the stabilization of n-GaAs. This conclusion was discussed in Ref. (1) We therefore have not included the partial current j_4 from E_{red} to E_{SR} in Fig. 1.

Derivation of equations.—The explicit equations for the rate constants in steps [1]-[3] will now be discussed. For step [1] the current j_1 is given by

$$j_1 = k_1 h^+ \quad [5]$$

with

$$k_1 = \langle q\sigma_1 vd\rangle \, (\mathrm{A{:}B}) \, e^{-(E_{VB} - E_{SB})/kT} \quad [6]$$

The quantities q, σ, v, and d are the electronic charge, hole capture cross section, hole thermal velocity, and reaction length, respectively. The term (A:B) represents the volume density of bonding electrons susceptible to corrosion (filled states). These electrons may be in bonds on the plane surface, at steps or kink sites, or at the ends of dislocation pipes. If these centers are uncharged, then it is not unreasonable to assume σ, the order to the atomic area, *viz.* 10^{-15} cm^2.

For j_{-1} we have

$$j_{-1} = k_{-1} \, (\mathrm{A{\cdot}B}) \quad [7]$$

with

$$k_{-1} = \langle q\sigma_1 vd\rangle \, N_v \quad [8]$$

where N_v is the density of states at the valence bandedge. The current j_2 is given by

$$j_2 = k_2 h^+ (\mathrm{A{\cdot}B}) \quad [9]$$

where

$$k_2 = \langle q\sigma_2 vd\rangle \quad [10]$$

The cross section σ_2 for capture of the second hole will depend strongly on charge associated with A·B. If a ligand such as OH^- neutralizes the positive charge due to the first hole capture, then σ_2 will probably not differ much from σ_1 (7), *i.e.*, $\sim 10^{-15}$ cm^2. If, however, OH^- concentration can be made very low as in a nonaqueous solvent, j_2 may be much lower due to coulombic repulsive effects on the cross section, *i.e.*, $\sigma_2 \approx 10^{-21}$ cm^2. This effect could significantly lower the corrosion rate in nonaqueous solvents.

Finally, j_3, the rate of hole capture by the reducing agent, is given by

$$j_3 = k_3 C_R h^+ \quad [11]$$

where C_R is the concentration of reducing agent. For the rate constant, k_3, we write (8, 9)

$$k_3 = \langle q\sigma_3 v_3 d\rangle \left(\frac{kT}{\pi\lambda}\right)^{1/2} e^{-(E_{VB} - E_{red})^2/4\lambda kT} \quad [12]$$

where σ_3 is the capture cross section of an ion or molecule in solution, v_3 is the mean relative thermal velocity of the hole, d is a reaction length (5-10Å), E_{VB} is the energy of the valence bandedge, E_{red} is the most probable energy level of the electron on the reducing agent, and λ is the rearrangement energy. This form of the rate constant is based on the approximation that only holes within $2kT$ below the valence bandedge react with the stabilizing agent.

A detailed expression was previously derived (1) for the stabilization efficiency, S. Briefly, this quantity is the ratio of the current j_3 to the total hole current j_p. It was shown earlier (1) that

$$j_2 = \frac{k_1 k_2 h^2}{k_{-1} + k_2 h} \quad [13]$$

and if $k_2 h << k_{-1}$ or equivalently $h^+ << N_V$, the second term in the denominator may be neglected. With aid of this approximation, and after solving Eq. [11] for h^+ and inserting the result into Eq. [13] we obtain

$$j_2 = \frac{k_1 k_2 j_3^2}{k_{-1} k_3^2 C_R^2} \quad [14]$$

Since $j_p = j_2 + j_3$ and $S = j_3/j_p$ we find

$$\frac{1}{S} = 1 + \frac{\alpha j_3}{C_R^2} \quad [15]$$

where α is $k_1k_2/k_{-1}k_3^2$. Equation [15] may be used to obtain the parameter α from plots of $1/S$ *vs.* j_3. The quantities S and j_3 are readily available from rotating-ring disk electrode (RRDE) corrosion studies (1, 10). Equation [15] will be applied to experimental stabilization data below.

Some further theoretical development is needed to show how λ_{red}, the rearrangement energy of the reducing agent, may be determined from photoelectrochemical corrosion studies using the above theory. Three different approaches may be made to the problem. All three are based on determining the value of α for the same electrode material under two or more different experimental conditions. Using Eq. [12] and α it is easily shown that

$$\frac{1}{\alpha} = \frac{k_{-1}}{k_1 k_2} \langle q\sigma_3 v_3 d\rangle^2 \frac{kT}{\pi\lambda} e^{\frac{-(E_{VB} - E_{red})^2}{2\lambda kT}} \quad [16]$$

The term E_{VB} is the energy of the valence bandedge and can be determined from capacitance/voltage measurements. The most probable electronic level of the reducing agent, E_{red}, is related to the redox Fermi level according to

$$E_{red} = E_F^{redox} - \lambda_{red} \quad [17]$$

If α is determined for two different reducing agents with different E_{red} and λ, the λ for one reducing agent may be determined if λ is known for the other. For such a case we have from Eq. [16] and [17]

$$\ln\frac{\alpha_1}{\alpha_2} = \ln\left(\frac{\lambda_1}{\lambda_2}\right) - \left[\frac{(E_{VB} - E_{F_2}{}^{redox} + \lambda_2)^2}{2\lambda_2 kT} - \frac{(E_{VB} - E_{F_1}{}^{redox} + \lambda_1)^2}{2\lambda_1 kT}\right] \quad [18]$$

All variables in Eq. [18] are known for experiment except the one λ value to be determined. Equation [18] assumes that $\sigma_3 d$ in Eq. [16] is the same for each of the two reducing agents.

A slight variation of Eq. [18] has been used in the present work. If α values for two redox couples with different $E_F{}^{redox}$ but same λ are used, a single λ valid for either reducing agent may be determined. Conditions for this application arise, for example, in the case of various Fe(II)-ethylene-amino-polyacetic acid chelates such as EDTA and DTPA. Since the inner coordination structure and overall size of these complex ions are approximately the same, we expect λ to be similar for each ferrous chelate. In the two methods just described Eq. [18] must be solved numerically.

A final approach to obtain λ is to vary the energy level of the solid while holding the solution levels constant (11). Since E_{VB} usually depends on pH in a regular way $dE_{VB}/dp\text{H} \approx 60$ mV/pH, variations in electrolyte pH will cause small shifts in the exponent of Eq. [16] leading to large changes in α and S. By taking the ln of Eq. [16], Eq. [19] is obtained

$$\ln 1/\alpha = \ln\left[\frac{k_{-1}}{k_1 k_2} <q\sigma_3 v_3 d>^2 \frac{kT}{\pi\lambda}\right] - \frac{(E_{VB} - E_{red})^2}{2\lambda kT} \quad [19]$$

It can be seen that a lot of ln $1/\alpha$ *vs.* $(E_{VB} - E_{red})^2$ yields λ from the slope and the intercept contains the ratio of the corrosion rate constants and the preexponential of k_3. Success of this method depends on the pH invariance of the corrosion process and constant solution redox chemistry. It is advisable to choose a pH range where the $E_{redox}{}^F$ is constant, because only then can one hope to have a single solvated form (a single energy level) dominate. This limits the useful pH range in some cases to 2-3 pH units. In the corrosion model the rate constants are for solid-state processes so that Eq. [19] would be applicable. Data below for Fe(II) EDTA/GaAs system are consistent with the pH independence of the corrosion process and the pH dependence of the stabilization process.

Experimental

The rotating ring disk electrode apparatus and technique have been described before (1, 10). All measurements were made on the 100 face of n-GaAs single crystals. The surfaces were chemomechanically polished and etched with an aqueous (1% V/V) solution of chlorox (5.25% sodium hypochlorite). Tellurium donor densities were 2×10^{18} cm$^{3\ -1}$.

Ferrous EDTA was prepared by dissolving ferrous perchlorate in 0.1M disodium salt of ethylene diamine tetraacetic acid (EDTA). Ferrous DTPA was made similarly from a 0.1M solution of diethylenetriamine-pentaacetic acid and NaOH.

Formal electrode potentials were measured using a bright Pt foil, an SCE electrode, and a Keithley 616 electrometer. The pH of all electrolytes was adjusted with either NH_4OH or $HClO_4$.

Experimental Results and Analysis

Figure 2 shows typical plots of reciprocal stabilization efficiency *vs.* redox stabilizing current for well-etched (100) n-GaAs. The data were plotted according to Eq. [15]. The open symbols refer to the case with 0.02M Fe(II) EDTA as the stabilizing agent while the closed symbols refer to the case with 0.02M Fe(II) DPTA. The current density, j_3, is the observed current on the ring divided by the collection efficiency (0.344) and the disk electrode area (0.195 cm^2). These low concentrations were chosen in order to observe large changes in S. The plots were fairly linear with unit intercepts as required by the theory (Eq. [15]). For the Fe(II) EDTA data it can be seen that the stabilization increases as the pH is lowered. This trend is expected if E_{red} lies below E_{VB}. The plot for Fe(II) DTPA is also very reasonable. The electrode potential of Fe(III-II) DTPA, −0.22V *vs.* SCE (12), is ~ 100 mV more negative than Fe(III-II) EDTA, −0.12V *vs.* SCE (13).

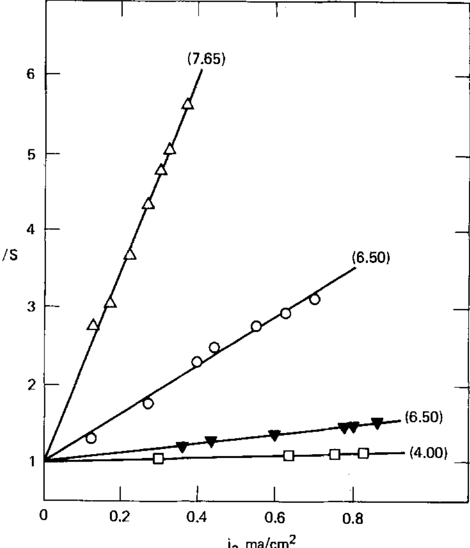

Fig. 2. Reciprocal stabilization efficiency vs. redox stabilization current for well-etched n-(100) GaAs at various pH values. Stabilizing agents: 0.02M Fe(II) EDTA (0.1M EDTA), open symbols; 0.02M Fe(II), DTPA (0.1M DTPA), closed symbols. Electrolyte pH is shown.

A pH shift of about 2 units with Fe(II) EDTA (ΔE_{VB} ~ 110 mV) produces the same effect on S as using the two different ferrous chelates ($\Delta E_F{}^{redox}$ ~ 100 mV) indicating a similar λ for each ferrous chelate in Fig. 2.

The rate constant ratio α for the n-GaAs/Fe(II) EDTA system was calculated from the slopes of the plots in Fig. 2 (Eq. [15]). Table I summarizes the data for $\alpha = k_1k_2/k_{-1}k_3{}^2$ when C_R is expressed as moles/liter along with the position of the valence bandedge on the SCE potential scale. A value of +0.20V *vs.* SCE at pH = 6.5 was assigned for the valence bandedge and a value of 0.055 V/pH was used to correct for changes in pH. Capacitance-voltage data (not shown) on n-type GaAs samples in EDTA solutions were used to obtain the electrode potential corresponding to E_{VB}.

Table I. Corrosion-competition data for (100) n-GaAs

Fe(II) EDTA	$E° = -0.125$V *vs.* SCE	0.02M
pH	α(M^2 cm^2)/A	E_{VB} (V *vs.* SCE)
4.00	0.117	+0.34
5.50	0.429	+0.25
6.00	0.920	+0.23
6.50	1.25	+0.20
6.70	1.50	+0.190
7.65	5.10	+0.137
8.20	6.47	+0.106
Fe(II) DTPA	$E° = -0.215$V *vs* SCE	0.02M
6.5	0.25	+0.20

Figure 3 shows a log plot of $1/\alpha$ vs. $(E_{VB} - E_{red})^2$ according to Eq. [19]. The quantity $(E_{VB} - E_{red})^2$ was calculated using the data of Table I and Eq. [17]. Note that λ must be assumed to calculate the abscissa in Fig. 3. In an iterative calculation the data for pH (4-6.7) were analyzed by least squares until the assumed λ was found in the calculated slope (Eq. [19]). The solid line in Fig. 3 shows the results of such calculation. The assumed λ was 0.72 eV and the calculated value was identical. The correlation coefficient was 0.992. This value of λ applies to the $[Fe(II)\ EDTA]^{=}$ ion which is the dominant species of the reduced form in the pH range 4.0-6.7. Deviations occur at pH > 6.7 as shown by the dotted portions in Fig. 3.

Inspection of the insert in Fig. 3 reveals that the measured formal electrode potential of the iron EDTA couple is independent of the pH in the same range where the solid line in Fig. 3 applies. It can also be seen that the deviations in the ln $1/\alpha$ plot occur at very nearly the same pH at which the formal electrode potential begins to become more negative. This behavior signals a change in solution chemistry which could lead to a different λ or capture cross section. No attempt was made to analyze this effect.

The value of λ may be calculated another way using Eq. [18]. The assumption is that λ for Fe(II) DTPA and Fe(II) EDTA are equal (as discussed above). From the α and electrode potential data in Table I, pH = 6.5, for these two reducing agents, a λ of 0.69 eV was calculated. This result at constant pH, and variable E_{red} agrees well with the constant E_{red} and variable pH calculation of Fig. 3. These two results for λ may be compared with λ calculated from kinetic data on homogeneous redox reactions. A Marcus-type analysis (14) of the rate constant for electron transfer between Fe(II) EDTA and Fe(III) CyDTA ($\Delta G^\circ \cong 0$) leads to $\lambda_{ox} + \lambda_{red} = 1.4$ eV. If it is assumed that $\lambda_{ox} = \lambda_{red}$ then a value of $\lambda = 0.7$ eV is indicated for Fe(II) EDTA. Again the agreeement with the two values derived from corrosion studies and this homogeneous reaction is good. It appears that the functional form of the rate constant k_3, Eq. [12], is essentially correct at least in the case when E_{red} lies below E_{VB}.

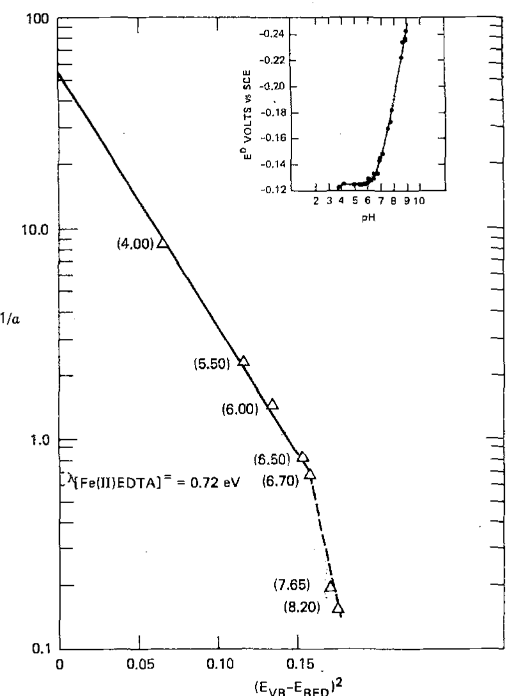

Fig. 3. Plot of logarithm of reciprocal rate constant ratio, $1/\alpha$, vs. energy level difference, $(E_{VB} - E_{red})^2$ for (100)-n-GaAs. Stabilizing agent is 0.02M Fe(II) in 0.1M Na_2 EDTA. The independent experimental variable is the electrolyte pH as indicated. The pH dependence of the formal electrode potential of 0.02M Fe(II)/Fe(III) perchlorate couple in 0.1M Na_2 EDTA is also shown in the figure. pH adjusted with NH_3 or $HClO_4$.

We turn now to an analysis of the solid-state aspect of the corrosion mechanism. From the intercept in Eq. [19] and Fig. 3 we have

$$\left(\frac{1000}{N_A}\right)^2 \frac{1}{\alpha_0} = \frac{k_{-1}}{k_1 k_2} (q\sigma_3 v d)^2 \frac{kT}{\pi\lambda} \qquad [20]$$

where we have introduced the Avogadro term ($1000/N_A$) to convert from molarity M, to particle density (cm^{-3}). The value of $1/\alpha_0$ from Fig. 3 was found to be 53.6 $A/M^2\ cm^2$.

We would like to evaluate the term k_1k_2/k_{-1} in Eq. [20] and eventually the activation energy for k_1, ($E_{VB} - E_{SB}$) in Fig. 1. In order to do this we must have estimates for the capture cross sections σ, thermal velocities, v, and reaction length d. The following values were used [σ, 2×10^{-15} cm^2; v, 10^7 cm/sec for holes; d, 10×10^{-8} cm and 2.5×10^{-8} cm (GaAs bond length) for the solution and solid-state reaction, respectively]. Using Eq. [6], [7], and [10] with $N_v = 7 \times 10^{18}$ cm^{-3} (15) and assuming σ in k_{-1} and k_1 are equal, we obtain

$$(A{:}B)\, e^{-(E_{VB} - E_{SB})/kT} = 6.9 \times 10^{23}\ cm^{-3} \qquad [21]$$

To proceed further we must estimate (A:B), the concentration of filled surface states (3). Several cases will be considered. We can determine an upper limit to ($E_{VB} - E_{SB}$) if we assume (A:B) equals the total surface valence electron concentration in back-bonds, ~ ½ (1.8×10^{23} cm^{-3}) for the (100) face. Using this value, ($E_{VB} - E_{SB}$) = −0.052 eV which places the back-level, E_{SB}, slightly above the valence bandedge. Experimental errors could still allow E_{SB} to be slightly below E_{VB}.

If the rate-limiting step involves the concentration of filled states at dislocations, then (A:B) will be ~ 4×10^{14} cm^{-3}, yielding ($E_{VB} - E_{SB}$) equals −0.55 eV. (The etch pit density of our crystals is ~ 10^7 cm^{-2} as reported by the supplier.) We note the surface bond level at a dislocation by this estimate would lie 0.55 eV above the valence bandedge. We can rule out this rate-limiting step since the first hole capture would be irreversible and S would be independent of j_p (1) which is inconsistent with experiment.

Finally, if (A:B) represents the concentration of filled states at steps, we estimate (A:B) = 4.5×10^{20} cm^{-3}. This gives ($E_{VB} - E_{SB}$) equals −0.19 and places E_{SB} 0.19 eV above the valence bandedge. This calculation assumes steps form a line across the whole surface at 1000Å intervals. We conclude the first hole is captured on a level in the energy range approximately $E_{VB} \pm 0.2$ eV. The reversible hole exchange that must be invoked is consistent with this energy range. The values of E_{SB} below E_{VB} are not inconsistent with surface back-bond tight-binding calculations of Chadi (4) who found for various relaxation models of the (110) GaAs surface, back-bond levels at ~ 1.0-1.9 eV below E_{VB}. These energy levels are for the clean defect-free relaxed (110) surfaces. In the case of corrosion in the presence of ligands such as OH^- which can be attached to GaAs surface atoms, the surface structure will more closely represent the tetrahedral bonding as in the GaAs bulk. This different bonding arrangement will tend to move the surface bond level back toward the valence bandedge. However, the higher electronegativity of oxygen could exert a small stabilizing effect (compared to bulk GaAs bonds) on the GaAs surface bonds and thus we might expect the surface bond level, E_{SB}, to be close to the valence bandedge.

In the near future we will make a similar study on CVD GaAs films. We exect to learn more about the role of defects in the corrosion process. We will also try to measure the corrosion activation energy by studying the temperature dependence of the stabilization efficiency, S.

Anodic Film Growth on Titanium at Temperatures from 200° to 257°C

A. L. Bacarella,* H. S. Gadiyar,[1] and A. L. Sutton[2]

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

An electrochemical study of anodic film growth on titanium in oxygenated 0.05M K_2SO_4 at temperatures from 200° to 257°C and at constant potential, below the O_2 evolution potential is presented. At constant applied potential, it is assumed that the voltage drop (V) across the oxide is constant and the field $E = V/X$, where X is the film thickness. The results are interpreted in terms of a rate expression derived by Dignam (20-22) and assume the effective field, E_e, assisting the ionic conduction process is the local field, $E_e = \delta K E$ for $K >> 1$, where K is the dielectric constant of the oxide and δ is a geometric factor having a value the order of unity.

Much of the work related to anodic film growth on valve metals consists of room temperature studies at high field strength (1-9), where applied voltages greater than 100V are often encountered. The current efficiencies for film growth in such studies are often less than 100% (due to O_2 evolution) and require physical methods (ellipsometry) to determine film thickness. When the temperature is increased above 200°C, sufficient thermal energy becomes available to grow significant film at potentials below the O_2 evolution potential with 100% current efficiency.

Here, the results of a study of anodic film growth on titanium in oxygenated 0.05M K_2SO_4 at 200°-257°C and at potentials below the O_2 evolution potential are presented. This work was begun to test the applicability of the equations developed for high field strength studies to film growth at "low" field strength but high temperatures (above 200°C) and, further, to test the applicability of local field concepts to the kinetic data.

The classical theory (10) of ionic conduction in valve metals predicts an exponential relation between the ionic current and field strength

$$i = i_o \exp\{-[\phi - qaE]/kT\} \qquad [1]$$

where qa is the apparent activation dipole, ϕ is the apparent activation energy, and E the applied macroscopic field. In 1966 Bacarella and Sutton (11) showed that the application of local field concepts to anodic film growth on zirconium provided a more satisfactory interpretation of the kinetic results. At potentials below the O_2 evolution potential, the anodic film growth current on zirconium was shown to be a hyperbolic sine function of the effective field strength, E_e

$$i = 2i_o \exp(-\phi/kT) \sinh(qaE_e/kT) \qquad [2]$$

They also showed that the unusually large values obtained for the apparent activation of dipole, qa, could be rationalized if the Mosotti-Lorentz (M-L) field $E_e = E(K+2)/3$ (12, 13), was the assumed effective field assisting ion transport during film growth. Here, K is the dielectric constant of the oxide.

Glasstone, Laidler, and Eyring (14) and even earlier, Hückel (15) used the M-L field to explain the abnormal mobility of protons in aqueous electrolyte. In 1941, Maurer (16) used the M-L field to explain the temperature dependence of the ionic conductivity of Na^+ ions in soda-lime glass. Subsequently, Young (17, 18) suggested the applicability of local field concepts to anodic film growth on valve metals.

Prior to these observations typical valve metal behavior was not expected for zirconium. There was evidence (17, 19) that the electric field in the oxide was thickness dependent, increasing with thickness for

Key words: anodic film growth, Ti, dielectric constant, high temperature.

constant applied current. More recent measurements by Hopper, Wright, and DeSmet (8) have provided additional evidence of typical valve metal behavior for Zr.

Measurements made by Young (1) and Young and Zobel (2) on Ta and Nb showed that the classical field-dependent rate expression, Eq. [1], did not fit the data. The relation between ln (i) and E was slightly nonlinear. A better fit was obtained if the activation distance was made a linear function of the field strength (17), ($a = \alpha - \beta E$) and the resulting rate expression

$$i = i_o \exp \{-[\phi - q\alpha E(1 - \beta E/\alpha)]/kT\} \quad [3]$$

was used. Estimates of ϕ, $q\alpha$, and β/α were obtained from measurements of the thickness as a function of time by *in situ* ellipsometry during anodization at constant potential. Later, Young (19) suggested the condenser pressure as a possible explanation for the quadratic term in E.

Dignam (20-22) arrived at the quadratic term from a detailed analysis of ionic transfer across three potential energy barriers, a clipped parabola potential, a cosine potential, or a Morse potential. From a consideration of the unusually large values for the activation dipole, it was assumed that the effective field assisting the ion transfer process would depend on the polarization of the oxide, P

$$E_e = E + \delta P/\epsilon_o \quad [4]$$

and since

$$P = (K - 1)\epsilon_o E \quad [5]$$

for $K >> 1$

$$E_e = \delta KE \quad [6]$$

Here, E is the applied field, ϵ_o is the permittivity of free space, and δ is a geometric factor having a value the order of unity. If the geometry for the M-L field is assumed (dielectric isotropy), $\delta = 1/3$. From such considerations, and assuming the M-L field, Dignam's equation becomes, using the symbols in this study

$$i = i_o \exp \{-[\phi - qa\delta KE(1 - qa\delta KE/c\phi)]/kT\} \quad [7]$$

Here, K is the zero field strength dielectric constant and c assumes values dependent on the shape of the assumed potential function. For the clipped parabola potential c = 4, for the cosine potential $c = \pi^2/2(\sim 4.9)$, and for the Morse potential c is a function of the mean field strength $\bar{E}$, $c = f(qa^*\bar{E}/\phi)$. From the available data for Ta, Nb, and Al, Dignam concluded that the Morse potential provided the best fit, and all three systems, $c \sim 3.4 \pm 0.2$.

If the activation distance in the classical rate expression, Eq. [1], is made a linear function of the effective field, E_e, ($a = \alpha - \beta E_e$), a rate expression empirically equivalent to Eq. [7] is obtained, and for $K >> 1$

$$i = i_o \exp \{-[\phi - q\alpha\delta KE(1 - \beta\delta KE/\alpha)]/kT\} \quad [8]$$

This expression differs from the one originally proposed by Young in that the activation distance is made a linear function of the effective field E_e, rather than the applied average macroscopic field E.

Ord, Hopper, and Wang (3), (O, H, & W) showed the nonlinear ln (i) *vs.* E behavior follows quite naturally from local field concepts and the experimental observation that at high field strength the dielectric constant is a linear function of the field strength, $K = K_o(1 - \gamma E)$. Combining this relation with the local field $E_e = \delta KE$, they showed

$$i = i_o \exp \{-[\phi - qa\delta KE(1 - \gamma E)]/kT\} \quad [9]$$

Corrosion engineers interpret corrosion data in terms of rate laws relating film growth (or rate) to time. In 1953 Charlesby (6) showed that these rate laws could be derived from the classical field-dependent rate expression, Eq. [1], and depend only on the parameter $Z(= qaE/kT)$. For values of $Z > 3$ the growth should be approximately a logarithmic function of time and the slope of the log (rate)-log (time) plot is close to -1; for $Z \sim 1$ the growth should be approximately cubic and the slope, (d log (i)/d log (t), is close to $-2/3$, and for $Z < 1$ the growth approaches the familiar parabolic rate law. For zirconium it was shown (23) that the cubic rate law applied and the slope, d log (i)/d log (t), was close to $-2/3$.

If the effective field assisting the ionic conduction process is the local field E_e, then the parameter Z is a function of the dielectric constant K, since the local field is proportional to the dielectric constant for large K, Eq. [6]. If the structure of the oxide grown at temperatures from 200° to 257°C is rutile, a value of $Z > 3$ is expected for titanium since the reported value for the dielectric constant of TiO_2 (rutile) at 25°C is much greater than the dielectric constant of ZrO_2. The dielectric constant for ZrO_2 at 25°C is 28 (6). TiO_2 (rutile) is anisotropic (24), the dielectric constant perpendicular to the optical axis is 86 and parallel to the optical axis, the dielectric constant is 200. On this basis, for $Z > 3$, the slope of the log (rate)-log (time) plot would be closer to -1.

Experimental

Measurements were made of the anodic film growth current at constant anodic potential at temperatures from 200° to 257°C on rod-type iodide bar titanium. The electrolyte solution was 0.05M K_2SO_4 saturated with 250 psig O_2 at 25°C. The potential of the electrode was held constant with an electronic potentiostat, and the anodic currents were measured by recording the voltage drop across precision resistors in the polarizing circuit. The design and installation of the reference electrodes (Pt or calomel) into the titanium reaction cell was previously (23) described. The apparatus and procedure for the rapid attainment of temperature were also previously (25) described. Cylindrical specimens approximately 5.7 cm long and 0.3 cm diam were used. The area of the specimens ranged from 4.80 to 6.00 cm^2. The electrodes were first polished in a freshly prepared solution containing 2:2:1 volume of lactic, nitric, and HF (48%) acids. They were rinsed thoroughly with tap distilled water and then triply distilled before being introduced into the cell. It was estimated that the ambient temperature of the cell was about 35°C.

In order to test the applicability of local field concepts to these data, the dielectric constant of the oxide was measured at each experimental temperature. The dielectric constants were obtained from measurements of the capacitance of the oxide as a function of thickness using a galvanostatic pulse technique. Current densities of about 2×10^{-3} A/cm^2 were pulsed through the electrode for about 3 msec, and the slope of the voltage-time trace during the first 20-50 μsec was obtained with the capacitance $C = i/(dV/dt)$. A roughness factor of unity was assumed. The validity of this assumption is discussed later.

A direct determination of the structure of the oxide was not made. References to the structure being "rutile" is assumed and is based on the large values obtained for the dielectric constant. Similarly to accommodate the design features for the electrochemical measurements at temperatures to 300°C and pressures to 2000 psi, and for the rapid attainment of temperature, the electrode design was such to preclude a direct determination of film thickness.

Results and Discussion

The results assume the potentials at the metal/metal oxide and metal oxide/solution interfaces are constant and independent of the anodic film growth current. Therefore, for constant applied potential, the voltage drop, V, across the oxide is constant.

The primary data obtained are measurements of the anodic film growth current as a function of time at constant potential. In Fig. 1 are shown log (i)/log (t) plots for three temperatures 473, 513, and 530 K. The actual experimental data points are shown for a typical run at 513 K, demonstrating the linearity in the log (i)/log (t) relationship. The slopes $d(\log i)/d(\log t)$ are −0.92, −0.91, and −0.94 for the three runs shown here and average about −0.92.

The polarization data at various times of exposure (film thickness) are shown in Fig. 2-4. It is seen that the O_2 evolution and O_2 reduction reactions are negligible at the constant potentials employed, and the anodic current is entirely TiO_2 film growth. The film

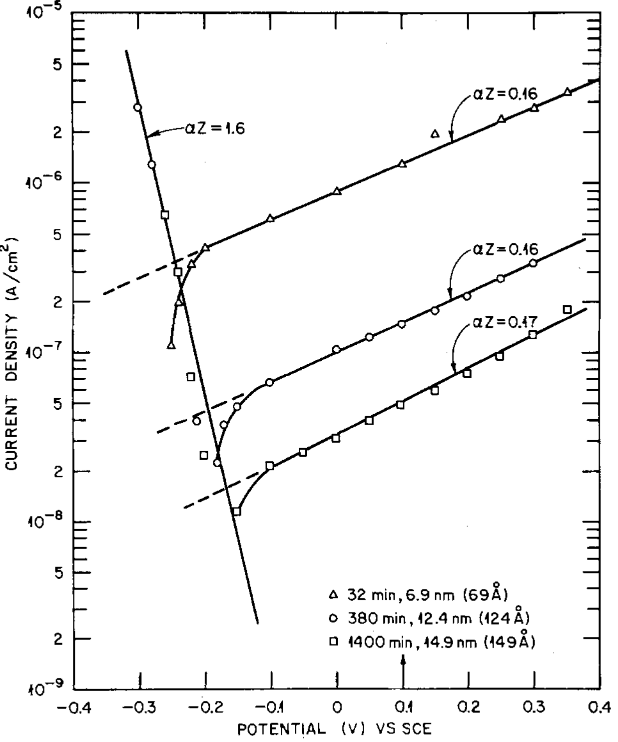

Fig. 2. The polarization of titanium in oxygenated 0.05M K_2SO_4 at 200°C (473 K) at several film thicknesses.

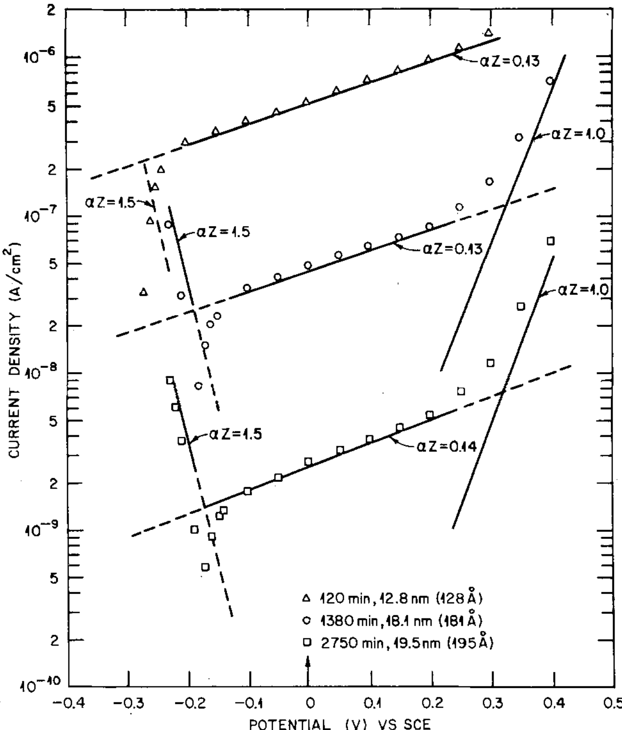

Fig. 3. The polarization of titanium in oxygenated 0.05M K_2SO_4 at 240°C (513 K) at several film thicknesses.

thicknesses were calculated as a function of time based on an estimate of 2.916×10^{-3} cm/min/(A/cm^2), and assumed the density for TiO_2 (rutile) at 4.26 g/cm^3. The electrode was in the solution at ambient temperature (*ca.* 35°C) for a period ranging from 1000-2000 min. An initial film is therefore present on the electrode prior to exposure to the experimental temperature. How this initial film affects the subsequent film growth kinetics at temperature cannot be evaluated. It is assumed that this initial (pre-exposure) film thickness is between 0 and 4 nm (40Å), and most likely about 2 ± 1 nm. An estimate of an initial film thickness of 3 nm on chemically polished Ta and Nb in 0.2N H_2SO_4 at 23°C was obtained by O, H, & W (**3**) from ellipsometric measurements during constant current anodic film growth.

The results in Fig. 1 show there is negligible film dissolution. If the film dissolution rate was significant

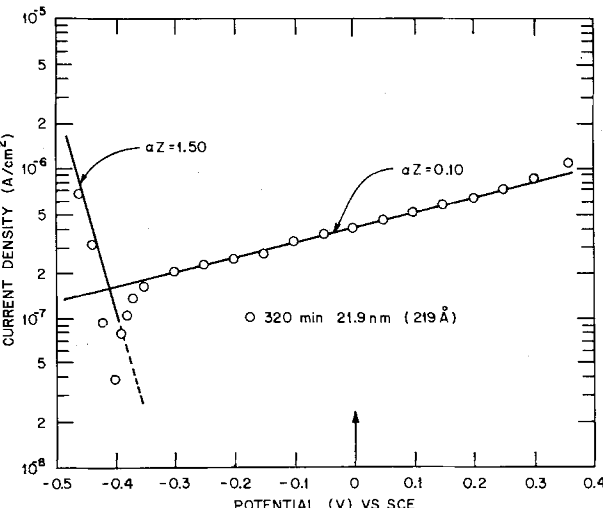

Fig. 4. The polarization of titanium in oxygenated 0.05M K_2SO_4 at 257°C (530 K).

the film growth current would begin to level off after prolonged exposure.

After a sufficient exposure period the solution was cooled and the anodic current, at constant potential, was recorded as a function of the decreasing temperature. A plot of these data is shown in Fig. 5. An average apparent activation energy of 1.22 eV (28.2 kcal/mol) is estimated from the slope, $d(\log i)/d(1/T)$. This estimate of activation energy assumes the potential drop across the oxide is constant during the temperature change.

Charlesby's (6) analysis of the field-dependent rate expression showed that for $10 < Z < 40$ the slope, $S(= \Delta \log (i)/\Delta \log (t))$, ranged from -0.87 to -0.95. Plotting these values for $Z(= qaE_e/kT)$ *vs.* S it is found for the value of $S = -0.92$, Fig. 1, that $Z = 22$. Our earlier studies on zirconium (11) have shown that the "true" activation dipole moment (qa) equals 0.15 e nm (1.5×10^{-8} e cm). Dignam (20) has presented arguments that oxygen ions are the ones involved in the ion transport process for all the valve metal systems and the activation dipole moment would not be expected to vary much from system to system. With this assumed value for $qa = 0.15$ e nm, and $Z = 22$, the effective field $E_e = ZkT/qa = 6.5 \times 10^7$ V/cm for the results at 513 K. After 8400 min exposure at 513 K the film thickness (assuming an initial film of 2 nm) is 30 nm (300Å). Choosing an intermediate film thickness of 15 nm, the voltage drop V across the oxide is estimated at ~97V if the average macroscopic field, V/X, is the assumed effective field E_e. Since the film was grown at a potential below the O_2 evolution potential, Fig. 2-4, *i.e.*, at 0.00V *vs.* Pt/O_2, it is unlikely that V could be 97V; more likely V is of the order of magnitude of 1 volt. If, however, the effective field is the local M-L field, $E_e = (K + 2)V/3X$, then for $V \sim 1$ volt and $E_e = 6.5 \times 10^7$ V/cm, it is estimated that the dielectric constant $K \sim 300$. Such a high value for the dielectric constant at 513 K may not be unexpected, considering that the dielectric constant at 298 K is 200 when measured parallel to the optical axis (24).

In Fig. 6 the reciprocal of the measured capacitance, $1/C_M$, at 513 and 530 K is plotted as a function of X. Using the parallel plate formula for a condenser, $C_M = (8.85 \times 10^{-8} K)/X$, the dielectric constant of the oxide film can be calculated from the slope, $d(1/C_M)/dX$. Since the dielectric constant of the oxide is large, the solution double layer capacitance, C_{dl}, in series with the oxide film capacitance, C_{ox}, is of comparable magnitude, and the measured capacitance, include a significant contribution from the solution double layer capacitance, $(1/C_{ox} = 1/C_M - 1/C_{dl})$. The double layer capacitance is obtained from an extrapolation of the measured capacitance, C_M, to $X = 0$. At $X = 0$, $1/C_{ox} = 0$ and $C_M = C_{dl} = 18$ μF/cm² for the measurements at both temperatures. Correcting the measured capacitances for the double layer, the dielectric constant K equals 452 ± 25 at both temperatures. Using this value for K and the M-L effective field, the voltage drop across the oxide is estimated at ~0.65V. This is a more reasonable value than the 97V estimated using the average macroscopic field, V/X, as the effective field. The dielectric constant was not determined at 473 K, but an estimate can be obtained from capacitance measurements at 513 and 530 K. Here, after a sufficient exposure period the solution was cooled and capacitance measurements were made at several temperatures during cooling to room temperature, Fig. 7. If the same double layer correction ($C_{dl} = 18$ μF/cm²) is assumed, independent of temperature, the oxide film capacitances are proportional to the dielectric constants, and $K = 411$ at 473 K.

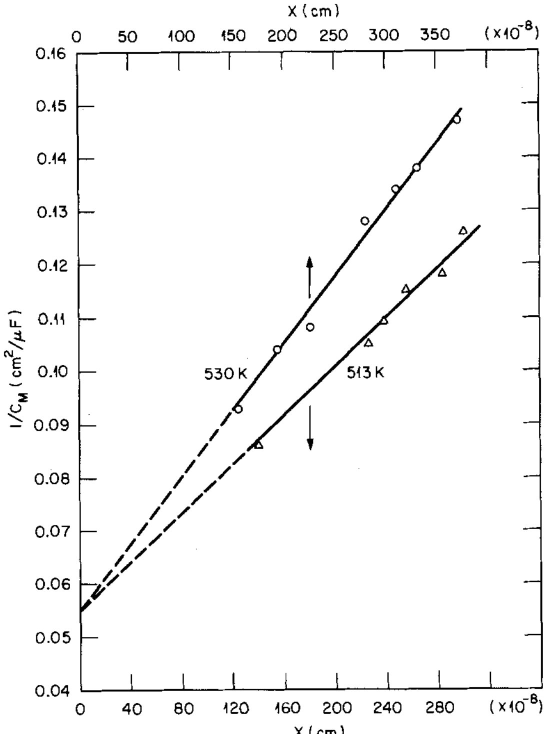

Fig. 6. The reciprocal of the measured capacitance, $1/C_M$, as a function of film thickness, for titanium in oxygenated 0.05M K_2SO_4 at 513° and 530 K and at 0.00V vs. Pt/O_2 (318 K).

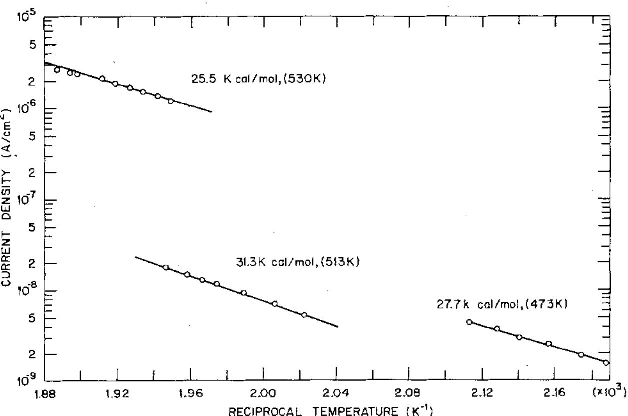

Fig. 5. The temperature dependence of the anodic film growth current at constant potential for titanium in oxygenated 0.05M K_2SO_4.

The classical field-dependent rate expression, Eq. [1], does not provide a fit to the data obtained in this study. A plot of $\log (i)$ *vs.* $1/X$ was not linear. A better fit is obtained by Eq. [7], [8], or [9]. These equations are empirically equivalent, and $\log (i)$ is a quadratic function of the field strength. In this study, the voltage drop across the oxide is constant, and therefore $\log (i)$ is a quadratic function of the reciprocal film thickness, $1/X$. Equation [9] includes local field concepts in its derivation (3) and meaningful estimates are obtained for the activation dipole moment, but the quadratic parameter, γ, does not include the dielectric constant and its usefulness is limited, particularly relating to the temperature dependence of γ. Equation [8] does include the dielectric constant in the quadratic parameter and the temperature dependence of this parameter is obtained if the ratio β/α is assumed constant. Equation [7] developed by Dignam (21) is the most general. Local field concepts are used, all the parameters are defined, and the temperature dependencies of the parameters can be obtained.

For the purposes of discussing the results obtained here, Eq. [7]-[9] are written in the empirically equivalent form

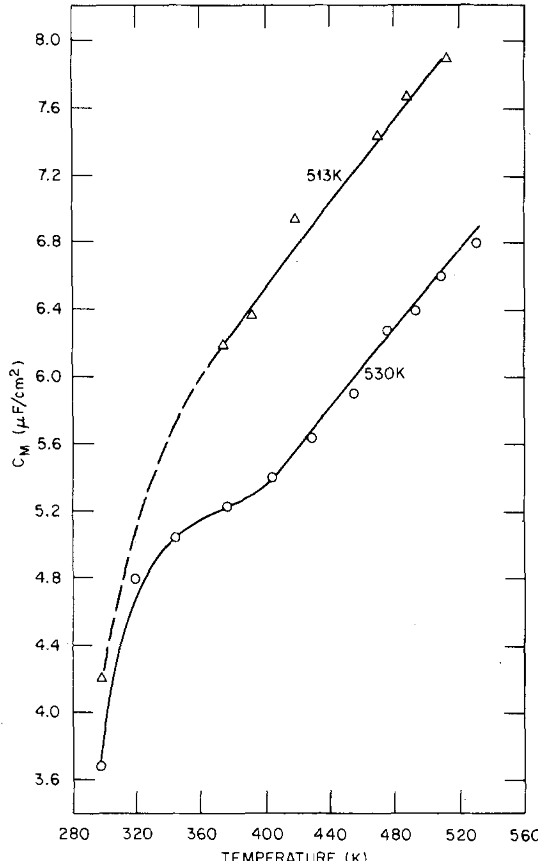

Fig. 7. The measured capacitance, C_M, as a function of temperature for titanium in oxygenated 0.05M K_2SO_4.

$$i = i_o' \exp \{[\mu^*V(1 - \gamma V/X)/X]/kT\} \quad [11]$$

where $i_o' = i_o \exp(-\phi/kT)$, $\mu^* = qa\delta K$, and $\gamma = qa\delta K/c\phi = \beta\delta K/\alpha$. A plot of log (i) *vs.* $(1 - 45 \times 10^{-8}/X)/X$ is shown in Fig. 8 for the data at 513 K. The value $\gamma V = 45 \times 10^{-8}$ cm was obtained from a linear least squares fit of log (i) *vs.* $(1 - \gamma V/X)/X$ for assumed values of γV. The determination of best fit

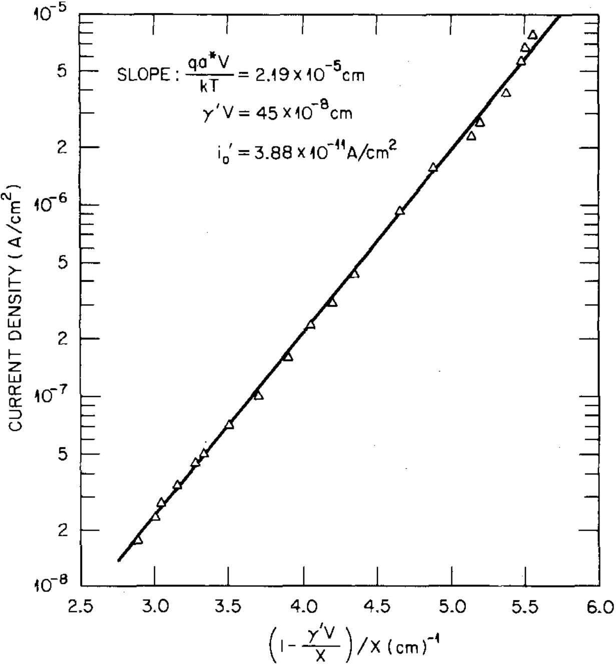

Fig. 8. The log of the anodic film growth current as a function of $(1 - \gamma'V/X)/X$, for titanium in oxygenated 0.05M K_2SO_4 at 513 K and 0.00V vs. Pt/O_2 (318 K): $\gamma'V = 45 \times 10^{-8}$ cm.

(best choice for γV) was made when the correlation coefficient (r^2) achieved maximal value. The slope and intercept provide values for μ^*V/kT ($=2.19 \times 10^{-5}$ cm) and i_o'($=3.88 \times 10^{-11}$ A/cm^2). Here, the calculation of the total film thickness X assumes an initial film thickness $X_o = 20 \times 10^{-8}$ cm, at $t = 0$, and the first calculated value of the total film thickness commences at $t = 10$ min for all temperatures. These calculations were made with a Texas Instrument SR52 programmable calculator using the linear regression program ST 1-08 from the statistics library. A more sophisticated treatment of the data was obtained using the Runge-Kutta technique in the Marquardt nonlinear least squares program (26-28). Estimates of the parameters (i_o', μ^*V/kT, γV), were obtained for data at 473, 513, and 530 K assuming values for $X_o = 0$, 10, 20, 30, and 40Å. Table I shows these estimates for $X_o =$ 20Å. From estimates of the parameters obtained for $X_o = 10$ and 30Å, the uncertainties in μ^*V/kT, γV, and i_o' are estimated at ±12%, ±7%, and ±50%, respectively, for $X_o = 20 \pm 10$Å. The values for qav were obtained using the M-L field, whereby $qaV = 3\mu^*V/K$.

The film thicknesses used in the least squares treatment of the data were calculated using a roughness factor of unity for the chemically polished Ti surface. In our previous work on chemically polished Zr (11) a roughness factor (σ) of unity was also assumed and the calculated film thicknesses agreed with a visual comparison of the thicknesses on a standard color gauge. Young (29) showed from a combination of Faraday's law, capacity, and spectrophotometric methods that the ratio of the effective to apparent area for chemically polished Ta was 0.99. Ord, Hopper, and Wang (3) assumed σ of unity for chemically polished Ta and Nb, and their measurements of the dielectric constant agreed with previously published values (17). Finally, the experimental errors of measurement are probably greater than any expected deviation of σ from unity.

An interesting analysis of the results can be made on the basis of Dignam's equation, Eq. [7]. Since $\mu^*V = qa\delta KV$ and $\gamma V = qa\delta KV/\phi$

$$c = (\mu^*V/\gamma V\phi) \quad [10]$$

and from the values for μ^*V and γV in Table I and $\phi = 1.22$ eV, $c = 1.90 \pm 0.16$ for the three temperatures. This value for c again suggests the form of the potential energy barrier is the Morse potential since $c =$ 4.0 for the clipped parabola potential and $c = 4.9$ for the cosine potential. Alternatively if a simple average film thickness, $\bar{X}$, is obtained at each temperature, the value of the parameter y can be estimated, where $y = \mu^*\bar{E}/\phi = \mu^*V/\phi\bar{X}$, with $\bar{E} = V/X$, the mean field strength. From Eq. [26] in Dignam's (21) paper, c can then be determined

$$y = [(1 + 2y^2/c)^{1/2} - 1] \{2 + \ln 2 - \ln [(1 + 2y^2/c)^{1/2} - 1]\} \quad [11]$$

Using the value for μ^*V in Table I, $c = 2.0 \pm 0.1$. The value of ϕ used in the above analysis requires further discussion. First, as already stated, the measurement assumes the voltage drop across the oxide is constant as the temperature changes. However, the effective field assisting the ion transfer process depends on the dielectric polarization of the oxide, and it has been shown that the dielectric constant K is temperature dependent. Therefore, although the applied potential is constant, the local field strength is not; the field strength decreases with decreasing temperature. Over the temperature range for which the activation energy was measured, Fig. 5, the dielectric constant K as estimated from the temperature dependence of C_M, changed by ~2-3%, Fig. 7. This results in only a 10% error in the estimate of ϕ, and the value of c is therefore in-

Table I. Parameters in the rate equation for anodic film growth on titanium

$$i = i_o' \exp \frac{\mu^* V}{kT} (1 - \gamma V/X)/X$$

$$\mu^* V = (qaVK)/3$$

creased by 10%, which does not significantly affect any of the conclusions made.

The following speculative discussion is an attempt to obtain the value for the activation dipole moment, qa, from the experimental data. In this study, the voltage, V, across the oxide is not known, and qa is obtained as a product with V, qaV. Ord, Hopper, and Wang (3) and Dignam (20, 21) report values for γ, the quadratic parameter, and K, for Ta, Nb, W, and Al at 298 K. From these values, the ratio γ/K is calculated: for W, γ/K = 8.4 Å/V/31 = 0.27 Å/V; for Ta, 4.8 Å/V/24 = 0.20 Å/V; for Nb, γ/K = 8.61 Å/V/38.5 = 0.22 Å/V; and for Al, $\gamma/K = (\mu^*/\phi)/K$ = (23.5 eÅ)/7.83 eV/8.85 = 0.33 Å/V. The average of these values is 0.25 ± 0.05 Å/V. Here γV and $\mu^* V (= qa\delta KV)$ are determined experimentally. Since $V = \mu^*V/\mu^*$, and $\gamma = \gamma V/V$, then $\gamma = (\gamma V/\mu^* V) \cdot qa\delta K$, and $\gamma/K = (\gamma V/\mu^* V) \cdot qa\delta$. Now, if the value for γ/K = 0.25 Å/V is independent of temperature on valve metal systems, then from the values for γV and $\mu^* V$ in Table I, $qa\delta$ = 0.58 eÅ. If the geometry of the M-L field is assumed. $\delta = 1/3$ and qa = 1.73 eÅ. This is a very reasonable value and compares with the estimate qa = 1.56 eÅ for Zr (11). If oxygen ions are involved in the ion transfer process for all the valve metal systems (20), then $qa\delta$ is not expected to differ greatly from one system to the next. Since the oxide is partially ionically bonded, a value of q between 1e and 2e is reasonable, and the activation distance $a \sim$ 1Å is approximately one-half the interatomic lattice spacing (30). The much larger apparent activation dipole $\mu^* (= qa^*)$ obtained experimentally is due to the dielectric polarization of the oxide, and the dielectric constant K is a measure of the polarization. If the temperature dependence of the dielectric polarization is accounted for by measurement of the dielectric constant, it is not unreasonable to expect γ/K to be independent of temperature.

Having obtained the value for qa (= 1.73×10^{-8} e · cm), the voltage drop across the oxide can be calculated, $V (= qaV/qa)$. These values are shown in col. 8 of Table I. Having the values for V, col. 9 gives the values calculated for γ (= $\gamma V/V$).

The value obtained for the activation dipole moment may be compared with those obtained by other investigators (31, 4, 5, 9). These results were obtained from constant current measurements at temperatures below 100°C. The structure of the oxide reported by each investigator was anatase. If the effective field is the M-L local field ($E_e = (K + 2)E/3$), and the dielectric constant K = 7 as reported by Allard, Ahrens, and Heusler, (A, A, & H) (9), then the activation-dipole moment, qa, can be obtained from the reported B values, where $B = qa(K + 2)/3kT$. From measurements made by (A, A, and H) (9) in sodium citrate buffered solution, pH = 5 at 25°C, qa = 2.1 e · Å. Ammar and Kamal (4, 5) made measurements at 30°C in acid, neutral, and basic solutions and assuming the roughness factor σ = 1 and K = 7, qa = 1.8 e · Å. Mizushima (31) used a 10% ammonium borate solution in ethylene glycol solvent (this solution probably contained some water). The measurements were made at several temperatures, ranging from 12° to 85°C. At 31°C, again assuming K = 7, qa = 2.0 e · Å. These values agree very well with the value qa = 1.7 eÅ reported here. However, if local field concepts were not used, an apparent activation dipole moment qa^* = 6 eÅ would be obtained from the measurements at 30°C, and for the measurements reported here, at 257°C, $qa^* \sim$ 261 eÅ. Such an unreasonably large value can only be rationalized if the local field is the effective field assisting the ion transport process and from such considerations the dielectric constant plays an important role. Therefore, from a measurement of the dielectric constant of the oxide, $K \sim 7$ at 30°C for TiO_2 (anatase) and $K \sim 452$ at 240°C for TiO_2 (rutile), an estimate for qa = 2.0 eÅ is obtained independent of temperature and oxide structure.

Mizushima (31) and Ammar and Ismail (32) obtained B as a function of temperature. The results obtained by Mizushima show B decreasing more rapidly than $1/T$ with increasing temperature. This implies the effective field, and therefore the dielectric constant K decreases with increasing temperature. Ammar and Ismail however show B constant with increasing temperature and therefore, conversely, K increases with temperature. Without a knowledge of the temperature dependence of K it is not possible to determine whose results are correct. A good test of the model postulating the local field as the effective field causing ion transport in TiO_2 (anatase) would be to measure the dielectric constant in addition to determining the kinetic parameters as a function of temperature.

Summary and Conclusions

Titanium was exposed to oxygenated 0.05M K_2SO_4 at temperatures from 200° to 257°C at constant applied potential below the oxygen evolution potential. The apparent activation energy, ϕ, for anodic film growth was measured, and the dielectric constant of the oxide film, at experimental temperature, was determined from measurements of the capacitance of the oxide as a function of film thickness. It was shown that the logarithm of the anodic film growth current was a quadratic function of the field strength.

In terms of a rate expression developed by Dignam, it was shown that the form of the potential energy barrier for the ionic conduction process was the Morse potential function, and if the M-L field is the effective field assisting the ionic transfer process, it was shown that the activation dipole moment qa = 1.73 eÅ. It was also shown that using the M-L field to calculate qa for TiO_2 (anatase) from the results of other investigators, excellent agreement is obtained, and qa = 2.0 eÅ.

Acknowledgment

The authors wish to express their appreciation to Dr. Wally Davis, Jr., of the Chemical Technology Division, for his very extensive analysis of the results using the Marquardt nonlinear least squares program. This analysis provided some estimates of the uncertainties in the values of the parameters in the rate expression. The authors also wish to express their appreciation to Dr. R. E. Meyer, of the Chemistry Division, for his critical review of the paper. This research was sponsored by

Oxidation of Ti Thin Films Deposited on Vitreous Carbon

R. Müller, M. Wittmer,* and S. Stucki

Brown, Boveri & Company, Research Center, CH-5405 Baden, Switzerland

ABSTRACT

Anodic oxidation of bulk Ti and Ti thin films deposited on vitreous carbon is studied by electrochemical methods, scanning electron microscopy, and Rutherford backscattering analysis. The results show that the resistance to oxidation of the Ti thin film is considerably inferior to that of bulk Ti. The carbon-titanium interface composition plays a major role in the resistance to oxidation of the Ti film. The formation of a thin TiC layer enhances its stability. The thickness of the Ti film plays only a minor role.

The mechanical, chemical, and electrochemical properties of Ti contribute a great deal to the success of this metal in industrial applications (1). There is undoubtedly a renewal of interest in the surface properties of Ti and its oxides. Research in this field is stimulated by the need for large surfaces of Ti with well-defined electrical and electrochemical properties for industrial applications such as electrolysis (2), and oxygen sensing (3). This work describes an attempt to prevent sacrificial oxidation of carbon anode current collectors for use in a membrane-type water electrolyzer (2) by evaporated films. A good resistance to oxidation and a perfect bond or adherence of the Ti film to the carbon substrate were our main interests. The electrochemical measurements were made in 1*N* sulfuric acid to produce conditions similar to those used in

* Electrochemical Society Active Member.

Key words: electrolyzers, oxide thin films, titanium.

electrolysis cells. These measurements, however, provide only phenomenological information on the oxidation and passivation process of the Ti thin film. Rutherford backscattering (RBS) analysis (4) was therefore used to study the oxygen distribution at the interface, in the film itself, and on the surface after evaporation, subsequent heat-treatment, and anodic oxidation. This information is very important for the use of Ti-covered anodes in electrolyzers. RBS also gives some information on the composition of the titanium-carbon interface following a heat-treatment. Finally, scanning electron microscopy of the surface of the film was used to analyze the surface morphology of the deposited and annealed Ti films.

Experimental

Ti films 300-3000Å thick were deposited at room temperature with an E-gun on vitreous carbon substrates at a rate of 10-15 Å/sec and in a vacuum of 10^{-7} Torr. The vitreous carbon substrate, supplied by Le Carbone (France), was cleaned prior to use by heating it for 2 hr at 1050°C in a 10^{-6} Torr vacuum. Some deposited Ti films were heat-treated in a vacuum of 10^{-6} Torr. A pure bulk Ti foil (99.9999%) from Ventron Corporation (USA), and Ar-arc melted Ti pellets, were also used for comparison measurements. The bulk samples were cleaned in hot oxalic acid of 10 weight percent concentration and rinsed in double distilled water prior to use.

Potentiodynamic measurements were made on the Ti samples in an electrochemical Pyrex cell using a PAR 173 potentiostat and a PAR 175 universal programmer. The cell had a standard calomel electrode (SCE) as reference and a carbon counterelectrode. In the following, all voltages indicated are *vs.* the SCE unless otherwise specified. Current was plotted *vs.* applied voltage on an X-Y recorder. The electrolyte was an aqueous solution of 1*N* H_2SO_4. The sweep rate of the potentiostat was generally 5 mV/sec. Rutherford backscattering analysis was performed to investigate the metallurgical composition of the deposited Ti films and their reaction with the oxygen and the carbon substrate after heat-treatments and after anodic oxidation.

Results and Discussion

It is well known that Ti builds up a thin passivating oxide film on its surface during exposure to oxygen. This oxide film protects the metal from further oxidation. For bulk Ti the thickness of this film in an aqueous solution has been found to increase linearly with anode potential at a rate of approximately 25 Å/V (5, 6). For evaporated thin films the situation is different. The oxidation behavior depends on the substrate, on the interface between substrate and Ti film, and on subsequent heat-treatments. The oxidation behavior of Ti thin films evaporated or sputtered onto hot (450°C) quartz substrates was studied by Armstrong and Quinn (7). This paper presents results on the differences in oxidation behavior between bulk Ti sheets, as evaporated and heat-treated Ti films on vitreous carbon substrates.

The anodic oxidation of bulk Ti has been measured by several research groups (6, 7), In order to have a fair comparison between bulk and thin film specimens, electrochemical properties of Ti were measured under the same experimental conditions. Figure 1 shows the anodic oxidation of Ti in 1*N* H_2SO_4 solution in the voltage range of 0-9V. A large increase in anodic current is observed above 3V during the first anodic polarization. This indicates the formation of an irreversible oxide layer. After 8-10 cycles between 0 and 9V the current *vs.* voltage (*I/V*) curve is fairly stable. The small current flowing above 3V is attributed to oxygen evolution. This result is in agreement with that of Paleolog *et al.* (8).

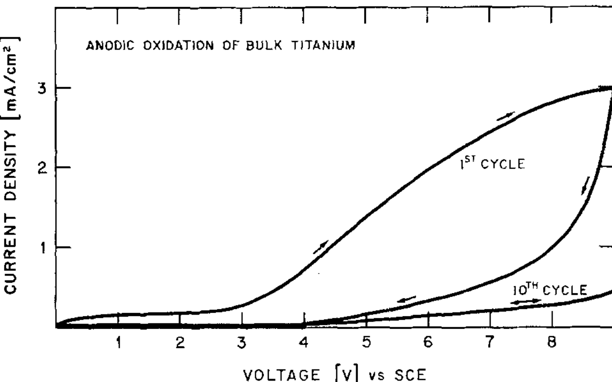

Fig. 1. Anodic polarization of bulk Ti in 1*N* H_2SO_4 electrolyte, 1st cycle and reversible behavior after 10th cycle. Sweep rate was 5 mV/sec.

The oxide grown on evaporated Ti thin films is less effective in preventing further oxidation than the one grown on bulk Ti. This phenomenon is seen in Fig. 2a, which shows the anodic oxidation of Ti thin films of different thicknesses. The *I/V* curves show that the oxidation process is characterized by passivation beginning above 0.8V, where the current decreases, or stays constant, followed by a rapid reincrease in current above *ca.* 1.25V. A further increase in potential leads to cracking of the Ti layer and subsequent peeling off. This might be due to the large Pilling-Bedworth ratio of 1.95 (the volume of oxide formed is almost twice the volume of metal), which results in a high internal stress leading to cracking of the layer. Similar arguments were put forward by Di Quarto *et al.* (9) for peeling of a surface layer on bulk Ti.

RBS analysis of the as-evaporated Ti film, before and after anodic oxidation, is shown in Fig. 3. The vertical arrows indicate the energy of $^4He^+$ particles scattered from surface positions of the corresponding

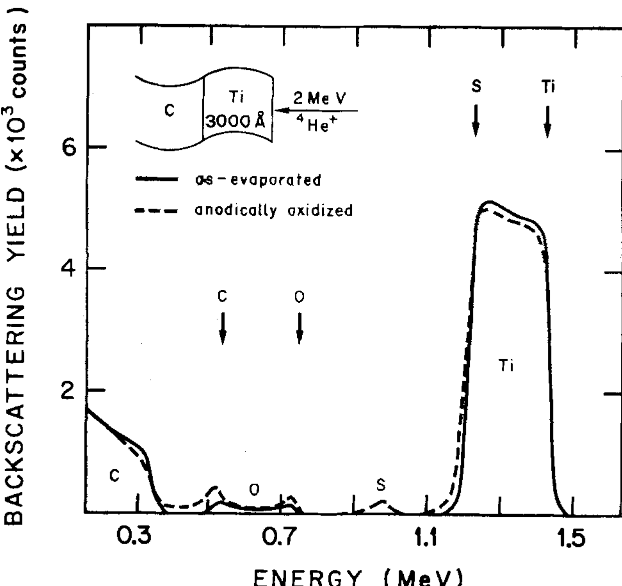

Fig. 3. 2 MeV-RBS spectra of 3000Å thick Ti film on a vitreous carbon substrate after evaporation (solid line) and after anodic oxidation (dotted line). The vertical arrows indicate the energy of the He ions scattered from surface atoms of the corresponding element.

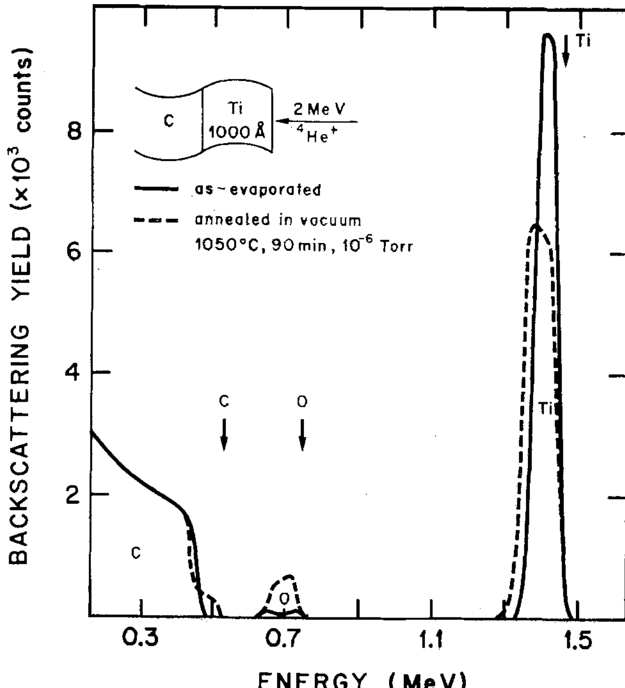

Fig. 4. 2 MeV-RBS spectra of a 1000Å thick Ti film on a vitreous carbon substrate after evaporation (solid line) and after annealing in a vacuum of 10^{-6} Torr for 90 min at 1050°C (dotted line). The vertical arrows indicate the energy of He ions scattered from surface atoms of the corresponding element.

atoms. The low mass of the carbon allows the analysis of the oxygen distribution in the Ti film. The RBS spectrum of the as-evaporated sample, before anodic oxidation, is given by the solid line. From this spectrum it is seen that a small amount of oxygen is present in the surface region of the Ti film, at 0.75 MeV, and near the carbon-titanium interface, at 0.55 MeV. The oxygen content in the Ti film is lower and amounts to about 8 atomic percent (a/o). The RBS spectrum of the Ti film after anodic oxidation is given by the broken line in Fig. 3. It shows a marked increase of the oxygen content in the surface and interface region of the film. The pronounced peak at about 1.0 MeV marked by "S" and the tail of the oxygen signal at energies below 0.5 MeV arise from sulfuric acid which has reached the carbon-titanium interface via cracks in the Ti film and which has diffused somewhat into the pores of the vitreous carbon substrate.

In most cases the evaporated Ti films peeled off the carbon substrates during the electrochemical measurements. In order to improve the adherence of the films, some samples were heat-treated for 90 min at 1050°C in a vacuum of 10^{-6} Torr following evaporation of the Ti film. The solid line in Fig. 4 shows a RBS analysis of a sample coated with a 1000Å Ti film before heat-treatment. Again, oxygen can be found in the surface and interface region of the film. The oxygen content in the film is about 6 a/o. This value is lower than the one found in the film whose RBS analysis is shown in Fig. 3. The amount of oxygen contained in the film depends on the evaporation process of the films, because Ti reacts strongly with residual oxygen contaminations of the vacuum system. The RBS spectrum of the annealed Ti film is given by the broken line in Fig. 4. From the oxygen signal it is found that the Ti film is uniformly oxidized. The plateau in the carbon signal at 0.5 MeV, extending almost to the surface position of carbon, indicates that a reaction of about ½ of the Ti film with carbon has taken place. The actual composition of the interface layer is difficult to identify, but is assumed to be some form of titanium-oxy-carbonate. For annealed Ti films 3000Å thick the interface layer was about one-fifth of the total film thickness.

For evaporated Ti thin films the breakdown voltage is low under anodic oxidation conditions, as shown in Fig. 2a. Annealed thin films are characterized by a small shift of the breakdown voltage by approximately 0.4V toward higher voltages (Fig. 2b). Many samples were investigated and the difference in breakdown voltage was found to be consistently reproducible. This shift results in an increased stability of Ti films, which is, however, still insufficient compared to the resistance to cracking of Ti oxide films grown on bulk Ti. RBS analysis, however, shows a clear metallurgical difference between evaporated and annealed Ti thin films.

The 3000Å thick annealed Ti films show a large peak in corrosion current around 0.75V. The height of this peak varies from sample to sample by approximately ±20%, but is always present. It is possible that the heat-treatment causes the development of microcracks in the film due to the large difference in thermal expansion between vitreous carbon and Ti at 1050°C. The passivation of the crack surface results then in the observed current peak.

The uniform oxygen distribution in the sample and the titanium-carbide formed at the interface during heat-treatments did not prevent the destruction of a 3000Å thick Ti layer under severe anodic oxidation conditions. At voltages over 2V large flakes of titanium oxide form and peel off. A scanning electron micrograph of this phenomenon is shown in Fig. 5. The upper right of the micrograph shows a large flake of titanium-oxide which is peeling off. Growing flakes of titanium oxide can be distinguished very clearly underneath. They are specially marked at their edges by ridges due to the volume expansion of the oxide relative to the metal. This "undermining process" has been observed in bulk Ti at voltages around 50V (9). Though the destruction of thick Ti films under severe anodic oxidation conditions is not eliminated by the heat-treatment, the adherence of the film was much improved compared to as-deposited thick Ti films.

Conclusions

Anodic oxidation of bulk Ti and Ti thin films was studied by electrochemical methods, scanning electron microscopy, and RBS analysis. The results show that

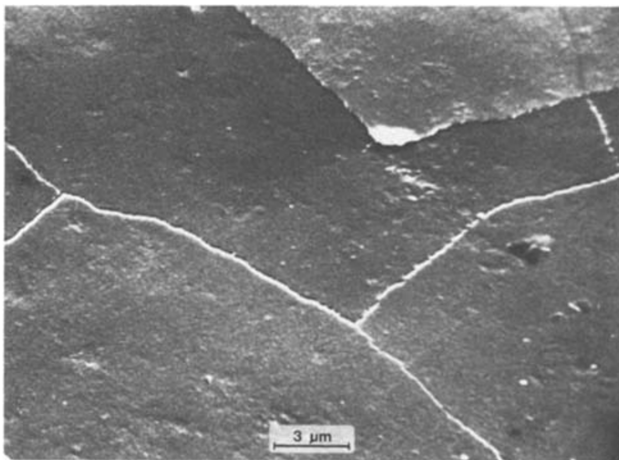

Fig. 5. Scanning electron micrograph of 3000Å thick film of Ti, heat-treated during 90 min at 1050°C in a vacuum of 10^{-6} Torr and anodically oxidized in 1N H_2SO_4 during 30 min at 1.75V vs. SCE.

the mechanical stability and resistance to oxidation of the Ti thin films is much inferior to that of bulk Ti. The stability of the Ti thin films depends primarily on the adherence to the substrate, because high internal stresses have to be overcome in the Ti film during oxidation. Though good adherence of the Ti films to the substrate is achieved by a heat-treatment at 1050°C, the resistance to oxidation of the films is improved only marginally. The thickness of the Ti film plays only a minor role.

A perfect protection of the graphite substrate cannot be obtained by an evaporated thin film of pure Ti because the formation of a protective oxide leads to mechanical failure. The importance of the oxide peeling effect for the breakdown of the coherent Ti film can be demonstrated by evaporating a layer of noble metal on top of the annealed Ti film. The noble metal layer, catalyzing the O_2 evolution, prevents the formation of the TiO_2 layer and thus the failure of the Ti film under anodic oxidation conditions. This was experimentally shown using a 500Å layer of Ru as noble metal. The lifetime of such electrodes is ruled by the lifetime of the Ru layer, Ru being known to corrode at potentials above 1.45V (10). Since one of the objectives of the present investigation was to find a protection for carbon without the use of noble metals, this route was abandoned.

Acknowledgments

The preparation of the samples by H. Keser, the performance of the electrochemical measurements by R. Loitzl, and the SEM analysis by R. Baumann are gratefully acknowledged. We thank the University of Zürich for providing us the opportunity of using their Van de Graff accelerator and R. Pixley for his technical assistance.

ABSTRACT

The reaction of phosgene with copper between 260° and 400°C leads to the formation of cuprous chloride CuCl. The rate law is of the paralinear type with a pressure influence especially during the parabolic stage. It was shown that, with our experimental conditions, the gaseous phase is always far from equilibrium. A mechanism accounting for the observed rate law is proposed. It involves simultaneously three rate-determining steps: the adsorption of phosgene, the adsorption of carbon monoxide, and the outer interfacial reaction.

Phosgene is an industrial product used today on a growing scale. The purpose of this paper is to present our results concerning its reaction with copper. The practical interest of this investigation is clear, but we shall also consider this corrosion from a theoretical point of view and propose a model describing the elementary steps of the reaction accounting for our observations.

* Electrochemical Society Active Member.

Key words: phosgene, copper, high temperature corrosion.

Very little has been published up to now about the reaction of phosgene with metals. Some rather old and always fragmentary results (1, 2, 3) deal, respectively, with the behavior of zinc, mercury, and tin. The paper of Tolley (4) on the reaction of phosgene with nickel-based alloys appears more complete. Nothing is known about the reaction with copper. On the contrary, the corrosion of copper by chlorine has been extensively studied by Tseitlin (5-7) and by Dagoury (8). According to Tseitlin this corrosion can be observed from 150°C up and is rapid enough above 290°C to produce important overtemperatures leading to the melting of the cuprous chloride formed. According to Dagoury, cuprous chloride CuCl forms in contact with the metal while $CuCl_2$ exists in the outer part of the scale. Under 140°C the rate law is logarithmic whereas at higher temperatures the importance of overtemperatures and the consequent partial sublimation of the reaction products deprive the rate laws experimentally found of any signification.

Thermodynamic Study of the Systems Involved

The system C-O-Cl.—It is well known that phosgene is a metastable compound at room temperature. Its thermal stability and its decomposition have been considered in numerous papers (9-12). We have undertaken a reinvestigation of the problem, taking into account 26 different species, all gaseous, with the exception of carbon. These species are the following: C_1, C_2, C_3, C_4, C_5, O, O_2, Cl, Cl_2, CCl, CCl_2, CCl_3, CCl_4, CO, CO_2, C_2O, C_3O_2, ClO, ClO_2, Cl_2O, C_2Cl_2, C_2Cl_4, C_2Cl_6, COCl, $COCl_2$, <C>.

The equilibrium pressures of these species were calculated in the system C-O-Cl by minimizing the total Helmholtz free energy (and not the Gibbs free enthalpy, as our experiments were realized at constant volume). For this minimization Goldfarb's method was used. Generally known as "conjugate gradient projection method" (13, 14), it gives the minimum of a nonlinear function (here the free energy) subject to linear constraints [in the present case the equation of mass conservation, cf. (15, 16)]. The values of the Gibbs free enthalpies of formation were taken from the JANAF tables (17).

Figure 1 shows the results obtained for an initial phosgene pressure of 100 Torr. Especially important is the fact that, at low temperatures (<400 K), the gaseous phase consists essentially of CO_2 and CCl_4 according to the reaction

$$2COCl_2 \rightleftarrows CO_2 + CCl_4$$

whereas at higher temperatures ($>$ 1100 K) the predominant species are CO and Cl_2 according to

$$COCl_2 \rightleftarrows CO + Cl_2$$

Between 230° and 900°C solid carbon is present. Table I gives some values of the equilibrium partial pressures of Cl_2 as a function of temperature.

The system C-O-Cl-Cu.—A similar calculation was made for the system C-O-Cl-Cu. The equilibrium composition of the gaseous and solid phases was computed, taking here into account 37 species, namely, the same as in the preceding case plus [Cu], [Cu_2], [CuO], [CuCl], [Cu_3Cl_3], (CuCl), <CuCl>, <$CuCl_2$>, <CuO>, <Cu_2O>, <Cu>. For these new species, the values of the Gibbs free enthalpy were taken from an INCRA publication (18). Two cases are to be distinguished:

1. If phosgene is in excess, that is if all copper is chlorinated, the reaction product is, most naturally, cupric chloride $CuCl_2$ while the composition of the gaseous phase remains the same as in the absence of copper (Fig. 1).

2. In the other case (copper in excess), the reaction product is cuprous chloride CuCl, and the equilibrium composition of the gaseous phase is different (Fig. 2). At 600 K, the only species present in nonnegligible amounts at equilibrium are CO_2, CuCl (solid), C (solid), and Cu (solid). Table II gives the corresponding mol numbers.

Figure 3 (curve a) gives the dissociation pressure of cupric chloride; curve b on the same figure gives the equilibrium chlorine pressure resulting from the decomposition of phosgene (initial pressure 100 Torr). It can be seen that, if equilibrium is reached, the chlorine pressure is sufficient to allow the formation of $CuCl_2$ up to 550°C.

Experimental Procedure

All experiments were conducted between 260° and 400°C using initial pressures of phosgene between 5 and 400 Torr. Phosgene (purity 99%) was supplied by the company PRODAIR and the copper foils (about $50 \times 10 \times 0.1$ mm) by Metals Research Company; the metal has a purity of 99.9%.

Kinetic curves were obtained in static atmospheres using a quartz spring thermobalance. The experimental procedure has been described in a previous paper (19). Qualitative analysis of the gaseous phase was performed with an infrared Wilks spectrophotometer.

Experimental Results

Reaction products.—The copper compound formed in most of our experiments was cuprous chloride CuCl. The chemical reaction can therefore be written

$$2Cu + COCl_2 \rightarrow 2CuCl + CO$$

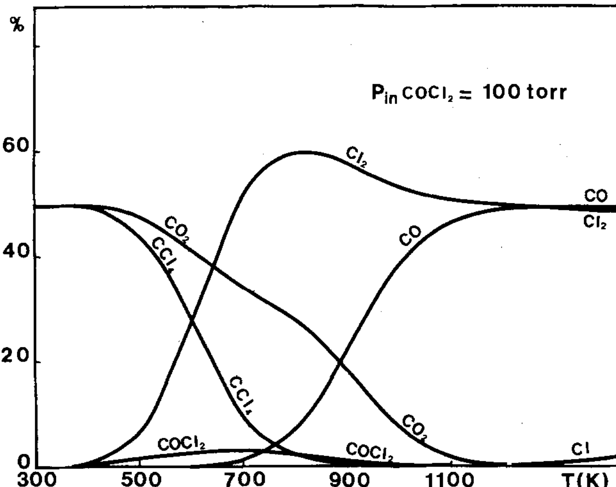

Fig. 1. Composition of the gaseous phase resulting from the decomposition of phosgene.

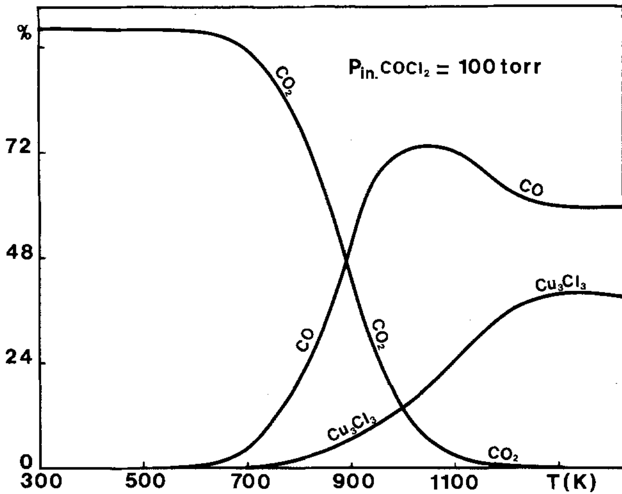

Fig. 2. Composition of the gaseous phase in equilibrium with an excess of copper.

Table I. Chlorine pressure at equilibrium for an initial phosgene pressure of 100 Torr (at room temperature)

T (K)	300	350	400	450	500	550	600	650	700	750	800
P_{Cl_2} (Torr)	0.004	0.34	0.60	2.5	11.25	36.5	70	112	168	211	242.5

Table II. Mol numbers of every species in equilibrium with an excess of copper

Initial mol number of <Cu> = 1	Initial mol number of $COCl_2$ = $1.344 \cdot 10^{-2}$		P initial (100 Torr)	T, 600 K
Species	CO_2	Cu Cl (S)	C (S)	Cu (S)
Mol number	$0.67 \cdot 10^{-2}$	$2.69 \cdot 10^{-2}$	$0.67 \cdot 10^{-2}$	$9.7 \cdot 10^{-1}$

Only at high temperature and when the reaction has been followed during a sufficiently long time, the formation of a little quantity of cupric chloride $CuCl_2$ could be observed. In this case, as $CuCl_2$ is readily hydrated in air, x-ray diffraction patterns showed the presence of CuCl and $CuCl_2 \cdot 2H_2O$.

Infrared analysis of the gaseous phase never showed another species than phosgene, the quantity of CO formed by the reaction being always well under the detection limit of our apparatus.

The influence of temperature on the rate law.—In the temperature range 260°-380°C and for an initial $COCl_2$ pressure of 100 Torr, kinetic curves show an initial deceleration followed by a linear stage (Fig. 4 and 5). The linear rate constant obeys the Arrhenius' law with an activation energy of about 100 $kJ \cdot mol^{-1}$.

Above 380°C the experimental results become meaningless as already observed by Dagoury (8) because of the sublimation of CuCl.

Influence of the gas pressure.—This influence was studied at 282°C for initial pressures of $COCl_2$ varying from 5 to 400 Torr (Fig. 6). At low pressures (under 20 Torr, the sublimation of CuCl is noticeable) the experimental results are not significant. For higher pressures an important effect of pressure on the initial stage of the reaction can be observed whereas the linear part of the curves is much less sensible to its influence.

Morphological observations.—Figure 7 shows a typical aspect of the surface of the CuCl layer formed at 282°C, under an initial phosgene pressure of 100 Torr. For lower pressures (10-15 Torr) some larger single crystals appear scattered on the sample (Fig. 8).

Additional experiments.—As chlorine is an important component of the gaseous phase at equilibrium, a comparative investigation of the reaction of pure chlorine and of chlorine-containing gas mixtures was performed.

At 282°C under 10 Torr (that is at a pressure much smaller than the equilibrium pressure resulting from $COCl_2$ decomposition) pure chlorine reacts so rapidly with copper that it is impossible to follow the kinetics

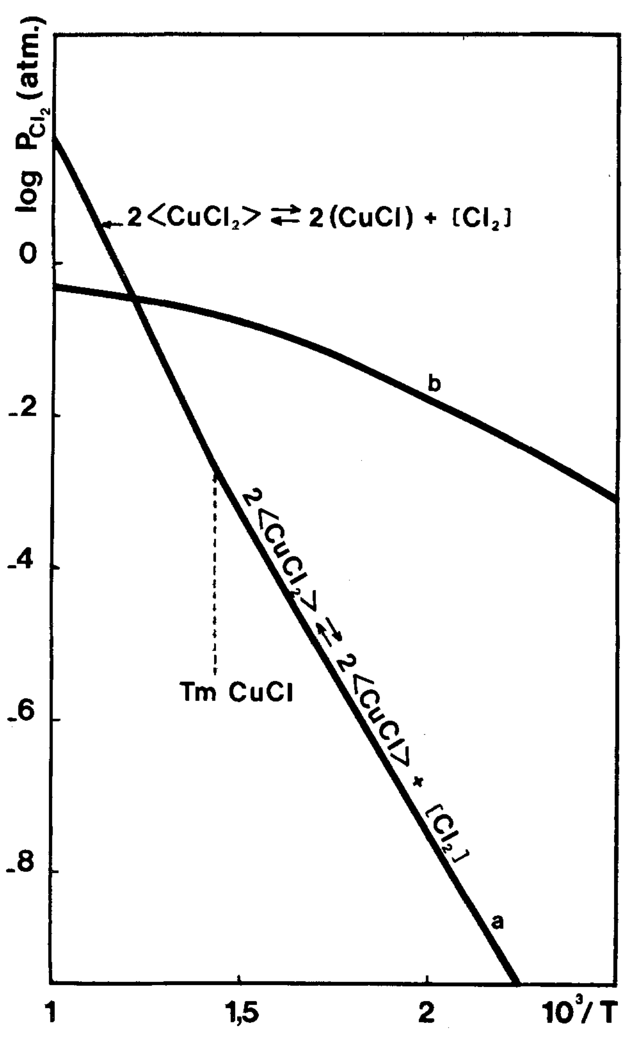

Fig. 3. Chlorine pressures resulting from the decomposition of $COCl_2$ and copper chlorides.

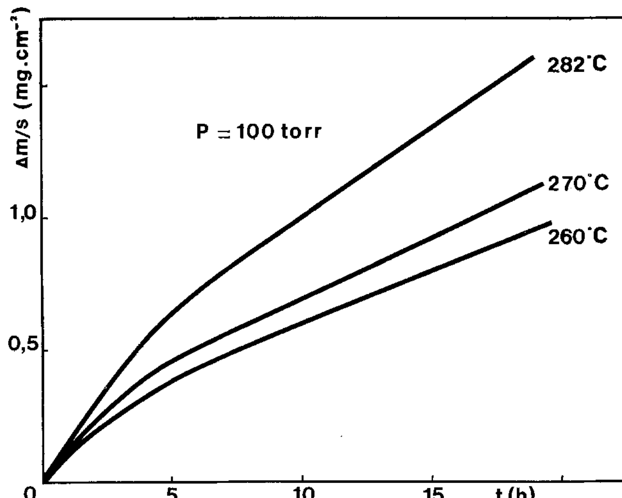

Fig. 4. Rate law: influence of temperature

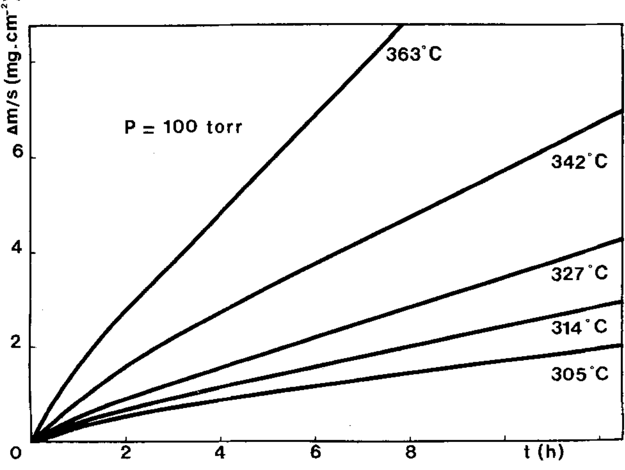

Fig. 5. Rate law: influence of temperature

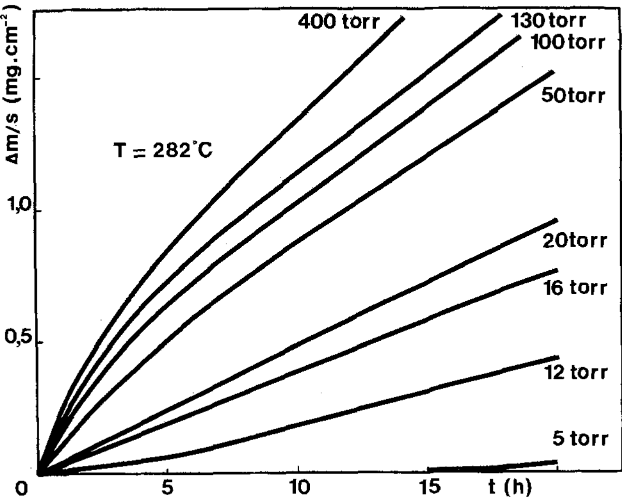

Fig. 6. Rate law: influence of pressure

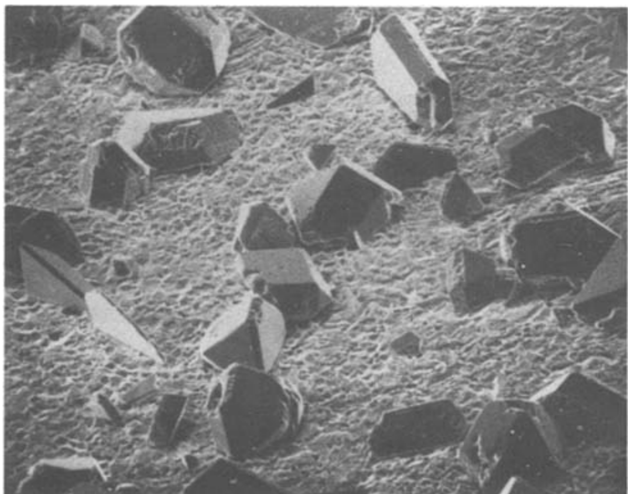

Fig. 8. Superficial aspect of CuCl formed at lower pressures. 400×.

of the reaction and that the cupric chloride formed sublimes. With mixtures of Cl_2 and CO (Fig. 9, curve 5) the reaction is always slower than with pure chlorine, but faster than with pure $COCl_2$ (Fig. 9, curve 1), at least during the first 5 or 10 hr of reaction. After

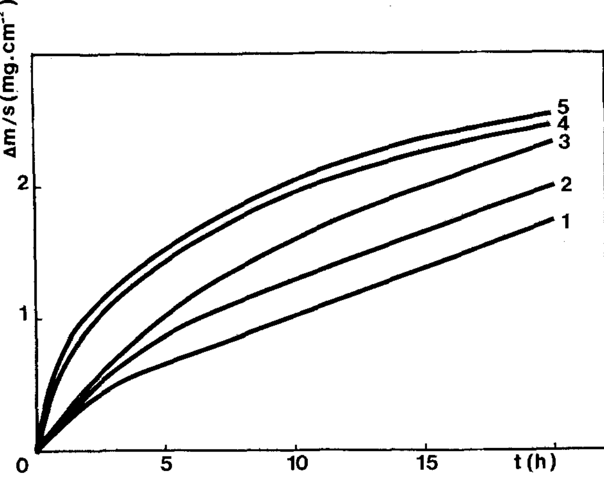

Fig. 9. Reaction of copper with the following gaseous mixtures: 1, $COCl_2$ (100T); 2, CO (4T) + Cl_2 (4T) + $COCl_2$ (92T); 3, CO (10T) + Cl_2 (10T) + $COCl_2$ (80T); 4, CO (10T) + Cl_2 (10T) + A (80T); 5, CO (10T) + Cl_2 (10T).

that time the reaction of CO + Cl_2 slows down and its rate becomes smaller than that of $COCl_2$.

On the other hand, addition of equal quantities of CO and Cl_2 to $COCl_2$ accelerates the initial stage of the reaction, but has little influence on the reaction rate of the linear part of the curves (Fig. 9, curves 2 and 3). Argon has practically no influence (Fig. 9, curve 4).

The prevailing defects in cuprous chloride (20) are known to be of Frenkel's type (interstitial cations and cationic vacancies). This was easily verified by completely reacting a copper wire with phosgene; on a cross section of the sample (Fig. 10) a hole is clearly visible in the axis of the wire, showing that the reaction proceeds essentially through cationic diffusion.

Discussion

The decomposition and adsorption of phosgene.—As no other species than phosgene is found in measurable quantity in the gaseous phase, it can be concluded that the decomposition equilibrium of $COCl_2$ is far from being reached. This assumption is supported by the fact that CO-Cl_2 mixtures react more rapidly with copper than pure phosgene.

On the other hand, their reaction is slower than that of pure chlorine at the same pressure as in the mixture. As in the case of phosgene, the only reaction product is cuprous chloride even when the partial

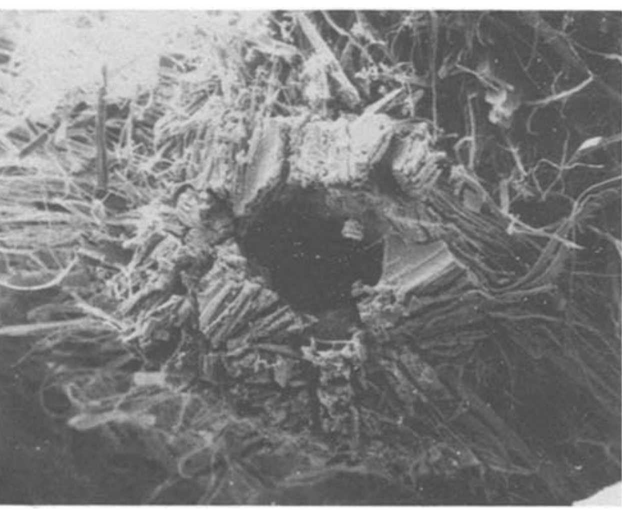

Fig. 10. Cross section of a copper wire completely reacted with $COCl_2$. 100×.

pressure of chlorine in the gaseous phase is larger than the thermodynamic value corresponding to the formation of cupric compound. All these facts imply that the chlorine activity in the adsorbed phase is low due to the occupancy of adsorption sites by CO.

A model accounting for the observed rate law.—In agreement with the preceding remarks we shall assume that the adsorption of phosgene on the CuCl layer formed by the reaction occurs with dissociation and that the adsorption sites occupied by CO and Cl are identical.

The different steps of the reaction can then be written as follows:

Dissociative adsorption of $COCl_2$ on CuCl:

$$COCl_2 + 3s \rightleftarrows Co - s + 2Cl - s$$

Desorption of CO:

$$CO - s \rightleftarrows CO + s$$

Outer interfacial reactions (Kröger's notation):

$$(e_1) : Cl - s + Cu_i^{\cdot} + e' \rightleftarrows Cu_{Cu} + Cl_{Cl} + s$$

$$(e_2) : Cl - s \rightleftarrows Cl_{Cl} + V_{Cu}' + h^{\cdot} + s$$

Diffusion of copper through vacancies and interstitial sites simultaneously.

Inner interfacial reactions:

$$(i_1) \quad Cu \rightarrow Cu_i^{\cdot} + e'$$

$$(i_2) \quad Cu + V_{Cu}' + h^{\cdot} \rightarrow Cu_{Cu}$$

As the rate law found experimentally is not parabolic, a diffusion-controlled reaction is excluded. On the other hand, the inner interfacial reaction is exactly the same with phosgene and with pure chlorine. As the two gases behave with copper very differently from one another the inner reaction can also be discarded as the rate-determining step.

Let us therefore assume that the overall reaction obeys a complex rate law controlled simultaneously by the adsorption of $COCl_2$, the desorption of CO, and the outer reaction. The following symbols will be used:

θ_1, θ_2: coverage ratios for the adsorption of CO and Cl respectively.

P: phosgene pressure

k_1, k_2, k_{e1}, k_{e2}: rate constants for the adsorption of $COCl_2$, the desorption of CO and the outer reactions.

v_e: velocity of the outer reaction, equal to the sum of the rates of reactions e_1 and e_2.

a_i: activities of the interstitial cations.

Neglecting then the opposite reaction (an assumption certainly valid far from equilibrium), one can write

$$\frac{d\theta_1}{dt} = k_1 P(1 - \theta_1 - \theta_2)^3 - k_2\theta_1$$

$$\frac{d\theta_2}{dt} = 2k_1 P(1 - \theta_1 - \theta_2)^3 - k_{e1}\theta_2 a_i - k_{e2}\theta_2 \quad [1]$$

$$v_e = k_{e1}\theta_2 a_i + k_{e2}\theta_2 \text{ (v_e in mols/surface unit/time unit)} \quad [2]$$

The activity of interstitial cations (and of cationic vacancies) is kept constant by the inner reactions which, according to our assumption, are equilibrated.

The reaction rate experimentally measured by the mass increase of the sample

$$v_r = \frac{d\Delta m}{dt}$$

is given by

$$v_r = 35.5 \left[\frac{d\theta_2}{dt} + v_e\right] + 28\frac{d\theta_1}{dt}$$

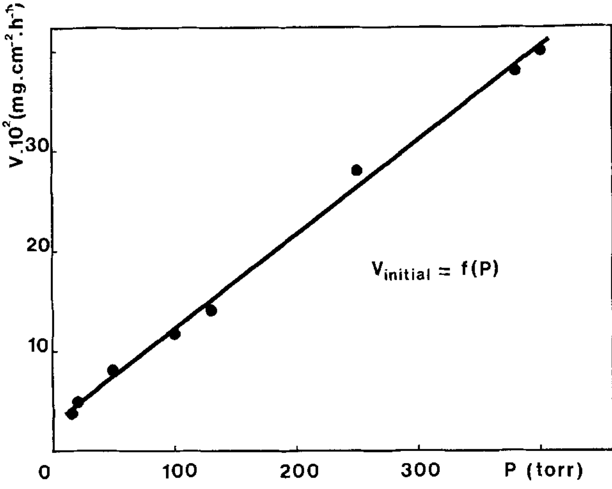

Fig. 11. Influence of pressure on the initial rate

or

$$v_r = 99k_1P(1 - \theta_1 - \theta_2)^3 - 28k_2\theta_1$$

(V_r in g/surface unit/time unit)

At the beginning of the reaction θ_1 and θ_2 increase and v_r decreases to a limiting value corresponding to a quasi stationary state (θ_1 and θ_2 constant). The rate law becomes then linear. The initial rate ($\theta_1 = \theta_2 = 0$) is proportional to the phosgene pressure (see Fig. 11).

The nonlinear differential system (1) cannot be solved analytically. We shall therefore consider only the quasi stationary (linear) state. The corresponding condition

$$\frac{d\theta_1}{dt} = \frac{d\theta_2}{dt} = 0$$

gives the following equations determining the limiting values θ_{11} and θ_{21} of θ_1 and θ_2

$$k_1P(1 - \theta_{11} - \theta_{21})^3 = k_2\theta_{11}$$

$$2k_1P(1 - \theta_{11} - \theta_{21})^3 = (k_{e1}a_i + k_{e2})\theta_{21}$$

showing that θ_{11} and θ_{21} are proportional. The reaction rate is then given by

$$v_r = 71k_2\theta_{11} = 71k_1P(1 - \theta_{11} - \theta_{21})^3$$

As θ_{11} and θ_{21} depend on P, it is not possible to derive explicitly the $v = f(P)$ relation. But, from the ratio between the reaction rate at $t = 0$ and in the linear part of the curves it is possible to estimate the sum $\theta_{11} + \theta_{21}$. This ratio is equal to $99/71(1 - \theta_{11} - \theta_{21})^3$.

Table III gives the results obtained for different pressures. These values which are always smaller than unity seem acceptable.

Manuscript submitted Oct. 2, 1980; revised manuscript received Jan. 22, 1981.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.

Publication costs of this article were assisted by A.D.R. Grenoble.

Characterization of Plasma-Deposited Silicon Dioxide

A. C. Adams,* F. B. Alexander, C. D. Capio, and T. E. Smith

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Silicon dioxide films have been deposited by reacting silane and nitrous oxide in a parallel-plate, radial flow, plasma reactor. Deposition parameters (temperature, power, and gas composition) have been systematically varied, and the films characterized by measuring the infrared spectra, deposition rate, density, etch rate, stress, refractive index, step coverage, breakdown voltage, and annealing behavior. The films, deposited at 100°-340°C and at rates of 200-360 Å/min, contain 2-9 a/o H bonded as H_2O, SiOH, and SiH. The films have densities of about 2.3 g/cm^3, refractive indexes of about 1.47, a compressive stress usually less than 1×10^9 dynes/cm^2, and etch rates about twelve times faster than thermally grown silicon dioxide. Films deposited below 200°C or at high power etch nonuniformly with part of the film etching very fast, possibly indicating a two-phase mixture. The step coverage is not conformal and the films are thin along vertical step walls. The films breakdown at fields of 4-10 MV/cm. During annealing in air at temperatures up to 400°C, the films lose hydrogen and become less dense, but do not crack. The properties of the plasma-deposited silicon dioxide are strongly dependent on the specific deposition conditions. In addition, simple correlations between the properties do not exist. Thus in characterizing plasma deposited silicon dioxide, the exact deposition conditions must be specified and all the film properties of interest must be measured.

There is considerable interest in the deposition at low temperature of silicon dioxide films using a glow discharge to supply the energy for the reaction. Previous depositions have used the oxidation of tetraethoxysilane (1-3), or the reaction of silane with oxygen (4), or with nitrous oxide (5-7). The deposition systems have been small, inductively coupled reactors (1-6); however, recent data have been reported using a large, capacitively coupled, radial flow reactor (7). The plasma-deposited silicon dioxide films are known to contain hydrogen (3, 6), to have a high etch rate (6), a high refractive index (1, 4-7), a low stress (7), and to be oxygen deficient (4, 6, 7). However, a systematic investigation of the effects of deposition conditions on the film properties has not been reported. We have deposited silicon dioxide films in a large, capacitively coupled, radial flow reactor by reacting silane and nitrous oxide in an argon carrier gas and have systematically varied the deposition parameters (substrate temperature, rf power, and gas composition). The effects on the film properties have been measured and are reported in this paper.

* Electrochemical Society Active Member.

Key words: deposition, films, stress.

Experimental

The plasma deposition reactor is similar to other radial flow reactors that have been described (7-9). The reaction chamber consists of a Pyrex cylinder approximately 15 cm high and 61 cm in diameter sealed with aluminum plates on the top and the base. The aluminum sample holder, 56 cm in diameter, has an area of 2440 cm^2 and can accommodate twenty-five 75 mm samples. The temperature is maintained by two resistance heaters embedded in the sample table. The gases, individually metered with flowmeters calibrated by volume displacement, are introduced at the outer edge of the sample table and are pumped through a 5 cm diam central port. The pressure is measured at the exit port with a capacitance manometer. The system is pumped by a Roots blower (164 CFM) backed by a 65 CFM mechanical pump. The rf power (13.56 MHz) is supplied through a 58 cm diam aluminum electrode. The spacing between the rf electrode and the grounded sample table is 2.5 cm. The gas mixture consists of argon, 3% silane in argon, and nitrous oxide. The usual conditions for deposition of silicon dioxide in this reactor are: electrode spacing, 2.5 cm; rf power, 24W; temperature, 200°C; pressure, 133 Pa (1 Torr); total gas

flow, 3 liters/min; and gas composition, 0.8% SiH_4, 52.0% N_2O, and 47.2% Ar. These conditions give a uniform deposition (within ±5%) over the entire sample table with a deposition rate of about 270 Å/min. The substrates are B-doped silicon wafers, 75 mm in diameter. Four samples are used for each deposition and the film properties are averages of at least three of these samples.

The deposition variables that have been investigated are: the sample temperature; the N_2O/SiH_4 ratio keeping the concentration of silane (0.8%) and the total gas flow (3.0 liters/min) constant; the concentration of silane at constant total gas flow and constant N_2O/SiH_4 ratio; and the rf power. These parameters are varied individually keeping all other variables constant.

The film thickness is measured optically with a prism coupler (10), or mechanically with a Taylor-Hobson Talystep. The film refractive index is measured at a wavelength of 0.6328 μm with a prism coupler (10). The film stress is measured by substrate bending using an optically levered laser beam to measure the radius of curvature. Infrared spectra are measured with a Perkin-Elmer Model 580 spectrophotometer using a clean silicon wafer in the reference beam. Etch rates are measured in dilute hydrofluoric acid (100:1 H_2O:49% HF) at 25°C. The film density is calculated from the film thickness, the weight loss after etching the film, and the area of the sample (calculated from the weight and thickness of the substrate using 2.33 g/cm³ for the density of single crystal silicon). Edge effects are avoided by using samples with areas of approximately 6 cm² cleaved from the central part of the silicon wafer. Breakdown voltages are measured using 0.076 cm diam (30 mil) aluminum dots formed by standard photolithography and etching techniques. The measurements are made with the aluminum dot biased negatively so the p-type silicon substrates are in accumulation.

Film Characterization

Infrared.—The infrared spectra of the plasma-deposited films are similar to the spectra reported for silicon dioxide chemically deposited at low temperatures (11, 12). The major absorptions observed in the plasma-deposited films are listed in Table I along with possible assignments suggested from published papers. The absorptions at 1070, 805, and 450 cm⁻¹ are characteristic of silicon dioxide. The two absorptions at high frequencies, 3620 and 3380 cm⁻¹, are O-H stretching modes, with the band at the higher frequency resulting from SiOH and the 3380 cm⁻¹ peak caused by loosely bonded SiOH or adsorbed H_2O. The 2270 cm⁻¹ absorption is an Si-H stretch and has been observed by several authors. The two absorptions at 940 and 885 cm⁻¹ are more difficult to identify. The 885 cm⁻¹ band is frequently observed in deposited silicon dioxide films (11, 12). This absorption has been assigned to: Si-OH (13, 15), Si-H (12), nonbridging oxygen (17), the SiO_2 network (14), and Si_2O_3 (6, 11, 16). The absorption at 940 cm⁻¹, which is less often observed, may be caused by an Si-OH vibration. There are strong correlations between the intensities of the 940 and 885 cm⁻¹ bands and the Si-OH and Si-H stretching modes as shown in Fig. 1. These correlations tend to support the Si-OH assignment for the 940 cm⁻¹ peak and the Si-H assignment for the 885 cm⁻¹ absorption, but several of the other proposed assignments are still possible.

Table I. Infrared absorptions for plasma-deposited silicon dioxide

Frequency, cm⁻¹			
Median	Range	Assignment	Ref.
3620	3605-3650	Si-OH	(11-13, 18, 19)
3380	3340-3390	H_2O, Si-OH	(11-13, 19)
2270	2260-2280	Si-H	(6, 11-14, 17, 18)
1070	1040-1080	SiO_2	(3, 11-17)
940	930-950	Si-OH	(3, 11, 16)
885	880-886	Si-H, Si-OH, Si-O SiO_2, Si_2O_3	(6, 11-17)
805	800-815	SiO_2	(3, 11-13, 15, 16)
450	445-450	SiO_2	(11-13)

In addition to the major absorption bands, less intense absorptions have been observed in some films. Absorptions, which have not been identified, occur at 3500 and 1500 cm⁻¹ for N_2O/SiH_4 ratios less than 15. These may be caused by NH or NH_2 impurities. Absorptions are also observed at 1630 cm⁻¹ (H_2O) (15) and 1460 cm⁻¹ for films deposited at temperatures less than 175°C. Absorptions usually observed in silicon nitride, Si-N at 850 cm⁻¹, Si-H at 2160 cm⁻¹, and N-H at 3350 cm⁻¹, are not observed. However, the SiN and NH bands, if present, would be obscured by the absorption bands in the oxide.

An estimate of the hydrogen concentration at the various bonding sites can be obtained from the peak intensities of the Si-H absorption at 2270 cm⁻¹ and the two OH bands at 3620 and 3380 cm⁻¹. The concentration of Si-H groups is expressed as

$$N = K\alpha H$$

where N is the number of bonds per cm³, K is related to the absorption cross section, α is the apparent absorption coefficient (2.303 A/d, where A is the absorbance and d is the film thickness), and H is the full width at half absorbance. Values for K determined from other films are: 5.9×10^{16} cm⁻¹ for plasma-deposited SiN (19); 10×10^{16} cm⁻¹ for thermally grown SiO_2 (18); and 10×10^{16} cm⁻¹ for oxygen-doped Si (17). Using an average of these three values and the measured half-width for the Si-H peak in the plasma oxide, 60 cm⁻¹, gives

$$N = 5 \times 10^{18}\alpha$$

The concentrations of OH as SiOH and as H_2O or weakly bonded SiOH are calculated using the method given for chemically deposited silicon dioxide assuming that the plasma-deposited films are stoichiometric SiO_2 with a density of 2.3 g/cm³ (11). The results of these calculations are given in Fig. 2 which shows the concentration of hydrogen bonded as SiH, SiOH, and H_2O (or weakly bonded SiOH) as a function of the deposition conditions. Also given is the atom percent hydrogen obtained by summing the hydrogen in the three bonding sites. Hydrogen bonded to other sites and adsorbed hydrogen are not included in the sum. The total hydrogen concentration varies between 2 and 9 a/o with most of the samples containing about 5 a/o H.

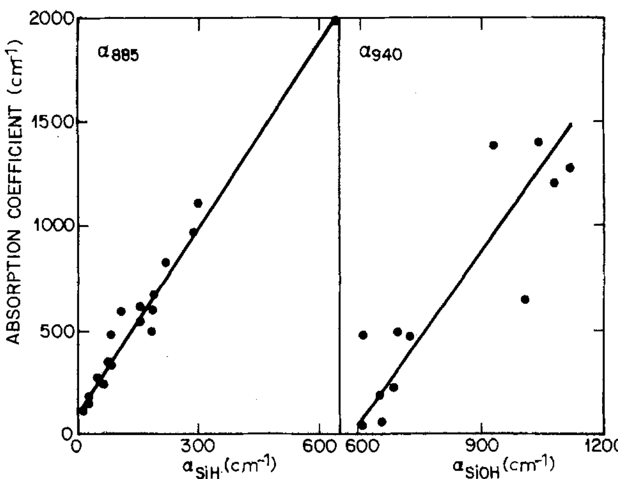

Fig. 1. The correlation between the absorption coefficient at 885 cm⁻¹ and the Si-H stretch at 2270 cm⁻¹; and the absorption coefficient at 940 cm⁻¹ and the Si-OH stretch at 3620 cm⁻¹.

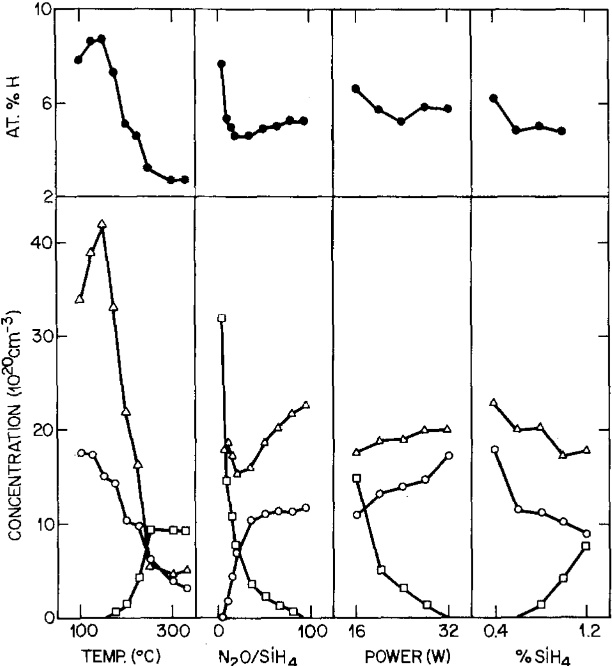

Fig. 2. The concentration of hydrogen groups and the total at percent H for different deposition conditions: triangles, H_2O; circles, SiOH; squares, SiH; closed circles, total hydrogen.

The relative concentration of hydrogen in the three bonding sites depends strongly on the deposition conditions. For instance, the Si-H is favored at high temperature, low N_2O/SiH_4 ratio, low power, and high percent SiH_4. The concentration of water or weakly bonded SiOH is a strong function of the deposition temperature, with very high concentrations observed for films deposited at low temperatures. The concentration of strongly bonded SiOH decreases with increasing temperature, increases with increasing N_2O/SiH_4 ratio until it saturates at about 11×10^{20} cm^{-3} for N_2O/SiH_4 greater than 50, and is weakly dependent on the power and the percent SiH_4. As these data show, the chemical composition of the film depends strongly on the specific deposition conditions.

Deposition rate.—Data showing the deposition rate, density, etch rate, stress, and refractive index are given in Fig. 3-6. The deposition rate increases linearly with temperature (Fig. 3). The apparent activation energy, calculated from an Arrhenius plot, is 0.85 kcal/mole (0.037 eV) and is much lower than for the thermally activated reaction, 32 kcal/mole (20). The low activation energy probably indicates that the deposition is limited by desorption of reaction products; however, other interpretations are also possible. The deposition rate is nearly independent of the N_2O/SiH_4 ratio, appears to increase with the square root of the silane concentration, and is proportional to the square root of the power. This last result contrasts to the more nearly linear power dependence observed at much higher powers and for a lower N_2O/SiH_4 ratio and a lower frequency (7).

Density.—The average film density for all depositions is 2.29 g/cm^3; half of the samples are within 2.26-2.35 g/cm^3. The density is nearly independent of all deposition variables except power, where high film densities are observed for low powers (Fig. 6). Often the density and the refraction index of silicon dioxide are related (the Lorentz-Lorenz equation or the Gladstone-Dale formula) (11). Neither relationship holds for these plasma-deposited films, probably because the film composition varies. The densities observed for these films are similar to other values reported for plasma oxides, 2.18-2.44 g/cm^3 (7); and are higher than the values for

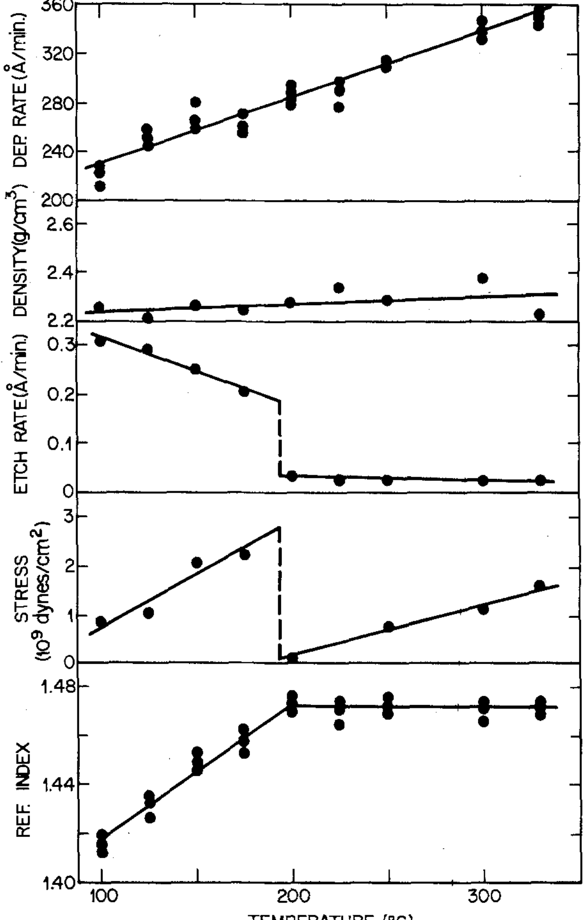

Fig. 3. Film properties vs. deposition temperature for $N_2O/SiH_4 = 65$, 0.8% SiH_4, and 24W.

fused silica, 2.20 g/cm^3 (11), or for chemically deposited silicon dioxide, 2.07-2.27 g/cm^3 (16, 21).

Etch rate.—Etch rates have been measured in a dilute hydrofluoric acid (100:1 H_2O:49% HF) which etches thermally grown silicon dioxide at about 25 Å/min (22). The plasma oxide deposited at temperatures above 200°C and at powers less than 28W have etch rates of about 200-600 Å/min, much faster than for a thermal oxide. The etch rate decreases as the N_2O/SiH_4 ratio increases or as the percent SiH_4 increases. The films etch much faster, up to 3000 Å/min, when deposited at low temperature or at high power. The etch rate data in Fig. 3 indicate a sharp transition occurring at about 200°C.

The fast etching films deposited at low temperature or high power do not etch uniformly. The initial etch rates, which are shown in Fig. 3 and 6, are much faster than the final rate. Etch rate data for a film deposited at 125°C are given in Fig. 7 which shows the film thickness, weight, refractive index, and density as functions of etch time. This film etches at a uniform rate of about 3000 Å/min for the first 1.75 min. Etching for additional time occurs at a much slower rate, less than 1000 Å/min. A similar change is shown in the plot of film weight *vs.* etch time. Surprisingly, the refractive index decreases from 1.43 to 1.08 during the first 1.75 min of etching and then remains nearly constant. The film density follows a similar pattern. These data indicate that the films deposited at low temperature or high power contain fast etching components or regions. As this material etches, a slower etching, porous film remains. The high porosity causes the low refractive index and low density. This etching behavior is confirmed by SEM cross sections which show a porous material remaining after partial etching of the film. The nonuniform etch-

ing behavior, which appears to be similar to the anomalous etching observed for rf sputtered silicon dioxide (23), is not observed for films deposited at temperatures greater than 200°C.

The etch rates in different chemical solutions are given in Table II for films deposited at 200°C. The plasma-deposited films etch about twelve times faster than the thermal oxides in the four etchants investigated.

Stress.—All the plasma-deposited oxides have a small, compressive stress which is nearly independent of the N_2O/SiH_4 ratio and the rf power (Fig. 4 and 6). The average stress for the depositions shown in Fig. 4 and 6 is 0.57 × 10^9 dynes/cm² with the values ranging between 0.07 and 0.97 × 10^9 dynes/cm². The film stress increases to 2.4 × 10^9 dynes/cm² for depositions at low percent SiH_4 (Fig. 5). The film stress increases with increasing temperature with a discontinuity between 175° and 200°C (Fig. 3). The film stress has not been correlated with other film properties; although, the discontinuity between 175° and 200°C is also observed in the etch rate, refractive index, and infrared spectra. For comparison, plasma-deposited silicon dioxide has been reported with a compressive stress between 0.1 and 4.0 × 10^9 dynes/cm² (7), silicon dioxide chemically deposited at about 400°-450°C generally has a tensile stress of 1-4 × 10^9 dynes/cm² (24, 25), films chemically deposited at higher temperatures have a low compressive stress, 0.6 × 10^9 dynes/cm² (21), and thermally grown silicon dioxide films have a compressive stress of 3-4 × 10^9 dynes/cm² (26).

Table II. Etch rates of silicon dioxide films deposited at 200°C, N_2O/SiH_4 = 65, 24W, and 0.8% SiH_4

Etchant	Etch rate, A/min.	
	Plasma SiO_2	Thermal SiO_2
100:1[a]	315	25
P-etch[b]	1635	130
Dilute P-etch[c]	125	10
BHF[d]	7010	580

[a] 100:1 H_2O: 49% HF.
[b] 3:2:60 49% HF: 70% HNO_3: H_2O.
[c] 3:2:710 49% HF: 70% HNO_3: H_2O.
[d] 10:1 40% NH_4F: 49% HF.

Refractive index.—The refractive index of the plasma-deposited silicon dioxide is about 1.47 except for films deposited at low temperatures or high power, where the refractive index is lower, and for films deposited at low N_2O/SiH_4 ratios, where the index is much higher. The average index is slightly higher than the values reported for chemically deposited silicon dioxide, 1.44-1.46 (11, 12, 16, 21), but within the range of values reported for plasma-deposited oxides, 1.4-1.9 (2, 5-7). The slightly high values probably result from an oxygen deficiency (7). The refractive index is not correlated with other film properties except that the fast etching films all have a low refractive index.

Step coverage.—Films deposited over very deep steps are thin along the vertical walls (Fig. 8). This contrasts to the completely conformal coverage observed for silicon dioxide films chemically deposited at reduced pressure and higher temperature (21). The cusps and crevices observed at the top and bottom of steps for chemically deposited phosphorus-doped silicon dioxide are not present in the plasma-deposited films

(27). The step coverage appears to be determined by line-of-sight arrival of species from the plasma with no evidence for surface migration.

Dielectric breakdown.—Breakdown voltages have been measured for samples approximately 1200Å thick. Distribution plots for samples deposited at two temperatures are given in Fig. 9. The sample deposited at 150°C has a maximum at 4.5-5.0 MV/cm with all the breakdowns occurring between 2.5 and 6.5 MV/cm. The distribution is nearly Gaussian. The distribution for the sample deposited at 250°C is no longer Gaussian, but appears to have two maxima centered at 7.0-7.5 and 9-10 MV/cm. This distribution is characteristic of samples deposited above 200°C. The high temperature samples all start to breakdown at 2-3 MV/cm and have a maximum in the distribution at 5-8 MV/cm but with a significant fraction of the capacitors breaking down at high fields, 9-10 MV/cm. Similar measurements on samples of chemically deposited silicon dioxide show more than 90% of the breakdowns occurring at 8-10 MV/cm, while very thin thermally grown silicon dioxide breaks down at 10-13 MV/cm (22).

Annealing.—In contrast to silicon dioxide films chemically deposited at low temperatures, the plasma-deposited films appear to be stable at room temperature (12). No change is observed in the infrared spectra of films exposed to laboratory air for six months. However, the films do change when annealed in air at temperatures of 150°-400°C. Data showing the annealing characteristics of two films are given in Fig. 10. In general, the film thickness remains nearly constant, and the film weight, the refractive index, and infrared ab-

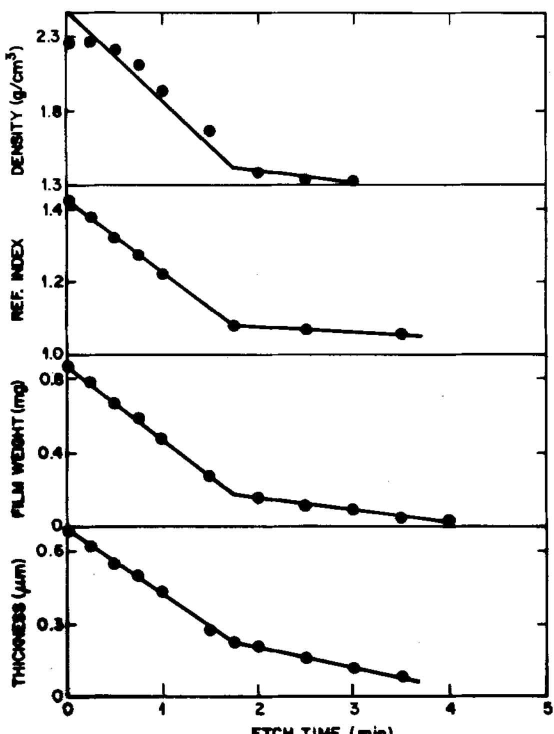

Fig. 7. Etching behavior for a film deposited at 125°C, N_2O/SiH_4 = 65, 0.8% SiH_4, and 24W.

sorptions at 3380 and 940 cm^{-1} (H_2O or SiOH) and at 2270 and 885 cm^{-1} (SiH) decrease during annealing. The infrared spectra show that the H_2O and SiH groups are lost during annealing (the SiOH groups absorbing at 3620 cm^{-1} are not affected by annealing); however, the loss in weight is somewhat larger than expected from the composition given in Fig. 2. Either the infrared spectra underestimate the concentrations of these groups or other groups are also removed during annealing. The film densities decrease during annealing to values of about 2.0-2.2 g/cm³, similar to the values observed for silicon dioxide chemically deposited at low temperatures (16, 21). The etch rates in dilute hydrofluoric acid are not affected by annealing at temperatures up to 400°C. Films deposited at low temperatures still etch nonuniformly with initial rates of about 3000 Å/min after annealing in air at 400°C. The film properties tend to stabilize after anealing at a given temperature for 1 hr or longer (Fig. 10). However, continued annealing at higher temperatures produces additional decreases in the weight, refractive index, and infrared intensities. The films do not crack

after annealing at temperatures up to 400°C (the highest temperature investigated).

Discussion

The plasma deposition system has many variables (for instance, temperature, pressure, power density, rf frequency, electrode spacing, gas composition, gas flow, pumping speed, and reactor geometry) several of which are interrelated (28). In the present work, four of these parameters have been systematically varied. Many properties of the deposited films are strong functions of these variables; consequently, the exact deposition conditions must be given when the properties of plasma-deposited films are described. The strong dependence on deposition conditions makes it very difficult to compare films from different reactors; in addition, the strong dependence on deposition conditions may also explain many of the discrepancies which have been reported, such as the differences in refractive index, etch rate, composition, and stress.

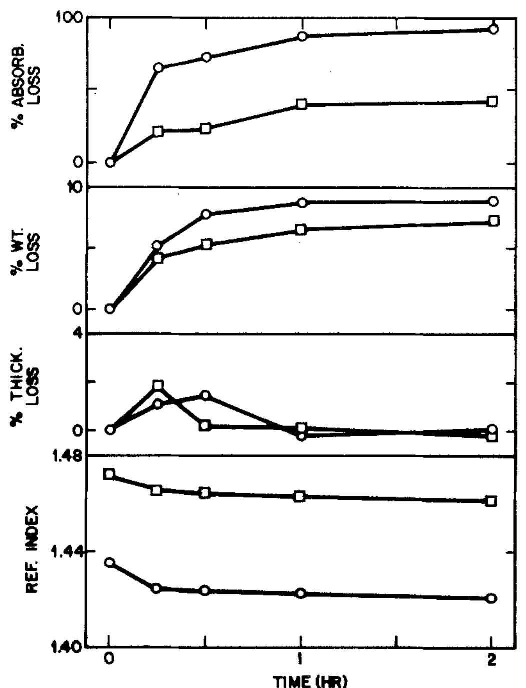

Fig. 10. Changes during annealing in air at 300°C for films deposited at $N_2O/SiH_4 = 65$, 0.8% SiH_4, and 24W: circles, deposited at 125°C; squares, 250°C.

Because of the variations in composition and in film properties, the name silicon dioxide may not be appropriate for these plasma-deposited films. Other possible names which emphasize the variable nature of the material are plasma silicon oxide, plasma oxide, or polysiloxane. However, the term plasma silicon dioxide has certain advantages. For instance, the composition and properties of the plasma-deposited films are similar to chemically deposited films which are often referred to as silicon dioxide. In addition, the technological uses and applications of the plasma-deposited films are similar to the uses of chemically deposited and thermally grown silicon dioxide films. For these reasons the name plasma silicon dioxide seems preferable. However, the name should not imply an exact chemical composition but rather a class of materials with compositions and properties close to those indicated by the name.

The initial deposition conditions give thickness variations of less than 10% over the deposition zone (twenty-five 75 mm wafers). However, changes in the conditions cause a deterioration in uniformity. The depositions at high power, high temperature, or low percent silane may have thickness variations as large as 40%. The other film properties also vary across the deposition zone but usually much less than the thickness. An exception is the concentration of hydrogen which may vary over the deposition zone by 50% for films deposited at high power or at low N_2O/SiH_4 ratios.

The plasma-deposited silicon dioxide contains hydrogen bonded as H_2O, SiOH, and SiH. The total hydrogen concentration varies between 2 and 9 a/o H, in good agreement with a previously reported value of 5.7 a/o H (19). The concentrations of the hydrogen containing groups (H_2O, SiOH, and SiH) are strongly dependent on the deposition conditions. Contrary to previous work, the present films contain SiH and OH groups even when deposited above 300°C (6). This difference may be caused by the different reactor geometries. There is no clear indication in the infrared spectra for chemically bonded nitrogen (as N-H or Si-N).

The deposition rate increases slowly with temperature, the apparent activation energy is only 0.85 kcal/mole, and appears to increase with the square roots of the rf power and the silane concentration. The deposition rate is independent of the N_2O/SiH_4 ratio. Previous reports using small, inductively coupled reactors have shown a decrease in deposition rate with increasing temperature, and a temperature dependence that is not Arrhenius (2, 3). These observations again show the strong dependence on geometry and on the specific deposition conditions, implying that the rate is governed by mass transport, reactive species lifetime, or gas phase diffusion rather than on chemical reaction rates.

Most of the films etch about twelve times faster than thermally grown silicon dioxide, and the etch rate is only slightly dependent on the deposition conditions. However, plasma oxide films prepared at low temperature or at high power etch nonuniformly with part of the film etching very fast. Infrared spectra of the material remaining after removing the fast etching portion of the film are nearly identical to the spectra of the original film, indicating that the fast and slow etching regions have similar compositions. This may indicate that films deposited at low temperature or high power are mixtures of two phases. A similar etching behavior has been reported for rf sputtered silicon dioxide (23). Analysis of the etch rate data assuming that the films

are two component mixtures shows that the amount of the fast etching component decreases from 80% for films deposited at 100°C to less than 1% for films deposited at 200°C.

The density of the plasma-deposited silicon dioxide is usually 2.26-2.35 g/cm^3 and is not strongly affected by the deposition variables. The density decreases to 2.0-2.2 g/cm^3 after annealing at temperatures up to 400°C. The film refractive index is about 1.47 except for low deposition temperatures and high power where the index is lower, and for low N_2O/SiH_4 ratios where the index is high. A high index at low N_2O/SiH_4 ratios has been reported before and may result from a silicon-rich stoichiometry (6, 7). The low refractive index correlates with the amount of fast etching component in the film. The deposited films have a compressive stress, often less than 1×10^9 dynes/cm^2. Correlations between stress and other film properties have not been found. Contrary to previous work, the step coverage is not conformal (7). It appears that deposition occurs by adsorption of species from the plasma with no surface mobility of the adsorbed species. Consequently, films deposited over steps are thin along the vertical walls. Dielectric breakdown occurs at fields of 4-10 MV/cm, significantly lower than the breakdown fields for chemically deposited or thermally grown silicon dioxide. The low breakdown field makes these films unsuitable as an insulator in many applications. The films lose hydrogen during annealing and become more porous, as shown by the lower refractive index and lower density, but cracking does not occur.

Many of the film properties change abruptly at deposition temperatures of 175°-200°C. For instance, discontinuities are observed in the stress, etch rate, refractive index, and infrared spectra. Depositions near this transition temperature should be avoided to insure reproducible and homogeneous film properties.

Summary

The properties of the films formed from silane and nitrous oxide in a large parallel-plate, radial flow reactor at 100°-340°C have been measured. The film properties are strongly dependent on the deposition conditions. This strong deposition dependence probably explains the large range in values previously reported for plasma-deposited silicon dioxide. In general the plasma-deposited films contain 2-9 a/o hydrogen, have a density of about 2.3 g/cm^3, have a refractive index near 1.47, have a low compressive stress, and breakdown at fields of 4-10 MV/cm.

Electrical Transport Properties of Hydrogenated p-Type InSb Films

A. L. Dawar,[1] O. P. Taneja,[2] B. K. Sachar,[1] K. V. Krishna, H. K. Sahajwani, and P. C. Mathur

ABSTRACT

Hall coefficient and d-c conductivity measurements were made on p-type polycrystalline InSb films exposed to hydrogen gas at different pressures. It has been found that the effect of hydrogen in the films is to reduce the concentration of the extrinsic carriers and to decrease their mobility.

The relative importance of various scattering mechanisms limiting the charge carrier mobility in films depends on the conditions under which the films are grown. The inhomogeneities, incorporated or introduced during growth of the film of a compound semiconductor, materially affect the transport properties (1-3). The inhomogeneities in the film can be affected by a number of methods, *e.g.*, doping of foreign elements by co-evaporation (4-6), diffusion (7, 8), annealing in the atmosphere of gases (9, 10), adsorption of gases under pressure (11-13) etc. The effect of adsorption of gases, by exposing the films to gases under various pressures, on the transport properties of the films of semiconductors has recently drawn the attention of many workers (10-13). Most of these workers have, however, studied the effect of adsorption of gases by introducing the gases at low pressures ($\sim 10^{-5}$ Torr to 10^{-2} Torr) for different durations.

In the present work, the effect of hydrogen on the electrical transport properties of p-InSb polycrystalline thin films has been studied by exposing the films to the gas at high pressures (300 and 500 psi). The concentration of the extrinsic charge carriers and their mobility is found to decrease with the increase of pressure of the gas. The motivation for exposing the films at high pressures was that the films exposed to lower pressures were found to have significant desorption effect and the conductivity, which rose due to exposure to the gas, decayed toward its initial value in time periods depending on the exposure parameters. On the other hand, the films exposed at higher pressures and longer durations were found to absorb hydrogen which remained indiffused in the films up to a time period of 30 days.

Experimental Details

Using tantalum masks, films of size 20 $\times$ 4 mm and thickness 0.8 μm were grown by evaporating p-type InSb on thin glass cover slips as substrate under a vacuum $\sim 5 \times 10^{-6}$ Torr. The substrate was cleaned chemomechanically by acetone, detergent, and deionized water using an ultrasonic agitator. The substrate was kept at 300°C during growth to maintain the stoichiometry of the film and was then cooled to room temperature in 6 hr in order to fix the structure of the films. A more abrupt cooling was found to result in poor nucleation. Using transmission electron diffraction studies, Dale and Senecal (14) have shown that InSb films grown at a substrate temperature of 300°C, showed characteristic patterns of InSb. Thickness of the film was measured with the help of a quartz crystal thickness monitor (15), which measures frequency differences up to 10 Hz. Considering the errors introduced due to differences in the density of bulk and thin films, the error in the thickness measurements is estimated to be $\sim$3%. The polycrystalline nature of the films was confirmed by electron diffraction studies and the average grain size was found to be $\sim$500Å. The films grown in the same batch were exposed to hydrogen gas of 99.995% purity at room temperature (at 300 and 500 psi) for 2 hr in a specially designed stainless steel cell of cylindrical shape, having a diameter of 2.5 cm and length 7 cm and provided with a pressure gauge.

Ohmic contacts were obtained by evaporating high purity silver under a high vacuum using tantalum masks. The contacts used to pass the current through the sample were spread over the entire width at the two edges while the Hall probe contacts were 0.5 mm in diameter. The ohmic nature of the contacts was confirmed by the linearity of the *I-V* characteristics, measured throughout the temperature range. The five probe technique, as described by Putley (16), was used to measure d-c conductivity and the Hall coefficient. The sample was mounted on a copper block (with electrical insulation) which was kept in a Dewar flask containing liquid nitrogen. The temperature was measured using a copper constantan thermocouple soldered to the copper block. Errors due to the thermomagnetic effects were eliminated by reversing the current and magnetic field directions. Since the length to width ratio of the film is $l/w = 5.0$, the geometrical errors in the Hall coefficient are negligible. Hall measurements as a function of temperature were taken over 2-3 runs and were found to be reproducible. The observed Hall coefficient was found to be independent of the sample current and the magnetic field applied. The error in R_H, taking into account the errors involved in measuring sample current, magnetic field, and thickness of the film was estimated to be about 3%. The overall error in Hall mobility is about 5%.

Measurements were made on a number of samples of the same thickness (within 5%) which was achieved with the help of electronic shutters, and the results were found to be reproducible within the experimental errors. There was no noticeable aging effect on the transport properties of the exposed films even after storing at room temperature for 30 days in a dessicator.

Results and Discussion

The variation of Hall coefficient R_H with temperature (log R_H *vs.* $1/T$) of the unexposed as well as the hydrogenated films (at pressures 300 and 500 psi) is shown in Fig. 1 for magnetic field $B = 5$ kG (no variation of R_H with B was found up to this limit). It is found that the value of R_H at any given temperature increases with the increase of pressure of the gas. The variation of R_H in the low temperature region is char-

Key words: conductivity, charge carrier mobility, films.

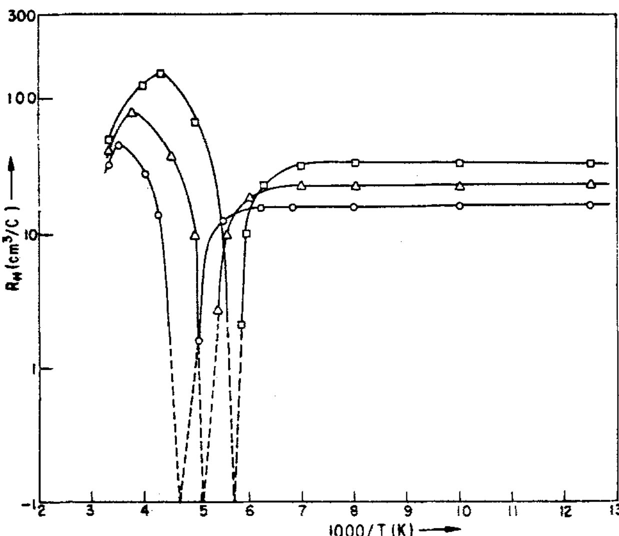

Fig. 1. Variation of Hall coefficient R_H with temperature (log R_H vs. $1/T$) for all the films: I, —○—; II, —△—; III, —□—.

acteristic of a degenerate extrinsic semiconductor. As the temperature increases, the value of R_H decreases and passes through zero at a temperature known as inversion temperature, at which $p = nb^2$, where p and n are the concentrations of holes and electrons, respectively, and b is the ratio of electrons to hole mobility. Above the temperature of inversion, R_H changes sign and increases algebraically with the increase of temperature. This is because of the increasing contribution of electrons to the conduction phenomenon due to their higher mobility. The value of R_H at any temperature is given by

$$R_H = \frac{1 - xb^2}{ep(1 + xb)^2} \quad [1]$$

where x is the ratio of the concentration of electrons n to that of holes p and e is the electronic charge.

It is also found from Fig. 1 that the Hall coefficient reaches a peak value of R_{H1} (algebraically maximum) and decreases again with further increase of temperature, indicating the onset of intrinsic behavior. At the temperature corresponding to the peak value of the Hall coefficient, the contribution of electrons and holes to the conduction process is equal, *i.e.*, $p = nb$. The values of b can be calculated with the help of the expression

$$\frac{R_{H1}}{R_{H2}} = \frac{(b-1)^2}{4b} \quad [2]$$

where R_{H2} corresponds to the extrinsic value of the Hall coefficient. The values of b thus calculated for all the films are shown in Table I. It is found that the value of b increases with the increase of pressure of hydrogen gas. The inversion temperature is found to shift towards lower temperatures with the increase of pressure of hydrogen gas. The onset of intrinsic conduction is also found to shift towards lower temperatures with the increase of pressure. There are two possible explanations for the observed results: (*i*) hydrogen provides surface states which trap the holes, or (*ii*) hydrogen in InSb acts as donor. The observed Hall coefficient data and the shift in the inversion temperature can be explained by both (*i*) and (*ii*). However, the observed decrease in the mobility of the extrinsic holes in the films exposed to hydrogen suggest that (*ii*) is more probable.

Table I.

Film No.	Figure Caption	Pressure of hydrogen gas in psi	$b = \mu_n/\mu_p$
I	○	0	14
II	△	300	15
III	□	500	18

The value of the intrinsic electron density n_i at the temperature corresponding to peak Hall coefficient is given by

$$n_i = \frac{N_a - N_d}{b - 1} \quad [3]$$

where $N_a - N_d$ is determined from the extrinsic Hall coefficient R_{H2} (N_a and N_d being the concentrations of acceptors and donors, respectively). Assuming that the value b is independent of temperature, the value of n_i at a temperature at which $R_H \rightarrow 0$ can be calculated from Eq. [1]

$$n_i = \frac{N_a - N_d}{b^2 - 1} \quad [4]$$

The values of n_i at other temperatures can also be found by solving Eq. [1] for x. The calculated values of n_i for different films at various temperatures are plotted in Fig. 2 to calculate the bandgap activation energy. The value of the activation energy is found to be 0.28 eV, which is in agreement with the reported value (17).

The variation of the observed mobility μ_H as a function of temperature (log μ_H *vs.* log T) is shown in Fig. 3. The solid line represents the experimental bulk mobility data for a degenerate ($p = 5 \times 10^{17}$/sec) bulk single crystal. It is observed from the figure that the value of μ_H increases with the increase of temperature, indicating the contribution of some scattering mechanism in which the mobility increases with temperature. The observed Hall mobility μ_H can be expressed as

$$\frac{1}{\mu_H} = \frac{1}{\mu_d} + \frac{1}{\mu_R} \quad [5]$$

where

$$\frac{1}{\mu_R} = \frac{1}{\mu_B} + \frac{1}{\mu_{IIS}} \quad [6]$$

where μ_B is the grain barrier limited mobility, μ_{IIS} the mobility limited by the ionized impurity scattering, and μ_d is the average carrier lattice mobility. Corrected for diffuse scattering it is given by (18)

$$\mu_d = \frac{\mu_l}{1 + \frac{3}{8\gamma}} \quad [7]$$

where μ_l is the bulk lattice mobility and γ is the ratio

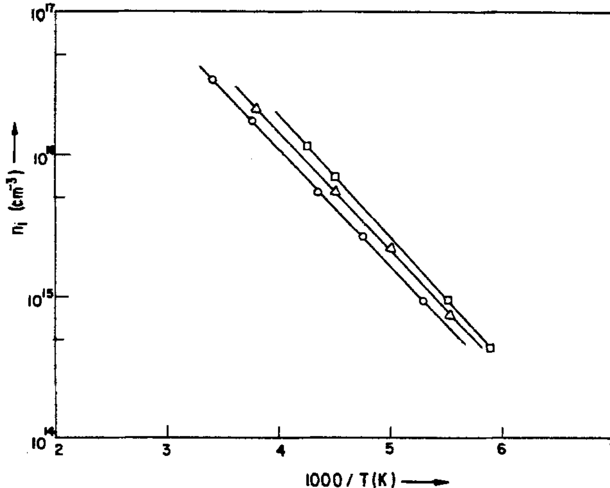

Fig. 2. Electron density n_i as a function of temperature (log n_i vs. $1/T$): I, —○—; II, —△—; III, —□—.

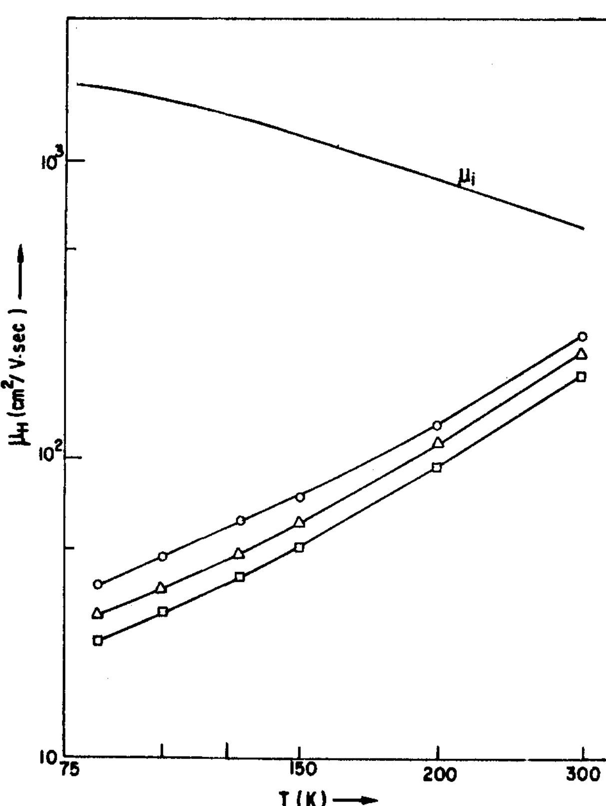

Fig. 3. Variation of Hall mobility μ_H as a function of temperature (log μ_H vs. log T): I, —○—; II, —△—; III, —□—. Solid line represents the bulk mobility μ_i.

of film thickness to the mean free path. The contribution of μ_{IIS} to the unexposed film is found to be negligible because, as shown in Fig. 4, the value of μ_R for this film is found to increase exponentially with temperature in accordance with the relation (19)

$$\mu_B = \frac{ev_{th}}{4NKT} \exp\left(\frac{-e\phi}{KT}\right) \quad [8]$$

where v_{th} is the average thermal velocity, N is the number of crystallites per unit length, and ϕ is the magnitude of the grain boundary barrier potential height. The value of ϕ as calculated from Eq. [8] is

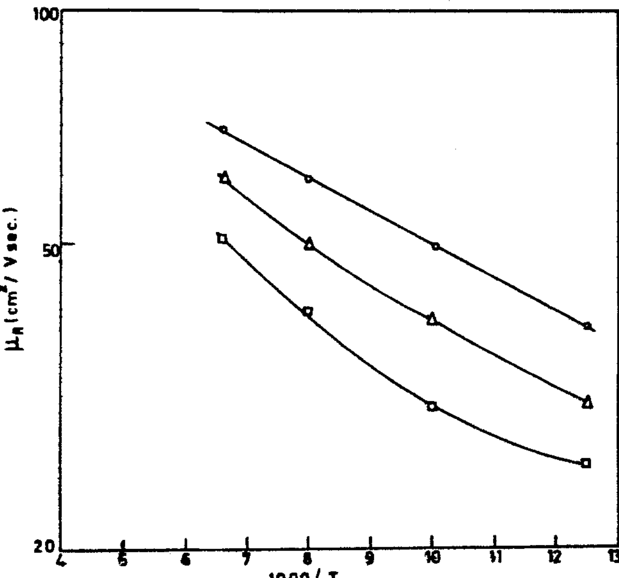

Fig. 4. Variation of remainder mobility μ_R with temperature (log μ_R vs. $1/T$): I, —○—; II, —△—; III, —□—.

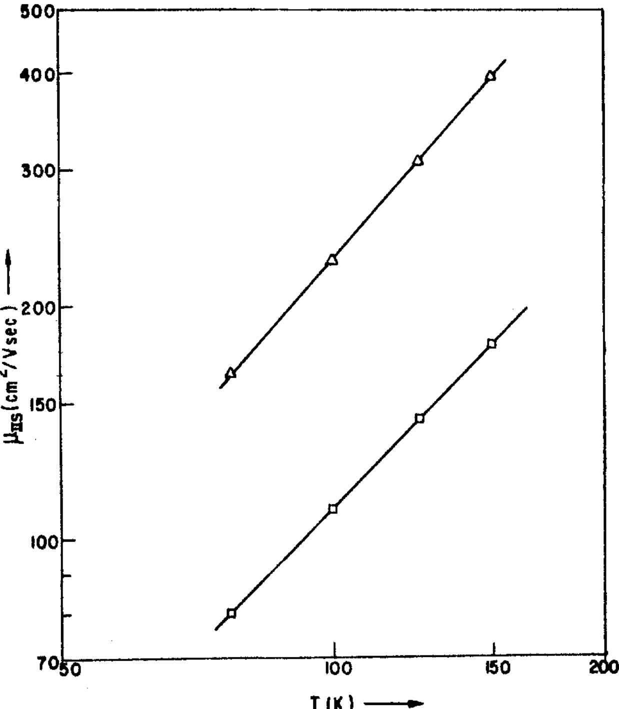

Fig. 5. Mobility limited by ionized impurity scattering μ_{IIS} as a function of temperature (log μ_{IIS} vs. log T): II, —△—; III, —□—.

found to be ~9 meV. On the other hand, for both the exposed films, μ_R shows deviations from exponential behavior which can be due to contribution of the ionized impurity scattering. At any temperature the value of μ_H is found to decrease with the increase of pressure of hydrogen. This explains the increase in the estimated value of b shown in Table I. Assuming the value of μ_B for all the films to be the same (average grain size for all the films is same), the value of μ_{IIS} is estimated as a function of temperature for both the exposed films, and the values are shown in Fig. 5. The values of μ_{IIS} and the slope of log μ_{IIS} *vs.* log T are found to be smaller for the film exposed to hydrogen gas at higher pressure showing the increase of compensating effects in the films with the increase of pressure of the gas.

It may be mentioned that the observed difference between the temperature variation of μ_R for the unexposed and exposed film can also be due to effect of hydrogen on the grain boundary barrier potential. However, since the log μ_{IIS} *vs.* log T plots for the exposed films, shown in Fig. 5, are linear (20) with slopes ~1.5, the analysis of the mobility data assuming ϕ to be same for all the films is justified.

Mechanisms of Plasma-Enhanced Silicon Nitride Deposition Using SiH_4/N_2 Mixture

Haiping Dun, Paihung Pan, Francis R. White, and Richard W. Douse

IBM General Technology Division, Essex Junction, Vermont 05452

ABSTRACT

The mechanism of plasma-enhanced vapor deposition of silicon nitride is studied by varying process parameters, such as substrate temperature, rf power, reactant gas ratio, and total pressure. The film composition (Si, N, O, and H) is determined by electron microprobe and infrared analysis. From these analyses, it is established that the film composition is determined not only by the reactant gas ratio, but also by a combined function of the rf power (W) and total pressure (P) in terms of W^x/P, with x a system-dependent factor. The dependence of film composition on W^x/P can be related to the radical generation processes. The substrate temperature is found to affect the film composition as well. Greater substrate temperature produces films with less hydrogen and more nitrogen, and hence, higher density. The film dielectric property and plasma etching rate are both studied and found to be dependent on the film composition. Finally, a three-step deposition mechanism, namely, radical generation, radical adsorption, and adatom rearrangement, is proposed to explain the reaction scheme, and an ion incorporation mechanism is proposed to explain the change of film physical properties.

Plasma-enhanced chemical vapor deposited (PECVD) silicon nitride film has been widely used as a passivation film in integrated circuit fabrication. The advantages of PECVD silicon nitride are low processing temperatures ($\lesssim 400°C$), good step coverage, and good passivation for both moisture and sodium ions. Several investigations of PECVD silicon nitride film processing have been reported (1-4). The majority of them use the SiH_4/NH_3 mixture as the reactive gas, since it was found that the SiH_4/N_2 process was less controllable (3). However, the SiH_4/N_2 process has less hydrogen incorporation (5) and a purer source gas. A comprehensive discussion on the deposition of the PECVD silicon-oxygen-nitride films was reported elsewhere (6).

Unlike the conventional chemical vapor deposition (CVD) technique, the PECVD technique should be classified as a highly nonequilibrium reaction process. Gas molecules are mainly dissociated by electron impact to produce very reactive radicals, atoms, and ions in the plasma. These reactive species then condense on the substrate surface to form an amorphous film. As a consequence of the large temperature difference between the impact electron ($\sim 10^5$ K) and the substrate surface (~ 600 K) the deposition can be regarded as a quenching process. The incorporated silane radicals are unable to give away their hydrogen due to the low substrate temperature and a hydrogen-containing film results. In addition, since the surface diffusion of adatoms is much retarded, the film normally contains more defects and has a smaller density compared to a high temperature processed film. A stoichiometric compound is not easily obtained due to this inhomogeneous deposition nature. A better understanding of the plasma state is required to control the film properties. In contrast to the CVD technique, which is controlled by the flow pattern and substrate temperature, a third set of variables dominates the PECVD process. This set of variables, which basically determines the "electron temperature" of the plasma, is rf power and frequency, electrode spacing, gas collision mean free path, and ion diffusivity. In principle, the PECVD process may be related to both the CVD and rf sputtering techniques. The radical generation rate, which is determined by the electron temperature, governs the film stoichiometry. The role played by the ions is still unclear; however, it is believed to be a key factor influencing the film conformity, adhesion, and stress. In this sense, the surface self-biased voltage appears to govern the film properties in terms of physical behavior. Since these parameters are interrelated, the process is difficult to model. A study of each variable, while keeping the rest constant, was performed in order to understand the plasma reaction.

Key words: PECVD, silicon nitride, radical dissociation, field promoted deposition.

In this paper, we present the results of a study for PECVD silicon nitride deposition using an SiH_4/N_2 gas mixture. The change of film properties is related to variations of process parameters. A better understanding of the reaction kinetics is derived from this investigation.

Experimental

Two LFE Incorporated Model PND-301 reactors were used to deposit all the silicon nitride films. The two reactors, although of the same model, did not give

identical results due to differences in the pumping speed, the rf impedance, and differences in calibration of the flow and pressure monitors. The reaction chamber and the equivalent circuit of the system are sketched in Fig. 1, where a combined LC circuit is used to generate the plasma. For the low power, or high pressure cases, the glow is generated between the gas injecting shower head (G) and the wafer holder (H). At high power, or low pressure, the glow starts to jump above the shower head (G) and eventually occupies most of the quartz bell jar region. The power density (W/cm^3) is drastically changed on the transition between these two modes. During the experiment, we maintained a plasma such that both L and C were excited to avoid any discontinuity in the process.

Reactant gases of SiH_4 (1.5% diluted in Ar) and N_2 were premixed in the flow line and injected through a perforated aluminum shower head to give a uniform flow pattern. When the system vacuum reached 50 mTorr or less, the silane gas was fed into the system and the pressure was recorded. Subsequently, the nitrogen gas was allowed to flow into the system and the total pressure was recorded again. The pressure difference was assigned to be the nitrogen partial pressure. The flow rates were monitored by a Tylan mass flow controller for the silane and a rotameter for the nitrogen. Due to a tendency of the silane flow controller to be clogged, the pressure ratio, instead of the flow ratio, was used for process control methods. This would give a significant error if the pumping speed varied strongly with the pressure. However, since both the silane and total pressures were detected in the same range, the systematic error was expected to be small. This is verified by simultaneously monitoring the gas flows.

Four process parameters, the substrate temperature (T), the rf power (W), the SiH_4/N_2 reactant gas ratio (R), and the total pressure (P), were systematically changed while the rest were held constant. Each experimental condition is listed in Table I. Films of two thicknesses were deposited. Thin films of about 100 nm were deposited over bare silicon wafer for the measurements of refractive index (n), deposition rate (G), and electronic properties.

Thick films of about 1 μm were deposited over bare silicon or aluminum-coated wafers for the measurements of film composition (% of Si, N, O), hydrogen bonds (Si-H, N-H), and the etch rate (E_r).

The deposition rate and refractive index were simultaneously obtained using an automatic ellipsometer ($\lambda = 632.8$ nm). The results for silicon-rich films were not corrected for the absorption component. It was expected that the errors due to absorption for thin films would be small.

The concentrations of Si, H, and O for all samples were measured by the electron microprobe analysis (Applied Research Laboratory Model SEMQ). The CVD silicon nitride (n = 2.01) and thermally grown silicon dioxide were used as the standards. The voltage of the incident electron beam was maintained at 5 kV and the beam current was held at ~3 μA. A thin layer

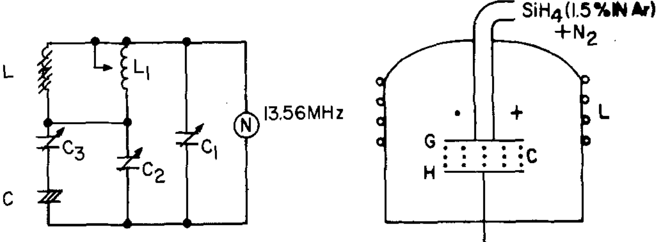

Fig. 1. Schematic of the deposition system and rf circuits

of carbon was evaporated on the film surface to reduce charge effects. The weight percentages of the elements were obtained using the MAGIC IV computer program (7). In this study, the total atomic concentration of Si, N, and O, was not adjusted to achieve 100%. The Si/N ratio, which is usually used as an indication of the film stoichiometry, is refined here to take into account the effect of oxygen, and is written as

$$\frac{\text{Si}}{\text{N}} \equiv \frac{[\text{Si atomic }\%]}{[\text{N atomic }\%] + 2/3\,[\text{O atomic }\%]}$$

where the factor of 2/3 for the oxygen is used to correct for the bond number. The effect of hydrogen is not included here, however, the Si/N value is used to indicate the amount of "excess silicon" in the film for comparison purpose.

Two infrared techniques were used for hydrogen analysis: the multiple reflection infrared (MRIR) technique (8), and the transmission Fourier transform infrared (FTIR) technique. For the former technique, films deposited over the aluminum-coated substrate were used, while for the latter, films deposited over bare silicon substrates were used. A typical infrared (MRIR) absorption spectra, ranging from 2000 to 3500 cm^{-1} for films deposited at different substrate temperatures, is displayed in Fig. 2, where the absorption peaks are due to N-H stretching bond (3350 cm^{-1}) and Si-H stretching bond (2160 cm^{-1}). For a semiquantitative analysis of the film hydrogen content, the unit areas (UA) of the absorption peaks at 3350 and 2160 cm^{-1} are calculated to represent the content of N-H and Si-H bonds, and the sum of them is used to relate to the total hydrogen content. They are defined as

$$[UA]_{\text{N-H}} \equiv 1.4 \times \left[\frac{\text{N-H bond area}}{\text{film thickness}}\right] \times 100$$

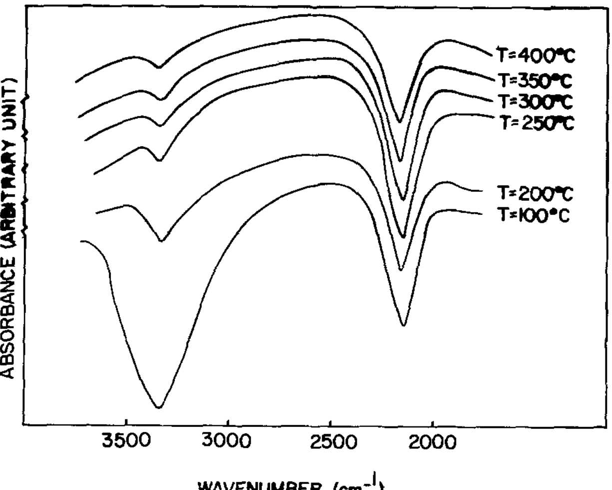

Fig. 2. Multiple reflection infrared absorption spectra ranging from 2000 to 3500 cm^{-1} for samples deposited at different temperatures.

$$[UA]_{\text{Si-H}} \equiv \left[\frac{\text{Si-H bond area}}{\text{film thickness}} \right] \times 100$$

$$[UA]_{\text{total H}} \equiv [UA]_{\text{N-H}} + [UA]_{\text{Si-H}}$$

where the correction factor of 1.4 assigned for the N-H bond was suggested by Lanford and Rand (9). The *UA* values are normalized to the film thickness instead of the Si-N bond area. This is because the Si-N bond area changes with both the film composition and thickness. The infrared absorption is directly proportional to, and hence, only normalized to, film thickness for the infrared measurement if the detection sensitivity remained unchanged. Since there was no independent calibration for each infrared technique (MRIR and FTIR) that direct comparison between data for the sets of temperature and rf power (Fig. 3b, 4b; MRIR)

and the sets of gas ratio and total pressure (Fig. 5b, 6b; FTIR) was not made.

The system used to etch the PECVD silicon nitride samples was a capacitively coupled, barrel plasma reactor with etch tunnel and quartz preheaters.

The etch conditions used were: 86 SCCM total flow, 75°C start temperature, 0.55 Torr, 100W. The gases used were DE100 and pure CF_4, and the samples were etched one at a time with laser end-point detector.

The film's electrical properties were measured using I-V and breakdown techniques. Aluminum metal dots, 30 mils in diameter, were evaporated over PECVD silicon nitride of thickness ~ 100 nm to form a contact. In order to retain as-deposited film properties, there

is no post contact 400°C forming gas anneal. The film resistivity was obtained from the *I-V* data measured at a field of 2 MV/cm and room temperature. The film breakdown strength was defined at the field where the current passing through the test dot reached 10 μA. A computerized automatic breakdown test system was used to find the film average breakdown strength and its statistical mean deviation over a test sample of 50 dots for each film.

Results

The change of film properties as a function of substrate temperature, rf power, reactant gas ratio, and total pressure are expressed in terms of deposition rate (*G*), refractive index (*n*), and Si/N value (Fig. 3a, 4a, 5a, 6a), together with the atomic percentages of Si, N, O, and the relative unit area (*UA*) of Si-H, N-H, and the sum of them (Fig. 3b, 4b, 5b, 6b). A summary of these experimental results is given below.

Substrate temperature (T) effect.—As the substrate temperature is increased from 250° to 400°C, the following results are observed: the deposition rate decreases with a slight increase of the refractive index, the silicon concentration decreases, the nitrogen concentration increases, the amount of oxygen remains unchanged to give a decrease of Si/N ratio (Fig. 3a); the total hydrogen, as well as the Si-H and N-H unit areas, decrease slightly (Fig. 3b). For temperature below 250°C, however, large amounts of oxygen are incorporated, *i.e.*, the oxygen concentration increases from 2 atomic percent (a/o) at $T = 250°C$ up to 13 a/o at $T = 100°C$.

The amount of hydrogen, also, increases significantly in this temperature range. Further, it was noticed that the N-H bond *UA* at $T = 100°C$ was about 29 times larger than that at $T = 250°C$, while the Si-H bond *UA* was nearly unchanged.

The large amount of oxygen incorporated at low temperature is believed to be due to moisture released from the inner wall of the reactor by the plasma. At high substrate temperature, the moisture would be desorbed from the wall as a result of heating prior to deposition.

RF power (W) effect.—As the rf power is increased, the deposition rate is increased and the refractive index is decreased. The silicon concentration decreased and the nitrogen concentration increased to give a decrease in the Si/N value (Fig. 4a). The hydrogen *UA* is relatively constant with the change of rf power, except for a minimum at 175W. The relative *UA* of Si-H and N-H, however, switches from the low power case to high power case (Fig. 4b). The oxygen concentration stays constant. The O-H bond peak at 3650 cm^{-1}, as detected from infrared analysis, was observed for the lowest power case (37.5W). All evidence indicates the increase of nitrogen radicals with rf power.

Reactive gas ratio (R) effect.—As the SiH_4 (1.5% diluted in Ar) flow is increased to give a high value of R (= SiH_4 [in Ar]/N_2), the deposition rate, refractive index, and Si/N ratio increased as expected. The silicon atomic percent increased, the nitrogen atomic percent decreased, while the oxygen remained nearly constant (Fig. 5a). The infrared data showed an increase of the Si-H bonds. The cause for the abrupt change in Si-H, N-H, and oxygen atomic percent for sample with $R = 0.76$ is not clear (Fig. 5b).

Total pressure (P) effect.—As total pressure increased, the deposition rate, refractive index, and the silicon atomic percent increased, while the nitrogen atomic percent decreased to give an increase of Si/N value (Fig. 6a). The Si-H bonds increased, the N-H bonds decreased, and the total *UA* of hydrogen remained nearly constant (Fig. 6b). At $P = 0.7$ Torr, the oxygen atomic percent showed a "bump" with a corresponding "bump" in the N-H bonds. This associated increase of the N-H bonds with the amount of oxygen was also observed for the previous figures (Fig. 3b, 4b, 5b). It appeared to be due to an oxygen-enhanced dissociation of the nitrogen molecules in the plasma.

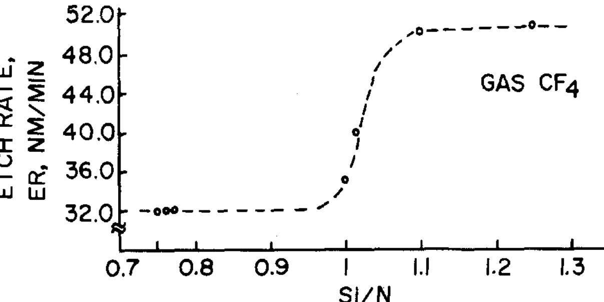

Fig. 7a. Etch rate plotted as a function of silicon-nitrogen ratio using pure CF_4 etching gas.

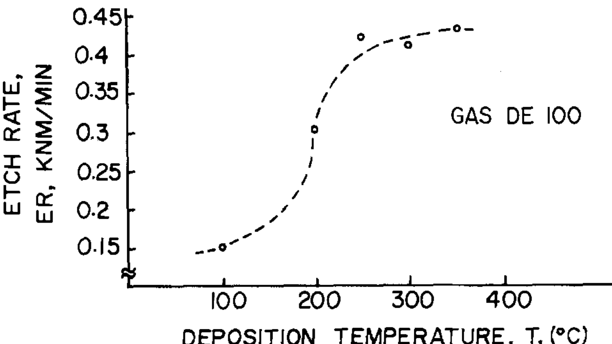

Fig. 7b. Etch rate plotted as a function of deposition substrate temperature using CF_4 + 8% O_2 etching gases.

The plasma etching study results are plotted in Fig. 7a and b. It was found that N_2 purge prior to deposition had no appreciable effect on either the etch rate (E_r), or the amount of oxygen incorporated into the films. However, when oxygen was purposely incorporated into the film by adding O_2 gas into the plasma during deposition, the etch rate decreased. The Si/N ratio of the films affects the etch rate with the silicon-rich films etching faster as seen in Fig. 7a. The break point occurs at an Si/N ratio between 1.0 and 1.1. Figure 7b shows etch rate for films deposited at different substrate temperatures. At temperatures above 250°C, little change in E_r is observed. For temperatures below 250°C, the etch rate decreases with decreasing temperature, which corresponds to an increase of the oxygen concentration in the films as previously discussed. Films processed at different rf powers were also studied as a function of etch rate, however, no conclusions could be drawn.

A sample processed at high pressure (>2 Torr) was etched and showed a radially dependent etch rate. The center of the wafer etched about 4 times faster than the edges indicating that the center had a higher silicon concentration. This can be explained from the following point of view. For the high pressure case, the center of the plasma was close to an arcing condition such that a low voltage, high current plasma was established. Meanwhile, the edge was still in the uniform glow condition such that a higher voltage plasma was maintained. This would result in a film more silicon rich at the center relative to the edge.

In this study, the resistivity (ρ), and the average breakdown strength (E_B) were measured. As shown in Fig. 8, the resistivity, which was measured at room temperature with an applied field of 2 MV/cm, increases from 10^7 Ω-cm up to 10^{14} Ω-cm as the Si/N ratio decreases from 1.6 down to 0.8. These samples

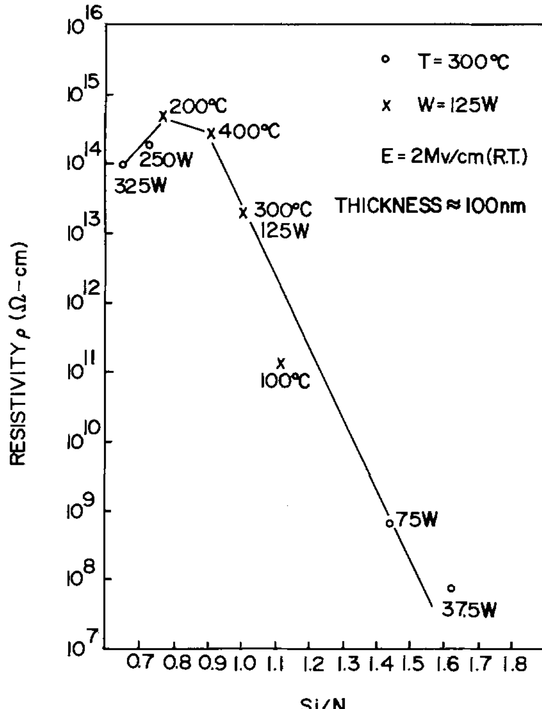

Fig. 8. The film resistivity measured at room temperature with a field of 2 mV/cm plotted as a function of Si/N ratio. ○ = Changing the rf power and fixing the substrate temperature at 300°C; × = changing the substrate temperature and fixing the rf power at 125W.

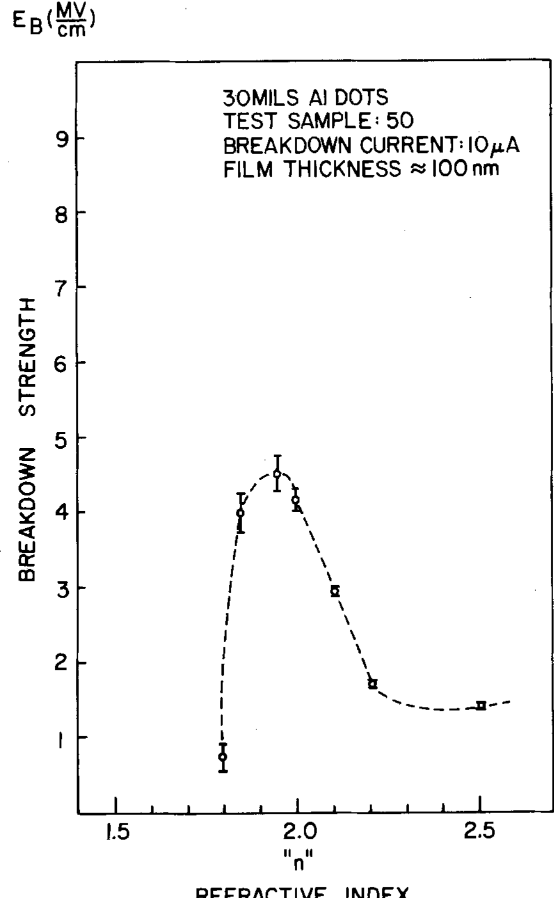

Fig. 9. The average breakdown strength plotted as a function of film refractive index. The error bar represents the statistical mean deviation of the measurements over 50 test dots.

were either processed at different substrate temperature or rf power. The exponential decrease of the resistivity *vs.* Si/N ratio is consistent with the earlier observation of Sinha and Smith (10), although, in their case, SiH_4 and NH_3 were used as the reactants. By changing the gas ratio only, another set of films of different index were deposited to test for breakdown strength. Figure 9 shows the average breakdown strength as a function of the refractive index. The error bar for each data point represents the statistical mean deviation of breakdown strength of 50 tested data across the wafer. The deviation expresses the degree of inhomogeneity of the film. Based on the results of Fig. 8 and 9, it is concluded that the near-stoichiometric film has the best dielectric properties, *i.e.*, minimum leakage and largest breakdown strength.

The resistivity of the best PECVD silicon nitride film obtained, however, is still much lower than the conventional CVD silicon nitride film. Figure 10 illustrates a comparison of the log I-$V^{1/2}$ behavior of one of the PECVD films ($n = 1.95$, Si/N $\cong 0.8$) with the CVD silicon nitride films reported in the literature (11, 12). The PECVD film, resembling the conventional CVD films, follows the Poole-Frenkel conduction behavior. The slope gives a dielectric constant of 5.7 which is close to that of CVD films. The intercept of the slope, which corresponds to the pre-exponential term, however, is orders of magnitude larger than that obtained for CVD films. This indicates the PECVD film has either a greater amount of traps and/or a shallower trapping level. The result is conceivable since a larger defect concentration is expected to exist in the PECVD silicon nitride film due to the low processing temperature and the great amount of hydrogen in the film.

Discussion

In order to explain the experimental observations, we divided the deposition into three kinetic steps, namely, radical and ion generation in the plasma; radical adsorption and ion incorporation onto the film surface; and surface adatom rearrangement.

Radical and ion generation.—The dissociation and ionization of gas molecules in a glow discharge are mainly produced by electron impact. Since the dissociation energy is lower than the ionization energy for many gas molecules, the generation rate for radicals is generally greater than that for ions. Positive ions will drift toward the negatively biased surface and recombine with electrons in the vicinity of, or at the wall surface, while neutral radicals may still stay in the plasma and have a longer lifetime. These two effects make the radical concentration higher than that of its ion form. Hence we believe neutral radicals form the major deposition agents.

In order to describe the gas dissociation mechanism, the concept of "electron temperature" is applied. The treatment is similar to that used by Reinberg (6) in the deposition of silicon-oxygen-nitride. The probability of molecules to be dissociated by electron impact can be calculated from the molecular dissociation energy, the electron energy distribution function, and the effective collision cross section (13, 14). With a very crude approximation it is proportional to $e^{-\Delta E/kT_e}$, where ΔE is the dissociation energy, T_e is the electron temperature, and k is the Boltzmann constant. Here the electron is assumed to be a Maxwellian gas. Since the molecular dissociation energy is closely related to its bond energy, the latter can be used to estimate the probability of dissociation without going into detailed calculations.

On increasing the electron temperature, gas species with a greater dissociation energy will undergo a greater change in radical concentration than species with lower dissociation energy. This change of radical ratio will result in a change of film composition. For the case of nitrogen and silane, the former has a bond energy of 9.9 eV and the latter has a bond energy of 3.1 eV (15), increasing the electron temperature will

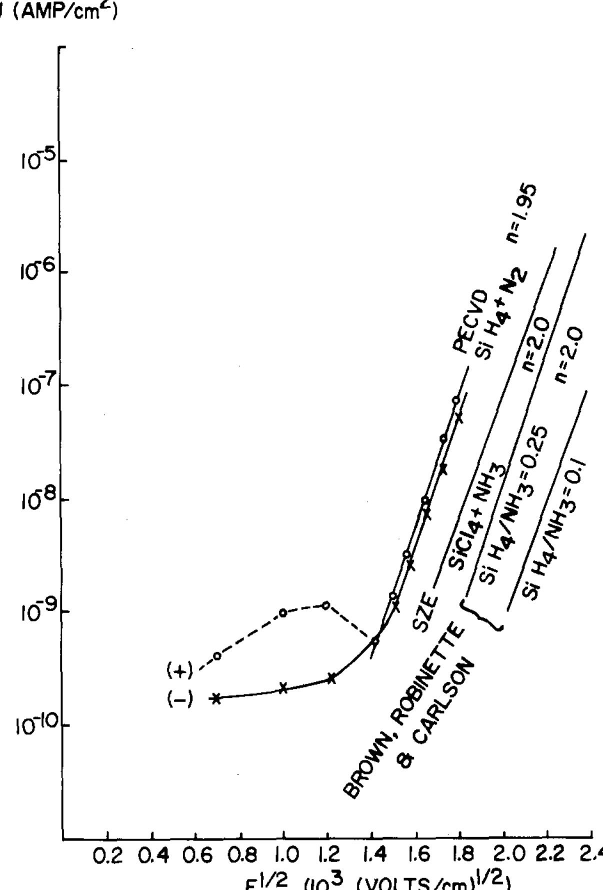

Fig. 10. The comparison of leakage current *vs.* field strength between PECVD silicide nitride and conventional CVD silicon nitride.

increase the radical ratio between nitrogen and silane, *i.e.*, $N\cdot/SiH_3\cdot$, to give a film of greater N/Si ratio. This explains the experimental observations in Fig. 4a and 6a, *i.e.*, the Si/N ratio is decreased by either increasing the rf power or decreasing the total pressure. Both will increase the electron temperature, a fact which is discussed later. For the case of ammonia and silane, the difference of dissociation energies is small. Hence, one would expect SiH_4/NH_3 process to be more controllable than SiH_4/N_2 process.

As mentioned in the beginning of this paper, the change of electron temperature in a high frequency plasma is a combination of many variables. It is well documented in the literature (16) that the plasma state could be defined in terms of three sets of parameters, i.e., E/P, P/ω, Pd, where E is the rf field strength, P is the pressure, ω is the rf frequency, and d is the electrode spacing. The first set of variables determines the ionization coefficient and the electron temperature. The second set of variables determines the frequence effect. The last set of variables is the high frequency Paschen's law which specifies the geometric effect. When the rf frequency and electrode spacing are fixed, the electron temperature for a specific gas will be solely determined by E/P. The value of E/P can be transformed into the form of W^x/P, where W is the rf power, and x is a system dependent factor which relates rf power to the peak-to-peak rf field strength. In our system, the rf frequence is 13.56 MHz, which falls in between the ion collision frequency and electron collision frequency, it is found that the rf field increases with rf power (*i.e.*, $x > 0$). Hence it is clear that increasing the rf power or decreasing the total pressure will result in the increasing of electron temperature. Other evidences for the increase in electron temperature with W^x/P are that a brighter glow color is observed and an increased NH bond is found in the film (Fig. 4b, 6b). The increase of NH bond in the film suggests more nitrogen radicals are generated in the plasma. A subsequent radical reaction in the plasma ($N + H \rightarrow NH +$ light) or more likely a surface recombination of adsorbed nitrogen and hydrogen adatoms yields more NH incorporation. The generation of ammonia radicals at high rf power was predicted by Reinberg (6) and should be avoided to minimize hydrogen incorporation.

Radical adsorption and ion incorporation.—This kinetic step deals with the plasma-surface interaction. The deposition surface, which is under electron and ion bombardment and u.v. irradiation, can provide many active sites for radical adsorption. Since radicals are highly reactive, they tend to be adsorbed on a colder surface readily. By maintaining a constant plasma state and only changing the substrate temperature, a change of Si/N ratio in the film was observed (Fig. 3). This indicates there is a possible preference of radical adsorption in favor of nitrogen radical and disfavor of silane radical at higher surface temperature. Moreover, a huge increase of NH bond at low substrate temperature may also reflect some preference of the NH radical adsorption at this temperature range. This latter observation, however, is complicated by the existence of large amounts of oxygen in the film.

The ion-surface interaction is strongly influenced by the surface d-c field and probably weakly dependent on surface temperature. The substrate can be self-biased in an rf plasma due to the difference of electron and ion mobility (17). The self-biased voltage across the substrate is determined by the rf peak-to-peak voltage, the area ratio of the counterelectrode geometry surrounding the plasma, and the external circuit connection (18-20). A direct measurement of the d-c voltage between the plasma and the substrate is not performed in our system. However, we believe large biased voltage can be developed during deposition because the rf power density is high and the substrate is surrounded by a confined geometry.

An independent study of the film stress *vs.* the rf power (21) showed that films produced in our system became more compressive at a greater power level. The measured stress almost changed linearly with rf power from 1×10^9 dyne/cm² tensile at 50W to 5.5×10^9 dyne/cm² compressive at 300W with the rest of the process variables kept constant ($T = 350°C$, $R = 1$, $P = 0.65$ Torr), This is in agreement with that of Sinha *et al.* (2), although we use SiH_4/N_2 mixture and our films generally tend to be more compressive. It was also found that the scratching resistance of the deposited film increased with rf power. Ion-surface interaction is believed to play a major role here in determining the film physical properties.

The influence of substrate bias upon the quality of sputtered film has been studied (22). The increase of density and decrease of resistivity with substrate bias were observed for the sputtering of metal films (23, 24). It was also reported that an improvement in film quality and better edge coverage could be obtained by applying a substrate bias for rf sputtered quartz (25). The explanation is based on the substrate resputtering mechanism. Contaminants and poorly adherent spots of the film are resputtered during deposition to give a denser film. The resputtered material will deposit on the side wall to provide a better edge coverage. This mechanism can be extended to some degree to explain the change of density with rf power (2), a better adhesion, and a better edge coverage (26) observed for the PECVD films.

The change of film stress is, however, more likely caused by positive ion incorporation. The phenomenon of ion incorporation into the sputtered film such as Ar and N_2 were reported (27, 28). For the PECVD process, the operating pressure is much higher than for the

rf sputtering process and the substrate bias voltage is normally low ($\lesssim$ 50V). Hence, the resputtering and ion bombardment effect is expected to be reduced. It is, therefore, unlikely for those nonbonding ions such as Ar^+ or N_2^+ to be implanted into the film to change its stress. However, the incorporation of some bonding ions such as H^+ or N^+, which are the building block of the film, can be promoted by a low surface field since these ions will probably have a large sticking coefficient.

This argument helps to explain the observed switch of Si-H and N-H bond concentrations at great rf power and low pressure. At a greater electron temperature, the silane would give up more hydrogen to produce more H^+ in the plasma and less Si-H bond in the film. The generation of N^+ ion was increased and a more negatively biased surface field was induced as a consequence of greater electron energy and density. Thus, there were more H^+ and N^+ ions incorporated into the film to produce more N-H bond. Although the production of N-H bond in the plasma was also possible, the chance was smaller compared to the surface recombination since a three body collision process was required. Similar observation for the field-promoted ion incorporation was also reported for the glow discharge produced amorphous silicon (29), where the incorporation of hydrogen was found to be enhanced or depleted depending on whether a negative or a positive d-c field was applied to the system.

This "field-promoted deposition," which is similar to the ion-assisted etching (30) case, results in a vertical incoming mass flux toward the substrate. Due to this additional ion flux, the film will relax in a lateral fashion to change the stress toward more compressive. This appears to explain the observed stress change with rf power even though the Si/N ratio remains relatively unchanged. A low frequency (~50 kHz) tool was reported to produce film of compressive stress (31). At this low frequency range, which is lower than the ion collision frequency (~100 kHz), the rf plasma resembles the d-c case. A much higher plate voltage is required to generate a plasma to overcome the ion shielding due to space charge around the plates. As a consequence of external circuit arrangement, a high substrate bias voltage is produced (20). This explains why the films produced in the tool were always in compressive stress.

Adatom rearrangement.—The last step of deposition is for adatoms bonded to each other to form a continuous film. The adsorbed radical has to diffuse into a stable site to become part of the growing film. This film stabilization mechanism is strongly influenced by substrate temperature. As the substrate temperature is increased, the surface adatom gains more energy to diffuse to a stable site faster. The film, thus obtained, will have better quality. The release of hydrogen from the incorporated SiH and NH bonds will also be promoted by substrate heating (Fig. 3b). Therefore, the film density increases with substrate temperature. Since a porous film gives a low refractive index (32) the increase of refractive index with substrate temperature agrees with the density trend (Fig. 3a). This observation is, however, inconsistent with the chemical analysis which shows a decreased Si/N value with temperature. Normally a large Si/N value (>0.8) will give a large refractive index (>2.0) due to more absorptive Si-Si bonds in the film such as shown in Fig. 4a, 5a, and 6a. In Fig. 3a, however, the large Si/N value for low temperature processed film gives an unexpected low refractive index. This indicates that the excess silicon exists mainly in the form of Si-H bond instead of the Si-Si. Thus, the density effect overshadows the Si/N effect, and gives a low refractive index at low substrate temperature.

Conclusions

PECVD silicon nitride deposition, using the SiH_4/N_2 gas mixture has been investigated. Film composition, *i.e.*, percent of Si, N, O, and H, has been found to be sensitively dependent on the process parameters such as substrate temperature, rf power, total pressure, and reactive gas ratio. The plasma etch rate and dielectric properties are studied and found to be influenced by the film composition as well.

The complex deposition process is divided into three kinetic steps, *i.e.*, radical generation, radical adsorption, and adatom rearrangement, to explain the observed change of film chemical and physical properties. The concentration change of silicon and nitrogen with rf power and total pressure is believed to be due to a change in the electron temperature. A combined function of rf power and total pressure, to be expressed as (W^x/P), influences the electron temperature, and hence the film composition. In both the high power and low pressure cases, the film tends to be less "silicon rich."

The change of hydrogen total content is affected by substrate temperature. However, the change of rf power and total pressure influences the hydrogen incorporation in the form of SiH or NH bond.

Acknowledgments

We acknowledge the constant encouragement and support of E. E. Gardner and P. C. Velasquez during the course of this study. Discussions and suggestions of the film stress phenomenon from G. Schwartz are highly appreciated. Thanks are also given to H. Geipel and N. Hsieh for help in measurements and interpretation of electrical properties, to B. Gleason and W. Natter for the infrared measurements, and to C. Kroll and R. Mohler for technical assistance. Finally, the critical review of the manuscript by R. Silverman is deeply appreciated.

ABSTRACT

The growth conditions required to epitaxially synthesize the tetragonal chalcopyrite semiconductor $ZnSiAs_2$ on cubic Ge and GaAs substrates are described. Some structural and electrical properties of the resulting epitaxial layers are reported. The routine unique epitaxial growth of (001) $ZnSiAs_2$ on (100) substrates of Ge and GaAs, in preference to the (100) or (010) $ZnSiAs_2$ orientations, has been demonstrated. Growth conditions have also been identified that have led to mixtures of the (010) and (001) orientations of $ZnSiAs_2$ on these (100) cubic substrates. The use of GaAs substrates has led to an autodoping problem similar to that observed for GaAs grown on Ge.

In a previous publication (1), the first successful synthesis of the tetragonal chalcopyrite $ZnSiAs_2$ by the open-tube chemical vapor deposition (CVD) process was reported. The II-IV-V_2 chalcopyrites are considered to be ternary analogs of the III-V compounds (2), and thus have several potential device applications. This work with $ZnSiAs_2$ has been primarily oriented toward the investigation of the chalcopyrite semiconductors for solar cells.

In the previous work the as-grown layers were either completely polycrystalline or were polycrystal with preferred orientations, exhibited p-type conductivity, and could be grown in this form on a variety of substrates. Other previous work on the open-tube vapor phase growth of the chalcopyrite $ZnSiP_2$ also resulted in nonepitaxial growth (3). In this paper the growth conditions which have led to the unique epitaxial deposition of $ZnSiAs_2$ on the cubic semiconductors Ge and GaAs by CVD are described. These substrate materials provide a good lattice match to $ZnSiAs_2$. By using CVD in an open-flow system the routine deposition of (001) $ZnSiAs_2$ with good surface morphology on (100) substrates of both Ge and GaAs has been achieved. This particular growth occurs in preference to the nucleation of either the (100) or (010) orientations of $ZnSiAs_2$ for a well-defined range of growth conditions in the growth system used in this work. Furthermore, the reactor growth conditions which result in crystallographic mixtures of the (010) and (001) orientations of $ZnSiAs_2$ on (100) Ge and GaAs have been identified. Such conditions of "mixed epitaxy," which can occur in deference to "unique epitaxy," require careful evaluation and understanding for the epitaxial growth of the tetragonal chalcopyrite semiconductors.

In the course of study of the reactor growth conditions an n-type phase of the $ZnSiAs_2$ chalcopyrite was observed. Previous work has indicated that bulk $ZnSiAs_2$ is inherently a p-type semiconductor (2, 4), although conversion to n-type conductivity has been reported using an arsenic annealing process following bulk crystal growth (5, 6). The interest in characterizing the electrical properties of both the p- and n-type $ZnSiAs_2$ led to the use of chromium-doped semi-insulating GaAs substrates for electrical isolation of the epitaxial layer from the substrate. The use of GaAs (Cr) has resulted in the identification of what appears to be an autodoping effect involving the outdiffusion of Ga from the substrate into the epitaxial layer. This problem was studied by secondary ion mass spectrometry (SIMS).

Materials Synthesis

The details of the horizontal reactor and the reactant distribution system used for the CVD of $ZnSiAs_2$ have been previously described (1). The growth system employs elemental Zn, SiH_4, and AsH_3 as reactants with H_2 as the carrier gas. The Zn is transported into the deposition region through physical evaporation from a Zn melt maintained at 610°C into a flowing H_2 carrier gas stream. The SiH_4 and AsH_3 reactants enter the reactor downstream from the Zn source, and the overall reaction is controlled primarily through the pyrolysis of SiH_4 which is apparently catalyzed by the presence of the Zn vapor. The film growth rate is linearly dependent on the SiH_4 flow rate for a range of growth conditions required for epitaxial growth, and these conditions will be subsequently discussed.

The Ge substrates were obtained from the vendor[1] chemically polished and ready for use. The GaAs substrates were purchased[2] either polished or as-sawn, depending on the availability of polished substrates. The unpolished GaAs was polished chemically, using an $Na_2CO_3/NaOCl/H_2O$ solution which was followed by an $NaOCl/H_2O$ solution. The results to be described here were obtained primarily on Ge and GaAs substrates with (100) orientations. These Ge substrates were n-type arsenic-doped crystals having a room temperature electron concentration of nominally 10^{18} cm^{-3}. The GaAs substrates were n-type undoped crystals with a nominal electron concentration of 7×10^{16} cm^{-3}. In addition, work has been conducted using Cr-doped semi-insulating GaAs substrates to facilitate Hall effect measurements on both the p-type and n-type $ZnSiAs_2$ deposits. Some experiments have been carried out using p-type Ge and GaAs substrates, and other substrate orientations have also been investigated. Preliminary work using (111)-oriented substrates has been carried out for both Ge and GaAs, and results were obtained for GaAs substrates which have been misoriented between 2° to 3° from the (100) to the (110) orientation.

In the standard growth sequence, the substrates are brought to the growth temperature and the reactant flows are initiated and terminated simultaneously. Following deposition at the growth temperature of approximately 650°C, the substrates are then cooled to near room temperature at a rate of 50°C/min and removed from the reactor. Epitaxial growth was achieved on clean prepolished substrates without *in situ* HCl vapor etching prior to deposition.

General Results

The growth temperature for the synthesis of $ZnSiAs_2$ by CVD was found to be above approximately 600°C in order to prevent the formation of second-phase structures of Zn_3As_2 and $ZnAs_2$, and to be below about 700°C to prevent the thermal decomposition of $ZnSiAs_2$ which generally led to an Si-rich phase (1). Through careful systematic study of the growth conditions, we have consistently and routinely achieved unique epitaxial growth of $ZnSiAs_2$ in the temperature range of 650°-670°C. The range of these growth conditions for the reactor described in Ref. (1) are stated in Table I.

These conditions result in epitaxial growth of (001) $ZnSiAs_2$ on (100) substrates of both Ge and GaAs. While less extensive experimentation has been carried out on (111) substrates, the general conditions in Table I have also led to epitaxial growth on this substrate orientation. Surface morphology on (100) Ge and GaAs substrates has varied from a dull gray to a metallic-mirrorlike finish. However, it has been more difficult to routinely achieve the mirrorlike morphology. Figure 1a illustrates the surface morphology, and for comparison Fig. 1b shows a micrograph of a polycrystalline deposit obtained at different growth conditions. The layers crystallized in the chalcopyrite structure with lattice constants measured by x-ray diffraction of a = 5.60Å and c = 10.88Å, in agreement with other published values (2).

In experiments using high SiH_4-to-Zn vapor ratios (greater than 4/1 SiH_4/Zn flow rates) n-type deposits were identified by thermal probing of layers grown on Ge substrates. These n-type layers were initially identified in experiments which were intended to study and extend the deposition region in the reactor.

The deposits were subsequently found to be a unique characteristic of the growth conditions in the reactor, which were not influenced by the type of substrate used. These n-type layers have been observed on Ge, GaAs, Si, and quartz substrates. The deposits are polycrystalline and have the correct constituent compositions, as determined from electron microprobe measurements compared to the same measurements on p-type deposits. The composition of the n-type deposits are relatively sensitive to the vapor phase reactant ratios. In-depth studies of the formation and properties of these n-type deposits will be the subject of future work.

Growth of Tetragonal $ZnSiAs_2$

$ZnSiAs_2$ crystallizes in the chalcopyrite[3] structure which has tetragonal symmetry. It can be viewed as two stacked zincblende unit cells as illustrated in Fig. 2. The (100) and (010) chalcopyrite orientations are not equivalent to the (001) orientation. In particular, the (001) axis is the only crystallographic direction with fourfold symmetry for the chalcopyrite structure, while both the (100) and (010) axes exhibit twofold symmetry. This is due to the ordered arrangement of Zn and Si atoms on the "A" sublattice.[4] The "B" lattice is occupied solely by the As atoms. It should be noted that the twofold symmetry axes exist because of the ordered arrangement of the two different atoms that occupy the "A" lattice and not as a result of the slight difference in the pseudocubic lattice dimension, a', along the c-axis direction (*i.e.*, $a' = c/2$ *vs.* a; see Fig. 2). In fact, for several of the chalcopyrites such as $CdGeAs_2$ $a' = a$ and $c/a = 2.00$. However, because of the ordered arrangement of Cd and Ge, the structure is still tetragonal. The significance of this fact is that the epitaxial growth of either the (100), (010), or (001) chalcopyrite orientations on a cubic (100) substrate is possible, but not equivalent.

[3] Same crystal structure as the mineral chalcopyrite, $CuFeS_2$, which is a tetragonal structure [Ref. (2), p. 3].

[4] We use the terminology that is commonly used for the III-V compounds in which the Group III atoms are viewed as occupying one of two interpenetrating fcc lattices denoted as the "A" lattice.

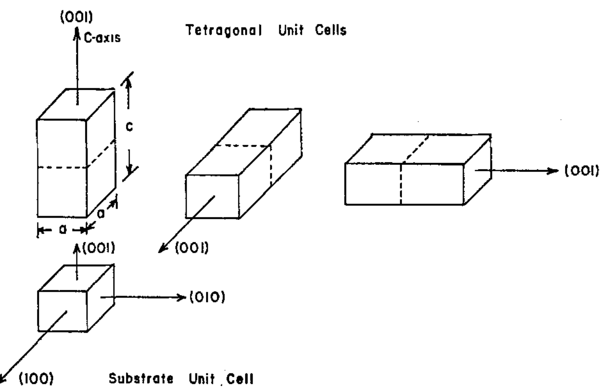

Fig. 3. Illustrations of the three possible epitaxial chalcopyrite orientations on a (100) cubic substrate.

The three possible chalcopyrite epitaxial unit cell orientations on a (100) cubic substrate are illustrated in Fig. 3. A similar situation also exists for the epitaxial growth of a (112)-oriented chalcopyrite on a (111) cubic substrate. For convenience, the definition "mixed epitaxy" will be used to describe a growth consisting of epitaxially deposited domains in which the c-axes of the various domains are not all parallel. A second definition termed "unique epitaxy" denotes the desired situation in which a true single crystal orientation with a unique c-axis direction is achieved throughout the grown layer.

The results of our investigation to date show that $ZnSiAs_2$ has been deposited with the chalcopyrite structure. This is clearly seen from the x-ray diffraction pattern shown in Fig. 4. This figure, taken for convenience on a polycrystalline sample, shows the splitting of the (100) and (110) reflections into the (020), (004) and (220), (024) doublets, respectively,

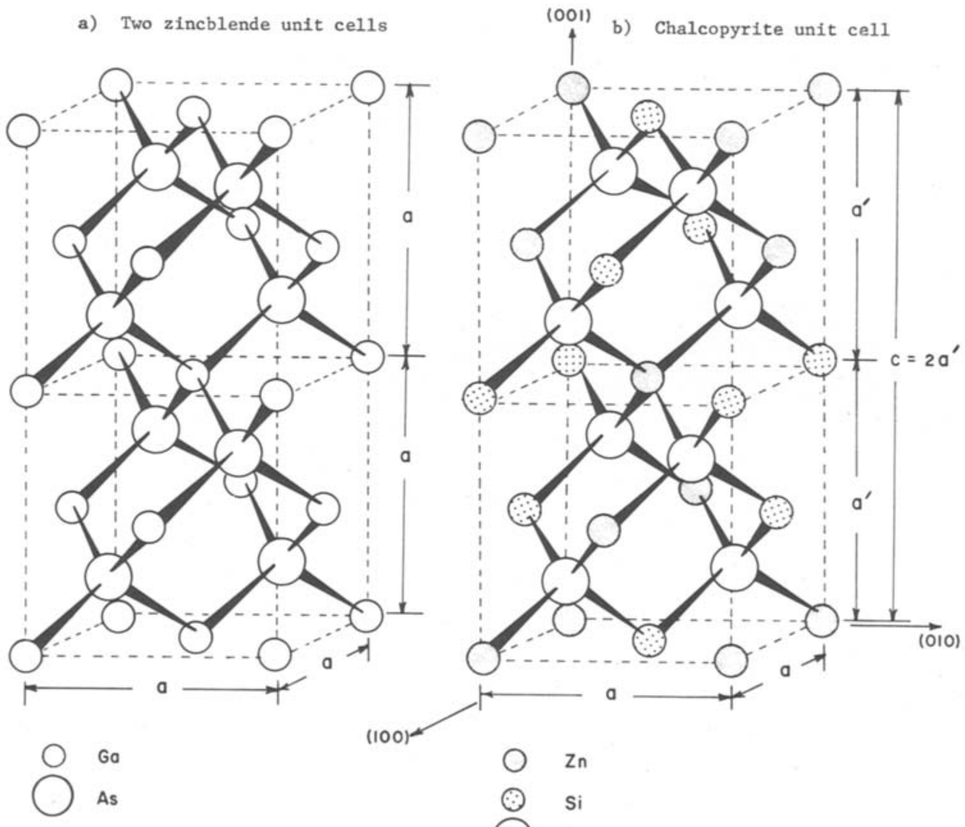

Fig. 2. Comparison of zinc blende and tetragonal chalcopyrite structures.

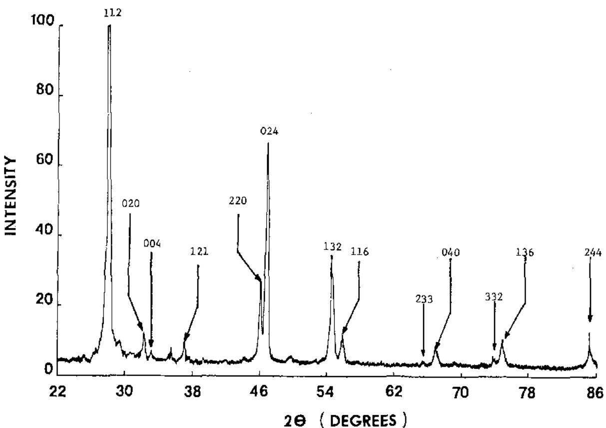

Fig. 4. X-ray diffraction pattern for a polycrystalline layer of $ZnSiAs_2$ having the tetragonal chalcopyrite structure. The Miller indexes for the various reflections are shown in the figure (CuKα radiation).

which is characteristic of the tetragonal chalcopyrite structure. In this work, both mixed and unique epitaxial growth have been observed with either (100) or (111) orientations of Ge and GaAs substrates. Table II compares the conditions that have led to the growth of the mixed epitaxy and unique epitaxy deposits.

As one would expect, the preferred orientation was (001) for unique epitaxial growth of $ZnSiAs_2$ on (100) Ge and GaAs substrates. However, of the three possible c-axis orientations available for the growth of (112) $ZnSiAs_2$ on (111) Ge and GaAs the one which is preferred appears to be the one that gives the c-axis oriented closest to the surface normal. Thus the (111) substrates apparently should be intentionally misoriented toward a (110) direction by several degrees.[5] This is a tentative conclusion at this time and needs to be investigated in greater depth.

Figure 5 is an x-ray diffraction pattern which shows the desired (001) $ZnSiAs_2$ orientation on (100) Ge or GaAs which is the unique epitaxial deposit obtained from the conditions listed in Table II. Figure 6 shows the pattern for the mixed epitaxial case. It was found that conditions of high AsH_3 flow rate caused the (010) $ZnSiAs_2$ to grow in preference to the (001) orientation, although the presence of the (001) orientation was still evident. The growth conditions were not optimized to enhance this growth habit. This case is illustrated through the x-ray diffraction pattern shown in Fig. 7. From these figures, it is seen that the (001) orientation can be deposited essentially to the exclusion of the (010) or (100) orientation and the reverse is also apparently possible. Sample 120B (see x-ray diffraction pattern in Fig. 7) was very close to this condition. The quality of this layer was somewhat poorer as evidenced by the broad, poorly defined peak. It is believed that the structural quality of the (010)-oriented material can be improved due to the existence of the reasonably well-resolved (040) peak seen in Fig. 6. However, this orientation has two possible and nearly equally probable c-axis orientations at right angles to each other and in the plane of the layer. It is expected that by tilting the substrate normal toward one of the (100) directions, a single c-axis orientation will be favored. This hypothesis has not been verified at the present time.

[5] The cases observed to date were on (111) Ge substrates with about 5° misorientation.

Table II. Table of growth conditions that have led to mixed epitaxial growth and unique epitaxial growth on Ge and GaAs substrates

	Mixed epitaxy	Unique epitaxy
Growth temperature (°C)	630-640	650-675
Zn flow rate (sccm)	3.8-5.0	3.8-5.0
SiH_4 flow rate (sccm)	12-15	6.5-8.0
AsH_3 flow rate (sccm)	12-30	6.5-10.0
Total flow rate (sccm) (H_2 balance)	4400	4400

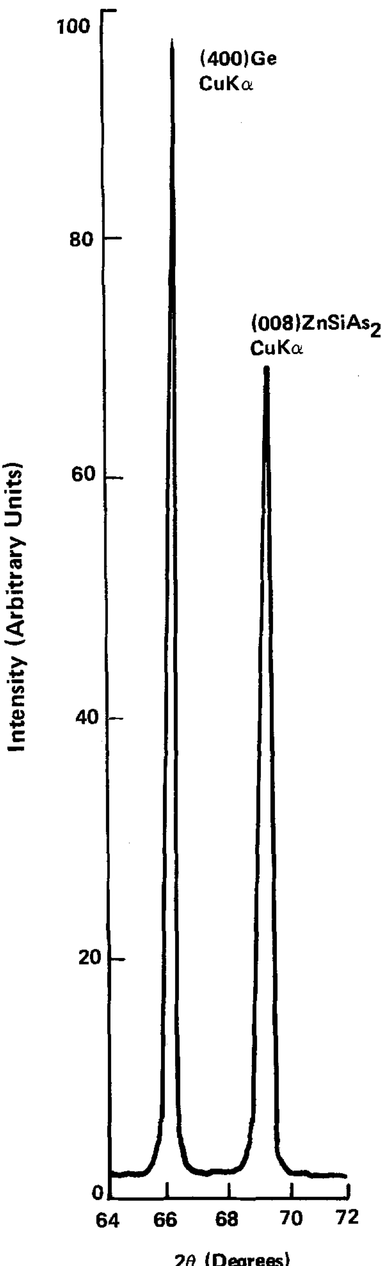

Fig. 5. X-ray diffraction pattern showing unique epitaxy deposition as evidenced by appearance of (008)$ZnSiAs_2$ reflection only.

Electrical Properties and Autodoping

The Ge and GaAs substrates used in this work have had some influence on the evaluation of the electrical properties of the $ZnSiAs_2$ layers. For example, the p-type epitaxial layers grown on n-type Ge were tested with a thermal probe and studied by Hall effect measurements. However, the electrical isolation between the Ge substrates and the epitaxial layers was generally poor. Thus, the interpretation of the Hall effect measurements is difficult and the influence of the substrate on these measurements is hard to ascertain. For these reasons Cr-doped semi-insulating GaAs substrates were the appropriate choice for growing layers suitable for Hall effect measurements. The use of these substrates resulted in good electrical isolation with the epitaxial layer.

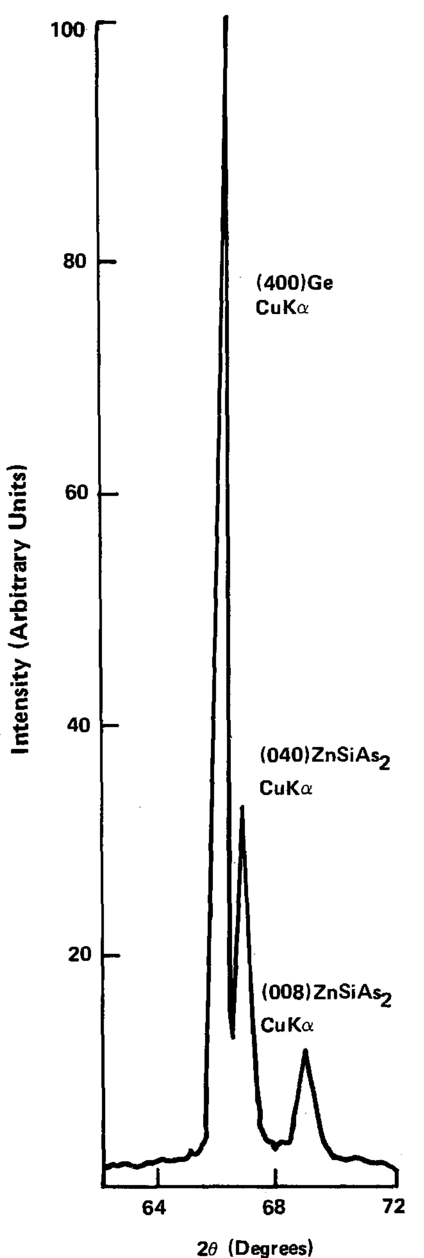

Fig. 6. X-ray diffraction of $ZnSiAs_2$ showing mixed epitaxy deposition as evidenced by appearance of both the (008) and (040)$ZnSiAs_2$ reflections.

The deposits on GaAs(Cr) substrates for the growth conditions listed in Table I are p-type with hole concentrations ranging from 5×10^{18} cm^{-3} to 5×10^{19} cm^{-3}, with 2×10^{19} cm^{-3} typically observed. These concentrations are relatively insensitive to the variation in growth conditions listed in Table I. Hole mobilities of 40-50 cm^2/Vsec are typical of these p-type layers. The insensitivity of the hole concentration to growth conditions suggested the possibility of an impurity problem arising from the substrate. For this reason secondary ion mass spectrometry (SIMS) was employed to analyze the layers and the interfacial region between the layer and substrate. These studies were conducted on $ZiSiAs_2$ layers grown on both Ge and GaAs.

Figures 8 and 9 show SIMS profiles of $ZnSiAs_2$ grown on a Ge and GaAs substrate, respectively. The $ZnSiAs_2$ grown on (100) Ge appears to be relatively uniform and exhibits a reasonably abrupt interface. However, the $ZnSiAs_2$ grown on (100) GaAs substrates shows a significant amount of Ga outdiffusion from the substrate into the $ZnSiAs_2$ layer. Since Ga has been reported to be an acceptor-like impurity for $ZnSiAs_2$ (4), these results suggest that an autodoping effect is present which could explain why the layers grown on semi-insulating GaAs substrates consistently resulted in heavily doped p-type $ZnSiAs_2$ layers, for which the background hole concentration was relatively insensitive to growth conditions. Finally, it is apparent that this choice of substrate is not an appropriate vehicle for Hall effect measurements unless steps can be taken to eliminate the autodoping mechanism. This type of problem has been prevalent in the growth of GaAs on Ge substrates, and in the GaAs/Ge system could be circumvented by capping the back side of the substrate with an encapsulant such as SiO_2 (7).

Summary and Conclusions

The open tube vapor phase epitaxial growth technique has been used to synthesize epitaxial layers of $ZnSiAs_2$. Of particular significance is the fact that the noncubic (tetragonal) structure admits well-defined growth conditions that result in truly epitaxial growth.

While $ZnSiAs_2$ does exhibit some degree of tetragonal distortion (c-axis compression gives a c/a ratio of 1.92), it is not known whether this is necessary in order to favor the growth of the (001) orientation over the (100) orientation. It would be necessary to study the deposition of a material such as $ZnSnP_2$ which has a c/a ratio of exactly 2.0 in order to determine whether some degree of c-axis compression is necessary to demonstrate the preference of the (001) over the (100) orientation. It is suggested here that it is the nature of the bonding rather than the lattice spacing that is crucial to the growth of one of these orientations over the other.

At this point, the high carrier concentrations encountered in these films remain a serious problem. Since an autodoping mechanism appears to be present, the high concentrations are not believed to be indicative of the inherent properties of $ZnSiAs_2$, but are more dependent on the choice of substrate and/or growth conditions. In fact, recent work using an organometallic Zn source has resulted in hole concentrations near 10^{18} cm^{-3}, which further supports this conclusion. Additional studies are underway to determine conditions for achieving much lower carrier concentrations.

The formation of n-type $ZnSiAs_2$ has been particularly encouraging in view of the earlier evidence that the chalcopyrites may have type-conversion problems similar to the II-IV compounds. Our results suggest the possibility of $ZnSiAs_2$ p-n junction formation, which is essential if this is to be a useful device material.

Implantation Gettering of Gold in Silicon

M. J. T. Lo,*[,1] J. G. Skalnik,* and P. F. Ordung

Department of Electrical and Computer Engineering, University of California, Santa Barbara, California 93106

ABSTRACT

Neutron activation techniques were used to study the efficiency of ion-implantation gettering of gold in gold-equilibrated silicon samples. The implantation species was 150 keV argon ions. An ion dose of 1×10^{16} Ar/cm^2 was found to be optimum. Within the range of ion current density investigated, the gettering efficiency increased with the ion current density. Implantation performed at a high temperature provided less gettering than that performed at a lower temperature. A postannealing temperature of either 900° or 1000°C could be superior to 1100°C in gettering gold, provided enough gettering time was allowed.

The optimum conditions for ion-implantation gettering were applied to a typical MOS processing cycle on as-recieved silicon samples. For an ion dose of 1×10^{16} Ar/cm^2, a total gettering time of 8 hr at 1000°C increased the MOS generation lifetime significantly compared with that for a control sample. The data from the MOS generation lifetime study are consistent with the results of the neutron activation analysis.

Ion-implantation gettering basically consists of two processing steps; namely, creation of an ion-damaged layer followed by gettering at an elevated temperature. Parameters of each step might influence the efficiency of the gettering. Buck *et al.* (1) found that increasing the gettering time increases the amount of gold gettered. The amount of gold gettered was also found to increase with gettering temperatures between 850° and 1150°C (2). Thus, the residual disorder after annealing seemed to be jointly dependent upon the temperature and time of the annealing (1-5).

Seidel, Meek, and Cullis (2) found that the efficiency of gettering gold by an ion-damaged layer was related to the amount and type of disorder after annealing, and that argon-damaged layers gettered gold more efficiently than layers damaged by other ions. The residual disorder after annealing was found to be dose dependent for various ion species (3, 6, 7). In the absence of good thermal contact between the sample and the sample holder, a high-current high-dose implantation may cause *in situ* sample heating and affect both the as-implanted disorder and the final disorder after annealing (3, 8). Using ion-implantation gettering, Nassibian *et al.* (9) were able to increase the MOS generation lifetime, but the increase was not reproducible.

The present study investigates the effect of several parameters of ion implantation and postannealing on the efficiency of gold gettering in gold-equilibrated silicon. Neutron activation techniques are used as the main investigative tools. The optimum conditions of ion-implantation gettering are applied to as-received silicon samples to study the effect on MOS generation lifetime. This work was not intended to investigate the detailed nature of the damage created by the ion implantation.

The following sections outline the experimental procedures used and include the results of a neutron activation analysis. The effect of ion-implantation gettering on the MOS generation lifetime is described. Finally, a general discussion of the results is given.

Experimental Procedures

For the study of gold gettering in silicon, (100) p-type 10-20 Ω-cm silicon wafers were scribed and cleaned. About 1000Å of Au was evaporated onto both sides of the sample. The sample was then equilibrated with Au at a temperature of 1080°C in a nitrogen ambient for about 6 hr. The gold-diffused samples were first dipped in buffer HF with ultrasonic agitation to remove the silicon oxide at the surface. A DI water rinse followed. The samples were then immersed in aqua regia for a few minutes and the samples were again rinsed in DI water.

A silicon etching technique was used to remove the surface pile-up of gold in silicon. The solution was composed of HF, HNO_3, H_2O, and $HC_2H_3O_2$. Based on our neutron activation analysis, the removal of 1.5 mils from each side of the sample was more than sufficient to remove the excess Au at the surface. One side of the sample was polished with Lustrox solution. The unpolished side was covered with 1 μm of CVD SiO_2, which was deposited at 380°C.

The unpolished side of the sample was attached to the sample holder with indium, which served as a good thermal contact during the implantation. Throughout all the implantation runs, Ar ions of 150 keV were selected and implanted into the polished side of each sample. Parameters such as ion dose, ion current density, and substrate temperature were separately varied from sample to sample. For each sample, all these parameters were carefully monitored.

After implantation, the indium was removed with hydrochloric acid and the CVD SiO_2 was removed with buffer HF. After cleaning, the samples were coated with CVD SiO_2 of about 1 μm on both sides to prevent possible outdiffusion of gold during the annealing. The samples were then annealed at temperatures between 900° and 1100°C for various time periods between one-quarter hr and 5 hr. After the gettering, the samples were packed with plastic and inserted into a plastic vial. The vial was then ready for neutron activation.

The technique of neutron activation analysis was used to determine the amount of gold contained in each silicon sample. The removal of a silicon layer by etching with a solution of HF, HNO_3, H_2O, and $HC_2H_3O_2$ was performed alternately with counting of gamma rays from the sample. The amount of gold contained in the damaged layer was determined as the difference in the amounts of gold contained in the sample before and after the removal of the damaged layer. The ratio of the amount of gold gettered in the damaged layer to the amount of gold contained in the whole sample was defined as the percentage of gold gettered by the damaged layer, or the gettering efficiency.

[1] Present address: Xerox Corporation, El Segundo, California 90245.

Key words: gettering, neutron activation, gold, lifetime.

The neutron activation was carried out either with the L-77 reactor at UCSB or the R-1 reactor at UCLA. For the L-77 reactor, the activation was performed at a flux density of 3×10^8 neutrons/(cm^2) (sec) for 3 hr. For the R-1 reactor, the activation was performed at a flux density of 1.5×10^{12} neutrons/(cm^2) (sec) for a half hour.

A thallium activated NaI detector was used to detect the gamma rays generated from the isotope ^{198}Au. The energy of the gamma ray is 0.412 MeV. The half-life of ^{198}Au is 2.7 days.

Results of Neutron Activation Analysis

The gettering was performed at 1100°C for 5 hr. Four substrate temperatures were chosen to study the dependence of gettering efficiency on the substrate temperature during the implantation. To achieve a high substrate temperature, a heater was installed directly under an aluminum substrate holder to heat the substrate to either 212° or 400°C. The heater was under vacuum during the implantation and the temperature was maintained constant by a temperature controller. For low temperature implantation, a hollow aluminum substrate holder was filled with water or liquid nitrogen for 35° or −196°C. All temperatures were monitored by a digital meter throughout the entire implantation process.

As shown in Fig. 1, the gettering efficiency increased with decreasing substrate temperature. This is believed to indicate increased disorder for ion implantation at decreased substrate temperatures. At each substrate temperature, the gettering efficiency is found to be higher for a dose of 1×10^{16} Ar/cm^2 than for 6×10^{15} Ar/cm^2.

The amount of gold detected before and after the removal of the CVD layer on the implanted side was always the same for each sample. This indicates that gold does not diffuse into the SiO_2 from the damaged silicon layer at 1100°C.

The projected range of 150 keV Ar ions in silicon at an incident angle of about 7° is known to be less than 1 μm (3, 9). The layer of silicon which getters gold is thus expected to be not more than 1 μm in depth. However, all samples which received a gettering cycle at 1100°C for 5 hr appeared to contain, to a depth of as much as 10 μm, a gold concentration higher than the equilibrated level.

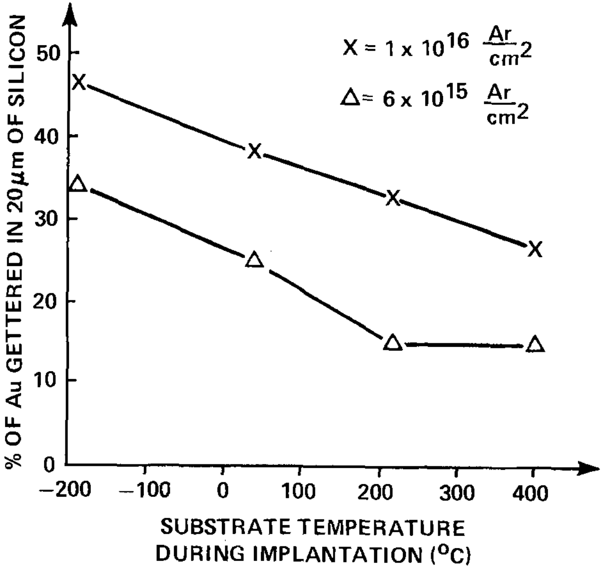

Fig. 1. Gettering efficiency vs. substrate temperature during implantation. The common conditions for all samples are Ar^+, 150 keV, 7° incident angle, 1.68 μA/cm^2, 5-hr postannealing at 1100°C. Samples are 406 μm thick.

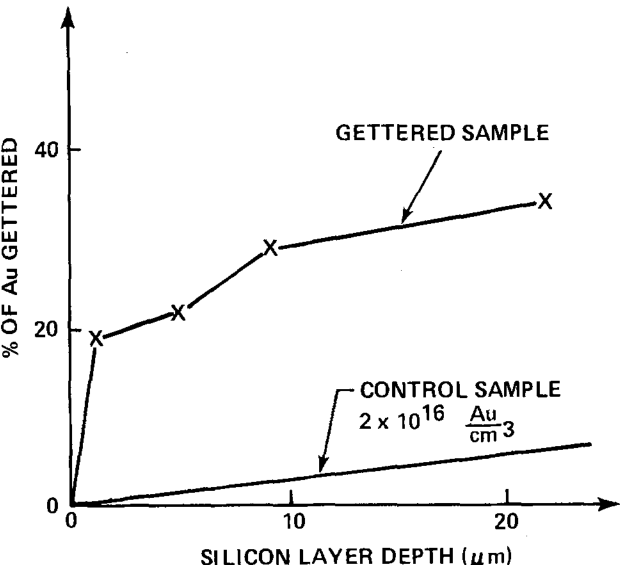

Fig. 2. A plot of percentage of gold gettered vs. the associated total layer depth of silicon in μm. Gettered sample is implanted with 1×10^{16} Ar^+/cm^2, 150 keV, 7° incident angle, 1.68 μA/cm^2, 212°C; postannealing at 1100°C for 5 hr was applied to both gettered and control samples; 396 μm thick.

Figure 2 gives an example of the distribution of gold impurities in layers up to about 20 μm. The percentage of gold gettered is plotted as a function of the total layer depth of silicon measured from the surface of the damaged side of the sample. The slope of each line connecting adjacent data points is proportional to the concentration of gold in that region. The straight line at the bottom of the figure shows an experimental result for a control sample which was uniformly equilibrated with gold to a concentration of 2×10^{16} Au/cm^3. Since the control sample also received a 5 hr gettering anneal at 1100°C, the gold distribution in this control sample indicates that the Si-SiO_2 interface does not getter Au during the gettering anneal. Figure 2 also shows that the gold concentration at depths up to 10 μm is higher than that for the control sample. Back-diffusion of gold from the gettered region to the bulk silicon is thought to be the cause.

To confirm the back-diffusion of gold from the gettered region after a 5 hr annealing cycle at 1100°C, samples receiving implantation under a fixed set of conditions were annealed at 1100°C for various time periods ranging from one-quarter hr to 5 hr. The result is shown in Fig. 3. Each number on the various curves represents an experimental point. The number indicates the number of hours of annealing at 1100°C. As the annealing proceeds, gold gradually moves toward the damaged region which is within 1 μm of the silicon surface. The amount of gold gettered in 1 μm depth of silicon increases with annealing time up to about 1 hr. For the curves with an annealing period of 1 hr or less, the gold concentration is higher than the equilibrating level only within a depth of 2 μm. A significant observation is that gold starts to be released by the damage and diffuses back to the bulk silicon after annealing at 1100°C for about 1 hr This fact is evidenced by comparing curves numbered "3" and "5" with that numbered "1." In the curves numbered "3" and"5," the gold concentration in the region between 6 and 12 μm is higher than the equilibrated level as indicated by the slope of the lines being larger than that for the control sample.

It is believed that after about 1 hr of annealing the damage created by the ion implantation, which has the set of conditions described in Fig. 3, starts to be annealed (3). The driving force for the gold gettering is

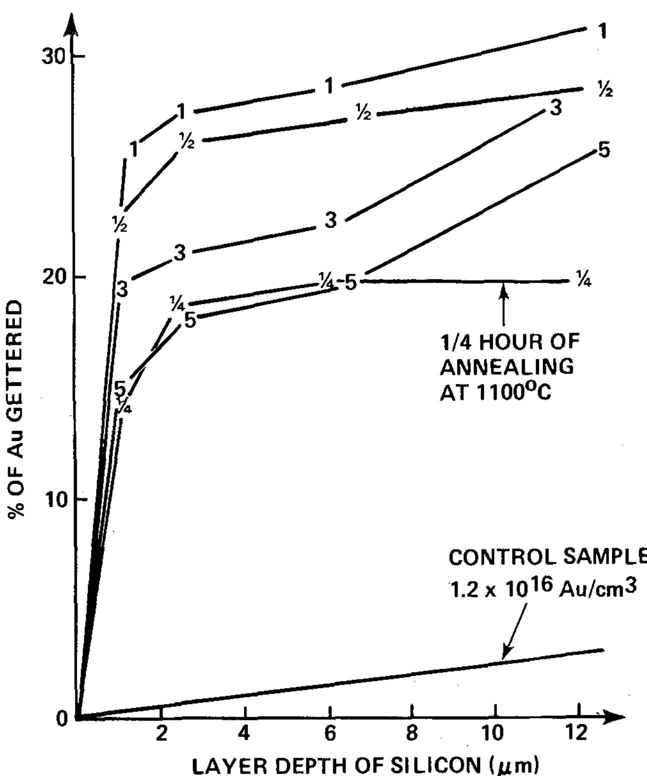

Fig. 3. Percentage of gold gettered vs. total layer depth of silicon on the implanted side. The parameter is number of hours of annealing at 1100°C. The common conditions of implantation for all samples are: 1×10^{15} Ar^+/cm^2, 150 keV, 7° incident angle, 1.68 $\mu A/cm^2$, 35°C. Samples are 406 μm thick.

thereby decreased and gold atoms are released in the damaged region. The gold concentration gradient causes gold atoms to diffuse back to the bulk silicon.

Three temperatures, 900°, 1000°, and 1100°C were selected to study the annealing-temperature dependence of gettering. The gettering efficiency is plotted as a function of annealing time for each temperature in Fig. 4. Each experimental point on a given curve in Fig. 4 was obtained from a given individual sample. Although the curve associated with 1100°C retrogrades after a 1 hr annealing cycle, the curves for 900° and 1000°C indicate a gettering efficiency that increases monotonically with annealing time to 5 hr. The curve for 1000°C is higher than that for 1100°C after about 1.75 hr. Also, the curve for 900°C exceeds that for 1100°C after about 2.5 hr.

In the first half-hour of annealing, the gettering efficiency is higher for a higher temperature. Basically the diffusivity of gold in silicon dominates the gettering process in the initial period of annealing. According to the result shown in Fig. 4, it is clear that the gettering temperature and time must be carefully chosen to achieve a desired gettering efficiency.

The dependence of the gettering efficiency on the ion dose and ion current density is illustrated in Fig. 5. The ion dose ranging from 6×10^{14} cm^{-2} to 2.5×10^{16} cm^{-2} is indicated on a log scale. Three ion current densities with a ratio of 1:2:4 are also specified.

At each ion current density, the gettering efficiency increases with ion dose to a value of about 1×10^{16} cm^{-2}, which is believed to be an optimum dose for efficient ion-implantation gettering. The relatively high value of 3.36 $\mu A/cm^2$ ion current density appears to getter gold more efficiently than the two lower ion current densities. It should be noted that the substrate temperature was held constant at 45°C during the implantations.

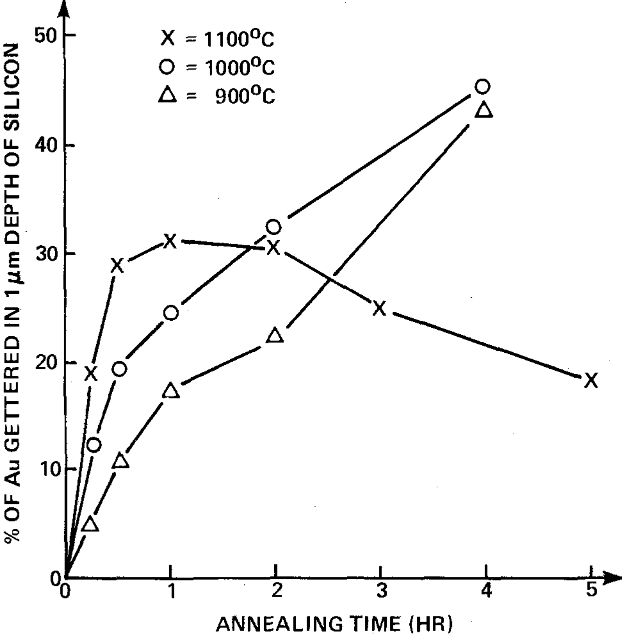

Fig. 4. Gettering efficiency vs. annealing time at various annealing temperatures. The common conditions of implantation for all samples are: 1×10^{15} Ar^+/cm^2, 150 keV, 7° incident angle, 1.68 $\mu A/cm^2$, 45°C. Samples are 280 μm thick.

MOS Generation Lifetime

The generation lifetime of an MOS capacitor is a parameter which heavily depends on the quality of the bulk silicon. The generation lifetime is inversely proportional to the density of generation centers for electron hole pairs. Therefore, it is appropriate to monitor the effect of ion-implantation gettering on the generation lifetime of an MOS capacitor.

To simulate standard MOS processing, MOS capacitors were built on as-received silicon samples in which no gold impurity was intentionally added. In addition, during the ion-implantation step, there was no indium between the sample and the sample holder. The beam heating effect in this case may be different from that in which indium serves as a thermal contact to the sample during the implantation. However, it was felt that the absence of indium corresponds more nearly to industrial practice.

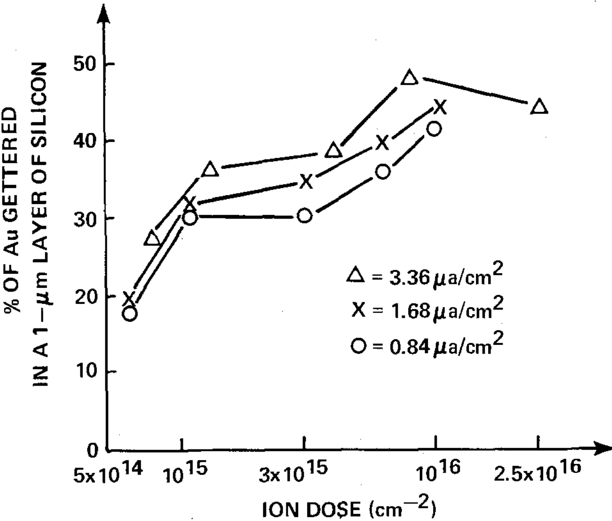

Fig. 5. Gettering efficiency vs. ion dose on a log scale. The parameter is ion current density. The common conditions of implantation for all samples are Ar^+, 150 keV, 7° incident angle, 1.1 hr postannealing at 1100°C. Samples are 280 μm thick.

Two Czochralski-grown p-type, 16 Ω-cm silicon wafers with a diameter of 2 in. and a thickness of 16 mils were scribed so that the comparison of generation lifetime could be made on pieces from the same wafer. The samples received an RCA cleaning (10). After the cleaning process, one sample from each wafer was not implanted and served as a control sample. The rest of the samples received back-side Ar implantation with a dose of either 1×10^{15} or 1×10^{16} cm^{-2}, at 150 keV and 2.2 $\mu A/cm^2$.

A temperature of 1000°C was used for the gettering and the oxidation. The implanted samples received various gettering periods in nitrogen before the oxidation cycle. The oxidation was performed in dry oxygen for 2.5 hr to grow 1100Å of SiO_2. Finally, the ambient was switched to nitrogen for a half hour to reduce the fixed-charge and surface-state densities.

A layer of 5000Å of aluminum was evaporated onto the front side of each sample. A mask which contains an array of circular dots surrounded by guard rings was used to define a pattern for the aluminum layer. To form an ohmic contact, the oxide on the back side of the samples was removed and 5000Å of aluminum was evaporated onto the back side of the samples.

Finally, an anneal was carried out at 450°C in forming gas for 20 min. The samples were then ready for C-t measurement.

A pulsed technique was used for the measurement of the minority carrier generation lifetime in the bulk silicon of an MOS capacitor. Conceptually, the pulsed technique measures the generation lifetime in silicon by observing the rate at which the inversion layer forms in an MOS capacitor after being pulsed to a deep-depletion condition (11). The transient response of the pulsed MOS capacitor was recorded as a plot of the capacitance of the MOS capacitor as a function of time.

Schroder and Guldberg (12) developed a simple approximate theory in which the C-t curve is fitted by a straight line. If t_F is the time required to form the inversion layer, an approximate equation for the extraction of the generation lifetime, τ_g, from the C-t plot was derived as follows

$$\tau_g = \frac{n_i}{8N_A} \frac{C_F}{C_{ox}} t_F \left(1 + \frac{C_o}{C_F}\right)^2$$

where n_i = intrinsic carrier concentration, N_A = doping density of the substrate, C_o = initial capacitance of pulsed MOS capacitor, C_F = final capacitance of pulsed MOS capacitor, and C_{ox} = oxide capacitance. This equation is convenient for a rapid evaluation of the generation lifetime of carriers in a large number of devices.

Table I. Comparison of the generation lifetime of the implanted samples with that for the control sample

Sample		Average generation lifetime (μsec)
Control sample		555
Ion dose (cm^{-2})	Gettering cycle at 1000°C	
1×10^{16}	O_2 2.5 hr N_2 0.5 hr	600
1×10^{16}	N_2 5.0 hr O_2 2.5 hr N_2 0.5 hr	918
1×10^{15}	O_2 2.5 hr N_2 0.5 hr	Same as control sample
1×10^{15}	N_2 5.0 hr O_2 2.5 hr N_2 0.5 hr	Shorter than control sample

Since the silicon surface was observed not to be inverted at zero bias, the guard ring was left floating. A C-t plot was performed and the generation lifetime determined for each MOS capacitor. The generation lifetime for each implanted sample was compared with that of the control sample, as shown in Table I. The average generation lifetime of the control sample is 555 μsec. When the total annealing time is only 3 hr, the improvement of the generation lifetime is insignificant for both dose levels. As the total annealing time is increased to 8 hr, the sample receiving a dose of 1×10^{16} cm^{-2} had an average generation lifetime of 918 μsec. The generation lifetime mapping of this sample is shown in Fig. 6. On the other hand, the sample receiving a dose of 1×10^{15} cm^{-2} and 8 hr of annealing had an average generation lifetime slightly shorter than that of the control sample. The slight reduction of the average generation lifetime could be due to local defects. It may also be due to the capture of the reduced damage by the oxidized front side of the silicon sample (4).

Discussion and Conclusion

Thirty minutes of annealing was found to be insufficient for efficient gettering, especially for 900° and 1000°C. On the other hand, ion damage is more permanent when the annealing is carried out at a lower temperature. High temperature annealing for a long time tends to anneal out the damage and reduce the gettering capability.

In the present work, the maximum gettering efficiency of gold is 50%. This corresponds to a few times 10^{18} Au/cm^3 in the gettered region. It is suspected that, at such a high gold concentration, the gettering capability is probably saturated. In the as-received wafer in which no gold is intentionally added, the gold concentration is expected to be 10^{14} Au/cm^3 or less (13). Thus, saturation should not occur and the gettering efficiency is expected to be higher than 50%.

The implantation process performed during normal device fabrication may not include a good thermal contact between the wafer and the wafer holder. In the absence of a good thermal contact, the wafer may be appreciably heated by the high energy ions. For instance, at an ion energy of 150 keV, an ion current density of 1.68 $\mu A/cm^2$ may heat the wafer to 204°C.

The gettering efficiency of gold increases with increasing ion current density and decreases with increasing substrate temperature. In general, the gettering efficiency may be expected to increase with the ion current density until the associated substrate temperature effect is large enough to dominate. For higher current densities, the gettering efficiency will decrease.

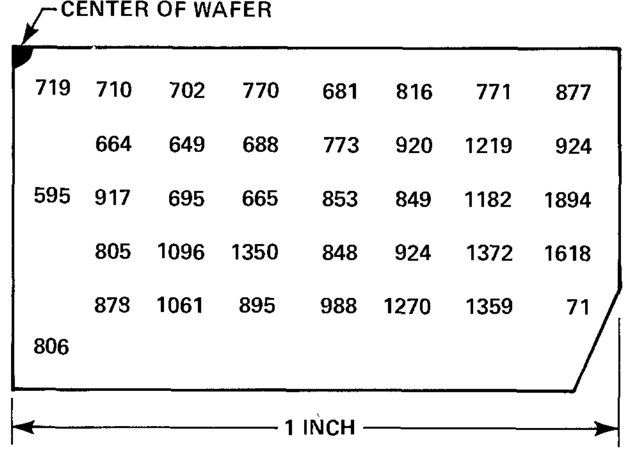

Fig. 6. Generation lifetime mapping of a gettered sample, in μsec. The conditions of implantation are 1×10^{16} Ar^+/cm^2, 150 keV, and 2.2 $\mu A/cm^2$. The average generation lifetime is 918 μsec. The 8 hr annealing cycle is listed in Table I.

Stacking Faults and Substructure in GaAs/(Ga,Al)As Heteroepitaxial Layers

I. Origin and Elimination

ABSTRACT

The origin of stacking faults and substructure observed in (Ga,Al)As layers grown by liquid phase epitaxy on Syton polished GaAs substrates has been studied. The stacking faults primarily originate at the substrate-epilayer interface. These faults presumably occur to accommodate misfit between coalescing islands observed in the early growth studies of heteroepitaxy of (Ga,Al)As on these substrates. The island-like growth appears to correlate with calcium contamination associated with the Syton polished substrates. In addition, dislocation substructure has been observed in (Ga,Al)As and GaAs epi-layers grown on Syton polished substrates. In the case of isoepitaxial layers, no stacking faults are seen. Thus growth of a buffer layer of GaAs eliminates the stacking faults but not the substructure. It is therefore suggested that the dislocation substructure arises from the replication of dislocations present in deformed surface regions of Syton polished substrates. On the other hand, heteroepitaxial layers of (Ga,Al)As grown on Br-methanol polished substrates are largely free from these structural defects.

Stacking faults (SF's), faulted loops, and dislocation tangles in (Ga, Al)As epi-layers, grown on GaAs substrates either by liquid phase epitaxy (LPE) or by vapor phase epitaxy (VPE), have been observed by several investigators (1-3). It is generally recognized that SF's originate at the substrate-epi interface. Since these substructural features are known to have deleterious effects on device performance and reliability, it is of fundamental as well as of technological importance to understand their origin and to devise procedures to eliminate them in device wafers.

In the present paper, the origin of SF's and substructure in ternary (Ga,Al)As layers grown by LPE has been studied by optical microscopy, etching, x-ray topography, transmission electron microscopy (TEM), x-ray photoemission, and Auger spectroscopy. As a result of these investigations, it has been possible to develop substrate preparation procedures using Br-methanol solution polishing which yield high quality device wafers.

Experimental

The n-type GaAs single crystals used in the present work were obtained from the Sumitomo Corporation, Japan. The average dislocation density is typically $2 \times 10^3/cm^2$. Prior to the LPE growth, (001) oriented substrates were either Syton[1] polished to a mirror finish or chemically polished in a 1% Br-methanol solution. The polished slices were degreased, followed by a 2-3 min dip in a solution consisting of 1 part HCl and 2 parts H_2O. The cleaned substrates were immediately rinsed in deionized water, dried, and loaded in a graphite slider boat for LPE. The boat containing Ga melts with GaAs and Te or Ge as a dopant was placed in a quartz epitaxial reactor tube at room temperature and flushed overnight with Pd-purified hydrogen flowing at the rate of 500 ml/min. In order to reduce the oxides that may be present, the melts were pre-

* Electrochemical Society Active Member.

Key words: defects, substrate preparation, damage, imperfections.

[1] A Monsanto trademark.

baked at 550°-600°C for about 90 min. After the prebake, Al was added to the melts. The temperature was then raised to ~850°C and maintained for 2-3 hr to homogenize the melts. In order to ensure against an inadvertent melt-back of the substrate or the dissolution of one layer in the subsequent melt, the compositions chosen were such that there was always excess GaAs in the melts. The following growth procedure was used to deposit different layers. The furnace was programmed to cool down at a rate of 0.2°C/min. After a drop of 1°C, the substrate was positioned under the Ga-Al-As melt and deposition was carried out for a 50°C drop. This procedure resulted in an approximately 40-50 μm thick, compositionally graded n:$Ga_{1-x}Al_xAs$ layer in which x varied from 0.35 to 0.24. For double heterostructure (DH) device wafers, a 0.5-1 μm active layer of p:$Ga_{0.9}Al_{0.1}As$ was grown next, followed by a 1-2 μm confining layer of p:$Ga_{0.75}Al_{0.25}As$.

Samples for TEM work consisted of disks, 3 mm in diameter, chemically thinned from the substrate side in a 1.5% Br-methanol solution. Thinned specimens were examined in a JEM 200 microscope operating at 200 keV.

To locate the initiation point of SF's, (110) cleaved sections were etched using H_3PO_4:H_2SO_4:H_2O_2 (100:100:1) solution. Etching was carried out at room temperature for 1-2 min under intense illumination. The etched specimens were examined either optically using Nomarski phase contrast or in a scanning electron microscope (SEM).

The stress and radius of curvature of some wafers were determined using a classical x-ray topography setup. The method is in principle equivalent to the ABAC (automatic Bragg-angle control) technique described by Rozgonyi and Ciesielka (4). The sample was moved manually with an accuracy of 10 μm and the $K_{\alpha 1}$ peak position measured using the half-width at half maximum method. The curvature was assessed using 220 reflections and Mo $K_{\alpha 1}$ radiation.

X-ray photoemission (Al K_{α}) and Auger spectra were obtained on Syton and Br-methanol polished surfaces utilizing a Physical Electronics Model 548 spectrometer. The instrumental resolution was 1.3 eV FWHM (full width at half maximum) for photoemission spectra; derivative Auger spectra involved 2 keV electron excitation and 3V peak-to-peak modulation.

Results and Analysis

Shown in Fig. 1 are linear features, approximately 30-50 μm in length, observed on the as-grown surface of a full device wafer by Nomarski contrast. The three DH layers were grown on a Syton polished substrate, and their respective thicknesses were ~50, ~1, and ~2 μm. These features have traces along the <110> directions lying in the (001) plane. This observation is consistent with these features being SF's or SF clusters having {111} habit.

Figure 2 illustrates a substructural feature seen in the top layer of a DH device wafer. In order to assess its crystallography, the feature was examined under different operating reflections. It was thus established that Fig. 2(a) shows two overlapping SF's lying on the $(1\bar{1}1)$ planes. The lower fault is intrinsic in nature and the top one is extrinsic. The two faults are interconnected via an intrinsic SF having the $(\bar{1}\bar{1}1)$ habit. The interconnecting fault is out of contrast in Fig. 2(a), but is visible in Fig. 2(b).

Another distinctive characteristic of the micrograph shown in Fig. 1 is shadows formed as a result of the interaction of growth terraces with the linear traces. This effect is not observed when terraces are nearly normal to the traces. Nonomura *et al.* (3) have recently reported similar observations on VPE grown GaAs layers. Since the step produced by an isolated SF on the (001) plane is extremely small, its interaction with a growth lamella would not be discernible. Therefore to rationalize the observations of Fig. 1, it is suggested that the linear features are stacking fault clusters.

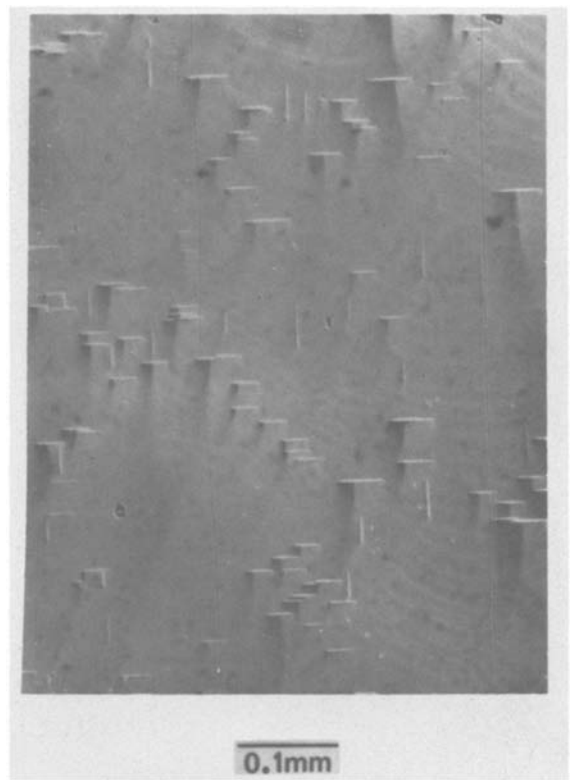

Fig. 1. An optical micrograph showing linear features on the top surface of a device wafer. Note the formation of shadows when growth terraces are nearly parallel to these linear features.

SEM micrographs of etching results on the (110) sections are shown in Fig. 3. Figure 3(a) depicts an SF that appears to originate very close to the substrate-epi interface. Nearly all the SF's examined had a similar origin. Occasionally SF's were observed to start from an inclusion embedded in the first layer. A typical example of this situation is shown in Fig. 3(b).

To assess the quality of the first (Ga,Al)As epi, a ~30 μm thick layer was grown on a Syton polished

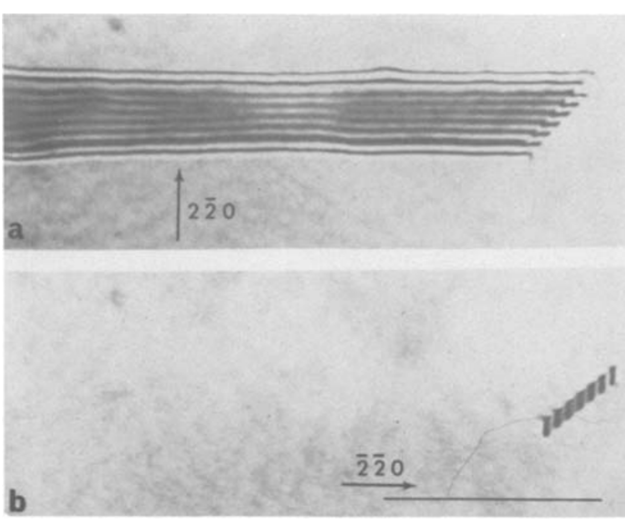

Fig. 2. Transmission electron micrographs showing two overlapping SF's observed in the top layer of a device wafer: (a) overlapping faults are in contrast; (b) a fault connecting the overlapping faults is in contrast. Plane of the micrograph in each case is ~(001). Marker represents 1 μm.

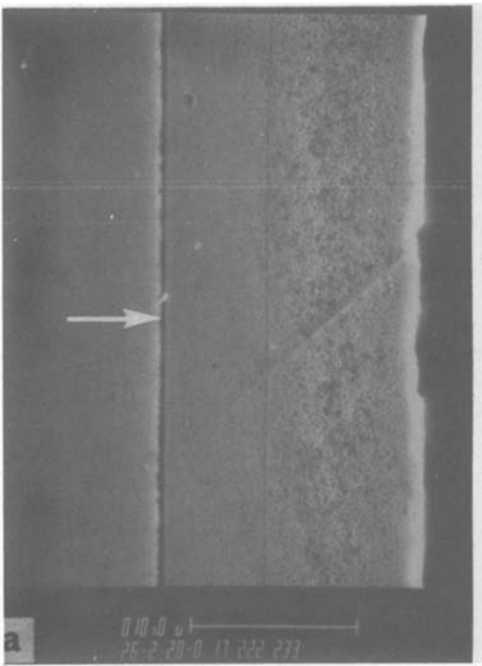

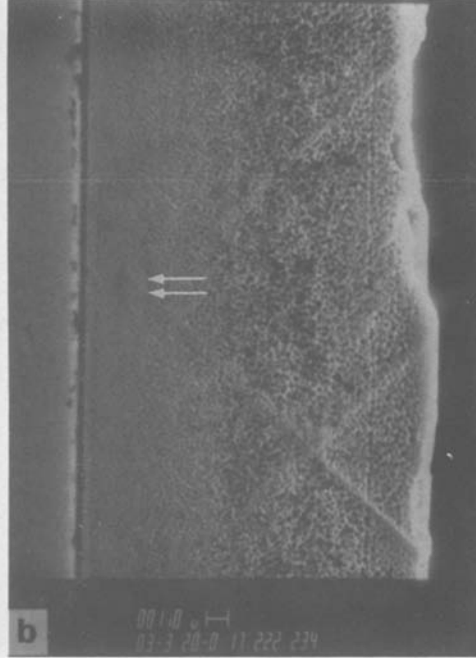

Fig. 3. SEM micrographs showing SF's on the cleaved and etched (110)) sections of a device wafer. (a) SF starts at the substrate-(Ga,Al)As epi interface, and this represents a typical situation. (b) SF's start from an inclusion. In both cases, substrates were Syton polished. The substrate-epi interface in (a) and the inclusion in (b) are delineated by single and double arrows, respectively.

wafer. Long SF's similar to those observed on the top layer of the full DH device structure were observed by optical microscopy. Figure 4 depicts the typical situation seen by TEM. Dense dislocation tangles aligned along the $[1\bar{1}0]$ direction are the most noticeable microstructural features. Some weakly developed dislocation clusters can also be seen. In addition, microcracks running along the $[1\bar{1}0]$ and [110] directions were observed in samples thinned for TEM. This implies the existence of an internal stress. The magnitude of the stress in the layer σ_e was estimated to be 1.7×10^9 dynes/cm^2 from radius of curvature measurements using an approximation which assumes that the layer thickness t_e is negligible with respect to that of the substrate, t_s, where (4, 5)

$$\sigma_e = -\frac{E}{1-\nu} \cdot \frac{1}{6R} \cdot \frac{t_s^2}{t_e}$$

Here $E/(1-\nu)$ is 1.23×10^{12} dynes/cm^2 calculated from recent data reported by Jordan (6), and R is the radius of curvature determined to be 0.65m using x-ray transmission measurements. The calculated stress value is a factor of 1.5 to 2 times higher than that reported previously (7, 8). However, in this case the ratio $t_e/t_s = 0.07$, which makes the negligible film thickness approximation questionable. Furthermore, contribution of the damage caused by the Syton polishing is not known and could be a factor in increasing the measured stress above that normally observed for layers in this composition range.

Fig. 4. A transmission electron micrograph substructure observed in a thick (Ga,Al)As layer grown on a Syton polished GaAs substrate. Plane of the micrograph is ~(001). Marker represents 1 μm.

Substrate surface contamination was examined using x-ray photoemission and Auger spectroscopy. Both techniques indicated that the major contaminants were carbon and oxygen. Photoemission spectra of the As $2p_{3/2}$ core levels (Fig. 5) show comparable amounts of oxide present as As_2O_3 on both Syton and Br-methanol polished surfaces. The areas and binding energy positions of the Ga $2p_{3/2}$ core level spectra are also comparable, although in this case the resolution of our instrument is insufficient to separate the 1.1-1.2 eV (9, 10) chemical shift between substrate (GaAs) and oxide (Ga_2O_3) signals.

Derivative Auger spectra taken from Syton (slice No. 9) and Br-methanol (slice No. 84) polished wafers from the same boule (9104-2) are shown in the bottom two panels of Fig. 6. Carbon and oxygen are the pre-

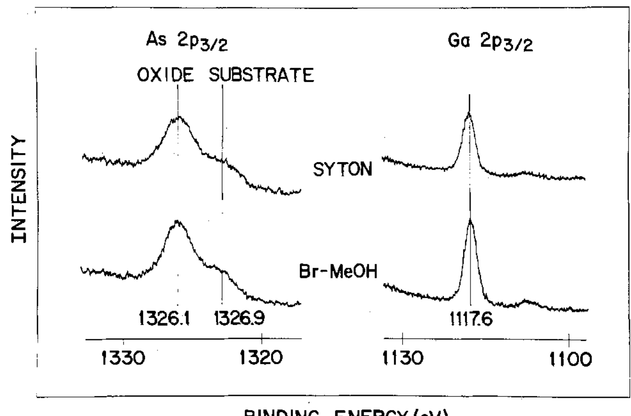

Fig. 5. X-ray photoemission spectra of the As and Ga $2p_{3/2}$ core levels observed on Syton (top) and Br-methanol (bottom) polished surfaces of GaAs.

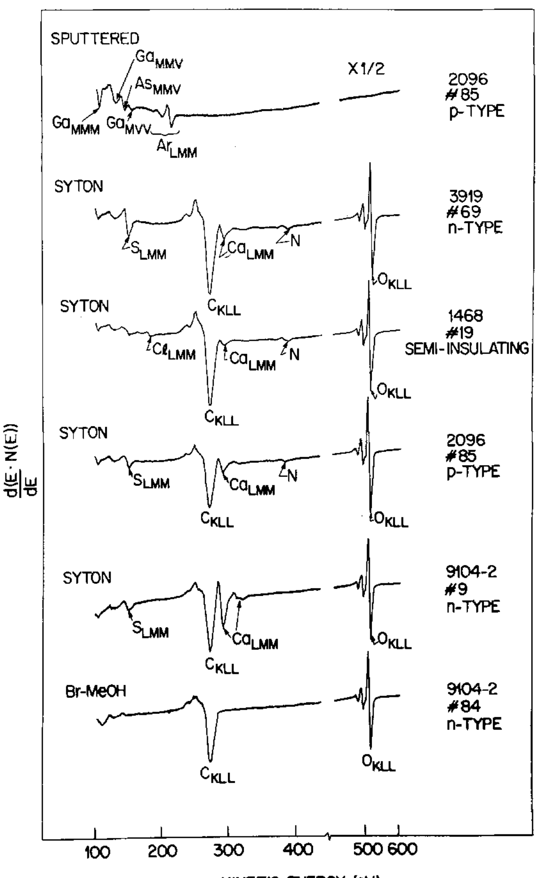

Fig. 6. Electron stimulated derivative Auger spectra for four Syton polished and one Br-methanol surface of GaAs.

dominant contaminants on both wafers, but appreciable calcium is also detected on the Syton polished surface along with traces of sulfur. The calcium signal decreases with time presumably due to electron stimulated desorption. Syton polished samples from three different boules with differing carrier types were also examined. Calcium was systematically detected on all Syton polished surfaces as a major contaminant in addition to carbon and oxygen. Traces of sulfur and nitrogen appear sporadically as minor contaminants. The chlorine signal observed on wafer No. 1468-19 probably originates from inadvertent handling since chlorine was not detected on any other wafer.

The p-type sample from boule No. 2096 was mounted on a hot stage and sputter cleaned with argon ions at 500 eV. Calcium was not observed to segregate to the surface after heating the sample to 350°C for 2 hr; the calcium detected on the surface of Syton polished wafers appears to be strictly a surface contaminant which was not removed by organic cleaning agents such as acetone and chloroform but should be removed by substrate etchants such as H_2SO_4:H_2O_2:H_2O (4:1:1).

To evaluate the influence of surface contamination on growth morphology, $Ga_{1-x}Al_xAs$ (x = 0.35) layers were deposited simultaneously from the same melt on GaAs wafers that were prepared in three different ways. These were Syton polished, Syton polished and etched in a 4:1:1 solution of H_2SO_4:H_2O_2:H_2O, and Br-methanol polished wafers. A third of the wafers with these surface preparations and the normal organic solvent cleaning filled the substrate recess in the slider boat for this experiment. For investigating the early stages of growth morphology, deposition was carried out only for 2 sec, and these results are reproduced in Fig. 7. It is evident that growth on a Syton polished substrate [Fig. 7(a)] occurs in an island-like fashion, whereas layers grown on Syton + chemically etched [Fig. 7(b)] and Br-methanol polished [Fig. 7(c)] substrates are more or less continuous. These morphological differences are indeed reflected in the structural characteristics of thicker layers, ~50 μm, shown in Fig. 8. Large SF's are observed in the layer grown on a Syton polished wafer [Fig. 8(a)], while these features are absent in Syton polished and chemically etched [Fig. 8(b)] and Br-methanol polished [Fig. 8(c)] substrates.

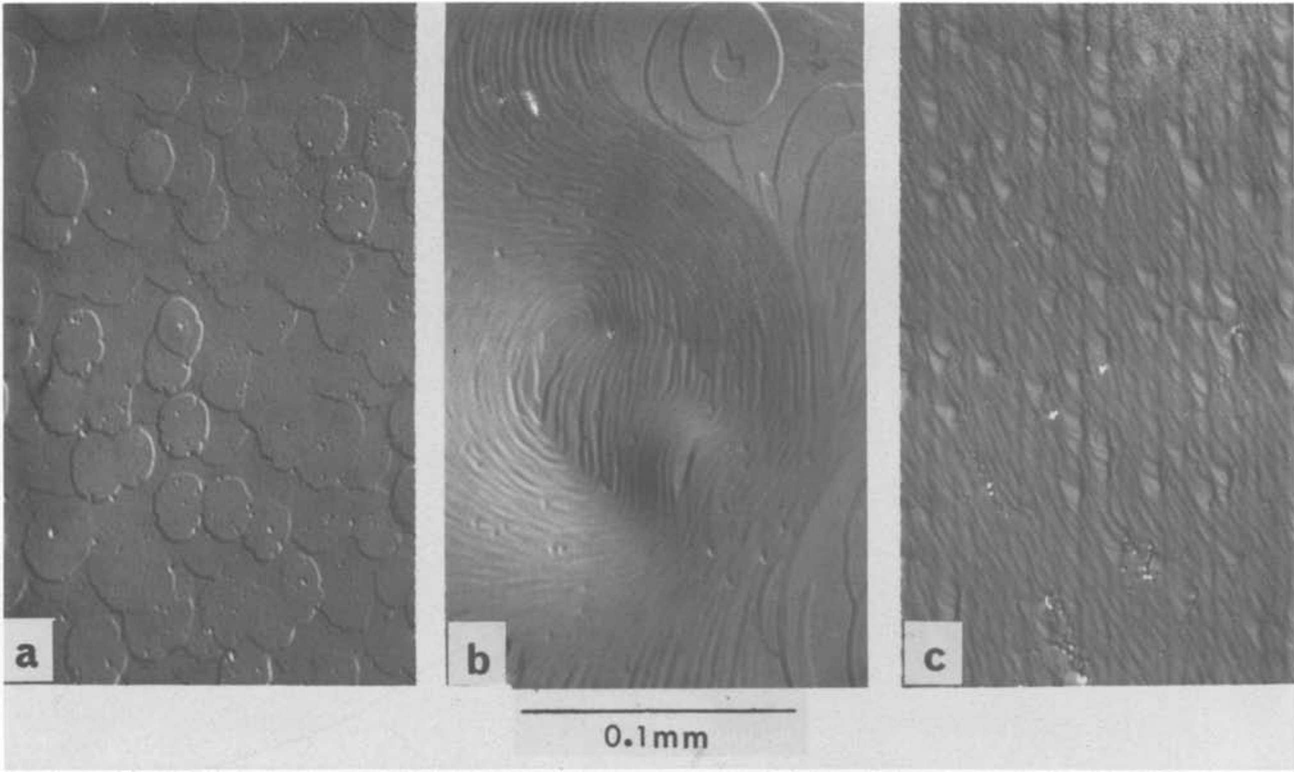

Fig. 7. Optical micrographs showing results of a 2 sec (Ga,Al)As epi growth on (a) Syton, (b) Syton polished and chemically etched, and (c) Br-methanol polished GaAs substrates. Note island-like growth morphology in (a).

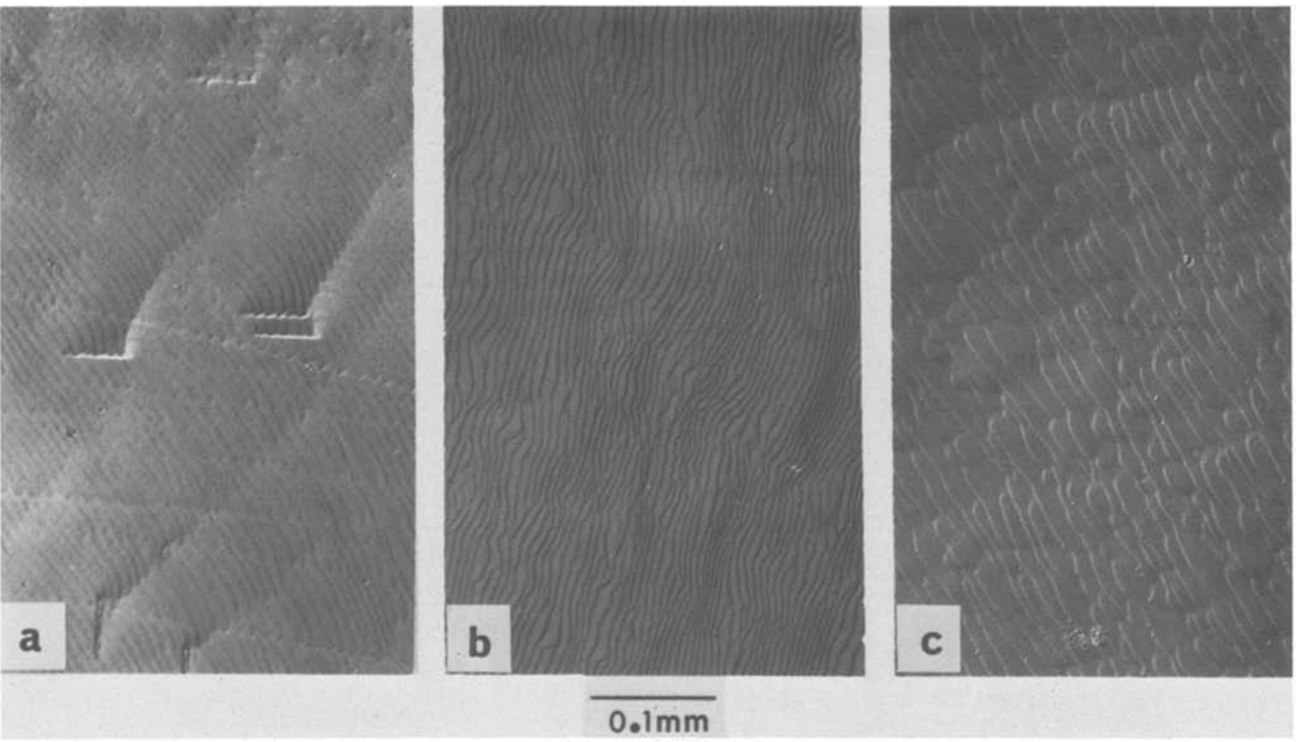

Fig. 8. Optical micrographs showing results of a 30 μm thick (Ga,Al)As epi growth on (a) Syton, (b) Syton and chemically etched, and (c) Br-methanol polished GaAs substrates. Note that SF's are only observed in (a).

In order to understand the origin of the defects, iso-epitaxial layers grown on Syton polished substrates were also studied. In this case the stacking faults were not observed, but the dislocation substructure was similar to that observed in Fig. 4 for the (Ga,Al)As/GaAs heteroepitaxy.

The above investigations suggest that the presence of calcium on the surface is a possible source for the origin of stacking faults. Two additional experiments were performed to ascertain the role of Ca, and consisted of simultaneous deposition of a 50 μm thick (Ga,Al)As layer on two substrates placed adjacent to each other. In the first case, the two substrates were cleaved from the same Syton polished wafer, but one of them was subsequently Ar-sputtered to remove Ca from the surface. The sputtering is estimated to remove 30-50Å of GaAs from the surface, essentially leaving the polishing damage unaffected. The ternary layer grown on the unsputtered wafer contained a large density of SF's while that on the sputtered sample showed virtually no faults. In the second experiment, the two substrates were cleaved from the same bromine-methanol polished wafer, but one was soaked in an aqueous solution of calcium nitrate to intentionally contaminate the surface with Ca. Prior to growth these two substrates were cleaned in chloroform and isopropanol. SF's were observed only in the ternary layer grown on the calcium contaminated substrate.

Discussion

The important observations which emerge from the preceding study are the following. (*i*) (Ga,Al)As epilayers grown on (001) oriented Syton polished substrates contain fairly long SF's or SF clusters and fairly well-developed slip bands aligned along the [110] and [1$\bar{1}$0] directions. (*ii*) These layers are internally stressed and have a small radius of curvature. (*iii*) In the early stages of LPE of (Ga,Al)As, island-like morphology is observed on Syton polished substrates whose surfaces are contaminated with Ca. (*iv*) (Ga,Al)As layers grown on Syton polished and chemically etched as well as on Br-methanol polished substrates are essentially free of SF's (*v*) Iso-epitaxy of GaAs on Syton polished GaAs is free from SF's but dislocation substructure is essentially similar to that observed in the case of (Ga,Al)As on GaAs. (*vi*) Calcium contamination appears to be necessary for the formation of stacking faults in the present situation.

The mode of nucleation and initial growth of epi-layers is governed to a large extent by the bonding between deposit and substrate. A qualitative description of different situations which may evolve during LPE can be developed using the expression, $\sigma_{SL} = \sigma_{SD} + \sigma_{DL} \cos \theta$, where θ_{SL}, σ_{SD}, and σ_{DL} are the surface free-energies of the substrate-liquid, substrate-deposit, and deposit-liquid interfaces and θ is the contact angle between the substrate and deposit which is assumed to be in the form of a hemispherical cap. Following Bauer (8), three distinct cases could arise during initial film formation. When a deposit wets the substrate, *i.e.*, $\theta = 0$, $\sigma_{SL} = \sigma_{SD} + \sigma_{DL}$ and growth would occur in a layer-by-layer manner as discussed by Frank and van der Merve (9). If $\sigma_{SL} < \sigma_{SD} + \sigma_{DL} \cos \theta$ and θ is finite, the layer nucleates by the formation of discrete three-dimensional islands which subsequently agglomerate to form a continuous layer. On the other hand, if $\sigma_{SL} > \sigma_{SD} + \theta_{DL} \cos \theta$, continuous layers may form initially and at a later stage, discrete nuclei may form on top of these layers. It appears from the present observations that, due to the presence of Ca on Syton polished surfaces, (Ga,Al)As layer growth falls into the second category. Furthermore, since it was feasible to grow SF-free GaAs LPE layers on Syton polished substrates, it is inferred that contamination-free surfaces are more crucial in the growth of (Ga,Al)As layers.

Based on the work that was mainly carried out by Matthews (13), Bassett *et al.* (14), Pashley (15), Bassett and Pashley (16), Phillips (17), and Bassett (18), Pashley (19) has discussed various possibilities for the introduction of dislocations during epitaxial growth, and these are: (*i*) the replication of substrate dislocations; (*ii*) the aggregation of point defects leading to the formation of dislocation loops; (*iii*) the accommodation of translational and rotational displacements between coalescing islands that are close to epitaxial

orientation; (*iv*) plastic deformation of the layer, both during growth and subsequent cooling. If dislocations are homogeneously distributed in the substrate and the density is low, source (*i*) is expected to be of primary significance under ideal growth conditions, *i.e.*, iso-epitaxy of thin layers on noncontaminated substrates (20). However, in the case of (Ga,Al)As epi growth on Syton polished GaAs substrates, the situation is more complex. Syton polishing is observed to introduce extensive dislocation damage in the surface regions of InP crystals (21), and it is very likely that a similar situation exists in the case of GaAs. This polishing-induced damage would certainly be replicated in epi-layers. In addition, the difference in the coefficients of expansion of (Ga,Al)As and GaAs may result in stresses during the cool down and this may promote deformation. The presence of high internal stress, small radius of curvature, and substructure observed in Fig. 5 are consistent with this suggestion. Furthermore, island-growth is certainly observed as shown in Fig. 8, but from the present experiments it is difficult to assess its contribution to the evolution of total substructures. It appears from the preceding discussion that probably all of the four sources listed above could be contributing to the observed dislocation structures.

The central question that remains to be resolved in the present study concerns the evolution of SF's in epi-layers. A plausible explanation may pertain to the accommodation of misfit between coalescing islands as discussed by Matthews (22). If the translational misfit between two agglomerating islands is equal to or close to an allowed shear vector for an SF, it is possible that a portion of the misfit is accommodated by the formation of an SF, whereas the remainder is taken up elastically. Similar arguments can be evoked to rationalize more complex situations involving the agglomeration of more than two islands. It appears that in the presence of a contaminant on the surface, the probability for the misfit to develop between two coalescing islands increases. It is however not clear why this probability is higher in the case of (Ga,Al)As epi-layers. This could be due to some complex interaction between Ca and Al.

The formation of the SF configuration observed in Fig. 2 can be rationalized if it is assumed that the Shockley partial bounding the lower fault dissociates into a stair-rod dislocation and another Shockley partial that can glide on the $(1\bar{1}1)$ plane. For example, if the lower fault is bound by the $\frac{1}{6}[121]$ partial, dissociation could occur according to the following reaction

$$\frac{1}{6}[121]_{(\bar{1}\bar{1}1)} \rightarrow \frac{1}{6}[01\bar{1}]_{\text{stair-rod}} + \frac{1}{6}[112]_{(1\bar{1}\bar{1})}$$

The $\frac{1}{6}[112]$ dislocation could glide to form the connecting fault. This partial may subsequently dissociate resulting in the $\frac{1}{6}[121]$ and $\frac{1}{6}[0\bar{1}1]$ dislocations. The glide of the former partial on the $(1\bar{1}1)$ plane could produce the top fault.

Conclusion

The stacking faults observed in the LPE of (Ga,Al)As on Syton polished substrates are attributed to surface contamination associated with calcium. On the other hand, the observed dislocation substructure could result from the replication of mechanical damage associated with the surface regions. Further, the layer are internally stressed, have a small radius of curvature and contain deformation-induced dislocation substructure. However, these problems can be obviated by chemical polishing with Br-methanol solutions which yields nearly defect-free layers.

Thermally Induced Defect Behavior and Effective Intrinsic Gettering Sink in Silicon Wafers

Fumio Shimura, Hideki Tsuya, and Tsutomu Kawamura

Nippon Electric Company, Limited, Fundamental Research Laboratory, Basic Technology Research Laboratories, Miyazaki, Takatsu, Kawasaki, Japan

ABSTRACT

Dislocation-free Czochralski silicon wafers have been subjected to a two-step annealing procedure to explore the intrinsic gettering (IG) phenomenon and the behavior of thermally induced microdefects using infrared absorption, preferential etching, and transmission electron microscopy (TEM). As a result, it is found that plastic lattice deformation introduced by dislocation and/or stacking faults is necessary for effective IG sinks. In spite of their extremely high density, microprecipitates with elastic strain but no plastic deformation do not result in effective IG. TEM observations clarify the change in density and/or structure of inner defects by precipitate dissolving after the second annealing at high temperature.

Czochralski-grown (CZ) silicon crystals are the main wafer source for the semiconductor devices such as bipolar and MOS. However, as a result of the precipitation of supersaturated oxygen, a variety of defects are produced when CZ silicon crystals are heat-treated because of their high concentration of oxygen.

These microdefects caused by oxygen precipitation are beneficial as is the case with intrinsic gettering (IG). Although IG has been regarded as an effective gettering technique for IC or LSI processing (1-7), effective sinks for IG and the behavior of inner defects during high temperature heat-treatments have not been examined closely yet.

The studies using infrared absorption, preferential etching, and transmission electron microscopy (TEM) analysis reported in this paper involve the IG phenomenon and the behavior of microdefects generated in two-step-annealed silicon wafers. As a result, the *sine qua non* of inner defects for IG effectiveness is shown. Furthermore, the TEM observation result of inner-defect conversion during the second annealing at high temperature (1230°C) suggests that inner defects should be freshly introduced during the following IC device processes.

Experimental

Samples used in this study were taken from the seed end of a 76 mm diam boron-doped <111> CZ crystal with regular diam overall length of approximately 30 cm and resistivity of 10-20 Ω·cm. Wafers 2 mm thick were etched to remove the damaged layer and then mirror polished on both sides in the usual fashion. Oxygen content of the as-grown specimen was 17.5-18.6 $\times$ 10^{17} cm^{-3} by the ASTM procedure F-121 (8). The radial distribution of oxygen content measured with a 0.4 $\times$ 10 mm infrared beam was observed to be uniform overall except at the rim of 5 mm in the wafers. In addition, the carbon content was less than 3 $\times$ 10^{15} cm^{-3} (detection limit). During the first annealing, specimens were subjected to heat-treatment at each temperature (600°, 750°, 950°, and 1100°C) for 16 hr in a dry O_2 atmosphere while the second annealing was at 1230°C for 2 hr in the same atmosphere. The heat-treated specimens were quenched by means of rapid withdrawal from a furnace and then were examined by infrared absorption, modified-Dash etching, and TEM with an accelerating voltage of 200 kV.

Results and Discussion

The infrared measurements, plotted as the concentration of interstitial oxygen before and after heat-treatments *vs.* the first annealing temperature, are shown in Fig. 1. A drastic change in the oxygen concentration occurred after the first annealing is mainly due to the precipitation of Si-O complex and the change after the second annealing is due to the synergism of Si-O precipitate dissolving (3) and the oxygen outdiffusion (9).

Surface- and inner-microdefect (about 100 μm from the surface) distribution in the annealed specimen is shown in Fig. 2. The first annealing temperature of the first quadrant in all specimens was 600°C, of the second quadrant in all specimens 750°C, etc., as shown in Fig. 2. After the first annealing no surface microdefects can be seen; however, swirl-like inner defect distribution can be observed in each quadrant except 600°C-annealed. On the other hand, surface microdefects were very apparent only in the 600°C-annealed quadrant after the second annealing.

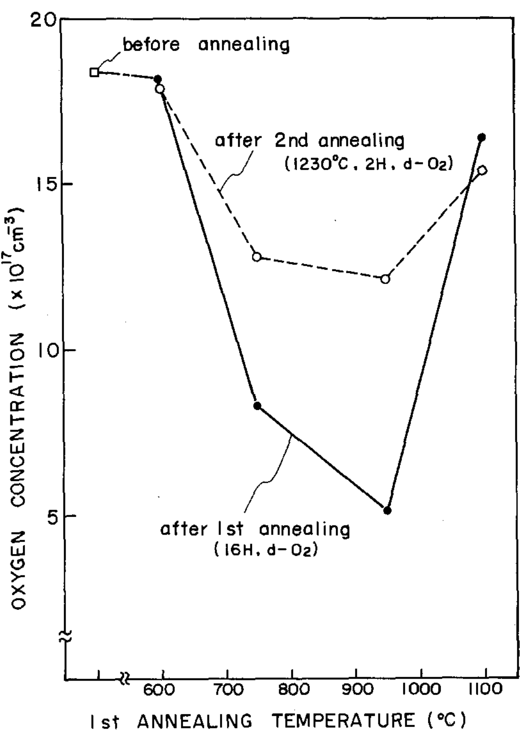

Fig. 1. Interstitial oxygen concentration change before and after first and second annealing.

Key words: plastic deformation, transmission electron microscopy, high temperature annealing, defect structure conversion, Si-O precipitate dissolving.

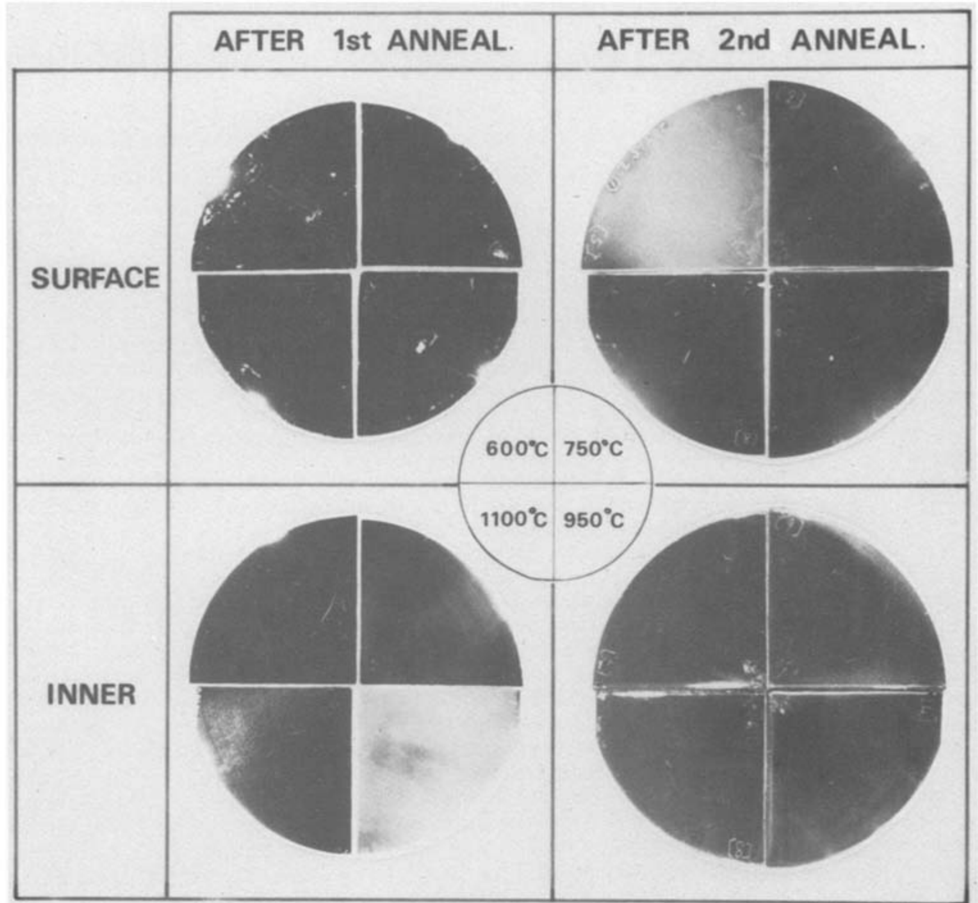

Fig. 2. Surface and inner defect distribution in annealed silicon wafer.

As previously reported (10), surface microdefects are apt to be generated in ungettered wafers annealed above 1100°C in a wet O_2 or above 1200°C in a dry O_2 atmosphere.

Optical micrographs of surface microdefects, revealed by modified-Dash etching, in each quadrant after the second annealing are shown in Fig. 3. Surface microdefects with the density of 4×10^6 cm^{-2} were generated only in the quadrant preannealed at 600°C. However, there are almost no surface defects in other quadrants. TEM observation revealed that most of surface microdefects were impurity clusters (11) and some of them were small stacking faults with precipitates at the center. The small stacking fault figure agrees with the TEM image previously reported (10) and quite different from inner microdefects being presented below. A slight peak suggestive of the existence of copper was obtained by STEM-XMA examination for the precipitates located at the center of the small stacking faults (10). This suggests that impurity

clusters mentioned above originate small stacking faults under certain conditions.

Recently, Kishino *et al.* (12) verified the ability of IG using inner microdefects on copper-diffused wafers with the help of a neutron activation analysis (NAA). The result showed that the copper concentration was enhanced in the bulk region where a high density of microdefects were induced and the concentration in the denuded zone near the surface was proved to be below the detection limit of the NAA technique.

Consequently, Fig. 2 and 3 distinctly illustrate the IG phenomenon since surface microdefects are possibly caused by process-induced "heavy metal contamination" such as copper while inner microdefects act as gettering sinks for IG.

Inner microdefect etched shapes in the quadrants after the first and second annealing are shown in Fig. 4. In specimens after the first annealing, defect generation depends on the annealing temperatures, resulting in the decrease in oxygen concentration shown in Fig. 1.

Oxygen precipitation occurs by heterogeneous nucleation with grown-in precipitates and/or lattice defects (13). The precipitated oxygen $\Delta[\mathrm{Oi}]_T$ at the temperature T may be qualitatively described by the simplified function

$$\Delta[\mathrm{Oi}]_T = f\,(D_\mathrm{T}, S_\mathrm{T}, N_\mathrm{T}, F, t) \quad [1]$$

where D_T is the diffusion constant of oxygen in silicon at T, S_T the supersaturated ratio of oxygen at T, N_T the number of "precipitate-nuclei" larger than critical radius at T, F the number and type of lattice defects introduced at the early stage of heat-treatment, and t the annealing time.

Although the oxygen precipitation depends on many factors as mentioned above, the most remarkable oxygen precipitation occurred in the specimen annealed at 950°C in this experiment. It is considered that the largest oxygen precipitation in the 950°C-annealed specimen may be mainly due to more faults F introduced during the heat-treatment. That is, lattice defects induced by oxygen precipitates can be secondary heterogeneous nuclei for following oxygen precipitation during heat-treatment. Detailed discussion on oxygen precipitation using Eq. [1] will be presented in another paper.

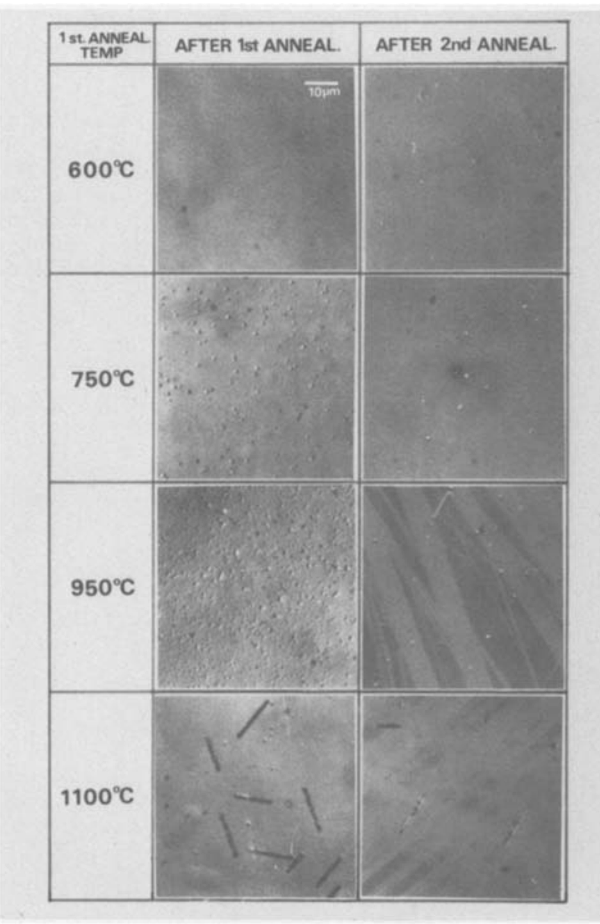

Fig. 4. Inner defects after first and second annealing revealed by modified-Dash etching.

The main defects in the 1100°C-annealed quadrant are large stacking faults. There are also microdefects with a low density. This shows that the swirl-like pattern in the 1100°C-annealed quadrant shown in Fig. 2 is mainly due to large (several tens micron) stacking faults, not to Si-O complex precipitates.

A distinct decrease in the density of inner microdefects is observed after the second annealing. This decrease is strongly correlated with the redissolving of Si-O complex precipitates. Differential infrared (DIR) and TEM studies have revealed that SiO_2 precipitates are obvious in an as-grown silicon crystal and the grown-in precipitates grow or shrink depending on annealing conditions (13).

Although modified-Dash etching cannot reveal inner microdefects in the 600°C-annealed specimen, the TEM weak-beam image indicates precipitate particles with a density of $\sim 1 \times 10^{14}$ cm^{-3}, as shown in Fig. 5. Dominant particles are around or under 60Å in size but are easily recognized by the strong compressive stress field in the surrounding matrix (14). The distribution of particle size in the annealed specimen may also depend on the grown-in precipitate size distribution in an as-grown crystal. The largest precipitate in the 600°C-annealed specimen is about 350Å and shows platelike morphology with a thickness of about 50Å. The result shows that the surface defects in the 600°C-annealed quadrant are not intrinsically gettered in spite of the high density of precipitates.

Figure 6 shows inner microdefects generated in the 750°C-annealed quadrant. Several hundred micron precipitates are dominant; in addition, dislocation dipoles and long-shaped dislocation loops are also observed.

Various kinds of microdefects such as precipitates, perfect dislocation loops (PL), and stacking faults (SF) with precipitate colonies at the center were observed in the 950°C-annealed quadrant as shown in Fig. 7. In Fig. 7(a) SF's (A, B, C, and D), that are extrinsic in nature and bounded by a/3 [111] Frank partials, are observable. From the observations under different conditions (g, z) as shown in Fig. 7(a), (b), (c), analysis of the SF faulted planes reveals A, B, C, and D to be $(11\bar{1})$, $(\bar{1}11)$, (111), and (111). Despite repeated observations and analyses of SF's, the frequency of the faults in any of the {111} planes did not exhibit any particular tendency. Consequently, any {111} plane could be the possible faulted plane. This homogeneous

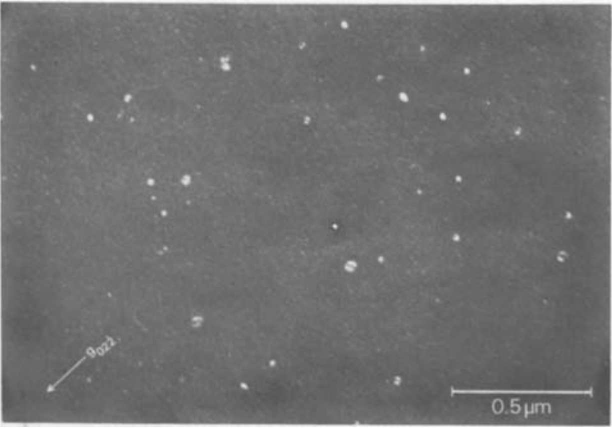

Fig. 5. TEM weak beam image of microprecipitates in 600°C-annealed specimen. $g = [02\bar{2}]$, $z \sim [433]$, $3g = 0$.

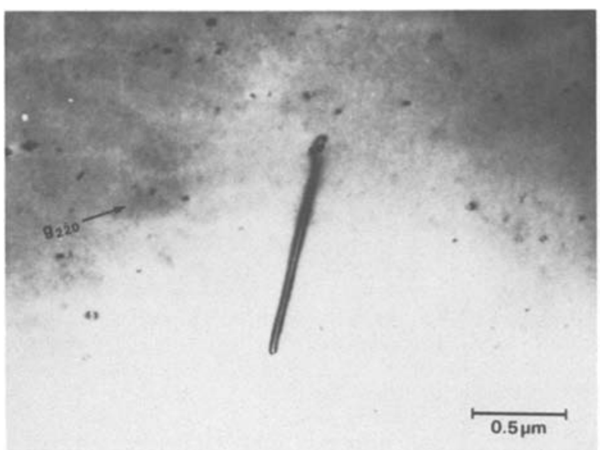

Fig. 6. Inner defects in 750°C-annealed specimen. $g = [2\bar{2}0]$, $z \sim [332]$.

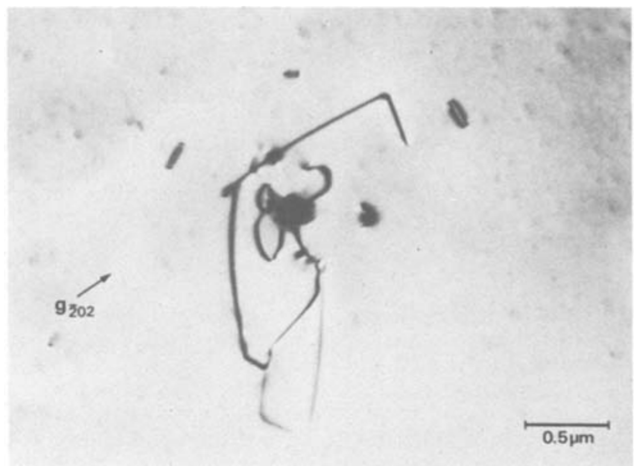

Fig. 8. Punched-out and climbing dislocations from octahedral precipitate in 1100°C-annealed specimen. $g = [\bar{2}02]$, $z \sim [111]$.

faulted plane distribution is explained by having prepared TEM samples at a 100 μm depth from the surface when SF size is only 0.6-0.8 μm. As a result, the influence of surface direction <111> is negligible. With extrinsic-type SF's the SF size increases nearer the wafer surface ($Si-SiO_2$ interface) because large vacancy undersaturation is generated by the oxidation process near the crystal surface (15). In fact, the SF size observed at a depth of 20 μm from the wafer surface is around 1.4 μm, or twice the size of SF's in the deeper region, as shown in Fig. 7.

In the 1100°C-annealed quadrant, regular octahedral precipitates, punched-out dislocations (POD), climbing dislocations (CD), and several ten micron SF's generated by the above precipitate (16) are observed. POD and CD from octahedral precipitate are shown in Fig. 8. Although the density of inner defects generated in the 1100°C-annealed quadrant is not large, as shown in Fig. 4, distinct IG phenomenon is observed in the 1100°C-annealed quadrant as shown in Fig. 2 and 3.

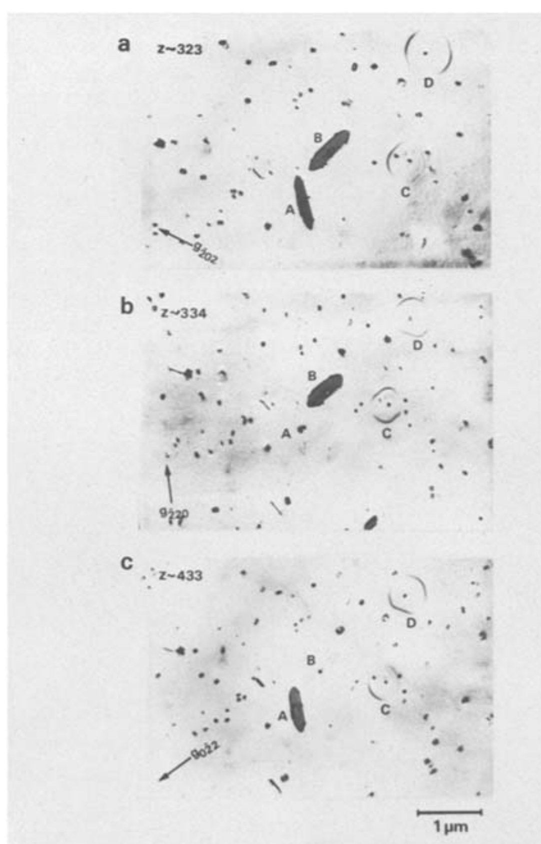

Fig. 7. Variety of inner microdefects in 950°C-annealed specimen: (a) $g = [\bar{2}02]$, $z \sim [323]$, (b) $g = [\bar{2}02]$, $z \sim [334]$, (c) $g = [0\bar{2}2]$, $z \sim [433]$.

The observations mentioned above support the conclusion that IG is determined more by the lattice defect and/or a precipitate being larger than a critical size than by the defect density. However, large precipitates which elastically compress the surrounding must repulse interstitial atoms rather than attract them. Consequently, the plastic deformation or dangling sites introduced by POD, CD, and SF may be necessary for IG when the IG mechanism and origin of surface microdefects is taken into consideration.

As mentioned previously, Si-O complex precipitates redissolve during the second annealing at 1230°C. Microprecipitates observed in 600°C- and 750°C-annealed specimens were not observed after the second annealing by TEM. They must have shrunk to an undetectable size as a result of redissolving (13). Although large SF's still existed, octahedral precipitates had become deformed in the 1100°C-annealed specimen after the second annealing, as shown in Fig. 9. The corners and edges of the octahedral precipitate are unclear because the unstable parts of corners and edges where dangling bonds exist redissolved preferentially. In addition, few POD and CD as shown in Fig. 8 were observable after the second annealing.

The most remarkable change in the inner defects before and after the second annealing occurred in the 950°C-annealed specimen. As shown in Fig. 7, many

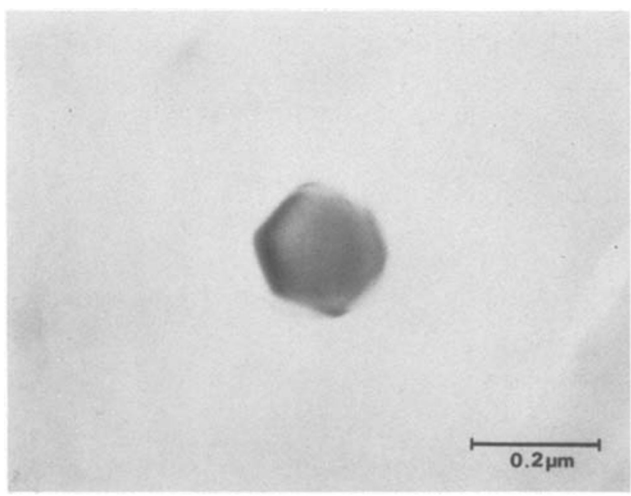

Fig. 9. Deformed-octahedral precipitate in specimen annealed at 1100°C for 16 hr and 1230°C for 2 hr. $g = [\bar{2}02]$, $z \sim [111]$.

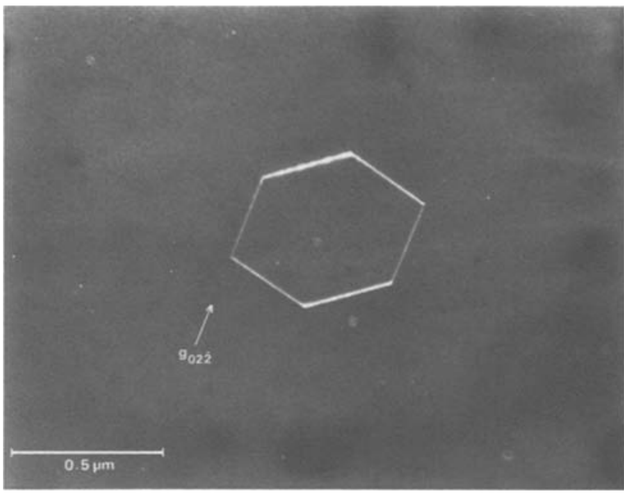

Fig. 10. TEM weak beam image of hexagonal perfect dislocation loop in specimen annealed at 950°C for 16 hr and 1230°C for 2 hr. $g = [02\bar{2}]$, $z \sim [433]$, $3g = 0$.

small precipitates and SF's with precipitate colonies at their center were observed in the 950°C-annealed specimen; however, few precipitates were observed after the second annealing. Instead, hexagonal-shaped perfect dislocation loops (PL) appeared, as shown in Fig. 10. This suggests that the conversion of the SF to PL occurred during the second annealing at high temperature. In the process oxygen atoms diffuse out of Si-O precipitates toward the bulk and silicon interstitials flow back to the precipitate location. Consequently, the vacancy-interstitial balance will be modified and the associated SF and dislocation are expected to change in shape and location. The mechanism for the conversion of SF to PL may be complicated, however, it is clear that the driving force for the change is oxygen redissolving and redistribution.

Conclusion

Intrinsic gettering (IG) phenomenon has been examined during two-step annealing and inner defects correlated with IG effectiveness analyzed using infrared absorption, preferential etching, and TEM techniques. As a result, it was found that plastic lattice deformation or dangling sites introduced by dislocation and/or stacking faults are necessary for effective IG sinks. Highly dense microprecipitates with elastic strain but no plastic deformation do not result in IG. In addition, TEM observation clarified the conversion of a stacking fault to a perfect dislocation loop and the precipitate dissolving during high temperature heat-treatment. The behavior of inner defects suggests that the effectiveness of introduced inner defects for IG probably decreases after annealing at high temperatures such as 1230°C and that inner defects should be freshly introduced during the following IC device processes.

Thermodynamic Approach to the Deposition of Nonstoichiometric Solids from the Gas Phase: Example of Titanium Carbide at High Temperature

L. Vandenbulcke*

CRCCHT (CNRS) and Université d'Orléans, 45045 Orléans Cédex, France

ABSTRACT

A thermodynamic approach based on the minimization of the Gibbs free energy is used to calculate the pressure-temperature-composition ranges of stability of various solid phases in multicomponent gas-solid systems including nonstoichiometric solid phases. The conditions for the chemical vapor deposition of nonstoichiometric titanium carbide from $TiCl_4$-CH_4-H_2 at high temperature are given. The influence of nonstoichiometry and uncertainties of the thermodynamic data on the deposition domains of the various solids are pointed out. The relationships between the composition of the gaseous phase and the composition of the solid are also discussed.

The computation of chemical equilibrium appears as the first step of a fundamental study in chemical transport and chemical vapor deposition of a polycomponent system.

In chemical transport, suitable solvent components and temperature gradient can be chosen on a theoretical basis. Thus feasibility of the transport can be derived from calculations of two equilibriums, at the source and sink end of the tube, by minimization of the Helmoltz free energy (1). Indications about the transport rate by diffusion and convection are obtained by a diffusion/laminar flow model using thermodynamic results of the Gibbs free energy minimization technique; this model takes into account all gaseous species and does not require specifying individual chemical reaction (1-3).

Chemical vapor deposition is also a very complex dynamic process, where chemical kinetics combined with mass transport often control the deposition rate. But at high enough deposition temperature and low mass flow rate, the deposition rate is limited only by mass transport since the temperature dependence of chemical rate-limiting steps is much greater than the temperature dependence of gaseous diffusion; thus, the heterogeneous chemical kinetics is sufficiently fast to allow equilibrium conditions at the gas-solid interface to be approached. In all cases, a model of mass transfer combined with a dynamic equilibrium at the gas-solid interface permits the calculation of maximum limits for the conversion of reactants into products at the interface, and of the deposition rate when homogeneous nucleation is avoided. It is the rate that would be achieved in the absence of significant surface resistances to the deposition (4, 5).

Therefore, of special interest is the increasing use of the thermodynamic approach to calculate the gas phase composition in equilibrium with the solid and the theoretical efficiencies of the deposition at equilibrium, to ascertain the chemical compatibility of the substrate with the gas phase in the first stages of the deposition, to define the pressure-temperature-composition ranges of stability of various solid phases in multicomponent gas-solid systems [reviewed in (6)]. All these calculations apply to the deposition of stoichiometric solids. But many solid solutions can be deposited, the compositions of which vary with temperature, pressure, and composition of the gas phase; moreover, good control of these compositions is necessary to obtain satisfactory results and optimize the properties of the materials. The calculations would be therefore extended to the deposition of nonstoichiometric solids.

In this paper, a thermodynamic approach to the chemical vapor deposition of nonstoichiometric titanium carbide from $TiCl_4$-CH_4-H_2 mixtures is presented. The Ti-C-H-Cl system has been extensively studied but stoichiometric TiC was generally considered (7-9). Only one paper was devoted to the deposition of nonstoichiometric TiC_x, but the method employed is not general as it imposes the composition of the TiC_x phase; thus, only the limits of the deposition domains of Ti + $TiC_{0.52}$ and TiC + C with the titanium carbide phase can be easily determined (9).

Generalities of the Calculation Procedure

The chemical equilibrium calculations involve the minimization of the total Gibbs free energy of the system, taking into account several constraints. In CVD systems, these constraints are the mass balance of each element, constant temperature, and constant total pressure. Several programs have been reported for such computation (10-12). A slightly modified version of SOLGASMIX program written by Eriksson (12) has been employed to perform the calculations of this paper. In this program, nonstoichiometric solids can be considered.

The calculation requires specifying the species which can be formed at equilibrium and the corresponding thermodynamic data.

Species in the Ti-C-H-Cl system.—The attack of the substrate during the initial stages of deposition (13), or of the CVD reactor wall, or of the tube in transport processes sometimes introduces new species in the system. Here, all of these solids are considered as inert toward the gaseous phase.

The following species have been considered: H_2, CH_4, C_2H_2, CCl_4, Cl_2, HCl, $TiCl_4$, $TiCl_3$, $TiCl_2$, and TiCl as constituents of the gas phase (other species like H, Cl... were eliminated as their equilibrium concentrations were negligible); pure Ti, pure C and TiC_x as solids [pure Ti was considered, as the solubility of C in Ti is low (14)].

Thermodynamic data.—To calculate the total free energy of the system, values of the Gibbs free energy of formation of the species from the elements in their chosen reference states have to be specified. For all species in the gaseous phase, values were taken from the JANAF thermochemical tables (15). However, data from other sources must be used in the case of nonstoichiometric titanium carbide.

Key words: solids, thermodynamics, CVD.

The extent of the homogeneity range of the TiC_x is fairly well known. At $T = 1900$ K, the limits of the atomic ratio C/Ti are about 0.51 and 0.98 (14). At this temperature, Storms has measured the Ti pressure over various composition of TiC_x using a mass spectrometer. His results (14) are reported in Fig. 1 with, in addition, the value of the Ti pressure over pure solid Ti given by Nesmeyanov ($p°_{Ti(1900\ K)} = 3 \times 10^{-6}$ atm) (16). In order to utilize these data, a relationship giving the activity or activity coefficient as a function of the composition must be known. In general, a polynomial expression is used which fits the curve to the set of data points by the method of least squares. For 0.51 < C/Ti < 0.98, the curve of Fig. 1 is inferred from the following relation

$$\ln \gamma_{Ti} = -1702.72 + 10865.97\ X_{Ti} - 26354.96\ X_{Ti}^2 + 28651.25\ X_{Ti}^3 - 11728.11\ X_{Ti}^4 \quad [1]$$

where γ_{Ti} is the activity coefficient for Ti and X_{Ti} is the molar fraction of Ti in TiC_x.

When C/Ti ≥ 0.98 (in the two-phases domain $TiC_{0.98}$ + C), the activity of C equals 1 and the activity of titanium is constant and equal to its value in $TiC_{0.98}$, that is

$$a_{Ti} = p_{Ti\ (in\ TiC_{0.98})}/p°_{Ti\ (pure)}$$

$$\gamma_{Ti} = 4 \times 10^{-5}/X_{Ti}$$

To define completely the thermodynamic properties of the TiC_x phase, one must know the values of the activity of carbon as a function of the composition. The activity coefficient of carbon can be obtained from the values of γ_{Ti} by integration of the Gibbs-Duhem equation. The following relation was obtained

$$\ln \gamma_C = -34.74 + 44.50\ X_C + 111.97\ X_C^2 - 46.89\ X_C^3 - 366.19\ X_C^4 - 162.03\ X_C^5 + 1256.05\ X_C^6 \quad [2]$$

which applies in the range 0.51 < C/Ti < 0.98.

When C/Ti ≤ 0.51 (in the two-phases domain Ti + $TiC_{0.51}$), the activity of titanium is supposedly equal to 1 and the activity of carbon is constant and equal to its value in $TiC_{0.51}$, that is $a_c = 1.448 \times 10^{-6}$.

Initial parameters.—The calculations of the complex equilibrium in the Ti-C-H-Cl system were carried out as a function of the initial composition in $TiCl_4$-CH_4-H_2. The temperature and total pressure were constant and equal to 1900 K and 1 atm, respectively.

Results and Discussion

Thermodynamic calculations are often used to specify the ranges of initial composition which will produce the desired solids at equilibrium. The location of the limits between the different domains of solid deposition can be influenced by taking into account the nonstoichiometry of the solids and by the accuracy of the thermodynamic data used.

Influence of nonstoichiometry and uncertainties of the thermodynamic data on the deposition domains of the solid phases.—Figure 2 shows how the phase boundaries change as a function of $TiCl_4$ and CH_4 partial pressures. Hydrogen makes up the difference between 1 atm and the sum of the titanium tetrachloride and methane partial pressures. The full lines give the boundaries obtained for nonstoichiometric titanium carbide (TiC_x); the dotted lines present, for comparison, the results obtained if deposition of stoichiometric TiC is assumed. The boundary shift is not very important, particularly for the limit between the TiC_x and $TiC_{0.98}$ + C domains of deposition. As expected, the TiC_x domain is enlarged relative to the stoichiometric TiC domain, in the Ti-rich region.

The accuracy with which an equilibrium composition can be computed lies in the uncertainties of the thermodynamic data used. Table I gives, as an example, the values of the free energy of formation of $TiCl_2$, TiCl, and CCl_4 from JANAF 1971 and JANAF 1966 (17). All the other values remain constant in the second edition.

Figure 3 shows the influence of these values on the amount of solid phases deposited at equilibrium for $p°_{TiCl_4} = 10^{-4}$ atm and different values of $p°_{CH_4}$. The calculations were carried out for stoichiometric TiC. Variations of the data used do not produce sensitive differences in the amounts of TiC and C which are represented as full lines. The amount of Ti is more influenced; it is reported, respectively, as a full line and a dotted line when data of JANAF 1971 and JANAF 1966 are used. For constant $p°_{CH_4}$, the amount of Ti decreases when the stability of the titanium dichloride increases.

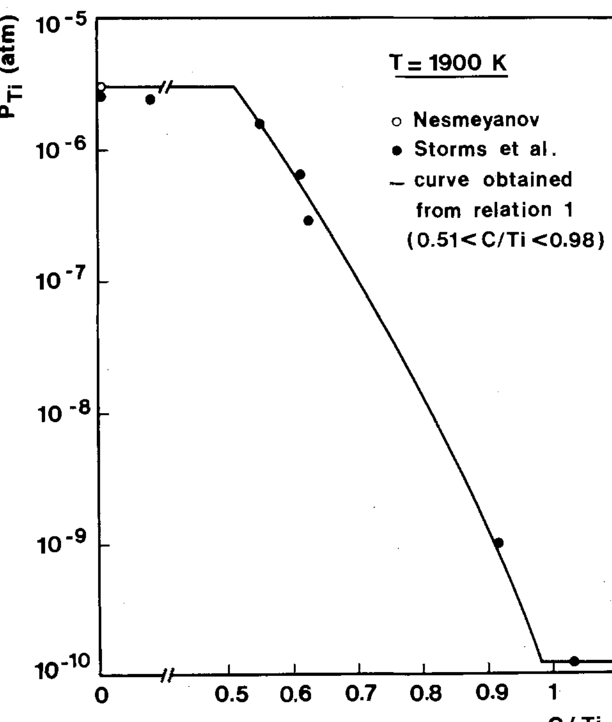

Fig. 1. Pressure of Ti over Ti-C solids

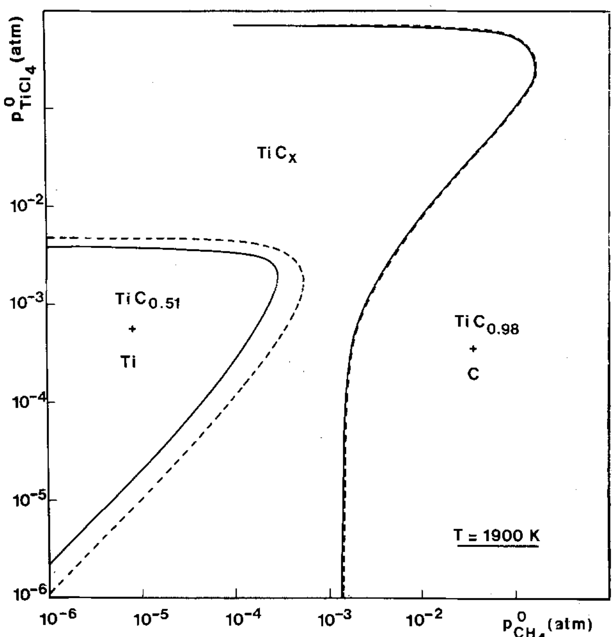

Fig. 2. Phase fields for solid species deposited at equilibrium. The full and dotted lines represent, respectively, the single phase limits of nonstoichiometric and stoichiometric titanium carbide. The hydrogen partial pressure brings the total pressure to 1 atm.

TiC	−38,291	

For comparison, the arrows give the deposition limits of the nonstoichiometric TiC_x single phase, which show that the influence of nonstoichiometry is lower than the influence of uncertainties in the thermodynamic data of the titanium subchlorides.

The primary interest in the present calculations, which take into account nonstoichiometric condensed species, lies principally in the determination of the variation of the TiC_x composition in the single phase domain.

Deposition of nonstoichiometric titanium carbide.—As shown on Fig. 2, titanium carbide is deposited at equilibrium as a single phase under a wide variety of initial composition. TiC_x is codeposited with C at high initial partial pressure of CH_4; it is codeposited with Ti at low $p°_{CH_4}$ except for high initial partial pressure of $TiCl_4$. This is a result of the high stabilities of TiC_x and titanium chlorides as compared to Ti.

The production of the different solids is bound to the composition of the gaseous phase, as can be seen in Fig. 4 which gives for $p°_{TiCl_4} = 10^{-4}$ atm and $p°_{CH_4}$ varying from 10^{-5} to 10^{-2} atm, the equilibrium yields (η) of the different gaseous and solid species. η are defined with respect to $n°_{TiCl_4}$ for titanium-containing species (curves in full lines) and $n°_{CH_4}$ for carbon-containing species (curves in dotted lines)

$$\eta = n_i\ (Ti_yX_z)/n°_{TiCl_4} \text{ and } \eta = n_i\ (C_yX_z)/n°_{CH_4}$$

where n_i represents the number of Ti and C atoms in species i at equilibrium and $n°_{TiCl_4}$ and $n°_{CH_4}$ the initial number of $TiCl_4$ and CH_4 moles ($n_i° = p_i°$ as $\sum_i n_i° = 1$ mole and $P = 1$ atm). The equilibrium yields of the following species $TiCl_4$, Cl_2, and CCl_4 are not reported as n_i is lower than 10^{-10} atoms. On the other hand the concentrations of H_2 and HCl are always important. Several facts can be noted from this figure.

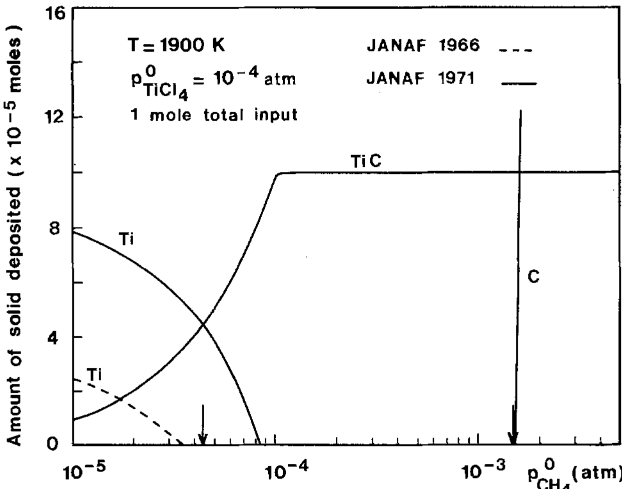

Fig. 3. Influence of the thermodynamic data on the single phase limits of stoichiometric TiC. The TiC/TiC + C limit is unchanged; the Ti + TiC/TiC limit varies. Arrows represent the limit for nonstoichiometric TiC_x ($0.51 \leq x \leq 0.98$).

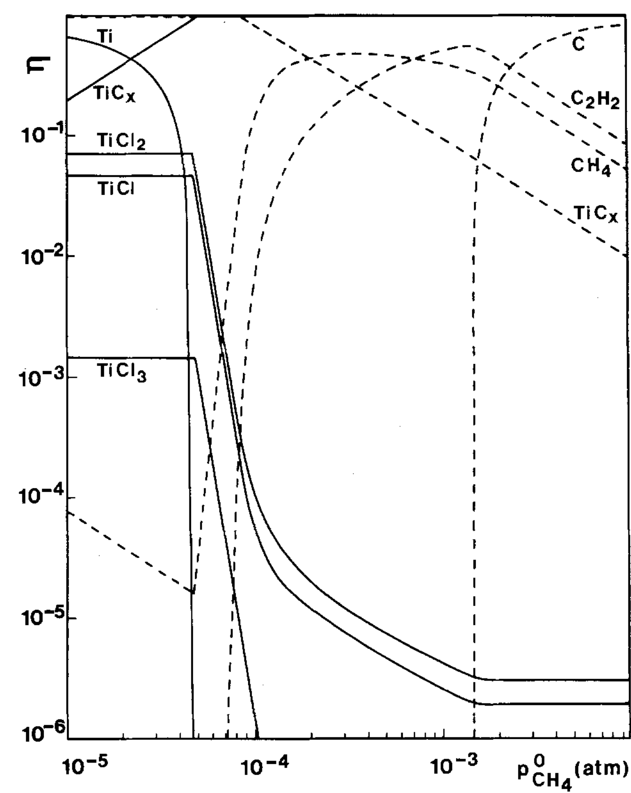

Fig. 4. Variations of the equilibrium yield of the principal species as function of $p°_{CH_4}$. (The value of $p°_{TiCl_4}$ is constant and equal to 10^{-4} atm, $T = 1900$ K).

1. The concentrations of the titanium subchlorides are high in the (Ti + $TiC_{0.51}$) two-phase domain and decreases in the TiC_x single phase domain as $p°_{CH_4}$ increases. Conversely, the concentrations of CH_4 and C_2H_2 which are negligible in the (Ti + $TiC_{0.51}$) deposition domain become preponderant in the ($TiC_{0.98}$ + C) one.

2. Accordingly, almost all titanium is engaged in the titanium carbide when $p°_{CH_4}/p°_{TiCl_4} > 1$ and all carbon is incorporated in the titanium carbide when $p°_{CH_4}/p°_{TiCl_4} < 1$. The amount of titanium carbide increases when $p°_{CH_4}$ increases, up to $p°_{CH_4}/p°_{TiCl_4} = 1$ where it reaches nearly the maximum possible value. The amounts of pure Ti and C are clearly strong functions of the excess in $TiCl_4$ and CH_4 input species.

The corresponding variation of the atomic ratio C/Ti in the titanium carbide phase is shown in Fig. 5 to-

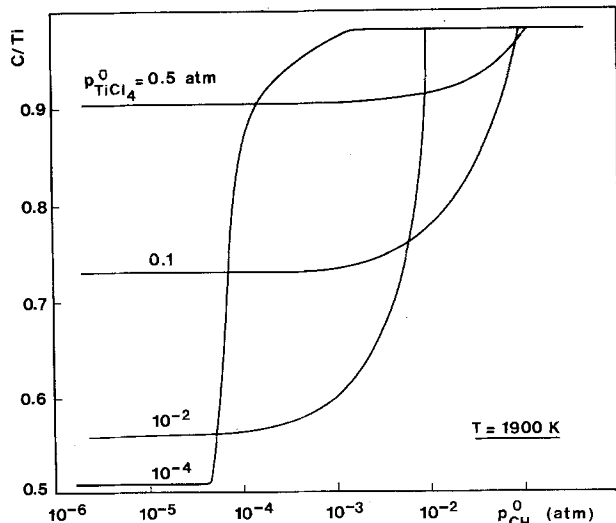

Fig. 5. Variations of the C/Ti ratio in the nonstoichiometric titanium carbide phase as function of $p°_{CH_4}$.

gether with the curves obtained for other values of $p°_{TiCl_4}$, equal to 10^{-2}, 10^{-1}, and 0.5 atm. One can note that the minimum possible value of C/Ti increases when $p°_{TiCl_4}$ increases. This fact can also be observed in Fig. 6 which represents the complete "CVD phase diagram" for Ti-C solids deposited from $TiCl_4$-CH_4-H_2. Titanium carbide can be deposited as a single phase from a wide variety of input gaseous compositions, but this diagram shows, the sensitivity to the experimental conditions for depositing this phase with the desired composition.

Comparison between this thermodynamic approach and some experimental results at high temperature cannot now be done. Only the experimental work of Nadal and Ducarroir was carried out at high temperature (1800 K); the limit between the titanium carbide and titanium carbide plus free carbon was experimentally found, but the compositions in the single phase domain were not determined (18). Their work on this is in progress (19).

Conclusions

The chemical transport and chemical vapor deposition in multicomponent gas-solid systems are complex processes in which many factors can affect the deposition mechanisms and the final composition and structure of the materials. In a first attempt, a thermodynamic approach gives information about the optimum conditions for the synthesis of specified solid phases, keeping in mind that the accuracy of the conclusions can be limited (*i*) by the uncertainties of the thermodynamic data; for many species, accurate values are not available; (*ii*) because significant departure from equilibrium can be produced, especially in open flow reactors; (*iii*) because important departure from equilibrium is necessary to produce specific solid structures, for example amorphous materials.

Another limitation is avoided by considering nonstoichiometric phases. For example, titanium carbide of all compositions within the homogeneity range can be deposited at equilibrium as a function of the initial parameters: temperature, total pressure, and principally the input composition of the gaseous phase. Information is also obtained about the composition of the gaseous phase in equilibrium with the different solids, which permits one to deduce the preponderant species and thus derive the principal chemical reactions.

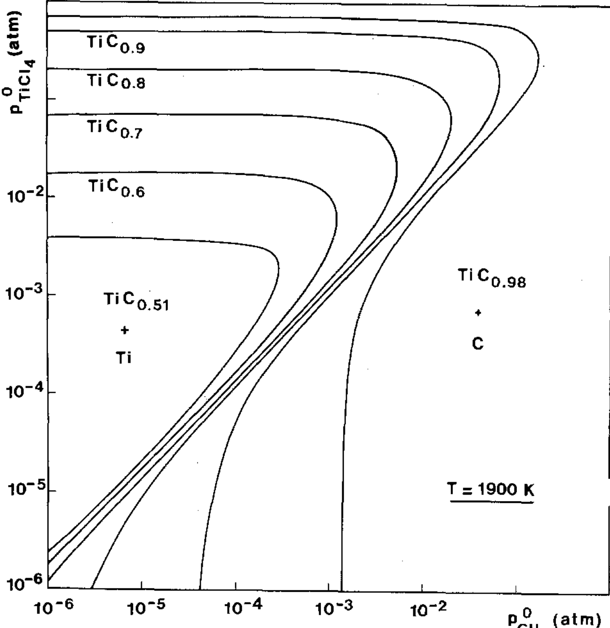

Fig. 6. Phase fields for solid species deposited at equilibrium in the Ti-C-H-Cl system, showing the iso-concentration curves in the titanium carbide single phase domain.

The thermodynamic approach to the deposition of nonstoichiometric titanium carbide will be extended to lower temperatures. More experimental results on the CVD of titanium carbide are indeed available at lower temperature and pressure, and the fundamental interest of such calculations lies also in determining the influence of some departure from equilibrium on the solid composition which often arises at low temperature [this factor was shown to be very important in the CVD of boron carbide at relatively low temperatures (5)]. Moreover, industrial applications have shown that control of the deposit's composition must be improved, for example, to optimize the wear resistance of coatings such as titanium carbide.

National Research Institute for Metals, Tsukuba Laboratories, 1-2-1, Sengen, Sakura-Mura, Niihari-Gun, Ibaraki-Ken, Japan

ABSTRACT

Aluminum nitride films were deposited at 0.15-0.33 μm/min on Mo by rf-reactive ion plating as an application of a low-Z material or a refractory coating. The structure, chemical state, and composition of the deposits were analyzed by scanning electron microscopy, x-ray diffraction, infrared and AES spectra, and x-ray microanalyzer; the deposits were confirmed to be aluminum nitride. Any nitride films improved the oxidation resistance of Mo up to 1100°-1200°C, and the adhesion and thermal cycle stability of the coatings were good. The composition of the deposit effectively depended on the partial pressures of reactant gases. The free Al of the nonstoichiometric deposits may lead to local film failure under high temperature vacuum. The relation between degree of nitridation and mean free path of the gas suggests that the reaction between Al and NH_3 occurs on the substrate surface. The morphology is discussed in terms of the mean free path, and the nitridation rate is also described.

Aluminum nitride has been regarded as a useful ceramic, because of its excellent mechanical properties and chemical stability at high temperature, and is applied as an insulator of electronic materials and as a material corrosion resistant to molten metals or salts. Recently, low atomic number (low-Z) materials are receiving increased attention for fusion devices. The release of plasma contaminants with large atomic number Z from first wall components in plasma devices causes significant increases in plasma resistivity and in plasma losses due to electromagnetic radiation. This can prevent the ignition of fusion reactions. The effect may be minimized by use of low-Z materials (1, 2). In our laboratory, a series of studies of ceramic coatings such as SiC (3) and Si_3N_4 (4, 5) on Mo have been carried out from the standpoint of low-Z coating and the oxidation-resistant coating. This report describes the preparation of the coatings of AlN on Mo by reactive ion plating. Recent work of Komiya *et al.* (6) points out that AlN deposited by physical vapor deposition is attractive also as a clean vacuum deposit on conventional substrate materials because of its low outgassing rate; nitride films such as TiN, Si_3N_4, and AlN form no hygroscopic oxide layer on the surface.

Bulk AlN has been synthesized by many methods; the direct nitridation of solid Al (7), chemical vapor reaction (CVR) with disproportionation of aluminum halide (8), d-c arc discharge (8), and the ammonolysis of $AlCl_3 \cdot xNH_3$ (9). Several authors have presented studies on the preparation of AlN films by reactive sputtering (10-13). Little work, however, has been done on the preparation of AlN by ion plating. Furthermore, there is no report on the AlN coating of Mo. The ion-plating technique consists of making the substrate (Mo) to be coated a part of a cathode of a d-c high voltage circuit, thermally evaporating the metal (Al) by electron beam power, and establishing a gas (NH_3 + evaporated Al) glow discharge by rf coil. One of the principal advantages of this method is that the reactive coatings can be formed without heating the substrate; the reaction is accelerated by the glow discharge. The standard Gibbs energies of formation $\Delta G°$, which indicate the driving force of reaction for several low-Z nitrides, are shown in Fig. 1. The order of the driving forces is B > Ti, Al > Si. BN is the most stable and TiN and AlN rank next. The reaction rate of reactive ion plating is accelerated by activation and/or ionization of the gas. The ionization energy gives a measure of this effect; the small ionization energy can be advantageous for the acceleration of the reaction. Furthermore, the molecules in the gas phase attract each other near the substrate surface to form the compound. The molecular association may depend on the difference in electronegativity, a large difference stimulating the association. Table I gives the ionization energy and electronegativity for each low-Z element. Al has the most advantageous values in both factors of ionization energy and electronegativity difference from N; Ti comes after it. Thus, the preparation of aluminum nitride ceramic proves to be advantageous by rf-reactive ion plating at low temperature.

Order of $-\Delta x_e$	Al,Ti > Si > B			

The structures, compositions, and chemical states of the deposits were analyzed by the scanning electron microscope (SEM), x-ray microanalyzer (XMA), x-ray diffractometer, infrared and AES spectra. The oxidation and the thermal cyclic testing of the AlN-coated Mo were examined by using thermogravimetry and an infrared-image furnace. In this paper the relation of the nitridation with the mean free path in the gas is described and the deposition mechanism is discussed.

Experimental

The rf-reactive ion-plating apparatus has been described elsewhere (4). Some gas molecules were ionized and/or activated in the glow-discharged region by rf power (13.56 MHz) and were accelerated to substrate by applying a negative d-c bias. The substrate was subjected to inert (Ar) ion bombardment and cleaned by sputtering. Since the ion bombardment was continued up to and during deposition, the surface was maintained clean. The ion bombardment confines the energy flux to the substrate surface giving high surface temperature without the need for bulk heating; the temperature rose to about 350°C in this work. This surface temperature enhances chemical reaction and diffusion. AlN was formed by the reaction of Al vapor and NH_3 gas. Al with a purity of 99.99% was used as the evaporation source, and the purity of ammonia used as a source of nitrogen was also 99.99% (Mathewson Gas Products). The substrate was prepared from sintered and electrochemically polished molybdenum sheet. Al was evaporated by an electron beam from a water-cooled copper hearth which was covered with tantalum sheet in order to avoid heat loss. An NH_3 gas was introduced into a chamber through a leak valve. The Al was weighed before and after deposition. The coating conditions are given in Table II: the rf power was 200-230W, d-c bias −0.4 to −0.6 kV, the electron beam power 2.0-3.5 kW, the pressure of NH_3 gas 1-7 $\times 10^{-3}$ Torr with residual pressure of 2.0 $\times 10^{-6}$ Torr; $\dot{m}_{Al}$ denotes the evaporation rate of Al. The evaporation was difficult to control by electron beam power; $\dot{m}_{Al}$ did not have similar values even for the same electron beam power. This may have resulted from differences in the rate of thermal loss from aluminum to the hearth and in different NH_3 gas pressure. The distance between the substrate and the hearth was about 10 cm and the coating time was 10 min.

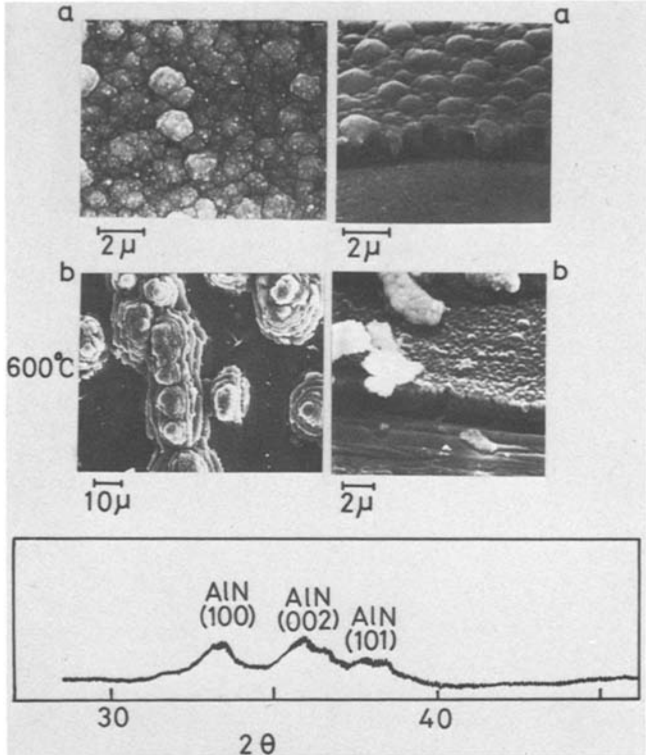

Fig. 2. Scanning electron micrographs and an x-ray diffraction pattern (run 22) of the deposits. a, Substrate was not heated (run 22); b, substrate was heated to 600°C (run 29).

Most of the coatings were carried out without heating the substrate, but for some coatings the substrate was heated by electroresistance heating. The substrate temperature was measured by Chromel-Alumel thermocouple placed in contact with its back side.

Results

Characterization of deposits.—The morphology, chemical composition, and structure of the deposits depended on the experimental conditions, especially on the partial pressures of NH_3 gas and Al vapor. Figure 2 shows SEM micrographs and an x-ray diffraction pattern of the deposits. The deposits with round growth features have x-ray diffraction peaks which indicate AlN. Deposit colors were dark green or brown, but some were blue. Contamination with impurities such as carbon and/or oxygen causes color changes for the deposits, as discussed by several authors (14, 15). The round growth features were also observed in the deposits of CVD-SiC (3) and ion-plated Si_3N_4 (4). The deposits prepared on the substrate heated to 600°C have also peaks indicating AlN in the x-ray diffraction pattern, but the coatings show comparatively large nodules on the surface (Fig. 2b); the deposits indicated gray color. The deposits with rugged features indicated the presence of free Al (x-ray diffraction) as shown in

Fig. 3. Such deposits have spherical fine particles on the surface, colored gray or black. The deposits with free Al were formed at high evaporation rate of Al. The chemical states of AlN were analyzed by infrared spectra (double-beam spectrometer) (Fig. 4). The deposits were mechanically removed from the substrate, ground to microsize with KBr, and the mixture was pressed into a pellet. A strong broad band with its center at 750 cm^{-1} indicated the Al-N bond. The peak location is close to that for hexagonal AlN crystal (16) and midway between those of sputtered deposited AlN by Itoh *et al.* (11) and Duchene *et al.* (12). The absorption intensity is weakened in AlN deposits with free Al. The Auger electron spectrum of a deposit sputter-cleaned by Ar ions, together with those of metal Al, Al_2O_3, and hot-pressed AlN, is shown in Fig. 5. The AES spectrum of ion-plated AlN indicates that carbon and oxygen are contained in the deposits as impurities. Peak locations and shapes of two Al peaks of the AES spectra at 50 and 1400 eV from the ion-plated AlN are in good agreement with those from hot-pressed AlN. X-ray diffraction, infrared and AES spectra confirmed that Al was present as AlN.

The chemical compositions of AlN deposits determined by XMA and their coating conditions are summarized in Table II. Single crystals of AlN and Al_2O_3 were used as the standard samples for Al, N, and O. R_d denotes the deposition rate of AlN. The degree of nitridation was good without substrate heating. The ratio (N)/(Al) exceeds unity for some deposits; the trend was severe in thinner films, perhaps because of error in the quantitative analytical method for nitrogen in the thin films. The peak-to-peak profiles from AES for deposits exposed to ambient air after preparation are shown in Fig. 6, in which Ar^+ was used as the sputtering ion. Oxygen is remarkably enriched on the surface; this may result from surface decomposition of AlN by the attack of H_2O contained in air (8). Heating of the substrate caused no apparent change in composition (run 29). The nitridation characteristics were governed mainly by the pressure of ammonia, P_{NH_3}, and the evaporation rate of Al. When m_{Al} was large (over ~0.1 g/min) a film of rugged morphology with free Al was deposited, as mentioned previously. Now, consider the dependence of the degree of nitridation of the deposits on the partial pressures of NH_3 and Al vapor. In the dynamic situation it is difficult to estimate P_{Al}. In this work. the equation of Langmuir (17, 18) was used for calculation of P_{Al}. Figure 7a and b show the dependence on the ratio of partial pressures P_{NH_3}/P_{Al} of the deposition rate R_d and the atomic concentration ratio (N)/(Al) of deposits. Values for m_{Al} calculated from the vapor pressure of Al (19) by the Langmuir equation (for $T = 1.5T_{Melt}$, T is the Al-source temperature) generally agreed with the experimental $\dot{m}_{Al}$ in this work. The deposition rate drastically

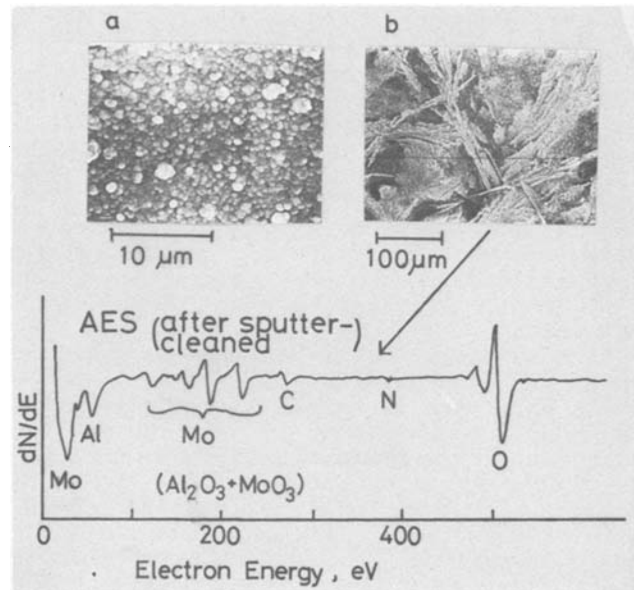

Fig. 9. Scanning electron micrographs and an Auger electron spectrum of the specimen after the oxidation test (run 20).

decreases with an increase of P_{NH_3}/P_{Al} (Fig. 7a). A similar relation was found between the deposition rate and P_{N_2} in sputtered-deposited AlN (11). The ratio (N)/(Al) increases almost linearly with P_{NH_3}/P_{Al} when P_{NH_3}/P_{Al} is small; such films indicated the morphology with rugged features (Fig. 3). The regime denoted as I in Fig. 7b is low in nitridation degree and that denoted as III is too low in deposition rate. Therefore, the area II shows the optimum condition for the preparation of AlN deposits by the ion plating (0.15-0.33 μm/min); these deposits correspond to those shown in Fig. 2.

Oxidation test and thermal cyclic stability test of the coatings.—The oxidation resistance was examined by thermogravimetry. Coated specimens of 0.5 cm × 0.5 cm × 0.07 mm were heated at a rate of 20°C/min in Ar-1% O_2 gas mixture with a flow rate of ~200 ml/min. Figure 8 shows the results of the oxidation test for typical coated specimens. Uncoated Mo specimen experienced a drastic weight decrease at about 790°C because of the evolution of MoO_3 which has a high vapor pressure. But AlN films protect the Mo substrate from oxidation in the high temperature environment up to 1100°-1200°C. Little difference in oxidation resistance between the stoichiometric and the nonstoichiometric coatings was observed. SEM micrographs and an AES spectrum of typical specimens after the oxidation test are given in Fig. 9. Figure 9a denotes the morphology of the coating surface at oxidation temperature where the drastic weight loss has not begun (arrow a in Fig. 8). No morphological change is found in the specimen of Fig. 9a. Figure 9b shows the specimen after the drastic weight decrease (arrow b in Fig. 8). The AlN films disappeared, and needle-like products covered the substrate surface (b). From the AES spectrum, the peak of nitrogen disappears and the product consists of Al_2O_3 and MoO_3.

In order to evaluate the stability of a coated specimen, a thermal cycle test was carried out in vacuum by use of an infrared-image furnace. The thermal cycle was set between 900° and 1200°C with a rate of temperature rise 130°C/min and a fall rate of −180°C/min. This thermal cycle condition simulates that of the JAERI Experimental Fusion Reactor (20). No weight loss was observed in any AlN coated specimens (Fig. 10). Figure 11 shows SEM micrographs after 10 thermal cycles. Cracks were observed in the stoichiometric films prepared on the unheated substrate, but spalling never occurred. On the other hand, no crack was observed for a nonstoichiometric coating containing free Al (Fig. 11) or for a stoichiometric coating on a heated substrate (not shown).

Discussion

The AlN coating improved the oxidation resistance up to about 1200°C, which is similar to the result of Si_3N_4 coatings (4). Pinholes present in the Si_3N_4 films ion plated on Mo cause the pitting corrosion of Mo under a high temperature oxidizing environment (5). A more severe problem occurred for the AlN coatings: no pitting corrosion was observed, but the AlN decomposed. AlN is unstable in water vapor (21), and ion-plated AlN may be decomposed by H_2O attack contained in the oxidizing gas.

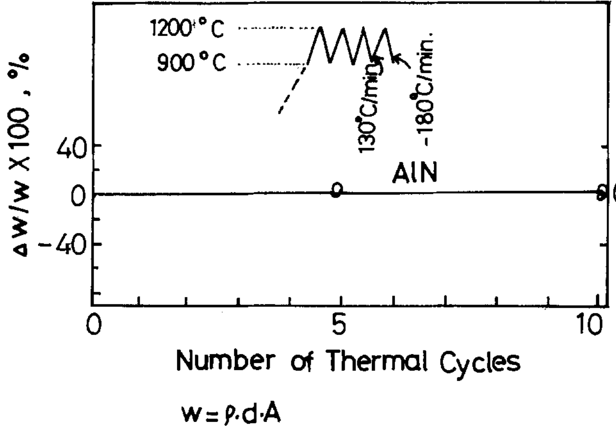

Fig. 10. Percentage of weight change of the deposits by thermal cycles under vacuum. ρ, d, and A are density, thickness, and surface area of the deposits.

Generally, the adherence of ceramic coatings on metals is poor. Si_3N_4 films coated on Mo by the ion plating showed poor adherence to the substrate (4, 5) upon bending the specimens. In the case of AlN coatings, only a small part of surface peeled off by bending through 90°, though cracks were observed (not shown). Furthermore, no spalling was observed for specimens after the thermal cyclic tests in vacuum at high temperature, as described in the previous section. Thus, the AlN coatings on Mo are comparatively good in adhesion.

Little difference between the stoichiometric and the nonstoichiometric (with free Al) coatings was observed in the oxidation test and the thermal cycle stability test. The test described below was carried out in order to make the difference clear. The coated specimens were kept in vacuum ($\sim 10^{-6}$ Torr) at 1400°C for 10 min. After this test, no change of the morphology and the thickness of the stoichiometric AlN film was observed (Fig. 12a). The weight of deposited AlN films was about 1.1×10^{-3} g/cm² (3.3 μm). The evaporation rate of high purity massive sintered AlN in vacuum in a temperature range of 1180°-1600°C is about 3.8×10^{-5} g/cm² sec (22). If the vaporized weight is calculated directly from this evaporation datum, such thin films should disappear after 30 sec. Actually, little evaporation of the stoichiometric deposits prepared by the ion plating (present work) was observed. The contamination of oxygen and carbon (Table II) may cause strengthening of the chemical bond of the AlN and lowering of the Al vapor pressure.

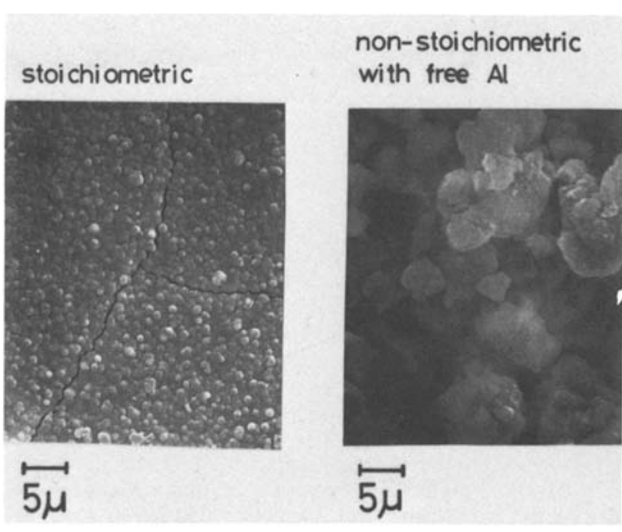

Fig. 11. Scanning electron micrographs of the deposits after the thermal cycle test.

A hole-like flaw is observed in the nonstoichiometric AlN film with free Al (Fig. 12b). The vaporization of free Al contained in the nonstoichiometric film is responsible for this local failure of film surface. Thus, nonstoichiometric AlN is not always suitable for high temperature use in vacuum, though the coated Mo specimens have good oxidation resistance and thermal cycle stability.

The nitridation degree correlated with the local vaporization of the deposits in a high temperature vacuum. The degree of nitridation and the deposition rate of films by ion plating depend on experimental factors such as partial pressures of reactants, electron beam power, bias voltage, and temperature. In the ion-plating deposition of Si_3N_4 (4), the most important factors were an electron beam power into the Si evaporation source and the rf-discharge power, which are effective for the ionization and/or activation of reactants. For the ion plating of AlN, however, the partial pressures of reactant gases strongly influence the nitridation rate of Al. With an increase of pressure, the mean free path of reactants becomes small and the number of molecular collisions in the gas phase increases. The mean free path of species i, λ_i, and the partial pressure P_i are related by (23)

$$\lambda_i = (\sum_j \pi((d_i + d_j)/2)^2 n_j((1 + M_i/M_j)^{1/2})^{-1}, \quad (i,j = \text{Al}, \text{NH}_3) \quad [1]$$

where d_i is the diameter of i, M_i is the atomic or molecular weight, and the number density of i, n_i, can be given by $n_i = P_i/k_BT$. The diameters used for the cal-

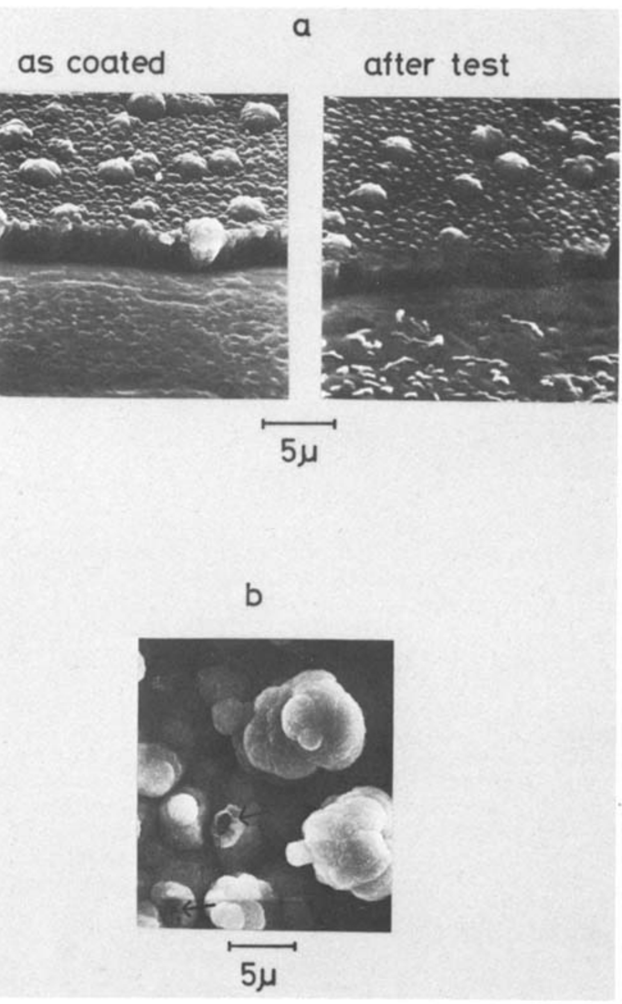

Fig. 12. Scanning electron micrographs of the coated specimens after keeping them in vacuum at 1400°C for 10 min. a, Stoichiometric film; b, nonstoichiometric film.

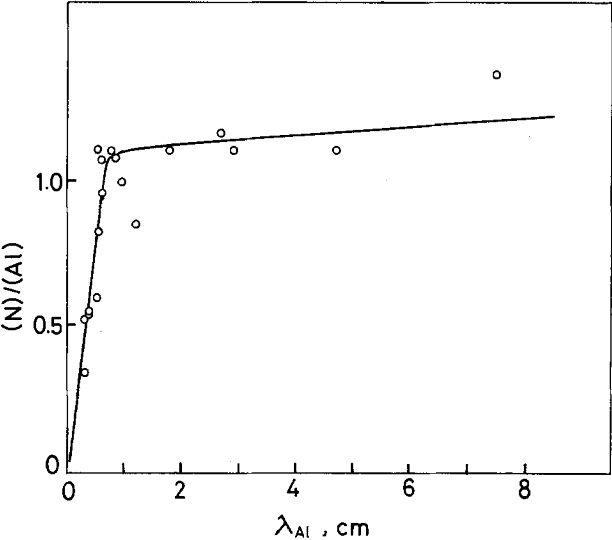
culation were 1.4Å for d_{NH_3} and 2.4Å for d_{Al}. In Fig. 13a and 13b, the nitridation degree, *i.e.*, atomic ratio (N)/(Al), is shown as a function of the mean free path. There is a similar trend between Al and NH_3. The ratio (N)/(Al) decreases drastically on the low side of the mean free path; the decrease is almost linear, and (N)/(Al) approaches zero when the mean free path is zero. When the mean free paths are very small, the number of the intermolecular collisions in the gas phase becomes very large. In the physical vapor deposition of metals, a combination of the evaporated atoms upon collision in the gas phase results in formation of clusters when the pressures are large (24). These clusters grow gradually because of the successive collisions, and large spherical particles are developed. For the ion plating of AlN, a similar process is expected, namely, evaporated Al atoms (and/or ions) collide with one another to grow to large particles in the gas phase when the mean free path is small (high pressure). Thus, such large particles are considered to cause the rugged morphology and the presence of the free Al in the AlN deposits. For a mean free path of over about 0.6 cm for λ_{Al} and 1 cm for λ_{NH_3}, the deposits have nearly stoichiometric concentration, independent of film thickness. Since the distance between the substrate and the hearth is 10 cm, the collision number of an Al atom with others in the gas phase is very small, 0-3 times for large λ_{Al} over 3 cm during the deposition. Nevertheless, the nitridation is sufficient. Furthermore, the (N)/(Al) ratio of the deposits becomes almost zero when the mean free paths approach zero. If collisions in the gas phase make some contribution to the reaction between Al and NH_3, (N)/(Al) should be comparatively large for small mean free path. Hence, the reaction is deduced to occur mainly on the substrate surface, not in the gas phase. Thus, the rate of reactant supply to the surface can be an important factor.



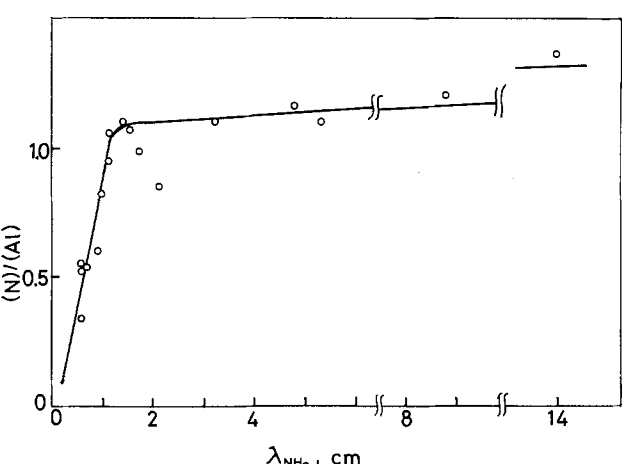


Fig. 13. Relation between (N)/(Al) and mean free path calculated from Eq. [1]. a (top), Al; b (bottom), NH_3.

The nitridation rate of Al, r_N, which is defined as the number of gram-atoms of nitrogen incorporated in deposits per unit area per unit time, can be given by

$$r_N = R_d \rho x_N \quad [2]$$

where x_N is the atomic fraction of N and ρ is atomic density of deposits. The averaged values of AlN and Al were used for ρ. The values of r_N, together with those of AlN prepared by other methods, are shown in Table III. The r_N value of the present work is smaller than those for CVR with disproportionation of aluminum halide and d-c discharge which are synthetic methods at high temperature. However, the present ion plating gives a large nitridation rate of Al without heating the substrate up to high temperature. The r_N value is larger by an order of magnitude than those of sputtering methods and corresponds to the reaction of $AlCl_3$ and NH_3 at 1000°C.

The reaction between Al and NH_3 was found to occur on the surface, and the reaction rate depends on concentrations of the reactants near the surface. There are three types of molecules (or atoms) in the glow discharge region: ionized (ions), activated, and unactivated neutral molecules. The neutral unactivated molecules have little contribution to the reaction because the ion plating was performed at rather low temperature. The rate of reactant supply to the surface J_i can be expressed by

$$J_i = n_i^+ v_i^{ac} + \tfrac{1}{4} n_i^* v_i^T \quad [3]$$

where n_i^+ and n_i^* are the densities of ionized and activated molecules of i, and v_i^{ac} and v_i^T are the velocity of ions accelerated by the bias and the thermal velocity, respectively. n_i^+ and n_i^* are proportional to the total number of i, n_i, *i.e.*, $n_i^+ = x_i^+ n_i$ where x_i^+ is the fraction of ionized molecules. Therefore, J_i is proportional to the pressure P_i ($P_i = n_i/k_BT$). The total surface concentration of these species is proportional to P_i, since it should be proportional to J_i. Hence, P_i indicates a measure of the surface concentration of i. Now, the nitridation rate will be analyzed by a typical method of chemical kinetics (25). Figure 14 gives the relation of the nitridation rate, r_N, with the product of partial pressures of reactants, $P_{Al}P_{NH_3}$. A linear relation is found between log r_N and log ($P_{Al}P_{NH_3}$), and its slope is about unity (0.9): the nitridation rate is almost proportional to the product of partial pressures. The result indicates that the nitridation mechanism is unchanged, independent of the partial pres-

Table III. Nitridation rates of AlN

Method	r_N (g-atom/cm² sec)	Temp (°C)
Direct N_2-nitridation of solid Al (7)	1.6×10^{-11}	530

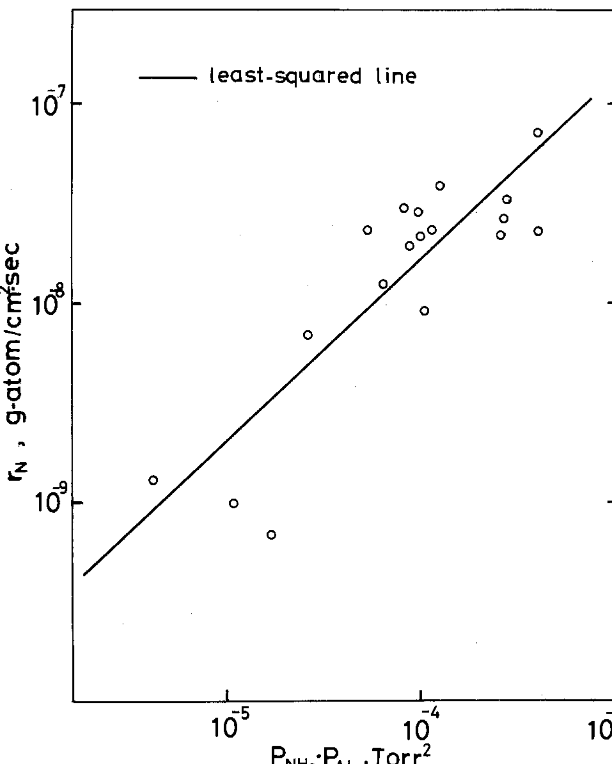

Fig. 14. Relation between nitridation rate r_N and (P_{NH_3} P_{Al})

sures (mean free path) and that activated and/or ionized aluminum and ammonia react on the substrate surface with second order. Thus, the reaction process is considered not to be affected by many intermolecular collisions in the gas phase. The gas-phase collision never affects the nitridation reaction on the surface, though at high evaporation rate of Al it causes the development of free Al.

The discharge effect will be briefly described. The ionization energies of Al and NH_3 are 138 and 241 cal/mol. The ionization of Al is much easier than that of NH_3; x_{Al^+} becomes large. In addition to the ionization, the NH_3 molecule decomposes in the glow-discharge region. The major decomposed state at 800°C is an active NH_2, confirmed by mass spectrometry (26). The decomposition energy of N-H bond is 93.4 cal/mol, which is small compared with that for the ionization of Al. This suggests that the decomposition of NH_3 is easier than the ionization of Al. NH_3 forms active states more easily than Al; the second term of Eq. [3] is rather important for NH_3. Hence, good nitridation can occur for low NH_3 pressures compared with that of Al vapor ($P_{NH_3}/P_{Al} \gtrsim 0.1$), as indicated in Fig. 7b. Direct evidence by using analytical methods such as infrared, Raman, photoemission, and mass spectra are needed for understanding the reaction mechanism.

Conclusions

Coatings of AlN on Mo were performed by rf-reactive ion plating with the intention to form a low-Z coating for the fusion reactor and a refractory coating. For most of the coatings, the Mo substrate was not heated during the deposition. The following conclusions are offered:

1. Analyses of the structure, composition, and chemical state of the deposits showed that Al was present as AlN. Nearly stoichiometric nitride deposits were formed, but nonstoichiometric films with free Al also were obtained when P_{NH_3}/P_{Al} was small. Contamination with C and O was observed.

2. The oxidation resistance up to 1100°-1200°C of Mo improved by AlN layers is similar to the results for Si_3N_4 coatings. No pitting corrosion was observed in the specimens after the test, but the AlN film disappeared; the needle-like products developed were found to consist of Al_2O_3 and MoO_3.

3. Ten thermal cycles from 900° to 1200°C in vacuum resulted in no weight loss for any AlN coated specimens; cracks were observed in the stoichiometric films, but no spalling was observed. The nonstoichiometric films had no cracks. Thus, the AlN coatings on Mo are good in adhesion.

4. Little difference in oxidation resistance and thermal cycle stability was found between the stoichiometric and nonstoichiometric coatings. However, the free Al contained in the nonstoichiometric film caused the local failure of films in vacuum at high temperature.

5. The surface reaction of Al and NH_3 (on the substrate surface) was suggested from the relation between the nitridation degree and the mean free path of gas. Furthermore, the relation of nitridation rate with the product of reactant pressures indicated that the surface reaction could be described by the second-order reaction.

6. The large particles developed by the successive collisions of Al in the gas phase are deduced to be responsible for the rugged morphology when P_{NH_3}/P_{Al} is small.

Acknowledgments

The authors would like to express their gratitude to Mr. T. Kimura and Mr. H. Araki for the measurement of XMA. The standard single crystal of AlN was prepared by Dr. M. Iwata, Dr. T. Sakai, and Dr. T. Sato of National Institute for Research in Inorganic Materials, and hot-pressed AlN was by Dr. H. Inomata and Dr. H. Tanaka of the same institute. Thanks are also due to them.

ABSTRACT

A number of equivalent exact and useful approximate equations for the liquidus of $(A_{1-u}B_u)_{2-y}C_y(s)$ with y near unity and with congruently melting end members ($u = 0, 1$) are obtained. These are general in so far as the liquid phase is concerned, except that the forms written for associated solution models of the liquid depend upon the species assumed. The congruent melting of the end members leads to important, usually ignored, links between the thermodynamic properties of the liquid and those of the binary compounds. It is shown that the common assumption that the heat capacity of a binary, end member, compound equals that of its supercooled liquid is generally incorrect and is unnecessary. The results are applied to a number of recent analyses of liquidus surfaces and lines.

The thermodynamic equation for the liquidus of a congruently melting, narrow homogeneity range compound has been derived in a number of papers (1-6). That given by Vieland (6) has been widely used, extended to ternary systems, and used with an associated solution model for the liquid (7-10) following Jordan's development of a simplified version of this model (11, 12). The derivation given by Vieland has been reexamined for the case of the liquidus of a pseudobinary solid (13). Although the derivation and liquidus equation given by Vieland are correct and simple, they have suffered in usage. First of all, one step of the thermodynamic cycle used in the derivation recognizes the equality of the Gibbs free enthalpy of the compound and its melt at the congruent melting point. However, equations that directly follow from this equality, and which provide an important link between the thermodynamic properties of the compound and the liquid, were not emphasized and are almost universally ignored. Secondly, the liquidus equation contains as one term the integral over temperature of the difference between the heat capacity of the compound and its supercooled liquid. This difference is almost always set to zero. In fact, such a step is unnecessary, is in principle usually incorrect, and in practice is often seriously incorrect when associated solution models are used for the liquid. Finally, there are other equivalent liquidus equations that are more convenient to use in certain cases. The purpose here is to demonstrate these points and to apply the results to a number of recent analyses.

We consider the liquid in equilibrium with a ternary solid solution, $(A_{1-u}B_u)_{2-y}C_y(s)$, with congruently melting end members ($u = 0, 1$). It is assumed that the C atoms occupy sites in their own sublattice and, because y is always near unity, that the site-fraction of atom point defects is small. The chemical potentials of AC and BC in the solid are then independent of y to a good approximation (14). Consequently, as we shall show, the thermodynamic equations for the liquidus surface of the solid solution depend upon u but not y. Thus the liquidus equations are formally identical with those for a pseudobinary solid. The liquidus equations for the binary compounds, AC(s) and BC(s) are of course obtained as special cases.

Liquidus Equations

We consider the equilibrium between $(A_{1-u}B_u)_{2-y}C_y(s)$ and a liquid phase in the solid-liquid-vapor system. The system has two degrees of freedom. We first seek equations that are general in so far as the liquid phase is concerned, and which are therefore applicable with any thermodynamically valid model of the liquid phase. At equilibrium the chemical potential of each component must be the same in the solid and liquid. This gives three equations

$$\mu_A{}^L = \mu_A{}^s \quad [1]$$

$$\mu_B{}^L = \mu_B{}^s \quad [2]$$

* Electrochemical Society Active Member.

Key words: liquidus equations, Vieland equation, thermodynamics.

$$\mu_C{}^L = \mu_C{}^s \quad [3]$$

By adding pairs of equations from Eq. [1]-[3], one obtains

$$\mu_A{}^L + \mu_C{}^L = \mu_A{}^s + \mu_C{}^s \quad [4]$$

$$\mu_B{}^L + \mu_C{}^L = \mu_B{}^s + \mu_C{}^s \quad [5]$$

Now we suppose the solid phase is a solution, $(A_{1-u}B_u)_{2-y}C_y(s)$, in which A and B are distributed among the sites of one sublattice and C occupies a second sublattice. If the range of y about the value 1 is less than about 0.01, then the right-hand members of Eq. [4] and [5] are independent of y to a good approximation (14) and can be written as

$$\mu_{AC}{}^s(u, T) = \mu_A{}^s + \mu_C{}^s \quad [6]$$

$$\mu_{BC}{}^s(u, T) = \mu_B{}^s + \mu_C{}^s \quad [7]$$

In writing the variables determining the chemical potentials of AC and BC in the solid, we omit the total pressure and rely upon the relative insensitivity of the thermodynamic properties of condensed phases to hydrostatic pressure. For the liquid phase the chemical potentials are of the general form

$$\mu_j{}^L = h_j - Ts_j + RT\ln(x_j) + \mu_j{}^{o,L}(T) \quad j = A, B, C \quad [8]$$

where $\mu_j{}^{o,L}(T)$ is the chemical potential of pure j liquid, h_j is the relative partial molar enthalpy of j, and s_j is the relative excess partial molar entropy of j. (To avoid excessive superscripts we do not follow the convention here that the excess quantities are marked by a superscript x or xs.) Both of these partial molar quantities are zero for pure j liquid, *i.e.*, when $x_j = 1$. Our basic equations are now Eq. [4] and [5]. The thermodynamic problem has thus been conveniently broken into two parts. That part retained in Eq. [4] and [5] relates the composition of the liquid phase to the solid composition variable u. Since y does not appear, the equations are identical to those for a pseudobinary solid solution. The second part would relate both y and u for the solid to the liquid composition and is not pursued here.

The chemical potentials of the components AC and BC in the solid solution can also be written formally in terms of relative partial molar enthalpies and excess entropies as

$$\mu_{AC}{}^s = h_{AC}{}^s - Ts_{AC}{}^s + RT\ln(1-u) + \mu_{AC}{}^{o,s}(T) \quad [9]$$

$$\mu_{BC}{}^s = h_{BC}{}^s - Ts_{BC}{}^s + RT\ln(u) + \mu_{BC}{}^{o,s}(T) \quad [10]$$

where $\mu_{AC}{}^{o,s}(T)$ and $\mu_{BC}{}^{o,s}(T)$ are the chemical potentials of pure AC(s) and pure BC(s), respectively. When $u = 0$, $h_{AC}{}^s = s_{AC}{}^s = 0$. When $u = 1$, $h_{BC}{}^s = s_{BC}{}^s = 0$.

The Gibbs free enthalpy of formation per mol of each binary compound from its liquid elements can be written as

$$\Delta G^o{}_f(AC) = \Delta H^o{}_f(AC) - T\Delta S^o{}_f(AC) = \mu_{AC}{}^{o,s} - \mu_A{}^{o,L} - \mu_C{}^{o,L} \quad [11]$$

$$\Delta G^o{}_f(BC) = \Delta H^o{}_f(BC) - T\Delta S^o{}_f(BC) = \mu_{BC}{}^{o,s} - \mu_B{}^{o,L} - \mu_C{}^{o,L} \quad [12]$$

The last equality in each equation follows from the fact that the chemical potentials of the pure compounds are independent of the deviation from stoichiometry for small deviations (15, 16). Using Eq. [6]-[12] in Eq. [4] and [5] gives the enthalpy-entropy of formation liquidus equations

$$h_A + h_C - T(s_A + s_C) + RT\ln(x_A x_C) = h_{AC}{}^s - Ts_{AC}{}^s + RT\ln(1-u) + \Delta H^o{}_f(AC) - T\Delta S^o{}_f(AC) \quad [13]$$

$$h_B + h_C - T(s_B + s_C) + RT\ln(x_B x_C) = h_{BC}{}^s - Ts_{BC}{}^s + RT\ln(u) + \Delta H^o{}_f(BC) - T\Delta S^o{}_f(BC) \quad [14]$$

These are sometimes convenient. Their usage guarantees that the sums of the chemical potentials in the binary melts AC(l) and BC(l) equal the Gibbs free enthalpies of formation of, respectively, AC(s) and BC(s). However, the melting points of the binary compounds calculated from these equations do not necessarily agree with the observed values unless two constraining equations are imposed. These are obtained from Eq. [13] and [14] by requiring the former be satisfied for $x_A = x_C = ½$ and $T = T_{AC}$, the melting point of AC(s), and the latter be satisfied for $x_B = x_C = ½$ and $T = T_{BC}$, the melting point of BC(s). As a result, not all of the parameters of the liquid phase model can be independent. The liquidus equations can be recast into a form that depends upon the enthalpy and entropy of melting of each binary compound by first expressing the temperature dependence of the enthalpy and entropy of formation for each binary compound. For AC(s) one can write in general that

$$\Delta H^o{}_f(AC) = \Delta H^o{}_f(AC, T_{AC}) + \int_{T_{AC}}^{T} \Delta C_{AC}{}^s\, dT \quad [15]$$

$$\Delta S^o{}_f(AC) = \Delta S^o{}_f(AC, T_{AC}) + \int_{T_{AC}}^{T} \Delta C_{AC}{}^s\, d\ln T \quad [16]$$

where the standard, relative, constant pressure, heat capacity per mol of AC(s), $\Delta C_{AC}{}^s$, is given by

$$\Delta C_{AC}{}^s = C_{AC}{}^s - C_A{}^{o,L} - C_C{}^{o,L} \quad [17]$$

and $C_A{}^{o,L}$ and $C_C{}^{o,L}$ are the constant pressure heat capacities per g-atom of, respectively, pure A(l) and pure C(l) and $C_{AC}{}^s$ is that of AC(s) per mol. Completely analogous equations hold for BC(s). Then, because the Gibbs free enthalpy of melting for AC(s) is zero at $T = T_{AC}$, one has two equations

$$\Delta H^o{}_f(AC, T_{AC}) = h_A{}^* + h_C{}^* - H_{AC}{}^m \quad [18]$$

$$\Delta S^o{}_f(AC, T_{AC}) = s_A{}^* + s_C{}^* + R\ln 4 - H_{AC}{}^m/T_{AC} \quad [19]$$

where $H_{AC}{}^m$ is the enthalpy of melting per mol of AC(s) and the asterisk superscript indicates that the partial molar quantities are evaluated at $x_A = x_C = ½$ and $T = T_{AC}$. The analogs for BC(s) are

$$\Delta H^o{}_f(BC, T_{BC}) = h_B{}^{**} + h_C{}^{**} - H_{BC}{}^m \quad [20]$$

$$\Delta S^o{}_f(BC, T_{BC}) = s_B{}^{**} + s_C{}^{**} + R\ln 4 - H_{BC}{}^m/T_{BC} \quad [21]$$

where T_{BC} is the melting point of BC(s), $H_{BC}{}^m$ is its enthalpy of melting, and the double asterisk indicates a quantity is evaluated at $x_B = x_C = ½$ and $T = T_{BC}$. The desired liquidus equations can now be obtained by using Eq. [15]-[16] and [18]-[21] to eliminate the enthalpy and entropy of formation quantities in Eq. [13] and [14]. Upon rearrangement the result is

$$T = \frac{h_A - h_A^* + h_C - h_C^* + H_{AC}^m + \int_T^{T_{AC}} (1 - T/r)\,\Delta C_{AC}^s dr - h_{AC}^s}{s_A - s_A^* + s_C - s_C^* + H_{AC}^m/T_{AC} + R \ln [(1-u)/4x_A x_C] - s_{AC}^s} \quad [22]$$

$$T = \frac{h_B - h_B^{**} + h_C - h_C^{**} + H_{BC}^m + \int_T^{T_{BC}} (1 - T/r)\,\Delta C_{BC}^s dr - h_{BC}^s}{s_B - s_B^{**} + s_C - s_C^{**} + H_{BC}^m/T_{BC} + R \ln [u/4x_B x_C] - s_{BC}^s} \quad [23]$$

where, it is emphasized, the partial molar entropies are excess quantities. Equations [22] and [23] are general in so far as the liquid phase model is concerned, and are exact except that the effect of hydrostatic pressure on the properties of the liquid and solid phases is neglected. The equations are not in general explicit equations for T unless ΔC_{AC}^s and ΔC_{BC}^s are zero and all the partial molar quantities are independent of T. They are consistent with a melting temperature of T_{AC} for AC(s) and T_{BC} for BC(s). Finally, r in the integrals is obviously a dummy integration variable.

The "exact" liquidus equations can be put in a form resembling Vieland's equation for a binary liquidus by using the thermodynamic definitions

$$RT \ln (\gamma_i) = h_i - Ts_i \quad i = A, B, C \quad [24]$$

$$RT \ln (\Gamma_{jk}) = h_{jk}^s - Ts_{jk}^s \quad jk = AC \text{ or } BC \quad [25]$$

and the equality below for A-C and an analogous one for B-C

$$h_A^* + h_C^* - T(s_A^* + s_C^*) = h_A^\dagger + h_C^\dagger - T(s_A^\dagger + s_C^\dagger) + \int_T^{T_{AC}} (1 - T/r)\,\Delta C_{AC}^L\,dr$$

$$= RT \ln (\gamma_A^\dagger \gamma_C^\dagger) + \int_T^{T_{AC}} (1 - T/r)\,\Delta C_{AC}^L\,dr \quad [26]$$

where $\Delta C_{AC}^L = C_{AC}^L - C_A^{o,L} - C_C^{o,L}$ is the constant pressure heat capacity of the 50 atomic percent (a/o) liquid, and hence ΔC_{AC}^L is the relative heat capacity of two g-atoms of the 50 a/o liquid, AC(l). (See Eq. [17].) The dagger superscript indicates evaluation at $x_A = x_C = 1/2$ and an arbitrary T. Upon rearrangement the result is

$$RT \ln \left[\frac{4\gamma_A \gamma_C x_A x_C}{\gamma_A^\dagger \gamma_C^\dagger (1-u) \Gamma_{AC}} \right] = H_{AC}^m (T/T_{AC} - 1) - \int_T^{T_{AC}} (1 - T/r)(\Delta C_{AC}^s - \Delta C_{AC}^L)\,dr \quad [27]$$

$$RT \ln \left[\frac{4\gamma_B \gamma_C x_B x_C}{\gamma_B^\dagger \gamma_C^\dagger u \Gamma_{BC}} \right] = H_{BC}^m (T/T_{BC} - 1) - \int_T^{T_{BC}} (1 - T/r)(\Delta C_{BC}^s - \Delta C_{BC}^L)\,dr \quad [28]$$

The differences $\Delta C_{AC}^s - \Delta C_{AC}^L$ and $\Delta C_{BC}^s - \Delta C_{BC}^L$ are the ΔC_p that appear in Vieland's equation and which have been indiscriminantly set equal to zero. Equations [27] and [28] are equivalent to Eq. [22] and [23]. For either binary system, A-C or B-C, they reduce to a generalization of the Vieland equation previously obtained by Jordan and Weiner. However, neither Vieland nor Jordan and Weiner explicitly stated the dependence of these equations upon the validity of the auxiliary conditions, Eq. [18]-[21], which is emphasized here. In Vieland's derivation, the Gibbs free enthalpy of formation of the binary solid compound is eliminated in favor of the enthalpy and entropy of fusion and other quantities using the results of a thermodynamic cycle. One step of this cycle involves the congruent melting of the binary compound and so could have been used to introduce Eq. [18] and [19]. Knowing the thermodynamic properties of the binary compounds, the auxiliary conditions impose two constraints upon the parameters of the liquid phase model in each of the A-C and B-C binaries. If the parameters of the liquid phase model are determined by a fit to phase diagram data without prior use of the auxiliary conditions, then their subsequent use allows a calculation of the enthalpy and entropy of formation of each binary compound (from its liquid elements and at its melting point) for check against the experimental values.

The standard relative heat capacities of the stoichiometric binary liquids appearing in Eq. [27] and [28] are determined by the liquid phase model used. Those of the binary compounds are to be obtained from experiment.

Approximate Equations when ΔG°_f for AC(s) and BC(s) are Linear Functions of T

The heat capacities are known for some compounds up to their melting points, but often they are not. On the other hand, the Gibbs free enthalpy of formation of compounds is frequently known at high temperatures and often is accurately given as a linear function of T. When this is the case, a useful approximate form of the exact equations given by Eq. [22] and [23] or Eq. [27] and [28] can be obtained. Assume the Gibbs free enthalpy of formation of AC(s) from the pure liquid elements is given in terms of a constant effective enthalpy of formation, $\overline{\Delta H}_f$, and a constant effective entropy of formation, $\overline{\Delta S}_f$ by

$$\Delta G^o_f(AC) = \overline{\Delta H}_f - T\overline{\Delta S}_f + \delta(T) \quad [29]$$

where $\delta(T)$ is a small correction that depends upon T. A parameter, Δ_{AC}, is defined as the difference between the effective enthalpy of formation and its actual value at the melting point by

$$\Delta_{AC} = \overline{\Delta H}_f - \Delta H^o_f(AC, T_{AC}) \quad [30]$$

From Eq. [29] and the thermodynamic equation for $\Delta G^o_f(AC)$, it follows that

$$\overline{\Delta S}_f = \Delta S^o_f(AC, T_{AC}) + \Delta_{AC}/T_{AC} + \delta(T_{AC})/T_{AC} \quad [31]$$

With Eq. [30] and [31], the integral in the numerator of Eq. [22] can be written as

$$\int_T^{T_{AC}} (1 - T/r)\Delta C_{AC}^s\,dr = \Delta_{AC}(T/T_{AC} - 1) + T\,\delta(T_{AC})/T_{AC} - \delta(T) \quad [32]$$

Substituting this equation into Eq. [22], and its analog for BC(s) into Eq. [23] and rearranging gives

$$T = \frac{(h_A - h_A^*) + (h_C - h_C^*) - h_{AC}^s + (H_{AC}^m - \Delta_{AC}) - \delta_{AC}(T)}{(s_A - s_A^*) + (s_C - s_C^*) - s_{AC}^s + (H_{AC}^m - \Delta_{AC} - \delta(T_{AC}))/T_{AC} + R \ln [(1-u)/4x_Ax_C]} \quad [33]$$

$$T = \frac{(h_B - h_B^{**}) + (h_C - h_C^{**}) - h_{BC}^s + (H_{BC}^m - \Delta_{BC}) - \delta_{BC}(T)}{(s_B - s_B^{**}) + (s_C - s_C^{**}) - s_{BC}^s + (H_{BC}^m - \Delta_{BC} - \delta(T_{BC}))/T_{BC} + R \ln [u/4x_Bx_C]} \quad [34]$$

These are still exact equations. The aproximation consists of neglecting the $\delta_i(T)$ terms. In particular cases it is possible that the effective enthalpies and entropies of formation can be chosen so that $\delta_{AC}(T_{AC})$ and $\delta_{BC}(T_{BC})$ are zero. The error in neglecting $\delta_{AC}(T)$ and $\delta_{BC}(T)$ in the numerators can then be easily calculated. Equations [33] and [34] in their approximate form are particularly convenient for they are explicit equations for T whenever all the partial molar quantities are independent of T.

Using Eq. [32] and its analog for B-C, the generalized Vieland equations given by Eq. [27] and [28] can be written as

$$RT \ln \left[\frac{4\gamma_A\gamma_C x_A x_C}{\gamma_A^\dagger \gamma_C^\dagger (1-u)\Gamma_{AC}}\right] = (H_{AC}^m - \Delta_{AC})(T/T_{AC} - 1) - T\delta_{AC}(T_{AC})/T_{AC} + \delta_{AC}(T) + \int_T^{T_{AC}} (1 - T/r)\Delta C_{AC}^L\, dr \quad [35]$$

$$RT \ln \left[\frac{4\gamma_B\gamma_C x_B x_C}{\gamma_B^\dagger \gamma_C^\dagger u\Gamma_{BC}}\right] = (H_{BC}^m - \Delta_{BC})(T/T_{BC} - 1) - T\delta_{BC}(T_{BC})/T_{BC} + \delta_{BC}(T) + \int_T^{T_{BC}} (1 - T/r)\Delta C_{BC}^L\, dr \quad [36]$$

With the use of thermodynamic definitions, the integrals above can be written as

$$\int_T^{T_{AC}} (1 - T/r)\Delta C_{AC}^L\, dr = h_A^* + h_C^* - h_A^\dagger - h_C^\dagger - T(s_A^* + s_C^* - s_A^\dagger - s_C^\dagger) \quad [37]$$

$$\int_T^{T_{BC}} (1 - T/r)\Delta C_{BC}^L\, dr = h_B^{**} + h_C^{**} - h_B^\dagger - h_C^\dagger - T(s_B^{**} + s_C^{**} - s_B^\dagger - s_C^\dagger) \quad [38]$$

Again the approximate liquidus equations result by neglecting the $\delta_i(T)$ terms in Eq. [35] and [36]. For both sets of equivalent approximate equations, those derived from Eq. [33] and [34] and those derived from Eq. [35] and [36], the effect of linearly temperature-dependent Gibbs free enthalpies of formation for AC(s) and BC(s) is to replace the integrals involving ΔC_{AC}^s and ΔC_{BC}^s by terms Δ_{AC} and Δ_{BC}, respectively, which modify the corresponding enthalpies of fusion. On the other hand, the integrals of Eq. [37] and [38] are in general both zero only if the partial molar quantities for the liquid phase components are independent of T, for then $h_A^* = h_A^\dagger$ etc. Otherwise, Eq. [37] and [38] contribute temperature-dependent corrections to the right-hand members of Eq. [35] and [36], whose magnitudes depend upon the model of the liquid phase.

Liquidus Equations for Associated Solution Models of the Liquid Phase

If the liquid phase is described by an associated solution model, three of the species will correspond to the uncombined components and their mol fractions are written as y_a, y_b, and y_c. Quantities associated with solution species will all be denoted by lower case subscripts. For internal equilibrium within the liquid, the chemical potential of each component must equal that of its corresponding uncombined species, *i.e.*

$$\mu_A - \mu^o_A = RT \ln (\gamma_A x_A) = RT \ln (\gamma_a y_a) = \mu_a - \mu^o_A \quad [39]$$

$$\mu_B - \mu^o_B = RT \ln (\gamma_B x_B) = RT \ln (\gamma_b y_b) = \mu_b - \mu^o_B \quad [40]$$

$$\mu_C - \mu^o_C = RT \ln (\gamma_C x_C) = RT \ln (\gamma_c y_c) = \mu_c - \mu^o_C \quad [41]$$

The exact enthalpy-entropy of formation liquidus equations given by Eq. [13] and [14] can be rewritten in terms of properties of the species using Eq. [39]-[41] as

$$RT \ln [\gamma_a\gamma_c y_a y_c/(1-u)\Gamma_{AC}] = \Delta H^o_f(AC) - T\Delta S^o_f(AC) \quad [42]$$

$$RT \ln [\gamma_b\gamma_c y_b y_c/u\Gamma_{BC}] = \Delta H^o_f(BC) - T\Delta S^o_f(BC) \quad [43]$$

These of course must be augmented by equations describing the equilibrium between each molecular species and the corresponding uncombined species.

The left-hand members of the approximate, generalized Vieland equations, given by Eq. [35] and [36] with the $\delta_i(T)$ quantities all set to zero, can immediately be written in terms of quantities referring to uncombined species with Eq. [39]-[41]. It is now desired to express Eq. [37] and [38] in terms of quantities referring to the species. In order to do so it is necessary to identify the species in the A-C and B-C binaries. We take them to be a, c, and ac, a molecule consisting of one A atom and one C atom, and b, c, and bc, a similar molecule composed of one B atom and one C atom. The necessary arguments are given here only for the A-C binary, those for the B-C binary being completely analogous. When $x_A = x_C = 1/2$, let $y_{ac} = y_{ac}^\dagger = z$. When in addition $T = T_{AC}$, let $y_{ac} = z^*$. Then $y_a^\dagger = y_c^\dagger = (1/2)(1-z)$ and the number of g-atoms of components per mol of species is $1 + z$. Therefore, the enthalpy and entropy of mixing of the stoichiometric liquid from the pure liquid elements can be written both in terms of the partial molar quantities for the components and those for the species as

$$h_A^\dagger + h_C^\dagger = \{2/(1+z)\}\{1/2\,(1-z)(h_a^\dagger + h_c^\dagger) + zh_{ac}^\dagger - z\Delta H_D\} \quad [44]$$

$$s_A^\dagger + s_C^\dagger = -R \ln 4 + \{2/(1+z)\}\{1/2\,(1-z)(s_a^\dagger + s_c^\dagger) + zs_{ac}^\dagger - z\Delta S_D - R(1-z) \ln [(1-z)/2] - Rz \ln z\} \quad [45]$$

where ΔH_D and ΔS_D are, respectively, the standard enthalpy and entropy of dissociation of pure ac molecule into its liquid elements. The corresponding asterisk quantities are obtained by replacing the dagger superscripts in Eq. [44] and [45] by asterisks, denoting the quantities evaluated at $x_A = x_C = 1/2$ are now also evaluated at $T = T_{AC}$, and by replacing z by z^*. Using Eq. [44] and [45] in Eq. [37] and the B-C analogs of Eq. [44] and [45] in Eq. [38], the integral terms involving the relative heat capacity of the binary stoichiometric liquids can be evaluated for the particular associated solution model used, both in the exact liquidus equations given by Eq. [27] and [28], and in the approximate equations given by Eq. [35] and [36] with the δ_i quantities all set to zero.

The pertinent equations for an associated solution model of the liquid can then be summarized as

(a) Liquidus equations

$$RT \ln \left[\frac{\gamma_a \gamma_c y_a y_c}{\gamma_a^\dagger \gamma_c^\dagger y_a^\dagger y_c^\dagger (1-u) \Gamma_{AC}} \right] = H_{AC}^m (T/T_{AC} - 1) - \int_T^{T_{AC}} (1 - T/r) \Delta C_{AC}^s \, dr + \int_T^{T_{AC}} (1 - T/r) \Delta C_{AC}^L \, dr \quad [46]$$

$$RT \ln \left[\frac{\gamma_b \gamma_c y_b y_c}{\gamma_b^\dagger \gamma_c^\dagger y_b^\dagger y_c^\dagger u \Gamma_{BC}} \right] = H_{BC}^m (T/T_{BC} - 1) - \int_T^{T_{BC}} (1 - T/r) \Delta C_{BC}^s \, dr + \int_T^{T_{BC}} (1 - T/r) \Delta C_{BC}^L \, dr \quad [47]$$

(b) Approximations for the case that the Gibbs free enthalpies of formation of the binary compounds, AC(s) and BC(s), are taken as linear functions of T

$$\int_T^{T_{AC}} (1 - T/r) \Delta C_{AC}^s \, dr = \Delta_{AC} (T/T_{AC} - 1) \quad [48]$$

$$\int_T^{T_{BC}} (1 - T/r) \Delta C_{BC}^s \, dr = \Delta_{BC} (T/T_{BC} - 1) \quad [49]$$

where ΔC_{AC}^s is defined by Eq. [17], Δ_{AC} by Eq. [30], and the corresponding quantities for BC are obvious by analogy.

(c) The last integral in the liquidus equations given by Eq. [46] and [47], involving the relative heat capacity of a stoichiometric binary liquid, is given in terms of the partial molar excess quantities of the components by, respectively, Eq. [37] and [38]. These forms are particularly convenient in those versions of the associated solution model (8, 9, 11) in which the excess chemical potentials of the solution species are written in terms of the atom fractions of the components. In more general versions of the associated solution model, these excess chemical potentials are written in terms of the mol fractions of the species. Then one can use Eq. [44] and [45] in Eq. [37], if the species in the A-C liquid are a, c, and ac, or obvious generalizations of Eq. [44] and [45] for some other choice of solution species. The equations for the B-C liquid for use in Eq. [38] and then Eq. [47] are entirely analogous.

The liquidus equations must of course be augmented by two equations describing the equilibrium between the associated complex, ac and its uncombined species and a similar equilibrium for bc. These equations follow from the fact that the chemical potential of ac must equal the sum of those for a and c, while that for bc must equal the sum of those for b and c. One uses Eq. [39]-[41] for the chemical potentials of the uncombined species, and the equations below for those of the associated complexes

$$\begin{aligned} \mu_{ac} - \mu^o{}_A - \mu^o{}_C &= RT \ln (\gamma_{ac} y_{ac}) + \mu^o{}_{ac} - \mu^o{}_A - \mu^o{}_C \\ &= RT \ln (\gamma_{ac} y_{ac}) - \Delta H_D(ac) + T\Delta S_D(ac) \\ &= h_{ac} - Ts_{ac} + RT \ln y_{ac} - \Delta H_D(ac) + T\Delta S_D(ac) \quad [50] \end{aligned}$$

$$\begin{aligned} \mu_{bc} - \mu^o{}_B - \mu^o{}_C &= RT \ln (\gamma_{bc} y_{bc}) + \mu^o{}_{bc} - \mu^o{}_B - \mu^o{}_C \\ &= RT \ln (\gamma_{bc} y_{bc}) - \Delta H_D(bc) + T\Delta S_D(bc) \quad [51] \end{aligned}$$

Discussion

In a number of published analyses, a starting liquidus equation has been obtained by setting $\Delta C_p = 0$ in Vieland's equation, *i.e.*, setting $\Delta C_{AC}^L = \Delta C_{AC}^s$ in Eq. [27], and the liquidus fit using some model for the liquid phase. One immediate application of the results obtained here is to assess the error incurred thereby in each specific analysis. This we shall do. However, it should be noted that another important potential use of the liquidus equations is to test the thermodynamic self-consistency of sets of experimental data, which would include liquidus point data and partial molar quantity data for the liquid among others. The liquidus equations given by Eq. [13] and [14] or by [22] and [23] would seem to be the ones most useful for this purpose since they involve only quantities for stable states and do not involve the relative heat capacities of the stoichiometric, supercooled binary liquids.

The liquidus lines (17) in III-V binaries and liquidus surfaces in related ternaries have been fit using simple solution models. Within the framework of our derivation these analyses justifiably use the approximate form of the generalized Vieland equations (Eq. [35] and [36] with $\delta_{AC} = \delta_{BC} = 0$) with $\Delta C_{AC}^L = \Delta C_{BC}^L = 0$ and $\Delta_{AC} = \Delta_{BC} = 0$. The relative heat capacities of the stoichiometric binary liquids are exactly zero since the partial molar enthalpies and excess entropies of the liquid model used are independent of T. Moreover, for a number of III-V compounds, $\Delta G^o{}_f$ is accurately a linear function of T and Δ_{AC} and Δ_{BC} (see Eq. [30]) are small relative to, and comparable to the accuracy of, the corresponding enthalpies of melting (18). However, the auxiliary conditions of Eq. [18]-[21], not being explicit in Vieland's derivation, were not applied so that the thermodynamic properties of the liquid phase established by the fit are inconsistent with the known properties of the binary compounds. A more extensive fit to four III-V binaries using a subregular model of the liquid does satisfy the auxiliary conditions (18). A recent fit (19) to the Ga-As-Sb ternary, including a fit to the tie lines, justifiably uses the same approximation of the generalized Vieland equations for the same reasons as cited above, but also ignores the auxiliary conditions. Again, the values of $\Delta H^o{}_f$ and $\Delta S^o{}_f$ of the binary compounds calculated from the parameters of the best fit liquidus are in significant disagreement with experiment.

We now discuss the specific form taken by Eq. [46] for two widely used versions of the associated solution model and the errors incurred for some specific binary systems by using the common form of the Vieland equation instead. This common form is of course Eq. [46] with both integrals set equal to zero. For the specific systems considered, the Gibbs free enthalpy of formation of the solid compound is a linear function of T to within present experimental error. Therefore, in obtaining numerical values for the errors the relative heat capacity of the solid compound is taken as zero. The error is then that introduced by indiscriminately taking the integral over the relative heat capacity of the stoichiometric binary liquid—a quantity determined by the liquid model and the values taken for its parameters—as zero.

In a separate study (20), we have used an extension of Jordan's model (11) to analyze the HgTe-CdTe-Te system. In the appendix to that work, Eq. [46] is evaluated for this model. It is found that the integral over ΔC_{AC}^L is zero only if the liquid is completely associated or completely dissociated. The error incurred in using the Vieland equation for the Cd-Te and Zn-Te systems (8) was found to be less than 1°C because the degree of dissociation taken was zero or near zero. (However, as a result the values predicted for the enthalpy and entropy of formation of the solid compounds through Eq. [18] and [19] are far from the experimental values.) The errors incurred (21) for the Ga-Sb and In-Sb systems were not calculated but, since the degree of dissociation is intermediate, are most likely not negligible.

Osamura *et al.* (9, 10) have developed another simplified version of the associated solution model for cases in which the degree of association is small. In the

earlier work (9), the chemical potentials given do not satisfy the Gibbs-Duhem relation and so this original model is not discussed further. The relative chemical potentials of components 1 and 2 are given by Eq. [3a, 3b] of Ref. (10). The relative partial molar enthalpies and entropies can be readily evaluated and the integral over the relative heat capacity of the stoichiometric binary liquid defined by Eq. [37] obtained. Changing their notation to consider the liquidus of a binary compound AC(s), rather than AB(s), the result is

$$\int_{T}^{T_{AC}} (1 - T/r)\Delta C_{AC}{}^{L}\, dr = (1/4)(\omega_{A,AC} + \omega_{C,AC} - \omega_{AC})F \quad [52]$$

where the ω's are constant interaction coefficients and

$$F = k^{*}[1 + \Omega(T_{AC} - T)/RT^{2}{}_{AC}] - k \quad [53]$$

Here k is the dissociation constant of the liquid phase molecule, ac, and is given in terms of two constants, k^{o} and Ω, by

$$k = k^{o} \exp(\Omega/RT) \quad [54]$$

The asterisk superscript on the first k in Eq. [53] means that it is evaluated at T_{AC}. Thus, the integral given by Eq. [52] is zero, and Eq. [46] reduces to the Vieland equation, only under the very special circumstances that $\omega_{A,AC} + \omega_{C,AC} - \omega_{AC} = 0$, or $k = k^{o} = 0$, or $\Omega = 0$, or $T = T_{AC}$. The liquid model parameters identified as giving the best fit to the liquidus lines of AlSb and GaSb are listed in Table III of Ref. (10). The quantities given there as κ_{AlSb} and κ_{GaSb} should be read (22) as, respectively, $1/k^{o}{}_{AlSb}$ and $1/k^{o}{}_{GaSb}$. Liquidus temperatures were calculated for each binary using Eq. [46] with both integrals set equal to zero. These are denoted at T_{v}. They were also calculated using Eq. [46] and Eq. [52] with the $\Delta C_{AC}{}^{s}$ in Eq. [46] set equal to zero. These are considered the "exact" temperatures. For GaSb, T_{v} is high by about 4°C at atom fractions of Sb near 0.1 and 0.9. This is comparable to the standard deviation of 4.6°C between observed and calculated liquidus temperatures [using the observed liquidus points tabulated in Ref. (18)] and is therefore not acceptable. For AlSb the error is even greater, T_{v} being high by 15° at $x_{Sb} = 0.2$ and high by 150°C at $x_{Sb} = 0.90$. As a result, the quantitative aspects of the analysis given in Ref. (10) are unfortunately of doubtful value. Because the excess Gibbs free enthalpy of mixing for Osamura's model depends upon the atom fractions of the components, Eq. [22]-[23] or [33]-[34] are more convenient for calculation purposes than the generalized Vieland form given by Eq. [46]-[47]. For more general versions of the associated solution model, the mol fraction of the species appears in the free enthalpy of mixing. Then the enthalpy-entropy of formation liquidus equations given by Eq. [42]-[43] are most likely the easiest to use.

Thermodynamic Analysis of the HgTe-CdTe-Te System Using the Simplified RAS Model

Tse Tung, Leszek Golonka,[1] and R. F. Brebrick*

Materials Science and Metallurgy Program, College of Engineering, Marquette University, Milwaukee, Wisconsin 53233

ABSTRACT

A quantitatively good overall fit is obtained to the phase diagram and thermodynamic data in the HgTe-CdTe-Te system. In the binaries the partial pressures along the three-phase curves are fit in addition to the liquidus points. Moreover, the liquid phase parameters are constrained so that the enthalpy and entropy of mixing of the stoichiometric binary melts are properly related to the enthalpy and entropy of formation of the binary compounds. Also included in the fit are the HgTe-CdTe pseudobinary liquidus and solidus points, the partial pressure of Hg in the pseudobinary melt, and the partial pressures of Hg, Cd, and Te_2 for the Te-saturated pseudobinary solid, $Hg_{1-u}Cd_uTe$. Finally, a choice is made for the most reliable ternary liquidus points and these are included. Portions of the phase diagram, as yet unmeasured, are then calculated and presented. The liquid phase is described by a simple extension of the regular associated solution model of Jordan and Szapiro in which the interaction coefficients and dissociation constants are allowed to depend upon temperature. The partial molar quantities for the liquid phase components are derived and used in liquidus equations that are more exact than the commonly used version of the Vieland equation. Errors in some previous studies are discussed in the appendix. It is concluded that the model cannot provide a satisfactory fit to the entire Hg-Cd-Te system. Neither can it fit analogous systems in which the liquidus lines of the binary compounds are asymmetric.

In this paper we gather the experimental data and report quantitatively good overall fits to all the phase diagram and thermodynamic data for the HgTe-CdTe-Te system. Recently derived liquidus equations (1), more generally valid than the commonly used Vieland equation (2), are used and the liquid phase is described by the simplified version of the associated solution model (3, 4). In the process this model is tested more extensively than previously. The liquid phase parameters leading to an overall optimum fit are used to generate calculated curves that are hopefully useful in smoothing, interpolating, and extrapolating the experimental data and guiding further experimentation.

The associated solution model offers a relatively simple way of obtaining a strong composition dependence in the properties of a liquid phase. Such a dependence has been observed in a number of cases, various properties showing an extremum at or near compositions at which solid phases appear at lower temperatures (5, 6). The model has become very popular recently, and has been applied to a number of systems including HgTe-CdTe-Te (7), Zn-Cd-Te (4), a number of III-V binaries (8, 9), and to Al-Ga-Sb (10). Unfortunately, the analyses cited are flawed to an unknown extent in that they take as their starting point liquidus equations arrived at by assuming the partial molar enthalpies and excess entropies of the liquid components are independent of T, an assumption that is generally invalid for associated solution models (1). Moreover, they ignore the fact that the enthalpy of formation of a congruently melting, narrow homogeneity range compound, AC(s), plus the enthalpy of fusion equals the enthalpy of mixing of the liquid of the same composition, as well as the corresponding entropy relationship (1, 11, 12).

Key words: liquidus, binary compounds, thermodynamics.

In the simplified version of the associated solution model developed by Jordan (3), mole fractions of species occurring in terms representing the interaction among these species are in effect replaced by atom fractions of the components and two interaction coefficients are assumed equal. As used here, the model is extended in a simple and obvious manner by allowing the interaction coefficients and dissociation constants to depend upon T. Thus, by setting certain parameters to zero the original model is regained. The simplified model is used here because it is reported to give good fits in systems with a high degree of ionic binding (3, 4, 7, 13). Moreover, it possesses the attractive feature that its central results are expressible in analytical form for binary systems. Here, not only are liquidus points fit, but also partial pressures; and this is done under constraints (Eq. [6]-[9]) that insure the satisfaction of the relations referred to above between the thermodynamic quantities of the binary compounds HgTe(s) and CdTe(s) and those of the stoichiometric binary liquids. Jordan has previously fit the liquidus points (3) and the partial pressures on the Te-rich side of the Zn-Te (13) and CdTe (14) systems. However, more recent and extensive partial pressure measurements are now available. Moreover, although he showed that the value calculated for the Gibbs free enthalpy of compound formation from the best fit liquid model was close to experiment, he did not check the enthalpy and entropy of formation individually.

Liquidus Equations

We use recently derived (1) equations for the liquidus in equilibrium with a pseudobinary solid, $A_{1-u}B_uC(s)$, with narrow homogeneity range, congruently melting end members, AC(s) and BC(s). In terms of symbols listed at the end of this paper, these equations are

$$T = \frac{h_A - h_A{}^* + h_C - h_C{}^* - h_{AC}{}^s + H_{AC} - \Delta_{AC}}{s_A - s_A{}^* + s_C - s_C{}^* - s_{AC}{}^s + (H_{AC} - \Delta_{AC})/T_{AC} + R \ln (1-u)/4x_A x_C} \quad [1]$$

$$T = \frac{h_B - h_B{}^{**} + h_C - h_C{}^{**} - h_{BC}{}^s + H_{BC} - \Delta_{BC}}{s_B - s_B{}^{**} + s_C - s_C{}^{**} - s_{BC}{}^s + (H_{BC} - \Delta_{BC})/T_{BC} + R \ln u/4x_B x_C} \quad [2]$$

The above equations follow from more fundamental ones (1) if the Gibbs free enthalpy of formation from the pure liquid elements of both AC(s) and BC(s) are linear functions of *T, e.g.*

$$\Delta G^\circ{}_f(AC) = \overline{\Delta H_f}(AC) - T\overline{\Delta S_f}(AC) \quad [3]$$

with $\overline{\Delta H_f}(AC)$ and $\overline{\Delta S_f}$ constants. Then, if $\Delta H^\circ{}_f(AC,T_{AC})$ is the actual enthalpy of formation of AC(s) at its melting point

$$\Delta_{AC} = \overline{\Delta H_f}(AC) - \Delta H^\circ{}_f(AC,T_{AC}) \quad [4]$$

Analogously we have

$$\Delta_{BC} = \overline{\Delta H_f}(BC) - \Delta H^\circ{}_f(BC,T_{BC}) \quad [5]$$

The liquidus equations are dependent upon the validity of relations based upon the zero change of the Gibbs free enthalpy upon congruent melting of both AC(s) and BC(s). These are

$$\Delta H^\circ{}_f(AC,T_{AC}) = h_A{}^* + h_C{}^* - H_{AC} \quad [6]$$

$$\Delta S^\circ{}_f(AC,T_{AC}) = s_A{}^* + s_C{}^* + R \ln 4 - H_{AC}/T_{AC} \quad [7]$$

$$\Delta H^\circ{}_f(BC,T_{BC}) = h_B{}^{**} + h_C{}^{**} - H_{BC} \quad [8]$$

$$\Delta S^\circ{}_f(BC,T_{BC}) = s_B{}^{**} + s_C{}^{**} + R \ln 4 - H_{BC}/T_{BC} \quad [9]$$

These auxiliary relations can be used to fix two liquid phase model parameters in each of the A-C and B-C binaries or, alternatively, to calculate values for the enthalpy and entropy of formation of the binary compounds.

Equations [1] and [2] reduce to equations that are the same as the commonly used Vieland equation (2) with his $\Delta C_p = 0$, except that $H_{AC} - \Delta_{AC}$ and $H_{BC} - \Delta_{BC}$ appear in place of the heats of fusion, only if the partial molar enthalpies and excess entropies of the liquid components are independent of T. This is not the case for the liquid model used here.

Liquid Model

Jordan (3) used a model of the liquid phase in the Zn-Te and Cd-Te systems that assumed the presence of binary molecules which interacted with one another and with the uncombined atoms like a regular solution. The interaction terms were simplified to depend upon the atom fractions of the components, rather than the mol fractions of the species, in order to obtain analytical expressions. This approach was generalized to a ternary system by Szapiro (4) and we adopt his equations defining this simplified regular associated solution model with two obvious extensions noted below. The pertinent equations are summarized below. Then, since it is desired to use the liquidus equations given by Eq. [1] and [2] and the auxiliary conditions given by Eq. [6]-[9], the equations for the partial molar quantities of the liquid phase components are given. This requires some algebra to obtain the partial molar quantities of the components. However, this effort is compensated by the more rapid computer calculations possible with Eq. [1] and [2] than with equivalent equations (1) depending upon the partial molar quantities of the solution species.

Consider a ternary A-B-C system. The mol fractions of the species are written as y_i and are related to the atom fractions of the components by the equations

$$y_a = x_A(1 + y_{ac} + y_{bc}) - y_{ac} \quad [10]$$

$$y_b = x_B(1 + y_{ac} + y_{bc}) - y_{bc} \quad [11]$$

$$y_c = x_C(1 + y_{ac} + y_{bc}) - y_{ac} - y_{bc} \quad [12]$$

The chemical potentials of the species are assumed to be given by the equations

$$\mu_a = \omega x_B{}^2 + \alpha_1 x_C{}^2 + (\omega + \alpha_1 - \alpha_2) x_B x_C + RT \ln (y_a) + \mu^\circ{}_A \quad [13]$$

$$\mu_b = \omega x_A{}^2 + \alpha_2 x_C{}^2 + (\omega - \alpha_1 + \alpha_2) x_A x_C + RT \ln (y_b) + \mu^\circ{}_B \quad [14]$$

$$\mu_c = \alpha_1 x_A{}^2 + \alpha_2 x_B{}^2 + (\alpha_1 + \alpha_2 - \omega) x_A x_B + RT \ln (y_c) + \mu^\circ{}_C \quad [15]$$

$$\mu_{ac} = \omega x_B(1 - 2x_A) + (\alpha_1 x_A + \alpha_2 x_B - 0.5\alpha_1)(1 - 2x_C) + RT \ln (y_{ac}) + \mu^\circ{}_{ac} \quad [16]$$

$$\mu_{bc} = \omega x_A(1 - 2x_B) + (\alpha_1 x_A + \alpha_2 x_B - 0.5\alpha_2)(1 - 2x_C) + RT \ln (y_{bc}) + \mu^\circ{}_{bc} \quad [17]$$

The form of Eq. [16] and [17] was chosen (4) so that the Gibbs-Duhem relation is obeyed for the ternary system. The standard chemical potentials define an enthalpy and entropy of dissociation and an equilibrium constant for each molecule through the equations

$$\mu^\circ{}_A + \mu^\circ{}_C - \mu^\circ{}_{ac} = \Delta H_D(ac) - T\Delta S_D(ac) = -RT \ln K_1 \quad [18]$$

$$\mu^\circ{}_B + \mu^\circ{}_C - \mu^\circ{}_{bc} = \Delta H_D(bc) - T\Delta S_D(bc) = -RT \ln K_2 \quad [19]$$

For internal equilibrium within the liquid, the chemical potential of ac must equal the sum of those for a and c and that of bc must equal the sum of those for b and c. Using Eq. [13]-[17] and Eq. [18] and [19], the equilibrium equations are

$$y_a y_c / y_{ac} = K_1 \exp(-\alpha_1/2RT) = \kappa_1 \quad [20]$$

$$y_b y_c / y_{bc} = K_2 \exp(-\alpha_2/2RT) = \kappa_2 \quad [21]$$

Using these last two equations and Eq. [10]-[12], the mole fractions of the species can be written as

$$y_c = x_C - y_c(1 - y_c)\{x_A/(y_c + \kappa_1) + x_B/(y_c + \kappa_2)\} \quad [22]$$

$$y_{ac} = x_A y_c (1 - y_c)/(1 - x_C)(y_c + \kappa_1) \quad [23]$$

$$y_{bc} = x_B y_c (1 - y_c)/(1 - x_C)(y_c + \kappa_2) \quad [24]$$

Thus, for given T, composition of the liquid in atom fractions of the components, interaction coefficients α_1 and α_2, and dissociation constants K_1 and K_2, Eq. [22] is a cubic equation in y_c and can be solved by various means. Equations [23] and [24] can then be solved for y_{ac} and y_{bc}, respectively, and Eq. [10] and [11] solved for y_a and y_b, respectively.

The model used by Jordan and Szapiro is extended for use here in two straightforward ways. The interaction coefficients appearing in Eq. [13]-[17] are assumed to depend linearly upon T

$$\omega = W + VT \quad [25]$$

$$\alpha_1 = \gamma_1 + \delta_1 T \quad [26]$$

$$\alpha_2 = \gamma_2 + \delta_2 T \quad [27]$$

and the dissociation constants defined by Eq. [18] and

[19] are allowed to be temperature dependent. Thus, the enthalpies of dissociation are allowed to be nonzero. For brevity of notation we take the κ-quantities defined in Eq. [20] and [21] as

$$\kappa_1 = a_1 \exp(-b_1/T) \qquad [28]$$

$$\kappa_2 = a_2 \exp(-b_2/T) \qquad [29]$$

For internal equilibrium within the liquid, the chemical potential of component A must equal that of species a and similarly for the chemical potentials of B and b and those of C and c. On this basis, the relative partial molar quantities for the components can be obtained using thermodynamic definitions and Eq. [13]-[15] and Eq. [25]-[27] as

$$s_C{}^t = -\partial(\mu_C - \mu^\circ{}_C)/\partial T = -\delta_1 x_A{}^2 - \delta_2 x_B{}^2 + (V - \delta_1 - \delta_2)x_A x_B - R \ln y_c - RT\, \partial \ln y_c/\partial T \qquad [30]$$

$$h_C = \mu_C + Ts_C = \gamma_1 x_A{}^2 + \gamma_2 x_B{}^2 + (\gamma_1 + \gamma_2 - W)x_A x_B - RT^2\, \partial \ln y_c/\partial T \qquad [31]$$

$$s_A{}^t = -Vx_B{}^2 - \delta_1 x_C{}^2 + (\delta_2 - \delta_1 - V)x_B x_C - R \ln y_a - RT\, \partial \ln y_a/\partial T \qquad [32]$$

$$h_A = Wx_B{}^2 + \gamma_1 x_C{}^2 + (W + \gamma_1 - \gamma_2)x_B x_C - RT^2\, \partial \ln y_a/\partial T \qquad [33]$$

$$s_B{}^t = -Vx_A{}^2 - \delta_2 x_C{}^2 + (\delta_1 - \delta_2 - V)x_A x_C - R \ln y_b - RT\, \partial \ln y_b/\partial T \qquad [34]$$

$$h_B = Wx_A{}^2 + \gamma_2 x_C{}^2 + (W + \gamma_2 - \gamma_1)x_A x_C - RT^2\, \partial \ln y_b/\partial T \qquad [35]$$

where the partial derivatives are taken at constant x_A, x_B, and x_C and where the superscript t indicates that the relative partial molar entropies are not excess quantities. Evaluation of the above equations depends upon the partial temperature derivative of y_c since those of y_a and y_b can be expressed in terms of y_{ac} and y_{bc} using Eq. [10] and [11] and these in turn can be expressed in terms of y_c using Eq. [23] and [24], respectively. The result for y_c is given by

$$\partial y_c/\partial T = N/D \qquad [36]$$

where

$$N = \{y_c(1 - y_c)/T\}^2\{x_A b_1 \kappa_1 (y_c + \kappa_2)^2 + x_B b_2 \kappa_2 (y_c + \kappa_1)^2\}$$

and

$$D = -y_c{}^2(1 - y_c)^2\{x_A(y_c + \kappa_2)^2 + x_B(y_c + \kappa_1)^2\} + (y_c + \kappa_1)^2(y_c + \kappa_2)^2(y_c{}^2 + x_C - 2x_C y_c)$$

The partial molar quantities of the components can be obtained in analytical form for the A-C and B-C binary systems. The equations for the former are given below, those for the B-C binary being completely analogous. The partial molar entropies given are again the excess quantities

$$h_A = \gamma_1 x_C{}^2 - x_C Q_1/(P_1 + 1 - 2x_C) \qquad [37]$$

$$h_C = \gamma_1 x_A{}^2 - x_A Q_1/(P_1 - 1 + 2x_C) \qquad [38]$$

$$s_A = -\delta_1 x_C{}^2 - x_C Q_1/(P_1 + 1 - 2x_C)T - R \ln[(P_1 + 1 - 2x_C)/(P_1 + 1)] + R \ln x_A \qquad [39]$$

$$s_C = -\delta_1 x_A{}^2 - x_A Q_1/(P_1 - 1 + 2x_C)T - R \ln[(P_1 - 1 + 2x_C)/(P_1 + 1)] + R \ln x_C \qquad [40]$$

where

$$Q_1 = Rb_1\{\kappa_1/(\kappa_1 + 1)\}\{(1 - P_1)/P_1\} \qquad [41]$$

and

$$P_1 = [1 - 4x_A x_C/(1 + \kappa_1)]^{1/2} \qquad [42]$$

Using the above equations, the constants appearing in the liquidus equations given by Eq. [1] and [2] can be written as

$$h_A{}^* + h_C{}^* = \tfrac{1}{2}\gamma_1 - Rb_1(1 - P_1{}^*) \qquad [43]$$

$$s_A{}^* + s_C{}^* = -\tfrac{1}{2}\delta_1 - 2R \ln[P_1{}^*/(1 + P_1{}^*)] - Rb_1(1 - P_1{}^*)/T_{AC} - R \ln 4 \qquad [44]$$

$$h_B{}^{**} + h_C{}^{**} = \tfrac{1}{2}\gamma_2 - Rb_2(1 - P_2{}^{**}) \qquad [45]$$

$$s_B{}^{**} + s_C{}^{**} = -\tfrac{1}{2}\delta_2 - 2R \ln[P_2{}^{**}/(1 + P_2{}^{**})] - Rb_2(1 - P_2{}^{**})/T_{BC} - R \ln 4 \qquad [46]$$

We note that $P_1{}^*$ and $P_2{}^{**}$ are the degree of dissociation of ac and bc, respectively, at the melting points of the solid compounds. Equations [43]-[46] are used also in the auxiliary conditions given by Eq. [6]-[9]. Thus, by using Eq. [43] in Eq. [6], γ_1 can be eliminated in favor of a_1 and b_1, etc. Thus, the A-C binary parameters γ_1 and δ_1 can be eliminated in favor of a_1 and b_1 of Eq. [28] and the B-C binary parameters γ_2 and δ_2 can be eliminated in favor of a_2 and b_2 of Eq. [29].

It can be seen from Eq. [37]-[42] that the partial molar quantities of the components in the A-C binary (and in the B-C binary) are functions of T because of the temperature dependence of κ_1 defined by Eq. [20] and [28]. If the parameter b_1 in Eq. [28] is zero, then κ_1 is a constant, Q_1 of Eq. [41] is zero, and all the partial molar quantities for the components are independent of T. The parameter b_1 is given by the equation

$$b_1 = [\tfrac{1}{2}\gamma_1 + \Delta H_D(\text{ac})]/R \qquad [47]$$

Therefore, the parameter b_1 is zero if either both γ_1 and $\Delta H_D(\text{ac})$ are zero or if $\tfrac{1}{2}\gamma_1 + \Delta H_D(\text{ac}) = 0$. In either case, the mol fraction of ac is strictly independent of T at all compositions. Neither case would appear to describe physically realistic situations.

Finally, even for the version of the simplified, regular associated solution model used here, in which the interaction coefficients and dissociation constant depend upon T, the quantities $h_A + h_C$ and $s_A + s_C$ in the A-C binary can be seen from Eq. [37]-[42] to be symmetric about $x_A = x_C = \tfrac{1}{2}$. Therefore, from Eq. [1] with $u = 0$, the liquidus line in equilibrium with the compound AC(s) is also symmetric about ½. This liquid model therefore suffers an inherent weakness.

Solid Solution Model

For a narrow homogeneity range solid solution, the thermodynamic analysis of the phase diagram can be broken into two steps (1). We are concerned with the first step which involves the liquidus in equilibrium with what can be treated as a pseudobinary solid solution (15). It therefore is necessary only to express the composition dependence of the chemical potentials of HgTe and CdTe in the solid, $(Hg_{1-u}Cd_u)Te(s)$. We assume the solid solution is quasiregular so that the chemical potentials are given by

$$\mu_{HgTe} = (W_s - V_s T)\, u^2 + RT \ln(1 - u) + \mu^\circ{}_{HgTe}(s) \qquad [48]$$

$$\mu_{CdTe} = (W_s - V_s T)(1 - u)^2 + RT \ln u + \mu^\circ{}_{CdTe}(s) \qquad [49]$$

where W_s and V_s are constants independent of T and u. Measurements of the optical absorbance between 220 and 700 nm of the vapor coexisting with solid solutions containing 0, 10, 20, 41.6, and 58.1 mole percent CdTe have been made (16, 17). These establish the partial pressures along the three-phase curves for each composition and, in principle, the above chemical potentials. However, although the partial pressure measurements are fairly precise, the relative chemical po-

tentials, especially that of HgTe, are relatively small differences of two large numbers. Consequently, the validity of the model incorporated in Eq. [48] and [49] and a precise determination of the model parameters, W_s and V_s, are not possible. The data do indicate (17) that the solid solutions depart from ideal, but only slightly with a value of $W_s - V_sT$ of about 600 cal at 880 K. Consistent with this, we adopt values of -333 cal for W_s and -1.0129 eu for V_s.

Experimental Data

HgTe.—For $X_{Te} > 1/2$ there are 12 liquidus points from thermal analysis (18) and 2 from optical absorbance measurements (19). The eutectic temperature determined from cooling curve halts for 7 compositions between 65 and 87.5 atomic percent (a/o) Te seems to be well defined as 413.3° ± 0.2°C and the eutectic composition is 83.5 ± 0.5 a/o Te. These points are shown in Fig. 1. Optical absorbance measurements (19) of the coexisting vapor give P_{Hg} and P_2 along the Te-rich leg of the three-phase curve for HgTe(s), agree with the maximum melting point of 670°C, and determine the standard Gibbs free enthalpy of formation of HgTe(s) from Hg(g) and Te_2(g). They give no indication of the liquid miscibility gap reported by Delves (20).

The vapor pressure of mercury is given to within 1% of selected values (21) between 0.5 and 10 atm by the equation

$$\log_{10} P^{\circ}_{Hg}(\text{atm}) = -3099/T + 4.920 \quad [50]$$

(In this paper $\log_{10}$ is the logarithm to base 10 while ln is the natural logarithm.) This equation also agrees to within 1% with measured values to 30 atm (22), with optical absorbance measurements of the vapor over pure Hg to 20 atm (19), and with one point near 30 atm obtained by detecting the complete vaporization of a known weight of Hg in a known volume by optical absorbance of the vapor (16). Between 10^{-3} and 10^{-1} atm, the selected values (21) are given to within 1% by the equation

$$\log_{10} P^{\circ}_{Hg} = -3157/T + 5.028 \quad [51]$$

At high pressures Hg(g) is nonideal. From the equation of state given by Sugawara and Sato (22), which is based in part on their vapor pressure measurements to 30 atm, the chemical potential is given by

$$\mu_{Hg(g)} = RT \ln f = RT \ln P_{Hg} + 4857.6\, P_{Hg}(-1.793/T + 251/T^2 + 0.001071) \quad [52]$$

where P_{Hg} is in atm and f is the fugacity. For the data considered here, the fugacity differs significantly from P_{Hg} only for the pseudobinary melt.

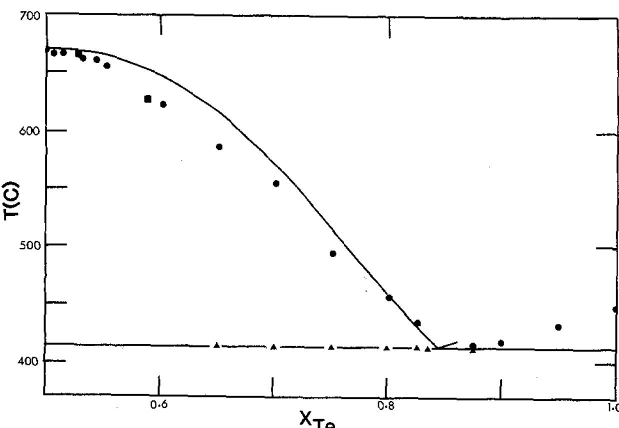

Fig. 1. HgTe-Te liquidus. Circles and triangles are from Ref. (18), two squares are from Ref. (19). Solid line is calculated using parameters in row 6 of Table II.

The saturated vapor over Te(l) is all Te_2(g) and the vapor pressure is taken as

$$\log_{10} P^{\circ}_2(\text{atm}) = -5960.2/T + 4.7191 \quad [53]$$

This equation does not agree with the selected values of Hultgren *et al.*, being about 20% higher at the 449.5°C melting point of Te but agreeing at about 600°C and higher. It does agree with the results of optical absorbance measurements (23) as low as 449°C and with a number of determinations (24-26) between 10^{-3} and 1 atm. Contrary to the choice made here, Hultgren *et al.* chose the silica Bourdon gauge data of Machol and Westrum (27), which show a pronounced curvature on a log P_2 *vs.* $1/T$ plot and fall increasingly below the values given by Eq. [53] as T is decreased from 600°C.

Using Eq. [50] and [53] and the data of Ref. (19), one obtains

$$\Delta G^{\circ}_f(\text{cal}) = -13933 + 9.5377T \quad [54]$$

for the reaction

$$\text{Hg(l)} + \text{Te(l)} \rightarrow \text{HgTe(s)} \quad [55]$$

Lacking any high temperature heat capacity or enthalpy data for HgTe(s), the effective quantities, $\overline{\Delta H_f}$ and $\overline{\Delta S_f}$ of Eq. [3] are taken from Eq. [54] and Δ of Eq. [4] taken as zero. These quantities, along with the corresponding ones for CdTe(s) discussed below, are collected in Table I.

To the best of our knowledge, there is only one reliable estimate for the enthalpy of fusion of HgTe(s) and its determination is unpublished. The value, given in Table I, was quoted by Steininger (28) and used subsequently by Laugier (7). It follows from a thermodynamic analysis of the combined liquidus point data and partial pressures along the HgTe(s) three-phase curve made by the last author of this paper. A value of 8.5 kcal/mol from total vapor pressure measurements (29) over the liquid and solid is obtained by a questionable thermodynamic argument, although it is close to the value in Table I. A value of 13.39 kcal/mol follows from requiring a quasichemical model of the liquid to fit the experimental Hg-rich liquidus points and therefore has no strong basis (30).

CdTe.—The liquidus points for Te-rich compositions are shown in Fig. 2. Steininger (31) and Lorenz (32) used thermal analysis. For three compositions, optical absorbance of the coexisting vapor (an essentially static technique), was used (33). Data from Kulwicki (34), as much as 40°-50°C higher, and from de Nobel (35), as much as 20°C higher, are rejected.

The optical absorbance measurements (33) also give P_2 along the Te-rich leg of the CdTe(s) three-phase curve, give a few values of P_{Cd} near the melting point, agree with a melting point of 1092°C, and establish the standard Gibbs free enthalpy of CdTe(s) relative to Cd(g) and Te_2(g). Partial pressures from two other sources are in poor agreement with the above and are rejected (32, 35).

Selected values (21) for the vapor pressure of Cd between 10^{-8} and 1 atm are reproduced to within 2.5% by the equations

Table I.

	mp (K)	Heat-of-fusion (cal/mol)	$-\overline{\Delta H_f}$ (cal/mol)	$-\overline{\Delta S_f}$ (eu)	Δ (cal/mol)
CdTe	1365.1	12,000	30,024	10.346	−144
HgTe	943.1	8,680	13,933	9.5377	0

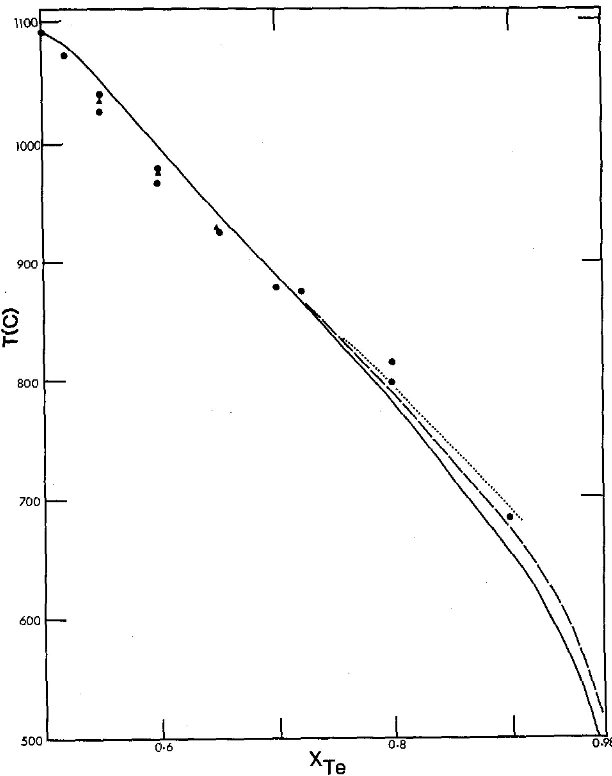

Fig. 2. CdTe-Te liquidus. Experimental points shown as circles are from Ref. (31)-(32). Solid line calculated with $a_2 = 5$, dashed line with $a_2 = 10$, dotted line with $a_2 = 20$. Values of other model parameters are given in Table IV in each case. Triangles are from Ref. (33).

$$\log_{10} P°_{Cd} = -5808/T + 5.956 \quad T < 594\,K$$
$$\log_{10} P°_{Cd} = -5317/T + 5.119 \quad T > 594\,K \qquad [56]$$

The tabulated, selected values (37) for the standard Gibbs free enthalpy for the reaction

$$Cd(l) + Te(l) \rightarrow CdTe(s) \qquad [57]$$

are accurately represented by

$$\Delta G°_f = -30{,}024 + 10.346T \qquad [58]$$

Optical absorbance measurements (33, 36) agree to within 200 cal/mol with the above equation for temperatures above 900°C.

The effective enthalpy and entropy of formation given in Table I are taken directly from Eq. [58]. The tabulated selected values (37) for $\Delta H°_f$ and $\Delta S°_f$ show an abrupt curvature at 1100 K, the highest temperature of the tabulation. Here we draw a straight line through the $\Delta H°_f$ points plotted against T, neglecting the 1100 K point. Extrapolation to the melting point leads to a relatively small value of -144 cal for Δ_{CdTe}.

There is only one experimental value for the enthalpy of fusion from Kulwicki which is given in Table I. The eutectic point from Kulwicki is nearly degenerate with the melting point of Te and the eutectic temperature is 449° ± 2°C. Partial pressures of Te_2 have also been determined for 55, 60, and 65 a/o Te liquids (33). The temperature ranges are too narrow to accurately establish the partial molar enthalpy and entropy of Te, but do fix the chemical potential of Te.

HgTe-CdTe pseudobinary.—Experimental liquidus (38, 39) and solidus points (40) have been scaled from graphs and are shown in Fig. 6. Most of the solidus points were obtained by chemical analysis of the first crystal to grow from a large volume of melt of known composition, the temperature being taken from a smoothed liquidus line separately determined by thermal analysis. Three of the solidus points come from optical absorbance measurements (17) and fit in well with the others cited. One set of solidus points scatters about those shown in Fig. 6 and are rejected (41).

The optical absorbance measurements (16, 17) also give P_{Hg}, P_2, and P_{Cd} over coexisting, Te-saturated solid solution and Te-rich liquid for known compositions of the solid of about 10, 20, 41.6, and 58.1 m/o CdTe. The relation between these partial pressures and the thermodynamics of the solid solution has been discussed in the "Solid Solution Model" section.

Steininger (39) has determined P_{Hg} for pseudobinary melts by a reflux technique for compositions between 0 and 60 m/o CdTe. The results for HgTe are in fair to good agreement with those from optical absorbance measurements. He finds the striking result that, for all the compositions, P_{Hg} is given by a single equation

$$\ln P_{Hg}(atm) = -7.149/T + 10.206 \qquad [59]$$

Ternary.—Liquidus temperatures in the Te-rich portion of the ternary have been obtained by thermal analysis for 5, 10, 15, and 20 m/o CdTe liquids, but are reported briefly with almost no experimental details (42). Using differential thermal analysis, Bower *et al.* (43) and Harman (44), as given in a preliminary report, obtain liquidus temperatures 30°-60°C lower. Schmit has also obtained liquidus temperatures and tie lines near 500°C in the growth of epitaxial films on CdTe substrates (45). The liquidus points are in fair agreement with the latter two studies and therefore in poor agreement with the first.

Analysis

The simplified regular associated solution model of the liquid phase contains 10 adjustable parameters: γ_1, δ_1, a_1, and b_1 for the Hg-Te binary; γ_2, δ_2, a_2, and b_2 for the Cd-Te binary, and W and V for the Hg-Cd binary. It proved impossible to obtain simultaneous, satisfactory fits to the liquidus points, partial pressures, and auxiliary conditions of Eq. [6]-[9] for the complete Cd-Te and Hg-Te binaries. This of course might have been anticipated, since the liquid phase model predicts the liquidus of AC(s) is symmetric about 50 a/o. The HgTe-CdTe-Te portion of the phase diagram, for which there are some ternary liquidus points, was therefore fit. Then the parameters W and V, along with the other eight, determine the properties of the pseudobinary and ternary liquid. The parameters for the pseudobinary solid, W_s and V_s, are fixed at, respectively, -333 cal and -1.0129 eu, as discussed in the "Solid Solution Model" section.

A measure of fit σ was defined by the equation

$$\sigma^2 = \left(\frac{\sigma_T}{w_T}\right)^2 + (\sigma_{Hg}/w_{Hg})^2 + (\sigma_{Cd}/w_{Cd})^2 + (\sigma_2/w_2)^2 \qquad [60]$$

where

$$\sigma_T^2 = \sum_{j=1}^{M} (T_{j,cal} - T_{j,obs})^2/M \qquad [61]$$

and

$$\sigma_j^2 = \sum_{j=1}^{N} [(P_{j,cal} - P_{j,obs})/P_{j,obs}]^2/N;$$
$$j = Hg, Cd, \text{or } 2 \text{ for } Te_2 \qquad [62]$$

The w's in Eq. [60] are estimated accuracies of the experimental values and were typically taken as 10°C, 0.1, 0.1, and 0.1 for, respectively, w_T, w_{Hg}, w_{Cd}, and w_2.

When data were missing or inappropriate, *e.g.*, σ_{Cd} in the HgTe-Te binary, the corresponding term was omitted in Eq. [60].

Best fit parameters were established by a trial and error search subroutine which varied the model parameters in an attempt to minimize σ. As an option, any

subset of the model parameters from none to all could be held fixed at the values initailly entered for them. The simultaneous solution of the liquidus equations given by Eq. [1] and [2] was considered accomplished when the right-hand members (RHM) of these equations agreed to within 0.001. Since the equations are not explicit equations for T, the RHM depending implicitly upon T, an iteration scheme was used to solve them when it was necessary to obtain a calculated value for T. This is not necessary, of course, when a partial pressure had to be calculated or when it was desired to calculate a liquidus isotherm for some set of the model parameters. As an illustrative example of the calculations, consider a fit to a set of ternary liquidus points. The experimental data input consists of sets of values for the observed values of T, x_{Hg}, and x_{Cd} and it is desired to obtain calculated values of T and u for each of these. For each liquidus composition, the value of u is varied by an interval-halving subroutine seeking to find a value that will make the RHM of Eq. [1] and [2] agree to better than 0.001°C. The interval-halving subroutine is contained within a do-loop defining an iteration scheme. The values of the RHM of Eq. [1] and [2] in the nth iteration, $T_{1,n}$ and $T_{2,n}$, respectively, are evaluated using $T_{1,n-1}$. For the first iteration, the experimental value of T is used. In the nth iteration, the interval-halving varies u until $T_{1,n}$ and $T_{2,n}$ differ by less than 0.001°C. Then, if $T_{1,n}$ and $T_{1,n-1}$ differ by 0.001°C or more, another iteration is performed. If not, then $T_{1,n}$ is taken as the calculated value for T. Usually five iterations or less were required. At each iteration, T and the liquid and solid compositions are specified. Therefore, the mol fraction of species c, y_c, can be calculated from Eq. [22]. This cubic equation in y_c was solved using Cardan's method to within the 16 significant figure accuracy of the computer.

The temperature derivative of y_c can then be calculated using Eq. [36] and the partial molar quantities for the components obtained from Eq. [30]-[35].

Results and Discussion

HgTe-Te binary.—Table II summarizes the fit to this binary. Rows 1-3 illustrate fits in which the auxiliary conditions given by Eq. [6] and [7] are used after the fit to obtain calculated values for ΔH°_f, ΔS°_f, and ΔG°_f at 670°C for the formation of the compound from its liquid elements. For rows 4-7, the auxiliary conditions are applied prior to the fit, and so these calculated quantities match our selected experimental values given in Table I. Row 1 corresponds to the parameters used by Laugier, in which the dissociation constant for the HgTe molecule is temperature independent and small and in which the Hg, Te, and HgTe species in the liquid form an ideal solution. Although the fit to the liquidus points is good, that to the partial pressures is not, the calculated values of P_{Hg} being much too small. Moreover, the calculated thermodynamic properties of the compound are in poor agreement with experiment. Row 2 corresponds to the best fit with a temperature—independent interaction energy and dissociation constant. The fit to the partial pressures has improved while that to the liquidus has deteriorated. The calculated thermodynamic properties of HgTe(s) are in better agreement with experiment. Row 3 gives the best fit to the liquidus alone with all four parameters free. The fit to the liquidus of 5°C is very good but at the expense of much too negative values for ΔH°_f and ΔS°_f. The fit to the Hg pressures is poor. Row 4 represents the best fit with the auxiliary conditions of Eq. [6] and [7] met and is satisfactory. However, the calculated eutectic temperature is too far from the experimental value of 413.3° ± 0.2°C. The best-fit values of a_1 and b_1 shown in row 4 lie on a "best-fit curve" in the a_1-b_1 plane. As the values of a_1 and b_1 are changed from their best-fit values, the quality of the fit changes only slowly if the best-fit curve is followed, but rapidly otherwise. A similar best-fit curve is found for the CdTe-Te binary and is a common phenomenon in least squares fits. Rows 5-7 show values of a_1 and b_1 from along the best-fit curve that give a eutectic temperature +1°, 0°, and −1°C from the experimental value. We choose the parameters of row 6 as giving the best overall fit. It should be noted that the fits of rows 4-7 are not much different, even though the predicted eutectic temperatures differ.

Figure 1 shows the experimental liquidus points with the calculated liquidus line from the parameters of entry 6. The calculated line is about 20°C too high between 60 and 66 a/o Te. This discrepancy is present for all of the rows 4-7 and can be removed only by ignoring the auxiliary conditions of Eq. [6] and [7].

CdTe-Te binary.—Table III summarizes some preliminary fits. Although the model parameters from the literature shown in rows 1 and 2 give the very best fits to the liquidus, they also give poor fits to the partial pressures and unacceptable values for the thermodynamic functions of CdTe(s). The parameters in row 3 from the literature were obtained using different partial pressures than are selected here. Row 4 shows the best fit obtainable with the same simplified version of the model as in Row 3 using the partial pressures selected here. The fit to the partial pressures is good, but that to the liquidus has deteriorated somewhat. Moreover, although the calculated value for ΔG°_f is close to experiment, those for ΔH°_f and ΔS°_f are too far removed to be acceptable. Row 5 shows the best simultaneous fit attainable to the liquidus and partial pressures with all 4 liquid parameters adjustable.

Further discussion of the CdTe-Te binary involves the first eight rows of Table IV. For all of the entries, Eq. [8] and [9] were applied prior to the fits so that the calculated values of ΔH°_f, ΔS°_f, and ΔG°_f at 1092°C agree exactly with our selected experimental values in Table I. The values of row 6, titled liq. σ_2, refer to the fit to the partial pressure of Te_2 for melts containing 55, 60, and 65 a/o Te (33). Although the parameters cover a wide range, there is no great change in the fits to the various quantities of the CdTe system. Values less

than 5 for a_2 give too low a eutectic temperature and so might be ruled out. The calculated liquidus curves for all the sets of parameters shown are essentially the same between 50 and 60 a/o Te and are all high by about 25°C at 60 a/o Te. As shown in Fig. 2, the calculated curves for various values of a_2 do tend to diverge between 80 and 90 a/o Te, values between 10 and 20 giving the closest fits. For all values of a_2 in Table IV, the mol fraction of CdTe molecules in the melt at 1092°C and 50 a/o Te is between 0.89 and 0.90.

Pseudobinary and ternary.—For each pair of values for a_2 and b_2 in Table IV, and the HgTe liquid parameters given in row 6 of Table II, the best fit to the pseudobinary liquidus and solidus points was used to fix W and V shown in rows 9 and 10. The fits are good and almost identical, as can be seen from rows 11 and 12. With all of the liquid and solid model parameters determined, fits to the remaining data were calculated and, except for those to the ternary liquid in row 17, are almost identical. In row 13, σ_{Hg} is the fit to 28 Hg pressures for the pseudobinary liquid (39). Rows 14-16 give the fits to the partial pressures over Te-saturated HgTe-CdTe solid solutions containing 9.4, 19.6, 41.6, and 58.1 m/o CdTe (16, 17). In row 17, it can be seen that 20 ternary liquidus points from Ref. (42) can be fit to an average of 10.6°C with $a_2 = 50$ but that values of 10 and 20 for a_2 give fits of, respectively, 34.5° and 23°C.

The wide range of ternary liquidus surfaces that can be generated while still maintaining almost equally good fits to the binaries, pseudobinary, and partial pressures is illustrated by Fig. 3, which shows the liquidus isotherm at 500°C for various values of the CdTe parameter, a_2. The ternary liquid surface for various fixed values of $x_{Cd}/(x_{Cd} + x_{Hg}) = u$ in the melt between 0 and 0.2 is shown in Fig. 4 for $a_2 = 5$ along with the experimental points. The experimental points from Ref. (42) for a $u = 0.2$ liquid are shown as the upper set of three circles, which are 30°-60°C higher than the calculated curve, while those for a $u = 0.1$ liquid are shown as the lower set of four circles which cross the calculated line for 0.2, but again are 30°-70°C higher than the calculated curve for 0.1. The experimental points for $u = 0.05$ and 0.15 liquids are omitted for clarity but are also high. The experimental points from Ref. (43) are shown as error bars along dashed lines. The upper set is for a $u = 0.10$ liquid while the lower set is for 0.067. The former fall 10°-15°C below the calculated line for $u = 0.1$ while the latter cross the calculated curve for $u = 0.05$. The two triangles are from Ref. (45), and the experimental data from this reference are summarized in

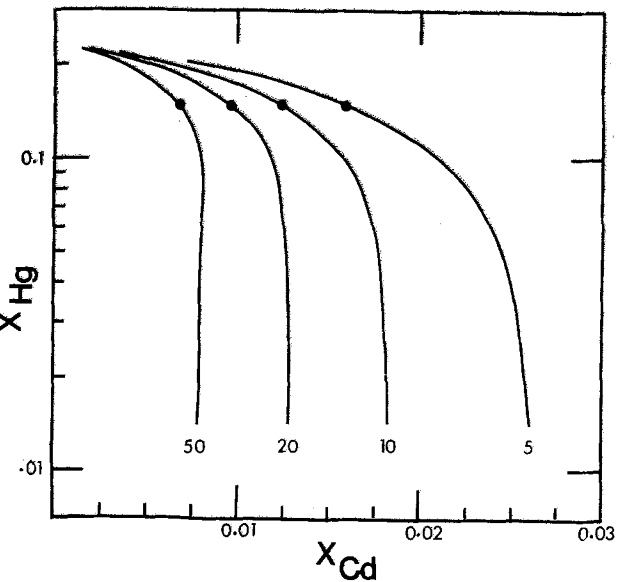

Fig. 3. Ternary liquid isotherms for 500°C calculated for labeled values of a_2. Circles mark liquid composition in equilibrium with a 40 m/o CdTe solid solution.

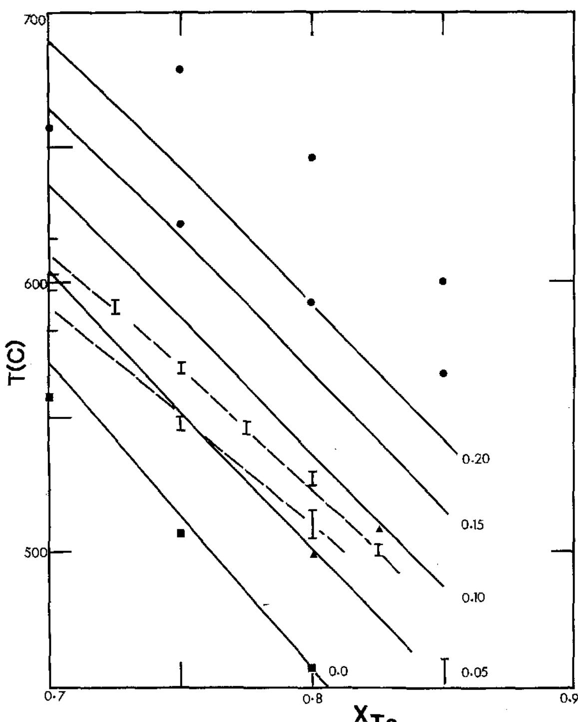

Fig. 4. Solid lines give temperature vs. atom fraction of Te for liquids with fixed, labeled, values of $u^L \equiv X_{Cd}/(X_{Hg} + X_{Cd})$ in the liquid as calculated with $a_2 = 5$ and other overall optimum parameters given in Table VI. Circles are from Ref. (42), the upper 3 are for $u^L = 0.20$, the lower 4 are for $u^L = 0.10$. Points with error bars and connected by dashed lines are from Ref. (43), the upper set corresponding to $u^L = 0.10$, the lower to $u^L = 0.067$. Two triangles are from Ref. (45) as summarized in Table V. The squares are from Ref. (18).

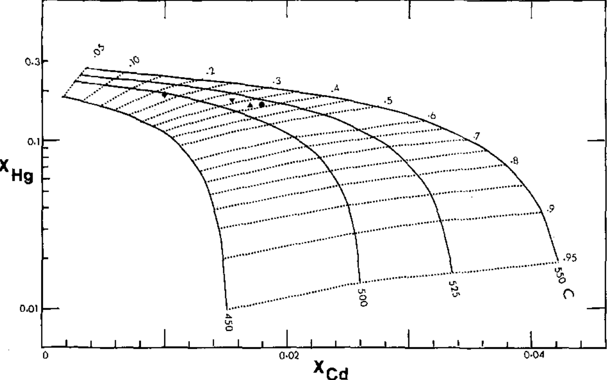

Fig. 5. Liquid isotherms (solid lines) and solid solution isoconcentration lines (dashed lines) as calculated with $a_2 = 5$ and other overall optimum parameters of Table VI. The symbols are from Ref. (45) as tabulated in Table V. Numbers along the upper curve give the mol fraction of CdTe in the HgTe-CdTe solid solution.

Table V. These latter experimental points are shown again in Fig. 5, which shows calculated liquidus isotherms and solid isoconcentration lines in the low temperature range for $a_2 = 5$. The left-most experimental point falls on the 500°C isotherm where it should be, but is slightly displaced from the calculated solid isoconcentration line for $u = 0.20$, falling closer to that for $u = 0.22$. The three clustered experimental points fall closer to the 515°C isotherm by interpolation than to that for 508°C. By interpolation they fall on isoconcentration lines for $u = 0.33$, 0.37, and 0.39 compared to the experimental values of, respectively, 0.29, 0.37, and 0.40. Although not perfect, the agreement is close.

Optimum fit to the HgTe-CdTe-Te ternary.—Here we take the data of Schmit in Table V as the most nearly correct ternary data and consequently take a_2 as equal to 5.0. The complete set of parameters is then fixed and is collected in Table VI. These lead to the optimum overall fit to all of the data considered, and we shall refer to the calculated data obtained with this set of parameters as the optimum fit. The optimum HgTe-Te liquidus line is, then, that shown in Fig. 1; that for CdTe-Te is that shown in Fig. 2 for $a_2 = 5$; and the optimum calculated ternary liquidus is shown in Fig. 4 and 5 for the low temperature range.

Table V. Composition of liquid given by the atomic fractions of Hg and Cd and that of the coexisting solid solution, $Hg_{1-u}Cd_uTe(s)$, from Ref. (45)

T (°C)	X_{Hg}	X_{Cd}	u
499	0.19	0.01	0.20
507	0.175	0.0156	0.29
508	0.163	0.017	0.37
508	0.162	0.018	0.40

The optimum calculated pseudobinary liquidus and solidus is shown in Fig. 6. Although the fits are good numerically, as can be seen from rows 11 and 12 in Table IV, the calculated solidus is slightly below all the experimental points but one.

The optimum calculated fit to P_{Hg} for the pseudobinary liquid ($X_{Te} = 0.5$) is shown in Fig. 7 along with the experimental points for various mol fractions of CdTe. For clarity only segments of the calculated lines are shown, each segment falling just below the associated experimental points for each mol fraction of CdTe. The calculated results are low by 21.3% as indicated in row 13, column 1 of Table IV. The correction for the nonideality of Hg(g) results in the calculated values for P_{Hg} being about 4% lower than if the correction were omitted. As can be seen, the calculated values of P_{Hg} for 10.8-60 m/o CdTe fall along slightly different lines, P_{Hg} being lower at a given T the larger the m/o CdTe. In contrast, the experimental points of Steininger (39) are tightly clustered and were represented as a single straight line by him.

Figure 8 shows calculated values of P_{Hg} for Te-saturated solid solutions of fixed mol percent CdTe and the experimental points. The fit to the experimental points between 10 and 58 m/o CdTe solid is about 9% and is good. The calculated values of P_{Hg} at the calculated solidus temperatures fall close to a straight line up to 70 m/o CdTe, the effect of increasing solidus temperature dominating the effect of decreasing Hg content. Between 95.2 and 95.3 m/o CdTe, P_{Hg} at the solidus temperature reaches a maximum value of 52.3 atm between 993.5° and 994.9°C and then decreases for larger Cd content. This calculated result is off-scale in Fig. 8.

Figure 9 shows the experimental points and the optimum calculated curves for P_2 over Te-saturated solid solutions of various mol percent CdTe. For comparison, the vapor pressure of Te(l) is shown as the upper-

Table VI. Values of the model parameters giving the best overall fit to the HgTe-CdTe-Te system. The degree of dissociation, β, of the liquid phase molecule, HgTe, at the melting point of HgTe(s) and that of the liquid phase molecule, CdTe, at the melting point of CdTe(s) as calculated from these parameters is also given

1, *i.e.*, HgTe	11,081	−12.0076	1936.01	8800	0.3827
2, *i.e.*, CdTe	2401.5	−1.4647	5.0	10,153	0.054
W (cal) = −15,160		V (eu) = 16.497		Pure ternary liquid parameters	
W_s (cal) = −333		V_s (eu) = −1.01292		Solid solution parameters	

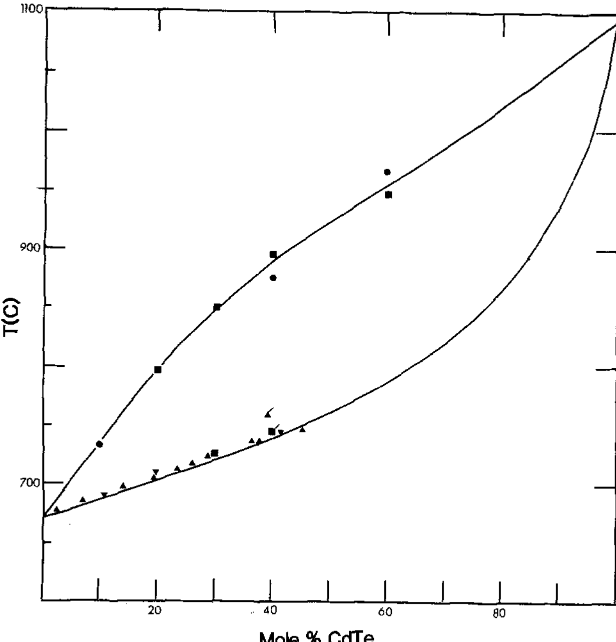

Fig. 6. Solid lines show the liquidus and solidus in the $Hg_{1-u}Cd_uTe$ pseudobinary as calculated using the overall optimum parameters of Table VI. Circles: Ref. (38), squares: Ref. (39), triangles: Ref. (40), inverted triangles: Ref. (16) and (17). Triangle and square with attached line segment were omitted from the fits.

most straight line. The fits are good as seen in row 16, $a_2 = 5$ column of Table IV. The experimental values for 9.4 and 19.6 m/o CdTe fall below the calculated curves near their maxima. In addition, the experimental points for different CdTe content tend to merge together at the lowest temperature to a greater degree than shown by the calculated curves. However, the measured values of P_2 are near the limit of detectability from the optical absorbance of $Te_2(g)$ in the visible. Moreover, at these low temperatures, internal equilibrium of the solid solution phase and equilibrium between it and the vapor phase is possibly not always achieved.

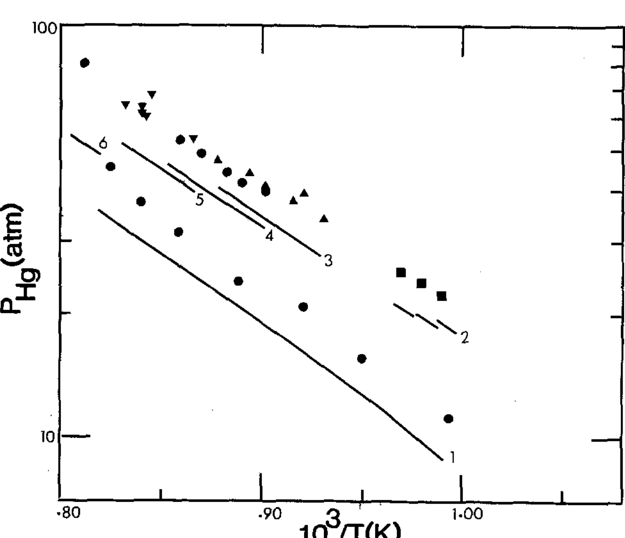

Fig. 7. The partial pressure of Hg(g) for various pseudobinary melts as a function of $10^3/T$ and for line 1, for a 60 a/o Te, 12 a/o Cd melt. Line segments are calculated using the parameters of Table VI and cover the same temperature range as the corresponding experimental points from Ref. (39) and, for the squares, from Ref. (17). Line 2, squares: 10.8 m/o CdTe pseudobinary liquid; line 3, triangles: 20 m/o CdTe; line 4, circles: 30 m/o CdTe; line 5, inverted triangles: 40 m/o CdTe; line 6; single circle: 60 m/o CdTe.

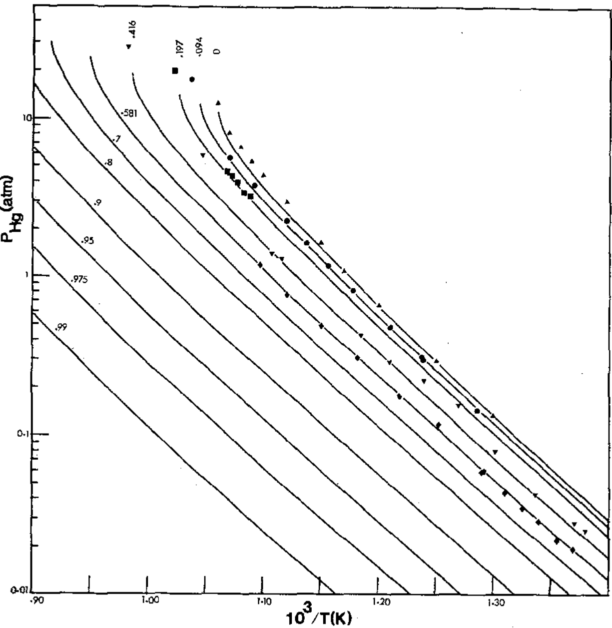

Fig. 8. The mercury partial pressure over Te-saturated $Hg_{1-u}Cd_uTe(s)$ as a function of $10^3/T$. Solid curves with labeled values of u are calculated using parameters of Table VI. Experimental points are from Ref. (16) and (17) and, for HgTe(s), from Ref. (19).

Figure 10 shows the experimental points and calculated curves for P_{Cd} over solid solutions of various mol percent CdTe. The experimental points are generally higher than the corresponding curves, particularly for 9.4 m/o Cd although the overall fit is to within 33% as seen in column 1, row 15 of Table IV. The calculated curves cross at high temperatures. The experimental data (17), which are available for both metal-saturated and Te-saturated solid solutions, do the same thing. At low temperatures, P_{Cd} is higher, the larger the mole percent CdTe, for both metal and Te-saturated solid solution.

General Discussion

A quantitative simultaneous fit to the phase diagram and thermodynamic data in the HgTe-CdTe-Te system

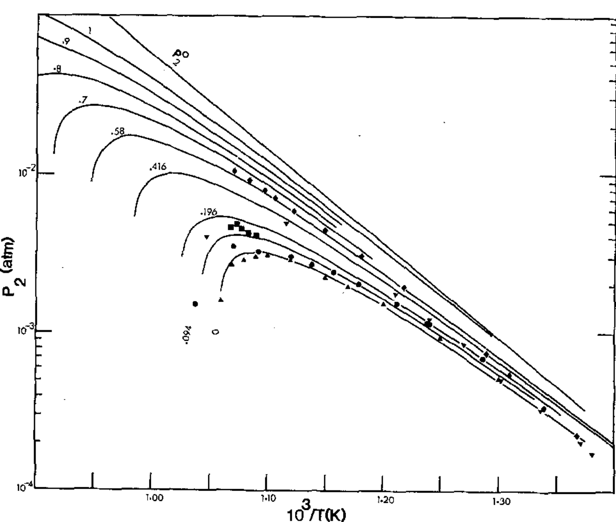

Fig. 9. The vapor pressure of Te shown as the uppermost line and the partial pressure of Te_2 over Te-saturated $Hg_{1-u}Cd_uTe(s)$ vs. $10^3/T$. Solid curves with labeled values of u are calculated using the parameters of Table VI. Experimental points are from Ref. (16) and (17). Those for CdTe from Ref. (33) are off-scale at higher temperatures.

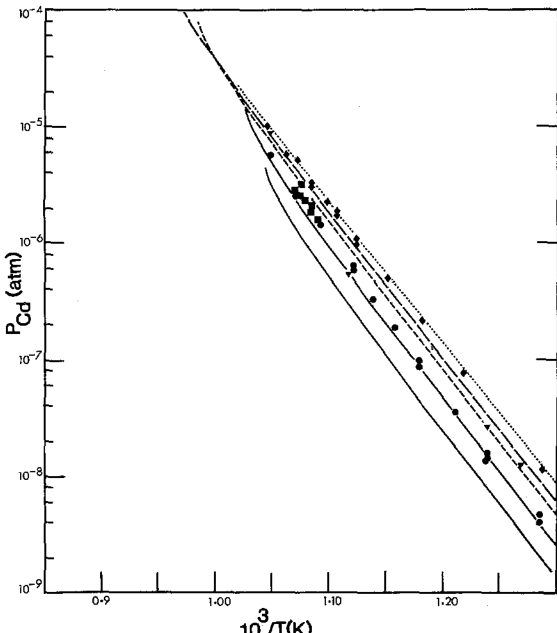

Fig. 10. The partial pressure of Cd over Te-saturated $Hg_{1-u}Cd_uTe(s)$ vs. $10^3/T$. Experimental points are from Ref. (16) and (17). Lines are calculated using the parameters of Table VI. Except for $u = 0.58$ and 1, they terminate at the solidus temperature. Uppermost, dot line: $u = 1.0$; 2nd, long-dash line, diamonds: $u = 0.581$; 3rd, short-dash line, inverted triangles: $u = 0.416$; solid line, squares: $u = 0.197$; bottom solid line, circles: $u = 0.094$.

has been obtained using an extension of the simplified, regular associated solution model of Jordan (3) and Szapiro (4) for the liquid phase. The analysis differs from previous ones based upon this model in a number of respects. First, the model is extended to allow the interaction coefficients and dissociation constants of the species to depend upon T. It is shown that this is necessary to obtain satisfactory fits. Second, more exact liquidus equations are used that are thermodynamically consistent with the temperature dependence of the partial molar quantities for the components in this liquid phase model. Third, the fits are much more extensive than any previously attempted with this model. As an example, not only are the liquidus points in the HgTe-Te and CdTe-Te binaries fit, but also the partial pressures along the three-phase curves for the binary compounds. Moreover, and most importantly, this is done with constraints applied to the liquid phase model parameters that insure that the thermodynamic properties of the stoichiometric liquids, HgTe(l) and CdTe(l), are consistent with the known enthalpies and entropies of formation of HgTe(s) and CdTe(s).

The quantitative fits obtained should prove useful for interpolating and extrapolating the experimental data and in guiding further experiments. In addition to this practical result, the present analysis provides the most extensive test of this liquid phase model to date. There are signs the model may not be flexible enough even in the HgTe-CdTe-Te system. There are portions of the data, such as parts of the HgTe-Te and CdTe-Te liquidus curves, and P_{Hg} over the pseudobinary melts, in which the calculated results seem to differ significantly from experiments. No firm conclusion can be drawn here, however, since these discrepancies may be due in large part to errors in the experimental input data including the enthalpies of fusion. A surer indication of an inherent weakness in the model lies in the theoretical demonstration here that it can only predict symmetric liquidus lines for a 50 a/o compound. Thus, it is found inadequate to fit well either the entire Cd-Te binary or the Hg-Te binary. Dividing such a binary

Table VII. A listing for various compounds of the melting point, the enthalpy of compound formation from the pure liquid elements at the melting point, the enthalpy of fusion, and the enthalpy of formation of the stoichiometric liquid at the melting point. All enthalpies are in kcal/mol

phase diagram in half, and fitting each half with different values of the parameters, has been done (3). However, this introduces discontinuities in the thermodynamic properties of the liquid phase and is unacceptable once one wishes to go beyond a fit to the liquidus line alone. (If both sets of parameters are required to satisfy the auxiliary conditions given by Eq. [6]-[7], the discontinuities at the melting point disappear. Then the partial pressures along the three-phase curve as well as the liquidus line are continuous at $x = ½$. Above the melting point the discontinuities in the liquid phase properties still exist.) Thus, although the model is attractive in view of its relative simplicity, and should prove useful in fitting significant portions of phase diagram data, a more powerful model is desirable. This might be found in the more general forms of the associated solution model in which the interaction terms are more properly written in terms of the mol fractions of the species, and not in terms of the atom fractions of the components. In studies of the Cu-S and similar systems (46, 47) the interaction terms among the solution species are assumed to depend upon cubic as well as quadratic terms in the mol fractions of the species, *i.e.*, subregular interactions.

We believe that those systems, which are difficult to fit and which probably will require complicated, many-parameter, liquid phase models, rather than simple solution or subregular models, can be anticipated. Generally they are liquids in which the ionic component of binding is significant. Specifically, they are liquids whose heat-of-mixing at the composition of a solid compound is a substantial fraction of the heat-of-formation of the compound itself, *i.e.*, systems in which the cohesive energy is not greatly altered by the loss of long-range order accompanying melting. This is illustrated in Table VII. For the III-V systems listed [data sources identified in Ref. (48)] the heat of fusion is comparable to the enthalpy of formation of the solid compound from its pure liquid elements at the melting point. Consequently, the heat-of-mixing of the liquid phase at the melting point is relatively small and a subregular liquid phase model can do well in fitting the phase diagram and thermodynamic data (48). The contrast with the other systems listed is marked.

APPENDIX

Previous applications (3, 4, 7) of the simplified RAS model have started with a version of the Vieland liquidus equation in which the heat capacity of the binary compound and that of the liquid of the same composition were taken as equal. Here we obtain the liquidus equation in a form similar to the Vieland form and written explicitly for the RAS liquid model, so that the above assumption can be critically judged. We consider only one of the two equations necessary to describe the ternary liquid in equilibrium with the pseudobinary solid, $A_{1-u}B_uC$, since the other is completely analogous. In terms of the activity coefficients, γ_i, and mol fractions of species, y_i, i = a, c, an "exact" liquidus equation is given by Eq. [46] of Ref. (1) and is

$$RT \ln\left[\frac{\gamma_a\gamma_c y_a y_c}{\gamma_a^\dagger\gamma_c^\dagger y_a^\dagger y_c^\dagger (1-u)\Gamma_{AC}}\right] = H_{AC}(T/T_{AC}-1) - \int_T^{T_{AC}} (1-T/r)(\Delta C_{AC}^s - \Delta C_{AC}^L)\,dr \quad \text{[A-1]}$$

Most of the quantities have been defined in the text in connection with Eq [1] and [2] The dagger superscript indicates a quantity is evaluated at $x_A = x_C = \frac{1}{2}$ and arbitrary T. (In the B-C analog of Eq. [A-1], the dagger superscript would mean evaluation at $x_B = x_C = \frac{1}{2}$.) The heat capacities appearing on the right side of Eq. [A-1] are those for AC(s) and the liquid of the same composition. Both are relative to the pure liquid elements, A(l) and C(l). For the A-C binary, $u = 0$, $\Gamma_{AC} = 1$.

The first point to be made in connection with Eq. [A-1] is that the temperature integrals of the heat capacities ought to be considered separately; that for the solid is experimentally accessible, if not yet determined; and that for the liquid is set by the liquid model and its parameter values in the type of application ordinarily made. In many cases, the Gibbs free enthalpy of formation of AC(s) from its pure liquid elements is very nearly a linear function of T. Then the integral over the relative heat capacity of AC(s) is given by Eq. [32] of Ref. (1) as

$$\int_T^{T_{AC}} (1-T/r)\Delta C_{AC}^s dr = \Delta_{AC}(T/T_{AC}-1) + T\delta(T_{AC})/T_{AC} - \delta(T) \quad \text{[A-2]}$$

where Δ_{AC} is defined by Eq. [4] and $\delta(T_{AC})$ and $\delta(T)$ are small terms that can often be neglected, as discussed in Ref. (1). Indeed, the quantity Δ_{AC} often turns out to be small and of the order of the accuracy in the heat of fusion, H_{AC}, [(48), "Experimental Section" of text here].

The integral over the relative heat capacity of the liquid, AC(l), is given by Eq. [37] of Ref. (1) in terms of the partial molar excess quantities of the liquid phase components and is

$$\int_T^{T_{AC}} (1-T/r)\Delta C_{AC}^L = h_A^* + h_C^* - h_A^\dagger - h_C^\dagger - T(s_A^* + s_C^* - s_A^\dagger - s_C^\dagger) \quad \text{[A-3]}$$

where the asterisk superscript indicates the quantity is evaluated as $x_A = x_C = \frac{1}{2}$ and $T = T_{AC}$. For assumed liquid species a, b, c, ac, and bc, the chemical potentials defining the simplified RAS liquid model are given by Eq. [13]-[17]. The partial molar excess quantities for the components are given by Eq. [37]-[42] for the A-C binary. Substituting these into Eq. [A-3] and rearranging gives

$$\int_T^{T_{AC}} (1-T/r)\Delta C_{AC}^L dr = (\Delta H_D + \tfrac{1}{2}\gamma_1)(1-T/T_{AC}) (\kappa^*)^{1/2}/(1+\kappa^*)^{1/2} + 2RT\ln\left[\frac{(1+\kappa)^{1/2}+\kappa^{1/2}}{(1+\kappa^*)^{1/2}+\kappa^{*1/2}}\right] \quad \text{[A-4]}$$

The interaction coefficients appearing in the defining Eq. [13]-[17] are assumed to depend linearly upon T as given by Eq. [26] and κ, the product of the dissociation equilibrium constant and the activity coefficient ratio for the liquid phase molecule, ac, is defined by Eq. [20]. Using Eq. [A-2] and [A-4], the liquidus equation given by Eq. [A-1] can be written as

$$RT\ln\left[\frac{\gamma_a\gamma_c y_a y_c}{\gamma_a^\dagger\gamma_c^\dagger y_a^\dagger y_c^\dagger(1-u)\Gamma_{AC}}\right] = [H_{AC} - \Delta_{AC} - (\Delta H_D + \gamma_1/2)\kappa^{*1/2}/(1+\kappa^*)^{1/2}]\,[T/T_{AC}-1] + 2RT\ln\left[\frac{(1+\kappa)^{1/2}+\kappa^{1/2}}{(1+\kappa^*)^{1/2}+\kappa^{*1/2}}\right] \quad \text{[A-5]}$$

This equation differs from that previously used by the presence of the Δ_{AC} term and the two terms containing κ and κ^*. The importance of these terms increases as T departs from T_{AC}. As mentioned above, neglect of Δ_{AC} is often justified. However, the magnitude of the other two terms depends upon the parameters of the liquid model and their neglect is not justified in general. When the degree of association becomes very strong, κ goes to zero and so do these additional terms. In the special case that $\Delta H_D + \gamma_1/2$ is zero, κ is independent of T, ΔC_{AC}^L is zero, and both terms involving κ disappear. Finally, when the degree of association becomes vanishly small and κ becomes indefinitely large, the two κ terms in Eq. [A-5] cancel one another and the integral over the relative heat capacity of AC(l) given by Eq. [A-4] goes to zero. The resulting liquidus equation is then what one expects for a liquid model in which the relative partial molar quantities are independent of T.

In fitting the Cd-Te and Zn-Te binaries, Szapiro (4) assumed the dissociation constant of the liquid molecules was independent of T, or in effect that $\Delta H_D = 0$ For the Te-rich side of each binary, he used $\kappa = 0$, thus incurring no error through his starting liquidus equation. For the metal-rich sides, he used values of 0.044 and 0.111 for κ. We have checked indirectly whether these are small enough to neglect the κ-terms in Eq. [A-5]. First, Szapiro's parameters were used in Eq. [1] for the A-C binary ($u = h_{AC}^s = s_{AC}^s = 0$) and with $\Delta_{AC} = 0$ to obtain "exact" liquidus temperatures. Secondly, the calculations were repeated to give approximate liquidus temperatures using Eq. [1] for the A-C binary and with $\Delta_{AC} = 0$, but with the asterisk superscript replaced by the dagger superscript. Such a replacement is valid if the relative heat capacity of AC(l), as given by Eq. [37] of Ref. (1), is set equal to zero. The exact and approximate liquidus temperatures agreed to within a few tenths of a degree centigrade for both Cd-CdTe and Zn-ZnTe. For Cd-CdTe our calculated temperatures also agree with those in Szapiro's Table 1 to within a few tenths of a degree, with the exception of $X_{Te} = 0.45$, for which he lists 1084.9°C and we get 1069.1°C. For Zn-ZnTe, our calculated temperatures differ by as much as 2°-3°C from Szapiro's. However, in view of the above, this is probably due to calculation errors rather than to the liquidus equation used. We have not carried out a similar check for the entire Cd-Zn-Te ternary. Neither have we checked Jordan's calculations (3), since as Szapiro has pointed out (4), Jordan's assumption that κ is independent of T is erroneous.

In a more recent analysis of the Ga-In-Sb ternary, Szapiro [*J. Phys. Chem. Solids*, **41**, 279 (1980)] has used the same liquidus equations as before, obtaining values of κ^* of 0.0104 and 0.303 for, respectively, GaSb and InSb. The latter value is most likely large enough that significant error is made in not using Eq. [A-5].

LIST OF SYMBOLS

A, B, C	components of ternary system corresponding to, respectively Hg, Cd, and Te
a, b, c, ac, bc	assumed species in ternary liquid; ac and bc are diatomic molecules containing one atom of A and one of C, and one atom each of B and C, respectively
x_i, i = A, B, C	atom fraction of component i in the liquid
y_j, j = a, b, c, ac, bc	mol fraction of species j in the liquid
u	mol fraction of BC in solid solutions, $A_{1-u}B_uC$(s)
T_{AC}, T_{BC}	maximum melting points in K of AC(s) and BC(s)
H_{AC}, H_{BC}	enthalpies of fusion in cal/mol of AC(s) and BC(s)

h_i, s_i, i = A, B, C relative partial molar excess enthalpy and entropy of component i in the liquid. The pure elemental liquids are taken as the standard state for each component

s_i^t, i = A, B, C, relative partial molar entropy (not excess) for component i in the liquid

* asterisk superscript indicates a quantity is evaluated at $x_A = x_C = \frac{1}{2}$ and $T = T_{AC}$

** double asterisk superscript indicates a quantity is evaluated at $x_B = x_C = \frac{1}{2}$ and $T = T_{BC}$

$\Delta H^\circ_f(AC, T)$, $\Delta S^\circ_f(AC, T)$ enthalpy and entropy of formation of AC(s) from its pure liquid elements in cal/mol and cal/K-mol, respectively

$\Delta H^\circ_f(BC, T)$, $\Delta S^\circ_f(BC, T)$ similar quantities for BC(s)

$\Delta \overline{H}_f(AC)$, $\Delta \overline{S}_f(AC)$ effective or average enthalpy and entropy of formation of AC(s) as defined in Eq. [3]

$\Delta \overline{H}_f(BC)$, $\Delta \overline{S}_f(BC)$ similar average quantities for BC(s)

Δ_{AC}, Δ_{BC} difference between the average enthalpy of formation and its actual value at the melting point for the compounds AC(s) and BC(s). Defined in Eq. [4] and [5]

h_{AC}^s, s_{AC}^s excess partial molar enthalpy and entropy of species AC in the solid solution, $A_{1-u}B_uC(s)$, relative to AC(s)

h_{BC}^s, s_{BC}^s similar quantities for species BC and relative to BC(s)

μ°_i, i = A, B, C chemical potentials of the pure liquid elements

μ°_{ac}, μ°_{bc} chemical potential of a hypothetical liquid consisting entirely of, respectively, ac and bc molecules

$\Delta H_D(ac)$, $\Delta S_D(ac)$, K_1 enthalpy and entropy of dissociation to the pure liquid elements and dissociation equilibrium constant for the liquid phase molecule, ac

$\Delta H_D(bc)$, $\Delta S_D(bc)$, K_2 similar quantities for the liquid phase molecule, bc

ω interaction coefficient between the liquid phase species a and b in cal/g-atom

α_1 interaction coefficient between the liquid phase species a, c, and ac, *i.e.*, Hg, Te, and HgTe

α_2 interaction coefficient between the liquid phase species, b, c, and bc, *i.e.*, Cd, Te, and CdTe

κ_1, κ_2 product of dissociation constant and activity coefficient ratio for ac and bc. Definitions given by Eq. [20] and [21]

W, V, γ_1, δ_1, γ_2, δ_2 temperature and composition independent parameters describing the linear temperature dependence of the interaction coefficients for the liquid phase species. Definitions given in Eq. [25]-[27]

W_s, V_s constant parameters describing the relative chemical potentials of the quasiregular solid solution. See Eq. [48]-[49]

$\mu^\circ_{HgTe}(s)$ chemical potential (or Gibbs free enthalpy of formation) of HgTe(s)

$\mu^\circ_{CdTe}(s)$ similar quantity for CdTe(s)

Technical Notes

The Effect of Heat-Treatments on the Chemical State of Phosphorus in SiO_2

Charge trapping centers in thermal SiO_2 cause deteriorating effects of the threshold voltage shift in short channel MOS transistors. Among the experiments for the reduction of the trapping centers, it has been reported that the implantation of phosphorus ions into SiO_2 followed by the annealing in oxygen is effective for trap reduction while annealing in nitrogen after the implantation has no effect (1).

To clarify the difference in the behavior of P atoms after O_2- and N_2-annealing, we made XPS (x-ray photoelectron spectroscopy) measurements of the chemical state of P atoms in SiO_2. So far, the structure of P-implanted SiO_2 has been investigated using infrared absorption spectra by Fritzsche and Rothemund (2), and Ahn, Gordon, and Pliskin (3). The latter authors observed the absorption due to P-O bonds (P=O) after the annealing. The XPS measurement has been reported for P-doped CVD SiO_2 and P-implanted thermal SiO_2 by Saxena and Powell (4). However, the change of XPS spectra due to heat-treatments has not been studied.

Experimental Procedure

SiO_2 films were grown thermally in pyrogenic steam at 950°C on the (100) surface of single crystal 1 Ωcm p-type (boron-doped) silicon wafers. Phosphorus ions were implanted into SiO_2 with the energy of 40 kV and the flux of 1×10^{16} ions/cm^2. After the implantation, samples were annealed in either dry N_2 or dry O_2 at 950°C for 20 min. SIMS measurement showed that the distribution of P atoms had its peak at 36-40 nm from the SiO_2 surface and the maximum concentration of P was 2.6×10^{21} cm^{-3} (6.9 weight percent). The distribution was changed little by the annealing.

The XPS spectra were obtained by using an ES-200 spectrometer (Kokusai Electric Company Limited) together with the data processing system DS-300. Samples were excited by Al Kα (1487 eV) radiation in a vacuum of 6×10^{-9} Torr at a temperature 25°C. The binding energy, E_B, of an electronic level with respect to the Fermi level is determined from the relationship $E_B = h\nu - E_k - \phi$ where $h\nu$ is the energy of the x-ray source (1487 eV), E_k is the measured kinetic energy of the photoelectron, and ϕ is the spectrometer work function. The value $h\nu - \phi$ has been determined as 1486.5 eV for the present measurement because the carbon ls line ($E_B = 284.5$ eV) appeared at $E_k = 1202.2$ eV. The measurement was made after the oxide was sputter-etched with an Ar^+ ion beam (1.25 kV, 20 μA/cm^2) until the peak in the P distribution was reached. The thickness of the removed oxide layer was determined from the etching time, assuming an etching rate for SiO_2 of 1.4 nm/min which was estimated from the rate of the decrease of the Si 2p signal in SiO_2.

Results and Discussions

Figure 1(a) shows the P 2p signals observed in as-implanted SiO_2 samples. The signal consists of four peaks, P1-P4, among which P3 and P4 are overlapped. Similar spectra for the N_2-annealed and O_2-annealed

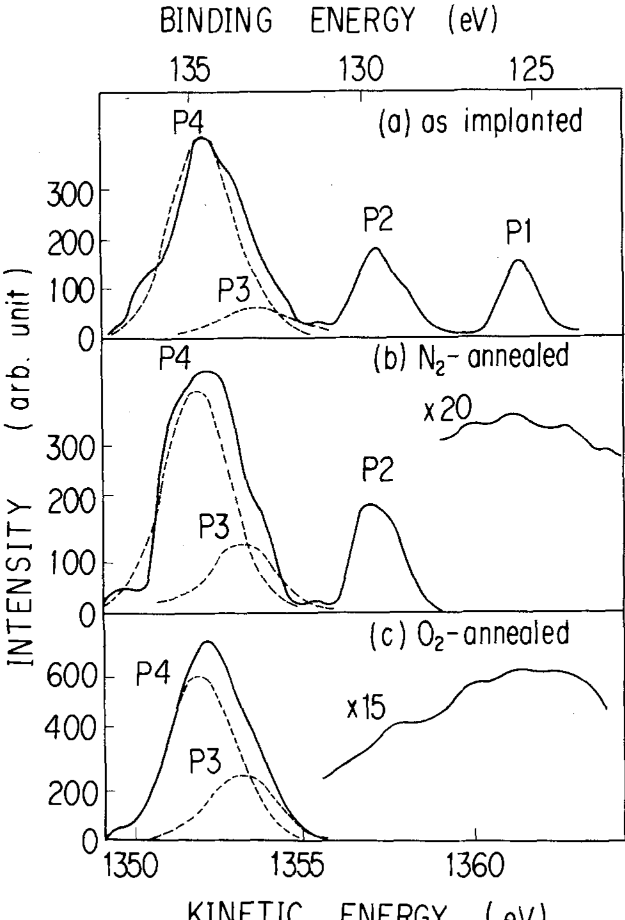

Fig. 1. P 2p peaks in (a) as-implanted, (b) N_2-annealed, and (c) O_2-annealed thermal SiO_2.

[1] Present address: Nippon Electric Company Limited, Kawasaki, Japan.

Key words: SiO_2, P-implantation, XPS spectra, annealing, trapping centers.

Table I. Binding energies of P 2p levels in SiO_2 (first two columns) and in several compounds (third column) (in eV).

This work	Saxena and Powell (4)	Pelavin *et al.* (5)
P1 125.6		
P2 129.7	E1 129.1 (implanted)	129.5 (BP)
P3 133.5	E2 133.3 (implanted) 133.5 (CVD)	
P4 134.7		134.4 ($POBr_3$)

samples are shown in Fig. 1(b) and (c). It is seen in these figures that the peak P1 appears only in the as-implanted samples and the peak P2 vanishes in the O_2-annealed samples. The peak shift due to the annealing is not observed clearly. The binding energies, E_B, of these peaks are listed in Table I together with those reported by other workers (4, 5).

From Table I it can be seen that the E_B value of our peak P2 is near to that of the E1 peak of Saxena and Powell, which they attribute to the interstitial P atoms in the network of SiO_4 tetrahedra, and it is also similar to that of phosphorus in its intermetallic compounds [for example, BP in Ref. (5)]. The P2 peak can therefore be attributed to P—Si bonds of P atoms in the interstitial site in the SiO_2 network. Our P3 peak nearly corresponds to the E3 peak of Saxena and Powell, which they attribute to P atoms substituting Si sites in SiO_4 tetrahedra, *i.e.*, PO_4^{-3}. Though P4 has no counterparts in Saxena and Powell's spectra, it has the E_B value in the range of those of P atoms with the oxidation number 5 [for example, $POBr_3$ in Ref. (5)]. Therefore, P4 can also be interpreted as the signal from P—O bonds in the SiO_2 network. The origin of P1 is presently unknown.

The integrated intensities of the peaks P2, P3, and P4, normalized by the summation of all the integrated intensities of P 2p peaks, are plotted in Fig. 2 for the as-implanted, N_2-annealed, and O_2-annealed samples. This figure shows that by O_2 annealing the P2 peak disappears and the P3 and P4 peaks simultaneously increase in intensity. Taking the assignment of the peaks into consideration, these results can be interpreted as evidence that O_2 annealing at 950°C has the effect of converting P—Si bonds to P—O bonds in the SiO_2 network while N_2 annealing has no such effect. These results coincide with those of the infrared absorption study by Ahn *et al* (3) which showed the increase of P—O bonds after the annealing in an oxidizing ambient. The present study proves that the XPS measurement is useful in evaluating the effects of heat-treatments of P-implanted SiO_2.

Observation of Growth Striations in Undoped GaSb Single Crystals

Shun-ichi Tohno and Akinori Katsui

Nippon Telegraph and Telephone Public Corporation, Ibaraki Electrical Communication Laboratory, Tokai, Ibaraki, 319-11, Japan

Observation of growth striations appearing in crystals grown from the melt is useful for the study of optimum conditions to grow high quality crystals. The growth striations are usually formed by doping impurities of high concentration. This note reports that the growth striations were observed in undoped GaSb

Key words: GaSb, growth striations, native defect, x-ray topography, chemical etching.

single crystals with low concentration of residual impurities.

GaSb crystals mentioned in this study were grown by the liquid encapsulated Czochralski (LEC) technique using B_2O_3-3.2 mole percent (m/o) Na_3AlF_6 as the encapsulant (1). The apparatus used consisted of a conventional RF-heating Czochralski puller. The growth conditions of single crystals were almost the same as those described in the previous paper (1). The major conditions are summarized in Table I. Contamination by impurities contained in the B_2O_3-3.2 m/o Na_3AlF_6 was negligibly small (1) and did not have direct influence on the results of this work.

Table II shows the levels of residual impurities in the grown crystals measured by spark source mass spectrometric analysis. It is confirmed that the total concentration of residual impurities in the crystal is less than 3 ppma (5×10^{16} cm^{-3}).

The growth striations were observed by x-ray diffraction topography (Mo $K\alpha_1$ radiation) and chemical etching technique, using specimens cut along the growth axis of the pulled crystals.

Figure 1 shows an x-ray transmission topograph of the initial diverging part of a crystal grown in the [111] direction at the rotation rate of 10 rpm. The growth direction is downward (arrow sign in the figure). Specimens were etched for 1 min at room temperature with a mixture of 9 HNO_3, 1 HF, and 20 CH_3COOH after mechanically polishing to about 200 μm thickness. The diffraction plane was (111). The growth striations are visible as many fine lines. The contrast of these striations reversed in the $(\bar{1}\bar{1}\bar{1})$ diffraction topograph. It is concluded, from this result, that the observed striations are formed by impurities segregation (2), not by their precipitation. As shown in Fig. 1, two regions can be distinguished in the crystal, although the resolution of the topograph is not so high that detailed structure of the striations is revealed. One is the off-facet region consisting of striations curved toward the growth direction at the periphery of the crystal. The other is the facet region, which locates in the central part of the crystal and consists of straight striations perpendicular to the growth direction. Observation of the striations using x-ray topography has been carried out on the <111> grown crystals by the LEC technique with the KCl + NaCl encapsulant (3).

Figure 2 shows a topograph diffracted from the (400) plane of a [100] pulled crystal. The striations are also encountered in the [100] pulled crystals. However, no central facet is visible.

Figure 3 shows an optical micrograph of the chemically etched {211} surface of a crystal grown in the $[\bar{1}\bar{1}\bar{1}]$ direction. In order to reveal growth striations, a mixture of 1 $KMnO_4$, 0.05M, 1 HF, and 1 CH_3COOH, which was developed for InSb (4), was employed. The mechanically polished specimen was etched with the mixture for 1-2 min at room temperature. The growth

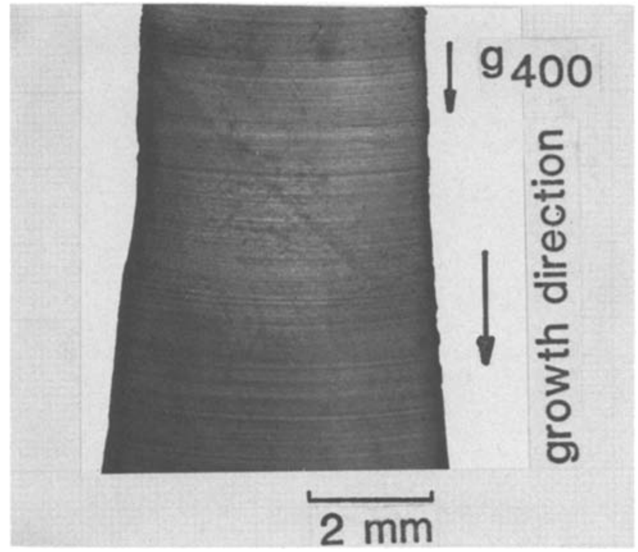

Fig. 2. X-ray topograph of undoped GaSb wafer cut parallel to [100] pulling direction.

striations in the facet and off-facet regions on the etched surface are observed with high resolution suitable for the study of the striations.

As described above, the growth striations are encountered in the undoped GaSb crystals in which the residual impurities concentration is low. The total impurities concentration is less than 5×10^{16} cm^{-3}, as shown in Table II. However, electrically active impurities concentration of approximately 1.1×10^{17} cm^{-3} was contained in the grown crystals, which was estimated by measurement of Hall coefficient. Excess impurities are attributed to native defects (5) caused by smaller atomic volume of Ga than that of Sb. Therefore, it is thought that the native defects arising from the deviation in stoichiometry lead to the formation of the growth striations in the undoped crystals.

Variations in sharpness, intensity, and periodicity of growth striations strongly reflect the growth conditions of the crystals. Figure 4 shows a micrograph of the etched {211} surface in the constant diameter part of $[\bar{1}\bar{1}\bar{1}]$ pulled crystal. This crystal was grown at two different rates of seed rotation. The upper and lower parts of the figure were pulled at rates of 10.5 and 6.2 rpm, respectively. Rotational striations with regular spacings appear in both regions which were grown at

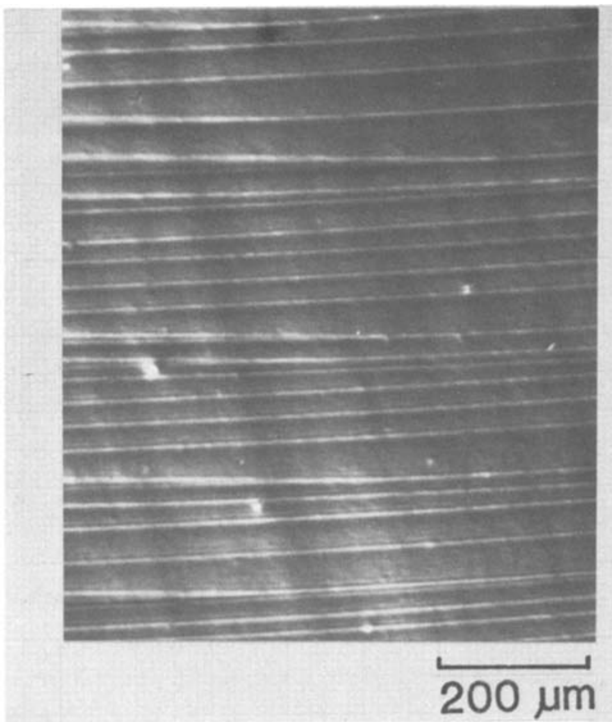

Fig. 3. Micrograph of etched {211} surface of $[\bar{1}\bar{1}\bar{1}]$ pulling crystal. Striations appearing in the boundary region between facet (straight lines in the left side of the figure) and off-facet are shown.

different rotation rates. As can be seen in Fig. 4, variation in the rate of the seed rotation had an apparent effect on the spacing of the rotational striations. Their periodic spacings agreed with values calculated from the pulling and rotation rates after correcting for the continuous decrease in the melt. On the other hand, in Fig. 1-3 which show the striations in the crystal diameter enlarging process, nonrotational striations are dominant and the striation spacings are irregular. This may be due to intense temperature fluctuations caused by such factors as rf power variation and irregular thermal convection in the melt.

Acknowledgments

The authors express their sincere thanks to Dr. N. Niizeki, Dr. H. Takata, and Dr. K. Kudo for their encouragement throughout this work, and to Mr. C. Uemura and Mr. S. Shinoyama for their valuable suggestions. We are much indebted to Mr. C. Honma for performing mass spectrometric analysis.

On the Removal of Insulator Process Induced Radiation Damage from Insulated Gate Field Effect Transistors at Elevated Pressure

A. Reisman,* J. M. Aitken,* A. K. Ray,* M. Berkenblit,* C. J. Merz,* and R. P. Havreluk*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

When subjected to radiative processes during fabrication, high levels of fixed positive charge and neutral traps are generated in the insulators of insulated gate field effect transistors (1), IGFET's. In the case of positive charge, the effect can be manifested by a drastic reduction in threshold voltage in n-channel IGFET's (2). In process sequences prior to metallization, such traps are readily annealed at 550°-600°C. Following metallization, however, when annealing temperatures

may, of necessity, be restricted to brief time periods at 400°C or thereabouts in forming gas or hydrogen, particularly in shallow junction devices, it is difficult to remove this damage to desirable device and circuit design levels. This represents both a time zero and more important, a reliability exposure. For example, when metal interconnection levels are delineated using E-beam lithographic techniques in the dose range from 5 to 30 $\mu C/cm^2$, or the metal itself is deposited using E-beam metal evaporation techniques, up to a few hundred mV of residual equivalent positive charge is detected in the gate insulator via hot electron injection techniques after conventional annealing treatments have been applied (1, 3). Such residual levels pose a design problem, because during normal device operation hot electrons penetrating the silicon-oxide interface are trapped by positively charged and neutral trap sites causing threshold shifts as a function of time.

Experimental Results and Discussion

Using an elevated pressure reactor of IBM design, to be described at a later date, the effects of 10% hydrogen-90% argon forming gas annealing at 400°C and 50 atm on radiation damaged metal gated capacitors, polysilicon gated capacitors, and insulated gate field effect transistors were studied. These results were compared with control samples annealed in either forming gas or pure hydrogen at 400°C and atmospheric pressure.

Both the metal and polysilicon gated capacitors were fabricated on p-type, 2 Ω-cm, 57 mm diam 0.38 mm (15 mil) thick silicon wafers. The insulators were grown in dry oxygen to a thickness of 35 nm. In the case of the metal gated capacitors, 0.81 mm (32 mil) diam aluminum dot patterns, 500 nm thick, were deposited through a physical mask using an rf heated aluminum source which causes no radiation damage. In the case of the polysilicon gated capacitors, a blanket layer of polysilicon 250 nm thick was chemically vapor deposited on the insulator. The polysilicon was then doped with phosphorous using $POCl_3$. A 500 nm thick aluminum dot pattern was then deposited on the doped polysilicon using the same physical mask as for the metal gated capacitors. This deposited aluminum dot pattern, in turn, was then used as a plasma etching mask for delineating the polysilicon gates. The aluminum dots were left in place after the polysilicon delineation to serve as probe contacts.

The insulated gate field effect transistors were fabricated in p-type, 0.5 Ω-cm silicon using a simplified polysilicon gate process. Junctions were phosphorous diffused to a depth of 0.5 μm and gate insulators were 35 nm thick. Isolation was planar (no recessed oxide) and was 350 nm thick. Junction contact metallurgy was Pd_2Si-Al. While the vertical characteristics of these devices, prepared via optical lithography techniques simulated 1 μm device design technology (4), horizontal dimensions covered a wide range of channel lengths and channel width to length ratios. For hot electron injection studies 2:1 width:length ratio devices with 100 μm (4 mil) channel lengths were the most appropriate for us to examine (1). Additionally, some measurements were made on special test devices of all E-beam lithography fabricated polysilicon gate, recessed oxide IGFET's.

Radiation damage was introduced into the finished polysilicon gated capacitors and the planar polysilicon gated transistors by first overcoating the wafers with 0.4 μm of photoresist, then blanket evaporating 500 nm of aluminum on top of the photoresist in an E-gun system which we have found causes significant insulator damage. The photoresist-aluminum composite was then lifted off leaving the radiation damaged wafers ready for measurement. E-beam lithography and E-beam metal evaporation doses were estimated to be in the 10^7 rad SiO_2 range.

The metal gated capacitors were employed solely as controls to insure that the high pressure annealing system created no problems in terms of contamination. Following fabrication, the metal gated capacitors were post metal annealed at 400°C for 20 min in either 10% hydrogen-90% nitrogen (forming gas, F.G.) at 1 atm or at 400°C for 20 min in pure hydrogen at 1 atm. These samples were then compared with capacitors annealed at 400°C for 20 min in 10% hydrogen-90% argon at 50 atm.

The 1 atm annealed capacitors exhibited flatband voltages ranging between −0.82 and −0.83V. The 50 atm annealed capacitors exhibited flatband voltages ranging between −0.80 and −0.81V. Interface trap density, D_{it} (5) was approximately $1 \times 10^{10}/cm^2$ eV at mid bandgap for the three types of annealed capacitors. These results provided confidence in the cleanliness of the high pressure system, at least for time zero measurements.

The results obtained with polysilicon gated capacitors are shown in Table I at different stages of processing. The different annealing treatments prior to irradiation included forming gas at either 1 or 50 atm. Following irradiation, annealing treatments were either in forming gas or hydrogen at 1 atm or in forming gas at 50 atm, as noted. As can be seen from Table I, wafers 1-8, conventional annealing in forming gas yielded flatbands ranging from −1.10 to 1.14V, while the elevated pressure annealed capacitors, wafers 9 and 10, exhibited values around −0.97V. Wafers which had initially received the forming gas 1 atm type of post metal annealing treatment, wafers 1 and 2, exhibited flatband voltages of approximately −2.6V following irradiation. After 1 atm annealing in forming gas or hydrogen for 20 min at 400°C, wafers 1-6, the flatbands recovered to values ranging from −1.25 to −1.28V. On the radiation damaged wafers subjected to 50 atm forming gas annealing at 400°C for 20 min, wafers 7-10, the flatbands recovered to values of −1.01 to −1.06V. These results indicate that on the large capacitor structures some 250 mV or equivalent unannealed positive charge remained following conventional annealing, while some 60 mV of charge remained following high pressure annealing. Because of the very large diameter of the capacitor structures, it was anticipated that fixed time annealing cycles might be less effective than they would be with transistor structures, since diffusion paths from the edges of the gate region into the insulator are many times greater in the capacitors than they would be in IGFET's, even in the large channel length structures discussed below. The cited results with elevated pressure capacitor annealing indicated that such a treatment is considerably more effective than 1 atm anneals. This was confirmed with IGFET annealing studies.

Following irradiation, IGFET device thresholds shifted negatively some 1.2-1.5V. After conventional annealing in pure hydrogen, these devices were subjected to hot electron injection (5×10^{13} electrons/cm^2) to assess residual positive charge levels. At this injection level, the radiation induced positive charges have been found to be annihilated completely by injected electrons (1). These large devices have been found to behave similarly to 1 μm channel length IGFET's in terms of damage susceptibility and annealing characteristics. The results are shown in Fig. 1 which is a plot of drain current, I_{SD}, *vs.* gate voltage, V_G of these radiation damaged devices. Trace 1 shows the *I-V* characteristic following radiation damage and subsequent 1 atm hydrogen annealing at 400°C for 30 min. The state of the device is here representative of an as yet unknown level of residual radiation damage after conventional annealing. Trace 2 shows the *I-V* characteristic after injecting 5×10^{13} electrons/cm^2 to neutralize such residual unannealed positive charge, and indicates that the residual positive charge follow-

ing conventional annealing was equivalent to approximately 115 mV, based on the magnitude of the observed threshold shift between traces 1 and 2. The range observed on such devices was 90-136 mV. Trace 3 shows the *I-V* characteristic after injecting an additional 1×10^{16} electrons/cm^2 to partially fill neutral traps. The neutral traps that are filled at this injection level, based on the earlier cited work (1), have cross sections greater than 10^{-15} cm^2. The observed shift between traces 2 and 3 indicates some 200 mV of residual neutral trap equivalent have been filled.

A companion wafer was given the same radiation damage treatment, followed this time by a 400°C, 30 min, 50 atm forming gas anneal. The results obtained with identical electron injection procedures are shown in Fig. 2. It is seen that <20 mV of residual positive charge equivalent, and some 80 mV of residual neutral trap equivalent have been filled, traces 2 and 3, respectively. The range of the positive charge equivalent was from approximately 12 to 18 mV, and that of the neutral traps from 80 to 100 mV. Both of these levels are quite acceptable from a device design point of view. In the absence of radiation damage, similar devices show <5 mV of positive charge equivalent and some 50 mV of neutral traps with cross section $>10^{-15}$ cm^2.[1]

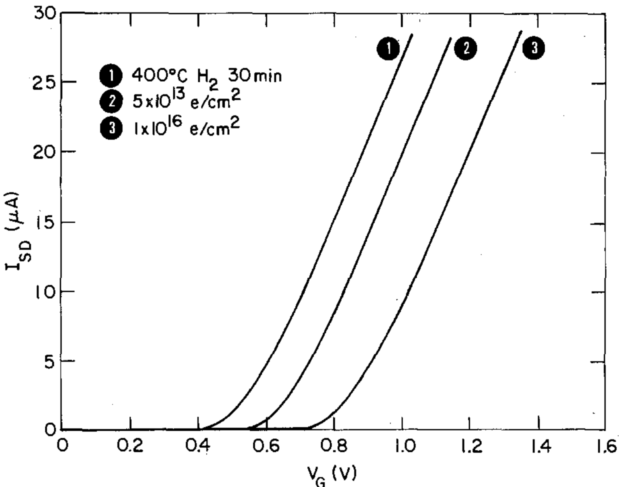

Fig. 1. Drain current vs. gate voltage following hot electron injection in a 1 atm hydrogen annealed device.

The small threshold differences on injected samples seen between Fig. 1 and 2 are due to normal oxide thickness variations, and normal wafer resistivity variations obtained by us on these devices.

Finally, one additional piece of pertinent information was obtained to support further the capacitor and IGFET results cited above. On 1 μm E-beam lithographically delineated device wafers, two identical radiation damage test device structures were incorporated. Their channel lengths, 10 μm, were identical, but the metal contact locations to them were different. In one of them, device A, the source drain contacts were close to the gate region, <2 μm, while in the other, device B, they were farther away, 12.5 μm. Consequently, in metal interconnection delineation E-beam lithography, the scattered E-beam dose seen by the device A gate insulator was considerably greater. Following hydrogen anneal, device A showed a threshold, V_T, of 0.700V, while device B showed a V_T of 0.735V.

[1] It should be noted that from a design point of view the positively charged traps, because of their large cross section, pose by far the most serious long-term device stability problem. The much smaller neutral traps only fill after these positive traps are neutralized, since the probability of trapping is proportionate to the cross-sectional area of the trap.

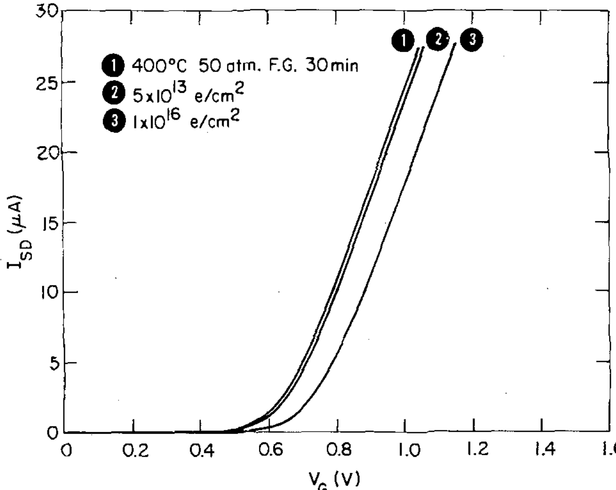

Fig. 2. Drain current vs. gate voltage following hot electron injection in a 50 atm forming gas annealed device.

This indicated greater residual unannealed radiation damage in the device A structure. However, after a 50 atm anneal in forming gas for 20 min, the device A threshold shifted 50 mV to 0.750V, while the less damaged device B threshold shifted 15 mV to 0.750V, our design value for such a device.

The high pressure annealing technique appears to provide a practical solution for process induced radiation damage removal, and is being investigated further as a function of annealing pressure, time, and temperature

Salt Water Vapor Interactions Using the Piezoelectric Effect

D. W. Rice* and P. Peterson

IBM Corporation, General Products Division, San Jose, California 95193

The chemistry and physics of salt and water vapor interactions play an important role in many practical problems. Water soluble salts on metal surfaces can significantly accelerate the metal's corrosion rate (1). Salt particles form the nucleation sites for raindrop formation (2) and are used in cloud seeding experiments (3). Fertilizer stability in humid environments is a subject of some concern (4). Electronic device failure is often associated with the interaction of water vapor and surface salt residues (5).

The interaction of water vapor with salt particles can be described by three water vapor pressure (P_{H_2O}) regimes. At low P_{H_2O}, the H_2O molecule physically adsorbs on the salt surface sometimes in clusters (6), but does not form stable bulk hydrates. At intermediate P_{H_2O}, for salts with multiple hydrates, solid-solid hydration reactions will be observed in addition to physical adsorption. Finally, at high P_{H_2O}, a salt solution will be in equilibrium with water vapor. Application of the phase rule teaches us that P_{H_2O} is invariant when three phases are present at a fixed temperature for a two component system. This will be the case when two solid hydrates and water vapor are present or when a solid, saturated solution and water vapor are present.

This note discusses the use of a piezoelectric quartz oscillator to measure water vapor and salt interactions for small quantities of water-soluble salts on gold surfaces. The majority of results focus on the equilibrium P_{H_2O} when a saturated salt solution and solid salt (or hydrate) are present. The relative humidity at this equilibrium is often referred to as the critical relative humidity (CRH). Large quantities of water are absorbed at this relative humidity and the salt dissolves.

Key words: environment, adsorption, inorganic, corrosion.

The advantage of the piezoelectric microbalance, in addition to its comparative ease and simplicity, is its 10^{-8} g/cm^2 sensitivity (7). Furthermore, because of the small amount of material required for a mass measurement, the response time is very fast (<10 sec) compared to powder beds (0.5 → 4 hr) (8). The piezoelectric technique has proven itself as a valuable tool in pressure, molecular weight, and mass measurements as demonstrated by Stockbridge (9). Important improvements in quartz cutting and piezoelectric theory (10) have broadened the potential of the method. Adsorption isotherms (11), oxidation kinetics (12), evaporation rates, and deposition rates (13) are among the more common gas-solid interactions examined by the technique. The latter is the most commercially exploited.

Experiment

Two AT-cut quartz crystals with gold surface electrodes were mounted in a 100 cm^3 Pyrex glass chamber with the associated frequency sensing and driver electronics. Commercially available evaporation rate monitoring equipment was used for these measurements. The partial pressure of water vapor was increased or decreased in the chamber at a rate of 0.15 Torr/min (0.75% RH/min) at 23.0°C. High purity nitrogen was used as the reference carrier gas and the partial pressure of water was measured by the dew point method (14). The total pressure was 740 ± 20 Torr. Figure 1 is a schematic of the experimental setup.

The experimental procedure involved, first, establishing a reference resonant frequency of the gold-

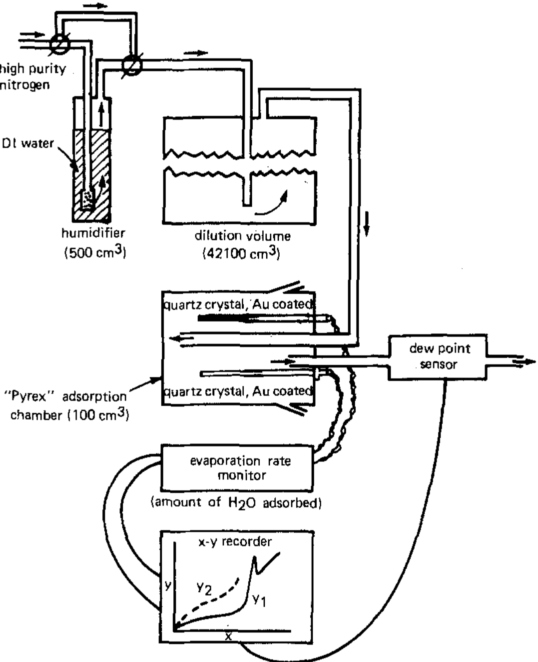

Fig. 1. Experimental setup of salt-H_2O adsorption

coated quartz oscillator at a $P_{H_2O} < 0.4$ Torr (<2% RH) in high purity nitrogen. A solution of water-soluble reagent grade salt was then added to the gold surface from a micropipette which contained a known concentration of salt. Both the amount and area could be easily varied by this method. The solution was then dehydrated to less than 2% RH and the new resonant frequency established. The weight/cm^2 actually added was used to determine the sensitivity factor, K, for the quartz crystal in the equation: M/A (weight/cm^2) $= K \cdot th$ (thickness in angstroms on the digital readout). The sensitivity factor was 0.021 ± 0.005 μg/cm^2 Å for the salts in this study. The next step in the procedure was to increase the P_{H_2O} slowly (0.15 Torr/min) and measure both the weight of water added, either adsorbed or absorbed, and the rate of H_2O addition. The P_{H_2O} was then decreased slowly.

In separate experiments, the time necessary to achieve an equilibrium mass when the P_{H_2O} was instantly stepped from 0.4 Torr to 10.5 Torr or 21 Torr was determined to be 1 and 7 sec, respectively, for 10 μg of NaCl on the Au surface. These are very rapid response times in comparison to both the P_{H_2O} scan rate (0.15 Torr/min) and powder bed response times which are the order of hours.

Results and Discussion

Figure 2 shows a typical adsorption isotherm for NaCl (26 μg/cm^2) on the gold-coated quartz piezoelectric crystal. The region of physical adsorption shows

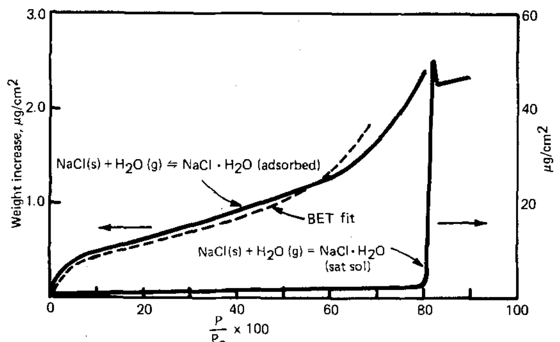

Fig. 2. Water adsorption/absorption (μg/cm^2) vs. percentage relative humidity ($P/P_o \times 100$), $t = 23°C$, HP nitrogen.

comparatively small quantities of adsorbed water. The data was fit to a Brunauer, Emmett, and Teller (BET) isotherm over the P/P_o (RH) range 0.02-0.5. The calculated heat of adsorption is 12.5 kcal/mol based on a heat of vaporization of 10.6 kcal/mol for water. Monolayer coverage occurs at 17% RH and the true surface area, Σ, of the adsorbing surface is 6.8 cm^2 based on a water molecule area on the surface of 10.5×10^{16} cm^2. The true area is therefore 6.8 times greater than the projected area of 1 cm^2. Kanazawa *et al.* have estimated monolayer coverage to occur at 7-9% RH from surface conductivity measurements (15). This value is less than our work, but demonstrates that in either case monolayer coverage occurs at comparatively low relative humidities. Hall and Tompkins have shown that heats of H_2O adsorption on both soluble (16) and insoluble (17) salts is 11-13 kcal/mol for a coverage, θ, greater than 0.1 (10%). This is in good agreement with the above value for NaCl. Papee and Laidler have measured the heat of adsorption by calorimetric methods (18). They calculate $\Delta H_{ad} = 36$ kcal/mol, but state that this is too high for physical adsorption. Surface area changes are speculated to result in these high heats by the authors.

The P_{H_2O} will reach a value that represents the equilibrium partial pressure above saturated NaCl. At this pressure, shown at the right of Fig. 2, large quantities of H_2O are absorbed until saturated NaCl is achieved. Note the sharp increase in mass.

A similar analysis of the physical adsorption isotherm was performed on LiCl, KCl, and RbCl. The summary is given in Table I.

Figure 3 shows some typical H_2O mass increase *vs.* P_{H_2O} curves for simple salts that do not form solid hydrates. Optical observation of the surface indicated that the peak in the curve is identical with the onset of solution formation. Also, the rate of H_2O pickup drops precipitously at the peak. The reason for a peak instead of a more subtle change in slope is not clear. One would expect that the amount of water should continue to increase above the solid-liquid vapor invariant pressure. The pressure would control the salt concentration and hence more water should deposit to decrease the salt concentration as P_{H_2O} increases. The peak most likely results from a local area increase around each surface solution nucleation site that results in a decrease in the mass per unit area. Data beyond the peak cannot be used until one understands the cause for apparent reduction in mass. The peak helps identify more precisely the equilibrium P_{H_2O} in the 3-phase system. Sodium iodide is the most complex of these salts. Significant quantities of H_2O were adsorbed before actual solution of the salt was observed.

Table II lists the equilibrium P_{H_2O} above saturated salt solutions (3-phase region) measured for the alkali halides in this study, the critical relative humidity, and other literature values.

The transition metal chlorides generally have many hydrated forms. The weight-pressure curves in this study were more complex than the alkali metal halides. Figure 4 shows some representative plots of weight increase *vs.* P_{H_2O}. For Fe, Co, and Ni chlorides, two pressure arrest points were observed. For $NiCl_2$

the pressures are similar to those measured for the reactions

$$NiCl_2\cdot 2H_2O\ (s) + 2H_2O\ (g) = NiCl_2\cdot 4H_2O\ (s)$$

$$NiCl_2\cdot 6H_2O\ (s) + H_2O\ (g) = NiCl_2\cdot xH_2O \quad \text{(saturated solution)}$$

The intermediate solid-solid hydrate reactions were not observed, which is indeed a puzzle. For example, we should have seen

$$NiCl_2\cdot 4H_2O\ (s) + 2H_2O\ (g) = NiCl_2\cdot 6H_2O\ (s)$$

Zinc, ferric, and calcium chloride showed no pressure breaks but very large adsorption of water. $ZnCl_2$ and

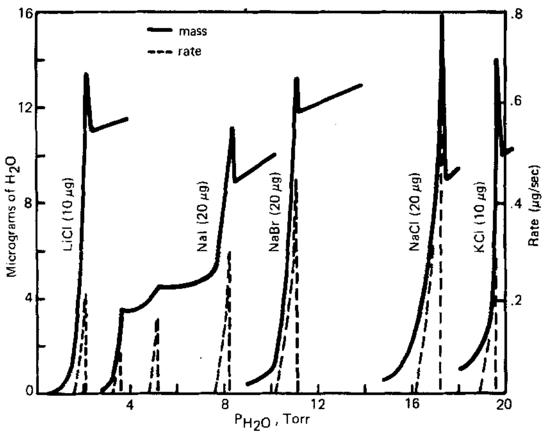

Fig. 3. Water weight increase vs. P_{H_2O} for simple salts. t = 23°C, HP nitrogen.

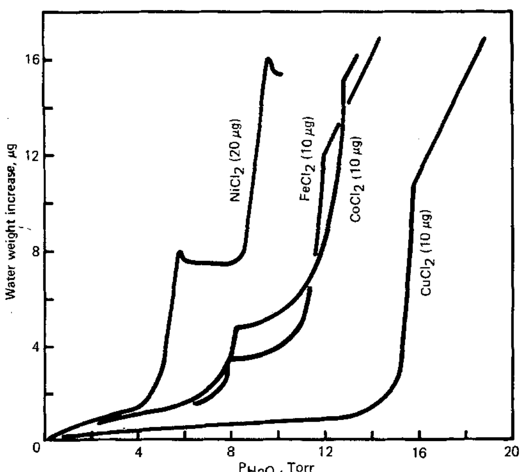

Fig. 4. Water weight increase of $NiCl_2$, $FeCl_2$, $CoCl_2$, and $CuCl_2$ salts vs. P_{H_2O}, Torr, t = 23°, HP nitrogen.

$FeCl_3$ are not stable in the presence of water vapor and will yield HCl and complex metal oxyhydroxides. These products showed no distinct pressure break.

The sulfates showed one pressure arrest for the reaction of the highest solid hydrate with gaseous water vapor to form a saturated sulfate solution. These are summarized in Table II. We could not detect solid-solid hydrate transformations for the sulfates even though they are known to exist.

Summary

The piezoelectric effect can be used to measure critical relative humidities for soluble salts as well as physical adsorption isotherms. The heats of adsorption of LiCl, NaCl, KCl, and RbCl were calculated from the BET isotherm to range between 11 and 13 kcal/mol. The technique could not generally measure solid-solid hydrate reactions except for the nickel, ferrous, and cobalt chlorides.

A Note on the Ability of CVD Polysilicon to Deposit Nearly Inaccessible Areas of IC Topology

W. E. Ham,* M. S. Abrahams,* and C. J. Buiocchi

RCA Laboratories, David Sarnoff Research Center, Princeton, New Jersey 08540

Abstract.--Cross sectional transmission electron microscopy (XTEM) samples having a cavity behind a thin microcrevice show subcrystalline deposits of chemically vapor deposited (CVD) polycrystalline silicon in the cavity. The ability of CVD poly silicon to migrate to extremely isolated areas of IC topology is thereby established. This data suggests the use of CVD poly silicon for different types of electrical and mechanical sealing applications.

We have recently had the opportunity to observe - quite by accident - the phenomenal ability possessed by CVD silicon to deposit in remote, nearly inaccessible areas of IC topology in the initial phases of its deposition. In order to understand the TEM micrograph which shows the observation, it is necessary to first describe the rather unusual conditions which lead to fabrication of the sample.

The sample was made in an attempt to observe the similarity between thermal oxidation of poly silicon layers on bulk silicon and similar oxidations of silicon-on-sapphire structures. The silicon-on-sapphire observations have been published elsewhere (1). The basic idea was to deposit a thin layer of poly silicon (5000 Å) (poly silicon I) (Fig. 1) on a bulk silicon wafer which had been oxidized (thermal oxide I), and to subsequently oxidize the poly silicon (thermal oxide II). It was recognized that the silicon substrate would also oxidize during the poly oxidation if an oxidation barrier were not used under the poly silicon. Therefore, the structure shown in Fig. 1 was used; the silicon nitride was intended to provide the oxidation barrier.

The deposited oxide layer (see Fig. 1) was defined using standard photolithographic methods and chemical etching. After stripping the photoresist, the poly silicon was etched in a KOH solution in a manner typically used for silicon-on-sapphire epi layers. At this point the usual procedure is to strip the deposited oxide in a strong HF solution and this was done. It was later found that this oxide stripping process also etched the Si_3N_4 layer and the thermal oxide under the Si_3N_4. This left the sample in a condition similar to that shown in Fig. 2. Fig. 2 is a reasonable guess only.

The thermal oxidation of the poly silicon (thermal oxide II) was done at 900°C in HCl/steam for 50 minutes. This oxidation also oxidized the exposed bulk silicon (see Fig. 2). After this oxidation, a very thick (≈ 5 μm) layer of poly silicon (poly silicon II) was deposited in order to outline the oxide. Both poly silicon layers were deposited at atmospheric pressure by silane decomposition in H_2 at ≈ 700°C. The result of this procedure is shown in Fig. 3, which is a cross sectional transmission electron micrograph of the final structure (2). It is clear from Fig. 3 that the thermal oxidation II has caused the silicon nitride ledge to become bent and depressed at its outer edge to the point where it is essentially resting on the thermal oxide II growing from the bulk substrate. The basic causes for this downward bending are not clearly understood but are not critical to the phenomenon being addressed in this note. This structure leaves a microcrevice between the outer edge of the silicon nitride layer and the thermal oxide II grown from the bulk substrate. A space exists immediately below the silicon nitride ledge which is partially filled with poly silicon from the deposition of the thick poly layer (poly silicon II).

The important point in this note is that the poly silicon in this space had to be transported through the microcrevice during the initial phase of the poly deposition before complete coverage was achieved. It is, of course, possible that the microcrevice was slightly wider at points along the edge other than shown in Fig. 3 and that some lateral transport along the edge occurred. Regardless of this possibility, a phenomenal amount of silicon was deposited in this

*Electrochemical Society Active Member.

nearly inaccessible region. CVD poly depositions in areas having severe retrograde slopes have been previously shown to occur at the edges of SOS islands and silicon epitaxy has been observed at the botton of deep grooves but the present observation is even more indicative of the penetrating ability of CVD poly silicon (1)(3). Low pressure depositions would probably enhance the effect.

This data suggests that perhaps CVD poly silicon can be used as a very effective sealant for many types of structural defects. This sealant could be of a mechanical or electrical nature depending on the application.

As a point of further note, the upper part of the poly silicon edge exhibits a sharp point and thinned oxide after oxidation in much the same way as the silicon-on-sapphire (1). Another point of interest is the small-grained poly silicon adjacent to the silicon nitride layer. The consequences of such a layer were discussed previously (1).

The authors thank E. M. Strouse for her expert sample fabrication and A. S. Buchholtz for his expert polishing and thinning of the samples.

Stabilization of n-Si Photoanodes to Surface Corrosion in Aqueous Electrolyte with a Thin Film of Polypyrrole

Terje Skotheim, Ingemar Lundström,* and Jiri Prejza

Laboratory of Applied Physics, Linköping Institute of Technology, 581 83 Linköping Sweden

All n-type narrow band gap semiconductor materials are susceptible to photoanodic decomposition in aqueous media. This has been the main impediment to the exploitation of the potential of electrochemical solar cells. Attempts at controlling the interfacial charge transfer processes at semiconductor-liquid junctions by derivatization of the semiconductor (1) or electrochemically growing thin polymer films on the semiconductor surface (2) and thereby preventing photoanodic corrosion/oxidation have yielded encouraging results. Photoelectrochemical generation of conductive polypyrrole films on n-GaAs electrodes has been reported to result in substantial stability in organic based solvents (2). However, film peeling in aqueous media remains a problem. We have studied the attachment of polypyrrole films to semiconductor surfaces and in this communication we describe a method for improving the adherence on n-Si by modifying the semiconductor surface with a 5Å Pt film before the electrodeposition of polypyrrole.

Electrodeposition of polypyrrole films on Au and Pt electrodes has been reported to yield film conductivities up to 100 $(ohmcm)^{-1}$ (3-5). Deposition of polypyrrole on Pt electrodes results in extremely good adherence to the substrate and the films are difficult to remove by chemical means. This observation prompted us to study the adherence of polypyrrole films to n-Si surfaces modified with a thin Pt film.

The semiconductor electrodes were 0.5 mm thick single crystal wafers of n-Si (1,0,0) purchased from Wacker Chemie. They had a resistivity of 2.0 ohmcm and had been polished to 0.25 µm. The electrodes were etched in 10% HF before use. Ohmic contacts were made with an In-Ga eutectic and the crystals were mounted with an epoxy on glass slides. The 5Å Pt film was deposited by a vacuum evaporation source at a rate of $1Å\text{-}sec^{-1}$ at 10^{-7} torr on the semiconductor substrates (at room temperature). Pt films of that thickness tend to form disconnected islands rather than continuous films.

The photoelectrochemical generation of thin polypyrrole films on the Si surface was performed with a tungsten-halogen lamp (140 mW/cm^2). The electrode potential was held constant at 1.0V vs. SCE (saturated calomel electrode). The monomer solution contained 0.1M pyrrole and 0.1 M Et_4NBF_4 in acetonitrile with 1% water. Deposition of polypyrrole on n-Si begins at 0.65V (SCE) vs. 0.8V on Pt electrodes. At lower voltages rapid oxide formation electrically passivates the n-Si anode. The thickness of the film was calculated on the basis of the amount of charge passed assuming the same value (50 µC cm^{-2} per monolayer) as on Au electrodes. For the photoelectrochemical measurements the counter electrode was Pt (~5 cm^2).

In order to determine the stability of the n-Si/Pt/polypyrrole electrodes against photo-oxidation the short circuit photocurrent was monitored as a function of time. The thickness of the polypyrrole layer was generally 100-250 monolayers. The medium was I_3^-/I^- redox couple in aqueous KCl solution. Data are shown in Fig. 1. The cell showed no decay running continuously for 6 days at ~9 mA cm^{-2}. The experiment was then interrupted and the cell irreversibly damaged at a current density of 35 mA/cm^2. For comparison a n-Si/Pt cell without polypyrrole decays in about 4 hours with an initial current density 7% higher. The somewhat lower current density for the n-Si/Pt polypyrrole cell is probably due to absorption in the slightly brown polypyrrole film. A n-Si/polypyrrole cell without Pt surface modification decays in a few minutes in this medium and with an initial photocurrent 36% of the value for n-Si/Pt/polypyrrole. A bare n-Si photoanode decays in ~1 min in this medium and the initial transient photo current is only 25% of n-Si/Pt/polypyrrole value. This is surprising as the cell without polypyrrole coating would be ex-

***Electrochemical Society Active Member.**
Key words: silicon, stabilization, electrode-deposition, polypyrrole.

pected to have contributions from the photo-oxidation current as well. This difference indicates efficient electron transfer across the interface and decreased rate of carrier recombination for polypyrrole coated electrodes.

The open circuit voltage was measured for a range of redox couples and was found to vary only slowly with the redox potential. For the $Fe(CN)_6^{4-/3-}$ couple (0.08V vs. SCE) V_{oc} was 345 mV and for $Ce^{3+/4+}_2$ (1.33V vs. SCE) it was 425 mV with 140 mW/cm^2 illumination. This slow variation of V_{oc} with the redox potential indicates substantial fermi level pinning.

Fig. 2 shows a current voltage curve for a n-Si/Pt/polypyrrole cell in an aqueous solution of 0.4M KI, 0.02M I_2 and 0.5M KCl under illumination of 60 mW/cm^2. The values are uncorrected for reflection and absorption in the electrolyte. Due to the cell construction the light passed through 3.5 mm of the solution which absorbed most of the light of wavelengths below 600 nm. The output characteristics are stable.

These results show that one may be able to control the semiconductor - liquid interface with electroactive polymer films and substantially suppress photodissolution/oxidation. The present work indicates that it may be possible to modify the polymer/semiconductor interaction to produce a sufficiently rugged interface for a practical electrochemical solar cell. The conversion efficiencies observed in our rather crude test cell are also encouraging.

ACKNOWLEDGEMENT

The authors thank ms. A Spetz for preparation of the electrodes and mr. O Inganäs for helpful discussions.

Chemically Deposited CdSe Thin Films for Photoelectrochemical Cells

Dexter R. Pratt, Margaret E. Langmuir,* Robert A. Boudreau, and R. David Rauh*
EIC Laboratories, Incorporated, Newton, Massachusetts 02158

The chemical deposition of thin films of CdSe on glass, copper, Si, and Ge substrates has been studied in detail by Kainthla, Pandya, and Chopra (1). We have applied this method to the preparation of thin CdSe films on titanium foil substrates for use in photoelectrochemical cells. The method does not require expensive capital equipment and can be scaled up to large electrode areas without problems of edge effects that one encounters in electrodeposition methods.

The principle of the deposition process is to provide a slow generation of Cd(II) and Se^{-2} ions such that the solubility product of CdSe is just exceeded. Growth of CdSe films then occurs preferentially on surfaces with a similar crystal structure where the free energy change of nucleation is small, thereby facilitating nucleation on the substrate as opposed to nucleation in the bulk solution.

The selenide ion concentration is controlled by the following equilibria:

$$SeSO_3^{2-} + OH^- \rightleftarrows SO_4^{2-} + HSe^-$$

$$HSe^- + OH^- \rightleftarrows H_2O + Se^{2-}$$

Cd(II) ion is complexed with ammonia, present in large enough concentration to prevent its precipitation as $Cd(OH)_2$. The overall reaction is therefore:

$$Cd(NH_3)_4^{2+} + SeSO_3^{2-} + 2OH^-$$

$$\rightleftarrows CdSe + 4NH_3 + SO_4^{2-} + H_2O$$

The equilibria for both ions are temperature dependent and therefore the growth rate may be controlled by the bath temperature. The reaction of Se^{2-} with dissolved oxygen to give Se and the precipitation of CdSe in the bulk solution are competing processes which must be minimized.

Titanium wire was spot-welded to one side of 1 cm^2 titanium foil substrates, and the assembly subsequently degreased in chromic acid and rinsed in distilled water. The substrates were dipped in a nitrogen or argon purged bath containing 0.05M $Cd(Ac)_2$, 0.05M Na_2SeSO_3, and 2.1M NH_4OH and maintained at 77°C for 60 to 90 minutes. After plating, the films were rinsed with distilled water, dried, and annealed. The annealed films appeared uniform, adherent, and specularly reflecting. The photoelectrochemical activity of the electrodes was evaluated in a three-electrode cell containing aqueous polysulfide electrolyte (1M Na_2S, 1M S, 1M NaOH).

The effect of annealing temperature was studied by maintaining the substrates at the given temperature for four hours in argon atmosphere. Figure 1 shows the results from temperatures from 350°C to 600°C. The similar symbols indicate substrates coated in the same batch. At 600°C, the films evaporate exposing the substrate, as evidenced by metallic behavior and no photoresponse when tested by current-voltage measurements under dark and light conditions. For films annealed 4 hours in argon, ∿500°C produces the optimum photoresponse. Air annealing has been shown to be beneficial for CVD prepared CdSe films on titanium (2). Therefore we have annealed some of our films in air. Those air annealed at 600°C for 7 minutes perform as well as those annealed 4 hours in argon at 500°C.

Surface treatment of the chemically deposited films increases their photoresponse much as one observes with single crystal n-CdSe (3) and painted CdSe films (4). The following etch and ion treatments have been used:

A - Dip in 10M HCl for 2 to 3 sec followed by distilled water rinse and air dry.

*Electrochemical Society Active Member

Key words: photoelectrochemical cell, solar cell, chemical deposition.

B - Treatment A followed by 10 sec dip in 2M $ZnCl_2$, partial rinse in distilled water, and air dry.

C - Treatment A followed by 10 sec dip in 2M $Na_2Cr_2O_7$ and rinse in polysulfide electrolyte.

D - Dip in 6M HCl saturated with sulfur for 2-3 sec followed by distilled water, rinse and air dry.

Figure 2 shows half cell photocurrent-voltage curves for electrodes given various surface treatments and tested in aqueous polysulfide.

Based on weight gain of the substrates, we calculate a terminal film thickness of about 0.4 micron for most substrates, although some substrates have been coated 1 micron thick. Optimization of deposition conditions may produce even thicker coatings. We have demonstrated that it is possible to add successive coatings to increase thickness. Figure 3 demonstrates the effect of increasing thickness of the deposit by two successive coatings. The short circuit photocurrent is increased significantly, probably due to increased absorbance of the incident light by the thicker film. The dashed line, B, is for an electrode with two coatings given successive etch treatments D and B. For the latter electrode, a light to power conversion efficiency of 2.7% at 67 mW/cm^2 Xe arc excitation has been achieved. Since Xe arc excitation is rich in sub-bandgap radiation compared to solar excitation for CdSe, we expect the performance of this electrode to be even better under AM2 conditions.

We are very encouraged by our initial results with chemical deposition of CdSe films on titanium substrates for use in photoelectrochemical cells. Additional experiments to relate process variables to cell efficiencies are now in progress.

Information Sources for Superconductors

Charles W. Moulton*

Chemical Abstracts Service, Columbus, Ohio 43210

The overall subject of superconductivity and superconducting devices—rather like all Gaul—can be divided into three more or less distinct areas of interest: (*i*) *superconductivity* as a fundamental physical phenomenon—the domain of the physicist; (*ii*) *superconductors* as materials—the domain of the chemist and the metallurgist; and (*iii*) *applications* of superconductivity and superconductors—the domain of the electrical engineer.

Information sources for superconductors are discussed here primarily from the standpoint of material scientists, chemists and chemical engineers, metallurgists, electrical engineers, and chemical and engineering physicists. Several abstracting organizations, as well as a number of specialized information centers, are described. *Chemical Abstracts* and its related services are also used as examples of secondary literature sources.

Information Services

The brief discussion that follows on organizations that furnish information on superconductors cannot be in any way exhaustive, but is intended to represent the major types of the various services that are available to the scientist searching for information about superconductors (1).

1. The American Institute of Physics began in January 1979 an association with the Deutsche Physikalische Gesellschaft and the Fachinformationszentrum Energie, Physik, Mathematik to publish *Physics Briefs* (PB) as a successor to the long-established *Physikalische Berichte*. PB, which is published in English in the Federal Republic of Germany, emphasizes the literature of physics.

2. The American Society for Metals (ASM) and the Metals Society of London cooperate to produce *Metals Abstracts* in the specialized area of metallurgy and the physics, chemistry, and engineering of metals and alloys. Related ASM services include *Metal Abstracts Index, Alloys Index*, and the *ASM Digest Series*. There are also the tape services *Metalert* for current awareness, and *Metadex*, which is *Metals Abstracts Index* on tape. ASM also cooperates with other societies throughout the world to produce *World Aluminum Abstracts*.

3. Cambridge Scientific Abstracts, Incorporated, publishes *Electronics and Communications Abstracts Journal, Science Research Abstracts Journal*, and *Solid State Abstracts Journal*, all of whch contain information on the physics and engineering of superconductors.

4. The Chemical Abstracts Service division of the American Chemical Society produces a wide range of services, including *Chemical Abstracts*, that direct the scientist to sources of information about superconductors in the primary literature. These services will be discussed in greater detail below.

5. *Engineering Index* emphasizes engineering and engineering physics. In addition to the principal EI abstract and index publications, there are available *Energy Abstracts* and the computer-readable file, *Compendex*.

6. The *INIS Atomindex* of the International Atomic Energy Agency emphasizes nuclear science and technology. A tape file is available.

7. The Institute of Science Information has a wide-ranging array of services. These include, in the *Current Contents* series, *Physical and Chemical Sciences* and *Engineering, Technology and Applied Sciences*. Also available are *Science Citation Index, Index to Scientific and Technical Proceedings*, and the tape files *Scisearch* and *Ascatopics*.

8. The Institution of Electrical Engineers of London, through its Information Service in Physics, Electro-Technology and Control (INSPEC), produces *Electrical and Electronics Abstracts* and *Physics Abstracts*, as well as current-awareness journals based on titles alone. The INSPEC data base is available on magnetic tape.

In addition to these particular items that have been mentioned, these services generally provide various other types of publications, tape files, and microform copies.

Information and Data Centers and Online Services

Another type of information source, the information and data centers, will now be briefly discussed. Four that compile information on superconductors from many other sources include:

a. Alloy Data Center. U.S. National Bureau of Standards in Washington, DC.

b. Cryogenic Data Center. US National Bureau of Standards in Boulder, Colorado.

c. Metals and Ceramics Information Center. Battelle Memorial Institute in Columbus, Ohio.

d. Superconductive Materials Data Center. General Electric Company in Schenectady, New York.

Of these, only the GE Center specializes in superconductors *per se*. The others process information on superconductivity as an alloy property or as an aspect of the technology of cryogenics.

Centers of this type may include in their holdings not only material selected from the standard primary technical literature, but also reports of limited availability. Some publish periodic current-awareness journals in their specialized areas, as well as bibliographies, monographs, and compilations of numerical data. They can provide computerized retrieval and microform copies of documents in their fields.

And lastly, there are the online services. Most of the abstract-index files that have been described are available to the online searcher through the domestic vendors such as the following:

a. Bibliographic Retrieval Services, Scotia, New York (BRS).

* Electrochemical Society Active Member.

Key words: superconductors, secondary literature sources, abstracting.

b. Lockheed Information Systems, Palo Alto, California (DIALOG).
c. SDC Search Service, System Development Corporation, Santa Monica, California (ORBIT).
d. US Department of Energy, Technical Information Center, Oak Ridge, Tennessee (DOE/RECON).

Online services are also becoming established through out many other parts of the world, including the following:

a. Canada Institute for Science and Technology, National Research Council, Ottawa, Canada (CISTI).
b. European Space Agency, Space Documentation Institute, Frascati, Italy (ESA/RECON).
c. Japanese Information Center of Science and Technology, Tokyo, Japan (JICST).

While these listings are far from complete, they are representative of the wide range of services available. For those with online access, these services can provide extremely rapid, efficient, and thorough searches of the technical literature by means of series of interrelated queries (known as search profiles in the jargon of the trade), framed by the individuals who request the search.

Familiarity with the relatively simple mechanics of making online searches is so readily mastered that anyone can have the satisfaction of obtaining his or her own information without relying on a library staff or spending long periods of time poring through volumes of printed publications. The online technique will, without a doubt, become the normal mode by which comprehensive searches of the scientific and technical literature are carried out.

Superconductors in Chemical Abstracts

The function of a comprehensive abstracting service such as Chemical Abstracts Service (CAS) is to furnish easy access to the primary technical literature by providing both abstracts and the indexes to them. CAS directs the searcher, both for current awareness and retrospectively, through its Collective Indexes, to the research papers, conference proceedings, books, and patents that report and discuss the chemical work carried out in the laboratories and industrial sites throughout the world. It does not provide either archival or critically evaluated compilations of data, nor does it judge the intrinsic validity or merit of the work that is reported; such judgments remain the responsibilities of the users of the information.

Abstracts.—Information on superconductors has appeared in Chemical Abstracts (CA) since shortly after its inception seventy-two years ago. The first Decennial Index to CA, covering the years 1907-1916, carries four references to superconductors, the first abstract having appeared in 1914. This was just three years after Kamerlingh Onnes' epochal papers on the discovery of superconductivity were published. In contrast, in Issue 2 of Volume 90, dated Jan. 8, 1979, and covering just one 2-week period, the researcher will find 28 abstracts concerned with superconductors and superconductor devices.

At CAS documents selected from some 14,000 journals and conference proceedings are routinely abstracted. These are, of course, predominately chemical in nature, that is, material-oriented. But large numbers of these documents overlap with certain areas of physics and engineering. For superconducting materials in particular, many of the journals most frequently cited would normally be regarded as devoted primarily to physics and engineering.

Most of the abstracts of papers and patents that deal with superconductors can be found in a section of CA entitled "Electric Phenomena" (Section 76). This is the section that is concerned most directly with materials of interest from the electrical standpoint. An entire subsection (8) is devoted to superconductors and to superconductivity as a material property.

However, various applications of superconductors can fall into several other sections, depending on the emphases of the studies; *e.g.*, metallurgical aspects in CA Section 56; magnets in CA Section 77, or, when intended for particle accelerators or fusion reactors, in CA Section 71; plant and laboratory apparatus in CA Section 47; certain aspects related to power generation and transmission in CA Section 52 (2).

Figure 1 illustrates an abstract of a paper that deals with a superconducting material. Included are the CA access number (volume and sequence numbers), the title, author names and work location, bibliographic data, language, and finally the abstract text, which provides a precis of the content of the document.

Indexes.—The usefulness of a secondary publication depends to a considerable extent on the adequacy of its indexing. The content of CA is indexed and cross-indexed in a variety of ways.

The *Keyword Index* printed in each of the Abstract Issues serves a current-awareness purpose, directing to those abstracts that appear in the various sections throughout that particular issue of CA dealing with a particular subject. An example of entries from this index is shown in Fig. 2. This is an alphabetically arranged, permuted keyword-in-context (KWIC) index, characterized by an uncontrolled vocabulary and an essentially unarticulated word string of restricted length, seldom more than four or five words. It is based mainly on the titles and abstracts, and so is not an "in-depth" index to the entire contents of the documents abstracted.

The *Subject Index* that is associated with each of the semiannual volumes of CA has, on the other hand, a controlled vocabulary insofar as the subject headings and certain subordinate details are concerned. It also represents a considerably greater depth of indexing. Figure 3 presents some of the principal subject headings that are concerned with superconductors. For the indexing of materials in CA, we have found that there is little point in trying to distinguish between superconductivity as a phenomenon and those materials that display it as a property; the main index heading in the

90: 65300a **Superconductivity in the barium lead bismuth oxide ($BaPb_{1-x}Bi_xO_3$) system.** Protasov, E. A.; Zaitsev-Zotov, S. V.; Venevtsev, Yu. N.; Bogatko, V. V. (Mosk. Inzh.-Fiz. Inst., Moscow, USSR). *Fiz. Tverd. Tela (Leningrad)* 1978, 20(11), 3503-5 (Russ). The superconducting transition temp. and crit. magnetic fields of polycryst $BaPb_{1-x}Bi_xO_3$ were detd. as functions of compn. ($x = 0.2$–0.5). The magnetic field dependence of the resistivity of $BaPb_{0.7}Bi_{0.3}O_3$ showed hysteresis at ≤ 5–10 kOe and neg. magnetoresistance at higher fields.

conceptual sense is thus Superconductors. But those documents that deal with devices are indexed under several other related headings. Superconductor devices is the major heading of this type, while certain types of devices that receive substantial numbers of index citations are provided their own headings (*e.g.*, Cryotrons, Magnets, Electric cables; note under the latter two headings the alerting phrase "superconducting").

Also illustrated in Fig. 3 are several examples of entries for superconductive substances. To facilitate organization of the index material for effective searching, the *CA Subject Index* is divided into two parts:

1. The *General Subject Index*—for those index entries that are concerned with scientific concepts, properties, processes, types of apparatus, and classes and poorly defined substances; and
2. the *Chemical Substance Index*—for those entries that are devoted to specific substances (elements, compounds, alloys).

An example from the Subject Index is shown in Fig. 4. Brief phrases appearing under the heading state the contexts of the studies, and are followed by the CA abstract numbers. The code letter R identifies a review paper; similarly, books are coded with a B and patents with a P.

Indexing policies that relate to the *Subject Index* are documented in an adjunct publication, the *Index Guide,* in the form of extensive general introductory descriptive material and by scope notes and cross-references. Figure 5 presents the note and cross-references that pertain to the heading "Superconductors."

In addition to the *Keyword* and *Subject Indexes*, there is a family of more specialized indexes:

(a) *Author*—an alphabetical index to the authors of documents and to the inventors and patent assignees in the patent literature;

(b) *Formula*—an alphanumeric index to molecular formulas;

Subject Index

Fig. 5. Index Guide

(c) *Ring Systems*—an alphanumeric index to the component rings of cyclic compounds, based on the numbers, sizes, and elemental compositions of the rings. (This and the Formula Index will take on increasing significance with the burgeoning interest in potential organic superconductors.);

(d) *Patent*—a numerical index of patent abstracts, arranged by issuing nation;

(e) *Patent Concordance*—a numerical index that interlinks those patents that have been applied for or granted in various nations for a particular invention; cross-references relate to the CA abstract numbers for those citations that had first appeared in CA.

These several indexes allow access to the content of CA by various complementary means, providing searchers with considerable flexibility in carrying out literature searches. All of these indexes are compiled for the semiannual volumes of CA, and are then incorporated into the five-year, ten-volume *Collective Indexes.* These indexes provide the means for retrospective searching, as distinct from the current-awareness purpose of the *Keyword Index.*

Specialized services.—The heart of the CAS services remains *Chemical Abstracts* itself, the printed *Abstract Issues* with their attendant indexes. But in addition, there is an array of special services made available in various formats for specialized purposes.

Among the services available in print, *Chemical Titles* is intended to alert the reader by document title to papers in some 700 of the most important journals of chemistry. Bibliographic data and author and keyword indexes are included. *Chemical Titles* is also available on magnetic tape; the file content is the same as that of the printed version.

The *Section Groupings* provide the total content of the *CA Abstract Issues* in five packages: the biochemical, organic, macromolecular, applied and engineering, and physical and analytical groupings. Complete bibliographic information is included, as well as the *Keyword Index* entries for the entire issue from which a particular grouping is extracted.

"Energy Reviews and Books" is a representative of a relatively new family of services, *CA Selects.* This is a printed current-awareness service, with the bibliographic information and abstracts for those review papers and book titles that appear throughout CA dealing with the general topic of energy. This publication, along with more than 100 others in specialized subject areas, was introduced to provide an inexpensive current-awareness service for those who either desire a conveniently scanned, brief abstract journal or are unable to rely on computerized information retrieval. The information provided for these various topics is extracted from the CAS data base by computerized retrieval based on customized search profiles.

The *Abstract Issues* and their indexes are also available on microform, both as microfilm and microfiche.

CA Search is a computer-readable tape service, issued biweekly, that the user can access through certain online servies. It contains a compilation of the bibliographic information, Section and Subsection numbers, keywords, Registry Numbers for specific substances, and the index entries that are subsequently compiled for the semiannual *Subject* and *Formula Indexes*. Abstracts are not included, but are associated with the file content through the abstract numbers that appear in the printed *Abstracts Issues*. *CA Search* is a merger of what had been provided by the previously available tape files *CA Condensates* (CACon) and *CA Subject Index Alert* (CASIA) (3).

Summary

A wide array of secondary information sources is available to those scientists and engineers who are concerned with superconductors. These sources range from the traditional printed services—abstracts, indexes, and various types of current-awareness publications, through the information and data centers which can provide batch-mode retrievals, to the expanding online services that provide access to a group of information files. These various types of services cover the gamut in content from the highly specialized (those data centers, for example, that deal exclusively with superconductors) to those that encompass nearly all of the scientific literature. The workers in the fields of superconductivity and of superconducting materials and devices thus have many valuable sources to rely on for their information needs.

Manuscript received March 12, 1980. This was Paper 405 presented at the Boston, Massachusetts, Meeting of the Society, May 6-11, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.

Chlorine-Caustic Soda

Production and capacity—After an 11% increase in chlorine production in 1979 to 12 million tons per year, U.S. production increased only 4% in 1980 to 12.5 million tons (1). Production capacity increased 1.3% from 14.4 million tons per year to 14.6 million tons (2).

An estimate of the capacity of various U.S. producers is shown in Table I (3).

Allied Chemical sold their last chlor-alkali plant to Linden Chemicals and Plastics (4).

PPG Industries completed a $150 million expansion of its chlorine and caustic production at Lake Charles, Louisiana. The 350 ton per day increase in chlorine capacity raises total capacity of the plant to 3000 tons per day, while the caustic increase of 400 tons per day raises its capacity to 3400 tons per day (5-7).

FMC announced that contrary to rumors, it has no plans to shut down its chlor-alkali facility at Charleston, West Virginia (8).

Hooker Chemical brought on line at Niagara Falls an energy from waste plant that produces 20% of the power required for its adjacent chlor-alkali plant (9).

Chloro de Tehuantepec began production of chlorine and caustic in a plant at Pajaritos, Mexico. This plant's capacity of 236,000 metric tons per year of chlorine more than doubled the existing Mexican capacity of 176,000 tons per year (10).

Canadian Industries, Limited completed a $100 million expansion of its chlor-alkali facility at Becanour, Quebec, which doubled the capacity to 255,000 metric tons per year of chlorine. The new plant

* Electrochemical Society Active Member.

[1] This report is sponsored by the Industrial Electrolytic Division of The Electrochemical Society. It represents a summary of the published information on production, plant capacities, consumption, markets and trends, prices, raw materials, new developments, health and environmental aspects in the electrolytic and related industries.

The material presented herein has been obtained from many sources, as noted in the list of references, and does not necessarily represent the opinions of the authors.

The Industrial Electrolytic Division is grateful for the support received from the Vittorio de Nora-Diamond Shamrock Fund in assisting with the publication costs of this report.

uses ICI-Solvay diaphragm cell technology. The DMT-43 cells are said to be more compact than the older cells because stabilized diaphragms allow for closer spacing of electrodes (11).

Diamond Shamrock announced it will increase its dry caustic soda capacity by 20% at Deer Park, Texas, by the fourth quarter of 1980 (12, 13).

Markets and prices.—The chlorine and caustic markets remained unbalanced during 1980 because of lack of demand for chlorine. As a result, caustic soda supplies were in short supply (14). In April, Gulf Coast prices for chlorine were $145 per ton and for caustic soda, $160-170 per ton (15). After that, however, steady price increases produced a December price of caustic soda of $220-260 per ton.

Early in the year U.S. chlorine demand was predicted to grow 3.1% per year through 1984 (16, 18). Later in the year, however, this growth rate was reduced to 2% per year, reaching 13.5 million tons per year by 1984 (21). World capacity increase should be somewhat greater at 4% per year reaching 45 million tons per year by January, 1984 (17).

Some of chlorine's markets, such as fluorocarbons and trichloroethylene, have been hurt by government regulations. Also, new technology, such as Arco's MDI route and du Pont's direct cyanation process for nylon production, may hurt future chlor-alkali markets. End uses of chlorine are as follows: plastics, 20%; pulp and paper, 13%; chlorinated methanes, 13%; inorganic chemicals, 11%; propylene oxide, 10%; other organic chemicals, 21%; water treatment, 6%; miscellaneous, 6% (16).

Early in the year, caustic soda demand in the U.S. was expected to grow at a somewhat higher rate than that for chlorine at 4.4% per year (20). Later in the year, however, the projected increase was reduced to 2.7% per year, reaching 14.5 million tons per year in 1984 (21). End uses of caustic soda are estimated to be: organic chemicals, 41%; pulp and paper, 17%; inorganic chemicals, 11%; aluminum processing, 6%; textiles, 6%; petroleum, 4%; soaps and detergents, 4%; miscellaneous, 11% (20, 21). Due to environmental pressures, such as neutralization of waste acids, caustic soda use will grow faster than that of chlorine, and thus it will remain in short supply.

Membrane cells.—Activity in the commercialization of chlor-alkali cell plants based on membrane cell technology remained at a high level in 1980.

Du Pont started up its first commercial facility to produce Nafion perfluorinated ion exchange membranes at its Fayetteville, North Carolina, works (22).

Olin Corporation and du Pont announced a cooperative program where Olin will evaluate high performance Nafion membranes from du Pont at its Charleston, Tennessee, facility (23, 24).

Diamond-Shamrock announced plans to spend $50 million to increase chlor-alkali capacity by 40% at its Laport, Texas, plant. The increase, estimated at between 600-1000 tons per day of chlorine, will use Diamond-Shamrock's proprietary membrane-cell technology (25-27).

ROT Quimica of Monterrey announced plans to install Diamond-Shamrock membrane cells to produce 14 tons per day of potassium hydroxide and 10 tons per day of chlorine. The caustic potash will be used to produce potassium carbonate for the Monterrey glass industry (28, 29).

Paik Kwang Pharmaceutical Company, Limited (South Korea) will build a 30 m tons per day chlorine-caustic soda plant using Diamond-Shamrock membrane cell technology by 1981 (42). Another chlor-alkali plant using Diamond-Shamrock membrane cell technology will be built by Taiwan Pulp Company. The 8000 m tons per year caustic soda plant is due on-stream in 1982 (43).

Akzo Zout Chemie has awarded a contract to Comprimo (Netherlands) to construct its 250,000 metric tons per year chlorine plant at Bottek. The plant using Asahi Chemical's membrane cell technology is scheduled for start-up in 1982 (30-33).

Asahi Chemical is planning to replace its mercury cells at Nobeoka with membrane cells by 1982. It is working to extend membrane life beyond the current 1-2 years (34). They also announced a licensing agreement with Tasman Pulp and Paper, Limited of Auckland, New Zealand. This company is the sixth licensee of their permionic membrane process. This plant will replace existing capacity of 5000 metric tons per year of chlorine by mid-1982 (35).

Kanagafuchi Chemical has developed an ion-exchange membrane process using monopolar cells which reportedly use less titanium than diaphragm cells. They will convert an existing 120,000 tons per year (Cl_2) diaphragm cell plant to the new process by the end of 1981. In addition, another two 60,000 metric tons per year mercury cell plants will be converted to membrane cells by 1985 (34).

Toyo Soda will test a new ion exchange membrane chlor-alkali process in a 5000 metric tons per year pilot plant. If successful, they will convert 132,000 metric tons per year mercury cell capacity to the new technology. They have already converted 59% of their capacity to diaphragm cells (36).

Tofte Cellulosfabrikk (Norway) will use Hooker MX membrane cells in a 14,000 metric tons per year chlor-alkali plant to be completed in 1981 (37).

Asahi Glass will build a 150,000-200,000 metric tons per year chlor-alkali plant at Kashima, Japan, by 1984 using its own membrane cell technology (38). They have also developed a membrane cell process to produce caustic potash and will build a plant using the technology at Amagasaki (34). Asahi Glass licensed its membrane cell technology to three West German firms, Uhde, Hoechst, and Bayer. Uhde plans to first evaluate the membranes in pilot cells and later to evaluate them in full scale cells (39). Asahi Glass announced a new chlor-alkali membrane cell process using a new Flemion membrane. The AZEC process requires 1950-2140 kW-hr/mT NaOH, which is 28-35% less than for mercury cells and 14.4-22% less than required for existing ion exchange membrane processes (41).

Ionics, Incorporated sold a 5 tons per day Chloromat membrane cell system to Trinidad to produce chlorine and caustic soda. This is the first chlor-alkali production facility on the island (40).

Health and environment.—The Supreme Court allowed OSHA to impose the NIOSH criterion limiting worker chlorine exposure to a 0.5 ppm ceiling limit. Chlorine producers must now install equipment necessary to meet this standard (44).

The Consumer Product Safety Commission ordered manufacturers and importers of certain types of consumer products to supply them with information regarding the use of asbestos. In particular, data concerning the purpose of asbestos in the products, the end use patterns of the products, testing of the products for asbestos fiber emissions, and possible substitutes for asbestos were requested. This information, which is due by February 20, 1981, is to be used to determine if any regulatory action is required to protect consumers from any risk of injury from asbestos in these products (45).

Unreleased studies by the U.S. Council on Environmental Quality found a link between heavily chlorinated drinking water and malignant tumors. These studies were made in North Carolina, Illinois, Wisconsin, and Louisiana (46). Because chlorine has

been found to be capable of producing over 200 toxic chemicals in drinking water, ozone and filtration are proposed as alternatives to achieve water purification. The possibility of fermentation of trihalomethanes and trichloroethylene and other such chlorinated compounds to more toxic compounds when soft drinks made from chlorinated water are left on the shelves too long was discussed. Ozone dissolved in water is claimed to destroy bacteria and viruses that can cause deterioration of bottled water products (47).

A continuous wastewater treatment process for removing mercury down to 0.01 ppm was developed by Energie and Industrias Argonesas and Quimica Industrial (Spain). The process utilizes an organic solvent to extract mercury chloride and permits the recovery of 99.9% (48).

Other Alkali or Chlorine Compounds

Caustic potash.—Domestic production of potash for the 1980 crop year was 2.2 million metric tons, or about the same as in 1979. Sales, however, declined 6% (49).

Prices rose steadily during the year to $36-40/100 lb for flake caustic potash by year's end (50).

Diamond-Shamrock and Oriental Chemical Industry set up a 50-50 joint venture to produce 10,000 m tons per year caustic potash and 10,000 m tons per year potassium carbonate in South Korea. The plant, scheduled for operation in 1981, will utilize Diamond-Shamrock's monopolar chlor-alkali membrane cells for the caustic potash production and also their technology for potassium carbonate (51-54).

Soda ash.—U.S. producers of naturally occurring soda ash continued to have an edge on world markets because of abundant supplies and ready access to shipping facilities. U.S. consumption of all types of soda ash in 1980 declined to 6,976,000 tons (67). U.S. consumption has grown only 2% per year, but exports have grown 12.5% per year since 1975. U.S. natural ash capacity is currently 8.9 million tons per year with actual production in 1980 of about 7.5 million tons per year (55). Total U.S. production of soda ash, including Solvay process material, was estimated at 8.2 million tons in 1980, or about the same as in 1979 (56, 67). The distribution of U.S. soda ash production by producer is shown in Table II (57).

Exports of soda ash increased to a record 1.2 million tons per year (67).

End use distribution of soda ash was 55% for glass production, 25% in chemical production, 5% in pulp and paper, 5% in soaps and detergents, and 10% in other uses (58).

Exports of soda ash were estimated to be 1 million tons per year (58). This has caused producers in other countries to cut back production. Imperial Chemical Industries said it will cut its work force by 18% at 3 soda ash plants within 2 years. This will eliminate 500 jobs and allow them to compete more favorably with producers in the U.S. who have a 10% advantage in production costs (59-61).

Kerr-McGee began supplying soda ash to East Coast markets in September from its California production facilities. The initial 25,000 ton shipment was made by ship (62).

FMC announced the development of a solution mining process for soda ash in Green River Basin, Wyoming. Commercialization of this technique will increase their capacity by 1 million tons per year (63).

Texasgulf announced plans for a $63 million expansion of its Granger, Wyoming, plant to increase capacity to 2 million tons of soda ash per year by 1987 (64).

Multi Mineral Corporation said they will construct a plant at Piceance Creek Basin, Colorado, to produce 3.7 million tons per year of soda ash, and 400,000 tons per year of alumina, if pilot plant tests are successful. Plant completion is scheduled by 1986 (65).

Kerr-McGee is spending $200 million to double the capacity of its Trona, California, soda ash plant. Future expansions in southern and central California may be severely restricted, however, by new Interior Department air pollution guidelines. These guidelines have redesignated 2 million acres of land near the Death Valley Monument as a Class 1 air pollution control area, and may add an additional 4 million acres (66).

Sodium chlorate.—Sodium chlorate prices rose throughout the year, reaching $405 per ton (68, 75). Potassium chlorate prices were also increased in November by 5 cents per pound to a range of 38-41.75 cents per pound (69, 70).

U.S. sodium chlorate capacity decreased by 40,000 tons per year when IMC sold its sodium chlorate plant at Orrington, Maine, to PPG Industries which plans to move it to Beauharnois, Quebec (Canada) (71-74). U.S. capacity now stands at 392,000 tons per year. Production, however, remains at about 250,000 tons per year. Total demand has grown less than 4% per year since 1980. The distribution of the U.S. production capacity is shown in Table III (75, 76).

About 80% of sodium chlorate production goes into paper bleaching. This has been a growing market over the past several years as environmental regulations have favored the use of sodium chlorate over other chemicals used for bleaching (77).

The only new sodium chlorate capacity announced in 1980 for the U.S. was for a $25 million expansion by Pennwalt at its Tacoma, Washington, facility (78). The engineering, procurement, and construction contract for the plant, to be completed in 1982, was awarded to Catalytic (79).

Activity in sodium chlorate production was much greater in Canada, with several sizeable new facilities being announced. Canadian Occidental Petroleum, Limited will build an $8.4 million, 8300 tons per year sodium chlorate solution plant at Nanaimo, British Columbia. Chemetics International has the design and construction contract (80). Another plant to be built in British Columbia was announced by Erco Industries. It will expand its facilities in North Vancouver, British Columbia, by 12,000 tons per year to a total of 70,000 tons per year by 1982. Erco also plans a 20,000 ton per year expansion at Thunder Bay (81). Also in British Columbia, B. C. Chemicals will increase sodium chlorate capacity by 6000 tons per year to 31,000 metric tons per year at Prince George. The $8.2 million plant using

Krebs technology should be completed by the second quarter of 1982 (82, 83).

PPG Industries, Stanchem Division, is moving IMC's Orrington, Maine, plant to Beauharnois, Quebec. The 40,000 tons per year expansion will raise total capacity at this site to 70,000 tons per year (84). The $20 million expansion will be completed in 1981 (85).

Metals

The Federal Emergency Management Agency finally released its proposed modernization plans for the $18.5 billion national defense stockpile of minerals and metals (86). After more than two years of work interrupted by administrative reorganization and by wild swings in commodity prices, the Agency is beginning its program cautiously, with only $152 MM in purchases in the fiscal year beginning October 1, 1980. Purchase of significantly more aluminum, lead, platinum, tin, and titanium sponge is planned due to concerns about availability of supplies or shortages in the U.S. defense requirements. The Agency has also assured mineral producers that any divestitures would be gradual to avoid upset of market conditions.

The U.S. is not alone in the renewed concern about building stockpiles of critical minerals. Of nine Common Market countries, however, only France and West Germany have taken definite steps to ensure emergency supplies, France actually beginning in 1975.

U.S. strategic and critical stockpile goals for those metals reviewed in this report of the electrolytic industries are shown as Table IV.

Aluminum.—Primary aluminum production in the U.S. during 1980 was estimated at 10.2 billion pounds (94). Aluminum shipments in 1980 were estimated at 13.7 billion pounds, but were expected to rise to 14.1-15.2 billion pounds in 1981 (87, 88). World aluminum consumption was predicted to decrease by 5% in 1980, but demand was expected to rise slightly more in 1981, and be up by 10% in 1982 (89). World primary aluminum production rose 3.1% in 1979 to 11,785 million metric tons (95). While U.S. domestic aluminum sales were down in 1980, particularly in the first half, world demand was brisk (91).

Shipments of recycled aluminum ingot dropped to the lowest level in four years at 1,651,395 pounds (96). Alcoa, however, increased its collection of metal cans for recycling by 118%, to 2.5 billion cans or 109 million pounds (97).

Growth in aluminum consumption during the 1980's will be held back by tight supplies, high energy costs, and inadequate plant capacity (90, 93). Producers will just about be able to keep up with the 5% rise in demand in an increasingly tight seller's market. This tightness will allow producers to pass along production cost increases and significantly increase company profits (92, 98, 100). Aluminum is predicted to be the only nonferrous base metal to be used in larger quantities in North American automobiles in the 1980's, but the amount to be used will be one-half of what was previously predicted (101).

A review of the economic aspects of the bauxite/aluminum industry cited an increasing decentralization trend. More capacity is being installed in nontraditional areas closer to bauxite sources (99).

Distribution of annual aluminum consumption to various markets in 1980 was as follows: transportation, 1.36 million tons; container/packaging, 1.695 million tons; building/construction, 1.34 million tons (103).

Noncommunist world primary aluminum production is shown in Table V (102).

Mitsui and Company's two joint ventures may make it the world's leading aluminum trader. It receives 25% of the 180,000 metric tons per year produced at Mt. Holly, South Carolina, and will receive 20% of the 238,000 metric tons per year to be produced in New South Wales, Australia, beginning in 1984.

Primary aluminum ingot was priced at 66¢ per lb at the beginning of 1980, but rose steadily throughout the year reaching 76¢ per lb in early October (105, 106).

The primary aluminum industry began 1980 with about 165,000 tons of annual capacity shut down in the Pacific Northwest (PNW) because of a power shortage. An additional 48,000 tons was shut down in March. Advance power and interruptible power were made available temporarily in April and May, and 190,000 tons of capacity was reactivated. However, curtailment of interruptible power in July and advance power at the end of September resulted in a shutdown of nearly 100,000 tons of capacity in the PNW in October. In other parts of the country, annual primary aluminum capacity in operation was reduced by a net total of over 200,000 tons during the year because of market conditions (94). By December some production was resumed in the Pacific Northwest. Alcoa restarted 78,000 short tons per year capacity idled since July 26 (107). Alcoa also announced it was bringing its 325,000 tons per year Rockdale, Texas, smelter to full capacity (108).

Apex International Alloys, Incorporated shut down its Mt. Holly, North Carolina, secondary aluminum smelter because of uneconomical costs to install EPA required pollution controls (109). A primary aluminum production plant was started up in Mt. Holly, North Carolina, by Alumax. This plant is the first grass-roots facility built in the U.S. since 1973. The $350-million plant will produce 197,000 tons per year. The company is owned 50% by Amax, 45% by Mitsui, and 5% by Nippon Steel (110, 111).

Coastal and Offshore Plant Systems, Incorporated announced plans to build a $400 million, 200,000 tons per year aluminum smelter near Tabor City, North Carolina (112). It received a state permit in November (114).

Table IV. U.S. Strategic and critical stockpile goals

Source: S. Spector of Oppenheimer & Co.

Alcoa announced plans to increase its U.S. production by 450,000 tons per year by 1985 to meet expected market requirements in aircraft and automobiles (113). Alcoa will add a 55,000 tons per year potline to its Badin, North Carolina, smelter by 1983 (115, 116).

Martin Marietta will expand its Goldendale, Washington, aluminum reduction plant by 65,000 tons per year at a cost of $125 million (117, 118).

A $100-million aluminum smelting plant was commissioned at Point Henry, Victoria (Australia) by Alcoa of Australia, Limited. The 65,000 metric tons per year expansion raises capacity to 165,000 metric tons per year making it Australia's largest (119).

Alcan Aluminum, Limited and Conalum SA will build a 45,000 tons per year primary aluminum smelter in Tampico, Mexico (120).

Southwire and National Steel plan to build a 180,000 metric tons per year primary aluminum smelter in Trinidad and Tobago using Jamaican bauxite (121).

Pechiney Ugine Kuhlmann plans to construct a 200,000-300,000 tons per year aluminum plant at Becancour, Quebec (Canada) for $800 million (122).

Alcoa Alumino SA (Brazil) is building a 500,000 metric tons per year bauxite-100,000 metric tons per year aluminum smelter complex near San Luis, Brazil; at a cost of $900 million (123).

Alcoa's new process for producing aluminum by electrolysis of aluminum chloride has proven successful, but the plant producing the aluminum chloride has had trouble. The $25 million, 15,000 tons per year smelter in Palestine, Texas, has been cut back to 7500 tons per year. The process uses 30% less energy and produces less pollution than the conventional process (124).

An air-aluminum power cell, fueled by water, has been developed at the Lawrence Livermore Laboratory. It is claimed to increase the range of electric cars and could be commercialized by 1990 (125).

Environmental Research and Technology Incorporated has developed a mathematical model to forecast dispersion patterns of air emissions from aluminum smelters under sponsorship of the Aluminum Association (126, 127).

The U.S. Justice Department has dropped an antitrust investigation into the U.S. aluminum industry. The probe focused on whether or not a shared monopoly existed in the industry, and if price signaling had taken place. Firms involved in the investigation included Kaiser Aluminum & Chemical Corporation, Aluminum Company of America, Reynolds Metals Company, Alcan Aluminum Limited, Anaconda Company, and Phelps Dodge Corporation (128).

Beryllium.—In 1980 the domestic production of beryllium minerals increased significantly relative to 1979. The United States, a major producer of beryllium ore in the world, almost exclusively mines the ore, bertrandite, and is in fact the only nation commercially exploiting deposits of this ore (129).

Approximately 1400 short tons of beryl, the second major beryllium ore, were imported into the United States in 1980 (130). It is interesting that from 1976 until 1979 Brazil had supplied 46% of the imported ore, with India and Argentina providing a further 25%. However, in 1980, the Peoples Republic of China became a major source of this ore.

Complete data for the consumption of beryllium is not yet available but total shipments of beryllium metal, beryllium alloys, and beryllium oxide in 1980 showed a distinct improvement over 1979. Primary uses of this metal are: (*i*) in the aerospace industry and in nuclear reactors (38%); (*ii*) as an alloy in electrical equipment (37%); and (*iii*) in electronic components (16%) (131).

As of November 1980, the government stockpile inventories were as follows:

Beryl ore (11% BeO)	720 short tons
Beryllium/copper master alloy	295 short tons
Beryllium metal	229 short tons

Brush Wellman, Incorporated (Cleveland, Ohio), has announced plans to expand its facilities at Delta, Utah, at an estimated cost of $6 MM. Completion late in 1981 will increase the plant's capacity to extract beryllium approximately 25%. A further $5 MM is also to be invested in expansions to the mines in Juab and Millard Counties in Utah (132, 133).

In 1980 Brush Wellman, Incorporated opened a new pilot plant in Tucson, Arizona, for the fabrication and metallization of beryllium oxide parts (130).

A consortium headed by J. Abeles has acquired Consolidated Beryllium (U.K.) from Cabot (U.S.) Consolidated Beryllium is the only manufacturer of beryllium ceramics in Europe (134).

It has been shown that beryllium is an excellent substrate material for optical mirrors, according to Kawecki Berylco Industries (135). The metal resists aging, recrystallization, and phase transformation up to temperatures as high as 800°C, providing long-term dimensional stability.

A new technique to remove impurities from the surface of beryllium-containing materials has been developed by Vacuumschmelve GMBH (West Germany) (136). The company has applied the process to the production of strip-mill Beryvac (copper/beryllium and nickel/beryllium alloys) to give good surface properties, which facilitates subsequent processing.

The new limits for exposure to beryllium proposed by OSHA in 1975 have yet to be imposed upon the industry and it appears unlikely to happen in the near future (130).

Chromium.—The slow U.S. economy took its toll on chromium demand in 1980, when it reached its lowest level since 1976. The reduced demand stemmed primarily from decreased stainless steel production. Consumption of chromite was 1,040,000 tons or 14% less than in 1979. Imports of chromite were about 990,000 tons, and the balance of that consumed came from industry stockpiles (137).

Chromium alloys, on the other hand, were imported in record amounts, reaching an expected 350,000 tons. South Africa accounted for 78% of these imports. Supplies of alloys were adequate and prices rose only slightly. At year end, domestic charge chrome containing 66-70% chromium sold for 48.5¢ per lb of contained chromium and low carbon ferrochrome sold for $1 per lb on the same basis (137). Union Carbide raised the price of electrolytic chromium metal by 9% in December (138). South African charge chrome containing 50-55% chromium was increased from 45-47¢ per lb of contained chromium to 50-51¢ per lb in December (143).

The U.S. Bureau of Mines estimates that 73,000 tons of chromium is lost in scrap every year. They are promoting a program to develop new chromium recovery methods and to determine domestic chromium supplies to avoid problems in supply if foreign sources are disrupted (139).

Zimbabwe's largest chromium mining and smelting group, Rhodesian Alloys (Pty), Limited, has gone public and is expanding its operations (140).

Toyo Soda Industries (Japan) announced an increase in chrome metal production capacity due to rising demand from high-grade alloy makers. It will increase the capacity of its Vamagata plant by 50 mtpm to 350 mtpm and add another 50 mtpm at a later date (141).

Outokumpu Oy (Finland) and Eikem Spigewerket (Norway) have signed an agreement with Turkish Etibank Company to provide equipment and engineer-

ing services to build a ferrochromium plant in central Turkey. The 100,000 metric ton addition will expand existing capacity (142).

Copper.—Production, U.S. and free world.—The strikes in the United States copper industry, which began in July and carried into late November before all companies had settled, unquestionably had an impact upon the world copper market. Obviously costly to the U.S. mining companies, the strikes did, however, offset a potentially large surplus of copper (~200,000 metric tons) and, in fact, the year end saw a deficit. It is estimated (144) that the loss of production, attributed to the 1980 strikes, amounted to approximately 350,000 metric tons of copper.

The unions struck over demands for a new three-year contract similar to the settlement negotiated by the steel industry in April. This pact provided a cost-of-living escalator that was equivalent to 30-37% wage increases over three years and the copper workers union bargained for similar considerations (145, 146). The labor strike was the longest in the history of the U.S. copper industry and at its peak immobilized most operations of ten major companies that normally account for 85% of domestic mine production and ~90% of refinery production (147).

Surprisingly, the mine production of copper in the free world declined only marginally in 1980 (144) due to significant increases in production in Canada, Zaire, the Philippines, and Mexico, and to new capacity coming on-stream in Yugoslavia. Domestic mine production decreased approximately 270,000 metric tons in 1980 according to the U.S. Bureau of Mines (147).

It was announced that Noranda (Canada) may close the 275,000 tons per year copper smelter at Rouyn in Quebec due to governmental requirements to improve collection of solid waste and install a sulfur dioxide recovery system (148). Noranda Mines Limited also suspended development of a copper mining project at Andacollo, Chile (149), a deposit estimated at 230 MM tons of ore averaging 0.56% copper.

Anaconda Copper Company will permanently close the copper smelter at Anaconda (Montana) because the 78 year-old facility cannot comply with state and federal clean air standards (150-152). Studies showed that the plant could not be "retrofitted" to satisfy the environmental standards and yet be cost-competitive with large-scale modern smelters. Similar considerations led to the closing of a refinery at Great Falls, Montana (Anaconda Copper Company) (147).

Construction began in late June on a 15,000 short tons per day open-pit copper mine and concentrating mill near Hillsboro, Sierra County, New Mexico (155). The $98 MM development, expected to be on-stream early in 1982, is a project of the Copper Flat Partnership, comprising Quintana Minerals Corporation (Tucson, Arizona) and Phibro Mineral Enterprises, Incorporated (New York). It is anticipated that the facilities will yield 20,000 tons of copper per year when fully operational.

Noranda Mines Limited has announced its intent to develop a copper-zinc mine in Gold Stream Valley, British Columbia, Canada. Scheduled for late 1982 at an estimated cost of $62 MM, the mine will produce 75,000 tons per year of copper concentrates (156).

Asarco, Incorporated has also announced plans to permanently close the refinery at Tacoma, Washington, which has been idle for approximately two years (147). Louisiana Land and Exploration Company plans to replace its copper smelting plant with an electrolytic facility at White Pine, Michigan (153). The 60,000 tons per year facility will be completed in 1982.

Noranda Lakeshore Mines, Incorporated has resurrected the copper mine and metallurgical complex on the Papago Indian Reservation near Casa Grande, Arizona. Currently, the company is block-caving oxide ore at a rate of 4000 short tons per day, vat leaching 2000 short tons per day for an electrowinning plant, and stockpiling the remainder of the ore (154). Although presently working at reduced capacity, it is expected that full capacity (~6000 short tons per day) would be achieved by the end of 1980.

Consumption, U.S. and free world.—Consumption of refined copper in the United States declined 13% to an estimated total of 1.87 MM tons (147), but imports nearly tripled to a total of 0.37 MM tons for 1980.

New capacity, new facilities.—Kennecott Corporation will invest an estimated $270 MM to modernize its facilities in Chino, New Mexico (158-160), which will increase the output to 110,000 tons per year. Under a preliminary agreement, Mitsubishi Corporation (Japan) will share the costs and receive part of the copper produced. The project also includes construction of a new concentrator and modifications to the smelting plant. The facilities are scheduled to be operational in 1984.

Copper Range Company (Denver, Colorado) has awarded a contract for $78,000 to Fluor Mining and Metals for the construction of an electrolytic refinery in White Pine, Michigan (161). Texasgulf, Incorporated (Stamford, Connecticut) announced plans to further expand its copper smelting facility in Kidd Creek, Ontario, to approximately 112,000 metric tons per year by 1985 (162, 163). The expansion also includes new oxygen and sulfuric acid plants and will cost an estimated $250,000.

Kennecott Corporation has started a new copper plant near Hayden, Arizona, based upon solvent extraction (SX) technology (164). The plant is expected to produce a more concentrated, high-purity copper electrolyte for the electrowinning process. Improvements in cathode quality are also anticipated. Production at the SX plant, designed by Jacobs Engineering Group for a maximum capacity of 108 short tons per

day, is presently approximately 90 short tons per day. The process was developed at Kennecott's Research Center in Salt Lake City and involved selection of a proprietary reagent P-5100 produced by Acorga Limited. The final extractant is the P-5100 diluted by a high purity kerosene (164).

Cities Service Company began construction of a second solvent extraction/electrowinning plant in mid-July, the site being at the new Pinto Valley operation west of Miami, Arizona. The facility is expected to produce 99.99% copper cathode from leach solutions recovered from waste dumps at Pinto Valley, waste dumps that have accumulated for several years (165). The company's first SX-EW plant was completed in 1976 and recovers copper from leach solutions circulated in underground workings of the old Miami mine, closed in the 1950's.

Future outlook for the copper industry.—According to T. D. Barrows (Kennecott Corporation), the copper industry may be in its strongest position in several years (166) due to the present shortages in the world supplies. Although a growth rate of only 2.8% per year has been realized through the last decade, it is believed that consumption will again reach the 4-5% per year growth rate by the mid-1980's (167).

A less rapid growth is predicted by R. G. Adams (Chase Econometrics, Bala Cynwyd), but with overall optimism regarding the copper industry. Although the market may remain "tight," Mr. Adams projects that the demand for refined copper in the free world will increase to 10.4 MM metric tons per year in 1990 (168).

The U.S. Bureau of Mines believes the copper industry to be in a competitive position for the future decades (169). Production in the United States should increase to 3 MM metric tons per year by the year 2000. The financial standing of the industry will be strengthened by diversification and merger, by joint venture to defray the risks of mining projects and by an increased reliance upon the financial community. G. B. Munroe (Phelps Dodge) was similarly optimistic concerning the U.S. copper industry through the 1980's (170).

Activity in various parts of the world would support the overall optimism, with expansions, new refinery mining developments in Albania (171), Poland (172), Yugoslavia (173), China (174), Bulgaria (175), Iran (176), Peru (177), Pakistan (178), and Chile (179).

New processes, new markets.—A Montana state research agency is seeking Department of Energy (and other) funding for a pilot copper smelter to evaluate a dead roast-segregation process developed by Amax Base Metals Research and Development (New Jersey). It is claimed that the new system reduces energy consumption 33% and is significantly less expensive to construct (180).

Scientists are developing a new extraction method for copper, called electro-slurry of finely ground ore, in a cooperative program between the University of Utah, Envirotech Research Center (Salt Lake City) and the R & D Laboratories of Martin Marietta Company (Baltimore). The technique avoids emission of sulfur dioxide and is expected to consume 25% less energy (181, 182). The University of Utah has developed a method of grinding the ore to particles of 2-3 microns and Envirotech developed the high current density electrolyzer.

Inco (Canada) is to undertake a feasibility study for a commercial-scale operation to reduce sulfur dioxide emissions from its smelting facility in Copper Cliff (183, 184). The new technology involves removal of the sulfur-rich pyrrhotite from the concentration prior to smelting.

Amax Incorporated is experimenting with a smelter process to allow production of copper-nickel at the Minnamax facility on a smaller scale than originally estimated (185). The process removes sulfur by roasting to leave a low-sulfur copper-nickel matte.

A process that converts existing copper reverbatory furnaces into oxygen flash smelters has been developed (186). While it is recognized that "oxygen sprinkle smelting" is costly to implement, it is claimed to greatly enhance plant metallurgy and economy and is an effective and cheaper way of modernizing outmoded plants.

Copper-based alloys with heat-triggered "memory" will be available on the European market in 1981. It is claimed that the memory range is from −100°C to +100°C depending upon the particular alloy (187). NV Bekaert and Metallurgie Hoboken-Overspelt (both Belgian companies) are developing the materials under the name "proteus." In the U.K. Delta Metal has formed Delta Memory Metal to manufacture approximately 600 new alloy products.

The use of copper-nickel alloys for antifouling of ships has been claimed to offer several advantages (188, 189). The cost of marine biofouling is significant and it has been shown that appreciable fuel savings can be realized by using the alloys in construction of the ships.

A new series of fine-grained, precipitation hardenable copper alloys shows an excellent combination of high strength, ductility, and good resistance to atmospheric and tap-water corrosion (190).

A. McCarthy, a physicist with General Dynamics Incorporated has developed an inexpensive method to produce Copper-65, a metal that could substitute for gold in electronics and other applications (191). The copper isotope is described as malleable, electrically conductive and more resistant to oxidation and corrosion.

Lithium.—Consumption of lithium in the U.S. during 1980 remained at about 3200 short tons. Exports of lithium products were about the same in 1980 at 2400 short tons of contained lithium (192, 193).

The U.S. continued to be the leading producer of lithium concentrates and compounds. The largest use, consuming one-third of the U.S. production, is in aluminum potlines where it is used to improve aluminum metal production. Other major applications are in glass, ceramic, and lubrication industries (192).

Year-end prices of lithium compounds were up 12% (192).

The lifting of economic sanctions against Zimbabwe has made some Li ores available which will be imported and distributed by Lithium Corporation of America (194).

Foote Mineral Company and Society Chilena de Litio Ltda (Chile) will jointly invest $26 million by 1984 to produce 12 million pounds per year of lithium chemicals (195).

The U.S. Bureau of Mines continued bench-scale experiments to develop methods of recovering lithium from clays (192).

Further information on the role of lithium in the treatment of psychiatric disorders was discovered at the National Institute of Mental Health. Lithium helps block the shift from depression to manic phase by interfering with receptors for the neurotransmitter (196).

Magnesium.—According to the estimates of the International Magnesium Association, the worldwide production of magnesium metal in 1980 was approximately 240,000 metric tons, representing 91% utilization of the industry capacity. This is also the highest recorded production of magnesium since 1945 (197, 198).

In the United States, the production of magnesium remained strong throughout the year, although a slight decline was observed in the fourth quarter (199). According to data published by the Bureau of Mines (199), 51,000 metric tons of magnesium and magnesium alloys were exported in 1980. Imports of the metal, in all forms, totalled only 3300 metric tons.

The price of magnesium increased during 1980 to $1.25 per lb of primary metal and $1.21 per lb for the die-casting alloy (199).

Strong growth was observed in both the sales and production of magnesium die-castings in the U.S. in 1980. The increase, estimated to be 21% (197), was achieved without substantial contributions from the U.S. auto industry. Nevertheless, sustained growth is anticipated because of the demand for light-weight, fuel-efficient cars. In this regard, the price ratio between primary magnesium and primary aluminum, long considered to be important, is beginning to approach the 1.5:1 equal-volume price ratio.

Further growth in the total consumption of magnesium is attributed to its increased use in ferrous desulfurization products. Again, the slowdown experienced in the U.S. steel industry in 1980 has not delayed the installation of desulfurization stations in the steel mills (197).

It was announced that Amax will acquire the magnesium plant at Rowley, Utah, offered for sale by N. L. Industries. The purchase price was stated to be $60 MM. Amax has indicated early expansions in the facility to meet the anticipated demands for magnesium, particularly by the U.S. auto industry (197, 209-212).

In South America two Brazilian plants are planned to come on-stream by the mid-1980s. The total production capability will be approximately 30,000 metric tons per year, sufficient to provide the majority of the magnesium required by Brazilian aluminum producers and steel makers and the Brazilian auto industry (197).

Norsk Hydro with an annual production of 50,000 metric tons of primary magnesium per year and the largest exporter of the metal in the world, has announced improvements and expansions to their facilities based on in-house R&D programs (205). The company is completing improvements in (*i*) the production of water-free magnesium chloride, (*ii*) new electrolysis technology, and (*iii*) new molding techniques.

Table IX. Production of primary magnesium, 1977-1985

Year	Production of primary magnesium (MT)* World	USA
1977	185,000	—
1978	209,000	135,000
1979	226,000	145,000
1980	~240,000	~151,000
Est. 1985	288,000	—

* From References (200-202).

Magnohrom Oour Bela Stena (Yugoslavia) has opened a 5000 metric tons per year plant at Baljevac Na Ibru, Serbia, based on magnetherm technology developed by So-Frem (213, 214). Production in 1980 was expected to reach 80% of capacity, one-half of which would be exported.

Dow Chemical (USA) will spend $20 MM to increase the production at Freeport (Texas) to approximately 125,000 metric tons magnesium per year. A new low-energy process will be incorporated into the facility and startup is scheduled for late 1982 (215, 216).

Short-term economic concerns have delayed plans for construction of a new 24,000 MT per year plant, outlined by Chromasco Limited and expected to begin during 1980 (197). The Canadian company has continued to upgrade capacity and improve operations at its plant in Haley, Ontario, thereby increasing capacity 100% since 1975.

Near the end of the fourth quarter of 1980, the American Magnesium Company closed its primary magnesium production facility at Snyder, Texas, due primarily to the lack of brine feed (199).

Fomb/Agusta SPA (Italy), a manufacturer of helicopters, has awarded a contract to produce high performance magnesium casting alloys to Magnesium Elektron (UK). MEL has developed a range of magnesium/zirconium alloys designed specifically for the aircraft industry (218).

The levels of magnesium in "soft" drinking water have been linked to sudden death, inchemic heart disease in studies at the Down State Medical Center (Brooklyn) of the State University of New York (219). The findings indicate that a deficiency of magnesium in the water may be a factor in the disease sequence of progressive vascostriction, coronary artery spasm, and sudden death.

Manganese.—There was no domestic production of manganese ore containing 35% or more manganese again in 1980. Low grade ores were produced and shipped from mines in Minnesota, New Mexico, and South Carolina. More manganese was imported as ferro-alloys than as ore, although consumption of both

Table X. Consumption of primary magnesium, 1977-1985
World consumption of primary magnesium (MT)*

Use	1977	1978	1979	Est. 1980	Proj. 1985	% Growth

NL Ind. (Amax)	USA	Electrolytic	45,000
Northwestern Alloys	USA	Thermal	24,000

was down. Ferromanganese imports were 20% lower than in 1979 (220).

Prices for high-carbon ferromanganese containing more than 78% manganese were from $490 to $530 per metric ton of alloy from domestic producers. Imported alloy of the same grade decreased from $430-$440 per metric ton at the beginning of the year to $350 per metric ton by mid-summer (220). Electrolytic manganese metal increased to 70¢ per lb in December (221-223).

Some companies have complained that current ferromanganese prices are too low to attract new investment (224). Others say expansion will be limited due to lack of mineral reserves and expensive energy (225).

It has been reported that offshore deposits of manganese could supply the U.S. with all its needs (226). South Africa has 12.14 billion tons of recoverable land-based manganese ore, while Russia has 2.6 billion tons (227).

About 95% of manganese ore produced worldwide ends up in steel, while the other 5% goes into many markets, including chemicals and batteries (228).

Following an increase in demand by the uranium processing industry, Rand London Manganese Mines opened a new mine in the Transvaal which will increase production by 3000-4000 mt per month (229). Delta Manganese (South Africa) will increase manganese metal production from 20,500 to 26,000 tons per year with a $17 million expansion (230).

Nickel.—The Bureau of Mines reported domestic mine production of nickel was 16,000 tons in 1980. Consumption of primary nickel in the U.S. decreased 15% to 165,000 tons in 1980. Total nickel consumption, including secondary nickel, was estimated at 197,000 tons (231).

Domestic production from ore mined in Oregon and nickel recovered from primary copper smelters in 1980 was about 12,500 tons. The Amax Nickel Refinery in Louisiana produced about the same amount of primary nickel in 1980 as in 1979 from imported matte (231). Low demand caused Amax to idle 15% of its 80 million lb per year capacity in September.

Weak demand for nickel resulted in Falconbridge Nickel Mines, Incorporated (Canada) shipping 54,159,000 lb in 1980 compared to 86,454,000 lb in 1979. Nickel inventories in Canada reached 155 million pounds by the end of 1980, up from 89 million pounds in 1979 (233).

Noncommunist world production and consumption of nickel were about in balance in 1980 at 1,200,000 million pounds (234).

Nickel prices were increased 25¢ per lb. This resulted in major nickel buyers holding off purchase (235). In order to stimulate purchases, major producers offered a 6% discount on nickel products in November (236). In August, mills were operating at 60% of capacity and buying 20% of the usual amount of nickel (237).

U.S. nickel consumption is expected to rise 4-4.5% per year in the 1980's and become tighter after 1985 (238). Domestic consumption in 1981 is predicted to equal that in 1980 (240). Current world nickel smelting and refining capacity is expected to increase from the current 700,000 mtpy to 715,000-760,000 mtpy by 1985 (239-244). New applications in the defense and energy related industries should contribute to the expanding demand in the 1980's.

Inco (Canada) will spend $15 million on process improvements to its Indonesian nickel project to try to reach its capacity of 100 million pounds. Corrosion problems severely limited production, which is expected to reach 60-65 million pounds in 1981 (245).

Nickel-SLN (France) has developed a process to produce super-refined nickel of 99.98% purity for the nuclear and aerospace industries. A 16,000 tons per year plant will be constructed to produce the material (246).

A new process for electrolytic nickel has been commercialized by Falconbridge Nikkelwerk (Norway) in a 38,000 mtpy plant. Nickel concentration in the air is kept below 0.2 mg/m^2 (247).

Inco (Canada) started up a 10 million lb per year expansion of its Clydach, S. Wales, smelter, raising its capacity to 120 million lb per year. The new process utilizes a fluid-bed roaster with the SO_2 being converted to sulfuric acid (248).

Cuba's plan to produce 100,000 tons per year of nickel by 1985 has been set back to 1990. Only $26 million of a planned $275 million have been spent and the second stage expansion will not be completed before 1984 (249).

Sumitomo Metal Mining (Japan) will partially re-equip its nickel smelter in 1982 with a resulting decrease in capacity from 23,400 to 21,360-21,600 tons per year (250).

Inco Limited is reducing sulfur dioxide emissions at its Sudbury, Ontario, nickel smelter by 25% through the installation of a $40 million pyrrhotite flotation process. This installation will allow it to meet governmental standards by 1983. The plant capacity will remain at 280 million lb per year nickel (251). The same firm will limit SO_2 emissions at its Thompson, Manitoba plant by producing high strength SO_2 to make sulfuric acid (252).

Although lung cancers and nasal sinus cancers among nickel smelter workers may result from the carcinogenicity of the metal, they may also be caused by the presence of chrysotile asbestos in the ores. Regardless of the cause, adequate hygiene measures must be taken to prevent inhalation of dusts arising during ore processing (253).

A process for recovering nickel from low-grade domestic laterite ores has been demonstrated by the Bureau of Mines in a 5 tons per day pilot plant. The process may lead to a reduction in U.S. dependence on imported nickel, currently 93% of consumption (254).

Sodium.—Data regarding the annual production of metallic sodium for 1980 have not appeared in the usual sources. However, it has been stated (255) that the current industry capacity of 190,000 short tons is expected to meet the demand for metallic sodium over the next several years.

It is expected that due to legislative controls on automobile emissions, the use of metallic sodium in the manufacture of tetramethyl and tetraethyl lead will continue to decline. This use accounted for approximately 80% of the metallic sodium produced.

Some growth may be expected in the use of sodium to produce metallic titanium. Other uses include the manufacture of herbicides, pesticides, dye stuffs, pharmaceutical chemicals, sodium hydride, and sodium borohydride, but little growth is anticipated.

Potential new uses for metallic sodium include sodium-sulfur batteries and as a heat transfer medium in nuclear reactors (255).

Titanium.—Although the predicted decrease in orders for commercial aircraft did occur in 1980, the de-

mand for titanium metal in other areas remained strong both in the United States and in Europe. Record customer orders were placed during essentially the first three quarters of 1980 so that the increased sponge and melting capacity in the industry led to record shipments. By the end of the year, however, the decline in the aircraft industry did have an effect and lead times for titanium products were noticeably reduced (256).

The U.S. strategic stockpile goal for titanium sponge was increased to 195,000 tons because of increased requirements and limited domestic capacity. Current inventories show approximately 32,000 tons of sponge metal (258).

The published price of domestic titanium sponge was increased from $3.98 per lb to $7.02 per lb in July 1980. Sponge metal imported from Japan also suffered a significant price change in April 1980, increasing from $3.60 to approximately $8 per lb (258).

RMI Company (Niles, Ohio), jointly owned by the National Distillers and Chemical Company and U.S. Steel, has completed an expansion to the facilities in Ashtabula, Ohio, at an estimated cost of $3.5 MM. The expansion effectively increases the company's capability to produce titanium sponge from 15 MM to 19 MM pounds annually (259).

D-H Titanium Company, a joint venture of Dow Chemical and Howmet (a subsidiary of Pêchiney-Ugine-Kuhlmann of France), began operation of a new semicommercial titanium plant this year. The plant, located in Freeport, Texas, utilizes nonconventional electrolysis technology. It has been reported that further expansion is being considered to allow production of approximately 5 MM pounds of titanium annually by 1982 (260).

IMI Titanium (Witton, U.K.) plans to double the company's present capacity to produce titanium alloy, *i.e.*, approximately 5000 MT/year, over the next five years. The initial stage involves expenditure of $18 MM to install vacuum-arc melting furnaces, plasma-welding units, rolling and finishing equipment (261).

Sumitomo Metal Industries, Osaka Titanium, and other members of the Sumitomo group, are considering expansion of metal titanium production. According to the announcement, an attractive site for a new titanium plant is Australia, with cheap power and an abundant supply of rutile (262). Plans are to increase titanium sponge capacity to approximately 18,000 tons per year. Osaka Titanium expects to increase its capacity to 5000 tons per year.

Billiton International, the metals subsidiary of the Royal Dutch/Shell group, is considering investment in a titanium plant in the United Kingdom. The total cost of the project is estimated to be $75 MM with Billiton providing 60-70% (263). The other partners in this project are Rolls Royce and IMI, the former being the priority customer of the 5000 tons per year plant, to ensure supplies of the metal for aero-engine production. Courtaulds Engineering has been awarded the construction contract and the plant is expected to come "on-stream" in 1982.

Osaka Titanium has also announced plans to install a new titanium ingot furnace at its plant in Amagasaki, capable of producing ingots of approximately eight tons and capacity of 200 ton per year. The furnace will be able to utilize scrap titanium as 10% of its feed (264).

Table XII. U.S. titanium metal supply and demand (257) (short tons)

		1979	1980
Titanium sponge	Imported	2,488	4,777
	Exported	180	113
	Consumed	23,937	26,937
Titanium ingots	Produced	37,414	41,786
	Consumed	35,987	42,477
Titanium scrap	Exported	4,967	3,300
	Imported	6,140	4,138
	Consumed	13,986	15,412

A feasibility study has been undertaken for the construction of a $100,000 titanium metal plant in New South Wales, Australia. General Dynamics (U.S.) is involved in this study under a 30% offset deal, since the company has recently submitted a proposal to build F-16 fighter planes for the Australian Air Force (265).

Howmet Turbine Components Corporation purchased the Whittaker titanium ingot facility in Reno, Nevada, which has been idle since 1976. This plant will supplement the melting operations in Whitehall, Michigan, and add a further 4 MM lb per year of ingot capacity (256).

Westinghouse Electric Corporation, Pittsburgh, Pennsylvania, was awarded a $1 MM contract by the Electric Power Research Institute to compare the performance of titanium and steel blades in steam turbines (266). Preliminary studies in the 100,000 kilowatt steam turbine in Georgia have yielded encouraging results in that the titanium blade is significantly more resistant to pitting.

NL Industries, Inc has developed a new modification of its sulfate pigment process which the company calls liquid phase digestion (267). The new procedure reportedly reduces air and water emissions, lowers manufacturing costs, and will effectively expand plant capacity. The agreement to install this new production system before September 1981 was part of a settlement with state and federal authorities in regard to alleged violations of environmental regulations at the pigment plant in Sayreville, New Jersey.

In March 1980 the Department of Commerce proposed a set-aside program for titanium products, to facilitate equitable handling of defense-rated orders under the Defense Materials System and the Defense Priorities System (266). A strong negative response to the program from the titanium industry prompted its withdrawal in May.

In a civil antitrust suit, arising from a criminal case in 1979 involving a price-fixing conspiracy, four titanium companies agreed to an injunction barring price fixing, bid rigging, or the trading of price information (266). The companies involved were RMI Company, Crucible, Incorporated, Lawrence Aviation Industries, Incorporated, and Titanium Metals Corporation of America. The suit against the fifth defendant, Martin Marietta Aluminum, Incorporated, is continuing.

Focusing on new materials, automotive designers are studying improved coil springs for suspension systems. Ford has indicated that titanium springs offer a 53% savings in weight (168).

Mine production of ilmenite decreased 14% in 1980, totalling 550,000 tons (estimated) in contrast to approximately 640,000 mined during 1979 (256, 258). The only U.S. plant producing synthetic rutile, located in Alabama, was reopened during 1980, but was operating at only 70% of capacity (258).

Imports of ilmenite, predominantly from Australia, were significantly higher than in 1979 and were estimated at 320,000 tons (258). One hundred sixty-one thousand tons of natural rutile, primarily from Australia, were imported in 1980, being essentially unchanged from 1979, whereas 37% less synthetic rutile was imported.

Associated Minerals Consolidated Limited (AMC), a subsidiary of the Consolidated Gold Fields, Australia, Limited, exercised its option to purchase the assets and mining rights of the Titanium Enterprises mineral sands operation at Green Cove Springs in Florida (266). AMC expects to produce 25,000 MT of rutile, 25,000 MT of zircon, and 50,000 MT of ilmenite annually over the next 15-20 years. The purchase price was reported to be $11.7 MM.

In the light of anticipated growth in the demand for titanium chemicals, Gulf and Western Natural Resources has announced plans to expand its facilities in Ashtabula, Ohio. The cost of construction is estimated to be $3.7 MM, completion expected in early 1982 (269).

Zinc.—Although the zinc industry in the United States experienced a severe mid-year slump, demand through the third and fourth quarters and an improved pricing forecast led to a better year than anticipated and a more optimistic outlook (270). However, uncertainty continues to surround both the automotive industry and the construction industry, particularly in light of 1980's high interest rates, and these industries are primary markets for zinc metal.

According to W. G. Weeks (Noranda Sales Corporation Limited) product research, market development and supply security must be successfully integrated for the zinc industry to move into the 1980's. The industry must recognize that it is essential to create zinc end-products that meet a need, which demands product research and market development, leading to a sound market and hence the investment to assure dependable supply (271).

Zinc demand is predicted to rise 1.5% per year through the 1980's in the free world, but this requires reduction in capacity to return the industry to profitability, according to the Commodities Research Unit (U.K.). Growth in Western Europe, U.S.A. and Japan will be less than 1.5% per year (272). World capacity for the production of zinc is shown as Table XIII.

The zinc industry in Western Europe may be required to increase exports or alternatively to reduce capacity (274) in order to maintain profitable operations. Although consumption of zinc in the developing countries has increased at approximately 8% per year for several years, these markets are dominated by Canada. Furthermore, the developing countries are themselves expanding smelter capacity. Ironically, the smelters in Western Europe are highly modernized and among the best and most economic producers of zinc in the world.

The opening of a new mine and the absence of strikes in 1980 appear to be factors that contributed to an estimated annual mine production of 310,000 metric tons, an increase of approximately 20% over 1979 (275). In contrast the primary production of zinc metal declined to 350,000 metric tons, decreasing 25% from 1979 production levels. World-wide shortages of

Table XIII. World zinc capacity (273) (metric tons)

	Nominal capacity 1980	Production capacity 1980	Nominal capacity 1985
Europe	2,325,000	2,000,000	
Africa	275,000	235,000	275,000
Canada	633,000	605,000	663,000
U.S.A.	613,000	557,000	240,000
Mexico	200,000	180,000	345,000
South America	193,000	160,000	325,000
Australia	325,000	310,000	295,000
Asia	205,000	158,000	295,000
Japan	1,000,000	900,000	1,000,000
Totals	5,769,000	5,106,000	6,301,000

Table XIV. Consumption of slab zinc in the United States (276)

End use	1979 Consumption (metric tons)	1980 Consumption (metric tons)
Galvanizing	411,200	345,100
Brass and bronze	139,000	96,400
Zinc-base alloys	282,400	208,300
Rolled zinc	22,000	22,000
Zinc oxide	35,500	29,860
Other	28,900	25,000
Totals	919,000	826,660

the zinc concentrates may have been a major factor in the curtailment of production (275) although several plant closings also occurred.

Consumption of zinc decreased 15% in 1980, probably due to the reduced activity in the automotive and construction industries (275). The major uses for slab zinc and estimated consumption in 1979 and 1980 are shown as Table XIV.

New Jersey Zinc Company, a unit of Gulf and Western Industries, announced that it will close its zinc smelting operation in Palmerton, Pennsylvania, including the zinc ore roasting, sulfuric acid and vertical retort facilities. Production of zinc oxide will be maintained however (275,277). Reasons cited for this decision were the decreased demand for zinc and rapidly rising production costs (278).

St. Joe Zinc (Pittsburgh), a division of St. Joe Minerals Corporation, closed the 250,000 tons per year electrothermic zinc smelter in Monaca, Pennsylvania, at the end of 1979 (279, 280). The primary reason cited was the failure of the domestic zinc industry to gain relief from excessive imports of slab zinc. After preliminary studies of designs for a new 120,000 tons per year electrolytic zinc refinery, St. Joe decided not to replace the Monaca smelter (281, 282). It was also announced (283) that negotiations for long-term purchases of 20,000 tons per year of zinc ingots were ongoing between St. Joe Minerals and several Japanese companies.

Citing poor market conditions, Jersey Miniere is planning to reduce production at the 90,000 short tons per year zinc refinery in Clarkesville, Tennessee, to approximately 40% of its capacity (284). Development work at the company's zinc mine at Gordonsville, Tennessee, will also be curtailed.

Japanese zinc smelters have efficiently reduced their energy consumption by (*i*) use of nighttime electrical power, (*ii*) recycling of hot gases, and (*iii*) introduction of new technology (285). However, it is expected that production will be reduced approximately 5% (*i.e.*, 40,000 tons per year) due to escalating power costs which already account for 60% of smelter revenues (286).

Preussag AG (Hanover, West Germany) announced plans to reduce capacity at the 100,000 tons per year zinc plant at Harz to allow the necessary modifications to be made to the facility to meet the stricter regulations governing air pollution (287).

STE Industrielle de Prayon (Belgium) announced that production of zinc ingots at the Ehein Electrolytic plant will be stopped due to the high cost of zinc concentrates and depressed prices in the zinc market (288). The plant had an annual capacity of 35,000 tons.

St. Joe Minerals expects to develop a recently discovered ore-body at Pierrepont, New York (275, 289). It is estimated that approximately 2.5 million tons of zinc ore (15% metal) may be realized from this deposit.

Bechtel (Canada) announced that it has been commissioned by Cominco Limited to design and construct a mine on Little Cornwallis Island (Northwest Territories) to produce ore containing 14.1% zinc and 43% lead. The size of the reserve will make the mine at least the 11th largest producer in the world (290).

The historic Broken Hill mining district in western New South Wales (Australia) is the scene of an exploration program estimated to cost $11 MM over the next five years (291). Australian Mining and Smelting Limited, a wholly owned subsidiary of Conzinc Riotinto of Australia, decided to intensify its efforts to establish sufficient reserves to supply smelters in South Australia and New South Wales into the 21st century.

Allied Metal Company (Chicago, Illinois) has begun operation of a new zinc smelter to increase plant capacity to approximately 20 MM tons per year. The ex-

pansion is estimated to have cost $200,000 and included installation of electronic controllers to monitor smelting operations (292).

Pacific Smelting Company has announced plans to construct a 10,000 tons per year zinc refinery in Memphis, Tennessee, based on muffle furnace technology. Completion of the project is expected to be late in 1981 (293).

A zinc plant owned by Cia Mineira de Metars (Brazil) became operational during the fourth quarter of 1979 (294). The plant has the capability to treat 500 tons per day of dry zinc ore in a large rotary furnace.

Hindustan Zinc Limited has undertaken a $13 MM improvement program at its smelting facilities at Debari. When completed early in 1983, zinc output capacity will be approximately 48,000 tons per year (295).

In September 1980, St. Joe Minerals reopened part of the smelter at Monaca, Pennsylvania, to produce French-process zinc oxide and prime western zinc, with a combined capacity reported to be 50,000 short tons per year (270).

The zinc output in Peru is expected to be increased to 130,000 tons per year in 1981 when operations at the new refinery at Cajarnaquilla begin (296).

Bunker Hill Company (Kellogg, Idaho) became the first domestic primary zinc producer to market zinc foundry alloys and is presently posting prices for three alloys (297). The emerging market for zinc as a foundry alloy affords the industry an opportunity to market aggressively. Bunker Hill has announced its intention to work closely with customers to develop applications. Texasgulf has announced its entry into this market (298) predicting that it could reach 385,000 tons within the next decade.

The zincex process for recovery of zinc from leach liquors has been incorporated into Metalquimica Del Nervio SA's plant at Bilboa, Spain, and into a new 11,000 metric tons per year plant in Lisbon, Portugal (299).

The Electrical Industry

The energy future.—A five-year overview and strategy summary recently published by the Electric Power Research Institute (EPRI) strikes a somber note regarding the energy future in the United States (300):

> "The issue is not a choice of conservation or coal or nuclear or renewable resources: rather it is our willingness to use conservation and coal and nuclear and renewable resources. We do not enjoy the luxury of selecting from these alternatives, we must utilize all of them."

The document is a summary of a more detailed study and the present focus of the Institute is clearly upon technological developments with anticipated pay-off within the next decade. It is pointed out that without expansion of the supply of electricity some areas of the nation may experience severe shortages of power over the next twenty years.

The report predicts the development of a "coal economy," demanding a two or threefold increase in the production of coal in less than twenty years. The electric utilities will consume approximately 70% of that coal by the year 2000. But even with this objective being realized, EPRI regards nuclear power generation as a matter of necessity (300).

A similar viewpoint was expressed by D. Schauster of the Bonneville Power Administration (301), who stated that there will be limited supplies of electrical energy during the 1980's at significantly increased cost to the consumer. In his opinion, it is unlikely that alternative sources of energy will be capable of relieving this situation until the end of this century. With particular references to the Pacific Northwest, Mr. Schauster cited mounting costs and regulatory obstacles as the major hurdles confronting the utilities in their efforts to establish new power stations. Additional generating capacity could cost 3-5 times as much as it did in the 1970's. Similar concerns were expressed by the aluminum makers, chemical companies, and forest-product companies (302).

The situation is further aggravated by the fact that construction of nuclear power plants may not occur without speedier licensing and higher power prices (301). Presently, it is estimated that approximately 33% of the cost of the new nuclear plants stems from construction delays. The uncertain growth of nuclear power generation and the concerns of the general public with respect to the environment and safety, may be reflected in the federal energy budget for the fiscal year 1981 (303). Here funding for the development of nuclear fusion technology has been reduced 22%.

Marshall McDonald (Chairman of the Board and Chief Executive Officer, Florida Power Light Company) believes that a major problem facing the electric utilities today is to convince the general public that there is an energy crisis (304) and that the solution will not be cheap.

A somewhat more optimistic outlook was expressed in a report produced by the American Petroleum Institute (API), which stated that the United States ought to be "in good shape" by 1990, if appropriate decisions are made now (305). The opportunities available, according to the API report, include the development of coal and nuclear programs, effective changes in the current environmental laws, and deriving more energy from federal lands.

The World Coal Study, an international project involving over eighty people from sixteen major coal-using and coal-producing countries, concluded that,

> "A massive effort to expand facilities for the production, transport, and use of coal is urgently required to provide for even moderate growth economically in the world between now and the year 2000. Without such increases in coal, the outlook is bleak." (306).

Power generation in the United States.—The economy, the weather, and conservation were three forces that impacted upon usage of electrical power in the United States in 1980. The predicted recession for the year became a serious depression, significantly worse than the downturn experienced in 1974-1975. On the positive side for the utilities a long, hot summer with record-breaking temperatures led to high demands for electricity. Through all of this, the consumer, facing high rates of inflation, was forced to "conserve" wherever possible in order to match income and expenses.

Sales of electricity in 1980 totaled 2097 billion kW-hr, which represents an increase of only 1% (307) but higher than forecast (308). A 2.7% decrease in sales to industry was offset by the increased sales to residential customers, 4% *vs.* 2.1% in 1979 (Table XV).

Revenues accumulated by the electric utilities increased approximately 18% to $91.7 billion in 1980 with increases of 16, 18, and 20% being realized from sales to industrial, residential, and commercial customers,

Table XV. Electric utility sales, 1978-1980 (307)
(Billions kW-hr)

	Residential	Industrial	Commercial	Other	Total
1978	679.2	782.1	480.7	75.8	2017.8
1979	693.8	813.6	494.4	75.9	2077.8
1980	721.1	791.6	509.8	74.4	2097
% Change 1978-1979	+2.1	+3.8	+2.7	—	+2.85
% Change 1979-1980	+3.9	−2.7	+3.0	—	+1.0

Table XVI. Average annual use, electric rate, and utility bill 1978-1980 (307)

Year	Residential			Industrial			Commercial		
	Avg. use (kW-hr)	Avg. bill (¢/kW-hr)	Avg. annual bill ($)	Avg. use (kW-hr)	Avg. bill (¢/kW-hr)	Avg. annual bill (%)	Avg. use (kW-hr)	Avg. bill (¢/kW-hr)	Avg. annual bill ($)
1978	8,849	4.03	356.7	1,702,939	2.59	44,156	53,085	4.1	2,177
1979	8,828	4.33	382.1	1,709,997	2.85	48,812	53,249	4.39	2,337
1980	8,973	4.93	442.3	1,657,317	3.41	56,464	53,640	5.1	2,733

respectively (307). The sharp rise in the revenues is attributed primarily to the increased power rates granted to the investor-owned facilities.

The conservation of energy by the residential customer seen in 1979 was not maintained in 1980, due probably to the long, hot summer. As is seen in Table XVI the average power usage increased 1.6% to 8973 kW-hr and the cost jumped 0.6¢ to set a new post-World War II high of 4.93¢ per kW-hr (308). In all, then, the average residential bill increased almost $60 over that of 1979.

In the five-year period since the end of 1975, the average residential usage has increased only 10%, but the rate has increased 50% and the average bill approximately 70% (307).

Repeated pleas for increases in the power rates appeared to be the utilities' defense against inflation, according to the *Wall Street Journal* (309). Hit hard by soaring costs of construction, fuel, and capital, the first half of 1980 saw approximately 86 utilities file requests for rate increases. From figures released by Ebasco Business Consulting Company (307), 97 utilities were granted $5.67 billion in rate hikes in 1980, an increase of 24% from 1979. A further 70 applications are pending (Table XVII).

Similarly, Edison Electric Institute reports $5.93 billion in rate increases in 1980 as an "improvement in the attitudes of state commissions towards the utilities" (307).

Generation capability for the electrical utilities increased 2.7% during 1980 and, based on data from DOE's Energy Information Administration, the year-end capability of all U.S. utilities was 613,582 MW compared with 597,523 MW as of December 1979. The consumption of the various fuels (Table XIX) shows approximately an 8% increase in the use of coal to generate electricity and as in 1979, there was a significant decrease in the amount of oil used.

Table XX, energy generated by fuel type, illustrates the marked, and accelerating, trend towards fossil fuels and the dominance of coal in this category.

Projected capability beyond 1981 is presented as Table XXI.

Capital expenditures primarily for generation, transmission, and distribution of electricity in the United States were $35.9 billion, which, compared with 1979, was essentially without growth, contrary to a projected increase of approximately 8.6% (307). A sluggish economy, reduced forecasts for load growth, and a poor financial picture were thought to have held down utility spending. The biggest change in capital expenditures between 1980 forecast and actual 1980 figures occurred in the area of municipal, state, and public-power-district system. Actual spending for this segment of the industry was off 60% from the estimated figures. It is added, however (307) that the forecast was highly uncertain due to limited information.

Table XVII. Electric rate increases 1978-1980 (307)

Year	Granted		Pending 12/1980	
	No. companies	$ MM	Applications	$ MM
1978	73	2,362.7	59	3,458.9
1979	80	4,567.0	70	4,715.4
1980	97	5,677.0	70	7,381.0

Energy from fossil fuels.—Over the last four to five years, approximately 70% of the power generated in the United States has utilized fossil fuels (see Table XVIII), and as stated earlier, a substantial decrease in the consumption of oil by the electrical utilities was maintained through 1980.

With respect to capability beyond 1980, planned addition would utilize fossil fuels to generate 46.7% of the electrical power (see Table XX).

Coal gasification.—The Department of Energy has given conditional approval for a $250 MM loan guarantee to partly finance construction of the Great Plains coal-gasification plant to be built near Beulah, North Dakota (310, 311). A consortium of five gas-pipeline companies, led by American Natural Resources Company of Detroit, expects to begin construction by the end of the year with the complex becoming operational in 1984. The plant is designed to produce 125 MM cubic feet of high-Btu gas per day, which is equivalent to 20,000 barrels per day of fuel oil.

Table XVIII. Energy generated and source 1978-1980 (307) (Billions kw-hr)

	Coal	Oil	Gas	Nuclear	Total
1978	976.6	364.2	305.4	276.4	1922.6
1979	1075.6	303	329.5	255.2	1967.6
1980	1161.2	245.8	345.9	251.1	2009.6

Combustion turbine	50,642	8.3	3,186	1.5	53,828	6.4
Total industry	613,582		204,507		818,089	

* Includes Pumped Storage.

Table XXI. Commercial applications of solar energy

Company	Application	Energy savings Btu/year
Campbell Soup (Sacramento)	Can washing	1.8 Billion
Johnson & Johnson (Sherman, TX)	Bleaching, sterilization	1.5 Billion
Lamanuzzi Foods (Fresno, CA)	Food drying	1.0 Billion
Reedy Creek Utility (Florida)	Air conditioning	800 Million
Gold Kist (Decatur, AL)	Soy bean drying	800 Million
Anheuser-Busch (Jacksonville, FL)	Pasteurization	500 Million
Riegel Textile (La France, SC)	Dyeing	400 Million

Northern Resources are considering the construction of a coal gasification plant in Billings, Montana, to produce approximately 19 MM cubic feet of medium-Btu gas per day. The Department of Energy may oppose the company's request for a grant to conduct a feasibility study, forcing Northern Resources to seek private financing (312).

The initial results from the underground coal gasification studies conducted in northeast Wyoming during 1979 are considered to successfully demonstrate the feasibility of *in situ* coal conversion (313). The project is sponsored by the Department of Energy and the Gas Research Institute. The final experiments in the so-called Deep-1 series will begin in the third or fourth quarter of the year and will be a study of the Uniwell gasification method, designed specifically for the coal common to western U.S.A.

Two U.S. energy companies will undertake a one-year feasibility study of an underground lignite gasification project in Texas. Following the award of a grant from the Department of Energy, Mitchell Energy and Development and Republic of Texas Coal will investigate controlled *in situ* gasification of lignite too deep to be mined economically (314).

Panhandle Eastern Pipe Line Company has a preliminary agreement to become partners with Pacific Gas and Electric Company, San Francisco, and Ruhrgas Aktiengesellschaft, Essen, West Germany, in its Wyoming coal gasification project (315).

A 15-month study has been initiated that may result in the first commercially sized coal gasification power plant (316). Central Maine Power Company, under a $3.5 MM grant from the Department of Energy, will examine the feasibility of integration of a large coal gasification plant with combined cycle (gas turbines and steam turbines) power generation. Located at Sears Island, Maine, the proposed plant would combine Texaco's coal gasification technology and General Electric's combined cycle technology. Two other studies for the design of integrated coal gasification/combined cycle power plants that could be in operation in 1981 have also been funded (317).

During the third quarter, the Tennessee Valley Authority began trial operations of a fully integrated coal gasification plant (318, 319). Located at Muscle Shoals, Alabama, the plant has utilized Texaco's partial oxidation technology, and the cost of the unit is estimated to be $43 MM with an additional expenditure of $20 MM for further trials over the next three years.

In Europe, Esso Nederland has revealed details of the Exxon technology to be utilized in a coal gasification complex planned for construction at its Rosenburg site (320). It is claimed that the catalytic process shows significant cost advantages. The National Coal Board (U.K.) is considering designs of a plant estimated to cost approximately $2 billion, which is expected to process 2000 tons of coal per day (321).

Coal liquefaction.—The Energy Department and Occidental Research have jointly developed a process to liquefy coal at pressures significantly lower than those employed by several advanced liquefaction processes (322). The method is based on flash pyrolysis to rapidly heat the coal at atmospheric pressures in a chamber filled with an inert gas. Under a new $4.5 MM contract, Occidental Research Laboratories in Irvine, California, will begin bench-scale trials of the process.

Exxon has successfully started up its coal liquefaction pilot plant at Baytown, Texas. The plant, estimated to have cost $118 MM, is currently using approximately 100 tons of coal per day. Operations over the next two to three years is expected to provide data on plant and equipment design, product quality, and engineering scale-up (323).

A comparison of several leading liquefaction processes indicates that the lowest cost energy, $3.13 per million Btu, is produced by the Dow process. By way of comparison, the energy cost stated for imported oil (at $25 per barrel and 5.8 MM Btu per barrel) is $4.51 per million Btu (324).

Preliminary results from continuing work by C-E Lummus, under contract with the U.S. Department of Energy, indicate that the company's advanced two-stage process can deliver higher liquid fuel yields, with lower hydrogen consumption and good catalyst performance (325, 326). The process development unit is being operated at the company's engineering development center in New Brunswick, New Jersey.

The initial coal processing phase of a large experimental coal liquefaction plant has been initiated according to Ashland Synthetic Fuels, Incorporated, a unit of Ashland Oil, Incorporated (327). A formal experimental program is expected to continue through 1981 using various types of coal. When operating at peak capacity, the plant is designed to process approximately 600 tons of coal per day to produce 1800 barrels of synthetic product.

Four companies of the Mitsubishi group in Japan claim to have improved their coal liquefaction process, recycling liquefied coal rather than using asphalt or other residual oils as the hydrogen donor (328). A pilot plant is already in operation and a second unit is under construction at the Mitsubishi Heavy Industries research center in Hiroshima.

The National Coal Board in the U.K. has completed designs for a coal liquefaction plant to be built at the Point of Ayr colliery in North Wales. The plant, the only coal liquefaction project that would be operating in the U.K., will use a process developed by the Coal Board in cooperation with British Petroleum (329).

Two major coal liquefaction plants are planned for construction in Victoria, Australia (330). Both plants will be joint ventures, one with Japanese companies and the other with West German interests. Both plants will utilize the brown coal mined in Victoria.

With both coal gasification and coal liquefaction processes advancing rapidly, the need for materials and equipment able to withstand particularly severe operating conditions becomes more urgent (331). The new technologies operate at higher temperatures and pressures than commercial, first-generation processes such as the modified Fischer-Tropsch synthesis used in South Africa by Sasol. Process designers have expressed concern about the lack of suitable equipment, but remain optimistic about early solutions to the problems.

Shale oil.—According to Exxon officials, the OPEC price increases in 1980 make shale oil competitive with imported oil (332, 333). Furthermore, the U.S. synthetic fuels potential is significantly larger than the domestic proven and undiscovered oil and gas reserves. It was claimed that there are 1.4 trillion barrels of

shale oil in the ground that an estimated 580 billion barrels could be recovered by surface mining. The U.S. shale oil and coal reserves were estimated to be capable of yielding 15 MM barrels of oil per day by the year 2010.

This optimistic view was not shared by D. Roger Loper, president of Chevron Shale Oil Company. Depending on rates of inflation, the cost of bringing a large facility "on-stream" may cost approximately $7 billion. However, forty companies have invested in the development of shale oil (333), ultimately providing a combined capacity of approximately 715,000 barrels per day within the next decade. The present pace of development is gradual, but with recent indications of an acceleration.

A study made by the Office of Technology Assessment is believed to lend credence to fears in the western United States that rapid development of the shale oil industry would create severe social and economic problems (334). However, the conclusion drawn from this study is that the capability to produce 400,000 barrels per day by 1990 can be achieved, allowing substantial technical, environmental, and economic information to be generated and reducing the socioeconomic impact.

Under the sponsorship of the Department of Energy, ten companies will work jointly on design and demonstration of a commercial-size facility to produce oil from Utah shale oil (335). The group, the Paraho Development Corporation, will require approximately eighteen months to plan and design a single, aboveground retort and the support facilities.

According to preliminary statistics developed by the Department of Energy, approximately 1000 billion barrels of oil could be found in the predominantly coal-rich fields of Kentucky, West Virginia, and Ohio (336). However, leading analysts have stated that because of low oil yields, the cost of extracting the oil would approach $40-50 per barrel, significantly higher than western shale oil.

A dispute over endangered fish appears to have delayed development of the White River oil shale project in Utah (337). The project is a joint venture of Phillips Petroleum, Sun Oil, and Standard Oil of Ohio. The Bureau of Land Management requires a decision from the Fish and Wildlife Service on the possible dangers to three species of fish caused by construction of a dam on the White River.

Energy from nuclear fuels.—For several years, advocates of nuclear power have had little to become excited about. Since 1975 only thirteen new nuclear power plants have been ordered in the United States, while plans for fifty plants have been canceled (338). Executives of utilities and companies that supply the nuclear power plants are presently optimistic that the new Reagan administration will be more helpful than its predecessor. It is believed (338) that the utility industry will press for changes in the Nuclear Regulatory Commission, particularly to ease "red tape" with respect to licensing. Delays have increased construction costs excessively.

The industry's most difficult obstacle may be the financial aspects (338). Cost overruns engulf almost every nuclear project. For example, a plant in Michigan is projected to cost $3.1 billion to construct, almost ten times the original estimate. With the slower growth in the demand for electricity, the utilities today have less capability to generate cash internally and outside investors are reluctant to provide the vast sums of capital required.

It was recently reported (339) that over the last three decades the federal government has subsidized the growth of commercial nuclear power to a level of $37 billion. This included support for initial research on nuclear reactors, supply of uranium fuel, production incentives for uranium miners, assistance to equipment manufacturers, and nuclear waste-disposal techniques.

Extensive analysis of the plant at Three Mile Island and of the accident which occurred there revealed the importance of several chemical processes and operations used at nuclear power plants (340). The initiating event, the unfavorable thermodynamic conditions for the reactor coolant during the accident, the zirconium-water reaction (which proved to be the most damaging occurrence), and the misunderstanding surrounding the "hydrogen bubble" could have been avoided or mitigated. However, the chemical industry and the utilities may benefit from the information now available to improve safety standards, operator training, emergency procedures, instrumentation and control philosophies in the design and operation of plants (340, 341).

The Nuclear Regulatory Commission concluded that existing methods are adequate for the decontamination and clean-up of Unit 2 at the Three Mile Island nuclear power plant. It is anticipated that only very small releases of radioactivity will result (342).

General Public Utilitites Corporation, owners of the utility that operates Three Mile Island power plant, has estimated that the cost of clean-up will be $855 MM with restoration of full service not likely before 1985 (343). GPU is asking other utilities and the federal government for assistance.

After a series of false starts, venting of krypton-85, trapped inside the crippled reactor at Three Mile Island since March 28, 1979, began June 30, 1980. Traces of radioactivity were detected by monitors on an observation platform overlooking the facility and on a nearby island in the Susquehanna River. However, federal officials stated that there was no danger to public health (344).

The Nuclear Regulatory Commission has allowed the Virginia Power Company to bring its nuclear power plant at Mineral, Virginia, to full power (345). The action came after the Commission had reviewed the results of an emergency drill conducted by the company and the Federal Emergency Management Agency. Since the moratorium against new licenses, the Agency has allowed two other facilities to begin low-power tests.

Electrical failure in a nonnuclear instrument panel closed down Unit 3 of Florida Power Corporation's nuclear power plant at Crystal River (346). All safety systems worked as specified and no leakage of radioactivity occurred.

The Tennessee Valley Authority decided against further deferrals of nuclear units and four projects, totaling 5200 MW, will be undertaken (347). TVA has three nuclear units on-line at Brown's Ferry and has plans for fourteen other plants into the 1990's. A major reason for the action is the latest estimates of the growth in demand through the year 2000 and the likelihood of "brown-outs" in the near future.

The Department of Energy's original plan for disposing of high-level nuclear waste by sealing it in underground repositories, has foundered on the fact that geology is not a predictive science. This inability to guarantee the stability of such repositories for at least a thousand years has forced a major shift in the approach to the problem of nuclear waste. Presently, the DOE is stressing the concept of multiple "engineered" barriers. The world's most advanced program of research on engineered barriers is the Swedish project KBS (348).

A new technique that disposes of low-level radioactive liquid wastes from nuclear power plants has successfully passed pilot plant tests. The Inert Carrier Radiowaste process, developed jointly by Norden Systems' Chemical Systems Division (Coyote, California)

and General Electric, reduces the volume of wastes approximately 90%. The wastes are then encapsulated in an impermeable plastic (349).

Nuclear waste disposal experts at Tennessee Valley Authority will spend $750,000 in 1981 to study several dry disposal methods that involve above- and below-ground safekeeping (350).

Energy from other sources.—Batteries, fuel cells.— A Management Review Task Force established by the Department of Energy has recommended increased spending on fuel cell technology for commercial use in 1986-1987 (351, 352). Present programs, having a five-year accumulated cost of approximately $130 MM, consist of field tests at fifty sites with natural gas companies (40 kW units), a 4-8 MW demonstration plant at Con Edison in New York City, and the research and development in molten carbonate systems with General Electric and United Technologies.

Hitachi (Tokyo) has developed a prototype methanol fuel cell that is expected to become commercial in 3-5 years. Recent developments incorporating a platinum-ruthenium catalyst have enabled the cell voltage to be increased to 12V, using 50% methanol solutions and air as the feed streams. Estimated cost of power produced by the unit is $47.60 per watt (353).

Gulf and Western Industries announced the development of a zinc-chlorine energy storage system designed to meet peak electricity demand in electric utilities and to make electric vehicles a reality (354, 355). Under development since 1972, testing has shown that the system now has lower cost, longer life and superior performance as compared to the lead-acid or nickel-zinc systems. By mid-1981, Gulf and Western will deliver the first one hundred units to a test facility near Hillsboro, New Jersey.

NASA has announced that a redox fluid battery system is ready for large-scale development (356). Industry has been requested to submit proposals for a multi-kilowatt prototype, scheduled for field tests in 1983. Recent improvements have enhanced the performance of the redox battery so that it is compatible with solar photovoltaic and wind energy storage applications.

Recent discoveries at the General Motors Research Laboratories have encouraged efforts to utilize the lithium electrode in the development of low-cost, long-life rechargeable batteries (357).

A promising battery system for vehicle propulsion has been successfully tested at Lawrence Livermore Laboratory (358-360). Based on aluminum-air electrodes, it is claimed that eventually the battery will be capable of operating in automobiles at a cost comparable to gasoline. A 300 mile range could be achieved by a 60 cell battery, weighing approximately 1000 lb, whereas the same weight of lead-acid cells could power a car for only 30 miles (360).

Construction of the world's largest storage battery, a lead-acid unit to be used as a load-leveling device, has been undertaken by the Wolverine and Northern Michigan Utilities (361). Made up of 2280 cells, the unit will weigh 5.25 MM lb and be able to supply 10 MM watts of power for three hours. The estimated cost of this unit is $8.5 MM.

The Environmental Protection Agency has proposed standards for control of air pollution to limit levels of lead emitted by lead-acid battery manufacturers in the U.S. (362). The new standards will affect approximately 200 plants.

General Motors Corporation, the only major U.S. automaker currently developing electric cars, has postponed the introduction of its battery-powered commuter car until 1985, a one-year delay from the original target date (363). A company spokesman indicated that it had been determined that the new technology required additional development time.

Thermonuclear fusion.—Thermonuclear fusion occurs when a mixture of hydrogen isotopes (deuterium and tritium), heated to extremely high temperatures and pressures, form heavier helium atoms with the release of large amounts of energy. It presently is believed that fusion may be achieved either by inertial confinement or by magnetic confinement (364). Opinion is that commercialization of thermonuclear fusion will occur through use of magnetic confinement techniques.

A 20 year, $20 billion research and development program to establish a magnetic fusion test facility by 1987 and a demonstration plant in the year 2000, was overwhelmingly approved by the House (365). The bill now moves to the Senate, presently considering its own significantly more modest bill to fund development of this technology.

Studies at Oak Ridge National Laboratories have identified beams of higher power that can be an integral part of the heating systems in magnetic confinement fusion devices (366).

The Elmo Bumpy Torus fusion concept, combining some of the best features of the Tokamak and magnetic mirror machines, will be tested at Oak Ridge, Tennessee, according to the Department of Energy (367). The new experimental facility will be built and operated by McDonnell Douglas Astronautics Company (St. Louis). The contract was reported to be approximately $100 MM (368).

Geothermal.—According to the U.S. Geological Survey, (369) the western United States and Canadian Cascade Mountain range could produce thermal energy as well as volcanoes. Under favorable conditions, it is possible to drill and tap energy in subterranean reservations and produce steam to drive a turbine. A special Congressional appropriation is helping to support research to determine the area's geothermal potential.

Presently, "The Geysers," approximately forty miles north of San Francisco, is the only site in the U.S. where electricity is being generated commercially from geothermal energy (369). The generating capacity installed at The Geysers is 663 MW, sufficient electricity to support a city of about 700,000 people.

Construction of the largest U.S. geothermal power plant has been approved by the Department of Energy (370). The agency is funding half the cost of the $143 MM, 50 MW demonstration project to be built by Bechtel Corporation in Sandoval County, New Mexico. The project should be completed in 1982.

A method to remove hydrogen sulfide from geothermal steam has been developed through the R&D programs at the Department of Energy's Pacific Northwest Laboratories (Richland, Washington). Geothermal steam is passed through a reactor packed with activated carbon in the presence of oxygen or air (371).

Ocean thermal energy conversion (OTEC).—This technology received attention and increased sponsorship from U.S. federal and state authorities during 1980. In the U. S. Congress, Representative Don Fuqua, chairman of the House Committee on Science and Technology, put into motion a bill to accelerate commercialization of the technology (372). The Department of Energy presently supports $40 MM per year of research in OTEC and is preparing a proposal to build a $500 MM, 40 MW plant in 1985 (373).

Three alternative concepts are being considered under DOE's guidance, all variations on the floating platform/closed cycle system (374): (*i*) "grazing" plantships that sail the world's oceans seeking the best thermal gradients; (*ii*) open-cycle systems which could produce fresh water as well as electricity; and (*iii*) mist- or foam-based lifting cycles that use pressure differentials caused by the thermal gradients to

force water across a power turbine. Most of the research studies are being conducted by the U.S. Solar Energy Research Institute (Golden, Colorado).

Photovoltaic.—Southern California Edison Company and Pacific Gas and Electric Company are to fund a development program for an automated solar cell production technique. The photovoltaic cells were developed by Westinghouse Electric Corporation and consist of ribbons, named dendritic webs, produced from molten silicon (375, 376).

A new process for producing wafer-thin silicon ribbon has been developed by A. D. Little (Cambridge, Massachusetts) and may accelerate the production of low-cost solar cells used for direct conversion of sunlight into electricity (377, 378).

Describing it as a breakthrough in thin-film, solar cell technology, research efforts at Boeing Aerospace Company have led to the development of a copper indium selenide/cadmium sulfide cell with an efficiency of 9.4% (379).

An organic solar cell that is claimed to essentially duplicate plant photosynthesis has been developed at the University of Western Ontario in Canada. It is estimated that for as little as $1000, the organic solar cells could provide sufficient energy for an average home (380).

The Department of Energy's Solar Energy Research Institute in Golden, Colorado, has awarded a $16.5 MM contract to Martin-Marietta for the design, construction, and operation of a 350 kW photovoltaic power system in Saudi Arabia (381).

Goals set by the Department of Energy for photovoltaic conversion have been a conversion efficiency of 10% with materials costs at 70¢ per watt. Results of research programs at the University of Delaware indicate that both goals may be achieved (382). Emphasis in their studies has been on the cadmium sulfide/copper sulfide cell and it is now believed that efficiencies of 12-16% will be realized. Furthermore, process development studies with respect to the materials suggest an overall cost of approximately 50¢ per watt (382).

A $14 MM plant in its final stages of construction in El Paso, Texas, may provide a "giant step towards commercialization" for photovoltaic devices (383). Photon Power, a joint venture of Compagnie Francaise des Petroles (55.5%), Libby-Owens-Ford (42.5%), and the cell's inventor, J. F. Jordan of El Paso (2%), will operate the plant to produce 5-7 MW per year of solar-powered units. The unit cell is a layer of tin oxide and cadmium sulfide sprayed onto float glass and part of the CdS is then converted to copper sulfide.

Solar energy.—The Department of Energy has selected seven proposals totaling $3 MM for new process applications to exploit sunlight (384, 385). Included for consideration for contracts are solar hot water and steam for electricity generation, solar-heated air for copper smelting, solar steam for enhanced oil recovery, solar steam for natural gas processing and superheated solar steam for a sugar mill process.

A large scale solar industrial process heat system contract was awarded to Stauffer Chemical Company (386) to furnish 25 billion Btu per year.

Typical commercial applications of solar energy presently in operation are shown in Table XXI (387).

The Li/Cl_2 in SO_2Cl_2 Inorganic Battery System

II. D Cell Discharge Characteristics

C. C. Liang,* M. E. Bolster, and R. M. Murphy*

Electrochem Industries (E·I) Incorporated, A Greatbatch Enterprises Company, Clarence, New York 14031

ABSTRACT

Investigations were conducted on the discharge and safety characteristics of the spirally wound D cells of the Li/Cl_2 in SO_2Cl_2 (Li/CSC) system. The realized capacities obtained for these cells further emphasized the effect of Cl_2 addition to SO_2Cl_2 on cell discharge behavior. Further, discharge tests showed that practical D cells of the Li/CSC system at ambient temperature yield energy densities of 0.8-1.1 W-hr cm^{-3} dependent on discharge rates (*e.g.*, 1.0-20.0Ω loads respectively). Cells were discharged at various temperatures from −30° to +93°C. Additionally, no significant loss in capacity has been observed for cells discharged at ambient temperatures after storage at 74°C for periods up to 30 days. The results of preliminary safety testing which included incineration, short circuiting, and the sequence of force discharge/charge further indicate that the Li/CSC system does indeed possess those characteristics necessary for a variety of high rate applications.

Although investigations of the lithium-thionyl chloride inorganic electrolyte system have been conducted in many laboratories (1), only a few studies have been undertaken for lithium-sulfuryl chloride. The discharge characteristics of the Li/SO_2Cl_2 system have been reported by Auborn *et al.* (2, 3) and Gilman (4, 5), while results of cyclic voltammetric studies have been given by Behl (6) and Blomgren *et al.* (7). Investigations were conducted in this laboratory to study the characteristics of the Li/SO_2Cl_2 inorganic electrolyte system, particularly relative to the effects of Cl_2 addition to SO_2Cl_2. Results using AA cells as the test vehicle for the Li/Cl_2 in SO_2Cl_2 (Li/CSC) system have been recently reported (8). In the present investigation, spirally wound D cells were used as the test vehicle in order to study both the discharge and the safety characteristics for this system. The realized capacities for spirally wound D cells further emphasized the effect of Cl_2 addition to SO_2Cl_2 on the cell discharge characteristics at ambient temperatures, especially at high drain rates. Furthermore, cells have been discharged at various temperatures from −32° to +93°C. Cells exhibited no loss in realized capacity when discharged at ambient temperature after storage at 74°C for extended periods up to 30 days. Spirally wound D cells with no vent structure were subjected to incineration, short circuiting, and the sequence of forced discharge/charge. In no instance did the cells vent with flame, explode, or in any way create a hazard to personnel.

Experimental

Lithium tetrachloroaluminate was prepared by the fusion of LiCl (Fisher Scientific Company) and $AlCl_3$ (Fluka) after an initial heating period of 20 hr at 100°C under dynamic vacuum. Sulfuryl chloride (Alfa-Ventron) was distilled after refluxing over lithium foil for 20 hr. The resultant liquid was colorless to pale yellow in color. The electrolyte solution was obtained by first preparing the desired solution of $LiAlCl_4$ in SO_2Cl_2 (a slight excess of the salt was necessary to compensate for a very small volume expansion upon chlorine addition). Chlorine was obtained by first condensing the Cl_2 (Matheson) gas in a liquid nitrogen/ethanol trap. The resultant liquid Cl_2 was then added to the solution with care. In contrast to the filling methods previously described (8), the D cells in the study were vacuum filled immediately upon solution preparation. The final concentrations of Cl_2 and $LiAlCl_4$ were determined by both weight gain and final volume measurements.

Practical, hermetically sealed D cells constructed from 304 stainless steel (Hudson Tool and Die Incorporated) were used throughout these experiments. The current collectors for both the anode and cathode consisted of an expanded nickel screen (Exmet Corporation) which extended the entire length of the respective electrodes. The separator material was Mead glass (6% binder, 0.013 cm thick). The lithium anode (Foote Mineral Company) was fabricated from 0.055 cm thick foil. An overlay of lithium foil was used to cover the area of the nickel screen exposed to that portion of the carbon electrode in the inner windings of the spirally wound cell components.

Two types of spirally wound D cells were fabricated for use in these studies: the first having a carbon electrode (Shawinigan black, 50% compressed) geometric surface area of 147 cm^2 (4.9 cm width × 15 cm length × 2 sides), the second having a carbon electrode geometric surface area of 294 cm^2 (4.9 cm width × 30 cm length × 2 sides). The average carbon electrode thickness for the two types were 0.30 and 0.15 cm, respectively. Cell filling was accomplished using vacuum filling techniques with especial care taken to avoid moisture contamination during filling. The typi-

Key words: electrode, cathode, capacity, discharge.

cal electrolyte fill volume was 27 cm^3 for both types of D cells. All manipulations involved with cell fabrication and filling were performed in a dry atmosphere (less than 0.5% humidity, −50°C dew point). Cells were discharged at −22° ± 2°C, −32° ± 2°C, ambient temperature (+25° ± 2°C), +76° ± 2°C, and +93° ± 2°C under constant loads. For those cells tested at the lower and higher temperatures, the loads were positioned in the ambient environment, externally to the temperature chamber. The load voltage was measured through use of a timed sequential electrometer and displayed on a recorder. D cells were stored at a constant temperature of 74° ± 2°C for periods up to 30 days. In addition, all realized capacities cited in this article were obtained to a 2V cutoff.

Three types of safety tests were performed on D cells: incineration, short circuiting, and the sequence of force discharge/charge. Cells of both the 147 and 294 cm^2 carbon electrodes were fitted with thermocouples to measure skin temperature and suspended approximately 10 cm above the surface of a naphtha reservoir. The results of the tests were monitored by either film or videotape. Cells were short circuited through a cable having a total resistance of 0.023Ω. The short-circuit current was measured using a Current Gun (F. W. Bell Incorporated, Model CG-100A) while the cell voltage and skin temperature were recorded throughout the short-circuit test. The sequence of force discharge/charge was accomplished through use of a Keithley 227 current source. Both the cell voltage and the skin temperature were measured throughout the entire test sequence.

Results and Discussion

Spirally wound D cells having carbon cathodes with a geometric surface area and thickness of 147 cm^2 and 0.30 cm, respectively, were fabricated and filled with 1M $LiAlCl_4$ in SO_2Cl_2 and 1M $LiAlCl_4$ in 0.3M Cl_2 in SO_2Cl_2. The ambient temperature discharge curves for both sets of D cells are presented in Fig. 1. Constant loads of 1.0 and 1.5Ω were employed. The realized capacities for the 1.0Ω discharge (approximately 3A) were 6.4 and 12.3 A-hr for the Li/SO_2Cl_2 and Li/0.3M Cl_2 in SO_2Cl_2 cells, respectively. At a load of 1.5Ω (approximately 2A), the realized capacities increased to 8.4 and 13.6 A-hr, for Li/SO_2Cl_2 and Li/0.3M Cl_2 in SO_2Cl_2, respectively. The corresponding average current densities for the 1.0 and 1.5Ω loads were 20.4 and 13.6 mA cm^{-2}, respectively, for the Li/0.3M Cl_2 in SO_2Cl_2 cells. It was noted that the initial load voltage for the Li/0.3M Cl_2 in SO_2Cl_2 cell discharged under a 1.0Ω load was 1.60V. The cell load voltages were measured by a sequential electrometer in conjunction with a recorder. The dwell time for any one measurement was 6 sec. The load voltage for the Li/0.3M Cl_2 in SO_2Cl_2 cell discharged under a 1.0Ω load was measured initially in this series of cells. It would be reasonable to assume that the second cell in the series (Li/0.3M Cl_2 in SO_2Cl_2 discharged under the 1.5Ω load) would also exhibit similar initial polarization. However, the recorded initial voltage for the Li/0.3M Cl_2 in the SO_2Cl_2 cell measured 6 sec after load application was 3.06V. Similar initial low load voltage levels are apparent for the Li/SO_2Cl_2 cells.

It is further evident from Fig. 1 that the effect of chlorine addition to SO_2Cl_2 increases not only the realized capacity but also the rate capability. The complete set of ambient temperature discharge curves for the Li/0.3M Cl_2 in SO_2Cl_2 D cells is presented in Fig. 2. The realized capacities for the set differ very little whether the discharge load is 1.0Ω (12.3 A-hr) or 150Ω (14.0 A-hr). A plot of realized capacity *vs.* log *I* (9) for this particular set of discharge data is presented in Fig. 3. The realized capacity is also nearly independent of the discharge load between 5.0 and 150Ω. There is, however, a slight decrease in realized capacity for the moderately high drain rates at 1.0, 1.5, and 3.0Ω.

The realized capacities obtained for Li/SO_2Cl_2 D cells discharged under 1.0, 1.5, and 3.0Ω loads were,

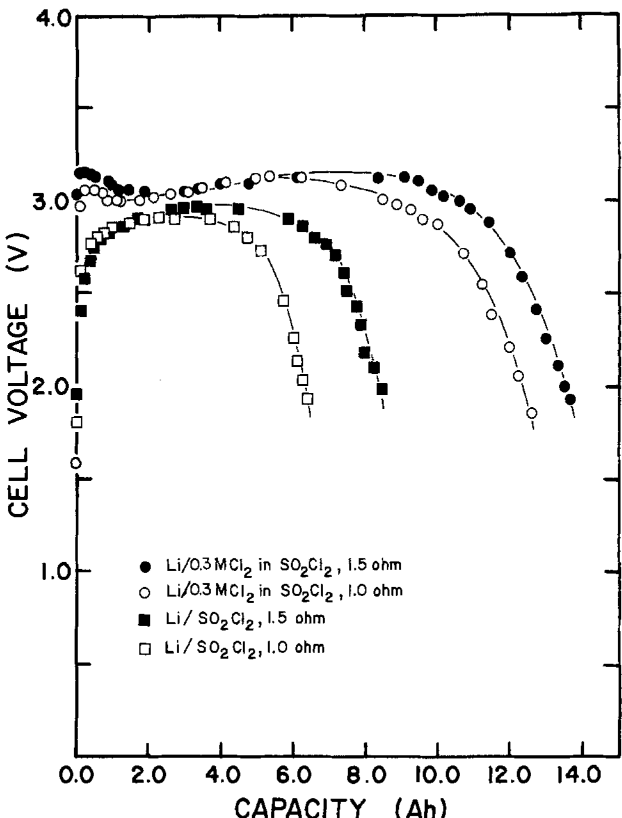

Fig. 1. Ambient temperature discharge curves of Li/SO_2Cl_2 and Li/CSC spirally wound D cells (geometric surface area: 147 cm^2).

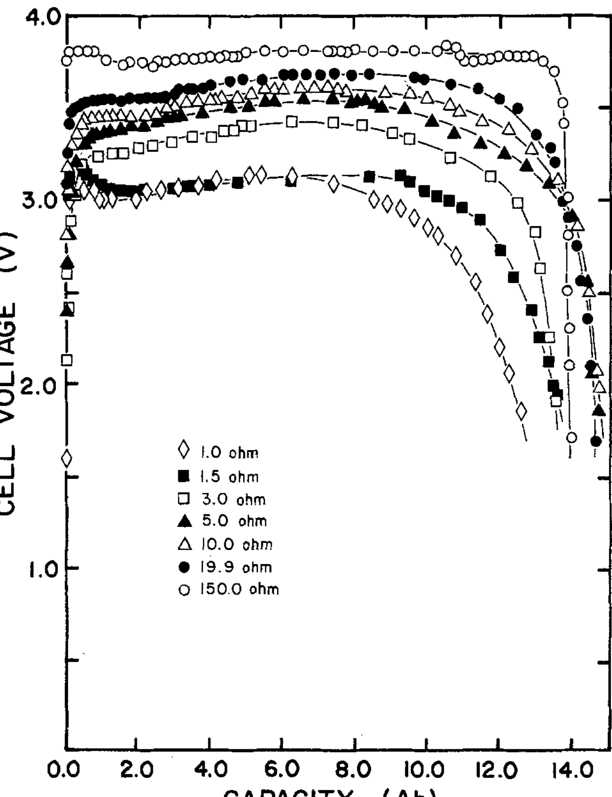

Fig. 2. Ambient temperature discharge curves of Li/0.3M CSC D cells (geometric surface area: 147 cm^2).

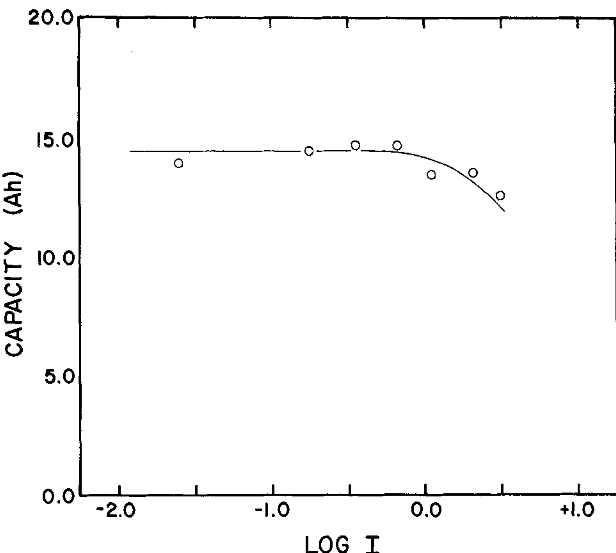

Fig. 3. Capacity vs. log I for Li/0.3M CSC D cells discharged at 25° ± 2°C.

respectively, 6.4, 8.4, and 8.9 A-hr. The capacities obtained for this system increase with decreasing discharge rates at a faster rate than those for the Li/Cl_2 in SO_2Cl_2 system. However, even at relatively low current densities of less than 1 mA cm^{-2} (8), the realized capacity was more than 15% higher for cells of the Li/CSC system than for cells of the Li/SO_2Cl_2 system. Further, the realized capacity of 12.3 A-hr for a Li/CSC D cell discharged under a 1.0Ω load represents a yield of approximately 80%, based on initial amounts of both SO_2Cl_2 and Cl_2 contained in the cell.

Investigations in our laboratory have also been concerned with studies of the effects of Cl_2 and $LiAlCl_4$ concentrations on the discharge characteristics of the Li/CSC system. Cells containing Cl_2 concentrations from 0.10 to 1.02M and salt concentrations from 1.0 to 1.5M were fabricated and discharged. It is evident that the discharge characteristics are enhanced by the addition of Cl_2 to SO_2Cl_2. However, the optimum performance is obtained from those cells which contain 0.25-0.60M Cl_2 in SO_2Cl_2. The discharge characteristics for cells with Cl_2 concentrations in this range are virtually identical. Table I shows typical discharge results for spirally wound cells containing various Cl_2 and $LiAlCl_4$ concentrations. It is apparent, especially in consideration of the data for those Cl_2 concentrations of 0.1 and 1.02M, that the results for the cell performance are less than optimal at these Cl_2 concentration extremes. It is also apparent from Table I, however, that the addition of Cl_2 at any concentration level enhances the discharge characteristics. The results for cells containing Cl_2 concentrations from 0.3 to 0.6M indicate that the Cl_2 concentration dependence is not critical, *i.e.*, the realized capacities for cells discharged at the relatively high drain rates of 1.0, 1.5, and 3.0Ω are within the experimental error of the measurement system.

The high temperature discharge characteristics for D cells have also been studied. Figures 4 and 5 show the results obtained for the Li/CSC system at 76° and 93°C, respectively. The realized capacities for these cells discharged at the elevated temperatures are only slightly less than those for cells discharged at ambient temperatures (*e.g.*, 3.0Ω constant load at 25°, 76°, and 93°C: 14.0, 12.8, and 10.7 A-hr, respectively). The load voltages, however, are higher than those at ambient temperature.

The low temperature discharge tests for cells constructed with carbon electrodes having a geometric surface area of 147 cm^2 showed a voltage delay as well as a low load voltage. For example, a load of 3.0Ω was applied to one such cell thermally equilibrated at −22°C. The voltage delay to reach a 2.5V level was about 20 min and the highest load voltage attained during the course of discharge was approximately 2.9V. In an attempt to alleviate the low load voltage and delay problems, a series of D cells were constructed with carbon electrodes having twice the geometric surface area (4.9 cm width × 30 cm length × 2 sides = 294 cm^2) and one-half the electrode thickness (0.15 cm) than those cells previously discussed. The low temperature discharge curves for these cells are presented in Fig. 6 and 7 for temperatures of −22° ± 2° and −32° ± 2°C, respectively. The realized capacities for cells discharged under a 3.0Ω load were 12.8 and 10.0 A-hr for −22° and −32°C, respectively. The corresponding load voltages, however, were 3.0 and 2.9V, respectively.

Cells comprising carbon electrodes of the greater geometric surface area were discharged at ambient temperature. The results are presented in Fig. 8. The realized capacities for these cells were between 11.8 and 13.3 A-hr when discharged under loads of 1.0 to 20.0Ω. These results represent a narrower capacity range than the realized capacity range for D cells having a carbon electrode geometric surface area of 147 cm^2 (Fig. 2). The load voltages for the cells, however, average approximately 0.2V higher than those in Fig. 2. The current densities for those cells with the larger geometric surface area are one-half that for the cells with carbon electrodes of 147 cm^2 geometric surface area, presumably the reason for the higher load voltage levels. Thus, the low temperature results for carbon electrodes of 294 cm^2 geometric surface area compare favorably to the ambient temperature results obtained for similarly constructed cells (13.2 A-hr).

Ambient temperature discharge curves for spirally wound D cells having the 147 cm^2 carbon electrodes and which were stored at 74° ± 2°C for periods as long as 30 days are shown in Fig. 9. The realized capacities obtained for the cells discharged under a 3.0Ω load were 14.4 and 13.5 A-hr for cells stored 11 and 30 days, respectively. These results compared favorably with

Table I. Realized capacities (A-hr) to a 2V cutoff for D cells having carbon electrodes of 147 cm^2 geometric surface area and containing various concentrations of Cl_2 and $LiAlCl_4$

Load (Ω)	Molar concentrations of Cl_2 and ($LiAlCl_4$)							
	0.0 (1.0)	0.1 (1.0)	0.3 (1.0)	0.4 (1.3)	0.4 (1.5)	0.5 (1.5)	0.55 (1.1)	1.02* (1.0)
1.0	6.4	6.6	12.3	11.7	12.0	11.2	10.2	11.6
1.5	8.4	10.9	13.6	12.5		13.8		11.7
3.0	8.9	13.1	13.5	14.4	14.2	14.7	14.4	12.9
5.0		14.2	14.7	14.6	14.6	14.4	14.5	13.8

20.0		14.3	14.6	14.0		14.6	14.0	13.5

* 1.02M Cl_2 represents a saturated solution of Cl_2 in SO_2Cl_2.

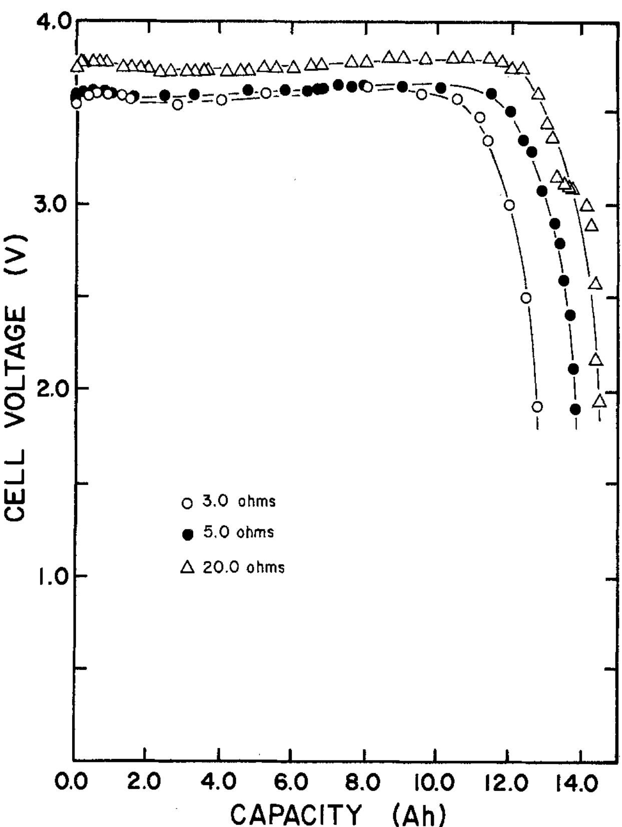

Fig. 4. High temperature (76° ± 2°C) discharge curves for D cells (geometric surface area: 147 cm^2, 0.45M Cl_2).

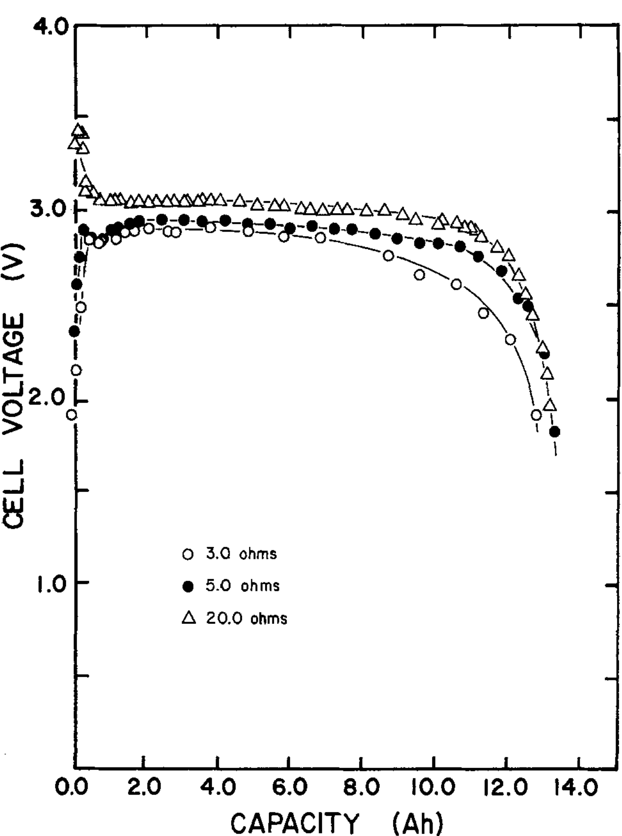

Fig. 6. Low temperature (−22° ± 2°C) discharge curves for D cells (geometric surface area: 294 cm^2, 0.44M Cl_2).

the capacity obtained for a newly fabricated cell discharged at ambient temperature (14 A-hr). The capacity results for the stored cells were well within the experimental limits for the measuring system. The load voltages of approximately 3.0V, however, were lower than the corresponding load voltages for newly fabricated cells (3.4V). Thus, storage of cells of the Li/CSC system at either ambient temperature or elevated temperatures results in decreased rate capability, but no decrease in realized capacity.

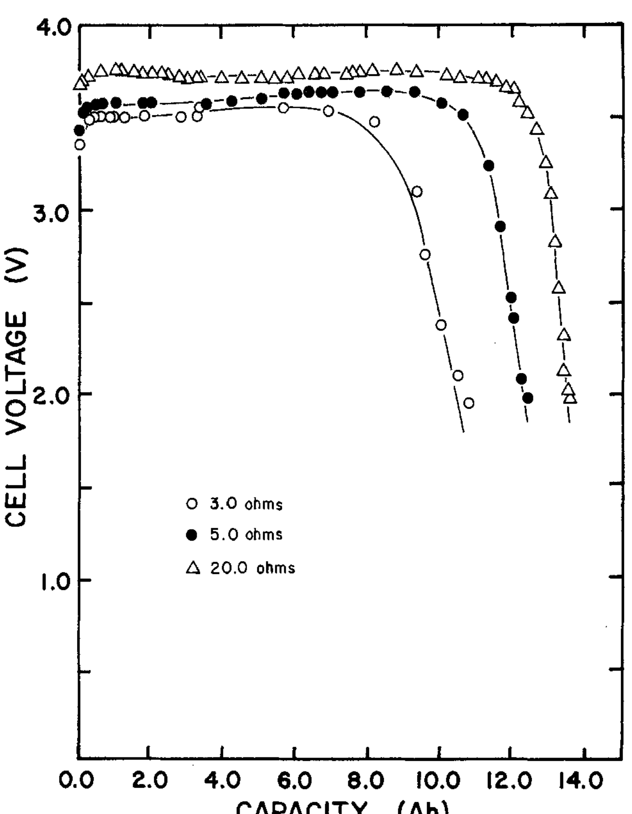

Fig. 5. High temperature (93° ± 2°C) discharge curves for D cells (geometric surface area: 147 cm^2, 0.35M Cl_2).

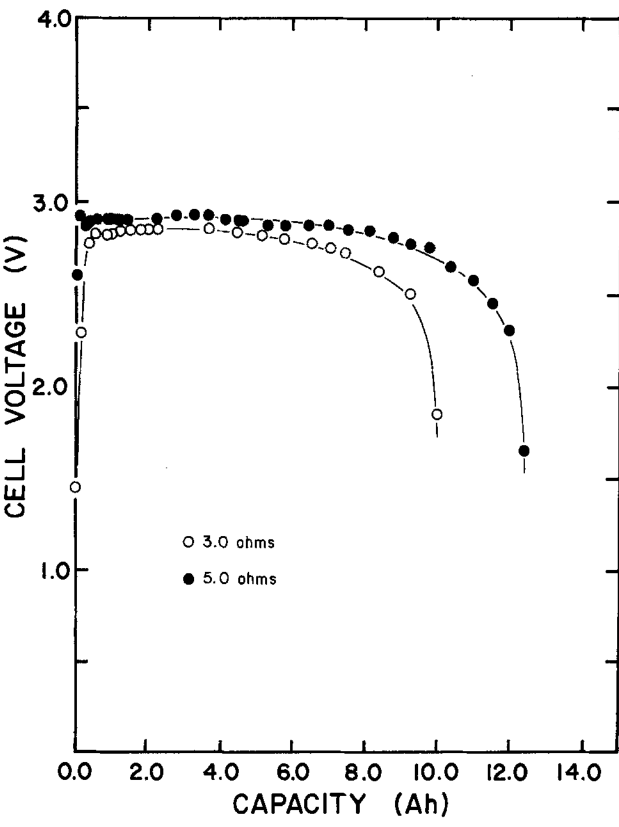

Fig. 7. Low temperature (−32° ± 2°C) discharge curves for D cells (geometric surface area: 294 cm^2, 0.45M Cl_2).

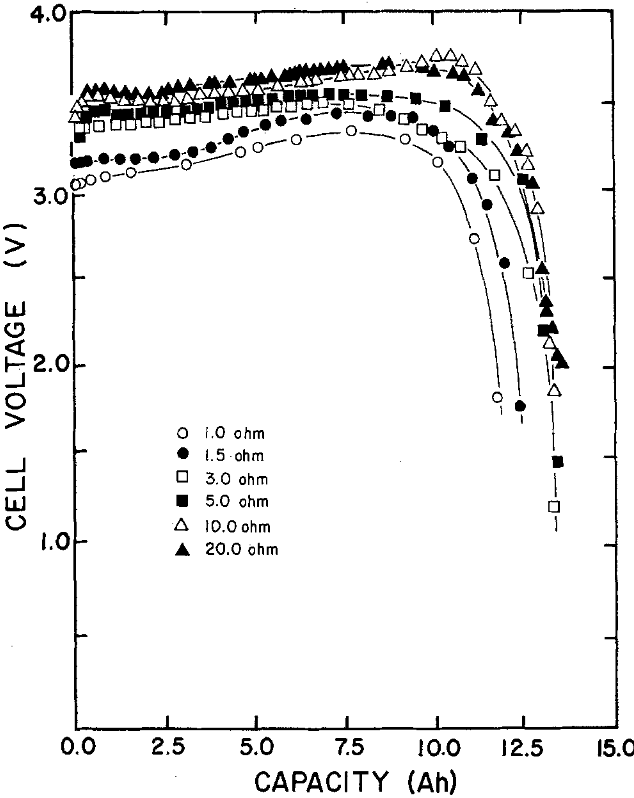

Fig. 8. Ambient temperature discharge curves of Li/0.45M CSC D cells (geometric surface area: 294 cm²).

Preliminary safety tests of D cells of the Li/CSC system indicate that the battery system in its present configurations exhibits exceptionally safe features under both normal and abusive conditions. Although containing no vent structure, Li/CSC D cells having both carbon electrodes were incinerated at 800°C in a naphtha flame for extended periods of time. The cells exhibited only mild venting through a rupture in the glass to metal seal. Indeed, depending on cell orientation above the flame, the venting gases/vapors often extinguished the flame.

Short-circuit tests were also performed on spirally wound D cells having both the low and high geometric area carbon electrodes (*i.e.* 147 and 294 cm²) at ambient temperatures. No explosion hazard was ever encountered during these tests. D cells have been force discharged and subsequently charged at a constant current of 1A. Figure 10 shows the results of one such test sequence. After a 16 hr force discharge period, the cell was charged at the 1A rate. Initially, the cell voltage remained slightly above the zero volt level. This was then followed by a rapid voltage increase to slightly greater than 4.0V. After a period of approximately 1 hr, the voltage reverted to a constant 3.85V and remained at that level for a period of approximately 20 hr. The charging mode was then interrupted, resulting in a decrease in cell voltage to approximately 3.0V. The cell was subsequently charged at a rate of 10A. After a period of 5 min in this latter mode, the cell vented mildly through the glass to metal seal. The cell skin temperature profile is analogous to the charging mode for the cell, *i.e.*, an abrupt increase in temperature immediately after onset of the 1A charging mode followed by a constant temperature plateau of 45°C for a period of 20 hr. After the 1A charging mode ceased, the temperature decreased to approximately 25°C. An abrupt rise in temperature was noted after the onset of the 10A charge. The temperature rapidly rose to 58°C whereupon the cell vented through the glass to metal seal.

At no time during any of the safety testing for spirally wound D cells did any cell explode, vent with flame, or create a hazard to personnel.

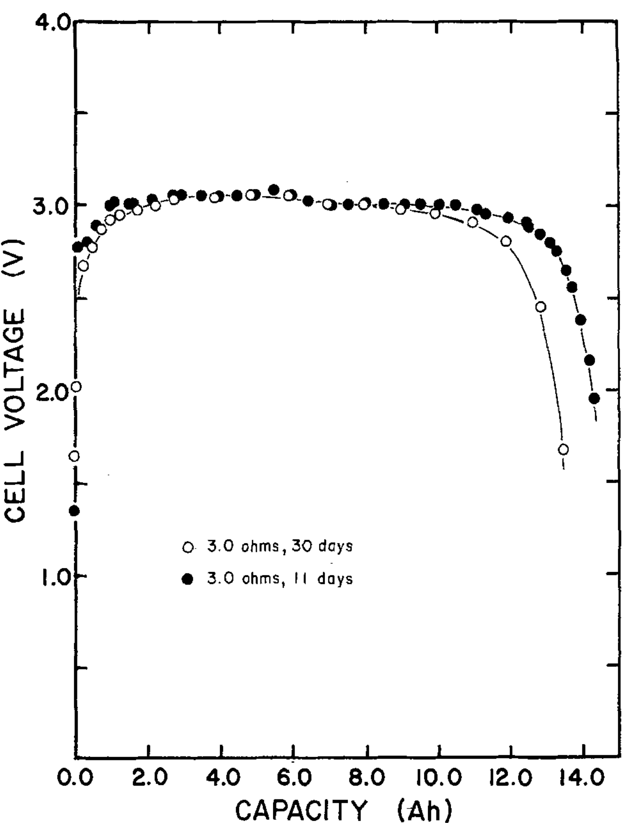

Fig. 9. Ambient temperature discharge curves for D cells after storage at 74° ± 2°C (geometric surface area: 147 cm², 0.3M Cl_2).

Conclusions

The Li/CSC system has a high current delivering capability even when spirally wound D cells comprising carbon electrodes of limited geometric surface area are discharged from ambient temperature to approximately 93°C. Furthermore, cells containing carbon electrodes of twice the geometric surface area deliver high currents at temperatures as low as −32°C. An increase in the discharge rate from less than 1 mA cm^{-2} to 21 mA cm^{-2} does not significantly affect the realized capacity. The shelf-life characteristics of the Li/CSC system indicate that little realized capacity is lost whether the cell has been stored at elevated temperatures or ambient temperature for extended periods

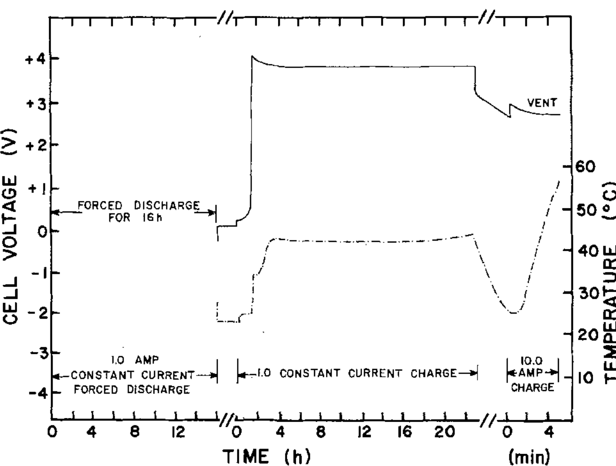

Fig. 10. Safety characterization of a D cell force discharged at 1A, charged at 1A, and finally charged at 10A (geometric surface area: 147 cm²; solid line, cell voltage; broken line, temperature).

of time. However, the load voltages and, therefore, the current capabilities are less than those for newly fabricated cells.

The safety features exhibited by the Li/CSC cells show them to represent no danger to personnel during use under both normal and abusive conditions. The mild venting observed for incineration tested cells often extinguished the naphtha flame.

These features indicate that the Li/CSC system represents a particularly safe battery for use under various high rate applications.

Electrochemical Investigation of the Lithium-Gallium System

C. John Wen*,[1] and Robert A. Huggins*

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

The thermodynamic properties of the lithium-gallium binary system have been investigated by the use of electrochemical methods, with special attention being given to the phase "LiGa." Measurements have also been made of the mass transport parameters in "LiGa," including the determination of the composition dependence of the chemical diffusion coefficient, the self-diffusion coefficient, and the enhancement factor. The data on emf *vs.* composition, obtained by use of the coulometric titration technique at 415°C, show that all three intermediate phases, whose nominal compositions are LiGa, Li_3Ga_2, and Li_2Ga, have appreciable ranges of stoichiometry. The existence of these three phases was further substantiated by x-ray diffraction analysis. At 415°C, the constant emf values in the two-phase regions are 565, 122, 91, and 20 mV with respect to pure liquid lithium, in the order of increasing lithium concentration. Measurements are reported on the temperature dependence of the most gallium-rich plateau, leading to values of the partial molar entropy and enthalpy of lithium in that two-phase region. The lithium activity has been found to follow Henry's law in liquid lithium-gallium alloys and electrochemical measurements of the temperature dependence of the solubility of lithium in liquid gallium confirmed earlier results. The activity of lithium in the vario-stoichiometric phase "LiGa" lies between 7.26×10^{-5} and 0.126 at 415°C over a composition range from 44.8 to 56.0 a/o Li. The Gibbs free energy of mixing was determined as a function of composition across the phase "LiGa," and found to have a minimum value of -25.8 kJ/mol at 47.6 a/o Li. The standard Gibbs free energy of formation of all three intermediate phases was evaluated at their nominal stoichiometric compositions; the values are -51, -115, and -62 kJ/mol, respectively. The chemical diffusion coefficient within the phase "LiGa" varies from 1.6×10^{-6} to 6.8×10^{-5} cm²/sec. On the lithium-rich side of LiGa, the chemical diffusion coefficient increases slightly with increasing lithium concentration. On the lithium-deficient side of the ideal stoichiometry, the chemical diffusion coefficient increases rapidly as lithium is deleted. After reaching a maximum value at 47.6 a/o Li, it gradually decreases again with further decrease in lithium content. The enhancement factor, which relates the chemical and self-diffusion coefficients, is also composition dependent. It reaches a maximum value of 56 at the same composition as the peak in the chemical diffusion coefficient and the minimum in the Gibbs free energy of mixing.

There is great current interest in lithium-based battery systems with molten salt electrolytes. These batteries are generally operated at temperatures of 400°-450°C. Present versions employ either lithium-aluminum (1, 2) or lithium-silicon (3-5) alloys as active constituents in their negative electrodes.

The work reported here is part of a series of investigations of the thermodynamic and kinetic properties of a number of lithium alloy systems which might be

Key words: thermodynamics, x-ray diffraction analysis, emf.

considered for use as either reactants or mixed-conducting matrices in lithium-based battery electrodes. The lithium chemical potential, and its compositional dependence, determine the potential and the capacity of electrode reactants. The fundamental parameter related to their kinetic behavior is the chemical diffusion coefficient, which controls the rate of compositional equilibration within the solid constituents of the electrode structure.

The phase designated as "LiGa," which is analogous to the important phase "LiAl" in the lithium-aluminum system, was first reported by Zintl and Brauer (6) to have the cubic NaTl (B32) type structure with a lattice parameter $a = 6.207$Å. Thummel and Klemm investigated the binary system of lithium-gallium by thermal analysis (7). They found the phase "LiGa" to exist over a wide composition range from 46 to 54 atomic percent (a/o) Li. The lattice parameter was shown to have a linear dependence upon the mol fraction of lithium in this phase. The phases Li_3Ga_2 and Li_2Ga (or Li_9Ga_4) have been reported to form by peritectic reactions. Yatsenko and co-workers (8) proposed a phase diagram for the lithium-gallium system which contains five intermediate phases, with LiGa melting congruently at 740°C. $LiGa_4$, $LiGa_2$, and Li_2Ga were indicated to decompose peritectically at the respective temperatures 290°, 365°, and 510°C, and Li_3Ga_2 to decompose peritectoidally at 480°C. The crystal structures of the phases Li_3Ga_2 and Li_2Ga have been determined by Muller and Stohr (9).

Yatsenko *et al.* (10) determined the thermodynamic properties of molten lithium-gallium alloys from emf measurements at 750°C. The partial and excess partial molar Gibbs free energies and enthalpies of mixing are negative. The integral molar Gibbs free energies, enthalpies, and entropies of mixing are also negative. Their maximum values occur close to the equiatomic composition. Schneider and Hilmer (11) used drop calorimetry to determine the enthalpy and entropy of fusion for nominal stoichiometric LiGa, with melting apparently occurring over a range of temperature, being complete at 760°C. The data indicate that the heat capacity at constant pressure is 12.9 cal/deg-mol for the solid in the temperature range 550°-700°C and 9.1 cal/deg-mol for the liquid in the temperature range 760°-820°C.

No data appear in the literature on the thermodynamic properties of the intermediate phases in the lithium-gallium system. An NMR study (12) on LiGa at or near the stoichiometric composition showed indications that the diffusive motion of lithium in that phase is extremely fast, and the activation energy was estimated to be 0.15 eV. However, the value of the self-diffusion coefficient of lithium in LiGa was not given.

Experimental Procedures

The coulometric titrations, emf, and chemical diffusion measurements were all made using the following three-electrode galvanic cell

$$\text{Al, "LiAl"} \,|\, \text{LiCl-KCl(eut.)} \,|\, Li_yGa \qquad [I]$$

In the above cell, Li_yGa is the lithium-gallium alloy under investigation. The LiCl-KCl eutectic molten salt was used as electrolyte. The reference and counter-electrodes, Al/"LiAl," were made of two-phase mixtures of lithium-aluminum with an overall composition of 40 a/o Li. A similar experimental setup has been described in more detail elsewhere (13-18). The emf *vs.* composition data were obtained by direct coulometric titration of lithium into pure liquid gallium, which was held in a molybdenum bucket within the salt. The electrochemical measurements were made by using either a PAR 173 potentiostat/galvanostat with a plug-in coulometer or an Aardvark PEC-1 potentiostat with a free-standing PAR 379 digital coulometer. The temperature was measured by Chromel-Alumel thermocouples sheathed with 304 stainless steel, and maintained constant within one or two degrees.

Cold-pressed and sintered pellets were used in diffusion measurements. The single-phase stoichiometric LiGa alloys were prepared by melting the lithium (99.9%, Foote Mineral) and gallium (99.9999%, United Mineral and Chemicals) metals together in the stoichiometric proportion in an Mo cup at a temperature about 750°C for approximately 10 min. The alloys were then annealed at 450°C for 66 hr in order to promote homogenization. After annealing, the cast alloy was cooled to room temperature in several hours. The solid alloys were powdered and sieved to 150 mesh. The alloy powder was pressed into pellets at a pressure about 9.0×10^4 psi. Because the "LiGa" phase is very hard and brittle, pressed pellets often partially collapsed when they were removed from a ⅜ in. stainless steel die. However, if extreme care was taken to handle the pellets properly, it was possible to obtain one or two intact pellets on about 20% of the trials. The surviving pellets were sintered at 705°C for about 5 min, after which they showed much better mechanical strength and physical integrity.

A ring of thin molybdenum sheet was tightened around the circumference of the thin pellets, and used as both sample holder and electrical lead. This shielded the edge, but permitted diffusion into the pellet from both flat sides. The LiGa pellet was first slowly preheated to drive off any residual gas before it was inserted into the molten salt electrolyte for diffusion measurements. After the sample electrode reached a steady state, the open-circuit voltage was measured with respect to the Al, "LiAl" reference electrode, a small voltage step of 4-8 mV was then imposed between the sample electrode and the reference electrode. The transient current, $I(t)$, was monitored as a function of time, t, until it became negligibly small. Another voltage step was then imposed to repeat the diffusion measurements. After each voltage step the chemical diffusion coefficient, $\tilde{D}$, was evaluated from the long-time expression for a potentiostatic experiment as follows (13)

$$I(t) = \frac{2Q\tilde{D}}{L^2} \exp\left(-\frac{\pi^2 \tilde{D} t}{4L^2}\right) \quad \text{if} \quad t >> L^2/\tilde{D} \qquad [1]$$

where L and Q were the half-thickness of the sample pellet and the total charge accumulated after a given voltage step. Since the current was controlled by the diffusion of lithium into the solid (from both flat sides), rather than transport through the liquid electrolyte, the current distribution within the electrolyte was of no consequence. While the samples may have not achieved 100% density during the sintering step, this question has relatively little influence upon the results obtained from this long-time solution to the diffusion equations.

The single-phase alloys used for x-ray diffraction analysis were made electrochemically by applying constant voltages determined from the coulometric titration curve to ensure that they were at the desired single-phase compositions. Upon removal from the cell, the alloys were allowed to rapidly cool to room temperature. They were then crushed and sieved to fine powder (150 mesh). The resulting powder was uniformly spread over double-stick Scotch tape (3M) using a glass slide as a support. A thin Kapton film was used to protect the powder from the ambient atmosphere. The x-ray diffraction analysis was accomplished using a Norelco diffractometer employing Cu Kα radiation and an Ni filter. LiCl and KCl salts were used as internal standards. The integrated intensity for each peak was estimated from the area under the diffraction curve above the background.

Results

The coulometric titration curve for the lithium-gallium system at 415°C, starting with pure molten gallium, is shown in Fig. 1. The emf with respect to pure lithium, E, at a given temperature, T (K), was calculated according to the expression (1, 13, 17)

$$E = E_{\text{meas}} + (451 - 0.220\,T(\text{K}))\,\text{mV} \qquad [2]$$

where E_{meas} represented the directly measured cell emf with respect to the two-phase Al, "LiAl" reference electrode. Figure 1 shows three intermediate phases and four two-phase voltage plateaus from pure Ga to a composition of 75 a/o Li. The nominal compositions of the three intermediate phases are LiGa, Li_3Ga_2, and Li_2Ga, respectively. The constant emf values in the two-phase regions are 565, 122, 91, and 20 mV relative to pure lithium at 415°C, in order of increasing lithium concentration. The corresponding lithium activities are 7.26×10^{-5}, 0.126, 0.215, and 0.967, respectively.

As shown in Fig. 1, all three intermediate phases have appreciable ranges of stoichiometry. The x-ray powder diffraction pattern of the phase LiGa was found to possess the NaTl (B32) structure, as reported by Zintl and Brauer (6). The lattice parameter was found to be 6.213Å at the ideal stoichiometric composition by a least square fit to the Nelson-Riley extrapolation function.

In 1977, Muller and Stohr (9) determined the crystal structures for the phases Li_3Ga_2 and Li_2Ga, but they gave no detailed information about their x-ray diffraction patterns. The x-ray powder diffraction patterns obtained in this work for these phases are given in Tables I and II. The phase Li_3Ga_2, which is isotypic with the phase Li_3Al_2 in the lithium-aluminum system (19), crystallizes with a rhombohedral unit cell, space group R3m-D_{3d}^5, $a = 4.367$Å, $c = 13.896$Å, $Z = 3$ formula units (hexagonal setting), with the Ga atoms forming layers of puckered six-membered rings (9). In Table I, the x-ray powder diffraction pattern of the phase Li_3Ga_2 was indexed on the basis of both rhombohedral ($a = 5.274$Å and $\alpha = 48.916°$) and hexagonal axes. Two extraneous lines with interplanar spacings (d values) of 3.576 and 2.718Å having relatively low intensities were found which could not be indexed with the others. Li_2Ga crystallizes orthorhombically, space group Cmcm-D_{2h}^{17}, $a = 4.562$Å, $b = 9.542$Å, $c = 4.364$Å, and $Z = 4$ formula units. In this structure, the Ga sublattice consists of zigzag chains (9). The x-ray powder diffraction pattern for this phase, given in Table II, produced interplanar spacings in excellent agreement with those calculated using the lattice parameters given above and the assigned Miller indexes.

For compositions less than about 8.3 a/o Li, the lithium activity in liquid lithium-gallium alloys was found to obey Henry's law, *i.e.*

$$-\mathbf{F}E = RT \ln a_{\text{Li}} = RT \ln \gamma_{\text{Li}} X_{\text{Li}} \qquad [3]$$

where $\mathbf{F}$, R, γ_{Li}, and X_{Li} are the Faraday constant, the gas constant, the activity coefficient of lithium, and the mol fraction of lithium, respectively. As shown in Fig. 2, the emf with respect to pure lithium, E, is a linear function of $\ln X_{\text{Li}}$. The slope $dE/d \ln X_{\text{Li}}$ is -5.93×10^{-2}V, which is identical to the value of $(-RT/\mathbf{F})$ at the temperature of 688 K. The activity coefficient of lithium in molten lithium-gallium at that temperature is thus 4.49×10^{-4}. The lithium activities in liquid alloys of lithium-cadmium (20),

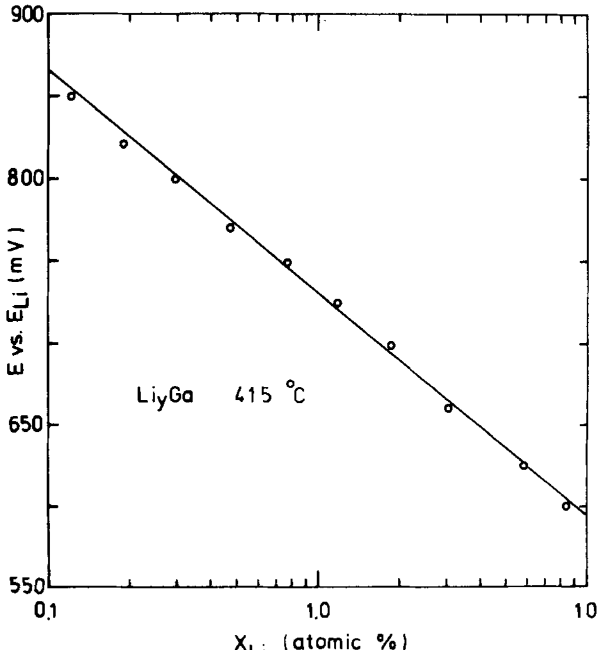

Fig. 2. Semi-logarithmic plot of the emf *vs.* mol fraction of lithium at 415°C.

lithium-indium (21), lithium-tin (22), lithium-lead (23), and lithium-bismuth (24) systems have also been found to obey Henry's law at low lithium concentrations.

Figure 3 presents the temperature variation of the emf of the two-phase system consisting of the saturated liquid alloy of lithium in gallium and the variostoichiometric intermediate phase "LiGa" at an overall composition of 40 a/o Li. Over the temperature range from 380° to 575°C, the emf of this liquid-solid mixture shows a linear dependence upon temperature, which can be expressed as

$$E = 929 - 0.532\,T(\mathrm{K})\ \mathrm{mV} \qquad [4]$$

The corresponding partial molar entropy and enthalpy of lithium in this two-phase region are −51.3 J/deg-mol and −89.6 kJ/mol, respectively.

The temperature dependences of these two-phase boundaries were investigated by use of the coulometric titration technique. The solubility of lithium in liquid gallium was found to be 10.0, 12.6, 18.2, and 26.1 a/o Li at 390°, 415°, 500°, and 585°C, respectively. These results are in close agreement with those reported in the literature (7). The gallium-rich phase boundary of the phase "LiGa" was observed to be essentially constant (44.8 a/o Li) over the temperature range of 390°-585°C. No effort was made to determine the lithium-rich phase boundary of "LiGa" because of a slow voltage drift with time at high lithium activities, due to electronic conduction in the electrolyte.

Figure 4 shows the detailed results obtained on the coulometric titration curve of the phase "LiGa." The emf *vs.* composition data can be approximated by two straight lines with different slopes. However, the change in slope does not occur at the ideal stoichiometry. The experimental data showed excellent agreement and reproducibility. This is illustrated by the correspondence of the data from three runs, as denoted by the different symbols in Fig. 4. At 415°C, the emf of the phase "LiGa" lies between 565 and 122 mV with respect to pure lithium and the lithium activity varies by more than three orders of magnitude over the composition range from 44.8 to 56.0 a/o Li.

The Gibbs free energy of mixing, ΔG_m, was calculated across this phase by graphical integration of the coulometric titration curve given in Fig. 1 using the expression (17, 18)

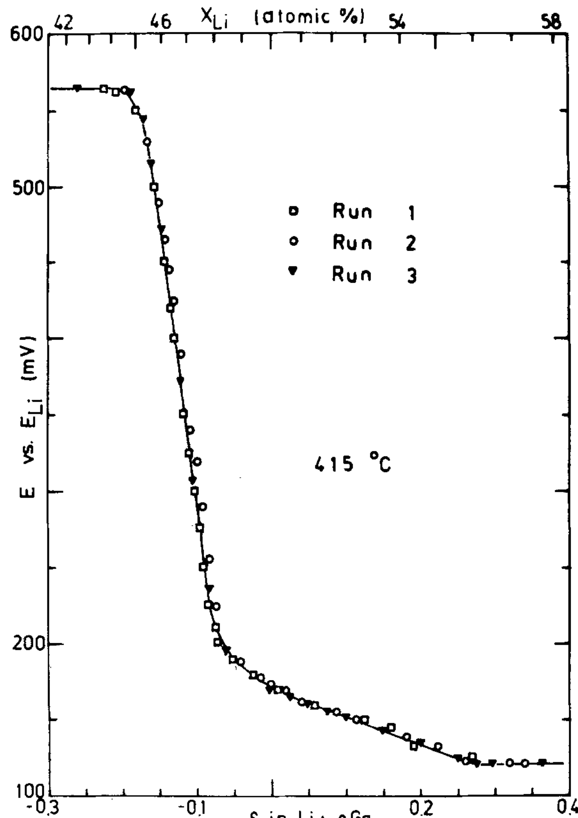

Fig. 4. Coulometric titration curve of the phase "LiGa;" three runs at 415°C.

$$\Delta G_m = -\frac{F}{1+y}\int_0^y E\,dy \qquad [5]$$

where y is the atomic ratio of lithium to gallium. The results are presented in Fig. 5, where it is seen that the Gibbs free energy of mixing shows a minimum of −25.8 kJ/mol at 47.6 a/o Li.

The standard Gibbs free energy of formation, ΔG_f, was evaluated according to the following expression

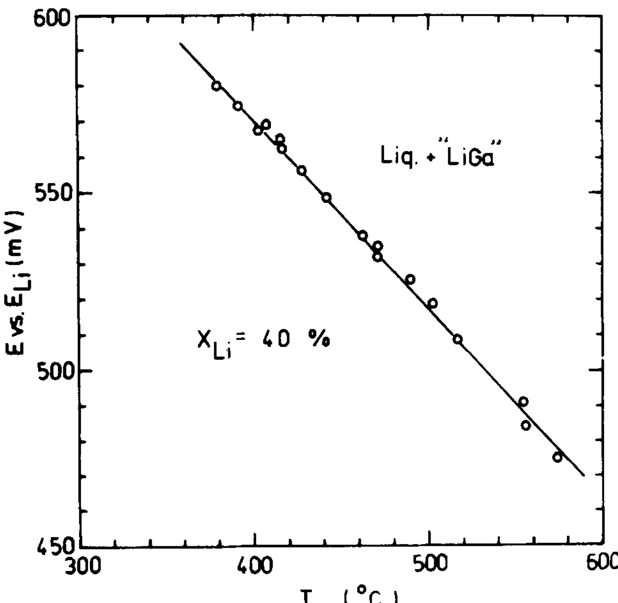

Fig. 3. Temperature dependence of the emf of two-phase lithium-gallium alloy with overall composition of 40 a/o Li.

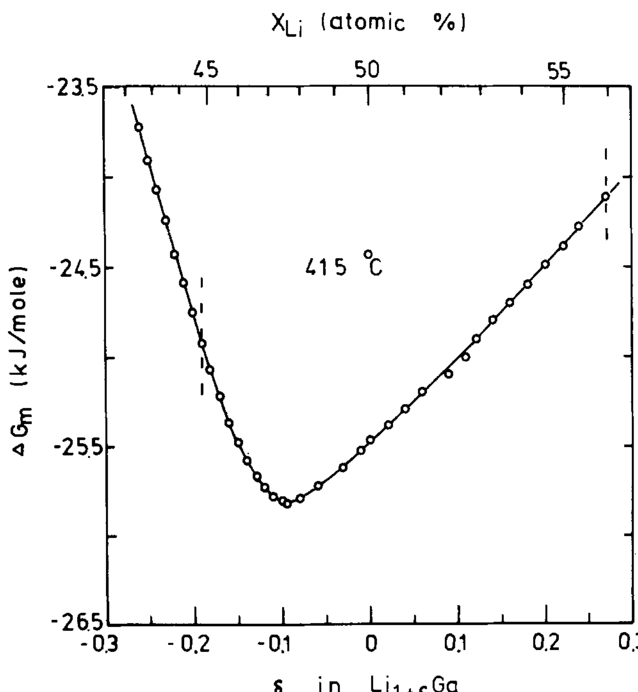

Fig. 5. Compositional dependence of Gibbs free energy of mixing over the compositional range of the phase "LiGa" at 415°C.

(17, 18)

$$\Delta G_f\ (\mathrm{Li}_a\mathrm{Ga}_b) = -b\mathbf{F}\int_0^y E dy \qquad [6]$$

where $y = a/b$. The values for the stoichiometric compositions within the phases LiGa, Li_3Ga_2, and Li_2Ga at 415°C are −51, −115, and −62 kJ/mol, respectively. The corresponding formation reaction can be described as

$$a\,\mathrm{Li}(l) + b\,\mathrm{Ga}(l) \rightarrow \mathrm{Li}_a\mathrm{Ga}_b(s) \qquad [7]$$

The chemical diffusion coefficient was determined as a function of composition within the phase "LiGa." The results are plotted in Fig. 6. It can be seen to vary from 1.6×10^{-6} to 6.8×10^{-5} cm²/sec, with a maximum value at the composition 47.6 a/o Li. On the lithium excess side of LiGa, the chemical diffusion coefficient increases only slightly with increasing lithium concentration. On the lithium deficit side of LiGa, however, it is very composition dependent, increasing rapidly with a small lithium deficiency, but again decreasing in value at greater lithium deficits after a maximum at 47.6 a/o Li.

The chemical diffusion coefficient, $\tilde{D}$, which concerns mass transport under the influence of a chemical potential gradient, is related to the lithium self-diffusion coefficient, D_{Li}, which describes the random motion of the lithium atoms or ions in the absence of a chemical concentration gradient, by the following expression (15, 25)

$$\tilde{D} = D_{Li}\left(\frac{d \ln a_{Li}}{d \ln (1+\delta)}\right) \qquad [8]$$

where δ represents the deviation from the ideal stoichiometry of the phase "LiGa." The above expression is valid only for the case that the gallium atoms (or ions) do not move appreciably compared with the lithium atoms (or ions). An NMR study of LiGa supports this approximation (12)

The quantity in the bracket on the right-hand side of Eq. [8], the enhancement factor, often assumes values greater than unity for alloy phases exhibiting nonideal thermodynamic behavior. Its magnitude was calculated as a function of composition by using the emf *vs.* composition data as follows

$$\frac{d \ln a_{Li}}{d \ln (1+\delta)} = -\frac{\mathbf{F}}{RT}(1+\delta)\frac{dE}{d\delta} \qquad [9]$$

where $dE/d\delta$ denotes the local slope of the coulometric titration curve at a given composition. The calculated results are shown in Fig. 7. On the lithium excess side of LiGa, the enhancement factor increases slightly with lithium concentration. However, it increases rapidly with decreasing lithium concentration on the lithium-deficient side, reaching a maximum value of 56 at 47.6 a/o Li. It then decreases again as the composition moves toward the gallium-rich phase boundary. As shown in Fig. 6 and 7, the compositional dependence of the chemical diffusion coefficient within the phase "LiGa" is quite similar to that of the enhancement factor, and they both peak at the composition corresponding to the minimum Gibbs free energy of mixing, *i.e.*, 47.6 a/o Li.

Figure 8 shows the compositional variation of the lithium self-diffusion coefficient at 415°C. For compositions greater than 48.0 a/o Li or less than about 47.6 a/o Li, this parameter was found to be independent of composition. The constant values are 1.1×10^{-6} and 5.0×10^{-7} cm²/sec on the lithium deficit and excess sides of LiGa, respectively.

Discussion

The work reported here is an example of the great power of electrochemical techniques for the quantitative determination of a host of both thermodynamic and kinetic data in alloy systems. Of special value is the ability to readily evaluate fundamental param-

eters which would be of importance in the application of such materials in electrochemical systems, such as primary or secondary batteries.

Questions such as the ranges of electrochemical stability of intermediate phases and the potentials and capacities of two-phase equilibria that might be used as ion reservoirs will play a critical role in the design of new electrode systems. While not specifically employing the results of this study of the lithium-gallium system, this approach has recently been used to design novel all-solid electrodes with composite microstructures containing a finely dispersed reactant imbedded in a stable mixed-conducting matrix with a high chemical diffusion coefficient for the electroactive species (26). Although they are fully solid, such electrodes can have the kinetic properties of conventional finely divided powders.

ABSTRACT

Three antimonial lead alloys have been continuously cast followed by rolling and expansion to standard battery grid designs. Cells were constructed and cycled to failure in a deep discharge regime. Cells of cast grids were similarly tested for comparison. In these tests the wrought grid cells failed prior to the cast due to excessive grid growth. Possible means to overcome the grid growth are discussed.

In recent years there have been many papers published concerned with the metallurgy and electrochemistry of cast low antimony lead alloys for use in low maintenance auto batteries (1-4). Similarly there has been much work published on the metallurgy, electrochemistry, and manufacture of calcium lead alloy battery grids for the same market. These latter papers encompass a good deal of work on the continuous production of wrought calcium-lead grids (5, 6). There has not as yet been work published combining the advantages of deep discharge behavior of antimonial lead alloys, with the economic advantage

* Electrochemical Society Active Member.

Key words: cast grids, grid growth, cell failure.

of continuous wrought grid manufacture for the mass production of grids for electric vehicle or load leveling batteries.

Many characteristics of batteries constructed of wrought grids are yet to be determined. While it is well known (7) that in battery service cast antimonial lead has the disadvantage of low hydrogen overvoltage as compared to calcium lead, electrochemical characteristics of wrought *vs.* cast antimonial leads have not been reported upon. Further, the creep resistance of wrought antimonial lead is known to be significantly less than that of the cast alloys. The effect this may have on battery life is unknown. Another factor of importance which may be affected by the metal structure is the corrosion rate under deep discharge cycling. Grid growth is another area which could affect battery life and which very likely depends on the metallurgical condition of the grid metal.

In order to test the feasibility of wrought grid, deep discharge, antimonial lead batteries, test cells were constructed using wrought grids of antimonial lead at three concentrations. These cells were cycled to failure in a severe deep discharge (75%) regime along with a set of cast grid cells as controls. The results proved the cast grid cells to be clearly superior to any of the wrought grid cells. There were, however, indications that wrought grids can be made to perform by adjustments to the design and metallurgical structure of the grids.

Materials and Fabrication

Wrought grids.—As a first step it was necessary to determine whether or not antimonial leads could be continuously cast. Casting was carried out at the Hazelett Strip Casting Corporation, Malletts Bay, Vermont, on a Model 21 machine. Four compositions were chosen all of which cast without mishap. The actual compositions are shown in Table I. Nominal arsenic and tin levels were supposed to be 0.5% as in some common cast grid alloys.

The alloys were cast continuously into strips 3.3 in. wide × 0.75 in. thick at a rate of about 20 ft/min. The melt temperature was held within the range 340°-370°C, and the casting emerged from the machine at about 180°C.

For each alloy starting with alloy A (1% Sb) about 1960# of metal was charged to the melting pot. Of that 1960# about 60% was cast producing a strip roughly 90 ft long. The middle 30 ft was retained for the project and the two remaining sections were returned to the pot for the following castings. Antimony, arsenic, and tin additions were made as hardener alloys. Unfortunately, the presence of high As and Sn in the addition ingots caused excesses of these elements in the product alloys.

The surfaces of the cast strips were generally smooth and uniform. Grain size of the castings decreased as alloy content increased. Some centerline shrinkage was apparent in each alloy, especially alloy D, see Fig. 1.

Rolling of the alloys was done on a 2-high laboratory mill using 4 in. diam rolls, 6 in. wide. The cast strip was cut to 6 in. lengths and rolled in a direction parallel to the casting direction. Each pass reduced the thickness by 0.08 in. to a thickness 0.1 in. From 0.1 in. to the final size 0.045 in. reductions were limited to 0.020 in. per pass. Alloys A and B rolled to final size without problems. Alloy D could not be rolled more than 3 passes, about 33% reduction in thickness, without separating through the wide centerline, a phenomenon known as "alligatoring." Alloy C required an intermediate anneal (150°C-1 hr-air cool) at about 60% reduction to prevent alligatoring. Strip of alloy D was finally produced by hot rolling at 150°C. Some edge cracking was noted on alloys C and D. Tensile strength of the strips measured one day after rolling are recorded in Table II.

Coils of strip (alloys A-D) rolled to 0.045 in. were shipped for expansion to a battery manufacturer presently producing expanded metal grids. This expander was unable to treat the metal supplied efficiently due to excessive camber in the coils. Insufficient high quality material was returned to allow a valid series of tests. It was made clear, however, that of the alloys supplied, alloy D was the most difficult to expand, excessive cracking being encountered.

Rolling technique was improved and fresh coils shipped to two other grid metal expanders. Expander I was shipped alloys A, B, C, and D while Expander II was shipped only alloys A, B, and C. Difficulty was reported by Expander I in expanding alloys C and D due to edge cracks in the rolled strip. Expander II could not expand alloy A due to excessive limpness (low strength).

Expander I provided grids of alloys A and B cut to shape ready for pasting. Expander II supplied strips of expanded alloys B and C about a yard long from which grids had to be cut by hand.

Cast grids.—Control cells were to be constructed of grids of moderate to low antimony content with weights and size similar to those of the wrought grids. Analyses of the cast grids obtained are included in Table I. A photograph of the cast and wrought grids is shown in Fig. 2.

Cell fabrication.—In all, five different grid types were tested: the cast, Expander I alloys A and B, and Expander II alloys B and C. Three cells were constructed of each grid type totaling 15 cells. Variations in the grid physical dimensions were dictated by the manufacturing equipment and were thus unavoidable. Overall dimensions of the grids prior to pasting are summarized in Table III. Note in column five of Table III, Approximate metal thickness, that the variation represents variation in setting on the expander rather than in the metal supplied which was 0.043 ± 0.002 in. Also note in column six of the same table that the overall thickness of the wrought grids reflects a degree of corrugation not present in cast grids.

Pasting of the grids was done using a conventional high density formula. Efforts were made to keep the paste weight per unit area of positive plate constant regardless of grid type. As the grids were inescapably of different sizes it was desired to keep the paste thickness the same in all 15 cells in order to make comparison more meaningful. Since the positive plate capacity was intentionally limiting in all cells, care was taken to obtain the same total weight of positive active material in each of the three cells of a test group. This was done by weighing all of the pasted

Table I. Alloy composition

	Sb (w/o)	As (w/o)	Sn (w/o)

plates and then sorting them into groups of similar aggregate weight. There were no side frames on the expanded metal grids, thus extreme care to avoid losing paste pellets along the side of the pasted plates was required. Such losses could account for a significant proportion of the total active material. Table IV contains data on the weight of active material in the cells.

The cells were constructed using, as far as was possible, methods and procedures similar to those employed in commercial battery fabrication.

Commercially available golf cart separators (Grace Armor-rib with 0.020 glass mat) were used. The cells were formed conventionally using constant current formation and an electrolyte of 1.110 sp gr After formation the cells were dumped and refilled with 1.320 sp gr acid, adjusting them individually to a final range of 1.265-1.275.

Cell testing.—Prior to the beginning of the automatic cycling manual cycles were run on each cell to determine initial cell capacities. Discharges were run at rates of 1.5, 8, 10, and 14A. The results agreed well with one another and with the theoretical capacity of the cells. Averaged data for the 1.5 and 10A tests are presented in Table V.

Using the capacity information obtained from the manual cycling, the automatic cycle apparatus was set to provide a 2 hr discharge followed by a 9.5 hr

Table III. Grid parameters

Alloy	Nominal % Sb	Grid rectangle size (in.)	Active area** (sq-in.)	Approx. metal thickness (in.)	Approx. overall thickness (in.)	Average grid weight (g)
Cast (control)	2.75	5.69w × 3.91h	21	—	0.043	42.2
I-A	1.0	5.69 × 4.12	21	0.045	0.11	51.0

charge twice each day. As the discharge time was the same for each cell but capacity varied (mainly due to plate size), it was necessary to vary discharge current load to yield the desired 75% depth of discharge for every cell.

The cells were charged for 9.5 hr through current limiting resistors from a regulated 2.6V bus. The current was limited to the 2 hr rate at the beginning of charge. Following charge there was a one-half hour rest.

Discharge was carried out so as to yield 75% depth after 2 hr. As the cells progressed toward the end of life the voltage dropped below 1.75V before the end of the 2 hr discharge period. In that case an automatic cell cut-off circuit terminated the discharge at 1.75V in order to avoid an unrealistically deep

* Theoretical capacities are based on total positive active material in cell. Paste formula yields 179.7 A-hr/kg of cured paste.

cycle. Failure was defined to have occurred when cell capacity fell below 50% of the capacity of the 10th cycle. Base capacity was defined as the 10th cycle value in order to avoid initial transients. The cells were individually taken off test after failure.

Cells were cycled at room temperature, separated from each other so as to minimize heating effects.

Cell dismantling.—After failure by the 50% capacity criterion the cells were fully charged and then carefully dismantled.

The positive plates were washed thoroughly in water and dried at room temperature. During handling some loss of active material pellets was experienced in the expanded metal plates. Tabs were removed from all plates after which they were weighed and measured. All weights reported in the tables are without tabs.

A representative set of positive plates from each of the five test groupings was chemically treated to remove all of the lead dioxide from the grids. The bare grids were then re-weighed.

Sections of the corroded grids were examined metallographically and compared. Photographs of samples taken from the center of typical plates are shown in Fig. 3-5.

Results

Cycles to failure, water required over life, active material loss, grid weight loss, and percent grid growth for each cell are presented in Table VI. The data are averaged per 100 cycles of life for each alloy

group in Table VII in order to obtain values directly related to rate of deterioration.

Discussion

From the data of Tables VI and VII it is clear that under the test conditions reported the cells made of cast grids out-performed the wrought grid cells. However, some interesting lessons can be learned by examining the data which may make future wrought low antimony lead grids more competitive.

First, the cycle life data of Table VI show that the greatest disparity in behavior lies between the wrought grids taken as a group and the cast grids rather than between alloy content groups or expander groups. Within the wrought grid groupings design variation seems overriding. For example, cells of group II-B performed significantly better than those in group I-B although the alloys were identical and the test conditions, other than cell size, similar. It seems unlikely that size difference could account for the variation in cycle life, considering the controls on each cell described above.

Water loss, although varying considerably cell to cell was on average (Table VII) consistently in the range 58-68 ml/100 cycles. The only exceptions were the cells made of the lowest antimony content grids (1% Sb), group I-A. These cells used water at the rate of only 16 ml/100 cycles. Clearly there is an advantage in reduced maintenance to the very low antimony level. This reduction in water loss is unexpected considering the paper of Ruetschi and Cahan (8) who reported a less than expected rate of decline in hydrogen overvoltage with increasing antimony (1-5%) in cast antimonial leads.

Active material loss was much greater in the wrought grid cells than in the cast even though the cast grid cells experienced a substantially greater number of cycles. Two possible reasons are proposed. First, it is possible that for some reason the well documented (9) paste adhesion of cast antimonial lead grids does not operate for wrought grids

Table VI. Results of cycling

Cell No.	Cycles to failure	Water added over life (ml)	Positive active material loss (%)	Grid weight loss (%)	% Grid growth width	% Grid growth height
1	305	275	39	41	0	1.0
2	245	153	27	22	0	0.5
3	242	120	37	20	0	0.5

II-C	187	60	20	16	1.7	3.4

of essentially the same composition. Second, it is possible that the larger pellet sizes of the wrought grids (Fig. 2) leads to reduced grid-active material interfacial area which together with increased grid growth brings on decohesion and loss of active material. While it is not possible in this work to tell which possibility is correct it seems likely that the wrought condition of the grids would not substantially change the mechanism by which antimony promotes adherence. Thus active material loss through reduced surface contact and increased grid growth seems more probable. The relationship between grid growth and active material loss has been confirmed in the literature (10, 11). Also scanning electron microscope examination of the active material from failed plates shows the structure of the oxides to be quite similar in the cast and wrought cells, see Fig. 6a and b. The relation between grid composition, oxide morphology, and paste adherence has been discussed by Burbank (9).

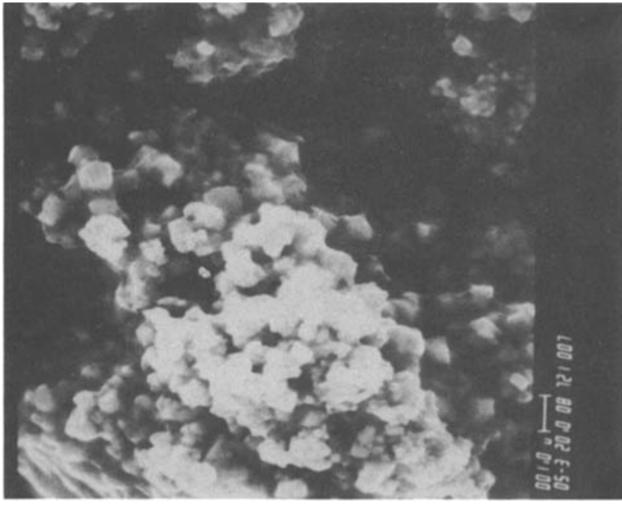

Fig. 6a. SEM image of active material from cell No. 2 after failure. 5000×.

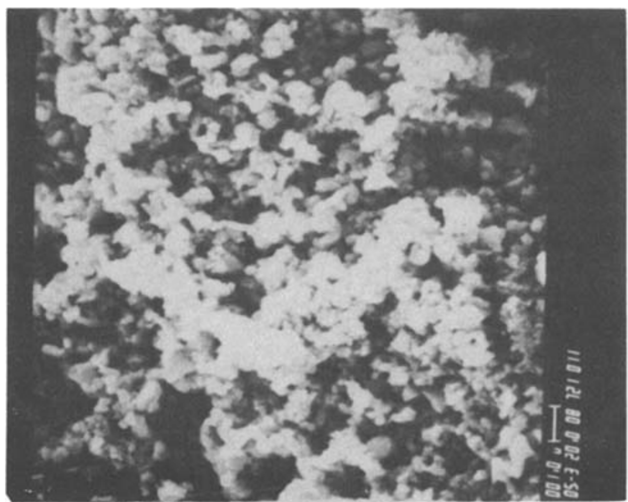

Fig. 6b. SEM image of active material from cell No. 14 after failure. 5000×.

Grid corrosion as measured by grid weight loss overall and per 100 cycles generally was higher in the wrought grids than in the cast grids. Again the exceptions were the very low antimony cells (I-A) emphasizing the importance of alloy content in these alloys. Without having the experimental data, one would expect the cast alloy grids to corrode more rapidly than the wrought grids of the same antimony content. This is because the continuous interdendritic eutectic phases found in castings have been shown (10) to be preferred regions of corrosive attack in battery grids. This continuous structure is broken up by the rolling process making deep penetration of corrosion more difficult. The photomicrograph in Fig. 3b confirms that interdendritic attack did occur in the castings while general dissolution seems to have been the mode of corrosion for the wrought alloys (Fig. 4b and 5b). The only excessive corrosion in the wrought grids as compared to the castings was in the vertices of the cruciate locations (Fig. 4a and 5a). Here the corrosion may have been enhanced by the presence of residual stress caused by the expansion process. It is also possible that the excessive Sn_4As_3 in the wrought alloy enhanced the corrosion rate. In any case corrosion was not observed to play a significant role in the failure of these cells with the possible exception of cell No. 1 which lasted far longer than any other.

The most striking variation in behavior between cast and wrought grids was in grid growth. This is believed to have been a major factor in causing cell failure as mentioned earlier. Growth in the cast grid cells was 1% or less overall and less than 0.2% per 100 cycles of life over a relatively long lifetime. Wrought grid expansion ranged up to 8.3% increase in height (cell 7) and ranged from 1 to 4% per 100 cycles over relatively shorter lives. The relation of cycle life to grid growth is shown graphically in Fig. 7. Antimonial lead standby batteries on constant charge are known to suffer gross grid growth by interdendritic corrosion causing the volume of the grid to effectively increase because of the corrosion product (10). Examination of the photographs in Fig. 3-5 shows this mechanism not to be operating in either the cast or wrought grids as there is virtually no sign of interdendritic attack below the immediate surface of the metal. The means by which growth occurs, then, must be mechanical. It is proposed that mechanical deformation of the grids occurred through repeated expansion and contraction of the active material during charge and discharge. A

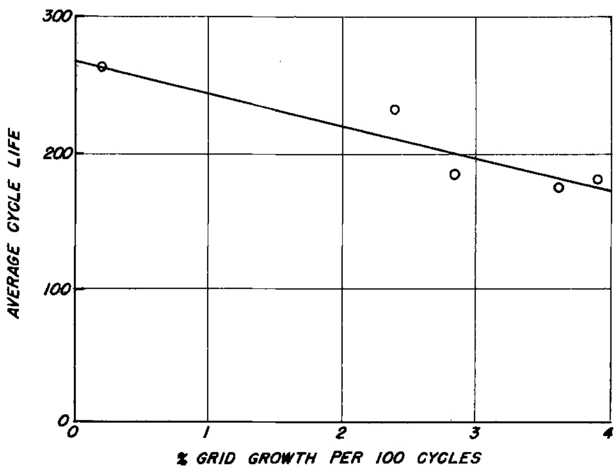

Fig. 7. Cycle life vs. grid growth

similar mechanical explanation of grid growth has been proposed by Lander (11) on unpasted lead. The cast grids, while subject to similar forces of expansion and contraction, are expected to possess tensile strength well in excess of the 4000-5000 psi determined for the wrought alloys as rolled. Further the cast grid design has been optimized over the years to reduce active material loss and growth. As may be seen the cast grids have substantial supporting members on each side and continuous supports running horizontally and at varying inclines to the vertical. The wrought grids in both designs were unsupported at the ends and tend to yield to stress not unlike an accordion. It is this structural instability which we believe allows excessive grid growth which in turn causes active material loss and shorting, the prevalent mode of failure.

Work underway at ASARCO has indicated that wrought low antimony grids can be hardened to tensile strengths in excess of 6000 psi with very short term heat-treatments. Further, recently reported potentiodynamic studies (12) show a relation between cold work and low H_2 overvoltage. A short anneal thus may improve the gassing rate of wrought grids. Also it now seems likely that the levels of arsenic and tin chosen for this test were high and that corrosion resistance and ease of working may be improved by smaller additions of those elements.

Conclusions

1. Continuous casting of low antimony grid alloys has been demonstrated.
2. Difficulty in cold working the continuous cast material increased with increasing alloy content. These problems would be significantly diminished in a commercial rolling situation.
3. Expansion of low antimonial lead alloy sheet for battery grids has been demonstrated.
4. In deep discharge cycling the expanded low antimony grids did not perform as well as did cells constructed with cast low antimony grids, although some of the wrought grid cells achieved more than 200 cycles to failure.
5. Failure of the wrought grid cells resulted from the effects of excessive grid growth not related to corrosion.
6. It is suggested that wrought grid cell life may be extended by (*i*) employing an alloy of 1-2% Sb with small addition of As and Sn; (*ii*) heat-treating the metal to achieve greater resistance to stress, and higher gassing voltage; and (*iii*) design wrought grids to provide more structural support.

The Behavior of Na-TiS_2 and Na-TiS_3 as Solid Solution Electrodes

Margherita Zanini, J. L. Shaw, and G. J. Tennenhouse

Ford Motor Company, Research Staff, Dearborn, Michigan 48121

ABSTRACT

We have investigated the behavior of TiS_2 and TiS_3 electrodes in a sodium cell at temperatures between 230° and 280°C using the solid electrolyte β''-alumina. The electrochemical reaction of TiS_2 with sodium was found to be reversible, while TiS_3 was found to decompose.

Several transition metal chalcogenides (TMC) can be intercalated with high concentrations of alkali metals (1). Although the sodium-TMC compounds are expected to have a large free energy of formation, high electrical conductivity, and high sodium diffusivity (2), their behavior as solid solution electrodes has not been so widely studied as that of the lithium-TMC compounds (1). Energy density considerations and difficulties associated with the electrolyte instability and the high sodium reactivity have made the lithium compounds more attractive for applications (3, 4). However, the compatibility of TMC's with sodium makes it possible to use and study these electrode materials in conjunction with the solid electrolyte β''-alumina (5). The stability of this electrolyte, its low resistivity, and the reliability of the Na/β''-alumina half cell (5) open very interesting possibilities of utilizing TMC's in rechargeable batteries with both high energy and power densities. In this paper we report studies of the behavior of TiS_2 and TiS_3 electrodes at temperatures between 230° and 280°C in a sodium cell using β''-alumina as an electrolyte. We discuss the reversibility and the energy density of Na-TiS_2 and Na-TiS_3 solid solution electrodes at high temperatures. We also discuss the advantages of using β''-alumina as an electrolyte both for studies and for applications.

Key words: electrolyte, decomposition, metals.

Experimental

Small crystallites of TiS_2 (platelets) and TiS_3 (fibers) were prepared by direct reaction of titanium wire (10 mils, 99.9% pure from MRC) and sulfur (99.999% pure from ASARCO). The elements were reacted in stoichiometric amounts in quartz ampuls at 650°C for TiS_2 (6) and at 560°C for TiS_3 (7). The Debye-Scherrer patterns obtained for these materials indicated the presence of a single phase. Analysis of the compounds by complete oxidation to TiO_2 showed that the compounds were stoichiometric within our experimental error of ±0.005. Microprobe, ESCA, and X-ray fluorescence tests were also made on the electrodes to verify their composition and to test that only trace impurities were present. Powders of TiS_2 from CERAC were also used in the experiments.

The TMC electrodes were made by isostatically pressing finely divided material with no binder into pellets about 3 mm in diameter and 50-100 microns thick. Thinner electrodes of TiS_2 (5-10m) used for the cyclic voltammetry experiments were pressed on aluminum foil as a support. The pressed TiS_2 pellets had very smooth surfaces, and did not crumble on handling, while the TiS_3 pellets had rougher surfaces. The pellets retained their structural integrity throughout the electrochemical tests.

The density of some pellets was measured by a gravimetric technique. First a sample was weighed (weight W_1). Then it was immersed in a liquid (either alcohol or ethylene glycol) for several hours and kept under a low pressure to favor degassing. As soon as a sample was removed from the bath, its surface was gently wiped and the sample immediately weighed (weight W_2). From the known densities of the bulk material (d_b) and of the liquid (d_l), the density of the pellet (d) was derived according to

$$d = \frac{W_1 \cdot d_l \cdot d_b}{W_2 \cdot d_b - W_1 \cdot (d_b - d_l)}$$

and found to be 80-90% of the bulk density. Samples 200 microns thick gave more reproducible results and less scattering in the data than 50 microns thick pellets, because of the more favorable volume to surface ratio.

Cells were made by sealing a β''-alumina disk (8) (12 mm in diameter, 1 mm thick) to the end of a ceramic container into which sodium was vacuum transferred. A spring loaded cell holder pressed the TMC pellet against the solid electrolyte. The whole unit was heated in a furnace. The temperature of the cell, monitored by a shielded thermocouple in the sodium bath, was controlled within 1°C. The measurements were made in a dry box. At the end of the measurements small fractions of the cathodes were removed and sealed in glass capillaries for x-ray diffraction tests.

The cells were automatically cycled in galvanostatic mode between preset voltage limits and their voltage recorded on a strip chart recorder. In some tests, the cell operation was automatically switched from galvanostatic to potentiostatic mode as soon as a voltage limit was reached. A coulometer measured the charge flowing during a cycle. Thus the concentration of sodium in the electrode was derived according to the reaction

$$Na^+ + e^- + nTiS_2 \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftarrows}} Na_{1/n}TiS_2$$

Quasi-equilibrium open-circuit voltage data were obtained by discharging a cell with a fresh electrode in steps at constant current. After each step, the cell voltage was measured every hour. When the voltage was observed to change in one hour less than 2% of the amount it changed during the first hour, the cell was considered in quasi-equilibrium.

Cyclic voltammetry was also used to characterize the TMC electrodes. Since the geometry of our cells did not allow the addition of a reference electrode, the sodium electrode was used both as counter and reference. This configuration did not introduce a large error since the polarization of the sodium electrode was low. This was verified by measuring the voltage across an Na/β''-alumina/Na cell, through which a constant current was flowing.

The *IR* drop of the Na/β''-alumina/TMC cells was measured by abruptly interrupting the current and measuring the sudden voltage change between positive and negative electrodes.

Results

Typical charge/discharge curves for TiS_2 electrodes are shown in Fig. 1 and 2. The data were obtained cycling the cells galvanostatically between voltage limits of 2.9 and 1.1V at current densities ranging from 0.2 to 2 mA/cm² and at temperatures of 230° and 280°C.

The curves show two regions, at molar concentrations of sodium of approximately $x < 0.4$ and $x > 0.7$, in which the voltage is relatively independent of x. These two plateaus occur around 2.1 and 1.5V in discharge and are also observed in equilibrium open-circuit voltage measurements. In between, the voltage changes almost linearly. These features can be detected in all the curves taken at increasingly higher currents, although the length of the plateaus decreases faster than that of the intermediate region. The total depth of the charge and discharge increases with the temperature and decreases with the current, suggesting that the full utilization of the electrode is kinetically hindered because of the slow diffusion of sodium into the bulk of the electrode. Typically, the electrodes were cycled about 5-7 times for each different current level and temperature. No appreciable loss in capacity (less than 1%) was observed between cycles done at the same current and temperature,

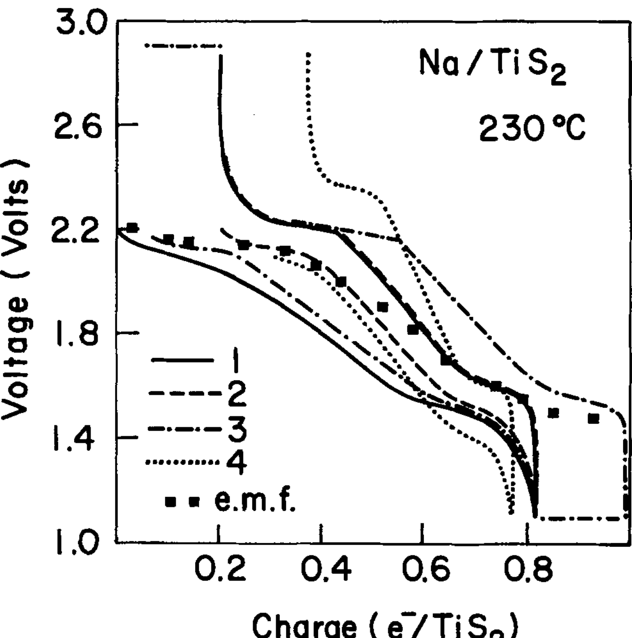

Fig. 1. Galvanostatic discharge and charge curves for a TiS_2 electrode of 2.3 mg. Curve No. 1 is the first cycle performed at 0.2 mA/cm²; No. 2 is the second at 0.2 mA/cm²; No. 3 the eighth cycle at 0.2 mA/cm² which was, however, prolonged in potentiostatic mode; No. 4 is the twelfth cycle which was performed at 0.5 mA/cm². The squares are quasi-equilibrium open-circuit values for a fresh electrode.

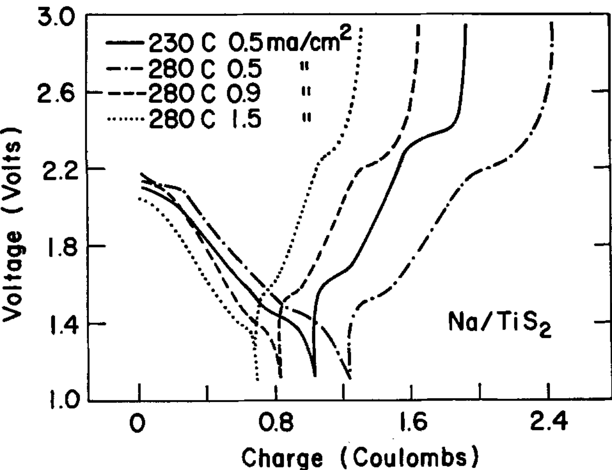

Fig. 2. Galvanostatic discharge and charge curves for TiS_2 at different current densities and temperatures. For this electrode a charge of 2.2C corresponds to a sodium molar concentration of 1.

indicating that the electrochemical process was reversible.

In some experiments (curve 4 in Fig. 1 for example), both the charge and the discharge tests, were continued in potentiostatic mode when the cell voltage reached, respectively, 2.9 and 1.1V. In this way, a rechargeable capacity as high as 0.96 e^-/TiS_2 (equivalents/mole) was measured. Furthermore, electrodes were cycled so that a fixed charge was obtained in each cycle, demonstrating that the loss of capacity in tests at higher currents is not due to irreversible phenomena.

The reversibility of the intercalation process is also demonstrated by slow scan rate cyclic voltammetry. In Fig. 3 we show a cyclic voltammogram obtained for an electrode less than 10 microns thick at a scan rate of 0.1 mV/sec. Three reduction peaks occur at 2.18, 2.12, and 1.46V and the corresponding oxidation peaks at 2.26, 2.18, and 1.54V. At higher scan rate (0.5 mV/sec) the two peaks at higher voltage become broader and are no longer resolved. The peaks observed in the voltammogram indicate that the intercalation process occurs in different steps according to the concentration range of the electrode. The presence of symmetrical reduction and oxidation peaks is an indication that each step is reversible. The potentials at which peaks appear in the voltammogram compare closely with the voltages at which plateaus are seen in the galvanostatic sweeps.

The voltage difference between the charge and discharge curves of Fig. 1 and 2 is essentially due to concentration polarization in the positive electrode, since *IR* drop contribution was found to be small. The observed high polarization does not seem to be related to poor stoichiometry of our electrode materials which can decrease the sodium diffusivity. This effect was previously observed in metal-rich TiS_2 (2, 9). However, chemical analysis of our compounds showed that the excess metal was less than 0.1%. In addition, our materials had been carefully annealed to remove defects. Both commercial material and our compounds showed similar behavior in our tests.

We found that at temperatures below 140°-160°C, the cell polarization was quite large. Since the resistivity of the electrolyte (5) decreases exponentially as the temperature increases (10), and the wettability of sodium to β''-alumina increases, we performed our tests above 180°C. Although we did not make tests above 300°C, the temperature of utilization of the cell should be only limited by the thermal stability of the chalcogenide electrode.

In Fig. 4 we show data obtained for a TiS_3 electrode. Although the first discharge for this material could be carried up to 2.4 e^-/TiS_3 at 0.1 mA/cm², subsequent cycles show a much smaller capacity (less than 1 e^-/TiS_3) and completely different features. Two breaks in the voltage *vs.* concentration curves are observed at about 2.1 and 1.5V, similar to what was observed for TiS_2. This is evidence that TiS_3 transforms into TiS_2 during the electrochemical reaction as confirmed by x-ray diffraction analysis. In fact, the Debye-Scherrer patterns of samples taken from the cycled electrodes showed the characteristic lines of TiS_2, although very broad, but no TiS_3 lines or other lines. Successive cycles are similar to the second discharge/charge, although the capacity progressively decreases.

Discussion

Our data show that at high temperatures TiS_2 can be used in a sodium cell as a reversible solid solution electrode in the concentration range $0 < x < 1$. Our results are in good agreement with the emf values reported by Winn *et al.* (2) for stoichiometric single crystals studied at room temperature. Instead, our findings disagree with the poor reversibility observed by Newman *et al.* (4) in their experiments with a room temperature cell using a liquid electrolyte. Also, the voltage *vs.* concentration data of our Na/TiS_2 cells are 200-300 mV higher than the values reported in Ref. (4). Such a difference cannot be attributed to the temperature because the cell voltage decreases, increasing the temperature.

The use of a solid electrolyte has the advantage of preventing side reactions with the electrodes and of avoiding electrolyte cointercalation in the electrode. It is therefore possible to study the intrinsic behavior of TMC electrodes free of other background reactions. In addition, the sodium electrode is free of contamination and polarization effects. On the other hand, we

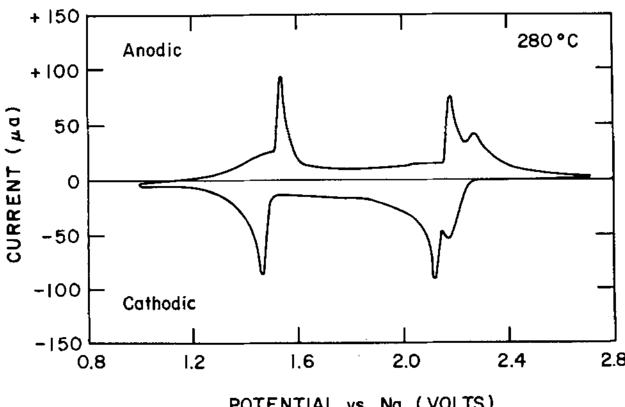

Fig. 3. A voltage scan for a thin TiS_2 electrode of 0.38 mg and 0.2 cm². The scan rate was 0.1 mV/sec.

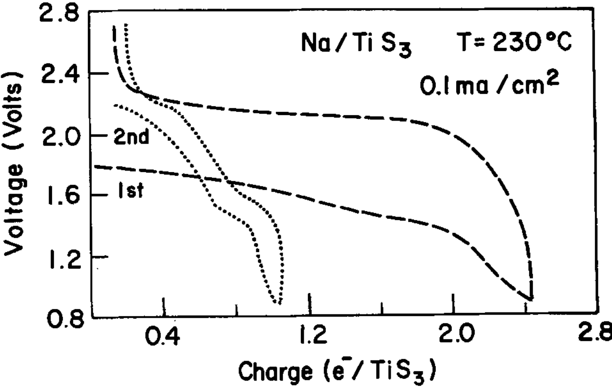

Fig. 4. Galvanostatic discharge/charge curves for a TiS_3 electrode of 2.2 mg.

probably do not achieve intimate contact between the TMC electrode and the electrolyte in our present configuration. The high polarization that we observed in our cells is likely due to poor contact and not to intrinsic low sodium diffusivity in the electrode material. The interfacial problem could be overcome by adding a suitable molten salt to the cathode or by sintering TMC's to β''-alumina.

In our nonoptimized cells with cathodes approximately 50 microns thick, we obtained a rechargeable capacity of about 0.8 e^-/TiS_2 at 0.2 mA/cm^2 and 230°C, as shown in Fig. 1, and a corresponding energy density of 290 W-hr/kg for the Na_xTiS_2 cathode. At lower discharge rates and/or at higher temperatures, this value increases. The maximum energy density (theoretical) for $NaTiS_2$ was derived from the emf data of Fig. 1 and found to be 360 W-hr/kg. This value is about 25% less than the theoretical energy density of $LiTiS_2$ electrodes, which is 480 W-hr/kg at room temperature (1).

The plateaus observed in the curves of Fig. 1 and 2, and the peaks seen in the voltammogram of Fig. 3, can be related to the phases of the Na-TiS_2 system. Previous x-ray diffraction studies (11) have found three structurally different phases. The first phase, observed for sodium concentration $0.17 < x < 0.33$, was described as a second stage compound with sodium occupying trigonal prismatic sites. The second, extending for $0.38 < x < 0.72$, was determined to be a first stage with sodium in trigonal prismatic sites. The third, for concentrations $x > 0.79$, was found to be a first stage with sodium in a trigonal antiprismatic (distorted octahedral) site. We associate the lower voltage plateau with the onset of the "octahedral" phase and the higher voltage plateau with the onset of the "trigonal prismatic" phase. The two peaks which appear in the cyclic voltammogram of Fig. 3 around 2.1V can be associated with the trigonal prismatic first and second stage phases. Detailed x-ray work on ternary compounds obtained electrochemically needs to be done to better understand the structural transformations of the Na-TiS_2 system and the concentration values for the phase boundaries.

The sodium diffusivity in TiS_2 could be substantially different for each phase (1). Our preliminary measurements of the diffusion coefficient of sodium in TiS_2 obtained with the voltage-relaxation method (2, 12), seem to show that diffusion is at least one order of magnitude slower for sodium concentrations approximately $x < 0.4$ and $x > 0.7$, although the change does not seem to occur abruptly. This correlates with the results of the galvanostatic sweeps which show that the length of the plateaus decrease at higher currents. Because of the uncertainty of the actual contact area in our cells, we cannot derive the absolute value of the sodium diffusivity, but we can compare values obtained for the same electrode.

As observed in the case of lithium (13, 14), TiS_3 transforms during the electrochemical intercalation of sodium and the high capacity of the first discharge is not recovered on subsequent cycles. This material does not therefore look attractive for practical purposes.

Conclusion

We have reported the feasibility of using TiS_2 electrodes coupled with β''-alumina electrolyte to build a high temperature rechargeable battery. The voltage range of our Na/β''-alumina/TiS_2 cell is about 15% lower on average than for Li/TiS_2 room temperature cells. However, the availability and the cost of sodium compared to lithium may make the sodium compounds more attractive for practical applications, especially if they are used with the stable β''-alumina electrolyte with a good interfacial contact. The diffusion rate in TMC's may be slower for sodium than for the smaller lithium ions, therefore reducing the power achievable in these cells. However, the use of a solid electrolyte allows the operation of this kind of cell at high temperatures where diffusion processes are faster. The diffusion mechanisms in solid solution electrode materials need to be studied further to prove the feasibility of a practical high power device.

Lightweight Rechargeable Storage Batteries Using Polyacetylene, $(CH)_x$ as the Cathode-Active Material

ABSTRACT

Polyacetylene, $(CH)_x$ can be controllably doped electrochemically through the semiconducting to the metallic regime using a solution of $LiClO_4$ in propylene carbonate and a lithium cathode. Flexible, golden, free-standing films of $[CH^{+y}(ClO_4)_y^-]_x$ ($y = 0$ to 0.06) having conductivities up to $\sim 10^3$ Ω^{-1} cm^{-1} are readily obtained. Electrochemical "undoping" of the $[CH^{+y}(ClO_4)_y^-]_x$ allows this doped film to be used as the cathode-active material in lightweight rechargeable storage batteries. The overall complete discharge reaction is

$$[CH^{+0.06}(ClO_4)_{0.06}^-]_x + 0.06x\text{Li} \rightarrow (CH)_x + 0.06x\text{LiClO}_4$$

A 0.5 cm^2 piece of the 6% doped film ($1.0 \times 0.5 \times 0.01$ cm; $\sim$3 mg) exhibited an open-circuit voltage of 3.7V and an initial short-circuit current of 25 mA. No change in the open-circuit voltage characteristics of a battery could be detected even after 326 successive constant current partial charge/discharge cycles. No degradation of the polyacetylene electrode was observed. Experimental energy densities of $\sim$176 W-hr/Kg were obtained based on the weight of the $[CH^{+0.06}(ClO_4^-)_{0.06}]_x$ initially employed and the weight of Li consumed (exclusive of weights of electrolyte, solvent, and packaging material) during partial discharge when $[CH^{+0.06}(ClO_4)_{0.06}^-]_x$ was converted to $[CH^{+0.024}(ClO_4)_{0.024}^-]_x$.

Polyacetylene, $(CH)_x$ is the first example of a covalent organic polymer which may be chemically doped either p- or n-type to give a series of semiconductors and ultimately "organic metals" (1). The electrical conductivity can be varied over twelve orders of magnitude depending on the dopant concentration (1). Detailed studies have shown that a semiconductor-metal transition occurs at dopant concentrations near 1 mole percent (m/o). In the metallic range, (1-10 m/o) the conductivity increases at a relatively slow rate as a function of dopant concentration up to a value of $\sim 10^3$ Ω^{-1} cm^{-1} at room temperature. We have shown previously that $\sim$0.1 mm thick films of $(CH)_x$ may also be controllably doped electrochemically in a very simple, rapid procedure, either in aqueous or nonaqueous solution, through the semiconducting to the metallic regime (2). Thus, the use of aqueous KI solutions or CH_2Cl_2 solutions of, *e.g.*, $[(n\text{-}C_4H_9)_4N]^+[ClO_4]^-$, $[(n\text{-}C_4H_9)_4N]^+[AsF_6]^-$, etc. yield flexible, golden-silvery films of $[CHI_{0.07}]_x$ ($\sigma_{25°C} = 9.7$ Ω^{-1} cm^{-1}), $[CH(ClO_4)_{0.0645}]_x$ ($\sigma_{25°C} = 970$ Ω^{-1} cm^{-1}), and $[CH(AsF_4)_{0.059}]_x$[1] ($\sigma_{25°C} = 260$ Ω^{-1} cm^{-1}), respectively. When doping is carried out using approximately 0.1 mm thick cis-rich $(CH)_x$ film as the anode and a platinum cathode with an applied potential difference of approximately 9V between the electrodes, the metallic-doped state is generally reached in 30-60 min (2). This relatively rapid doping is undoubtedly assisted by the fact that the film consists of an interwoven network of *ca.* 200Å $(CH)_x$ fibrils which fill only about one-third of the volume of the film (1). The surface area of the $(CH)_x$ fibrils in the film is 40-60 m^2/g^2 (1). A 1 cm^2 piece of film 0.1 mm in thickness therefore has an effective surface area of approximately 2.5×10^3 cm^2. In the doped state, the polyacetylene is believed to exist as the stabilized polycarbonium ion, $(CH^{+y})_x$, with the corresponding number of monovalent counter anions such that the overall composition is $[(CH^{+y})A_y^-]_x$ (1). In the case of iodine doping, it has been shown that at least a large amount of the iodine exists as the I_3^- ion (3).

The anode reaction occurring upon doping, using $[(n\text{-}C_4H_9)_4N]^+A^-$ as an electrolyte, involves oxidation of $(CH)_x$, *viz.*

$$(CH)_x \rightarrow (CH^{+y})_x + xye^- \quad [1]$$

The corresponding cathode reaction, at an inert electrode such as platinum, is

$$xy[(n\text{-}C_4H_9)_4N]^+ + xye^- \rightarrow xy\text{"}[(n\text{-}C_4H_9)_4N]°\text{"} \quad [2]$$

The $[(n\text{-}C_4H_9)_4N^+]$ upon reduction may be regarded as producing "$[(n\text{-}C_4H_9)_4N]°$" momentarily. This will then break down in a complex manner to give amines and hydrocarbons. The overall electrochemical doping reaction may therefore be summarized as

$$(CH)_x + xy[(n\text{-}C_4H_9)_4N]^+[A]^- \rightarrow [(CH^{+y})A_y^-]_x + xy\text{"}[(n\text{-}C_4H_9)_4N]°\text{"} \quad [3]$$

It will be noted that the A^- ion is not oxidized or reduced during the electrochemical reaction. It serves only as a negative counterion to preserve electrical neutrality in the system.

An important extension of the electrochemical doping study is the attempted electrochemical "undoping" of $[(CH^{+y})A_y^-]_x$ to reform the original $(CH)_x$. This also has now been accomplished. The doping reaction given by Eq. [1], involving partial oxidation of the $(CH)_x$, may also be regarded as a possible battery

* Electrochemical Society Active Member.

Key words: polyacetylene, battery, doping, lithium, perchlorate.

[1] Elemental analyses (Schwarzkopf Microanalytical Laboratory, Woodside, New York, 11377) show that the material has the composition $[CH(AsF_4)_{0.0592}]_x$: Found: C = 54.71; H = 4.74; As = 20.19; F = 20.81% (Total = 100.45%). Calc.: C = 54.79; H = 4.60; As = 20.16; F = 20.45%. An unknown side reaction apparently occurs to reduce $(AsF_6)^-$ to $(AsF_4)^-$.

"charging reaction" to produce a doped polymer which could be utilized as a cathode-active battery material. The discharge reactions are the reverse of those given above.

A number of different dopant ions, solvents, electrolytes, electrolyte concentrations, and battery configurations have been investigated, only one of which is described below in order to illustrate the potential application of $(CH)_x$ in batteries. This system is not necessarily the most preferred one nor are its parameters necessarily optimized to give the best output characteristics.

Experimental

Materials and reagents.—Cis-rich $(CH)_x$ film (*ca.* 80% cis isomer; *ca.* 0.1 mm thickness; density *ca.* 0.4 g/cm^3) was prepared as previously described (4).[2] Propylene carbonate (Aldrich Reagent grade) was stirred over lithium chips for 14 days. This was used to make a 0.3M solution of $LiClO_4$ which was passed through Woelm activated basic alumina to yield a colorless solution. Anhydrous $LiClO_4$ (Alfa-Ventron) was dried by melting *in vacuo* before use. Lithium metal (Alfa-Ventron Company) was scraped under an $LiClO_4$ solution in propylene carbonate with a knife immediately before use.

Doping experiments.—Doping experiments were carried out in a dry, inert atmosphere using a glass vessel containing the $LiClO_4$/propylene carbonate solution. A strip of $(CH)_x$ film ($3 \times 1.5 \times 0.01$ cm), to the top of which a platinum wire had been attached by mechanical pressed contact, was placed in the solution so that the film and wire were completely immersed. A platinum counterelectrode (3 cm^2) was placed in the solution at a distance of ~12 cm from the $(CH)_x$ working electrode. An Ag/Ag^+ (0.1M $AgNO_3$ in CH_3CN) reference electrode was then placed in the container ~1 cm from the $(CH)_x$ working electrode. The three electrodes were attached to a Princeton Applied Research (PAR) Model 173 potentiostat/galvanostat equipped with a PAR Model 179 digital coulometer.

Electrochemical doping of the $(CH)_x$ with $(ClO_4)^-$ was accomplished by having it serve as the anode. It was held at a potential of +1.0V with respect to the Ag/Ag^+ reference electrode. After 10 sec, the film was withdrawn so that the top of the platinum wire was ~3 mm above the surface of the solution. The 10 sec doping period increased the conductivity of the $(CH)_x$ film around the platinum wire contact. Although it is not really necessary to withdraw the platinum wire from the electrolyte since one is operating at a potential where no oxidation of the electrolyte or solvent occurs, this technique was found in certain cases to control the rate of doping. As doping proceeded and the conductivity of the film increased, the current also increased. The extent of doping was followed by observing the value of the current. At the very beginning, the current was 40 μA and after 43 min it had increased to 4 mA. It stayed constant at this value for an additional 4 min and then began to decrease. Doping was discontinued at this stage, the film was washed several times with propylene carbonate, then with CH_2Cl_2, and dried *in vacuo* with constant pumping overnight. The flexible, golden film had a 4-probe conductivity of 700 Ω^{-1} cm^{-1} at room temperature. Its composition from the number of coulombs passed was $[CH(ClO_4)_{0.043}]_x$. This composition is not necessarily expected to agree exactly with that obtained from elemental analysis since there is uncertainty in the extent of doping of that 3 mm portion of the film above the solution. A portion of that part of the film which had been completely immersed in the solution was analyzed commercially.[3] Its composition was $[CH(ClO_4)_{0.058}]_x$. Found: C = 63.23% H = 5.71%; Cl = 10.21%; O (by difference) = 20.85%. Calc. for $CHCl_{0.058}O_{0.232}$: C = 63.96%; H = 5.37%; Cl = 10.95%; O = 19.77%.

Battery experiments.—A strip of $(CH)_x$ film ($0.5 \times 1 \times 0.01$ cm), either undoped or previously doped, was placed in the 0.3M solution of $LiClO_4$ in propylene carbonate as described previously. Platinum wire was attached to the top of the film as in the doping experiments. The lithium counterelectrode ($0.5 \times 2 \times 0.1$ cm) was placed ~0.5 cm from the (working) $(CH)_x$ electrode. A similar strip of lithium metal was placed approximately equidistantly from the working and counterelectrodes and was used as the reference electrode. In one experiment, a 0.5 cm^2 piece of $(CH)_x$ film, on one side of which 600Å of gold had been evaporated, was employed. Platinum wire was attached to one end by pressed mechanical contact and the electrode was then placed in 0.5M $LiClO_4$ in propylene carbonate.

In some experiments, $(CH)_x$ film previously doped with perchlorate was used initially. This was because the composition of that 3 mm portion of the film above the surface of the solution would then be the same as that below the surface. When undoped $(CH)_x$ film was used initially, it could not necessarily be assumed that the composition of that portion of the film above the surface of the solution was fully doped or whether it might become more doped on each charging cycle during a series of charge/discharge cycles. When undoped $(CH)_x$ film was employed, it was first electrochemically doped *in situ* at a constant current of 1 mA for *ca.* 26 min for a 0.5 cm^2 piece of film, to give a film of composition $[CH(ClO_4)_{0.06}]_x$ (6% doping) as calculated from the weight of the film employed and the number of coulombs passed. In some instances, film doped only to 5% was employed.

Discharge/charge studies were carried out using two different methods: (*i*) Constant current investigations employed a Model 173 galvanostat where the change in voltage *vs.* a lithium reference electrode during a discharge or charge cycle was monitored by means of a Keithley Model 177 digital multimeter connected to a Houston Omnigraphics 2000 XY recorder. Voltage *vs.* time measurements were recorded at a number of different discharge currents (0.1-4 mA); (*ii*) short-circuit studies involved discharge through a Keithley Model 177 digital multimeter, where current and voltage were measured until the cell was completely discharged. The battery was recharged to its original level after each discharge cycle by means of a d-c power supply set at 4V or by a constant current method using the PAR 173 galvanostat at 1 mA.

Results and Discussion

Doping of $(CH)_x$ with $(ClO_4)^-$.—We have shown previously that $(CH)_x$ film can be doped readily to composition $[CH(ClO_4)_{0.0645}]_x$ from a 0.5M solution of $[(n\text{-}C_4H_9)_4N]^+[ClO_4]^-$ in CH_2Cl_2 when it is used as the anode with an applied potential difference between the anode and cathode of approximately 9V. In the present study, we have shown that doping may also be carried out conveniently to *ca.* 6% using a 0.3M solution of $LiClO_4$ in propylene carbonate at an applied potential of +1.0V (*vs.* Ag/Ag^+) during 47 min at room temperature.

When $LiClO_4$ is used instead of $[(n\text{-}C_4H_9)_4N]^+A^-$, and Li metal is used instead of Pt at the cathode, then the reaction corresponding to Eq. [2] is

$$xyLi^+ + xye^- \rightarrow xyLi^o \quad [4]$$

The overall doping reaction corresponding to Eq. [3]

[2] Similar results were obtained with $(CH)_x$ film kindly supplied by Rohm and Haas Company, Bristol, Pennsylvania.

[3] Galbraith Laboratories, Incorporated, Knoxville, Tennessee 37921.

is then

$$(CH)_x + xyLi^+(ClO_4)^- \rightarrow [(CH^{+y})(ClO_4)_y^-]_x + xyLi^0 \quad [5]$$

Battery experiments.—The simplest battery configuration is shown diagrammatically in Fig. 1. It consists basically of a piece of $(CH)_x$ film, nearly all of which was immersed in a propylene carbonate solution of $LiClO_4$. The top of the film was attached by means of a wire to the positive terminal of a galvanostat. The negative terminal was attached to a lithium metal electrode immersed in the solution. The battery was charged at 1 mA for *ca.* 30 min to give a film of approximate composition $[CH(ClO_4)_{0.06}]_x$ The overall charge reaction is given by Eq. [5] (y = 0.06).

The anode discharge reaction, assuming complete discharge is

$$0.06xLi \rightarrow 0.06xLi^+ + 0.06xe^- \quad [6]$$

and the corresponding cathode reaction is

$$[CH^{+0.06}(ClO_4)_{0.06}^-]_x + 0.06xe^- \rightarrow (CH)_x + 0.06x(ClO_4)^- \quad [7]$$

The net discharge reaction, is, therefore

$$[CH^{+0.06}(ClO_4)_{0.06}^-]_x + 0.06xLi \rightarrow (CH)_x + 0.06xLiClO_4 \quad [8]$$

Short-circuit discharge characteristics.—The open-circuit voltage, (V_{oc}), of a 6% predoped film, *i.e.*, $[CH(ClO_4)_{0.06}]_x$, prepared by passing 1.7C was 3.7V and the short-circuit current (I_{sc}), was 23 mA for a 0.5 cm^2 (~3 mg) piece of film. This varied from ~15 to 35 mA depending on the sample of $(CH)_x$ film employed and the extent of doping, etc. The high current density may be related to the large effective surface area of the $(CH)_x$ fibrils in the film. Because of the small mass of the film used in these experiments, the short-circuit current falls rapidly as the battery discharges. For example, after ~30 sec of short-circuit discharge, the voltage was essentially unchanged and I_{sc} was 17 mA. More than half of the total coulombs evolved were given off during this period. After 1 min, the voltage was 3.2V and I_{sc} was 3.2 mA. After a total of 3.0 min, the voltage began to fall rapidly and I_{sc} decreased to 0.1 mA. At this stage, a total of 1.0C, (59% recovery) had been released and the dopant concentration was reduced to 2.4%, a concentration approaching that defining the metal-semiconductor transition where the conductivity of p-doped $(CH)_x$ films begins to fall rapidly. The discharge reaction involved in this particular experiment is given by Eq. [9]

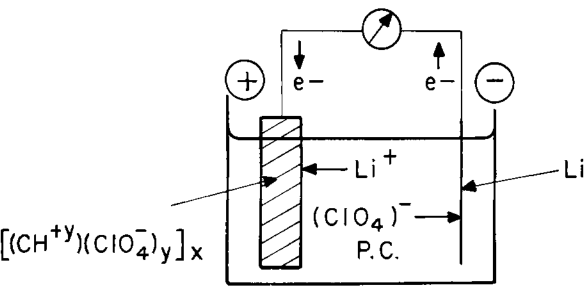

Fig. 1. Schematic representation of the discharge process in a $(CH)_x/LiClO_4/Li$ rechargeable storage battery. Electrons flow in the external circuit from the Li to the $[CH^{+y}(ClO)_y^-]_x$ while at the same time Li^+ ions and $(ClO_4)^-$ ions migrate towards the $[CH^{+y}(ClO_4)_y^-]_x$ and the Li electrodes, respectively. (See eq. [6]-[9]).

$$[CH^{+0.06}(ClO_4)_{0.06}^-]_x + 0.036xLi \rightarrow [CH^{+0.024}(ClO_4)_{0.024}^-]_x + 0.036xLiClO_4 \quad [9]$$

Successive short-circuit discharging to 3% dopant concentration (V_{oc} = 2.7V; I_{sc} = 1.0 mA) and recharging to 6% dopant concentration showed that the number of coulombs involved in the charging and discharging process were identical to within experimental error.

The I_{sc} values and the average V_{oc} value during the above partial discharge give an energy density of 176 W-hr/kg based on the weight of the $[CH^{+0.06}(ClO_4)_{0.06}^-]_x$ initially employed and the weight of lithium consumed according to the reaction given by Eq. [9]. Since the weight of lithium consumed is extremely small compared to the weight of the $[CH^{+0.06}(ClO_4)_{0.06}^-]_x$, an essentially identical energy density value is obtained even if the weight of lithium used is that obtained from the reaction given by Eq. [8]. The theoretical energy density for the reaction given by Eq. [8], assuming complete discharge, is 307 W-hr/kg. Empirical rules may be applied to obtain a rough estimate of the expected energy density of a packaged battery, including the weight of electrolyte, solvent, and casing, from the experimental energy density of 176 W-hr/kg. A reduction factor of seven gives a reasonably conservative estimate and results in a value of 25 W-hr/kg for the completely packaged battery. This is approximately the same value as that found for the average lead/acid automobile battery. Although these energy densities are interestingly large even with 6% doped film, they are not necessarily the maximum obtainable since as shown in the following section it is possible to dope $(CH)_x$ to values greater than 6% with $(ClO_4)^-$; furthermore, other dopants such as Br_3^-, I_3^-, AsF_4^-, etc. are known (1, 2) where higher doping levels might possibly be achieved.

It is more difficult to obtain meaningful estimates of the power density of the $[CH(ClO_4)_{0.06}]_x/Li$ battery in the final packaged state. The product of the initial V_{oc} (3.7V) and I_{sc} (23 mA) obtained above for 4.5 mg of $[CH(ClO_4)_{0.06}]_x$ film and the weight of lithium consumed in the reaction given by Eq. [8] yields a value of 19,000 W/kg. On dividing by a factor of four to obtain an approximate value of the useful power available (when the resistance of the external load and of the battery are equal), and then by a factor of seven for weight of electrolyte, solvent, and packaging, a value of 680 W/kg is obtained. This is considerably in excess of common power densities and is presumably related to the open fibrillar morphology of the $(CH)_x$ film but it should be regarded with the utmost caution in view of the large approximations made in arriving at this value.

In a real battery operation, the weight of the cathode current collector electrode must also be added to the weight of the cathode-active material. In the $(CH)_x$ cathode configuration, because the $(CH)_x$ is a free-standing metal itself, it serves both as the current collector and as the cathode-active material, thus saving significantly in total weight. Furthermore, as mentioned earlier, the (metallic) conductivity of $[CH(ClO_4)_y]_x$ changes relatively little for values of $y \simeq$ 0.02-0.06. Hence, a large fraction of the material can be gainfully used electrochemically without significant change of those current-collecting properties related to its conductivity.

Constant current discharge characteristics.—A number of experiments were carried out at constant charge and discharge currents, with the charge and discharge currents having the same value. The change in voltage was recorded throughout each experiment. An example of such an experiment is summarized in Fig. 2. This involved three complete

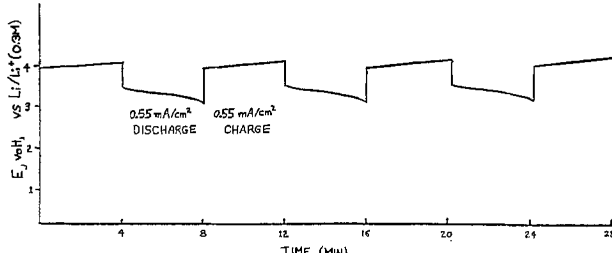

Fig. 2. Three complete charge/discharge cycles of a $(CH)_x/LiClO_4/Li$ (0.3M $LiClO_4$ in PC) rechargeable storage battery at a controlled constant current of 0.55 mA for a 0.5 cm^2 piece of $(CH)_x$ film.

charge/disharge cycles using currents of 0.55 mA and a 0.5 cm^2 piece of cis-rich $(CH)_x$ film (total surface area of both sides, 1.0 cm^2). There is no particular significance in the choice of this current value; it is simply of a convenient magnitude. The charging voltage at the end of a charge cycle was 4.1V. This fell instantly to 3.7V at the very beginning of a discharge cycle. At the end of a discharge cycle it was 3.2V. Each charge and discharge cycle involved 120 mC and took 4 min for the charge cycle and 4 min for the discharge cycle.[2] The composition at the beginning of each of the charge cycles at 0.55 mA (shown in Fig. 2) was $[CH(ClO_4)_{0.045}]_x$, and at the end of each charge cycle it was $[CH(ClO_4)_{0.050}]_x$, (10% discharge). The difference in composition [involving 0.005 mol of $(ClO_4)^-$] was obtained from the coulombs passed.

Studies involving longer discharge periods at lower controlled constant current conditions were also carried out. For example, a single, constant current discharge at 0.55 mA resulted in a drop in voltage to 2.7V after 25 min (0.83C liberated) and a 2 mA discharge gave a voltage of 2.7V after 7 min (0.84C liberated). Voltage recovery was noted under certain conditions when a period of discharge was followed by a rest period during which no current was drawn from the cell. Thus, after the last discharge cycle shown in Fig. 2, (when $V_{oc} = 3.2$) the cell was permitted to stand for ~3 min. It then again displayed a voltage of 3.7V and a further discharge cycle at 0.55 mA had similar characteristics to those given in Fig. 2. To the accuracy of the measurements, the $(CH)_x$ electrode was found to be reversible with no observable degradation. It should also be noted that the cell does not spontaneously lose its charge. Thus a charged cell after standing for 48 hr still showed the same initial open-circuit voltage (3.7V) and discharged at 0.55 mA exactly as before.

An extension of these studies involved an 0.5 cm^2 piece of $(CH)_x$ film to which electrical contact was made by means of a 600Å coating of gold on one side. It was initially oxidized to composition $[CH(ClO_4)_{0.097}]_x$ by means of the passage of 2.73C and was then discharged and recharged for 326 cycles, each cycle consisting of a 100 sec discharge at 2.0 mA (0.20C; 7.3% discharge) and a 100 sec charge at 2.0 mA. Before the first discharge, the open-circuit voltage was 4.13V; at the end of the 320th discharge cycle, it was 4.16V.

The results of the present studies on the use of doped polyacetylene as the cathode-active material in batteries are most encouraging. They suggest the possibility of relatively inexpensive lightweight rechargeable batteries made with polyacetylene which may have a variety of potential technological applications.

Current Distributions in Soluble Battery Electrodes

I. Theoretical

Y. Yamazaki[1] and N. P. Yao*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

The current or reaction distribution in a soluble porous electrode has been formulated using a migration model. The mathematical equations were numerically solved for Zn/zincate electrode in alkaline solution. The result of the calculation revealed different reaction distributions during charge and discharge processes, even in a relatively small electrode current region where no passivation exists. The origin of the difference was discussed in terms of the resistivity variation of pore electrolyte and the interfacial reaction resistance at the electrolyte and the pore wall in the electrode.

The basic processes which limit the cycle life of the porous electrodes used in rechargeable batteries are: (*i*) irreversible side reactions, (*ii*) mechanical failure, and (*iii*) mismatching of the reaction distributions in the porous electrode between charge and discharge processes. The irreversible side reaction refers to gradual changes of active materials to inactive form during the cycle, such as in the lead/lead dioxide electrodes (1-3). The mechanical failure refers to a break off or a shedding of active material from the electrode plates caused by the agitation of gas evolution or by the concentration of thermal stresses or crystallographic stresses generated during the electrode reaction. The mismatching of the reaction distributions in a porous electrode between charge and discharge processes causes dimensional changes in pore structure and in electrode shape (4, 5), consequently, the process sometimes brings serious troubles in a soluble electrode such as the Zn/zincate electrode. An accurate description of these dimensional changes is important in engineering studies to improve the performance of battery electrodes.

It has been shown by Choi, Bennion, and Newman (6) that the mismatching will occur ih an alkaline zinc electrode if the electrolyte flows in the porous electrode by the electro-osmotic pressure across the battery separator. The reaction distribution in sparingly soluble systems was studied by Dunning, Gu, and Newman (7, 8), and intensive discussions were made on the relationship between the current profile and the change of reaction surface area caused by a precipitation of reaction products on the pore wall. The concentration variation in the pore electrolyte is a fundamental parameter for current distribution analysis. Normally the effect was discussed through the polarization equation (9-11), however, it is difficult to handle the equation without the knowledge of the electrode reaction steps which will give the appropriate values of the reactant concentration during the ion discharge step. Actually, for Zn/zincate electrode, it was reported that the exchange current density does not depend on the zinc concentration in the electrolyte (12, 13). In this study the reaction rate of the electrochemical step on the pore wall is assumed independent of electrolyte concentration and to be a linear function of the overpotential.

Mathematical Treatment

The electrode is assumed one dimensional as shown in Fig. 1. The potential gradient along the electrode thickness is given by Ohm's law (14)

$$-\frac{d\phi}{dx} = Ri_m \qquad [1]$$

where ϕ is the potential in the pore solution, x is the distance measured from the front of the electrode, R is the longitudinal resistance of pore electrolyte for a unit area of electrode, and i_m is the migration current in the pore solution for a unit area of electrode. The potential in the pore solution is also related to the current toward the pore wall as

$$-\left(R^* \frac{di_m}{dx} + R_s \frac{di}{dx}\right) = \phi \qquad [2]$$

where R^* is the transverse resistance of the pore electrolyte, R_s is the resistance related to the electrode reaction at the pore wall, and i is the total current in the pore solution for a unit area of electrode, *i.e.*, the sum of the migration and the diffusion currents

$$i = i_m + i_d \qquad [3]$$

Resistances of R, R^*, and R_s are related to electrode parameters as

$$R = \frac{\rho}{\epsilon} \qquad [4]$$

$$R^* = \frac{\delta\rho}{} \qquad [5]$$

Key words: battery, current distribution, porous electrode, zinc electrode.

$$R_s = \frac{R_d}{\gamma} \quad [6]$$

where ρ is the resistivity of pore electrolyte, ϵ is porosity, δ is pore radius, γ is pore wall area per unit volume of electrode, and R_d is the resistance for a unit area of pore wall and is caused by the electrode reaction involving the charge transfer process at the pore wall. The diffusion current i_d is related to the concentration gradient of the reactant in the pore electrolyte as

$$-\frac{dc}{dx} = \frac{i_d}{\epsilon z \mathbf{F} D} \quad [7]$$

where c is concentration, D is diffusion coefficient, ϵ is porosity, z is ionic charge, and $\mathbf{F}$ is Faraday's constant.

The resistivity in pore solution is a function of the concentrations of ion species, then

$$\rho = \frac{1}{\kappa} \quad [8]$$

$$\kappa = \sum_r z_r \lambda_r c_r \quad [9]$$

$$\sum_r z_r c_r = 0 \quad [10]$$

where ρ is the resistivity, κ is the conductivity of electrolyte, and z_i, λ_i, and c_i are equivalence, equivalent conductivity, and the concentration of species i, respectively. The ion species which play a role in the conduction process must include those species generated by the chemical reaction between the electrolyte and the ionized species at the pore wall.

Calculation for alkaline zinc electrode.—In the case of alkaline zinc electrode, zinc cation reacts with hydroxyl ion and forms zincate ion (15) as

$$Zn^{2+} + 4\,OH^- \rightarrow Zn(OH)_4{}^{2-} \quad [11]$$

For simplicity we discuss the case where the charge compensation for the zinc ion concentration change is achieved by OH^- concentration change, *i.e.*

$$\Delta c_{OH^-} = 2\Delta c_{Zn^{2+}} \quad [12]$$

where Δc_{OH^-} and $\Delta c_{Zn^{2+}}$ are the concentration changes of hydroxyl and zinc ions measured from the bulk electrolyte. The formation of zincate ion in the pore electrolyte consumes the free hydroxyl ions, consequently it reduces the conductivity of the pore electrolyte. The conductivity of the pore electrolyte κ is

$$\kappa = \kappa_o + \Delta\kappa \quad [13]$$

$$\Delta\kappa = \lambda_{OH}(\Delta c_{OH^-} - 4\Delta c_{Zn^{2+}}) + 2\lambda_{Zn}\Delta c_{Zn^{2+}} \quad [14]$$

Substituting Eq. [12] gives

$$\kappa = \kappa_o + 2(\lambda_{Zn} - \lambda_{OH})\Delta c_{Zn^{2+}} \quad [15]$$

where κ_o is the conductivity of bulk electrolyte.

Numerical calculation.—The reaction current densities $-(di/dx)$ were calculated for several values of R_d by solving Eq. [1]-[8] and [15] with the additional condition

$$i_d = \xi i \quad [16]$$

where ξ is constant. The boundary conditions are

$$i = I \text{ at } x = 0 \quad [17]$$

$$i = 0 \text{ at } x = L \quad [18]$$

$$c = c_o \text{ at } x = 0 \quad [19]$$

where I is electrode current, L is electrode thickness, and c_o is the reactant concentration in the bulk electrolyte. The constants employed for the calculation are $\epsilon = 0.5$, $\delta = 1.0 \times 10^{-3}$ cm, $\gamma = 1.0 \times 10^3$ cm^{-1}, $D = 6.8 \times 10^{-6}$ cm^2/sec, $\xi = 0.15$, $z = 2$, $L = 0.1$ cm, $c_o = 1.2 \times 10^{-3}$ mol/cm^3, $\kappa_o = 0.45\ \Omega^{-1}$/cm, $\lambda_{OH} = 33.0\ \Omega^{-1}$ cm^2/equiv., and $\lambda_{Zn} = 15.0\ \Omega^{-1}$ cm^2/equiv.

Results

The calculated reaction rate and the zincate concentration change for $I = \pm 120$ mA/cm^2 and $R_d = 10\ \Omega$ cm^2 are shown in Fig. 2. From the graphs we see that the charging reaction rate is less than the discharging one at the entrance of the pore, but the relation is reversed at the end of the pore. Generally the differences between the charging reaction rates and the discharging ones are large for large values of $|I|$ and R_d. The penetration of the current in solution phase and the thickness of the reaction zone are large for large values of R_d.

The results of the calculations for the different values of I and R_d are summarized in Table I. The variation of the concentration in pore electrolyte is large at large values of $|I|$ and R_d. From Table I we see more than 25% of concentration change in pore electrolyte at the end of the pore for $|I| = 100$ mA/cm^2 and $R_d = 1.0$ and 10.0 Ω cm^2. The penetration depth of the solution-phase current i, and that of the reaction current density $-(di/dx)$ depend strongly on R_d, especially when the value of R_d is greater than 0.01 Ω cm^2. We see about 2.2% of difference in reaction rate at the pore entrance between charge and discharge process for $|I| = 100$ mA/cm^2 and $R_d = 10\ \Omega$ cm^2, and about 1% of difference was calculated for $|I| = 100$ mA/cm^2 and $R_d = 1.0\ \Omega$ cm^2.

Discussion

Reaction distribution.—From the calculated results shown in Table I, we see two origins for the mismatching between charging current profile and discharging current profile. First, the profile changes by the electrolyte resistivity change which is caused by the concentration variation in the pore solution. Second, the current profile depends on the reaction resistance R_d which exists between the pore solution and the electrode matrix. A difference in R_d between charge and discharge may arise because of a dependence of R_d on the concentration of reactant in the solution phase. Generally the reaction rate may be written for the charging process as

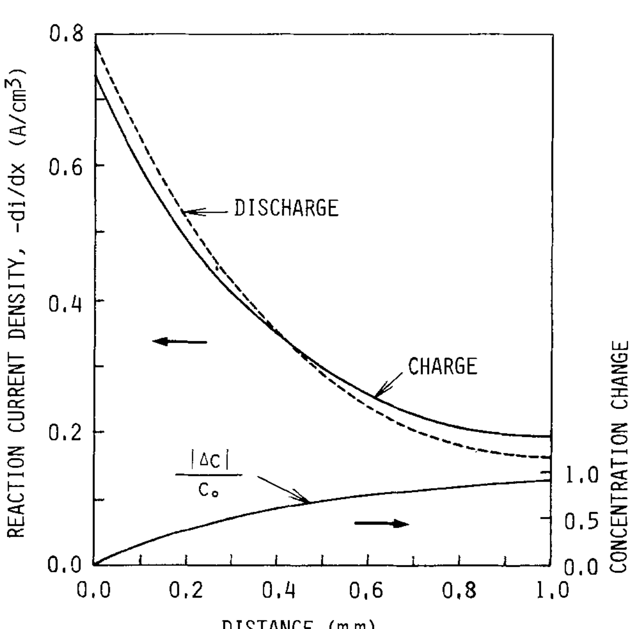

Fig. 2. Calculated distributions of the reaction current density and the zinc ion concentration change in Zn/zincate porous electrode for the electrode current of ± 120 mA/cm^2, $R_d = 10\ \Omega$ cm^2.

Table I. Calculated reaction current densities at $x = 0$, the penetration depth of the reaction zone, and the zinc ion concentration deviation at the end of the pore

Electrode current (mA/cm²)		Reaction current density at $x = 0$ (A/cm³)	Penetration depth of reaction zone* (mm)	Concentration change at $x = L$ (%)

* Penetration depth refers to the point where the reaction current density $-(di/dx)$ reduces to $1/e$.

$$\frac{di}{dx} = ai_o \frac{c_1}{c_1^o} \exp\left[-\beta(\Phi_1 - \Phi_2)\right] \quad [20]$$

where i_o is exchange current density in Tafel polarization, c_1^o is the reference concentration of the reactant, $\beta = \alpha z\mathbf{F}/RT$, Φ_1 and Φ_2 are potentials in the matrix and in the solution phase, respectively. On the other hand, the discharging reaction rate is

$$\frac{di}{dx} = ai_o \exp\left[\beta'(\Phi_1 - \Phi_2)\right] \quad [21]$$

where $\beta' = (1 - \alpha)z\mathbf{F}/RT$. However, it is reported that the exchange current density measured with an alkaline zinc electrode does not depend on the concentration of zinc in the electrolyte (12, 13) for a wide range of 0.016-0.64 mol/liter in 7*N* KOH electrolyte. The origin of the experimental result is believed to be that dislocation and diffusion of adsorbed zinc atoms is the rate-determining step. Using this result, we see that a change of rate-determining step may also change the reaction current distribution through the change of R_d. The charge transfer resistance ($R_D = RT/z\mathbf{F}i_o$) calculated from the reported exchange current densities (12) ranges from 0.2 to 0.9 Ω cm². These values give the lower limit for the estimation of the real value of R_d.

Overpotential.—The overpotential of the porous electrode is obtained by substituting the calculated value of di/dx at $x = 0$ to Eq. [2]. Table II shows the calculated values of the potential ϕ_o for $I = 10$ mA/cm² and different values of R_d. It is noted that the overpotential ϕ_o is not proportional to R_d but to $\sqrt{R_d}$ because the increase of the penetration depth of i with R_d brings an increase in the reaction area in the electrode, consequently it reduces the electrode impedance.

Effect of pore size.—The effects of the pore size on the charging characteristics of the electrode can also be discussed using the same model. A decrease in pore size with a constant porosity brings an increase in surface area of the porous electrode. Table III compares the calculated results of the working characteristics of the electrodes for a porosity of 0.5 and for pore sizes of 1, 10, and 100μ. The surface area γ was calculated using a straight-pore model, *i.e.*, $\gamma = 2\epsilon/\delta$. From the result we see that an increase in the penetration of the reaction zone is accompanied by an increase in electrode overpotential as the pore size increases. Thus the desire to reduce electrode impedance with the fine pore structure must be carefully balanced with the undesirable reduction of the utilizable area in the electrode caused by the limited penetration of reaction zone into the electrode.

Diffusion rate.—The ratio of the diffusion current to the total solution-phase current, introduced as ξ in Eq. [16], is an important parameter. However, the estimation or the formulation of the value as a function of x is difficult. The value of ξ depends on the potential gradient in the solution phase and on the dissociation rate of zincate ion to zinc cation under the local electric field. Equation [1] is useful for the estimation of the potential gradient.

Convective flow.—Another point which we have to mention is the convective flow which may change the concentration profile in the pore solution. Actually considerable amount of down flow of electrolyte near the surface of a flat and vertical zinc electrode is experimentally observed in a discharging process. This convective flow may reduce the concentration variation in pore electrolyte. The calculation of the reaction rate distribution under a gravity convection flow is not impossible, however, we need actual geometric data of the front face of the electrode and the facing separator, and also we need the flow resistivity which may depend on the pore size distribution on the electrode.

Conclusions

A mathematical model on the reaction profile in soluble porous electrodes has been developed and the reaction profiles in a zinc/zincate electrode have been calculated for a set of typical electrode parameters. The calculated results showed that considerable differences in current distribution exist during charge and discharge processes. The physical origins for the differences could be traced to a resistivity change in pore electrolyte and to a change in interfacial reaction resistance at the electrolyte and pore matrix surface. The electrolyte resistivity change is caused by a chemical reaction between the pore electrolyte and the product species of the electrochemical reaction on the pore wall. The calculation suggests that the pore structure of an alkaline zinc electrode will change

Table II. Calculated overpotential on the Zn/zincate porous electrode for different reaction resistances and for the electrode current of 10 mA/cm²

during discharge and charge cycles even in a relatively small current region where no passivation film is formed. The effect of pore size on the current distribution and on the overpotential of the electrode was also numerically discussed using the model.

Current Distributions in Soluble Battery Electrodes

II. Experimental

Y. Yamazaki[1] and N. P. Yao*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

A simulated, sectioned porous electrode was developed using the photolithography technique. The current distributions in Zn/zincate and $Cu/CuSO_4$ porous electrodes were measured using the simulated electrodes for the study of charge and discharge processes. The result showed different current distributions for charge and discharge processes; the charging reaction current in the Zn/zincate system penetrated more deeply into the electrode than the discharging current did. The discharging reaction current in the $Cu/CuSO_4$ system penetrated more than the charging current. These observed characteristics of the current distributions were analyzed using the theoretical results which were mathematically derived based on a migration model. Other applications of the simulated porous electrodes were also demonstrated for study of electrode passivation phenomena and for transient current distribution measurements.

As has been theoretically derived (1), there are considerable differences in the current distributions in a porous zinc electrode during charge and discharge processes even in the relatively low current density regions where no passivation occurs. In this paper the reaction distributions in soluble porous electrodes are experimentally demonstrated. For this purpose, a novel sectioned porous electrode was designed for the *in situ* measurement of the reaction current distribution within the electrode.

Key words: battery, current distribution, porous electrode, zinc electrode.

Normally, current distribution within a porous electrode has been determined indirectly through a chemical analytical method (2, 3) or directly by a sectioned electrode method (4-7). The former method can be adapted to a variety of electrodes and the measurements can be made using commercial electrodes. However, the measurements are limited to the operating range where the electrode reaction causes sufficient precipitation of reaction products to be observed. On the other hand, the sectioned electrode method has an advantage of the continuous *in situ* measurements of the reaction current distribution. Unfortunately, very few results have been reported about the sectioned electrode method because of the difficulty of the electrode fabrication and experimentation. The accuracy of the current distribution measurement with a sectioned electrode largely depends on the electrode design. Particularly it is important to design the experimental electrode so that the real electrode system is well simulated and that the reaction profile is not disturbed by connecting measuring circuits.

Recently the sectioned electrode method was improved when thin film technology was introduced by Szpak and Katan (4) for the fabrication of the electrode segments. By using this technique, they succeeded in reducing the pore size and the thickness of the electrode segments. However, the small interface area at the electrolyte and the matrix of their single pore electrode may generate an error in the measurement. Another deficiency in their design was the large spaces between the segments. Experimentally it is very difficult to reduce the segment distance without the risk of breaking the electric insulation between the segments.

This paper discusses a novel method of fabricating a sectioned porous electrode based on the photolithography technique. The method remedies the deficiencies of conventional experimental sectioned electrodes. Porous sectioned electrodes based on this method have been effectively applied to the study of current distributions within porous zinc/zincate and copper/copper sulfate electrodes.

Experimental

Measurement circuit.—The concept of the sectioned electrode designed for the current distribution measurements is shown in Fig. 1. The measurement circuit connected to the electrode is shown in Fig. 2. The currents passing through each segment of the electrode were measured by the voltage drops across shunt resistors (0.33Ω). A low voltage scanning switch (Keithley Instruments, Incorporated, Model 702/7029) and a strip chart recorder with a high sensitivity plug-in module (Hewlett Packard, Model 17505A) were used for the measurement of the voltages across the shunt resistors. A precision power supply (Hewlett Packard, Model 6114A) was used as a potential source, and the total amount of charge passed through the electrode was monitored with a digital coulometer (Princeton Applied Research, Model 379).

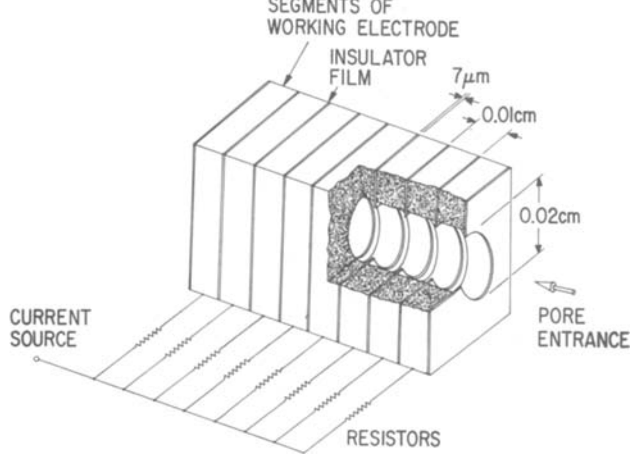

Fig. 1. Schematic representation of the segmented porous electrode.

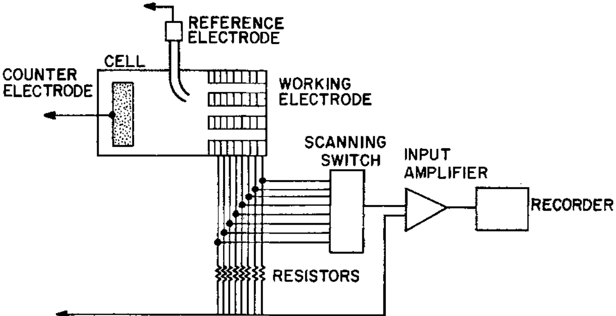

Fig. 2. Schematic diagram of the equipment for current distribution measurement.

Preparation of sectioned electrode.—The perforated metal sheets representing the segments in Fig. 1 were fabricated by conventional photolithography techniques. First, the pore pattern of the electrode was designed and the drawing was photographed with a high contrast film (Kodak High Contrast Copy Film) to make a photolithography mask. The metal sheets were then coated by photoresist resin and the pore pattern was printed using the prepared mask and a mercury-xenon arc lamp. The process was carried out on both sides of the metal sheets. In order to obtain a close fitting of the pore patterns between both sides of the metal sheets, the mask positions were carefully adjusted. The exposed photoresist films were developed by the spray developing method. The metal sheets covered with the developed resist films were dried at 121°C for 10 min and then etched in the solution shown in Table I. The photoresist films on both sides of the metal sheets act as insulators in the fully assembled electrode. The conditions for the photofabrication of the porous segments are shown in Table I. The prepared metal sheets coated with insulator films were stacked to align the holes and then fixed with a lucite frame. Figure 3 shows the stacked segments after wiring, and Fig. 4 shows the mounted electrode stack. The elements were pressed from both sides with a lucite frame (shown as F in Fig. 4) to facilitate close stacking. The electrode parameters are listed in Table II.

Electrolyte preparation.—Electrolytes used for the experiment were prepared as follows: (*i*) KOH [40 weight percent (w/o)] aqueous solution which had been prepared by dissolving AR grade KOH into distilled and oxygen purged water and then stirred overnight in a nitrogen atmosphere; and (*ii*) $CuSO_4$ aqueous solution (1 mol/liter) was prepared by dissolving AR grade $CuSO_4$ in distilled water.

Experimental procedure.—A fresh electrolyte was placed in the cell for 2 hr before the potential was applied to the electrode. The electrode was first dis-

charged at constant cell voltage and the currents passing through each segment were recorded using the scanning switch. The scanning rate was 0.5 sec/segment for the first 1 min of the measurement, then it was changed to 2 sec/segment. The current profile usually varied for a period which was dependent on the total electrode current, then it became steady. The measurement was usually continued for 2 hr. After the discharge measurement, the cell was disconnected from the power source and was permitted to stand for 2 hr before a charging potential was applied. The charging current measurement was made with the same conditions as the discharge case and was terminated after the same quantity of charge had passed through the cell.

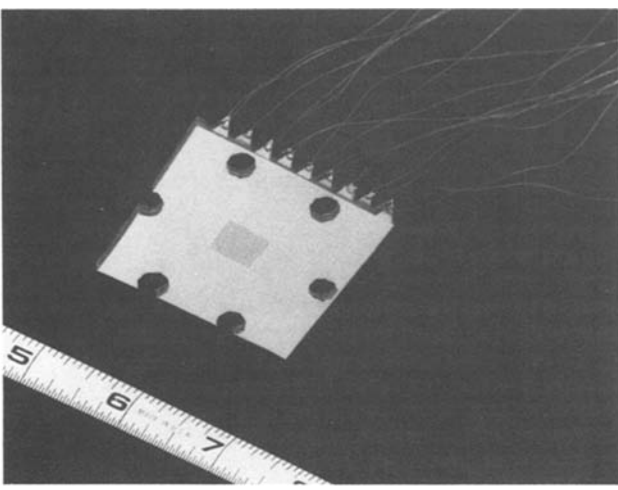

Fig. 3. Stacked zinc electrode segments

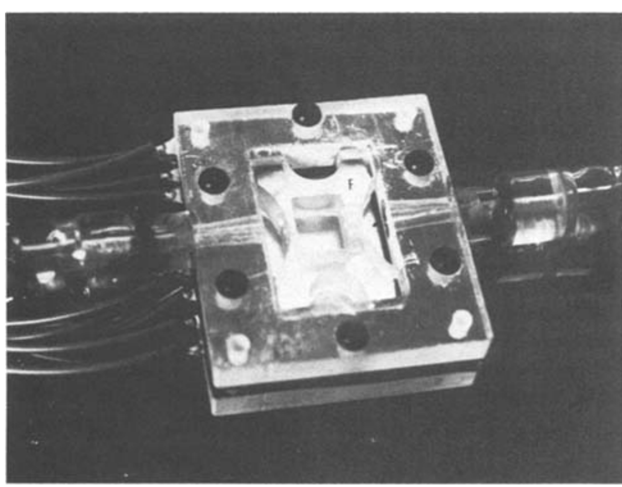

Fig. 4. Mounted electrode stack

The reaction current density was calculated from the measured current through the segments by using the relation

$$i_{reac} = \frac{i_n}{Sd} \quad [1]$$

where S is the electrode surface area, d is the thickness of an electrode segment, and i_n is the current passing through segment n. The reaction current density i_{reac} is equivalent to $-(di/dx)$, where i is the current in the solution phase for a unit area of electrode and x is the distance measured from the front of the electrode.

Results and Discussion

Reaction distributions in the Zn/zincate electrode.—The reaction current distributions measured with the Zn/zincate electrode are shown in Fig. 5 and 6 for electrode currents of 15.8 and 78.9 mA/cm², respectively. The unit of the vertical axes of the figures indicates the transfer current from solution to matrix phase for a unit volume of the electrode. Generally the reaction currents for the charging process penetrated more deeply into the electrode than that of the discharging process. The difference is in good agreement with the theoretical result obtained based on a migration model (1). The calculated curves for charging and discharging processes, in solid and dotted lines, are also shown in the figures. The calculation

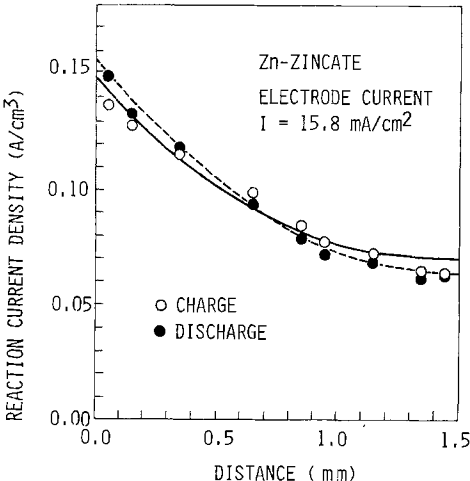

Fig. 5. Reaction distribution in porous zinc/zincate electrode. The curves are theoretical values for $R_d = 4.7\ \Omega\ cm^2$ and $\xi = 0.25$.

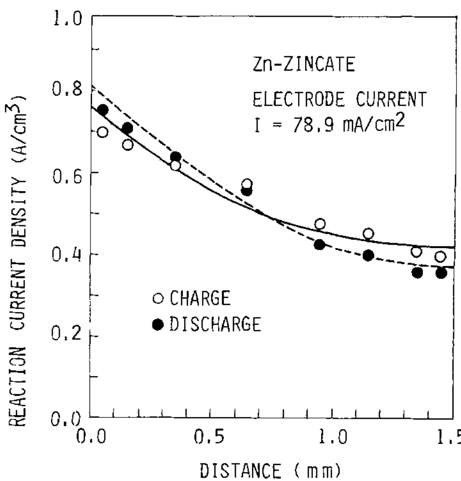

Fig. 6. Reaction distribution in porous zinc/zincate electrode. The curves are theoretical values for $R_d = 6\ \Omega\ cm^2$ and $\xi = 0.07$.

was made using the experimental conditions of pore size, porosity, and electrode thickness shown in Table II. The agreement between the calculated curves for the current density of $I = 15.8$ mA/cm², $R_d = 4.7\Omega$ cm², $\xi = 0.25$, and the experimental data is good. However, the agreement deteriorates somewhat at the higher current density of $I = 78.9$ mA/cm². The values of R_d, which were determined by comparing the theoretical curves to the experimental data, are reasonable since the charge transfer resistance (8)

$$R_D = \left(-\frac{\partial\eta}{\partial i}\right)_{\eta=0} \quad [2]$$

measured with an alkaline zinc electrode using the double pulse method was 0.2-1.0Ω cm² at room temperature and R_d is the sum of R_D and the additional resistance based on the concentration polarization at the vicinity of the pore wall.

Table III compares the measured potential of the bulk electrolyte and the theoretical overpotential which is calculated for the pore electrolyte at the front end of the electrode (1). The agreement is reasonably good. The difference in the calculated potential between charge and discharge processes is originated by the resistivity change of pore solution caused by the concentration change.

Reaction distribution in $Cu/CuSO_4$ electrode.—The reaction distribution was also measured with the $Cu/CuSO_4$ electrode. The theoretical calculation was conducted in the same manner as for the Zn/zincate electrode. However, we must change Eq. [15] shown in the theoretical part of this study (1), to

$$\kappa = \kappa_0 + 2\Lambda_{CuSO_4}\Delta c_{CuSO_4} \quad [3]$$

$$\Delta c_{CuSO_4} = c_{CuSO_4} - c_{CuSO_4,b} \quad [4]$$

where Λ_{CuSO_4} is the equivalent conductivity of $CuSO_4$, c_{CuSO_4} and $c_{CuSO_4,b}$ are the concentrations of $CuSO_4$ in the pore and in the bulk solution, respectively, and κ_0 is the conductivity of the bulk electrolyte.

Figure 7 shows the measured reaction distributions in the $Cu/CuSO_4$ electrode for a small electrode current of 0.79 mA/cm². The charging current concentrates at the front part of the electrode. The theoretical curve for the charging reaction, the solid line, is shown in the figure. The calculation was based on $\Lambda_{CuSO_4} = 27.0\ \Omega^{-1}$ cm²/equiv., $\kappa_0 = 0.053\ \Omega^{-1}$/cm, $D = 1.0 \times 10^{-5}$ cm²/sec, $R_d = 3.0\ \Omega$ cm², and $\xi = 0.1$. The measured reaction distribution for the discharging process shows a deeper penetration into the electrode. The theoretical curve for $R_d = 20.0\ \Omega$ cm² is also shown in the figure as the dotted line. The large value of R_d for the discharge curve is probably due to a formation of Cu_2O film on the pore wall. The film will decompose during the charging process. The concentration variations in pore solution discussed in previous paper (1) was very small because of the low (0.79 mA/cm²) electrode current imposed. The calculated reaction rate differences at the pore entrance gives the differences of 1.0% for $R_d = 3.0\ \Omega$ cm² and 1.2% for $R_d = 20.0\ \Omega$ cm².

The calculated electrode overpotential for the charging curve ($R_d = 3.0\ \Omega$ cm²) was 21.8 mV. This agreed well with the measured overpotential of 18.9 mV. The calculation for the discharging process gave

Table III. Polarization data for the Zn/zincate porous electrode

Electrode current (mA/cm²)		Experimental value (mV)	Theoretical value (mV)
15.8	Charge	24.2	19.7
	Discharge	26.0	20.7
78.9	Charge	93.0	115.0
	Discharge	95.0	123.0

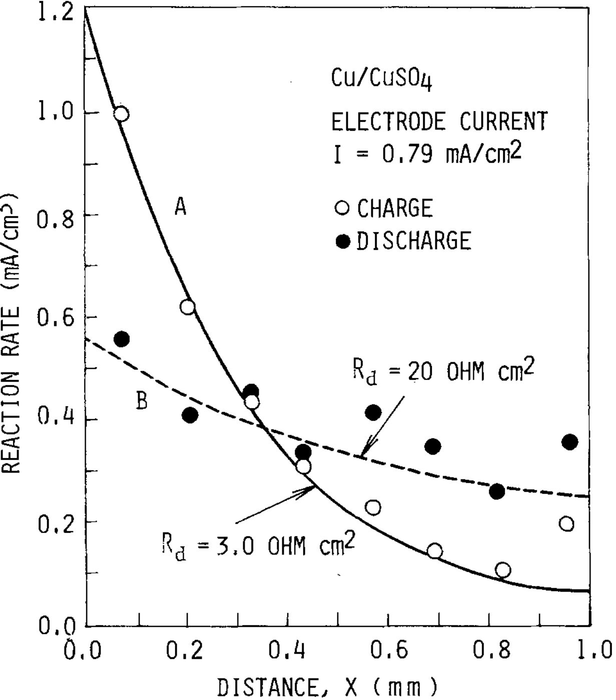

Fig. 7. Reaction distribution in porous copper/copper sulfate electrode. Curves A and B are theoretical values for $R_d = 3.0$ and 20 Ω cm², respectively, and $\xi = 0.1$.

a relatively large value of 61.7 mV compared to the measured overpotential of 24.3 mV.

Passivation in Zn/zincate electrode.—When a relatively large (649 mA/cm²) discharge current was passed through the Zn/zincate electrode for 3 min, an abrupt current reduction was observed. From the change in the current profile shown in Fig. 8, we see a masking of active area on the pore wall by the formation of a passivation film (9, 10). The observed result that the passivation starts from the entrance of the pore is consistent with the result of the microscopic examination reported by Katan (11) on a formation of passivation films in a single pore zinc electrode.

Transient measurement.—By using this type of sectioned electrode, the time progression of the reaction profile could be detected. Figure 9 shows the result of a transient measurement during the discharging process in the Zn/zincate electrode. The measurement was made for 35 min from the beginning of the electrolysis. As seen from the figure, the reaction currents decreased initially and then gradually increased to constant values. These changes in the reaction currents

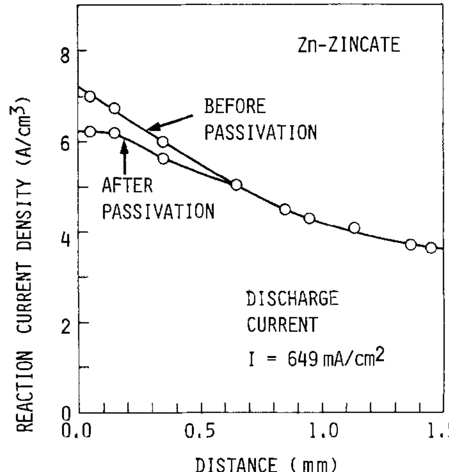

Fig. 8. Reaction distribution in partially passivated porous zinc/zincate electrode.

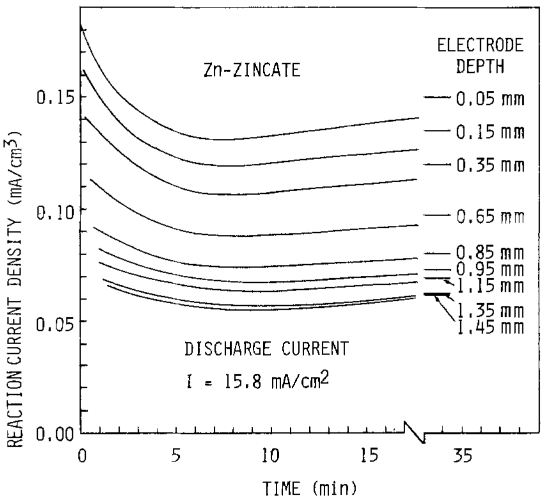

Fig. 9. Time progression of reaction current in porous zinc/zincate electrode at various electrode depth.

are particularly large at the front part of the electrode.

Summary and Conclusions

Novel sectioned porous electrodes based on the photolithography technique have been developed and applied to the measurement of reaction distributions within the porous electrodes. The measured reaction profile in the Zn/zincate porous electrode showed a difference in penetration depth of reaction zone between charge and discharge processes. The amount of the difference agreed well with the theoretical value calculated based on a migration model. The reaction resistance at pore electrolyte and pore matrix, determined by comparing the measured reaction profile and the calculated one, showed reasonable values. The effectiveness of this experimental method was also demonstrated, capable of determining the resistance of the thin film formed on the anode surface of the $Cu/CuSO_4$ electrode.

Passivation of Zinc Anodes in KOH Electrolytes

Ming-Biann Liu,* G. M. Cook,* and N. P. Yao*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

Passivation times of horizontally upward-facing and downward-facing zinc microanodes in KOH electrolytes of five concentrations are reported. These measurements extend passivation data into a low current-density region for evaluating conflicting interpretations of published work. To interpret our data, a new mechanism for anodic passivation is proposed. In high current-density regions, passivation occurs when compact ZnO covers the electrode surface; in low current-density regions, passivation occurs when the mass transfer of hydroxide ions across a porous ZnO layer is less than that required for anodization. This work also discusses passivation in porous zinc battery electrodes.

Alkaline batteries employing zinc electrodes are under development for use in electric vehicles. Knowledge of the passivation behavior of a zinc electrode in KOH electrolyte is required for optimizing the electrode design.

The utilization of a zinc electrode in alkaline batteries depends on the ability of the electrode to remain active during the anodic dissolution process. At anodic potentials near the equilibrium value, the soluble oxidation product of zinc in concentrated alkaline solutions is $Zn(OH)_4^{2-}$, as evidenced by nuclear magnetic resonance (NMR), and Raman and infrared reflection spectroscopic studies (1-3). Many workers (4-25) have made galvanostatic studies using planar zinc electrodes in alkaline solution. These studies describe derivations of the zinc passivation mechanism, morphological observation of the passivation film, and the relation of passivation time to the current density. Several techniques were used to study the passive films. Microscopic observation provided morphological data (15, 16, 23, 24). An ellipsometer measured the relative changes of amplitude and phase of light specularly reflected by the passivation film (14, 25). X-ray analysis identified ZnO as the passivation film (21); however, this analytic method requires the removal and subsequent drying of the passivation film, which could result in the conversion of all the zinc-containing species to ZnO. *In situ* identification of the chemical nature of the passivation film is not available.

The mechanism of passivation and the relationship between current density and passivation time for zinc anodes in alkaline solution has been reviewed by the authors (26) and will be discussed later. In the literature, there are conflicts in the treatment of passivation data and in the interpretation of the process for determining passivation time. In the former, for a given electrolyte, Dirkse and Hampson (13) indicated that a single modified Sand equation could cover the current-density region from 0 to 10 A/cm^2. Bartelt and Landsberg (7) found that two equations were required: one for high current-density regions (>0.32 A/cm^2) and one for lower current-density regions. In the latter, Hampson and his co-workers (11, 13) postulated that the electrode passivates instantly when ZnO is precipitated from supersaturated zincate at the electrode surface. Other investigations (14, 16, 25) indicated the passivation is not likely to happen at the moment ZnO is produced. These conflicts were not resolved since the measurements in the literature were usually complicated by free convection. Therefore, we have used electrodes designed to minimize free convection to carry out passivation measurements in five concentrations of KOH electrolyes over a wide range of current densities (0.06-1.53 A/cm^2). Based on our results, we propose a new scheme that describes the passivation time in terms of sequential reaction steps. We have extended measurements to the current-density region of interest in battery design (below 0.1 A/cm^2 at 7M KOH). These data were then used to estimate the effect of passivation on the utilization of a porous zinc battery electrode.

Experimental

The standard experimental cell and other apparatus used is described elsewhere (26). Rectangular zinc electrodes, 0.05 × 0.13 cm, were cut from a zinc sheet of 99.99% purity purchased from United Mineral and Chemical Corporation (New York). The impurities were specified to be as follows: Cd, 5 ppm; Pb, 5 ppm; Fe, 3 ppm; Cu, 2 ppm; Au, 1 ppm; Sn, 1 ppm; Fe, 0.5 ppm; and In, 0.5 ppm. The electrodes, set in acrylic plastic (purchased from Fulton Products Corporation, Saxonburg, Pennsylvania), were mounted horizontally in either the upward- or downward-facing position. The upward-facing microanode has the following special features: (*i*) It provides conditions required for a stable stratification of fluid near the electrode surface since the electrochemically formed zincate is denser than the bulk electrolyte, (*ii*) the acrylic plastic surrounding the anode provides the means to maintain a high zincate concentration at the edge of the electrode, *i.e.*, there is no sharp change in the diffusion boundary layer at the edge, and (*iii*) the small size of the electrode (0.05 × 0.13 cm) compared to its distance from the counterelectrode (1.5 cm) provides a relatively uniform electric field over its surface. The electrolyte was reagent-grade KOH at concentrations of 0.784, 2.92, 4.98, 7.24M KOH or 7.24M KOH saturated with analytical reagent-quality zinc oxide. The solutions were prepared with doubly distilled water and deaerated by bubbling purified nitrogen through them. The experiments were performed at room temperature (approximatelty 20°C).

Before each experiment, the zinc electrode was anodically etched at 10 μA for 5 sec and then allowed to stand for at least 10 min to ensure a quiescent state in the electrolyte and to establish electrode/electrolyte equilibrium conditions. Before an electrode was reused, it was repolished and its surface finish was measured with a calibrated optical microscope. Periodically, experiments were repeated to determine experimental reproducibility; average reproducibility of the experimental data was found to be 8.4% about the mean value.

Results

The relationship between current density, i, and passivation time, t, is usually expressed by the modi-

* Electrochemical Society Active Member.

Key words: battery, mass transfer, porous electrode, oxide.

fied Sand equation (26)

$$i = kt^{-1/2} + i_e \quad [1]$$

where k and i_e are constants. Therefore, least squares fitted passivation data are plotted in the form of i *vs.* $t^{-1/2}$ in Fig. 1-3. Plotted in Fig. 1 are the data for upward- and downward-facing zinc microelectrodes which were anodized in 7.24M KOH electrolyte at current densities ranging from 61 to 1620 mA/cm^2 and for upward-facing electrodes anodized in 7.24M KOH saturated with ZnO at 122-1530 mA/cm^2. For passivation times less than 7 sec, the data for upward- and downward-facing anodes in 7.24M KOH electrolyte are in agreement within experimental uncertainty. However, for longer times, a downward-facing anode has a longer passivation time at a given current density. The data also show that the presence of zincate in the electrolyte shortens the passivation time.

Figure 2 presents the passivation data for the upward-facing anode in four concentrations of KOH (0.784, 2.92, 4.98, and 7.24M). The data show that for passivation times less than 100 sec ($t^{-1/2} = 0.1\ sec^{-1/2}$), higher concentrations of KOH result in longer passivation times at any given current density. For passivation times longer than 100 sec, these data are plotted on the expanded scale of Fig. 3. It is clear that the KOH concentration effect is the same for the longer passivation times. (Current densities below 100 mA/cm^2 are of interest to battery applications.)

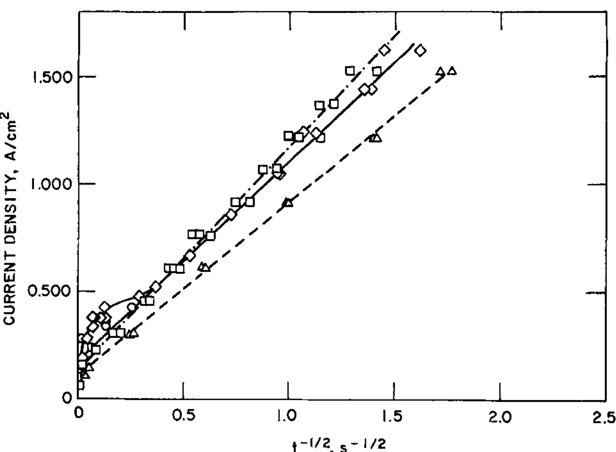

Fig. 1. Effect of orientation and bulk zincate on current density *vs.* passivation time, *t*, of zinc anodes in 7.24M KOH (squares, upward anode; diamonds, downward anode; circles, downward anode with 1 mm plastic channel; triangles, upward anode using electrolyte saturated with zincate).

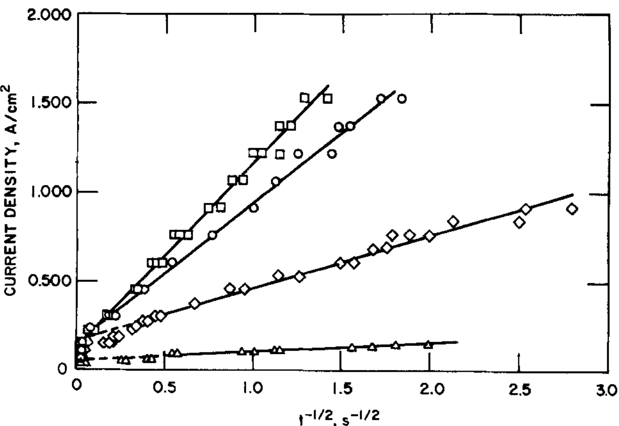

Fig. 2. Current density *vs.* passivation time for upward-facing zinc anodes in 7.24M (squares), 4.98M (circles), 2.92M (diamonds), and 0.784M (triangles) KOH electrolyte.

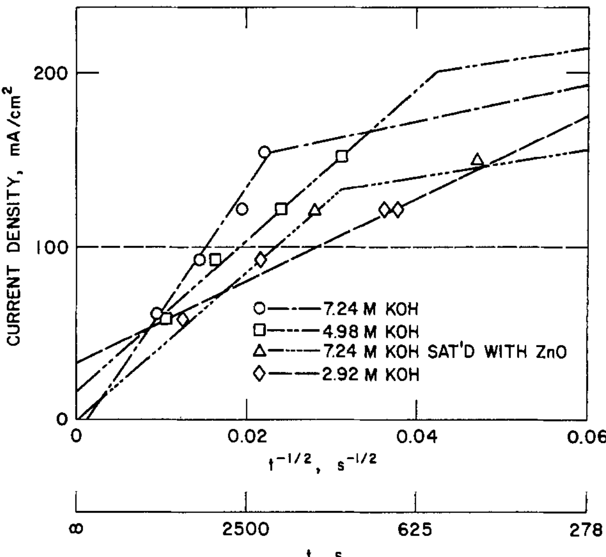

Fig. 3. Current density *vs.* passivation time for upward-facing anodes (low current-density region).

The constants of Eq. [1] (k, i_e) for zinc microelectrodes in the KOH electrolytes are tabulated in Table I. Since, for the upward-facing anode, the passivation times are substantially longer at low current densities than at high values, the constants are given for two current-density regions. From Table I, in the low current-density region, the intercept (i_e) for 7.2M KOH is near zero. On this basis, a zero intercept of the i *vs.* $t^{-1/2}$ curve was assumed in order to calculate k for the low current region of series 3 from the single datum at 122 mA/cm^2.

Discussion

Potential-time curve.—Our potential *vs.* time curves were similar to those observed by Dirkse and Hampson (13), except that we observed a short-life transition just prior to the onset of passivation, as also observed by Bartelt and Landsberg (7) and Elder (12). Since the electrode potential at the transition is in the vicinity of the Zn/ZnO standard potential, the transition may be associated with the direct formation of the passivating type II ZnO film observed by Powers and Breiter (15).

Relationship between current density and passivation time.—It is generally agreed that a zinc oxide film is responsible for the passivation of zinc anodes in alkaline electrolytes (26). The disagreement relates to the nature of the rate-determining steps in the processes associated with passivation. Table II summarizes the rate-determining steps and the relationships between current density and passivation time proposed in the literature.

Table I. The constants of Eq. [1] for the zinc anodes ($i = kt^{-1/2} + i_e$)

Expt. series*	Electrolyte (M)	Current density (mA/cm^2)	$k \times 10^{-2}$ ($mA/sec^{1/2}/cm^2$)	$i_e \times 10^{-2}$ (mA/cm^2)
1	7.24	200-1530	10 ± 0.2	1.3 ± 0.2
		60-153	69 ± 7	−0.08 ± 0.12
2	7.24	525-1620	9.2 ± 0.5	1.9 ± 0.6
3	7.24	200-1530	8.1 ± 0.1	1.1 ± 0.1
	(Saturated with ZnO)	0-122	44	0
4	4.98	200-1530	7.8 ± 0.2	1.7 ± 0.2
		60-153	43 ± 2	0.18 ± 0.05

6	0.784	60-153	0.54 ± 0.04	0.52 ± 0.04

* The electrode orientation was horizontally facing-upward except in series 2 where it was horizontally facing-downward.

Table II. Comparison of proposed rate-determining steps given in the literature for the passivation of zinc anodes in alkaline electrolytes

Authors	Rate-determining steps	Relationship between current density and passivation time[c]
Dirkse *et al.* (13)	Diffusion of zincate[a]	$i(t^{1/2}) = (C_{crit} - C_b)nF\sqrt{\pi D/4}$
Eisenberg *et al.* (6)	Diffusional and convective mass transfer of zincate[b]	$(i - i_e)t^{1/2} = k$
Elder (12)	Chemical reaction of discharged product to zincate and diffusion of zincate[a]	$i(t^{1/2}) = k_0 - k_1 i$
Yamashita *et al.* (14)	Diffusion of zincate and growth of ZnO film[a]	$(i - i_e)t^{1/2} = k$

[a] No convection.
[b] Free convection.
[c] C_{crit} — the critical concentration of zincate ions for the precipitation of ZnO. C_b — the concentration of zincate ions in the bulk electrolyte.

Dirkse and Hampson (13) postulated that passivation occurs when a critical concentration of zincate ion is established in the layer of electrolyte in contact with the electrode surface. According to their hypothesis, the slope of i *vs.* $t^{-1/2}$ can be estimated using the equation shown in Table II. In comparison with the k values predicted by the equation of Dirkse and Hampson with our experimental values in Table I, our calculated k values are about the same (0.86-1.5 times) in the high current-density region and about one order of magnitude lower in the lower current-density region. The i_e value predicted by this equation is zero (independent of current-density region); however, our experimental data are not zero in the high current-density region. These results indicate that their mechanism is not useful for describing our experimental data.

Eisenberg *et al.* (6) introduced a concept of free convection to interpret their passivation data. An estimated diffusion-excluded convective current density, i_e, is used to modify the Sand equation to the form given in Table II. The magnitude of i_e corresponds to the rate of mass transfer of zincate ions away from the electrode surface by free convection. If the applied anodic current density is below i_e, a critical concentration of zincate ions is never established at the electrode surface and no passivation occurs.

Free convection at a horizontal electrode occurs when (*i*) the passivation time is sufficiently long and (*ii*) heavier fluid overlies a lighter one (unstable stratification) (27). The formation of zincate ions during the discharge of a zinc anode increases the density of electrolyte at the electrode surface. Under this circumstance, condition (*ii*) is met by a downward-facing electrode. Free convection could develop if condition (*i*) is also met. For the upward-facing anode condition, (*ii*) is not met; therefore, free convection is not expected to occur. We may use our data to determine the existence of condition (*i*) for the downward-facing electrode. When the passivation time is shorter than 7 sec, at a caustic concentration of 7.24M KOH, electrodes with either upward-facing or downward-facing orientation behave in the same way within experimental uncertainty (Fig. 1). When the passivation time of the downward-facing electrode is longer than 7 sec, for any current density <525 mA/cm^2, the passivation time is longer than that of the upward-facing electrode. Therefore, condition (*i*) is met only at times longer than about 7 sec. Accordingly, Eisenberg *et al.* (6), would predict $i_e = 0$ for passivation times shorter than 7 sec. Since our data show that $i_e = 186$ mA/cm^2 in the high current-density region, the diffusion-excluded convective current concept does not explain our results.

Elder (12) proposed that either chemical dissolution of zinc or complex formation of dissolved zinc species is a rate-controlling step in the passivation process of zinc anodes in alkaline media. Thus, he used the equation given in Table II to correlate his data. According to his hypothesis, i is not linearly related to $t^{-1/2}$ in any region of current density. Since our data show linear relationships, his approach does not provide an acceptable description of our results.

Yamashita *et al.* (14) discovered two distinct discontinuities in the optical phase shift *vs.* time curve for light reflected by the zinc electrode during an anodic discharge. They proposed that the first discontinuity, t_1, occurred when the type I zinc oxide film began to form and grow on the anode. The second discontinuity, t_2, occurred when the passivation compact type II zinc oxide was forming. Yamashita *et al.* (14) demonstrated that t_1 varied with current density according to the expression given by Dirkse and Hampson (Table II). Their equation in Table II is of the same form as that of Eisenberg *et al.* (6), the term i_e is not diffusion-excluded convective current density. Therefore it also does not predict the two regions found in our work.

In summary, none of the mechanisms given in Table II can satisfactorily explain our data.

Proposed passivation mechanism.—In order to explain our experimental data, we propose the scheme shown in Fig. 4 for all processes associated with the anodic passivation of zinc in alkaline solutions. In the first step, the anodic reaction proceeds for a time, t_a, producing zincate ions which accumulate near the electrode surface because diffusion is too slow to dissipate them. Finally zincate ions accumulate to a concentration, C_{crit}, at which point type I ZnO begins to precipitate. The value of C_{crit} is believed to be a factor of three to four times the solubility of ZnO in KOH solution (11, 13, 14, 29, 30) and is independent of the initial zincate concentration (C_b). The term ($C_{crit} - C_b$) (Table II) implies that the presence of zincate in the electrolyte shortens the passivation time; our results confirm this conjecture (Fig. 1). However, it is difficult to detect the time at which C_{crit} is attained on

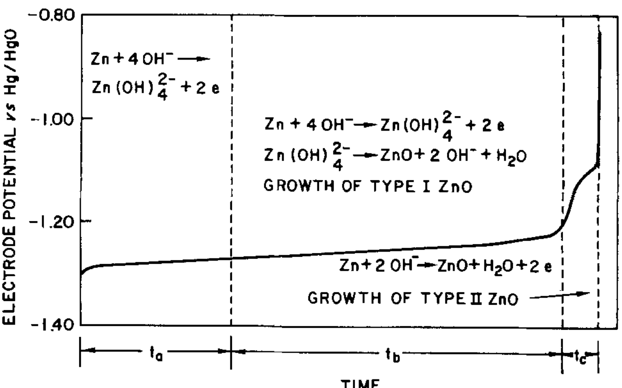

Fig. 4. Proposed scheme for the processes associated with the anodic passivation of zinc in alkaline solutions.

chronopotentiograms. The partial transformation of zincate to zinc oxide (type I) and the mass transport of OH^- ions through this porous zinc oxide (15) permit the continuation of the electrode reaction. After a time, t_b, the rate of mass transfer of hydroxide ions through the ZnO falls below that required for the zincate formation reaction. Thus the formation of type II zinc oxide is initiated on the electrode surface. After an additional time, t_c, the electrode surface is covered by compact type II ZnO, thereby limiting the transport of OH^- ions and passivating the electrode. This proposed mechanism of anodic film growth is in agreement with observations by Smith using ellipsometry and scanning electron microscopy (25).

The total time to passivation is expressed by

$$t = t_a + t_b + t_c \qquad [2]$$

As concluded by Yamashita *et al.* (14), one may use ellipsometry to determine t_a or use the expression of Dirkse and Hampson (13) to estimate it from C_{crit} and D (Table II). The example in Fig. 5 illustrates how to obtain $t_b + t_c$ from the passivation data for the upward-facing anodes in 7.24M KOH. Line a is predicted by the Sand equation (13) with the assumption that the passivation is caused by the exhaustion of OH^- species at the electrode surface without any precipitates. Line b represents t_a calculated by substituting the solubility data for electrochemically generated ZnO (29) and the diffusion coefficient of zincate (28) into the equation of Dirkse *et al.* (13) (Table II). Curve c shows our passivation time data. Curve d was derived from curve c and line b, *i.e.*, $(t - t_a)$. At the intersection of line b and curve d, $t_a = t_b + t_c$. To the left of this intersection, $t_b + t_c > t_a$ and to the right, $t_a > t_b + t_c$.

According to our proposed mechanism, the following can be derived:

1. If $t_a >> t_b + t_c$, then $t = t_a$. This is the case proposed by Dirkse and Hampson (13) in which the electrode is instantaneously passivated by the formation of compact ZnO once a given level of zincate is achieved.
2. If $t_b >> t_a + t_c$, then $t = t_b$. Here the passivation is caused by limitation of mass transfer by a thick porous ZnO layer.
3. If $t_c >> t_a + t_b$, then $t = t_c$. In this case, passivation is caused by mass transfer, limited by immediate formation of compact ZnO layers.
4. If t_c is negligible, then $t = t_a + t_b$. This is the case proposed by Yamashita *et al.* (14).
5. If t_b is negligible, then $t = t_a + t_c$. Here, formation of compact ZnO follows immediately after a critical zincate concentration is established at the electrode surface.
6. If t_a is negligible, then $t = t_b + t_c$. In this case, passivation is caused by mass transfer, limited by the immediate formation of porous ZnO followed by the formation of compact ZnO.
7. If t_a, t_b, and t_c are of the same order of magnitude, then $t = t_a + t_b + t_c$.

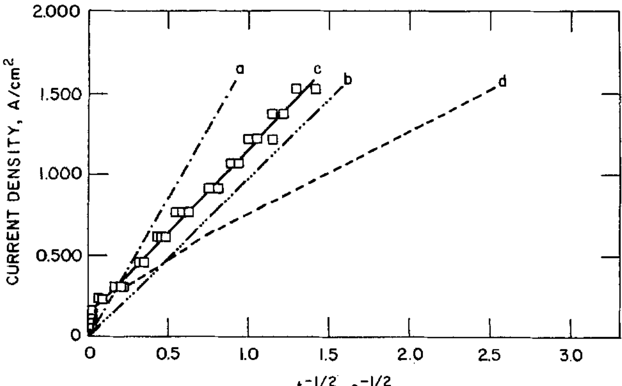

Fig. 5. Analysis of passivation data for upward-facing Zn anodes in 7.24M KOH (significance of the various lines is explained in the text).

In Fig. 1 and 2 we obtained nonzero intercepts when correlating our high current-density data, because, as shown in Fig. 5, our high current-density data probably belong to example 7 in which the intercepts are not diffusion-excluded convective current densities.

The values of i_e for the low current-density data are nearly zero (Table I and Fig. 3). Figure 5 shows that the slope of the low current-density data is greater than the slope of line a. Therefore, it is likely that the passivation of the zinc anodes was not caused by the limited rate of diffusion of OH^- ions across a boundary layer. The calculation using the equation of Dirkse and Hampson (13) (Table II) shows that t_a is only 1.5-8.4% of the passivation time shown in Fig. 3 for the low current-density region. The time, t_c, is probably only a small fraction of t since it takes only a short time to grow a thin layer of type II ZnO (porosity 0.003) (25). Therefore, it is likely that the low current-density data belong to case 2 in which $t_b >> t_a + t_c$. The electrode finally passivates because the anodic reaction rates are limited by the transport of OH^- ions through this zinc oxide film (25). In our experiments, in which the electrodes were set in acrylic plastic, the anodic dissolution of Zn erodes the solid zinc, leaving space surrounded by the plastic wall for the growth of the type I ZnO film, which has pores of about 7500Å on the average (24) and an average porosity of 0.056 in 0.5M KOH and 0.28 in 6M KOH (25); this film, consequently, presents some resistance to mass transfer. To obtain a quantitative description of the mass transfer resistance of the type I ZnO film, we assumed that, at the electrode surface, the rate of supply of OH^- ions is equal to the rate of consumption of OH^- ions by the electrode reaction. Therefore, if there is no convective mass transfer, the equation describing the consumption of OH^- ions can be written as

$$\frac{4i}{n\mathbf{F}} = \frac{\epsilon^{1+\xi}D_3}{\delta}(C_{3b} - C_{3s}) + \frac{-it_3}{z_3\mathbf{F}} + \frac{2yi}{n\mathbf{F}} \qquad [3]$$

where the term on the left-hand side is the consumption rate of OH^- ions by the anodic process; the terms on the right-hand side represent the supply of OH^- ions by diffusion, migration, and precipitation of ZnO (Fig. 4), respectively. In Eq. [3], ϵ and ξ are the porosity and the tortuosity factor of the ZnO film, respectively; D_3 is the diffusion coefficient of OH^- ions; C_{3b} and C_{3s} are the concentrations of OH^- ions in the bulk and at the electrode surface, respectively; y is the ratio of the rate of precipitation of ZnO to that of the electrochemical formation of zincate, and δ is the thickness of the mass-transfer boundary layer (assumed to be equal to the thickness of the ZnO film); z_3 and t_3 are the charge number and the transference number of OH^- ions, respectively. The thickness of the ZnO increases with time and therefore affects the OH^- supply. The rate of increase in the thickness of the ZnO film can be written as

$$\frac{d\delta}{dt} = \frac{\overline{V}_{ZnO}}{(1-\epsilon)}\frac{yi}{n\mathbf{F}} \qquad [4]$$

where $\overline{V}_{ZnO}$ is the partial molar volume of ZnO. Since, in the low current-density region, the time required to establish C_{crit} is negligible in comparison to the passivation time, $\delta = 0$ at $t = 0$. Therefore, from Eq. [4] we obtain

$$\delta = \frac{\overline{V}_{ZnO}}{(1-\epsilon)}\frac{yi}{n\mathbf{F}}t \qquad [5]$$

Combining Eq. [3] and [5]

$$\frac{\bar{V}_{ZnO}}{(1-\epsilon)}\frac{y}{n\mathbf{F}}\left[\frac{(4-2y)}{n\mathbf{F}}+\frac{t_3}{z_3\mathbf{F}}\right]i^2t = \epsilon^{1+\xi}D_3(C_{3b}-C_{3s}) \quad [6]$$

At the time when C_{3s} is equal to zero, the electrode passivates. Thus

$$i(t^{1/2}) = \left\{\frac{\epsilon^{1+\xi}D_3C_{3b}}{\frac{\bar{V}_{ZnO}}{(1-\epsilon)}\frac{y}{n\mathbf{F}}\left[\frac{(4-2y)}{n\mathbf{F}}+\frac{t_3^o}{z_3\mathbf{F}}\right]}\right\}^{1/2} \quad [7]$$

By comparing Eq. [7] with Eq. [1], we obtain

$$i_e = 0$$

and

$$k = \left\{\frac{\epsilon^{1+\xi}D_3C_{3b}}{\frac{\bar{V}_{ZnO}}{(1-\epsilon)}\frac{y}{n\mathbf{F}}\left[\frac{(4-2y)}{n\mathbf{F}}+\frac{t_3^o}{z_3\mathbf{F}}\right]}\right\}^{1/2} \quad [8]$$

k can be estimated from Eq. [8] for the low current-density region. The value of y is probably close to unity since the rate of mass transfer of zincate ions from the electrode surface through the ZnO film to the bulk electrolyte is small in comparison to the rate of $Zn(OH)_4^{2-}$ formation of Fig. 4. By using the data: $y = 1$, $D_3 = 3 \times 10^{-5}$ cm²/sec (28); $\xi = 0.5$, $\bar{V}_{ZnO} =$ 14.51 cm³/mol, and $t_3 = 0.72$ (31); $z_3 = -1$, and $\epsilon =$ 0.056 and 0.28, k was calculated and is compared with the experimental results (Table I) in Table III. The calculated values of k are of the same order of magnitude as the experimental values. Therefore, we conclude that in the low current-density region, passivation may be caused by a limited mass transfer rate of OH^- ions across the thick porous ZnO layer.

Application to Battery Technology

In Ni/Zn alkaline batteries under development for vehicle propulsion, the electrolyte is typically 30% KOH (7M) saturated with ZnO with the zinc anode formed *in situ* by electrodeposition. Anode passivation should be avoided to achieve maximum utilization. From our data, we estimate the conditions necessary for passivation, noting the following differences between our zinc electrodes and those of Ni/Zn batteries

Electrodes used in this study	Ni/Zn battery electrodes
Solid zinc electrode	A porous zinc electrode (in most cases)
Excess electrolyte	Limited electrolyte
Uniform current density	Current densities dependent upon location on and in the electrode

Table III. Comparison of the calculated values of k (Eq. [8]) and experimental results for the low current density region of upward-facing electrodes

Expt. series[a]	$k \times 10^{-3}$, mA-sec$^{1/2}$/cm²		
		Calculated	
	Experimental	$\epsilon = 0.056$	$\epsilon = 0.28$
1	6.9 ± 0.7	3.5	10
3[b]	4.3	3.2	9.4
4	4.3 ± 0.2	2.9	8.6
5	2.3 ± 0.3	2.2	6.6

[a] The experimental series was defined in Table I.
[b] OH^- concentration = 5.96M.

The basic assumption is that an electrodeposited-zinc porous battery electrode cycled at the 2 hr rate has an apparent current density of 20 mA/cm². To compare planar electrodes with porous electrodes, it is necessary to assess the effective interfacial surface area per unit macroscopic area and then to calculate the corresponding current density in the porous electrode

The assessment of the effective interfacial surface area requires a knowledge of the structure of zinc electrodeposits. Naybour (32) observed that the deposits were dendritic at 100 mA/cm², consisted of layered growths with some granular growths at 20 mA/cm², and were mossy or spongy at 4 mA/cm². The zinc electrode in a typical Ni/Zn battery cycled at a 2 hr rate (*i.e.*, 20 mA/cm²) consists of metallic sponge zinc (33) with a charge density of 144 C/cm². From the charge density data and the size and density of the spongy deposits described by Naybour (32), the porosity of the expected deposit is 0.6 Using these data and the molar volume of solid zinc [9.15 cm³/mol (31)], it is calculated that, during a single charge, zinc deposits to a thickness of 114 μm or slightly more than the characteristic reaction penetration depth, 90 μm (34). Therefore, the characteristic reaction depth is used to estimate the effective interfacial surface area.

Since the specific surface area is about 300 cm²/cm² [Ref. (31)], an effective interfacial surface area of 2.7 cm²/cm² of electrode area is calculated. This yields an effective current density of 7.4 mA/cm². The equation in this current density range (Table I) is

$$i = (4.3 \times 10^3)t^{-1/2} \quad [9]$$

Using Eq. [9], a passivation time of 9 hr is calculated. This is much longer than the 2 hr discharge time.

Assuming that the effective interfacial surface area remains constant the maximum current density for 100% utilization of the zinc electrode can be calculated from Eq. [9] and the equation of utilization

$$Q = 10^{-3}it \quad [10]$$

where Q is the capacity of the electrode, in C/cm², t is the passivation time, in seconds, and the constant 10^{-3} is used to convert the current density from mA/cm². to A/cm². Since Q equals 144 C/cm², a maximum current density of 125 mA/cm² is calculated. This corresponds to a current density of 338 mA/cm² for the porous zinc electrode and is 17 times the designed current density, which is not expected to occur even under severe driving conditions. Therefore, simple surface passivation is not expected to limit the utilization of a newly formed porous zinc electrode.

Conclusions

The passivation time of zinc anodes in KOH electrolytes can be expressed by the equation, $t = t_a + t_b + t_c$; where t_a is the time at which a critical concentration of zincate is established, and t_b and t_c are the times during which the respective porous and compact ZnO films are formed. At high current-density levels, passivation occurs when compact ZnO covers electrode surface. In low current-density regions, passivation occurs when mass transfer of hydroxide ions across a porous ZnO layer is less than that required for anodization. Finally it can be concluded that simple surface passivation does not limit the utilization of a newly formed porous zinc battery electrode.

Photoelectrochemical Characterization of the Passive Films on Iron and Nickel

S. Mark Wilhelm* and Norman Hackerman**

Department of Chemistry, Rice University, Houston, Texas 77001

ABSTRACT

Increases in surface reaction rates caused by periodic illumination of iron and nickel passive films with polychromatic and monochromatic light have been measured. The electrode photoresponse is caused by excitation of a surface film which is the product of anodic oxidation. The dependence of the photocurrent magnitude on electrode potential and excitation energy suggests that the passive layers possess semiconductor characteristics. Capacitance and kinetic measurements are reported which support a proposed model.

The phenomenon of metal passivity has been actively investigated for almost two centuries (1). Although any metal which resists corrosion in spite of a thermodynamic tendency to react may be described as passive, the traditional definition of passivity is limited to metals in which the active and passive surfaces cannot be distinguished visually. Fe, Cr, and Ni are the best examples and it is with these metals that the phenomenon of passivity is most commonly associated. Iron is unique among metals which passivate in that the process is seemingly reversible. Under certain conditions, iron can oscillate between an active and passive condition with a period on the order of several seconds (2).

The exact chemical and structural compositions of the passive films on iron and nickel are still unresolved. Several oxides and hydroxides have been postulated. Although passive surfaces have been subjected to rigorous analysis, most techniques suffer from the inability to scrutinize films *in situ*. The most widely accepted model in the case of Fe is a duplex film of Fe_2O_3 and Fe_3O_4 (3). For Ni, an NiO film has been suggested (4). There is general agreement that such films are inhomogeneous and hydrated.

It has been suggested (5-10) that the passive films which form on iron and nickel are semiconductors and that their electrochemical behavior is due, at least in part, to their solid-state electronic properties. This postulate is supported by observations of the semiconducting properties of thick anodic oxides on other metals (11) and those of polycrystalline iron and nickel oxides (12-14).

One method of determining the electronic structure of semiconducting electrode materials quantitatively is to observe the effect of illumination on electrochemical reaction rates. The influence of light on the iron passive

surface was first noted by Oshe and Rosenfeld *et al.* (15-18). They detected changes in electrode potential caused by irradiation with u.v. light. The effect of light on semiconductor electrodes is to produce electrons and holes in the conduction band and valence band, respectively. In an electrochemical cell this translates into photovoltages and photocurrents which arise from the separation of charge. Recently, the present authors reported measurements of photocurrents generated by illumination of the iron passive film (13). This investigation has been expanded to include the nickel passive film and the process of anodic oxidation in near neutral pH solutions.

We have chosen to interpret the photocurrent data presented here in terms of the theory of semiconductor electrodes. It is customary in discussing the electrochemistry of semiconducting materials to simplify the band structure, *i.e.*, to assume well-defined parallel energy bands of infinite width. This is a reasonable conceptual simplification for single crystal semiconductors (19). Although the same simplification will be adopted here, it should be pointed out that the interaction of electronic energy levels in transition metal oxides does not necessarily give bands in a traditional sense. In fact some studies (20) suggest that the conductivity of Fe_2O_3 and NiO differ fundamentally from that of broad band semiconductors. Additional difficulties in defining the electronic structure of thin passive films are introduced by their polycrystalline and possibly amorphous nature. It has been demonstrated, however, that explanations of the electrochemistry of metal oxides based on a simplified energy level diagram are useful and accurate within proper limits.

Experimental

All solutions were made with triply distilled water ($R > 10^6$). Chemicals were reagent grade or better. The solutions were degassed with purified nitrogen (99.95% N_2) which had passed through a heated (350°C) column of copper turnings to remove traces of oxygen. The temperature of all experiments was 297 ± 2 K.

The aqueous solutions were 1*N* in Na_2SO_4 unless noted. Sodium borate and H_3BO_3 were added in ratios which buffered the solutions to a *p*H between 6 and 9. The standard buffer solution of *p*H 8.4 was 0.0375M in $Na_2B_4O_7$ and 0.10M in H_3BO_3. Solutions containing the redox couple were 1*N* in Na_2SO_4 and buffered to *p*H 8.4. The hexacyanoferrate redox couple was 0.10*N* in $K_3Fe(CN)_6$ and 0.10*N* in $K_4Fe(CN)_6$.

A standard three-compartment electrochemical cell was used. The main compartment incorporated a working electrode, a gas inlet, and an optical quartz window through which light could be focused on the working electrode surface. The counterelectrode was platinum gauze and the reference electrode was a saturated calomel electrode (SCE). All electrode potentials are reported *vs.* SCE.

Electrodes were prepared from 1 cm × 1 cm × 2 mm pieces of zone-refined iron (99.99% Fe) or high purity nickel (99.99% Ni). One side of each electrode was abraded with successively finer grades of silicon carbide paper, 4/0 emery paper, and finally polished to a mirror finish with 0.05μ aluminum oxide. Electrodes used in photocurrent experiments were not polished with aluminum oxide, rather their surfaces were left abraded in order to increase the surface area. After polishing, a microscopic examination revealed no impurity particles (SiC, Al_2O_3) on the electrode surface. Roughness factors of 1.3 and 2 for the polished and abraded surfaces were estimated by comparison of capacitance values. Electrical contact was made to the unpolished side of the electrode by silver epoxy to a nickel wire enclosed in a glass tube. The sides and back of the electrode were covered by silicone adhesive (Dow Corning) leaving only a flat 1 cm² surface exposed to solution.

In photoelectrochemical experiments the working electrode was positioned 1 cm from an optical quartz window through which polychromatic or monochromatic (15 nm bandwidth) light was focused on the electrode surface. A phase sensitive amplification system (13) was employed to measured photocurrents. The light beam was periodically chopped ($F = 34$ Hz) and the corresponding periodic component of the electrode current was selectively amplified. In some experiments the photoresponse was of sufficient magnitude to record it directly without phase sensitive amplification. A 150W xenon light source was used. The absolute photon flux at each wavelength (Φ_λ) was measured with a calibrated Oriel Model 7090 pyroelectric detector. The monochromatic irradiance was between 1 and 200 μW/cm² and the polychromatic irradiance was about 2 mW/cm². Spectral data are reported as absolute efficiencies ($\alpha = i^*/\Phi_\lambda$) and are not corrected for reflection at the film solution interface. In polychromatic light experiments, the incident beam was filtered to remove wavelengths greater than 900 nm.

Iron electrodes were cathodically treated (20 μA/cm²) for 1 hr and the solution replaced under nitrogen prior to all experiments unless noted. Similarly the Ni electrodes were held at a cathodic potential of −1.0V for 30 min and the solution changed prior to any measurements. Typical polarization curves for freshly prepared electrodes are shown in Fig. 1. The potentials were scanned in the anodic direction at +0.5 mV/sec. The results shown in Fig. 1 are for electrodes in which the final surface preparation was with emery paper (4/0). In all cases, the electrochemical behavior of unpolished electrodes was identical to that of electrodes polished to a mirror finish.

Tafel plots were obtained for planar Ni and Pt electrodes prepassivated for 1 hr in pH 8.4 solutions. The electrodes were transferred under nitrogen to a cell containing the redox couple (0.10M $K_3Fe(CN)_6$, 0.10M $K_4Fe(CN)_6$) and scanned potentiodynamically at 0.2 mV/sec in the anodic direction. Exchange current densities were calculated using the linear polarization method.

Results and Discussion

When illuminated with light of energy greater than their bandgaps, the passive films on iron and nickel generate photocurrents which have a sizable magnitude considering the thicknesses of the films. The appearance of a photoresponse demonstrates not only conductivity but also implies a degree of crystallinity. Although an amorphous or loosely coordinated lattice might absorb visible light, it is doubtful that this would result in a measurable photoresponse unless there exists at least some short range order. The photoresponse also implies that the lattice anion is oxide rather than hydroxide, at least in that portion of the film which gives rise to the photoresponse. The light sensitive semiconductor properties of iron and nickel oxides are

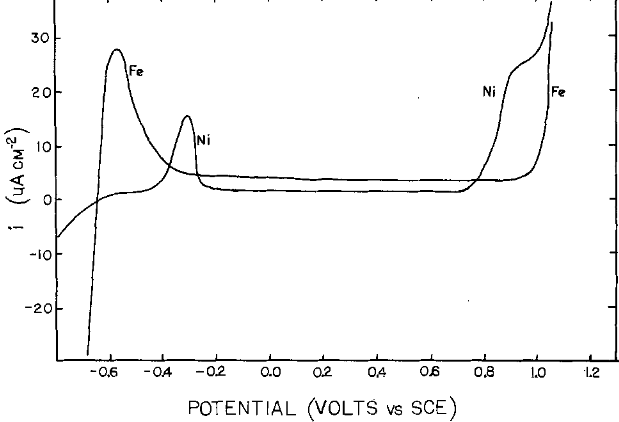

Fig. 1. Current *vs.* potential; *p*H 8.4; scan rate +0.5 mV/sec

well documented while photoconductivity, or even conductivity for that matter, has not been observed on iron or nickel hydroxides.

Periodic illumination of semiconductor electrodes under potentiostatic control has two separate effects on electrochemical reaction rates. First, the creation of electron-hole pairs by sufficiently energetic radiation alters the concentration of minority carriers at the surface and thereby can accelerate kinetic reactions which are minority carrier limited if the relative position of solution and solid energy levels are appropriate. Second, alteration of the electrode charge distribution by sudden illumination is manifested by capacitance charging currents and charge flow to reverse the tendency of the bands to move toward the flatband condition under illumination (21). The latter phenomenon does not require the direct participation of minority carriers in the charge transfer process and accounts for the observation of photocurrents of opposite sign to those expected from conductivity type (13).

The magnitude of the photoresponse is a function of several parameters (22) including the absorbtivity (α) of the absorbing molecules, the photon flux (Φ), the amount of band bending ($V - V_{FB}$), the thickness of the absorbing layer (ρ), the electrode capacitance (C), and the concentration of electron donors or acceptors in solution. The amount of band bending affects both recombination and charge transfer rates and hence strongly influences photogenerated carrier lifetime. For thin (<50Å) films the Debye length, the carrier diffusion length, and light penetration depth are limited by the film thickness and therefore the film thickness can be the dominant factor in determining the photocurrent magnitude.

In Fig. 2 and 3 the total current (i) and photocurrent (i^*) were measured when an electrode was suddenly (<1 msec) polarized to a potential in the passive region (+0.70V for Fe, +0.60V for Ni). Prior to each measurement the electrodes were cathodically reduced as described previously. The exponential decrease in the total current with time is characteristic of oxide growth (3, 4). The increase in the photoresponse corresponds to the increasing amount of metal oxide on the electrode surface. At $t = 60$ sec the magnitude of i^* is assumed to be 90% of the value after 1 hr of polarization. For Ni the 90% point was reached in approximately 30 sec. This behavior suggests that the semiconducting nature of the films is not a slowly developing process and that the film is inherently photoconductive. The increase in i^* as the total current is decreasing offers strong evidence that the observed photoresponse is not derived from excitation of any solution species. Photocurrents were not affected in any way by solution agitation.

The thickness of the films were calculated by integration of the anodic charging curves of Fig. 2 and 3 after 1 hr growth period. Oxidation of Fe and Ni was assumed to form Fe_2O_3 and NiO of densities of 5.1 and 6.8 g/cm^3, respectively. The solutions were analyzed (atomic absorption) and the charge corresponding to dissolved Fe^{2+} or Ni^{2+} cations was subtracted from the total charge passed during the experiment. Films grown on iron after 1 hr +0.70V in pH 8.4 solution are approximately 30Å thick and on nickel are approximately 10Å thick. The total amount of charge passed for the abraded electrodes was approximately twice that of polished electrodes of the same apparent surface area. The larger magnitude of the photoresponse of Fe films grown at constant potential as opposed to Ni films grown in the same manner is due in part to the fact that the Fe films are thicker.

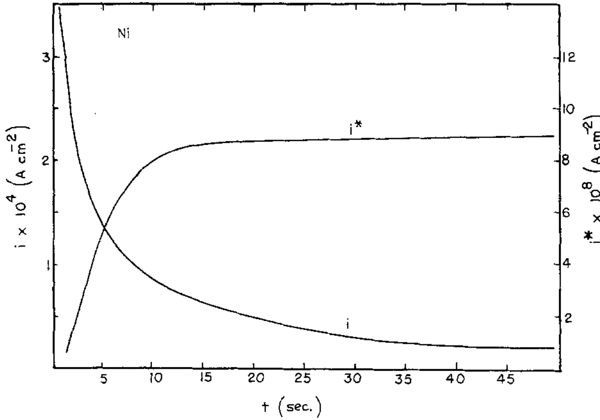

Fig. 3. Current (i) and photocurrent (i^*) vs. time for sudden anodic polarization, Ni, +0.060V, pH 8.4, polychromatic light, $200 < \lambda < 900$ nm.

The magnitude of the photoresponse as a function of electrode potential was measured with polychromatic light and is shown in Fig. 4 and 5. In order to maintain a constant film thickness and/or stoichiometry, a potential pulse technique was used. The electrode was held at its growth potential (+0.70V for Fe, +0.60V for Ni) prior to each measurement. The electrode was then suddenly polarized (<1 msec) to the desired potential, the photoresponse measured (<1 sec), and the potential returned (<1 msec) to its original value. The reason for this procedure was the observation in steady-state measurements of i^* that when the electrode potential was altered, the magnitude of i^* equilibrated rapidly at the new potential and then decayed (for negative shifts in V) or increased (for positive shifts in V) slowly with time, reaching a new steady-state value in approximately 30-60 min. We presume that either the amount of absorbing material changed slowly with time or more likely that the magnitude of i^* is sensitive to the defect concentration which is

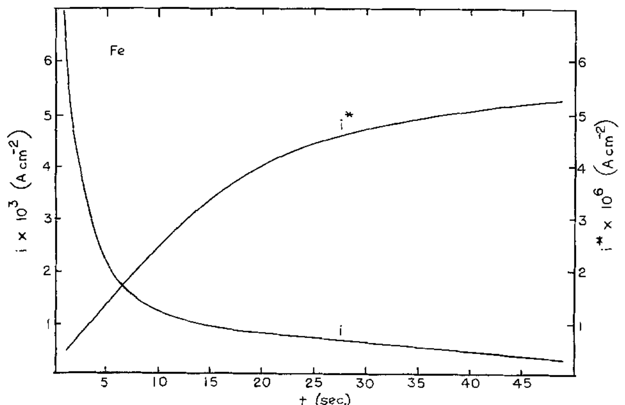

Fig. 2. Current (i) and photocurrent (i^*) vs. time for sudden anodic polarization, Fe, +0.70V, pH 8.4, polychromatic light; $200 < \lambda < 900$ nm.

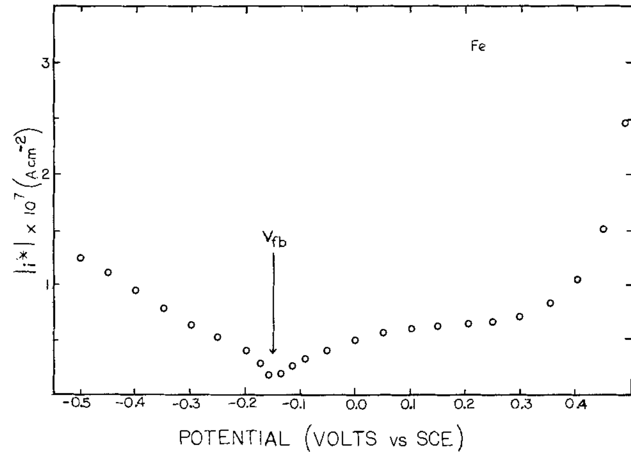

Fig. 4. Photocurrent vs. potential, Fe, pH 8.4, polychromatic light, $200 < \lambda < 900$ nm.

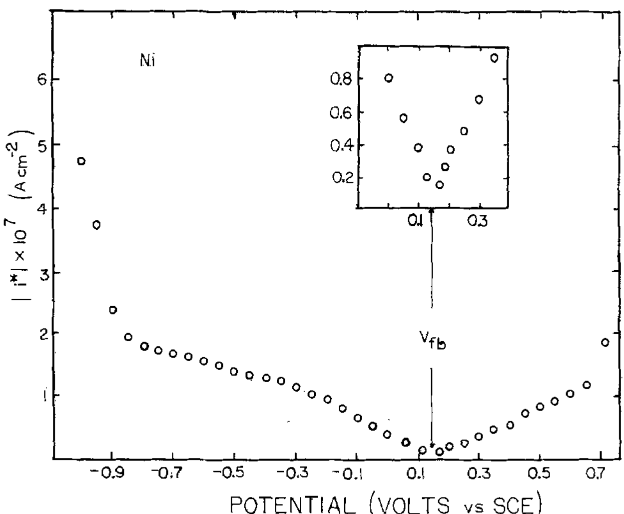

Fig. 5. Photocurrent vs. potential, Ni, pH 8.4, polychromatic light, $200 < \lambda < 900$ nm.

affected by changes in electrode potential. The time constant for the process is on the order of that expected for an ionic transport process (23).

The instantaneous measurement of i^* describes the electronic distribution of the film prior to any defect rearrangement and is proportional to the amount of band bending. In Fig. 4 and 5 the photoresponse vanished at a characteristic potential which in the semiconductor model would be V_{FB}. The absence of a net photocurrent response indicates that potential where the rate of photoassisted oxidative charge transfer is equal to the rate of photoassisted cathodic charge transfer and defines the situation where the bands are flat. The sign of i^* also inflected at V_{FB}. The change in sign was detected with a storage oscilloscope and with the lock-in amplifier at a 180° phase shift in the quadrature component. Anodic of V_{FB}, i^* was anodic while at potentials negative to V_{FB}, the increase in current due to illumination was cathodic.

Although both positive and negative photocurrents could be detected near V_{FB}, at larger displacements in potential the photocurrents were in accord with those expected from conductivity type. The passive film on Fe (n-type) showed larger photocurrents at potentials anodic to V_{FB} and the film on Ni (p-type) showed larger photocurrents cathodic of V_{FB}. Cathodic photocurrents were attributed to either film reduction or hydrogen evolution. At intermediate anodic potentials, photogenerated holes (h^+) may participate directly in further oxidation of the metal surface

$$2Fe + 6h^+ + 3\,OH^- \rightarrow Fe_2O_3 + 3H^+ \quad [1]$$

$$Ni + 2h^+ + OH^- \rightarrow NiO + H^+ \quad [2]$$

or indirectly via surface states. Equations [1] and [2] serve only as examples of innumerable pathways. At more anodic potentials oxygen evolution becomes the principal photoassisted reaction.

The position of V_{FB} from photocurrent measurements was compared to that obtained from Mott-Schottky plots. Parameters derived from capacitance data at different values of solution pH are given in Table I with a comparison of V_{FB} from photocurrent and capacitance data given in Table II. The analysis of capacitance data was performed in the manner described previously (24). Although it is generally agreed that Mott-Schottky plots should not be relied on for an accurate determination of V_{FB} and to some extent donor/acceptor densities, two aspects of the capacitance data are applicable and support the assumed semiconductor character of the passive films. First, the sign of the slope of the C^{-2} vs. V plot is an indicator of conductivity type. As expected the sign of the Mott-Schottky

Table I. Semiconductor parameters from Mott-Schottky plots

Material	Type	pH	N_D (cm^{-3})	N_A (cm^{-3})	V_{FB} (V)
γFe_2O_3	n	6.9	10^{20}	—	−0.173

V_{FB} = flatband potential from capacitance measurements.
V_{FB^*} = flatband potential from photocurrent measurements.

slopes determined for the passive films indicated p-type conductivity for the Ni film and n-type conductivity for the Fe film. Second, the change in V_{FB} is in the anodic direction with decreasing pH for both photocurrent and capacitance data and the slopes are close to the theoretical 59 mV/unit pH. Donor and acceptor identity is inferred from semiconductor data on bulk Fe and Ni oxides. Ferric oxides tend to be oxygen deficient and Fe^{2+} donors give rise to n-type conductivity. Nickel oxides tend to be cation deficient with p-type conductivity arising from Ni^{+3} acceptors.

The separation of energy levels which give rise to photoassisted charge transfer was determined from the dependence of i^* on light energy for films grown for 1 hr at constant potential. The spectral response curves (Fig. 6 and 7) were identical except for magnitude regardless of solution composition (pH, K^+, Na^+, Fe^{2+}, Cl^-, NO_3^-, SO_4^{2-}, $B_4O_7^{2-}$) or electrode potential. This suggests that the chemical environment of oxidized metal ions does not change significantly with varying electrolyte conditions or electrode potential.

The approximate bandgap can be obtained from the extrapolation of the linear portion of the normalized spectral response curve. The values obtained (2.5 eV for Fe, 3.1 eV for Ni) compare favorably with bandgap measurements on bulk αFe_2O_3 [2.0 eV (25)] and NiO [3.7 eV (26)] and with a photoconductivity edge at 3.7

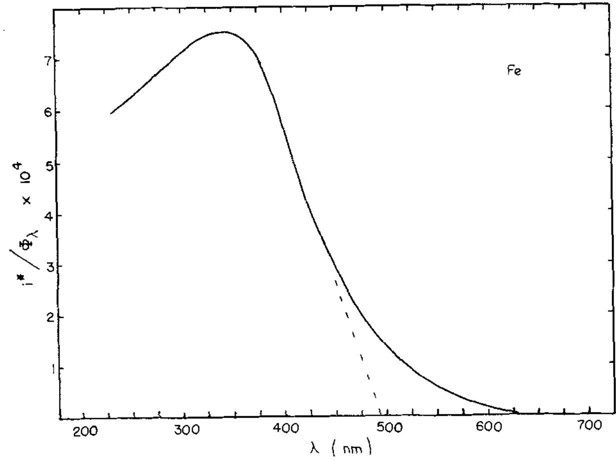

Fig. 6. Photocurrent efficiency (α) vs. wavelength (λ), Fe, pH 8.4, constant potential $V = +0.70V$.

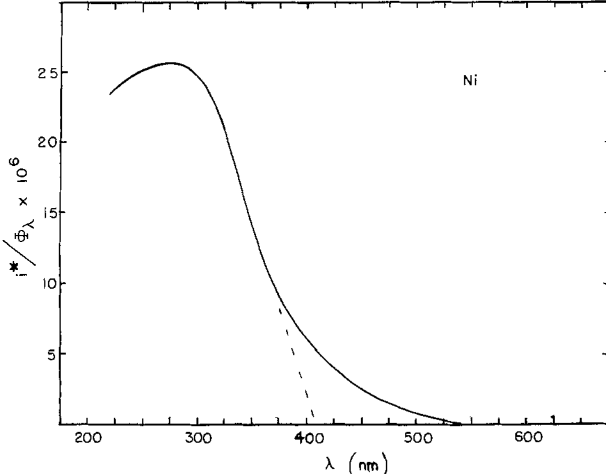

Fig. 7. Photocurrent efficiency (α) vs. wavelength (λ), Ni, pH 8.4, constant potential $V = +0.60V$.

eV that has been reported for NiO (27). This infers that the separation of energy levels for Fe^{3+} or Ni^{2+} in the octahedral oxygen lattice of the passive films is roughly equivalent to that of more stoichiometric materials.

The dominant feature of the optical absorption spectra of both NiO (28) and αFe_2O_3 (29) is a characteristic absorption edge which is several orders of magnitude more intense than crystal field transitions. The photocurrent spectra presented here show a dependence on wavelength which appears to coincide with this optical absorption edge. There is considerable disagreement as to the exact nature of the electronic excitation which gives rise to this absorption. Some authors (29, 30) state that the principal absorbances in the visible-near u.v. region are charge transfer related

$$Fe^{3+} + O^{2-} + hV \rightarrow Fe^{2+} + O^{-} \quad [3]$$

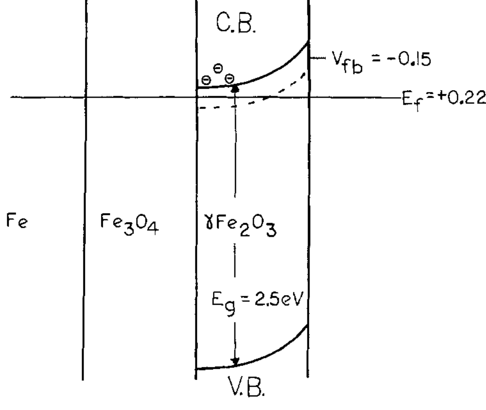
$$Ni^{2+} + O^{2-} + hV \rightarrow Ni^{+} O^{-} \quad [4]$$

Photoconductivity is likely to be of the Verway type (31) in this case. Alternatively more recent interpretations which take into account electronic correlation and electron-phonon coupling describe the excitation as allowed transitions of the ground-state metal ions ($3d^8 \rightarrow 4d^7 4s$ NiO, $3d^5 \rightarrow 3d^4 4p$ Fe). Conductivity in this case can be described in terms of a narrow band model. At present there is no clear resolution to this question.

The long wavelength "tail" in the photocurrent spectra indicates deviation from a fixed stoichiometry in the absorbing oxide. This is to be expected for thin films in that cations near the metal or at the surface (surface states) will have a perturbed distribution of energy levels. Photocurrents due to a smaller separation of energy states will be superimposed on the normal spectrum at longer wavelengths. The same phenomenon may account for the displacement of the absorption edge to longer wavelengths over that of bulk materials.

From the semiconductor parameters determined herein, models of the band structure of the passive films on iron and nickel can be constructed. One reason for this exercise is that band models are predictive to some extent in explaining rates of electron transfer reactions (ETR) at film covered electrodes. Some knowledge of the electronic distribution in the solid phase is prerequisite to successful calculations of ETR rates. Details of the procedures involved in such calculations and in constructing models have recently been discussed (32). Pictoral representations of the band diagrams for Fe and Ni passive films at the redox potential of $Fe(CN)_6^{-3}/Fe(CN)_6^{-4}$ are shown in Fig. 8.

As depicted in the diagrams, V_{FB} gives the position of the conduction or valence bandedge if we assume



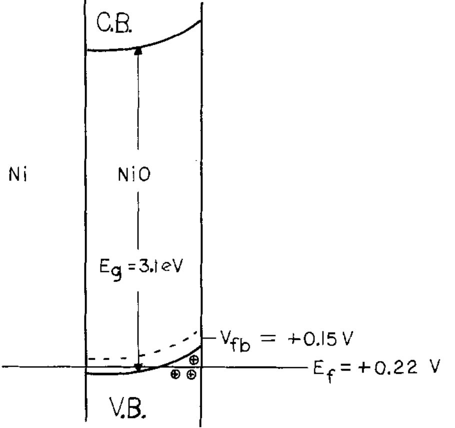


Fig. 8. Energy level diagram for the Fe and Ni passive films at 0.22V, pH 8.4.

that the Fermi energy (E_f) lies between the donor level and conduction band for n-type conductors and between the valence band and acceptor level for p-type and that the separation of donor or acceptor levels from their respective bands is small (100% ionization). At the redox potential the bands are bent "up" at the surface giving rise to a depletion of majority carriers in the case of Fe and an accumulation of majority carriers in the case of Ni.

One aspect of the mechanism of ETR is of interest in connection with the present study of semiconductor properties of iron and nickel films. It has been postulated that charge transfer at passivated metals occurs not only between metal and solution but also between film and solution. In the former case the film is considered to act as a barrier to electron tunneling between the metal and solution and hence film thickness is rate controlling. In the latter case, the excess surface charge density resides in the film itself and the rate of charge transfer will depend on the electronic distribution in the film, band bending, and the partition of the potential drop between oxide and solution. There is substantial evidence to support the postulate that the conductivity and electronic distribution of the passive film has a sizable influence on ETR rates even for very thin films.

For comparative purposes, exchange current densities (i_o) were measured for Fe and Ni anodic oxide electrodes in the hexacyanoferrate redox couple. The difference in i_o at Fe (10^{-7} A cm^{-2}) and Ni (10^{-4} A cm^{-2}) anodic oxides is significantly greater than can be accounted for by the difference in film thickness. In fact, if one accepts a duplex layer model for the film on Fe, the thickness of the semiconducting layer (γFe_2O_3) might be roughly equal to that on Ni. Also, i_o at a thermal Fe oxide is essentially equal to i_o on the anodic oxide (10^{-7} A cm^{-2}). The thickness of the semiconducting layer on the thermal oxide (αFe_2O_3) is at least 100 times that of the anodic oxide (13).

Additional evidence for film conductivity and for the direct participation of the film in ETR comes from analysis of the structure of the Tafel plots (Fig. 9). The rate of ETR on semiconductor electrodes is usually larger for transfer corresponding to conductivity type, *i.e.*, p-type materials show a greater oxidative capability and n-type materials a greater reductive capability. This results in Tafel plots which are asymmetrical. At single crystal semiconductor electrodes, ET opposite to conductivity type can be completely blocked except under illumination when minority carriers are generated. At semiconducting film covered electrodes, Tafel assymetry is mitigated by alternative ET mechanisms, such as direct elastic tunneling between the metal and solution, which do not depend strongly on the semiconducting characteristics of the film.

In Fig. 9, asymmetrical Tafel behavior is exhibited by the Ni anodic oxide. The larger diffusion limited current for the anodic branch of the Tafel plot is in accord with the p-type conductivity of Ni electrodes. At Fe electrodes, the cathodic reaction is favored in accord with n-type conductivity (32).

From the band models derived herein, some qualitative explanations of the above-described behavior can be advanced. First, at the redox potential of $Fe(CN)_6^{-3}/Fe(CN)_6^{-4}$ (+0.22V *vs.* SCE) a depletion layer exists in the Fe film, *i.e.*, the band bending is such that the concentration of majority carriers is greatest near the metal rather than at the surface. This requires charge transfer to occur by tunneling either from the conduction band or the metal and therefore lower exchange currents are to be expected. A similarity in kinetic behavior between anodic and thermal Fe oxides (13) infers that tunneling involves participation of the conduction band in the case of Fe (33).

At nickel oxide electrodes the situation is reversed. At the redox potential, majority carriers (holes in the valence band) are accumulated and exchange currents should be large as observed. Asymmetry in the redox kinetics results from the fact that accumulated valence band holes have a higher probability for oxidative ET because of the shorter tunnel distance involved. An accumulation of majority carriers at potentials anodic to V_{FB} as opposed to a depletion layer is manifested, therefore, by higher exchange current densities and rates of ET that approach those of Pt. The higher conductivity inherent in this situation also results in a larger portion of the potential drop across the interface to be in the Helmholtz layer. Since the potential drop in the film strongly affects film thickness, this may account for the fact that Fe films grow to a greater thickness at constant potential than do Ni films and more generally that p-type films (Ni, Cr, Cu) have smaller thicknesses than do n-type films (Fe, Ti, Sn, Nb).

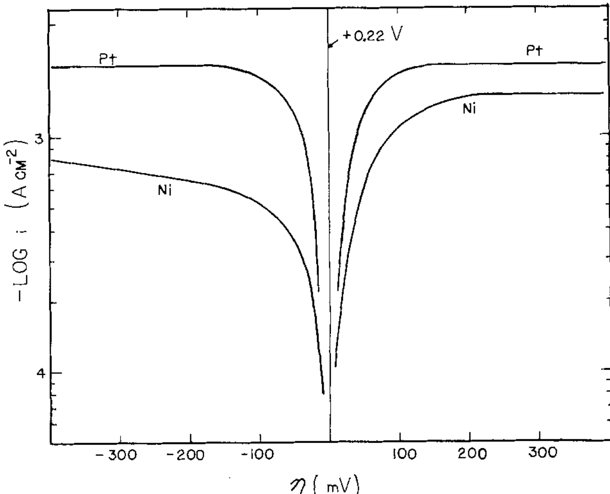

Fig. 9. Tafel plots for Ni and Pt electrodes, 0.10*N* $K_3Fe(CN)_6$, 0.10*N* $K_4Fe(CN)_6$, pH 8.4.

Conclusions

Semiconductor characteristics of Fe and Ni passive films are manifested by the following experimental observations:

1. When directly illuminated with sufficiently energetic radiation, a photoresponse is observed at Fe and Ni films that is proportional to the surface thickness of their respective anodic oxidation products.
2. The sign of the photoresponse in each case inverts at a characteristic potential where the rates of oxidative and reductive charge transfer are equal. This potential changes with pH in a manner consistent with its identification as V_{FB}.
3. The dependence of the photoresponse on light energy shows a characteristic absorption edge that is comparable to that observed on Fe and Ni oxides.
4. Charge transfer via Fe and Ni films is favored in the direction indicated by conductivity type.

ABSTRACT

Mixed Fe-Mo and Mo naphthalocyanine samples have been synthesized and investigated by XPS and electrochemically using cyclic voltammetry and rotating disk techniques. As loadings on carbon black supports for industrial-type electrode structures, they present higher activities than the corresponding iron samples, for both anodic and cathodic polarizations. Data are interpreted with the aid of electron transfer theories in terms of bridged-type mechanisms which reveal reversible conditions for both adsorption and transfer steps.

The interest of Fe naphthalocyanine films as loadings on carbon black supports for air cathode catalysis has been stressed recently (1). Under both anodic and cathodic recycling, the life expectancy increased with the dilution of the loadings. The generation of H_2O_2 occurs only after a time equal to the life expectancy of the support. In addition, using the ultrathin electrode technique, it has been shown that the introduction of molybdenum ions into the structure corresponds to an extension of the Tafel zone of polarization over that of iron by more than one decade. This enhancement was interpreted as being due to a drop of the resistance of the solid phase. Therefore, one may seek to synthesize Mo naphthalocyanine (NP_c) samples and to undertake similar investigations as for $Fe(NP_c)$.

The gas-solid activity of mixed iron molybdenum phthalocyanines for fast oxygen uptake and desorption has been reported by Inoue (2). For the 3d metal transition series the effect of the central ion on the electroreduction of oxygen on the phthalocyanine compounds has been investigated (3). A linear relationship between the potentials at a constant current density and the redox potential of the central ion has been emphasized (4). More generally a linear relationship between the redox potential of the central ion in porphyrin or phthalocyanine structure and corresponding redox potentials in various solvents can be established (5a, b). For solutions in aqueous media, Mg, H_2, and Pd lie at the bottom of the scale with a redox potential close to the H_2/H^+ couple. Sn and Mn are at the top corresponding to oxygen evolution, Fe and Mo couples being located near the O_2/H_2O couple.

The aim of the present work is first to synthesize Mo (with or without iron) naphthalocyanine structures and to prove their efficacy as catalyst materials for cathodic reduction or anodic evolution of oxygen in alkaline media. As XPS[1] results (6) were useful in the case of iron polyphthalocyanine compounds for showing correlations between their structure and their electrochemical properties, this technique is employed in the present study, mainly for the identification of the oxygen species present on the surface.

In addition, as the interpretation of the data obtained on industrial types of porous electrode structures are very often difficult, cyclic voltammetry is also performed on the same materials on a rotating disk (1).

Experimental

Synthesis and elementary analysis.—The mode of synthesis is similar to that performed for iron naphthalocyanine (1). The molybdenum donor compound consists of ammonium paramolybdate in the ratio of 1 mol per 4 mols of dicyanonaphthalene. The samples have been prepared by heating the reactant mixture at 300°C for 20 hr. After preparation the samples were thoroughly washed with benzene, ethanol, 10% HCl, distilled water, and ethanol. In addition some of them have undergone a washing treatment with 5M KOH for 12 hr in order to eliminate the remaining oxide.

By varying the amount of ammonium paramolybdate with respect to the amount of iron dipivaloylmethane it has been possible to vary the ratio Mo/Fe in the overall structure. Three sorts of samples have been prepared: samples (I, Fe) consisting of Fe naphthalocyanine as in Ref. (1), samples (II, Fe-Mo) where the ratio Mo/Fe is about 1, and samples (III, Mo) containing only Mo.

[1] X-ray photoelectron spectroscopy.

A typical elementary analysis for samples (II, Fe-Mo) is given in Table I. The ratios found for the various components in C and H agree with the theoretical composition. Fe appears to be 30% below the theoretical value. However, a systematic deficiency in nitrogen content can be noted. In order to rule out a distortion due to the technique of analysis, Fe and Mo contents have also been measured by x-ray fluorescence.[2] In comparison with the theoretical value, an excess of molybdenum for samples (III, Mo) has been determined while the iron content value previously obtained can be confirmed for (I, Fe) and (II, Mo-Fe).

XPS analysis.—The XPS investigations have been performed using the HP 5950 A spectrometer described in Ref. (6). In addition a glove box has been set up to allow the introduction of samples under deaerated conditions.

The samples prepared under argon atmosphere as indicated in Ref. (1) were examined after different times of exposure to air. Before introduction into the apparatus, some samples have been treated with ethanol and deionized water to speed up the wetting process and to reveal any effect associated with the adsorption of water. In order to discriminate between the effects associated with iron from those with molybdenum, these experiments have been carried out with Mo samples (III, Mo) and Fe (I, Fe).

While on samples (III, Mo) the intensity of the O_{1s} peak is higher in approximately the ratio 1.5/1 on unwetted samples than on the wetted, a reverse effect is observed on samples (I, Fe).

On these compounds (I, Fe), however, for longer times of exposure at air, no appreciable differences between wetted and unwetted can be detected. In addition, if the samples are kept under vacuum in the apparatus, the O_{1s} signal of the wetted samples drops and after 2 hr becomes nearly equal to that of the unwetted samples.

At the introduction into the apparatus, the O_{1s} signal, initially split into two components on samples (I, Fe), yields a single peak under flood gun (electron bombardment) conditions, an effect which is characteristic of a mixture rather than a well-defined compound. These phenomena are not observed with samples (III, Mo).

As a function of the time of exposure at air the O_{1s} signal grows continuously on both samples (I, Fe) and (III, Mo). After 1 min, however, the intensity of O_{1s} on (III, Mo) samples is about 2-4 fold higher than on (I, Fe). On these latter samples (I, Fe), the saturation signal is not observed after less than 2 months, while it is attained within 2 weeks with (III, Mo) samples. In this case, the intensity remains 3-4 fold higher with (III, Mo) than with (I, Fe) samples. This occurs mainly by an enhancement of the component located at 532.3 eV.

The iron samples (I, Fe) prepared and introduced under deaerated conditions present only slight traces of oxygen with a high binding energy of about 534 eV. Under air exposure times shorter than a few minutes an oxygen form with $E_B = 533.0$ eV readily develops. For longer times of exposure Fe^{III} becomes apparent and an oxygen form with $E_B = 531.0$ eV is more and more apparent.

In the case of sample (III, Mo) analysis, after short exposure times (about 1 min) at air, two distinct forms of oxygen are visible at $E_B = 531$ and $E_B = 532.2$ eV. This latter form becomes predominant for the samples which have been thoroughly washed with concentrated KOH to eliminate the oxide component.

For samples (III, Mo) the relative intensities of the $Mo^{3d\,3/2\text{-}3d\,5/2}$ signals are given *vs.* the times of exposure at air in Table II. While the Mo^{V} signal remains relatively stable and below 5%, the growth of the Mo^{VI} signal occurs simultaneously with the drop of the Mo^{IV} component.

On samples (I, Fe) and (III, Mo) the different oxygen species are given in Table III in accord with the possibilities of coordination of the central ion in the naphthalocyanine structure or perhaps in the oxide in the case of samples (III, Mo). It should be pointed out in this last case that for short exposure times in air (less than 1 min) the $O_2^{\delta-}$ species is predominant, while in the case of (I, Fe) samples the predominant form turns out to be O_2 with a covalent character. This effect corresponds to a stronger bond than in the case of samples (I, Fe).

Electrochemical investigations.—Two techniques of investigation have been worked out as described in Ref. (1). An investigation on a porous electrode structure (A) (industrial type) and a porous electrode structure (B) confined in the hollow cavity of a rotating ring disk equipment. In order to allow comparisons with data obtained on the iron samples investigated as in Ref. (1) the same ex CO carbon black support has been chosen for impregnation at the loading 2.5%.

Electrode structure A.—Tests have been carried out in 8M KOH solutions at 22°C with air. The samples were cycled between + 10 mA/cm² during 1.5 hr and − 100 mA/cm² during 0.5 hr to test the effect of oxidation of the support and the stability of the electrode texture or for cathodic polarizations the effect of O_2 depletion. Data at a scan rate of 1.5 mV/sec are presented in Fig. 1 for iron (Fe) and (Fe-Mo) samples, solid and dashed lines, respectively. At 100 mA/cm² the working potential lies at approximately 900 mV above the potential of the hydrogen electrode, about 200 mV more positive than the value obtained with pure Fe samples. For anodic polarizations on (II, Fe-Mo) samples, oxygen evolution takes place at about + 400 mV Hg/HgO on the anodic scan. From previous work (1) the peak near O can be identified with H_2O_2 formation.

Data for both samples after a 150 cycle treatment for samples (II, Fe-Mo) and a 350 cycle treatment for samples (I, Fe), under the same scanning conditions, are represented in Fig. 2. For cathodic polarizations the activities are now almost identical while for anodic polarizations samples (II, Fe-Mo) remain slightly more active. However, the main difference with the

preceding experiment concerns the H_2O_2 generation. As with the ex CO carbon black support a high peak is apparent with mixed Fe-Mo samples (II, Fe-Mo) while the H_2O_2 formation remains below the detection threshold in the case of pure Fe samples (I, Fe).

Electrode structure B.—In order to provide an interpretation of these data obtained with structure A [mainly the observed initial high activity followed by its decline after anodic and cathodic scans on samples (II, Fe-Mo) and (III, Mo)], fundamental studies have been performed using the rotating disk equipment and the preparations described in Ref. (1). The same scan rate has been used as in the case of structure A.

With the rotating disk technique, the cathodic performances obtained on samples (I, Fe), (II, Fe-Mo), and (III, Mo) are represented in Fig. 3, in the Tafel region, *vs.* an Hg/HgO reference electrode. It should be pointed out that differences in activity are relatively small. The limiting currents, which are not plotted here, are identical for all these samples within the limits of reproducibility. These data substantiate those obtained on the ultrathin electrodes (1).

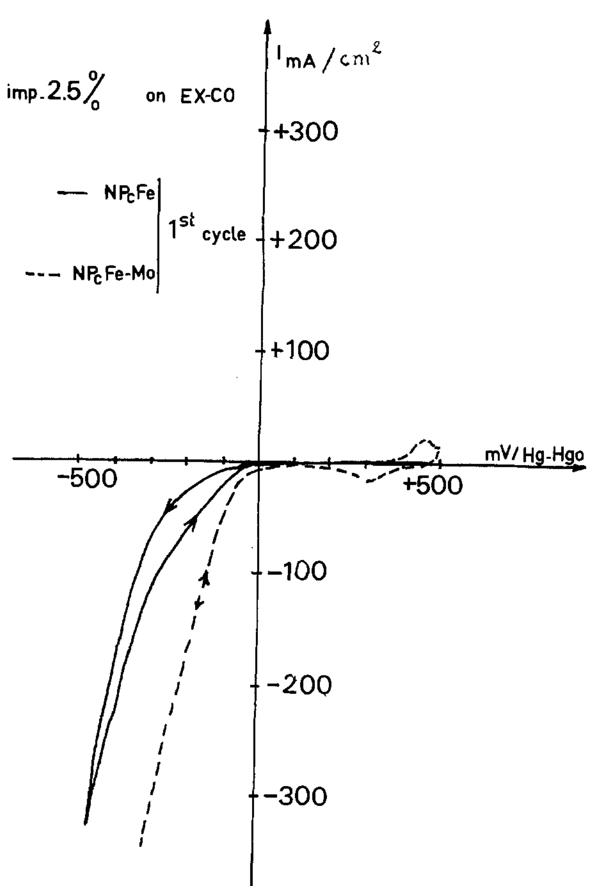

Fig. 1. Cyclic voltammetry curves on industrial-type porous electrodes. Solid line: samples (I, Fe) on ex CO carbon black support. Dashed line: samples (II, Fe-Mo) supported as (I, Fe) 2.5% loading.

The activities of the same samples under anodic polarizations are shown in Fig. 4. In contrast to the preceding experiments, samples (II, Fe-Mo) and (III, Mo) are notably more active with respect to samples (I, Fe), at constant current density the potentials being about 120 mV more negative. These curves were obtained after several cycles and remain stable under further anodic scanning conditions. They are closely similar to those obtained recently on $La_{0.5}Ba_{0.5}CoO_3$ (7).

For the studies of the activities *vs.* temperature a small Hg/HgO reference electrode has been employed and arranged inside the electrochemical cell in order to minimize the temperature gradient between the working and the reference electrode.

The effect of temperature on the activities of samples (I, Fe), (II, Fe-Mo), and (III, Mo) for reduction is given in Fig. 5. The curves have also been obtained in the Tafel region as in Fig. 3. No appreciable differences are visible between the different samples. It should be pointed out that after correction for the shift of the reference electrode *vs.* temperature given in Ref. (8) the current potential plots are almost superposable: the measured shift calibrated with H_2 is 0.37 mV/K *vs.* 0.29 mV/K given for the reference electrode.

For anodic polarizations, the effect of temperature variation is given in Fig. 6. In the case of samples (II, Fe-Mo) and (III, Mo) a lack of stability of these

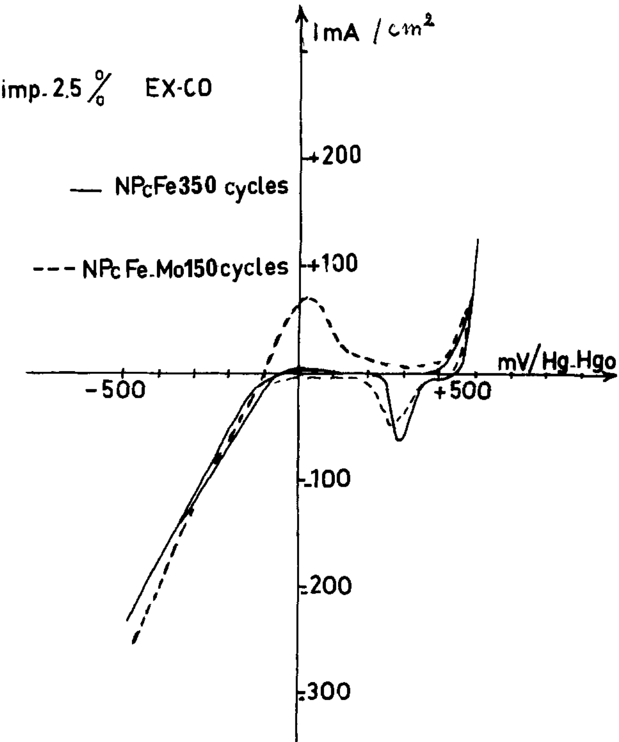

Fig. 2. As in Fig. 1 after 150 cycles, samples (II, Fe-Mo) and 350 cycles, samples (I, Fe).

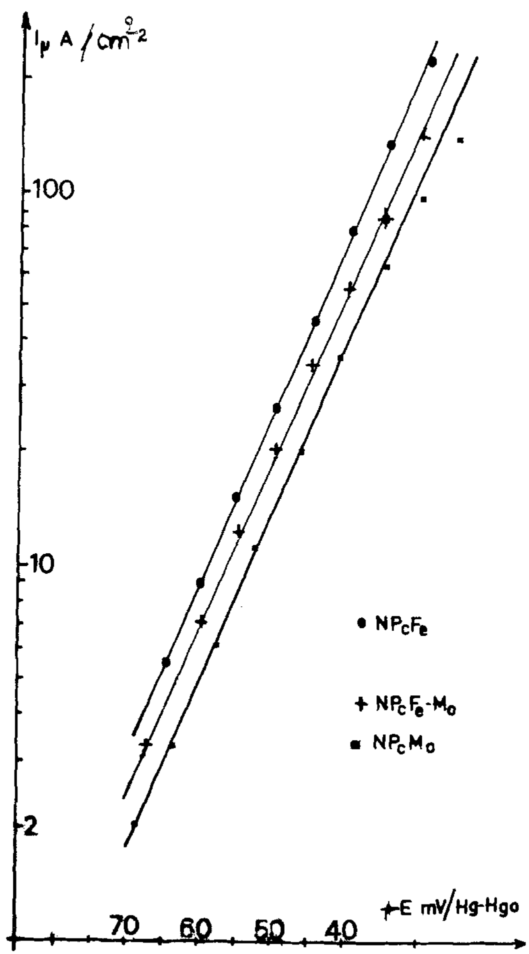

Fig. 3. Cyclic voltammetry on rotating disk electrode in the cathodic Tafel region. Samples supported as in Fig. 1. ●, NP_cFe (I, Fe); +, NP_cFe-Mo (II, Fe-Mo) ■, NP_cMo (III, Mo). N = 80 rps, v = 0.2 mV/sec.

plots at the lowest applied potentials can be noticed. However, after several cycles, the activity becomes reproducible in the region where oxygen evolution is taking place. In this region the same conclusions about temperature variations can be drawn as for cathodic polarizations: the observed differences in activity are almost negligible after correction of the shift of the reference electrode (0.48 mV/K) at $i = 300\ \mu A/cm^2$. They drop at 0.33 mV/K at $i = 500\ \mu A/cm^2$.

Discussion

It should be pointed out first that the similar plots (with the absence of H_2O_2) obtained on the different samples with the rotating ring disk technique involve the 4 e O_2 reduction reported (9) on porphyrin- and phthalocyanine-type compounds. As shown previously the rds is a coupled chemical and electrochemical reaction between radicals (10).

In contrast in the case of structure A electrodes no Tafel region is observed and the differences in potentials for the Fe and Mo samples at constant C.D. are much higher than in this preceding case, therefore a different rds must be assumed. In view of the high current densities observed, the rate-limiting process can be assumed to be due to the low conductivity into the solid phase as shown in Ref. (11, 12). The application of the same charge transfer complex models developed in Ref. (13) requires that the conductivity is higher in the solid phase with Mo-containing samples than with (I, Fe) samples. This can be easily explained on the basis of XPS experiments involving a faster Mo^{IV}/Mo^{VI} couple compared to Fe^{II}/Fe^{III}.

Before entering into a sophisticated analysis of the relationship between the binding energies of molybdenum electronic levels and their structure of coordination with the oxide or the naphthalocyanine lattices, it must be pointed out that a difference in the state of the active couples in the electrochemical reaction must be detectable between experiments in an inert atmosphere and those at short exposure times to air. This time of 1 min required for the XPS experiment appears exceedingly large compared with the time in which the electrochemical reaction occurs. As the oxygen penetration is found to be a slow process in both cases of samples (I, Fe) and (III, Mo) the difference in favor of samples (III, Mo) may play a role just for the life expectancy.

If this model is valid (13), the decline in the (III, Mo) performances can perhaps be correlated with the variations in the stoichiometry of the oxide or the naphthalocyanine structure due to a depletion in the more labile oxygen content and the subsequent sta-

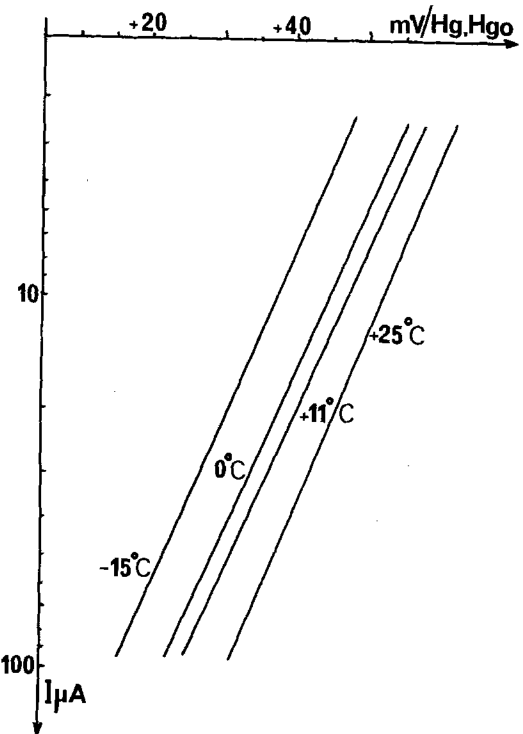

Fig. 5. Influence of temperature: cyclic voltammetry as in Fig. 3. Numbers in parenthesis are temperature (Celsius d°). Variations among samples (I, Fe), (II, Fe-Mo), and (III, Mo) are not significant. The corrections are not made here for the shift of the reference electrode.

bilization of one valency of the metal instead of the initial mixing of two valence states.

In the case of anodic polarizations, where a catalytic effect is observed as molybdenum ions are introduced into the structure, an interpretation of the data can be sought through the differences in nature of the adsorbed oxygen species. In this respect, the main difference between molybdenum and iron is concerned (as seen by XPS) by the development of the $O_2^{\delta-}$ species with molybdenum instead of the covalent form of oxygen observed with iron. These radicals may act as bridges (14) between free oxygen molecules and OH^- ions, the donor character of the intermediate (readily regenerated during the reaction) being enhanced with a destabilizing effect resulting from the filling of the antibonding orbitals of the oxygen molecule. Therefore, one can assume coupled electron transfer reactions are taking place among the oscillations of the Mo^{IV}/Mo^{VI} valencies, metal/oxygen ligand exchange, and OH^- oxygen ligand exchange. They may involve OH or HO_2 radical formation as already explained in Ref. (9). The reaction sequence can be written as[3]

surface ligand/central ion transfer: $2\delta\, \underset{\text{ligand}}{O_2^{\delta-}} + Mo^{VI} \rightarrow Mo^{IV} + \underset{\text{ligand}}{O_2}$ [I]

bulk: $O_2\, Mo^{IV}\, L\, Mo^{VI} \rightarrow \underset{\text{ligand}}{\overset{\text{acceptor center}}{O_2}}\, Mo^{VI}\, L\, Mo^{IV}$ [II]

surface electron transfer through ligand: $4\,OH^-\, \underset{\text{ligand}}{O_2}\ \ Mo^{VI} \rightarrow \underset{\text{ligand}}{O_2\, O_2^{\delta-}}\ \ Mo^{VI} + 2H_2O$ [III]

One may hope to gain some information from theories (15, 16) concerning the effects of intermediate species on the rate process and the Marcus (17) and Levich (18) theories for electron transfer in redox systems in order to achieve an optimization of the catalyst structure.

In the case of adsorption of intermediate species (15, 16) the rate expression must contain a factor f which can be written as

$$f = \exp - \beta \frac{(\Delta G_{ads})}{RT} \qquad [1]$$

[3] The coordination structure of Mo ions will be presented in a future work.

where ΔG_{ads} represents the standard free adsorption energy of the intermediate species and β a factor generally equal to one-half.

In the domain of transfer control the current density i can be expressed as (18)

$$i = nF \frac{kT}{h} KN_s\, \theta \exp - \frac{\Delta F^+}{RT} \qquad [2]$$

where n is the number of exchange electrons, K is the transmission coefficient generally independent of the temperature, θ the coverage of the active site N_s per unit area, and ΔF^+ the free energy of activation which includes an entropy factor of activation ΔS^+. In Eq. [2] ΔF^+ is expressed in the same units as RT, ΔS^+ as R (standard state 1 atm).

$$\Delta F^+ = \Delta H^+ - T\Delta S^+ \qquad [3]$$

which can be also written as

$$\Delta H^+ = \Delta F^+ - Td \frac{\Delta F^+}{dT} \qquad [4]$$

ΔF^+ is a function of the applied potential and can be expressed as

$$\Delta F^+ = \Delta F_o^+ - n'\alpha F\,(E - E_R) \qquad [5]$$

where n' is the number of electrons in the activation state and ΔF_o^+ represents the free energy of activation of the exchange current at $E = E_R$ either for cathodic ΔF_o^{+c} or for anodic polarizations ΔF_o^{+a}.

In the present work the domain of polarizations corresponding to the transfer control appears to be too narrow compared to the domain of overvoltage $E - E_R$ to allow from the data a direct determination of ΔF_o^{+c} or ΔF_o^{+a} which hence must be obtained from a calculation. However, from the studies *vs.* temperature one obtains (correction being made for the shift of the reference electrode)

$$\Delta F^{+c} = 0.8RT \qquad [6]$$

$$\Delta F^{+a} = 1.2RT \quad i = 300\ \mu A/cm^2$$
$$\Delta F^{+a} = 0.8RT \quad i = 500\ \mu A/cm^2 \qquad [7]$$

These relationships mean that for $E \neq E_{1/2}$ for cathodic polarizations ($E_{1/2}$ being approximately the potential where $i = I_{L/2}$, I_L being the diffusion limiting current)

$$\Delta F^{+c} < RT \quad (E \neq E_{1/2}) \qquad [8]$$

For anodic polarizations, the same expression is valid when $E = E_w$, E_w being the potential corresponding to rapid oxygen evolution, *e.g.*, 500 $\mu A/cm^2$ or above

$$\Delta F^{+a} < RT \quad E \neq E_w \qquad [9]$$

Hence from Eq. [5]

$$\Delta F_o^{+c} \neq n_c'\alpha F\,|E_{1/2} - E_R| \qquad [10]$$

$$\Delta F_o^{+a} \neq n_a'\alpha F\,|E_w - E_R| \qquad [11]$$

where $n_{a,c}'$ is the number of electrons in the activation state, anodic and cathodic.

Writing Eq. [4] in the case of the 4 electron process one obtains with $\alpha = 0.5$, $n_c' = 4$

$$\Delta H_o^{+c} = 2F(E_R - E_{1/2}) - 2FT \frac{d\eta}{dT} \qquad [12]$$

and for the anodic process $n_a' = 1$

$$\Delta H_o^{+a} = 0.5F(E_w - E_R) + - 0.5FT \frac{d\eta}{dT} + \Delta F^{+a} \qquad [13]$$

Substituting $E_{1/2}$, E_w, and $d\eta/dT$ by their experimental value: $|E_{1/2} - E_R| = 270$ mV $d\eta/dT = -0.08$ mV/K for cathodic polarizations, $E_w - E_R = 150$ mV

$d\eta/dT = -0.33$ mV/K for anodic polarizations, and $t = 30°C$ (neglecting dE_R/dT)

$$\Delta H_o{}^{+c} = 56.7 \text{ kJ mol}^{-1} \quad [14]$$

$$\Delta H_o{}^{+a} = 12.7 \text{ kJ mol}^{-1} \quad [15]$$

The value obtained $\Delta H_o{}^{+c}$ for cathodic polarizations fits remarkably with the $T\Delta S$ value of 56 kJ mol^{-1} (19) corresponding to only the loss of the degrees of freedom of the oxygen molecule (standard state 1 atm) hence ΔG (Gibbs free energy) = 0 for O_2. The adsorption and the transfer steps obey reversible conditions as also reported (20) for the transfer on similar compounds.

For the anodic process the $T\Delta S$ corresponding to the solvation of OH^- ions reference hydrogen is from the table (21) 3.16 kJ mol^{-1}. As the evolution reaction involves 4 mols of OH^-, one finds the same conclusions as previously for the O_2 adsorption case. Therefore, for both anodic and cathodic polarizations in the case of NP_cMo samples the irreversibility of the process appears to coincide with the enthalpy equal in this case to the entropy change due to the fixation of one molecule of O_2 or 4 OH^- ions from the liquid phase to the surface.

As the rate processes are equivalent for cathodic polarizations between (I, Fe) and (III, Mo) samples, one can assume that electronic factors such as the work function or electron energy densities on Fe and Mo sites are similar under the control of the ligand structure. For improving our knowledge of the structure of the solvent at the interface, XPS data concerning the interaction of the surface with water may throw some light.

Experiments comparing wetted and unwetted samples display a very weak type of interaction. These data substantiate findings of Ref. (22) where from infrared techniques, no adsorption of water takes place on phthalocyanine materials. They conflict with other references (23), but in this latter case it should be pointed out that adsorption of water on the iron sites obeys slow kinetics. Therefore, on both theoretical and experimental supports one can assume that the rate of electron transfer is limited because of the too distant approach of the water molecule from the active sites.

Conclusion

From a practical view point of applications in the problem of generators or electrolyzers, the substitution of iron by molybdenum into the naphthalocyanine structure seems to be rather promising under the double condition of fast oxygen transfer and ohmic drop limitations in the solid phase. On both cathodic and anodic polarization the rate appears to obey reversible conditions for the adsorption and transfer steps.

It might also be considered first that in the synthesis a common material is used for the central metal introduction instead of a more elaborate compound.

Second, the improvements of the performances for both anodic and cathodic polarizations on industrial types of electrode have to be emphasized. At constant current densities, compared to iron samples the drop in the overvoltage reaches about 100 mV for cathodic and 130 mV for anodic polarizations.

XPS and cyclic voltammetry techniques on a rotating disk equipment have substantiated an interpretation of the data and of the decline of the cathodic performances observed after more than 100, 2 hr cycles of both cathodic and anodic polarizations.

The enhancement of the activity with Mo ions can be related to a redox process in the solid phase which occurs simultaneously with a better oxygen penetration in the Mo-containing samples. In the case of cathodic polarizations data can be explained by an increase of the conductivity of the naphthalocyanine films. For anodic polarizations the presence of negatively charged oxygen ligands acts as bridges for the electron transfer processes.

The decline in the cathodic performances appears to be mainly due to changes in the solid phase stoichiometry, presumably in the oxide which is less stable, remaining present with the naphthalocyanine structure.

For both anodic and cathodic polarizations, the investigations *vs.* temperature reveal a nonactivated process which can be interpreted with the aid of the Marcus and Levich theories as a quantum mechanical tunneling. The rate appears, therefore, to be limited by a too distant approach of the solvent molecules from the active sites (central ion and oxygen ligands). The entropy factor and the tunneling term of probability in the rate expression are both dependent on the closest distance of approach, the latter being much more sensitive to this than the former.

Activation Energies of Anodic Gold Reactions in Aqueous Alkaline Cyanide

C. P. Thurgood,* D. W. Kirk, F. R. Foulkes,** and W. F. Graydon**

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A4

ABSTRACT

The kinetics of the anodic reactions of gold in aqueous alkaline cyanide in the potential range −0.81 to +0.64V were studied by means of potentiostatic and potentiodynamic measurements for the temperature range 0°-50°C. The effects of mass transfer were also investigated. As in earlier works, three distinct regions of anodic activity (*i.e.*, regions of anodic reactions) were found in potentiostatic measurements. The kinetic behavior of the gold reaction in each of these regions was found to behave in the manner predicted by the single reaction mechanism

$$Au + CN^- \rightarrow AuCN_{ads}^- \quad [1]$$

$$AuCN_{ads}^- \rightarrow AuCN_{ads} + e^- \quad [2]$$

$$AuCN_{ads} + CN^- \rightarrow Au(CN)_2^- \quad [3]$$

The dissolution reaction in the most cathodic of the three regions (−0.56 to −0.26V) was characterized by a high apparent activation energy (93 ± 8 kJ/mol) and a lack of dependence on mass transfer. The second step in the reaction mechanism was identified as the rate-determining step. The gold dissolution reaction in the intermediate potential region −0.26 to +0.39V was found to have a relatively high apparent activation energy (47-55 kJ/mol) and a small dependence on the mass transfer. The second step in the reaction mechanism was identified as the rate-determining step. In the most anodic of the three regions (−0.39 to +0.64V), the gold dissolution reaction was found to be under diffusion control with an apparent activation energy of 16-18 kJ/mol. The third step in the reaction mechanism was identified as the rate-determining step. A fourth region (−0.81 to −0.56V) observed in potentiodynamic measurements was found to have an apparent activation energy of 62 ± 2 kJ/mol with little dependence on mass transfer. The reaction was identified as an adsorption reaction.

An understanding of the electrochemical behavior of gold in alkaline cyanide media is required for the development of efficient methods of electrochemical gold recovery from industrial liquors, electroplating wastes, and scrap metal (1).

Although the anodic behavior of gold in aqueous alkaline cyanide has been the subject of a number of studies (2-8), the nature of some of the complex behavior has only recently been identified (9-11). In slow potential sweep measurements or steady-state measurements, three potential regions are found which display an anodic current peak. Between these regions passivation of the gold surface is evident (11). The cause of the anodic reactions was uncertain until gold weight loss measurements were conducted in each of the regions (6, 9) and were interpreted as indicating the same overall dissolution reaction for all regions (6, 9)

$$Au + 2CN^- \rightarrow Au(CN)_2^- + e^-$$

The dissolution process has been shown to follow the sequence (5, 6) given in the Abstract.

This reaction sequence, unlike some of the other mechanisms found in the literature (2, 3), provided an explanation for the gold dissolution behavior at each of the anodic peak regions. Although the same overall reaction was found for the three regions, the rate-determining step was not the same for the three regions. The gold dissolution reaction rates in the two most cathodic regions (−0.81 to −0.26V and −0.26 to +0.39V[1] *vs.* SHE) were reported to be controlled by step [2] of the reaction sequence while the dissolution rate in the most anodic region (−0.39 to +0.64V) was reported to be controlled by step [3].

In addition to this steady-state behavior, the potentiodynamic measurements of Kirk and Foulkes (10) revealed an additional anodic potential peak in the region −0.81 to −0.56V for sweep rates greater than 2 $mV \cdot sec^{-1}$. Cyclic potential sweep measurements carried out by MacArthur (4) at elevated temperatures revealed only two prominent anodic regions. It is not clear whether the change in temperature or the repetitive potential cycling is responsible for the disappearance of two of the anodic regions found at room temperature.

As a result of the complexity of the anodic behavior of gold in aqueous alkaline cyanide and of the fact that many industrial processes are carried out at elevated temperatures (1), a study of the variation of the

Key words: metal, activation, voltammetry.

[1] All potentials are reported *vs.* SHE.

anodic reactions with temperature was carried out. The determination of activation energies for each of the anodic reactions provided an independent method of identifying the rate-controlling steps involved. The influence of mass transport was also studied.

Experimental

The equipment consisted of a Wenking potentiostat (Model 70TS1), Wenking voltage scan generator (Model VSG 72), and a Wenking Integrator (Model SS170). The potential sweep measurements were recorded on a Princeton Applied Research X-Y recorder (Model 9002-A).

The cell consisted of a Pyrex container with a Teflon top. Two glass fitted tubes set either side of the working ing electrode housed the counterelectrodes. A Luggin capillary was used to hold the saturated calomel reference electrode and the capillary tip was drawn to a diameter of 0.1 cm and set 0.2 cm from the surface of the working electrode. This configuration has been found to reduce *IR* drop to a negligible value. Other details of the cell have been described previously (6).

The cell was operated in a Plexiglas water bath that was connected to an external reservoir of water. A Tecam (Model TE-7) combination heater/pump controlled temperatures to within $\pm$ 0.2°C. Pure gold (99.99%) was used for both the working and counterelectrode. Solutions were prepared from analytical grade reagents and doubly distilled water. All runs used 1.0M KOH + 0.1M KCN as the electrolyte.

Purified nitrogen was obtained by passing the gas through an oxygen scrubber containing an aqueous solution of vanadous chloride. The electrolyte was then deoxygenated by bubbling the purified gas through it for at least 30 min. The rate of mass transfer at the gold solution interface was controlled by altering the rate of gas bubbling through the cell, and hence altering the boundary layer thickness.

A standard pretreatment was necessary to achieve reproducible measurements. The electrode was first immersed in aqua regia for 5 sec, washed in doubly distilled water, and then heated gently above a natural gas flame. Finally, the electrode was given a 5 min reduction interval in the electrolyte at -0.96V.

For the temperature measurement in the potential region of peak 1, the pretreatment procedure was modified in order to improve the resolution of the peak 1 complex. After immersion in the aqua regia for 5 sec, and washing in doubly distilled water, the electrode was held at +0.39V for 2 min in a 0.1M KOH + 0.1M KCN solution. The brown film that formed on the surface as a result of this procedure was eliminated by gently heating the electrode over a natural gas flame. The reduction period in the electrolyte at -0.96V was increased to a minimum of 10 min.

Slow potential sweep measurements (2 mV/sec) were used in the peak 1 region so that peak 1 and peak 1a could be distinguished. For peaks 2 and 3, a fast potential sweep (500 mV/sec) was used to set the potential of the electrode at the working value after cathodic reduction at -0.96V. This was to ensure that the surface was not perturbed due to dissolution at the preceding peaks. A minor manual adjustment in the potential was made to set the current at its maximum value. The maximum current was recorded after reaching steady state. This usually occurred within 3-5 min for peak 2 and within 1 min for peak 3.

The surface area of the electrode was determined from potential scan measurements using the linear relation between the current peak height and the square root of the voltage scan rate for the reversible oxidation of $Fe(CN)_6^{4-}$. The relation given by Nicholson and Shain (12) is

$$\frac{i_p}{nFAC_o\left[\frac{D_o nFV}{RT}\right]^{1/2}} = 0.4463$$

where C_o is the concentration of $Fe(CN)_6^{4-}$ (mol · cm^{-3}), D_o is the diffusion coefficient of $Fe(CN)_6^{4-}$ (cm^2 · sec^{-1}), i_p is the peak current (A), A is the area (cm^2), n is the number of electrons transferred in the oxidation, V is the scan rate (V · sec^{-1}), and **F**, R, and T have their usual meanings. For a 4 mM solution of $Fe(CN)_6^{-4}$ in 1M KCl, $D_o = 6.32 \times 10^{-6}$ cm^2 · sec^{-1} at 25°C (13).

In order to reduce the effect of changing surface area, a correction was applied to the measured surface area for each run. This was calculated by assuming a linear variation of the area with the number of coulombs passed through the electrode between successive surface area determinations. This correction was small as the area changed only by about 5% between successive determinations.

Results and Discussion

In Fig. 1 a typical potential scan of gold in aqueous alkaline cyanide is presented. The temperature and sweep rate were 29.6°C and 2 mV · sec^{-1}, respectively. The three dominant anodic regions seen in the figure are identified as peak 1, 2, and 3. The small peak cathodic of peak 1 is identified as peak 1a. This small peak is an anodic reaction which is only observed in potentiodynamic measurements.

Before the variation of the rate of reaction with temperature was studied, it was necessary to determine the effect of temperature on the peak potentials. Since the reference electrode (a saturated calomel electrode) was within the cell and therefore at the same temperature as the solution, a temperature-dependent potential correction was required to convert the potential measurements to the SHE scale. The temperature coefficient of the SCE electrode is -0.67 mV/°C (14). Figures 2 and 3 show the variation of the peak potentials with temperature from slow potential sweep measurements (2 mV · sec^{-1}). The three peaks (1, 2, and 3) found in steady-state measurement all have a peak potential which becomes more negative (cathodic) with increasing temperature. The rate of cathodic shift for peaks 1, 2, and 3 are 2.0 $\pm$ 0.5, 1.7 $\pm$ 0.8, and 2.5 $\pm$ 0.8 mV/°C, respectively. These temperature coefficients are greater than that predicted for the

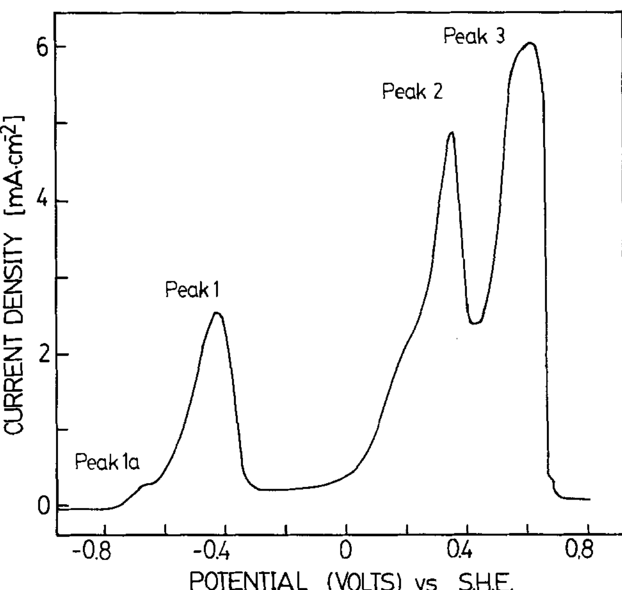

Fig. 1. A typical voltage scan in a 0.1M KOH + 0.1M KCN electrolyte; sweep rate = 2 mV/sec; temperature = 29.6°C; quiescent solution.

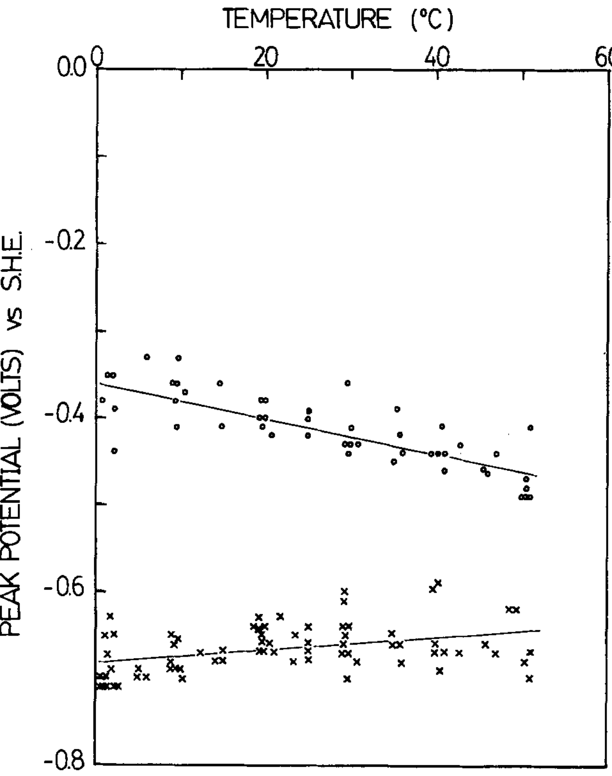

Fig. 2. Peak potential vs. temperature; ×, peak 1(a); ○, peak 1

variation of the reversible potential (0.176 mV/°C) of the gold dissolution reaction. (See Appendix for details.) Some of this difference may be attributed to the change of the effective concentration of $[CN^-]$ and $[Au(CN)_2^-]$ with temperature. In addition, the peak formation has been shown to be the result of competing passivating reactions (11) and would therefore also be affected by the temperature dependence of these reactions. Peak 1a does not show the same peak potential variation as the other peaks, and shifts in the positive (anodic) direction with increasing temperature. This contrast in behavior of peak 1a relative to peaks 1, 2, and 3 suggests that the reaction causing peak 1a may be fundamentally different from that of the other peaks.

As a result of the cathodic shift of peak 1 and the anodic shift of peak 1a, the two peaks overlap at higher temperatures and result in peak 1a appearing as a small shoulder on peak 1 at elevated temperatures. From the potential scan in Fig. 1 a small shoulder can be observed at the base of peak 2. This shoulder becomes more prominent at higher temperatures but was not studied because the narrow temperature range over which it could be distinguished, was insufficient to allow the determination of the apparent activation energy.

The results of the activation analysis for peak 1a are presented in Fig. 4 (a discussion of the use of peak potentials for activation analysis is given in the Appendix). The current density changes by about two orders of magnitude over the temperature range 0°-50°C. A regression analysis carried out using the 44 experimental measurements presented in Fig. 4 yields the relationship

$$\log i_p = (9.70 \pm 0.20) - \left(\frac{3248 \pm 177}{T}\right)$$

with a linearity coefficient $r^2 = 0.98$ (15). The apparent activation energy is 62 ± 3 kJ/mol. The activation energy is unchanged when the sweep rate is increased from 2 mV · sec^{-1} to 10 mV · sec^{-1} indicating that pseudo-equilibrium is achieved during the potential sweep. The high activation energy indicates that the peak 1a reaction is activation rather than diffusion controlled over the temperature range 0°-50°C. This, combined with the fact that peak 1a is not observed

[2] $r = 1$ indicates perfect linearity of the data.

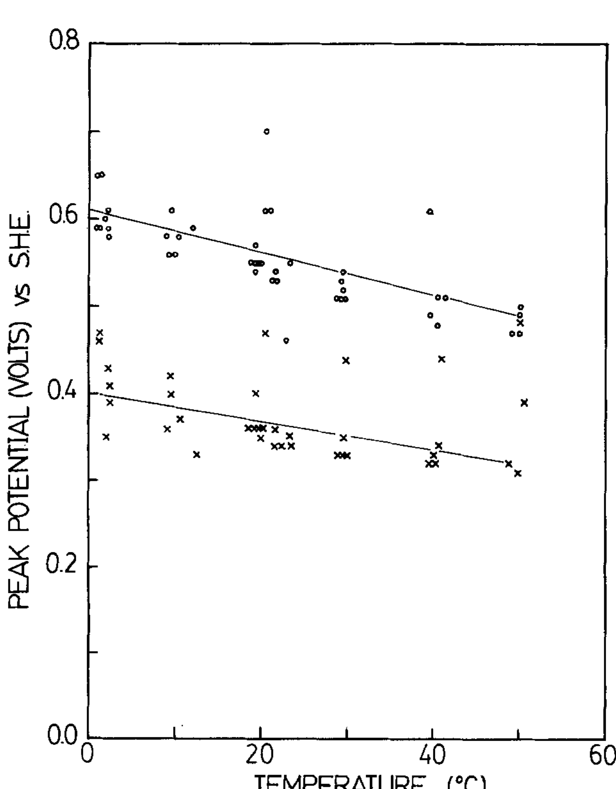

Fig. 3. Peak potential vs. temperature; ×, peak 2; ○, peak 3

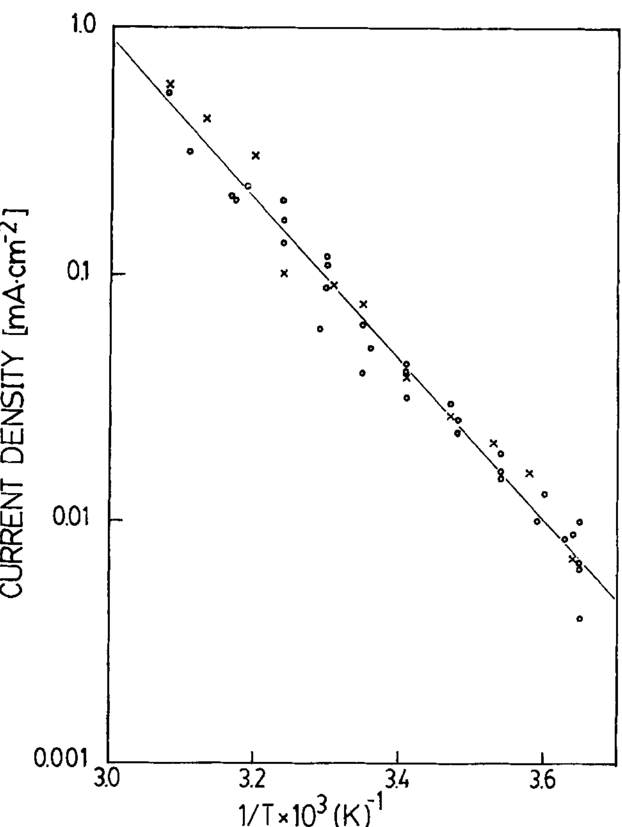

Fig. 4. Peak current density vs. reciprocal temperature for peak 1(a); ○, sweep rate = 2 mV/sec; ×, sweep rate = 10 mV/sec; 0.1M KOH + 0.1M KCN; quiescent solution.

in steady-state measurements and therefore does not directly result in gold dissolution, indicates that the reaction is an adsorption reaction.

The results of the activation analysis for peak 1 are presented in Fig. 5. The peak current density increases by three orders of magnitude over the temperature range 0°-50°C. A regression analysis for the 46 experimental points presented in Fig. 5 yields the relationship

$$\log i_p = (15.69 \pm 0.51) - \left(\frac{4876 \pm 418}{T}\right)$$

with a linearity coefficient of $r = 0.96$. The apparent activation energy is 93 ± 8 kJ/mol. The activation energy is unchanged when the sweep rate is increased from 2 mV · sec^{-1} to 10 mV · sec^{-1} indicating that pseudo-equilibrium is achieved during the potential sweep. The magnitude of the activation energy clearly indicates activation rather than diffusion control. From the reaction sequence [1], [2], and [3], steps [1] and [3] should show some diffusion control and therefore step [2] of the reaction mechanism is indicated as the rate-determining step. This is in agreement with earlier work (10).

The results of the activation analysis for peak 2 are presented in Fig. 6. These data, obtained from steady-state measurements, show that the current density for peak 2 changes by approximately two orders of magnitude from 0° to 50°C. Above 30°C however, some measurements show a much reduced current density (see Fig. 6). These data sugggest that the dissolution reaction is being passivated by other reactions occurring on the gold surface. The cause of the premature passivation is not known. A regression analysis for the 34 experimental measurements from 0° to 30°C presented in Fig. 6 yields the relationship

$$\log i_p = (8.87 \pm 0.23) - \left(\frac{2474 \pm 235}{T}\right)$$

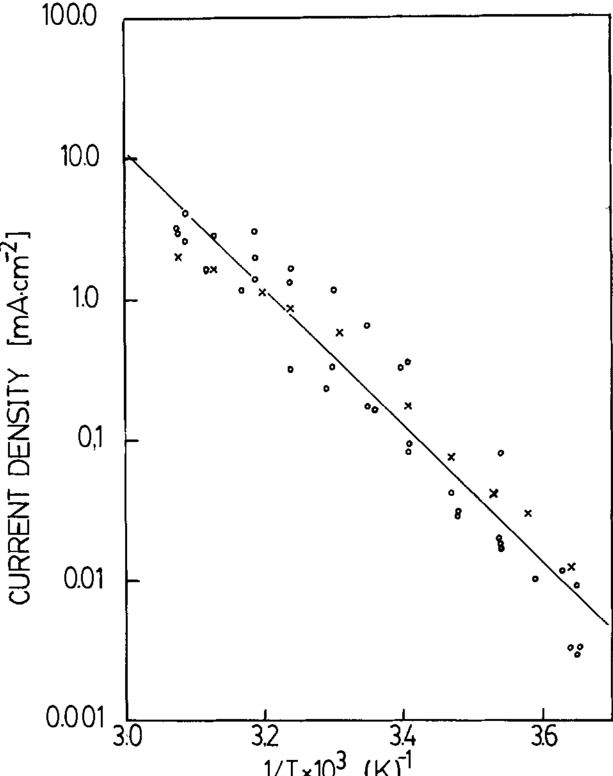

Fig. 5. Peak current density vs. reciprocal temperature for peak 1; ○, sweep rate = 2 mV/sec; ×, sweep rate = 10 mV/sec; 0.1M KOH + 0.1M KCN; quiescent solution.

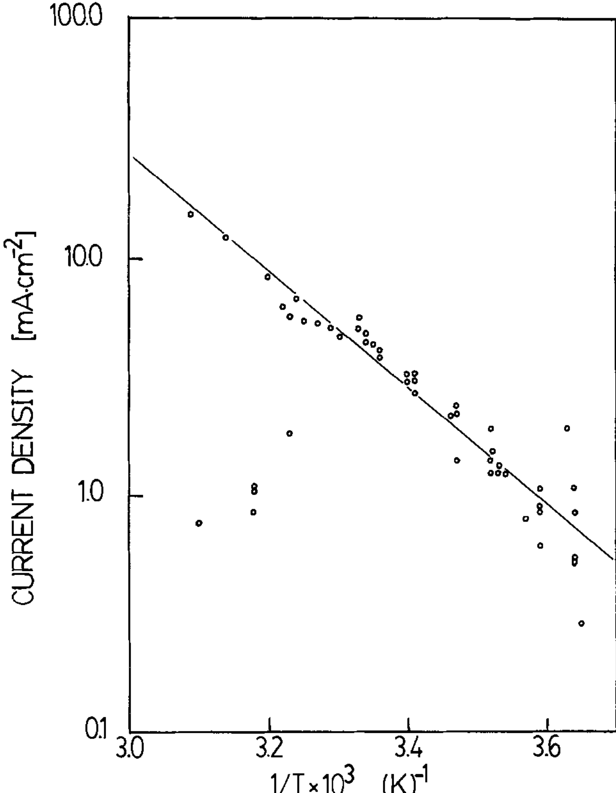

Fig. 6. Peak current density vs. reciprocal temperature for peak 2; 0.1M KOH + 0.1M KCN; quiescent solution.

with a linearity coefficient of $r = 0.95$. The data above 30°C that do not show the passivation phenomena fit the correlation. The apparent activation energy is 47 ± 5 kJ/mol. Although the activation energy is much smaller than either peak 1 or peak 1a, the magnitude is sufficient to predict a rate-determining step which is activation rather than diffusion controlled. To confirm this prediction the experiments were repeated with nitrogen gas vigorously bubbling through the solutions to promote an increased mass transfer rate. The results are presented in Fig. 7. The dissolution current does increase at a slightly greater rate with temperature than in the unstirred case. The apparent activation energy for the data 0°-30°C is 55 ± 6 kJ/mol. Although the values for the stirred and unstirred cases are very close, a statistical test (11) shows that the hypothesis that the activation energies are the same can be rejected at the 95% confidence level. Therefore, although the process is predominantly activation controlled, there is also some influence from mass transfer. Since activation control is found, step [2] of the reaction mechanism is predicted to be the rate-determining step. This is the same rate-controlling step as predicted for peak 1. Since the rate of reaction at peak 2 is approximately 20 times the rate at peak 1, the partial influence of mass transfer on the reaction rate at peak 2 is reasonable. The identification of step [2] as the rate-determining step is in agreement with earlier work (6).

The results of the activation analysis for peak 3 are presented in Fig. 8. These data, obtained from steady-state measurements, show that the current density for peak 3 changes by approximately threefold from 0° to 50°C. A regression analysis for the 19 experimental points presented in Fig. 8 yields the relationship

$$\log i_p = (3.91 \pm 0.02) - \left(\frac{957 \pm 30}{T}\right)$$

with a linearity coefficient of $r = 0.998$. The reduced scatter in the measurements allowed fewer points to

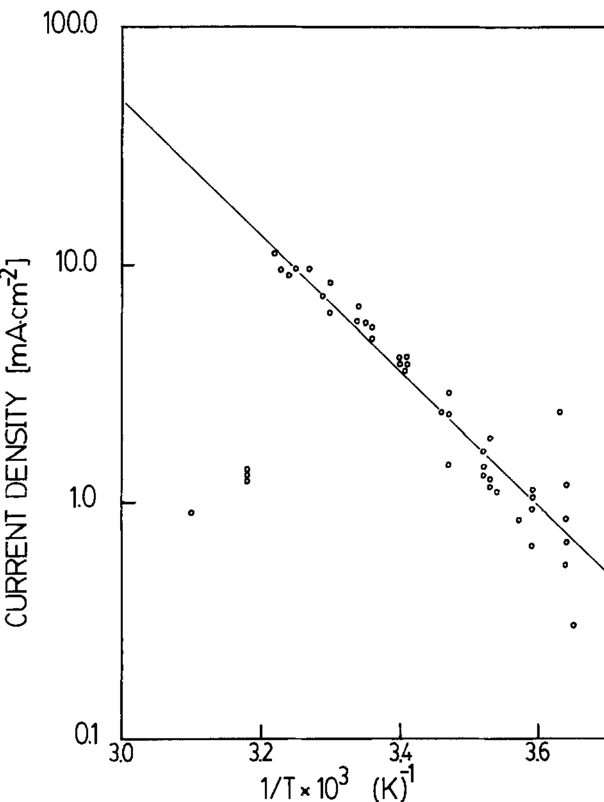

Fig. 7. Peak current density vs. reciprocal temperature for peak 2; 0.1M KOH + 0.1M KCN; stirred solution.

be taken than in the other peak regions and still achieve a good correlation. The apparent activation energy is 18.3 ± 0.6 kJ/mol. This value is much smaller than those for the previous peaks and predicts a diffusion-controlled reaction. To confirm this prediction the measurements were repeated with vigorous gas bubbling through the solutions to promote an increased mass transfer rate. The results are shown in Fig. 9. The increase in the mass transfer rate from the gas bubbling causes an increase in the current density of approximately 80% compared to the unstirred case. These results are characteristic of a diffusion-controlled reaction in which stirring reduces the diffusion layer and causes a greater current density. The apparent activation energy with stirring is 16 ± 4 kJ/mol. A statistical test (15) shows that the two activation energies are not significantly different. The reaction rate at peak 3 is greater than that of peak 2 and it would appear that the mass transfer rate has become the rate-controlling mechanism. Thus, step [3] is predicted to be the rate-controlling step in agreement with earlier work (6).

The effect of mass transfer has been shown to be negligible at small dissolution rates (peak 1), to exert some influence at moderate reaction rates (peak 2), and to dominate the dissolution process at the greatest reaction rates (peak 3).

Summary

1. The persistence of the four peaks over the temperature range 0-50°C indicates that the reaction mechanism remains unchanged over the same temperature range.
2. Peak 1a, with an apparent activation energy of 62 ± 3 kJ/mol, is an activation-controlled reaction, most likely an adsorption reaction.
3. Peak 1 is an activation-controlled dissolution reaction with an apparent activation energy of (93 ± 8) kJ/mol.
4. Peak 2 is a dissolution reaction predominantly controlled by activation with an apparent activation energy of 47-55 kJ/mol.
5. Peak 3 is a diffusion-controlled dissolution reaction with an apparent activation energy of 16-18 kJ/mol.
6. The reaction mechanism [1], [2], and [3] is consistent with the activation energies for each peak and with the effects of mass transfer.

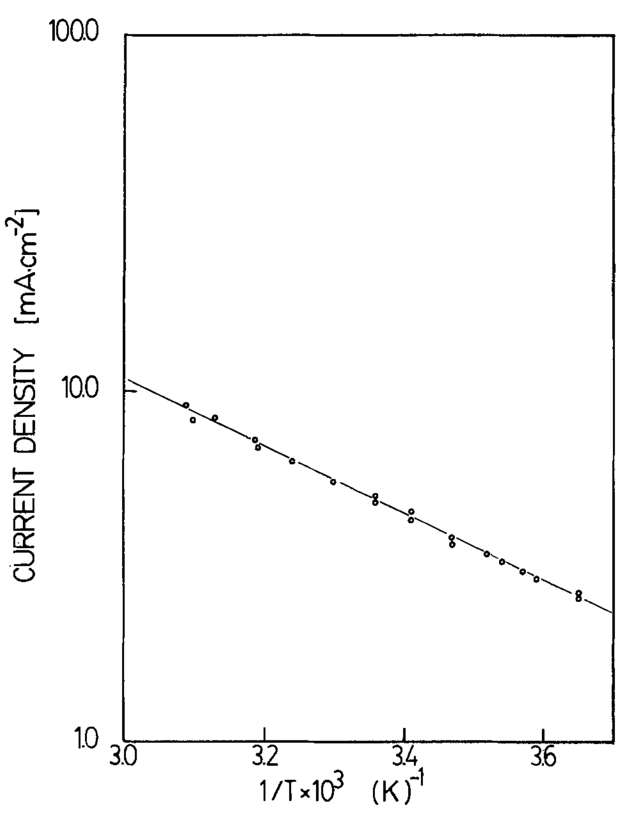

Fig. 8. Peak current density vs. reciprocal temperature for peak 3; 0.1M KOH + 0.1M KCN; quiescent solution.

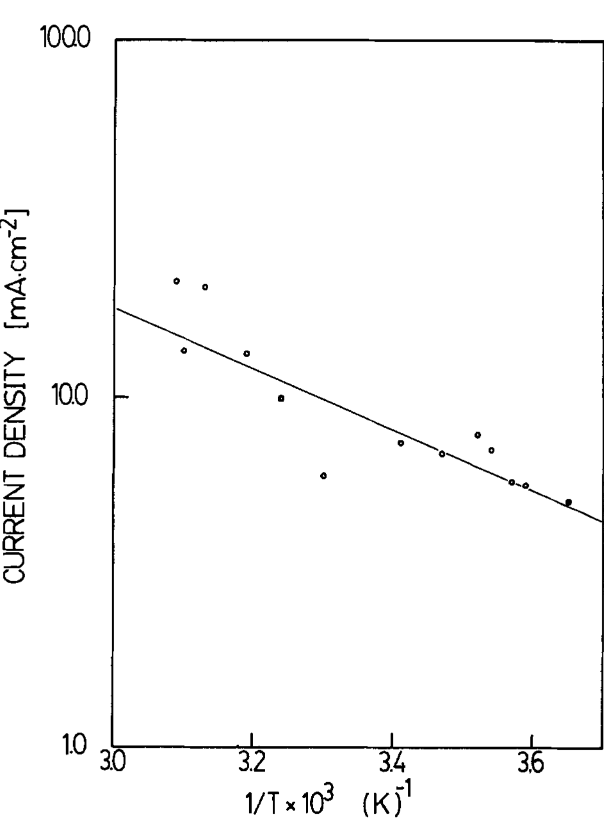

Fig. 9. Peak current density vs. reciprocal temperature for peak 3; 0.1M KOH + 0.1M KCN; stirred solution.

APPENDIX

Use of Peak Potentials for Activation Analysis

For the conditions of constant overpotential and composition, the required applied potential can be calculated knowing the variation of the thermodynamic reversible potentials of the half-cell reaction and the reference electrode reaction.

For the reaction

$$Au + 2(CN)^- \rightarrow Au(CN)_2^- + e^-$$

ΔG at 25°C[3] $= -5.899 \times 10^4 J$

ΔG at 50°C[4] $= -5.941 \times 10^4 J$

converting the data to thermodynamic potentials ($\Delta G^\circ = -n\mathbf{F}\epsilon^\circ$)

$$\Delta\epsilon \text{ reversible} = +0.176 \text{ mV/°C}$$

The saturated calomel electrode potential decreases by 0.67 mV/°C (14). This value was used to convert the potential scales to the SHE scale. Thus, the condition of constant overpotential would require that the applied potential be increased by 0.176 mV/°C after correcting for the change in the potential of the reference electrode. This assumes that the peak potential is not exceeded (resulting in passivation of the reaction) and that the electrolyte composition remains fixed. The measurement of peak potentials (*vs.* SHE) in Fig. 2 and 3 shows that the potential shifts by about 2 mV/°C. Thus, the difference between the conditions of constant overpotential and peak potential is apparently ~1.8 mV/°C. However, the condition of constant composition must be carefully examined.

The Nernst relationship is

$$\epsilon = \epsilon^\circ - \frac{RT}{\mathbf{F}} \ln \frac{a_{CN}{}^2 - a_{Au}}{a_{Au(CN)_2^-}}$$

If it is assumed that the activity change due to temperature change is small, then a_{CN^-} is approximately constant since the concentration of $[CN^-] = 0.1M$ and the dissolution of gold will not significantly alter the $[CN^-]$ bulk concentration during the course of the experiment. However, the activity of the $Au(CN)_2^-$ species will depend on the rate of formation and the rate of removal from the surface. The rate of formation is directly proportional to the current while the rate of removal depends on diffusion and conduction forces. Indeed, conduction will only aid $Au(CN)_2^-$ removal negative of the pzc (*i.e.*, at potentials $< -0.08V$ in 0.1M KOH) (18). It is therefore likely that the surface concentration of $Au(CN)_2^-$ will rise with increasing current and this will shift the reversible potential to more positive values. Thus the difference between the potential required for constant overpotential and that of the peak potential will be less than 1.8 mV/°C calculated above, and because of the uncertainty of surface concentrations, the peak potentials are probably the most appropriate values to use in this situation.

The determination of the difference between activation analysis carried out under constant overpotential and peak potential for peak 1a is very difficult since the application of the reaction sequence [1], [2], and [3] may not be appropriate. The behavior of the reaction causing peak 1a is quite different from that of the other peaks. (The temperature coefficient of the peak potential is positive and the reaction is only detected under nonsteady-state conditions.)

ABSTRACT

The effects of pretreatment (*i.e.*, activation and acceleration) and substrate species on the magnetic properties of Co-P electrolessly plated thin films for high density storage medium were investigated with various $PdCl_2/SnCl_2$ catalysts and accelerators. The activity of surfaces to be plated controlled the magnetic properties of Co-P thin films, and the coercivity became lower with increase in the catalytic activity of surfaces. The magnetic properties of Co-P films were also affected by the substrate species and were controlled by grain size of substrate surfaces, but the larger surface roughness which was produced by emery papers did not affect the magnetic properties. The Co-P thin film on acetylcellulose whose coercivity was the highest in the experiments was investigated with transmission electron diffraction analysis. The pretreatment for electroless plating was observed to influence not only the distribution of crystallite grain sizes but also the orientation of the c-axis of the hexagonal α-cobalt lattice plated onto acetylcellulose.

For high density storage applications, thin recording media are in demand, and since Fischer's paper (1) a number of workers have studied metallic thin-film layers of electrolessly or chemically deposited Co-P (or Co-Ni-P) as one of the thin-film formation techniques for high density storage media. The magnetic properties are strongly dependent on the preparation conditions and are affected by many factors such as phosphorus content, film thickness, crystallite grain size, crystallite orientation, substrate materials, and so on. Among those factors, the phosphorus content is considered to play the most important role in determining the magnetic properties of the thin film, and the relationship between phosphorus content and crystallite grain size has been discussed by many workers (2-5). The maximum value of the coercivity was reported to be around 600Å thickness for Co-P and Co-Ni-P by Bate *et al.* (4, 6, 7). The effect of substrate material on magnetic properties was extensively studied by Tago *et al.* (8), and the high coercivity and high squareness of thin films were obtained by using a proper substrate. We have examined mixed $PdCl_2/SnCl_2$ catalysts for electroless metal deposition and have reported that the activated surface conditions are largely dependent on catalyst and accelerator species (9, 10). Since the surface conditions of the substrate are considered to critically affect the magnetic properties of electroless Co-P plating film, in this paper we investigate and discuss the effects of activation and acceleration on electroless Co-P plating film formation and its magnetic properties.

Experimental

Four samples of mixed $PdCl_2/SnCl_2$ catalysts, which were used in the previous study (9, 10), were employed in the experiments. The samples "A" (low catalytic activity) and "D" (high catalytic activity) were prepared in our laboratory with reference to some patents, and the samples "E" and "F" were the commercial ones of Hitachi Kasei Company HS-101B and Shipley Company Cataposit No. 44 where the latter is one of the salty catalysts using NaCl instead of HCl. The details of preparation and composition were previously shown in Ref. (9 and 10). Five accelerators, 1M NaOH, 6M HCl, 1.12M H_2SO_4, 1M NH_4OH, and 1M NH_4BF_4 were used in accordance with several papers (11). The ammoniacal alkaline cobalt tartrate plating bath was adopted as the electroless Co-P plating bath [$CoSO_4$ 0.05M, $Na_2C_4H_4O_6$ 0.5M, $(NH_4)_2SO_4$ 0.50M, NaH_2PO_2 0.20M, pH 9.2 adjusted with NH_4OH, bath temperature 80°C]. The process of electroless plating was as follows: polished with MgO powder (only in the case of Cu sheet), degreased in ethanol or acetone, immersed in 10% HCl, activated in mixed $PdCl_2/SnCl_2$ catalyst solution (3 min), immersed in accelerator solution (3 min), and electroless plating was started (plating time *ca.* 30 sec). A water rinse was used after each of the steps. The deposition rate and the film thickness of the deposits were calculated from weight change, which was measured by a Mettler microbalance (the density of deposits was assumed to be 8.6 $g \cdot cm^{-3}$). Copper sheet was used as substrate and the mixed potential measurement for monitoring the initial time of plating was performed with copper wires. Electrolessly plated Ni-P (Blue Sumer, Japan Kanigen Company Limited), Ni-Cu-P (Niculoy 22, Shipley Far East Limited), Cu (Cuposit Copper Mix 328L, Shipley Far East Limited), Au (Noncyanide electroless gold, Nippon Engerhard Company Limited), and acetylcellulose were also used for the tests of substrate species. Acetylcellulose sheet was rendered hydrophilic by immersing in 0.1M NaOH solution before activating its surface. The surface roughness was varied with several emery papers and measured with a stylus technique (Rank-Taylor-Hobson Talystep 1). The compositional analysis of cobalt and phosphorus in the electroless Co-P plated films was done by atomic absorption spectroscopy for cobalt, and by spectrophotometry using the molybdenum blue

method for phosphorus. The electrochemical measurement technique was previously shown in Ref. (9 and 10). A gold wire or disk was used as the test electrode. Silver/silver chloride (Ag/AgCl) and mercury/mercuric oxide (Hg/HgO) were used as reference electrodes and all potentials are referred to a saturated calomel electrode (SCE). The coercivity and squareness of the films were measured with a sensitive vibrating sample magnetometer (VSM-3 Type, Toei Kogyo Company Limited) and a digital BH curve tracer (DG-1, Sakata Works Limited). Electron microscopy measurements were made using a JEOL JEM-7A instrument with a 100 kV electron source. Electron diffraction patterns were analyzed with reference to the instrumental factor determined by a standard sample of evaporated gold. Samples for transmission electron microscopy and transmission electron diffraction analyses were prepared with the Co-P plating on acetylcellulose sheet. Samples for reflection electron diffraction analysis were the Co-P films electrolessly plated on copper sheet.

Results and Discussion

Acceleration effect on catalyst activity for electroless cobalt plating.—The catalyst activity can be determined from the mixed potential measurements, as previously shown in Ref. (9). The induction time from immersion to initiation of plating can be obtained from the dramatic potential change, and the reciprocal order of the induction time corresponds to the order of catalyst activity. Typical mixed potential variations in the electroless cobalt plating bath are shown in Fig. 1, and the induction times with various conditions of activators and accelerators are also demonstrated in Table I. The arrows in the figure show the starting point of plating. The variation of the induction time in this case became smaller than that in the previous case of nickel deposition [cf., Ref. (9)], and sometimes no cobalt deposition was observed in the case of nonacceleration. The catalytic activity order can be identified as follows: E $\simeq$ D $>$ F $>$ A, and after acceleration, the order of activity is poorly characterized because of the induction time being almost the same. The activity in the case of NaOH, however, may be the highest in these five cases. Since the films initially deposited, in the case of nonacceleration, are patched and uneven, even though the induction time is generally shorter than that in the case of nickel deposition, the acceleration in the case of cobalt deposition is considered to be a very significant process as well as in the case of nickel deposition. The variation of the immersion time in the accelerator solution on the induction time was observed to become constant after *ca.* 5 min for sample A, and after several tens of seconds for sample D; except for the case of NaOH, the

A	2.2	1.7	No dep.	No dep.	No dep.	No. dep.
D	0.9	1.0	1.2	0.9	1.0	2.3
E	0.9	0.9	0.8	0.8	0.8	1.0
F	0.8	0.8	0.9	0.9	0.8	1.0

* The condition of films initially deposited in the cases of NH_4OH and NH_4BF_4 was worse than those in the cases of NaOH, HCl, and H_2SO_4.

** The induction time in the case of no acceleration did not show good reproducibility, and sometimes no cobalt deposition was observed. The initially deposited films in the case of no acceleration were patched and uneven.

induction time gave the minimum value around 1 min immersion time and gradually increased with the increase in immersion time. The catalytic activity in all cases except for NaOH is considered to be constant after initial immersion; however, in the case of NaOH accelerator, the catalytic activity gradually becomes lower after long immersion time, which may be caused by the removal of active nuclei.

Though the effects of dissolved oxygen in the mixed catalyst solution were of importance in the preparation process as pointed out in Ref. (9), the effects of dissolved oxygen in the electroless plating solution on the induction time were scarcely observed.

Determination of plating time.—Figure 2 shows the relationship between plating time and film thickness for several accelerations after activation with catalyst D. The film thickness increases linearly with the increase in the plating time up to *ca.* 1000Å for each case. The highest and lowest deposition rates were observed in the cases of NaOH and NH_4OH accelerators. The 500Å thickness of the electrolessly plated cobalt film is obtained by plating *ca.* 30 sec. The variation of coercivity of the film plated for *ca.* 30 sec indicated that the coercivity is almost the same value in the region around 30 sec (*i.e.*, around 500Å thickness). Therefore, we adoped 30 sec for all cases because the

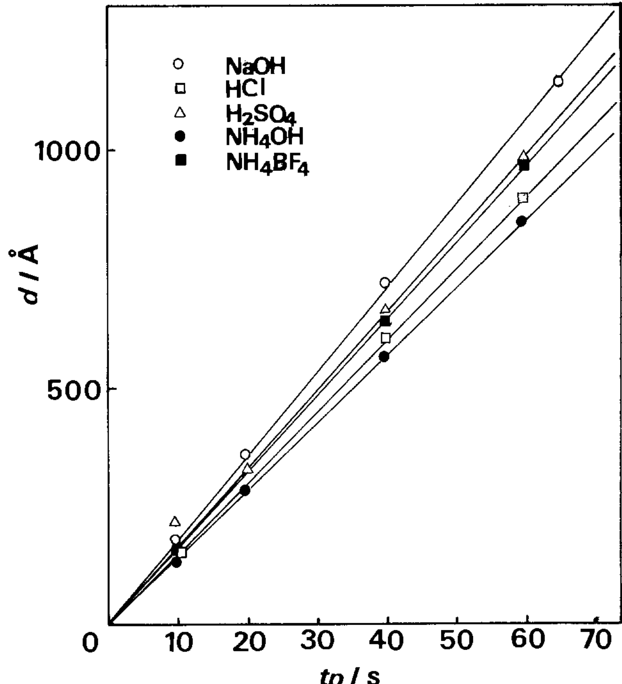

Fig. 2. Effect of acceleration on deposition rate in the Co-P electroless plating bath. Activation and acceleration were performed with sample D for 3 min and with various accelerators for 3 min. t_p designates the plating time.

coercivity of the film was scarcely affected by the variation of film thickness around 500Å.

Electrochemical approach using gold electrode.—Figure 3 shows single anodic voltammograms on a gold electrode in 1M HCl after activation with D and acceleration with several accelerators. It has been confirmed in the previous paper (9) that the three anodic peaks at *ca.* −0.10, *ca.* 0.20, and *ca.* 0.45V correspond to the desorption of adsorbed Sn(O), the oxidation of Sn(II) to Sn(IV), and the dissolution of Pd(O), respectively. The residual amount of Sn on the substrate surface after acceleration can be qualitatively compared with the two anodic peaks at *ca.* −0.10 and *ca.* 0.20V. In the cases of NaOH and HCl accelerators, the anodic peaks due to the desorption of $Sn(O)_{ad}$ and the oxidation of Sn(II) were not observed, and only the anodic peak due to the dissolution of Pd(O) was observed. The order of the residual amount of Sn can be $H_2SO_4 > NH_4BF_4 \simeq NH_4OH > NaOH \simeq HCl$. Since the two anodic peaks due to Sn desorption and oxidation were not observed in the single anodic voltammograms after activation with E and acceleration with HCl and NH_4BF_4, which were previously shown Ref. (9), the residual amount of Sn on the surface is considered to depend also on the activator species. In view of the fact that the order of the Sn residual amount corresponds nearly to that of the induction time, catalytic activity is affected by the residual amount of Sn which is controlled not only by activators but also by accelerator species.

Effects of activation and acceleration on magnetic properties.—The variation of magnetic properties of

Co-P films, where various activators and accelerators are used for the pretreatment of copper substrate, is demonstrated in Table II. The cobalt-phosphorus film was not deposited in the case of activator A using accelerators of H_2SO_4, NH_4OH, and NH_4BF_4. There is an approximate tendency for the accelerators NaOH and HCl to give relatively lower coercivity and higher squareness compared to the accelerator group of NH_4OH and NH_4BF_4. In these systems, the squareness tends to increase with the decrease in the coercivity. The coercivity of the film plated with galvanic initiation, which is shown in Table IV, becomes lower than that of the film plated with activation and acceleration. It is very interesting that the magnetic properties of thin film can be varied widely by changing the activation and acceleration processes. It is clearly attributed to the difference of catalytic activity of surface conditions which are controlled by the pretreatment process.

The relationship between the phosphorus content and the coercivity of Co-P film is shown in Table III. It is shown that the pretreatment giving the higher catalytic activity tends to produce the higher phosphorus content of the film. Tasaka *et al.* (12) reported that palladium is useful as a catalyst for the oxidation of hypophosphite ion in alkaline solution. The XPS results (9) showed that the Pd-Sn active sites on surfaces consist of a system in which the ratio of Pd/Sn depends on the catalytic activity and that the Pd/Sn ratio of the active sites increases with increasing catalyst activity. Since the oxidation of hypophosphite ion which is accelerated by the active sites of catalysts enhances not only the reduction of cobalt but also the phosphorus deposition which may be caused by the side oxidation reaction of hypophosphite ion, the pretreatment giving the higher catalytic activity is considered to result in the higher phosphorus content in the film. One of the authors (13) and Spelitios *et al.* (6) reported that the coercivity shows a maximum with the increase in the phosphorus content up to 5-7 w/o for these very thin Co-P storage films and that the above correlation is mainly attributed to the grain size, which is determined by the phosphorus content in these systems. Therefore, the tendency for the thin film having the higher phosphorus content to have lower coercivity might also be explained by the above assumption.

Effects of substrate species and surface roughness on magnetic properties.—Magnetic properties of the Co-P films in the cases of six kinds of substrate materials are tabulated in Table IV, where the Co-P films de-

† These films were electrolessly plated.

posited with galvanic initiation are also shown for discussion. In the case of electrolessly deposited copper, the magnetic properties were not obtained because of the dissolution of copper in the activator solution. The deposition on acetylcellulose by galvanic initiation also did not occur because the substrate was not a conductor. The coercivity on acetylcellulose is the highest, and among the metal substrate species, the order of coercivity becomes as follows: electrolessly plated Ni-P > electrolessly plated Ni-Cu-P > electrolessly plated Au > Cu. The coercivity and squareness of the film initiated with activation and acceleration processes tend to become higher than those in the case of galvanic initiation. Tago *et al.* (8) reported that the materials of Ni-P, Rh, and Au are useful as the substrate of cobalt film for storage medium and concluded that the variation of magnetic properties with various substrates may be attributed to the difference of grain size of the substrate surfaces.

The effect of surface roughness of copper sheet on magnetic properties is shown in Table V, where the film is deposited with activation (D) and acceleration (NaOH). The coercivity and squareness of the film do not vary with various roughness of R_{max} (maximum value of roughness). Therefore, it is concluded that the larger variation of surface roughness obtained by such

Table V. Effect of substrate roughness on magnetic properties

Number of emery paper	R_{max} (μm)	H_c (oe)	$B_r \cdot B_m^{-1}$
1500	0.17	510	0.68
800	0.50	515	0.68
400	2.30	510	0.68
240	3.70	500	0.66

as emery paper is too rough to affect the magnetic properties and that the smaller variation of surface roughness produced by the difference of crystallite grain size influences largely the magnetic properties. It is natural that the finest surface condition of acetylcellulose produces the highest coercivity in these experiments.

Effects of activation and acceleration on magnetic properties using acetylcellulose substrate.—Figure 4 shows the typical transmission electron micrographs of Co-P films plated on acetylcellulose with various pretreatment conditions of D accelerators. The grain size of Co-P films on acetylcellulose increases with the increase in coercivity such as 200 ~ 500Å for H_2SO_4 accelerator (590 oe), 500 ~ 800Å for NaOH (900 oe), and 1000 ~ 2000Å for HCl (1220 oe). In the case of ammonia-containing systems (D-NH_4BF_4 and D-NH_4OH), the grain sizes are uneven and there is no correlation between grain size and coercivity. As we pointed out in a previous paper (10), the active surface conditions after acceleration with the ammonia-containing solution group was quite different from those of the former three cases. Ammonia-containing group accelerators coagulate the small particles after activation to produce high density particles and it may result from some ammoniate compounds such as Pd-ammonia complexes. The above different surface conditions in the case of ammonia-containing accelerators result in the uneven grain size conditions of Co-P film which give no correlation between coercivity and grain size. Therefore, it can be concluded that the surface conditions activated with various catalysts and accelerators affect largely the magnetic properties of electrolessly plated Co-P films and that grain size of the film may be one of the important factors to control the magnetic properties of Co-P films.

Since the three cases of H_2SO_4, NaOH, and HCl show the clear correlation between coercivity and grain size, the typical results of transmission electron diffraction profiles of Co-P films on acetylcelluose are demonstrated in Table VI. The d values directly observed from the diffraction radii and the intensity of diffraction rings are given as d_{ob} and I. The calculated d values named as d_{cl} are calculated by using the hexagonal lattice parameters of a and c shown in Table VI, which are determined from the lattice constant becoming nearly constant when the Miller indexes h, k, l are alloted to d_{ob} values. It is shown by the good agreement of d_{ob} with d_{cl} that the Miller index allotment is fairly proper in these cases. Since β-cobalt with fcc lattice and cobalt phosphide alloy such as Co_2P with orthorhombic lattice are not observed in the case of electrolessly plated Co-P films, the electrolessly plated cobalt film is considered to be α-cobalt with the hexagonal lattice as reported by

d_{ob} and d_{cl} mean the lattice constants observed and calculated, respectively. I means relative intensity of diffraction ring (vs: very strong, s: strong, m: medium, w: weak).

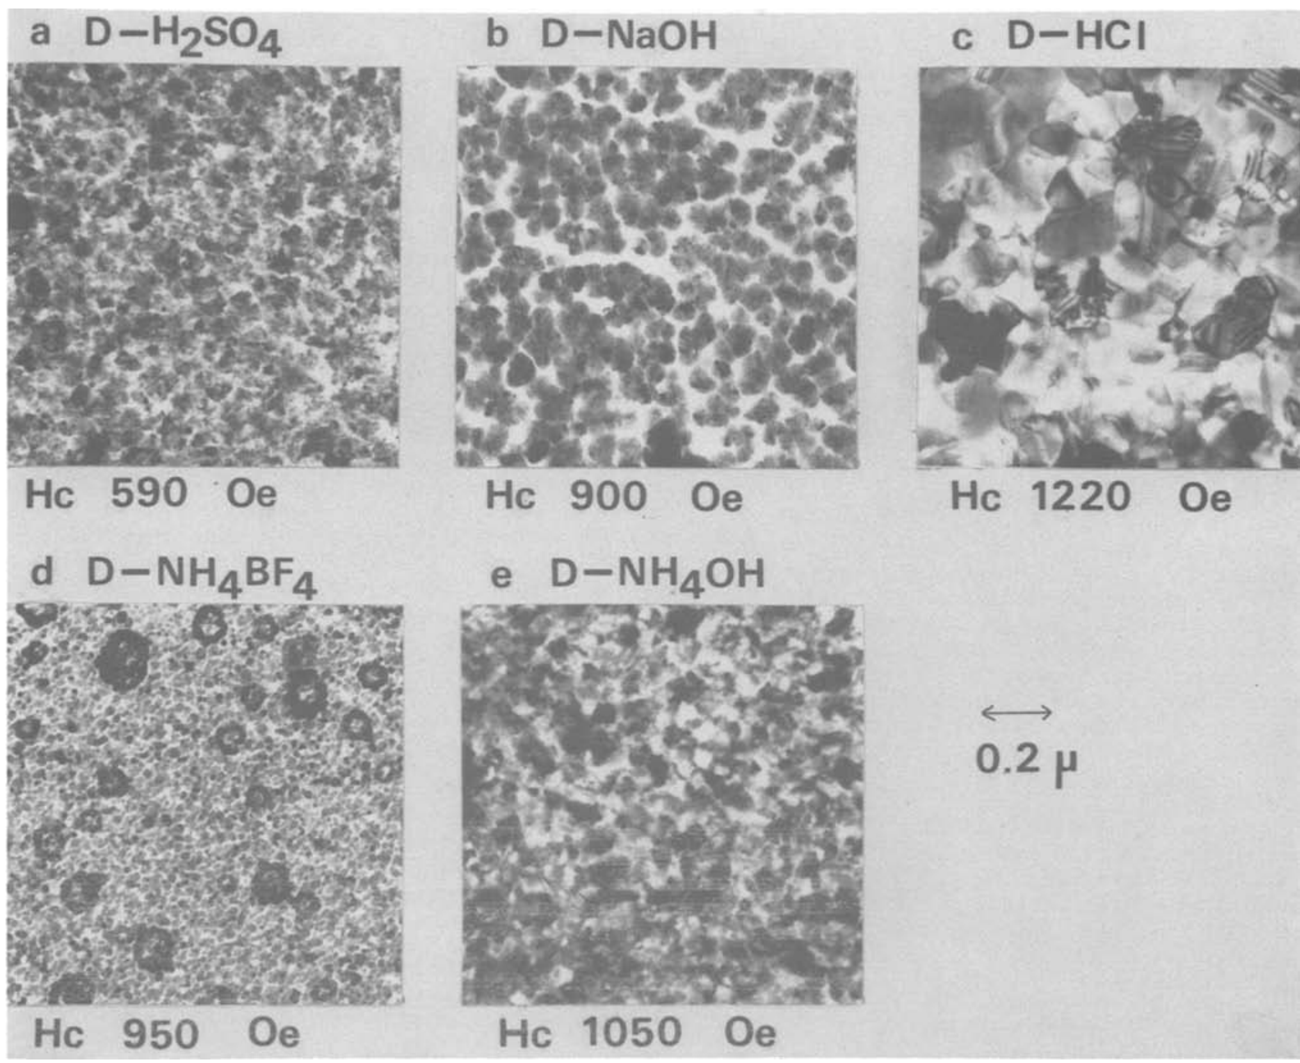

Fig. 4. Transmission electron micrographs of Co-P film on acetylcellulose with various surface conditions produced by using several accelerators. a, D-H_2SO_4; b, D-NaOH; c, D-HCl; d, D-NH_4BF_4; e, D-NH_4OH.

Aoki *et al.* (2). The lattice parameters in these cases are a little larger than those in the case of α-Co (a = 2.502Å and c = 4.061Å), and it might be attributed to the addition of phosphorus in the α-cobalt lattice. It is very interesting that the c-axis of Co films in the cases of D-NaOH and D-HCl orients preferentially normal to the film because of the presence of (100) plane with no appearance of (002) plane, and that the c axis in the case of D-H_2SO_4 orients preferentially parallel to the film because of the presence of a strong diffraction ring of the (002) plane. Therefore, the orientation of the c axis of α-cobalt of electrolessly plated thin-film Co-P can be controlled by the pretreatment combination. In the cases of ammonia-containing accelerators (which are omitted in Table VI), the polycrystallite α-cobalt thin film was observed because of strong diffraction rings of both (100) and (002) planes being observed and it might be attributed to the uneven surface conditions after acceleration. The Co-P films plated on copper sheet with various pretreatments showed only the case of the c axis being parallel to the substrate plane, which was confirmed by the results of reflection electron diffraction profiles. Therefore, it can also be concluded that the pretreatment and substrate affect not only the grain size contribution but also the orientation of the c-axis of the α-cobalt hexagonal lattice of electrolessly plated Co-P films.

Acknowledgments

The authors would like to thank Professor Dr. Tadashi Yoshida, Waseda University, Dr. Takashi Furuoya and Mr. Yoji Suganuma, Basic Technology Laboratories, Nippon Electric Company, for their encouragement of this research, and also Mr. Fumio Sugawara for his experimental assistance. They are greatly indebted to the Kurata Research Grant from the Kurata Foundation and the Research Fund of Waseda University for financial support.

Adsorption and Alloy Formation of Zinc Layers on Silver

G. Adzic,*[,1] J. McBreen,* and M. G. Chu*

Brookhaven National Laboratory, Department of Energy and Environment, Upton, New York 11973

ABSTRACT

The deposition of zinc on silver from alkaline zincate solutions has been investigated using cyclic voltammetry, potential pulse methods, x-ray diffraction, and scanning electron microscopy. Approximately one monolayer of zinc is formed in the underpotential deposition region prior to bulk deposition. The underpotential shift (ΔE_p) is 0.15V. Zinc forms at least two alloys with the substrate. One was identified as $AgZn_3$ and the other as the β' phase of AgZn. The bulk zinc deposit consists of hexagonal platelets that are oriented both parallel and perpendicular to the basal plane.

The deposition of zinc on silver is of technological importance because of the use of silver current collectors in zinc-silver oxide and zinc-nickel oxide batteries (1). When zinc electrode formulations contain either zinc sheet or zinc powder in contact with the silver, the current collector turns to a gray zinc-like color on the addition of KOH electrolyte (2). This was investigated by Dirkse and Vrieland (3) and they found that the phenomenon did not depend on amalgamation of the electrode. Thermodynamically, the only satisfactory explanation is that a surface alloy of zinc is formed.

Straumanis and Fang (4) found that when silver was electrochemically displaced by zinc that the zinc deposited as a very thin layer on the surface of the silver grains. Raub and Wullhorst (5) studied deposition of silver-zinc alloys from cyanide solutions. All phases present in the phase diagram were found except the ζ phase.

The underpotential deposition of Tl (6), Pb (7), Bi (8), and Cd (9) on silver has been investigated in some detail. Kolb, in his review (10), refers to unpublished results for underpotential deposition of Zn on silver from sulfate solutions.

The present study was part of an investigation of substrate effects on zinc deposition on several metals from zincate solutions. The techniques used were cyclic voltammetry potential pulse methods, scanning electromicroscopy, and x-ray defraction.

Experimental

Cell.—The electrochemical measurements were made in a simple PTFE beaker cell with a machined PTFE cover that had a Viton O-ring seal and PTFE pipe fittings for gas feed, electrical connections, and a reference electrode Luggin capillary. An Hg/HgO reference electrode and a nickel screen counterelectrode were used.

Working electrodes.—Two types of working electrodes were used. One was a simple "flag" type sheet electrode (1 × 1 cm), the other a machined disk electrode (0.686 cm^2). The silver electrodes were polycrystalline and were at least 99.998% pure.

The silver sheet electrodes were degreased in acetone and washed with triply distilled water prior to incorporation in the cell. The silver disk electrodes were mounted in a PTFE holder with a Kel-F collar compression seal. The disks were polished successively with 600 grit SiC paper, Microcut Sheets (Buehler Limited), 5 and 0.5μ alumina. The electrodes were finally washed with triply distilled water prior to incorporation into the cell.

Amalgamated "flag" electrodes were also used. These were prepared by deposition of mercury from a 2% solution of HgO in a 1:1 mixture of distilled water and glacial acetic acid, at a current density of 9 mA/cm^2, using platinum counterelectrodes. Various deposition times from 5 to 60 min were used.

Electrolytes.—The electrolytes were prepared from triply distilled water, reagent grade KOH and ZnO (New Jersey Zinc USP-19).

Electrochemical studies.—After cell assembly, the solutions were deaerated by bubbling nitrogen through the solution for 15 min prior to the start of measurements. The nitrogen was purified by passage through molecular sieves.

All the cyclic voltammetry studies were made in voltage envelopes that were more negative to +0.020V.[2] At no time did the voltage scan go into a potential region where the substrate could oxidize.

The potential step experiments consisted of zinc deposition at various potentials between −1.11 and −1.46V followed by an anodic pulse at −1.25V and a second anodic step to −1.0V. One of the problems with using the cathodic potential pulse methods in zinc deposition is interference by coevolution of hydrogen

Key words: amalgam, battery, electrodeposition.

[2] All potentials are with respect to an Hg/HgO reference electrode in the same electrolyte.

to an unknown extent. Despic has proposed the use of an anodic pulse following the cathodic pulse as a solution to the problem (11). In this work, a two step anodic pulse was used in an attempt to separate the contributions of underpotential deposition, bulk deposition, and alloy formation.

Scanning electron microscopy and x-ray diffraction.—Sample preparation for the scanning electron microscopy and the x-ray diffraction studies was as follows. The zinc was deposited on the "flag" sheet electrodes at a fixed potential until a required number of coulombs were deposited. The electrode was immediately removed from the electrolyte, washed repeatedly in distilled water, rinsed in acetone, air dried, and stored in a desiccator until mounted in either the scanning electron microscope or the x-ray goniometer. The diffraction pattern was determined using Cu-Kα radiation. The samples prepared for the morphology and deposit orientation studies were deposited from 8.4M KOH + 0.74 ZnO. Three samples on each substrate were prepared. The deposition conditions were 0.5 C/cm^2 at −1.40V, 2 C/cm^2 at −1.42V, and 5 C/cm^2 at −1.44V.

Results

Cyclic voltammetry.—Figure 1 is a cyclic voltammogram on a silver sheet electrode in the potential envelope +0.020 to −1.345V in 1M KOH + 0.08M ZnO. A cyclic voltammogram in 1M KOH is shown for comparison. Underpotential deposition of zinc starts at about −1.08V. In this case there were well-defined current peaks in the underpotential deposition region. With some electrode samples, particularly by the disk electrodes, there were no sharp peaks. Samples that yielded two peaks in the underpotential deposition region could be prepared by the peroxide-cyanide etch method, described by Bewick and Thomas (6). Figure 2 is a cyclic voltammogram for silver sheet in 1M KOH + 0.08M ZnO in the voltage envelope +0.020 to −1.4V. When the electrode is continuously swept, the pattern for underpotential deposition and zinc deposition and dissolution can be clearly discerned. However, if the electrode is held at a potential of −1.4V for 4 sec two other dissolution peaks, one at −1.05V and the other at −0.2V, become apparent. When the cyclic voltammetry is carried out in the voltage envelope +0.020 to −1.5V the two extra dissolution peaks are also apparent.

Several attempts were made to further elucidate the nature of these dissolution peaks by cyclic voltammetry. Figure 3 shows what happens when the sweep is arrested for 5 sec at −1.4V and the potential swept

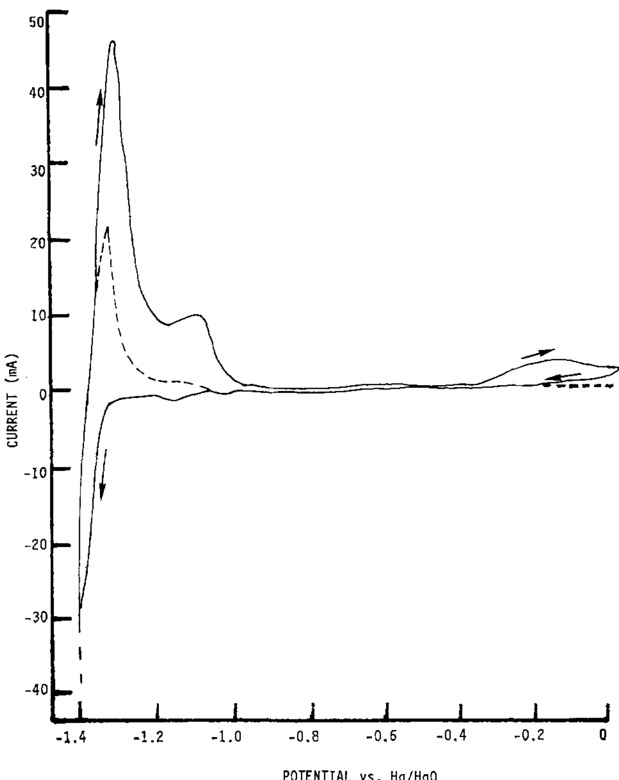

Fig. 2. Cyclic voltammogram for Ag sheet electrode (2 cm^2) in 1M KOH + 0.08M ZnO; broken line is a continuous sweep; solid line is for electrode held at −1.4V for 4 sec, sweep rate 100 mV/sec.

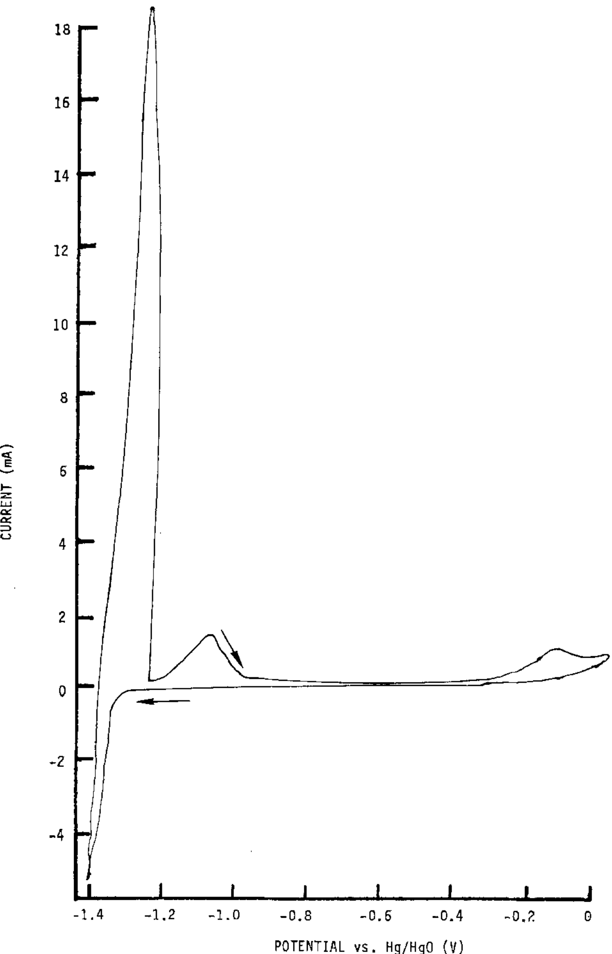

Fig. 3. Cyclic voltammogram on Ag disk (0.686 cm^2) in 1M KOH + 0.08M ZnO. Potential was held at −1.4V for 5 sec and arrested on the anodic sweep at −1.24V for 5 min, sweep rate 100 mV/sec.

anodically to −1.24V where it is again arrested until the current reached zero (5 min). Upon resumption of the anodic sweep, the two dissolution peaks are clearly discernable. When the anodic arrest is increased to −1.17V (Fig. 4), the first peak is decreased whereas the peak at −0.2V remains unaffected. Figure 5 is a plot of the total anodic charge under the peak at −0.2V *vs.* the reciprocal of the square root of the sweep rate when the voltage envelope is between +0.020 and −1.5V. The dependence is linear. Figure 6 shows cyclic voltammograms in the voltage envelopes

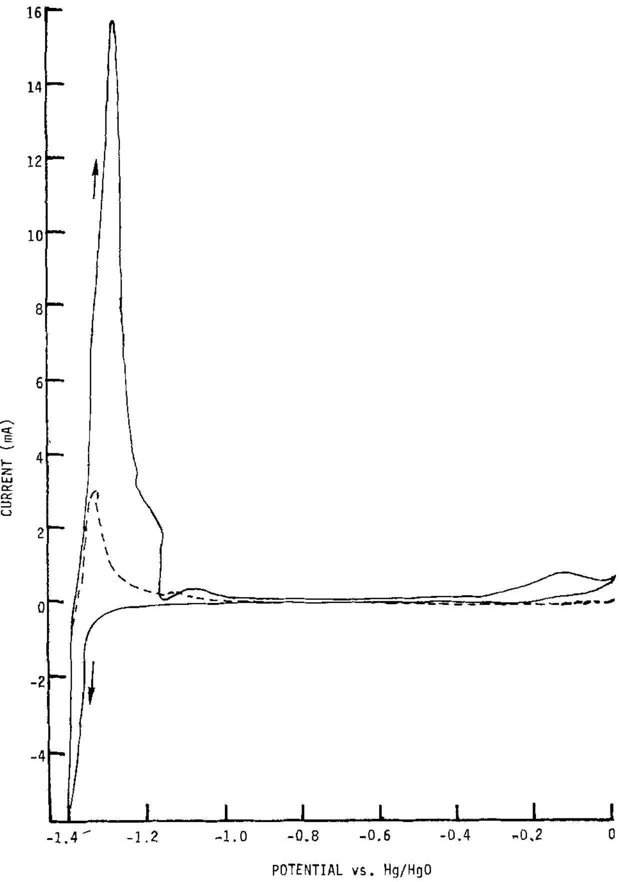

Fig. 4. Cyclic voltammogram on Ag disk (0.686 cm²) in 1M KOH + 0.08M ZnO; potential was held at −1.4V for 5 sec and arrested at −1.17V on the anodic sweep for 5 min, sweep rate 100 mV/sec; broken line is a continuous sweep.

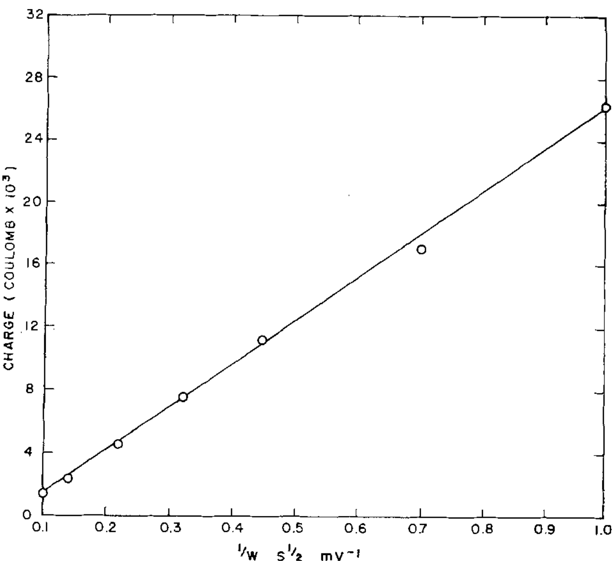

Fig. 5. Anodic charge under peak at −0.2V vs. reciprocal square root of the sweep rate; for Ag disk (0.686 cm²) in 1M KOH + 0.08M ZnO. Cyclic voltammetry voltage envelope +0.020 to −1.5V.

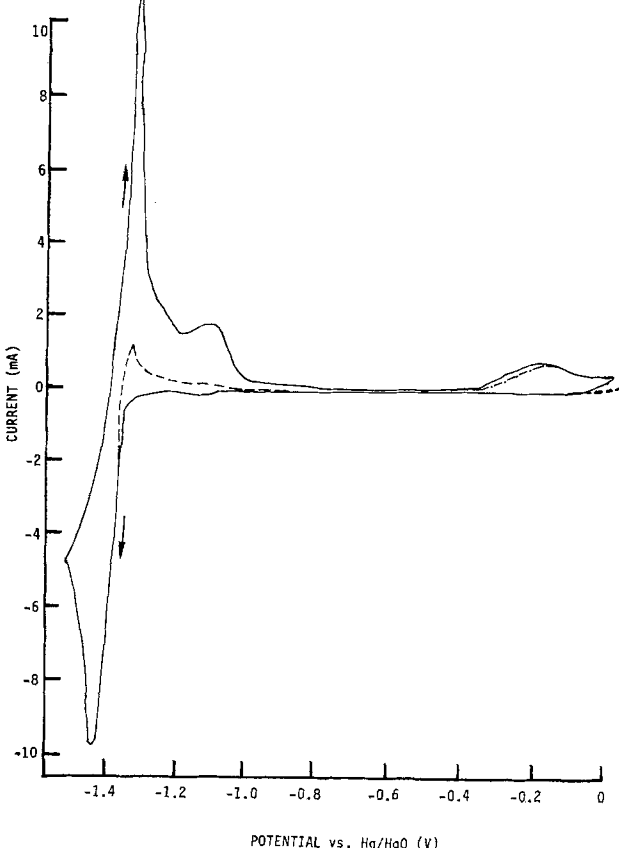

Fig. 6. Cyclic voltammogram on Ag disk electrode (0.686 cm²) in 1M KOH + 0.08M ZnO; solid line for a voltage envelope between 0.02 and −1.5V; broken line for a voltage envelope between 0.02 and −1.35V; lines with dashes and dots show anodic peak after 5 min arrest at −0.65V, sweep rate 50 mV/sec.

+0.02 and −1.35 and +0.02 and −1.5V. When the cyclic voltammogram between +0.020 and −1.5V is arrested in the anodic sweep at −0.65V for 5 min the anodic peak at −0.2V is only minimally affected. Figure 7 shows a cyclic voltammogram in the voltage envelope +0.020 to −1.5V followed by a number of cyclic voltammograms in the voltage envelope −0.9 to −1.5V and finally by another cyclic voltammogram between +0.20 and −1.5V. When the electrode is swept in the voltage envelope −0.9 to −1.5V the cathodic peak at −1.42V decreases, the anodic peak at −1.3V increases, and the anodic peak at −1.14V decreases. On extending the sweep to +0.20V after three sweeps between −0.9 and −1.5V there is an increase in the anodic peak at −0.2V.

Cyclic voltammetry studies were also carried out in 6M KOH 0.8M ZnO and in 7.85M KOH + 0.74M ZnO. No features were found in the other electrolytes that did not exist in 1M KOH. Thus, only the results in 1M KOH are presented in detail here.

The investigations on amalgamated silver were preliminary in nature. Typical results are shown in Fig. 8. Amalgamation completely suppresses underpotential deposition and reduces the cathodic current at −1.4V.

Potentiostatic pulse studies.—Figure 9 shows the current-time behavior for zinc deposition at various potentials for 100 sec. The anodic stripping profile at −1.25V is also shown. The anodic peak current increases with deposit thickness. Figure 10 shows the anodic stripping charge for two potentiostatic pulse profiles in 8.40M KOH + 0.74M ZnO. The results indicate that about one monolayer of zinc is deposited before the bulk zinc deposition. When the bulk deposit is stripped in two stages (−1.25 and −1.0V) most of the dissolution occurs at −1.25V. The remainder of the deposit (up to 30 monolayers) is stripped at −1.0V.

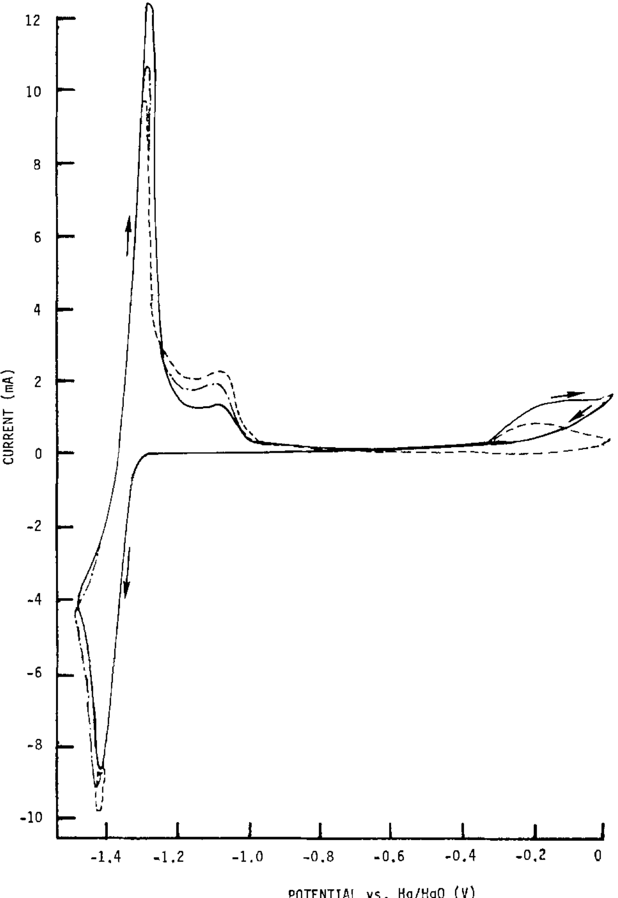

Fig. 7. Cyclic voltammogram on Ag disk (0.686 cm^2) in 1M KOH + 0.08M ZnO; broken line is first sweep between 0.02 and −1.5V. This was followed by three sweeps between −0.9 and −1.5V; solid line is final sweep between −1.5 and 0.02V, sweep rate 50 mV/sec.

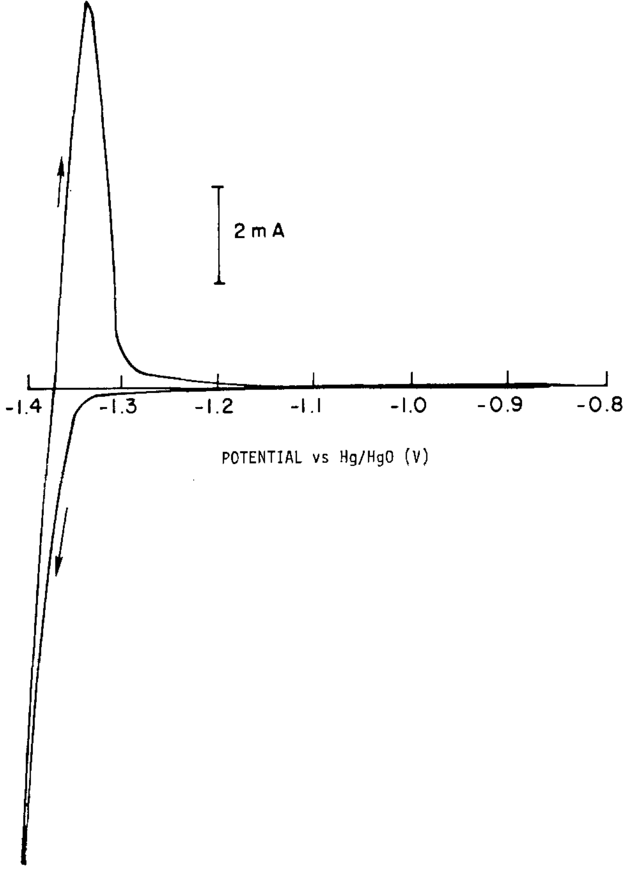

Fig. 8. Cyclic voltammogram on amalgamated Ag sheet (2 cm^2) in 1M KOH + 0.08M ZnO, sweep rate 100 mV/sec.

Figure 11 shows the results when all of the deposit is stripped at −1.0V. The anodic current-time profile is indicative of a fast dissolution process followed by a slow dissolution process.

X-ray diffraction studies.—Table I summarizes some of the x-ray diffraction results for the silver-zinc system. The cycling regime on the three samples were as follows:

Sample I: Sample I was swept in the cathodic direction in 1M KOH + 0.08M ZnO at a sweep rate of 50 mV/sec to a potential of −1.45V and held there for 1 hr prior to removal and washing.

Sample II: Sample II was treated in a similar fashion, held at a potential of −1.44V, and then swept to a potential of −1.1V at 1 mV/sec before removal from the cell.

The treatment of sample III was similar to sample II except that the anodic sweep was to a potential of −0.7V. The d values for Zn, Ag, $AgZn_3$, and the ζ phases of AgZn are shown in Table I for comparison. There was no evidence of a ZnO pattern in any of the samples.

The x-ray diffraction results may be summarized as follows. In sample I there was a clear pattern for Zn, Ag, and $AgZn_3$. In sample II there was no pattern for Zn. However, there was a strong $AgZn_3$ pattern. In sample III there was no evidence of zinc and the $AgZn_3$ pattern was weaker than in sample II. There was slight evidence of an AgZn pattern in samples I and III. However, its presence could not be unequivocally determined in these samples. However, in the samples prepared for morphology and deposit orientation studies, strong diffraction peaks at $2\theta = 28.4°$, 50.05°, and 58.65° occurred. These could be attributed to either the β' or ζ form of AgZn.

Deposit morphology and orientation.—Figure 12 is a scanning electron micrograph of a zinc deposit on silver. The deposit consisted of hexagonal platelets. The x-ray diffraction results indicated that the deposit consisted of a combination of layers parallel to the basal plane and perpendicular to the basal plane. There were no significant morphology changes in the thickness range of 1-5 C/cm^2.

Discussion

The cyclic voltammetry, potential pulse, and x-ray diffraction studies indicate that the deposition of zinc on silver is a rather complex process consisting of

underpotential deposition, alloy formation, and growth of bulk zinc.

Underpotential deposition.—Approximately a monolayer of underpotential deposited zinc is formed prior to bulk deposition and alloy formation. The underpotential shift (ΔE_p) is ~0.15V. This is in good agreement with the results of Kolb (10) and correlates well with the differences in work function between silver and zinc. On this basis, the suppression of underpotential deposition by amalgamation is to be expected (Fig. 8).

The degree of structure in the current peaks in the underpotential deposition region varied from sample to sample and depended on electrode pretreatment. This is presumably due to differences in the adsorption behavior on various crystal faces, as was observed by Bewick and Thomas for the case of Tl on silver (6, 12). They found good qualitative agreement between the underpotential deposition pattern for Tl on chemically polished polycrystalline silver and the chemical polished 110 face of single crystal silver. In the present work, well-defined peaks were only obtained on silver sheet electrodes. These were fabricated from rolled silver sheet that had a preferred 110 orientation. The ill-defined peaks, particularly on the disk electrodes are presumably due to deviations from this orientation.

Bulk deposition and alloy formation.—Quantitative treatment of the cyclic voltammograms and cathodic current transients is essentially impossible because of the unknown contribution of the hydrogen evolution reaction. However, the anodic dissolution behavior in the cyclic voltammograms and the anodic current transients in the potential step experiments yield valuable information which complements the results of the x-ray diffraction analysis. The results of the cyclic voltammetry studies (Fig. 2-7) indicate the formation of at least two alloys by diffusion of zinc into metal. On holding the electrode at −1.4V for 4 sec (Fig. 2) two additional current dissolution peaks appear at −1.05 and −0.2V. Potential arrests on the anodic

sweep do not affect these dissolution peaks (Fig. 3-4) so therefore they are not due to dissolution of bulk zinc.

In the x-ray diffraction analysis (Table I), at least two silver-zinc alloys could be identified. One was $AgZn_3$ with a hexagonal ϵ-brass structure. The other was an alloy with a lower zinc composition. The x-ray results indicate that this may be β'-phase of AgZn. The work of King and Massalski (13) indicated that the ordered body-centered cubic β'-phase was the equilibrium structure at room temperature, for alloys with close to 50% Zn. This alloy is very stable and dissolution does not occur until −0.2V. The sweep dependence of the amount of alloy formed (Fig. 5) indicates that it is formed by diffusion into the bulk metal. For simple diffusion with a zinc concentration of C_o at the surface the dependence of the dissolution charge (Q) on reciprocal square root of the sweep rate $(1/\omega)^{1/2}$ should be

$$dQ/d(1/\omega)^{1/2} = 4\mathbf{F}AC_o(D/\pi)^{1/2}$$

where $\mathbf{F}$ is the Faraday constant, A the electrode area, and D the diffusion coefficient of zinc in silver. If one assumes a value of $C_o = 10^{-1}$ M/cm^3 then $D = 3.35 \times 10^{-12}$ cm^2 sec^{-1}. This value is high, but it is reasonable when compared with an estimated value of $D < 10^{-14}$ cm^2 sec^{-1} for cadmium in silver at room temperature (9). The β'-AgZn phase is very stable as indicated by its high dissolution potential (−0.2V) and by the fact that a 5 min arrest of the anodic sweep at −0.65V only minimally affects the dissolution peak (Fig. 6).

The results of the cyclic voltammograms in Fig. 7 indicate that $AgZn_3$ is initially formed and is transformed into β'-AgZn. On cycling in the voltage envelope −0.9 to −1.5V, the dissolution peak for $AgZn_3$ at −1.05V decreases. However, on extending the sweep to −0.02V there is a considerable increase in the dissolution peak at −0.2V, indicating a transformation of the $AgZn_3$ to AgZn.

The results of the potential pulse measurements essentially confirm the results of the cyclic voltammetry. Because of the small underpotential shift it is difficult to quantitatively separate the charge associated with the underpotential deposited layer. However, it approximates to a monolayer. When dissolution is carried out in two steps, at −1.25 and −1.0V, the anodic dissolution of $AgZn_3$ can be separated from bulk zinc dissolution. The results in Fig. 10 indicate the formation of up to 50 monolayers of $AgZn_3$. The amount of alloy formation increases with potential. This has been observed for other systems and has been attributed to an increase in surface vacancies due to a decrease in surface energy at more negative potentials (14). If all the dissolution is carried out at −1.0V the current transient for the dissolution of $AgZn_3$ can clearly be seen (Fig. 11).

The cyclic voltammetry results (Fig. 2-7) and the potential pulse measurements indicate that the apparent nucleation overvoltage for zinc deposition on silver is low. Similar results were found by Despic (11) for zinc deposition on copper and gold from sulfate solutions and these were correlated with the presence of underpotential deposited layers. In an investigation of lead deposition on silver in perchlorate solutions, Lorenz and his co-workers (15) found that the rate of three dimensional nucleation decreased with increase in the coverage by the underpotential deposited layer. Unfortunately, the present results are of little help in resolving this controversy since the results can either be due to the absence of a nucleation overvoltage or to alloy formation in the potential region between the reversible deposition potential and the underpotential deposition region.

Deposit morphology and orientation.—The hexagonal growth habit of the deposit is typical for growth parallel to the basal plane (16). This is in agreement with the x-ray results. It has been found that the surface area of zinc deposits, oriented parallel to the basal plane, increases with deposit thickness (17). The anodic current transients in Fig. 9 indicate an increase in dissolution activity with deposit thickness. This is probably due to an increase in the amount of steps and edges that act as active dissolution sites.

Summary

1. Approximately a monolayer of zinc is formed on polycrystalline silver prior to bulk deposition. The underpotential shift (ΔE_p) of ∼0.15V is in good agreement with the differences in work function. Amalgamation suppresses underpotential deposition.

2. At least two alloys of silver and zinc are formed. One was identified as $AgZn_3$ the other as β'-phase of AgZn.

3. Bulk deposition proceeds without any detectable nucleation overvoltage. This may be due to alloy formation. The deposit consists of hexagonal platelets that are oriented either parallel or perpendicular to the basal plane.

Measurement of the Viscosity and Specific Conductivity of an Aluminum Plating Bath— The Non-Stokesian Mechanism of Electrolytic Conductivity

E. Peled,* M. Brand, and E. Gileadi

Department of Chemistry, Tel-Aviv University, Ramat Aviv, Israel

ABSTRACT

The viscosity, conductivity, and density of solutions of Al_2Br_6 and KBr (or LiBr) in several aromatic hydrocarbons were determined, as the function of the composition of the bath and of temperature. The alkali bromide has a major role in increasing both the viscosity and the conductivity, while its effect on the density of the solution is relatively minor. The results observed lend further support to the non-Stokesian relay-type mechanism of conductivity proposed earlier for this system. The data presented can be useful in the design and routine operation of aluminum plating baths.

In a previous study, the mechanism of high conductivity in a medium of low dielectric constant consisting of Al_2Br_6 and MBr in toluene was discussed (1). The specific conductivity and the viscosity of solutions were measured over a wide range of concentrations of Al_2Br_6 and MBr, where M stands for Li, K, and in a few experiments also Rb. At low concentrations (below 10^{-2}M) the molar conductivity was found to decrease with increasing concentration in a manner consistent with the theory of Fuoss and Kraus (2-4) for strong electrolytes in a medium of low dielectric constant. At higher concentrations, however, the molar conductivity was found to increase rapidly with increasing concentration reaching values as high as 5-6 $cm^2\ \Omega^{-1} mol^{-1}$.

Measurement of the transference numbers in the concentrated solutions led to the conclusion (1) that the predominant ionic species were complex ions formed in the following reaction

$$3MBr + 3Al_2Br_6 \rightarrow [K_2(Al_2Br_7)]^+ + [K(Al_2Br_7)_2]^- \quad [1]$$

Accordingly, the equivalent conductivity is three times the molar conductivity, *i.e.*, 15-18 $cm^2\ \Omega^{-1}$ $equiv^{-1}$. This should be compared to a value of *ca.* 90 $cm^2\ \Omega^{-1}$ $equiv^{-1}$ for a 1M aqueous solution of KBr, bearing in mind that the viscosity of the concentrated nonaqueous solution is more than twice that of water at the same temperature.

The high value of the equivalent conductivity along with several other experimental observations (1) led to the conclusion that electrolytic conductivity cannot occur by way of the regular hydrodynamic movement of ions through the viscous medium. It was assumed that aggregates were formed in the solution, consisting of the various ionic species and probably also the neutral molecules of Al_2Br_6. An ion could reach an aggregate on one side and another ion would emerge at the other end almost simultaneously, in a relay-type mechanism. The virtual movement of the ion through the aggregate leads in this way to an enhanced apparent mobility and explains the high conductivity observed.

The formation of aggregates is expected to lead to an increase of the viscosity of the solution. It was indeed observed that an increase of conductivity was associated with an increase of viscosity. This is in sharp contrast to the behavior of simple ions in aqueous solutions, where the conductivity is inversely proportional to the viscosity.

In the present study, the measurements of viscosity and conductivity were extended over a temperature range of 0°-80°C in an attempt to gain further experimental information which could verify the relay-type mechanism of conductivity discussed above (1).

The system of Al_2Br_6 and MBr dissolved in an aromatic hydrocarbon can serve as a plating bath for the electrodeposition of aluminum (5-10). Therefore, the results derived below are of practical as well as theoretical value.

Experimental

General procedure.—Solutions were prepared in a glove box (VAC, Model DL001-D-G) filled with highly purified argon, which was continuously passed through a catalytic purifier (VAC Model HE-493 DRI-TRAIN).

* Electrochemical Society Active Member.

Key words: mechanism of conductivity, non-Stokesian conductivity, electroplating of aluminum, nonaqueous electrochemistry, aluminum bromide.

Details of purification of materials and preparation of solutions were given elsewhere (11-13). The viscosity and conductivity were measured in the cells shown in Fig. 1a and b, respectively. The cells were filled with solutions of a given composition inside the glove box, closed to the atmosphere with Rotaflo valves, and removed from the glove box to a thermostat, where the temperature was controlled to ± 0.3°C. The concentrations of aluminum and potassium or lithium were determined at the end of a series of experiments by atomic absorption spectroscopy, as described earlier (5, 6). In a given series of experiments, the ratio of concentrations of Al_2Br_6 to MBr was maintained strictly constant, since all solutions were prepared by diluting the most concentrated solution with the solvent.

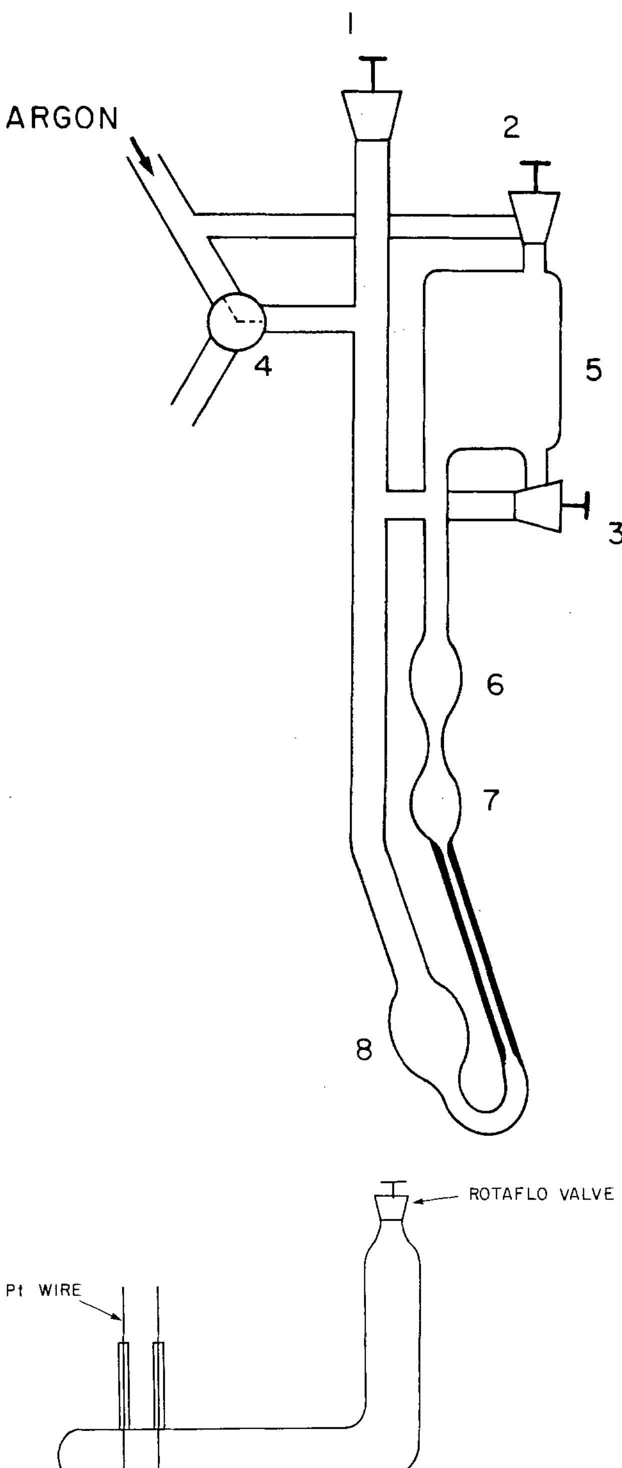

Fig. 1. a (top) Modified Ostwald viscosimeter for measurement of the viscosity under a controlled atmosphere. b (bottom) Cell for conductivity measurements.

Measurement of viscosity.—The viscosity was measured with a modified Ostwald viscosimeter shown in Fig. 1a. The viscosimeter was loaded with a fixed volume (13 cm^3) of solution inside the glove box, through stopcock 1. All stopcocks were then closed and the viscosimeter was transferred to the thermostat and connected to the line of pure argon. Stopcock 4 was turned to allow the argon into the viscosimeter. This pushed the solution from bulb 8 through the capillary into bulb 7 and part of bulb 6. Stopcock 4 was then turned to let the argon out through the other branch. Stopcock 2 was opened next for a few seconds to release the pressure on the other side of the viscosimeter. (By releasing pressure through this stopcock, oxygen and humidity cannot come in contact with the solution.) Stopcock 3 is opened next for equalization of the pressure on the two branches of the viscosimeter and left open throughout the rest of the experiment. The time taken for the liquid to flow through the capillary was measured in the usual manner (1), after the pressures in the two tubes have been equalized. Bulb 5 has a large volume, relative to bulbs 6 and 7, to minimize pressure changes when the liquid is transferred from one side to the other in the viscosimeter.

The viscosity was measured several times at each temperature and some of the measurements were repeated at ascending and descending temperatures. The color of the solution did not change during measurement, indicating that the amount of air entering the viscosimeter during the pressure-equalizing step was negligible.

The viscosimeter was calibrated with distilled water over the temperature range of measurement (10°-80°C).

Conductivity.—The cell used for conductivity measurements is shown in Fig. 1b. Two platinized platinum wires (ϕ = 0.5 mm; l = 13 mm) were sealed into the glass at a distance of 13 mm. The cell constant was determined with 0.1M KCl as 1.30. Conductivity was measured with a four digit autoranging conductometer (Opal) at a frequency of 1000 Hz. The accuracy varied from 0.1 to 1.0% in different ranges of measurement.

Density.—The density was determined with a regular picnometer, which was fitted with a graduated capillary closed at the top. It was filled with distilled water to a certain level near the bottom of the graduated capillary and weighed accurately. Subsequently it was placed in the thermostat at various temperatures and the height of the water in the capillary was noted. The volume of the picnometer and capillary were determined from the known dependence of the density of water on temperature.

The picnometer was next filled with the test solution inside the glove box, sealed with a tapered glass joint which had the graduated capillary, and transferred to the thermostat. The volume was determined at each temperature from the height of the liquid in the graduated capillary, which has been calibrated with water. Weighing the picnometer before and after filling then yielded the density as a function of temperature.

Results and Discussion

Density.—The density of solutions of Al_2Br_6 and MBr (M = K or Li) in toluene and mesitylene was measured over a range of temperatures from 10° to 80°C as a function of concentration. The data in Fig. 2 are for two temperatures and two solvents, employing a fixed ratio of concentrations $R = c(Al_2Br_6)/c(KBr)$ of 1.1 in the case of toluene and 1.2 in the case of mesitylene. While the variation of density with concentration is very significant (*ca.* 60% increase in 1M Al_2Br_6, 0.9M KBr compared to the pure solvent) it is relatively independent of the solvent (only 2% difference) and the

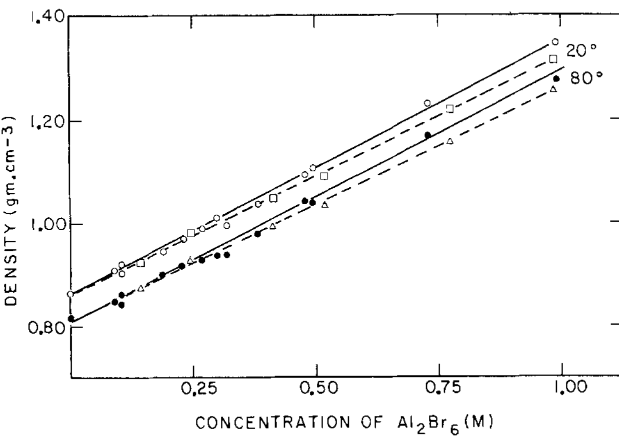

Fig. 2. Density vs. concentration of Al_2Br_6. Solid line: toluene ($R = 1.1$); broken line: mesitylene ($R = 1.2$).

decrease of density with increasing temperature amounts to about 4.2% between 20° and 80°C.

Replacing KBr by LiBr results in somewhat lower densities, and removal of MBr altogether reduces the density even further, as seen in Fig. 3. However, the density is much more sensitive to the concentration of Al_2Br_6 than to that of KBr. Thus, of the 60% increase from the pure solvent to the most concentrated solution tested, only *ca.* 10% can be attributed to the presence of KBr while *ca.* 50% is due to Al_2Br_6, as evidenced by the lowest line in Fig. 3.[1]

In view of the possible application of this solvent system for the electroplating of aluminum, it may be noted that the marginal dependence of the density on the type of solvent, the temperature, and the concentration of MBr, combined with its rather large dependence on the concentration of Al_2Br_6, may allow a rapid estimation of the concentration of the latter in industrial plating operations for routine quality control purposes.

Viscosity.—The viscosity of the solutions studied was found to be a sensitive function of the concentration, as shown in Fig. 4 for mesitylene as the solvent, at a constant ratio of concentration of the inorganic salts ($R = 1.2$). In 1.0M Al_2Br_6 (and 0.83M KBr) the viscosity at 20°C is 5.7 times that of the pure solvent, while at 80°C the ratio is decreased to 3.3. A comparison of toluene and mesitylene as the solvent is shown in Fig. 5. Unlike the density, the viscosity changes significantly with the solvent and its variation may serve as an indication for changes in the composition of the solvents in industrial plating baths during extended periods of time. Ethyl benzene was also used as a solvent. The resulting viscosity was found to be intermediate between that of toluene and mesitylene but closer to the former.

Replacing KBr by LiBr decreases the viscosity significantly, as seen in Fig. 6. Rather surprisingly, this is

[1] This is the reverse of the effect on conductivity, as will be seen later.

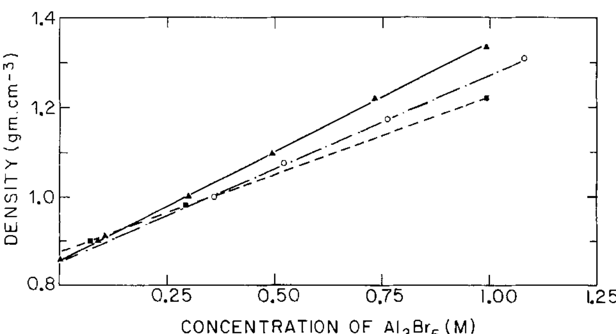

Fig. 3. Density vs. concentration of Al_2Br_6 in toluene at 30°C. ▲▲▲ KBr ($R = 1.1$); ○○○ LiBr ($R = 1.21$); ■■■ no MBr.

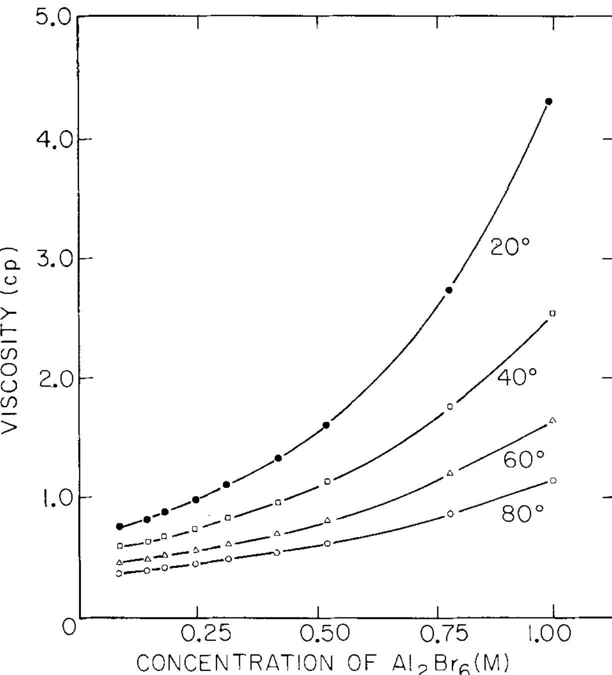

Fig. 4. Viscosity vs. concentration of Al_2Br_6 in mesitylene ($R = 1.2$).

accompanied by a decrease in specific conductivity, as will be shown below.

The viscosity as a function of temperature in solutions of toluene is shown in Fig. 7 at a number of concentrations of Al_2Br_6 and a fixed ratio of concentrations ($R = 1.1$). It is clearly seen in this figure that both the value of the viscosity and its temperature dependence increase significantly with increasing concentration of the solutes. This result is important for the understanding of the structure of these solutions as will be discussed below.

In Fig. 8 the variation of viscosity with temperature is compared for a few systems, all at high concentration of Al_2Br_6. Mesitylene is compared to toluene and KBr is compared to LiBr in the same solvent (toluene). The two lowest curves refer to concentrated solutions of Al_2Br_6 in mesitylene and in toluene with no MBr

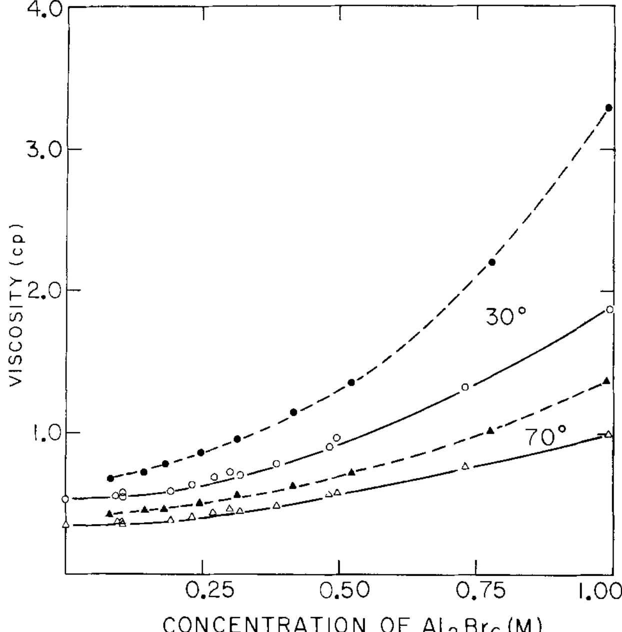

Fig. 5. Viscosity vs. concentration of Al_2Br_6. solid line: toluene ($R = 1.1$); broken line: mesitylene ($R = 1.2$).

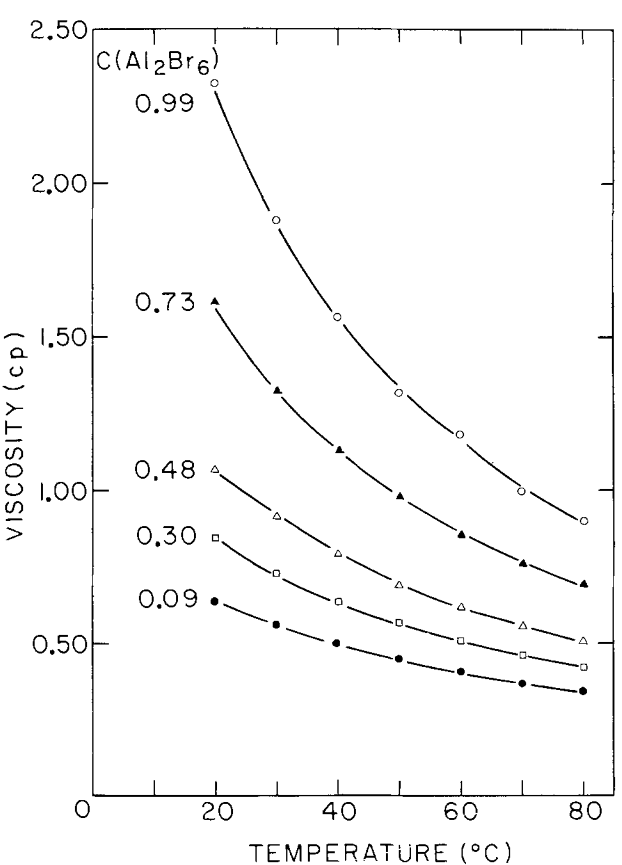

Fig. 7. Viscosity vs. temperature for different solution compositions in toluene ($R = 1.1$).

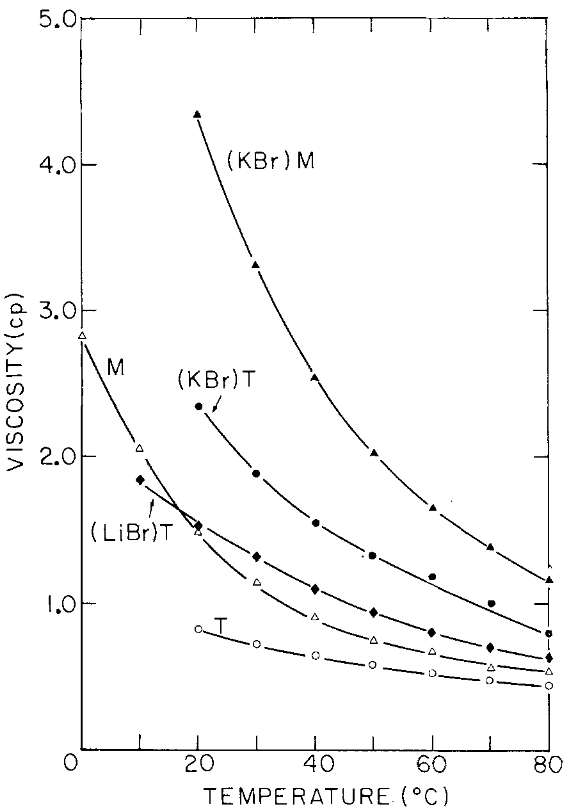

Fig. 8. Viscosity vs. temperature. Comparison of LiBr to KBr and of mesitylene to toluene. ○○○ toluene, 1.0M Al_2Br_6 no MBr; △△△ mesitylene 0.86M Al_2Br_6 no MBr; ◆◆◆ toluene 1.08M Al_2Br_6 0.86M LiBr; ●●● toluene 1.0M Al_2Br_6 0.91M KBr; ▲▲▲ mesitylene 1.0M Al_2Br_6 0.83M KBr.

added. Removal of the monovalent salt results in a very substantial decrease in viscosity (from 4.32 to 1.48 cp in mesitylene at 20°C and by a similar factor in toluene). Thus, unlike the density, the viscosity is very sensitive to the concentration of MBr and is significantly affected by the nature of M.

Apparent energies of activation $E^{\ddagger}$ for the viscosity were calculated from plots of log η *vs.* reciprocal temperature, and are shown in Fig. 9 as a function of concentration. The steady increase of $E^{\ddagger}$ with increasing concentration in both solvents clearly indicates a change in the structure of the solution and the fundamental hydrodynamic processes occurring in it, as will be discussed below.

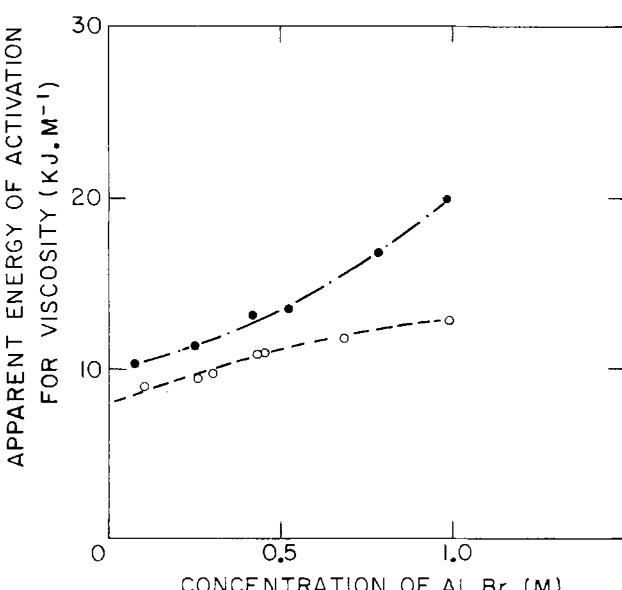

Fig. 9. Apparent energy of activation for viscosity vs. concentration of Al_2Br_6. ●●● mesitylene ($R = 1.2$); ○○○ toluene ($R = 1.1$).

The kinematic viscosity.—The kinematic viscosity ν, defined as the ratio of viscosity to density (η/d) is shown in Fig. 10 for toluenes as the solvent at two temperatures, as a function of the concentration of Al_2Br_6. It is very interesting to note that in the presence of KBr (constant ratio $R = 1.1$) the kinematic viscosity grows rapidly with concentration of Al_2Br_6, while in its absence, ν is essentially independent of the concentration of Al_2Br_6. Similar results were observed when ethyl benzene or mesitylene were used as the solvent. In mesitylene, the kinematic viscosity increased to some extent with concentration of Al_2Br_6 in the absence of KBr at 20°C, but at 80°C it was found to be entirely independent of concentration, as observed for toluene and ethyl benzene.

The viscosity and the kinematic viscosity depend on the structure of the liquid in a complex manner and a detailed molecular theory has not yet been developed. The difficulty of theoretical interpretation is even further compounded when a multicomponent solution is considered. It is well known, however, that the formation of small particles or large molecular aggregates will increase the viscosity significantly. This can be qualitatively seen by considering the kinematic viscosity as a function of concentration for a number of inorganic salts and acids shown in Fig. 11. The value of ν changes relatively little in all cases, except in solutions of sulfuric and phosphoric acids, which are known to be highly associated.

Thus the large change of the kinematic viscosity with concentration of Al_2Br_6 at a constant ratio of concentration of Al_2Br_6 to KBr ($R = 1.1$) shown in Fig. 10, is consistent with a model assuming the formation of aggregates, which has been suggested previously (1). These aggregates form only in the presence of MBr, as seen by the lack of dependence of ν on the concentration of Al_2Br_6 when KBr is not present.

The effect of KBr on the kinematic viscosity is shown in a different way in Fig. 12 where ν/ν (solvent) is plotted as a function of the concentration of KBr at a constant concentration of Al_2Br_6 (1.0M). It is important to note that the relative increase of ν (compared to the value in the pure solvent at the same temperature) decreases as the temperature is increased. This is also consistent with the notion of formation of aggregate, which may be expected to dissociate partially as the temperature is raised, leading to a smaller effect on the kinematic viscosity at higher temperatures.

The specific conductivity.—The specific conductivity σ is shown in Fig. 13a and b for toluene and mesitylene as the solvents, respectively, as a function of temperature. The value of σ is about 4.5-5.0 times higher in toluene than in mesitylene at 20°C and about 3.0-4.0 times higher at 80°C, depending on the concentration of the solutes. The variation of the specific conductivity with concentration of Al_2Br_6 (at a fixed ratio of concentrations $R = 1.1$ for toluene and 1.2 for mesitylene) is shown in Fig. 14 at two temperatures. It should be noted that the scale for mesitylene is 2.5 times that for toluene in the last two figures. When ethyl benzene is used as the solvent, the specific conductivity is found to be about halfway between that of toluene and mesitylene at comparable concentrations of the solvents.

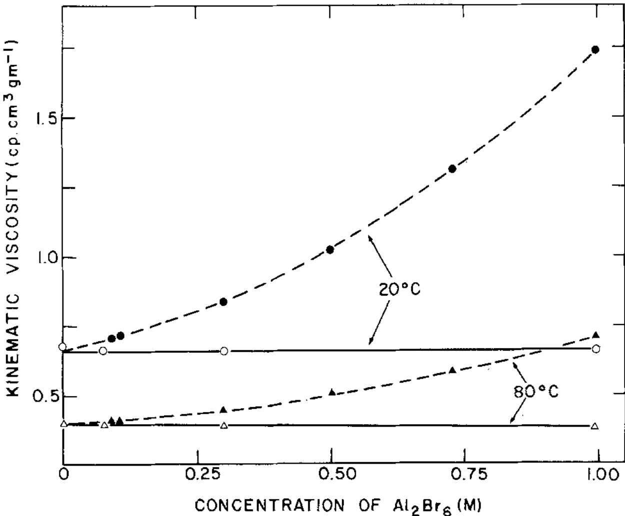

Fig. 10. Kinematic viscosity *vs.* concentration of Al_2Br_6 in toluene. ●●● and ▲▲▲ $R = 1.1$; ○○○ and △△△ no MBr.

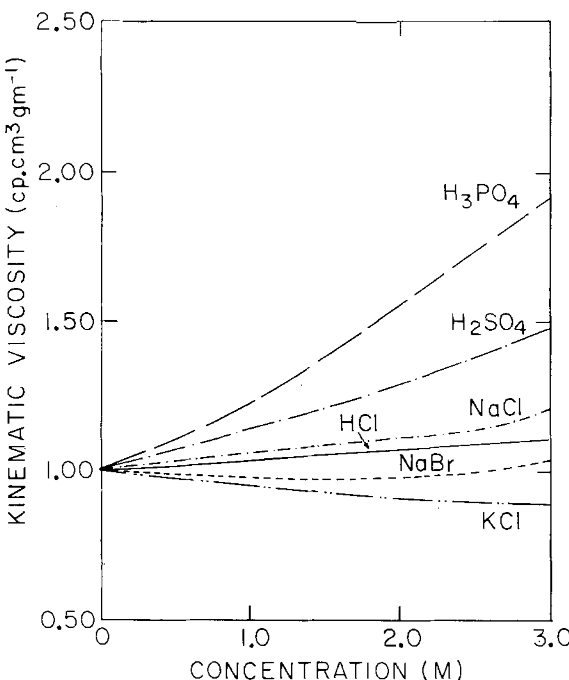

Fig. 11. Kinematic viscosity *vs.* concentration for some aqueous electrolytes.

The molar conductivity.—It was shown earlier (1) that the conductivity of very pure solutions of Al_2Br_6 in toluene is extremely low, increasing by several orders of magnitude upon the addition of KBr or LiBr. It was therefore considered appropriate to calculate the

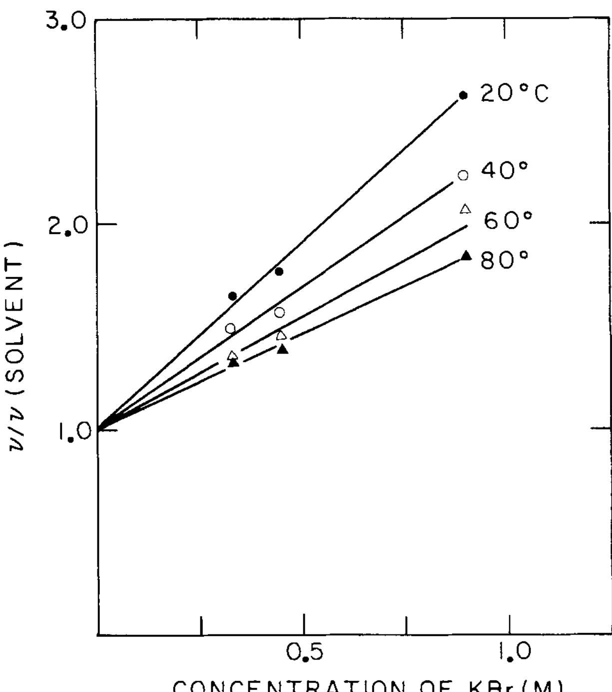

Fig. 12. Relatie value of the kinematic viscosity *vs.* C(KBr) at constant C (Al_2Br_6) = 1.0M in toluene.

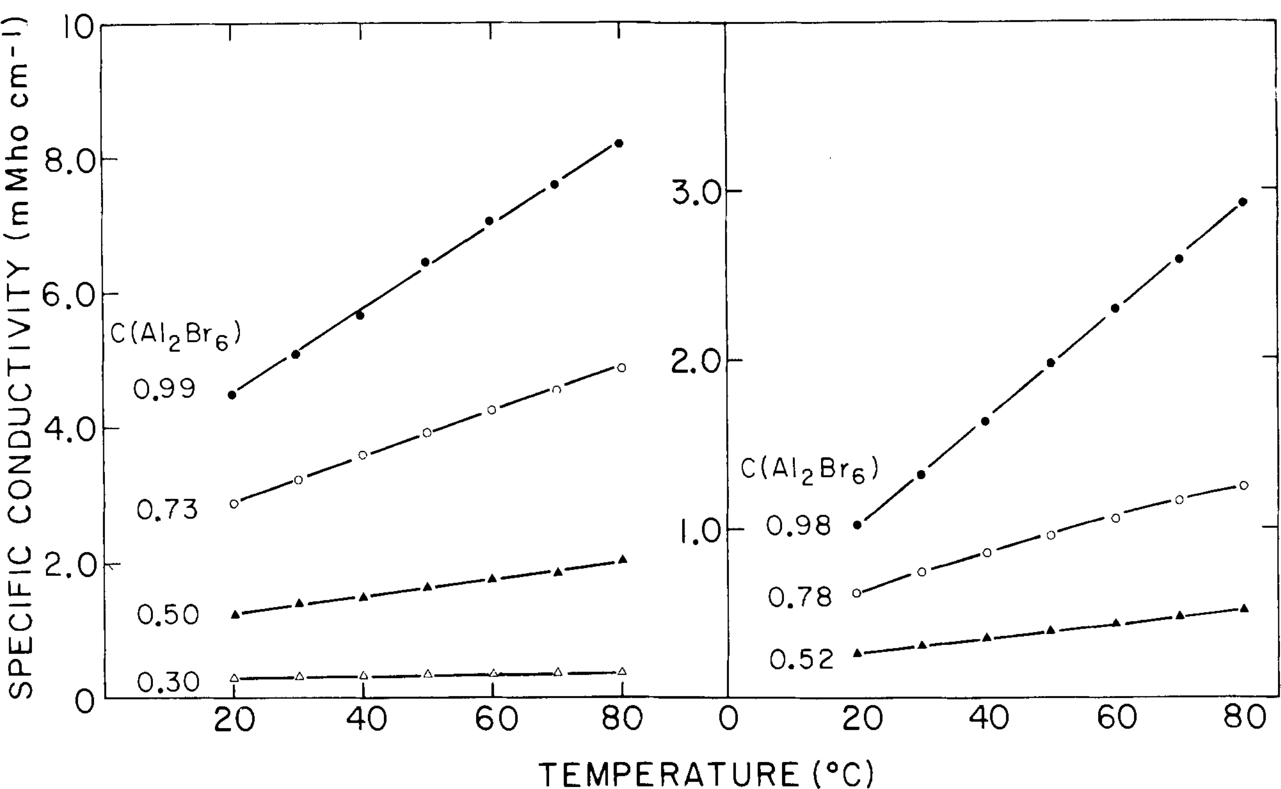

Fig. 13. Specific conductivity vs. temperature: (a) toluene ($R = 1.1$), (b) mesitylene ($R = 1.2$)

molar conductivity Λ on the basis of the concentration of MBr rather than that of Al_2Br_6. In Fig. 15 the molar conductivity calculated in this manner is plotted as a function of concentration of Al_2Br_6 for toluene and mesitylene at two temperatures. As in Fig. 13 and 14, the scale for mesitylene is 2.5 times that for toluene.

The molar conductivity is seen to increase with increasing concentration, contrary to the behavior observed in aqueous solutions of simple salts, pointing to the possibility that new ionic species are formed in solution as the concentration is increased and that the mechanism of conduction may be radically different in concentrated solutions than that in dilute solution or in aqueous media.

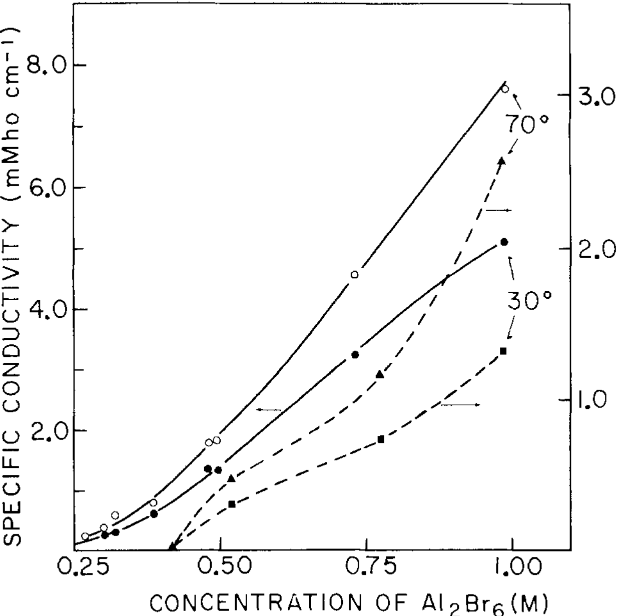

Fig. 14. Specific conductivity vs. concentration at two temperatures. Solid lines: toluene ($R = 1.1$); broken lines: mesitylene ($R = 1.2$).

The Walden product.—For an ion moving through a viscous fluid under the influence of an external electric field, Stokes law yields

$$\lambda\eta = Kr \quad [2]$$

where λ is the molar conductivity of the ion and r is its solvated radius. Thus the Walden product $\lambda\eta$ should be independent of temperature, to the extent that the radius of solvation is constant over the range of temperature considered. Such behavior is observed for most ions in aqueous solutions except for H_3O^+ and OH^- as shown in Fig. 16. It is well known (14) that proton conduction in acid and alkaline media occurs by a non-Stokesian hopping mechanism [the Grotthus mechanism (15)] which is not associated with movement of the whole ion through the viscous medium. As a result, the decrease of viscosity with increasing temperature does not lead to a corresponding increase of molar conductivity. On the other hand, the hopping mechanism is believed to depend on the existence of

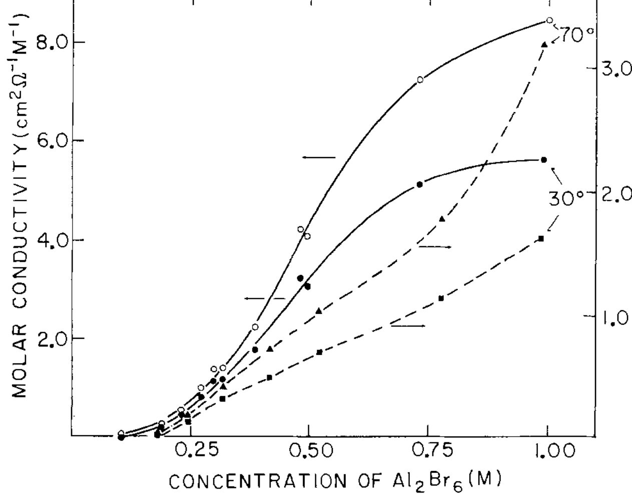

Fig. 15. Molar conductivity vs. concentration at two temperatures. Solid lines: toluene ($R = 1.1$); broken lines: mesitylene ($R = 1.2$).

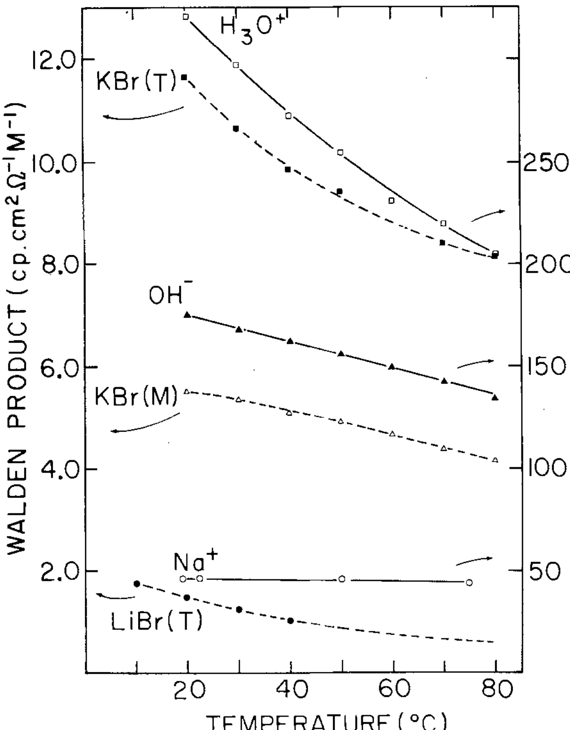

Fig. 16. Walden product in concentrated solutions of Al_2Br_6 and MBr in toluene and mesitylene. Comparison to ions in aqueous solutions.

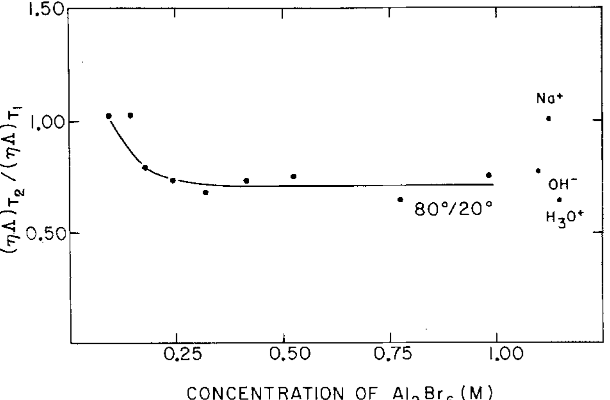

Fig. 17. Ratio of Walden products at two temperatures 80°/20°C as a function of concentration of Al_2Br_6 ad KBr in mesitylene ($R = 1.2$). Values for three ions in aqueous solution are given for comparison.

aggregates of solvent molecules and/or a certain degree of long range order, both of which are gradually eliminated as the temperature is increased. Thus a significant decrease in the Walden product $\lambda\eta$ with increasing temperature is indicative of an unusual mechanism of conduction, probably associated with the hopping of a relatively light charge carrier between larger aggregates or a relay-type transfer of charge along a chain. The latter behavior was indicated recently in measurements of the conductivities of Br^- and I^- ions in liquid bromine and iodine, respectively (16-18). In these systems the specific conductivity was found either to be independent of temperature or to decrease somewhat with increasing temperature. Thus, a substantial decrease of the Walden product with increasing temperature was again associated with a non-Stokesian mechanism of conduction.

In Fig. 16 the dependence of $\lambda\eta$ on temperature for three ions in aqueous solutions is compared to that of concentrated solutions of KBr (or LiBr) and Al_2Br_6 in toluene or mesitylene. While the data had to be plotted on a different scale for the aqueous and the nonaqueous solvents to accommodate them on the same diagram, it can be clearly seen that the present system behaves very much like the H_3O^+ and the OH^- ions and unlike Na^+ and most other ions in aqueous solution. It could be argued that the molar conductivity Λ, which is given for a one-one electrolyte by

$$\Lambda = \alpha(\lambda_+ + \lambda_-) \quad [3]$$

may depend on temperature, due to the variation of the degree of dissociation, α, with temperature. This, however, would lead to an effect opposite to that observed experimentally, since α will most likely increase with increasing temperature.

In Fig. 17 the ratio of the Walden product at two temperatures is plotted as a function of the concentration of Al_2Br_6 in mesitylene. The data points for H_3O^+, OH^-, and Na^+ in aqueous solutions are shown for comparison. Similar results were observed when toluene was used as the solvent or when KBr was replaced by LiBr. Down to about 0.30M Al_2Br_6, a non-Stokesian mechanism of conductivity is seen to be predominant, leading to a value of $(\lambda\eta)_{80°}/(\lambda\eta)_{20°}$ significantly lower than unity, somewhere between the values reported for H_3O^+ and OH^-. As the concentration is further decreased, the above ratio approached unity gradually, indicating a change in the mechanism of conduction to regular hydrodynamic movement of the ions in the viscous medium.

Conclusions

Mechanisms of conductivity.—The results presented above lend further support for the non-Stokesian relay-type mechanism of conductivity proposed earlier (1). The values of the molar conductivity observed are unexpectedly high in view of the low dielectric constant and the high viscosity of the electrolyte. The Walden product is found to decrease with increasing temperature in a manner similar to that found for H_3O^+ and OH^- in aqueous solution and for Br^- and I^- in liquid bromine and iodine, respectively.

In solutions of Al_2Br_6 alone in toluene, the kinematic viscosity is independent of concentration (while the density increases by over 50% from the pure solvent to a 1M solution of Al_2Br_6). In mesitylene a slight increase is observed at 20°C which disappears completely as the temperature is raised to 80°C. When KBr or LiBr are added, the kinematic viscosity increases very significantly. These observations are consistent with the assumption that large molecular aggregates are formed in concentrated solution containing both solutes. It may reasonably be expected that aggregates would tend to dissociate with increasing temperature. It is indeed observed (*cf.* Fig. 12) that the relative increase of kinematic viscosity upon the addition of KBr to a solution having a fixed concentration of Al_2Br_6 is lowered as the temperature is increased.

Determination of the Walden product as a function of temperature in solutions of different composition indicates that a transition from the relay-type mechanism of conductivity proposed here to a more conventional Stokesian mechanism starts below a concentration of *ca.* 0.25M Al_2Br_6 and 0.22 KBr in toluene, although the rapid increase in molar conductivity with concentration has been observed in our previous study (1) at concentrations about an order of magnitude below this value.

Operation of plating bath.—The data presented above can be useful in the design and routine operation of aluminum plating baths.

First it is noted that both the viscosity and the specific conductivity depend on the nature of the cation in MBr. The use of KBr is preferred to LiBr in most cases because of the significantly enhanced specific conductivity, in spite of a moderate increase in viscosity. RbBr was found (1) to behave much like KBr. Other

salts, particularly of the NR_4Br type, may be found to yield even higher values of the specific conductivity.

Increasing the temperature would be desirable, since it increases the specific conductivity and decreases the viscosity. This should, however, be weighed against a possible decrease in the lifetime of the bath, due to higher rates of evaporation of the solvents, faster rates of undesirable side-reactions (particularly if the bath is not kept under rigorously dry conditions), and enhanced corrosion of all the components in the system.

Rapid analysis for quality control is of major importance in any industrial plating bath operation. Careful analysis of the data given above indicates that a combination of measurements of density, viscosity, and conductivity could serve to obtain the desired information. It was noted above that the density was mainly a function of the concentration of Al_2Br_6, and varied very little with solvent. The viscosity, on the other hand, depends very much on the concentration of MBr and on the nature of the solvent. One mode of deterioration of a wet bath is the formation of higher molecular weight solvent molecules. This could probably be detected by a significant increase in viscosity. Since the concentration of MBr is the least likely to change during operation of the bath, a decrease of conductivity associated with increasing viscosity would also be an indication for a change in the composition of the solvent. On the other hand, a significant increase in the specific conductivity can be due to the contamination of the bath with water, which leads to the formation of HBr. This will cause a decrease in the cathodic efficiency and shorten the lifetime of the bath (5, 6).

Electrodeposited Chromium-Graphite Composite Coatings

Raj Narayan and B. H. Narayana[1]

Department of Metallurgical Engineering, Indian Institute of Technology, Kanpur 208016 India

ABSTRACT

Electrodeposited chromium-graphite composite coatings have been produced by suspending graphite particles, using mechanical stirring, in a conventional chromium plating bath. The effect of various plating variables on the graphite content of the coating has been studied. It has been concluded that under the plating conditions studied, the second adsorption step of the two-step adsorption mechanism proposed by Guglielmi controls the deposition kinetics in this system.

A variety of particles like borides, *e.g.*, TiB_2 (1), ZrB_2 (2, 3); carbides, *e.g.*, B_4C (1, 4), B_6C (1, 4), Cr_3C_2 (5), TiC (1); sulfides, *e.g.*, MoS_2 (1); and oxides, *e.g.*, Al_2O_3 (1, 6), SiO_2 (5, 6), ZrO_2 (6) have been codeposited with chromium. Very little work has been reported on codeposition of graphite particles with chromium. Young (1) showed that codeposition of graphite with chromium was possible in the presence of Li^+ ions. However, the effect of various bath parameters on the amount of codeposited graphite was not studied.

The present investigation was undertaken to study the effect of various plating bath variables on the amount of graphite codeposited with chromium. The applicability of Guglielmi's model in the chromium-graphite composite coating system was also studied.

[1] Present address: R and D Centre, Hindustan Brown Boveri Limited, Baroda, India.

Key words: codeposition, adsorption, Guglielmi's model.

Experimental

Graphite powder particles were added to the chromium plating bath of the following composition at the indicated conditions: chromic acid, 250 g/liter; sulfuric acid, 2.5 g/liter; temperature, 50°C; current density, 50 A/dm^2 unless otherwise stated; and plating time, 10 hr.

The solution containing the graphite powder was blended for about 3-4 hr to ensure good wetting and uniform distribution of the powder particles in the bath. Water was added to make up evaporation loss during plating.

Graphite content of the coatings was determined gravimetrically by dissolving it in concentrated sulfuric acid containing a few drops of formaldehyde, diluting the acid approximately 4:1 to prevent it from attacking the filter paper, filtering through a previously weighed Whatman filter paper No. 40, drying, and reweighing.

The microhardness of the coating was measured on a Tukon microhardness tester with 156° apex angle diamond pyramid identor at 1 kg load.

Results

Increasing the graphite powder content in the plating bath increases its content in the coating at 50 A/dm^2 at different temperatures (Fig. 1). This behavior is in agreement with the results of other investigators in other plating systems.

Variation of current density from 20 to 55 A/dm^2 has practically no effect on the graphite content of the coating (Table I). This behavior is observed at all graphite contents in the plating bath.

In a conventional plating bath the concentration of chromic acid in the plating bath is about 250 g/liter. Decreasing this concentration, at a fixed ratio 1:100 between sulfuric acid and chromic acid, to 150 g/liter results in practically no codeposition of graphite, whereas increasing its concentration to 400 g/liter has practically no effect on the amount of codeposited graphite (Table I). The chromic acid concentration of the conventional plating bath, therefore, appears to be adequate for codeposition of graphite with chromium.

Increasing the solution blending time, to ensure adequate wetting and distribution of graphite in the plating bath, increases the graphite content of the coating up to 3 hr of blending (Table I). Blending beyond 3 hr does not have much effect. This trend is observed at two different bath loads of graphite, and it is expected that the trend will follow at other bath loads also.

To see the effect of aging of the plating bath on the amount of codeposited graphite, the plating baths containing different graphite contents were allowed to

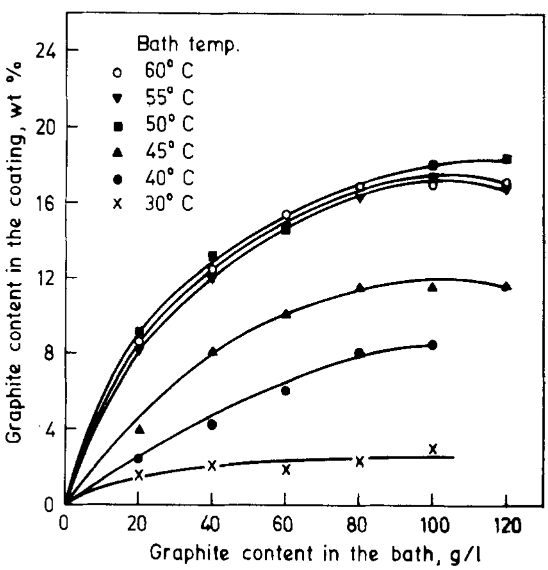

Fig. 1. Effect of graphite content in the plating bath on its content in the coating at 50 A/dm^2 and different temperatures.

age at room temperature. Aging up to 8 days has practically no effect (Table I).

Increasing the temperature of the plating bath from 30° to 50°C increases the amount of codeposited graphite. Beyond 50°C increasing temperature has practically no effect (Fig. 2).

Coating thickness at the center and at the edge of the specimen at two current densities and two bath loads was uniform for all practical purposes.

The microhardness of composite coatings increases with increasing graphite content, the effect becoming less pronounced with increasing annealing temperature (Fig. 3). Increasing the annealing temperature decreases the microhardness of all coatings. The beneficial effect of graphite appears to be practically lost as the annealing temperature increases (Fig. 4).

The cathode current efficiency increases with increasing current density up to about 50 A/dm^2 beyond which there appears to be practically no effect (Fig. 5). Variation of graphite content in the bath at a given current density does not appear to have any effect on cathode current efficiency.

Discussion

In order to explain the mechanism of codeposition Guglielmi (7) proposed a mechanism based on two successive adsorption steps. In the first step, loosely adsorbed particles are in equilibrium with particles

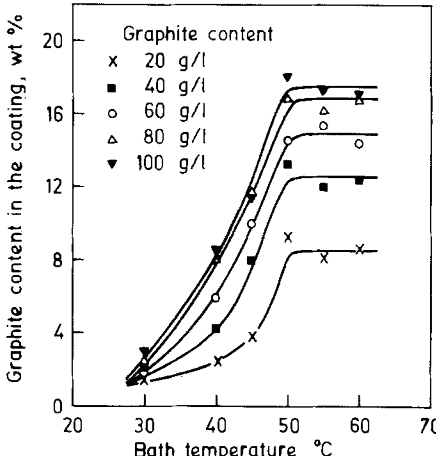

Fig. 2. Effect of plating bath temperature on the graphite content in chromium coating at 50 A/dm^2 and different graphite contents in the bath.

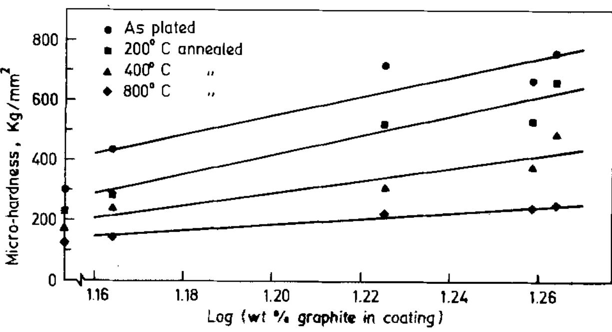

Fig. 3. Variation of the microhardness of the coating with the graphite content in the coating after annealing at different temperatures for 4 hr. (Similar effect is observed after annealing for 2 hr.)

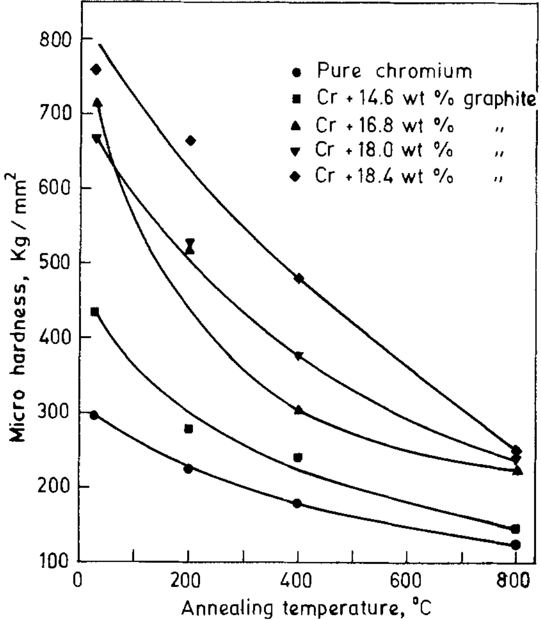

Fig. 4. Effect of annealing for 4 hr at different temperatures on the microhardness of Cr and Cr-graphite composite coatings. (Similar effect is observed after annealing for 2 hr.)

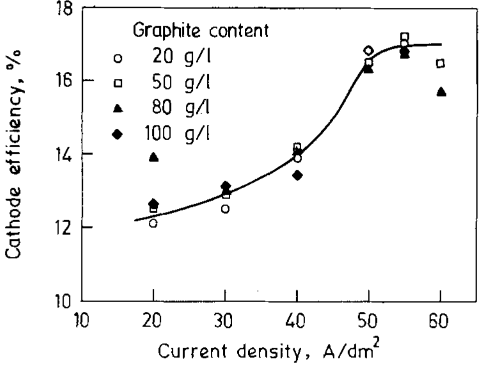

Fig. 5. Variation of cathode efficiency with current density at 50°C and different graphite contents in the bath.

in suspension and are surrounded by adsorbed ions and solvent molecules. In the second step, these adsorbed ions and solvent molecules break away from the particles so that a strong irreversible electrochemical adsorption of particles on the cathode takes place. Then these invisibly adsorbed particles are engulfed in the depositing metal. By a mathematical treatment the following expression, relating the concentration of codeposited particles to the suspension concentration and the electrode potential, was deduced

$$\frac{C}{\alpha} = \frac{Wi_0 e^{(A-B)\eta}}{nFdv_0} \cdot \left(\frac{1}{K} + C\right) \quad [1]$$

where C = concentration of particles in the bath expressed as volume percent, α = volume fraction of particles in the deposit, W = atomic weight of the deposited metal, n = valence of the metal, d = density of the metal, $\mathbf{F}$ = Faraday's constant, η = overpotential, K = adsorption constant, i_0, A = constants related to metal deposition, and v_0, B = constants related to particle deposition.

According to this model, if C/α is plotted against C at different overpotentials, a set of straight lines converging at the point where $C = 1/K$ is obtained. It has been shown that this model is valid in Ni-TiO_2, Ni-SiC, and Cu-Al_2O_3 systems. The significance of the rate-determining adsorption step and relative values of A and B in terms of the amount of codeposited particles at different current densities has been discussed in an earlier publication (8). On the other hand, the Tafel relationship gives

$$\eta = \frac{2.303RT}{\alpha n\mathbf{F}} \log (i_0/i)$$

Therefore, if the above model is applicable to any composite plating system, plotting C/α against C for different values of i or T should give a set of straight lines converging at a point where $C = 1/K$.

On plotting C/α against C at different temperatures, for the present investigation we obtain a set of straight lines converging at a point where $1/K = -0.95$ (Fig. 6). Although there is some scatter in the results, especially at low temperatures, it seems reasonable to conclude that the two-step mechanism proposed by Guglielmi is also applicable in the present chromium-graphite system.

After establishing the validity of the two-step adsorption mechanism in the system, attempts have been made to determine the rate-controlling adsorption step in the system by studying the effect of different

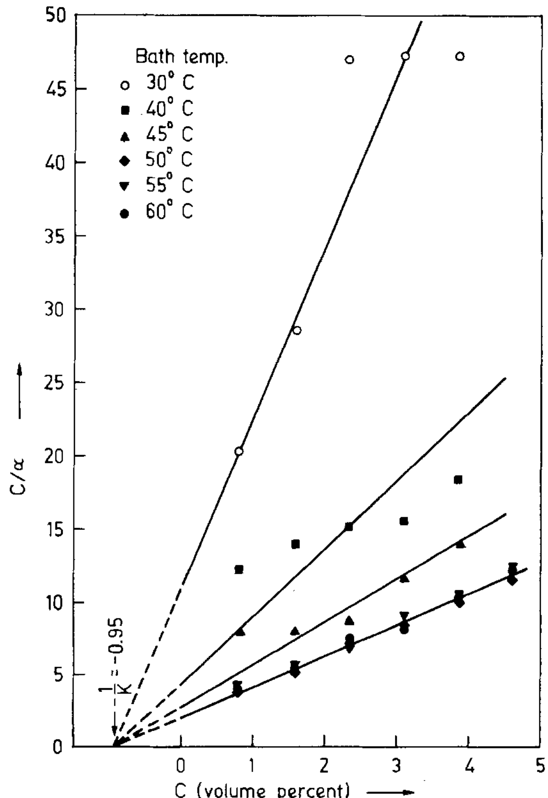

Fig. 6. Variation of the parameter C/α with C at different temperatures and 50 A/dm² in Cr-graphite system.

plating variables on the amount of codeposited particles at 50°C. The volume fraction of the codeposited particles in the coating, α, was plotted against the volume percent of particles in the bath, C, at different current densities. The resulting curve had the characteristic asymptotic shape (Fig. 7), indicating that at all current densities studied at 50°C the deposition kinetics were under the control of the same adsorption step. On plotting $\alpha i/C$ against current density, i, we observe that the term $\alpha i/C$ does not tend to become constant but keeps on increasing at all current densities at different volume percents of particles in the bath (Fig. 8). This, as discussed earlier (8), indicates that the deposition kinetics is controlled by the second adsorption step.

Plotting C/α *vs.* C at different current densities at 50°C yields a straight line (Fig. 9). This indicates that the two-step adsorption mechanism is also valid under these conditions. However, a single straight line is obtained instead of a set of straight lines. This would mean that under these conditions $B = A$. It was discussed earlier that when the second step controls the deposition kinetics and $B = A$, then the amount of particle codeposited, α, would be independent of current density. Our experimental results confirm this conclusion (Fig. 10).

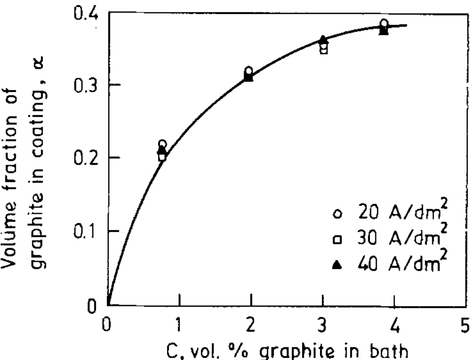

Fig. 7. Variation of the parameter α with C at different current densities at 50°C. (Data at 50, 55, and 60 A/dm² are not shown in the plot due to overlapping.)

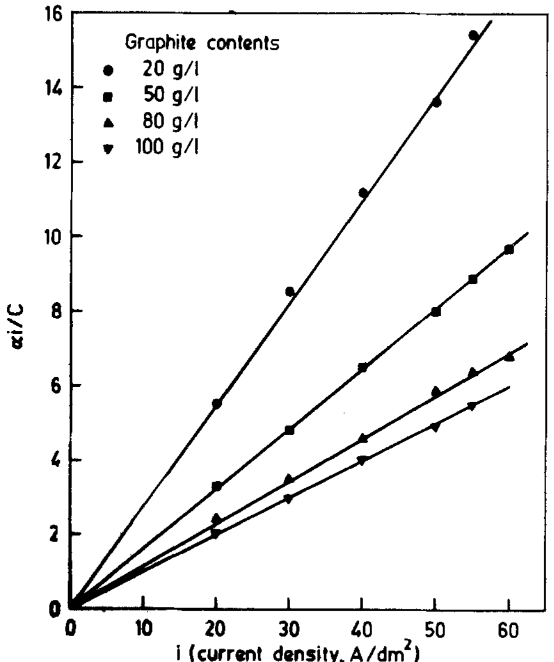

Fig. 8. Variation of the parameter $\alpha i/C$ with i at different graphite contents in the bath at 50°C in Cr-graphite system.

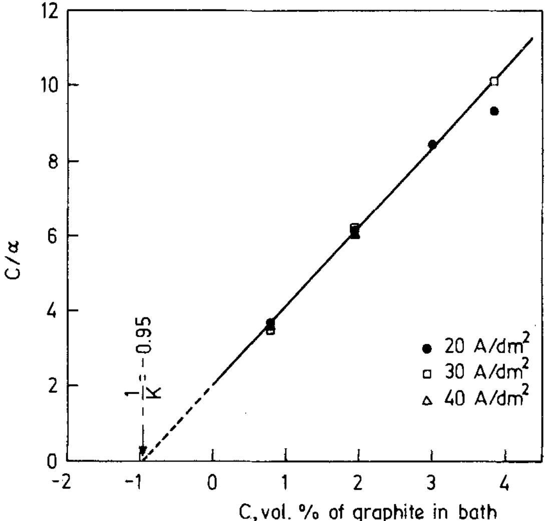

Fig. 9. Variation of the parameter C/α with C at different current densities at 50°C. (Data at 50, 55, and 60 A/dm² are not shown in the plot due to overlapping.)

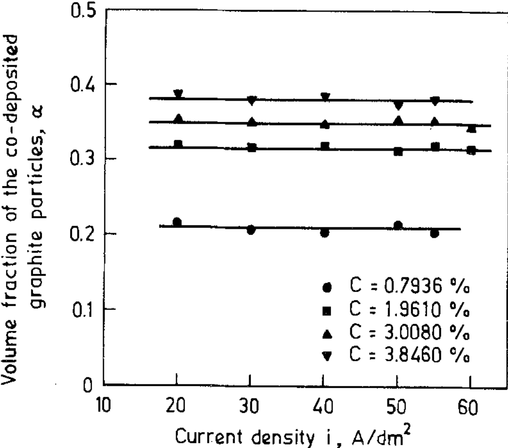

Fig. 10. Effect of current density on the volume fraction of the codeposited graphite particles at 50°C and different graphite contents in the bath in Cr-graphite system.

From Fig. 2 it can be seen that the amount of graphite codeposited with chromium increases with increasing temperature up to about 50°C, and thereafter it was practically independent of temperature. The Tafel relationship shows that both temperature and current density affect overpotential and, therefore, the amount of codeposited particles in the coating in the same way. Thus these results would indicate that up to 50°C, $B > A$ and beyond this temperature $B = A$.

At low concentrations of chromic acid, *e.g.*, 150 g/liter, practically no codeposition of graphite particles takes place (Table I) and C/α becomes infinity. Assuming Guglielmi's two-step adsorption mechanism to be valid in this case, it follows that in Eq. [1] C/α can become infinity only if either i_0 or η is equal to infinity or the parameter v_0 or K is equal to zero. The parameters i_0 and η are related to the metal deposition, and since the cathode efficiency of the plating bath remains practically constant with the decrease in chromic acid concentration in the bath (Table I), it would appear that the parameters i_0 and η do not become infinity on decreasing the concentration of chromic acid in the plating bath. Decreasing the chromic acid concentration in the bath decreases the amount of chromium ions available to be adsorbed on the graphite particle and their subsequent reduction. The parameter v_0, which is related to the rate of re-

duction of these adsorbed ions, can become zero if no adsorption of chromium ions takes place on the graphite particle. On the other hand, if adsorption of these ions takes place, but is not sufficient to bring about any interaction of these particles with the cathode, then K may become equal to zero. It can, therefore, be concluded that by decreasing the chromic acid concentration in the bath either the parameter v_0 or K becomes equal to zero.

Conclusions

1. It is possible to codeposit graphite from commercial hexavalent chromium plating baths without the addition of Li^+ ions.
2. The amount of graphite in the coating increases with its content in the bath at all temperatures.
3. The amount of graphite in the coating increases with increasing temperature up to about 50°C beyond which it remains constant.
4. Current density and aging time of the bath have practically no effect on the amount of graphite in the coating.
5. Codeposition of graphite with chromium does not occur if the chromic acid concentration in the plating bath is reduced to 150 g/liter.
6. Sufficient blending time is essential to obtain optimum codeposition at any bath load of graphite.
7. For all practical purposes the thickness of the coating was uniform.
8. Microhardness of the coating increases with increase in graphite content of the coating in both as-received and annealed conditions. The effect becomes less pronounced with increasing annealing temperatures.
9. Cathode current efficiency increases with increasing current density up to 50 A/dm^2, beyond which it practically remains constant at about 16.5%. Temperature and chromic acid concentration have practically no effect.
10. Guglielmi's two-step adsorption mechanism is valid in this system.
11. The second adsorption step controls the deposition kinetics under the plating conditions studied.
12. On decreasing chromic acid concentration to 150 g/liter the amount of chromium ions adsorbed on the graphite particles either become equal to zero resulting in $v_0 = 0$ or insufficient to cause any interaction between the graphite particles and the cathode, resulting in $K = 0$.

Electrodeposition of Silicon onto Graphite

Gopalakrishna M. Rao,* Dennis Elwell,* and Robert S. Feigelson

Center for Materials Research, Stanford University, Stanford, California 94305

ABSTRACT

Dense, well-adherent silicon was successfully deposited at -0.75 ± 0.05V *vs.* Pt or Ag onto an inexpensive graphite substrate from the K_2SiF_6/LiK-KF molten salt system at 745 ± 5°C. The solute concentration was in the range of 8-14 m/o. Cross-sectional views through the deposits indicate a nodular or dendritic growth up to several millimeters on top of an underlying coherent layer of 0.2-0.5 mm thick silicon. The polycrystalline silicon has a columnar structure with normal grain size of 250 μm. The impurities detected were Cu, Fe, and Ni at levels less than 0.005%. The room temperature resistivity has been found to be greater than 1Ω cm. The dependence of the electrodeposition parameters on the morphology and the possibility of direct use of electrodeposited polycrystalline silicon in solar cells are discussed.

Crystalline silicon is one of the most promising materials for terrestrial solar cells and extensive research has been directed toward cost reduction.

The production of low cost solar cell grade silicon by electrodeposition from a solution of K_2SiF_6 in a fluoride melt is very attractive because 99% pure K_2SiF_6 can be produced cheaply as a fertilizer by-product. Well-adherent, inclusion-free, and relatively pure (impurities less than 10 ppm) silicon electrodeposited onto silver from such solutions at 750°C was reported recently (1). Silver is clearly a very expensive material for use on a large scale and, although the substrates could be reused if bulk silicon were stripped from the cathode after deposition, a less expensive substrate material would be preferable.

The deposition of silicon layers on electrically conducting low cost substrates such as steel, brass, nickel, tungsten, or graphite would be a very promising approach to reduce the material processing cost of solar cells. Unfortunately, the majority of these substrates are not suitable for silicon electrodeposition since

* Electrochemical Society Active Member.

they form silicides at the operating temperature of 750°C. Because of its availability in the United States, graphite appears to be a good candidate as an inexpensive substrate, especially since its reactivity with silicon at 750°C is low.

A carbon cathode was first used for electrodeposition of silicon in 1854 (2). Several workers (3-6) have since then employed graphite cathodes in their studies. Although the work of Monnier *et al.* (4) yielded up to 99.99% pure silicon, the electrodeposits on graphite were, in general, powdery and incoherent and required a subsequent separation process to remove entrapped solvent.

The objective of the present study was to electrodeposit high purity silicon onto a low cost graphite substrate, in bulk form or as films with large grain size, from an inexpensive source. The morphology of the polycrystalline films produced and its dependence on the electrodeposition conditions are discussed.

Experimental

The apparatus, chemicals, and most experimental conditions used were similar to those reported by Rao *et al.* (1). An "ultracarbon" rod cathode with vitreous carbon, pyrolytic graphite or 0.73 g cm^{-3} density graphite crucible anodes, and silver or platinum flag reference electrodes were used in this study.

Because higher solute concentrations were previously found to give improved deposits (1), 8-14 mole percent (m/o) of K_2SiF_6 was mixed with the KF/LiF binary eutectic (mp 492°C), which was prepared earlier and melted to form a solution. This melt was later purified by pre-electrolysis and the purified solution was used for two or three deposition experiments.

The electrodeposition was performed at 745° ± 5°C in a three-electrode configuration with the melt contained in a vitreous carbon crucible except when the crucible was used as anode.

The morphology of the deposits was investigated by scanning electron microscopy and optical microscopy. The samples were analyzed for impurities by x-ray diffraction and by energy dispersive x-ray, electron microprobe, and emission spectroscopic analysis. Four-probe resistivity and spreading resistance measurements were made on representative samples.

Results

Electrochemical.—Dense, coherent, and well-adherent silicon was successfully electrodeposited onto graphite at constant potentials from the K_2SiF_6 system.

In our previous publication (1) it had been shown that high K_2SiF_6 concentrations were essential to obtain continuous inclusion-free silicon films. The solute concentration was, therefore, maintained in the range of 8-14 m/o. Because the same melt was used in two or three experiments, and solute volatility was appreciable at this working temperature, the values of solute concentration given in column 2 of Table I are estimates which are corrected for volatilization by weighing the melt before and after deposition and assuming all the evaporation to be of K_2SiF_6.

Both Pt and Ag quasi-reference electrodes behaved similarly. Since Pt foil anodes were attacked and tended to fracture at the metal-vapor interface during prolonged electrolysis, graphite anodes of various types (although they are prone to fluoride attack) were used in this study. Of the graphite anodes studied, the relative rate of anode consumption was greatest for the low density graphite (0.73 g cm^{-3}) and least for pyrolitic graphite.

The deposition potential was calculated from current-potential plots for each experiment. Reproducibility was rather poor between experiments, and these values varied by ±50 mV between runs in each experiment. Such variations are anticipated when uncertainties in the solute concentration and the shift in reference potential are considered (1). In contrast to experiments using a silver cathode, a nucleation overpotential of 30-100 mV was required to initiate the electrodeposition of silicon onto graphite. Although Table I shows a few extreme values, the applied potential was generally −0.75 ± 0.05V.

Current fluctuations were very common but the observed current densities were normally in the range of 10-100 mA cm^{-2}. Regular oscillations from 10 to 15 mA in amplitude were frequently noted during the deposition of uniform, dense, silicon electrodeposits. The cathodic current efficiencies were low at low charge densities. Higher efficiencies of up to 80% were, however, achieved during electrolysis for large charge densities.

Morphology.—Silicon electrodeposits up to 1 mm thick at the side wall and up to 2 mm thick at the edge of the graphite rod were obtained during electrolysis for several days; this wedge shape was similar to the deposits on small silver electrodes (1). It is interesting to note that electrodeposited silicon could be stripped as a sheet from the graphite substrates with little applied force. The fairly smooth surface at the silicon-graphite interface suggested uniform adhesion between the deposit and the graphite. A typical micrograph of a silicon-graphite interface is shown in Fig. 1 and provides evidence for the absence of voids, inclusions, or other discontinuities at the interface.

Cross-sectional views through the deposits, as in the example of Fig. 2, indicate nodular or dendritic growth up to several millimeters on top of an underlying coherent layer of 0.2-0.5 mm thick silicon. The upper

layers of thick deposits are, in general, porous. Layers produced during electrolysis for short periods were often spongy and less crystalline (Fig. 3a), but prolonged electrolysis, however, led to densification (Fig. 3b). A grain size of 250 μm (Fig. 4) was normal, but larger grains up to 750 μm in diameter were observed in a few deposits. Large grains were common in the deposits produced over several days or in electrolysis involving large charge densities. The increase in grain size with increasing film thickness as shown for silicon electrodeposits on silver (1) is characteristic of samples presently produced by this method.

Figure 5 shows the grain structure of a typical deposit as revealed by an HNO_3/HF etch. Growth is columnar with a large grain size as required for the material to be used directly for solar cell fabrication.

Purity.—X-ray analysis showed only polycrystalline silicon. Moreover, electron microprobe and energy dispersive x-ray analysis did not show any impurities. Although impurity levels in the order Li > Cr > Ni > Fe > Cu > Ag > Mn > Pb > Al up to 0.02% were detected in emission spectroscopic analysis for a few samples, the most common impurities were Cu, Fe, Ni, and Ag of total concentration less than 0.005%. Among the latter impurities, Cu, Fe, and Ni at this concentration level would not seriously degrade the solar cell performance (7). The fluoride attack on the furnace and the electrode materials could contaminate the melt (1) and these easily reducible metal ion contaminants are likely to co-deposit with silicon as major impurities. The source of Li could be from the entrapped melt since LiF, a major component of the melt, is highly insoluble in water or acids, and is therefore not easily removed from the deposit during cleaning.

The purity of electrodeposits, greater than 99.99%, must be compared with a purity of only 99% for the starting materials employed in the melt preparation. Thorough pre-electrolysis of the melt and an alternative furnace design as suggested in our previous report (1) would certainly yield silicon of greater purity and better quality.

Resistivity.—Preliminary measurements by a four-probe method on selected samples gave encouraging results. The measured resistivities were different in different locations of the electrodeposited silicon. Spreading resistance measurements confirmed that the major variations were due to surface roughness, but the room temperature resistivity of electrodeposited

silicon from this system has been found to be always greater than 1 Ω cm.

Discussion and Conclusions

The mechanism for the transformation of silicon in the fluorosilicate into a crystalline form under the influence of an electric field is very complicated. It was suggested (1) that polynuclear silicon complexes are present in the fluoride melt and their slow dissociation, a preceding step to the charge-transfer reaction, favors the deposition of coherent films.

To explain powdery and dendritic or spongy deposits on silver during deposition at the higher cell potentials (−2V *vs.* Pt) used and on prolonged electrolysis of dilute K_2SiF_6 solutions at the deposition potential, respectively, we have proposed a reaction between the deposited silicon and the melt (1)

$$Si + Si^{4+} \rightleftarrows 2Si^{2+} \quad [1]$$

Deposition of silicon and subsequent dissolution due to reaction [1] may be a plausible explanation for the 10-15 mA current oscillations under constant potential electrocrystallization. Initially deposited silicon is assumed to be partially redissolved because of its interaction with tetravalent silicon ions in the solution according to reaction [1] to give divalent silicon ions. In consequence of this secondary reaction, the deposits for short periods of electrolysis were spongy (Fig. 3a) and of low current efficiency (Table I). When the divalent silicon ions concentration exceeded the equilibrium value (that is, upon continued electrolysis for longer periods), reaction [1] should shift to the left. This condition results in a coherent, dense, and crystalline deposit (Fig. 3b). It is interesting to note that the growth process appeared to correct the initial spongy appearance of the deposit during electrolysis for several days (Fig. 3a and b).

The porous outer surfaces of some deposits (*e.g.*, Fig. 3b) are believed to be due to vapor phase attack of the sample while it was left above the melt in the furnace during cooling. In an independent experiment, a silicon wafer held for 6 hr above the KF-LiF melt lost nearly 0.05g and showed a brittle, black top layer. Furthermore, Cohen has also reported the vapor phase attack of electrodeposited silicon (8).

The characteristics required of a polycrystalline silicon layer for use in photovoltaic cells are as follows: (*i*) 100-200 μm thick to capture an acceptable fraction of the incident sunlight; (*ii*) individual grains of at least 100 μm to yield an efficiency of photovoltaic energy conversion greater than 10%; and (*iii*) relative absence of impurities that would give rise to deep-level recombination centers.

The electrodeposited silicon onto graphite from K_2SiF_6 solutions has the following properties: (*i*) coherent layers of 0.2-0.5 mm thick; (*ii*) a grain size of 250 μm; (*iii*) impurity level of 0.005% of Cu, Fe, Ni, and (*iv*) resistivity greater than 1 Ω cm.

Since crystals doped with Cu, Fe, and Ni have no observable discrete levels (7), these electrodeposited silicon samples with columnar structure show considerable promise toward meeting the requirements of solar-grade material.

Taking into consideration the cost of slicing bulk deposits into thin wafers, the electrodeposition of thick layers does not appear to be economically viable even if nodular or dendritic growth could be avoided. Deposition of thin layers of adequate grain size is the most effective way to minimize material costs. Increasing the grain size and the purity of the deposits would be highly advantageous to improve the solar cell performance. Ongoing studies will include attempts to increase the grain size by laser annealing and to reduce the impurities by the use of an alternative furnace design with internal graphite element and water-cooled stainless steel jacket.

Electrogrown silicon surfaces, in general, are not microscopically smooth. An irregular surface could have a beneficial effect in solar cells because of an increased surface area of light absorption.

Silicon costs probably represent the major economic barrier to meeting the Department of Energy cost goals for nonconcentrating arrays in the early 1980's. It was mentioned earlier (1) that electrodeposition has the potential to yield solar grade silicon at about \$1-\$2 per kg. Although deposition on silver leads to easier silicon nucleation and better morphology of the deposits, graphite has the great advantage of low cost and the greater cathodic current efficiencies. Thus, graphite appears highly promising as an inexpensive substrate for the deposition of solar-grade silicon.

Electrodeposition of Silicon at Temperatures above Its Melting Point

Robert C. De Mattei, Dennis Elwell,* and Robert S. Feigelson

Center for Materials Research, Stanford University, Stanford, California 94305

ABSTRACT

The electrowinning of molten silicon has been achieved for the first time using a $BaO/SiO_2/BaF_2$ melt. The silicon formed roughly spherical or ellipsoidal droplets up to 15 mm in diameter in the small experimental system used, and these solidified with a grain size of up to 1 mm. Material of 99.97% purity can be produced from 99.5% pure starting material without additional purification or pre-electrolysis.

The electrodeposition of silicon was first achieved in 1854 (1), and it was recently (2) shown that material of 99.999% purity can be produced by this method. A major limitation in electrodeposition of solids is that a growing solid-liquid interface becomes unstable at a critical current density of approximately 40 mA/cm^2 (3), which for silicon would correspond to a linear growth rate of about 45 $\mu m/hr$. This limitation does not apply to electrodeposition of liquids, and the Hall process for production of aluminum is commercially viable because deposition occurs at temperatures above the melting point of aluminum. An industrial unit for Al electrodeposition operates at a current of 100-200 kA which has the additional advantage that the deposition temperature can be maintained by Joule heating by the deposition current.

The aim of this investigation has been to develop an analogous process which can be used for electrodeposition of molten silicon. Although the energy cost of electrodeposition at temperatures above 1415°C is high, this disadvantage can be more than offset by the much higher deposition rate which is possible when the cathodic product is in the liquid state.

The furnace which was developed for electrodeposition at temperatures in the range from 1420° to 1500°C used an internal, resistance-heated graphite element with two graphite heat shields and an outer silica shield (4). The melt used for electrolysis was contained in a graphite crucible 6 cm in diameter and in height, supported on an alumina pedestal. The stainless steel jacket and brass flanges were water cooled, arrangements being provided for evacuating the chamber and for the introduction of a flowing argon atmosphere. The upper flange had fittings for the insertion into the melt of a central cathode through a vacuum feedthrough with rotation and translation capability, and for an anode which was inclined to the vertical at an angle of 6°. Both electrode fittings were insulated from the flange by machinable glass inserts which were individually cooled and attached to the flange by epoxy cement. The upper flange also had a 5 cm sapphire viewpoint which was normally protected by a movable shutter. The furnace temperature was controlled by a Eurotherm controller with step-down transformer, the controlling element being a sheathed Pt-6% Rh/Pt-30% Rh thermocouple.

The most suitable source material for silicon electrodeposition at $\sim$ 1450°C is SiO_2. Microcrystalline silica deposits of 99.5% purity are found in large quantities near Cairo, Illinois.[1] This material was formed from the skeletal remains of marine creatures of the Devonian period and has been purified by the action of ground water. The major impurities are 0.15 weight percent (w/o) CaO and 0.025 w/o Fe_2O_3, with 50-100 ppm each of Al_2O_3, MgO, and TiO_2.

In view of the high melting point of SiO_2, a binary or ternary system must be used to permit electrolysis at 1450°C. The simplest choice of melt is an alkali metal or alkaline earth silicate obtained by reacting the SiO_2 with the appropriate carbonate. There are three competing reactions in an electrolytic cell, which give rise, respectively, to silicon, silicon monoxide, or the alkali or alkaline earth metal as the cathodic product

$$3MSiO_3 \rightleftharpoons 3MO + \underline{/Si/} + 2SiO_2 + O_2 \quad [1]$$

$$4MSiO_3 \rightleftharpoons 4MO + \underline{/2SiO/} + 2SiO_2 + O_2 \quad [2]$$

$$2MSiO_3 \rightleftharpoons \underline{/2M/} + 2SiO_2 + O_2 \quad [3]$$

Thermodynamic data for calculation of the free energy changes are not available in all cases of practical interest. However, estimates of the range of free energies over which the favorable reaction [2] will occur can be made (5) following the method of Johnson (6). These estimates indicate that potassium and sodium silicates are unfavorable for silicon electrodeposition, while aluminum, calcium, lithium, and magnesium silicates are much more favorable.

An additional consideration is that the metal oxide/SiO_2 system chosen should have one or more eutectic points below 1415°C. Most alkali metal and alkaline earth silicate systems meet this requirement, and attempts to deposit silicon at temperatures around 1450°C have been made on a range of compositions. Silicon was not produced from Rb_2O/SiO_2 or CaO/SiO_2 melts, and it was found that potassium was the primary product of electrolysis of several K_2O/SiO_2 compositions. Electrolysis of lithium silicate melts has given silicon, but not at temperatures above 1415°C. Best results were obtained using BaO/SiO_2 melts, with BaF_2 added to facilitate melting and lower the viscosity of the melt. Silicon has also been electrodeposited from melts in the system $SrO/SiO_2/SrF_2$.

The BaO/SiO_2 system has a single eutectic point (7) around 1370°C and composition 53 w/o SiO_2; 47 w/o BaO. A mixture of barium carbonate and silica of the corresponding molar concentration reacts and melts very slowly at 1500°C but the addition of a few percent of BaF_2 greatly facilitates melting through its fluxing action.

Figure 1 shows a current *vs.* voltage plot for a melt of original composition 63.2 mole percent (m/o) SiO_2; 22.2 m/o $BaCO_3$; 14.5 m/o BaF_2 at temperatures above and below the melting point of silicon, using graphite electrodes. The minimum deposition potential in both cases is in the region of 0.25V and the difference in the slopes is about 60%.

Deposition normally proceeds at a constant potential in the range 0.8-16V, with a corresponding current

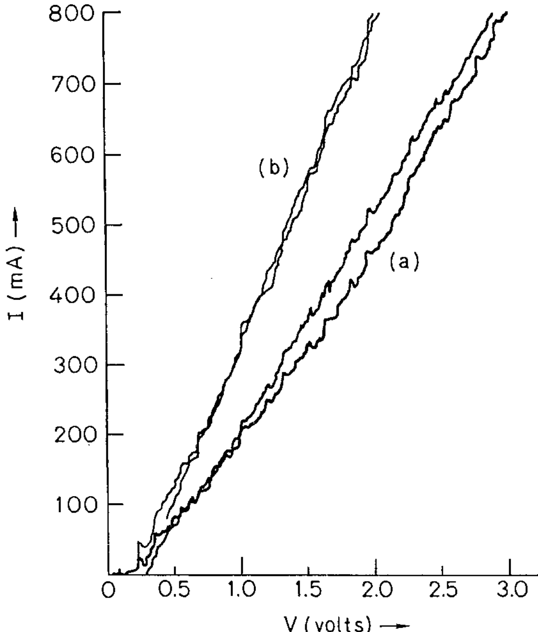

Fig. 1. Plot of current vs. potential difference between graphite electrodes for $BaO/SiO_2/BaF_2$ melt at (a) 1393°C, (b) 1465°C.

between 120 mA and 2.0A on a cathode area of about 2 cm^2. The deposit is in the form of small lumps roughly spherical in shape and up to several mm in diameter. A typical deposit is shown in Fig. 2. The silicon normally gathers in a horizontal layer close to the end of the cathode rod. The density of the silicon appears to be very similar to that of the melt and it does not show a marked tendency to rise or sink, the rate of movement being very slow because of the high melt viscosity. In order to remove the silicon efficiently from the melt it is desirable to collect the deposit into larger pieces. This coagulation may occur during prolonged electrolysis, and Fig. 3 shows an example of a single lump of silicon weighing over 1.6g, produced from a 125g melt. This lump contained a little over 1/3 of the total silicon deposited.

The faradaic efficiency (weight deposited divided by weight calculated by Faraday's law) of deposition is typically 15-22%, but 40% has been achieved during electrolysis for about two days. The origin of the departure from 100% efficiency has not been fully established, but the simultaneous liberation of silicon monoxide is a competing process and ohmic conduction in the melt may occur via electronic conductivity or via carbon particles which become detached from the anode and float on the melt surface. Variations in

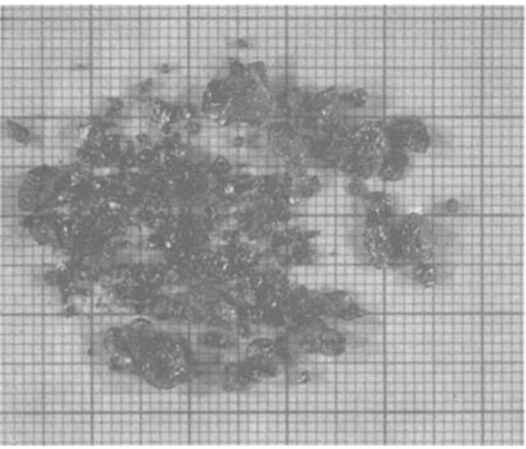

Fig. 2. Silicon produced in a typical electrodeposition experiment from $BaO/SiO_2/BaF_2$ melt at temperature above its melting point.

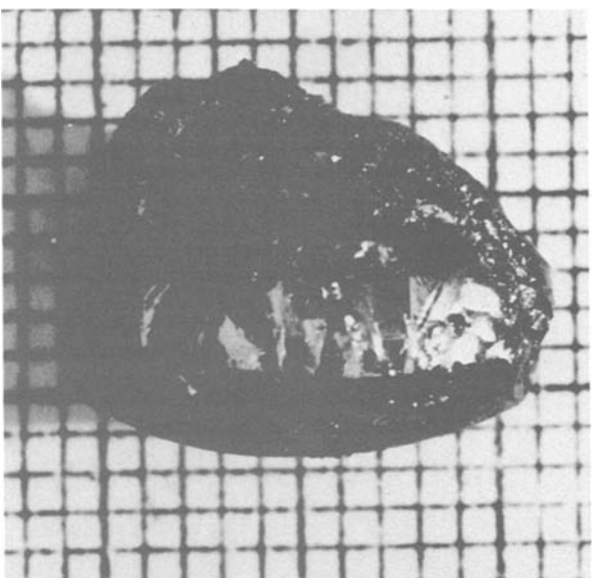

Fig. 3. Lump of electrdeposited silicon weighing 1.6g, produced during an experiment of 50 hr duration.

cathodic efficiency cannot be correlated with the concentration of fluoride in the melt, which has been varied from 8 to 20 m/o. It appears likely that the efficiency is reduced by the back-reaction between anodic and cathodic products, since it depends on the geometry of the electrode arrangement.

The purity of material produced to date is 99.97 w/o, the major impurities being 0.02 w/o iron, 0.003 w/o calcium, 0.002 w/o manganese, 0.001 w/o strontium, and 0.001 w/o titanium. This level of impurities is, of course, much too high for solar cell applications, but experience has shown that the impurity level can be reduced by pre-electrolysis using a sacrificial cathode (2, 8) or other techniques. Reduction of the impurity level by an order of magnitude or more should be possible without significant increase in the complexity or cost of the process.

The room temperature resistivity of the silicon is about 0.2 Ω-cm. If allowance is made for grain boundary effects, this value corresponds (9) to an active impurity concentration of $\sim 10^{18}$ carriers cm^{-3}. This level is considered promising in view of the fact that a pre-electrolysis stage was not used.

Purification will be a major aspect to be studied in future work, as will improving the deposition efficiency and developing a technique for removing the silicon from the melt.

Mass Transport Characterization of Donnan Dialysis: The Nickel Sulfate System

Patrick K. Ng* and Dexter D. Snyder*

General Motors Research Laboratories, Electrochemistry Department, Warren, Michigan 48090

ABSTRACT

There is a need for reliable models of the mass transfer characteristics of hollow tube Donnan dialyzers, to guide application to industrially significant problems such as recovery from electroplating waste water. This work is focused on determining mass transport correlations in a shell-and-tube dialyzer, fabricated from ion-selective membranes, used to extract nickel from dilute nickel sulfate solution with sulfuric acid as the stripping agent. Correlations between mass transport coefficient and Reynolds number are reported for both laminar and turbulent flow regimes.

Donnan dialysis concentration of ions, using selective membranes and a chemical potential gradient, has only recently been considered seriously as an industrial separation and purification technique. Wallace, an early advocate, used the approach to concentrate uranyl, strontium, lanthanum, silver, and copper salts (1, 2). Until very recently, Donnan dialysis has been judged too slow to be practical. Since separation is diffusion controlled, one typically needs extremely thin membranes which are effective ion-selective barriers. Membranes available in the late 1960's and early 1970's were relatively thick and lacked chemical durability. Better membranes are available today, but there is a lack of data and models by which to design practical systems.

Elements of Donnan dialysis concentration of nickel ions are illustrated in Fig. 1. The cation-selective membrane ideally excludes the anions, but permits cations to exchange as the system approaches the equilibrium dictated by the Donnan relation, in this case

$$\frac{(a_{Ni}{}^{I})}{(a_{Ni}{}^{II})} = \frac{(a_{H}{}^{I})^2}{(a_{H}{}^{II})^2} \quad [1]$$

in which a is the activity of the ions on either side of the membrane. If the gradient of the stripping chemical, sulfuric acid in this case, is kept high, the nickel ions can actually be transported against their activity gradient. In the present case where 0.5M sulfuric acid is used to strip nickel from 0.0017M nickel sulfate (100 ppm Ni), the nickel ions can be transferred almost quantitatively. The rate at which this ion exchange occurs depends both on the membrane properties and on the boundary-layer film at the membrane-solution interfaces.

Wallace and other workers (1, 3) dealt with relatively slow flows of both feed and stripping streams. However, the hydrodynamic environment of the membrane often controls the performance. Lake and Melsheimer (4) approached this issue by examining the exchange of sodium, potassium, and hydrogen ions across a cation-selective membrane, using a plate-and-frame dialyzer. Their approach involved determining the membrane resistance at high agitation, and determining the boundary-layer mass transport coefficients using a computer iteration scheme. For Reynolds numbers up to 500, they observed a dependence of ion transport rate on the 0.65 power of the Reynolds number.

Eisenmann and Smith (5) carried out an extensive evaluation of Donnan dialysis softening as a possible adjunct to distillation desalting of brackish water. With limited success, they introduced the affinity driving force and built an analytical model of the process which they used for economic projections. They found a dependence of the sodium-calcium exchange rate on a power of the Reynolds number in the range 0.33-0.67 for a tortuous path spacer. Eisenmann (6) recently reported on the use of Donnan dialysis to recover nickel sulfate concentrate from dilute plating rinse

Key words: membrane, interfaces, connection, ion exchange.

water. Using perfluorosulfonic acid membranes, in hollow tube form, he measured nickel fluxes in the range 0.3-3 $\times$ 10^{-9} mol/(cm^2 · sec) for a feed in the range 25-100 ppm nickel ion. His experiments spanned the Reynolds number range 50-300.

The present work was focused on determining mass transfer correlations for the boundary layer, and on estimating the interdiffusion coefficient of nickel in the membrane. The two-cation system offers results which can be interpreted and compared with previous results, and the nickel waste is also a significant industrial problem worthy of better solutions than now exist commercially. Tubular cation-selective membranes were selected for their suitability in designing recovery and recycle modules with high surface-to-volume ratios, giving potentially higher volumetric nickel separation rates. Both sulfuric acid and nickel waste streams were circulated continuously through the dialyzer.

Experimental

Membrane dimension measurements.—Table I shows the dimensions of the membranes used in this study. Dimensions were determined by first soaking a piece of the tubing in a mixture of nickel sulfate (100 ppm in nickel) and 1*N* sulfuric acid. The tubing was then cut open and its thickness measured with a micrometer. Its outside diameter was measured using a microscope and the inside diameter was subsequently calculated.

Apparatus.—The dialyzer is pictured in Fig. 2, and a schematic diagram of the experimental setup is shown in Fig. 3. Membranes used were commercial perfluorosulfonic acid type. The shell-and-tube module was 17.15 cm long and the inside diameter of the shell was 0.48 cm. For membrane 810, only a single membrane tube was used. In the case of the smaller membrane 811, three membrane tubes were used to guarantee an appreciable change in nickel concentration over the experiment period. Nickel sulfate solution (100 ppm in nickel) was circulated through the tube side, while sulfuric acid (1, 2, or 4*N*) was pumped continuously through the shell side. Each stream contained initially 250 ml solution, and its flow rate was controlled by a tubing pump and monitored with a flowmeter.

Preliminary results suggested that the boundary-layer resistance on the feed solution side (nickel sulfate) was dominant. In practice, the process does not depend on which side of the membrane each solution contacts. However, with the feed solution being the principal target of this study, one could achieve higher linear velocities when this feed was passed through the tube, and this extended the range of the correlation which was ultimately established.

Procedures.—The dialyzer was first flushed with distilled water to remove any nickel sulfate and sulfuric acid left in the system. This water was then drained and both streams of electrolyte were pumped through their respective loops to start the experiment. Samples were taken from each reservoir at time intervals, and the nickel concentration of each was determined by atomic absorption analysis. To minimize the error of changing volume, the total amount taken for sampling over the experiment was limited to less than 10% of the initial reservoir volume (250 ml). At the end of the experiment (3-4 hr), the volume of each stream was measured by draining the solution. In addition, both temperature and *p*H of the solutions were measured. Results indicate that *p*H of the tube-side reservoir changed typically from about 5.5 to 2.2. The shell-side *p*H remained relatively constant, with a maximum increase of about 0.1 *p*H unit. Due to heat generated by the tubing pumps, temperature increases from 2°C (low flow rates) to 7°C (high flow rates) were found. All experiments indicated a volume decrease for the tube-side reservoir of 5-6 ml. This can be explained by a combination of evaporation, osmotic transport, and the migration of hydration water with the ions.

Table I. Membrane dimensions

Membrane	Thickness (cm)	Inside diam (cm)	Outside diam (cm)
810	0.0368	0.2383	0.3119
811	0.0127	0.0637	0.0891

Results and Discussion

This work was focused on separating the membrane and boundary-layer effects in the Donnan dialysis concentration of nickel sulfate from an extremely dilute starting solution. This has been approached by studying the nickel transport rate as a function of the hydrodynamic condition of the membrane dialyzer.

Specifically, the nickel concentration-time relation is determined for a membrane tube dialyzer operated under preset flow conditions.

Rate constant of the tube-side reservoir.—Figure 4 shows typical results for the 810 membrane. The mass of nickel in the reservoir is here plotted instead of concentration to eliminate any discrepancy introduced by change in volume due to sampling. Qualitatively, higher nickel feed rates favor faster removal of nickel from the reservoir. The nickel mass increase in the sulfuric acid reservoir was found consistently to be a mirror of the decrease in the feed reservoir. Thus, the membrane appears to be neither source nor sink for nickel in this process. These nickel mass-time results (Fig. 5) suggest that the reservoir can be regarded as a reactor with a first-order rate constant (m) equaling the slope of the best fit line.

Experiments were also conducted to study the effects of shell-side flow rate and sulfuric acid concentration on the transfer rate, and the results are shown in Fig. 6a and b. From examination of Fig. 6a, it is clear that both acid-side flow rate and acid concentration (1-4N) are unimportant in affecting the nickel transport rate. These findings agree with the work of Lake and Melsheimer (4), where they find that the boundary-layer resistance on the acid side is small. The independence from sulfuric acid concentration is reasonable because the acid gradient remains high in this 1-4N range. Temperature effects can be considered to be small because the maximum change at high flow rate was only 7°C.

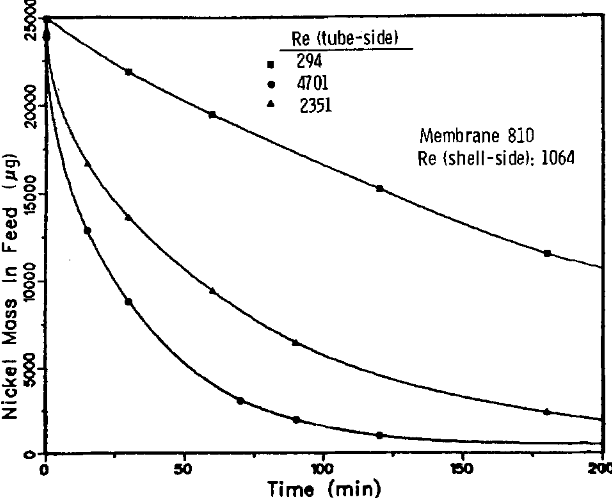

Fig. 4. Transient variation of nickel mass in the reservoir

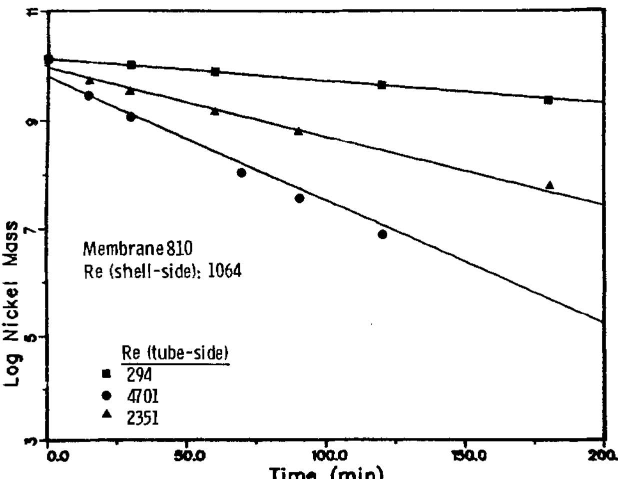

Fig. 5. Transient variation of log nickel mass in the reservoir

Boundary layer and membrane resistances.—Results in Fig. 6 indicate that the tube-side boundary-layer resistance and the membrane resistance are the controlling factors for the nickel transport. The relative values of these two resistances can be estimated with a series model used by Helfferich (7), Gregor (8), and others. For the case of nickel and hydrogen, we will assume complete coion exclusion and define diffusion coefficients by the following flux equations

$$J_{Ni} = \frac{\overline{D}_{Ni\text{-}H}}{l} (\overline{C}'_{Ni} - \overline{C}''_{Ni}) = \frac{D_{Ni}}{\delta} (C_{Ni}{}^{I} - C'_{Ni}) \quad [2]$$

$$J_{H} = \frac{\overline{D}_{Ni\text{-}H}}{l} (\overline{C}'_{H} - \overline{C}''_{H}) = \frac{D_{H}}{\delta} (C_{H}{}^{I} - C'_{H}) \quad [3]$$

$\overline{D}_{Ni\text{-}H}$, and D_{Ni} and D_H are the diffusion coefficients in the membrane and the boundary layer, respectively. Figure 1 gives meaning to the other symbols. An effective mass transfer coefficient (K_m) can also be defined for the membrane as

$$K_m = \frac{\overline{D}_{Ni\text{-}H}}{l} \quad [4]$$

At each interface, the ions are assumed to be distributed according to the Donnan equilibrium, ignoring activity effects

$$\frac{C'_{Ni}}{\overline{C}'_{Ni}} = \frac{(C'_H)^2}{(\overline{C}'_{H}{}^2)} \quad [5]$$

on feed side and

$$\frac{C_{Ni}{}^{II}}{\overline{C}''_{Ni}} = \frac{(C_H{}^{II})^2}{(\overline{C}''_H)^2} \quad [6]$$

on acid side.

Electroneutrality within the membrane is expressed by

$$\Sigma z_i \overline{C}_i - \overline{X} = 0 \quad [7]$$

where $\overline{X}$ is the concentration of fixed negative charges in the wetted membrane. With zero net current, the fluxes are related by

$$\Sigma z_i J_i = 0 \quad [8]$$

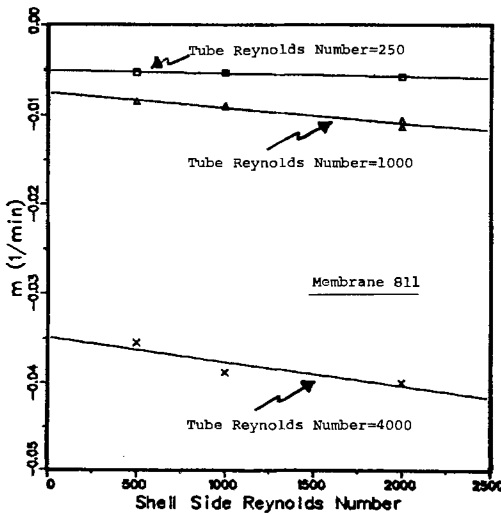
The interfacial concentrations can be written as follows by rearrangement of Eq. [2] and [3], and by use of Eq. [8]

$$C'_{Ni} = -\frac{\delta J_{Ni}}{D_{Ni}} + C_{Ni}{}^{I} \quad [9]$$

$$C'_H = \frac{2\delta J_{Ni}}{D_H} + C_H{}^{I} \quad [10]$$

Equations [2], [5]-[7], [9], and [10] can now be solved for fluxes and interfacial concentrations as functions of bulk concentrations, diffusivities, and membrane and boundary-layer thicknesses. Figures 7a and b show the result of such a calculation using parameter values close to those expected in the experiments. For bulk nickel concentration less than 10^{-5} mol/ml, the boundary layer is the major controlling factor for the nickel transfer. The membrane resistance is negligible until the bulk nickel concentration reaches 10^{-4} mol/ml. Helfferich (7) gives a detailed description of these resistances.

Figure 7 suggests that the tube-side boundary-layer resistance is the dominant limitation for nickel transfer in the concentration range studied in this work. This resistance depends on the hydrodynamic conditions and is best characterized by a mass transfer coefficient, K_{BL}. K_{BL} can be calculated from the rate constant of the reservoir based on a model with the following assumptions: (i) Nickel concentration at the membrane surface is negligible compared to the bulk concentration; (ii) the tube-side solution is well mixed and its concentration is thus uniform and equal to the



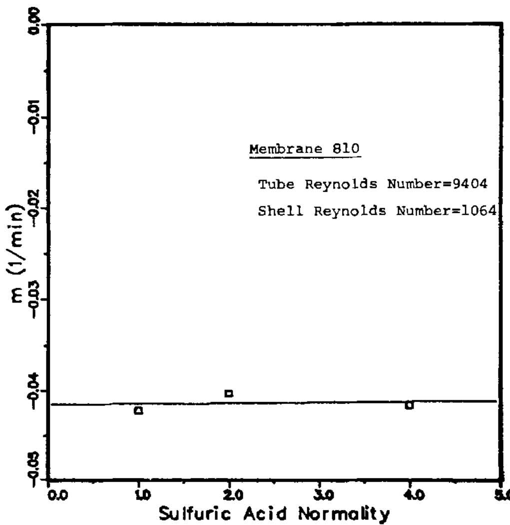


Fig. 6. Dependence of mass transfer on secondary factors. (a) Shell side (1N H_2SO_4) Reynolds number; (b) sulfuric acid concentration

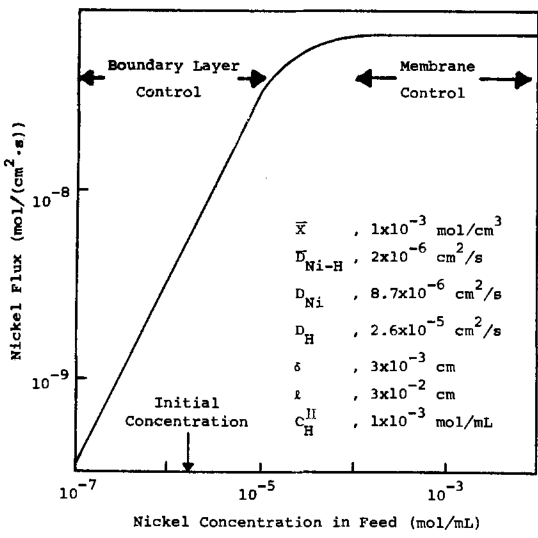

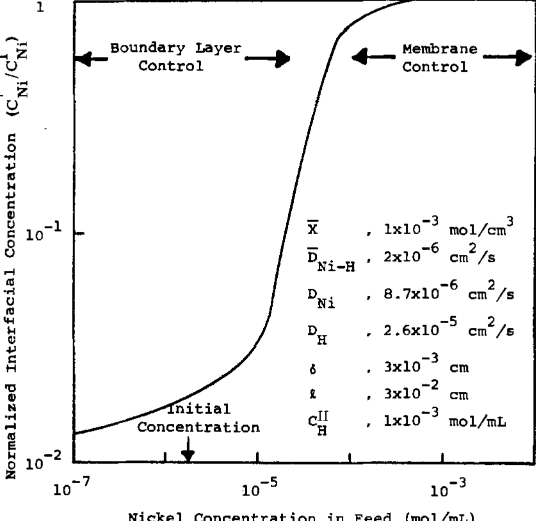

Fig. 7. (a, left) Dependence of flux on bulk nickel concentration; (b, right) dependence of interfacial nickel concentration on bulk nickel concentration.

outlet concentration; (*iii*) at each time, the dialyzer operates at steady state.

The first assumption implies that any nickel transferred to the membrane surface will be transported immediately through the membrane, and its validity is illustrated in Fig. 7b. Assumptions (*ii*) and (*iii*) are reasonable if the flow rates are relatively high. Referring to the schematic diagram in Fig. 3, one can obtain a mass balance equation for nickel in the tube side of the dialyzer, as follows

$$Q(C_i - C_o) = K_{BL}AC_o \quad [11]$$

where A is the membrane area based on the inside diameter and Q is the volumetric flow rate. C_i and C_o represent the bulk concentration of Ni in the tube side and are understood to be the same as C_{Ni}^I in Fig. 1. Similarly, a mass balance of the reservoir gives

$$V_R \frac{dC_i}{dt} = Q(C_o - C_i) \quad [12]$$

where V_R is the reservoir volume. The results in Fig. 5 also imply that

$$C_i = C_i^o \exp(mt) \quad [13]$$

where C_i^o is the initial nickel concentration in the reservoir, and m is the rate constant. Combining Eq. [11]-[13], one obtains the relationship between K_{BL} and m, that is

$$K_{BL} = \frac{-mV_R}{A\left(1 + \frac{mV_R}{Q}\right)} \quad [14]$$

The flux J can also be calculated by

$$J_{Ni} = \frac{Q}{A}(C_i - C_o) = \frac{-mV_R}{A}C_i \quad [15]$$

With the K_{BL} values calculated by Eq. [14], mass transfer correlations were subsequently obtained and are shown in Fig. 8. The exponent on the Schmidt number (Sc) was taken as 1/3 according to convective mass transfer in the pipe. Kinematic viscosity of water and diffusion coefficient of $NiSO_4$ at infinite dilution ($D_{NiSO_4} = 8.674 \times 10^{-6}$ cm²/sec) were used to estimate Sc. The transition from laminar flow to turbulent flow occurs at Reynolds numbers in the range 1000-2000. The generally accepted Reynolds number transition value for smooth tubes is about 2100, but vibration of this membrane tubing could well introduce turbulence at lower Reynolds number. Least square fits to the two regions give the following correlations

$$\mathrm{Sh} = 0.00272\ \mathrm{Re}^{1.024}\ \mathrm{Sc}^{1/3} \quad 10^3 < \mathrm{Re} < 10^4$$
$$\mathrm{Sh} = 0.1663\ \mathrm{Re}^{0.475}\ \mathrm{Sc}^{1/3} \quad \mathrm{Re} < 10^3 \quad [16]$$

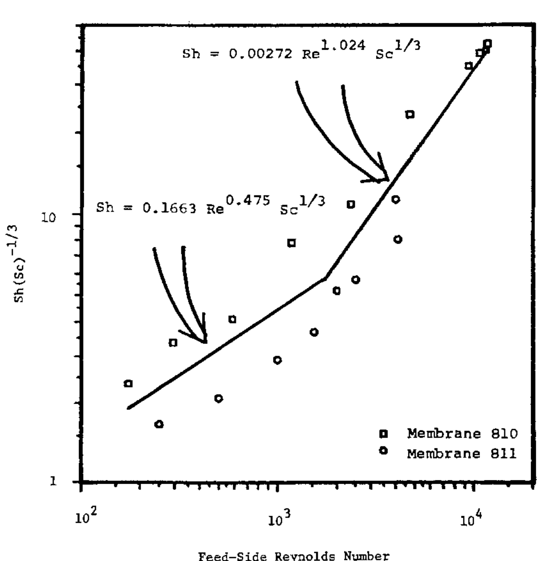

Fig. 8. Mass transfer correlations

An important property of the membrane is the interdiffusion coefficient of nickel and hydrogen ions ($\bar{D}_{Ni-H}$). Although experiments were performed where boundary-layer resistance is controlling, $\bar{D}_{Ni-H}$ can be estimated by extrapolating results at high flow rates. As the flow rate increases, the membrane becomes more dominant and the interfacial concentrations can be approximated by bulk concentrations. Equations [2], [5], [6], and [7] can then be used to calculate K_m at any flow rate and bulk nickel concentration. By extrapolating the data in a plot of 1/Re *vs.* $1/K_m$, one can obtain the value of K_m at infinite flow rate where membrane is the only resistance. Figure 9 shows the result of this exercise for membranes 810 and 811 at bulk nickel concentrations of 100 and 55 ppm. Interdiffusion coefficients ($\bar{D}_{Ni-H}$) thus calculated are summarized in Table II and their magnitude agrees with the range reported in literature. The dependence of $\bar{D}_{Ni-H}$ on bulk concentration needs further investigation.

Conclusions

Donnan dialysis, even with its low transfer rate, is now a promising separation technique with the availability of hollow fiber membranes from which modules can be built to give high surface area-to-volume ratio. The transfer rate depends, in general, on both membrane properties and hydrodynamic conditions outside

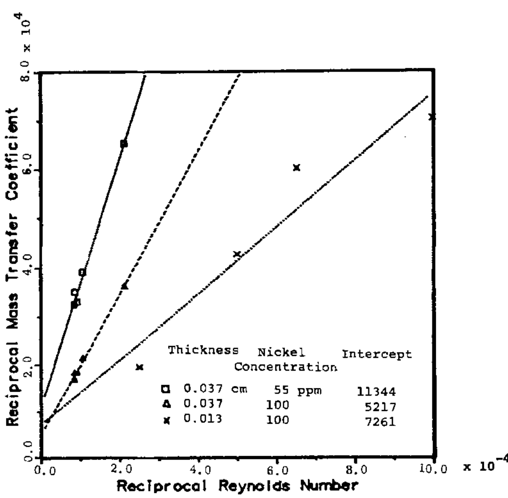

Fig. 9. Extrapolation of membrane resistance

Table II. Membrane interdiffusion coefficient

Membrane	Bulk Ni concentration mol/ml (×10⁶)	$\bar{D}_{Ni-H}$ cm²/sec (×10⁶)
810	1.7	7.053
810	0.935	3.244
811	1.7	1.75

the membrane. For removal of nickel from dilute sulfate solution, this work characterized these two dependencies, particularly that for hydrodynamic conditions and generated correlations for design purposes.

Within the 0-0.0017M range of nickel concentration studied, the results indicate that the boundary layer is the major resistance to nickel transport. Membrane resistance is important only at high flow rates and high concentrations. A series model was employed to estimate the relative importance of these two resistances under different experimental conditions.

The boundary-layer effect is characterized by mass transfer correlations based on a mass balance for the dialyzer. In dimensionless quantities, these correlations are given by

$$\mathrm{Sh} = 0.00272\, \mathrm{Re}^{1.024}\, \mathrm{Sc}^{1/3} \qquad 10^3 < \mathrm{Re} < 10^4$$

$$\mathrm{Sh} = 0.1663\, \mathrm{Re}^{0.475}\, \mathrm{Sc}^{1/3} \qquad \mathrm{Re} < 10^3$$

and the exponents are in reasonable agreement with values in the literature.

The membrane interdiffusion coefficient ($\bar{D}_{Ni-H}$) can be estimated by extrapolation, using data at high flow rates. Its magnitude (10^{-6} cm²/sec) agrees with the range reported in literature for other metal ions. As Lake and Melsheimer (4) have indicated in their work, the extrapolation technique gives more reliable results at high concentrations. However, at high concentrations, the membrane and the acid-side boundary layer may contribute significantly to the nickel transfer rate, and study of this more complex system is beyond the scope of this work.

Photoelectrochemical Properties of n-Type In_2O_3

J. F. McCann[1]

Chemistry Discipline, School of Physical Sciences, Flinders University, Bedford Park 5042, South Australia

and J. O'M. Bockris

Chemistry Department, Texas A & M University, College Station, Texas 77843

ABSTRACT

The electrochemical and photoelectrochemical properties of single crystal n-type In_2O_3 were examined in 1M NaOH and 1N H_2SO_4. The photocurrent-wavelength response indicated the absorption edge is an indirect transition of about 2.3-2.5 eV. The flatband potentials were determined from Mott-Schottky plots to be −0.72 and 0.22V (*vs.* SCE) in 1M NaOH and 1N H_2SO_4, respectively. The photocurrent from the n-In_2O_3 electrode was steady during 13 hr while illuminating the sample in 1M NaOH at 0.3V (*vs.* SCE).

A wide range of semiconductors have been investigated to assess their performance as photoelectrodes in solar photoelectrolysis cells (1). In this work we have applied standard electrochemical and photoelectrochemical techniques to examine single crystal n-type In_2O_3 electrodes. To the authors' knowledge the photoelectrochemical properties of n-type In_2O_3 have not been previously reported, although a study of the dark current-voltage characteristics has been published (2).

Experimental

Single crystals of In_2O_3 which had been grown by two different techniques were donated by Dr. J. H. W. De Wit of the Inorganic Chemistry Department, University of Utrecht, Utrecht, The Netherlands. The first sample was grown in a PbO-B_2O_3 flux as described elsewhere (3). Two electrical contacts were made by soldering indium onto the back of the crystal. The *i-V* relation was linear indicating that the In contacts were ohmic. The resistivity of this sample was determined as 0.004 Ω·cm. The color of pure In_2O_3 powder is light yellow, whereas this crystal was black. This observation suggests that the crystal had occluded impurities from the flux medium during its growth. In subsequent photoelectrochemical studies of this sample using medium intensity xenon irradiation (~ 26 mW cm^{-2}), the photocurrent was negligible as a function of applied voltage.

The second sample was an In_2O_3 single crystal grown from the vapor phase as described in Ref. (3). The crystal was green and was transparent. An indium contact was soldered onto the back of the crystal. The sample was then fabricated into an electrode by soldering a tin-coated copper wire to the indium contact and fixing the sample in a Teflon holder with epoxy. The resistivity of the sample was measured from a high frequency impedance plot and calculated as ~ 1200 Ω cm which was much higher than that of the flux grown In_2O_3 crystal. However, since the photoelectrochemical response of the electrode fabricated from the vapor grown crystal was substantial, the results reported in this study were derived from this sample.

A Wenking potential stepping motor control Model SMP 69 and a PAR Model 173 potentiostat fitted with a PAR Model 176 current-to-voltage converter were used to control the electrode potential and also to perform current-voltage scans. A 900W xenon lamp was used as the light source. An infrared absorbing filter (Oriel G-776-7100) was placed between the lamp and the cell to reduce heating effects. The illumination intensity was measured with a Hewlett-Packard Radiant Flux Detector Model 8334A. Monochromatic light was obtained by passing xenon light through a high intensity Bausch and Lomb scanning monochromator. Monochromatic light intensities were measured with a Carl Zeiss calibrated thermopile Model VT Q3/A. Capacitance measurements were made with the use of a General Radio impedance bridge Model 1608-A fitted with a General Radio tuned amplifier Model 1232A. The reference electrode was saturated calomel (SCE) and the counterelectrode was Pt. Rectified alternating photocurrent voltammograms were performed using the technique and apparatus to be reported elsewhere (4).

Results and Discussion

A flux grown n-In_2O_3 single crystal electrode examined in this study exhibited negligible photoelectrochemical activity. Other flux grown semiconductor electrodes including Fe_2TiO_5, $CoTiO_3$, and $PbTiO_3$ which were examined by the authors, but have not been reported here, have also lacked photoelectrochemical activity. It is probable that the absence of

Key words: indium oxide, photoelectrolysis, oxide electrochemistry, energy conversion.

significant photoelectrochemical responses for all of the above-mentioned flux grown single crystals is a direct consequence of the occlusion of flux impurities in the samples during the crystallization stages. The impurities act as recombination centers for photogenerated carriers according to the relation

$$\tau_p = (\sigma_p^{imp} V_p \rho_p^{imp})^{-1} \quad [1]$$

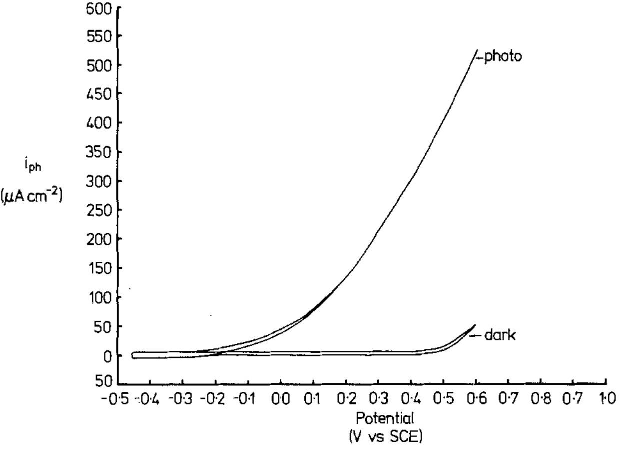
where τ_p is the hole lifetime, σ_p^{imp} is the capture cross section of holes by the impurity recombination center, V_p is the thermal velocity of holes, and ρ_p^{imp} is the density of impurity recombination centers. Clearly the larger the magnitude of ρ_p^{imp} the smaller the hole lifetime and subsequently the smaller the photocurrent. It is conceivable that for very large ρ_p^{imp}, as might be the case in the flux grown samples, that τ_p could become so short as to render the sample photoinactive.

Cyclic voltammograms of the vapor phase prepared n-In_2O_3 electrode were recorded using a voltage scan rate of 20 mV/sec both in the dark and under illumination from a 900W xenon lamp (26 mW cm^{-2}) in 1M NaOH and 1*N* H_2SO_4 and are shown in Fig. 1(a) and (b). The dark current was small in both electrolytes ($< 1.5 \times 10^{-5}$ A cm^{-2}) up to a critical positive applied voltage after which a steep increase in the anodic current was observed (presumably due to either dark H_2O_2 formation or O_2 evolution and/or dissolution). The d-c photocurrent commenced at about −0.2 and 0.6V (*vs.* SCE) in 1M NaOH and 1*N* H_2SO_4, respectively, and steadily increased as the applied voltage was increased in both instances. The hystereses of the dark curves and the illuminated curves were small.

The rectified alternating photocurrent-voltage (RAP-V) curves recorded using a voltage scan rate of 20 mV/sec in the forward direction in 1M NaOH and 1*N* H_2SO_4 are shown in Fig. 2(a) and (b), respectively. According to these relations, the photocurrent commences at −0.57 and 0.11V (*vs.* SCE) in 1M NaOH and in 1*N* H_2SO_4, respectively.

The shape of an RAP-voltammogram can be divided into two regions—the onset region and the plateau region. The plateau region represents the saturation of the tuned amplifier and does not refer to the saturation of the photocurrent at the semiconductor electrode. The onset region ideally represents the photocurrent near to the flatband potential of the semiconductor electrode. The differences between the onset of the photocurrent in the d-c photovoltammograms and the RAP-V curves (~0.37V in 1M NaOH and ~0.49V in 1*N* H_2SO_4) can be attributed to the fact that RAP voltammetry tends to be much less sensitive to the depression of the photocurrent due to surface recombination that occurs in d-c voltammetry. This arises because in RAP-voltammetry the illumination is modulated and the resulting modulated photocurrent is amplified by a large factor. Hence in RAP-voltammetry the onset of the photocurrent occurs at either the real flatband potential of the semiconductor, V_{FB} or at the potential close to V_{FB}.

The difference between the potential onsets of both the d-c photocurrent and RAP potential curves in 1M NaOH and 1*N* H_2SO_4 were 62 and 53 mV/*p*H unit,



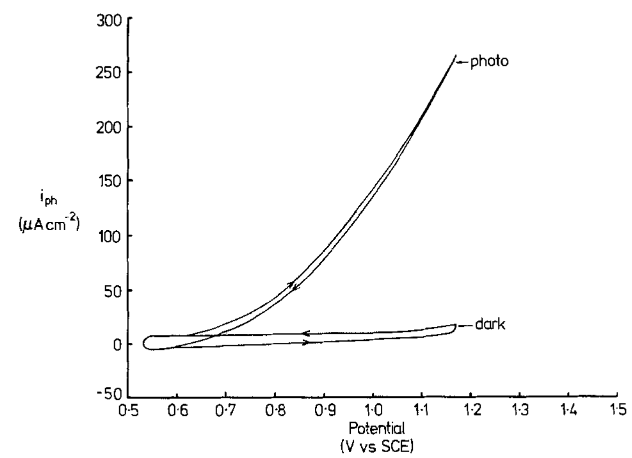


Fig. 1. Dark and photocurrent *vs.* voltage curves for n-In_2O_3 (a, left) in 1M NaOH and (b, right) in 1*N* H_2SO_4. Illumination intensity of xenon light 26 mW cm^{-2}.

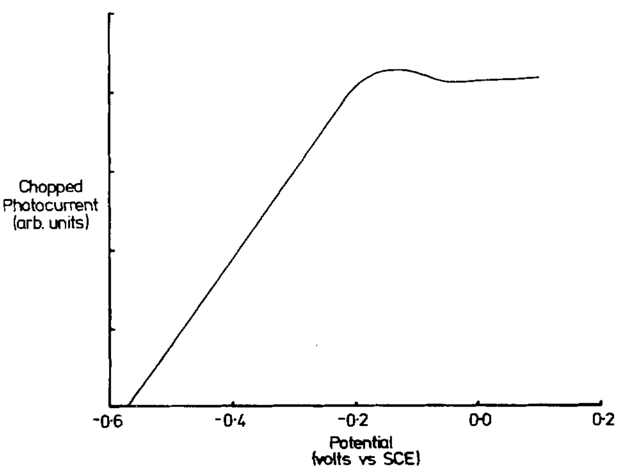

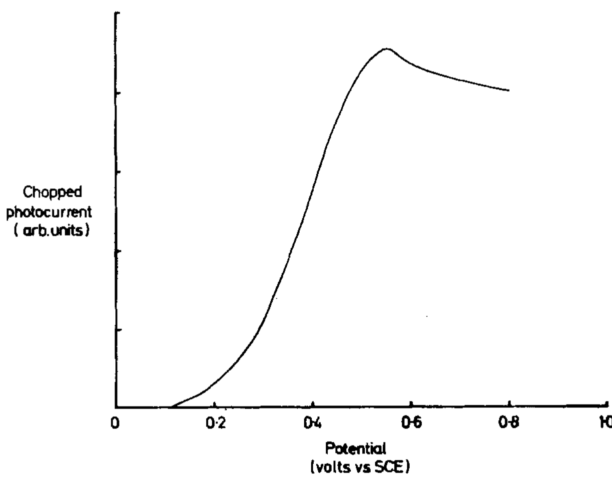

Fig. 2. Rectified alternating photocurrent voltammograms for n-In_2O_3 (a, left) in 1M NaOH and (b, right) in 1*N* H_2SO_4. Chopping frequency 70 Hz. Xenon light illumination intensity, 26 mW cm^{-2}.

respectively. These observations are consistent with a (*p*H dependent) Nernstian equilibrium of the following type occurring at the In_2O_3/electrolyte interface (5)

$$-\mathrm{In}-\mathrm{O}^- + \mathrm{H}^+ \rightleftarrows \mathrm{In}-\mathrm{OH}$$

The differences between the Nernstian predicted 59 mV/*p*H unit difference and the measured differences of 62 mV/*p*H unit and 69 mV/*p*H unit are attributed to experimental error. Typically the dark and d-c photocurrent-voltage curves of a stable conductor are reproducible and any hysteresis is slight. The hystereses of the dark and photocurrent *vs.* voltage curves for the In_2O_3 electrode were small over the potential ranges measured in both electrolytes [see Fig. 1(a) and (b)]. In addition, the curves were reproducible. These observations suggest that n-type In_2O_3 is a stable electrode in 1M NaOH and 1*N* H_2SO_4 within the limits of the potential ranges studied.

Spectral response curves were measured from 3000 to 5200Å for applied potentials of 0.45, 0.30, 0.10, and 0.0V (vs. SCE) in 1M NaOH. Quantum efficiencies were calculated as a function of wavelength using the relation (6)

$$\eta = \frac{i_{ph} - i_{dark}}{N_{ph}(0)} = \frac{\text{Number of photoelectrons}}{\text{Number of incident photons}} \quad [2]$$

where η is the quantum efficiency, i_{ph} and i_{dark} are the electrode current densities with and without irradiation, and $N_{ph}(0)$ is the incident photon intensity. The calculated quantum efficiency *vs.* wavelength curves are shown in Fig. 3 It is clear from these plots that for a specified wavelength less than the absorption edge the quantum efficiency is larger the greater the applied anodic potential. This is expected since the semiconductor depletion layer width widens as the anodic potential is increased resulting in a large number of photoholes reaching the semiconductor surface which raises the quantum yield. In the wavelength range 4000-5200Å, the photoconversion efficiency was always less than 2%. Below 4000Å, the quantum efficiency increased steadily and reached a maximum value at about 3100Å for all potentials. A significant proportion of the energy of the visible solar spectrum lies between 5200 and 4000Å (~33%). If n-type In_2O_3 was an efficient photoconverter in this wavelength range, then it could be considered as a serious prospect as a photoelectrode in a heterotype n-p photoelectrolysis cell. It is therefore appropriate to consider the most likely factors which may have caused the low conversion efficiencies observed in the visible wavelength range for the n-type In_2O_3 electrode examined in this study.

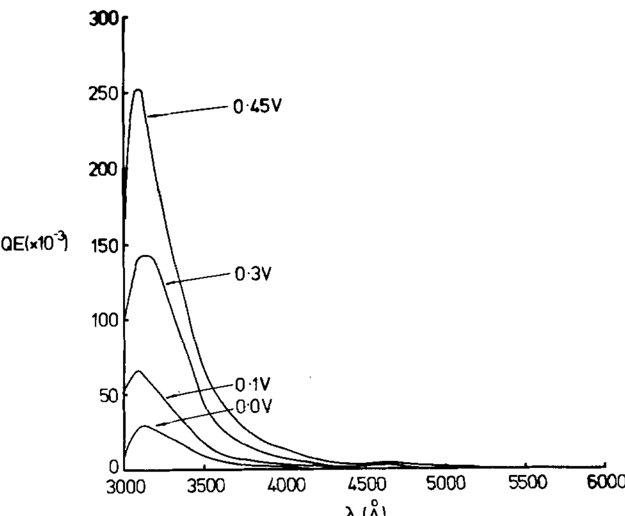

Fig. 3. Quantum efficiency vs. wavelength curves for n-In_2O_3 at 0.45, 0.30, 0.10, and 0.00V in 1M NaOH.

Normal incidence photons are absorbed in semiconductors according to the Bouguer-Lambert-Beer law

$$N_{ph}(x) = N_{ph}(0)e^{-\alpha(\lambda)x} \quad [3]$$

where $N_{ph}(x)$ is the photon flux after passing through x cm of semiconductor, and $\alpha(\lambda)$ is the absorption coefficient for a designated wavelength λ. The magnitude of $\alpha(\lambda)$ is an intrinsic property of a given material determined by the effective photon absorption cross section, $\sigma(\lambda)$, and by the concentration of the absorption centers, *N*, according to the relation (7)

$$\alpha(\lambda) = \sigma(\lambda)N \quad [4]$$

For indirect bandgap semiconductors, such as In_2O_3, the magnitudes of the $\alpha(\lambda)$'s are typically small in the wavelength region just less than the semiconductor absorption edge. It follows from Eq. [3] that for visible wavelength illumination, the majority of the holes photogenerated in an In_2O_3 electrode will be created deep inside the semiconductor. The smaller the value of $\alpha(\lambda)$, the greater the distance inside the semiconductor that an average photohole is formed and the higher the probability that it will recombine before it can reach the surface and react. The recombination rate in an illumination n-type semiconductor is mainly dependent on the values of the hole lifetime and the hole mobility. The values of the hole mobility and hole lifetime in a given semiconductor are affected by the densities of stacking faults, dislocations, and defects and by the concentration of impurities. Therefore, their values vary from sample to sample and they are determined to a significant extent by the method used to prepare the semiconductor electrode. Since the spectral response of only one sample of n-In_2O_3 has been measured, it follows that further experiments need to be performed on other samples of n-In_2O_3 prepared by various methods, to ascertain whether the mobility and lifetime and hence whether the quantum efficiencies of this semiconductor can be increased significantly for the wavelength range between 4000 and 5200Å.

For a wide bandgap semiconductor/electrolyte junction the quantum efficiency is related to the photon energy by (8)

$$\eta \alpha \frac{(h\nu - E_g)^{n/2}}{h\nu} \quad [5]$$

where $h\nu$ is the photon energy, E_g is the energy gap, and n is a parameter whose value depends on the nature of the optical transition ($n = 1$ for a direct transition and $n = 4$ for an indirect transiiton).

A plot of $(\eta h\nu)^{1/2}$ *vs.* $h\nu$ at an applied potential of 0.45V *vs.* SCE in 1M NaOH is shown in Fig. 4. The relationship is linear which confirms that the band transition for n-In_2O_3 is indirect, close to the absorption edge. The magnitude of the energy gap was determined as 2.27 eV from the $h\nu$ intercept of the plot. The values of the bandgap determined from similar plots to the one shown in Fig. 4 for applied potentials of 0.3, 0.1, and 0.0V (*vs.* SCE) were 2.32, 2.36, and 2.46 eV, respectively. A similar dependence of the value of the energy gap on the applied potential has been reported previously for WO_3 (14). The effect was attributed to potential induced crystallographic distortions. It is the latter phenomenon that may also be responsible for slight discrepancies between the values determined for the energy gap by the photoelectrochemical method and those determined by solid-state absorption or reflection techniques in which there is no applied potential. For example, in this instance the value reported for the energy gap of In_2O_3, which was determined by solid-state techniques, of 2.6 eV (11) differs slightly from the values of 2.27-2.246 eV deter-

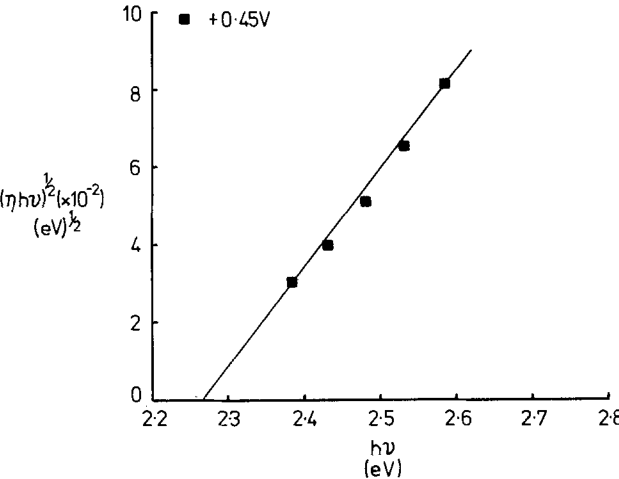

Fig. 4. $(\eta h\nu)^{1/2}$ *vs.* $h\nu$ relationships for n-In_2O_3 at 0.45V in 1M NaOH.

mined in the present study by the photoelectrochemical method.

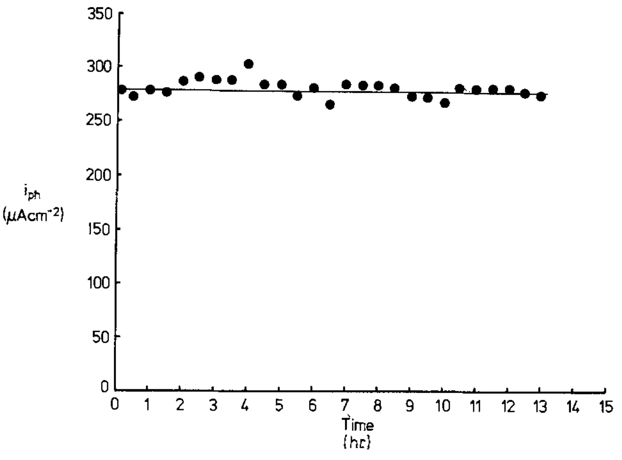
The photocurrent for n-In_2O_3 in 1M NaOH was monitored over 13 hr for an applied potential of 0.3V (*vs.* SCE) in 1M NaOH and a xenon light illumination intensity of 26 mW cm^{-2} in 1M NaOH. The photocurrent density (275 $\mu A\ cm^{-2}$) did not deteriorate during the experiment [see Fig. 5(a)]. In addition, there was no apparent visible change in the electrode surface at the completion of the experiment. In another i_{ph} *vs.* t experiment under similar conditions (0.3V, xenon irradiation intensity of 26 mW cm^{-2}, 1M NaOH) over 20 hr, the photocurrent density did not deteriorate and the weight of the electrode remained constant. The photocurrent was also monitored for n-In_2O_3 in 1*N* H_2SO_4 over 10.5 hr at an applied potential of 0.6V and a xenon illumination intensity of 26 mW cm^{-2} [see Fig. 5(b)]. In this experiment, the photocurrent density dropped from about 6 $\mu A\ cm^{-2}$ to 5 $\mu A\ cm^{-2}$ after 2 hr and then remained steady for 3.5 hr. There was no visible change in the electrode surface at the end of the experiment.

The stability of the photocurrent as a function of time as well as the reproducibility and slight hysteresis of the dark and photocyclic voltammograms suggest that n-In_2O_3 is a stable photoelectrode in 1M NaOH. In 1*N* H_2SO_4, the n-In_2O_3 electrode examined in this study was semistable at low photocurrent densities. However, since In_2O_3 is slightly soluble in solutions of low *p*H, it would be impractical to consider it as a possible photoelectrode in acidic electrolytes.

The capacitance of the system n-In_2O_3/electrolyte/platinized Pt was determined as a function of electrode potential in 1M NaOH and 1*N* H_2SO_4 at both 10 and 20 kHz. The flatband potentials were determined from the linear plots of $1/C^2$ *vs.* V shown in Fig. 6(a) and (b) as −0.72 and 0.22V (*vs.* SCE) in 1M NaOH and 1*N* H_2SO_4, respectively, a difference of 72 mV/*p*H unit. The capacitance in both electrolytes was dependent on frequency [see Fig. 6(a) and (b)]. According to Dutoit *et al.* (9) this behavior originates from dielectric relaxation phenomena in the semiconductor. The flatband potential for an n-type semiconductor is given by

$$V_{FB} \approx EA + \Delta_{fc} - E_0 + \Delta_{pH} \quad [5]$$

where EA is the electron affinity of the semiconductor, E_0 is the potential of the reference electrode relative to vacuum level, Δ_{fc} is the difference between the doped Fermi level and the bottom of the conduction band,



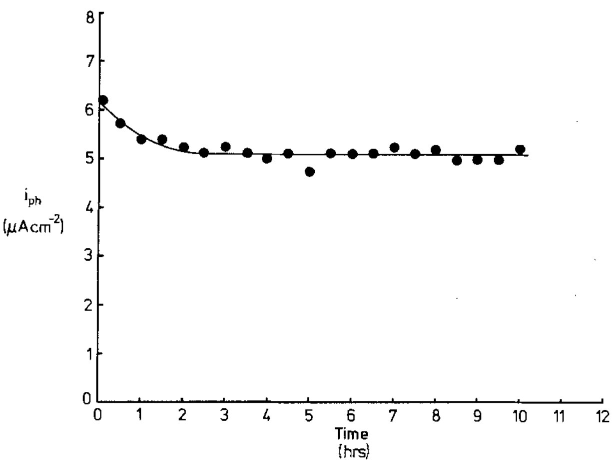


Fig. 5. Photocurrent-time relationships for n-In_2O_3 (a, left) in 1M NaOH (0.3V *vs.* SCE) and (b, right) in 1*N* H_2SO_4 (0.6V *vs.* SCE). Illumination intensity of xenon light 26 mW cm^{-2}.

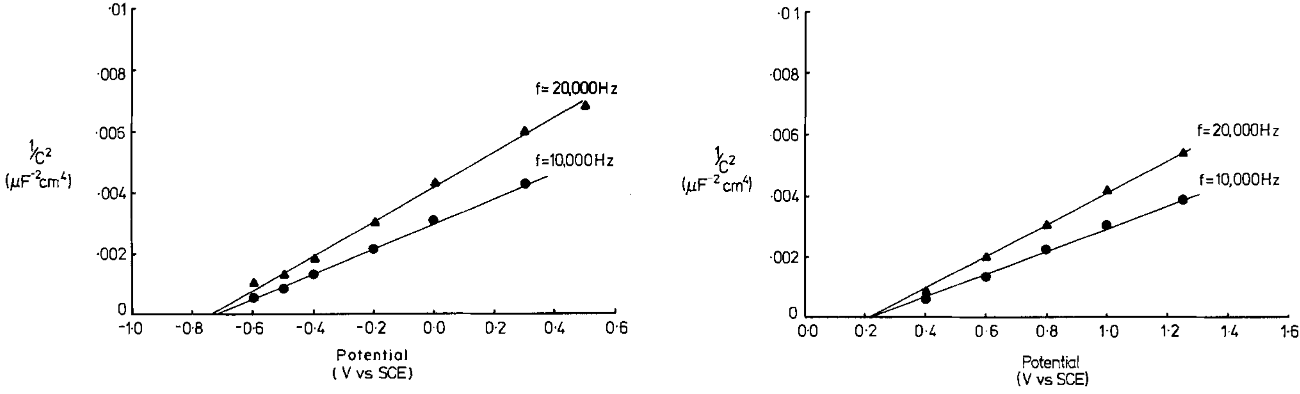

Fig. 6. Mott-Schottky plots for n-In_2O_3 (a, left) in 1M NaOH and (b, right) in 1*N* H_2SO_4

and Δ_{pH} is the correction term due to the net surface charge of the adsorbed species on the electrode surface (this term may be neglected at the zeta potential of zero charge).

The electron affinity was calculated with the usual relation (8)

$$EA = \chi(In_2O_3) - \frac{1}{2} E_g \quad [6]$$

where $\chi(In_2O_3)$ refers to the electronegativity of In_2O_3 determined from

$$\chi(In_2O_3) = [\chi^2(In)\chi^3(O)]^{1/5} \quad [7]$$

The pH where the zeta potental is zero (pzzp) was estimated to be 12.5 from a correlation between the electronegativity and pH that has been reported by Butler and Ginley (10). The calculated V_{FB} and the value of V_{FB} at pzzp determined by interpolating the experimental values obtained for V_{FB} in 1M NaOH and 1N H_2SO_4 together with the value of each parameter used in the calculation are listed in Table I. The calculated value of −0.61V (*vs.* SCE) agrees satisfactorily with the experimentally interpolated value of −0.66V.

The minimum bias required for photo-oxygen evolution on an n-type semiconductor in a Schottky-type photoelectrolysis cell, $V_{n\text{-min bias}}$, when the flatband potential, $V_{n\text{-FB}}$, is more positive than the $2H^+/H_2$ redox potential, V_{2H^+/H_2} is

$$V_{n\text{-min bias}} = V_{n\text{-FB}} - V_{2H^+/H_2} \quad [8]$$

Substituting either −0.72V (from Mott Schottky plots) or −0.57V (from RAP voltammetry) for the $V_{n\text{-FB}}$ of In_2O_3 and −1.03V for V_{2H^+/H_2} in 1M NaOH, into Eq. [8] values of 0.31 and 0.46V, respectively, are obtained. Hence the minimum bias required for an n-In_2O_3/1M NaOH/Pt cell to decompose water is in the range 0.31-0.46V. On the other hand, it may be possible to use n-In_2O_3 in an n-p photoelectrolysis cell without applying a bias provided a stable p-type semiconductor is used whose onset potential for H_2 evolution is more positive than −0.72V in 1M NaOH.

Summary and Conclusions

The electrochemical and photoelectrochemical properties of an n-type In_2O_3 single crystal electrode have been studied. The spectral response and photocurrent-time curves obtained in this work suggest that In_2O_3 may be potentially useful as a photoelectrode in a solar photoelectrolysis cell. The flatband potentials have been determined in 1M NaOH and 1N H_2SO_4 from Mott-Schottky plots. The flatband potential (V_{FB}) determined from the calculated electronegativity of n-In_2O_3 agreed satisfactorily with V_{FB} at pzzp estimated by interpolating the experimentally determined V_{FB}'s.

Table I. Values of the parameters used to calculate the flatband potential of n-type In_2O_3 at the potential of zero zeta potential (pzzp) as well as the calculated and estimated V_{FB}'s

Parameter	Literature or calculated value	Estimated value from present experiments
$\chi(In_2O_3)$	5.24 eV	—
E_g	2.6 eV (11)	2.27-2.46 eV
EA	3.94 eV	—
E_o (*vs.* SCE)	4.55V (12, 13)	—
Δ_{fc}*	—	—
Δ_{pH}	—	—
$pH_{(pzzp)}$	12.5	—
V_{FB}(pzzp) (*vs.* SCE)	−0.61V	−0.66V

* The energy level difference between the conduction band and the Fermi level was neglected.

Mechanisms of Charge Transfer at the n-GaAs/Room Temperature Molten Salt Electrolyte Interface

P. Singh[*,‡] **and K. Rajeshwar**

Department of Electrical Engineering, Colorado State University, Fort Collins, Colorado 80523

ABSTRACT

Photoelectrochemical (PEC) characterization was carried out on n-GaAs electrodes in contact with a room temperature molten salt electrolyte comprising mixtures of $AlCl_3$ and n-butyl pyridinium chloride (BPC) in varying molar ratios. The ferrocene/ferricenium ion couple was used as the redox system in these studies. The barrier height for charge transfer, which determines the ultimate efficiency of any photovoltaic system, was determined from dark current-voltage measurements. These data were in good agreement with previously determined values from capacitance measurements. The residual barrier heights in the illuminated PEC system were determined from open-circuit voltage and short-circuit current densities using Schottky barrier theory. A simple method for estimating the reorganization energy (λ) of a redox system from dark current-voltage measurements is presented. A value of $\lambda = 0.23$ eV was thus deduced for the ferrocene/ferricenium ion couple in the $AlCl_3$-BPC electrolyte. The acidic $AlCl_3$-BPC electrolyte showed larger dark currents and inferior photoresponse relative to the case of n-GaAs electrodes in contact with basic electrolytes. Using the measured values of λ and the semiconductor bandedges, energy band diagrams were developed for the present PEC system as a function of electrolyte composition. The direct correlation which was seen between PEC performance and electrolyte composition is rationalized on the basis of these diagrams. The larger dark currents in the acid electrolytes were shown to result from greater overlap of the empty redox levels with the conduction bandedge in n-GaAs. On the other hand, in basic electrolyte systems, the filled redox levels overlap better with the n-GaAs valence bandedge leading to more efficient charge transfer on illumination. The role of surface states in mediating charge transfer and degrading PEC performance is discussed in this regard. A key finding of the present work is that the electrical behavior of semiconductor/electrolyte junctions is well described by Schottky barrier theory once the differences in the energy distribution in metals vis-à-vis electrolytes, are rationalized.

Photoelectrochemical (PEC) methods of solar energy conversion have been the topic of much discussion in recent years (1, 2). A major obstacle to practical applications of PEC devices is the photodissolution undergone by the semiconductor photoanode. Most small bandgap semiconductors are prone to photoanodic dissolution in contact with aqueous electrolytes (1). Attempts have been made, therefore, in recent years to construct PEC devices based on nonaqueous electrolytes (3-5). A promising class of solvents in this regard are the room temperature molten salts; these electrolytes offer the combined advantage of good electrical conductivity coupled with aprotic chemical characteristics (6). The feasibility of solar energy conversion in PEC devices, based on molten salt electrolytes, was demonstrated in this laboratory using a model system comprising the n-GaAs/$AlCl_3$-n-butyl pyridinium chloride (BPC) interface[1] (7). An attractive feature of the $AlCl_3$-BPC system is the possibility of varying the Lewis acid-base characteristics of the electrolyte over a wide range by suitable adjustment of the relative molar ratios of the two components. This immediately points toward strategies of modifying the potential and charge distribution across the electrode/electrolyte interface and thereby tailoring a particular system to optimum requirements for PEC applications. For example, in a PEC device, the barrier height which determines the ultimate photovoltaic efficiency is given by $V_{FB} - V_{redox}$, where V_{FB} is the flatband potential of the semiconductor and V_{redox} is the equilibrium redox potential. The more negative the V_{FB} value is with respect to V_{redox} for a given semiconductor/electrolyte junction, the greater will be the ultimate solar conversion efficiency. The V_{FB} values in the n-GaAs/$AlCl_3$-BPC system were found to shift in the negative direction at the rate of 120 mV/pCl[2] when the electrolyte was made more basic by the addition of BPC (8), while the redox potential of the ferrocene/ferricenium ion ($Fe(Cp)_2$/$Fe(Cp)_2^+$) couple was insensitive to electrolyte composition (7). From the above, this would imply a higher photovoltaic efficiency for devices based on basic electrolytes relative to the case of acidic $AlCl_3$-BPC mixtures. This was indeed found to be the case for the n-GaAs/$AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2^+$/C PEC system (7). In this paper, we present more detailed correlations of the PEC behavior with electrolyte composition for the above model system. A variety of PEC characterizations including dark current-voltage measurements were utilized to establish the degree of overlap of electrolyte energy levels with the corresponding electronic states in the semiconductor. A simple method of estimating the reorganization energy, λ, of a redox couple from dark current-voltage measurements is also presented.

Key words: photoelectrochemistry, Schottky barrier theory, Lewis acid-base equilibria.

[1] It is perhaps more correct to use the term "interphase" in place of "interface" because the semiconductor/electrolyte junction is not sharp and the region between the two is several angstroms thick. The two terms, however, are used synonymously in the following discussion bearing this distinction in mind.

[2] The magnitude of the shift in V_{FB} with pCl was found to be sensitive to the crystallographic orientation of the electrode surface exposed to the electrolyte. Thus the <111>-orientation showed a shift of 120 mV/pCl as compared to 60 mV/pCl for <100> orientations (9).

A secondary objective of this work was to examine the efficacy of the Schottky barrier model for semiconductor/electrolyte junctions (10), in which the electrolyte replaces the metal in a Schottky barrier. Two major differences exist in the electrical properties of a metal vis-à-vis an electrolyte: (*i*) charge transfer in a metal occurs via electronic conduction (*i.e.*, conduction by electrons or holes) whereas in an electrolyte, the conduction is ionic, and (*ii*) there is a continuum of electronic energy states below the Fermi level in a metal whereas the energy levels are more localized in an electrolyte [cf. Ref. (11)]. In this work, the dark current-voltage characteristics of the model system comprising the n-GaAs/$AlCl_3$-BPC interface were analyzed by equations conventionally adopted in the treatment of metal/semiconductor contacts (12). The selected variables were temperature and electrolyte composition. A key finding of the present work was that semiconductor/electrolyte junctions are reasonbly well explained by Schottky barrier theory once the differences noted above are taken into account.

Experimental

Wafers of single crystal n-GaAs (Te-doped, As-terminated <111> orientation, donor density: 2:17 × 10^{17} cm^{-3}) were obtained from commercial sources (Laser Diode Laboratories Incorporated, New Jersey). They were degreased with xylene, rinsed with methanol, and dried under nitrogen. They were then given a chemomechanical polish with 1% solution of bromine in methanol. Individual electrodes were scribed from these wafers after providing them with ohmic contacts consisting of thermally evaporated Ge-Au alloy on the back surface which was subsequently annealed in nitrogen at 450°C for 15 min. A Teflon-coated copper wire was attached to the contacts using conducting silver epoxy. The entire back surface and the edges of the electrodes were covered with nonconducting epoxy resin. The electrodes were etched in 10% HCl for 15 min to remove any native oxide and the damaged surface layers. This was followed by etching in H_2SO_4:H_2O_2:H_2O (3:1:1) for 15 sec. The electrodes were rinsed with deionized water and etched for 30 sec in 6M HCl. After rinsing with deionized water and ethyl alcohol the electrodes were dried under vacuum and then transferred into the dry box. The geometric area of the electrodes was nominally 0.10-0.25 cm^2. A vitreous carbon plate (nominal dimensions: 1.5 × 15 × 30 mm) was used as the counterelectrode in the PEC devices.

Molten salt electrolytes consisting of $AlCl_3$ and BPC in the 1:1 molar ratio were prepared according to procedures described elsewhere (7). Ferrocene was obtained from commercial sources and purified by extraction with petroleum ether and subsequent recrystallization. Ferricenium chloride was prepared using standard procedures (13). Nominal concentrations of $Fe(Cp)_2$ and $Fe(Cp)_2Cl$ in the electrolyte were 0.2M and 20 mmols, respectively. All manipulations with the electrolytes and redox chemicals were carried out in a dry box.

A 300W tungsten halogen lamp was used to illuminate the n-GaAs electrodes. The intensity of the light source was calibrated using a radiometer/photometer. The light intensities reported herein are not corrected for reflection and absorption losses in the cell and in the electrolyte.

Dark current-voltage measurements were performed using a PAR 173 potentiostat (Princeton Applied Research Corporation, Princeton, New Jersey) equipped with PAR 179 coulometer accessory. Three-electrode geometry was employed for these measurements. An aluminum wire immersed in the $AlCl_3$-BPC electrolyte (2:1 molar ratio) and separated from the main cell compartment by a fine-porosity glass frit was employed as the quasi-reference electrode. Photocurrent *vs.* potential data were obtained by using a Hewlett-Packard 721 A power supply in series with the PEC cell. The cell current was monitored by measuring the potential drop across a 10 kΩ resistor in series with the cell.

Results and Discussion

Barrier height from photocurrent-voltage measurements.—At the semiconductor/electrolyte interface, the net photocurrent generated in the semiconductor can be split into two components: current due to minority carriers generated within the depletion layer and that arising from carriers photogenerated in the bulk which diffuse into the depletion region (14). Based on arguments presented by previous authors, the net hole current density for an n-type semiconductor is given by the expression (14, 15)

$$J_p = -q\phi_o[\exp(-\alpha W) - 1] + q\phi_o\frac{\alpha L_p}{1+\alpha L_p}\exp(-\alpha W) + qp_o\frac{D_p}{L_p} \quad [1]$$

where ϕ_o is the photon flux, L_p is the hole diffusion length, D_p is the hole diffusion coefficient, W is the depletion layer width, α is the optical absorption coefficient, and p_o is the equilibrium hole concentration in the dark. The depletion layer width is given by the expression (15)

$$W = W_o(V - V_{FB})^{1/2} \quad [2]$$

where V is the applied potential relative to a reference electrode and W_o is a constant for a particular semiconductor given by the equation

$$W_o = \left(\frac{2\epsilon_s\epsilon_o}{qN_D}\right)^{1/2} \quad [3]$$

Here N_D is the semiconductor doping density, ϵ_s is the low frequency dielectric constant of the semiconductor, and ϵ_o is the dielectric permittivity of free space.

If the last term in Eq. [1], is neglected, rearrangement of Eq. [1], after substitution of Eq. [2] yields the following equation

$$J_p \simeq q\phi_o\left(1 - \frac{\exp[-\alpha W_o(V - V_{FB})^{1/2}]}{1+\alpha L_p}\right) \quad [4]$$

If the additional assumptions are made that $\alpha L_p << 1$ and $\alpha W_o (V - V_{FB})^{1/2} << 1$, the exponential term in Eq. [4] can be expanded to yield the following relation between photocurrent and applied potential (15)

$$V - V_{FB} \cong \left(\frac{J_p}{q\phi_o\alpha W_o}\right)^2 \quad [5]$$

According to Eq. [5], a plot of J^2 *vs.* V should be a straight line with an intercept on the potential axis given by V_{FB}. Figure 1 illustrates such plots for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2^+$|C system at two different light intensities. The electrolyte in this case was adjusted to be slightly on the basic side of the neutral (1:1 molar ratio, $AlCl_3$:BPC) composition. Although the straight line relationship is obeyed in apparent agreement with Eq. [5], two points are worthy of note: (*i*) the intercept shifts to more negative potentials with increasing light intensity and (*ii*) the value for V_{FB} obtained from the intercept is significantly positive of that obtained (−0.90 ± 0.05V *vs.* Al/Al^{+3}) from capacitance voltage measurements for the same electrolyte composition (7).

The above discrepancies can be rationalized on a reexamination of the assumptions underlying Eq. [5]. Assuming the following typical values for n-GaAs: $\alpha = 5 \times 10^4$ cm^{-1}, $D_p = 100$ cm^2/sec, $L_p = 10^{-3}$ cm (16), we obtain the ratio, $D_p/L_p = 10^5$ cm/sec. How-

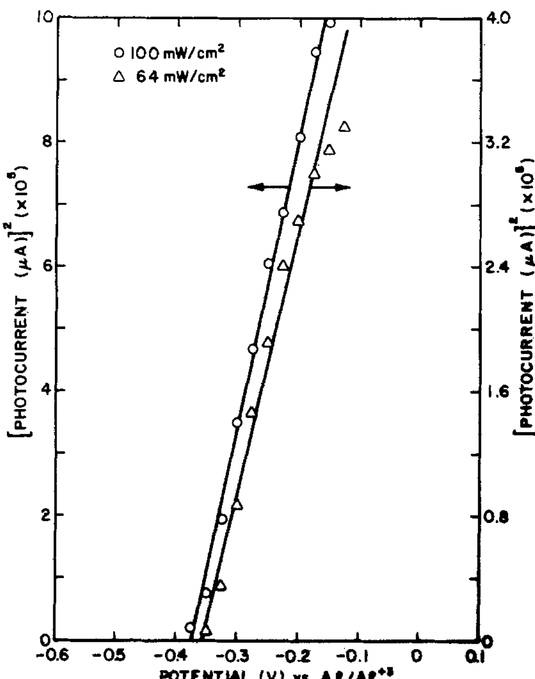

Fig. 1. Plot of square of the photocurrent vs. applied potential (cf. Eq. [5] in text) for n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|C system. The electrolyte was adjusted to be slightly on the basic side of the neutral 1:1 composition.

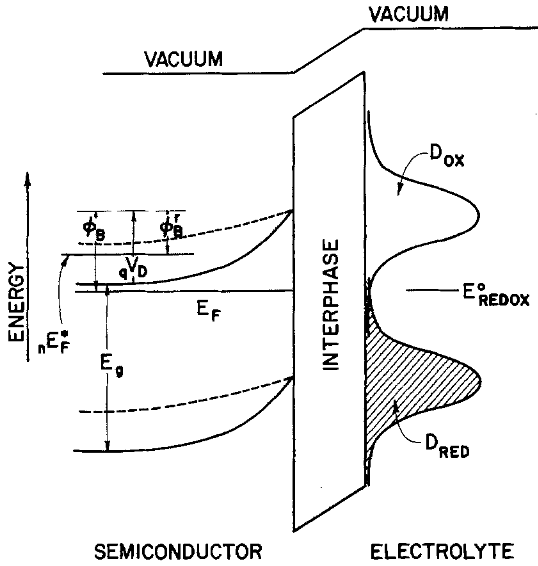

Fig. 2. Energy-band diagram for a semiconductor/electrolyte interface. The solid lines represent the dark (equilibrium) case and the dotted lines denote the interface under illumination. E_F = Fermi level in the dark, ${}_nE_F^*$ = quasi-Fermi level for majority carriers, E_g = energy bandgap. Other symbols are defined in the text.

ever, the equilibrium hole concentration p_o is negligibly small so that the above assumption that the term $qp_o\, D_p/L_p$ may be neglected in comparison with the first term in Eq. [1] is valid under normal operating conditions. On the other hand, $\alpha L_p = 50$ so that the assumption that $\alpha L_p << 1$ is clearly invalid in this case. Again taking $\epsilon_s = 10.9$ (16), $N_D = 2.2 \times 10^{17}/\text{cm}^3$, and $V - V_{FB} = 1\text{V}$, we obtain $\alpha W_o\, (V - V_{FB})^{1/2} \simeq 0.37$ so that the assumption that $\alpha W_o\, (V - V_{FB})^{1/2} << 1$ is reasonably valid. It is easily shown that Eq. [4] would yield a straight line relationship even if αL_p is not $<<1$, but now the intercept is no longer V_{FB} and is shifted from the "true" V_{FB} by a constant term.

The shift in intercept potentials toward more negative values with increasing light intensity (Fig. 1) suggests that the true V_{FB} will be attained only at very high light intensities (>>100 mW/cm²) when the energy bands in the semiconductor are completely flattened at the surface. The residual barrier height or the barrier height remaining under illumination (10) may be estimated in the following manner.

Consider the energy band diagram shown in Fig. 2. At equilibrium equal and opposite exchange currents, J_o, flow through the device such that the magnitude of J_o may be related to the barrier height, ϕ_B by the expression (12)

$$J_o = A^*T^2 \exp(-\phi_B/kT) \quad [6]$$

where T is the absolute temperature and A^* is the Richardson's constant given by the expression

$$A^* = \frac{4\pi m_e^* qk^2T^2}{h^3} \quad [7]$$

Here m_e^* is the effective mass of an electron, and the other terms have their usual significance.

Under illumination, electron-hole pairs are generated in the semiconductor by bandgap excitation (Fig. 2). The field across the barrier separates these pairs so that electrons move into the semiconductor bulk and the holes are drawn to the surface. A current density equal to J_{sc} and directly proportional to the incident light intensity, I_L is obtained under short-circuit conditions. We assume for the following analyses (*vide infra*) a current collection efficiency of unity such that there is no rate limitation for the discharge step at the interface. The approximation may then be made that $J_{sc} \cong J_L$ where J_L is the light-generated current density. Under open circuit, an equilibrium is established such that (10)

$$J_e = J_{sc} \quad [8]$$

where J_e is the current density for electron flow from the semiconductor into the electrolyte. Comparison of Eq. [6] and [8] yields the following relation between the short-circuit current density, J_{sc}, and the residual barrier height, $\phi_B{}^r$

$$J_{sc} = A^*T^2 \exp(-\phi_B{}^r/kT) \quad [9]$$

Values of $\phi_B{}^r$ computed from Eq. [9] are assembled in Table I for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|C system. A^* was taken to be 8.6 A cm^{-2} K^{-2} for these computations (12). Data are shown at three different light intensities and electrolyte compositions. The $\phi_B{}^r$ values show the expected decrease with increasing light intensity. Furthermore, even at an I_L value of 155 mW/cm², $\phi_B{}^r$ shows a nontrivial magnitude supporting the above interpretation of the data in Fig. 1.

The barrier height, ϕ_B, under equilibrium is given by $\phi_B{}^r + qV_{oc}$, where V_{oc} is the open-circuit voltage. Values for ϕ_B computed from calculated values of $\phi_B{}^r$ (Eq. [9]) and measured V_{oc} are also shown in Table I. A check for the internal consistency for these results is provided by a comparison of ϕ_B values in Table I with data obtained previously from capacitance measurements (7). As noted above the barrier height for a semiconductor/electrolyte interface in equilibrium is given by $q(V_{FB} - V_{redox})$. Using measured values for V_{FB} and V_{redox} of -0.90 and 0.30V (*vs.* Al/Al^{3+}), respectively, (7), we obtain a value for ϕ_B of 1.2 eV which is in good agreement with that shown in Table I for the slightly basic electrolyte.

The systematic increase in $\phi_B (=qV_{oc} + \phi_B{}^r)$ values in Table I with increasing light intensity is to be noted. The barrier height, ϕ_B, should be ideally independent of the value of I_L. We attribute this to the error involved in the computation of $\phi_B{}^r$ at high values

Table I. Residual barrier heights in the n-GaAs/$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$/C system as a function of light intensity and composition

Parameter	Composition								
	Slightly acidic			Neutral			Slightly basic		
I_L, mW/cm²	14	50	155	14	50	155	14	50	155
J_{sc}, 10^6 A/cm²	193	675	1550	308	1083	2710	340	1268	3350
V_{oc}, V	0.366	0.412	0.457	0.490	0.591	0.651	0.625	0.693	0.746
ϕ_B^R, eV	0.55	0.52	0.50	0.54	0.51	0.49	0.54	0.51	0.48
$qV_{oc} + \phi_B^R$, eV	0.92	0.93	0.96	1.03	1.10	1.14	1.17	1.20	1.23

of I_L when the above assumption that $J_{sc} \propto I_L$ breaks down. Charge transfer limitations at the n-GaAs/$AlCl_3$-BPC interface lead to departure from the linear dependence of J_{sc} on I_L so that the J_{sc} values that are actually measured are lower than they should be under conditions of infinite rate of charge transfer (*i.e.*, no carrier recombination). This behavior was observed in a previous study at I_L values above ~100 mW/cm² (17). The lowering of ϕ_B^r with increasing I_L is thereby reduced (*cf.* Eq. [9]) resulting in an artifactual increase in ϕ_B with increasing I_L (Table I).

Barrier height from dark current-voltage measurements.—The current-voltage characteristics of a semiconductor/electrolyte junction may be represented in terms of Schottky barrier theory by the equation (12)

$$J_e = J_o[\exp(qV/nkT) - 1] \quad [10]$$

Here J_e is the measured dark current density, J_o is the reverse saturation current density (Eq. [6]), and n is the junction identity factor. For bias voltages in excess of $3kT/q$, the last term in the bracket in Eq. [10] may be neglected so that J_o is given by the zero bias intercept of a linear plot of ln J_e *vs.* V whose slope is given by $1/n$. Such plots are shown in Fig. 3 for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|C system with temperature as a parameter.

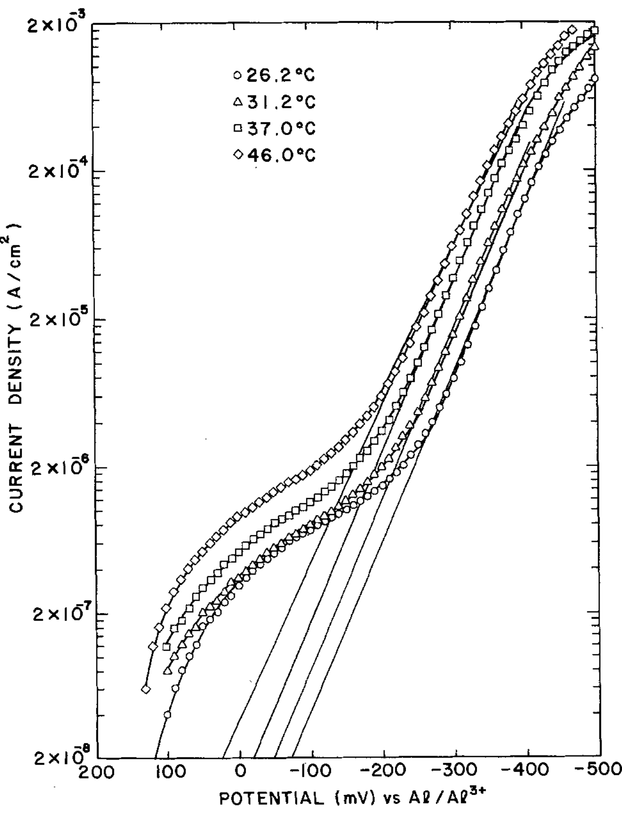

Fig. 3. Dark current-voltage characteristics of the n-GaAs/$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$/C system with temperature as a parameter. Electrolyte composition same as in Fig. 1. The cell potential zero lies at +170 mV (*vs.* Al/Al^{+3}).

The effect of the identity factor, n, on the current-voltage characteristics is clearly seen in the data in Fig. 3. An ideal device ($n = 1$) would show linear ln J *vs.* V characteristics. At low values of reverse bias, the voltage dependence of J_e is seen to slow down appreciably in Fig. 3. At large forward bias, on the other hand, the ln J-V characteristics depart from linear behavior because of series resistance effects (12). The intermediate voltage region yields a straight line region with an n value of ~1.5. Values of n greater than 1 are attributed to current-voltage behavior dominated by carrier recombination and generation effects either at the surface or in the semiconductor bulk (18). The above value of n is in good agreement with that deduced from previous measurements on the n-GaAs/$AlCl_3$-BPC system at varying light intensity (17).

Rearranging Eq. [6] and taking logarithms, we obtain

$$\ln(J_o/T^2) = \ln A^* - q\phi_B/kT \quad [11]$$

so that a plot of ln (J_o/T^2) *vs.* $1/T$ yields the barrier height and A^* from the slope and intercept, respectively. Figure 4 illustrates a typical plot for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|C system. The electrolyte was again adjusted to be slightly basic of the neutral 1:1 composition. Values of J_o at various temperatures were obtained from extrapolation of the straight-line region in Fig. 3 to zero cell potential. The barrier height, ϕ_B, obtained from the slope is 1.0 ± 0.1 eV which is in agreement with that obtained from photovoltage and capacitance measurements (*vide supra*) within limits of experimental error. The inter-

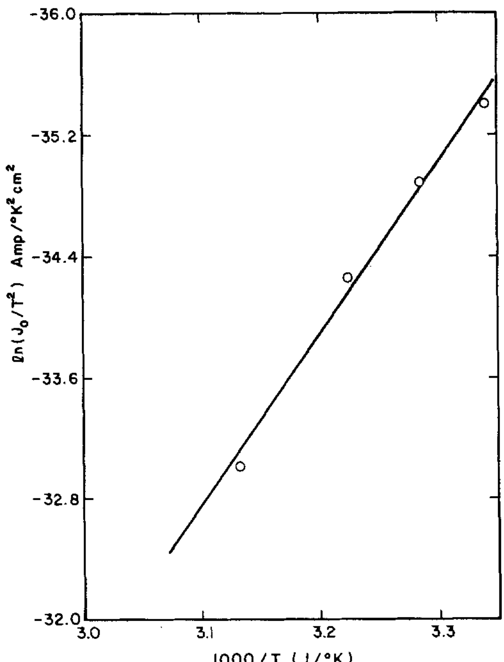

Fig. 4. Plot of ln (J_o/T^2) *vs.* $1/T$ (*cf.* Eq. [11] in text) for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|C system. Electrolyte composition same as in Fig. 1.

cept in Fig. 4 yields a value of $A^* = 9.6 \pm 0.2$ A cm^{-2} K^{-2}. This may be compared with $A^* = 8.6$ A cm^{-2} K^{-2} reported for n-GaAs-based Schottky barrier diodes (12).

It is noted here that the barrier heights obtained from capacitance measurements do not take into account image-force lowering (12), since the differential capacitance is determined by the width of the depletion region which depends only on the diffusion voltage, V_D, (cf., Fig. 2) and the donor density. On the other hand, barrier-height lowering by image forces is implicit in the analysis of current-voltage data and the quantity that is measured (cf., Eq. [9] and [11]) is actually $\phi_B^1 = \phi_B - \Delta\phi_{bi}$ (where $\Delta\phi_{bi}$ is the amount of barrier-height lowering). However, $\Delta\phi_{bi}$ is usually small (~0.1 eV) so that the accuracy of the present analyses does not warrant a distinction between ϕ_B and ϕ_B^1.

Reorganization energy of $Fe(Cp)_2/Fe(Cp)_2^+$ redox couple in the $AlCl_3$-BPC electrolyte.—An important parameter underlying the performance of PEC devices is the reorganization energy of the redox couple, λ, which determines the extent of separation of empty, D_{ox}, and filled energy levels, D_{red}, in the electrolyte (19). Ideally, λ should have a small value so that the degree of overlap of D_{ox} with the conduction band in the n-type semiconductor and, thereby, the extent of the deleterious back reaction is minimized. In order to assess the effect of variations in electrolyte composition (*vide infra*) on PEC performance, it is necessary to map the relative disposition of the electrolyte and semiconductor energy levels on a common energy scale. Since values of λ for the $Fe(Cp)_2/Fe(Cp)_2^+$ couple in the $AlCl_3$-BPC electrolyte were not available in the literature, a method was devised to estimate λ from dark current-voltage data.

The current flow associated with charge transfer between the semiconductor conduction band and D_{ox} is given by (20)

$$J_e = J_o \left[\exp\left(\frac{qV}{kT}\right) - 1 \right] \quad [12]$$

where the exchange current density, J_o, is given by the expression

$$J_o = q\overline{K}(E_c) \left(\frac{kT}{\pi\lambda}\right)^{1/2} \exp\left[-\frac{(E_c + qV_{redox} - \lambda)^2}{4\lambda kT} \right] \cdot c_{ox} n_{so} \quad [13]$$

Here, $\overline{K}(E_c)$ is the average transfer coefficient at the conduction bandedge (16), E_c is the conduction bandedge, c_{ox} is the concentration of oxidized redox species, and n_{so} is the surface concentration of electrons at equilibrium. Equation [13] may be rewritten as

$$J_o = AT^{1/2} \exp\left[-\frac{(E_c + qV_{redox} - \lambda)^2}{4\lambda kT} \right] \quad [14]$$

where the constant A is assumed to be temperature independent[3] and is given by

$$A = q\overline{K}(E_c) \left(\frac{k}{\pi\lambda}\right)^{1/2} c_{ox} n_{so} \quad [15]$$

Taking logarithms and rearranging Eq. [14], we have

$$\ln (J_o/T^{1/2}) = \ln A - \frac{(E_c + qV_{redox} - \lambda)^2}{4\lambda kT} \quad [16]$$

According to Eq. [16] a plot of $\ln (J_o/T^{1/2})$ *vs.* $1/T$ should be a straight line and λ may be estimated from the slope if E_c and V_{redox} are known. Figure 5 illustrates a typical plot for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|C system. Values for J_o were obtained from Fig. 3. From previously measured values, $V_{redox} = 0.3V$ (*vs.* Al/Al^{+3}) and $E_c \simeq qV_{FB} \approx -0.9$ eV (*vs.* Al/Al^{3+}) (7) and solving for the quadratic in the slope of Eq. [16], a value for $\lambda = 0.23$ eV was deduced. [The second root of the quadratic was too large (6.3 eV) to be of physical significance.]

[3] The charge-transfer coefficient $\overline{K}(E_c)$ is a function of temperature. The temperature range in the present study, however, is small enough that this dependence may be ignored.

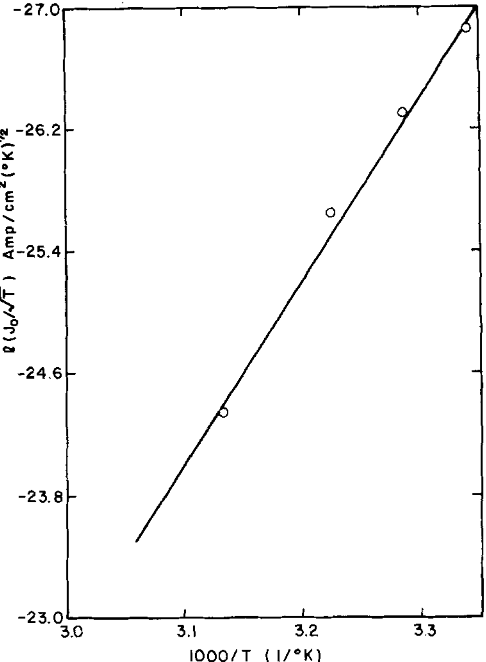

Fig. 5. Plot of ln $(J_o/T^{1/2})$ vs. 1/T (cf Eq. [16] in text) for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|C system. Electrolyte composition same as in Fig. 1.

Two points are worth noting here: (*i*) the above value of λ for the $Fe(Cp)/Fe(Cp)_2^+$ couple in the $AlCl_3$-BPC electrolyte is significantly lower than values observed in aqueous solutions [*e.g.*, $\lambda \simeq 1$ eV for $Fe(CN)_6^{3-/4-}$] (12). A value of 0.45 eV has also been recently reported for $Fe(Cp)/Fe(Cp)_2^+$ in ethanol (21), and (*ii*) the weak interaction and the relative insensitivity of V_{redox} for the $Fe(Cp)/Fe(Cp)_2^+$ couple in the $AlCl_3$-BPC electrolyte (7) to electrolyte composition suggest that λ does not vary significantly with the relative molar ratios of $AlCl_3$ and BPC. The lower values of λ for redox couples in aprotic solvents relative to aqueous solutions offer a significant advantage in the use of these electrolytes in PEC systems (*vide supra*) and is a consequence of the reduced degree of solvation in nonaqueous media in general.

Effect of electrolyte composition on current-voltage behavior.—In previous studies in this laboratory (7, 8), the location of the bandedges of n-GaAs electrodes was found to show a systematic variation with electrolyte composition in the $AlCl_3$-BPC system. The consequences of the observed negative shift in V_{FB} values for more basic electrolytes are threefold: (*i*) since V_{redox} is fixed, basic electrolytes are expected to show a higher photovoltaic output relative to acidic systems (*vide supra*), (*ii*) there is a critical electrolyte composition in the basic range beyond which photocurrent suppression (2) would result because of unfavorable matching of D_{red} of the $Fe(Cp)_2/Fe(Cp)_2^+$ couple with the valence bandedge in n-GaAs, and (*iii*) the degree of overlap of D_{ox} levels with the conduction bandedge in n-GaAs would be greater for the acidic electrolyte so that increased dark currents and consequent deterioration in photovoltaic output ensue.

Typical results illustrating the effects of (*i*) and (*iii*) above are shown in Fig. 6 and 7, respectively.

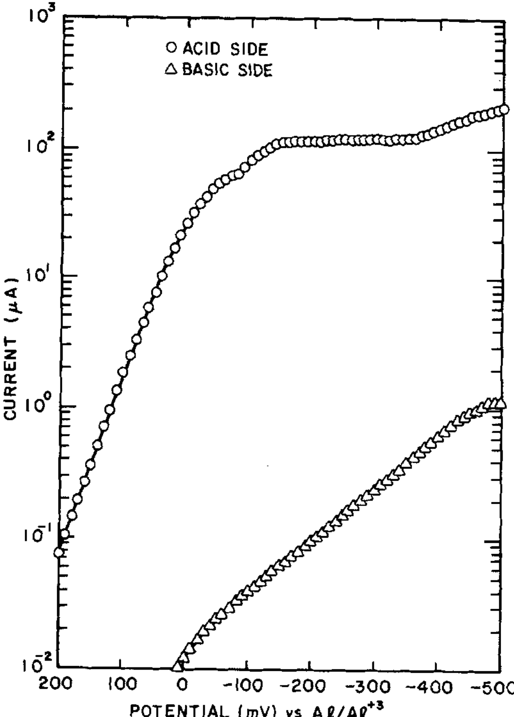

Fig. 6. Dark current voltage behavior of n-GaAs as a function of electrolyte composition. The electrolyte and redox couple were $AlCl_3$-BPC and $Fe(Cp)_2/Fe(Cp)_2^+$, respectively.

The same n-GaAs electrode was used in both the electrolytes for ease of comparison. The two electrolytes were adjusted to be slightly acidic and basic of the 1:1 composition by addition of small amounts of $AlCl_3$ and BPC, respectively. Further illustration of the direct correlation between electrolyte composition and photovoltaic performance is provided by the results shown in the last column in Table I. The barrier height increases in the order: slightly acidic < neutral < slightly basic. More basic electrolytes ($AlCl_3$:BPC molar ratio < 0.75:1) showed a deterioration in photovoltaic output consistent with (*ii*) above.

The above trends may be understood with the help of energy band diagrams shown in Fig. 8 where the relative positions of the semicondutcor energy levels and the redox energy distribution in the $AlCl_3$-BPC electrolyte are compared on a common potential scale for the basic electrolyte (Fig. 8a) and acidic case (Fig. 8b). The interphase layer is not shown in these diagrams for the sake of clarity. It is, however, pertinent to note that alterations in the potential distribution

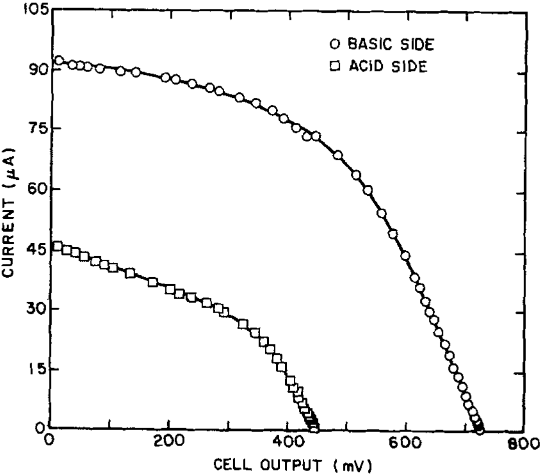

Fig. 7. Effect of electrolyte composition on the PEC behavior of the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|C system (8).

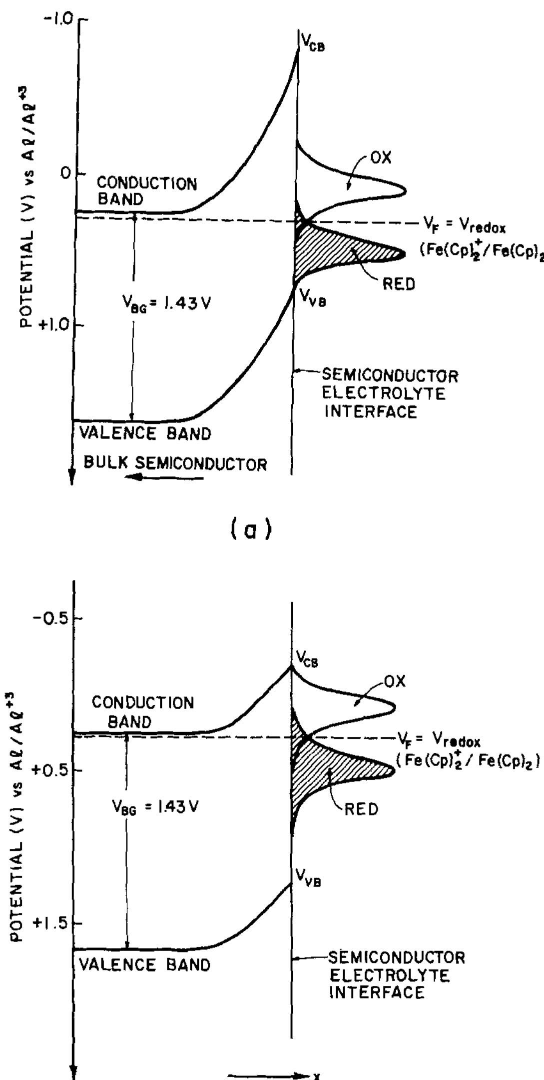

Fig. 8. Comparison of the relative position of the n-GaAs band-edges and the $Fe(Cp)_2/Fe(Cp)_2^+$ redox levels in (a) basic $AlCl_3$-BPC and (b) acidic $AlCl_3$-BPC electrolytes. The interphase is not shown for clarity.

across this layer brought about by specific ion adsorption (8) and other chemical interactions (*e.g.*, dissociation equilibria involving surface species) are undoubtedly an important factor in the observed shift in energy levels in the two cases (Fig. 8a and b).

Mechanisms of charge transfer at the n-GaAs/$AlCl_3$-BPC interface.—Based on the data presented above, the various charge transport mechanisms in the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|C system are schematized in Fig. 9. The filled circles represent processes taking place in the dark and the open circles denote light-assisted processes. It is emphasized that the two sets of charge-flow paths act in opposite directions and the greater the extent to which the filled circles are minimized in the device, the better will be its ultimate light conversion efficiency. This is accomplished to a greater degree in the basic $AlCl_3$-BPC electrolyte case relative to the acidic system for reasons discussed in the preceding section. The dark current processes labeled a, b, c, and d represent, respectively, thermionic emission of electrons from the semiconductor over the top of the barrier into the electrolyte, quantum-mechanical tunneling through the barrier, space-charge recombination-generation and recombination generation in the neutral region (12). The process labeled e denotes isoenergetic charge

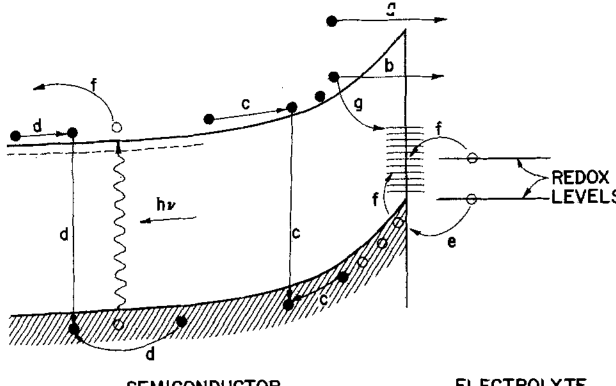

Fig. 9. Charge transport mechanisms at the illuminated n-GaAs/$AlCl_3$-BPC interface. The interphase and the distribution of energies in the redox system are not shown for the sake of clarity.

transfer between D_{red} and the valence bandedge in n-GaAs. This process is expected to be more predominant in the basic electrolyte case relative to the acidic electrolyte because of the relative positions of V_{redox} and V_{VB} (compare Fig. 8a and b). Additional processes in the illuminated n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2^+$|C system are the charge transfer paths f and g involving electronic states in the bandgap of the semiconductor. Evidence for mediation of surface states in the charge-transfer process was presented in a previous study where it was shown that dark reduction of the $Fe(Cp)_2^+$ ion occurred at potentials well positive of V_{FB} (7). Process f represents surface-state assisted photooxidation of solution species (D_{red}) by photogenerated holes in the semiconductor. Process g involves inelastic tunneling of an electron to the surface state where it reduces back the oxidized species. Alternatively, this process may be viewed as a recombination current involving photogenerated electron-hole pairs. Examination of Fig. 8 again suggests that processes f and g play a more dominant role in the charge-transfer dynamics in the acidic electrolyte relative to the basic $AlCl_3$-BPC system. All the processes described above with the exception of e and f have a deleterious influence on the photovoltaic output of the system. The propensity of processes a-d and g at the n-GaAs/$AlCl_3$-BPC interface was indicated by data from a previous study (17) and is also suggested by the current-voltage behavior shown in Fig. 3. Kinetics undoubtedly plays a major role and the more facile process f is, the greater will be the degree to which processes g, c, and d can be suppressed. Processes a, b, and g will play a dominant role at high values of forward bias. Process b is dependent to a large degree on the depletion layer width and on doping density (22).

The precise chemical nature of the surface states at the n-GaAs/$AlCl_3$-BPC system is not clear although we speculate that adsorbed Cl species induce electronic states in the n-GaAs bandgap [cf., Ref. (23)]. A tentative scheme for the sequence of photoprocesses in the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2^+$|C system offered below

$$2AlCl_4^- \underset{}{\overset{dark}{\rightleftharpoons}} Cl_{bulk}^- + Al_2Cl_7^- \quad [17]$$

$$Cl_{bulk}^- \overset{dark}{\rightleftharpoons} Cl_{ads}^- \quad [18]$$

$$Cl_{ads}^- + h^+ \overset{h\nu}{\rightleftharpoons} Cl_{ads}^{\cdot} \quad \text{(process f)} \quad [19]$$

$$Cl_{ads}^{\cdot} + Fe(Cp)_2 \overset{h\nu}{\rightleftharpoons} Fe(Cp)_2^+ + Cl_{ads}^- \quad [20]$$

$$Cl_{ads}^{\cdot} + e \overset{dark}{\rightleftharpoons} Cl_{ads}^- \quad \text{(process g)} \quad [21]$$

$$Fe(Cp)_2 + h^+ \overset{h\nu}{\rightleftharpoons} Fe(Cp)_2^+ \quad \text{(process f)} \quad [22]$$

$$Fe(Cp)_2^+ + e \overset{dark}{\rightleftharpoons} Fe(Cp)_2 \quad \text{(process g)} \quad [23]$$

The above scheme is consistent with several experimental observations: (*i*) equilibrium [17] lies far to the right in basic $AlCl_3$-BPC electrolytes (24) which explains the negative shift in V_{FB} for more basic electrolytes, (*ii*) the charge transfer under illumination is quite sluggish at the n-GaAs/$AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2^+$ interface (17). This is surprising because of the rapid kinetics typical of the $Fe(Cp)_2$/$Fe(Cp)_2^+$ couple in other electrolytes and suggests that electron transfer may be mediated via surface adsorbed $Cl^{\cdot}$ species (Eq. [20]), and (*iii*) cathodic current spikes are observed with chopped light indicating the back reaction of either $Cl_{ads}^{\cdot}$ or $Fe(Cp)_2^+$ via reactions [21] and [23]. Experiments are in progress in this laboratory to distinguish between reactions [19] and [20] representing the photoanodic processes and between [21] and [23] comprising the cathodic dark current flow.

Comparison of metal/semiconductor and electrolyte/semiconductor junctions.—The similarity of the current-voltage expressions in Schottky barrier theory (Eq. [10]) and the fluctuating energy level model (Eq. [12]) is worthy of note. The former has been conventionally applied to metal/semiconductor contacts (12) whereas the latter pertains to semiconductor/electrolyte junctions (19, 20). The major difference lies in the formal expressions for the exchange current densities (compare Eq. [6] and [13]) and underlines the aspects where the two approaches start to diverge from each other.[4] The thermionic-emission theory represented by Eq. [6] considers the control exercised on the current by the number of Bloch states in the metal which can communicate with corresponding energy levels in the semiconductor (12). On the other hand, the fluctuating level mechanism (Eq. [12]) explicitly takes into account the discreteness in the distribution of energy levels in the electrolyte in contrast to the metal case. The key question which the present study has attempted to address is whether it is valid to employ the two approaches in an interchangeable fashion in the treatment of semiconductor/electrolyte junctions once the above differences are rationalized. The present data show that it is. The following observations support this argument: (*i*) the forward-bias current-voltage behavior of semiconductor/electrolyte junctions show good adherence to Eq. [6] (Fig. 4), (*ii*) the V_{oc} values show the logarithmic dependence on I_L as predicted by Schottky diode equations (25), and (*iii*) values of A^* obtained from Eq. [6] for the n-GaAs/$AlCl_3$-BPC interface (*vide supra*) are in good agreement with those measured on GaAs/Au Schottky diodes (12).

Further analogies may be drawn on the effect of the interface layer on the electrical behavior of metal/semiconductor and electrolyte/semiconductor junctions. The role of this layer in modifying barrier heights in Schottky diodes is well recognized (26). This has led to the development of a class of devices based on metal-insulator-semiconductor (MIS) junctions wherein an interfacial layer is intentionally incorporated to improve the photovoltaic performance (27). The present data have clearly shown how changes in the interface layer can affect the PEC behavior of electrolyte/semiconductor junctions. This layer comprises the inner Helmholtz region and any

[4] It must be noted that the use of both Eq. [6] and [13] involves the implicit assumption that the processes of diffusion and drift of the electronic carriers within the semiconductor are not limiting the current flow at the semiconductor/electrolyte interface. Charge-transfer processes at the interface are assumed to be the major impediment to current flow.

surface layer on the electrode surface formed by prior treatment (*e.g.*, etching).

The Investigation of Current Doubling Reactions on Semiconductor Photoelectrodes by Temperature Change Measurements

Yasuhisa Maeda, Akira Fujishima,* and Kenichi Honda

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113, Japan

ABSTRACT

Current doubling effects in the photoanodic reactions of HCOOH or HCOONa on n-type semiconductor electrodes (ZnO, CdS, and TiO_2) and the photocathodic reaction of $(NH_4)_2S_2O_8$ on a p-type semiconductor (GaP) were studied by the measurement of the temperature change of a semiconductor electrode surface. The results of the temperature change measurements show that these photoelectrode reactions proceed with quantum efficiencies greater than 1 but less than 2. The temperature changes are interpreted in terms of the current doubling process.

Morrison *et al.* (1-4) proposed that the photoelectrochemical oxidation of the formic ion on a ZnO photoanode occurs by the current doubling mechanism, a two-step oxidation process. According to this mechanism, in the case of an n-type semiconductor electrode such as ZnO, a current doubling reagent R is first oxidized to $\overset{+}{R}\cdot$ by a hole photogenerated in the valence band, and then an electron from $\overset{+}{R}\cdot$ is injected into the conduction band and $\overset{+}{R}\cdot$ is converted to R^{2+}. In this case, the maximum value of the quantum efficiency for the photoelectrode reaction will be 2.0.

We have studied photoelectrochemical reactions at semiconductor electrodes by the temperature change technique and determined the quantum efficiencies and the energy efficiencies of the reactions (5-7).

In this paper, the current doubling phenomenon was studied by the direct measurement of the temperature change of the surface of a semiconductor electrode [n-type (ZnO, CdS, and TiO_2) and p-type (GaP)] to

* Electrochemical Society Active Member.

Key words: photoelectrochemistry, semiconductor electrode, quantum efficiency.

obtain the intrinsic quantum efficiency of the current doubling reaction and to elucidate the reaction mechanism.

When a semiconductor electrode is illuminated with a pulse of monochromatic light having an energy E (eV/photon) with an average absorbed intensity I (photons/sec) for a time t (sec), the relationship between temperature change and potential is represented by Eq. [1] which applies in a limited photocurrent region (5)

$$E\frac{\Delta T}{\Delta T^\circ} = \frac{Q_{s.c.} + T\Delta S}{It} + \eta e(V - V_{FB}) \quad [1]$$

where ΔT = temperature change of the semiconductor surface, ΔT° = temperature change of the semiconductor surface in the open circuit, ΔS = entropy change of the semiconductor electrode reaction, $Q_{s.c.}$ = heat evolved in the semiconductor via recombination and radiationless processes, η = quantum efficiency of the photoelectrode reaction, V = applied potential (V *vs.* reference electrode), V_{FB} = flatband potential (V *vs.* reference electrode).

Under conditions of constant illumination, *i.e.*, EIt = constant, a plot of $E(\Delta T/\Delta T^\circ)$ *vs.* $(V - V_{FB})$ yields the quantum efficiency, η, from the slope of the straight line, and information related to the electrode reaction heat is obtained from the intercept (the value of $E(\Delta T/\Delta T^\circ)$ at $V = V_{FB}$).

As reported in previous papers (5-7), the evaluation of the slope from the measurement of the temperature change for various photoreactions at semiconductor electrodes in the absence of a current doubling reagent yielded a maximum quantum efficiency of 1.0. However, in case of a photoelectrode reaction occurring by the current doubling mechanism, the temperature measurement is expected to yield a maximum quantum efficiency of 2.0.

Experimental

The experimental method was described in previous papers (5-8). The photothermal responses were obtained for the photoelectrodes during polarization and under open-circuit conditions in the electrolyte solutions. The temperature changes and the photocurrent were plotted as a function of the potential *vs.* flatband potential or the applied potential. The light source was a 500W high pressure mercury lamp (Ushio Electric). An interference filter was used to provide monochromatic light (340 nm), and a shutter was employed to fix the irradiation period precisely. The current-potential and current-time curves were measured under potentiostatic conditions using a potentiostat and a potential programmer (Nikko Keisoku). The semiconductors used were n-type polycrystalline ZnO, single crystal CdS [Teikoku Tsushin, $(000\bar{1})$], single crystal TiO_2 [Nakazumi Crystal, (001)], and p-type single crystal GaP [Sumitomo Metal Mining, (100)]. A platinum electrode was used as the counterelectrode and a saturated calomel electrode as the reference electrode. All chemicals were of reagent grade and were used without further purification.

To measure the temperature changes, we used a matched pair of thermistors (Shibaura Electronics, BSB4-41A). The thermistors were used in a differential arrangement with one held against the front surface of the semiconductor electrode and the other positioned behind the electrode but not touching it. The cell was carefully positioned so that the monochromatic light beam struck only the electrode and not the thermistors. The temperature change caused by irradiating the electrode resulted in a resistive change in the thermistors and a voltage imbalance in the d-c bridge. This small voltage was amplified and then displayed on a recorder.

Results and Discussion

ZnO-HCOOH.—In Fig. 1, a plot of $E\Delta T/\Delta T^\circ$ *vs.* applied anodic polarization potential is shown for the ZnO polycrystalline photoanode with and without formic acid. In the supporting Na_2SO_4 electrolyte solution, the photoelectrode reaction at the electrode/electrolyte interface is the dissolution of ZnO (9)

$$ZnO + 2p^+ \rightarrow Zn^{2+} + 1/2\,O_2$$

$E\Delta T/\Delta T^\circ$ increased linearly with anodic polarization, and from the slope of the line, the quantum efficiency of the ZnO photoanode was found to be 0.90, which was in close agreement with the value obtained by chemical actinometry (6, 7). Like this, quantum efficiencies of one-step oxidations can be obtained from the temperature method (5-7).

When sufficient quantity of formic acid was added, current doubling was observed. The quantum efficiency was found to be 1.8, which was twice as large as the value obtained in the supporting electrolyte. We propose the following current doubling mechanism

$$ZnO + 2p^+ \rightarrow Zn^{2+} + O^*$$

$$O^* + 2HCOO^- \rightarrow 2COO^{\bar{\cdot}} + H_2O$$

$$2COO^{\bar{\cdot}} \rightarrow 2CO_2 + 2e^-$$

$$ZnO + 2p^+ + 2HCOO^- \rightarrow Zn^{2+} + H_2O + 2CO_2 + 2e^-$$

because we have observed that with HCOONa present in solution the current efficiencies of the products of Zn^{2+}, O_2, and CO_2 are 0.5, 0.0, and 0.5, respectively, in accordance with the stoichiometry of the above equation (10). In these reactions, we have proposed O^* as an intermediate chemical species, which we have not proved directly. This mechanism is different from that proposed by other workers (1-4).

CdS-HCOONa.—In Fig. 2, plots of photocurrent and $E\Delta T/\Delta T^\circ$ *vs.* V applied to the CdS photoanode are

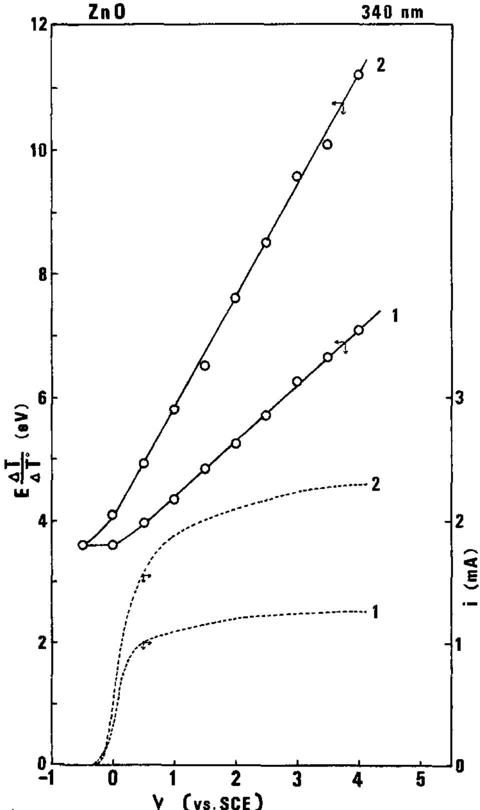

Fig. 1. Normalized temperature change *vs.* potential and photocurrent *vs.* potential of a ZnO polycrystalline electrode. Curve 1, 0.2M Na_2SO_4; curve 2, 0.3M HCOOH in 0.2M Na_2SO_4.

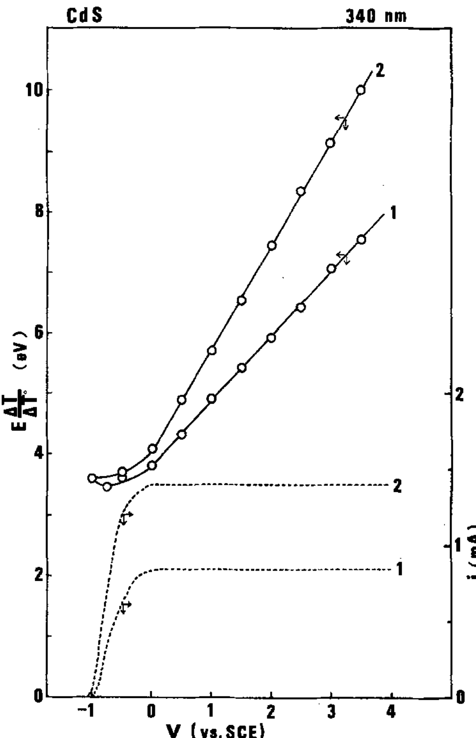

Fig. 2. Normalized temperature change *vs.* potential and photocurrent *vs.* potential of a CdS single crystal electrode. Curve 1, 0.1M Na_2SO_3 in 0.2M Na_2SO_4; curve 2, 0.5M HCOONa in 0.2M Na_2SO_4.

shown for the sulfate solutions containing either sulfite or HCOONa. In the supporting electrolyte we account for the photocurrent by a photoelectrode reaction of the dissolution of CdS

$$CdS + 2p^+ \rightarrow Cd^{2+} + S$$

In the case of Na_2SO_3 (curve 1), the photoelectrode reaction is the oxidation of $SO_3{}^{2-}$ which occurs only by a hole transfer reaction, but not the photodissolution reaction of CdS (11)

$$SO_3{}^{2-} + p^+ \rightarrow 1/2\, S_2O_6{}^{2-}$$

The quantum efficiency of the one-step reaction of $SO_3{}^{2-}$ was found to be 1.0 from the slope of the linear plot.

In the case of HCOONa (curve 2), the observed photocurrent was probably due to the oxidation of $HCOO^-$

$$HCOO^- + p^+ \rightarrow HCOO\cdot$$

$$HCOO\cdot \rightarrow CO_2 + H^+ + e^-$$

because the current efficiencies of Cd^{2+} and CO_2 formed were approximately 0.0 and 0.5, respectively. The quantum efficiency was found to be 1.7. The quantum efficiency was not 2.0, *i.e.*, double the value for Na_2SO_3 alone, probably because part of the intermediate species ($HCOO\cdot$) (12) formed in the first hole transfer reaction could not inject electrons into the conduction band.

TiO_2-HCOONa.—In Fig. 3, plots of photocurrent and $E\Delta T/\Delta T°$ *vs.* V for the TiO_2 photoanode are shown for electrolytes containing Na_2SO_4, with or without HCOONa. In the absence of HCOONa (curve 1), the photoelectrode reaction results in oxygen evolution. The quantum efficiency of the oxygen evolution reaction was found to be 0.53. [The quantum efficiency of the TiO_2 electrode was found to be dependent on the degree of reduction of the TiO_2 crystal resulting from a pretreatment to increase its conductivity (5).] An increase in the photocurrent was observed when HCOONa was added to the electrolyte. However, the amount of increased photocurrent was smaller than

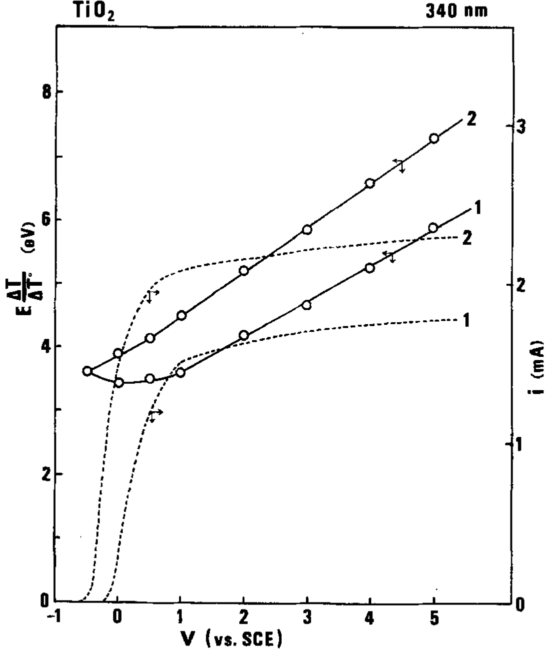

Fig. 3. Normalized temperature change *vs.* potential and photocurrent *vs.* potential of a TiO_2 single crystal electrode. Curve 1, 0.2M Na_2SO_4; curve 2, 1M HCOONa in 0.2M Na_2SO_4.

that in the case of ZnO or CdS, even when a large quantity of HCOONa was added. The observed photocurrent was also believed to be due to the oxidation of $HCOO^-$ as in the case of CdS, because oxygen formation measured by an oxygen meter could not be observed, but CO_2 was generated. However, we do not understand why the current doubling effect for TiO_2 is considerably smaller than that observed for ZnO and CdS. The quantum efficiency was found to be only 0.70.

GaP-$(NH_4)_2S_2O_8$.—As shown in Fig. 4, irradiation of the p-type GaP semiconductor electrode resulted in a cathodic current and $E\Delta T/\Delta T°$ increased linearly with the cathodic polarization in the sulfuric acid solution. The cathodic photoelectrode reaction was due to hydrogen evolution, and the intrinsic quantum efficiency was 0.75 as obtained from the slope of the linear relationship between $E\Delta T/\Delta T°$ and V.

When $(NH_4)_2S_2O_8$ was added to the sulfuric acid solution, the cathodic photocurrent increased. According to Memming (13), the photoelectrode reaction is due to the reduction of the persulfate ion through a two-step mechanism. The first step occurs by an electron transfer from the conduction band, and the second step by hole injection into the valence band

$$S_2O_8{}^{2-} + e^- \rightarrow SO_4{}^- + SO_4{}^{2-}$$

$$SO_4{}^- \rightarrow SO_4{}^{2-} + p^+$$

In this case, the slope of the $E\Delta T/\Delta T°$ *vs.* V plot was 1.5, a value twice as large as that obtained with only sulfuric acid. It was ascertained by the temperature measurement that the photoelectrode reaction of $(NH_4)_2S_2O_8$ on the p-type GaP electrode proceeded with high quantum efficiency.

Interpretation of the temperature changes from the current doubling mechanism.—The behavior of the temperature changes observed during the current doubling reactions can be explained by charge transfer in the space charge layer, as shown in Fig. 5. In the case of an n-type semiconductor, when the photogenerated electrons in the conduction band move from the surface of the electrode through the potential gradient of the space charge region to the bulk of the semiconductor, heat is produced in an amount depending on the polarizing potential and the electron current. Con-

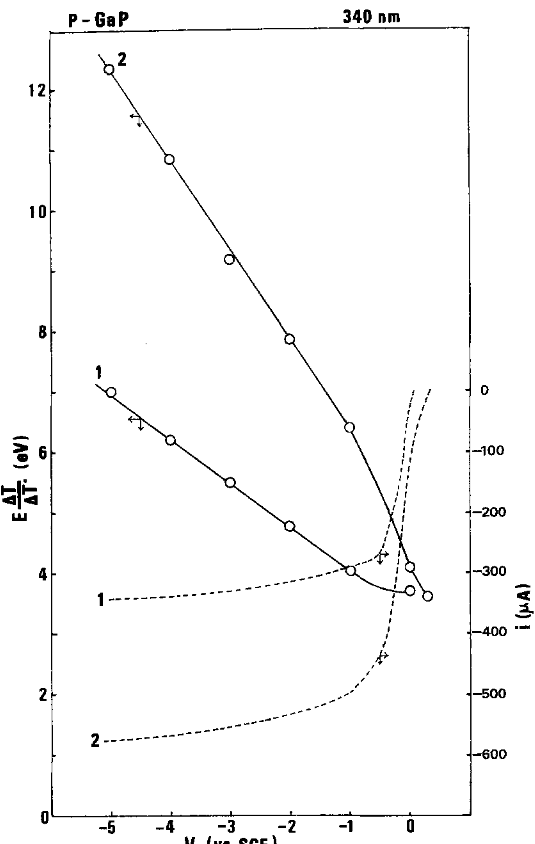

Fig. 4. Normalized temperature change vs. potential and photocurrent vs. potential of a p-type GaP single crystal electrode. Curve 1, 0.5M H_2SO_4; curve 2, 0.1M $(NH_4)_2S_2O_8$ in 0.5M H_2SO_4.

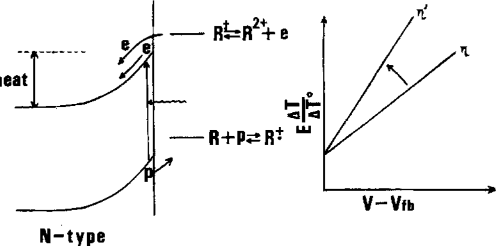

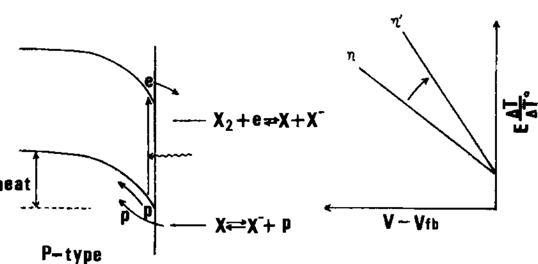

Fig. 5. The mechanism of current doubling, and the relation between the behavior of the temperature change and applied potential. (Upper left) For an n-type semiconductor, a current doubling reagent R is first oxidized by a photogenerated hole in the valence band to $R^{+}\cdot$ which then injects an electron to the conduction band. (Lower left) For a p-type semiconductor, a current doubling reagent X_2 is first reduced by a photogenerated electron in the conduction band to X and X^-, X then injects a hole to the valence band. η and η' are quantum efficiencies obtained from the plots of $E\Delta T/\Delta T^{\circ}$ vs. $(V - V_{FB})$ for both the n-type (upper right) and the p-type (lower right) semiconductors in the absence and the presence of a current doubling reagent, respectively.

sequently plots of $E\Delta T/\Delta T^{\circ}$ vs. $(V - V_{FB})$ (or V) increase linearly and their slopes are equal to the quantum efficiencies, as already mentioned.

Addition of a current doubling reagent, such as $HCOO^-$, caused the slope to nearly double except in the case of TiO_2. This fact can be interpreted by a mechanism in which heat is produced not only by the photoexcited electron flow, but also by the flow of the electrons injected from the intermediate chemical species. Namely, the increase in the slope is due to the increase in the number of electrons flowing within the conduction band.

In the case of a p-type semiconductor, the heat is produced by the photogenerated hole in the valence band flowing from the surface of the electrode to the semiconductor bulk. This heat becomes larger with the polarizing potential. Then, the plot of $E\Delta T/\Delta T^{\circ}$ vs. $(V - V_{FB})$ is a linear relationship similar to that of an n-type semiconductor. By the addition of $(NH_4)_2S_2O_8$ into the sulfuric acid supporting electrolyte, the slope nearly doubled, which shows that the second hole was injected from the intermediate chemical species formed as a result of the first electron transfer into the valence band.

These observations suggest that an increase in the slope results from electron injection into the conduction band for an n-type semiconductor electrode, and hole injection into the valence band for a p-type one.

The value obtained by extrapolation of the linear portion of $E\Delta T/\Delta T^{\circ}$ vs. $(V - V_{FB})$ plots to 0V (*i.e.*, $V = V_{FB}$) corresponds to $(Q_{s.c.} + T\Delta S)/It$. The heat of the electrode reaction thus obtainable may give information about the current doubling mechanism. This subject is currently under investigation.

In conclusion, the temperature measurement method proved to be useful for obtaining information about the current doubling effect.

The Measurement of the Flatband Potentials of n-Type and p-Type Semiconductors by Rectified Alternating Photocurrent Voltammetry

J. F. McCann[1] and J. Pezy

Chemistry Discipline, School of Physical Sciences, Flinders University, Bedford Park, 5042, South Australia

ABSTRACT

The flatband potentials (FBP's) of a number of n-type and p-type semiconductors have been measured by rectified alternating photocurrent voltammetry (RAPV). The values of the FBP's obtained by this technique have been compared with those obtained from capacitance-potential (*C-V*) measurements. A correlation was observed between the values of the respective FBP's obtained from RAPV and *C-V* measurements. The advantages of using RAPV to determine the FBP of a semiconductor are described.

The value of the flatband potential, V_{FB}, of an n-type or p-type semiconductor predetermines the maximum open-circuit photovoltage, $V_{oc}(\max)$ of a given semiconductor/electrolyte/counterelectrode cell according to the relation (1)

$$V_{oc}(\max) = V(\text{redox}) - V_{FB} \qquad [1]$$

where $V(\text{redox})$ is the redox potential of the electrolyte.

Therefore, in order to determine the $V_{oc}(\max)$ of a liquid junction photocell it is necessary to measure the V_{FB} of the semiconductor in the particular electrolyte used in the cell. In this report we describe how rectified alternating photocurrent voltammetry can be used to determine V_{FB} for an n-type or p-type semiconductor. Firstly, however, the limitations of some other methods that can be used to determine V_{FB} will be briefly discussed. The discussion is in terms of n-type semiconductor/electrolyte systems but the arguments are equally applicable to p-type semiconductor/electrolyte systems.

The capacitance of an n-type semiconductor with no surface states in an electrolyte is related to V_{FB} by the Mott-Schottky relation (2)

$$\frac{1}{C_{sc}^2} = \frac{2}{qD_\epsilon \epsilon_0 N_D}(V - V_{FB}) \qquad [2]$$

where C_{sc} is the capacitance of the semiconductor space charge layer, q is the electronic charge, D_ϵ is the dielectric constant of the semiconductor, ϵ_0 is the permittivity of a vacuum, N_D is the donor density, and V is the semiconductor potential. Strictly a kT/q term should also be included in the $(V - V_{FB})$ term but it is frequently neglected.

In practice the measured capacitance does not necessarily correspond to the exact value of C_{sc} due to the addition of other capacitances such as that of the Helmholtz layer, the Gouy layer, surface states, deep donor levels, and dielectric relaxation. Therefore, it would be advantageous to use an alternative method to check the value of V_{FB} derived from capacitance-potential studies.

An alternative method for measuring V_{FB} is from photocurrent-potential plots. Consider a typical n-type semiconductor/electrolyte/counterelectrode cell. Such a cell is depicted schematically in Fig. 1. Neglecting depletion layer recombination, the hole current reacting at an irradiated n-type semiconductor surface from the interior of the semiconductor, $i_p^{CT}(o)$ is

$$i_p^{CT}(o) = i_p^{DL} + i_p^{B} - i_p^{SR} \qquad [3]$$

where i_p^{DL} is the hole current generated in the depletion layer, i_p^{B} is the hole current at the depletion layer/bulk layer boundary, and i_p^{SR} is the surface recombination current. The following expression can be derived for $i_p^{CT}(o)$ [see Ref. (3) and (4)]

$$i_p^{CT}(o) = -P_{CT} q I_o \left(1 - \frac{e^{-\alpha W_o (V - V_{FB})^{1/2}}}{1 + \alpha L_p}\right) \qquad [4]$$

where I_o is the effective photon intensity, W_o is the depletion layer width for a potential drop of 1V across the depletion layer, α is the absorption coefficient, L_p is the hole diffusion length, and P_{CT} is the charge transfer probability given by (4)

$$P_{CT} = \frac{v_{CT}}{v_{CT} + v_{SR}} \qquad [5]$$

Equation [5] represents a form of Gartner's relation, Ref. (3), which has been modified to take surface recombination into account. For a more detailed treatment of charge transfer at semiconductor/electrolyte interfaces and the effect of the surface recombination velocity, the reader is referred to Ref. (5).

In cases where thermodynamic factors can be neglected, the potential onset of the d-c photocurrent, V_{onset}, will differ from V_{FB} when $v_{SR} >> v_{CT}$. The value of v_{SR} partially depends on the potential difference $(V - V_{FB})$. However, the way in which v_{SR} varies with $(V - V_{FB})$ is complex and not readily

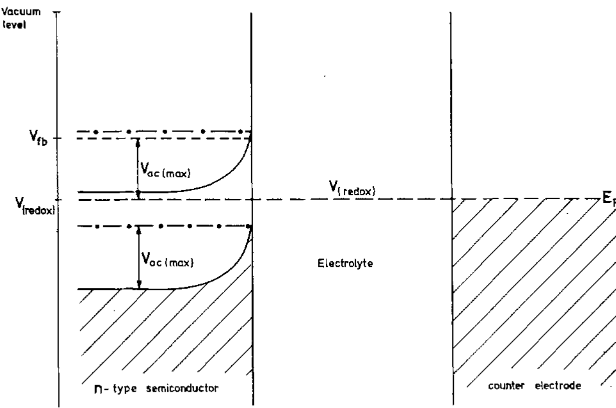

Fig. 1. Schematic diagram of an n-type semiconductor/electrolyte/counterelectrode cell.

[1] Present address: Physics Department, University of New South Wales, Kensington, N.S.W. Australia 2033.

Key words: photoelectrochemical, solar energy, semiconductor electrode, capacitance.

calculable without simplifying assumptions. Despite the problems associated with calculating the exact value of v_{SR}, it is known that v_{SR} usually decreases as $(V - V_{FB})$ increases [see, *e.g.*, Ref. (5)]. Hence it can be seen in a qualitative way from Eq. [4] that the magnitude of the difference $(V_{onset} - V_{FB})$ will depend on the initial magnitude of v_{SR} and how the value of the latter parameter changes with potential. These effects vary from sample to sample for a particular semiconductor material and also from semiconductor to semiconductor, since the number of surface recombination centers and their energy distribution are partially dependent on intrinsic factors such as crystal orientation and partially on surface preparation (5). Schematic quantum efficiency-potential relations with and without surface recombination effects which are shown in Fig. 2 qualitatively illustrate the effect of v_{SR} on the photocurrent-potential curve [see Ref. (5)].

It is apparent from Eq. [4] and Fig. 2 that it should be possible to determine V_{FB} from the V_{onset} of a photocurrent-potential plot even when P_{CT} is small if very small photocurrents are detected and monitored. Below a method is described for detecting V_{onset} using a simple but sensitive photocurrent detection circuit.

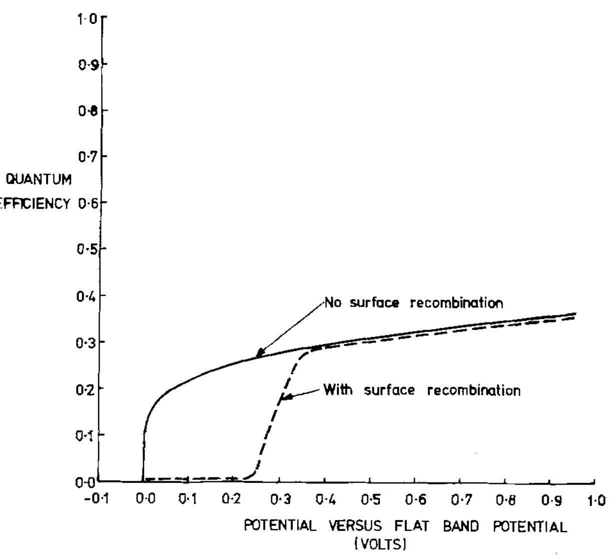

Fig. 2. Schematic diagram of the quantum efficiency-potential relations of an n-type semiconductor electrode with and without surface recombination.

Experimental

The method employed for measuring low photocurrents consisted of detecting a modulated photocurrent with a tuned amplifier, amplifying the signal, and plotting the rectified amplified photocurrent as a function of potential on an X-Y recorder. A schematic diagram of the experimental setup used for measuring rectified alternating photocurrent voltammograms (RAPV's) is shown in Fig. 3. The potential of the semiconductor electrode was controlled and the current measured with a PAR potentiostat (Model 173) fitted with a PAR current to voltage converter (Model 176). The potential was swept at the desired rate with respect to SCE by connecting the output of a Wenking SMP 69 potential stepping motor control to the external potential signal input of the potentiostat. An IR filter (Oriel Model G-776-7100) and a PAR mechanical light chopper (Model 175) operating at 70 Hz were interposed between the xenon light source (900W xenon lamp powered by a Canrad Hanovia

Fig. 3. Schematic diagram of the experimental setup for rectified alternating photocurrent-potential measurements

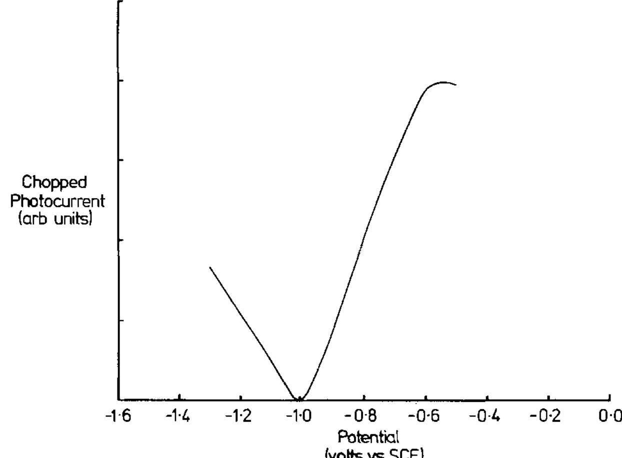
1000W power supply) and the semiconductor electrode in the electrochemical cell. The modulated photocurrent from the current to voltage converter was detected and amplified with a General Radio tuned amplifier (Model 1232-A), amplified with a power amplifier (Mini-Lab Model bwd 603A), rectified, filtered, and finally recorded on a X-Y recorder (Hewlett-Packard Model 7004B) as a function of potential. Measurements of d-c dark and photovoltammograms were made by using the appropriate instruments described above and the usual techniques. A conventional circuit described elsewhere (6) was used to measure the semiconductor electrode capacitance as a function of potential. A General Radio impedance bridge (Model 1608-A) was used in this circuit. Electrodes were fabricated by epoxying single crystals of InSe and p-type GaSe into Teflon holders which fitted into an electrochemical cell. Both electrodes were abraded and etched in conc. HNO_3 for 1 min and then rinsed in 10% W/V KCN to dissolve any excess selenium from the surfaces of the electrodes. A calcium titanate single crystal doped with 0.5 weight percent (w/o) NiO and 0.2 w/o Co_2O_3 was reduced in H_2 at 1000°C for 8 hr to make it electrically conducting before fabricating it into an electrode. Ohmic contacts were made to the three crystals using a 50:50 Ga:In amalgam. A wide variety of other n-type and p-type semiconductors have also been examined.

Results and Discussion

The values obtained for the flatband potentials of n,p-InSe, p-GaSe, and n-$CaTiO_3$ as determined by d-c photovoltammetry, capacitance voltage measurements, and RAPV are discussed below in detail to illustrate some features of RAPV.

In the case of the n,p-InSe electrode used in this study, the d-c photocurrent in 1M NaOH passed through an anodic-cathodic photocurrent transition at − 1.02V [see Fig. 4(a)]. Since the modulated photocurrent in RAPV is rectified, the RAP voltammogram should pass through a minimum at the voltage of the anodic-cathodic photocurrent transition. A minimum photocurrent was in fact observed in the RAP voltammogram of this electrode at − 1.0V as expected [see Fig. 4(b)]. This potential also corresponded to the value of the flatband potential (− 1.0V) determined from a Mott-Schottky plot [see Fig. 4(c)]. Hence for this particular indium selenide electrode the values of the flatband potential determined by the three methods under consideration were the same within the experimental error.

The d-c dark and photovoltammograms for a p-GaSe electrode in 1*N* NaOH are shown in Fig. 5(a). The onset of the d-c photocurrent occurred at about − 0.51V. Mott-Schottky plots and an RAP voltammogram for the p-GaSe electrode in 1M NaOH are shown in Fig. 5(c) and (b), respectively. A value of − 0.2V for the flatband potential was determined from these latter plots. This electrode represents a case where there is a significant discrepancy between the d-c photocurrent onset and the flatband potential. The discrepancy can be readily explained as being due to a surface recombination controlled $i_p^{CT}(o) - V$ relation. That is, between − 0.51 and − 0.2V the effective surface recombination velocity v_{SR} is large enough to cause the d-c photocurrent to be negligible in this potential range for the particular p-GaSe electrode which was examined. On the other hand, it proved possible with RAPV not only to detect the photocurrent between − 0.51 and − 0.2V but also to observe a cathodic-anodic photocurrent transition at − 0.2V [see Fig. 5(b)]. The observed potential at which the cathodic-anodic photocurrent transition occurs represents the potential at which the conduction and val-



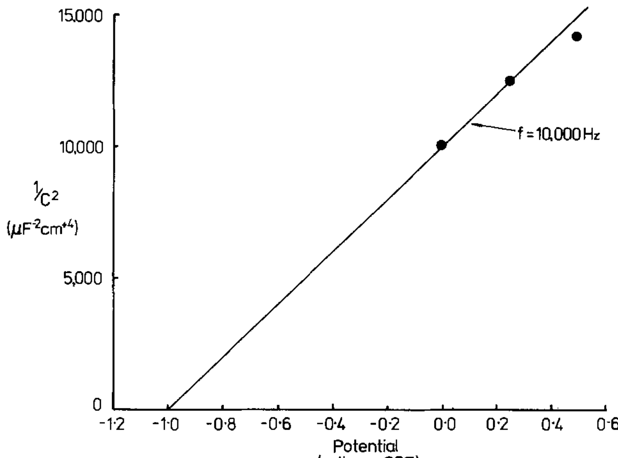


Fig. 4. Indium selenide electrode in 1M NaOH (a, top left) d-c dark and photocurrent-potential curves, (b, top right) RAPV voltammogram, and (c, bottom left) Mott-Schottky relation. Xenon illumination 26 mW cm^{-2}.

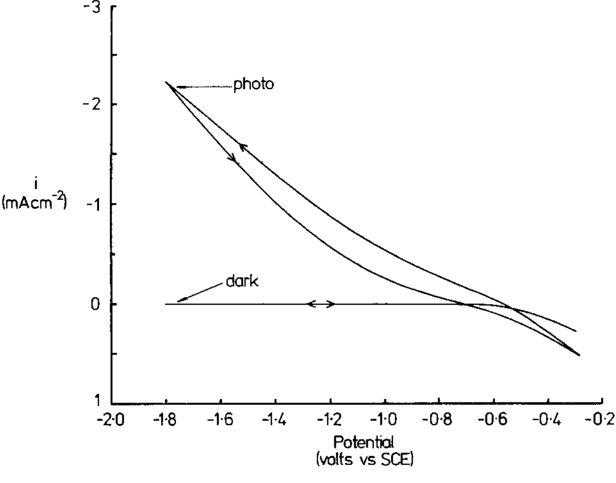

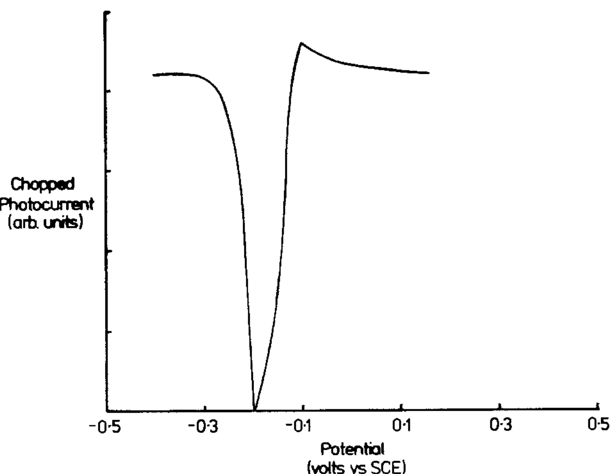

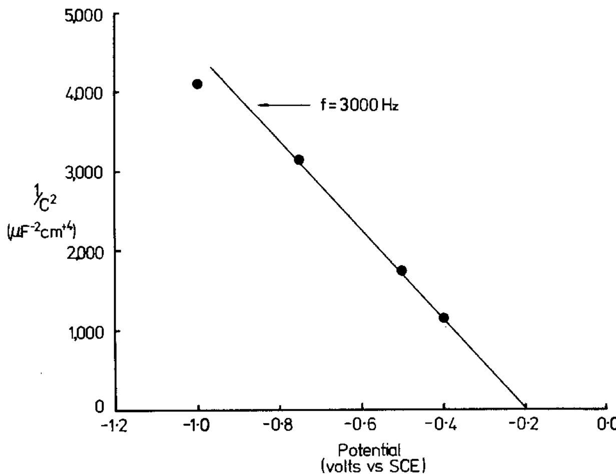

Fig. 5. Gallium selenide electrode in 1M NaOH (a, top left) d-c dark and photocurrent-potential curves, (b, top right) RAP voltammogram, and (c, bottom left) Mott-Schottky relation. Xenon illumination 26 mW cm^{-2}.

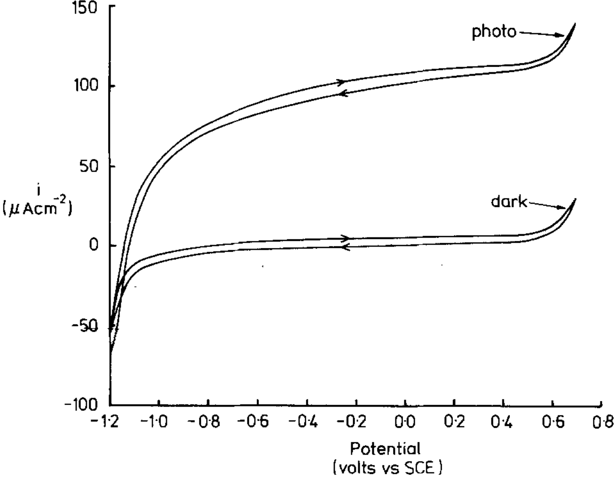
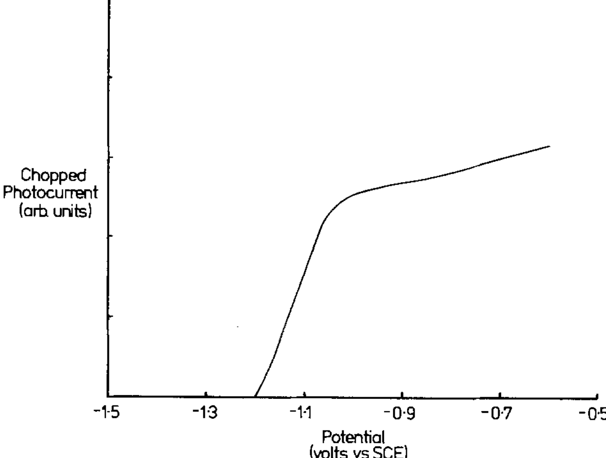
ence bands are flat, since for p-GaSe for potentials negative of − 0.2V the bands are bent up (*i.e.*, GaSe behaves as a p-doped photocathode) and for potentials positive of − 0.2V the bands are bent down (*i.e.*, GaSe behaves as a photoanode). Hence we have classified the potential of the cathodic-anodic photocurrent transition for p-GaSe, that is − 0.2V, as the V_{FB} of this particular sample of the semiconductor in 1M NaOH. This conclusion is supported by the experimental finding that the values of V_{FB} determined from Mott-Schottky plots (− 0.2V in 1M NaOH) coincided with the potential observed for the cathodic-anodic photocurrent transition. It is noted that Gerischer *et al.* (6) have reported the V_{FB} for p-GaSe as being about 0.5V and *p*H independent. The differences between the latter results and the present results which show a *p*H dependence are attributed to intrinsic differences and different surface pretreatments. In the present study the p-GaSe was not oriented but abraded and etched whereas in the previous study (6) the face exposed to the electrolyte was specifically chosen as either ||C or ⊥C axis. Similarly, the V_{FB}'s reported for InSe in this study refer to an abraded and etched electrode and not to an oriented sample.

Attention is drawn to the fact that although anodic-cathodic photocurrent transitions were observed for both InSe and GaSe electrodes, a distinction has been drawn between the doping concentrations of the two electrodes. Indium selenide has been classified as a highly doped both n-type and p-type semiconductor on the basis that the photocurrents were of such magnitudes at potentials both anodic and cathodic of the transition that they can be easily seen on the d-c photovoltammograms of this electrode [see Fig. 4(a)]. That is, n-type and p-type areas of the InSe electrode were in contact with the electrolyte giving rise to the observed behavior. However, for GaSe only a cathodic photocurrent was observable on the d-c photovoltammogram as would be expected for a p-doped semiconductor photocathode. The anodic photocurrent for this electrode was only detectable as a highly amplified modulated photocurrent [see Fig. 5(b)]. The latter observation is consistent with a low n-type character in the GaSe electrode. Therefore, for the GaSe electrode the potential of the cathodic-anodic photocurrent transition has been classified as the V_{FB} of a p-doped sample.

The d-c dark and photovoltammograms for an n-$CaTiO_3$ electrode in 1M NaOH are shown in Fig. 6(a). The potential onset of the d-c photocurrent occurred at about −1.16V. Mott-Schottky plots and an RAP voltammogram for the n-$CaTiO_3$ electrode in 1M NaOH are shown in Fig. 6(c) and (b), respectively. The values for the flatband potential determined from these plots were −2.09 and −1.2V, respectively. In this case the potential onset of the d-c photocurrent (−1.16V) agreed with that of the RAPV (−1.2V) indicating that for this sample of n-$CaTiO_3$, the v_{SR} was small in comparison to the v_{CT} or in other words the onset of the photocurrent was not appreciably controlled by surface recombination. The striking observations for this particular n-$CaTiO_3$ electrode were the large discrepancies between the value of V_{FB} determined by d-c and RAP voltammetry (−1.16 and −1.2V, respectively) and that determined from the Mott-Schottky plots (∼ −2.09V) of −0.93 and −0.89V, respectively. It appears in this instance that the intercepts of the Mott-Schottky plots for this particular n-$CaTiO_3$ electrode do not correspond to the real flatband potential of n-$CaTiO_3$.

On the other hand it seems that the values for V_{FB} determined by d-c and RAPV approximate to the





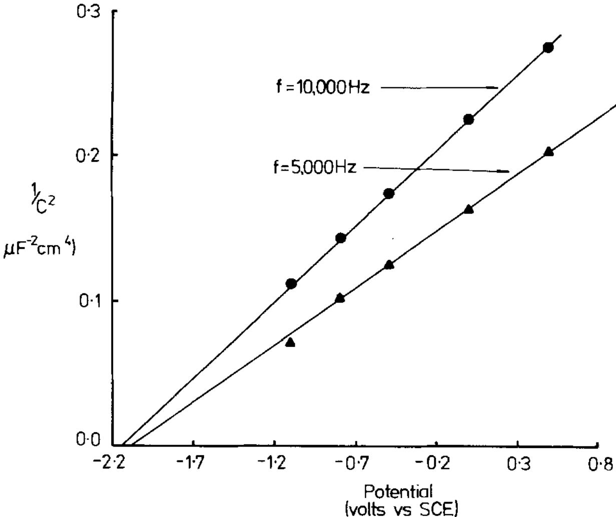


Fig. 6. Calcium titanate electrode in 1M NaOH (a, top left) d-c dark and photocurrent-potential curves, (b, top right) RAP voltammogram, and (c, bottom left) Mott-Schottky relations. Xenon illumination 26 mW cm^{-2}.

correct value within the experimental error. The evidence for this is that the value of V_{FB} for n-$CaTiO_3$ in 1*N* H_2SO_4 reported by Tchernev (7) of −0.50V is in agreement with the values obtained by d-c and RAPV in this work when the −0.59 V/*p*H shift is taken into account. Secondly, V_{FB} at the zeta potential of zero change (*p*H ∼ 14) has been calculated as −1.172V (8) which is also in agreement with the value obtained by RAPV in this study. One possible reason for the highly negative V_{FB}'s determined from capacitance measurements for the $CaTiO_3$ sample examined might be due to the presence of $NiCo_2O_4$ which may have formed during the H_2 reduction of the doped $CaTiO_3$ crystal.

The flatband potentials for a wide range of n-type and p-type semiconductors which have been determined from Mott-Schottky plots and RAPV are listed in Table I. It can be seen from these results that with the exception of the n-$CaTiO_3$ electrode used in this study the values obtained from the Mott-Schottky plots and RAPV agree within experimental error. This suggests that RAPV can be used as a method for determining the V_{FB} of a semiconductor. Difficulties may arise in using RAPV to measure V_{FB} when the semiconductor photocorrodes and desposits the products on the electrode surface. In such a case the measured V_{FB} may be significantly different from the real V_{FB} due to the change in surface composition. In such instances it would be more appropriate to measure V_{FB} in the dark using the capacitance method.

Anodic-cathodic photocurrent transitions were observed for all the p-type semiconductors examined in this study whereas no such transitions were observed for the n-type semiconductors. The origin of the n-type behavior for p-type materials could have been due to the larger intrinsic electron concentrations in the p-type semiconductors which had significantly smaller bandgaps than the n-type semiconductors examined. Alternatively the p-type materials may have been inadvertently doped with some n-type impurities during their crystal growth.

It is noted that a typical RAPV has a similar appearance to a d-c photovoltammogram. This is a sharp

rise in the photocurrent followed by a saturation region. It should be pointed out that this saturation is not due to the saturation of the photocurrent but is in fact due to the saturation of the tuned amplifier. Further, the accuracy of the value of V_{FB} determined by RAPV of semiconductors which do not have a detectable anodic-cathodic photocurrent transition will depend on sensitivity of the tuned amplifier. The General Radio tuned amplifier used in the present study was found to be satisfactory but this may not necessarily apply to other brands of tuned amplifiers.

The small photocurrents measured near the flatband potential have been interpreted in this study as being due to photoelectrochemical effects. However the observations might also originate from modulation effects such as photoconductivity or photocapacitive behavior. It is noted however, that even if either of the latter interpretations is more correct the method presented here for determining V_{FB} is not invalidated.

Summary

In the present study the use of rectified alternating photocurrent voltammetry as a method to determine the flatband potentials of n-type and p-type semiconductors has been presented. The values of the V_{FB}'s for the p-type semiconductors examined in this study coincided with potentials which clearly represented anodic-cathodic photocurrent transitions. For the n-type semiconductors examined no such transitions were observed and the values of the V_{FB}'s for these electrodes were taken as the potential onsets of the rectified amplified alternating photocurrents. The technique of RAPV has the advantage over capacitance-potential measurements of being easy to set up and run in the laboratory on a routine basis.

Cathodic Electrochromism of Lutetium Diphthalocyanine Films

M. M. Nicholson* and F. A. Pizzarello

Rockwell International, Autonetics Strategic Systems Division, Anaheim, California 92803

ABSTRACT

Cathodic electrochromism of lutetium diphthalocyanine films on insulating substrates was investigated by a moving-boundary technique. Reduction occurred by injection of electrons from a gold contact and cations from a liquid electrolyte. Light blue products formed with aqueous or organic solutions of alkali metal salts, while a dark violet product formed with aqueous hydrochloric acid. The dark material had a charge-carrier mobility of 8×10^{-7} cm²/Vsec and an estimated bulk resistivity of 1800 Ω-cm. Reduced forms of the dye appear to be solid cation conductors.

Previous papers from this laboratory have reported investigations of anodic processes in lutetium diphthalocyanine films (1-4). Generally, these are 2-electron oxidations in which the color of the dye changes from green to red. The electrochromic reaction was shown to occur with migration of anions from the aqueous electrolyte into the organic solid. With a chloride solution, it is represented[1] by

$$LuH(Pc)_2 + 2Cl^- \rightarrow LuH(Pc)_2^{++} \cdot 2Cl^- + 2e \quad [I]$$

A solid-state moving-boundary technique was used to determine the faradaic n values, ionic mobilities, and

[1] H_2Pc is the usual abbreviation for metal-free phthalocyanine; $Pc^=$ is the anion $C_{32}H_{16}N_8^=$, and $LuH(Pc)_2$ is commonly called lutetium diphthalocyanine.

approximate bulk resistivities in the red phases formed with chloride and sulfate ions (1). The anion mechanism was confirmed in a subsequent tracer study (2), and its dependences on ambient water vapor and oxygen were reported recently (4).

Lutetium diphthalocyanine also undergoes cathodic reactions. As a result, it is a multicolor electrochromic material of considerable interest for display applications (5-7). Colors of the reduced films can range from blue-green through blue, dark blue, and violet. Reference (5) gives absorption spectra recorded at 0.1V intervals on a tin-oxide supported film under essentially open-circuit conditions in both anodic and cathodic ranges. Spectral characteristics as well as Munsell and CIE color coordinates are summarized in Ref. (5) and (6).

This paper describes the results of cathodic moving-boundary experiments on lutetium diphthalocyanine films supported by insulating substrates. The electrolytes were aqueous HCl, aqueous KCl, KI in acetonitrile (AN), and LiCl in dimethyl sulfoxide (DMSO). Again, the solid reaction products appeared to be ionic conductors. The propagated color was light blue with the metal salt solutions and violet with HCl.

Experimental

Lutetium diphthalocyanine films were prepared by vacuum sublimation of the dye onto sapphire or Mylar strips 1.25 cm wide and approximately 5 cm long. The weight of dye per cm^2 was determined from the optical density (OD) of the green film at the 670 nm absorption maximum. The geometric film thickness was estimated from this weight and the approximate crystal density. It ranged from 530 to 1060Å. Details of the dye synthesis and specimen preparation were given previously (1). The other materials were reagent-grade chemicals. The organic solvents were dried by allowing them to stand over a molecular sieve.

A sputtered gold contact was applied at the upper end of the dye film, and the lower end was immersed in the liquid electrolyte. The counterelectrode was silver foil. A drawing of the moving-boundary cell is given in Ref. (1). The cell was assembled in a helium-atmosphere glove box, where the oxygen level did not exceed a few ppm. Constant cathodic currents of 0.2-2 μA were applied with a PAR 173 galvanostat, and the total applied voltage was monitored with a Keithley 610C electrometer and a strip-chart recorder. The boundary-propagation distance was measured by viewing the film against a back-lighted screen of millimeter graph paper under $\sim 2\times$ magnification. The electric field in the color-converted film could be determined by raising the electrolyte level in successive increments and observing the corresponding voltage decreases. In several cases, the specimens were examined after propagation by energy-dispersive x-ray spectroscopy (EDS), using an ETEC Autoscan scanning electron microscope. Comparisons of lutetium, potassium, and chlorine levels in different regions of the films were made in this way.

Results and Discussion

Visual observations.—The color change always began at the dye/electrolyte interface and traveled upward toward the electronic contact. This behavior is consistent with an ion-injection mechanism. It differs from that of Yamana's qualitative experiments, wherein the blue coloration of erbium diphthalocyanine films on glass began at the metal contact (8). In our experience, color-converted diphthalocyanine films are prone to crack and peel away from glass. If this occurred in Yamana's cell, the dye could have become wet with electrolyte by capillary action. Cathodic reaction then would have occurred in the upper part of the film.

The adhesion problem was mitigated, though not fully avoided, in the present work by using a sapphire or Mylar substrate.[2] With aqueous electrolytes, the cathodic boundary propagation tended not to proceed as uniformly as it did for the anodic green-to-red process (1), but the boundary velocity and field were measurable in a number of experiments, as shown by Fig. 1-3. Occasionally, the boundary was too irregular for quantitative use.

An additional difficulty arose with the organic electrolytes. Although the initial green form of the dye was insoluble in several organic liquids, including AN and DMSO, the blue reduced form was soluble. This led to poor electrical contact during the boundary propagation and prevented determination of the field by changing the electrolyte level.

The propagated color depended on the electrolyte cation. With HCl, the product was dark violet. With KCl, KI, and LiCl, only a light blue appeared. In contrast, we have observed that anodic boundary propagation with different anions yields a single red color (4).

[2] The dye film adheres well to tin oxide, but that substrate cannot be used in moving-boundary studies because it is electronically conductive.

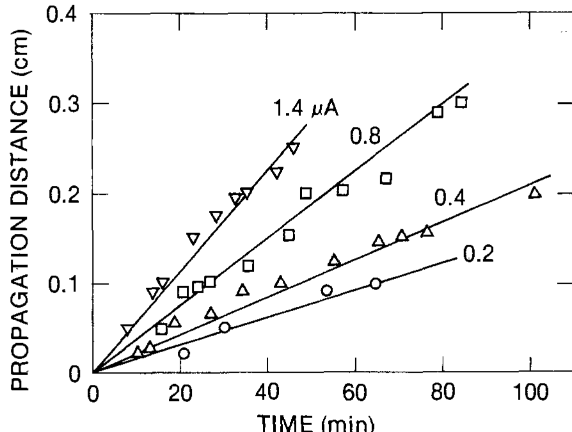

Fig. 1. Dependence of boundary propagation distance on time with aqueous 1.2M HCl electrolyte. Specimen 1.

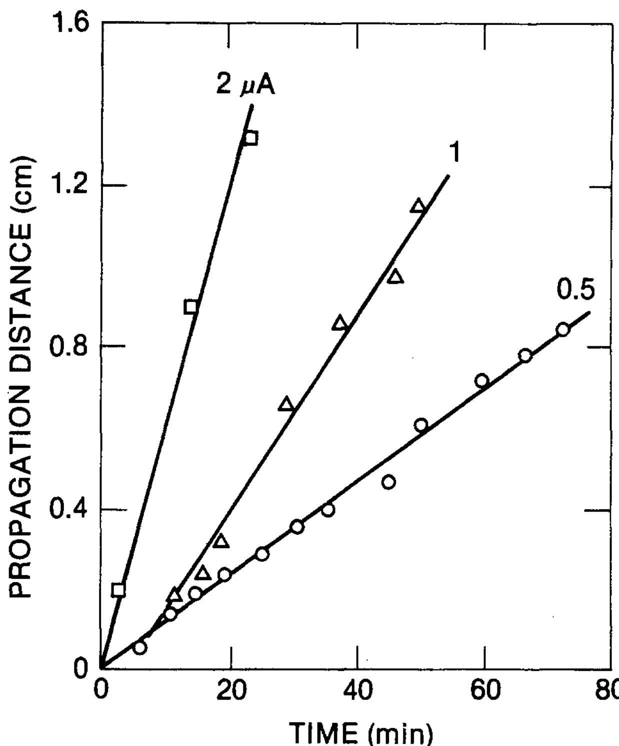

Fig. 2. Dependence of boundary propagation distance on time with aqueous 1M KCl electrolyte. Specimens 3, 4, and 5.

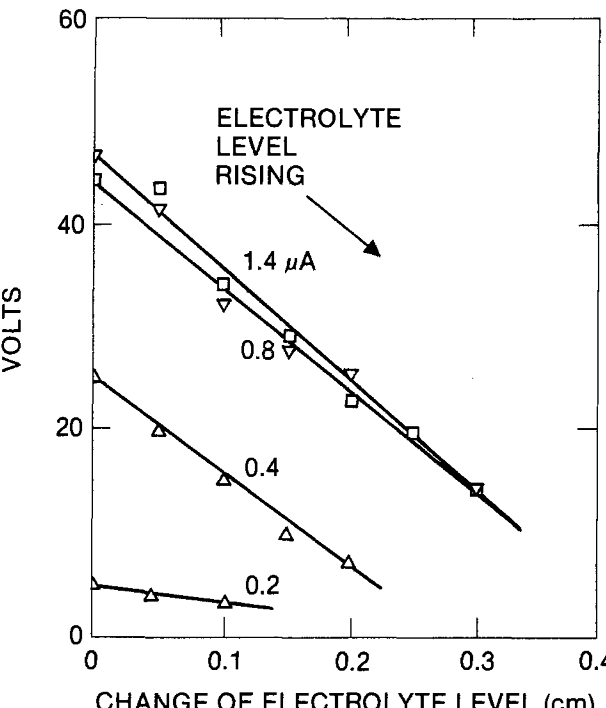

Fig. 3. Plots for determination of electric field in the blue film with aqueous 1.2M HCl electrolyte. Specimen 1.

Electrical parameters.—The results for aqueous and nonaqueous solutions are summarized in Table I. Although the total applied currents were in the microampere range, the estimated current densities through the cross sections of the films were 15-200 mA/cm^2. This range includes current densities that would be used in potentiostatic switching of a diphthalocyanine electrochromic display (7).

The apparent number n of electrons transferred per molecule of dye was calculated from the current, the area converted per unit time, and the optical density of the green film. Plots for evaluating the boundary velocity are shown in Fig. 1 and 2. With aqueous KCl, n was 1.9 $\pm$ 0.2. With HCl, the apparent n was considerably larger, and on specimen 1, it was shown to increase systematically with the applied current. The large apparent n's in the acid solution probably were caused by a side reaction forming elemental hydrogen. The apparent n at 0.4 μA was 5.2 for specimen 1 and 12 for specimen 2. One could surmise from this comparison that the sapphire substrate was more conducive than Mylar to proton transport beneath the dye film, but further investigation would be needed to verify such a mechanism. Extrapolation of the apparent n to zero current yielded a value of 3.5 for the Mylar-supported film contacted by 1.2M HCl. Fewer data were recorded for nonaqueous electrolytes because of the blue-solubility problem, but an n value of 1.1 was obtained with both Mylar- and sapphire-supported films contacted by LiCl-DMSO.

A carrier mobility μ in the converted film was found from the relationship

$$\mu = v/\mathcal{E} \quad [1]$$

where v is the boundary velocity and $\mathcal{E}$ is the electric field determined by raising the electrolyte level (1). Figure 3 shows plots for the evaluation of $\mathcal{E}$ in the Mylar-supported film propagated from aqueous HCl. The average mobility was 8×10^{-7} cm^2/Vsec. Since the current and the approximate film thickness were known, the bulk resistivity ρ_b of the blue phase could be estimated from Eq. [2], where I is the current density

$$\rho_b = \mathcal{E}/I \quad [2]$$

The average resistivity for specimen 1 was 1800 Ω-cm. This is similar to the resistivities of 1300 and 2000 Ω-cm for the red oxidation products containing chloride and sulfate ions (1).

Interpretations.—The violet phase propagated from an aqueous HCl interface appears to be an ionic conductor. This is suggested by the magnitude of the carrier mobility, which is compared in Table II with those of related solid electrolytes. Dependence of the reduction-product color on the electrolyte cation also is consistent with a cation-injection mechanism. Moreover, EDS analysis confirmed the presence of potassium, and the absence of chlorine, in blue areas propagated from KCl, while neither of these elements was found in green areas of the same plates.

The reaction for aqueous KCl may be written

$$\underset{\text{Green}}{LuH(Pc)_2} + 2K^+ + 2e \rightarrow \underset{\text{Light blue}}{LuH(Pc)^{2=} \cdot 2K^+} \quad [II]$$

This process is analogous to the anodic oxidation utilizing two chloride ions and forming the divalent organic cation.

The measurements with LiCl in DMSO indicated a 1-electron reduction, which might be represented by

$$\underset{\text{Green}}{LuH(Pc)_2} + Li^+ + e \rightarrow \underset{\text{Light blue}}{LuH(Pc)_2^- \cdot Li^+} \quad [III]$$

With dissolved lutetium diphthalocyanine, Corker, Grant, and Clecak also reported cathodic formation of a radical anion (11). The electrolyte was tetrabutylammonium fluoborate in dimethylformamide, and the working electrode was platinum. Reduction beyond the 1-electron stage with LiCl in the moving-boundary cell might have been prevented by separation of the two phthalocyanine rings to form LiHPc and LuPc. Such a process could account for the higher solubility in organic solvents.

Further work is needed to characterize the reduction products. It is significant, however, that dark blue or violet colors never were obtained with metal cations in the moving-boundary experiments, even at a current density as high as 200 mA/cm^2. An acidic electrolyte is

required to form the dark product in insulator-supported films. Yet dark blue and violet are readily obtained with aqueous KCl when the dye is on semiconductive tin oxide (5,6). We propose the following mechanisms to account for this difference in the electrochromic behavior.

With an adequate supply of protons, reduction of the dye can proceed by a double-injection mechanism similar to that of reaction [II]

$$LuH(Pc)_2 + nH^+ \; ne \rightarrow LuH_{n+1}(Pc)_2 \quad [IV]$$

Green Dark blue or violet

All or part of the $n+1$ hydrogen atoms may be ionized in the solid state. When the supply of protons is insufficient, the dye may be converted at a tin oxide electrode by a coupled chemical reaction rather than direct electron transfer

$$H_2O + e \rightarrow H \cdot (Ads) + OH^- \quad [V]$$

$$LuH(Pc)_2 + nH \cdot (Ads) \rightarrow LuH_{1+n}(Pc)_2 \quad [VI]$$

Green Dark blue or violet

The reactive intermediate is represented as an adsorbed hydrogen atom because a species with such characteristics is known to form on tin oxide at cathodic potentials (12, 13). Furthermore, a *p*H increase accompanies cathodic formation of a blue product on tin oxide in aqueous KCl, and hydrogen ions are released to the solution on its anodic oxidation (14).

The dark blue and violet forms cannot yet be distinguished on the basis of the *n* values. One of our previous investigations provides evidence, from correlation of absorption spectra with approximate open-circuit potentials of the reduced films, that the dark blue and violet colors may involve two discrete oxidation states of the dye (5). We now estimate that *n* is 2 or 3 for the dark blue state, and 3 or 4 for the violet.

Moskalev and Kirin originally proposed field-induced ionization to H^+ and $Lu(Pc)_2^-$ to account for the cathodic electrochromism of lutetium diphthalocyanine films (15). The present study has shown that these color changes are due, instead, to faradaic processes. Although the acidic hydrogen may not be firmly bound to the organic structure in rare-earth diphthalocyanines (16), it is the electrolyte cation that plays a vital role in the electrochromism at cathodic potentials.

Photoelectrochemical Characterization of CdSe Thin Film Anodes

K. Rajeshwar, L. Thompson, and P. Singh*,[1]

ABSTRACT

Photoelectrochemical characterization of CdSe thin films prepared by a chemical solution growth technique was carried out by linear-sweep voltammetry, current-voltage measurements under forward and reverse bias, photocurrent-wavelength measurements, and electrical impedance measurement techniques. The quality of the present CdSe/electrolyte junctions for photovoltaic applications was assessed by examining the effect of varying light intensity on current-voltage behavior. The ideality factors (n) were determined for these junctions by modeling the CdSe/electrolyte junction in terms of a Schottky barrier. Values of n close to 2 were obtained and were attributed to the dominating influence of recombination-generation currents (either at the surface or in the depletion region) on the overall photovoltaic characteristics. The presence of a thin, tunnelable CdS layer on the CdSe electrode surface was postulated as causing the nonideal current-voltage behavior particularly in the reverse-bias regime. Equivalent circuits for the CdSe/electrolyte interface were developed using a novel technique for measuring the equivalent parallel conductance and capacitance as a function of signal frequency and applied bias. A method of extracting flatband potentials based on conductance measurements is demonstrated using the CdSe thin film/electrolyte interface.

Cadmium selenide has shown considerable potential for applications related to photoelectrochemical (PEC) methods of solar energy conversion. Stable and efficient CdSe-based PEC devices have been reported recently (1, 2). Photoanodes have been fabricated from n-type CdSe in the form of single crystal (3, 4), sintered aggregates (1, 4), pastes (2), and thin films (4, 5-7). Both aqueous (1-6) and nonaqueous electrolytes (7, 8) have been employed in these PEC devices.

In this work, we describe the photoelectrochemical characterization of CdSe thin films prepared by a chemical solution growth technique (9). This technique is relatively inexpensive, simple, and amenable to routine manufacture on a large scale. A variety of electrical and electrochemical techniques was employed to assess the quality of photoresponse of these films. These included linear-sweep voltammetry, current-voltage measurements under forward and reverse bias, photocurrent-wavelength measurements, and electrical impedance characterization as a function of signal frequency and applied bias. The sensitivity of the photoresponse to light intensity was also studied as an effective measure of the junction quality for applications related to solar energy conversion.

Equivalent circuits were developed for the n-CdSe/electrolyte interface from conductance and capacitance data as a function of frequency and applied bias. A novel technique for extracting semiconductor flatband potentials from electrical impedance measurements is presented. Frequency dispersion in the measured space-charge capacitance values is often a problem in the determination of flatband potentials (10). This difficulty is circumvented in the present approach by utilizing conductance data and exploiting the relationship of equivalent parallel conductance to the space-charge capacitance in the semiconductor (11).

Experimental

Thin films of CdSe on titanium foil substrates were prepared at the Indian Institute of Technology, New Delhi, by the overall chemical reaction

$$Cd(NH_3)_4^{2+} + SeSO_3^{2-} + 2\,OH^- \rightarrow CdSe + 4NH_3 + SO_4^{2-} + H_2O \quad [1]$$

Relevant details on the growth of these films are given elsewhere (9, 12). The films labeled Film 1, 2, and 3, were prepared at 85°C with 2.1, 2.8, and 3.5M NH_3 concentrations and had thicknesses ~0.7, 0.85, and 0.9 μm, respectively. The as-grown films were n-type with resistivity ~10^7-10^8 Ω-cm. On annealing at 280°C for 30 min in vacuum (10^{-5} Torr), the resistivity was brought down to the range 1-10 Ω-cm. The annealed films had carrier concentrations in the range 5×10^{17}-5×10^{18} cm^{-3} and carrier mobilities in the range 1-10 cm^2/V-sec.

Electrode fabrication consisted of cutting the 3×4 cm^2 as-prepared sheets of thin films into small wafers of area in the range 0.15-0.5 cm^2. The CdSe film was scraped off from one side of the wafer and a back contact was made to the exposed titanium by application of conductive silver epoxy. A Teflon-coated copper wire was attached to the back contact by using the same epoxy. The entire back surface and edges of the electrodes were then covered with nonconducting epoxy resin.

A mixture of solutions of 1M Na_2S, 1M S, and 1M NaOH in deionized water was used as the electrolyte in the PEC cells. The cells were continually purged with a slow stream of prepurified argon gas. Both two-electrode and three-electrode PEC configurations were employed. A vitreous carbon plate (1.5 × 15 × 30 mm, Atomergic Chemetals Corporation, New York) was used as the counterelectrode in both cases. A saturated calomel electrode (SCE) was used as the reference electrode for potentiostatic measurements.

Two types of etching were employed for the CdSe thin film photoanodes prior to their use in the PEC cells: a chemical etch consisting of successive non-

convective dips in 6, 1, and 0.1M HCl for 3-5 sec followed by a rinse in deionized water, and a photoetch according to the procedure described by a previous author (2), wherein the photoelectrode is illuminated under short-circuit conditions in a dilute aqueous acid solution, for example 0.1M HCl.

Current-voltage measurements were carried out on a Princeton Applied Research (PAR) Model 175 universal programmer and PAR 173 potentiostat/galvanostat in the case of three-electrode PEC cells or on a custom-built variable load current-to-voltage converter for studies on two-terminal devices.

A 150-W ELH tungsten-halogen lamp was used to illuminate the CdSe photoanodes. The intensity of the light source was calibrated by using neutral density filters and an Ealing Corporation Model LIMS 920 radiometer/photometer. The light intensities quoted below are not corrected for reflection and absorption losses in the cell and in the electrolyte.

A Bausch and Lomb light source and a high-intensity monochromator in conjunction with a series of narrow bandpass filters were used for the photocurrent-wavelength measurements. The working electrode was potentiostated against the SCE reference electrode and the photocurrents were measured on the PAR electrochemistry system.

Electrical impedance measurements were carried out on the n-CdSe/electrolyte interface by an automated technique developed in this laboratory (13). This technique utilizes measurements of the changes in the amplitude and phase characteristics of a small amplitude a-c signal to generate values of the parallel conductance and capacitance as a function of a-c signal frequency and applied bias. These values are then used to derive equivalent circuit elements for the semiconductor electrode/electrolyte interface. A Hewlett-Packard (HP) frequency synthesizer (Model HP-3320B), an HP Model 3570A network analyzer, and an HP Model 9825A desk-top computer were used for these measurements. Further details may be found elsewhere (13).

Results and Discussion

Current-voltage measurements.—Figures 1-3 illustrate the current-voltage behavior of PEC cells based on solution-grown CdSe thin films. These data were obtained on two-terminal devices although no significant differences in behavior were observed in the potentiostatic mode with three-electrode PEC cells. Polarization effects at the counterelectrode (*vide supra*) can be therefore ignored in the following discussion. Open-circuit potentials (V_{oc}) in the range 0.20-0.26V, short-circuit current densities (J_{sc}) ranging from 0.1 to 2 mA/cm^2, and fill-factors spanning the range 0.20-0.35 were observed for the various devices depending on the prior thermal treatment of the film and surface preparation. Table I summarizes the performance parameters for the various PEC devices tested in the present study. In general, photo and chemical etching tends to improve the J_{sc} values and therefore the energy conversion efficiency of the device. Film No. 3 was found to yield better quality electrodes than films No. 1 and No. 2 (Table I) as expected from thickness considerations (*vide supra*). No attempt was made in these experiments to optimize cell geometry, redox concentration, etc. since the main objective of this work was to characterize the overall photoelectrochemical behavior of solution-grown CdSe thin films. However, by using suitably recrystallized and etched CdSe film deposited on SnO_x:F coated glass substrates, V_{oc} values in the range 0.40-0.62V, J_{sc} up to 6 mA/cm^2 (50 mW/cm^2 light intensity), and fill-factors as high as 0.50 have been obtained. The details of these prior treatments and the performance of the corresponding PEC cells are reported elsewhere (14).

Figure 4 compares the current-voltage behavior in the dark and under illumination for film No. 3. These data were obtained under potentiostatic conditions. Similar behavior was observed for films No. 1 and 2. The usual rectification behavior expected in the reverse bias regime for semiconductor/electrolyte junctions in the dark is observed here. From Fig. 4 and similar data for the other films, the flatband potential (V_{FB}) is seen to be more negative than *ca.* − 1.0V (*vs.* SCE) in the polysulfide solution. A more precise location of the V_{FB} value is obtained from the electrical impedance measurements described below.

A feature worthy of note in the data shown in Fig. 4 is the gradual increase in current with increasing reverse bias in the dark. This increase is particularly pronounced on illumination of the device. At voltages significantly anodic of *ca.* 0.5V (*vs.* SCE), a very rapid increase in current (not shown in Fig. 4) was noted for all the films examined in the present study. This behavior is commonly encountered in solid-state devices and is attributed to dielectric breakdown (15). The gradual increase in current prior to this abrupt change, however, is of more relevance to this study. There are three possible explanations for this "anomalous" behavior: (*i*) in the reverse bias direction, the presence of an interfacial layer causes the effective barrier height to decrease with increasing bias, so that the reverse current does not saturate (15), (*ii*) hole-electron pairs are thermally generated in the depletion region under conditions of large reverse bias (*i.e.*, large band bending in the semiconductor), and (*iii*) the current increases due to the onset of electron injection from the electrolyte because the barrier becomes thin enough for tunneling to take place.

Of the above possibilities, we prefer the explanations based on (*i*) and (*iii*) above. Support for (*i*) derives from observations (5, 16, 17) on the formation of a thin CdS layer on the surface of the CdSe electrodes by S/Se substitution. On the other hand, the more pronounced increase in the currents in the reverse bias direction on illumination relative to the dark case (Fig. 4), suggests that the tunneling process (*i.e.*, electron injection from the electrolyte) might be enhanced because of the slight increase in the majority carrier density at the interface. Under potentiostatic conditions such as those employed for the measurements in Fig. 4, this is equivalent to heavier doping of the semiconductor and hence a thinner surface barrier.

A more detailed discussion of the current-voltage characteristics and the effect of interfacial layers is postponed to a later section.

Effect of light intensity.—If we model the semiconductor/electrolyte interface as a Schottky barrier, it is possible to represent the current-voltage characteristic by the following expression (18)

$$J = J_{ph} - J_d = J_{ph} - J_o [\exp (qV/nkT) - 1)] \quad [2]$$

Here J is the net current density (current per unit area), J_{ph} and J_d are the photocurrent density and dark current density, respectively, J_o is the reverse saturation current density, V is the voltage, n is the "junction-ideality" factor, and other terms have their usual significance. For bias voltages exceeding $3kT/q$, we can neglect the last term in the bracket in Eq. [2]. Also at equilibrium (open-circuit conditions), $J_{ph} = J_d$ and $V = V_{oc}$ so that rearrangement of Eq. [2] yields

$$V_{oc} \cong \frac{nkT}{q} \ln \frac{J_{sc}}{J_o} \quad [3]$$

where V_{oc} is the open-circuit voltage and J_{sc} is the short-circuit current density. If we further assume that $J_{sc} \propto I_L$ (= incident light intensity) and $J_{sc} >> J_o$, Eq. [3] reduces to the following expression

$$V_{oc} \propto \frac{nkT}{q} \ln I_L \quad [4]$$

A plot of V_{oc} against $\ln I_L$ should yield a straight line from which values of n may be determined for the particular device. An ideal device should have an n value of unity so that the slope of a straight line plot of V_{oc} *vs.* $\log I_L$ should be *ca.* 60 mV. Figure 5 illustrates such plots for CdSe films No. 1, 2, and 3. An alternative method involves plotting V_{oc} *vs.* $\log J_{sc}$ (cf. Eq. [3]). The slopes determined by these analyses are assembled in Table II. The magnitudes of these slopes can be rationalized only if $n \simeq 2$.

The above assumption that J_{sc} is directly proportional to the light intensity is borne out by the data shown in Fig. 6. The linear dependence also demonstrates that transport of electroactive S^{2-} species to the CdSe/electrolyte interface is not limiting the rate of the overall charge-transfer reaction over the range of light intensities employed in this study.

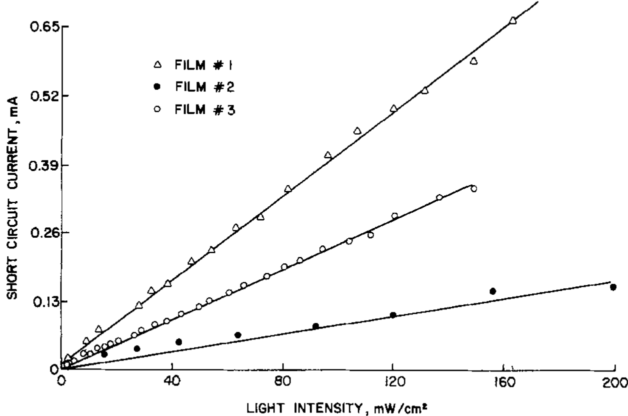

Fig. 6. Dependence of short-circuit current density on light intensity for solution-grown CdSe photoanodes.

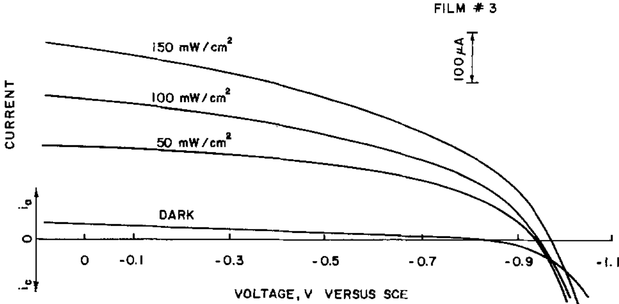

Fig. 4. Potentiostatic current-voltage curves in the dark and under illumination for solution-grown CdSe photoanodes (film No. 3).

Table II. Junction ideality factors for the illuminated CdSe/electrolyte interface

Method of determination	Slope (V) Film No. 1	Film No. 2	Film No. 3	n Film No. 1	Film No. 2	Film No. 3
V_{oc} *vs.* log J_{sc}	0.120	0.108	0.107	2.03	1.83	1.81
V_{oc} *vs.* log I_L (cf. Eq. [4])	0.108	0.130	0.115	1.83	2.20	1.95

The functional dependence of J_{sc} and V_{oc} on light intensity for CdSe-based PEC cells was noted by previous authors in studies on single crystals (3) and on thin films prepared by vacuum evaporation (6).

Photocurrent-wavelength measurements.—Figure 7 illustrates the spectral response of solution-grown CdSe thin film electrodes in polysulfide solution. The sharp decrease in response below ~520 nm is consistent with the increased absorption of polysulfide solutions below these wavelengths (1, 3). The long wavelength cutoff is less sharp relative to the behavior of single crystal electrodes (6) and reflects the nonoptimized thickness of the present CdSe films leading to a consequent deterioration in long wavelength response. The gradual decrease in photoresponse into the short-wavelength region is indicative of surface recombination of photogenerated minority carriers presumably mediated by electronic states in the bandgap [cf. Ref. (19, 20)]. Application of reverse bias to the electrode results in the expected increase in photocurrents arising from better field separation of photogenerated carriers although the surface recombination component is not significantly reduced (Fig. 7).

Equivalent circuit representation.—Equivalent circuit representation of the semiconductor/electrolyte interface (21, 22) enables identification of specific components of the overall electrical network that are responsive to potential and current perturbations. Figures 8a, b, c, and d illustrate successive reductions of the equivalent circuit for a model semiconductor/electrolyte interface leading to the highly idealized system shown in Fig. 8d. Here C_{sc} is the space-charge capacitance, C_H is the Helmholtz layer capacitance, C_G is the Gouy layer capacitance, R_B is the internal series resistance comprising the contributions from the electrolyte, bulk semiconductor, and the back ohmic contact, R_F is the resistance associated with Faradaic charge-transfer processes at the interface, and C_{SS} and R_{SS} are the capacitance and resistance terms arising from surface states or traps at the interface. For an ideal device, C_G and C_H should be large relative to

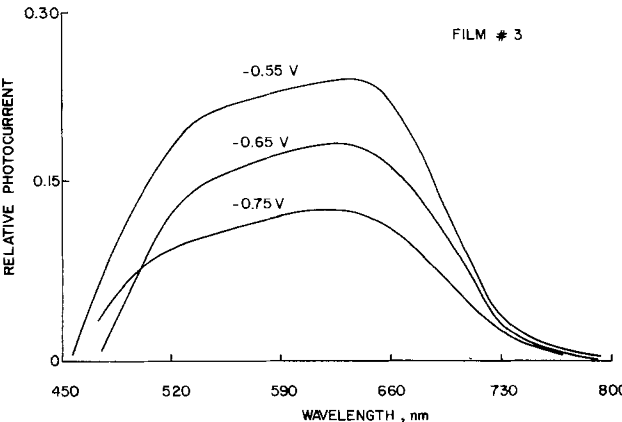

Fig. 7. Photocurrent-wavelength characteristics for solution-grown CdSe photoanodes (film No. 3) at various values of reverse bias. The voltages refer to SCE reference electrode. The photoresponse was normalized to take into account variations in intensity and quantum flux with wavelength.

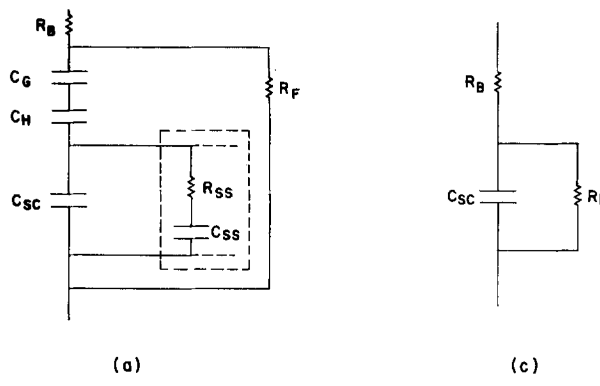

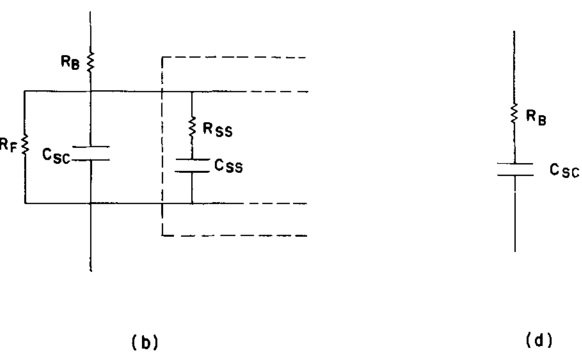

Fig. 8. Equivalent circuit representations of the semiconductor/electrolyte interface. Figures 10a, b, c, and d show successive reductions in the complexity of the electrical network. See text for description of symbols.

C_{sc}, R_B should be small, R_F should be large, and surface-state effects should be absent or at least minimal. In concentrated electrolytes such as those employed in the present study, the C_G term may be ignored and since usually $C_H >> C_{sc}$, an expression for the parallel admittance may be derived (13) (cf. Fig. 8c)

$$\omega C_p = \frac{(G_B + G_F)(\omega G_B C_{SC}) - \omega G_B G_F C_{SC}}{(G_B + G_F)^2 + (\omega C_{SC})^2} \quad [5]$$

and

$$G_{p/\omega} = \frac{(G_B G_{F/\omega})(G_B + G_F) + G_B \omega C_{SC}^2}{(G_B + G_F)^2 + (\omega C_{SC})^2} \quad [6]$$

It is noted that in the above, effects from surface states have not been taken into account *per se*. The conductance terms G ($= 1/R$) have been employed in the above expressions in place of resistances, since the measured quantity here is the parallel conductance.

Each C-G combination above causes a peak in $G_{p/\omega}$ *vs.* ω curves. Unless the G_F term becomes very large, it will not overlap the peak that is caused by the C_{sc}-G_B combination. The more ideally polarized the interface, the smaller is the G_B term and hence the lower the frequency range at which it will have an appreciable effect. For very low frequencies ($\omega \rightarrow 0$) and for $G_B >> G_F$, $G_p \simeq G_F$. Typical $G_{p/\omega}$ *vs.* ω curves are shown in Fig. 9 and 10 for films No. 1 and 3, respectively. Values for C_{sc} and R_B can be determined from these data from the expressions (11, 13)

$$C_{sc} = 2[G_{p/\omega}]_{max} \quad [7]$$

$$R_B = 1/G_B = 1/(2\omega[G_{p/\omega}]_{max}) \quad [8]$$

G_F (or R_F) is given by the extrapolated value of the low-frequency data to the $G_{p/\omega}$ axis (*cf.* Fig. 9 and 10). Values of C_{sc}, R_B, and R_F thus determined and the

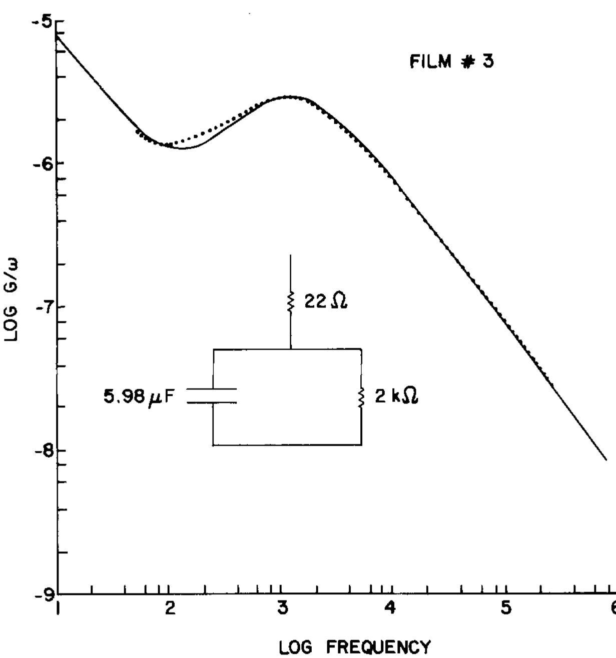

Fig. 10. Impedance spectra of solution-grown CdSe photoanodes (film No. 3). Description same as in Fig. 11. Electrode potential, −0.80V (vs. SCE).

overall circuit for the CdSe/electrolyte interface are shown in the inset of Fig. 9 and 10. The solid circles in Fig. 9 and 10 represent experimental data; the lines are "theoretical" curves based on calculated values of the circuit elements. Computational procedures for data fitting and other relevant details may be found elsewhere (13).

It is again noted that the circuit representations in Fig. 9 and 10 for the CdSe/electrolyte interface are somewhat idealized since surface-state effects have been ignored. Based on previous measurements in this laboratory on the n-GaAs/molten-salt electrolyte interface, the discrepancy between the theoretical curves and the experimental data in the intermediate frequency regime in Fig. 9 and 10 may be attributed to the influence of surface states. Attempts to include this effect in computation of the theoretical $G_{p/\omega}$ curves were not entirely successful because adequate resolution of peaks arising from C_{ss}-G_{ss} and C_{sc}-G_B combinations, was impeded by the shift of the C_{sc}-G_B peak toward lower frequencies relative to the GaAs case (23). Either a decrease in G_B (with constant C_{sc}) or an increase in C_{sc} (with constant G_B) can cause this shift (13).

The C_{sc} values computed from Eq. [7] under conditions of varying bias may be utilized to determine V_{FB} values by the Mott-Schottky relationship (24)

$$1/C_{sc}^2 = \frac{2}{q\epsilon_s N_D A^2} (V - V_{FB} - kT/q) \quad [9]$$

Here ϵ_s is the permittivity of the semiconductor, N_D is the semiconductor doping density, and A is the electrode area. Figure 11 illustrates Mott-Schottky plots for films No. 1 and 3. A V_{FB} value of −1.56 ± 0.06V (*vs.* SCE) was deduced from plots such as those shown in Fig. 11 for the CdSe films examined in this study. This value pertains to that obtained in the polysulfide electrolyte and may be compared with values of −1.45, −1.34, and −1.30V (*vs.* SCE) reported by previous authors for single crystal, vacuum-deposited thin films and for sintered pellets, respectively (3, 4).

General Discussion

In a broad sense, the present data may be regarded as representative of the manner in which many analogous features in the electrical characteristics of the semiconductor/electrolyte junction and a Schottky barrier (25) may be utilized to assess the quality of the photoactive junction in a PEC electrode/electrolyte interface. For example, n values close to 2 have been observed for the present CdSe thin film electrodes (cf. Table II). Values of $n = 2$ are characteristic of the propensity of recombination processes involving photogenerated electron-hole pairs either at the semiconductor surface or in the depletion region (18). This causes a deviation from the ideal current/voltage characteristic especially at low values of applied bias. We postulate that a significant factor in this nonideal behavior is the presence of an ultrathin, tunnelable layer consisting of CdS on the CdSe surface (cf. Fig. 12). This layer is believed to be electrically insulating because of compensation of excess Cd and/or Se vacancies (16). The effect of this insulating layer on the photovoltaic characteristics of the CdSe/electrolyte junction is twofold: (*i*) because of the potential drop across this layer, the zero-bias barrier height, $\phi_b°$, is lower than it would be in the absence of this layer (cf. Fig. 12) and (*ii*) when a bias is applied, part of the bias voltage is dropped across the CdS layer so that the barrier height, ϕ_b, will be a function of bias voltage. The effect of this bias dependence of ϕ_b is to

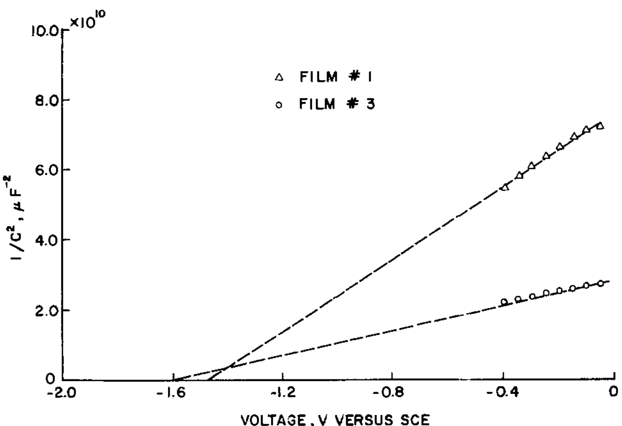

Fig. 11. Mott-Schottky plots for CdSe thin-film photoanodes (films No. 1 and 3).

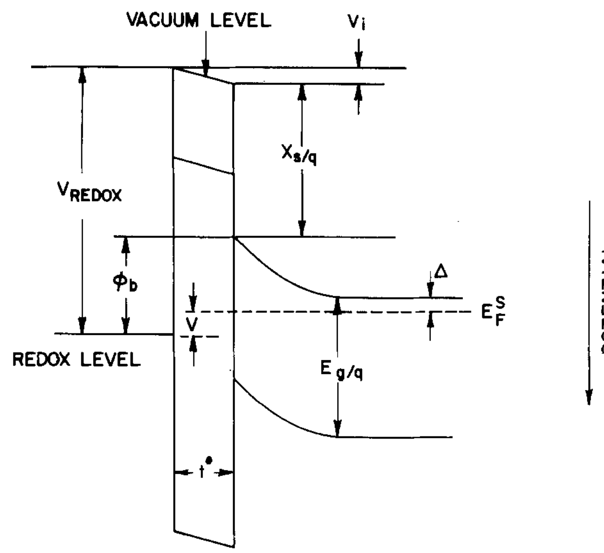

Fig. 12. Energy band diagram for the CdSe/electrolyte interface under any arbitrary forward bias. V_{redox} is the redox potential, χ_s is the semiconductor electron affinity, $E_F{}^S$ is the Fermi level in the semiconductor, and E_g is the energy bandgap in the semiconductor. Other symbols are defined in the text.

change the shape of the current/voltage characteristic in a manner represented by the inclusion of an ideality factor, n (cf. Eq. [1]).

The above effects may be represented by the expression (26)

$$\phi_b = \phi_b{}^\circ - \alpha(2qN_D/\epsilon_s)^{1/2}\left(\phi_b - V - \Delta - \frac{kT}{q}\right)^{1/2} \quad [10]$$

Here $\alpha = t\epsilon_s/(\epsilon_i + qtD_{ss})$, ϵ_i is the permittivity of the insulating layer, t is its thickness, D_{ss} is the surface state density, and Δ is the difference between the conduction bandedge and the Fermi level.

Figure 12 illustrates the electrostatic aspects of the semiconductor/electrolyte interface in the presence of an ultrathin insulating layer. An estimate of the barrier-height lowering may be obtained from Eq. [10], assuming $t = 20Å$, $D_{ss} = 10^{17}$ eV^{-1} m^{-2}, $\epsilon_s = \epsilon_i \simeq 9\epsilon_o$ (27), and $(\phi_b - V - \Delta + kT/q) \simeq 1V$; a value $\phi_b{}^\circ - \phi_b = 0.02V$ is obtained. This effect will be enhanced by a larger doping level in the semiconductor and a thicker insulating CdS layer. [Depth profiles reported by previous authors for CdSe photoelectrodes indicate a layer thickness of the order of 80Å, Ref. (16). The above value therefore is to be taken as a conservative estimate.] The barrier-height lowering would also be more pronounced under reverse bias because of the increase in the $(\phi_b - V - \Delta - kT/q)^{1/2}$ term in Eq. [10].

The electrical impedance measurements illustrate the manner in which difficulties encountered in "conventional" capacitance measurements with frequency dispersion of C_{sc} values (10) may be avoided. Meaningful V_{FB} values may be extracted by utilizing the relationship of $G_{p/\omega}$ peak maxima with C_{sc} (cf. Eq. [7]). Indeed, capacitance measurements using the standard lock-in technique (28) at discrete signal frequencies failed to yield reproducible Mott-Schottky plots for the present CdSe thin films. An additional advantage with the present approach is that changes in electrical conductance with voltage are much greater than corresponding variations in the capacitance (11), thereby enhancing the sensitivity of the technique. Further details of this new technique for measuring V_{FB} values are being published in companion papers (29).

Work is continuing in these laboratories toward improvement of the surface quality of solution-grown CdSe thin films and thereby optimizing their performance in regenerative PEC devices for conversion of solar energy into electricity.

Effect of Temperature on the Operation of a Photoelectrochemical Device: Studies on the n-GaAs/Room Temperature Molten Salt Electrolyte Interface

K. Rajeshwar, P. Singh,*,[1] and R. Thapar*

Department of Electrical Engineering, Colorado State University, Fort Collins, Colorado 80523

ABSTRACT

The effect of temperature on the photovoltaic performance of a photoelectrochemical (PEC) system was evaluated by measurements on a model system comprising the n-GaAs|$AlCl_3$-butyl pyridinium chloride (BPC)|carbon cell containing the ferrocene/ferricenium ion ($Fe(Cp)_2/Fe(Cp)_2^+$) couple. Changes in the solar cell parameters for this system with temperature were monitored for the range from ambient to 85°C. The short-circuit current densities (J_{sc}) showed a systematic increase over the temperature range while the open-circuit voltage (V_{oc}) and fill-factor (FF) showed a linear decrease at the rate of 3.6 mV/°C and 0.001/°C, respectively. The energy conversion efficiency (η) of the device showed a maximum at an intermediate temperature (~50°C) beyond which the decline in V_{oc} and FF outweighed the beneficial effect of temperature on J_{sc}, leading to a rapid fall-off in η at temperatures above ~60°C. The linear decrease of V_{oc} with increasing temperature was seen to be directly related to the increased dark current density at elevated temperatures. Analysis of the dark current *vs.* voltage data by Schottky diode theory revealed the expected exponential dependence of the reverse saturation current density on temperature for the model PEC system. Measurement of the semiconductor flatband potential (V_{FB}) for the n-GaAs/$AlCl_3$-BPC interface at varying temperatures revealed a further origin for the increase in dark currents with temperature. The shift in V_{FB} to positive potentials with increasing temperature reduced the effective activation energy (or barrier height) for electron injection from the electrolyte into the semiconductor in the dark. These results are discussed in terms of two mechanisms: (*i*) direct charge transfer between the semiconductor and the occupied redox levels in the electrolyte and (*ii*) electron injection into the semiconductor mediated by trap levels in the energy bandgap of the semiconductor. Finally, the effect of temperature on the Schottky diode parameters of the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|carbon cell is discussed in terms of enhanced surface and bulk carrier recombination effects at elevated temperatures. These lead to the observed deterioration in the fill-factor because of the increased series resistance associated with recombination-generation current flow paths.

There has been much discussion in recent years on photoelectrochemical (PEC) methods of solar energy conversion (1, 2). A key element of PEC devices is the semiconductor/electrolyte interface. The degree of effectiveness of minority-carrier charge transfer across this interface will have a direct bearing on the ultimate energy conversion efficiency of the system. The strategy of enhancing this charge exchange by elevating the temperature (3) has the added advantage of utilizing the near *IR* region of the solar spectrum, which otherwise would be wasted. Temperature also has beneficial effects on the optical properties of the semiconductor. Thus, recent studies have shown a red shift in the wavelength response of SnO_2-based PEC cells (4). Although semiconductor bandgap narrowing is a favorable mechanism contributing to improved solar efficiency, analogous studies on solid-state devices have revealed a simultaneous deterioration in the blue response because of carrier recombination at the surface (5). The objective of the present study was to critically evaluate the effect of temperature on the photovoltaic performance of a model semiconductor/electrolyte interface. Of particular relevance to this work was the finding that temperature-induced changes in the charge and potential distribution at the interface have substantial effects on the overall PEC behavior. The main conclusion from this study is that there is an optimum temperature beyond which the beneficial effects of temperature on the electronic and optical properties of the semiconductor/electrolyte interface are nullified by unfavorable shifts in the flatband potential (V_{FB}) to positive potentials leading to a reduced barrier height (or band bending) in equilibrium. The consequence is a lowered open-circuit voltage (V_{oc}) and increased dark

Key words: flatband potential shift, diode quality factor, Schottky barrier theory.

currents and carrier recombination with a concomitant deterioration in the overall energy conversion efficiency of the PEC system.

Experiments were carried out on a model PEC cell comprising the n-GaAs|$AlCl_3$-n-butyl pyridium chloride (BPC), ferrocene/ferricenium ion couple|carbon system (6-8).

Experimental

PEC devices were fabricated from single crystal n-GaAs (Te-doped, <111> orientation with As exposed to the electrolyte) electrodes. These electrodes had doping densities of 2.17×10^{17} cm^{-3} as quoted by the manufacturer (*vide infra*). Electrode fabrication, etching, and other surface treatment procedures followed those outlined previously (7). The surface area (uncorrected for surface roughness) of these electrodes was nominally 0.23 cm^2.

Molten salt electrolytes consisting of mixtures of $AlCl_3$ and BPC in varying molar ratios were prepared according to procedures described elsewhere (6). Redox chemicals were obtained from commercial sources and purified further by recrystallization. Nominal concentrations of ferrocene ($Fe(Cp)_2$) and ferricenium chloride ($Fe(Cp)_2Cl$) were 0.2M and 20 mmols, respectively. All manipulations with the electrolytes and redox chemicals were carried out in a dry box.

A 300W tungsten halogen lamp was used to illuminate the n-GaAs electrodes. A nominal light intensity of 100 mw/cm^2 (AM1 solar simulation) was used for these experiments. The solar cell parameters reported herein are not corrected for light reflection and absorption losses in the cell and in the electrolyte.

Dark current-voltage measurements were performed as outlined previously (7, 8). Three-electrode geometry was employed for these measurements as well as for the capacitance voltage measurements using the lock-in technique (6). An aluminum wire immersed in the $AlCl_3$-BPC electrolyte (2:1 molar ratio) and separated from the main cell compartment by a fine-porosity glass frit, was employed as the quasi-reference electrode. Solar cell measurements were carried out on two-electrode PEC cells using vitreous carbon as the counterelectrode.

Measurements at elevated temperatures were carried out in a thermostated cell assembly. The temperatures reported below are accurate to ±1°C.

Results and Discussion

Figure 1 illustrates current-voltage census for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|carbon PEC cell with temperature shown as the parameter. The $AlCl_3$-BPC electrolyte in this case was adjusted to be slightly basic of the 1:1 ($AlCl_3$:BPC) molar ratio composition since previous studies had shown this composition to be most suitable in combination with n-GaAs electrodes for photovoltaic applications (6-8). An increase in the short-circuit current density (J_{sc}) and a decrease in the open-circuit voltage (V_{oc}) are observed with increasing temperature. These trends are better illustrated by the data shown in Fig. 2 on the variation of J_{sc}, V_{oc}, fill-factor (*FF*), and solar conversion efficiency (η) with temperature. The V_{oc} values decrease at the rate of ~3.6 mV/°C whereas the *FF* shows a corresponding decline of ~0.001/°C. We note here that similar decreases in V_{oc} with temperature (2.3-2.6 mV/°C) have been noted by previous authors for solid-state p-n junction and Schottky barrier devices based on silicon (9, 10).

The observed increase in the J_{sc} values for the present cells has its origin both on temperature-induced changes in the optical and electrical properties of the semiconductor as well as on corresponding variations in the potential and charge distribution across the semiconductor/electrolyte interface (*vide infra*). For the purposes of the present study, we will concentrate on the latter aspect since previous studies on solid-state cells (5) have clearly shown how temperature affects the electronic and optical behavior of the semiconductor. We briefly note, however, that these studies

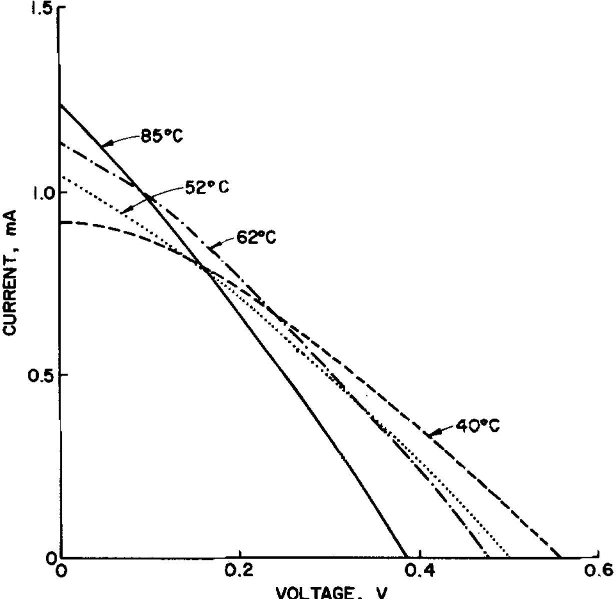

Fig. 1. Current-voltage curves for two-electrode n-GaAs 1:1 $AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|carbon PEC cell at different temperatures. Illumination with tungsten-halogen lamp at ~100 mW/cm^2 incident light intensity (uncorrected, see text).

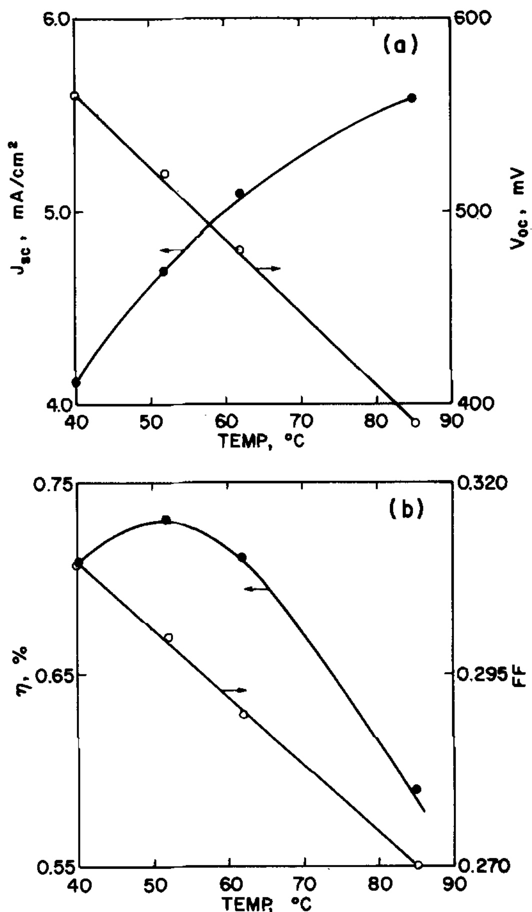

Fig. 2. (a) Variation of short-circuit current density (J_{sc}) and open-circuit voltage (V_{oc}) with temperature for model PEC device. (b) Variation of energy conversion efficiency (η) and fill-factor (*FF*) with temperature for model PEC device.

have revealed the following: (*i*) the wavelength response shifts toward the red with increasing temperature because of bandgap narrowing, (*ii*) the diffusion length of photogenerated carriers increases with increasing temperature, and (*iii*) the absorption coefficient at longer wavelengths increases with increasing temperature because of (*i*) above. All of the above contribute to the observed increase in J_{sc} values with increasing temperature (Fig. 1 and 2).

In order to understand the temperature dependence of V_{oc} (Fig. 2), we consider the Schottky diode equation for the semiconductor/electrolyte interface (11)

$$J = J_{ph} - J_d = J_{ph} - J_o [\exp (qV(nkT) - 1] \quad [1]$$

where J is the total current density, J_{ph} is the photocurrent density, J_d is the dark current density, J_o is the reverse saturation current density, V is the bias voltage, and n is the diode quality factor [$n = 1$ for an ideal device; $n > 1$ for a nonideal device, cf. Ref. (6)]. For bias voltages exceeding $3kT/q$, we can neglect the last term in the bracket in Eq. [1]. Moreover at equilibrium (open-circuit conditions), $J_{ph} = J_d$ and $V = V_{oc}$ so that rearrangement of Eq. [1] yields

$$V_{oc} \simeq \frac{nkT}{q} \ln \frac{J_{ph}}{J_o} \quad [2]$$

Equation [2] shows that the larger the value of J_o the smaller will be the V_{oc} value generated by the device for same value of J_{ph}. Figure 3 is a plot of J_o as a function of temperature for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|carbon PEC cell. Values of J_o were obtained from the intercept with the current axis of the extrapolated linear portion of $\ln J_d$ *vs.* V curves at zero cell potential. The exponential increase in J_o with temperature is consistent with the equation (11)

$$J_o = A^* T^2 \exp (-\phi_b/kT) \quad [3]$$

where A^* is the Richardson's constant [$\sim$9 A cm^{-2} K^{-2} for the present PEC system, Ref. (11)] and ϕ_b is the barrier height at equilibrium. Equation [3] clearly shows that J_o is thermally activated. In PEC systems, ϕ_b is given by the difference between E_{CB} and E_{redox}, where E_{CB} is the energy corresponding to the semiconductor conduction bandedge and E_{redox} is the equilibrium redox potential (cf. Fig. 4).

Since recent studies have shown that charge transfer in PEC systems is largely mediated via surface-states (6, 7, 12), an alternative picture of the situation at the semiconductor/electrolyte interface is also shown in Fig. 4 where E_t denotes a discrete trap level at the interface introduced by defects, specifically adsorbed

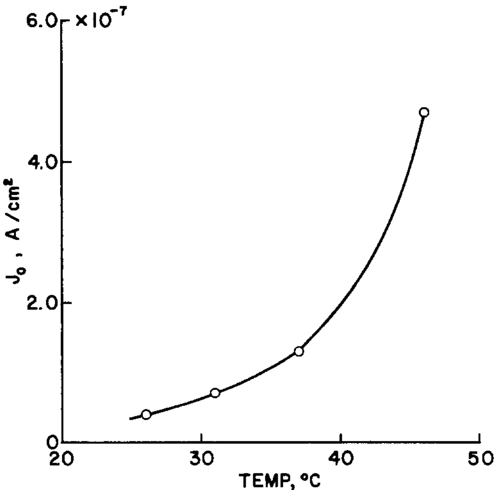

Fig. 3. Variation of reverse saturation current density (J_o) with temperature for model PEC device.

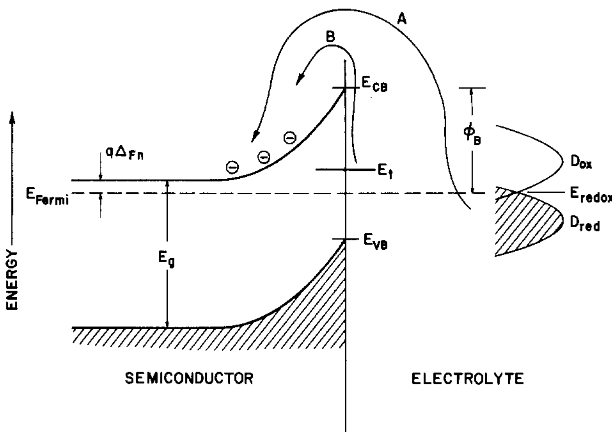

Fig. 4. Energy-band diagram for a PEC device at equilibrium. E_g is the semiconductor energy bandgap, D_{red} is the reduced redox levels, and D_{ox} denotes the oxidized (empty) levels in the electrolyte. See text for description of other symbols. electrolyte ions, etc. Evidence for the mediation of surface states in charge transfer in the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|carbon system was presented in previous work (6). It was also speculated that specific adsorption of Cl^- ions on the n-GaAs surface was the origin of these bandgap states (8). Under condition of relatively large reverse bias such that there is high band bending and consequently majority carrier depletion at the interface, we can neglect the forward current flow of electrons from the semiconductor into the electrolyte. We then have the following equation for the rate of electron transfer from the trap level into the semiconductor conduction band (13)

$$J_o \cong q \frac{dn_t}{dt} = -qK_n n_t N_c \exp \left(-\frac{E_{CB} - E_t}{kT} \right) \quad [4]$$

where K_n is the rate constant given by $\bar{c}\sigma$ ($\bar{c}$ = thermal velocity of electrons and σ = capture cross section of trap level), n_t is the density of occupied trap states, and N_c is the density of available states in the conduction band. Equation [4] shows that electron injection is thermally activated with an activation energy $E_{CB} - E_t$. We also see from Eq. [3] and [4] that the relative position of the semiconductor energy levels with respect to either the trap or redox levels is an important parameter in determining the magnitude of this activation energy. For the following discussion, we assume that $qV_{FB} \simeq E_{CB}$ which is a reasonable approximation for relatively heavily doped semiconductors since the difference $|E_{CB} - qV_{FB}| \leq \sim 0.1$ eV.

Figure 5 illustrates the dependence of V_{FB} on temperature for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|carbon system. The data are displayed in the form of conventional Mott-Schottky plots (14). The $AlCl_3$-BPC electrolyte in this case was adjusted to be basic (pCl = $\sim$7) by addition of appropriate amounts of BPC to the neutral 1:1 composition. A systematic shift in V_{FB} to positive potentials is evident in the data in Fig. 5. This shift has important consequences on the magnitude of J_o and therefore J_d (cf. Eq. [1]). Considering the direct charge exchange between the reduced redox species in the electrolyte and the conduction band in the semiconductor (represented by scheme A in Fig. 4 and Eq. [3]), we now estimate the corresponding temperature-induced changes on E_{redox}. We have the following Nernst equations

$$E_1 = E^0 + \frac{kT_1}{n_e q} \ln \frac{[ox]}{[red]} \quad [5]$$

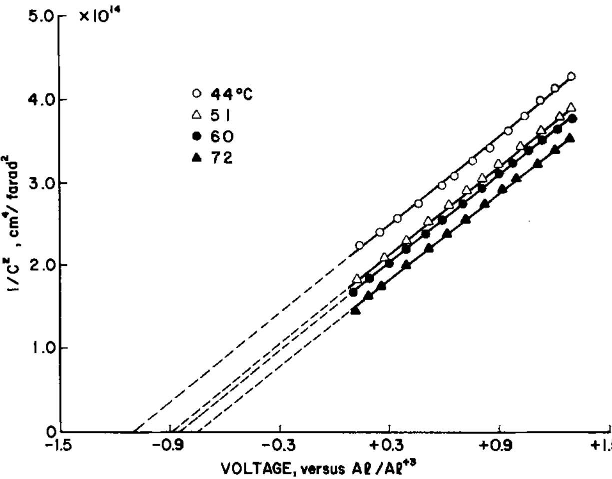

Fig. 5. Mott-Schottky plots for the n-GaAs|$AlCl_3$-BPC interface at different temperatures. The a-c signal frequency was 10 kHz for these measurements.

$$E_2 = E^0 + \frac{kT_2}{n_e q} \ln \frac{[ox]}{[red]} \quad [6]$$

where E^0 is the standard redox potential, [ox] and [red] denote bulk concentrations of oxidized and reduced redox species, respectively, n_e is the number of electrons involved in the redox reaction, and the subscripts 1 and 2 denote two different temperatures. To a first approximation we can neglect temperature-induced changes in the redox concentrations and the reference electrode potential, so that subtraction of Eq. [6] from Eq. [5] yields

$$\Delta E_{redox} = E_2 - E_1 = \frac{k(T_2 - T_1)}{q} \ln (0.1) \quad [7]$$

where the molar concentrations of $Fe(Cp)_2^+$ and $Fe(Cp)_2$ have been inserted. An estimate of ΔE_{redox} from Eq. [7] and corresponding changes in V_{FB} as a function of temperature are shown in Table I. The data clearly show that changes in V_{FB} (and therefore E_{CB}) far outweigh the effect of temperature on E_{redox}. For all practical purposes, therefore, the direction of the shift in V_{FB} with temperature will immediately indicate the magnitude of the dark current density at elevated temperatures. Again the implicit assumption is involved that E_{CB} does not shift with applied bias or illumination. In the presence of high surface-state densities and consequent dependence of the potential distribution across the semiconductor/electrolyte interphase on the bias voltage, the simple model described above will be no longer applicable. The present data on the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|carbon cell as well as previous work (6, 7), however, suggest a behavior consistent with this simplified model. The barrier-height reduction with temperature is shown in Table II for this PEC system.

By arguments analogous to those described above, we see that the barrier height $E_{CB} - E_t$ is also modi-

fied at elevated temperatures (cf. scheme B in Fig. 4 and Eq. [4]). The location of E_t is not expected to vary appreciably with temperature so that the magnitude of the activation energy, $E_{CB} - E_t$, is largely determined by the shift in E_{CB}. Contrary to the direct charge transfer case (cf. scheme A in Fig. 4), however, experimental evidence is less conclusive in support of the trap-mediated electron injection mechanism in the present PEC system. For example, barrier-height data obtained from the slopes of J_o/T^2 vs. $1/T$ plots [cf. Eq. [3], see Ref. (8)] are in excellent agreement with the results of capacitance measurements on the n-GaAs|AlC_3-BPC, $Fe(Cp)/Fe(Cp)_2^+$|carbon PEC system. On the other hand, if we place the location of E_t/q as −0.1V (vs. Al/Al^{+3}) based on the observed position of reduction waves on n-GaAs (6), we obtain $E_{CB} - E_t = 0.65$ eV for the slightly basic $AlCl_3$-BPC electrolyte [$V_{FB} = -0.75$V, Ref. (6)] which is considerably less than the value (~1 eV) obtained from dark current-voltage data (8). The above alternative model was considered as a general case since its occurrence in other PEC systems is supported by previous studies in the literature (12).

The temperature dependence of V_{FB} has been discussed by previous authors (15) in terms of the following expression

$$qV_{FB} = EA - E_o - q\Delta_{fn} - q\Delta V_H \quad [8]$$

Here EA is the electron affinity of the semiconductor, E_o is the position of the reference electrode relative to the vacuum level, Δ_{fn} is the potential difference between the Fermi level and the bottom of the conduction band (cf. Fig. 4), and ΔV_H is the potential across the Helmholtz layer due to adsorbed ions. We speculate that the origin of the positive potential shift in V_{FB} with temperature (Fig. 5) in the n-GaAs|$AlCl_3$-BPC system lies in temperature-induced desorption of Cl^- ions from the n-GaAs electrode surface. The surface thereby acquires an increasing positive charge with increasing temperature leading to the observed shift in V_{FB}.

We note that the slopes of the Mott-Schottky plots in Fig. 5 yield semiconductor doping densities of 0.74×10^{17} cm^{-3} at 44°C, 0.71×10^{17} cm^{-3} at 51°C, 0.71×10^{17} cm^{-3} at 60°C, and 0.74×10^{17} cm^{-3} at 72°C, respectively. The constancy of these values at different temperatures provides a further check on the reliability of the Mott-Schottky analyses in Fig. 5.

Table III shows the effect of temperature on Schottky diode parameters for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|C system. The parameter V_o is determined by the change in the voltage, ΔV, for a decade change in the current density (16) and was computed from the dark-current vs. voltage data in Ref. (8). For nonideal Schottky diodes, V_o is given by (16)

$$V_o = nkT/q \quad [9]$$

The diode quality factor is therefore given by the equation

$$n = V_o/kT/q \quad [10]$$

Values of n computed from Eq. [10] as a function of

Table III. Schottky diode parameters for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2^+$|C system

46	27.5	50.7	1.84

* Computed from experimental data in Ref. (8).

temperature are assembled in Table III. By analogy with the behavior of p-n junction solid-state devices, values of $n > 1$ may be interpreted in terms of the dominating influence of recombination-generation currents on the current-voltage behavior of the device (7, 8). The systematic increase in n with temperature is indicative of the propensity of such processes either in the semiconductor bulk or at the interface at elevated temperatures. The deterioration in the fill-factor as seen in Fig. 2b may be therefore attributed to the series resistance associated with recombination-generation current flow paths. Precedence for such effects is found in previous work on solid-state p-n junction devices where the blue wavelength response is seen to degrade at elevated temperatures, presumably because of carrier recombination effects at the surface (5).

Summary and Conclusions

Although temperature has beneficial effects on the short-circuit current densities of a PEC device, there is an optimum temperature beyond which the deleterious effect of high dark current densities begins to degrade the overall energy conversion efficiency of the system. Apart from the thermal activation of the reverse saturation current density at elevated temperatures, which is analogous to the case of a solid-state Schottky barrier device, temperature brings about unfavorable modifications in the potential and charge distribution across the semiconductor/electrolyte interface. The consequence of positive potential shifts in V_{FB} at elevated temperatures is a net reduction in the barrier height at equilibrium and a concomitant increase in the reverse saturation current density. It must be noted, however, that the direction of the shift in V_{FB} and V_{CB} is determined largely by temperature-induced changes in the chemistry of the semiconductor/electrolyte interface and as such must be specific to each semiconductor/electrolyte combination.

Technical Note

Enhancing Performance of the Ti(III)/Ti(IV) Couple for Redox Battery Applications

C. C. Liu*,[1] and R. T. Galasco

Department of Chemical and Petroleum Engineering, University of Pittsburgh, Pittsburgh, Pennsylvania 15261

and R. F. Savinell*

Department of Chemical Engineering, The University of Akron, Akron, Ohio 44325

Redox battery systems in recent years have generated interest as a means for large-scale energy storage. Of the redox couples, Fe-Cr ($E^\circ = 1.18V$) (1, 2) and Fe-Ti ($E^\circ = 0.67V$) (3-7) are considered promising. However, the Fe-Ti system was less attractive due to a combination of unfavorable pH and kinetic effects. Recent analysis of the Fe-Ti system indicates that the titanium half-cell reaction during discharge is the rate-limiting one (5, 6). Improvement in the performance of this half-cell is needed for the Fe-Ti system in order to make it into an attractive energy storage device.

In our earlier studies, it was suspected that the kinetic activation limitations in the titanium half-cell might be caused by partial blockage of active anodic surface area by TiO_2 precipitation. This TiO_2 precipitation is most likely the result of a reaction between the titanium (IV) oxide with water in the bulk electrolyte. Schematically, this reaction sequence can be represented as

$$Ti^{+3} + H_2O \rightarrow TiO^{+2} + 2H^+ + e^-$$
(anodic charge transfer reaction)

$$TiO^{+2} + H_2O \rightarrow TiO_2 \text{ (electrode)} + 2H^+$$
(deactivation reaction)

If TiO_2 precipitation does occur, this precipitation can be hindered by adding a soluble chelating agent to the anolyte. Consequently, this may lead to the enhancement of the performance of the titanium half-cell as well as the redox battery system. Due to the strong affinity of titanium for oxygen, thus, theoretically, oxygen chelating agents in acid solution can be expressed as

O O ⇌ O OH —(TiO^{+2})→ O O (TiO^{+2})
R R R R R R

Additionally, the chelating agent may enhance the stability of the titanium (IV) oxide, resulting in more favorable kinetics for the cathodic reaction. Of course, in order for a chelating agent to be effective in an actual battery system, the chelation reaction must allow for the reduction of the stabilized TiO^{+2} species when the battery is undergoing charge.

Another possible method of minimizing the formation of TiO_2 in the titanium half-cell would be the addition of a reducing agent to the anolyte. The reducing agent can react with the titanium (IV) oxide producing titanium (III) ions in the bulk anolyte. It is possible that this reaction will occur preferentially to the TiO_2 formation reaction both during battery charge and discharge modes of operation.

In addition to the possible minimization of TiO_2 formation, the reducing agent itself may be a primary participator in the electrode reaction, *i.e.*

$$M \rightarrow M^{+z} + ze^-$$

This reaction may either replace or supplement the anodic charge transfer from the titanous ion. In either case, the role of the reducing agent must be reversible so that the agent can be regenerated upon charging the battery. Otherwise, consumption of the agent will result eventually in a change of electrolyte characteristics and in excessive costs.

Experimental

The chelating agents used in this study should be highly soluble and physically stable in the concentrated $HCl-TiCl_3$ anolyte and good chelates for titanium (IV) oxide in the acid solution. Acetylacetone, disodium EDTA, oxalic acid, and glycerol were selected as possible chelating agents.

The reducing agent used in the system should be able to reduce titanium (IV) oxide ions to titanium (III) ions at a reasonable rate. Also, solid reducing agents should have a high H_2 overpotential and should be relatively stable in the concentrated $HCl-TiCl_3$ anolyte.

Reducing agents used for the reduction of titanium (IV) ions to titanium (III) ions have been reported and are generally in the form of granular metal or amalgams, metal or amalgam foils, or liquid amalgams with excess mercury. For the system studied, liquid amalgam would be impractical, hence granular metals and solid amalgams were chosen in this investigation.

Granular lead particles (Fisher Scientific) and porous lead structure (10 pores per linear inch, Energy Research and Generation, Incorporated, Oakland, California) were evaluated as well as granular tin and amalgams of zinc and cadmium. Since the reducing agent must be stable in the electrolyte, a qualitative visual examination was used to determine those agents which do not, at least apparently, generate hydrogen gas when in contact with solution. The test solutions are given in Table II. In the electrolyte having sodium

Key words: redox, battery, titanium.

chloride salt, the salt replaced the acid to a certain extent with the intention of reducing protons available for hydrogen production while maintaining sufficient supporting electrolyte for adequate charge transfer in solution.

The redox prototype used in this study was a stationary cell which is shown schematically in Fig. 1. The membrane separator employed was the MA-3475 commercial membrane produced by Ionac Chemical Sybron Corporation (Birmingham, New Jersey). Graphite foil of 0.0254 cm thickness (Grade GTA, Union Carbide Corporation) was used at the cathode and as the anode current collector. The electrodes and the membrane had an exposed area of 19.6 cm^2. In the earlier experiments the chelating agent was added to the anolyte only. In all cases the molar ratio of chelating agent to $TiCl_3$ was greater than one. For example, in the case of acetylacetone, 12.5 cm^3 of acetylacetone was added to 50 cm^3 of anolyte (1M $TiCl_3$/3*N* HCl) giving a molar ratio of chelating agent to reactant of 2.4 to 1.

In the later experiments the reducing agent was added to the anode compartment as solid granules. For example, when lead was studied as the reducing agent, 35g of lead granules were added to 16.6 cm^3 of anolyte. The result was a mixture having a lead to $TiCl_3$ molar ratio of 10.2.

Results and Discussion

Table I summarizes the experimental results of using chelating agents in the anolyte of the Fe-Ti redox system.

Of the chelating agents studied, only oxalic acid and acetylacetone showed evidence of possible chelation through color change. However, the discharge performance of cells having these agents present in the electrolyte were unchanged or inferior when compared to the standard Fe-Ti cell.

The experimental results of the system using acetylacetone indicated a decrease of approximately 70 mV in anodic overpotential at a discharge current density of 8.5 mA/cm^2. The amount of acetylacetone addition in this work was the same as reported by Reid and Gahn (3). However, they report a lowering of anodic overpotential by 300 mV. Furthermore, they observed a corresponding increase in cell discharge potential of 300 mV (presumable, with constant load discharge, the operating cell current density of their cell appears to be ~10 mA/cm^2). In our study with acetylacetone, the enhanced anodic performance was not accompanied by a corresponding increase in overall cell potential. Consequently, we observed no net gain in cell discharge performance.

In our studies with reducing agents, the qualitative test for determining metal stability in electrolyte shows that only lead was apparently stable. Some reaction

Chelating agent	Molar ratio TiCl₃ : chelating agent	Visible chelation	Performance
2-4 pentanedione (acetylacetone)	2.4:1	Yes	Discharge performance similar to standard cell
Disodium EDTA	1.05:1	—	Precipitates rapidly from solution
Oxalic acid	1:1	Yes	Poor discharge performance
Glycerol	2:1	No	Discharge performance similar to standard cell

was obviously occurring at the surface of tin while copious amounts of hydrogen were produced at the surfaces of the zinc amalgam and the cadmium amalgam.

The open-circuit potentials for Fe-Ti systems containing lead or tin reducing agents are listed in Table II. The open-circuit potential of the Fe-Ti cell without any reducing agent is shown for comparison. With a reducing agent present, the open-circuit potential increased between 350-400 mV depending upon electrolyte composition. At this time we are unsure of the cause of this increase in observed potential but we suspect that it may be due to Nernstian effects and/or electrochemical oxidation of the reducing agent. The basis for this suspicion is the fact that a lead chloride deposit was found on the lead particles following a cell discharge. Further studies were restricted to using lead as the reducing agent.

Although the lead chloride found on the granules may be formed by the reaction

$$Pb^\circ + 2H^+ + 2Cl^- \rightarrow PbCl_2 + H_2$$

we do not believe this reaction to be of significance in this case. The chemical oxidation of lead in acid chloride medium has been reported as being of less importance as compared to electrochemical oxidation (8). In our qualitative stability test for the reducing agents in electrolyte, we observed no hydrogen generation from lead. Furthermore, the lead chloride deposit only was found after cell discharge.

One reaction which may account for the lead chloride formation and the enhanced cell potential is

$$Pb^\circ + 2TiO^{+2} + 2Cl^- + 4H^+ \rightarrow PbCl_2 + 2Ti^{+3} + 2H_2O$$

In order to account for the magnitude of increase observed in the open-circuit potential, the activity ratio of Ti^{+3}/TiO^{+2} must be *ca.* 10^6. The above mechanism also would create a favorable effect on reaction rates. That is, since this reaction occurs at the lead surface, it would increase the reactant concentration at the surface and diminish the product concentration. Consequently, with first-order forward and backward kinetics, the rate of Ti^{+3} oxidation should be enhanced.

Another possible explanation for phenomena in the anode compartment of a Fe-Ti redox cell can be given

Table II. Battery open-circuit potentials for Fe-Ti systems containing reducing agents (mole reducing agent/moles $TiCl_3$ = 10.2)

Type of reducing agent	Electrolyte concentration	Open circuit potential (V)	Anode potential *vs.* SHE (V)	Cathode potential *vs.* SCE (V)
None	3.0*N* HCl in catholyte 3.5*N* HCl in anolyte	0.782	0.071	0.853
Pb	3.0*N* HCl in catholyte 3.5*N* HCl in anolyte	1.193	−0.366	0.825
Pb	0.53*N* HCl, 2.5M NaCl	1.17	—	—
Sn	3.0*N* HCl in catholyte 3.5*N* HCl in anolyte	1.17	—	—
Sn	0.53*N* HCl, 2.5M NaCl	1.14	—	—

as the following reaction

$$Pb^\circ + 2Cl^- \rightarrow PbCl_2 + 2e \; E^\circ = -0.513V \; (vs. \; SCE) \quad [9]$$

In this case, enhanced performance may be directly attributed to the electrochemical characteristics of this reaction. The oxidation of lead in chloride medium has been recently reviewed by Kuhn (9). Although $PbCl_2$ will often passivate the electrode, with some forms of $PbCl_2$ deposits and under certain operating conditions this will not occur (8, 10-13). Barradas (13) has shown that a lead electrode in HCl solution undergoes the 2-electron oxidation reaction of

$$Pb \rightleftarrows Pb^{+2} + 2e^-$$

$$Pb^+ + nCl^- \rightleftarrows PbCl_n^{2-n}$$

where $4 > n > 0$. In this mechanism the high chloride concentration favors the complex ion formation of the second reaction which in turn diffuses to the bulk electrolyte. Under these conditions, the oxidation of lead occurs with considerable reversibility. In our studies we have found the presence of titanium chloride to be necessary for maintaining the enhanced performance of a lead electrode in an acid chloride medium.

A comparison of constant load short-term discharge between a standard Fe-Ti cell and an Fe-Pb(Ti) cell is shown in Fig. 2. The Fe-Ti cell shows a useful cell discharge potential approaching only 20% of the initial ($t = 0$) cell open-circuit potential after a short discharge time. Moreover, battery performance is limited by the anodic overpotential which is greater than 40% of the initial cell open-circuit potential. By comparison, the Fe-Pb(Ti) cell has a useful cell discharge potential near 40% of the initial cell open-circuit potential. The anodic overpotential is less than 14% of this open-circuit potential. However, the cathodic overpotential now represents a more significant contribution to cell polarization at 27% of open-circuit potential. The increase in cathodic overpotential and membrane *IR* loss are a direct result of the greater discharge current (constant load discharge) obtained with the Fe-Pb(Ti) cell.

We have examined the role of lead and titanium chloride in an Fe-Pb(Ti) cell. The results of this investigation along with charge/discharge operating characteristics of this cell will be reported in a separate communication.

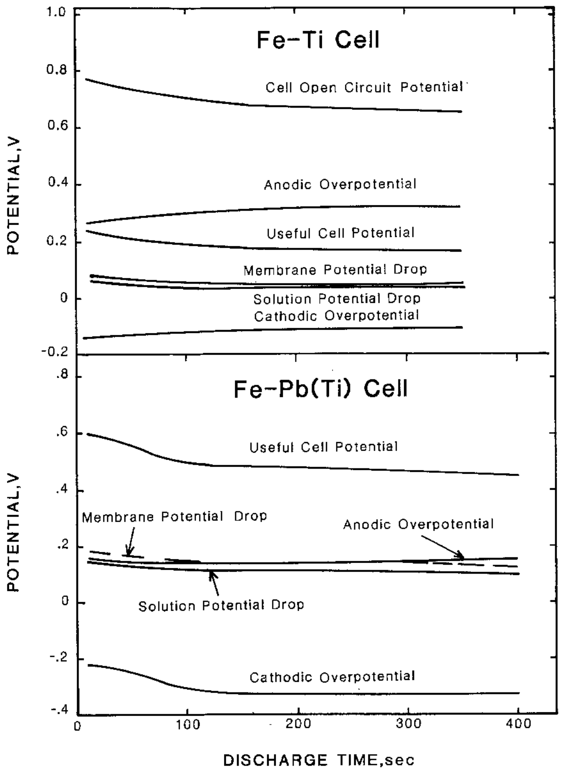

Fig. 2. A comparison of short-term constant load (1Ω) discharge performance of the standard Fe-Ti cell [reported in Ref. (5)] with the Fe-Pb(Ti) cell.

Conclusions

In summary, the results of this study showed that the approach of using a chelating agent in the anolyte for an Fe-Ti redox system only shows marginal improvement in cell discharge performance. However, the application of a solid reducing agent in the anolyte, particularly lead, showed enhancement in the performance of the redox system. This effect has been investigated and will be reported in detail separately.

ABSTRACT

Novel vinyl monomers containing the α-CF_3 group are shown to increase the propensity toward chain scission during radiation degradation and increase the electron beam sensitivity in copolymers with methyl methacrylate and methacrylonitrile. The incorporation of 32 m/o of α-trifluoromethacrylonitrile (TFMAN) into poly(methyl methacrylate) increases sensitivity from 20×10^{-5} to 3×10^{-5} C/cm^2 (at 2 keV), increases G_s from 1.3 to 3.1, and decreases the etch rate from 100 to 79 Å/min. Similar beneficial results come from incorporating TFMAN into methacrylonitrile (MCN) copolymers. Poly(trifluoroethyl methacrylate) is a highly sensitive resist ($Q = 2$ to 3×10^{-5} C/cm^2) but it exhibits a high etch rate (230 Å/min). Incorporation of 31 m/o MCN into this polymer decreases the etch rate to 93 Å/min while preserving a high sensitivity ($3\text{-}4 \times 10^{-5}$ C/cm^2). The G_s and G_x values of these homo- and copolymer systems as well as the copolymer of methacrylonitrile with methyl α-fluoroacrylate (MFA) were obtained. The homopolymer of MFA cross-links on irradiation but its MCN copolymers tend to be positive resists with G_x values lower than that expected if G_x were a linear function of the MFA mole fraction.

The incorporation of fluorine and chlorine into vinyl polymers for use as electron-beam (1) or x-ray (2) resists is a topic of increasing interest. Fluorine and chlorine each have high x-ray absorption coefficients. The atomic absorption coefficient at 4.15Å for chlorine is 1614 (21 times that of carbon) while that for fluorine at 8.3Å is 1898 (3.4 times that of carbon). Also, the incorporation of halogens might modify the radiation degradation chemistry (3) by providing favored pathways for chain scission. Indeed, we have shown that poly(methyl α-chloroacrylate) exhibits a very high chain scission propensity ($G_s > 6$) (4). Recently, we reported that fluorine incorporation at the α-position of an acrylate (*i.e.*, $[CH_2C(F)(CO_2CH_3)]_n$) dramatically reversed the degradation behavior found for other α-substituents (*e.g.*, CN, CH_3, Cl, $CH_2CO_2CH_3$), to that of a predominantly cross-linking negative resist (5, 6). In contrast, fluorine incorporation into the ester group of methacrylate polymers (*e.g.*, $[CH_2C(CH_3)(CO_2CH(CF_3)_2)]_n$) was found to enhance the chain scission susceptibility over that of the classical system, poly(methyl methacrylate) (5).

Such studies provide the fundamentally important radiation G-values and allow successful prediction of radiation resist behavior for integrated circuit fabrication applications. We now report further novel fluorine-containing polymers including those where the α-substituent is $-F$ or $-CF_3$, as well as copolymers of 2,2,2-trifluoroethyl methacrylate (TFEM) with methacrylonitrile (MCN). The monomer α-trifluoromethylacrylonitrile (TFMAN) was copolymerized with methacrylonitrile and methyl methacrylate (MMA), while methyl α-trifluoromethylacrylate (TFMMA) was copolymerized with methyl methacrylate. The radiation degradation susceptibilities, electron beam sensitivities, and plasma etch rates for these systems have been obtained. The structural formulas and designated abbreviations used throughout the paper are shown on the following page.

These polymer structures are of particular interest in view of Kakuchi's report (7) that the electron beam sensitivity of poly(hexafluorobutyl methacrylate) was 4×10^{-7} C/cm^2 and its x-ray sensitivity was 46 times more sensitive than poly(methyl methacrylate), *e.g.*, PMMA. They represent new structures in a larger program in our laboratories to ascertain the radiation degradation susceptibilities, electron beam behavior, and plasma etch rates of potential resist polymers as a function of polymer structure (8-16).

Experimental

Polymer molecular weights were determined by gel permeation chromatography (GPC) or membrane osmometry (MOSM). GPC was performed using a Water Associates Model 201 chromatograph equipped with four microstyragel columns (exclusion sizes: 10^6, 10^5, 10^4, and 10^3). GPC measurements were made at a flow rate of 1.0 cm^3/min of $CHCl_3$, THF, or DMF; the solvent used was dictated by the copolymer solubility. The "Universal Calibration" method was used to analyze the GPC data, and the PMMA calibration curve was used for $CHCl_3$ and THF data. A polystyrene calibration curve was used for DMF GPC data. MOSM was performed with a WESCAN Model 230 Osmometer at 30° using acetonitrile or MEK as solvent. Molecular weight data for the polymers synthesized and fractionated in this study, prior to irradiation, are found in Table I. γ-Irradiations and data analysis to obtain G (scission), G_s, and G(cross-link), G_x, were carried out as described previously (8-13).

The synthesis of methyl α-fluoroacrylate, MFA, has been described elsewhere (14) and the preparation of trifluoromethacrylonitrile and methyl α-trifluoromethylacrylate will be described subsequently (15). The MFA/MCN copolymers were prepared by emulsion polymerization at 50° using $K_2S_2O_8$ as the initiator and sodium lauryl sulfate as the surfactant. The emulsions were deoxygenated by nitrogen purging and stirred magnetically. The copolymer lattices were coagulated by pouring into stirred methanol, filtered, and dried overnight *in vacuo* at 40-50°C. MFA/MCN copolymers were fractionated by dissolving 25g of polymer into 650 ml of acetonitrile and adding methanol dropwise in the usual fashion. The copolymer compositions were determined by elemental analysis for fluorine and for carbon. The synthetic details are given in Table II.

2,2,2-Trifluoroethyl methacrylate was prepared in good yield from methacrylyl chloride and 2,2,2-trifluoroethanol in the presence of triethylamine using standard methods. It was copolymerized with MCN using the emulsion method described above for MFA/MCN copolymerizations and the conditions and results are in Table II.

Trifluoromethacrylonitrile was copolymerized with MMA or MCN by bulk polymerization using azobisisobutyronitrile (*e.g.*, AIBN) as the initiator. The monomers and AIBN were weighed into an ampul and the solution was degassed by three alternate vacuum freeze thaw cycles. The ampul was sealed, immersed in an oil bath for the reaction period, cooled, broken, and the resulting block of polymer was dissolved in acetone. The copolymers were purified by reprecipitations from acetone into methanol followed by drying *in vacuo*. Methyl α-trifluoromethylacrylate was copolymerized with MMA in the same manner. Table II lists conditions and results.

The electron beam resist sensitivities, in Table IV, were obtained at 20 keV using an ETEC LEBES E-beam microfabricator. The values are for a 6800Å original resist thickness with no loss in unexposed resist thickness during development. Resist film thicknesses were measured with a Tencor Alpha-step profilometer.

Plasma etch rates were obtained with either an IPC 4005 or Tegal 421 reactor. The rf power during etching was 100 and 150W for the IPC 4005 and the Tegal 421, respectively. The pressures were 0.7 and 0.5 Torr of CF_4/4% O_2 and CF_4/8% O_2 gas mixtures, respectively. The reported values are reproducible to ±15%.

Results and Discussion

The MFA/MCN copolymers, when γ-irradiated *in vacuo*, predominantly degrade, as shown in Table III. The MCN homopolymer exhibits a large (3.3) value of

[a] See Table I for compositions and initial molecular weights of these polymers.
[b] See Ref. (1).

G_s and G_x is zero, whereas the MFA homopolymer is a negative resist ($G_s - G_x = -1.1$). As one increases the MFA content of MFA/MCN copolymers from 16 to 20 to 49 mole percent (m/o), the values of G_s fall from 2.3 to 2.0 to 1.9, respectively. It is remarkable that the G_x value is zero for both the 16 and 20 MFA m/o copolymers and that of the 49% copolymer is almost zero (i.e., 0.04) when the G_x value for the MFA homopolymer is about +1. Apparently, the cross-linking is a second-order process which is largely "diluted out" in the copolymer samples. These results are graphically displayed in Fig. 1. As we recently found for other copolymers, G_s is approximately linearly related to the M_1/M_2 composition and G_x varies as a power dependence. This was previously shown for several copolymer systems including: methyl α-chloroacrylate/methacrylonitrile (4), methyl α-fluoroacrylate/methyl methacrylate (6), α-chloroacrylonitrile/methyl methacrylate (16), and vinylidene chloride/methyl methacrylate (16). The G_x experimental values all fall below those predicted by a straight line drawn between the homopolymer values.

The homopolymer of 2,2,2-trifluoroethyl methacrylate, TFEM, and its methyl methacrylate, MMA, copolymers were shown to be positive resists. The homopolymer exhibits $G_s = 2.3$ and $G_x = 0$. Similarly, TFEM/MCN copolymers degrade efficiently over the entire M_1/M_2 composition range and no evidence for cross-linking was found (*e.g.*, $G_x = 0$, see Table III). Since $G_x = 0$ for both the homopolymers of TFEM and MCN, this was expected for the copolymers. As the MCN content increases, G_s increases.

All these copolymers have a greater propensity toward scission than MMA. The MCN component dominates because PMCN has the larger homopolymer G_s value.

The goal of examining the effect of α-trifluoromethyl substitution was achieved by (*i*) preparing α-trifluoromethylacrylonitrile and methyl α-trifluoromethylacrylate, (*ii*) copolymerizing the former with MMA and MCN, and (*iii*) copolymerizing the latter with MMA. Radical initiated homopolymerizations of these new monomers were sluggish and their homopolymers were not examined. Since the C-F bond is stronger than the C-H bond and F is much more electronegative than H, the effect of replacing $-CH_3$ by $-CF_3$ on chain scission was of interest. As shown in Table III, the incorporation of 9 or 32 m/o of TFMAN into TFMAN/MMA copolymers causes a large increase in G_s (*e.g.*, to 3.1 in the latter case *vs.* $G_s = 1.3$ for PMMA). No tendency to cross-link was found for TFMAN/MMA, TFMAN/MCN, or TFMMA/MMA copolymers (*e.g.*, $G_x = 0$). The TFMAN/MCN copolymers degrade with approximately the same propensity as PMCN. Furthermore, when only 11% TFMMA is incorporated into the TFMMA/MMA copolymer, G_s increases to 2.4 from its value of 1.3 for PMMA. Taken together, these results show that an α-CF_3 group at a quaternary position leads to ready radiation degradation.

These systems were next studied as electron beam resists. Lithographic images can be developed with poly(methacrylonitrile), PMCN, but toxic nitrile developers need to be used. However, PMCN does have a high glass transition temperature ($T_g = 120°$) and good plasma etch resistance. Thus, its copolymers, which are soluble in a variety of solvents, are logical resist candidates. Poly(2,2,2-trifluoroethyl methacrylate), PTFEM, exhibits an electron beam sensitivity of $2\text{-}3 \times 10^{-5}$ C/cm^2 which is 1.6× more sensitive than PMCN, but PTFEM has a lower T_g (69°) and a poorer CF_4/O_2 etch resistance than PMCN (*i.e.*, 230 Å/min for PTFEM *vs.* 36 Å/min for PMCN). The TFEM/MCN

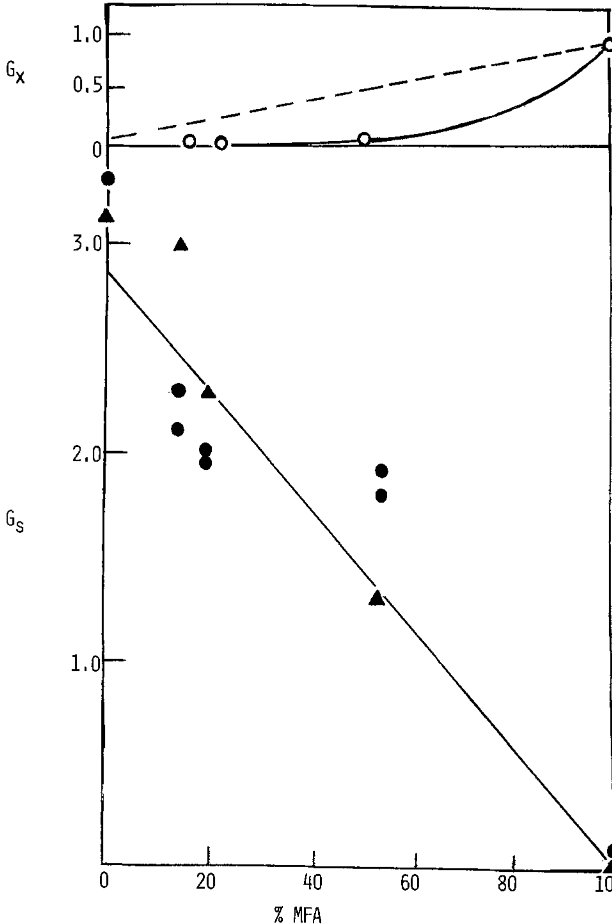

Fig. 1. G_s and G_x vs. m/o MFA for irradiated MFA/MCN copolymers. The solid line (lower) is a least squares fit of all G_s data. The triangles are GPC data, the closed circles MOSM data, and the open circles GPC data. The upper solid line is a power curve fit of the G_x data, $G_x = 9.44 \times 10^{-10}$ [MFA]$^{4.5}$. The dash line is a straight line connecting the homopolymer G_x values.

copolymer system should blend the better characteristics of both homopolymers. Indeed, the 69/31 TFEM/MCN copolymer ($G_s = 2.2$, $G_x = 0$) was found to have an intermediate glass transition temperature of 86° and an intermediate CF_4/O_2 etch rate of 93 Å/min while maintaining a sensitivity 5-6 times higher than that of PMMA (*i.e.*, $Q = 3\text{-}4 \times 10^{-5}$ C/cm² for this copolymer *vs.* $Q = 20 \times 10^{-5}$ for PMMA, 5-7 $\times 10^{-5}$ C/cm² for PMCN, and 2-3 $\times 10^{-5}$ C/cm² for PTFEM).

The observed E-beam resist sensitivity of the 70/30 TFEM/MMA copolymer (2-3 $\times 10^{-5}$ C/cm²) is very close to that of the PTFEM homopolymer value. Since this copolymer, like the 69/31 TFEM/MCN copolymer, contains about 70% TFEM, these sensitivities are not surprising. Approximately half of the increase in sensitivities vs. PMMA can be accounted for on the basis of the larger copolymer G_s values. The remainder must be attributed to dissolution rate effects caused by the buildup of deesterification radiation products (*e.g.*, CO, CO_2, CH_3CF_3, etc.) in the polymer.

The MFA/MCN copolymers behave as positive resists. When the MFA concentration is ≥50%, however, the resist dose working range gets prohibitively small and swelling of the resist becomes unacceptably poor, as is observed for the negative behaving PFMA homopolymer. At 20/80 MFA/MCN, however, the copolymer performs well and swelling is minimal. The sensitivity of the 20/80 MFA/MCN copolymer is very close to that of PMCN, and its Tg is higher. The etch rates for all the MFA/MCN copolymers are low as expected, based on the low etch rates of PMFA and PMCN (see Table IV).

Table IV. Plasma etching rates and electron beam sensitivities of fluorine-containing homo- and copolymers

Polymer or copolymer	F-containing monomer (m/o)	Plasma etch rate[a] (Å/min)	Sensitivity (at 20 keV) $Q \times 10^5$ C/cm²
PFMA	100	40	>>1[b]

PMMA	0	100	20
P(TFEM-co-MMA)[d]			

[a] Using CF_4/O_2 plasmas (see Experimental section).
[b] A negative resist at 10 keV.
[c] Resist swells badly (see text).
[d] This polymer exhibits a T_g of 75° which is between that of PMMA (105°) and PTFEM (69°).

The effect on lithographic properties of incorporating an α-trifluoromethyl group can be illustrated by the 32/68 TFMAN/MMA copolymer (Table IV). Its electron beam sensitivity was 3×10^{-5} C/cm² which is about the same as that exhibited by P(TFEM) and 6-7 times that of PMMA. This is consistent with its high observed G_s value of 3.1 and undetectable (*i.e.*, $G_x = 0$) cross-linking propensity. Another benefit is this copolymer's relatively high T_g value (98°C). Finally, the incorporation of 32 m/o TFMAN reduced the CF_4/O_2 plasma etch rate from 100 Å/min for PMMA to 79 Å/min. Clearly, the incorporation of $-CF_3$ at the alpha position leads to improved resists.

The same beneficial properties were observed for the 12/88 TFMAN/MCN copolymer. Its etch rate (33 Å/min) was slightly lower than that of PMCN (36 Å/min) and its sensitivity (5×10^5 C/cm²) was slightly better than that of PMCN (see Table IV). Even the incorporation of only 11 m/o of TFMMA into an MMA copolymer increased the electron beam sensitivity from 20×10^{-5} to 15×10^{-5} C/cm². This correlates with this copolymer's high G_s value of 2.4 and $G_x = 0$. Thus, the α-CF_3 group appears to be a very promising structural feature to incorporate into electron beam lithographic resists. Synthetic work to prepare copolymers with higher TFMAN and TFMMA contents are now underway.

Nonstoichiometry in $SrTiO_3$

N.-H. Chan,* R. K. Sharma,* and D. M. Smyth*

Materials Research Center, Lehigh University, Bethlehem, Pennsylvania 18015

ABSTRACT

The defect chemistry of polycrystalline $SrTiO_3$ has been studied by means of the equilibrium electrical conductivity as a function of temperature, oxygen activity, Sr/Ti ratio, and impurity additions. Reduction, excess TiO_2, and acceptor impurities all contribute to the oxygen vacancy content and their effects are therefore highly interdependent. The effect of added donor-impurities, *e.g.*, 500 ppm Nb, is highly dependent on the presence and amount of excess TiO_2.

While the equilibrium defect chemistry of $BaTiO_3$ has been studied in considerable detail as a result of its application as a ferroelectric and piezoelectric material (1-9), $SrTiO_3$ has received comparatively little attention. Walters and Grace measured the electrical conductivity in the temperature range 900°-1300°C in H_2O-H_2 mixtures (10), and Yamada and Miller used the Hall effect to measure the electron concentration at room temperature for samples quenched from 1200°-1400°C after equilibration with oxygen pressures in the range $10^{-12} < P_{O_2} < 10^{-7}$ atm (11). Both of these studies on single crystalline $SrTiO_3$ are in good agreement with a model in which the major defects are doubly ionized oxygen vacancies and electrons created by loss of oxygen from the crystals at low P_{O_2}. Yamada and Miller also found good agreement between measured density changes and those calculated from the doubly ionized vacancy model. There was no indication of the precise Sr/Ti ratio of the crystals used in either of these studies. The existing phase information for $SrTiO_3$ gives no indication of any solubility for excess TiO_2 (12), while the phase diagram of Rase and Roy for the BaO-TiO_2 system implies a single phase region from the ideal composition of $BaTiO_3$ up to about 51 mole percent (m/o) TiO_2 at 1400°C (13) [a value which we now feel to be much too high (14)]. Since excess TiO_2 can be accommodated by the formation of relatively favorable point defects such as strontium vacancies and oxygen vacancies, V_{Sr}'' and $V_o^{\cdot\cdot}$, some solubility is to be expected. The incorporation of excess SrO by a simple point defect model, on the other hand, requires the formation of either interstitial strontium and oxygen, $Sr_I^{\cdot\cdot}$ and O_I'', or titanium and oxygen vacancies, V_{Ti}'''' and $V_o^{\cdot\cdot}$. The difficulty of fitting large ions into interstitial sites in the close-packed perovskite structure, and the high formal charge on the titanium vacancy, makes simple solution of excess SrO in significant amounts quite unlikely. It is known, however, that excess SrO can be accommodated in layers separated by n perovskite layers in a homologous series SrO · nSrTiO$_3$ (15, 16). This may account for the region of apparent excess SrO shown in the phase diagram of Cocco and Massazza [included in Ref. (12)].

$SrTiO_3$ which has been equilibrated with air is a light colored, insulating material at room temperature. By analogy with $BaTiO_3$, one would expect this to represent an oxygen-excess composition, with p-type conduction, since n-type material is dark colored and semiconducting. The equilibrium conductivity has not previously been investigated for the region of high P_{O_2}, and a conductivity minimum reflecting a transition from n-type conduction at low P_{O_2} to p-type conduction at high P_{O_2} has not been reported. This paper presents equilibrium conductivity measurements made on sintered, polycrystalline samples over the range $10^{-20} < P_{O_2} < 1$ atm, at temperatures from 750° to 1000°C, and includes results obtained from donor-doped and acceptor-doped samples and from samples having different Sr/Ti ratios.

Experimental

The $SrTiO_3$ was prepared by a modification of a technique developed by Pechini (17). Several liters of titanium stock solution were prepared by combining batches made in the following way: 200 ml of tetra-iso-propyl orthotitanate, obtained from E. I. du Pont de Nemours as Tyzor "TPT," was added with stirring to 2 liters of Fisher Certified ethylene glycol; 350g of Fisher Certified ACS Anhydrous citric acid was added and the mixture was stirred until complete solution was achieved and then heated until the strong odor of isopropyl alcohol disappeared. Presumably during this procedure the isopropoxy groups attached to the titanium are replaced by the multifunctional ethylene glycol, which can thermally polymerize with the multifunctional citric acid by an esterification reaction. After the combined batches had been allowed to homogenize for 2 weeks in a polyethylene container, weighed samples were thermally polymerized and ignited to TiO_2 to determine the Ti content of the solution, which was 0.054504g TiO_2/g solution. Donor- and acceptor-dopant solutions were prepared by solution of niobium oxalate, obtained as a 10% solution from Kawecki-Berylco, and Eastman practical grade tri-

iso-propyl aluminate, respectively, in ethylene glycol. Both solutions were assayed by the ignition of weighed portions to the corresponding oxide.

The source of Sr was Johnson-Matthey Specpure $SrCO_3$, reported to contain 5 ppm Ba, 2 ppm Fe, 1 ppm Ag, and <1 ppm Ca, Cu, and Mg, all on a weight basis. Approximately 7g samples of $SrTiO_3$ were prepared by dissolution of weighed amounts of the $SrCO_3$, dried by ignition in CO_2, in weighed portions of the Ti stock solution, containing weighed amounts of dopant solution where appropriate. Dissolution of the carbonate, by reaction with the citric acid content, was achieved by heating over a period of several hours. The viscosity was kept low by additions of water until solution was complete. The mixture was then allowed to polymerize thermally to a glassy solid, without phase separation, to transform the homogeneity of the liquid solution to the solid glass which was then calcined at 900°C to yield a fine $SrTiO_3$ powder. All chemical preparations were performed in clear fused SiO_2 or Pt, and stock solutions were stored in polyethylene or polypropylene containers.

The sample compositions are expressed in terms of Sr/Ti ratios where it should be understood that the Ti includes any added Al or Nb content, since these dopants are assumed to occupy only Ti sites, based on their similarity in size. These ratios are thus actually site occupation ratios. Accordingly, for each gram atom of dopant added, one mol of TiO_2 was left out, *i.e.*, Al_2O_3 and Nb_2O_5 were substituted for $2TiO_2$. The dopant and impurity contents are expressed in ppm atomic based on Ti sites, *e.g.*, (No. of added Al atoms $\times 10^6$)/(No. of Ti and added Al atoms).

Samples of 0.6g of the powder, with 7% by weight water to improve pressability, were pressed into rectangular bars at 100,000 psi. All faces and edges were scraped with the edge of a silica slide to remove contamination from the steel die. The samples were typically sintered at 1420°C for 16 hr in a fore-pump vacuum and furnace-cooled. Final dimensions were about 1.5 × 5.5 × 13 mm. Voltage leads of 10 mil Pt wire were sintered into the samples by insertion through two holes drilled through the largest face prior to sintering. Unfluxed Pt paste, Engelhard 6926, was fired onto the ends to serve as current leads. The conductivity was measured by four-point d-c technique, using both polarities with applied currents in the range 10^{-7}-10^{-2}A to maintain a voltage drop of about 0.1V.

Figure 1 shows an SEM view of the microstructure of a fracture surface of a typical sample, demonstrating the large grain size and low porosity. While most fracture is transgranular and does not show the grain size clearly, there are occasional small areas such as that shown in Fig. 1 where intergranular fracture occurs.

The major impurity in titanates prepared by this technique is silicon. Extensive investigation of the starting materials and the process steps by emission spectroscopy indicate that the major sources are the tetra-iso-propyl orthotitanate and the container used during the calcination of the polymeric glass. When fused silica or conventional glazed porcelain crucibles were used for the latter step, silicon contents of 1800-2600 ppm have been observed. The TiO_2 residue obtained by ignition of the orthotitanate in a Pt crucible contains about 400 ppm Si. During the latter part of this study, all samples have been prepared in Pt crucibles and typical Si contents are in the 500-1000 ppm range. The Pt content is 30-40 ppm. Similar impurity levels have been found in a much more extensive study of $BaTiO_3$, during which similar samples have been studied and no effect of variable Si content on the equilibrium conductivity has been discerned. It is our opinion that the conductivity is not affected.

The Si contents observed in this work are similar to those reported in a number of studies of polycrystalline

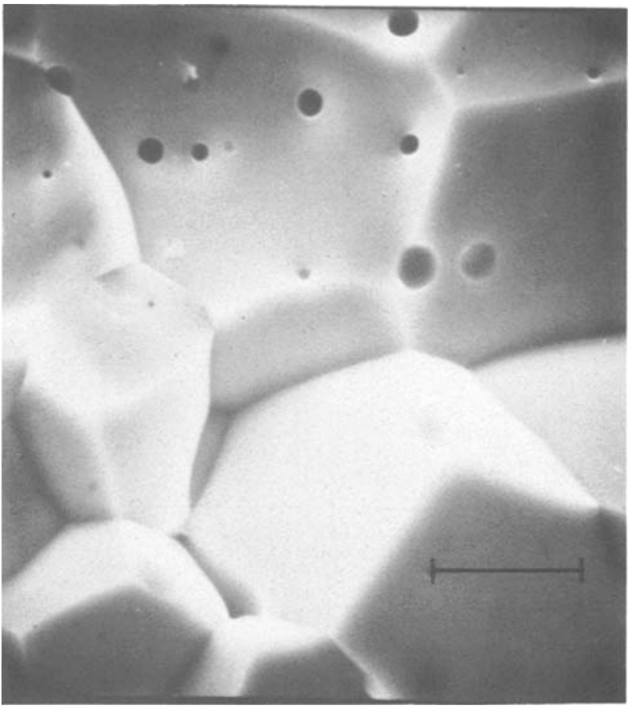

Fig. 1. Scanning electron micrograph of a fracture surface of undoped, polycrystalline $SrTiO_3$ with Sr/Ti = 1.0000. Scale mark = 5 μm.

$BaTiO_3$, prepared by a variety of ways. The potential chemical significance is distorted, however, by the common practice of reporting impurity contents in ppm or percent by weight, particularly in this case of a light element like Si in a heavy matrix like $SrTiO_3$ or $BaTiO_3$. The multiplying factor needed to transform a weight basis of Si to a formula unit basis is 6.53 for $SrTiO_3$ and 8.30 for $BaTiO_3$. Thus a level of 0.01% by weight, commonly reported for $BaTiO_3$, corresponds to 830 ppm based on atoms of Si per formula unit of $BaTiO_3$.

Additional impurities found by spark-source mass spectrographic analysis are listed in Table I. These results were obtained from Micro-Trace Analytical Services, Santa Barbara, California 93103, while the emission spectroscopy was done by the Burgess Analytical Laboratory, North Adams, Massachusetts 01247.

The regions of high and low P_{O_2} were obtained by precisely metered mixtures of $Ar-O_2$ and $CO-CO_2$. For the intermediate pressure range, a CaO-stabilized ZrO_2 closed-end tube, with inner and outer platinized electrodes, was inserted into the sample area to serve as an electrochemical oxygen leak or pump. The inside of the ZrO_2 tube was exposed to air, and the resulting oxygen concentration cell was allowed to discharge through a variable resistance, or was operated as an electrochemical pump by means of an applied voltage, to obtain the desired P_{O_2}. The resulting oxygen activity was determined by measurement of the emf of a separate closed-end tube of stabilized ZrO_2, platinized inside and outside only at the tip, and continuously flushed with oxygen, which was located adjacent to the conductivity samples.

The sample holder accommodates three samples. One end of each was connected to a common lead while the other leads passed through separate alumina tubes which were supported by a metal spacer well outside of the hot zone.

Results and Discussion

Typical experimental results are shown in Fig. 2. The similarity to results presented previously for $BaTiO_3$ (3, 4, 5, 9) is quite striking. Results obtained in this laboratory for both compounds are compared

Table I. Impurity content of sintered $SrTiO_3$ by spark-source mass spectrographic analysis (Micro-Trace Analytical Service).* Includes only those impurities present in amounts >0.1 ppm by weight.

* (Silicon, sodium, sulfur, copper, zinc, selenium, and bromine could not be determined because of interference. Sodium, copper, and zinc were not detected by emission spectroscopy, which indicates levels of <10 ppm by weight. Silicon is discussed in the text).

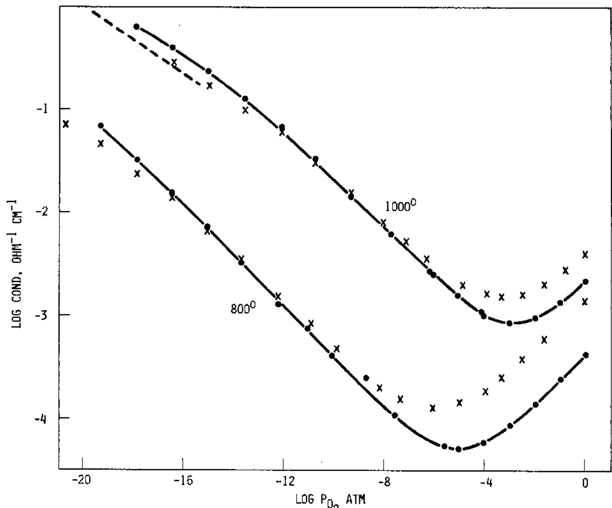

Fig. 3. Equilibrium conductivity profiles of polycrystalline $SrTiO_3$ ●, and $BaTiO_3$ × (5), at 1000° and 800°C. Both materials undoped and Sr/Ti = Ba/Ti = 1.0000. - - -, $SrTiO_3$ single crystal at 1000°C (10).

directly in Fig. 3. The coincidence of results in the oxygen-deficient, n-type region, where the conductivity increases with decreasing P_{O_2}, suggests that the properties in this region are almost wholly determined by the Ti-O sublattice. The results differ somewhat more in the p-type region, particularly in the case of the temperature dependence near $P_{O_2} = 1$ atm. Some experimental results from Walters and Grace for single crystalline $SrTiO_3$ are also shown (10). Their data cover a much lower range of P_{O_2} and barely overlap with ours, but appear to be quite comparable. Comparison of conductivity data obtained for polycrystalline and single crystalline $BaTiO_3$ has shown similar agreement (9), which indicates that the conductivity is determined by bulk properties in these large grained, polycrystalline samples.

The experimental results can be correlated by means of a model in which doubly ionized oxygen vacancies, $V_o^{\cdot\cdot}$, are the key defect and for which three major sources are postulated. The defect notation is that developed by Kröger and Vink (18)

Reduction or loss of oxygen

$$O_o \rightleftharpoons 1/2\, O_2 + V_o^{\cdot\cdot} + 2e' \quad [1]$$

Cation nonstoichiometry in the sense of excess TiO_2

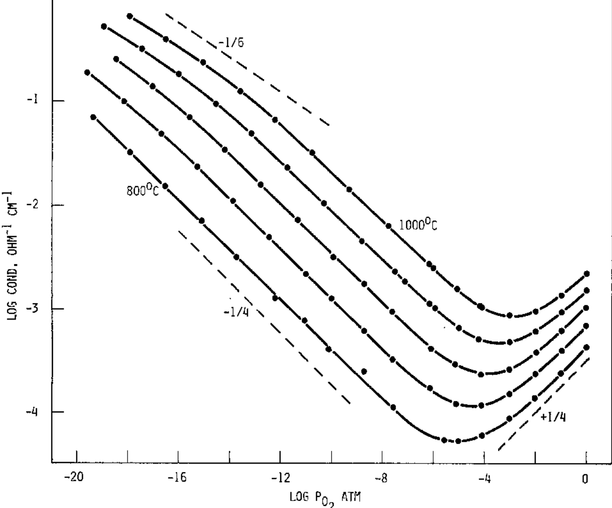

Fig. 2. Equilibrium conductivity profiles of polycrystalline $SrTiO_3$, undoped, Sr/Ti = 1.0000. Temperatures at 50°C intervals. Dashed lines indicate ideal log-log slopes.

$$TiO_2 \rightarrow Ti_{Ti} + 2\,O_o + V_{Sr}'' + V_o^{\cdot\cdot} \quad [2]$$

The incorporation of acceptor-type impurities such as substitution of Al_2O_3 for $2TiO_2$

$$Al_2O_3\,(-\,2TiO_2) \rightarrow 2Al_{Ti}' + 3\,O_o + V_o^{\cdot\cdot} \quad [3]$$

The reduction reaction is indicated as an equilibrium reaction because it is reversible in reasonable time spans at both the sintering temperature and at the temperatures used for conductivity measurements. The lack of saturation of electrical properties with additions of up to 1080 ppm Al indicates that the solubility limit has not been exceeded and the acceptor impurities are thus assumed to be completely and irreversibly incorporated during the sintering step. The irreversibility is supported by indications of extremely low cation diffusion on the Ti-sublattice of the perovskite structure, even at the sintering temperature (19). Excess TiO_2 will dissolve up to its solubility limit during the sintering process, and it will be assumed that the excess TiO_2 content is frozen at 1000°C and below, where the conductivity measurements were made. At the time of final equilibration of the sample with excess TiO_2, we can assume local equilibrium. From the mass-action expression for this process

$$[V_{Sr}''][V_o^{\cdot\cdot}] = K_2 a_{TiO_2} \quad [4]$$

where a_{TiO_2} is the activity of TiO_2 in the $SrTiO_3$, we can see that the solubility limit for TiO_2 will depend on the number of $V_o^{\cdot\cdot}$ present due to acceptor impurities and the reduction reaction. For cases where sufficient excess TiO_2 is available, therefore, its solubility will be a function of the oxygen partial pressure, the impurity content, and the final equilibration temperature.

For undoped and acceptor-doped $SrTiO_3$, the complete expression for the condition of charge neutrality is

$$2[V_o^{\cdot\cdot}] + p = 2[V_{Sr}''] + [A'] + n \quad [5]$$

where $[A']$ represents the net acceptor content, both accidental and added, expressed as the equivalent concentration of single-level acceptor centers, $n \equiv [e']$, and $p \equiv [h^{\cdot}]$. The conductivity plots, *e.g.*, Fig. 2, can be divided into three characteristic regions depending on whether the $SrTiO_3$ has a stoichiometric deficiency or excess of oxygen, and depending on which terms in Eq. [5] are most important. The following analysis is very similar to that previously proposed for $BaTiO_3$ (5, 9, 20), and a schematic representation of the defect model is shown in Fig. 4.

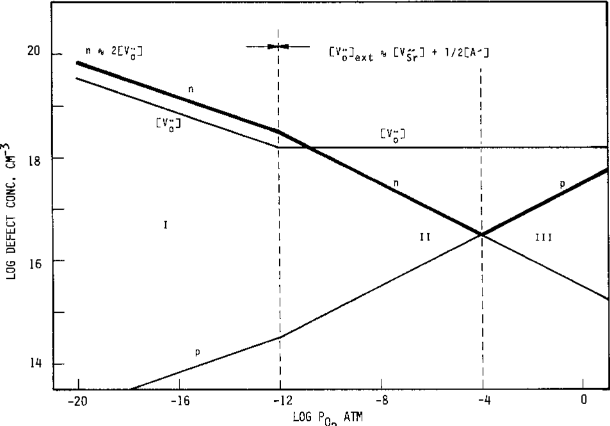

Fig. 4. Schematic representation of equilibrium defect model for undoped and acceptor-doped $SrTiO_3$. Defect concentrations calculated from conductivities at 1000°C with $\mu_n = 0.2$ cm^2/V·sec and $\mu_p = 0.1$ cm^2/V·sec. Regions I, II, and III defined in text.

Region I.—In the region of lowest P_{O_2}, the material is oxygen deficient and the reduction reaction, Eq. [1], is the major source of defects and the approximate condition of charge neutrality is thus

$$2[V_o^{\cdot\cdot}] \approx n \qquad [6]$$

The mass-action expression for the reduction reaction is

$$[V_o^{\cdot\cdot}]\, n^2 = K_1 P_{O_2}^{-1/2} \qquad [7]$$

Combination of Eq. [6] and [7] leads to

$$n \approx (2K_1)^{1/3} P_{O_2}^{-1/6} \qquad [8]$$

which agrees with the P_{O_2} dependence of conductivity found by Walters and Grace (10) and of the electron concentration found by Yamada and Miller (11). The agreement between the P_{O_2} dependence of the conductivity and the electron concentration found by these two groups indicates that the electron mobility is not composition dependent under these conditions. Our own results barely reach into Region I at the lowest P_{O_2} and highest temperature and exhibit this P_{O_2} dependence in a very limited region.

Region II.—This region is bounded on the low P_{O_2} side by Region I and on the high P_{O_2} side by the conductivity minima. The pressure dependence of the conductivity is approximately $P_{O_2}^{-1/4}$ which indicates oxygen-deficient, n-type behavior. This P_{O_2} dependence for the electron concentration can be obtained from the mass-action expression for the reduction reaction, Eq. [7], if $[V_o^{\cdot\cdot}]$ is independent of P_{O_2}, *i.e.*, if there is an extrinsic source of $V_o^{\cdot\cdot}$ such that the reduction reaction is no longer the major source of $V_o^{\cdot\cdot}$. This could be due to either excess TiO_2 or to acceptor impurities, Eq. [2] and [3]. It is proposed that even in undoped material with Sr/Ti = 1.000, there is sufficient accidental net excess of acceptor impurities to control $[V_o^{\cdot\cdot}]$ in this region (5). Only in the region of lowest P_{O_2} and highest temperatures does the reduction reaction, Eq. [1], become the major source of $V_o^{\cdot\cdot}$. The preponderance of acceptor impurities is related to the relative natural abundances of such impurity elements as compared to donor impurity elements and is supported by the analytical results reported in Table I. The approximate condition of charge neutrality is then

$$[V_o^{\cdot\cdot}] \approx [V_{Sr}''] + 1/2\,[A'] \qquad [9]$$

where $[V_{Sr}'']$ represents the contribution to $[V_o'']$ made by excess TiO_2, while 1/2 $[A']$ is the contribution made by the net excess acceptor content. The sum of these two contributions will be referred to as the extrinsic $V_o^{\cdot\cdot}$ content. Combination of Eq. [7] and [9] gives

$$n \approx \left\{ \frac{K_1}{[V_{Sr}''] + 1/2\,[A']} \right\}^{1/2} P_{O_2}^{-1/4} \qquad [10]$$

This P_{O_2} dependence is characteristic of a wide region of our experimental results.

Region III.—This is the oxygen excess, p-type region lying between the conductivity minima and $P_{O_2} = 1$ atm. As suggested previously (5), it is proposed that the stoichiometric excess of oxygen is accommodated by the extrinsic $V_o^{\cdot\cdot}$ present because of a net excess of acceptor impurities or an excess of TiO_2

$$1/2\, O_2 + V_o^{\cdot\cdot} \rightleftharpoons O_o + 2h^{\cdot} \qquad [11]$$

Thus there is no crystallographic excess of oxygen and no need to propose such unfavorable defects as O_I'' or V_{Ti}''''. This is in accord with the very modest enthalpy of oxygen addition as indicated by the small temperature dependence of conductivity in this region. The approximate condition of charge neutrality is the same as in Region II, Eq. [9], as long as a negligible fraction of the extrinsic $V_o^{\cdot\cdot}$ is consumed by the oxygen excess. Combination of the mass-action expression for Eq. [11]

$$\frac{p^2}{[V_o^{\cdot\cdot}]} = K_{11} P_{O_2}^{1/2} \qquad [12]$$

with Eq. [9] gives

$$p \approx K_{11}^{1/2} \{[V_{Sr}''] + 1/2\,[A']\}^{1/2} P_{O_2}^{1/4} \qquad [13]$$

This is a good representation of the P_{O_2} dependence of conductivity observed in this region.

Figure 5 shows an Arrhenius plot of the conductivity at $P_{O_2} = 1$ atm for several samples. The plots are not linear, tending to be concave downward. The slopes indicate activation enthalpies between 0.7 and 1.2 eV,

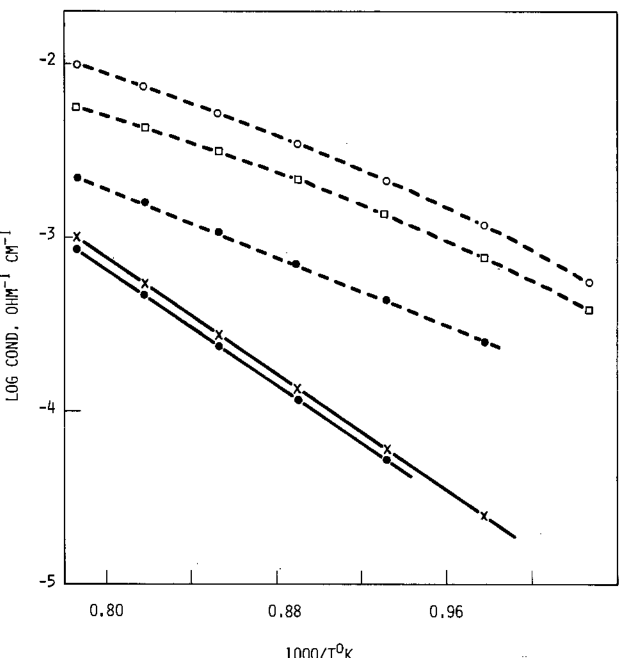

Fig. 5. Arrhenius plots of equilibrium conductivity data for polycrystalline $SrTiO_3$. Dashed lines, in equilibrium with 1 atm O_2. Solid lines, at the conductivity minima.

	ppm added Al	Sr/Ti
●	None	1.0000
□	None	0.9950
○	1080	0.9950
×	1080	0.9950

with the most linear result, that for the undoped sample with Sr/Ti = 1.000, giving 0.98 eV. These are all considerably higher than the value of 0.4 eV found for the same region in $BaTiO_3$ (9).

The conductivity minima.—The conductivity minima correspond to the p-n transitions where the electron and hole contributions to the conductivity are equal

$$n\mu_n = p\mu_p \quad [14]$$

where μ_n and μ_p are the electron and hole mobilities. At the point of exact compensation, which is offset from the conductivity minimum by the mobility ratio, the only source of carriers is by ionization across the bandgap

$$nil \rightleftharpoons e' + h^{\cdot} \quad [15]$$

$$np = K_{15} = K_{15}' \, e^{-E_g^\circ/kT} \quad [16]$$

where *nil* refers to the standard state with all electrons in the lowest available energy states, and E_g° is the bandgap at 0 K or the enthalpy of the ionization reaction, Eq. [15]. At the point of compensation

$$n = p = (K_{15}')^{1/2} \, e^{-E_g^\circ/2kT} \quad [17]$$

The temperature dependence of the minima is primarily determined by E_g°; the small contribution of the temperature dependence of the mobility and density of state terms has been discussed elsewhere (9). Arrhenius plots of the minima are also shown in Fig. 5, and the slopes indicate $E_g^\circ = 3.30$ eV, very close to the values of 3.1 and 3.27 eV found for $BaTiO_3$ (4, 9) and in good agreement with the optically determined value of 3.2 eV for single crystalline $SrTiO_3$ (21, 22).

The effects of excess TiO_2 and acceptor impurities.—By combination of Eq. [10] and [13], the P_{O_2} at the minimum, P_{O_2}(min.), can be expressed as

$$P_{O_2}(\text{min.}) = \left(\frac{\mu_n}{\mu_p}\right)^2 \frac{K_1}{K_{11}} \frac{1}{\{[V_{Sr}''] + 1/2\,[A']\}^2} = \left(\frac{\mu_n}{\mu_p}\right)^2 \frac{K_1}{K_{11}} \frac{1}{[V_o^{\cdot\cdot}]^2_{ext}} \quad [18]$$

Where $[V_o^{\cdot\cdot}]_{ext}$ is the extrinsic $V_o^{\cdot\cdot}$ concentration. The shift of P_{O_2}(min.) with $[V_o^{\cdot\cdot}]_{ext}$ is independent of the mobilities

$$\frac{d \log P_{O_2}(\text{min.})}{d \log [V_o^{\cdot\cdot}]_{ext}} = -2 \quad [19]$$

Thus at a given temperature, the minimum moves to lower P_{O_2} by two orders of magnitude for each order of magnitude increase in $[V_o^{\cdot\cdot}]_{ext}$, and this shift serves as a measure of the relative extrinsic $V_o^{\cdot\cdot}$ contents of various samples. This parameter is independent of the absolute values of the conductivity and thus of the sample geometry and density.

Figure 6 shows conductivity profiles at 1000°C for three samples of undoped $SrTiO_3$ prepared so as to have Sr/Ti ratios of 1.000, 0.999, and 0.995, which correspond to 50.000, 50.025, and 50.125 m/o TiO_2, respectively. The conductivity minima occur at lower P_{O_2} for Sr/Ti < 1, indicating an increase in extrinsic $V_o^{\cdot\cdot}$ content with excess TiO_2, as expected from Eq. [2]. Since the positions of the P_{O_2} minima are similar for Sr/Ti = 0.999 and 0.995, it would appear that for the conditions under which these samples were sintered, the $SrTiO_3$ saturates with TiO_2 at less than 50.1 m/o.

Figure 7 shows conductivity profiles at 1000°C for some acceptor-doped samples, as well as for the undoped sample having Sr/Ti = 1.000. For a sample containing 281 ppm Al and Sr/Ti = 0.995 the minimum occurs at significantly lower P_{O_2}, while the addition of 1080 ppm Al moves the minimum to even lower P_{O_2}, representing the expected effect on the concentration of extrinsic $V_o^{\cdot\cdot}$.

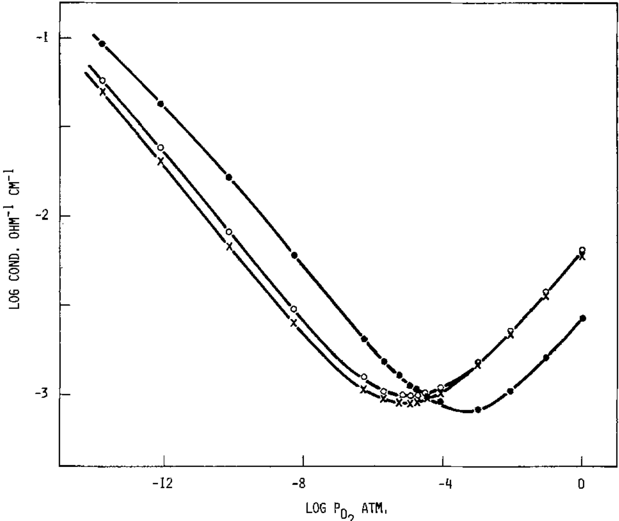

Fig. 6. Equilibrium conductivity profiles of undoped, polycrystalline $SrTiO_3$ at 1000°C. ● Sr/Ti = 1.0000, × Sr/Ti = 0.9990, ○ Sr/Ti = 0.9950.

Takahashi has reported large ionic contributions to the conductivity of perovskite-structure oxides containing large amounts of acceptor impurities (23). For $SrTiO_3$ with 10% of the Ti replaced by Al, for example, he reports ionic transport numbers between 0.6 and 0.9 in the temperature range 650°-1000°C. This material has a relatively P_{O_2}-independent conductivity at 800°C for $10^{-6} > P_{O_2} > 10^{-16}$ atm, presumably due to the P_{O_2}-independent concentration of extrinsic $V_o^{\cdot\cdot}$. In our data, an ionic contribution would be most apparent at the conductivity minima. Figure 8 shows several conductivity minima compared with the ideal shape. The experimental curves have been placed such that they blend asymptotically into the ideal curve on either side of the minimum. At 1000°C, the undoped sample with Sr/Ti = 1.000 has an almost ideal minimum, while at 800°C it is somewhat raised and flattened. At the latter temperature, the minima become higher as the extrinsic $V_o^{\cdot\cdot}$ content is enhanced by additions of TiO_2 and Al_2O_3. The shapes of the minima in these cases are in good agreement with an ideal minimum with an additive, P_{O_2}-independent contribution which could represent oxygen vacancy conduction.

Wernicke found a value of 1×10^{-4} cm²/sec for the effective diffusion constant of $V_o^{\cdot\cdot}$ at 1000°C in single

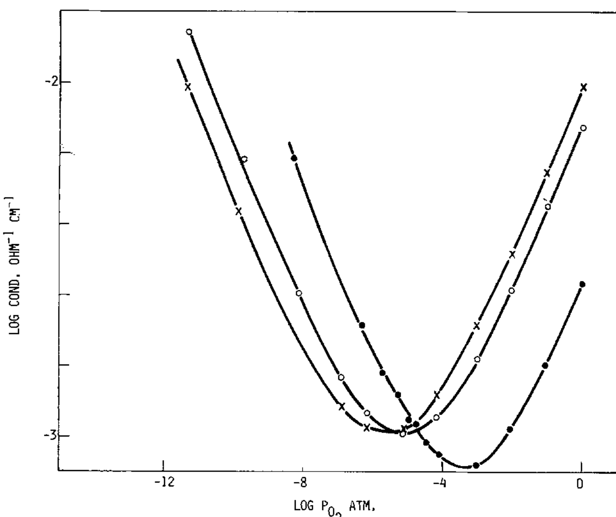

Fig. 7. Equilibrium conductivity profiles of acceptor-doped, polycrystalline $SrTiO_3$ at 1000°C. ● undoped, Sr/Ti = 1.0000; ○ 281 ppm Al, Sr/Ti = 0.9950, × 1080 ppm Al, Sr/Ti = 0.9950.

○	800	1080	0.9950

crystal $SrTiO_3$ (24). This was derived from the time dependence of the conductivity following step changes in the oxygen partial pressure. If it is assumed that the diffusion experiment involved ambipolar diffusion of $V_o^{\cdot\cdot}$ and electrons, the true vacancy diffusion constant is 1/3 of the effective value. From the Nernst-Einstein relationship, this corresponds to a $V_o^{\cdot\cdot}$ mobility of 6×10^{-4} cm²/sec at 1000°C. For the most highly doped sample in Fig. 8 (1080 ppm Al) this gives an ionic conductivity of 1.5×10^{-3} Ω^{-1} cm^{-1}. The conductivity minimum for this sample lies about 25% above the value of 9×10^{-4} Ω^{-1} cm^{-1} for the undoped sample with Sr/Ti = 1.000, suggesting an ionic contribution of 2.2×10^{-4} Ω^{-1} cm^{-1}, somewhat less than predicted by the diffusion data. If the effectiveness of Al for producing apparent $V_o^{\cdot\cdot}$ concentrations is similar in $SrTiO_3$ to the values found recently in $BaTiO_3$ (25), the predicted contribution is 4×10^{-4} Ω^{-1} cm^{-1}, which is within a factor of two of the observed effect. Since the conductivities were measured with a d-c current, the effect of the ionic conduction may have been reduced by polarization. Some slight polarization effects were observed in the vicinity of the conductivity minima.

Paladino determined the chemical diffusion constant for oxygen in $SrTiO_3$ from the rate of weight change following step changes in P_{O_2} (26). His value at 1000°C is about half that reported by Wernicke. The data of Takahashi yield a mobility which predicts a smaller contribution than is indicated by our results. If the 10% Al content used by Takahashi is beyond the solubility limit, and the resulting extrinsic $V_o^{\cdot\cdot}$ content is thus less than 5%, his results are in closer agreement with ours.

Wernicke reported an activation energy for oxygen diffusion in $SrTiO_3$ of 1.1 eV (24), while Paladino found values of 0.98, 1.13, and 1.27 eV (26, 27). The first of these was obtained from the oxidation kinetics of reduced $SrTiO_3$ while the last two were obtained from the isotopic exchange rate. If the total oxygen vacancy contents of these samples were extrinsic, as postulated in the model described here, these energies should represent the enthalpy of motion of $V_o^{\cdot\cdot}$. These enthalpies are less than 1/2 E_g° which we found to be 1.65 eV. Thus the minima have a greater temperature dependence than does the mobility of $V_o^{\cdot\cdot}$, and ionic conductivity should make larger fractional contributions with decreasing temperature. This agrees with our observation that the minima become flatter with decreasing temperature as demonstrated in Fig. 8.

In any case, the level of vacancy conduction needed to account for the observed shapes of the conductivity minima is not unreasonable. A similar deviation from the ideal shape of the conductivity minimum has been observed in $BaTiO_3$ (28). The conductivity levels at the minima in Fig. 6 and 7 differ probably by a combination of the effect shown in Fig. 8 and because of small geometric differences between samples.

Donor-doped samples.—The effect of the Sr/Ti site occupation ratio is particularly striking in the case of donor-doped samples. Figure 9 shows conductivity profiles at 1000°C for three samples having identical amounts of added Nb, but Sr/Ti ratios of 1.000, 0.999, and 0.995. It is doubtful that the former two samples were completely equilibrated for $P_{O_2} > 10^{-10}$ atm. The $V_o^{\cdot\cdot}$ content in these cases should vary as $P_{O_2}^{-1/6}$ over this range, and the resulting low $V_o^{\cdot\cdot}$ concentration leads to very slow equilibration. The sample with Sr/Ti = 1.000 behaves very much like donor-doped $BaTiO_3$ (5). The replacement of $2TiO_2$ by Nb_2O_5 can be written

$$Nb_2O_5\ (-2TiO_2) \rightarrow 2Nb_{Ti} + 4\,O_o + 1/2\,O_2 + 2e' \qquad [20]$$

The expulsion of the fifth oxygen from the filled lattice leaves free electrons which compensate the charged donor centers. This leads to a region of impurity-controlled, P_{O_2}-independent electron concentration and conductivity. In the case of Sr/Ti = 0.999, the conductivity is significantly reduced in the impurity-controlled region, and for Sr/Ti = 0.995, the donor-doped behavior is lost completely and the conductivity plot looks very much like that of an undoped sample. Apparently, as the $V_o^{\cdot\cdot}$ content increases with the amount of excess TiO_2, increasing amounts of the extra oxygen carried by the Nb_2O_5 can be accommodated in the lattice until finally it is all retained and the characteristic donor-type behavior is no longer

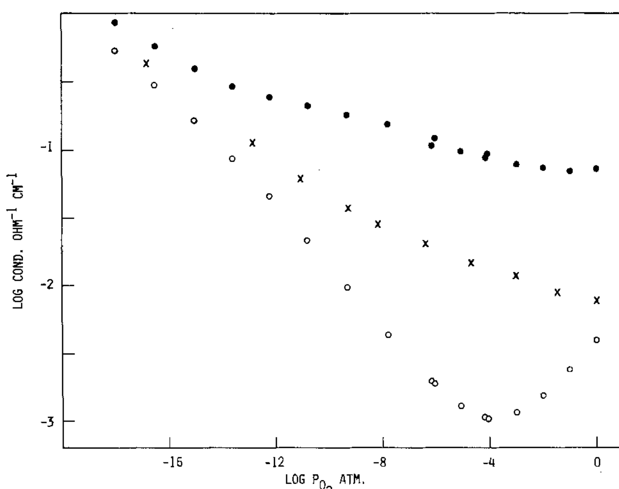

Fig. 9. Conductivity profiles of donor-doped, polycrystalline $SrTiO_3$ at 1000°C. ● 498 ppm Nb, Sr/Ti = 1.0000; × 498 ppm Nb, Sr/Ti = 0.9990; ○ 498 ppm Nb, Sr/Ti = 0.9950.

observed.

$$Nb_2O_5 + V_o^{\cdot\cdot}(-2TiO_2) \rightarrow 2Nb_{Ti}^{\cdot} + 5\,O_o \quad [21]$$

Since the Nb content corresponds to only 249 ppm extra oxygen, and there is a large change in properties as the TiO_2 excess is increased from 1000 to 5000 ppm, there must be an equilibrium between O_2, $V_o^{\cdot\cdot}$, e', and $h^{\cdot}$, essentially as represented by Eq. [7] and [16], rather than a complete accommodation where every $V_o^{\cdot\cdot}$ can be filled. In contrast to undoped and acceptor-doped samples, donor-doped $SrTiO_3$ shows a dramatic change in properties as Sr/Ti is reduced from 0.999 to 0.995. This suggests that the solubility of TiO_2 may be enhanced by the tendency of the Nb_2O_5 content to reduce the $V_o^{\cdot\cdot}$ content. This phenomenon results in a dramatic change in room temperature properties for $SrTiO_3$ containing modest amounts of donor impurities. After equilibration in air or oxygen, the material can be either a dark colored semiconductor if Sr/Ti = 1.000, or a light colored insulator if Sr/Ti < 1.000. The conductivity can be changed several orders of magnitude by very modest changes in the Sr/Ti ratio.

Conclusions

In the temperature range included in this report, 800°-1000°C, $SrTiO_3$ maintains equilibrium with the oxygen activity in the ambient. It behaves as a degenerate semiconductor with all donor levels introduced by reduction giving mobile electrons, and each oxygen in excess of stoichiometry contributing two mobile holes. Carrier mobilities have not been measured in this temperature range, but since the conductivity is almost identical with that of $BaTiO_3$ in the reduction region, and the enthalpies of the reduction reaction and intrinsic ionization are also almost identical, similar mobilities should be anticipated.

Perluzzo and Destry have measured Hall mobilities in $SrTiO_3$ from room temperature to 650 K (29). Their result of about 6 $cm^2/V \cdot sec$ for single crystalline material at room temperature agrees well with a value of 5.8 $cm^2/V \cdot sec$ obtained by Gerthsen, Härdtl, and Csillag for both single crystalline and polycrystalline $SrTiO_3$ (30). If the mobility results of Perluzzo and Destry are fit to a $T^{-3/2}$ temperature dependence, which is a good approximation to the electron mobilities measured for $BaTiO_3$ up to 1000°C by Seuter (4, 31), extrapolation to 800° and 1000°C gives electron mobilities of 0.5 and 0.4 $cm^2/V \cdot sec$, respectively, for $SrTiO_3$. These are somewhat higher than the values obtained from the expression used by Ihrig (31) to describe the results obtained by Seuter (4) for $BaTiO_3$, 0.19 and 0.15 $cm^2/V \cdot sec$ at 800° and 1000°C. There is no quantitative information on hole mobilities in either compound, although the results of Seuter indicate that $\mu_p < \mu_n$. These extrapolated values seem a little high when compared with the results obtained from donor-doped samples where n is determined by the net excess donor content. Although the data shown in Fig. 9 for a sample with 498 ppm Nb and Sr/Ti = 1.000 are poorly equilibrated at high P_{O_2}, the trend near $P_{O_2} = 10^{-12}$ atm suggests a leveling off at a conductivity of about 0.2 Ω^{-1} cm^{-1}. Assuming a net donor excess of 400 ppm, this gives $\mu_n \sim 0.2$ $cm^2/V \cdot sec$. In the schematic plot of defect concentrations in Fig. 4, this value has been used for μ_n, and μ_p has been arbitrarily set at 0.1 $cm^2/V \cdot sec$, in order to derive carrier concentrations from the measured conductivities.

The additive effect of reduction, excess TiO_2, and acceptor impurities is a strong indication that all three lead to a common defect, the doubly ionized oxygen vacancy. This implies little or no defect association under the conditions of conductivity measurement. The dielectric constants of $SrTiO_3$ and $BaTiO_3$ remain high even at elevated temperatures. The high frequency dielectric constants at 500°C, far into the paraelectric region, have been reported to be 150 and 450 for $SrTiO_3$ and $BaTiO_3$, respectively, (32), and the static values must be even higher. This parameter is a measure of the polarizability of the lattice, which reduces the electrostatic attraction between charged defects accordingly. Thus for "normal" compounds like MgO and NiO, which have dielectric constants similar to those of the alkali halides, high temperature association between multiple charged defects should be a major effect, but this is drastically reduced in $SrTiO_3$ and $BaTiO_3$ because of their extreme polarizabilities.

The results and defect model discussed here suggest that the sintering conditions can play an important role in determining the properties of polycrystalline $SrTiO_3$ when excess TiO_2 is available. The solubility of TiO_2 should depend on the total $V_o^{\cdot\cdot}$ content which can be enhanced by the presence of acceptor impurities and reduced P_{O_2}. Of course, the solubility should also be temperature dependent. The effect of variations in sintering conditions are currently under investigation.

Compositional Studies Related to Sputtered Cd-Si-As Films

A. F. Carroll,*[,1] C. F. Smith,[2] L. C. Burton, and L. H. Slack[2]

Departments of Materials and Electrical Engineering, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061

ABSTRACT

Thin films containing Cd, Si, and As were rf sputtered from a $CdSiAs_2$ target and $Si/CdAs_2$ composite targets. The compositions of the films were found to be a function of the sputtering power, substrate temperature, postdeposition heat-treatment in a Cd and As_4 atmosphere, and in the case of the composite targets, the $Si/CdAs_2$ area ratio. These results are related to differences in sputtering yield and the different resputtering tendencies of the elements. The films were amorphous as deposited, but became polycrystalline with the chalcopyrite structure during the postdeposition heat-treatments.

$CdSiAs_2$ is a semiconducting compound having the chalcopyrite crystal structure (1, 2). It is a II-IV-V analog of the III-V compounds, and as such, it has many potential electronic applications, one of which is photovoltaic energy conversion. The $CdSiAs_2$, which is p-type and has a bandgap of 1.55 eV (3), could potentially be used in homojunction and heterojunction configuration. Of special interest is its good lattice and electron affinity match with n-type CdS. A close lattice match between the absorber ($CdSiAs_2$) and window (CdS) layers would tend to minimize the recombination rate at the heterojunction. CdS has a (110) spacing of 5.851Å, compared with the (100) lattice parameter for $CdSiAs_2$ of 5.885Å, providing a lattice mismatch of less than 0.6%.

The purpose of this work is to achieve a workable method of preparing $CdSiAs_2$ thin films, but evaluation of their photovoltaic characteristics is beyond the scope of this paper. In order to enhance the compositional homogeneity, radio frequency sputtering from large (3 in. diam) targets was used. This technique provides the necessary compositional versatility (4, 5) and good film adherence (6) to substrates. The good adhesion results from the plasma interaction with the substrate which results in substrate cleaning before and during the initial stages of deposition and/or aids in the formation of interfacial compounds.

Procedure

Target fabrication.—Two target designs were used, one being a macroscopically homogeneous $CdSiAs_2$ plate and the other being an Si plate containing inserts of $CdAs_2$. The first target was prepared by direct fusion of $CdSiAs_2$ that had previously been synthesized by direct fusion from the pure elements. Crushed pieces of $CdSiAs_2$ (containing small amounts of $CdAs_2$, Cd_3As_2, and SiAs) were placed in a fused silica cylindrical container which contained a 3 in. graphite disk on which the $CdSiAs_2$ rested. The container, 3¼ in. in diameter and 2 in. high, was evacuated and sealed. It was then heated according to the thermal schedule shown in Fig. 1. When the container was rapidly cooled, the sides and top were kept hot with insulating material so that the more volatile components would not condense on the vessel, but onto the target. This target had an irregular shape approximately 2 in. in diameter and ¼ in. thick. It was bonded to an aluminum backing plate with conducting epoxy.

The composite targets, one shown in Fig. 2, were prepared by core drilling 23/64 in. holes in a 3 in. diam polycrystalline silicon plate and inserting 11/32 in. $CdAs_2$ disks into those holes. The silicon and inserts were bonded to a 3-1/4 in. diam copper backing plate, again with thermosetting epoxy.

The $CdAs_2$ inserts were synthesized by weighing stoichiometric quantities of pure (5$\bar{N}$) cadmium and arsenic into hollow graphite cylinders, which were in turn sealed into evacuated heavy-wall silica tubing. The graphite liners kept the final ingot from fracturing on cooling. The thermal schedule used for melting and

solidification of this compound is also shown in Fig. 1.

The resulting $CdAs_2$ ingots were found to be single phase and crystalline by electron microprobe and x-ray diffraction analyses, respectively. The relative ease of $CdAs_2$ synthesis is associated with its congruent melting and solidification behavior. The ingots were sectioned into disks and ultrasonically cleaned in acetone and methanol.

Four composite targets have been fabricated. The first was a silicon disk with a single $CdAs_2$ disk bonded at its center (bullseye-BE). It was used to characterize the geometry of sputtering from a single insert as a test of possible imaging effects (7) between the two-phase target and the substrate plane.

The other three composite targets (HEX A, HEX B, and HEX C) consisted of an Si plate with $CdAs_2$ disks inserted in a hexagonal array. The number and spacing of the inserts were chosen to yield Si/$CdAs_2$ area ratios of 1.00, 1.47, and 2.27 (HEX A, HEX B, and HEX C).

Sputtering.—The radio frequency sputtering system used to deposit Cd-Si-As thin films consisted of a commercial sputtering module[3] mounted on a vacuum system utilizing a turbomolecular pump.[4] The sputtering parameters used are listed in Table I.

The film thicknesses were determined by weighing the substrates before and after deposition, and assuming a composition of $CdSiAs_2$ of near theoretical density, 5.0 g/cm^3. These thicknesses were within ± 5% agreement of those obtained by optical interferometry.[5]

The rate of material removal from the target was also monitored by determining the geometrical profile of the target surface with a sheet metal micrometer.

Heat treatments of films.—Some of the films were heated either during the sputtering process or afterwards. In the first case, the stage supporting the substrates was heated to a controlled temperature during

Table I. Sputtering parameters

Sputtering target	RF power (W)	Argon pressure (mTorr)	Substrate + heating (°C)	D-C voltage (kV)	Duration (hr)
$CdSiAs_2$	40-220	5-32	*RT* to 535	1.5-4.0	3.0-7.5
Bullseye (BE)	80-190	7-16	—	0.7-1.8	2.5-6.0
HEX A (Si/$CdAs_2$ = 1.00)	100-200	9-32	—	0.4-1.6	1.5-3.5
HEX B (Si/$CdAs_2$ = 1.47)	100-200	9-12	—	2.0-3.0	3.0-6.0
HEX C (Si/$CdAs_2$ = 2.27)	100-200	7-15	—	2.1-3.3	3.5-4.0

the deposition. The rf plasma heated the top surface of the substrates to a temperature higher than the control temperature by 150° ± 10°C, as determined by a platinum thin film surface temperature measuring device.[6]

In the second case, the coated substrate and a small fragment (approx. ½ g) of $CdAs_2$ were sealed in an evacuated Vycor ampul. The ampul was heated to 600°C for one day. The $CdAs_2$ provided an overpressure of Cd and As_4 vapor.

Film characterization.—Elemental compositions of the films were determined by electron microprobe analysis[7] (EMPA) and their structures by x-ray diffraction analysis (XRD). The films were thick enough (~1 μm) to intercept all of the radiation in the EMPA experiments so that the analysis was not affected by the substrates.

Two sets of standards have been used for the microprobe analyses. The first was Cd, GaAs, and Si. A fresh surface of Cd was exposed for microprobe analyses on a daily basis. Because the Si and As x-ray emission peaks overlap, some error was found to exist using these initial standards. The overlapping of these peaks in the Cd-Si-As films, but not in the standards, was responsible for this error. The second set consisted of SiAs crystals (a mica-like cleavable material synthesized here in ingot form by melting the pure elements in evacuated sealed silica ampuls using the thermal schedule shown in Fig. 1) and Cd metal. The second set of standards provides analyses on bulk $CdSiAs_2$ that agreed with careful chemical analyses. All of the microprobe results reported here were made using the second set, or were corrected using appropriate correction factors.

Results and Discussion

Films from ternary target.—The films formed by sputtering from the polycrystalline $CdSiAs_2$ target were cadmium deficient. Attempts to induce crystallinity by heating the substrates were not successful. The effect of substrate heating on film composition is seen in Fig. 3. The first substrate support temperature shown in Fig. 3 is that obtained without applying power to the substrate heater. The temperature was measured inside the substrate support. When the substrates were heated to only 270°C, the cadmium content had dropped to less than 2%, and became even lower as higher substrate support temperatures were used. At very high temperatures (above 400°C), the As content also dropped from 53 to 30%.

The re-emission of Cd and As_4 from the thin film is probably a result of the combined effects of thermal and particle impact induced decomposition mechanisms. These two mechanisms occur simultaneously during the sputter deposition process in an interdependent manner.

A study (8) of the thermal decomposition of bulk $CdSiAs_2$ in vacuum determined the temperature range for Cd and As_4 sublimation to be 570°-710°C. Both species were sublimed in an approximate ratio of 4 to 1, respectively, leaving a residue of SiAs. At temperatures exceeding 710°C, As_4 was sublimed from the SiAs leaving a residue of Si. The two steps of this decomposition process were separated by a temperature difference of 140°C. The temperature difference between the two same steps occurring in the presence of a high energy plasma is greater than 130°C shown in Fig. 3. The relatively constant difference in temperature indicates that the same bonds are broken in the thermal decomposition of the previous study and the thermo-physical decomposition of this study.

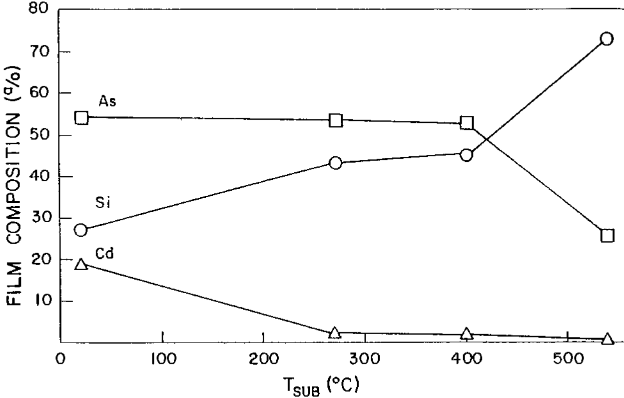

Fig. 3. Effect of substrate support temperature on film composition.

The difference in temperature is related to the different bond strengths of the Cd-As and Si-As bonds in the $CdSiAs_2$ crystal. Another indication of the different bond strengths is the difference in melting temperature of $CdAs_2$ and decomposition temperature of $SiAs_2$, 621° and 944°C, respectively.

The cadmium content was also found to be a function of the previous service of the polycrystalline $CdSiAs_2$ target. This is evident in data reported in Table II where the Cd content dropped from 21 to 17%, and to 11% in three 200W runs. This table is a chronological summary of the progressive depletion of Cd from the films sputtered at 200W and the effect of substrate temperature on this depletion. It is evident that the target surface was becoming Cd deficient with continued use and this depletion was hastened when the chamber was heated by turning on the substrate heater. Deliberate substrate heating was discontinued and the substrate holder was cooled with circulating room temperature water in the subsequent research.

The composite $Si/CdAs_2$ targets were adopted because of their greater ease of fabrication and the flexibility gained by the variable $Si/CdAs_2$ ratio.

Films from bullseye target.—Sputtering from the first composite target (BE), consisting of a single $CdAs_2$ disk at the center of a silicon plate, established that the transport of sputtered particles was a multicollision process between the target and substrates. The Cd and As atoms were evenly distributed over the entire substrate holder area, even though they originated from a small spot. This is shown by the microprobe elemental analyses of Cd, As, and Si shown as a function of substrate location in Fig. 4. If the atoms had not experienced the mixing effects of numerous collisions with argon atoms (and each other), then the Cd and As concentrations would have followed a cosine law (6) with distance from the center of the substrate holder. This experiment confirmed that there would be no imaging effects between the two-phase target and the substrates.

Table II. Chronological listing of unheated sputter depositions using the ternary $CdSiAs_2$ Target

RF power (W)	Argon pressure (mTorr)	Composition		
		Cd	Si	As
200	18	21.1	27.5	51.4
*				
190	7	18	27.4	54.6
200	7	17	27.4	55.6
**				
80	32	14.3	35.7	50.0
200	14	11.2	35.6	53.2

* The substrates were heated as high as 300°C.
** The substrates were heated as high as 535°C.

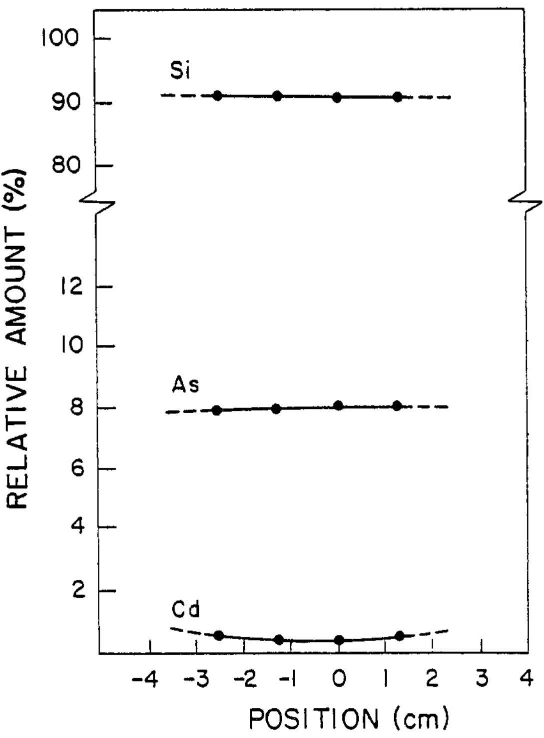

Fig. 4. Bullseye target film compositions as a function of substrate position.

Films from hexagonal targets.—In these experiments, the films' compositions are controlled by varying the $Si/CdAs_2$ area ratio of the target, by heat-treatment, and by varying the power level used during sputtering.

The effect of the target's $Si/CdAs_2$ area ratio on film composition is shown in Table III. The films here were all sputtered at 100W. As the target's Si area increases, the silicon content increases and the Cd and As contents decrease. If the Cd, Si, and As atoms sputtered in proportion to their concentrations in the target surface, then the HEX A target would have provided stoichiometric $CdSiAs_2$, but the Si content was too low by a factor of approximately two. It is apparent that Si sputters more slowly than the $CdAs_2$ inserts. This was confirmed by monitoring the surface profile of the target, where it was found that the $CdAs_2$ inserts sputter about 5-8 times faster than the silicon.

The As/Si atomic ratio approached the stoichiometric ratio of 2 when the $Si/CdAs_2$ target area ratio was increased to 2.27, but the film was Cd deficient. When this film was heat-treated at 600°C for one day in an overpressure of Cd and As_4 vapor, the film was replenished in Cd and the composition was $Cd_{0.97}$ $Si_{1.05}$ $As_{1.98}$. This is close to the ideal $CdSiAs_2$, but slightly deficient in Cd and As.

The x-ray diffraction pattern obtained from this film indicated that the film had crystallized in the chalcopyrite structure (2). The pattern was undistorted, further indicating that the film was near to stoichiometry. No other crystalline phases were detected.

The rf power level used during sputtering also controls the composition. The HEX C target is used here as an example and is representative of the trends seen with the other hexagonal targets. The effect of power on film composition (center of substrate stage) is shown in Fig. 5 for the HEX C target. The Cd content decreases from 17 to 12 atomic percent (a/o) as the power is increased from 100 to 200W. The other components increase correspondingly.

Table III. Film composition for films sputtered in position 3 at 100W

Target	$Si/CdAs_2$ ratio	Composition (%) Cd	Si	As	Elemental ratios As/Si	Cd/Si	As/Cd
Stoichiometric $CdSiAs_2$		25.0	25.0	50.0	2.00	1.00	2.00
HEX A	1.0	25.4	14.8	59.9	4.05	1.72	2.35
HEX B	1.47	25.7	17.6	56.7	3.22	1.46	2.21
HEX C	2.27	17.2	28.7	54.1	1.89	0.60	3.15
HEX C (Heat-treat at 600°C in Cd, As_4 ambient)	2.27	24.2	26.3	49.5	1.88	0.92	2.04

The additional effect of substrate location on the substrate cooling plate is shown in Fig. 6. The cadmium content is consistently less in the center of the substrate holder, and this effect is more pronounced at the higher power levels. The Cd contents of the films varied about 1% over the central 2 cm when power levels of 100 and 150W were used. At 200W the variation was 9.5%.

These cadmium deficiencies at and near the center of the stage are associated with elevated temperatures in the films. The thin film temperature sensor detected a center temperature of 540°C when the power level was 200W, and only 325°C when it was 100W. In the latter case, the temperature was 319°C at 2 cm from the center and 179°C at 4 cm. These strong temperature profiles are due to the greater plasma densities near the center and cause more pronounced Cd re-emission. These findings indicate that large targets and lower power levels are needed to provide films with uniform Cd contents.

Increasing the rf power alters the rf plasma-substrate interaction. There are several effects that occur at the substrate in the gas discharge environment (3): (*i*) condensation of sputtered material; (*ii*) bombardment by energetic ions and neutral particles; and (*iii*) heating (due in major part to electron bombardment). All three of these effects are interactive and operate simultaneously in the sputter deposition process.

The film that forms during cosputtering of $Si/CdAs_2$ targets is a result of the different sputtering yield (emission), condensation, and re-emission (resputtering, sublimation) behavior of each elemental constituent. The $CdAs_2$ disks sputtered 5-8 times more rapidly than the Si, as measured by a micrometer, but the films had Cd/Si and As/Cd ratios nearer to the desired values of 1 and 2. This results from the fact that Si has a higher condensation rate and a lower re-emission rate than does either Cd or As.

Conclusions

1. All of the sputtered Cd-Si-As films were amorphous as deposited, even though many of the compositions were far from the bulk glass-forming region.

2. All of the films from the ternary target were Cd deficient with respect to $CdSiAs_2$ because Cd tended to re-emit from the substrates. This effect became more pronounced as the substrates were deliberately heated. Cadmium's tendency to be resputtered is associated with its low bond strength with the other atoms and high vapor pressure at 298 K.

3. The $Si/CdAs_2$ composite targets maintained a constant surface composition during several runs, and consequently the compositions of the films remained constant. This was not the case with the polycrystalline $CdSiAs_2$ target, probably due to target heating during substrate heating experiments.

4. The features of the composite $Si/CdAs_2$ target are not imaged in the compositions of the films. Evidently, the sputtered atoms experience multiple collisions with argon atoms (and perhaps each other) on their way to the substrates.

5. The Si/As ratio can be controllably adjusted in large steps by changing the $Si/CdAs_2$ area ratio in the target. It can be fine-adjusted by varying the sputtering power.

6. The Cd content of the films can be adjusted by adjusting the target's $Si/CdAs_2$ ratio, sputtering power, substrate temperature, and by heating the films in a Cd atmosphere.

Annealing Behavior of Molybdenum Films Containing Rhenium

Keiichiro Uda,[1] Yoshiaki Matsushita,[2] and Shin-ichiro Takasu[2]

Cooperative Laboratories, VLSI Technology Research Association, 4-1-1, Miyazaki, Takatsuku, Kawasaki, Japan

ABSTRACT

The annealing behavior of molybdenum (Mo) films containing from 3 to 30 w/o rhenium (Re) is investigated with high resolution scanning electron microscopy. The grain size of the alloy films decreases with the increase of Re content. The electrical resistivity of Mo films with 10% Re is approximately twice that of pure Mo films, and the activation energy for the grain growth is higher than the pure Mo films one. The interdiffusion of Mo, Re, and Si atoms across the metal-SiO_2 interface is also observed after 1000°C annealing.

The study of gates and interconnection materials with low resistivity has become essential to the rapid progress of LSI technology (1). Intense study of refractory metals such as molybdenum (2) and tungsten has produced fine-patterned and high speed device fabrication technologies. These metals, which are fine grained, produce high quality devices and can withstand high temperature heat-treatments. However, the corrosion properties of these materials make them troublesome to deal with in device fabrication processes. Conversely, refractory metal silicides are easy to handle, and exhibit a higher resistance to oxidation than the refractory metals (3).

In the present study, the refractory metal Re, which is resistant to corrosion (4), is added to Mo films for possible use as a new gate material. The annealing behavior of the alloy films is examined with a high resolution scanning electron microscope (SEM), and the electrical characteristics of the alloy are also explored.

Experimental Procedure

p-Type 1-2 Ω · cm (100) oriented silicon wafers were used as the substrate, and 3000Å Mo films containing Re were deposited by electron gun co-evaporation on 1500Å thermally grown silicon dioxide films. The Re content in the Mo films was varied from 3 to 30%. The deposition rate of Mo and Re was 15-20 Å/

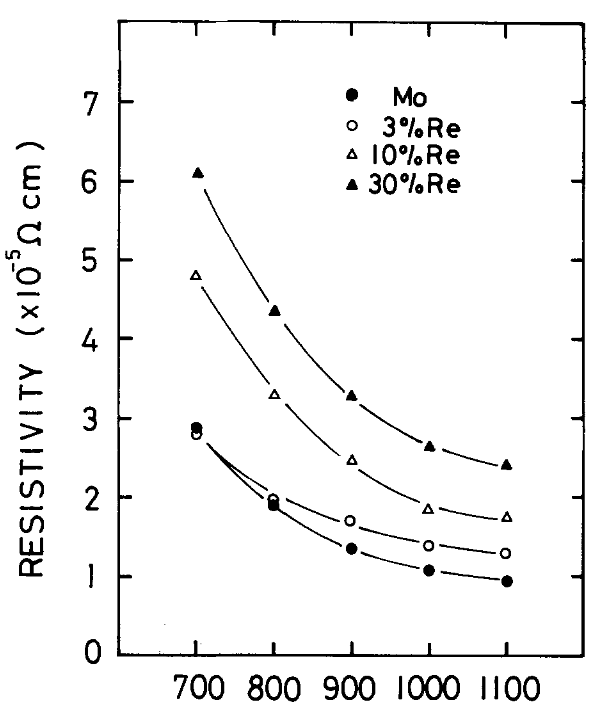

Fig. 1. Relation between resistivity and annealing temperature for Mo films containing various amounts of Re.

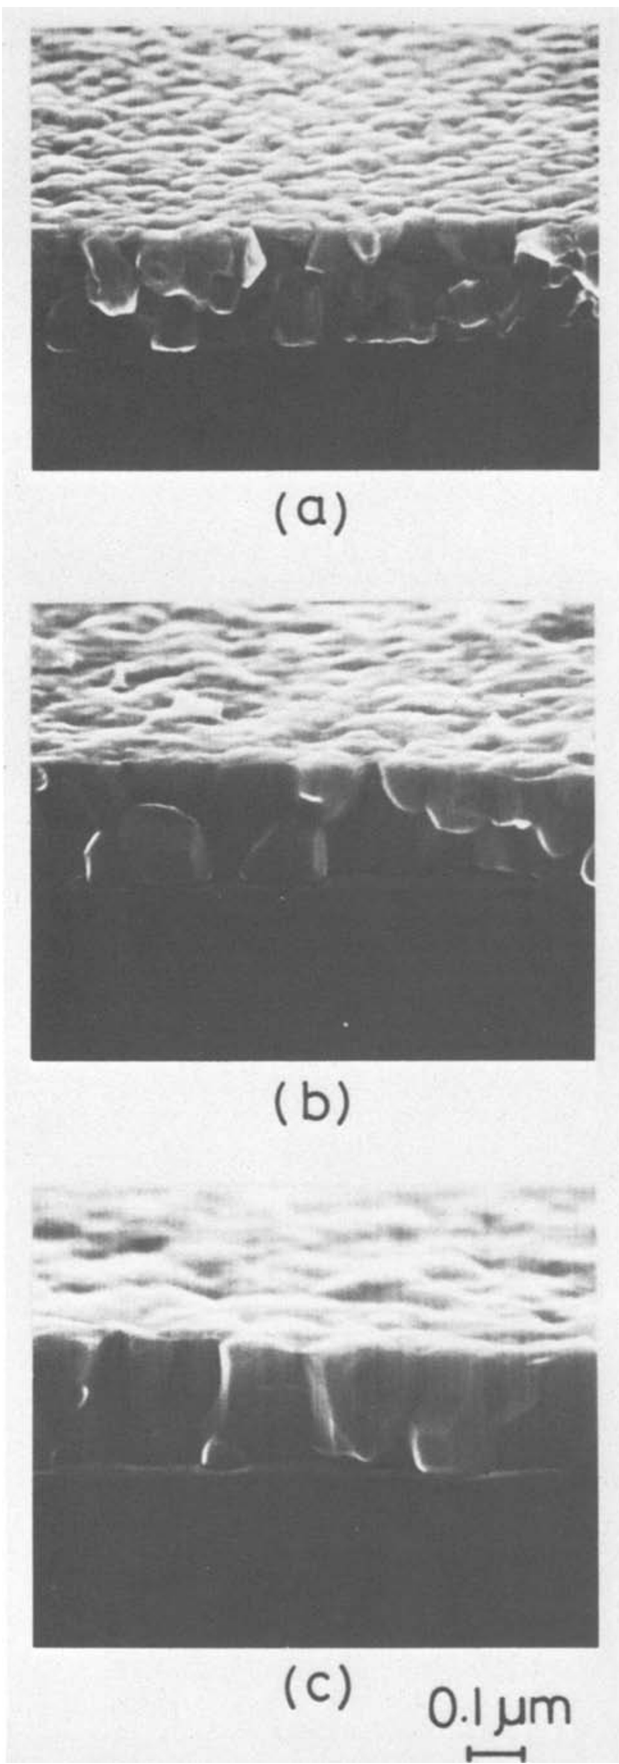

Fig. 2. SEM images of cleaved 3000Å Mo films annealed at (a) 900°C, (b) 1000°C, and (c) 1100°C.

sec and 0.4-4 Å/sec, respectively, and each film thickness was also monitored. During evaporation, substrates were held at 150°C and vacuum pressure was below $3 \cdot 10^{-6}$ Torr. Samples were carefully annealed at 700°-1100°C in a dry N_2 atmosphere for 3-100 min. A JEOL Model JEM-100C high resolution scanning electron microscope was used to directly observe the microstructure and grain size at cleaved surfaces of the samples. The electrical resistivity of the samples was measured with a four-point probe, and in-depth profiles of Mo, Re, and Si atoms were made before and after heat-treatment with an ion microanalyzer (CAMECA, IMS-300), where O_2 leak was used.

Results and Discussion

Figure 1 shows the relation between electrical resistivity and annealing temperature as a function of Re content. Pure Mo films show the lowest resistivity, and the resistivity decreases as the annealing temperature increases. However, the resistivity of the films containing Re increases with the increase of the Re content. The resistivity of the film with 30% Re is two to three times higher than that of the pure Mo film, both before and after annealing.

Figure 2 shows SEM images of three cleaved 3000Å Mo films (2) which were annealed at 900°, 1000°, and 1100°C. The microstructure of the sample annealed at 900°C is faceted, with grain size less than 1000Å. Annealing at 1100°C induces significant grain growth, and the microstructure of the films shows an almost columnar structure. Figure 3 shows the SEM images of Mo films annealed at 1000°C which contain from 3 to 30% Re. The more Re that is present, the smaller the grain size becomes. The grain size of Mo films with 30% Re is several hundred angstroms in diameter, even after the 1000°C annealing. However, when an excess of Re is added to the Mo films, the film demonstrates some undesirable characteristics. In the case of 30% Re, film adhesion to the substrate is drastically weakened. Such effects will be the subject of a future report.

Figure 4 shows three SEM images of cleaved 10% Re films, where samples were annealed at 900°, 1000°, and 1100°C. The grain size of these films is smaller

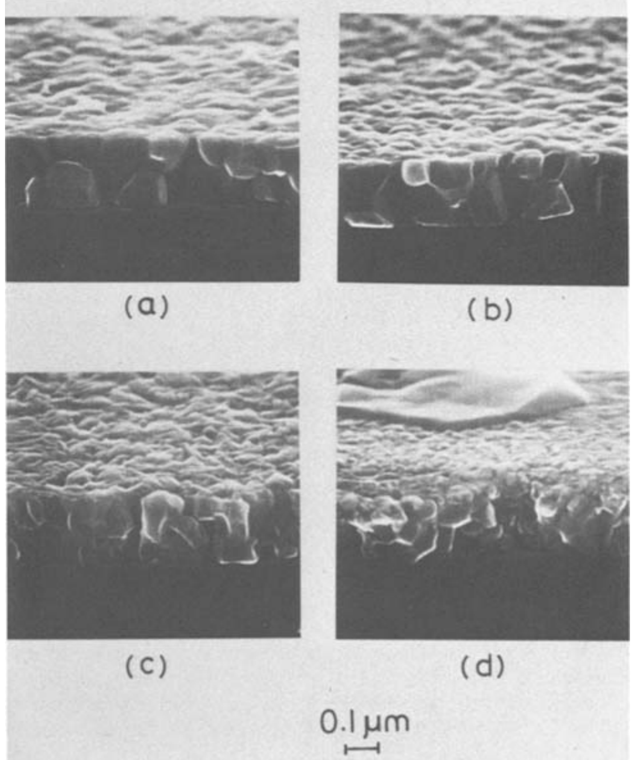

Fig. 3. SEM images of cleaved Mo films containing various amounts of Re, (a) pure Mo, (b) 3% Re, (c), 10% Re, and (d) 30% Re after 1000°C annealing.

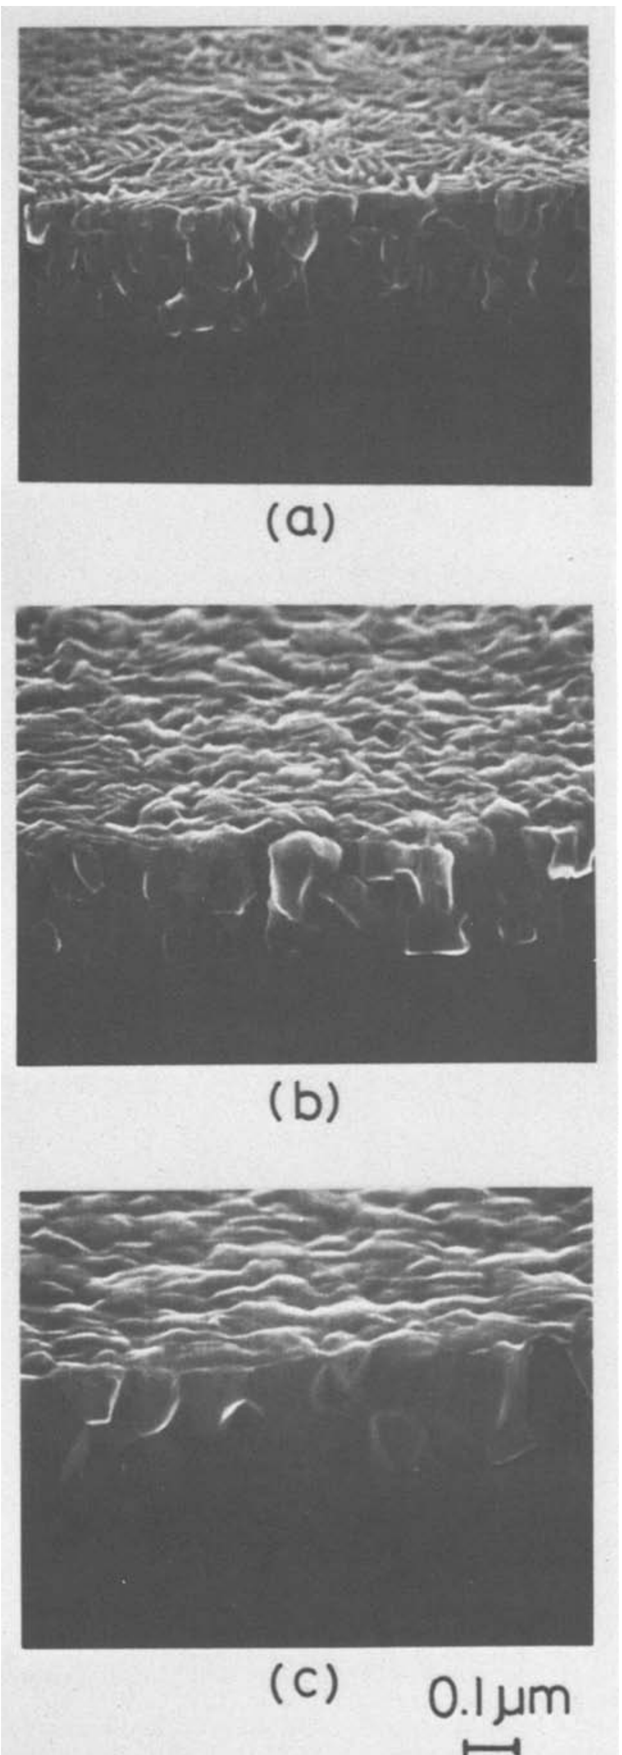

Fig. 4. SEM images of cleaved Mo films with 10% Re annealed at (a) 900°C, (b) 1000°C, and (c) 1100°C.

than pure Mo films (Fig. 2). In our investigation, Mo films containing 10% Re exhibited the most favorable characteristics for LSI technology. In the Arrhenius

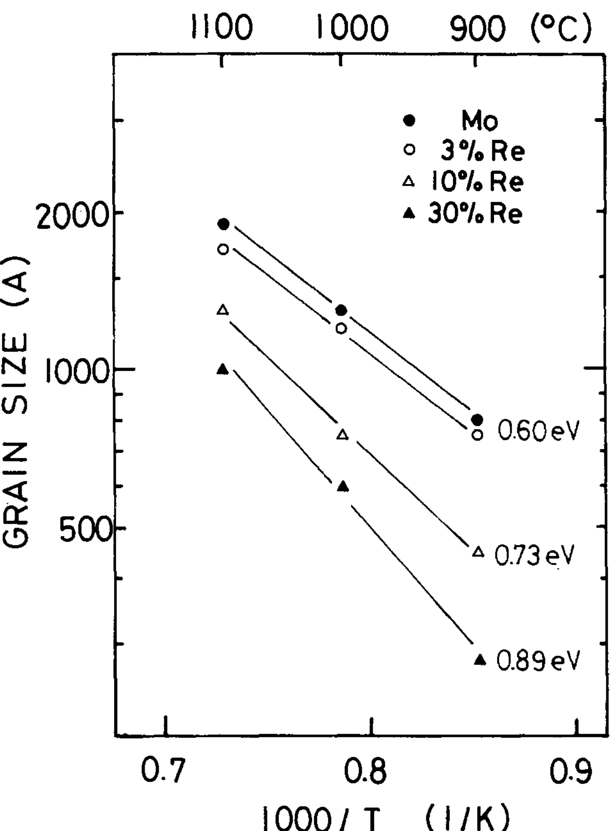

Fig. 5. Arrhenius plot of grain size for Mo films with various amounts of Re.

plot shown in Fig. 5, the mean grain size is shown as a function of Re content. In this work, the grain size of the films was directly and statistically measured using scanning electron microscopy, where surfaces and cleaved faces of the films were carefully observed. As observed in Fig. 2-4, the mean grain size of the pure Mo film shows the largest value, about 2000A after 1100°C annealing. The activation energy of this sample is 0.6 eV. On the other hand, Mo films containing Re had smaller grain size, and the greater the Re content, the higher the activation energy. The 10 and 30% Re samples had activation energies of 0.73 and 0.8 eV, respectively. These phenomena may be due to a blocking effect by Re during the grain growth.

Figure 6 shows in-depth profiles obtained with the ion microanalyzer for Mo^+, Re^+, and Si^+ ions with a

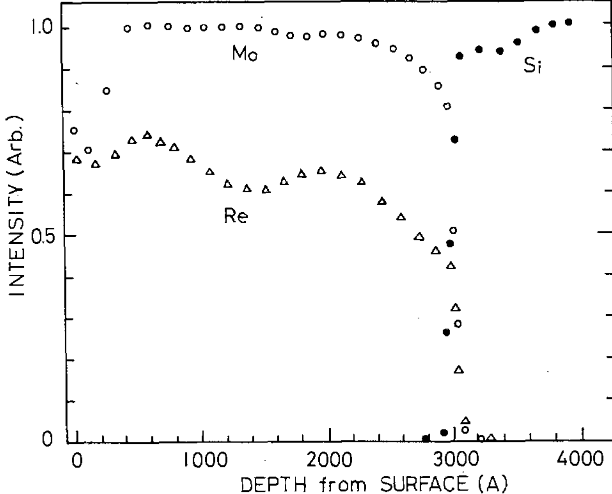

Fig. 6. In-depth profiles for Mo, Re, and Si atoms of Mo films with 30% Re before annealing.

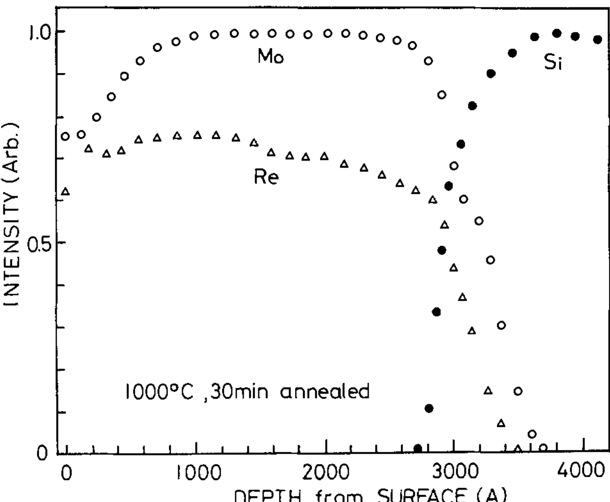

Fig. 7. In-depth profiles for Mo, Re, and Si atoms of Mo films with 30% Re after 1000°C annealing.

3000Å sample with 30% Re before annealing. Mo and Re atoms show a fairly uniform distribution in the film, and are not segregated at any locale. In this sample, the intensity of each ion shows drastic decrease at the metal-SiO_2 interface. However, as shown in Fig. 7, interdiffusion of Mo, Re, and Si atoms across the interface was observed after 1000°C annealing. The Mo atom penetrates deeper into the SiO_2 film than the Re atom. In our measurement, O_2 leak technique was used to reduce matrix effect. Therefore, this phenomenon can be considered a result of the diffusion coefficient difference between Mo and Re atoms.

Summary

Annealing behavior of 3000Å Mo films containing Re has been investigated. The electrical resistivity of the alloy films increases with the increase of Re content. The microstructure of Mo films with Re exhibits a similar structure as that of pure Mo film. However, the grain size of the alloy films decreases with the increase of Re content. The activation energy for the grain growth of alloy films is higher than that of the pure Mo films. The interdiffusion of Mo, Re, and Si atoms across the metal-SiO_2 interface is also observed after 1000°C annealing.

Thin Film Growth of InP LPE for MESFET Applications

T. Ishibashi, Y. Imai, and M. Ida

Musashino Electrical Communication Laboratory,
Nippon Telegraph and Telephone Public Corporation, 3-9-11, Midori-Cho, Musashino-Shi, Tokyo 180, Japan

ABSTRACT

InP epitaxial layers with submicron thickness were grown employing a phosphorus ambient LPE technique without In melt etching. The grown layer surfaces were smooth and there was no wave-like morphology, which showed good melt wetting on the substrates. The measured electron Hall mobility in the epilayer was maintained large near the interface with the substrate, and the electron saturated velocity in the FET channel was estimated at $v_s = 2.8 \times 10^7$ cm/sec. InP MESFET's with 0.8×200 μm gate dimensions were fabricated in the grown layers. A d-c maximum transconductance of 22 ms and a current gain cutoff frequency of about 40 GHz have been obtained.

InP field effect transistor (FET) has been expected to have better microwave and switching performances than GaAs FET, due to the higher electron peak drift velocity. About 50% higher current gain cutoff frequency of InP MESFET's than that of GaAs MESFET's was reported (1). Since the active layer for a MESFET is very thin, its electrical properties are greatly affected by substrate and growth conditions in the initial stage of epitaxy. Morkoc *et al.* pointed out the substrate dependence of InP MESFET performances, for their VPE layers (2, 3). The reported electron velocity in the FET channel, for a current saturation region, was 1.7×10^7 cm/sec for a Cr-doped substrate and 1.3×10^7 cm/sec for an Fe-doped substrate. These values are smaller than the desirable electron peak drift velocity of about 2.5×10^7 cm/sec (4). If the drift velocity is further improved by better crystal quality, higher FET performance can be achieved.

Key words: films, transistors, growth.

Liquid phase epitaxy (LPE) is expected to provide better interface than VPE as the LPE growth proceeds from quasi-equilibrium solution. InP LEP growth is not so commonly applied for MESFET fabrication because of somewhat poorer morphological uniformity of the epitaxial layers and the problem of substrate surface degradation in the growth procedure. Interface characteristics of LPE InP have not been studied from a MESFET performance viewpoint.

InP surface degradation is a serious problem as the phosphorus partial pressure in InP is relatively high

compared with GaAs. In order to remove the surface damage, melt etching by In has usually been employed in the InP LPE process. However, surface flatness becomes worse for relatively deep etching, making submicron photolithography for MESFET's fabrication difficult.

Clawson *et al.* reported the elimination of thermal damage by introducing PH_3 in H_2 ambient (5). They showed that the threshold PH_3 partial pressure for InP decomposition corresponds to that in In-P liquidus. The phosphorus ambient technique will provide useful means of preventing the InP surface degradation, especially for the thin film LPE growth.

In this paper, the LPE InP preparation for MESFET's using PH_3 introduction is described. Growth conditions for submicron thick InP layers, such as the growth temperature, substrate misorientation, and PH_3 flow rate in the reactor were studied. The In melt etching was not made. In order to ensure melt wetting of the substrate, fresh melt pushed just prior to the growth was used, and the surface morphology of the grown layer was investigated. The electron mobility had a relatively high value near the interface with substrate.

A Ge-doped, submicron-thick InP epilayer grown on Fe-doped substrate was used for MESFET's fabrication. The electron saturation velocity in the FET channel under the gate was measured in order to verify the crystal quality, which is the most important electrical property for MESFET.

S-parameter measurements were carried out for the MESFET's with 0.8×1.2 μm gate dimension, and current gain and power gain were calculated. It was demonstrated, from the electrical evaluation and the microwave performance on InP MESFET's, that the LPE growth of InP under the PH_3 ambient has high quality epitaxial layer feasibility with submicron thicknesses.

Experimental Procedure

Prior to the LPE growth experiment, the conditions for PH_3 partial pressure in the H_2 gas, which prevent the substrate thermal degradation, were studied under the same situation as that for LPE growth. The apparatus consisted of a graphite slider boat centered at a uniform temperature zone (± 0.2°C) about 25 cm long, in a 55 mm diam quartz tube. The flow of dilute PH_3 (0.1 volume percent in H_2) was controlled by a mass flow controller and mixed with Pd-diffused H_2. The total flow rate in the reactor was 1000 cm^3/min. Residual O_2 content and dew point in H_2 were below 0.02 ppm and about -70°C, respectively. Fe-doped semi-insulating substrates, with a 10^7-10^8 $\Omega \cdot$ cm resistivity, were mechanochemically polished and deep-etched about 10 μm by 5% Br-methanol solution. About 10 μm deep-etch was sufficient for suppressing the enhanced thermal damage, such as scratches, which would make the characterization of surface difficult. The specimens were annealed for 80 min in various PH_3 contents at temperatures of 600°, 650°, and 700°C. The surface observation was made by a Nomarski optical microscope, and thermal pits were investigated. Leakage current of substrate surface was measured in order to check the electrical conversion produced by thermal degradation.

LPE growth experiments were carried out as follows. Epitaxial layers were grown at the PH_3 flow rate which provided no morphological defects on the substrate surface. About twice as high PH_3 flow rate than that of threshold for an elimination of the thermal degradation was chosen for each growth temperature. The substrate was held exposed to the ambient on the graphite boat until the growth started. The dew point of ambient in the exhaust was typically -65°C when the growth started, after the quartz tube had been set in the furnace for about 1.5 hr. Six-nines In (Johnson-Matthey; A1A) of 1.5g was etched in HCl-ethanol solution and rinsed by water, then loaded in the melt well. In purification by long time baking in H_2 was not intentionally made. Step-cooling growth was used to grow LPE layers at the precise supercooling temperature and to minimize temperature nonuniformity of In melts. Growth temperatures were 593°, 615°, and 638°C, and the supercooling temperatures at the starting point of the growth was 10°C for each case. The phosphorus saturation of In melt was achieved by contacting an undoped InP wafer with In melt for 60 min. Two kinds of graphite boats were used. One was a conventional slider boat. The other had a two-well structure, as shown in Fig. 1, in which the fresh melt was pushed just prior to the growth and contacted with the substrate. The grown epilayers were electrically evaluated by van der Pauw-Hall measurements. The carrier concentration and mobility depth profile were then determined. InP MESFET's were fabricated in a 0.3 μm thick epilayer doped with Ge. The electron saturation velocity under the FET gate was evaluated from d-c characteristics and FET S-parameters were measured by means of an automatic-network analyzer.

Results and Discussions

Annealing of Fe-doped InP substrates.— InP surfaces annealed at 650°C for 80 min, with the PH_3 introduction of 50, 100, and 200 ppm, are shown in Fig. 2. With 50 ppm PH_3 concentration, the surface was heavily thermal etched and rectangular pits, which lie in the $\langle 110 \rangle$ direction, were observed. The In drops are seen in the pits whose depths range from several tenths of a micron to a few microns. When the PH_3 concentration is increased to 100 ppm, the rectangular pit disappears; however, the shallow pits spread on the surface. Here, the shallow pit pattern does not depend on crystallographic orientation, and In drops are not observed. No morphological surface variation from the one that was not thermally treated was observed for the surface annealed with 200 ppm PH_3. At another annealing temperature, similar thermal pits to the 650°C case were observed, below the threshold PH_3 density. Beyond the threshold, thermal pits were completely eliminated from the surface, up to 700°C. For characterization of the thermally degraded surface, they are classified into three types: (*i*) deeply etched surface with In drops, (*ii*) weakly degraded surface with shallow pits and without In drops, and (*iii*) surface with no morphological change. In Fig. 3, the surface degradation dependence on temperature and PH_3 concentration is shown. The two solid lines indicate the reported P_2 and P_4 partial pressures in the equilibrium with the liquidus in the In-P system (6). The PH_3 partial pressure is considerably higher than P_2 and P_4 partial pressures. As the PH_3 decomposes thermally by the following reaction

$$PH_3 = aP_2 + 1/4\,(1 - 2a)P_4 + 3/2\,H_2$$

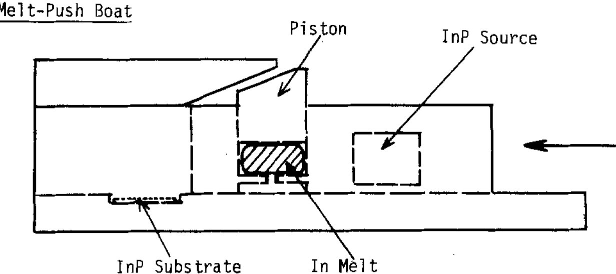

Fig. 1. Carbon boat for InP LPE. The In melt saturation by P is made by contacting the InP source wafer to the side wall of the melt. Fresh melt is pushed to the neighboring area from the upper well.

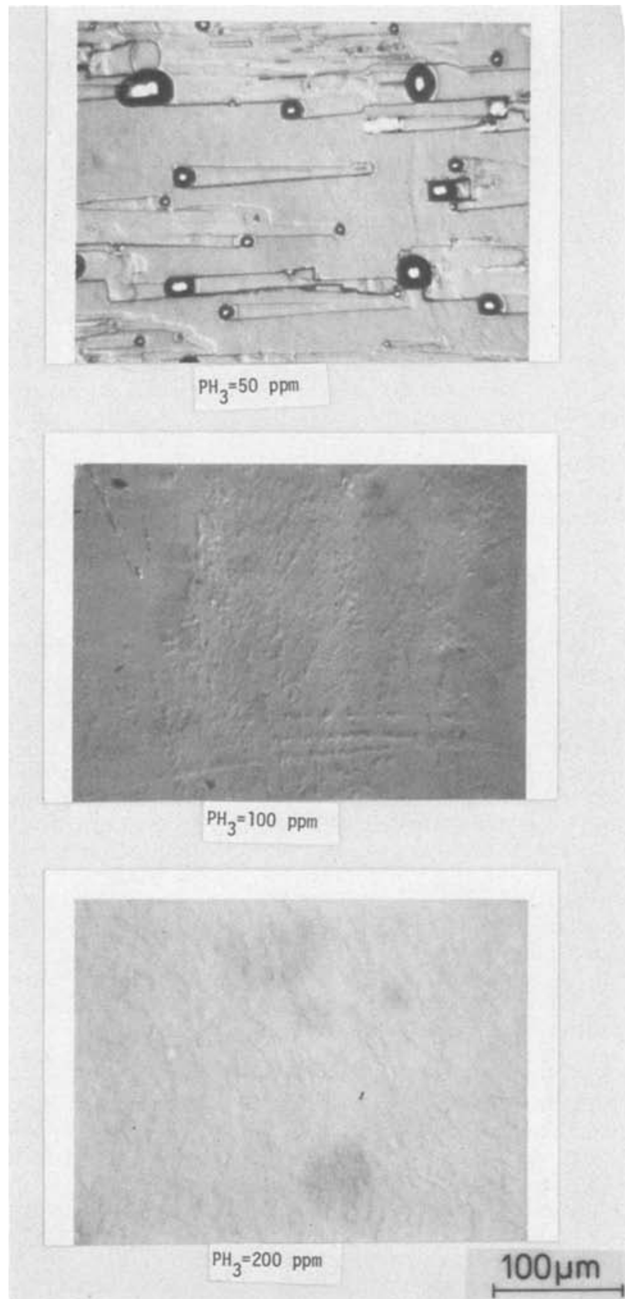

Fig. 2. Fe-doped (100) surface annealed at 650°C for 80 min. In various PH_3 concentrations, the total flow rate was maintained at 1000 cm^3/min.

the phosphorus pressure is reduced from the PH_3 value by a factor of 2-4. Considering these factors, the PH_3 required for thermal damage elimination is about five times for 700°C and about 100 times for 600°C larger than the phosphorus pressure in equilibrium. As described by Clawson *et al.*, the thermal degradation occurs at a lower phosphorus pressure than the equilibrium. Our results show that the effective phosphorus partial pressure depends strongly on the temperature and the apparatus. Ban *et al.* (7) reported the PH_3 decomposition rate in their VPE system as 40% at 700°C and 25% at 600°C. Therefore, the difference in 700°C data may be explained mainly by inadequate PH_3 decomposition. The larger excess PH_3, at a temperature lower than 700°C, reveals the phosphorus vapor loss absorbed by the carbon boat and quartz tube.

Surface leakage current for 650°C annealed samples was measured in the dark and under a W lamp illumination. Figure 4 shows leakage currents between

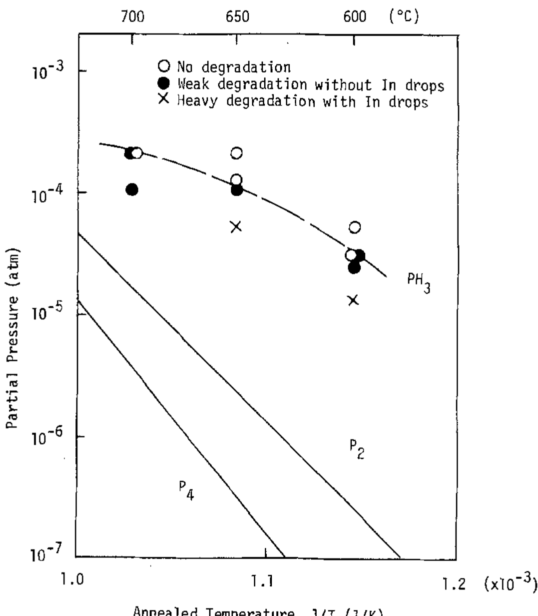

Fig. 3. (100) surface thermal degradation dependence on temperature and introduced PH_3 partial pressure. P_2 and P_4 show reported phosphorus partial pressures in equilibrium with the liquidus in the In-P system (6).

two 3 mm spaced Sn alloyed electrodes, applying 10V. In the dark, the leakage currents for 50 and 100 ppm treated samples show about twice the value for untreated sample. However, the 200 ppm treated sample shows no change from an untreated one. Excess current under the illumination is proportional to light intensity for each case. The 50 ppm treated sample, which is deeply degraded, has the largest photocurrent. This large photocurrent implies an increase in carrier lifetime near the InP surface. It was shown that the electrical conversion on the surface can also be eliminated by phosphorus ambient.

LPE growth.—Undoped InP epitaxial layers were grown under the step-cooling condition with a 10°C supersaturation temperature, flowing 60 ppm PH_3 at

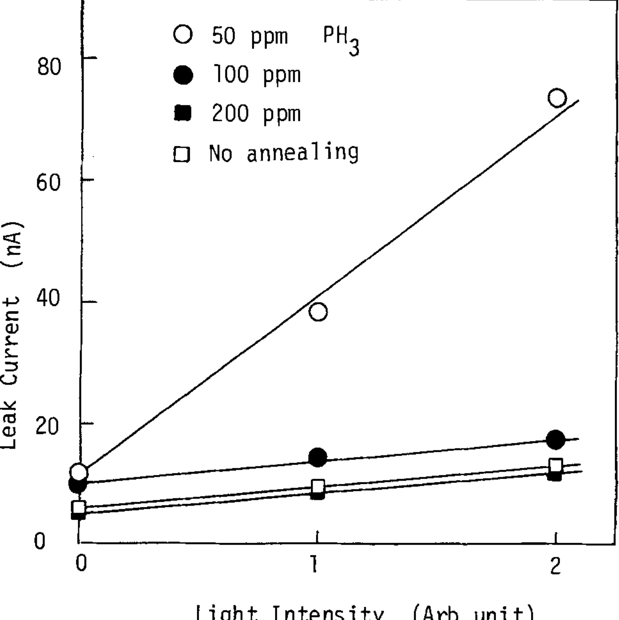

Fig. 4. Surface leakage current of annealed and nonannealed Fe-doped substrates. 10V was applied between two electrodes with 3 mm spacing.

593° and 615°C, and 120 ppm at 638°C growth temperatures. Figure 5 shows epitaxial layer thickness *vs.* growth time, where the melt-push type boat with a 1 mm melt thickness was used. The grown layer thickness was determined by an optical microscope on the cleaved and stain-etched layer and/or by sheet carrier variation with step-etching. The calculated saturated grown thickness was deduced from the 10°C supersaturation, indicated by ●, ⊙, and □. Published data by Hsieh (8) are also included in Fig. 5. Up to about 200 sec, the layer thickness varies with the $\sqrt{t}$ law. After that time, it shows a saturation tendency. The difference between 638°C growth and Hsieh's data is reasonable in the $\sqrt{t}$ law region. It was shown that, at relatively low growth temperature around 600°C, the InP epitaxial layer thickness was controlled to submicron thickness.

The morphology dependence on substrate misorientation and the effect on pushed fresh melt were also investigated. Figure 6 shows the surface of LPE layers about 0.5 μm thick, grown at 593°C. The slider boat was used for (A), (B), and (C) and the melt-push boat was used for (D). On the grown layer with (100) ± 0.5° oriented substrate in Fig. 6(A), a wave-like morphology is observed. The wave direction does not depend on the wipe direction of melt. With an exactly oriented substrate (100) ± 0.1° in Fig. 6(B), the "wave" is almost not seen on the surface where the growth melt wets the substrate properly. However, poor wetting sometimes occurred around the growth edge in the case of the slider boat, as shown in Fig. 6(C). Shallow voids on the epilayer were observed. Dark spots were also seen, which were considered to be slag left by growth melt when it was wiped off. When the melt-push boat was used, better and more reproducible wetting was obtained, as shown in Fig. 6(D). There is no feature in the morphology. These results indicated that adequate melt wetting with the substrate can be provided by the contact with fresh melt in PH_3 ambient growth, in spite of no melt-etching. It was made clear that the wave-like morphology arises from substrate misorientation.

The electron concentration and Hall mobility of grown layers were measured for undoped and Ge-doped InP. For undoped samples, carrier concentration of $7 \times 10^{15}/cm^3$ with 77 K mobility of 27,000 $cm^2/Vsec$ was obtained. The Ge distribution coefficient was $K_{Ge} = 0.006$ in atomic fraction, which was in good agreement with published data (9).

The electrical properties near the interface between epilayer and substrate are important, especially for MESFET's applications, since the channel is formed there. Figure 7 shows the carrier concentration and mobility profiles in depth for Ge-doped n-InP epilayer, grown at 615°C, for 15 sec. The profiles were determined by repeated Hall measurement after every 500Å etching step. The etchant used was $H_2SO_4:H_2O_2:H_2O = 4:1:1$, which gave good uniformity for InP. The measured area was 1 mm square in the cloverleaf pattern. As shown in Fig. 7, electron mobility at the surface is 3800 $cm^2/Vsec$ which is as large as that in the thick epilayers. The mobility decreases gradually toward the interface. Its drop near the interface is only about 20% from the surface value. The dashed line in the carrier profile shows the extrapolated slope obtained from *C-V* measurement. The arrow indicates the interface determined by sheet carrier variation in Hall measurement. These results imply that the thin InP epilayer grown without melt-etching has considerably good electrical characteristics and carrier profile suitable for MESFET's applications. The electron saturated velocity determined by FET's d-c characteristics is described in the next section.

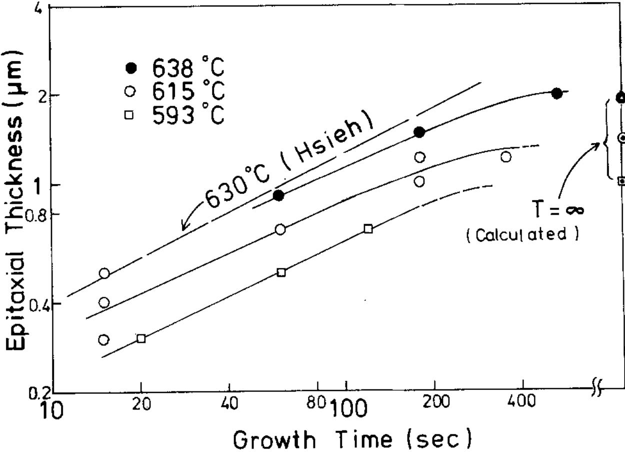

Fig. 5. Grown thickness of InP epilayers. Supercooling temperature was 10°C for each case.

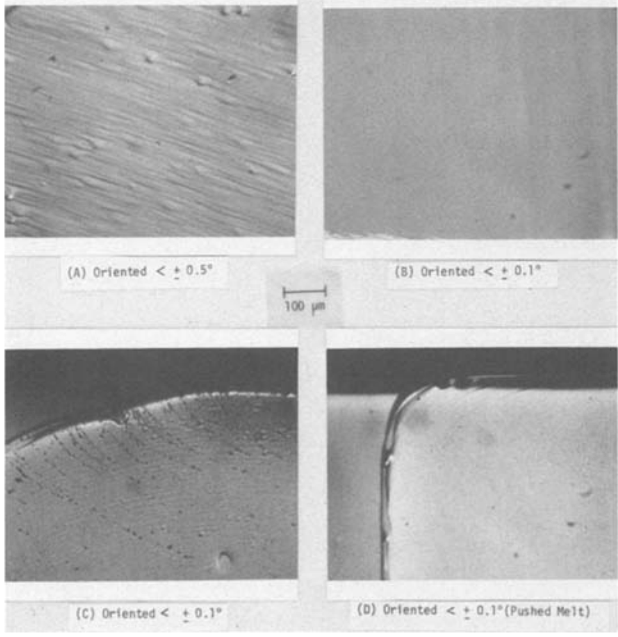

Fig. 6. Surface morphology of grown layer under the Nomarski micrograph. A conventional slider boat was used for (A), (B), and (C), and a melt-push boat was used for (D).

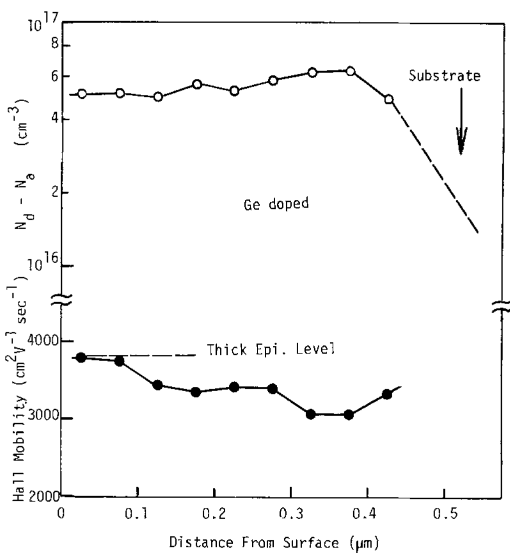

Fig. 7. Carrier concentration and Hall mobility profiles for InP epilayer grown at 615°C for 15 sec.

MESFET performances.—InP MESFET's with 0.8 μm gate length were fabricated in Ge-doped epilayer grown at 593°C. The carrier concentration and thickness of the active layer determined by Hall measurements were $n = 6 \times 10^{16}/cm^3$ and 0.3 μm, respectively. The sheet mobility was 3400 cm^2/Vsec and the mobility at the surface was 3600 cm^2/Vsec. After the device area was isolated in mesa structure by ion-milling, Au · Ge/Ni source and drain contacts were defined by the lift-off process, and were alloyed at 450°C for 15 sec. The evaporated Au · Ge/Ni thickness was 1500Å and the source-drain spacing was 3.6 μm. The recess structure was made, and then a Schottky barrier gate was formed by lifting off the vacuum evaporated Ti(1000Å), Al(5000Å), and Pt(100Å). Two kinds of MESFET's with gate width of 200 and 20 μm were fabricated on the same wafer.

Drain *I-V* characteristics for a MESFET with a 0.8 $\times$ 200 μm gate dimension are shown in Fig. 8. Maximum transconductance (g_m) is 22 msec and pinch-off voltage (V_p) is -2.2V. In order to evaluate the electron saturated velocity under the FET gate, the drain current *vs.* effective gate bias V_{eff} is plotted in Fig. 9. Here, the smaller MESFET with a 0.8 $\times$ 20 μm gate dimension was used for the evaluation in order to obtain the better uniformity for the pinch-off. The built-in voltage of $V_{bi} = 0.41$ eV, measured for a large area diode, was used in the estimation. The saturated velocity was calculated as $v_s = 2.8 \times 10^7$ cm/sec, from drain current slope (10). The slope holds its linearity up to the vicinity of the pinch-off voltage. This fact indicates the good uniformity of carrier concentration and saturated velocity. The obtained value of $v_s = 2.8 \times 10^7$ cm/sec is larger than that in the device fabricated by VPE grown InP layer, reported by Morkoc *et al.* (3). They estimated $v_s = 1.3 \times 10^7$ cm/sec for Cr-doped substrate. The evaluated velocity in the present LPE layer is as high as the peak velocity in bulk InP. Our results show that the LPE layer has good interface characteristics concerning the electron drift velocity.

The S-parameter measurement was made for the FET with 0.8 $\times$ 200 μm gate dimension, and current gain and power gain were calculated. $|H_{21}|^2$ and $|S_{21}|^2$ are shown in Fig. 10. The current gain cutoff frequency f_T of about 40 GHz has been obtained. The maximum oscillating frequency was about $f_{max} = 46$ GHz. The $f_T = 40$ GHz is about twice that in GaAs MESFET in the same dimensions, although f_{max} is smaller. The improved current gain is consistent with the high electron saturated velocity in the LPE InP active layer.

Conclusion

Thermal degradation of the Fe-doped InP surface was investigated under various PH_3 partial pressures, in order to find the condition for the eliminating of thermal pits. The InP LPE layer grown on the accurately oriented substrate had a smooth surface and showed no wave-like morphology. Fresh melt pushed just prior to the growth provided adequate wetting on the substrate without melt etching. The mobility in the epilayer was maintained large near the interface and the electron saturated velocity in the FET channel was $v_s = 2.8 = 10^7$ cm/sec, which almost agreed with that in bulk InP. The MESFET with 0.8

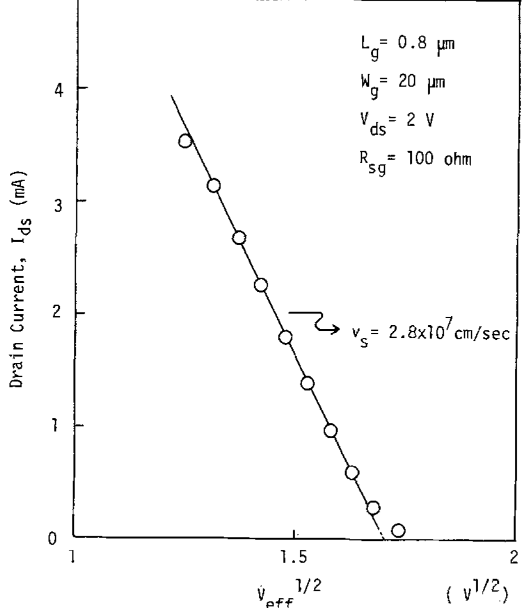

Fig. 9. Drain current *vs.* effective gate bias voltage $V_{eff} = V_{bi} + I_dR_{sg} + E_m \cdot L_g - V_{gs}$. The threshold field E_m of 10 kV/cm was assumed.

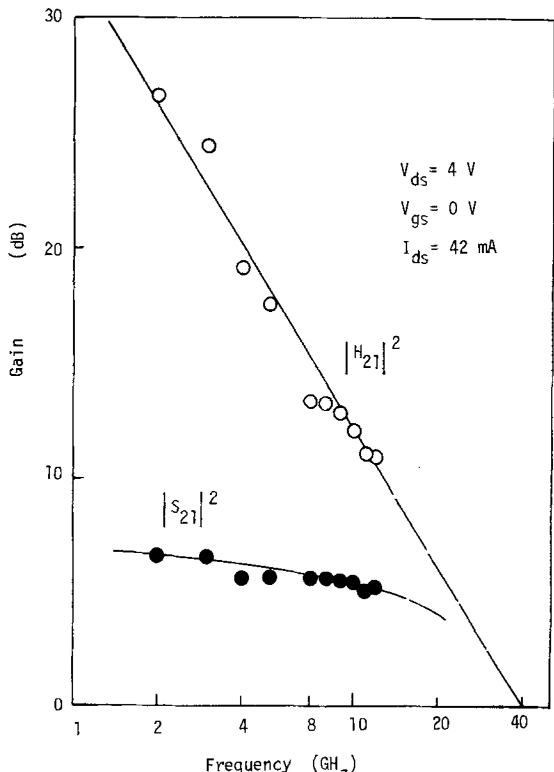

Fig. 10. Frequency dependences of $|H_{21}|^2$ and $|S_{21}|^2$ of InP MESFET with 200 μm gate width.

μm gate length showed a transconductance of 22 ms for 200 μm gate width and a current gain cutoff frequency of about 40 GHz was obtained. The results in electrical properties and rf performance indicate the capability of InP LPE growth, under the PH_3 ambient without In melt etching, for MESFET applications.

Acknowledgment

The authors are extremely grateful to Y. Ishii for supplying the photomasks designed for GaAs MESFET, and to Y. Uchida for helpful discussions in device fabrication. Also the authors would like to thank Dr. M. Ohmori, Mr. M. Fujimoto, and Dr. M. Watanabe for their encouragement and suggestions.

Manuscript submitted Dec. 12, 1980; revised manuscript received Feb. 20, 1981.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.

Publication costs of this article were assisted by Nippon Telegraph and Telephone Public Corporation.

Interfacial Structure Studies of Gold-Tin-Aluminum Metallizations on GaAlAs

S. Nakahara* and R. J. McCoy

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A transmission electron microscope (TEM) was used to study the cause for an erratic adhesion problem which occurred between Au-Sn-Al metallizations and GaAlAs during the fabrication of light emitting diodes (LED's). A cross-section study revealed that the metallization layer was actually separated from much of the GaAlAs surface by a complex void structure. The presence of such an interfacial void is thus a potential source for poor adhesion. Previous TEM studies have shown that the void structure in fact consists of two prominent features: isolated hemispherical pores and an almost continuous interfacial crack. In this work, Sn-Au interdiffusion mechanisms are proposed to explain the origin and nature of the complex void structure. Rapid grain boundary diffusion of Sn into Au and rapid bulk diffusion of Au into Sn are used to describe the origin of the observed pores. On the other hand, the occurrence of the interfacial crack is attributed to interdiffusion-induced high tensile stresses whch cause the separation of the metallization layer from the GaAlAs substrate. The microstructure of the Sn and Au layers is shown to be important in determining the possible formation of such a void.

Gold-tin-aluminum metallizations are employed in the large-scale production of GaAlAs LED's for various opto-electronic devices. The processing using this metallization scheme, the details of which have been described elsewhere (1), results in ohmic contacts with excellent electrical properties. More recently, however, difficulties in achieving uniformly good adhesion between the metallization and GaAlAs were encountered with this particular procedure. This problem was solved by a simple modification of the original metallization (2).

Previous analyses of both as-deposited and post-annealed Au-Sn-Al/GaAlAs[1] interfaces have revealed the presence of voids which are seen to separate the metallization layer from much of the semiconductor surface (2, 3). From these results it was concluded that the presence of such interfacial voids could explain the erratic adhesion obtained with the original metallization scheme. Although these analyses also showed room temperature interdiffusion of Sn and Au to be responsible for the void formation, the exact diffusion mechanisms remained unresolved.

In order to understand further how the voids are formed, we have made additional TEM studies on the original Au-Sn-Al metallization. It will be shown that the voids generally observed in previous TEM work (3) arise from rapid grain boundary diffusion of Sn into Au coupled with rapid bulk diffusion of Au into Sn. Furthermore, it is proposed that the Sn-Al interdiffusion at room temperature prior to post-annealing induces high tensile stresses in the metallization. A model using such stresses is presented as an explanation for the observed interfacial cracking.

Key words: TEM, LED's, metallizations.

[1] We are here adopting a notational convention that follows successive metal layers into a substrate. For example, Au-Sn-Al/GaAlAs means that Al is the layer in contact with the substrate (GaAlAs), Sn is on top of Al, etc.

Experimental

All samples discussed in this work were metallized by conventional electron beam deposition in a vacuum of $\leq 1 \times 10^{-6}$ Torr. Some metallized GaAlAs samples were post-annealed at 420°C for 10 min in a reducing gas environment. This particular annealing treatment is employed in order to obtain ohmic contacts (1). All other samples were stored at room temperature after metallization.

Metallizations were performed on two types of substrates in this study: GaAlAs and NaCl. Samples were prepared from metallizations deposited on the n-side of (001) GaAlAs wafers. In this case, the production scheme (1) used in the fabrication of LED devices was employed. A schematic cross-sectional view of this metallization is shown in Fig. 1. Metal layer thicknesses are 35Å (Al), 500Å (Sn), and 30,000Å (Au) (1).

Air-cleaved (001) NaCl substrates were also used in this work. Here, various combinations (and thicknesses) of Al, Sn, and Au were employed as shown in Fig. 2. The use of this substrate was justified on the basis of the observation (2) that void formation essentially results from Sn-Au interdiffusion at room temperature, with the underlying substrate playing no important role in the diffusion. The use of an inert substrate such as an NaCl crystal permitted simple sample fabrication for the TEM. Metallized layers were directly examined after dissolving away the NaCl in distilled water. Cross sections of metallized GaAlAs for TEM examination were prepared by the following procedure. Metallized GaAlAs wafers were first cut into small (0.5×2.5 mm^2) pieces using a diamond saw. The sliced pieces were then sandwiched with their metallized faces together and glued with epoxy cement. About seven pieces could be glued as a laminate within the 3 mm diam area which is the maximum allowable size for a TEM specimen stage. The wide plane, in which the metallized cross section lies, was then mechanically polished to a thickness of ~25 μm. The laminated samples were finally ion-milled using a Technics MIM IV ion-milling machine.

Transmission electron microscopy was carried out using a JEM 200 electron microscope operated at 200 kV. For the observation of small (~10Å) voids, the defocus contrast technique (4) was used.

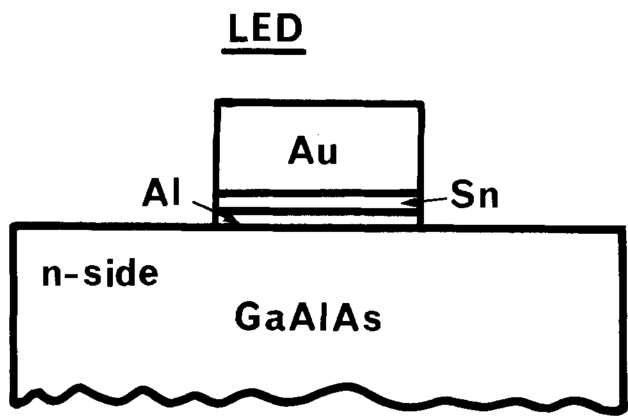

Fig. 1. A schematic view showing the cross section of the metallized n-side in GaAlAs LED's. Metal film thicknesses are 35Å (Al), 500Å (Sn), and 30,000Å (Au) (1).

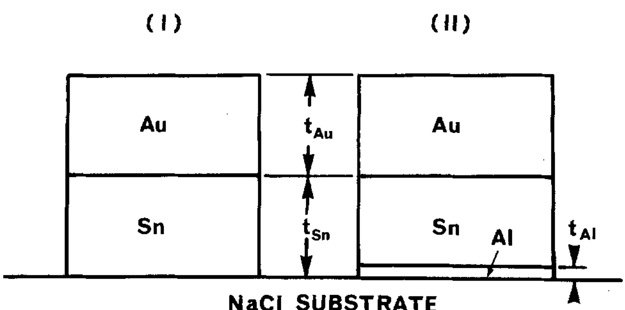

Fig. 2. A schematic view of metallization on air-cleaved (001) NaCl substrates. Two metallizations are shown: (I) Au-Sn and (II) Au-Sn-Al. Symbols, t_{Au}, t_{Sn}, and t_{Al} denote the thickness of Au, Sn, and Al films, respectively.

Results

Metallizations on GaAlAs.—Metallizations deposited on the GaAlAs were often found to be readily peeled off the substrate (2). The peeled face of the metal films contained a high density (~6×10^6 cm^{-2}) of large (1000 ~ 3000Å diam) pores. A typical example of this pore structure observed on the back side of an as-deposited metallization layer is shown in Fig. 3. It was found that the pore size and shape in the as-deposited film was not significantly altered after the post-annealing treatment. This result indicates that the void formation is nearly completed during the film deposition and/or subsequent room temperature aging period prior to post-annealing. Furthermore, an examination of the peeled GaAlAs surface before annealing revealed essentially no indication of interfacial reactions with the metallization layer. This further confirms that the void formation primarily takes place during the room temperature interdiffusion of Au and Sn.

A similar void structure was also observed from cross-sectional studies of as-deposited metallizations. Figure 4 is an SEM micrograph, showing the presence of the large pores at the Au-Sn-Al/GaAlAs interface. Figure 4(b) is taken at slightly higher magnification from the regions of Fig. 4(a) in order to bring up more details of the interfacial structure. The use of the high-resolution defocusing technique in the TEM (4) permitted the detection of a hidden important structural feature in addition to the isolated pores. As seen in Fig. 5, a slit-like crack running along the exact interfacial plane is revealed. This crack apparently separates the metallization layer from most of the GaAlAs substrate surface and provides an explanation for the origin of the erratic adhesion problem in this metallization. In Fig. 5, we also note the details of a large pore, the size of which was found to be about 500Å high and 2000Å wide. In addition to the pores, there are some islands left within a thickness of 500Å from the inter-

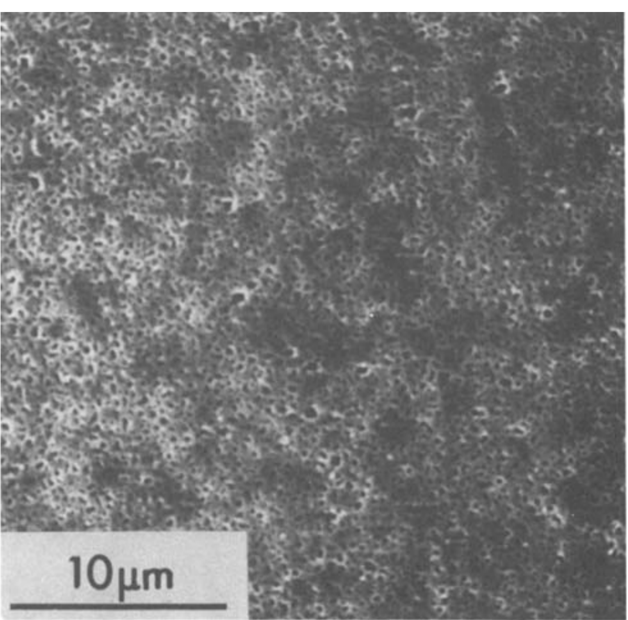

Fig. 3. SEM micrograph of the back side of an Au-Sn-Al metallization layer peeled from a GaAlAs substrate, showing a high density of large isolated pores.

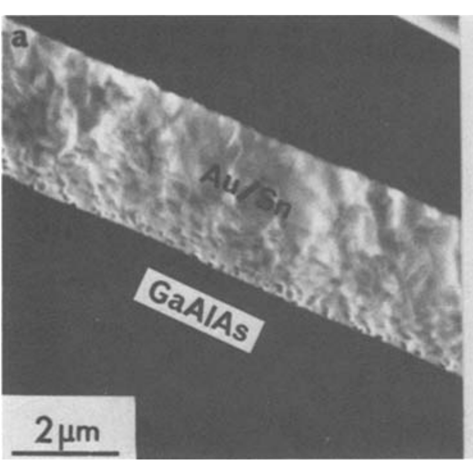

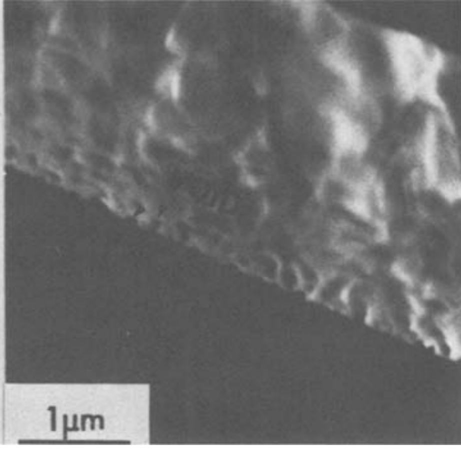

Fig. 4. SEM micrograph showing the cross-sectional view of as-deposited, metallized GaAlAs. The presence of interfacial pores is indicated with arrows in (b) which is taken at a slightly higher magnification from the region shown in (a).

face. An electron diffraction analysis has shown that these islands consist of intermetallic compound AuSn. From these observations, three prominent structural features, *i.e.*, pores, interfacial crack, and AuSn compound formation, are seen to evolve during the room temperature interdiffusion of Au and Sn.

As already mentioned, the basic void structure is not significantly altered by the post-annealing treatment. In Fig. 6, pores and interfacial crack similar to those observed in the as-deposited sample are also visible after post-annealing. An additional feature in the cross section after that treatment is the appearance of an acicular reaction product between Au and GaAlAs (see arrows in Fig. 6). Some aspects of the reaction product have previously been discussed elsewhere (3).

Metallizations on NaCl.—Figure 7 compares the structure of 500Å Sn with 500Å Sn-35Å Al films. Both films grow as islands in this thickness range, but the latter structure appears to be a little finer and more uniform than the former. The thin Al deposition seems to increase the subsequent Sn nucleation density, thus resulting in the somewhat more uniform structure. As will be seen below, this minor structural modification is not significant for the void formation.

With the use of an offset configuration (5) in the deposition pattern, it is demonstrated in Fig. 8 how the metallization structure evolves after Au is deposited on Sn. In the offset configuration, three regions, *i.e.*, pure Au, Au-Sn (or Au-Sn-Al) overlap, and pure Sn (or Sn-Al) can be fabricated simultaneously on one substrate by masking a portion of the substrate for an Sn (or Sn-Al) deposition, and offsetting the mask before Au is deposited. Figures 8(a), (b), and (c) represent the structure of 500Å Au, 500Å Au-500Å Sn-35Å Al, and 500Å Sn-35Å Al films obtained from the offset configuration. Comparing Fig. 8(a) and (c) with (b), we find that the overlap region (b) appears to be effectively the superposition of the structures (a) and (c). In detail, however, the overlap region is not exactly the superposition of the two. It is noted in Fig. 8(b) that voids are formed around the perimeter of each Sn island. An electron diffraction analysis has shown that the islands surrounded by the voids consist of AuSn, whereas the fine-grained film outside the islands is pure Au. The presence of Al could not be detected. It is interesting to note that the overlap region is characterized as a duplex structure, in which reacted AuSn islands and unreacted pure Au exist. Finally, in Fig. 9, the overlap region of 500Å Au-500Å Sn also shows a similar duplex structure to that of 500Å Au-500Å Sn-35Å Al [compare with Fig. 8 (b)]. This demonstrates that the Al deposition plays a minor role in the Au-Sn interdiffusion.

Discussion

It has been previously shown that the void formation primarily takes place during room temperature inter-

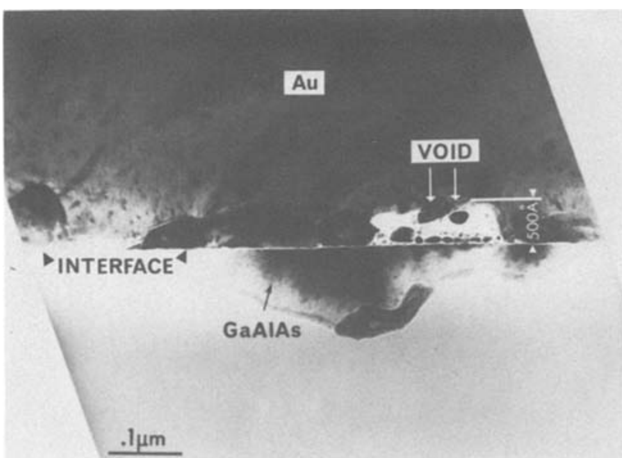

Fig. 5. TEM micrograph of the cross section of metallized, as-deposited GaAlAs, taken using the high-resolution defocusing technique (4). In addition to an interfacial void, the presence of a slit-like crack is now revealed along the exact interfacial plane. Due to a preferential etching effect by ion-milling, only a small piece of GaAlAs is seen to remain.

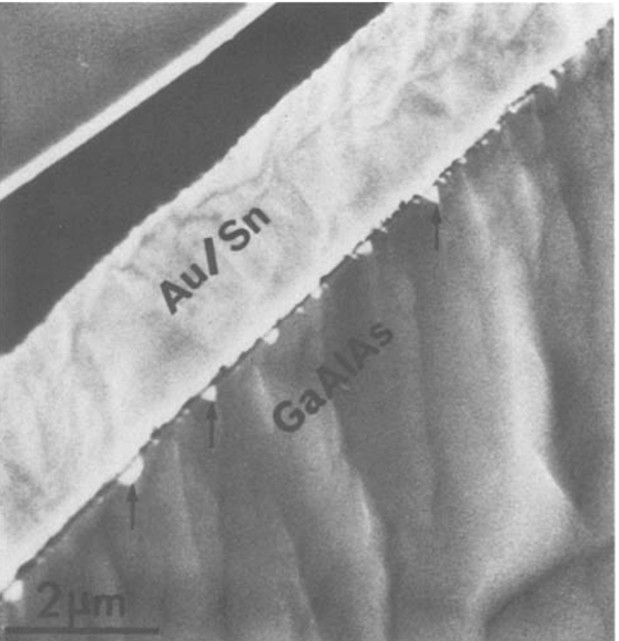

Fig. 6. Cross-sectional view of metallized GaAlAs after post-annealing. In addition to the presence of voids and interfacial crack, acicular reaction products (such as denoted by the arrows) are seen to have grown into the GaAlAs.

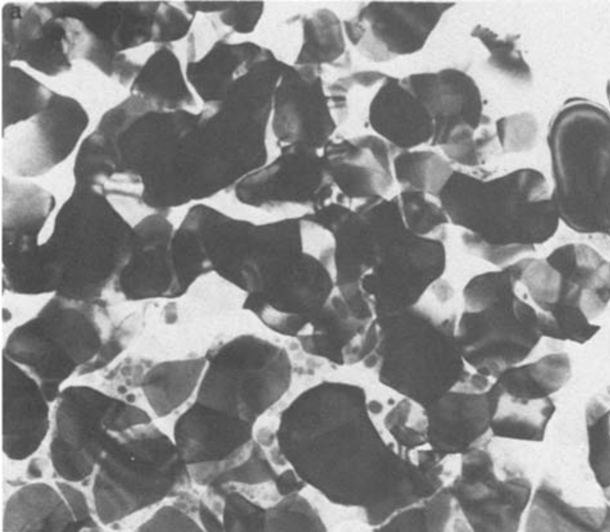

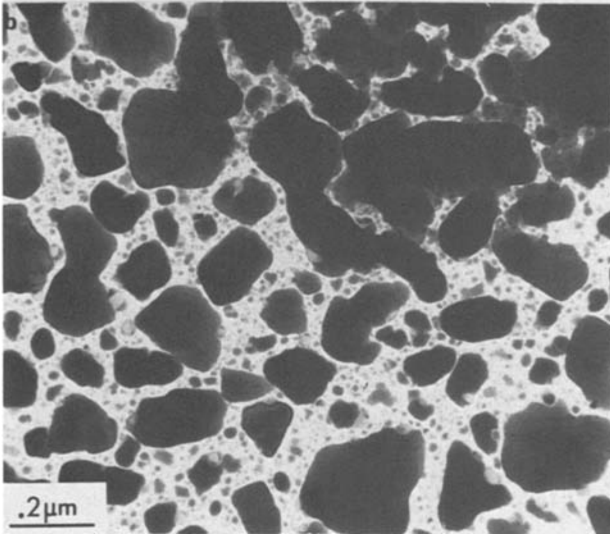

Fig. 7. Structure of (a) 500Å Sn and (b) 500Å Sn-35Å Al films deposited on NaCl. Both films are seen to grow in the form of islands but (b) appears to produce somewhat smaller and more uniform islands than (a).

diffusion of Sn and Au (2). The obvious conclusion from the analysis of the metallized GaAlAs samples is that Sn is the faster diffusing species in an Sn-Au diffusion couple, as Sn is found to diffuse into Au completely, leaving apparently large Kirkendall voids (pores). This conclusion is, however, not consistent with past work (6) where it was found that Au is the faster diffusing species in Sn-rich Sn-Au alloys. On the other hand, the void structure in the Au-Sn and Au-Sn-Al films prepared on NaCl clearly demonstrates that Au is the faster diffusing species, in agreement with Ref. (6). In this case, the rapid diffusion of Au into Sn islands transforms the islands into intermetallic compound AuSn and at the same time produces void regions around the perimeter. The formation of these voids effectively prevents the surrounding Au from further reaction. This in fact explains why the duplex structure (*e.g.*, Fig. 8b) of reacted and unreacted regions is produced.

Thus, Sn-Au interdiffusion observations on metallized GaAlAs and NaCl give apparently opposite identities for the fast diffusing species. Moreover, the shape of the voids produced in these two systems is different. For the case of Au-Sn-Al films on NaCl, one sees voids delineating the perimeters of AuSn islands. On the other hand, pores are observed at Au-Sn-Al/GaAlAs interfaces and these possess an empty, roughly hemispherical shape. It is clear that an understanding of the exact diffusion mechanism (or mechanisms) is needed to interpret these results.

One obvious difference between the NaCl and GaAlAs samples is the film thicknesses employed. The metallizations on GaAlAs have a thickness ratio t_{Au}/t_{Sn} which is extremely large ($\sim$60) and corresponds to $\sim$99% Au-rich alloy if complete intermixing is assumed. Diffusivities for both Au and Sn in Au-rich alloys have been previously determined (7, 8). When extrapolated to room temperature (25°C), these diffusivities amount to $10^{-32} \sim 10^{-29}$ cm²/sec for Au and $10^{-27} \sim 10^{-26}$ cm²/sec for Sn in Au-Sn alloys for which $C_{Sn} = 0 \sim 1.5$ atomic percent (a/o). Such bulk diffusivities are extremely small and cannot account for the Au-Sn-Al/GaAlAs observations. On the other hand, the metallizations performed on NaCl have a thickness ratio $t_{Au}/t_{Sn} \sim 1$, corresponding to $C_{Sn} \sim$ 40 a/o. In this range, the room temperature diffusivity of Au can be estimated from AuSn phase growth rates (9) to be $\sim 10^{-14}$ cm²/sec. This high value can indeed account for the perimeter void growth observed in Fig. 8 and 9. Thus, the concentration dependence of the bulk diffusivity of Au in Au-Sn alloys explains why

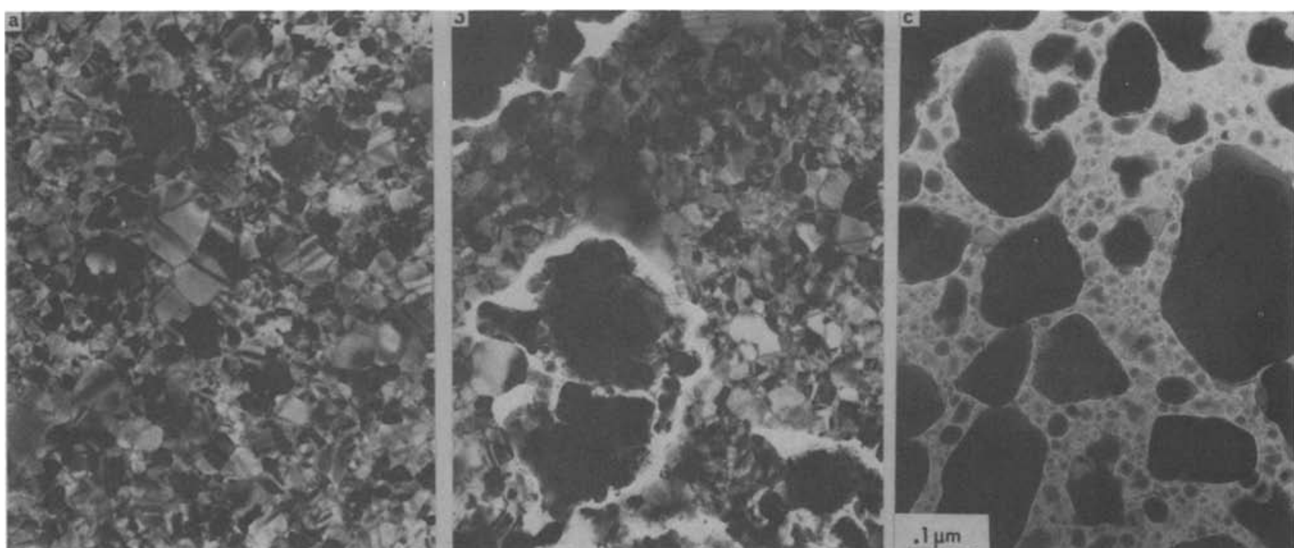

Fig. 8. TEM micrographs showing the structure of (a) 500Å Au, (b) 500Å Au-500Å Sn-35Å Al, and (c) 500Å Sn-35Å Al films deposited on NaCl in an offset (5) configuration. Note that voids around the perimeter of the original Sn islands delineate the islands and leave pure fine-grained Au unreacted.

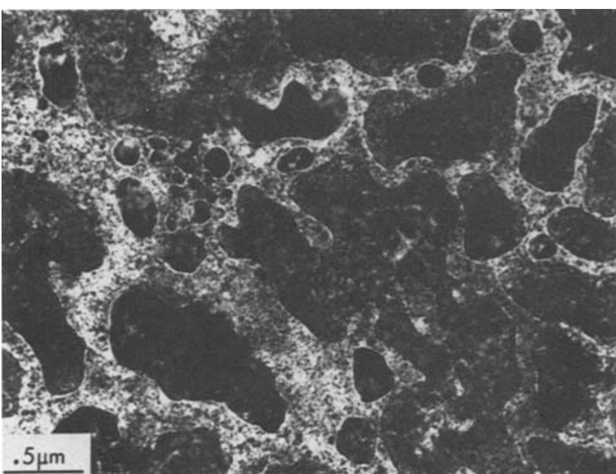

Fig. 9. Structure of 500Å Au-500Å Sn film deposited on NaCl. The film exhibits a well-defined duplex structure, in which the original Sn islands are seen to be delineated by the formation of voids around their perimeter. Unreacted pure Au surrounds the islands.

rapid Au diffusion is not observed in the case of the GaAlAs samples.

The above discussion shows that the observed rapid diffusion of Sn into Au seen for Au-Sn-Al/GaAlAs cannot be accounted for by a bulk diffusion mechanism. The only other possible mode of Sn diffusion is through Au grain boundaries. Indirect evidence supporting this diffusion mechanism can be found in an Auger electron spectroscopy (AES) analysis of similar metallized GaAlAs specimens (10). Depth profiling has shown that an as-deposited Au-Sn-Al film contains an essentially constant amount of Sn throughout the Au thickness and ~25Å Sn on top of the Au surface. We interpret these results as follows. The constant Sn concentration throughout the Au thickness suggests that the high diffusing paths along Au grain boundaries homogenize the Sn concentration, as opposed to the usual bulk diffusion in which a gradual concentration decay of Sn from the interface is expected. The presence of 25Å Sn on the top surface of Au is probably due to the formation of SnO_2 (10). If the rapid diffusion of Sn into Au is due to a grain-boundary mechanism, most of the diffused Sn atoms are expected to lie in Au grain boundaries unless an infinite Sn consumption occurs at the Au surface by the formation of, for example, SnO_2. As already seen by AES (10), the Au top surface is not an infinite sink for Sn atoms. The possibility that all diffused atoms can be accommodated in Au grain boundaries is readily justified. If it is assumed that the average grain size in the 30,000Å thick Au film is 250Å (5), a simple calculation shows that the available grain boundary area greatly exceeds the space which would be required by monolayer coverage of all the Sn atoms in the 500Å thick Sn layer. Therefore, most of the Sn atoms can diffuse out from the Sn layer and leave the observed pores at the interface. It should be noted that the Sn atoms lying at Au grain boundaries do not diffuse into Au grains, as this diffusion process involves the extremely small bulk diffusivity of Sn in Au-rich alloys (7, 8). The grain boundary diffusion mechanism postulated here has been directly verified in other work (5).

It has been shown that the deposition of the thin (35Å) Al film plays a minor role in the void formation. The Al layer appears only to increase the nucleation sites for the subsequent Sn deposition (Fig. 7). Examination of thicker (500Å Sn-500Å Al) films has shown that the Al film and the subsequent Sn layer maintain their original structure without detectable interdiffusion. Furthermore, the depth profile obtained by AES also shows (10) that the Al layer is retained at the interface without appreciable diffusion. From these observations, it is reasonable that the room temperature interdiffusion takes place between only Au and Sn without significant influence from the thin Al deposition.

The above observations now permit the construction of a model of how the pore formation observed at the Au-Sn-Al/GaAlAs interface comes about. It is clear that rapid grain boundary diffusion of Sn into Au is operating. Furthermore, the presence of AuSn compound formation indicates that rapid bulk diffusion of Au into Sn is simultaneously present. The observed large pore sizes, however, indicate that Sn grain boundary diffusion is dominant. The fact that AuSn formation proceeds at a diffusivity of $\sim 10^{-14}$ cm^2/sec at room temperature (9) then sets this value as a lower bound for the grain boundary diffusivity of Sn into Au.

It is interesting to note from these observations that the Au-Sn system possesses rapid, room temperature diffusion mechanisms for both species which can operate at the same time and in opposite directions. Additionally, it is seen that variation of t_{Au}/t_{Sn} can identify and separate these mechanisms (5).

It is well known (11) that rapid interdiffusion generates high stresses and can induce a local plastic deformation. For example, the formation of dislocations has been observed during interdiffusion (12, 13) as has the formation of cracks (14). During the Au-Sn interdiffusion, high tensile stresses are therefore expected to be developed near and/or at the Au-Sn-Al/GaAlAs interface. If grain-boundary diffusion is assumed to be the dominant interdiffusion mechanism, it is possible to estimate the magnitude of this interdiffusion-induced tensile stress. Using the formula given by Schlipf (15), we obtain $\sim 1.5 \times 10^8$ g/cm^2 (1.1×10^{10} psi) for the stress. This value is a few orders of magnitude larger than the yield stress of any solid, and thus a plastic deformation is inevitable during interdiffusion.

Since, for the case of Au-Sn-Al/GaAlAs, the metal layers are known to be weakly bonded to the substrate (2), the induced tensile stress will act primarily to break the bonding, resulting in the observed interfacial cracking. The way the interfacial cracking proceeds is shown schematically in Fig. 10. Here, Sn atoms diffuse out of the islands and travel along a network of Au grain boundaries. During this diffusion, a high tensile stress develops in such a way that the interfacial bonding is broken. The Sn outdiffusion also leaves voids similar in shape to the original Sn islands.

The details of the stress development, of course, depend on the Sn morphology. Since the Au-Sn interface follows the profile of the Sn islands, a more complex stress pattern is to be expected than for the case of a planar interface (14). The initially high stresses become gradually smaller as void nucleation and growth proceeds at the sites of the Sn islands. The tendency of stress relaxation has been discussed theoretically by Schlipf (15) and observed experimentally by Geguzin *et al.* (14).

The occurrence of interdiffusion-induced stress cracking has also recently been noted by Buene (16) in a similar thin film couple. According to his observation, during the deposition of Au onto a previously In-coated bell jar wall, a violent reaction between Au and In takes place, resulting in the film cracking and flaking off the bell jar wall. This observation suggests that an interdiffusion-induced high stress develops during the Au deposition leading to cracking at the weakly-bonded interface between the metal film and the glass.

The erratic adhesion problem associated with the Au-Sn-Al metallization on GaAlAs has been recently solved (2) by an alternative metallization in the sequence Au-Sn-Au-Al (28 kÅ Au, 500Å Sn, 2 kÅ Au, 35Å Al). Cross-section studies of this metallization have indicated the absence of both pores and interfacial crack (2, 3). From our proposed model of interdiffusion-induced tensile stress, it is now clear that the deposition of 2000Å Au prior to the Sn layer is essential in

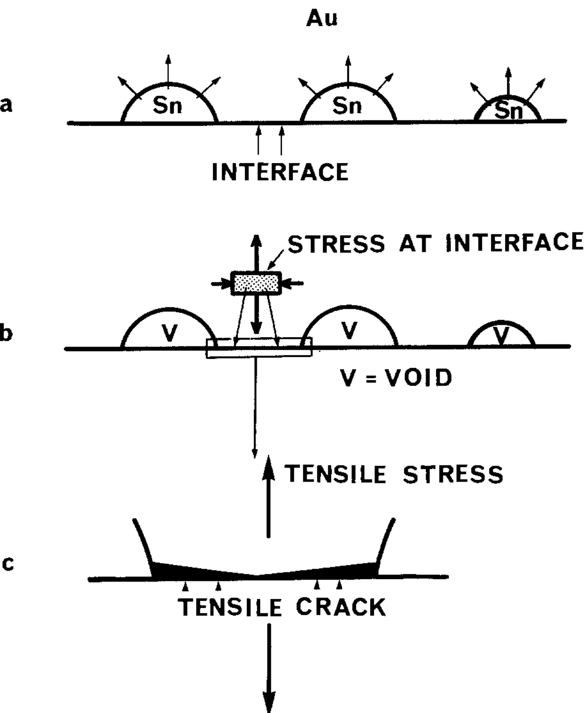

Fig. 10. A schematic view illustrating how interfacial cracking may take place during the Au-Sn interdiffusion. The illustration shows that Sn diffuses rapidly along Au grain boundaries in (a). This interdiffusion induces a tensile stress which acts to separate the film from the substrate and at the same time form voids at the sites of Sn islands as shown in (b). The action of the tensile stress results in the interfacial cracking shown in (c).

order to avoid the generation of stress at the GaAlAs interface. Furthermore, the absence of pores strongly indicates that both bulk and grain boundary diffusions are taking place uniformly. With respect to the GaAlAs interface, the essential change in the new metallization scheme is from Au-Sn to Sn-Au. We also deposited Sn-Au films on NaCl in order to see how the structure might change from that of Au-Sn. Figure 11 compares the microstructures of (a) 500Å Au-500Å Sn with (b) 500Å Sn-500Å Au. It is seen that the new scheme provides a considerable improvement in homogeneity. This observation is consistent with that of Buene *et al.* (17). Homogeneity in the Sn-Au metallization indicates that Sn nucleates uniformly on Au. This suggests an absence of void formation within the LED metallization for the sequence Au-Sn-Au-Al.

Conclusion

A transmission electron microscope was used to determine the cause for an erratic adhesion problem which occurred between Au-Sn-Al metallization layers and GaAlAs substrates. A cross-section study of the Au-Sn-Al/GaAlAs interface revealed the presence of large isolated pores and a slit-like interfacial crack. The formation of the pores and interfacial crack were found to result primarily from the room temperature interdiffusion of Sn and Au. It is proposed that the rapid diffusion of Sn into Au via a grain-boundary mechanism induces high tensile stresses which cause the separation of the metallization layer from much of the GaAlAs substrate. This interdiffusion-induced high stress can be partially relieved by the formation and growth of pores at the sites of original Sn islands. Structural comparison with metallizations on NaCl substrates provided additional information on the nature of Au-Sn interdiffusion mechanisms, in which both bulk and grain boundary diffusions are found to be operative. A model for the interfacial cracking is proposed to explain the origin of the erratic adhesion problem in Au-Sn-Al metallization scheme.

An Analysis of Color-Changing Penetration-Type Cathodoluminescent Phosphor Screens

Willi Lehmann*

Westinghouse R&D Center, Pittsburgh, Pennsylvania 15235

ABSTRACT

Electron penetration through solid barrier layers into polycrystalline cathodoluminescent phosphors can be described by a relatively simple mathematical equation which, in turn, permits the computation of color changes available from phosphor blends containing such coated particles. An extension of the analysis covers also multilayer cathodoluminescent films. The calculations permit predetermination of the efficiencies and color characteristics of such screens and design of screens to meet given specifications.

The principle most frequently used in voltage-sensitive color-changing cathodoluminescent phosphor screens involves a simple blend of two individual phosphor powders of different colors and of different brightness-voltage dependences. For instance, the blend may consist of a red and a green component. The red phosphor may be a normal material showing essentially linear voltage dependence of the emission intensity while the particles of the green phosphor are overcoated with nonluminescent surface layers which the electrons have to penetrate to reach the luminescent core. The emission intensity, B, of such "onion-skin" phosphor" increases strongly superlinearly with low voltage, V, but approaches roughly linear dependence above a somewhat diffuse threshold, the "dead voltage," V_o.[1] An example is shown in Fig. 1. It is clear that the emission color of such blend varies with the voltage; it is more red at low and more green at high voltage.

Several variations of color-changing phosphors have been described in the literature (1-10) but at least some of them appear to be obtained only by trial and error and are far from optimized. The technically most important aspects are the efficiency which, naturally, is desired to be as high as possible, the voltage range where the color change occurs, and the rate of color change within this voltage range. The following analysis offers a way to calculate these properties in advance for any given phosphor combination and permits (within limits) tailoring the phosphor blends to given specifications. The analysis is first limited only to phosphor powders but later is extended to cover phosphor films. For simplicity, only color changes between red and green will be considered but the analysis also is applicable to phosphor systems changing between any two given end colors.

* Electrochemical Society Active Member.
Key words: phosphors, luminescence, cathodoluminescence, color, electron penetration.
[1] The expression "dead voltage" is somewhat of a misnomer since some weak emission appears even below V_o. Nevertheless, it is so much in common use that it may be maintained here.

Phosphor Powders

Most of our experimental work on color-changing phosphor powders was restricted to blends of green $Zn_2SiO_4{:}Mn^{2+}$ (ZS) and red $YVO_4{:}Eu^{3+}$ (YVOE). The particles of the latter were left uncoated while those of the ZS were coated with layers of Al_2O_3 by precipitation of $Al(OH)_3$ out of aqueous solution of $AlNH_4(SO_4)_2$ and subsequent dehydration of the hydroxide. An example of such coated particles is shown in Fig. 2. The phosphors were tested in a demountable cathode ray tube with E-beams of low current density ($\sim$1 μA/cm^2). The emission intensities were compared to that of uncoated ZS whose brightness-voltage dependence was ascertained to be essentially linear over the voltage range of interest ($\sim$5-25 kV) except an insignificant dead voltage ($\sim$60V) possibly due to surface contaminations on the particles.

The emission intensity of the uncoated YVOE varies essentially linearly with voltage so that the efficiency is approximately constant. The external efficiency of

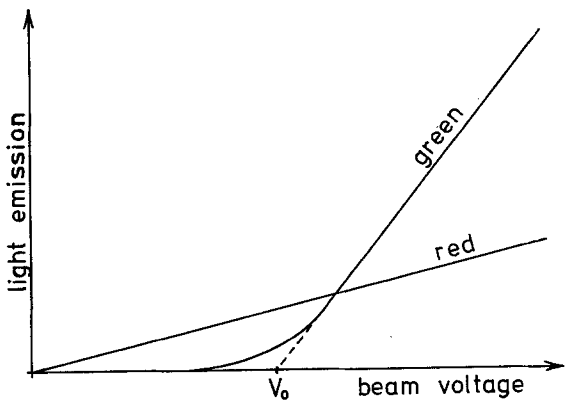

Fig. 1. Emission contributions from two phosphor components in a color-changing penetration-type cathodoluminescent screen (schema).

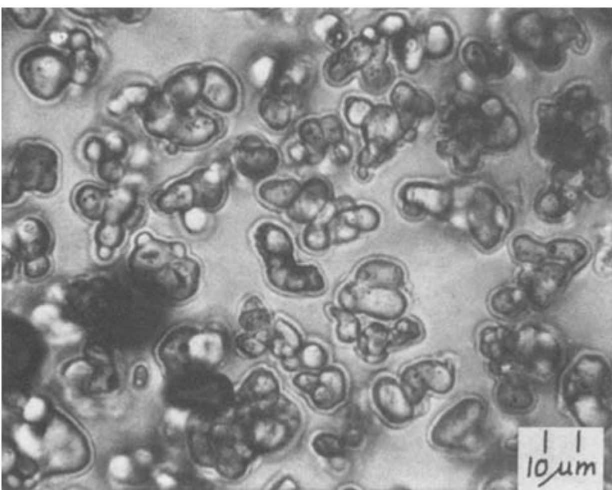

Fig. 2. ZS phosphor particles coated with aluminum oxide. $V_0 =$ 13 kV.

the coated ZS, however, varies strongly with the voltage, and this variation depends on the thickness and on the uniformity of the dead coat. Defective and nonuniform coats can visually be identified by optical microscopy; they cause the efficiency to vary relatively slowly with the voltage. Conversely, the more uniform the coat is the steeper does the efficiency, η, increase with the voltage, V. In best samples where microscopic inspection reveals nearly defect-free coats of uniform thickness, we observe a good fit of the experimental data to the equation

$$\eta = A \exp(-2V_0^2/V^2) \quad [1]$$

where V_0 is the dead voltage. The constant A contains the internal efficiency of cathodoluminescence of the uncoated material and the current density of the exciting E-beam. This equation has been tested on many samples in diagrams where log η is plotted as function of $1/V^2$. Some examples are shown in Fig. 3. The coating on sample C in Fig. 3 is slightly imperfect, causing a deviation from the straight line at low voltage. Included in Fig. 3 are also points (curve E) taken from a diagram published by Kingsley and Prener (5) on coated (0.381 μm) ZnS phosphor claimed to be very uniform in coat thickness. The good fit to straight lines is evident. We believe it to indicate that Eq. [1] very closely describes the voltage dependence of cathodoluminescence of coated phosphors under best conditions.

It is somewhat surprising that an equation as simple as [1] can describe the situation so closely. Nevertheless, we do not believe Eq. [1] to have a simple physical interpretation. Electron penetration through thin layers is a very complicated effect, particularly if these thin layers cover irregularly shaped and oriented phosphor particles. Equation [1] probably is nothing more but a good approximation describing a much more complicated reality.

Since the emission intensity, B, is proportional to $\eta \times V$, the $B(B)$ dependence of a coated phosphor follows

$$B = AV \exp(-2V_0^2/V^2) \quad [2]$$

This equation is graphically shown in Fig. 4 for several different values of V_0. Although the approximation to straight lines at $V > V_0$ is quite good, the $B(V)$ dependence in that range is not linear but is S-shaped and contains a point of inflection which, by differentiation, is determined to be at $V_1 = 2V_0$. The slope of the curve at that point is $dB/dV = 2A \exp(-½)$ $\approx 1.213A$ and the tangent through it intersects the abscissa at V_0. For an uncoated phosphor, of course, $V_0 = 0$ and $B = AV$.

The opposite of a phosphor particle coated with a dead layer is a dead particle coated with a phosphor layer (11). Its $B(V)$ dependence must be the difference between that of an uncoated phosphor ($V_0 = 0$) and Eq. [2] *i.e.*

$$B = AV [1 - \exp(-2V_0^2/V^2)] \quad [3]$$

This function is graphically shown in Fig. 5. It may especially be noted that the curves go through a maximum and approach zero (although very slowly) with increasingly high values of V.

In either case, the quantity V_0 measures the layer thickness. The relationship between V_0 and the physical thickness, S, of the surface layer is not linear. It has been determined by Kingsley and Prener (5) to be approximately $S = CV_0^{1.65}$ which is very close to

$$S = CV_0^{5/3} \quad [4]$$

In this instance, C is a constant essentially describing the stopping power of the material for electrons. For Al_2O_3 and for ZnS, $C \approx 0.0115$ if the thickness is measured in μm and the dead voltage in kV. For other coatings, the stopping power can reasonably be expected to be proportional to the densities of the coating materials.

The above equations can be used to calculate the characteristics of color-changing phosphor blends as

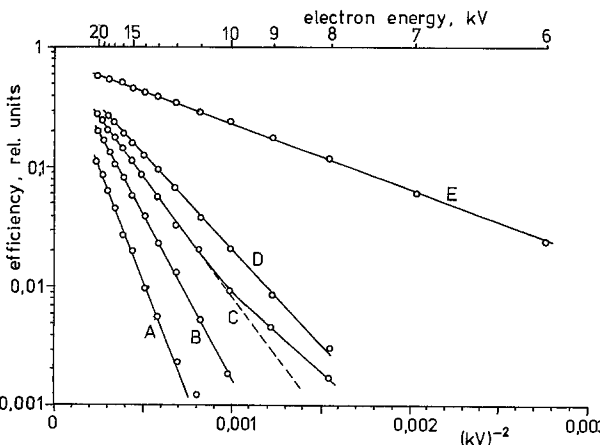

Fig. 3. Efficiencies of some coated phosphors showing validity of Eq. [1].

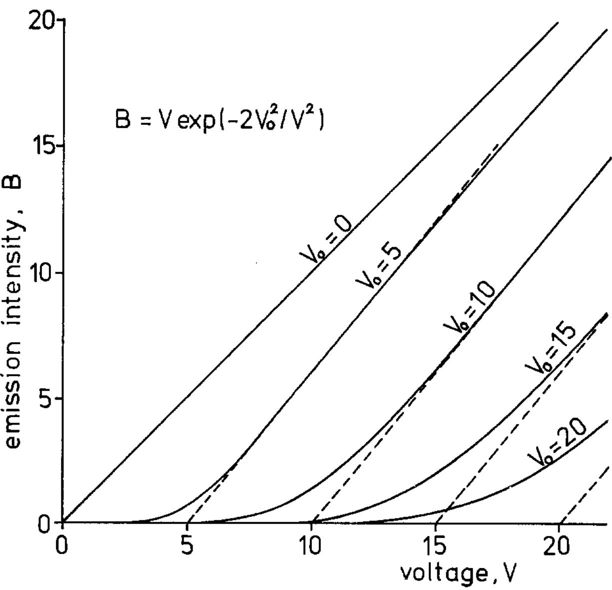

Fig. 4. *B(V)* functions of phosphor particles surrounded by dead layers.

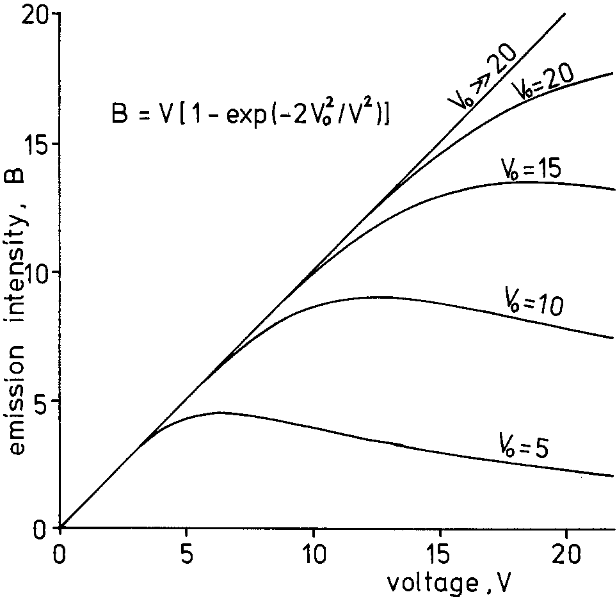

Fig. 5. $B(V)$ functions of dead particles surrounded by phosphor layers.

function of the electron beam voltage. An example is shown in Fig. 6 for the assumed case of a blend consisting of 8% (by volume) of red YVOE and 92% green ZS. The particles of the latter are coated with a dead layer corresponding to $V_o = 16$ kV which, for Al_2O_3, translates to a physical thickness of about 1.2 μm. Figure 6 indicates the red-green color shift to occur between about 12-20 kV.

Phosphor Films

Cathodoluminescent film screens consisting of several phosphor and other layers deposited on top of each other have been reported by Feldman (12-14).

For an analysis, consider a thin nonluminescent film covering a thick phosphor film (Fig. 7, top) The exciting electrons have to penetrate the dead film to reach and excite the phosphor. The situation is qualitatively identical to the case of a coated phosphor powder but it is quantitatively different because of the different geometry. Certainly, Eq. [1] cannot be used to describe the $B(V)$ dependence. An approach is possible by a generalization of Eq. [1]

$$B_1 = AV \exp\left[-a(V_{01}/V)^n\right] \qquad [5]$$

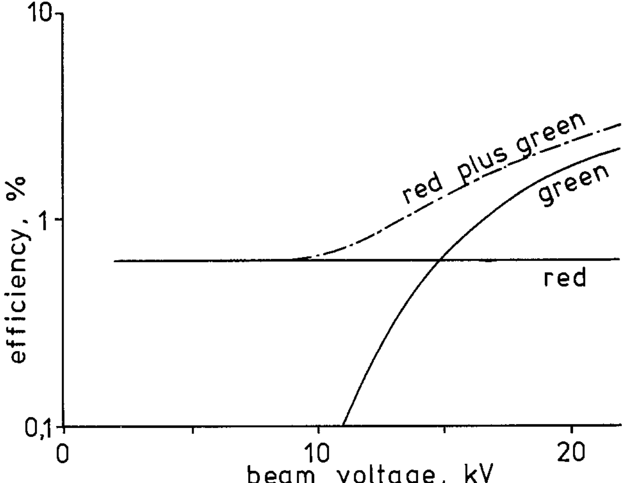

Fig. 6. Characteristic of a powder screen containing a blend of 8% red YVOE (uncoated) and 92% green ZS (coated, $V_o = 16$ kV). The efficiencies of uncoated YVOE and ZS are assumed to be each 7%.

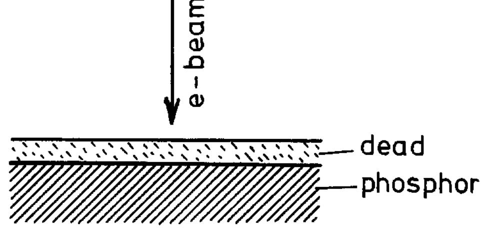

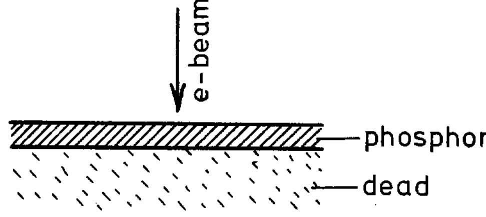

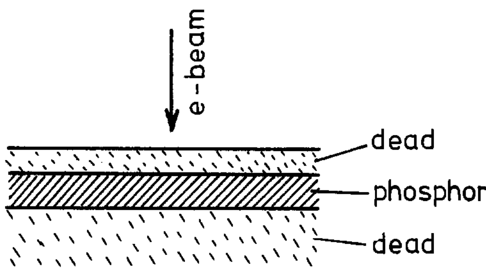

Fig. 7. Some combinations of phosphor and dead films

where the values of the constants a and n still have to be determined. As in case of Eq. [1], the dead voltage, V_{01}, may be defined by the intersection of the tangent through the point of inflection of the S-shaped curve with the abscissa. Differentiation yields the relationship

$$a = [n/(n-1)]^{n-1} \qquad [6]$$

As in case of powders, $V_{01} = 0$ means a plain phosphor without dead material, responding linearly to the voltage: $B = AV$. The difference between this and Eq. [5]

$$B_2 = AV\{1 - \exp\left[-a(V_{02}/V)^n\right]\} \qquad [7]$$

must be the $B(V)$ dependence of a thin phosphor film covering a dead substrate (Fig. 7, center). One might also visualize a phosphor film on a dead substrate and covered by a dead film (Fig. 7, bottom). The $B(V)$ dependence of such structure follows a combination of [5] and [7] to be

$$B_3 = AV\{\exp\left[-a(V_{01}/V)^n\right] - \exp\left[-a(V_{02}/V)^n\right]\} \qquad [8]$$

where V_{01} represents the thickness of the top dead layer and V_{02} the combined thickness of the top dead layer and the phosphor layer. An approximate conversion to physical thickness is again possible with the help of Eq. [4].

Equation [7] has been checked against a $B(V)$ curve on Gd_2O_3 (0.35 μm thick) published by Prener (15). A very good fit is obtained for $n = 8/3$ (Fig. 8). Accepting this value, the constant a becomes

$$a = (8/5)^{5/3} \approx 2.189$$

and above equations change to

$$B_1 = AV \exp\left[-2.189(V_{01}/V)^{8/3}\right] \qquad [5a]$$

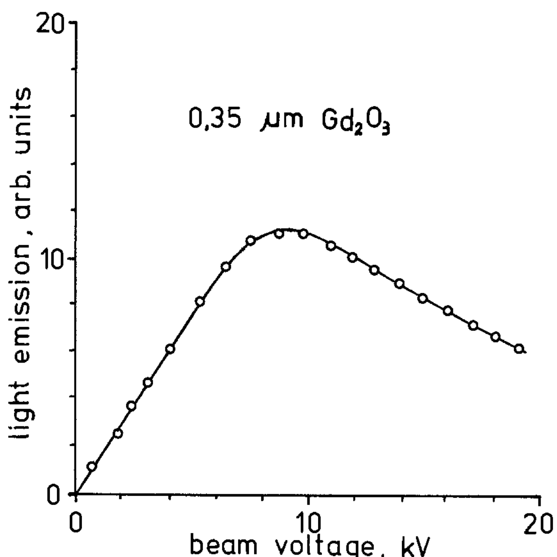

Fig. 8. Fit of Eq. [7] for $n = 8/3$ and $V_{02} = 7.6$ kV (solid curve) to experimental points by Prener.

$$B_2 = AV\{1 - \exp[-2.189(V_{02}/V)^{8/3}]\} \quad [7a]$$

$$B_3 = AV\{\exp[-2.189(V_{01}/V)^{8/3}] - \exp[-2.189(V_{02}/V)^{8/3}]\} \quad [8a]$$

The two Eq. [5a] and [7a] describe a somewhat steeper variation of the emission intensity with voltage of films compared to powders. An example is shown in Fig. 9.

The above equations can be used to calculate the color variation of a screen consisting of several thin films deposited on top of each other. An example is shown in Fig. 10 where two ZnS-CdS:Ag films, red and green, are each assumed to possess internal efficiencies of cathodoluminescence of 10%. That is just about possible with these materials if the films are translucent or otherwise slightly light scattering (16). Figure 10 indicates a range of red-green color variation between 12-18 kV.

Discussion

The present analysis of color-changing penetration-type phosphor screens is mainly application oriented.

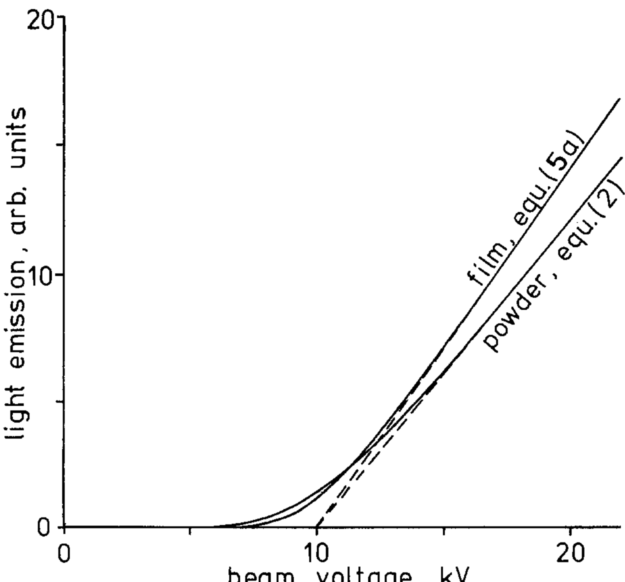

Fig. 9. $B(V)$ dependence of a phosphor coated with a thin dead layer, comparison of powder and film. $V_0 = 10$ kV in both cases.

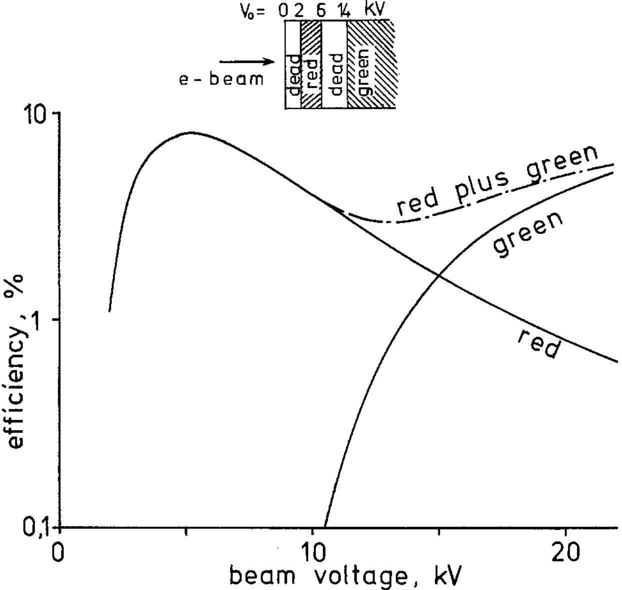

Fig. 10. Calculated characteristic of a multiple film screen (insert) containing two translucent ZnS-CdS:Ag films each assumed to show 10% internal cathodoluminescent efficiency. Physical thicknesses of the individual films: first dead film: ~0.045 μm; red film: ~0.19 μm; second dead film: ~0.61 μm; green film: >2 μm.

It permits the "design" of powder blends or film structures to meet given requirements. The obtainable color range, the color resolution (*i.e.*, the rate of color change), the voltage range where the color change occurs, and the external efficiency can be calculated.

A weak point of the analysis is the necessary knowledge of the internal cathodoluminescent efficiencies of the individual phosphor components since these affect the color balance of the final screen. The color variation can be predetermined only to that degree of accuracy as the internal efficiencies of the components are known. Fortunately, these internal efficiencies are relatively well under preparational control for powder phosphors so that the color characteristic of a powder screen can fairly reliably be predicted. The situation is not as well defined with film screens since our present state of technology does not yet permit a close control of the internal efficiencies of cathodoluminescent phosphor films. That will probably improve, however.

The external efficiency of a color-changing screen containing any dead material must necessarily be lower than the internal efficiencies of the phosphor components. It is possible to construct screens without any dead material, their external efficiencies are comparable to those of the phosphor components, but such screens show very poor color resolution. Conversely, the higher the required color resolution, the more dead material must be incorporated into the screen, and the lower external efficiency of the entire screen. High external efficiency and high color resolution are mutually exclusive.

Molecular Orbital Studies of Positive Electron Resists

Tsukasa Tada[1]

VLSI Technology Research Association, Cooperative Laboratories, Takatsu, Kawasaki, 213, Japan

ABSTRACT

The overlap population (F) in the HOMO (highest occupied molecular orbital) is calculated by the extended Hückel method, assuming that the HOMO plays an important role in radiation chemistry. For representative samples, calculated results are closely associated with the experimental $G(S)$ values. Based on this result, F values are calculated for the model compounds of various positive electron resists in order to elucidate the electronic structure and scission efficiency. Several predictions are made in cases where experimental results are not available. Thermal stability of positive electron resists is also discussed based on the population analysis.

Up to now many investigations on electron or x-ray resists seem to have been focused mainly on the following two items. The first concerns the studies on resist processing, such as problems on resist profiles, baking conditions, developing conditions, etch resistance, and so forth. The second concerns the studies of energy dissipation in the resist film when exposed to x-ray or electron beam radiation. The analysis of this problem is essential, particularly in correcting for proximity effects, and is carried out using the depth-dose function or the Monte Carlo method from a macroscopic viewpoint.

On the other hand, there exists relatively little literature on the molecular structure of resist materials. Moreover, studies on this subject have been carried out only from a macroscopic viewpoint and are highly qualitative. For example, it is often pointed out that the incorporation of a phenyl ring makes the polymer less sensitive to ionizing radiation. However, it is not well understood why a phenyl ring causes the polymers to react defensively to ionizing radiation.

Considering a positive electron resist, its sensitivity is closely associated with the following two factors: Scission efficiency and solubility characteristics. Therefore, study on these factors is important for the analysis and development of positive electron resists. Of these two factors, scission efficiency is conclusively determined by the molecular electronic structure, regardless of the other factors, such as the developing process. In this paper, argument is focused mainly on scission efficiency.

In treating scission efficiency, it is essential to take a quantum mechanical approach, since the chemical reactions caused by ionizing radiation are essentially quantum mechanical phenomena. Here, the LCAO-MO theory has been employed since it is the most successful theory which treats many-electron systems in molecules.

The purpose of this paper is to characterize the electronic structures of resist materials by employing the LCAO-MO theory in order to elucidate and predict scission efficiency and to provide a basic foundation for the design of positive electron resists. In the first half of this paper, a basic theory of scission efficiency is presented and is confirmed by being applied to existing positive resists. In the latter half, based on the results of the first half, we present some applications of this theory to various positive electron resists including some theoretical resists. Several predictions are also made in cases where experimental results are not available.

The Role of the HOMO in Radiation Chemistry

Radiation chemistry, especially that of organic molecules, is highly complicated in terms of predicting specific mechanisms. Furthermore, mechanisms differ from molecule to molecule. However, as far as the primary process is concerned, it is generally considered that all molecules pass through the same process.

Figure 1 is a diagram of the primary process in radiation chemistry. In the first stage of radiation chemistry, as shown in Fig. 1, ionizing radiation causes high energy electrons, positive holes, and in some cases, atomic displacements. In the case of an electron beam of 10-30 keV or soft x-ray, atomic displacements can be neglected. Ejected high energy electrons also cause electronic excitations, positive holes, and secondary electrons. The electronic excitations may lead to luminescence or decomposition of molecules. The positive holes created by high energy electrons also may lead to decomposition. On the other hand, remaining positive holes after ejection of high energy electrons may lead to decomposition or recombine with ejected electrons.

[1] Present address: Toshiba Research and Development Center, Saiwai, Kawasaki, 210, Japan.

Key words: electron beam, positive resist, HOMO, extended Hückel, population analysis.

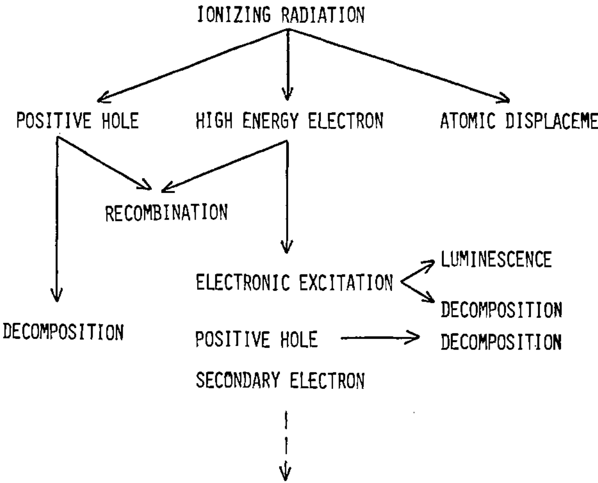

Fig. 1. Diagram of primary process in radiation chemistry

Therefore, there are two decomposition patterns, as follows: (*i*) Ionization leads to decomposition; and (*ii*) electronic excitation of a neutral molecule leads to decomposition. In analyzing these two cases in terms of energy levels, two or three processes can be expected in each case, as shown in Fig. 2.

In the case of ionization, ionizing radiation ejects an electron from one of the various occupied levels. Ejection of an electron from the HOMO directly causes a positive ion in its ground state. When an electron is ejected from the inner level, its electronic state is immediately converted to the ground state through a rearrangement of remaining electrons. In another case, ionizing radiation may cause a super excited state (1), which is immediately converted to the ground state of the positive ion. As mentioned above, by ionizing radiation, a neutral molecule is immediately converted to a positive ion in its ground state. Chemical reactions are considered to begin after these processes.

In the case of excitation, an electron is excited from the HOMO or the inner levels, and the remaining electrons are immediately converted to the state where the previous HOMO is occupied with an unpaired electron. It is considered that the chemical reactions begin after this state.

IONIZATION FROM INNER LEVEL

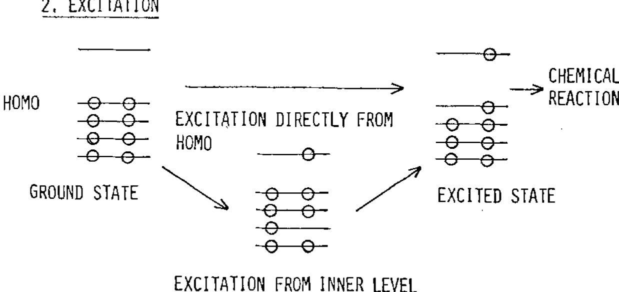

Fig. 2. Energy level diagram in radiation chemistry

In both cases, ionization and excitation, it should be noticed that the HOMO is always perturbed by ionizing radiation. From this point of view, it can be easily expected that the HOMO makes an important contribution to the chemical reaction caused by ionizing radiation. Consequently, it is also expected that the region of the largest HOMO density is the most reactive one in a molecule. In other words, the extent of the HOMO localization can be regarded as a measure of chemical reactivity by ionizing radiation.

Therefore, from this standpoint, one can predict the reactivity of a molecule when exposed to ionizing radiation by analyzing its molecular wave functions. In the case of polymer materials, the HOMO localization can be visualized by taking the case of two different models, specifically polymer A and polymer B, as shown in Fig. 3. In the case of polymer A, whose HOMO is largely localized on the main chain bond region, its reactive site corresponds to the main chain bond region. Accordingly, it is expected that polymer A is easily degraded by ionizing radiation. On the other hand, polymer B, whose HOMO is largely delocalized or shifted toward its side chain, is not expected to be as easily degraded by ionizing radiation as is polymer A.

As a measure of the HOMO localization in the bond region, overlap populations in the HOMO are employed in this paper. This is because, as analyzed by Mulliken (2), they can be used firstly as a measure of charge density between two different nuclei X and Y, and secondly as a measure of bonding and antibonding strength of X-Y covalent bond. In the present calculations, the overlap population of X-Y bond in the HOMO is defined as follows

$$F(\mathrm{X\ Y}) = 2 \sum_{\mu}^{\mathrm{X}} \sum_{\nu}^{\mathrm{Y}} c_{\mu} c_{\nu} S_{\mu\nu}$$

where c_{μ} and c_{ν} are coefficients of atomic orbitals ϕ_{μ} and ϕ_{ν} in the HOMO, and $S_{\mu\nu}$ is the overlap integral between the atomic orbitals ϕ_{μ} and ϕ_{ν}.

Calculation

Calculations were performed by the extended Hückel method (3), the simplest all-valence electron procedure. In spite of the well-known shortcomings of this method, particularly in the quantitative prediction of observables, it faithfully models the shape of the molecular wave functions of any molecule compared with even more sophisticated methods. In addition, it has the advantage of short computing time.

Consequently, in most cases, the extended Hückel method gives a reasonable qualitative or semi-quantitative picture of the electronic structures of mole-

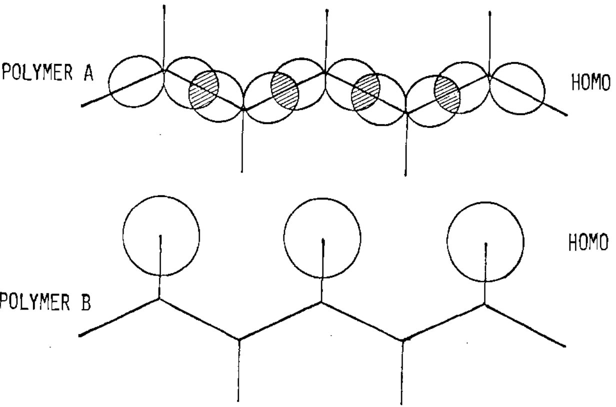

Fig. 3. Shape of HOMO for two different polymers

cules with comparatively short computing time. Therefore, extended Hückel calculation is sufficient for gross estimation of the shape of molecular wave functions and is suitable for treating large molecules because of its short computing time.

In the extended Hückel secular Eq. [1]

$$\det|H_{\mu\nu} - \epsilon S_{\mu\nu}| = 0 \qquad [1]$$

the diagonal element is approximated by the ionization potential, and the off diagonal element is approximated by the Wolsberg-Helmholtz formula (4) as [2] and [3]

$$H_{\mu\mu} = -I_{\mu} \qquad [2]$$

$$H_{\mu\nu} = \frac{K}{2}(H_{\mu\mu} + H_{\nu\nu})S_{\mu\nu} \quad (\mu \neq \nu) \qquad [3]$$

where I_{μ} is the ionization potential of the atomic orbital ϕ_{μ}, $S_{\mu\nu}$ is the overlap integral between the atomic orbital ϕ_{μ} and ϕ_{ν}, and K is a constant.

In treating resist materials, calculations were carried out on the model compounds of resist materials as shown in Fig. 4. We restrict our considerations to the region within the frame of the dotted line, which corresponds to a polymer unit. The estimations of overlap population F and total overlap populations (2)P were made on bonds 1, 2, and 3. The gross atomic populations (2)Q were calculated on α-carbon.

The geometries of the model compounds were based on the data shown in Table I. For other geometries, Pople's standard geometrical models (5) were employed. For the ionization potential, Pritchard's data (6) were employed. Constant K was taken to be 1.75.

Polymer Materials Containing Quaternary Carbon in Their Main Chains

In most cases, polymer materials containing quaternary carbon in their main chains are employed as positive electron resists, because this kind of polymer is usually degraded by ionizing radiation, for example, by a soft x-ray or a high energy electron beam. In this section, using the following four samples that have representative structures in this kind of polymer, we have calculated their molecular wave functions, F values, and total overlap populations, P. Representative samples are, poly(isobutyrene) PIB, poly(methacrylonitrile) PMN, poly(methyl methacrylate) PMMA, and poly (α-methylstyrene) PαMS. Of these polymers, PIB is in the simplest structure and has the highest $G(S)$ value. On the other hand, PαMS is known to be considerably insensitive to ionizing radiation and has excellent resistance to reactive ion etching. PMMA is a typical and widely used positive electron resist, and most of the reported positive electron resists consist of PMMA family. PMN is also reported to be a sensitive positive electron resist (7).

Calculated F values are summarized in Table II, together with the experimental data on $G(S)$ and electron beam sensitivity, where $F(1)$ and $F(2)$ represent the F value of side chain bonds 1 and 2, respectively (in this case, bond 1 corresponds to the C—CH_3 side chain bond), and $F(3)$ represents that of the main chain bond 3, as shown in Fig. 4. Table II indicates the following interesting results.

Firstly, $F(3)$ have exceedingly high values, compared with $F(1)$ and $F(2)$ values. In the case of PIB, for example, $F(3)$ has a value of 0.188. On the other hand, $F(1)$ and $F(2)$ have a value of -0.014. This result might give one of the reasons for the fact that the polymer materials containing quaternary carbon in their main chains are usually degraded by ionizing radiation, instead of crosslinking.

Secondly, it should be noticed that the $F(3)$ values, which indicate the reactivity of the main chain bond by ionizing radiation, are closely associated with the experimental $G(S)$ values. For example, $F(3)$ of PIB has a value of 0.188, and $F(3)$ of PαMS has a much smaller value of 0.067, which indicates that PIB is easily degraded by ionizing radiation and PαMS is not as easily affected by ionizing radiation as PIB is. For experimental $G(S)$ values, PIB has a value of 4.0 and PαMS has a smallest value of 0.3. Therefore, calculated results in Table II are closely associated with the experimental results. In other words, these results confirm the assumption that the HOMO makes an important contribution to the chemical reactions caused by ionizing radiation. Consequently, it can be said that this expedient method of calculating F values provides a reliable prediction of scission efficiency, at least as far as C—C σ bonds are concerned. The reported sensitivities in Table II are also generally associated with the $F(3)$ and $G(S)$ values.

Table II. Calculated F and experimental data for representative polymers containing quaternary carbon

Polymers	$F(1)$	$F(2)$	$F(3)$	$G(S)$	Sensitivity ($\mu C/cm^2$)
PIB	−0.014	−0.014	0.188	4.0[a]	20[a]
PMN	−0.027	0.018	0.139	2.1[b]	15[7]
PMMA	−0.022	0.029	0.123	1.7[a]	50[a]
PαMS	0.021	−0.020	0.067	0.3[a]	100[a]

The differences among calculated $F(3)$ values can be rationalized in terms of the perturbation theory or, in other words, from the standpoint of substituent effects. In the case of PIB, the HOMO is mainly localized on the main chain bond. In cases where another substituent group is incorporated into PIB, some interactions between the unperturbed HOMO and the orbitals of the substituent group more or less take place. If orbitals of the substituent group strongly interact with the HOMO, the HOMO is very much perturbed by this interaction and the $F(3)$ value is drastically changed. For example, the orbitals of a phenyl ring strongly interact with the HOMO. Therefore, if a phenyl ring is incorporated, the HOMO is perturbed and is largely delocalized into the π orbitals of the phenyl ring. The fairly small $F(3)$ value of PαMS is a consequence of this orbital interaction.

Since $F(3)$ represents not only HOMO density but also the HOMO's contribution to the bonding strength, another explanation for the differences among the $G(S)$ values can be put forward by analyzing the total overlap populations of the main chain bond, in other words, from the standpoint of bond energies. Table III shows the calculated total overlap populations of the C—C main chain bond of four representative samples, where $P(3)$ and $P^+(3)$ represent the total overlap populations in the preionized neutral molecule and ionized positive ion, respectively.

As analyzed by Mulliken, the total overlap populations give a measure of the non-Coulombic parts of bond energies. Therefore, as far as C—C covalent bonds are concerned, the total overlap populations can be roughly regarded as a measure of the covalent bond energy or the covalent bonding strength. One may expect that the bond energy or bonding strength have a close correlation with the $G(S)$ value. From this point of view, $G(S)$ values are expected to be increased with a decrease in $P(3)$ values. However, Table III indicates the opposite result. For example, PIB has the highest $P(3)$ value with the highest $F(3)$ and $G(S)$ values. This result implies that the bonding strength in the preionized state does not always have a close correlation with scission efficiency caused by ionizing radiation.

On the contrary, it is rather the $P^+(3)$ value that is generally associated with the $G(S)$ value. For example, PIB has the lowest $P^+(3)$ value and PαMS has the highest $P^+(3)$ value, indicating that the main chain bonding strength of ionized PIB is weaker than that of ionized PαMS. These results imply that, while the main chain bonding strength of PIB is fairly decreased by being ionized, that of PαMS is affected very little by being ionized. Consequently, it can be said that the bonding strength in the ionized state is generally associated with the $G(S)$ value, at least as far as C—C covalent bonds are concerned. These results also confirm that the ionized state plays an important role in radiation chemistry.

As mentioned above, the differences among the $G(S)$ values can also be explained in terms of bonding strength or bond energy. However, since the $F(3)$ value corresponds to the difference between the $P(3)$ and $P^+(3)$ values, the above explanation is, in a sense, equivalent to the explanation in terms of HOMO density.

Table III. Calculated $P(3)$ values in neutral and ionized states

Polymers	$P(3)$	$P^+(3)$	$F(3)$	$G(S)$
PIB	0.779	0.591	0.188	4.0
PMN	0.731	0.592	0.139	2.1
PMMA	0.754	0.631	0.123	1.7
PαMS	0.762	0.695	0.067	0.3

Although the excited levels have been neglected so far, they are also worthy of being analyzed because, in some cases, the excited state is expected to contribute to polymer degradation. In order to rigorously calculate the excited levels and their wave functions, it is necessary to use the CI or other sophisticated methods based on the SCF MO theory. Nevertheless, even within the extended Hückel framework, one can get some insights into the excited states on the basis of the virtual orbitals. Analysis of the virtual orbitals provides the following interesting results.

Concerning PIB, the LUMO (lowest unoccupied molecular orbital) level is found to be of a considerably high energy level (1.05 eV). Although certain LUMO density is observed in the main chain bond region, the LUMO has a bonding character in this bond region. Slightly antibonding character is observed in the C—H bond region.

On the other hand, relatively low excited levels are found in the rest of the samples, and their excited levels are mostly localized or delocalized to their side chains. In the case of PMMA, the C=O π^* level (−8.71 eV) is found as the LUMO. This π^* level corresponds to the excited level caused by deep-u.v. radiation. PMMA is known to be a positive working resist for deep-u.v. radiation (8), as are other poly(methacrylate) series positive electron resists. Furthermore, it is reported that even poly(glycidyl methacrylate) negative electron resist acts as a positive working resist for deep-u.v. radiation (9). These experimental results suggest that the C=O π^* state contributes to the degradation of poly(methacrylate) series polymer materials. However, since little LUMO density is observed in the main chain bond region, it is considered that the C=O π^* state contributes to the main chain bond dissociation through the secondary process. In the case of PMN, the C≡N π^* level (−7.90 eV) is found as the LUMO. The vacant π^* levels (−8.35 ∼ −4.76 eV) of the phenyl ring are found in the case of PαMS, indicating that the relatively low excited levels of PαMS are mostly concentrated on the phenyl π-system. These π^* states, being relatively stable ones, may contribute little to the polymer degradation.

Poly(methacrylate) Series Positive Resists

Most of the reported positive electron resists consist of poly(methacrylate) series polymer materials. However, their reported sensitivities are considerably different according to their ester side chains. In this section, we focus our attention primarily on the following questions: (*i*) To what extent does the substitution of an ester side chain affect the electronic state of the C—C main chain bond region? (*ii*) Which factor plays an important role in determining the sensitivities of these resists? In order to study these problems, we have calculated F values for a series of poly(methacrylate) resists and compared them with the experimental values of electron beam sensitivity. Calculated results are listed in Table IV together with the experimental results, where $F(1)$, $F(2)$, and $F(3)$ represent the F values for the same position as in the previous section.

For poly(methacrylic acid) and poly(alkyl methacrylate) resists, although one can observe a trend whereby $F(3)$ value is slightly decreased with an increase in the size of the alkyl group, their $F(3)$ values amount to almost the same value, namely around a 0.12 value. These results indicate that the electronic state of the C—C main chain bond region is little affected by the size of alkyl ester side chain. In other words, it is indicated that poly(alkyl methacrylate) resists have generally the same scission efficiency when exposed to ionizing radiation. Reported $G(S)$ values of PMMA, PEMA, and PnBMA are 1.7, 1.3 (10), and 0.7 (10), respectively. Therefore, these $G(S)$ values

Table IV. F values and electron beam sensitivity for poly(methacrylate) series polymers

Polymers	$F(1)$	$F(2)$	$F(3)$	Sensitivity ($\mu C/cm^2$)
PMA	−0.022	0.029	0.122	—
PMMA	−0.022	0.029	0.123	50
PEMA	−0.021	0.030	0.121	75
PnBMA	−0.020	0.031	0.118	0.5
PTFEMA	−0.022	0.029	0.122	4.5
PTCEMA	−0.024	0.029	0.125	1.25
PPhMA	0.000	0.004	0.003	155
PMTMA	−0.005	0.116	0.049	7.5

PMA: poly(methacrylic acid), PMMA: poly(methyl methacrylate), PEMA: poly(ethyl methacrylate), PnBMA: poly(n-butyl methacrylate), PTFEMA: poly(trifluoroethyl methacrylate), PTCEMA: poly(trichloroethyl methacrylate), PPhMA: poly(phenyl methacrylate), PMTMA: poly(methyl thiomethacrylate).

confirm above indication. However, electron beam sensitivity is drastically enhanced by butyl substitution into the ester side chain. This discrepancy between the value of $F(3)$ and electron beam sensitivity indicates that the high PnBMA sensitivity is mainly due to solubility characteristics, rather than scission efficiency. In the case of PnBMA, considerable decrease in T_g (glass transition temperature) is also observed at the same time. There might be some relationship between T_g and solubility characteristics.

The same trend is also observed for poly(haloalkyl methacrylate) resists. For example, PTFEMA and PTCEMA (EBR-1) (11) have almost the same $F(3)$ value as that of PEMA, indicating that halogen substitution into the ester side chain has no significant effect on the electronic state of the C—C main chain bond region. On the other hand, their electron beam sensitivities are drastically enhanced compared with that of PEMA. These results suggest that halogen substitution into the ester side chain mainly improves solubility characteristics.

Contrary to alkyl or halogenated alkyl substitution, phenyl substitution into the ester side chain or sulfur substitution of oxygen atom in an ester group have significant effects on the electronic state of the C—C main chain bond region. As is evident from the $F(3)$ values of PPhMA and PMTMA, phenyl substitution drastically reduces the $F(3)$ value, and sulfur substitution reduces the $F(3)$ value and enhances the $F(2)$ value. Therefore, the relatively high PMTMA sensitivity can be attributed to its good solubility characteristics. On the other hand, the considerably low $F(3)$ value for PPhMA suggests low scission efficiency and low sensitivity. The reported $G(S)$ value (0.44) (12) and sensitivity are consistent with the calculated result. This result also predicts that the same trend is also observed in the case of other aryl substitution into the ester side chain.

Substituent Effects on the α-Position of Acrylate Polymer Materials

In the previous section we discussed substituent effects into the ester side chain of poly(methacrylate) resists. Another feasible modification is a substitution on the α-position. In this section, concern is on substituent effects on the α-position. In order to estimate these substituent effects on the electronic state of the C—C main chain bond region and scission efficiency, we have specifically calculated F values for poly(trifluoroethyl acrylate) series polymer materials including theoretical ones, regardless of the polymer synthesis possibility. Calculated results are listed in Table V with experimental data on electron beam sensitivity, where $F(1)$, $F(2)$, and $F(3)$ values represent the F values of the C-substituent, C—$COOCH_2CF_3$, and C—C main chain bonds, respectively.

Table V. F values and electron beam sensitivity for α-substituted poly(trifluoroethyl acrylate) series polymers

α-substituents	$F(1)$	$F(2)$	$F(3)$	Sensitivity ($\mu C/cm^2$)
Cl	−0.042	0.032	0.165	0.75
OCH_3	−0.029	0.038	0.136	—
CH_3	−0.022	0.029	0.122	4.5
CF_3	0.007	0.038	0.119	—
NH_2	−0.062	0.106	0.118	—
CN	0.017	0.030	0.109	20
SiH_3	0.166	0.084	−0.045	—
COOH	0.063	0.061	−0.049	—

In Table V, it should be noted that Cl and OCH_3 substituents enhance the $F(3)$ value compared with the case of poly(methyacrylate), suggesting that these substituents enhance scission efficiency when exposed to ionizing radiation. Accordingly, enhancement of the sensitivity can be expected by chlorine or methoxy substitution on the α-position.

On the other hand, an opposite trend is observed in the case of other substituents. The $F(3)$ value is somewhat decreased by CF_3, NH_2, and CN substituents, and is drastically decreased by SiH_3 and COOH substituents. Among them, NH_2 and SiH_3 substituents enhance the $F(2)$ and $F(1)$ values, respectively, indicating that the HOMO is shifted toward the side chain bond region in these cases. Therefore, the enhancement of the sensitivity cannot be expected by these substitutions, provided that solubility characteristics are not so much changed. Table V also indicates that there is no simple relationship between the $F(3)$ value and the electron-withdrawing nature of α-substituents. Detailed discussion on this problem is given in the next section.

For experimental data, electron beam sensitivity is enhanced by chlorine substitution and is rather deteriorated by cyano substitution compared with that of poly(methacrylate). These experimental results are consistent with the calculated results. Therefore, the higher sensitivity of poly(trifluoroethyl α-chloroacrylate) EBR-9 (13), compared with poly(trifluoroethyl methacrylate), can be attributed to the enhancement of the $F(3)$ value. Helbert *et al.* (14) reported the $G(S)$ value of poly(methyl α-chloroacrylate) to be 5.1. This experimental result is also consistent with the present calculated results. However, they also reported the $G(S)$ value of poly(methyl α-cyanoacrylate) to be 11 (15),[2] which is comparable to that of PBS (16). Even if the large fluctuations among the reported $G(S)$ values are considered, this $G(S)$ value seems to be too high, and is inconsistent with the present calculated and experimental results. If this $G(S)$ value is sufficiently reproducible, this discrepancy means that the author's theory is not a good approximation to poly(α-cyanoacrylate).

As mentioned above, substitutions on the α-position fairly affect the $F(3)$ value in comparison with substitution into the ester side chain. However, it should be noted that no substituents in Table VI enhance the $F(3)$ value more than that of PIB. Therefore, although the enhancement of $G(S)$ values can be expected to some extent by α-substituents, drastically high $G(S)$ values are not generally expected from the calculated results.

Substituents Electron-Withdrawing Effect on Scission Efficiency

It is often suggested that polar side chains weaken the main chain bond and lead to enhancement of scission efficiency (15, 17). However, there is no theoreti-

[2] Such a high $G(S)$ value means that poly(methyl α-cyanoacrylate) can be a highly sensitive positive electron resist comparable to PBS. However, its electron beam sensitivity is not reported.

Table VI. $F(3)$ and $Q(\alpha)$ values for 1, 1-substituted vinyl polymer materials

Substituents	$F(3)$	$Q(\alpha)$
Cl	0.133	3.30
CN	0.103	3.71
CH_3	0.188	3.88
$COOCH_3$	−0.049	3.94

cal justification on this suggestion. In this section, arguments are focused on the problem as to whether some relationship exists or not between the electron-withdrawing nature of side chains and scission efficiency. As a measure of electron-withdrawing or electron-donating nature of side chains, we have employed the gross atomic populations (2)Q of the α-carbon atom in the main chain.

Table VI shows the calculated $F(3)$ and $Q(\alpha)$ value of 1, 1-substituted vinyl polymer materials, where $F(3)$ and $Q(\alpha)$ represent the F value of the main chain bond and the Q value of α-carbon, respectively. As shown in Table VI, polymers with CH_3 and $COOCH_3$ substituents have relatively large $Q(\alpha)$ values. On the other hand, Cl and CN substituents reduce the $Q(\alpha)$ value. This result indicates that Cl and CN substituents have an electron-withdrawing effect compared with CH_3 and $COOCH_3$ substituents. However, the $F(3)$ value is rather decreased by the electron-withdrawing substituents such as Cl and CN groups. Table VI also indicates that the $F(3)$ value is drastically decreased by $COOCH_3$ substituents. Therefore, the $F(3)$ values have no simple correlation with the electron-withdrawing effect of substituents, and scission efficiency is not expected to be enhanced by the electron-withdrawing substituents in this kind of polymer.

Table VII shows the calculated $F(3)$ and $Q(\alpha)$ values of α-substituted poly(trifluoroethyl acrylate) polymer materials, where $F(3)$ and $Q(\alpha)$ represent the F value of the main chain bond and the Q value of α-carbon, respectively. In Table VII, calculated polymers are the same samples discussed in the previous section and are rearranged according to their $Q(\alpha)$ values. In this case, polymers with relatively high $F(3)$ values can be found in those with electron-withdrawing substituents such as Cl or OCH_3 group. However, the $F(3)$ value does not always have a correlation with the $Q(\alpha)$ value. For example, poly(α-chloroacrylate) has a higher $F(3)$ value than poly(α-methoxyacrylate) does.

As mentioned above, the $F(3)$ value does not always correlate with the electron-withdrawing nature of the substituents. Therefore, these calculated results indicate that there is no simple relationship between scission efficiency (by ionizing radiation) and electron-withdrawing nature of substituents. Secondly, it should be noticed that substituent effects differ according to the kinds of polymers. In the case of 1, 1-substituted vinyl polymers, for example, Cl substituent reduces the $F(3)$ value compared with the case of CH_3 substituent. On the other hand, an opposite result is obtained in the case of poly(trifluoroethyl acrylate) polymers. From the standpoint of the perturbation theory, the change in $F(3)$ value is considered to be a result of complicated orbital interactions between the unperturbed orbitals on the main chain and the substituent orbitals. The above results indicate that the orbital interactions are too complicated to be rationalized in terms of electron-withdrawing or donating nature of substituents.

Table VII. $F(3)$ and $Q(\alpha)$ values for α-substituted poly(trifluoroethyl acrylate) series polymers

Substituents	$F(3)$	$Q(\alpha)$

SiH_3	−0.045	4.26

Thermal Stability of Positive Electron Resists

Since thermal stability is an important factor for positive electron resists, it is worthy of being analyzed in terms of the molecular orbital theory. As previously mentioned, total overlap populations P give a measure of the covalent bonding strength. Therefore, they are expected to provide some insights into the thermal stability of positive electron resists.

Thermal stability is considered to be a function of bonding strengths of all chemical bonds constituting a polymer material. However, it is also considered that thermal stability mainly depends upon the main chain bonding strength, provided that the bonding strengths in side chains do not seriously differ. Therefore, the P value of the C—C main chain bond can be roughly regarded as a measure of the thermal stability. In this sense, poly(trifluoroethyl acrylate) series polymer materials provide a context in which to check this assumption.

Table VIII shows calculated P values for poly(trifluoroethyl acrylate) series polymer materials, where $P(3)$ and $P(1)$ represent the P values of the main chain and C-substituent bond, respectively. The experimental data on the initial thermal degradation point $T_d(i)$ are also presented in Table VIII. As can be seen in Table VIII, $P(3)$ have generally the same value among polymers with Cl, CH_3, and CH_2F substituents. This result suggests that poly(α-chloroacrylate) has the same thermal stability as poly(methacrylate) does. On the other hand, the $P(3)$ value is fairly decreased by CN substituent, suggesting that the thermal stability of poly(α-cyanoacrylate) is deteriorated compared with that of poly(methacrylate).

As to the experimental data, measured $T_d(i)$ are generally consistent with the calculated results. In particular, $T_d(i)$ is considerably decreased by CN substituent, as suggested by the calculated results. Therefore, in spite of a crude approximation, this method of calculating P values can provide a prediction of thermal stability to some extent.

As is evident from Table VII and VIII, there also exists no simple relationship between the $P(3)$ value and the electron-withdrawing nature of substituents. The $P(3)$ value is rather associated with the $P(1)$ value. This result means that the s character of the main chain bond is decreased with an increase in the s character of the C-substituent bond, in this kind of polymer. Therefore, the relatively poor thermal stability of poly(α-cyanoacrylate) can be attributed to the relatively high s character of C—CN side chain bond rather than the electron-withdrawing effect of the CN group.

Conclusions

The following principal conclusions derive from the present work and are worthy of special mention.

1. In chemical reactions caused by ionizing radiation, the HOMO plays an important role. In four typical

Table VIII. P values and $Td(i)$ for α-substituted poly(trifluoroethyl acrylate) series polymers

Substituents	$P(3)$	$P(1)$	$T_d(i)$ (°C)
Cl	0.757	0.606	230
CH_3	0.754	0.714	240
CH_2F	0.750	0.737	230
CF_3	0.733	0.800	—
CN	0.700	0.913	180

polymers containing quaternary carbon in their main chains, for example, their different $G(S)$ values can be explained in terms of the HOMO density on their main chain bonds.

2. Since the overlap population F in the HOMO can be employed as a measure of the HOMO density on a covalent bond, the method of calculating the F value provides a reliable prediction of the C-C bond's scission efficiency when exposed to ionizing radiation, to some extent.

3. Concerning poly(methacrylate) series polymer materials, the F values of their main chains are not so much affected by substitutions into the ester side chain, with the exception of phenyl-including substituents. Their sensitivities are determined mainly by solubility characteristics rather than by scission efficiency.

On the other hand, α-substituents fairly affect the F value. However, drastically high scission efficiency is not generally expected by the substitution on the α-position.

4. Scission efficiency by ionizing radiation is not always associated with that by heating. The former is associated with F values and the latter is associated with total overlap populations P, at least as far as C-C covalent bonds are concerned. Therefore, P values give some information about the thermal stability of positive electron resists. As a practical positive electron resist, it is desirable that the main chain bond have a high F value and a high P value.

5. No simple relationship exists between scission efficiency and the electron-withdrawing nature of side chains. Moreover, the substituent effects differ according to the kinds of polymers. Scission efficiency by heating is rather associated with the s-character of the C-substituent bond, at least in the case of α-substituted poly(acrylate) series polymers.

A Computer Model for Pulsed Laser Heating of Device Structures

D. J. Godfrey,[1] A. C. Hill, and C. Hill

Plessey Research (Caswell) Limited, Allen Clark Research Centre, Caswell, Towcester, Northants., England

ABSTRACT

A rigorous, two-region implicit Crank-Nicolson finite difference solution of the heat diffusion equation for pulsed laser heating has been developed. The computer model includes the temperature, phase, and material dependences of the major optical and thermal properties. Melting is modeled by separating the heat equation into three distinct regions. The first corresponds to the solid phase, the third to the liquid phase, and the second to the situation where latent heat is being stored. The run time required for the most complex model situation is approximately 40 min c.p.u. time. The model is applied to a typical device structure which includes photoengraved thermally grown silicon dioxide with unimplanted and implanted windows. Good agreement is obtained in situations where experimentally measurable effects can be compared with model predictions, and the application of the model to laser annealing of oxide covered silicon is discussed with reference to parallel experimental studies.

The use of pulsed laser annealing to remove ion implantation damage has been reported by many authors (1). Much of this work has concentrated on the materials aspects of laser annealing and there has been less effort directed toward practical device structures. A typical structure to which laser annealing might be applied is shown in Fig. 1. Here a thermal oxide layer is used to define the regions for implantation and to passivate the silicon surface. For successful laser annealing it must be possible to anneal the implantation damage in the windows without deleteriously affecting the SiO_2/Si interface. Experimental studies of such structures show that the SiO_2/Si interface is disturbed at the incident energy densities required for annealing the implant (2). Figure 2 shows an optical micrograph of such a structure where an implant of 40 keV 1×10^{16} ions cm^{-2} As and a 1.9 J cm^{-2} 25 nsec ruby laser pulse has been used. Ripple is visible in the surface over large areas of the annealed region. A model has been proposed for this rippling (2) which requires the oxide to move with respect to the underlying silicon; where this movement is constrained rippling may take place. In order to obtain a clear understanding of such effects it is necessary to be able to predict the temperature cycling of both the oxide and the underlying silicon during laser annealing. For this reason the computer model described in the next section has been developed.

Computer Model of Laser Heating

The light energy from the laser is absorbed by excitation of electrons which transfer their excess energy to heating the lattice in very short times ($\sim 10^{-12}$ sec) (3). Thus for pulse lengths greater than a few nanoseconds, the spatial distribution of the absorbed light is a good indication of the initial distribution of the heat energy. This local heating can then diffuse in the usual manner by thermal conduction. Hence, the thermal effects induced can be described by using the heat equation with a source term to include light absorption. If we ignore sideways diffusion the following form of the equation describes the temperature variation with depth and time.

$$c\rho \frac{\delta T}{\delta t} = \alpha I(z,t) + \frac{\delta}{\delta z} K(T) \frac{\delta T}{\delta z}$$

where c is the heat capacity, ρ is the mass density, α is the absorption coefficient, K is the thermal conductivity, I is the laser power density, t is the time, and z is the depth.

Several analytical and numerical solutions of this equation are available in the literature (4). The major limitations of the analytical solutions are their inability to include the temperature and material dependences of the optical and thermal parameters and the change of phase. The numerical solutions available have been nonrigorous in their treatment of layered structures and have required a large amount of computer time to model realistic time and depth scales. However, the present numerical solution has been developed to give a more general and rigorous

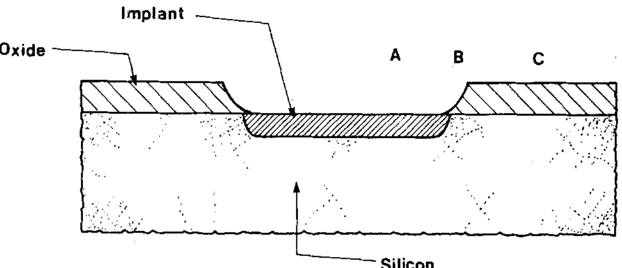

Fig. 1.

Key words: pulsed laser annealing, numerical analysis, thermal cycling, silicon device structures.

approach while requiring less computer time. There are two major reasons for this improvement. First, the modeling of layered structures (such as oxide on silicon) has been treated as two separate regions with two separate heat equations joined at the interfaces by boundary conditions. Previous numerical solutions have assumed that layered structures can be modeled by allowing the optical and thermal parameters to vary discontinuously across the boundary while solving one diffusion equation for the complete structure. However, as will be shown in a further publication (5), this approach is mathematically inconsistent. Second, previous numerical solutions have used an explicit mathematical formulation of the problem. This approach leads to a severe constraint on the depth and time increments which will allow the solution to converge. The approach adopted here is an implicit solution using the Crank-Nicolson (6) method, which enables larger increments in depth and time while achieving sufficient accuracy in the solution. This allows practical time scales (up to 1 μsec) and depth scales (up to 10 μm) to be modeled with reasonable speed and accuracy (typical run time for nonmelting version of the program ~2 min with accuracy ~0.5%). The accuracy of the numerical solution has been tested against a number of analytical solutions to the diffusion equation. For example, Fig. 3 shows the variation of surface temperature with time for a "top hat" laser pulse. The numerical solution is indistinguishable from the exact analytical solution. The numerical solution has been compared with a solution of the heat equation where the thermal conductivity varied with temperature. Again, the error introduced by the numerical solution was of the order of 0.5%. The computer program which has been developed allows the parameters α and K in the diffusion equation to be temperature and material dependent and c and ρ to be material dependent. Also, the effect of multiple reflections at the material interface is included. Further details of the mathematical formulation and the validation of the computer model will be given in a future publication (5).

Modeling the Phase Change

For short pulse lengths (less than 10^{-7} sec) melting is required for appreciable distances of crystal growth (1). Thus a fundamental requirement of any model is the incorporation of the phase change. This is particularly difficult in analytical solutions due to the discontinuity at the solid liquid interface. However, numerical models are more able to deal with the phase change. For example, the model developed by **Baeri *et al.*** (4) treats melting in the following manner. When the temperature of a particular numerical slice reaches the melting point, any further heat received, either by absorption or conduction, is stored as latent heat. Once the amount of latent heat required for melting has been received the layer melts and the temperature begins to rise again. This change of phase requires that a moving boundary, equivalent to the melt front, be included in the mathematical modeling.

The inclusion of such a boundary within an implicit numerical solution is technically more difficult. The effect of the phase change in the present model has been incorporated in the following manner. The diffusion equation has been rewritten as below (7)

$$\frac{\delta H(T)}{\delta t} = \alpha I(z,t) + \frac{\delta}{\delta z} K(T) \frac{\delta T}{\delta z}$$

The function $H(T)$ is shown in Fig. 4. In the first region $H = c\rho T$ to give the normal diffusion equation. The second region approximates the storage of latent heat at a constant temperature by a region of finite width (typically 10°-100°C wide). For many experimental situations using a range of temperature of which melting occurs is physically more reasonable than the approach outlined above. The third region of the $H(T)$ junction again reduces to the normal diffusion equation with the possibility of using different values for c and ρ. This transformation of variable has the effect that the $H(T)$ function is single valued for all temperatures. Again, two layer structures (*e.g.*, oxide on silicon) have been modeled by solving two separate diffusion equations with different $H(T)$ functions.

Summary of Parameter Values Used in the Model

A major difficulty in applying the computer model has been the limited number of experimental measurements available for the optical (8) and thermal (9) parameters under the conditions found in pulsed laser annealing. Table I gives the basic materials constants used in the program. Figure 5 summarizes the values taken for the temperature-dependent thermal conductivity in this present work and Fig. 6 and 7 give the values taken for the absorption coefficient for the ruby and Nd:YAG wavelengths. It can be seen that the strongest temperature dependences for both the thermal conductivity and the absorption coefficient are found for single crystal silicon, emphasizing the need to take such temperature effects into account if reliable modeling is to be achieved. At present there is some difficulty in obtaining convergence in the

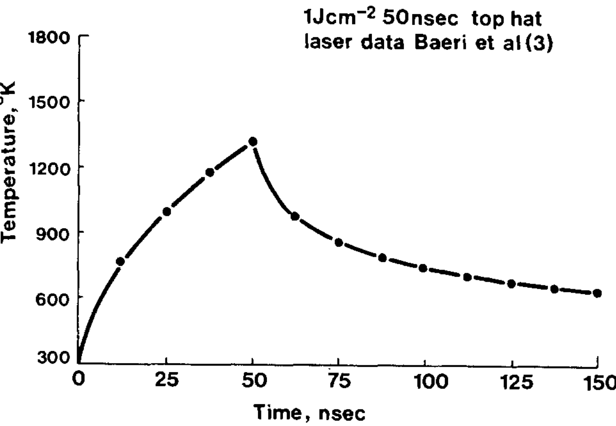

Fig. 3. Comparison of numerical solution with analytical solution

Melting Point (°C)	1385	1200	1800
Latent Heat (Jg^{-1})	1809	1220	1200
Refractive Index (Ruby)	3.865	4.0	1.47
Refractive Index (Nd:YAG)	3.37	3.37	1.47

model when liquid thermal conductivities are included. This is due to the rapid change in thermal conductivity [typically a factor of ~20 over a small temperature range (~100°C)]. Thus, unless explicitly stated, the temperature profiles given in this paper do not include the effect of the high value of the liquid thermal conductivity. In conclusion, it should be noted that as the absorption coefficient and thermal conductivity are not well known, they constitute a major source of uncertainty in the computed profiles.

Modeling of Pulsed Laser Heating of Single Crystal Silicon

In this section the heating of single crystal silicon by a pulsed ruby laser has been modeled. Figure 8 shows the time for which the surface is molten as a function of the energy density (25 nsec FWHM Gaussian pulse). It can be seen that once a threshold energy density is reached, the length of time of the melt increases linearly with energy density. It is also possible to calculate the penetration of the melt depth as a function of time for given energy densities (see Fig. 9). From this figure it is possible to find the maximum melt depth which can then be drawn as a function of energy density (see Fig. 10). Again, once a threshold energy is reached the maximum melt depth increases approximately in a linear fashion with energy density. The slope of this line is 2.2 J $cm^{-2}/\mu m$ compared with a value of 2.5 J $cm^{-2}/\mu m$ obtained by Baeri *et al.* (3) for a 50 nsec Gaussian pulse. The major reason for this is that parameter values used in the two programs are not identical.

The results detailed above were obtained with the temperature dependence of the solid thermal conductivity taken throughout. Figure 11 illustrates the difference obtained for the surface temperature when the liquid thermal conductivity is included. The major effects are to greatly reduce the peak surface temperature and lessen the length of time for which the surface is molten. Both these effects are due to the increased diffusion of heat away from the surface into the bulk.

Temperature Profiles Obtained for Device Structure

A major application of the computer model described in this paper is studying the thermal cycling of device structures such as shown in Fig. 1. This structure can be approximated by three separate regions: (*i*) Single crystal silicon (corresponding to unimplanted or low dose implanted windows), (*ii*) thin amorphous layer on a single crystal substrate (corresponding to a high dose implant such as 1×10^{16} ions cm^{-2} 40 keV As emitter), and (*iii*) oxide layer on silicon substrate (corresponding to the defining oxide shown in Fig. 1). It has been shown that the thermal and optical parameters of these three regions are very different (see Fig. 5, 6, and 7.) A further difference which must be considered is the reflectivity of these layered structures. It is known (10) that a surface oxide can act as an antireflection coating in laser annealing. Thus, the reflectivity found in region (*iii*) will be dependent upon the oxide thickness for coherent light. However, in parallel experimental studies a waveguide has been used in order to obtain a more uniform energy density for the laser. This causes the laser light to be highly divergent, such that the conditions for constructive and destructive interference are met over a wide range of angles. This effectively reduces the amplitude of the interference effect. However, the mean reflectivity will still be higher than for bare silicon. In the computer model this average reflectivity is calculated from the following equation

$$R = \frac{(n_1 - n_2)^2 + (K_1 - K_2)^2}{(n_1 + n_2)^2 + (K_1 + K_2)^2}$$

where $n_1' = n_1 - iK_1$ and $n_2' = n_2 - iK_2$ and n_1' and

n_2' are the complex refractive indexes of the two materials involved. This approach has been adopted for the thin amorphous region and for the liquid reflectivity once the melt depth is greater than the skin depth.

Figure 12 shows the temperature profiles present at the peak of a 0.5 J cm^{-2} 25 nsec FWHM Gaussian pulse for the device structure. In this figure and in Fig. 13 the values for the liquid thermal conductivity and liquid absorption coefficients have been included. It can be seen that the reduced reflectivity of the oxide-covered silicon causes the interface temperature to be greater than for the bare silicon case. This is in spite of some heat loss from the silicon due to conduction into the oxide. For 0.5 J cm^{-2} no melting is obtained for the photoengraved structure at the peak of the pulse whereas for 1.0 J cm^{-2} (see Fig. 13) melting occurs in all three cases. It can be seen that the largest melt depth at the peak of the pulse is obtained for the ion-implanted region and that the silicon dioxide layer is only heated to above 400°C to a thickness of 0.15 μm. It is also useful to be able to determine the heating of the oxide as a function of time. Figure 14 shows temperature profiles for oxide on silicon at 25 nsec intervals after the peak of the pulse. It can be seen that the whole oxide is heated quite slowly and a temperature of above 800°C is only reached 100 nsec after the peak of the pulse when the underlying silicon has almost resolidified.

A model previously proposed (2) to explain ripple in oxide overlayers on silicon after pulsed laser anneal required both melting of the silicon and simultaneous compressive stress in the oxide. The stress was attributed to thermal expansion, requiring temperatures in excess of 1500°C to account for the observed ripple. The present computation shows that melting does indeed occur under commonly used experimental conditions but that oxide temperatures are much lower than were assumed. More recent experimental evidence (11) suggests that the compressive stress is inbuilt in the oxide and that the ripple is due to elastic strain which can occur at the low oxide temperature computed here.

Melting for 1 × 10^{16} ions cm^{-2} 40 keV As Implanted Silicon

A further area where the present model can be applied is the calculation of the melt depth achieved for high dose As implants. Laser annealing is a particularly promising technique for such implants as good single crystal material with levels of dopant above the solid solubility limit can be produced. Much experimental effort has been focused in this laboratory on the annealing of 1 × 10^{16} ions cm^{-2} 40 keV As emitter

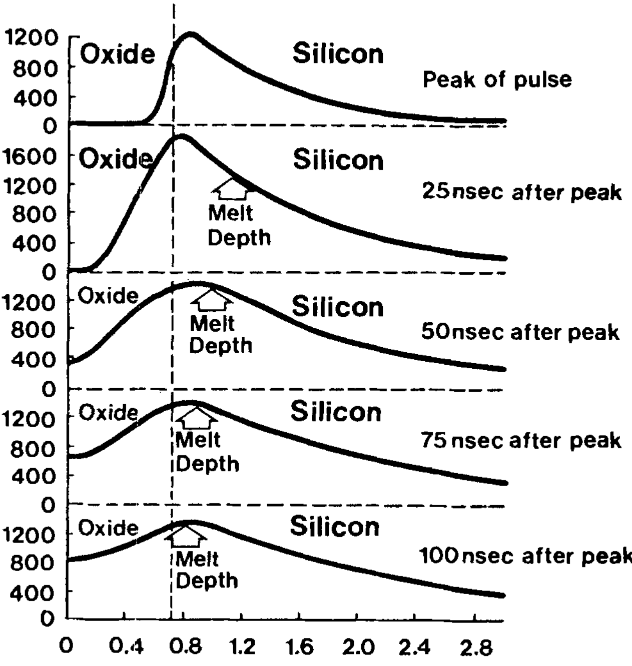

Fig. 14. Development of oxide heating with time. 1.0 J cm^{-2} 25 nsec ruby pulse on oxide covered silicon.

implants. A process technology has been developed (10) which allows the oxide to be protected during laser anneal. Figure 15 shows the junction depth obtained from such an implant after varying energies of pulsed ruby laser heating. Also shown in this figure is the calculated maximum melt depth from the computer program. It can be seen that the threshold for melting is approximately 0.75 J cm^{-2} and that the slope of the graph is 3.5 J $cm^{-2}/\mu m$. Using the computer model, it is possible to calculate the melt depth as a function of time and energy density. The expected junction depth can then be found using $x = N\sqrt{Dt}$. The result of such calculations is shown in Fig. 15. It can be seen that the agreement between the theoretical and experimental junction depth is good.

Figure 16 shows the calculated melt depth for an Nd:YAG laser pulse of the implanted silicon. Due to the lower absorption coefficient for this wavelength in both the amorphous and single crystal regions, the threshold for melting is much higher than for the ruby wavelength. However, once melting occurs the differences in the optical parameters for the solid are less important. Thus the slopes of the two lines for the ruby and Nd:YAG laser pulses are similar.

Summary of Computer Model

A fast implicit Crank-Nicolson numerical solution to the heat diffusion equation has been produced. The model treats rigorously the temperature dependences of the optical and thermal parameters, the change of phase, and two layer structures. A computing time of approximately 1 hr is required for runs involving the most complex situations for which the model has been developed. If melting is not required a faster program (run time 2 min) can be used.

The results obtained from the model agree reasonably well with experimental values, where direct comparison is possible. A major difficulty in applying the program is the lack of reliable experimental data available for the optical and thermal parameters. A major application of the model is for situations where experimental measurements are not possible (for example, the transient heating of oxide layers). The reliability of such predicted temperature profiles is dependent upon the level of known physical effects which are included in the model. It is for this reason that such a large amount of effort has been expended in producing this first rigorous solution of the heat diffusion equation for laser heating.

Further developments of the program will include improvements in the range of values which may be taken for the thermal and optical parameters. At present there are difficulties with convergence when liquid thermal conductivity is taken into account. It is also hoped that the effect of carrier diffusion may be included in the source term of the equation. However, this effect can only be fully included by the solution of two coupled diffusion equations. Finally, the present model could be used to calculate the diffusion of dopants during pulsed laser annealing.

Antimony Diffusion from Spin-On Doped Oxide

Schyi-yi Wu*

Motorola, Semiconductor Group, Phoenix, Arizona 85008

ABSTRACT

A new antimony diffusion process using spin-on doped oxide source was characterized and developed. Diffusion is enhanced in dilute oxidizing ambient due to increased surface concentration while diffusivity remains essentially the same in both nitrogen and dilute oxidizing ambient. Wright etch reveals no diffusion induced dislocation when surface concentration is less than 2.4×10^{19} cm^{-3}. The thinner and less concentrated glass diffused in lower oxygen concentration ambient is less prone to glass devitrification. This process was proven to be suitable for buried layer formation in the fabrication of bipolar integrated circuits.

In the fabrication of silicon bipolar integrated circuits, the first diffusion step is the buried layer diffusion, which is followed by epitaxial growth. The bases and emitters are fabricated on epitaxial layers. The device performance is related to the epitaxial quality which in turn is related to the buried layer quality. Buried layers can be fabricated by arsenic diffusion or antimony diffusion. Two advantages associated with arsenic are (*i*) its nearly perfect match in silicon lattice; and (*ii*) high solid solubility in silicon, both of which are required for very low resistivity buried layers.

Antimony is larger than silicon in atomic size and has lower solid solubility than arsenic. However, antimony has lower diffusivity and lower vapor pressure and thus would exhibit less out-diffusion than arsenic in subsequent high temperature processes. Less lateral out-diffusion is desired for increased device packing density. Less autodoping into epitaxial layers is desired for thin and low resistivity epi which is required for high speed circuitry.

A new antimony diffusion process using proprietary spin-on doped oxides (1), suitable for buried layer formation is described. The thickness of glass can be easily controlled by spin speed and viscosity of the antimony glass solution. This spin-on method of source application offers higher throughput with better uniformity than the conventional atmospheric chemical vapor deposition process, better processing simplicity than the low pressure CVD process, and lower capital requirement than the ion implantation process. The spin-on antimony diffusion process results in improved yield compared to the spin-on arsenic process and device speeds comparable to that obtained by antimony ion implantation for low power Schottky T^2L devices.

Experimental

Antimony source.—The antimony concentration in the glass is controlled by the weight ratio of an antimony compound to TEOS (tetraethylorthosilicate). The viscosity of the antimony glass solution, and thus the thickness of the spun film, are controlled by the weight ratio of TEOS to solvent.

Silicon wafers.—Wafers were CZ grown, boron-doped 3 in. diam. Three types of wafers were used: (*i*) <100> crystal orientation, 0.8-1.2 Ω cm; (*ii*) <100> crystal orientation, 7-17 Ω cm; and (*iii*) <111> crystal orientation, 7-17 Ω cm.

Wafer clean.—Wafers were cleaned by 1 min 10 H_2O:1 HF (49%) and/or 10 min 7 H_2SO_4:3 H_2O_2 at 110° ± 10°C, with UPDI H_2O rinse between the two steps. Wafers were spin-rinsed and spin-dried in hot N_2.

Source application.—The wafer was placed on a Headway EC101 spinner, and the antimony glass solution was applied to the surface. The wafers were spun at various speeds for 10 sec to achieve the desired thickness and baked at 150° or 400°C in N_2 ambient for 30 min.

Diffusion.—Temperatures inside the polysilicon diffusion tube were measured by calibrated thermocouples and temperature indicators. Temperature was uniform within 2°C across the "flat zone" without a wafer load. The actual temperature uniformity with a wafer load can vary by more than 2°C (2). Wafers were placed in a quartz boat and pushed at 4 in./min into the diffusion tube at 800°C (except where noted) to prevent thermal stress induced dislocations and warpage. The temperature was ramped to 1250°C, kept at 1250°C for various times, then ramped down to the starting temperature. Wafers were pulled at 4 in./min. Nitrogen and oxygen of various flow rates (10-11 liters/m total, measured by rotameters) were passed through the diffusion tube.

Evaluations.—Thickness of oxides (antimony glass after source bake, and antimony glass-thermal oxide composite after diffusion) was measured by an IBM 7840 film thickness analyzer using the refractive index for thermal oxide. Wafers were etched in HF solution to remove all oxides. Sheet resistance was measured by four point probe. Five points were measured on each wafer: center and four equi-spaced peripheral points, one-third of an inch from the wafer edge. Junction depth was measured by grooving, staining, and fringe counting with an interferometer. Spreading resistance probe measurements were used to determine the dopant profile.

Results and Discussions

Diffusion ambient.—Pertinent data for the 3 hr diffusions at 1250°C in two diffusion ambients (0% O_2 and 10% O_2) are shown in Tables I and II. Source concentration was 2.77×10^{21} cm^{-3}, source thickness was variable, and source bake temperature was 400°C. The above data show that the 10% O_2 ambient resulted in lower sheet resistance, deeper junction, higher sheet conductivity, and thus higher surface concentration as well as higher doping level than the 100% N_2 ambient. This kind of effect is also observed in arsenic diffusion from doped oxide sources including CVD oxide (3) and spin-on oxide (2). Sakurai *et al.* (3)

attributed this effect to the difference in properties of the interface between doped oxide and silicon. For diffusion in N_2, arsenic is reduced by silicon and accumulated at the interface and the surface concentration in silicon is not so high. On the other hand, for diffusion in an oxidizing ambient, the accumulation phenomenon is not observed and the surface concentration is higher than that obtained by diffusion in N_2. When N_2 was used in antimony diffusion from spin-on doped oxide (≥ 0.1 μm) a hydrophobic surface with brown stain was obtained after the oxide was etched off in HF solution following the diffusion. The brown stain may be an indication of antimony accumulation at the interface. No brown stain was observed for 0.056 μm source since oxidation occurred due to residual oxidant in N_2 ambient (Table I). Listed in Tables I and II are also some estimated diffusivity data assuming Gaussian distribution of dopant and substrate concentration equal to 1.34×10^{15} cm^{-3}. The latter value is the average substrate concentration of the wafers used in these experiments. These estimated diffusivity data were calculated by using $t = 3$ hr. The effective diffusion time at 1250°C is greater than 3 hr since wafers were loaded and unloaded at 800°C. It can be shown later that the Gaussian distribution is valid for the calculations of diffusivities reported in Tables I and II. The diffusivity is essentially the same for both 100% N_2 and 10% O_2 ambients. Hence the enhanced diffusion reported herein is due to increased surface concentration in oxidizing ambient. This is not to be confused with "oxidation-enhanced diffusion" reported by Francis and Dobson (4). In the latter case diffusivity is increased due to growth of stacking faults by oxidation.

Figure 1 shows sheet resistance *vs.* oxygen concentration for $C_o = 9.01 \times 10^{21}$ cm^{-3} for various source thicknesses diffused for 3 hr at 1250°C. These data were obtained by using 150°C source bake. In general, higher oxygen concentration is required for thicker source to achieve minimum sheet resistance. For $C_o = 9.01 \times 10^{21}$ cm^{-3}, 5% O_2 resulted in the lowest sheet resistance for 0.1211 μm source, whereas 10% O_2 resulted in lowest sheet resistance for 0.1690 μm source. This indicates that enhanced diffusion is a function of oxide growth. The rate of oxidation is increased as oxygen concentration is increased, and the source thickness is decreased. That is, higher oxygen concentration is required for thicker source than for thinner source to grow the same amount of oxide. When oxygen concentration is too high, the oxidation process competes with the diffusion process and higher sheet resistance is obtained. Among the diffusion ambients studied, lowest sheet resistance and highest surface concentration were obtained in 1% O_2 for $C_o = 2.77 \times 10^{21}$ cm^{-3} and $X_s = 0.0762$ μm; in 5% O_2 for $C_o = 9.01 \times 10^{21}$ cm^{-3} and $X_s = 0.0900$ μm. Again diffusivity is essentially the same for all sources. Sheet resistance and junction depths obtained for the 3 hr diffusion at 1050°C in 0.75, 10, and 100% O_2 are shown in Table III for three sources. These data show that the effects of diffusion ambients are also true at 1050°C.

Source bake temperature and wafer clean.—The effects of these two variables on sheet resistance were determined in a 3 hr diffusion at 1250°C in 3% O_2 ambient. Wafers were cleaned by 10 H_2O:1 HF(49%) or 7 H_2SO_4:3 H_2O_2 (piranha). The source with $C_o = 9.01 \times$

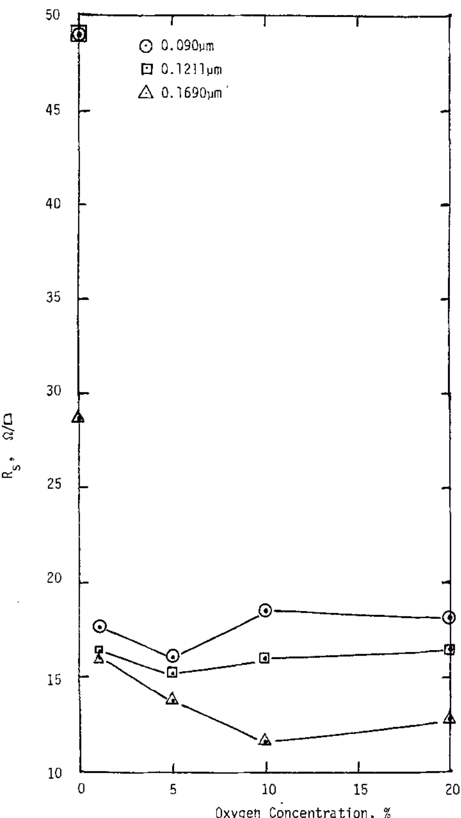

Fig. 1. Sheet resistance as a function of oxygen concentration in diffusion ambient: $C_o = 9.01 \times 10^{21}$ cm^{-3}, $T_b = 150°C$, $T = 1250°C$, $t = 3$ hr.

10^{21} cm^{-3} was spun at 4 Krpm. The spun wafers were baked at 150° or 400°C. Source thicknesses are 0.0800 and 0.0670 μm, respectively. Sheet resistances and final oxide thicknesses measured after diffusion are listed in Table IV. The 400°C source bake resulted in higher sheet resistance than the 150°C source bake. This may be in part caused by more dopant loss at the higher bake temperature. Atomic absorption analysis showed that antimony concentration was decreased from 34.8 to 31.1% when bake temperature was increased from 150° to 400°C for the source of same concentration ($X_s = 0.1211$ μm if baked at 150°C). More reduction in antimony concentration is expected for the thinner source. Note that the melting point of Sb_2O_3 is 650°C. The difference in sheet resistance also appears to be related to oxide growth, which in turn is related to

Piranha	15.56	0.1071	20.44	0.0986

sheet resistance as discussed earlier. Specifically, Fig. 1 shows that for $C_o = 9.01 \times 10^{21}$ cm^{-3}, sheet resistance is increased as the oxide growth is decreased from that amount produced by 3% O_2 ambient. The sheet resistance was lower and the final oxide was thicker when source was baked at 150°C than at 400°C. This indicates that the more densified glass has a greater resistance to silicon oxidation in diffusion ambients of $\leq$ 3% O_2. When the source was baked at 400°C, piranha clean resulted in higher sheet resistance and thinner final oxide than the H_2O/HF clean. The very small amount of oxide produced by piranha appears to be a significant resistance to oxidation in $\leq$3% O_2 ambient.

Dopant profile and diffusivity.—Typical R_s *vs.* X_s data are represented by Fig. 2 for diffusion at 1250°C for 1 hr in 10% O_2 ambient for substrate resistivity ranging from 7 to 17 Ω cm. Junction depth *vs.* time data are presented in Fig. 3 for two substrate resistivity ranges 7-17 and 0.8-1.2 Ω cm. The average substrate concentrations, $\overline{C}_B$, are 1.34×10^{15} and 1.72×10^{16} cm^{-3} for the two resistivity ranges. The junction depth data are applicable to surface concentration range from 1.5×10^{19} cm^{-3} to 3.0×10^{19} cm^{-3}. This range corresponds to 80 Ω μm $\leq R_sX_j \leq$ 137 Ω μm for $\overline{C}_B = 1.34 \times 10^{15}$ cm^{-3} and 71.5 Ω μm $\leq R_sX_j \leq$ 116 Ω μm for $\overline{C}_B = 1.72 \times 10^{16}$ cm^{-3}. Deeper junctions were obtained for the lower substrate concentration. If dopant profiles follow Gaussian distributions (5), then

$$X_j = 2\sqrt{D(\Delta t + t)}\ [\ln(C_s/C_B)]^{1/2} \quad [1]$$

where t is the diffusion time at 1250°C and Δt accounts for diffusion during the ramp up and the ramp down cycles. Equation [1] indicates that junction depth is decreased as substrate concentration is increased or surface concentration is decreased. For surface concentrations between 1.5×10^{19} and 3.0×10^{19} cm^{-3}, the junction depth should vary within 3.6% for $\overline{C}_B = 1.34 \times 10^{15}$ cm^{-3} and 5.1% for $\overline{C}_B = 1.72 \times 10^{16}$ cm^{-3}. These variations are within measurement errors. The error in junction depth measurement is ± 0.135 or 0.27 μm. For data presented in Fig. 3, the minimum error in junction depth measurement is 5% for $C_B = 1.34 \times 10^{19}$ cm^{-3} (0.27 μm ÷ 5.4 μm), and 5.6% for $C_B = 1.72 \times 10^{16}$ cm^{-3} (0.27 μm ÷ 4.86 μm). The measurement errors are greater for shallower junctions. Thus, within experimental error, junction depth can be considered to be independent of surface concentration in the range 1.5×10^{19} to 3.0×10^{19} cm^{-3}. Equation [1] can be written as

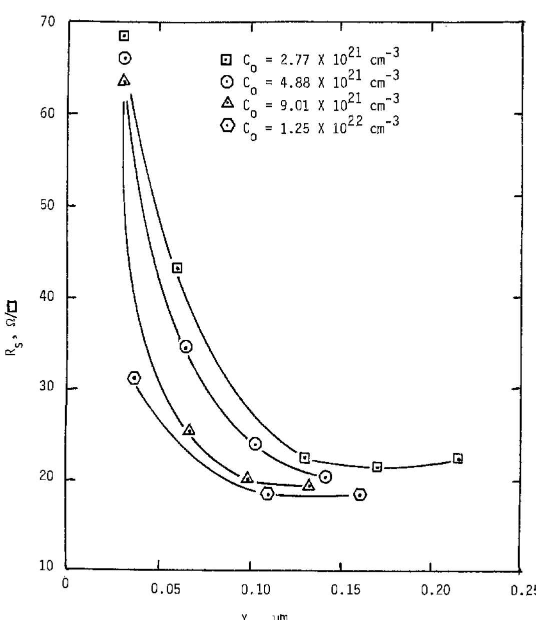

Fig. 2. Sheet resistance data for 1 hr diffusion at 1250°C in 10% O_2 ambient: T_b = 400°C.

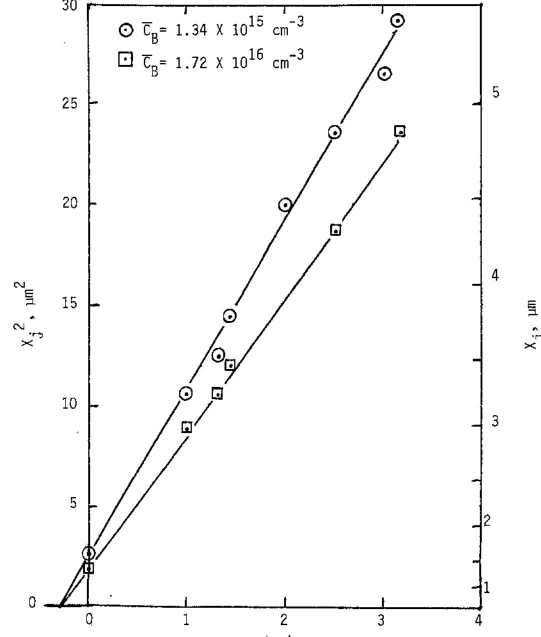

Fig. 3. Junction depth data for various diffusion time: T = 1250°C, diffusion ambient = 10% O_2.

$$X_j^2 = 4\,D\,\Delta t \ln \frac{C_s}{C_B} + 4\,Dt \ln \frac{C_s}{C_B} \quad [2]$$

and $t = -\Delta t$ when $X_j = 0$.

Thus, a plot of X_j^2 *vs.* t should be straight line [when ln (C_s/C_B) = constant], and the intercept at $X_j = 0$ is an estimate of Δt. Figure 3 shows that the plots of X_j^2 *vs.* t are straight lines and Δt = 0.3 hr which is the equivalent diffusion time at 1250°C for the combined ramp up and the ramp down cycles.

The dopant profile obtained by spreading resistance probe measurements for the 2 hr diffusion at 1250°C in 1% O_2 ambient using $C_o = 9.01 \times 10^{21}$ cm^{-3} and X_s = 0.1160 μm is shown in Fig. 4. The solid curve represents the theoretical Gaussian distribution with $C_s = 2.5 \times 10^{19}$ cm^{-3} and $4D(\Delta t + t)$ = 1.95 μm^2. It can be seen that the dopant profile follows a Gaussian distribution very well. The junction depths obtained, 4.32 μm for $\overline{C}_B = 1.34 \times 10^{15}$ cm^{-3} and 3.78 μm for $\overline{C}_B = 1.72 \times 10^{16}$ cm^{-3}, also agree very well with the Gaussian distribution. Since Δt was estimated to be 0.3 hr, diffusivity, D, can be calculated to be 0.212 μm^2/hr. This is to be compared with 0.173 μm^2/hr reported by Fuller and Ditzenberger (6).

Surface quality.—Diffusion-induced dislocations and glass damage are related to buried layer quality and epitaxial layer quality. No dislocations were revealed by 1 min Wright etch when surface concentration was lower than 2.4×10^{19} cm^{-3}. When surface concentration was greater than 2.4×10^{19} cm^{-3}, shallow etch pits were observed. Rao, *et al.* (7) observed dislocations for surface concentrations greater than 2.4×10^{19} cm^{-3} using the same sources. The major glass damage is caused by devitrification. Glass devitrification causes raised steps on the silicon surface. The raised steps appear like rosettes (Fig. 5) or irregular in shape (Fig. 6). Thinner and less concentrated glasses used in lower oxygen ambient are less prone to devitrification. Surface conditions, such as particulates, residual photoresist, and impurities, are thought

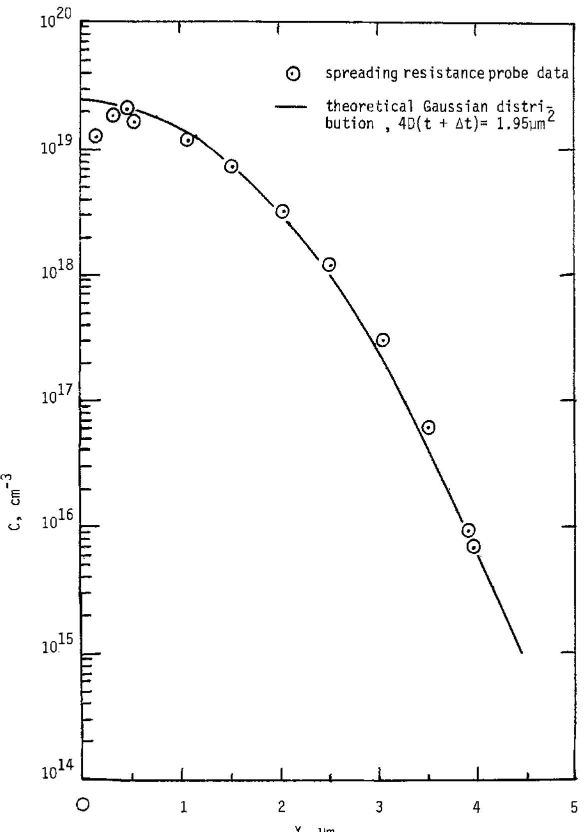

Fig. 4. Carrier concentration profile after 2 hr diffusion at 1250°C in 1% O_2 ambient: $C_o = 9.01 \times 10^{21}$ cm^{-3}, $X_s = 0.116$ μm ($T_b = 150$°C).

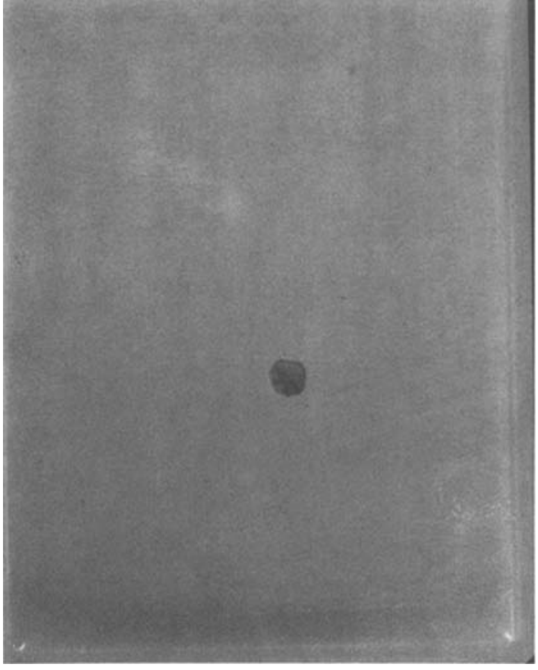

Fig. 5. Glass devitrification called rosetts (700×)

to be related to glass devitrification. Another type of surface damage is surface roughness caused by reaction between glass and moisture in air during source application. With proper source formulation, the spun glass film is insensitive to humidity up to at least 50% RH.

Uniformity and repeatability.—Typical sheet resistance uniformity defined by the coefficient of variability (2× standard deviation ÷ mean), is ≤5% over a wafer, and 6% over an 80 wafer load. Even though

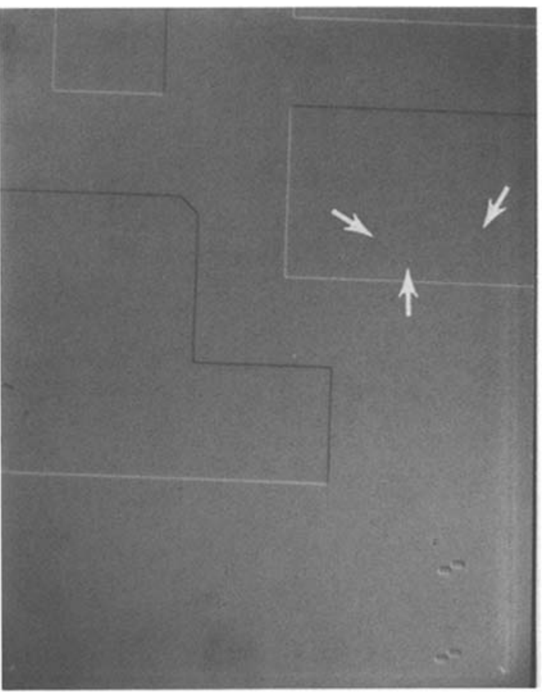

Fig. 6. Raised steps, irregular in shape, caused by glass devitrification. (130×)

the temperature of the empty diffusion tube is uniform within 2°C across the "flat zone," the actual temperature nonuinformity with a wafer load may be greater than 2°C (2). The load size and the load uniformity are essentially limited by temperature uniformity and length of the diffusion tube. Sheet resistance repeatability, such as 22.83 ± 2.62 Ω/□, was obtained for six runs, diffused over 50 days.

Summary and Conclusions

A new antimony diffusion process using spin-on doped oxide was developed and characterized. The major points are listed below.

1. Diffusion is enhanced by some oxide growth which results in lower sheet resistance, higher surface concentration, and higher doping density while diffusivity remains essentially the same. As oxygen concentration in the diffusion ambient is increased from 0%, sheet resistance is decreased to a minimum. As oxygen concentratiion is further increased, sheet resistance is increased. Higher oxygen concentration is required for thicker source to achieve minimum sheet resistance. The 400°C source bake results in less oxide growth and higher sheet resistance than the 150°C source bake in a 3 hr diffusion at 1250°C in 3% O_2 ambient. Under the same diffusion conditions, piranha clean results in less oxide growth and higher sheet resistance when source is baked at 400°C. These two results indicate that the more densified glass and the very small amount of oxide produced by piranha appear to be significantly resistant to oxidation in 3% O_2 ambient.

2. The electrically active dopant concentration profile follows a Gaussian distribution for practical application in buried layer fabrications.

3. Wright etch reveals no diffusion-induced dislocations when surface concentration is lower than 2.4×10^{19} cm^{-3}.

4. The thinner and less concentrated glass diffused in lower oxygen concentration ambient is less prone to glass devitrification. A properly formulated source is not sensitive to humidity up to 50% RH.

5. Typical sheet resistance uniformity is ≤5% for individual wafers, and 6% for an 80 wafer load. The size of the wafer load is diffusion tube length limited.

6. Run to run repeatability, such as 22.83 ± 2.62 Ω/□, was achieved.

Linear devices have been fabricated with spin-on antimony buried layers (13-50 Ω/□ and 9 μm) and the device yields are comparable to those obtained with spin-on arsenic buried layers (13-30 Ω/□ and 5 μm). Evaluation on low power Schottky T^2L devices showed that spin-on antimony buried layers resulted in improved device yields over the spin-on arsenic buried layers and gave comparable switching speeds to ion implanted buried layers.

Effects of Material Properties and Overlay Processing Variations on Magnetic Bubble Device Performance

W. A. Johnson,* F. B. Hagedorn,* R. Wolfe, G. P. Vella-Coleiro, J. L. Smith, and R. S. Wagner

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The effects of the uniaxial anisotropy field, high processing temperatures (≥300°C), film spacings, pattern misalignments, and film stresses on device operation are described. It is found that accurate process control, particularly with respect to processing temperatures, and a specification for the uniaxial anisotropy field are required for consistent device performance. The best device operation is obtained with high H_k epitaxial garnet material, low stressed overlay films, and geometric spacings that minimize the bubble-stress field interaction.

The Bell System is now using magnetic bubble devices in the 13A Voice Announcement System (1). This system uses the 29A (2) magnetic bubble package which contains four "matched" 68,121 bit reentrant shift register chips. Details of the design of this chip and its operating parameters have been reported elsewhere (3). Major-minor loop chips such as those described by Bonyhard *et al.* (4) have also been used in a similar four-chip package. As the production of these devices has increased, so has the need to obtain more consistent chip to chip device operation. The latter is essential to improve circuit and package yields and for reduced testing times.

This investigation was undertaken to determine the extent to which various film overlay processing parameters and epitaxial material properties affect device performance. Particular attention was devoted to those parameters that affect the minimum current required to nucleate a bubble or that limit bias field operating margins. These included: (*i*) the effects due to the initial uniaxial anisotropy field of the epitaxial

* Electrochemical Society Active Member.

Key words: uniaxial anisotropy field, epitaxial film, process control.

garnet film, (*ii*) the effects due to exposure of the wafers and their overlay circuit structure to temperatures ≧300°C during processing, (*iii*) the effects due to different geometric film spacings and/or pattern misalignments, and (*iv*) the effects due to overlay film stresses.

Circuit Fabrication and Testing

For this study, standard 16 μm period field access circuit structures consisting of 4000Å SiO_2 prespacer/5000Å 4.5 weight percent (w/o) Cu-Al conductor/4000Å SiO_2 insulator/4500Å Permalloy propagator and detector/10,000Å SiO_2 passivation/levels were fabricated on nominal 3 μm $Y_{1.2}Lu_{0.5}Sm_{0.4}Ca_{0.9}Ge_{0.9}Fe_{4.1}O_{12}$ epitaxial films (5). Either rf sputtering or plasma-assisted CVD processes were used to deposit the SiO_2 films. The 4.5 w/o Cu-Al alloy films used for the conductor metallization were deposited by single source e-beam or by S-gun techniques. The Permalloy films were deposited by either single source e-beam or by rf sputtering techniques. The nominal deposition temperatures that were used in these processes and the typical stresses that were measured for the deposited films are listed in Table I.

No operational differences were measured when device structures were fabricated by different deposition techniques so long as comparable film deposition temperatures were used and comparable film stresses were achieved. Thus, no differences were observed in the operational behavior between devices fabricated with S-gun or e-beam deposited Al-Cu alloy metallizations. The effects of film stresses on measured bias field operating margins are discussed.

The material specifications for the garnet epitaxial films are listed in Table II. Note that a specification for the uniaxial anisotropy field of the epitaxial film has been included. The need for such a specification is one of the primary subjects of this paper and is discussed in detail. For hard bubble suppression (6) the epitaxial films were implanted with 100 kV Ne^+ ions at a dose of $2 \times 10^{14}/cm^2$.

Full function bias field operating margins, ΔH, and the current required to nucleate a bubble, I_g(min.), were measured either by a visual quasi-static technique (7) or electronically at 100 kHz with a computer-controlled test station (8), both of which have been described previously. For determining the I_g(min.) values, a 0.3 μsec current pulse was used and the bias field margins were typically measured at a nominal 40 oe rotating field drive. The initial uniaxial anisotropy field of the epitaxial film, H_k, was measured either directly by a microwave resonance technique (9) on the as-grown garnet films or calculated from other epitaxial film properties (strip width, collapse field, film thickness) which were measured by standard techniques (10).

Table I. Nominal film deposition temperatures and film stresses for various deposition processes

Process	Nominal deposition temperature (°C)	Nominal film stress (× 10⁹ dynes/cm²)
RF sputtered SiO_2	200-225*	−1.5
Plasma SiO_2	150-270	−2.5
E-beam Al-Cu	25	~0.1**
S-gun Al-Cu	25	~0.1**
E-beam Permalloy	300-350	+5.0
RF sputtered Permalloy	≦200*	NM

* Heat sinking by wafer clamping is required to maintain these temperatures.
** Stress of Al-Cu will increase with increasing temperatures, typical stresses are $+4 \times 10^9$ dynes/cm².

Uniaxial anisotropy field, H_k	1900 ± 200 oe

Minimum Generator Current Measurements

The geometric configuration of the nucleate generator that was characterized in this study is outlined in Fig. 1. The dependences at 25°C of the minimum current required to generate a bubble, I_g(min.), on the effective anisotropy field, $H_k - 4\pi M_s$, for as-processed wafers (250°C maximum processing temperature) and after these same wafers were successively annealed at 310°, 380°, and 440°C, are shown in Fig. 2. The linear dependences of I_g(min.) on the initial H_k of the epitaxial garnet film for the different maximum processing temperatures are clearly demonstrated. Although the latter results conflict with early data re-

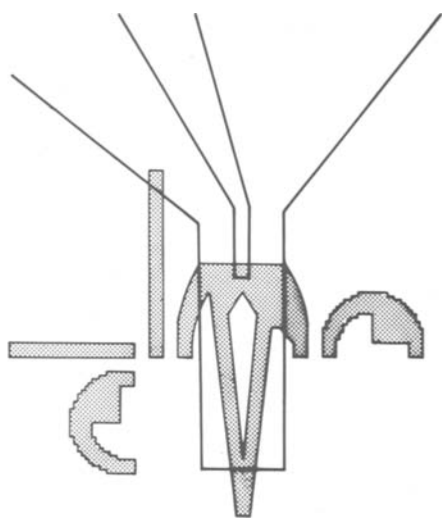

Fig. 1. The nucleate generator design

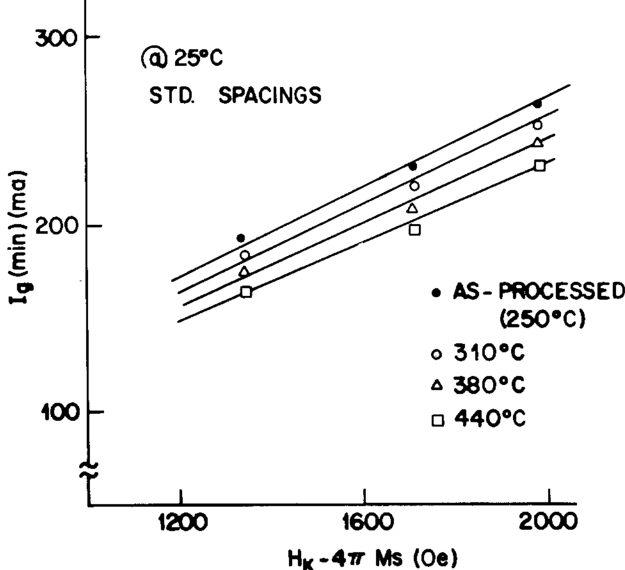

Fig. 2. Plots of the minimum generator currents measured for fully processed wafers vs. the effective uniaxial anisotropy field of the epitaxial garnet films and the maximum temperature to which the wafer was exposed during processing or subsequent annealing.

ported by Nelson *et al.* (11), the annealing results are consistent with observations previously reported by Wolfe and Johnson (12). In that work, the reduction in the I_g(min.) values with increasing annealing temperatures was correlated with stress buildups in the overlaying Al-Cu conductor metallization.

The linear dependence of I_g(min.) values on H_k was not observed in early processing days because the H_k value for each wafer was not accurately known, and at times wafers were exposed nonuniformly to high processing temperatures. Processes in which the high temperatures can still be a problem are the deposition of Permalloy by either e-beam or rf sputtering techniques, and the rf sputter deposition of SiO_2. Wafer temperatures in excess of 500°C have been observed when wafers are not properly clamped and heat sunk during rf sputter deposition of SiO_2. Similarly, temperature spikes of 60°-80°C that are superimposed on the standard 300°C predeposition temperature soak have been measured during e-beam deposition of Permalloy (13).

To check the possibility that any annealing of the implant layer affects the I_g(min.) values measured, wafers with known H_k values were annealed at 440°C for 2 hr under flowing N_2 prior to the fabrication of the overlaying circuit structure. The I_g(min.) values that were measured were found to correspond closely to the values obtained for 250°C as-processed wafers. Reductions of I_g(min.) were measured only when these wafers were given subsequent anneals at temperatures $\gtrsim$300°C with the conductor metallization in place. Therefore, annealing of the implant layer is not a factor in the I_g(min.) shifts that are measured.

Measurements of I_g(min.) and H_k at temperatures other than 25°C show that I_g(min.) and H_k have identical temperature dependences over the normal device operating temperature range 0° to +70°C. Measured values for the temperature coefficient of I_g(min.) range from −0.6 to −1.0 mA/°C depending upon the 25°C H_k value of the epitaxial garnet material. Similar temperature dependences have been reported by Danylchuk and Bobeck (14).

As a consequence of these combined effects, a wide range of I_g(min.) values will be obtained unless tight controls are specified for both the H_k of the epitaxial material and the wafer temperatures during processing. In production it has been found practical to control the H_k values at 25°C to 1900 ± 200 oe (15). This range of H_k values ensures I_g(min.) values that are high enough to prevent unwanted nucleations of bubbles at other current-controlled functions such as the replicator, particularly at high device operating temperatures, yet low enough to ensure bubble nucleation at low device operating temperatures for the specified minimum generator current.

The geometric factors associated with the overlay circuit structures that affect I_g(min.) values are: (*i*) the spacing between the hairpin conductor and the garnet surface, SiO_2I; (*ii*) the spacing between the Permalloy film and the hairpin conductor, SiO_2II; and (*iii*) any misalignment of the overlaying Permalloy pattern with respect to the hairpin conductor. The geometric complexity of the nucleate generator structure precludes any quantitative predictions of the spacing dependences from magnetostatic theory. However, qualitative considerations would indicate that higher I_g(min.) values should be measured if either the conductor to garnet spacing (SiO_2I) or the conductor to Permalloy spacing (SiO_2II) is increased. In the latter case, the interaction of the Permalloy with the current conductor fields which causes the fields in the garnet to be "intensified" is reduced with increased conductor to Permalloy spacing. The data that were obtained in this investigation for variable SiO_2I and SiO_2II spacings are shown in Fig. 3-5.

The expected trends where higher I_g(min.) values are measured for wafers with thicker SiO_2I or SiO_2II layers are seen in Fig. 3 and 4, respectively. The sensitivity of I_g(min.) to SiO_2I variations ($\Delta I_g/\Delta SiO_2 \sim 30$ mA/1000Å of SiO_2) is higher than that determined for SiO_2II variations ($\Delta I_g/\Delta SiO_2 \sim 20$ mA/1000Å of SiO_2) since both the conductor field and the Permalloy-conductor field interaction in the garnet are reduced with increased SiO_2I spacing. For increased SiO_2II spacing, only the Permalloy-conductor field interaction is reduced.

The data that were obtained with variable SiO_2I spacings but constant SiO_2I + SiO_2II spacing is shown

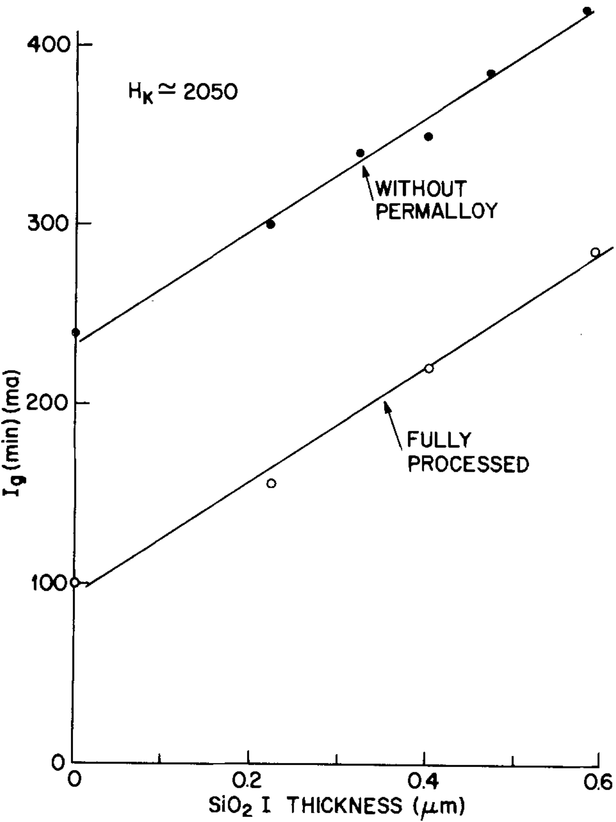

Fig. 3. Plots of the minimum generator current measured on fully processed wafers (and the same wafers after the Permalloy had been etched off) vs. the plasma deposited SiO_2I (Prespacer) thickness.

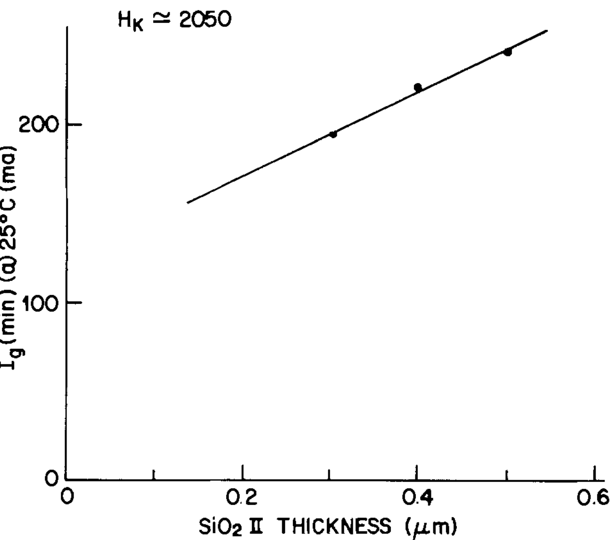

Fig. 4. A plot of the minimum generator current measured for fully processed wafers vs. the plasma deposited SiO_2II (Insulator) thickness.

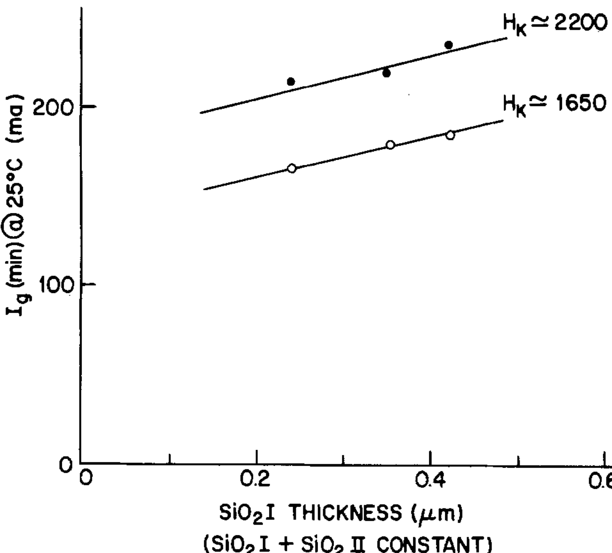

Fig. 5. Plots of the minimum generator current measured for fully processed wafers vs. variable conductor spacing but constant Permalloy to garnet spacing.

in Fig. 5. In this case, the spacing sensitivity that is measured ($\Delta I_g/\Delta SiO_2I \sim 10$ mA/1000Å of SiO_2) is small, because the Permalloy-conductor field interaction increases and offsets the effects due to the increased conductor to garnet spacing (SiO_2I). This result can be useful in device production since it gives a means to make real time compensations in SiO_2II thicknesses to correct for erroneous SiO_2I deposition thicknesses. However, it is preferred that both SiO_2I and SiO_2II be controlled independently since other device functions also depend on the thicknesses of the insulating layers.

To measure the magnitude of the Permalloy-conductor field interaction, the Permalloy elements were etched off the wafers in which the thicknesses of the SiO_2I were varied. The results of the conductor-only I_g(min.) measurements are shown in Fig. 3. It is seen that at all SiO_2I thicknesses that the conductor-only I_g(min.) values are substantially higher (~130 mA) than those measured for the standard structure. Thus, the Permalloy-conductor interaction that acts to "intensify" the magnetic fields generated in the garnet is significant and should be considered for all current-controlled functions.

To test the sensitivity of the Permalloy pattern placement with respect to the hairpin conductor loop. a wafer was rotationally misaligned. Photographs of the various misalignments that were obtained and the I_g(min.) values that were measured are shown in Fig. 6. Inspection of the data shows that the values of I_g(min.) do not vary significantly unless the overlay Permalloy element is pulled back from the end of the hairpin loop such that the Permalloy to garnet spacing is increased by the conductor thickness (5000Å). At this point, the measured values of I_g(min.) increase abruptly by approximately 75 mA. Thus, the placement of the Permalloy pattern over the hairpin loop can be critical. In production it has been found that a coded 2 μm overlap is sufficient to cover the ±1 μm misalignments that are encountered.

Bias Field Operating Margin Measurements

The same variables that affect the values of the minimum generator current can also affect the strength of the interaction between magnetic domains and the stress field gradients associated with the overlaying circuit structure. The results of bias field margin measurements, in which the high ends of the margins are limited by stress field interactions, are discussed in this section.

To determine the effects of the uniaxial anisotropy field, H_k, on bias margins, a number of device batches with low and high H_k wafers were processed with major-minor loop circuit structures such as those described by Bonyhard *et al.* (16). The geometric configuration of the gate regions for the read and the write lines are shown in Fig. 7 and 8, respectively. The full function bias margins that were measured at 70°C for both 35 and 45 oe rotating drive fields at 100 kHz are listed in Table III. For a given wafer batch, it is seen that higher bias field margins are consistently measured for the wafers with the higher H_k values. These results are consistent with the work reported by Dishman *et al.* (17) in that the strength of the interaction between bubbles and the stress field gradients associated with the overlay circuit structure is predicted to decrease with increasing H_k values.

The different bias field margins that were measured for a given H_k material between different device lots were interpreted to be due in part to exposure of the different wafer batches to different maximum processing temperatures. As described in the previous section, higher processing temperatures lead to larger stress-field interactions due to the increased stress of the Al-Cu metallization. This effect is more clearly demonstrated with the data presented in Fig. 9. For this experiment, the bias field operating margins of the replicator function (Fig. 7) were measured at 70°C on an as-processed wafer, and after it had been given subsequent anneals at 400° and 450°C. While it appears that the annealing causes a low end margin loss, this is not the case. Post-process annealing affects the ion implanted layer as well as the stress of the Al-Cu metallization.

Independent annealing experiments on various implanted wafers have shown that annealing causes the stability range of the bubbles to shift uniformly with the increase in the free bubble collapse field. The magnitudes of these shifts are determined by the implant conditions and the time and the temperatures of the anneals (18). Thus, the apparent low end bias margin losses seen in Fig. 9 are in reality due to the combined effects of: (*i*) a shift of the bubble stability range to higher bias fields (implant anneal) and (*ii*) an increased stress field interaction that costs high end margin losses that are proportional to the stress field interaction.

The dielectric levels overlaying the conductor metallization will also contribute to the stress field gradients found at conductor edges. From elementary line edge stress theory (19), it can be shown that compressively stressed dielectric films will enhance the stress fields associated with a tensile-stressed conductor level whereas tensile-stressed dielectrics will reduce or "balance-out" these stress fields. To determine the magnitudes of these effects in this investigation, bias field margins were measured before and after various dielectric passivations and for various combinations of stressed insulator and prespacer levels with the standard tensile-stressed Al-Cu metallization.

Table III. Average measured minimum generator currents and bias field margins for various processed wafer batches

Batch	No. of wafers	H_k (oe)	$\langle I_g(\text{min.})\rangle$ (mA)	$\langle \Delta H \rangle$ (oe)
1	4	2600	186	13.1
1	3	1900	148	10.1
2	3	1920	153	17.5
2	3	1600	132	14.4
3	3	2000	163	13.9
3	3	1770	142	11.0

5	3	1500	126	10.8
6	2	2300	171	15.3
6	3	1900	152	14.8

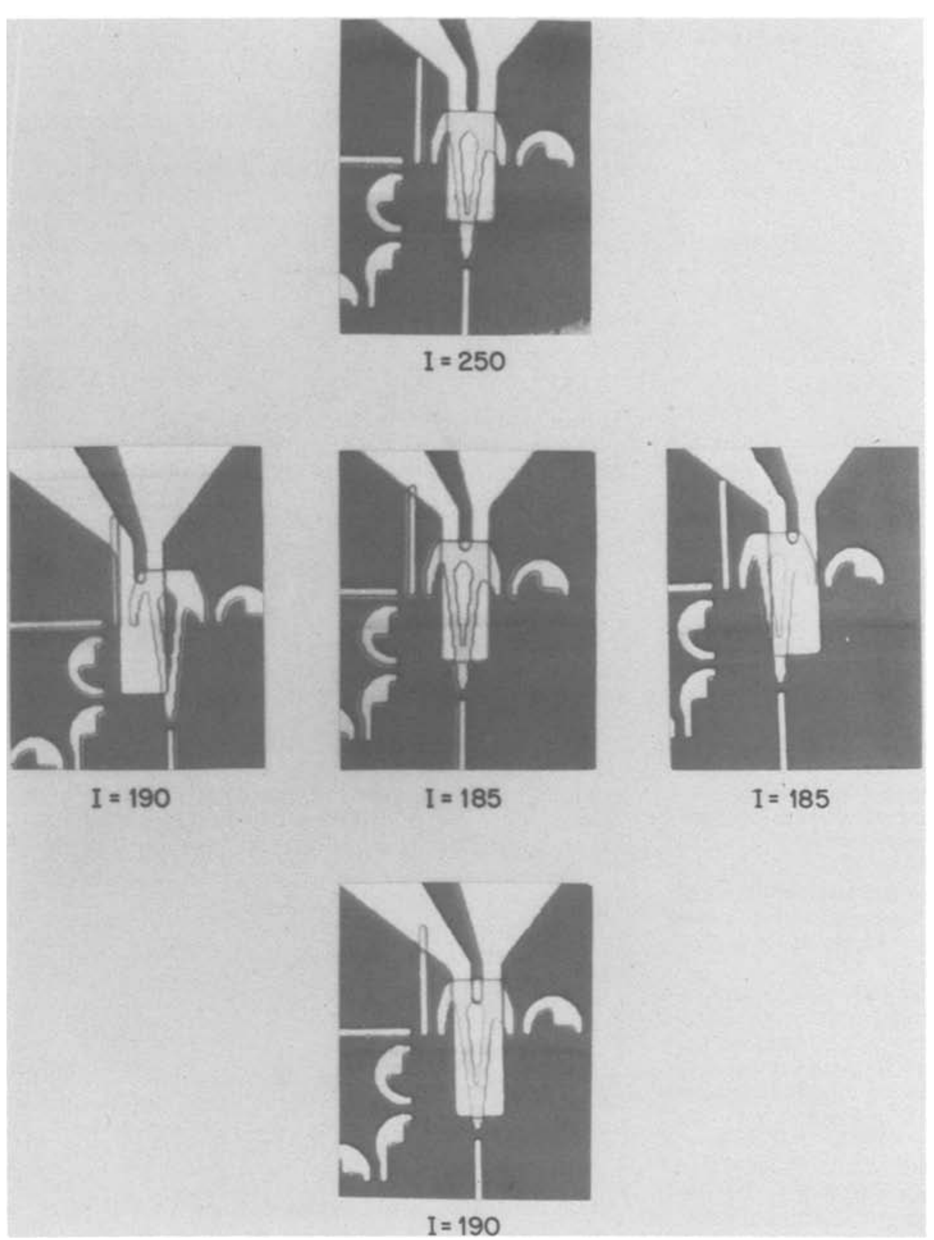

Fig. 6. Photomicrographs of different Permalloy to conductor pattern misalignments and the corresponding minimum generator currents that were measured.

The results that were obtained when highly compressive plasma-deposited SiN films (-7×10^9 dynes/cm^2) were used to passivate circuits using write gates such as those shown in Fig. 8, are shown in Table IV. It is seen that the stress interaction roughly scales

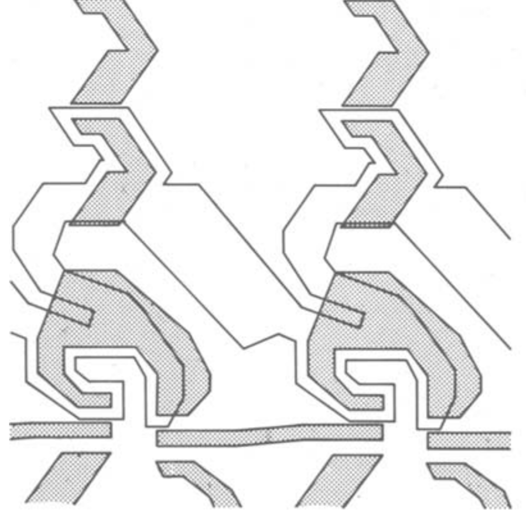

Fig. 7. The replicator gate design

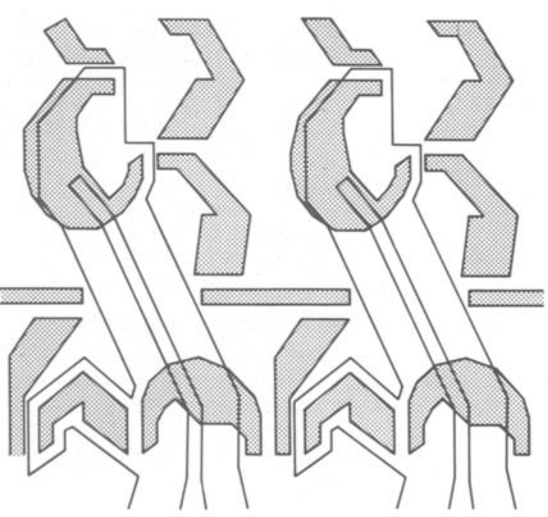

Fig. 8. The write line (swap gate) design

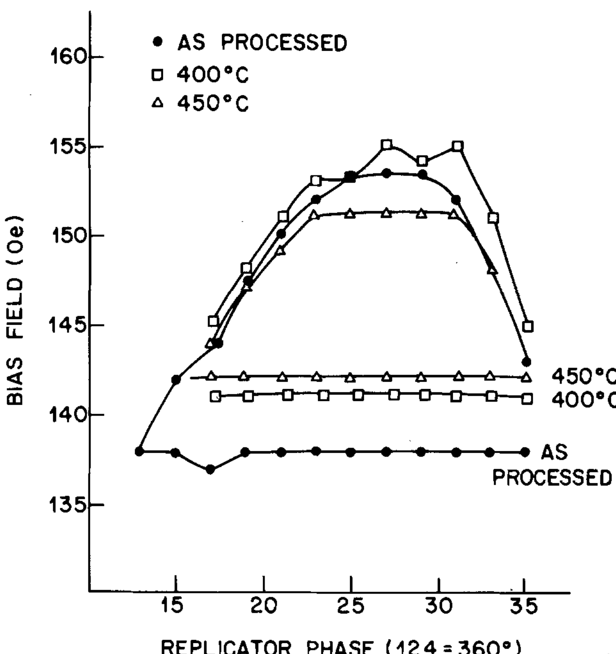

Fig. 9. Plots of the bias field margins measured for fully processed wafers vs. the phase of the replicator pulse and the maximum temperature to which the wafers were exposed during processing or subsequent annealing.

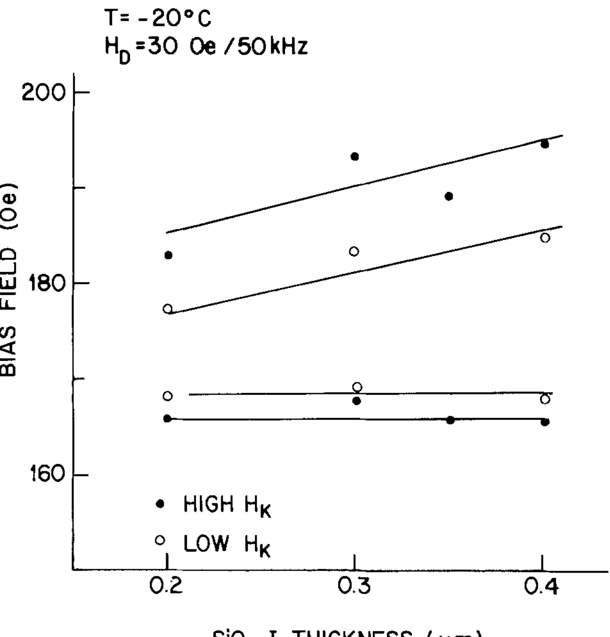

Fig. 10. Plots of the bias field margins measured for fully processed wafers vs. the rf sputtered SiO_2I (Prespacer) thickness. The data for two different values for the uniaxial anisotropy of the epitaxial garnet films are shown.

with the thickness of the stressed SiN film and that the full bias field margins are recovered when the SiN is stripped off. The failure mechanism that is observed is bubble hang-up on the leading conductor edge until the rotating field causes the minor loop pickup element to become attractive. Then the bubble is spontaneously transferred into the minor loop. (No blocking current was applied to the conductor.)

The bias field margins that were measured when different stress levels were used for the insulator level (SiO_2II) are listed in Table V. Analysis of the data shows that the best operating bias margins were obtained when the stress of the dielectric level was tensile and tended to "balance" the tensile stress of the Al-Cu metallization. Similar results have been reported by Roman *et al.* (20). However, since a routine process for obtaining tensile-stressed dielectric films has not been developed, the general procedure to date has been to utilize low stressed SiO_2 films, to minimize Al-Cu metallization stress buildups by using low temperature processes and to minimize stress field gradients by taper-etching the conductor metallization.

Table IV. Average bias field margins measured for different device structures (with and without passivation)

Device structure	Average bias margins At H_D = 45 oe	Average bias margins At H_D = 35 oe
SiO_2I/Al-Cu/SiO_2II/Permalloy (no passivation)	21.8	13.8
Above with 1200A of SiN(C)	21.5	13.4
Above with another 1.2 μm of SiN(C)	16.4	7.1
SiO_2I/Al-Cu/SiO_2II/Permalloy (SiN stripped off)	22.4	13.4

Table V. Average bias field margins measured for device structures with different plasma deposited SiO_2II (Insulator) stress levels

Wafer*	Structure**	Plasma deposited SiO_2II (Insulator) stress ($\times 10^9$ dynes/cm^2)	Average bias field margins (oe) At H_D = 35 oe	Average bias field margins (oe) At H_D = 45 oe
3409B2	SiO_2(C)/SiN(T)	+2.0	13.5	20.9
3346B2	SiO_2(C)/SiN(T)	+0.2	12.1	18.4
3703C2	SiO_2(C)/SiO_2(C)	−2.0	12.2	18.9
4310D1	SiO_2(C)/SiN(C)	−5.0	10.8	16.1

* Note: These are not "matched" H_k wafers.
** (T) Tensile stress. (C) Compressive stress.

To determine the effects of increasing the spacing between the Al-Cu conductor metallization and the garnet film, two sets of matched H_k wafers in which pairs of low H_k and high H_k wafers were processed with different SiO_2I thicknesses but constant garnet to Permalloy spacings. The bias field margins that were measured at −20°C (where the stress interaction is strongest) are shown in Fig. 10. It is seen that improved bias margins are measured both for increased SiO_2I thicknesses and for wafers with higher H_k values.

Conclusions

The results reported in this paper show the importance of accurate process control, particularly with respect to temperature, and the need to include a specification for the uniaxial anisotropy field in a list of the epitaxial film property requirements. These considerations are important not only in manufacture for obtaining more consistent device operation but also when any new device designs or processing techniques are developed. In the latter cases, the maximum use of batch processing at all fabrication steps (except the one being tested) and the use of "matched" H_k wafers (preferably from the same growth dip) minimize any possible erroneous conclusions that could be obtained when test results are compared.

ABSTRACT

The redistribution of the compensating dopants, iron or chromium, in semi-insulating indium phosphide has been studied using secondary ion mass spectrometry. Annealing with silicon nitride encapsulation results in impurity accumulation within the first 1000Å of the surface followed by depletion extending to a depth of ~1 μm. Profiles resulting from the implantation of "neutral" elements (He, B) exhibit accumulation at the surface and also accumulation at the projected range peak. The profiles are explained in terms of gettering of the compensating dopant to defect-rich regions.

InP and its related alloys are attracting considerable attention due to their applications in microwave and optoelectronic devices. Semi-insulating InP is extremely important in the fabrication of such devices because it can serve as a substrate for the subsequent growth of an epitaxial device layer, and it can provide the necessary device isolation when implantation directly into the material itself is employed. Whereas presently almost all semi-insulating GaAs is undoped or chromium-doped, semi-insulating InP can be obtained by doping either with chromium or iron. Cr has a much lower solid solubility in InP than in GaAs, which necessitates the use of high purity starting material to achieve high resistivity (1). Since such purity in InP is still not routinely obtained, Fe, which has a higher solid solubility in InP than does Cr, is being used as an alternative in the growth of semi-insulating InP (2, 3). Recently, a number of studies have shown the redistribution of Cr in annealed GaAs (4-6) and in implanted GaAs (7, 8). We report here the redistribution of the bulk compensating dopants, Fe or Cr, in annealed and implanted semi-insulating InP.

Experimental Methods

The (100) semi-insulating InP used in this work was grown by the liquid-encapsulation Czochralski (LEC) method at the Naval Research Laboratory (9). The Fe-doped material had a resistivity $\rho \sim 1 \times 10^7$ Ω cm, and the Cr-doped material had $\rho \sim 5 \times 10^3$ Ω cm. Implantations were performed at room temperature with the sample normal inclined 7° from the incident beam to minimize channeling effects. The encapsulant employed to suppress thermal degradation during annealing was an essentially oxygen-free Si_3N_4 (10), rf plasma-deposited at 350°C to a thickness of ~2300Å on both sides of the sample. All samples were annealed in a silica furnace tube with a flow of 200 cm^3/min of desiccated forming gas (4% H_2 in N_2). Following the anneals, the Si_3N_4 encapsulant was removed in electronic grade HF and the samples were rinsed in deionized water and standard solvents.

Impurity profiles were measured by secondary ion mass spectrometry (SIMS) using the CAMECA IMS-3f ion microscope. The O_2^+ primary beam (7.7 keV impact energy) was rastered over areas of ~250 μm^2 and standard precautions were taken to reject spurious signals arising from the crater walls. A Sloan Dektak

stylus instrument was used to measure the resultant crater depths. These measurements together with the assumption of a constant sputtering rate were used to convert the time scale to a depth scale. Our experience and that of others (8) show the uncertainty in such measurements to be ±5-6%. The concentration scales for Fe and Cr were obtained from a standard prepared by implanting Fe and Cr into semi-insulating InP. The conversion factor relating ion intensity to concentration was corrected for background effects in the standard. In this manner we determined the background concentrations in these samples to be: Cr, 6.5×10^{16} cm^{-3}; Fe, 8.1×10^{16} cm^{-3}.

Redistribution Resulting from Annealing

Figures 1 and 2 exhibit the profiles of Fe and Cr resulting from annealing the substrates with an Si_3N_4 cap. With the exception of a large Fe accumulation within the first 1200Å of the surface, the Fe profile in the 550°C, 30 min anneal is otherwise indistinguishable from the unannealed profile. This is not true of the profile resulting after a 800°C, 30 min anneal. Again, an Fe accumulation region with a maximum concentration of $\sim 4 \times 10^{17}$ cm^{-3} extends from the surface to a depth of ~1000Å. However, following this zone is an Fe depletion region. This broad, flat-bottomed region originates within 1000Å of the surface and returns to the normal background level at a depth of ~1.2 μm. The minimum Fe concentration within this region is $\sim 1.4 \times 10^{16}$ cm^{-3}.

The redistribution of Cr resulting from annealing differs significantly from that of Fe. As with Fe there is no evidence of major redistribution resulting from a 550°C, 30 min anneal. Qualitatively, the Cr profile after a 800°C, 30 min anneal is similar to that of Fe, in that

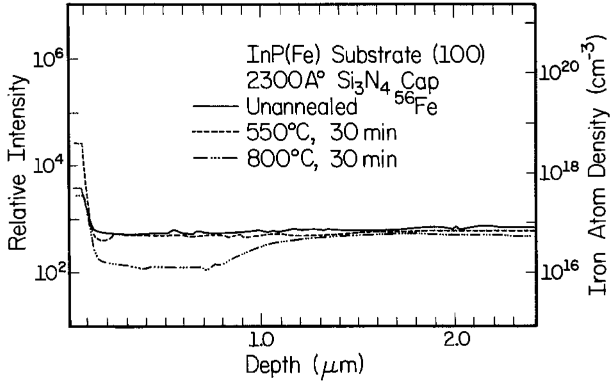

Fig. 1. SIMS profiles of Fe in a semi-insulating InP substrate following 30 min anneals at 550° and 800°C with an Si_3N_4 encapsulant.

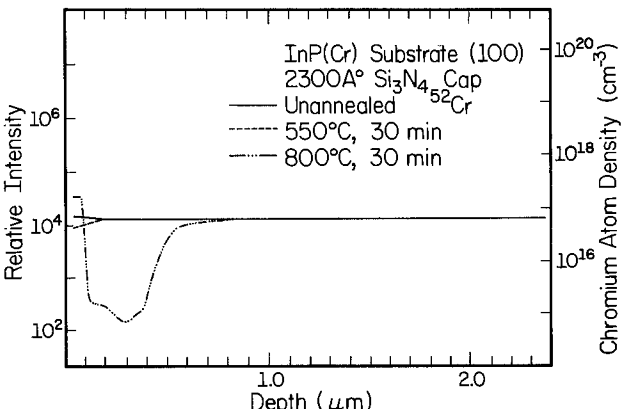

Fig. 2. SIMS profiles of Cr in a semi-insulating InP substrate following 30 min anneals at 550° and 800°C with an Si_3N_4 encapsulant.

a surface accumulation region and a depletion zone appear. The surface accumulation zone ends at a depth of ~1000Å, while the Cr depletion region extends to a depth of ~8000Å. The minimum Cr concentration within this region is $\sim 9.2 \times 10^{14}$ cm^{-3}. Although redistribution of Cr occurs over a region of ~8000Å *vs.* ~12,000Å for Fe, Cr redistribution is more severe in the sense that the concentration of the compensating dopant is an order of magnitude lower in the depletion zone than in Fe-doped substrates.

The depletion regions observed in the Fe- and Cr-doped substrates are in keeping with reports of conductive surface layers following thermal annealing of InP substrates (11, 12). Additionally, the redistribution is very similar to recent reports of Cr migration in annealed GaAs substrates (4-6, 8). Originally, the accumulation and subsequent depletion regions of Cr in GaAs were speculated to be due to a strain-induced effect caused by the thermal mismatch between the encapsulant and the GaAs (7). However, recent work by Vasudev *et al.* (8), indicates the Cr redistribution in GaAs is not significantly influenced by the encapsulant and is in fact larger under capless anneal conditions. Moreover, Kasahara and Watanabe (6) reported that Cr redistribution in GaAs is controlled by the partial pressure of arsenic during the anneal, which confirms an early observation by Tuck *et al.* (4) concerning the role of As overpressure with relation to Cr redistribution. At present, therefore, it appears that the best explanation of Cr redistribution in GaAs is the gettering of Cr to surface regions which have high concentrations of defects introduced either by annealing or by mechanical damage (13). There is reason to believe that the same relationship between defects and compensating dopant also explains our results in InP. It is unclear at present what importance should be attached to the quantitative differences observed between Fe and Cr redistribution profiles in InP. Possibly the differences can be explained in terms of the surface solubility and original background density of the compensating dopant, as suggested by Vasudev *et al.* (8). Furthermore, differences between Cr and Fe outdiffusion into the Si_3N_4 cap must be considered. Obviously further work is needed to determine if important differences do indeed exist between Fe and Cr redistribution in InP as our results suggest.

Redistribution Resulting from the Implantation of Neutral Dopants

Impurity gettering to damaged (*i.e.*, vacancy-rich) regions produced by ion implantation is often observed in Si (14, 15) and in GaAs (7, 8, 16, 17). In this section we report the gettering of Fe and Cr to damaged regions produced by the implantation of electrically neutral species in semi-insulating InP. Helium was chosen as one such species because it should remain electrically and chemically inactive in the crystal, thereby having no effect on the compensating dopants except for the damage it creates. It is possible for "gas bubbles" or voids to form by the diffusion of insoluble gas atoms to nucleation sites (18, 19). To rule out redistribution due to the possible presence of such voids, we implanted a nongaseous element, boron. We assume that boron fills column III sites, and is therefore electrically inactive in the crystal (although the possibility of chemical activity cannot be completely ruled out).

An He fluence of 1.06×10^{15} cm^{-2} was implanted into the samples at 51 keV and 0.5 μA scanned current. Under these conditions the LSS projected range is 3640Å with the profile of energy deposited into nuclear collisions peaking at ~3200Å (20). Figures 3 and 4 show the Fe and Cr profiles, respectively, resulting from 30 min anneals of He-implanted InP. As in the previously discussed unimplanted samples, a surface accumulation zone exists within the first 1000Å for both types of compensating dopants. Surface accumulation of Fe is much more pronounced than that of Cr,

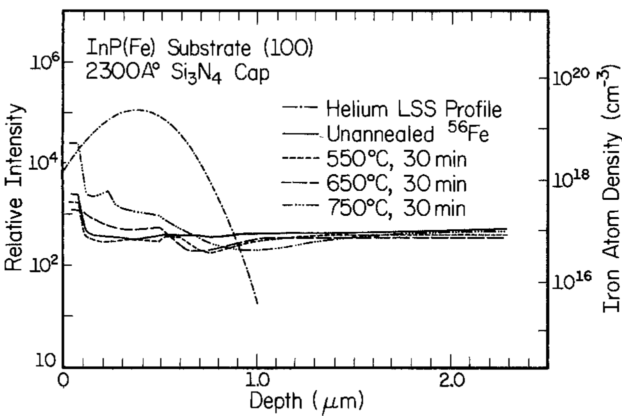

Fig. 3. SIMS profiles of Fe in a semi-insulating InP substrate implanted with He (1.06 $\times$ 10^{15} cm^{-2}, 51 keV) and annealed for 30 min at the indicated temperatures with an Si_3N_4 encapsulant.

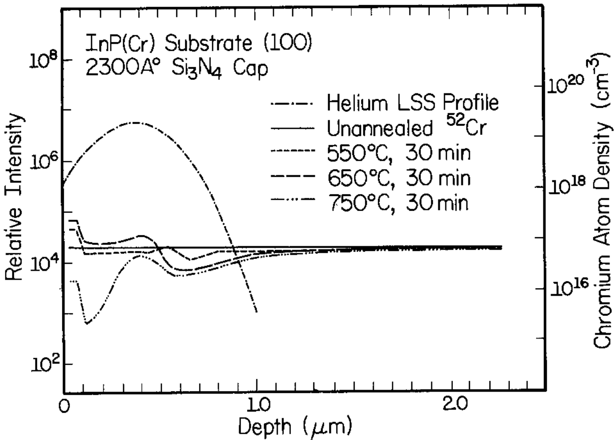

Fig. 4. SIMS profiles of Cr in a semi-insulating InP substrate implanted with He (1.06 $\times$ 10^{15} cm^{-2}, 51 keV) and annealed for 30 min at the indicated temperatures with an Si_3N_4 encapsulant.

which is also consistent with our previous results. However, unlike the profiles in the unimplanted samples, we find in the He-implanted samples an accumulation region followed by a depletion region rather than broad depletion regions extending to ~1 μm. It is clear that both Fe and Cr accumulate in a region about the projected range of He. The 550°C, 30 min anneal profiles show little restructuring except for small depletion regions on the bulk side of the projected range peak. The 750°C, 30 min annealed Fe-doped sample has an accumulation zone with a concentration of ~2.6 $\times$ 10^{17} cm^{-3} and a depletion zone with a concentration of ~3.4 $\times$ 10^{16} cm^{-3}. The Cr-doped sample annealed under identical conditions shows even larger variations of concentration in the various regions.

Boron was implanted at 126 keV and 0.5 μA to a fluence of 6.8 $\times$ 10^{14} cm^{-2} in Fe-doped InP substrates. The LSS projected range is 3640Å and the damage profile peaks at ~2890Å (20). The as-implanted boron profile obtained by SIMS is shown in Fig. 5. As in the 550°C profiles of He-implanted Fe-doped InP, an Fe depletion zone is formed on the bulk side of the projected range peak with a minimum Fe concentration of ~1.6 $\times$ 10^{16} cm^{-3}. Accumulation of Fe into the implant region and toward the surface is evident in the 650° and 750°C anneals. The qualitative similarities between the redistribution of Fe in the He- and B-implanted samples appears to indicate that we are observing the gettering of the compensating dopant by implant related defects rather than diffusion due to gas voids or chemical effects.

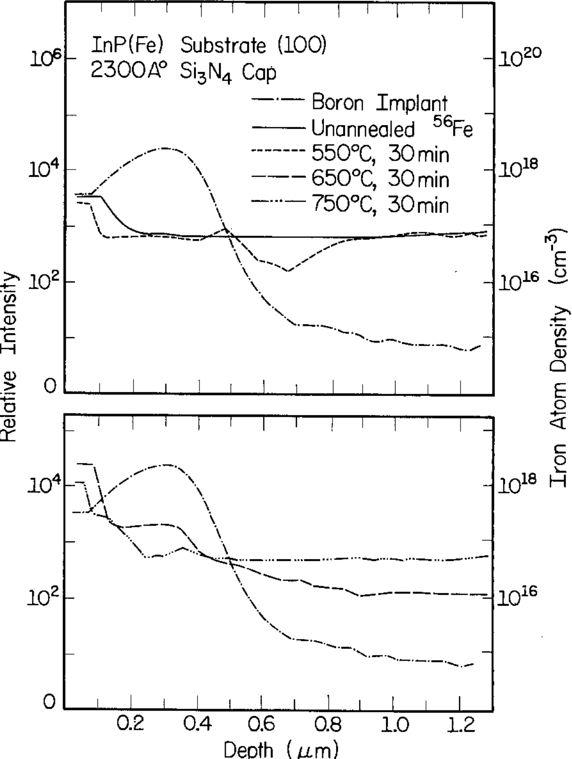

Fig. 5. SIMS profiles of Fe in a semi-insulating InP substrate implanted with B (6.8 $\times$ 10^{14} cm^{-2}, 126 keV) and annealed for 30 min at the indicated temperatures with an Si_3N_4 encapsulant.

Conclusions

We have studied the redistribution of the compensating dopants Fe or Cr in semi-insulating InP, resulting from annealing only and from the implantation of electrically inactive elements. Annealing with an Si_3N_4 cap forms an accumulation region within the first 1000Å of the surface followed by a depletion region extending to a depth of ~1 μm. Cr profiles exhibit larger concentration gradients under these conditions than do Fe profiles. Profiles resulting from the implantation of "neutral" dopants exhibit surface accumulation regions followed by accumulation regions under the projected range peak.

We believe these results can be explained by the gettering of the compensating dopant to defect-rich regions. In the case of simple anneals, a defect-rich region is produced at the interface which getters Fe or Cr, leading to the accumulation and depletion zones observed. This same mechanism is probably responsible for the surface accumulation regions observed in the implanted profiles. However, where the annealed-only profiles exhibit depletion regions, implant profiles show accumulation regions. Since this accumulation occurs in the implanted region, we presume this effect to be due to gettering of the compensating dopant to defect regions produced by the implantation. By implanting electrically and chemically inactive impurities, we believe we have excluded the possibility of redistribution arising from effects other than those related to implant damage.

Two-Phase Annealing of Single Crystal CdS

J. W. Sherohman

Lawrence Livermore National Laboratory, University of California, Livermore, California 94550

ABSTRACT

Single CdS crystals of low resistivity have been converted to high resistivity material by annealing them in the presence of a two-phase system consisting of a CdS solid and a liquid rich in sulfur. Ambient temperature measurements of dark d-c resistivity indicated that resistivity values greater than 10^{13} Ω cm were obtained.

The possibility of applying electro-optics to the design of tunable filters has resulted in an interest in producing CdS crystals in the form of a thin plate of high resistivity ($>10^{12}$ Ω cm). Crystals of CdS having high resistivity have been grown by the vapor transport technique (1-6). However, due to the sensitivity of the electrical conductivity to the partial pressures of Cd and S during growth of CdS crystals (7, 8), it is often difficult to consistently produce material having very high resistivity. A study has shown that annealing can be used to convert single crystal CdS material of low resistivity ($<10^2$ Ω cm) to that of high resistivity ($>10^{13}$ Ω cm). The method developed uses a controlled vapor-phase heat-treatment to produce thin CdS plates with high resistivity by annealing them in the presence of a two-phase system of solid CdS and a sulfur-rich liquid.

Annealing in the presence of a multi-phase system is a method to control the stoichiometry of a compound having a single phase width (9-11). However, in the case of influencing the electrical conductivity, and hence resistivity, the purpose of a controlled atmosphere of Cd and S surrounding the CdS crystalline material is to insure that the neutral vacancy concentrations of both Cd and S remain essentially unchanged (*i.e.*, there is no self-diffusion) while, at the same time, existing charged defects proceed to an equilibrium state through chemical diffusion.

Key words: resistivity, chemical diffusion, stoichiometry.

Experimental

A two-phase compound was prepared by arbitrarily mixing 140g of CdS powder with 40g of sulfur in a quartz ampul. The mixture was then heated with a hot-air gun until the sulfur liquefied and reacted with the CdS. The ampul was vacuum sealed and heat-treated for 2 hr at 300°C. The furnace temperature was then raised at 200°C/hr to a temperature of 900°C and held there for 24 hr. The ampul was cooled in the furnace and the resulting compound was used as the two-phase material for the annealing of as-grown single crystals of CdS.

Single crystals of CdS grown by the vapor phase transport technique were oriented and sawed in the direction of the c-axis of the crystal. The sawed plates were lapped, polished, cleaned in perchloroethylene and HCl, and then given a deionized water and an acetone rinse. At ambient temperature, measurements of the dark d-c resistivity of the prepared sample were taken in a guard-ring configuration using ohmic contacts provided by an In-Ga alloy. Data are included in Table I.

The two-phase material (CdS + S) and single crystal CdS samples were placed in separate quartz tubes

Table I. Resistivities of single crystals of CdS before and after two-phase annealing

Sample	Resistivity before annealing (Ω cm)	Heat treatment	Resistivity after annealing (Ω cm)
5-30-6	2.5	900°C for 5 min	3.0×10^{15}
5-30-6	2.5	900°C for 5 min	2.8×10^{15}
3-2-18	9.8	900°C for 35 min	6.9×10^{15}
3-23-19	15.9	900°C for 2 hr	6.7×10^{13}
6-15-18	2.5	900°C for 112 hr	7.8×10^{13}
11-29-7	0.82	900°C for 115 hr	5.3×10^{13}

designed to fit together by ground points (see Fig. 1). The ground joints permitted the quartz tubes to be reused. The tubes, after being connected, were inserted inside a quartz ampul 4 cm in diameter by 23 cm long. Ampuls were subsequently sealed in vacuum and annealed at 900°C for various periods of time. After furnace cooling to ambient temperature, the inner tubes were removed from each ampul. The single crystal samples were again cleaned and their d-c resistivity in a dark environment was measured.

Results and Discussion

The dark d-c resistivities of the samples, measured at ambient temperatures, before and after annealing are given in Table I. All samples showed marked increases in resistivity, to values greater than 10^{13} Ω cm. Figure 2 shows the variation of resistivity with time in a dark environment for two samples of different thickness. Both samples had been heat-treated at 900°C for 5 min. The resistivity curves of the samples are essentially identical. Other samples annealed for longer times at 900°C had resistivities that were also very high, but not as high as samples annealed for 5 min.

A two-phase annealed sample that was heat-treated at 900°C for 5 min is compared in Fig. 3 with that of a high resistivity CdS crystal obtained from Cleveland Crystal Company, Cleveland, Ohio. The two-phase annealed sample had the same resistivity behavior as the Cleveland crystal sample, but reached a higher maximum resistivity.

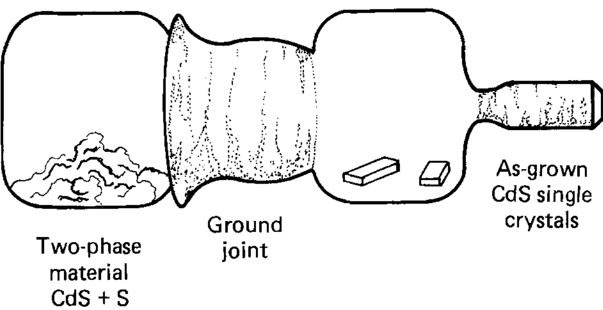

Fig. 1. Quartz apparatus for the two-phase annealing of CdS single crystals.

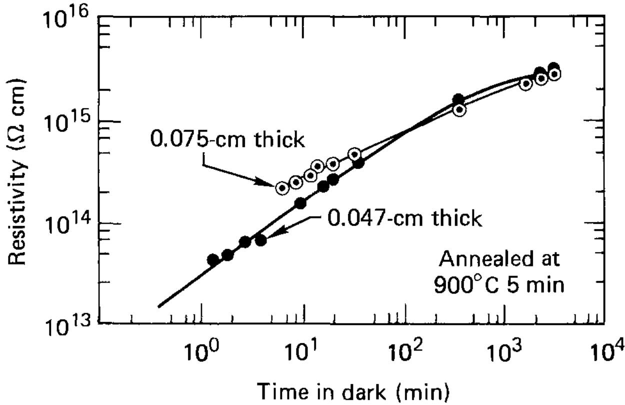

Fig. 2. A comparison of the d-c dark resistivity of two samples of different thickness that had been two-phased annealed for 5 min at 900°C.

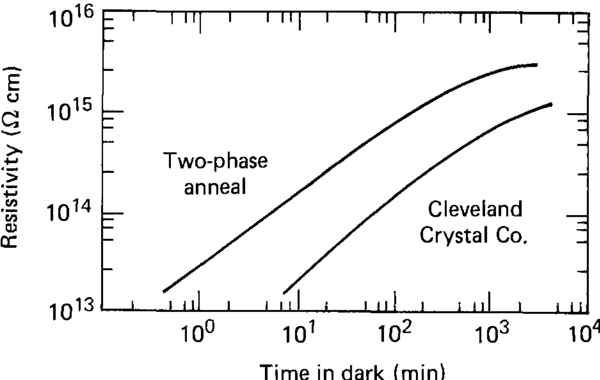

Fig. 3. A comparison of the d-c dark resistivity of a two-phase annealed sample with that of a high resistivity sample obtained from Cleveland Crystal Company, Cleveland, Ohio.

The atmosphere in which the single crystal samples of CdS were heat-treated is fixed by the two-phase mixture. As long as the two phases are present, the mixture provides a constant partial pressure of both Cd and S. These fixed partial pressures, if given enough time, will force the stoichiometry of a CdS crystal to the sulfur-rich side of its single-phase width. At that point the partial pressure of Cd and S above the crystal equals the partial pressure of Cd and S generated by the two-phase mixture. The crystal remains single phase with its stoichiometry fixed by the sulfur-rich side of the single phase width. However, this occurs by a slow self-diffusion process. The purpose of the two-phase mixture is to insure that the neutral vacancy concentrations of both Cd and S in the CdS crystals remain essentially unchanged for various time period anneals.

The electrical conductivity of CdS can be affected by chemical diffusion of existing charged defects (12-14). Chemical diffusion, which does not depend on the product of the diffusivity and concentration of the defect, is a rapid diffusion process as compared to self-diffusion (15). It has been suggested that in the presence of high activity of sulfur (low P_{Cd} condition), the diffusion of S is controlled by neutral interstitials, while the diffusion of Cd is controlled by ionized cadmium vacancies, V_{Cd}'' (13). If it is assumed that the chemical diffusion process is controlled by V_{Cd}'', the chemical diffusion coefficient would be on the order of $D_{V_{Cd}''}$, where $D_{V_{Cd}''} = D_{Cd}^*/(V_{Cd}'')$. D_{Cd}^*, the tracer diffusivity of Cd, has been observed at 900°C under a low P_{Cd} condition to have a value of approximately 10^{-11} cm^2 sec^{-1} (12, 13). The (V_{Cd}'') at this temperature, as given in Ref. (13), is on the order of 10^{-8} site fr. for $P_{Cd} = 10^{-5}$ atm. This indicates that D_{chem} is in the range of 10^{-4}-10^{-3} cm^2 sec^{-1} and that chemical diffusion of existing defects would occur in less than a minute within a 1 mm thick sample at 900°C. The very high resistivity of the samples after a heat-treatment of 5 min suggests the presence of a fast chemical diffusion process.

The major finding of this study is that by annealing as-grown, single crystal CdS material in an atmosphere fixed by a two-phase mixture consisting of solid CdS and a sulfur-rich liquid, resistivity of the material can be raised by more than ten orders of magnitude.

Acknowledgments

The author would like to thank B. Corson for making the d-c resistivity measurements, C. Seeger for growing the CdS single crystals, and C. Wiersma and J. Stevens for preparing the samples. This work was performed at Hughes Aircraft Company, Industrial

Products Division, Carlsbad, California.

Desalination by Photoelectrodialysis. II.

George W. Murphy*,[1]

Solar Energy Research Institute, Golden, Colorado 80401

ABSTRACT

Continuing experiments on photoelectrodialytic desalination now include the addition of a cell buffer compartment to keep unwanted ions leaking through imperfect membranes from contaminating the product water, different membranes, and thin film polycrystalline n-CdSe electrodes in sulfide/polysulfide electrolyte. Both the rate and extent of desalination have been markedly improved. Economic feasibility projections are updated.

A laboratory demonstration of photoelectrodialytic desalination was recently announced (1); the symbolic representation of the 4-compartment cell employed is

n-GaAs/0.16M Na_2Se,0.02M Na_2Se_2-C-0.06M NaCl(2)
| A
Pt/0.16M Na_2Se,0.02M Na_2Se_2-C-0.06M NaCl(1)

where C is a cation and A an anion selective membrane. Irradiation of the n-GaAs leads to desalination of compartment 1 and salt enrichment in 2. In this communication we furnish additional experimental details, extend the experimental investigation in several ways, and assess the economic potential. Photoelectrodialytic desalination is one of several model systems which couple a photoelectrochemical driving unit through ion selective membranes to cell components containing raw materials and deliver a useful product (2).

Experimental

Construction features for all experimental cells are illustrated by the 4-compartment cell drawing in Fig. 1, other details of which are given in Ref. (1). In this cell product water is subject to selenide ion contamination because of imperfect selectivity of the membrane separating the two solutions. One remedy for this problem is the introduction of a fifth "buffer" compartment as illustrated schematically in Fig. 2. Contamination of this compartment can occur, but the reject salt solution contained is swept out at a rate sufficient to keep the product water contamination free.

Another problem encountered in early work was makeup of the selenide solution. Colorless alkali metal selenides are extremely air sensitive, forming orange-

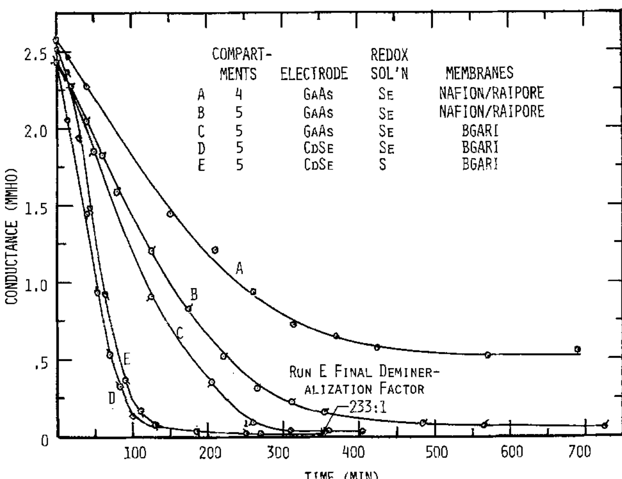

Fig. 3. Results of five desalination experiments

brown polyselenide. Cerac Chemical Company 99.9% Na_2Se packed under argon formed an optically dense aqueous solution even with nitrogen atmosphere glove box technique. Consequently the solution employed in the first desalination experiment (1) contained an unknown but considerably larger amount of diselenide than the "made-up" 0.02M. The principal effect is to decrease the amount of light reaching the electrode, therefore decreasing the desalination performance. Selenide solutions employed subsequently were made by bubbling H_2Se (Scientific Gas Products) through alkali metal hydroxide solutions (3). The amber color of the resulting solution was caused by traces of air during transfer operations. No elemental selenium was added. The solution employed in subsequent desalination experiments is designated 0.18M Na_2Se,(Na_2Se_2), instead of 0.16M Na_2,0.02M Na_2Se_2.

Two sets of membranes were employed: Nafion 417 9G-3009 cation (du Pont) and Raipore 5035 anion-selective [RAI Research Corporation 5035 has essentially the same properties as 5025 employed in Ref. (1)]; and Ben Gurion University of the Negev Applied Research Institute (BGARI) cation- and anion-selective, obtained through the courtesy of Prof. Chaim Forgacs. Preparation of the latter membranes has been described by de Körösy and Schorr (4).

In addition to the single crystal n-GaAs electrode described previously (1), a thin film polycrystalline n-CdSe disk electrode was received from Weizmann Institute of Science, Israel (5) for testing. This electrode had been deposited on a titanium disk substrate, to which we cemented with silver epoxy a brass counterelectrode. The Hodes etching procedure (5) was followed prior to photodesalination experiments. This electrode was coupled first with the 0.18M Na_2Se (Na_2Se_2) and later with 0.1M Na_2S,0.1M Na_2S_2 redox electrolyte solutions.

In desalination experiments fresh 0.06M NaCl solution from an overhead reservoir was run sequentially through the "buffer" and the salt-enriched compartments at a rate of about 1 ml/min. A peristaltic pump (Scientific Industries Model 700) circulated solution via a closed loop between the two selenide (or sulfide) ion compartments at a rate of about 1 ml/min.

Results

The results of several desalination experiments are graphed in Fig. 3. Curve A is from Ref. (1). The improvement shown in curve B is due both to the elimination of product water contamination and the reduction of solution light absorption. The further improvement shown in curve C is due to the higher conductivity of BGARI membranes. Curves D and E are impressively still better, due probably to the lower overall resistance of the electrode assembly. The excellent performance shown in curve E is particularly important, because it proves that selenide can be replaced by a cheaper and less obnoxious solution.

The economic potential of photoelectrodialytic desalination has been examined briefly (2); it was concluded that about \$35 m^{-2} could be afforded for cell construction as a generally applicable method for desalting brackish water, based on assumed 7% light to electric energy conversion, 10 year lifetime, and \$0.28 m^{-3} product water. Adjusted for inflation, this figure would now be about \$50 m^{-2}. However, there are potential remote installations that could justify an expenditure several times higher, and the first developmental stage could focus on this limited market. The thin film polycrystalline n-CdSe (and CdSe-CdTe alloys) coupled with BGARI membranes appear capable of satisfying these cost requirements, if lifetime conditions can be met. The cost of CdSe for a 0.02 mm film would be less than \$10 m^{-2}. The membranes, not presently in mass production, are estimated at \$5 m^{-2}, with four required per square meter of cell area.

Electrodialytic desalination driven by solid-state solar cells is now being considered seriously (6, 7), first in sunny regions remote from conventional power sources, but later extended to more general usage as the cost of solar cells comes down and conventional power costs continue their inexorable rise.

What theoretical advantage does photoelectrodialysis have over electrodialysis driven by solid-state or electrochemical solar cells? The answer is less barrier area, *i.e.*, the sum of membrane and electrode area. Other things being equal, barrier area determines total process cost. In the latter case both the driving and driven units must have separate electrode sets, whereas in the former they are shared. Less electrode overpotential loss would also be a factor favoring photoelectrodialysis.

What advantage does solar driven electrodialysis have over solar distillation? The answer is a much lower energy requirement. Consider the minimum energy requirement for electrodialysis, obtained through the Nernst equation in the concentration approximation. Per differential equivalent of salt removed at the reversible concentration potential

$$E = \frac{2RT}{\mathbf{F}} \ln \frac{C_2}{C_1} = 0.1183 \log \frac{C_2}{C_1} \qquad (25°C)$$

it is the product $\mathbf{F}E$, where $\mathbf{F}$ is the Faraday constant, and C_1 and C_2 are the depleted and enriched salt stream concentrations. Suppose $C_1/C_2 = 100$. The potential difference is then $2 \times 0.1183 = 0.2366$V, and the minimum energy requirement to desalt is $0.2366 \times 96{,}500/1000 = 22.8$ kJ. If the source water is 0.06M, a

typical brackish concentration, the amount of desalted water produced is 1 mol/0.06 mol liter^{-1} = 16.67 liters. To distill the same amount of water would require 16,667g × 2.32 kJ/g = 38,732 kJ, a factor of 1697 greater. If the power for electrodialysis is to be furnished photoelectrically, one must enter an efficiency factor of about 10%. Still, solar driven electrodialysis has at least a 170-fold advantage over single stage solar distillation, no allowance having been taken in the latter case for imperfect collection efficiency.

Variation of the Conductivity of MnO_2 with Lithium Insertion

M. Voinov*[,1]

Leclanché S.A., 48 route de Grandson, 1401 Yverdon, Switzerland

ABC

The variations of the electrode potential of Li_xMnO_2 with x has been reported (1,2) and attributed to a modification of the band structure of MnO_2 when Lithium enters its lattice. It was proposed that this modification is such that Li_xMnO_2 turns from a small bandgap into a wide bandgap n-type semi-conductor at 0.5 Li inserted per mole. Consequently at this amount of Li inserted the conductivity of Li_x-MnO_2 should decrease.

In fact it is already known that the electronic conductivity of a similar compound, namely H_xMnO_2 decreases during reduction (3) but its variation with x has not been published. On the other hand, increases of the total internal impedance of Zn-MnO_2 (4) and Li-MnO_2 (1) cells with depth of discharge have been reported but the contribution of the depolariser electronic conductivity variation to the total change was not isolated. The purpose of the present investigation was precisely to determine such a contribution in the case of Li_xMnO_2 and to check the predictions made about its band structure modification at x=0.5.

Short of a full frequency response analysis, it is not conceptually possible in an electrochemical cell to separate the electrolyte and depolariser ohmic drops from the various interface and Warburg impedances. With the further complication introduced by porous electrodes, even the utility of such a frequency response analysis is doubtful except in a few simple cases (5). One must use approximate methods.

In the present approach, Li-MnO_2 cells were partially discharged by known amounts. They were then left in open-circuit to smooth out diffusion gradients. Subsequently the cells were addressed with small (1 µC) discharge pulses. It is assumed that, during these pulses, no diffusion gradients are established in the depolariser or in the electrolyte to contribute a Warburg impedance. It is also assumed that the interface impedance between Lithium and the electrolyte remains the same during discharge of the cells. Therefore the variations with depth of discharge of the total cell tension drop at the end of a pulse should reflect mainly the variations of the ohmic drop in Li_xMnO_2 with a possible contribution of the interface impedance between Li_xMnO_2 and the electrolyte.

Cathode limited Li-MnO_2 button cells (Ø 11.6 h 2 mm) were assembled in a glove box (< 1 ppv H_2O, 20 ppv O_2). The MnO_2 was heat-treated at 350°C for 24 hours then mixed with 10% by weight of carbon and 5% by weight of a fluorinated hydrocarbon binder. The mixture was then pressed in the shape of 50% porous pellets. The solvent was Propylene Carbonate distilled at 90°C under vacuum. The electrolyte was $LiClO_4$ (1 M) dried under vacuum.

The cells were discharged at room temperature to various degrees. They were then left in open-circuit until their tensions did not vary by more than 10 mV/24 h. As the electrolyte is invariant during discharge, the open-circuit tensions of the cells represented the electrode potential of Li_xMnO_2 versus Lithium in the same solution (fig. 1). Short (1 ms, 2 µs rise time) low intensity (1 mA)

[1]Present address: 74 route de Saint Julien, 1212 Grand Lancy , Geneva, Switzerland

constant current discharge pulses corresponding roughly to the demand of a minature step motor, were applied to the cells and their responses recorded with a Digital Storage Oscilloscope (Gould OS 4000).

It is observed that the internal impedance variation (potential drop after 1 ms divided by 1 mA, minus the corresponding value for the undischarged cell) increases sharply at 0.5 Li inserted per MnO_2 (Fig. 1). As the carbon used has about the same conductivity as undischarged MnO_2, this increase cannot be due to the volume increase of Li_xMnO_2 during discharge. Furthermore tha value of 0.5 Li/mole corresponds precisely to the prediction made about the increase of resistivity of Li_xMnO_2. This band model modification proposed (1,2) is therefore to that extent verified. Furthermore, between 50°C and -20°C the impedance variation decreases with increasing temperature. The approximate activation energy is 0.25 eV for x = 0.75 and a pulse current of 1 mA.

However, it was also predicted (1,2) that above 0.5 Li/MnO_2 the resistivity should again decrease slightly. This is not what is observed, and the matter needs more experimental results rather than ad hoc assumptions about the Li_xMnO_2 - electrolyte interface impedance.

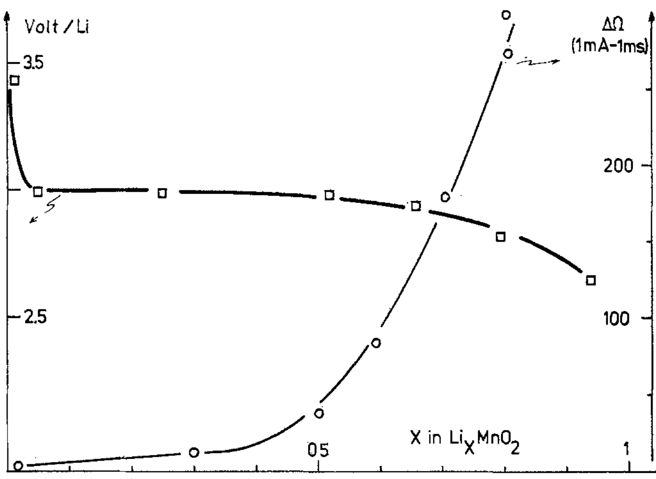

Figure 1.Electrode potential of Li_xMnO_2 (□) and internal impedance increase (O) of partly discharged and open-circuited Li-MnO_2 cells.

Surface Stabilization of Polycrystalline-Silicon Films during Laser Recrystallization

T. I. Kamins*

Hewlett-Packard Laboratories, Palo Alto, California 94304

In the past several years numerous attempts have been made to recrystallize thin films of fine-grain CVD polycrystalline silicon into large-grain material in order to reduce the influence of the grain boundaries. Recrystallization with a scanned CW laser has been found to increase the average grain size to several microns (1). The consequent reduction in defect concentration makes possible the fabrication of active devices, such as MOSFETs with their active channels within the layer of laser-recrystallized polysilicon (2,3). Such devices can be used in monolithic silicon integrated circuits to improve packing density or performance or can be constructed in silicon films deposited on inexpensive substrates for applications such as flat-panel displays.

In the initial work, recrystallization was found to occur more satisfactorily when the polysilicon was deposited on silicon-nitride-coated silicon wafers, rather than on oxidized wafers. In the latter case, at the high laser powers needed to melt the entire thickness of the polysilicon, the silicon tends to agglomerate or delaminate, leaving regions of the underlying oxide exposed. Although the recrystallization proceeds more controllably on silicon nitride, the electrical properties of an underlying polysilicon/silicon-dioxide interface are far superior to those of a polysilicon/silicon-nitride interface (4). Consequently, attempts were made to improve the controllability of the recrystallization process on silicon dioxide.

* Electrochemical Society Active Member

Keywords: Polycrystalline silicon, laser recrystallization, silicon nitride

Initial work by the Stanford group (5) utilized an 1100°C furnace anneal in a nitrogen atmosphere for one hour to prevent agglomeration during the subsequent laser recrystallization, thus broadening the useful range of laser powers. This high temperature anneal, however, is not compatible with the future direction of IC technology, which restricts processing to lower temperatures to avoid wafer deformation. In addition, the high temperature nitrogen anneal often degrades the unprotected silicon surface. Consequently, a better method of stabilization is needed. This note will show that the stabilization is an effect occurring at the exposed top surface of the polysilicon, rather than being predominately related to a change in the bonding at the underlying polysilicon/silicon-dioxide interface. It will also demonstrate that a thin layer of silicon nitride deposited on top of the polysilicon provides an optimum surface stabilization layer.

Auger analyses were performed to study the depth profiles of the surface layers formed by the thermal or laser processing. While the Auger depth profile after nitrogen annealing did not indicate any significant nitrogen-containing layer, the thickness of the native oxide layer on the surface of the polysilicon increased from approximately 15 Å to about 50 Å during the nitrogen anneal. This layer did not change significantly during the subsequent laser recrystallization. We believe that the 50 Å thick oxide layer stabilizes the surface during laser melting by changing the surface-tension forces which tend to pull the molten layer of silicon apart. Although no oxygen is purposely introduced into the furnace during the nitrogen anneal, the hot wafer surface

could be exposed to oxygen from backstreaming of oxygen into the furnace or during removal from the furnace tube, as well as by trace quantities of oxygen in the nitrogen supplied to the furnace.

The presence of a surface layer which stabilizes the film during laser recrystallization is consistent with other observations: (1) The beneficial effect of the 1100°C nitrogen anneal is removed by etching the surface in a standard buffered oxide etch for a short time (∿1 min) before laser recrystallization. (2) Although no difference is seen before laser recrystallization, the surfaces of films with and without the thermal anneal appear markedly different under an optical microscope after laser recrystallization. Films which have been thermally annealed retain the appearance of the fine-grain polysilicon films (a fine-scale surface roughness) even though the grain size has increased. Films which have not been thermally annealed before laser recrystallization exhibit greatly different surface features, corresponding to large-grain material.

Once it was shown that the high-temperature anneal formed a thin, protective layer on the polysilicon surface, experiments were performed to develop a surface stabilization process more compatible with advanced IC fabrication technology.

In all cases to be discussed below, the polysilicon films were 0.5μm thick and were deposited by low-pressure CVD at 625°C from SiH_4 onto silicon wafers covered with 1.4μm of thermally grown SiO_2. A CW argon laser (Coherent, Inc. Model 5000 laser annealer) was used to recrystallize the polysilicon, although the results are expected to be applicable to any scanned laser (or possibly electron beam). The laser beam was scanned across the wafer surface with galvanometer-controlled mirrors at a velocity of 25 cm/sec. The spot size was approximately 80μm, and the beam was stepped about 40μm between successive scans. The substrate temperature was 500°C during recrystallization.

Films of silicon oxide (from N_2O and SiH_2Cl_2) approximately 50 Å thick and of silicon nitride (from NH_3 and SiH_2Cl_2) approximately 90 Å thick were deposited in the LPCVD reactor. While the oxide layer was somewhat effective in stabilizing the surface, the nitride layer provided marked surface stabilization. In the latter case, after laser recrystallization the surface was smoother than observed in any previous experiment, and a wide range of laser powers produced satisfactory recrystallization. At the higher powers, however, isolated irregularities (protrusions or pits) formed, their density increasing with increasing laser power.

In a more detailed experiment three different thicknesses of LPCVD nitride (approximately 60, 90, and 140 Å) were deposited on polysilicon. In addition, a 100 Å-thick layer of nitride was deposited from NH_3 and SiH_4 in a hydrogen carrier gas at atmospheric pressure in order to avoid the presence of any chlorine species. Each sample was recrystallized with a series of different laser powers with one watt increments from 8 W until significant agglomeration occurred or the upper limit of the laser power (17W) was reached. After recrystallization, the microstructure was observed in an optical microscope, and the power necessary for the formation of the large-grained structure was noted along with the power which caused agglomeration. The difference indicated the range of satisfactory laser powers which could be used, with the largest possible allowable range being desired for process flexibility. In the case of the nitride layers, an upper limit was set by the formation of the isolated irregularities since the films did not agglomerate even at the highest laser power. As can be seen from Table I the largest allowable range was obtained with the thinnest LPCVD nitride layer. No isolated irregularities were seen at even the highest laser power. By contrast, irregularities were seen in the nitride film deposited from SiH_4, indicating that these irregularities are not caused by chlorine inclusion.

Other stabilization treatments investigated provided additional insight into the process. Heat treatments at 900°C in 1% O_2 with the balance either argon or nitrogen formed about 35Å of oxide in each case.

These thin oxide layers appeared to provide a small increase in the allowable range of laser powers (Table I). An anneal at 1000°C in 1% O_2 with the balance nitrogen formed about 60 Å of oxide. While this oxide layer increased the allowable range, the change was much less than caused by a layer of CVD nitride of similar thickness. This result, coupled with the previous observation of only a slight increase in the allowable range from a deposited oxide layer, indicates a fundamental difference between the effects of oxide and nitride layers. This difference may possibly be related to the stiffer silicon nitride film better resisting the surface-tension forces which tend to pull the molten silicon film apart. A thermal oxynitride film formed in a 1% O_2 -49% NH_3 - 50% N_2 ambient at 1000°C (target thickness 30-50Å) increased the allowable range noticeably but not as significantly as did the deposited nitride layer.

The surface topology seen after laser recrystallization is quite different for films with the various stabilization layers. In particular, the silicon nitride stabilization layer leads to a markedly smoother surface, as has been reported in Ref. 6. Sirtl etching after recrystallization to reveal the grain boundaries and other defects, however, shows that the grain structure of all films is qualitatively similar (as also reported in Ref. 6 for silicon nitride). The elongated grains characteristic of laser-recrystallized polysilicon (1) are clearly visible in all cases, indicating that the basic nature of the recrystallization process is not greatly altered by the presence of the different stabilization layers.

In summary, the formation of a foreign surface film on the top surface of a polysilicon layer can markedly widen the allowable range of laser powers which can be used to recrystallize polysilicon films deposited on silicon dioxide. Of the layers investigated, a 50-100 Å-thick, CVD silicon nitride layer has been found to provide the best control over the successful recrystallization of polysilicon to form a large-grain structure.

ACKNOWLEDGEMENT

The author would like to thank Drs. C.J. Dell'Oca, A. Gat, and D. Ilic for encouragement during this investigation and S. Eglash, M. Guerin-Brown, and Y. Strausser for the Auger analyses.

Electrochemistry of Dimethyl Sulfite

Su-Chee Simon Wang*,[1] and Douglas N. Bennion*,[2]

Chemical, Nuclear, and Thermal Engineering Department, University of California, Los Angeles, California 90024

ABSTRACT

The reactions occurring in cells of the type $Li/LiClO_4$, $(CH_3O)_2SO/C$ have been investigated. One charge plateau at 5.1V and two discharge plateaus, one about 4.2V and the other about 3V, were observed. The possible involvement of solvent, $(CH_3O)_2SO$, in the cell reactions was studied by using nuclear magnetic resonance (NMR) to test the electrolytic solution in the cell compartments. Based on these experimental results, it is shown that the solvent is the primary reactant. It is also found that the solvent is degraded at a potential above 4.6V relative to a lithium wire reference electrode.

A battery system using a lithium negative electrode, an electrolytic solution of $LiClO_4$ and dimethylsulfite (DMSU), and a graphite positive electrode has been reported (1-4). It was proposed (2) that a lamellar compound of graphite formed at the positive electrode

$$nC + LiClO_4 = Li^+ + C_nClO_4 + e^- \qquad [1]$$

Later results (4, 5) suggest that other reactions also occur during anodic operation of the graphite electrode and that DMSU is involved directly in the reaction. Deshpande and Bennion (5) proposed that DMSU oxidized during charging, forming radical cations

$$(CH_3O)_2SO \rightarrow [(CH_3O)_2SO]^+ + e^- \qquad [2]$$

or

$$(CH_3O)_2SO \rightarrow [(CH_3O)_2SO]^{+2} + 2e^- \qquad [3]$$

In this paper, the involvement of DMSU in electrochemical reactions and its suitability as a solvent for electrochemical systems is investigated.

Experimental

DMSU was vacuum distilled in the apparatus described by Tiedemann (6). Water content was reduced to less than 100 ppm. No reaction was observed between purified DMSU and lithium over two weeks of observation. Test solutions were 2.0m $LiClO_4$ in DMSU. The biggest source of impurity was H_2O with the $LiClO_4$, even though the powdered $LiClO_4$ had been vacuum dried at 150°C for several weeks. The DMSU-$LiClO_4$ solution was stirred with lithium chips for more than one day to reduce active impurities further.

Natural graphite powder, 99.95% pure, 0.8 μm in size, originating from Madagascar was used for the test electrodes. Teflon molding powder and Union Carbide National C-34 glue were used as binders for the graphite powder and to hold it to either carbon cloth or titanium sheet backing plates.

Three views of the glass test cell are shown in Fig. 1. The test electrode and the lithium counterelectrode are held on the bottom of their respective compartments by glass sleeves, 2 cm inside diameter, 1.25 cm high. Each compartment contained about 10 cm^3 of electrolytic solution. The reference electrode was a lithium wire. All experiments were run inside an argon atmosphere glove box. The electrical circuit is shown in Ref. (7). A Varian T-60 NMR Spectrometer and a Varian CFT-20 C13-NMR Spectrometer were used to analyze the electrolytic solution before and after cell operation. Further details are given elsewhere (7).

Three basic types of electrodes were tested. Types A and B are shown in Fig. 2.

(A) Titanium backing plate, titanium side walls forming a cavity of 0.38 mm thick and 1 cm^2 area. The cavity was filled with 0.0419g graphite powder with enough C-34 glue to make a thick paste. The electrode was cooked for 1.5 hr at 1000°C under vacuum. After cooling, a piece of nonwoven polypropylene cloth was placed over the cavity and held in place with a ring of 0.001 in. thick sheet Ti spot welded in place.

(B) Same as (A) except an extra sheet of 0.38 mm thick Ti was spot welded in place to allow a gap be-

tween the sintered graphite and covering polypropylene cloth as shown in Fig. 2.

(C) This electrode was prepared by spreading 0.07g of graphite powder and C-34 glue over a 2 cm^2 area and cooking for 0.5 hr under vacuum.

All three electrode types had porous structures which adhered well to the backing materials. The resistance across the electrodes as measured with probe contacts was about 10Ω. Electrodes were soaked in DMSU-$LiClO_4$ solution for 4 hr before use.

The potential between the positive electrode and the lithium wire reference electrode was measured as a function of time at constant current.

Results and Discussion

There were two major, cathodic discharge plateaus, one beginning at 4.2V, the other at 3.0V. Current was 1.0 mA/cm^2. The upper plateau varied between a small shoulder up to one-third of the total discharge capacity. The lower plateau varied between 3.0 and 2.0V. Charging took place at a constant potential of 5.1V. A typical cycle is shown in Fig. 3.

Examining the upper plateau, the charge out is shown in Fig. 4 as a function of the charge in. Type A and B electrodes show fixed capacities of about 0.02 milliequivalents, independent of the quantity of charge put in. Electrode A increased in volume roughly proportional to the charge put in until the covering separator was stretched and restrained further expansion. Electrode B could expand more freely, and showed higher initial capacity. The swelling is believed to be an indication of increasing internal surface area. The primary anodic reaction product is believed to be an oxidized form of DMSU which adsorbs or possibly intercalates into the swelling graphite. On subsequent cathodic discharge, the adsorbed reaction product is hypothesized to react at near 4.2V to reform DMSU. No direct experimental evidence has yet been realized which allows direct confirmation of the primary anodic reaction product (PARP). It appears that the PARP desorbs and further reacts to form secondary products as discussed below. After 10 hr wet stand, the upper cathodic discharge plateau disappears.

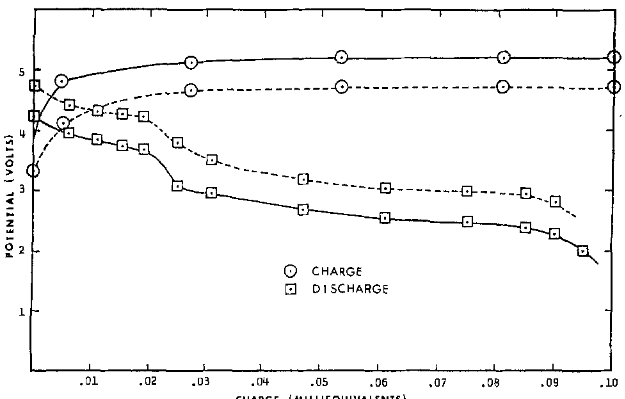

Fig. 3. Galvanostatic charge and discharge curves for the cell Li/$LiClO_4$, DMSU/C (electrode A), cycle 7, i = 1 mA/cm^2. ——— Galvanostatic potential; - - - - - - open-circuit potential.

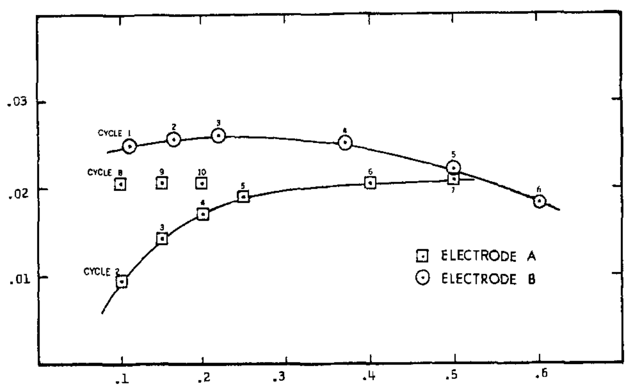

Fig. 4. Galvanostatic charge in vs. charge out curves for the cell Li/$LiClO_4$, DMSU/C (electrode A or B), i = 1 mA/cm^2. Upper discharge plateau only.

Electrode type C was used to create reaction products in high enough concentration to detect. Anodic operation was begun at 2 mA/cm^2 after a short forming cycle of 0.1-0.05 milliequivalents. Much larger charge input was used compared to the earlier runs. The 4.2V cathodic discharge plateau was very small compared to the anodic charge plateau or the subsequent discharge at the 3.0V plateau. Samples were taken from positive and negative compartments at 5.4 and 13.49 milliequivalents, for example, during charging. The electrolytic solution volume was 10 cm^3 in each compartment. Samples were sealed into nuclear magnetic resonance (NMR) tubes inside the argon filled glove box. Solution level in each compartment was kept constant by adding fresh solution to each compartment to replace the 1.0 cm^3 removed as a sample. Results of the NMR spectra for the positive compartment are shown in Fig. 5. Four new peaks appeared and became larger as charging continued. Figure 6 shows an NMR spectra for the negative compartment. One new peak formed. Initially, the only hydrogen in the system is in the DMSU molecule. New peaks are due to altered structure of the basic DMSU molecule causing shifts in the resonance frequency for the hydrogen atoms. Thus, four reaction products have been identified for the anodic charging reaction. The NMR peaks which appear and grow with continued discharge are conclusive evidence that DMSU reacts anodically above 4.6V forming soluble reaction products.

A cathodic discharge half cycle at 2 mA/cm^2 was begun immediately after the 13.49 milliequivalents anodic cycle. Samples were taken, for example, after 4.9 and 6.9 milliequivalents of cathodic operation. The NMR spectra are shown in Fig. 5. Peaks 1, 3, and 4 diminish or disappear during cathodic operation and

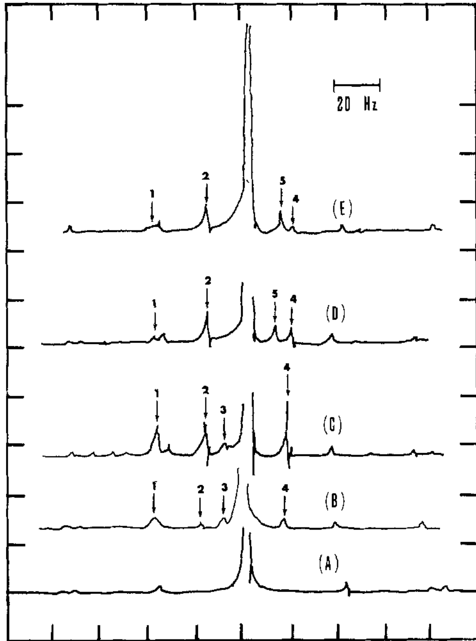

Fig. 5. NMR spectra of the electrolytic solutions: (A) before charging; (B) after 5.4 milliequivalents charged in; (c) after 13.49 milliequivalents charged in; (D) after 4.9 milliequivalents discharged following charging; (E) after 6.9 milliequivalents discharged following charging. Data for second cycle of a cell Li/ $LiClO_4$, DMSU/C.

a new peak, labeled peak 5, appears. These observations indicate that at least one of the anodic products, peak 2, is not cathodically, active. In addition, all or some of the products of the subsequent cathodic or discharging reaction are a material named peak 5 which is not DMSU. A complete, reversible charge-discharge cycle does not exist under the conditions tested. However, at least limited cyclic operation does occur.

To further examine cyclic operation of the DMSU reaction, multiple cycles were run consecutively. A

Table I. The positions and intensities of peaks in the C^{13} NMR spectrum after 9.44 milliequivalents were charged in, cycle 4 of the cell Li $LiClO_4$, DMSU C (electrode C)

Peak No.	Relative intensities	Positions (Hz)
1	18	1998.8
2	14	1858.4
3	13	1826.2
4	14	1793.7
5	18	1482.2
6	14	1287.7
7	27	1282.0
8	19	1278.0
9	18	1272.9
10	300	1259.0
11	12	1151.2
12	13	271.4

type C electrode was operated anodically at 2.5 mA/cm^2 for 10.84 milliequivalents and then discharged cathodically to a 2.0V cutoff potential which allowed 6.3 milliequivalents of cathodic current to be passed. Samples were taken following the 3rd complete cycle and after 9.44 milliequivalents charged in at 2 mA/cm^2 on the anodic or first half of the 4th cycle. Peak 5 appears to persist following cathodic discharge, indicating that the species corresponding to peak 5 represents a species not or at most partially electrochemically active.

As a double check on DMSU involvement in the electrochemical reactions, a C^{13} NMR spectrum was run on the sample taken in the 4th cycle. Positions and intensities of peaks are shown in Table I. Peaks 2, 3, and 4 are for deuterium chloroform used to lock the spectrum during accumulation of signals. Peak 12 is for tetramethyl silane (TMS), used as the standard. Peak 10 is for DMSU. The remaining seven peaks are derivatives of DMSU which accumulate as cycling proceeds.

The accumulation of DMSU reaction products in the positive compartment and the appearance of a DMSU reaction product in the negative compartment indicates that at the extreme potentials investigated DMSU is degraded.

Conclusions

1. Lamellar compound of graphite formation is not an effective charge storage mechanism in competition with dimethylsulfite reactions at a positive electrode.
2. An upper cathodic plateau at 4.2V *vs.* Li/Li^+ reference electrode is an electrochemically reversible reaction involving an adsorbed or intercalated primary reaction product formed by anodic oxidation of dimethylsulfite.
3. The primary reaction product of anodic oxidation of dimethylsulfite desorbs and forms secondary oxidation products, of which at least some are electrochemically reactive in subsequent cathodic, electrochemical reactions.
4. Some of the reaction products of cathodic and anodic reactions are not electrochemically active. Thus, a simply closed, complete secondary battery cycle does not appear to exist although numerous charge-discharge cycles are possible in an excess of dimethyl.-sulfite.

Ionic Conductivity in Lithium and Lithium-Sodium Beta Alumina

J. L. Briant* and G. C. Farrington*[,1]

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

This paper presents measurements of ionic conductivity in single crystals of Li^+ and mixed Li^+/Na^+ beta alumina. The crystals were prepared by ion exchange of Na^+ beta alumina crystals in LiCl, $LiNO_3$, or $LiNO_3$ with $NaNO_3$ added. The measured room temperature conductivity of Li^+ beta alumina, about $3 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$, is higher than earlier values. The activation energy was found to be 0.24 eV from −80° to 400°C. Room temperature conductivities of Li^+/Na^+ beta alumina crystals pass through a minimum as the composition is varied from pure Na^+ to pure Li^+ beta alumina. The activation energy achieves a maximum at the same composition. The theory of Hendrickson and Bray for mixed-alkali conduction in glasses is adapted to explain this effect. The deleterious effect of water on lithium transport in beta alumina is also examined.

Many research efforts over the past 15 years have searched for a solid electrolyte with high room temperature Li^+ conductivity. Although beta alumina was one of the first Li^+ solid electrolytes investigated, earlier measurements of its conductivity were inconclusive. Reported room temperature conductivities varied from $1.3 \times 10^{-4}\ \Omega^{-1}\ cm^{-1}$ (d-c measurements) (1) to $8.3 \times 10^{-4}\ \Omega^{-1}\ cm^{-1}$ (dielectric loss) (2). In addition, Whittingham and Huggins (1) found an increase in the slope of the Arrhenius plot for the conductivity of lithium beta alumina around 180°C, the only such observation for a beta alumina isomorph. Table I summarizes the pre-exponential factors and activation energies found for Li^+ beta alumina by dielectric loss, d-c conductivity, and tracer diffusion measurements. Figure 1 illustrates the discrepancies among these data.

Many other Li^+ solid electrolytes have also been investigated. Shannon *et al.* (3) explored ionic conductivity in a variety of structures consisting of isolated polyhedra. Of the compounds they described, one of the best conductors is polycrystalline $Li_{0.8}Zr_{1.8}Ta_{0.2}P_3O_{12}$, which has a conductivity of $4.1 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$ at 25°C (extrapolated) and $9.1 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$ at 300°C (see Fig. 1). Hong (4) synthesized a new compound, $Li_{14}Zn(GeO_4)_4$ (LISICON), and reported it to have a conductivity of $1.2 \times 10^{-1}\ \Omega^{-1}\ cm^{-1}$ at 300°C. von Alpen (5) estimated the single crystal conductivity of LISICON by complex admittance analysis of polycrystalline LISICON samples. He found a much lower conductivity, $2 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$ at 50°C and $1.2 \times 10^{-2}\ \Omega^{-1}\ cm^{-1}$ at 200°C. Ionic conductivity in single crystals of Li_3N was measured by von Alpen *et al.* (6) and found to be 5.4×10^{-4} at 25°C. However, conductivity measurements on this material are complicated by hydrogen doping (which enhances conductivity) and surface layers of LiOH and Li_2CO_3 (which degrade conductivity) (7). While Li_3N is the only lithium ion conductor shown to be stable in contact with molten lithium, it is unstable in contact with the atmosphere.

In 1977 Roth and Farrington (8) observed that certain mixed Li^+/Na^+ beta alumina polycrystalline ceramics (Li:Na about 1:1) have very high room temperature conductivities. They estimated the equivalent single crystal conductivity of mixed Li^+/Na^+ beta alumina (1:1) to be about $1 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$. Because this value was higher than the values of 1×10^{-4} to $8 \times 10^{-4}\ \Omega^{-1}\ cm^{-1}$ previously reported for pure Li^+ beta alumina, they postulated that the increased conductivity of the mixed Li^+/Na^+ composition was due to a co-ionic effect. The initial goal of the present research effort was to confirm the earlier measurements of mixed Li^+/Na^+ beta alumina conductivity on single crystal instead of polycrystalline specimens. These values were indeed confirmed, but a much more interesting observation was also made, namely, that earlier measurements significantly underestimated the conductivity of pure Li^+ beta alumina. We have found that the conductivity of pure Li^+ beta alumina is about $3 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$ at 25°C. Li^+ beta alumina is therefore the most conductive Li^+ solid electrolyte yet reported. We have also found that the conductivities of mixed Li^+/Na^+ beta alumina compositions do not

vary linearly between pure Na^+ and Li^+ beta alumina conductivities, but instead go through a minimum. This effect is analogous to mixed alkali conduction in glasses and consistent with the properties of mixed Na^+/K^+ beta aluminas (2, 9) and Na^+/K^+ beta and beta″ gallates (9), analogous structures to the beta and beta″ aluminas.

In this paper we present our results on three topics: (*i*) The conductivity of pure lithium beta alumina; (*ii*) the conductivity of mixed Li^+/Na^+ beta alumina; and (*iii*) the influence of water on ionic conductivity of all of these materials. Discussions of each topic follow the results in each section. We also offer a likely explanation for the confusion of earlier measurements. No review of the beta alumina structure is included. We refer readers interested in detailed discussions of the structure of sodium beta alumina to several other papers (10, 11, 12).

Experimental

Single crystal samples (typically 1 × 2 × 4 mm) of sodium beta alumina were cut from a single crystal boule grown by the Union Carbide Corporation. The weight changes observed for samples of this type upon ion exchange of sodium by potassium or silver indicate that their compositions vary from about 1.13 $Na_2O \cdot 11\ Al_2O_3$ to 1.24 $Na_2O \cdot 11\ Al_2O_3$. Other investigators (13, 14) have observed that samples cut from the outside of Union Carbide sodium beta alumina boules have lower Na_2O contents than samples cut from the center. Lithium beta alumina samples were prepared by ion exchange in highly pure LiCl at 675°C. Mixed Li^+/Na^+ beta alumina samples were prepared by ion exchange in molten $LiNO_3$ with 0-1% $NaNO_3$ added. The extent of ion exchange for each sample was determined by measuring its weight before and after exchange.

Single crystals were mounted on alpha Al_2O_3 substrates for complex impedance measurements. Conductivity was measured using blocking Au electrodes and a-c complex impedance analysis. Samples were dried at 350°C in a dry He atmosphere in the measurement cell before measurement and maintained in this He atmosphere during measurement. Details of these techniques have been described elsewhere (15).

Results and Discussion

Ionic conductivity in lithium beta alumina.—Our results indicate that lithium beta has the highest ionic conductivity at 25°C of all lithium ion solid electrolytes yet reported. The conductivities of five crystals measured at 25°C varied from $2.1 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$ to $3.7 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$ (see Table II). Since all of the samples were prepared by ion exchange, they could have contained variable amounts of residual sodium (1-2%) or slight concentrations of secondary alkali or divalent ions. Such small variations in composition or in stoichiometry might reasonably have produced the range of conductivities we observed. We will demonstrate that the variation is not due to thermal aging effects.

The conductivities of three samples were measured as a function of temperature from 25° to 400°C, and two others were measured from −80° to 400°C. The temperature dependence of conductivity for each sample followed a simple Arrhenius relationship (Eq. [1]). Activation energies (E_A) ranged from 0.23 to 0.25 eV with an average value of 0.24 eV. The straight-line Arrhenius behavior observed here contrasts with the two-line behavior reported by Whittingham and Huggins (1), who found a change in activation energy around 180°C (see Fig. 1)

$$\sigma T = \sigma_0 \exp(-E_A/kT) \quad [1]$$

We have also briefly examined the influence of heating to 675°C upon ionic conductivity in Li^+ beta alumina. These experiments were suggested by the work of Whittingham and Huggins (1), who found that annealing Li-exchanged beta alumina above 800° produced a marked decrease in conductivity, and of Dubin *et al.* (16), who found that heating Li^+/Na^+ beta alumina at 900°C for 4 hr results in the trapping of a fraction of lithium ions in immobile sites presumably located in the spinel block. In our experiments heating to 675°C had no significant influence upon conductivity. Two experiments were carried out. Although most samples were exchanged in LiCl at 675°C for about 1 hr, two samples were exchanged for about 16 hr. Their conductivities at 25°C and activation energies are comparable to values observed for crystals exchanged for only 1 hr. Another crystal was exchanged for 30 min, heated in air at 675°C for six days, and then re-exchanged for 30 min. Its conductivity and activation energy are also comparable. If trapping does occur at 675°C, it influences conductivity very slowly.

The high conductivity of lithium beta alumina focuses attention on several aspects of the microscopic mechanism of Li^+ migration in the beta alumina structure. Previous investigators have explained the apparently low conductivity of lithium beta alumina by noting that Li ions are too small to occupy sites on the conducting plane and bond simultaneously to both close-packed oxygen layers. Therefore, Li^+ should be displaced toward one or the other close-packed layers. Because of their high charge to radius ratio, lithium

[a] Hours in LiCl at 675°C.

ions are more polarizing than other alkali ions. Li ions therefore can form stronger covalent bonds with the oxygen atoms in the conducting plane of beta alumina. Covalent bonding increases the activation energy for conductivity and decreases the conductivity at 25°C. The only study (17) of the structure of beta alumina containing lithium ions, which was carried out on a mixed (1:1) Li^+/Na^+ composition, has indeed located Li ions off the conduction plane above the mid-oxygen sites bonded to either of the two close-packed oxygen layers. The Li^+ diffusion pathway probably then involves ionic hopping along the close-packed oxygen layers or the movement of Li^+ from one close-packed oxygen layer to the other across the conduction plane. If Li^+ ions hop between positions above and below the conduction plane, this motion should give rise to a dielectric dispersion in the c direction of the crystal. Anderson (18) has reported observing the effect of Li^+ ion hopping parallel to the "c" axis in the low energy excitation spectrum of Li^+ beta alumina. Off-plane bonding can explain why the activation energy for conductivity in Li^+ beta alumina (0.24 eV) which we observed is considerably larger than that of Na^+ beta alumina (0.16 eV).

Ionic conductivity in mixed Li^+/Na^+ beta alumina.—In 1967 Yao and Kummer (19) published classic data on the ion-exchange properties of Na^+ beta alumina in mixed $NaNO_3$-XNO_3 melts (X = Ag, Li, K, Tl, Rb, Cs). They demonstrated that thermodynamic equilibrium at 300°-350°C favors the reaction

$$NaNO_3 + Li^+ \text{ beta alumina} \rightarrow LiNO_3 + Na^+ \text{ beta alumina}$$

Because of the trace quantity of sodium in nominally pure $LiNO_3$, Na^+ beta alumina crystals immersed in $LiNO_3$ become only 60-80% exchanged to Li^+ beta alumina. Addition of 1% $NaNO_3$ to nominally pure $LiNO_3$ lowers the extent of exchange to about 35%. Small variations in such data from melt to melt are presumably due to variations in the amount of sodium impurity.

The results of our conductivity measurements on Li^+/Na^+ beta alumina are summarized in Table III. Activation energy and room temperature resistivity as functions of composition are shown in Fig. 2 and 3. Both the activation energies and room temperature resistivities pass through maxima at compositions of about 70% Li, 30% Na.

All of the Arrhenius plots which we measured are straight lines except one (sample D, Fig. 4). This sample was exchanged in $LiNO_3$ and had a composition of 75% Li, 25% Na. Its Arrhenius plot is very similar to that described by Whittingham and Huggins for Li^+ beta alumina. The room temperature conductivities are comparable and both plots have a change in activation energy from 0.18 eV below 180°C to 0.38 eV above 180°C. Such unusual behavior could be the effect of either this particular mixed composition or of hydration. We suggest that the discrepancies in earlier data are due to measurement of samples with uncertain Li^+/Na^+ compositions and uncertain states of hydration.

Table III. Conductivity of Li^+/Na^+ beta alumina

Sample	Composition (% Li)	$\sigma_{(25°C)}$ (Ω^{-1} cm^{-1})	σ_0 (Ω^{-1} cm^{-1})	E_A (eV)
	0	2.5×10^{-2}	3.6×10^{3}	0.16
A	12	6.7×10^{-3}	2.5×10^{3}	0.18
B	39	1.5×10^{-3}	9.5×10^{3}	0.26
C	50	4.9×10^{-4}	4.9×10^{3}	0.27
D	75	2.1×10^{-4}	6.8×10^{1}	0.18 below 180° 0.38 above 180°
E	84	4.2×10^{-4}	6.1×10^{3}	0.28
Average	100	2.7×10^{-3}	8.4×10^{3}	0.24

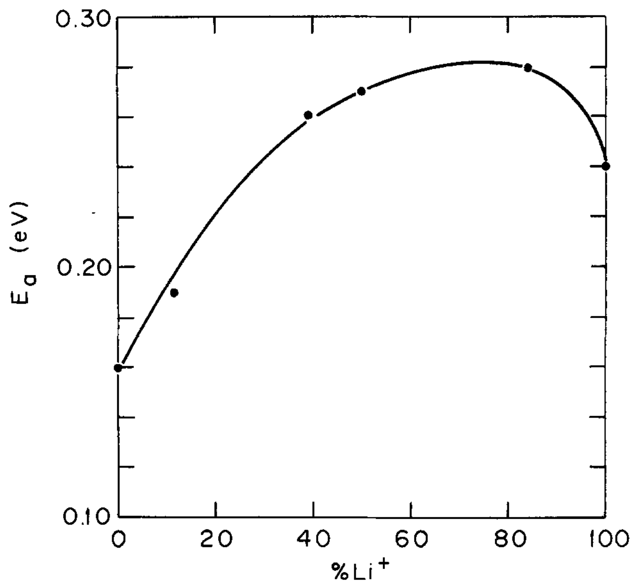

Fig. 2. Activation energy for conduction as a function of Li-Na beta alumina composition.

The only other investigation of the ionic conductivity of mixed Li^+/Na^+ beta alumina was described by Kaneda *et al.* (20). They measured the conductivity of a single crystal of 18% Li^+, 82% Na^+ beta alumina prepared by ion exchange of Union Carbide sodium beta alumina, the same starting material which we used. They found a room temperature resistivity of about 160 Ω-cm and a straight-line Arrhenius plot with an activation energy of 0.23 eV. The resistivity is consistent with ours but their activation energy is somewhat higher.

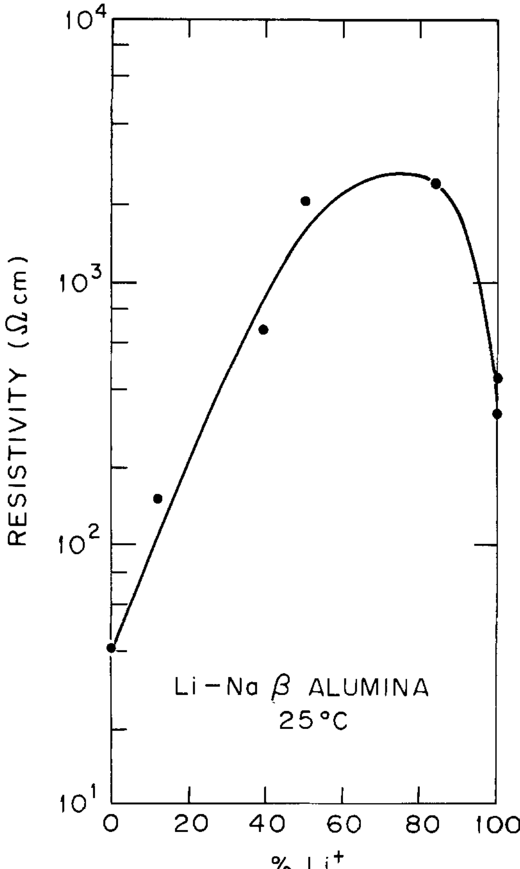

Fig. 3. Resistivity at 25°C as a function of Li-Na beta alumina composition.

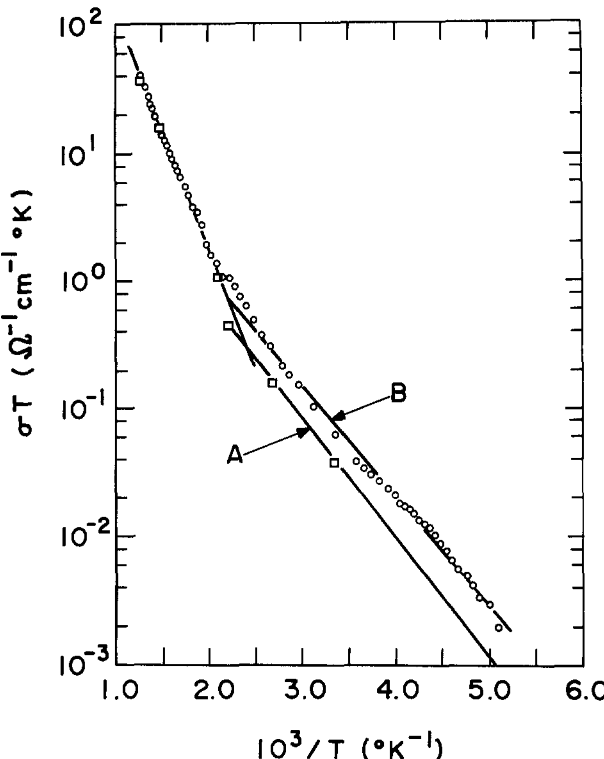

Fig. 4. Examples of nonlinear Arrhenius plots. A: sample composition reported to be pure lithium beta alumina (1); B: sample composition was 75% Li, 25% Na (this work).

The conduction properties of mixed Li^+/Na^+ beta alumina are consistent with those of Na^+/K^+ beta and beta" gallates (9), Na^+/K^+ beta alumina (2, 9), and mixed alkali conduction in glasses. In all these materials the resistivities and activation energies for conduction pass through maxima at some intermediate composition.

Although the mixed-alkali effect in glasses is best known as it applies to conductivity, it also can be seen in many other properties including viscosity, density, transformation temperature, softening temperature, chemical durability, and mechanical properties. The magnitude of the effect depends on the difference between the masses of the alkalis. Many theories have been proposed which can account for the mixed alkali influence on certain, but not all properties. However, Hendrickson and Bray (21) have proposed an attractive theory which explains the mass dependence of the effect and has the potential of accounting for the nonlinearity in all these properties. Their idea is simple and can be applied easily to Li^+/Na^+ beta alumina.

Hendrickson and Bray consider two types of alkali ions residing in sites in a glass network. These ions oscillate about the energy minima of their sites in thermal equilibrium with their environment. Since each positively charged ion in its negatively charged site forms an electric dipole, the vibration of each ion produces an oscillating dipole field in its neighborhood. Other nearby ions respond to this field. Each of these oscillating dipoles has a natural resonant frequency determined by the ion mass, temperature, and the curvature of the energy minimum. Different alkali ions (and even different isotopes) will clearly have different frequencies. While like neighboring ions will drive each other at resonant frequency, unlike ions will drive each other at off-resonant frequencies. Hendrickson and Bray have derived both classical and quantum mechanical expressions for the interaction energy and have shown that it is in general negative for unlike ions. (It is zero for identical ions.) Therefore the potential energy wells of mixed ion pairs are deeper and the activation energy for ion motion should be larger.

This theory can provide an explanation of the mixed-alkali effect in beta alumina. The mobile alkali ions in beta alumina reside in sites in the layered conduction planes. While the sites form an ordered crystalline array, occupancy of the sites is believed to be considerably disordered. Furthermore, beta alumina contains excess alkali (in this case 13-24% excess) over the composition of one alkali ion per unit cell in the conduction plane. Therefore, while three-quarters of the cells will be singly occupied, one-quarter will be doubly occupied. A widely accepted calculation by Wang *et al.* (22) has shown that the activation energy for motion of an ion in a singly occupied cell of Na^+ beta alumina is very high, about 2 eV. However, the activation energy calculated for motion of the interstitialcy pairs in doubly occupied cells is much lower (0.14 eV) and agrees well with experimental data (0.15-0.16 eV). It is therefore likely that such interstitialcy pairs provide most of the ion motion in beta alumina. In Li^+/Na^+ beta alumina many such pairs can be expected to consist of unlike ions, which will interact as off-resonant oscillating dipoles as in glasses. Indeed the problem of small variations in the curvature of the energy minima in glasses has been eliminated in beta alumina, because the sites are identical crystallographically. Therefore the activation energies and resistivities of Li^+/Na^+ beta alumina compositions should pass through maxima.

This theory also predicts an interesting effect which has already been observed in the mixed Na^+/K^+ beta and beta" gallate system. It predicts that the mixed ion effect should be substantially reduced in the beta" structure from the beta structure. Since there are two low energy ion sites in each plane unit cell of the beta" structure while there is only one in the beta structure, all excess alkali ions can be accommodated in these low energy sites in the beta" structure and interstitialcy pairs are less likely to form. The predominant conduction mechanism is expected to be individual ion hopping. Ion-pair interactions and consequently the mixed alkali effect are expected to be considerably reduced. Chandrashekhar and Foster have indeed observed that Na^+/K^+ beta gallate shows a more pronounced mixed alkali effect than Na^+/K^+ beta" gallate in both conductivity and activation energy (9).

Influence of H_2O on conductivity in lithium beta alumina.—Kline *et al.* (23) have previously reported that exposure of sodium beta alumina powder to water vapor results in a broadening of the NMR line associated with sodium ion motion. Heating the hydrated sample above about 200°C restores a normal sodium ion spectrum. Yao and Kummer (19) have also indicated, on the basis of infrared absorption measurements, that water appears to reversibly intercalate into the conduction planes of lithium and sodium beta alumina.

We have found that the conductivities of lithium beta alumina crystals at 25°C decrease steadily when exposed to atmospheric humidity. Heating to 350°-400°C results in a constant high conductivity. In separate thermogravimetric analysis experiments we found that powdered samples of lithium beta alumina reversibly absorb and desorb about 3 weight percent water when exposed to 10 Torr water vapor partial pressure at 25°C. The water is reversibly lost in a single dehydration step around 250°C. Our data show that high conductivity is only observed for carefully dried samples of lithium beta alumina.

Furthermore, the hydration of Li^+ beta alumina crystals distorts the shapes of their complex impedance and admittance plots and can even render them uninterpretable. Well-dried specimens exhibit classically shaped and easily interpreted complex impedance and admittance plots.

Conclusions

When small single crystals of sodium beta alumina are immersed in very pure molten LiCl at 675°C, essentially complete ion exchange takes place. The product, lithium beta alumina, has a lithium ion conductivity at 25°C of about 3×10^{-3} $(\Omega\ cm)^{-1}$. The variation of the conductivity of lithium beta alumina with temperature follows a straight line Arrhenius plot from −80° to 400°C with an activation energy of 0.24 eV. Lithium beta alumina hydrates rapidly upon exposure to water vapor at 25°C. Hydration dramatically decreases its conductivity. High conductivity is regained by heating at 350°C. It is possible that incomplete ion exchange or incomplete dehydration contributed to the higher resistivities reported earlier for Li^+ beta alumina (1, 2, 19).

The conductivity of mixed Li^+/Na^+ beta alumina displays the classic mixed alkali effect. At 25°C it goes through a minimum of 2×10^{-4} $(\Omega\ cm)^{-1}$ at an approximate composition of $Li_{0.93}Na_{0.37}Al_{11}O_{17.12}$. The conductivities of the mixed compositions also follow straight line Arrhenius plots over the range of our measurements (−80°-400°C). Hendrickson and Bray's theory of the mixed alkali effect can be adapted to explain the resistivity maximum of Li^+/Na^+ beta alumina.

Although lithium beta alumina is an exceptionally good lithium ion conductor, it cannot be used in direct contact with molten lithium metal. As are essentially all Li^+ solid electrolytes, lithium beta alumina is rapidly reduced by molten lithium. At elevated temperatures, lithium beta alumina could not be used in the presence of low lithium activity, perhaps buffered from direct contact with lithium by a molten salt. At lower temperatures, lithium beta alumina could function well as a separator in lithium nonaqueous electrolyte cells. Solid-state cells with direct contact between lithium and lithium beta alumina should also be stable, since slow kinetics should preclude significant lithium/electrolyte reactions.

Finally, in considering applications of lithium beta alumina, we should emphasize that the conductivities reported in this paper are single crystal values. Because single crystals of beta alumina conduct in only two dimensions and cleave readily, polycrystalline membranes must be used in practical applications. Polycrystalline ceramics contain grain boundaries which introduce additional impedance to ion transport. Conductivities attained in actual solid electrolyte devices are therefore typically lower ($2\text{-}10^3$ times) than those observed for single crystals.

On the Stability of Boron Nitride with Lithium Alloy Electrodes in Molten Salt Cells

Ram A. Sharma* and Thompson G. Bradley*

General Motors Research Laboratories, Electrochemistry Department, Warren, Michigan 48090

ABSTRACT

Experiments were carried out to determine the stability of boron nitride separator material in molten salt cells using lithium chloride-potassium chloride (LiCl-KCl) eutectic electrolyte and two stainless steel screen electrodes. The potentials of these electrodes were set by two separate electrical circuits and a lithium-silicon (Li-Si) reservoir electrode. The boron nitride separator was found stable at potentials above −136 mV with respect to a lithium-aluminum reference electrode at 700 K. The separator reacted with lithium and became conductive at potentials more reducing than ∼ −200 mV. Formation of a boride and Li_3N led to the conductivity.

Compact cells comprising lithium-aluminum or lithium-silicon negative electrodes, iron disulfide positive electrodes, lithium chloride-potassium chloride electrolyte, and boron nitride separators are undergoing development for batteries of high specific energy and high specific power (1-3). In the case of the lithium-aluminum electrode, the cell operates at 700 K in the α-β region of the lithium-aluminum phase diagram (4) at a negative electrode potential of 290 mV with respect to pure lithium (5). Some of the cells lasted more than 10,000 hr (1) and post-test analysis showed that failure was not due to chemical attack of the boron nitride separator by the lithium-aluminum electrode (6).

In the case of the lithium-silicon electrode, the cell operates at 700 K in the composition regions, Si-Li_2Si, Li_2Si-$Li_{21}Si_8$, and $Li_{21}Si_8$-$Li_{15}Si_4$. The respective plateaus of potential corresponding to these composition regions occur at 330, 281, and 154 mV with respect to pure lithium (5). During charging of the cell, high self-discharge is observed in the region where $Li_{15}Si_4$ is formed. Boron nitride has been observed to react with pure lithium at ∼700 K (6). It may also react with $Li_{15}Si_4$ to form a conductive boride permitting self-discharge.

This investigation was carried out to develop a technique suitable for evaluating separator materials for lithium-alloy/iron disulfide cells in general and to determine the stability of boron nitride in particular, at the potential of the $Li_{21}Si_8$-$Li_{15}Si_4$ plateau and, further, to determine the range of potentials at which boron nitride is stable. These data will help select compositions of the negative electrode which will allow cell operation with minimal self-discharge.

Experimental

All of the experimental work was done in a helium atmosphere glove box. The data were obtained by a cell (Fig. 1) in which two stainless steel screen electrodes and lithium chloride-potassium chloride electrolyte were used. The electrodes sandwiched the boron nitride separator, and the potentials were set by two separate electrical circuits and a lithium-silicon reservoir (counter) electrode in the cell. The electrical circuit is shown in Fig. 2. This arrangement allowed us to subject the boron nitride to various potentials (*i.e.*, various lithium activities) and to monitor the lithium consumed in the reaction with boron nitride.

For preparing the reservoir (counter) electrode, a nickel current collector (98% porous) was placed in a circular stainless steel chamber one face of which was already closed by spot-welding a double layer of stainless steel screens (400 mesh followed by 150 mesh). The chamber was vibration-loaded with 60/100 mesh particles of Li_2Si and its open face was closed by spot-welding a double layer of the screens. Complete details of the electrode and Li_2Si preparation are described in Ref. (7). The electrode was 3.5 cm in diameter and of 2.6 A · hr capacity.

Each screen electrode was made by spot-welding a stainless steel screen (150 mesh) onto a stainless steel ring (2.5 cm diam). They were cleaned by acetone and deionized water rinses in an ultrasonic cleaner.

A lithium-aluminum reference electrode whose composition was always maintained in the α-β phase region (4) was used. Preparation of the reference electrode is given in the Appendix and the potential with respect to pure lithium is given (5) by the equation

$$V(\text{mV}) = 464.438 - 0.2488T \quad [1]$$

The boron nitride cloth was 2 mm thick, had twill weave, and was purified by vacuum treatment as described in Ref. (6). The cloth was impregnated with electrolyte at ∼725 K under vacuum.

The LiCl-KCl eutectic electrolyte mixture was prepared using 99.6% pure lithium chloride and 99.9% pure potassium chloride. The mixture was purified by bubbling chlorine through the melt at ∼725 K for about 14.5 ksec and subsequently scavenging the chlorine by bubbling helium for about 3.6 ksec (5).

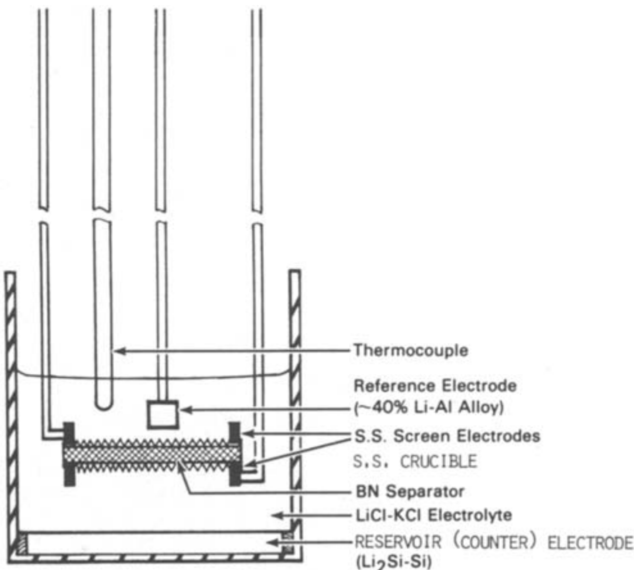

Fig. 1. Schematic diagram of the cell

* Electrochemical Society Active Member.

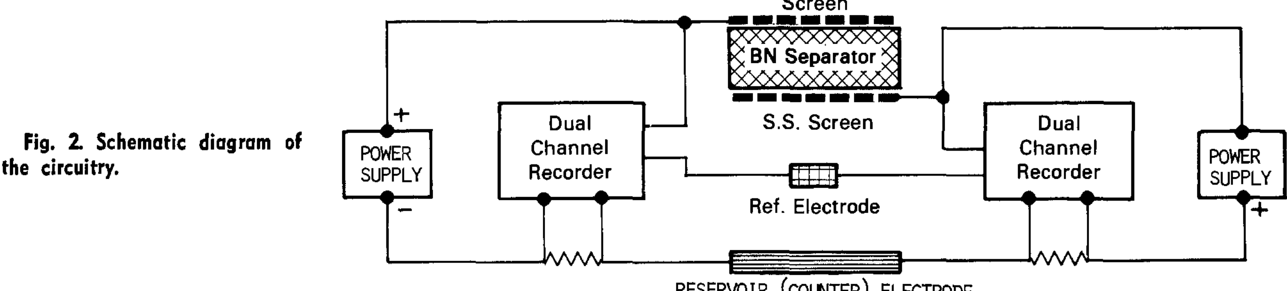

Fig. 2. Schematic diagram of the circuitry.

A tubular furnace (150 mm high, 75 mm diam) was used in conjunction with a variable transformer to heat the cell. Chromel-Alumel thermocouples and a millivolt potentiometer were used for temperature measurements. The other electrical instruments included two d-c power supplies and two dual-channel recorders for measuring current and potentials. In addition, two digital meters were used to check the voltages and currents recorded by the dual-channel recorders.

Procedure

About 250g of the electrolyte was placed in the stainless steel container with the reservoir (counter) electrode attached. The container was inserted into a quartz enclosure in the furnace. The electrolyte was heated to the operating temperature. The screen electrodes with the boron nitride separator, reference electrode, and thermocouple were positioned in the melt. After thermal equilibrium, the top screen electrode (anode) was set as 0.5V or 1.5V with respect to the lithium-aluminum reference electrode,[1] and the bottom screen electrode (cathode) was held at the desired potential. Steady-state currents to maintain the potentials at the screen electrodes were measured. In the absence of electronic conductivity in the separator the cathodic current in the bottom screen supports two electrochemical phenomena. These are the scavenging of impurities and the production of lithium which either is transported by diffusion and convection processes to the bulk electrolyte or reacts with the boron nitride separator. The reaction with boron nitride is distinguished from the other phenomena by comparison of currents measured under two types of experiments. In the first type, base level currents were measured with the boron nitride contacting only the anode. This was done to preclude the reaction of the boron nitride with lithium while maintaining the same potentials and hydrodynamic conditions as for the subsequent measurements. In the second type of experiments carried out to study the boron nitride reaction with lithium, the boron nitride was in contact with both the cathode and anode or only with the cathode.

Results and Discussion

Base-level current data are given in Table I and Fig. 3a. In order to obtain these data, the bottom screen was set at 1.5V and the top screen was set at potentials between −75 and −280 mV. The values are averaged from three sets of readings taken over a period of 1350 ksec. Cathodic current to deposit lithium on a screen is positive in the table and anodic current to remove lithium from a screen is negative.

Steady-state current data for various imposed potentials of the bottom screen electrode (cathode) at 725 K when both screens were in contact with the boron nitride cloth are also given in Table I and presented graphically in Fig. 3b. The top screen (anode) was held at 500 mV. Upon setting the bottom screen (cathode) potential, the current surged and then characteristically tapered off. But at lower potentials (~ −267

[1] Henceforth all of the potentials will be given with respect to the lithium-aluminum reference electrode.

* Base level current data.

mV), the current again increased irregularly, at far greater than the base level currents, indicating the reaction of boron nitride with lithium at these potentials. After ∼700 ksec the separator became electronically conductive. The top screen potential could not be maintained at 500 mV by passing even 10 mA anodically in its circuit. Rather, it fell to the potential of the bottom screen. A large quantity of charge was necessary to attain this shorted condition. This charge was removable. Lithium equivalent to ∼0.9 A · hr could be discharged from 1g of the separator using both the top and bottom screens with a total anodic current of 77 mA. Subsequently, the top screen anodic current diminished to 2 mA and its potential increased to 500 mV. This indicated that the separator lost its electronic conduction after the discharge. Henceforth, lithium could be repeatedly cycled between the separator and the reservoir (counter) electrode. The third cycle is shown in Fig. 3c. The discharge of this cycle was carried out using the circuit of the bottom screen only. A voltage plateau indicative of a well-established compound decomposition, possibly Li_7B_6 was observed. At the end of the plateau, the open-circuit potential was −142 mV. Later, the open-circuit potential of the reacted separator was −147 mV over a period of 55 ksec at the end of the fifth discharge.

At the end of the test, the fibers of the boron nitride separator were observed to be destroyed. Only a solid mass in the shape of the separator cloth remained. This mass reacted with water, evolving a gas. This reaction was presumably due to lithium contained in a reaction product boride.

In another test, vitreous carbon was used for the top electrode (anode) which contacted the boron nitride separator and was held at 1.5V. The bottom electrode (cathode) also in contact with boron nitride was a stainless steel screen held at −136 mV. The currents (0.7 mA in the top circuit and 1 mA in the bottom circuit) obtained during 3600 ksec of operation at 700°C were essentially the same as the base-level currents (Table I).

Steady-state current data were also obtained with only the cathodic electrode contacting the boron nitride cloth. The current in the circuit of the bottom screen (cathode) was indicative of the lithium consumed in the reaction with the boron nitride cloth. The top electrode (anode) was set at 1.5V and the bottom electrode (cathode) in contact with cloth was held at −135, −195, and −244 mV at 700 K. The magnitude of the current in both circuits increased above the base level indicating the reaction of boron nitride when the potential of the bottom screen (cathode) was less than −200 mV.

After maintaining a potential of −210 mV for 280 ksec, chromatographic analysis of the helium above the electrolyte indicated 216 ppm by volume of nitrogen as compared with 22 ppm nitrogen in the helium atmosphere of the glove box. The source of this nitrogen was lithium nitride dissolved in the electrolyte. The imposed potential, 1.5V between the top screen (anode) and the reservoir (counter) electrode, decomposed the dissolved nitride evolving nitrogen at the (anode) screen and depositing lithium at the counterelectrode. The nitrogen from the (anode) screen escaped into the space above the electrolyte.

The boron nitride separator was freed from lithium by discharging it at ∼25 mA for 8 hr. Again it was observed that the separator reacted with lithium at potentials lower than ∼ −200 mV to hold ∼0.2 A · hr. Any remaining lithium in the separator was removed by holding both screens at 1.5V for a few days. During this time, the magnitudes of the currents in both circuits dropped to practically zero. The separator was removed from the cell and cleaned by washing with water.

Microscopic examination indicated that the cloth, which was in contact with the screen wires, was compressed and dented by the wires. Photographs by scanning electron microscope (SEM) of some representative sections of the separator indicated a crusty reaction product and some fine fibers formed from the original boron nitride fibers (Fig. 4). The crusty reaction product, some of which was sticking to the original fibers of boron nitride, is shown at higher magnification in Fig. 5. The fine fibers of the reaction product are also shown in Fig. 6.

The standard free energy change, $\Delta G^\circ_{reaction}$, for the reaction

$$BN(s) + 3Li(l) = B(s) + Li_3N(s) \quad [2]$$

is 100 kJ at 700 K (8). This reaction is not thermodynamically favored. Boron nitride has been observed to react with lithium at 700 K forming Li_3N and a boride (6). The possibility of forming Li_7B_6 and LiB_3 has also been reported (9). Lithium nitride has been reported to be soluble to the extent of 10.1 mol percent (m/o) in lithium chloride at 923 K (10).

Fig. 4. SEM photograph showing boron nitride fibers, crusty reaction product, and fine fibers of the reaction product. Magnification 300×.

A small amount of Li_3N was added to a lithium chloride-potassium chloride eutectic melt in a stainless steel cup at 700 K. A potential of ~1.8V was imposed between the cup and a carbon rod which was placed at its center. The lithium nitride was observed to decompose evolving nitrogen at the rod. The decomposition potential decreased with further addition of Li_3N to the melt and ultimately reached ~0.4V which is very near to the literature value, 0.31V (8). The carbon electrode polarized possibly due to nitrogen evolution when a layer of zirconia fabric was wrapped around it. Thus, Li_3N is appreciably soluble in lithium chloride-potassium chloride eutectic melt. It decomposes by any imposed potential in the range of 0.3-1.8V forming nitrogen and lithium.

In the case of boron nitride which is subjected to the lower potentials of lithium, the following reaction should be considered

$$BN(s) + (3 + x)[Li]_{in\ alloy} = Li_xB(s) + (Li_3N)_{in\ solution} \quad [3]$$

The boron nitride is at unit activity; the lithium activity will be governed by the imposed potential. The boron activity will be the same in the boride and the boron nitride; it will be unity when the boride is in equilibrium with boron. In this case

$$-\Delta G^{\circ}_{reaction} = RT \ln a_{Li_3N} - 3RT \ln a_{Li} \quad [4]$$

where a is the activity of the designated component, R is the gas constant, and T is the temperature degree Kelvin.

Activities of Li_3N with respect to pure solid L_3N can be calculated at the different imposed potentials (corresponding to various lithium activities) from the equation. The mol fractions can be calculated using the

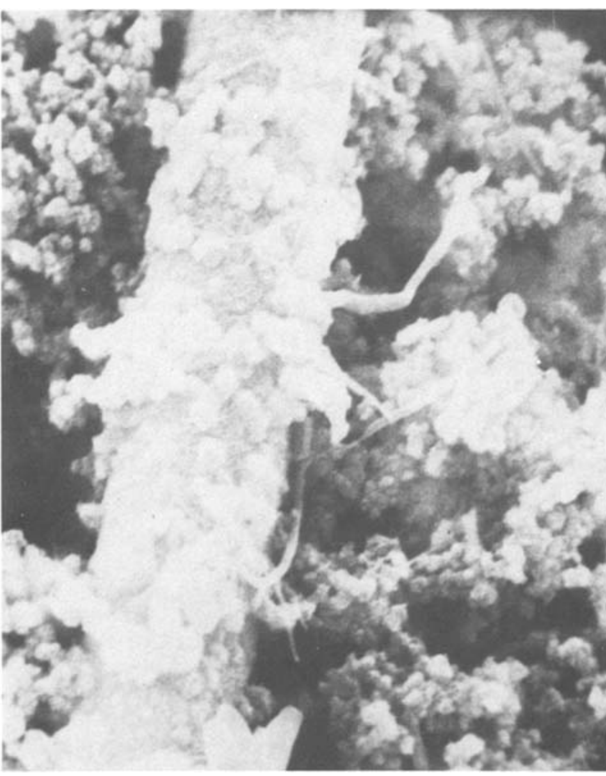

Fig. 5. SEM photograph showing one slightly reacted boron nitride fiber; mostly crusty reaction product and a few fine fibers of the reaction product. The surface of the original fiber indicates the formation of the crust and fibers in the product. Magnification 6000×.

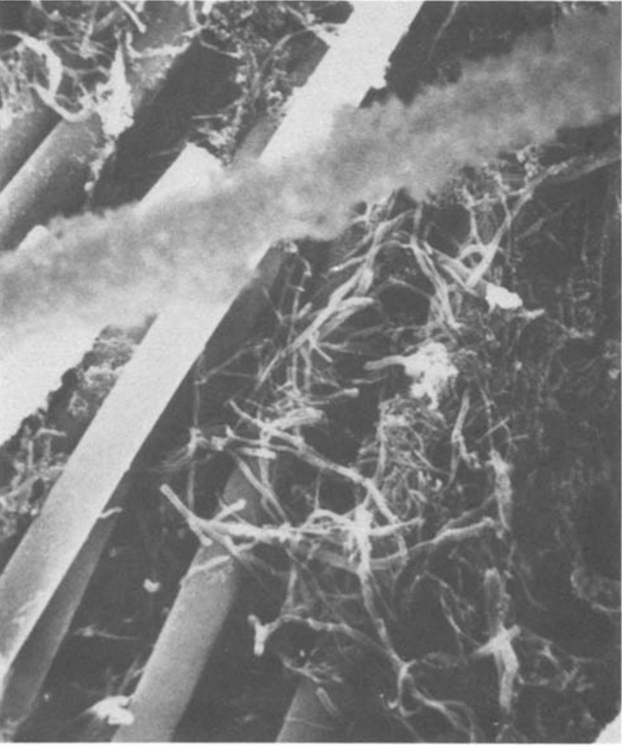

Fig. 6. SEM photograph showing the original boron nitride fibers and the fibers of the reaction product. Magnification 2000×.

activity coefficient of Li_3N, 6.1×10^{-4}, the same as reported in pure lithium chloride at 923 K (10). The activity coefficient remains constant below the mol fraction of Li_3N of 0.005. The equilibrium formation potential, E, of lithium nitride can be calculated from the relation

$$E = E^\circ - RT/n\mathbf{F} \ln a_{Li_3N}$$

where E° is the standard formation potential, n is the number of electrons, and $\mathbf{F}$ is the Faraday constant. The calculated data are given in Table II.

The measured current corresponding to the imposed potential of the bottom screen electrode (cathode) are shown against time in Fig. 7. These data were taken after the bottom screen electrode (cathode) had been in the cell for 234 ksec at -267 mV (Table I). As observed from the curves, the residual current dropped to zero and remained so for ~3.5 ksec when the potential increased from -253 to -195 mV. During this time the top screen electrode (anode) was at 500 mV and the current in its circuit was practically zero (Table I). In another case, the potential of the bottom screen electrode (cathode) was allowed to float while its circuit was used in charging the reference electrode for ~7 ksec. During this time, the top screen (anode) was at 500 mV with no current flowing in its circuit. When the bottom screen electrode (cathode) was put in the circuit, its potential at zero current was observed to be -190 mV. These two observations indicate the decomposition potential of Li_3N to be 500 mV when the bottom screen electrode (cathode) was held between -190 and -195 mV. This is in good agreement with the calculated value of 460 mV (*i.e.*, 750 mV with respect to lithium) as given in Table II.

The activities and potentials of Li_3N in Table II indicate that boron nitride will react with litihum even at its very low activities. The reaction will continue and go to completion if a potential between any two electrodes in the electrolyte greater than the potential of Li_3N formation at its activity is imposed. This is true in the case of lithium alloy/iron disulfide cells, where the potential between the negative and the positive electrodes varies from 1.325 to 1.9V (1-3).

On the other hand, lithium nitride can also be scavenged by the silicon in the negative electrode, particularly, in the region of Li_2Si and silicon.

Table II shows that an electronically conductive boride, possibly Li_7B_6 (9), may form at potentials more reducing than ~ -147 mV. The formation of this boride will make boron nitride an unsuitable material for a separator in lithium-alloy/iron sulfide cells which have negative electrodes with potentials smaller than -147 mV. A nonconductive boride (LiB_3) or boron may form at potentials greater than -147 mV. In the case of the formation of boron which is practically an insulator [resistivity, 1.8×10^6 Ω · cm (11)], boron nitride will not become conductive. Boron density, 2.5 g/cm^3, is not much different from that of boron nitride,

2.27 g/cm^3 (11). Therefore, formation of boron should not destroy the structural integrity of boron nitride. A boron coating on the surface of boron nitride may form and inhibit further reaction. The compound, LiB_3, may also behave just like boron. This may be the reason that boron nitride separators have lasted for thousands of hours in lithium-aluminum/iron sulfide cells which have negative electrodes of lithium potentials higher than -147 mV.

In static immersion tests of boron nitride in lithium, negligible amounts of lithium nitride at its equilibrium concentration will form, so boron nitride can appear stable in these tests. In tests of two lithium electrodes with a boron nitride separator in LiCl-KCl electrolyte, the boron nitride will react with lithium. The reaction will continue to form lithium nitride only up to its equilibrium concentration and then will stop. Because the potential between the two lithium electrodes is smaller than the potential of lithium nitride decomposition at its equilibrium concentration, boron nitride tested in such cells reacted only slightly (6).

Conclusion

Boron nitride is chemically stable with lithium at potentials greater than -136 mV with respect to a lithium-aluminum reference electrode at 700 K. That means boron nitride is stable with $Li_{15}Si_4$ which displays the above lithium potential and which is used as the negative electrode reactant of the $Li\text{-}Si/FeS_2$ cells.

Boron nitride reacts with lithium at potentials below -200 mV with respect to the reference electrode forming a boride and lithium nitride.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.

Publication costs of this article were assisted by General Motors Research Laboratories.

APPENDIX

Reference Electrode

A clean aluminum wire (15 cm long, 0.08 cm diam, 0.083g) was coiled around one end of a 0.3 cm diam

rod of stainless steel. A cover of stainless steel screen was formed over the coil by spot-welding. The coil was first charged at 30 mA to have its composition in the β-phase of the lithium-aluminum phase diagram (4) in a cell with lithium chloride-potassium chloride electrolyte and lithium-silicon counterelectrode at ~700 K. The composition of the coil at the end of the charge was the β-phase. The coil was then discharged to have its composition in the α-β two-phase region. The final composition of the reference electrode was frequently checked and maintained at the above composition.

Caustic Leaching of Al-Cu-Zn Alloys to Produce Raney Catalysts

I. Morphological Development

J. B. Friedrich, D. J. Young,* and M. S. Wainwright

School of Chemical Engineering and Industrial Chemistry, The University of New South Wales, Kensington, N.S.W. 2033, Australia

ABSTRACT

The leaching behavior in aqueous NaOH of Al-Cu-Zn alloys containing 50 weight percent (w/o) Al has been examined and interpreted in terms of alloy phase constitution. Alloys containing approximately 0, 5, 10, 17, 26, 33, and 50 w/o Zn having quenched structures consistent with the ternary phase diagram were partially leached and the product material examined metallographically. In all cases a sharply defined interface developed between the as yet unaffected alloy and the reaction product layer. This layer was of uniform thickness. The principal reaction product was porous copper (containing small amounts of zinc and aluminum) which resulted from leaching of the alloy $Cu(Zn)Al_2$ phase. The microstructure of the alloy was reproduced in the reaction product, suggesting that the mechanism is one of selective dissolution.

A recent study (1) has shown that zinc-promoted Raney copper catalysts can be used for the production of methanol from carbon monoxide and hydrogen. This novel range of catalysts is produced from aluminum-copper-zinc alloys by extraction of aluminum and zinc with aqueous sodium hydroxide to leave porous reaction product zones which act as the catalysts. In that study the inclusion of zinc in the Cu-Al alloy was found to increase the activity of the catalyst for the production of methanol. The effect of Raney copper-zinc catalysts on some other reactions has been reported.

Sultanov and Maslennikova (2) reported the use of a Raney copper-zinc catalyst for the reduction of furfural to sylvan and recommended as the most effective catalysts one which had an initial alloy composition of 33 weight percent (w/o) copper, 50 w/o aluminum, and 17 w/o zinc. Standfield and Robbins (3) presented a kinetic study of the hydrogenation of various functional groups of organic molecules using Raney copper-type catalysts and reported that the addition of zinc to replace aluminum in the alloy failed to yield a more active catalyst. In none of the above studies on Raney copper-zinc was any attempt made to examine the leaching behavior of the various phases in the Al-Cu-Zn system. A recent paper by Young *et al.* (4) contains information on the leachability of the phases present in a Cu-50 w/o Al alloy. This alloy had a quenched structure, containing $CuAl_2$ as primary precipitate, and material of the composition of the binary Al-$CuAl_2$ eutectic. The $CuAl_2$ leached to form Raney copper whereas the eutectic mixture leached completely, leaving no solid residue. Since the leaching process will in a large part determine the physicochemical properties of the resultant catalyst, the reaction is of some interest.

The dissolution of a component from an alloy to leave behind a spongy material is a familiar, albeit poorly understood, phenomenon. Dezincification of brass is possibly the best known example (5-7), but others have also been studied (8, 9). Two mechanisms have been suggested for the process in binary alloys. In the first, it is supposed that simultaneous dissolution of both constituents is followed by reprecipitation of the less reactive metal. The difficulty with this mechanism is that mass transfer is required from a source of low activity, the alloy, to a region of high activity, the pure metal. Alternatively, it is suggested that the more reactive constituent is selectively removed leaving an accumulation of the less reactive metal at the

Key words: metals, catalysis, dissolution, corrosion.

alloy surface. For this mechanism to be available, diffusion within the alloy must be sufficiently fast to support the leaching process. Although solid-state diffusion coefficients are low at ambient temperatures, the highly porous nature of the leached alloys indicates a reaction morphology which requires only short diffusion distances. The production of a Raney catalyst is a reaction of the type under discussion. In the absence of leaching studies, however, it is not possible to say which of the above mechanisms is operative.

The present work is divided into two parts. The first part provides new information on leaching of the various phases in the Al-Cu-Zn system by a systematic study using metallographic, x-ray diffraction, and electron microprobe methods of analysis. In the second part, the kinetics of aqueous sodium hydroxide attack on the various aluminum-copper-zinc alloys are investigated.

Experimental

Alloy and catalyst preparation.—Alloy melts were prepared by induction melting the required proportions of copper (99.5% pure), aluminum (99.9% pure), and zinc (99.8% pure) as described by Marsden *et al.* (1). The homogeneous melts were cast onto a chilled copper mold to form a plate from which rectangular prisms ($6 \times 6 \times 9$ mm) were machined. The actual compositions of the alloys are listed in Table I and are shown plotted on the Al-Cu-Zn liquidus projection diagram in Fig. 1. The samples machined from the castings were used in leaching experiments without further heat-treatment.

Leaching experiments were carried out by reacting the rectangular prisms isothermally at 50°C with 20 w/o aqueous NaOH, the amount of solution provided being equivalent to three times the stoichiometric amount of aluminum present in the alloy. No means of stirring was provided. After various times of reaction the partially extracted alloy pieces were thoroughly washed with distilled water until the pH of the wash water was 7. The samples were then mounted in cold setting resin, cross sectioned at right angles to an original face of the specimen, and metallographically polished to a 1 μm finish. The reaction-affected rim of the alloy piece was then clearly visible under an optical microscope.

Alloy pieces of 500-700 μm diam were leached to provide material for x-ray diffraction studies and atomic absorption analysis. In these runs 20g of the alloy was placed in 111g of distilled water at 50°C. After the apparatus had been thoroughly flushed with hydrogen, 40 w/o caustic solution was added over a time period of 0.75 hr so that the reaction temperature was kept to 50° ± 2.5°C. No means of stirring was provided. After complete extraction had taken place (as determined by the hydrogen evolved from the reaction) the catalysts pieces were thoroughly washed with distilled water until the pH of the wash water was 7.

Phase identification.—Phases present in the unaffected alloy and in the reacted rim were analyzed with an electron probe microanalyzer. Point counts obtained

from the probe were analyzed with respect to $CuAl_2$, Al, and Zn standards. Systematic corrections were applied to the data for atomic number, mass absorption, and fluorescence effects.

Microprobe results were supplemented by powder x-ray diffraction studies. Samples of powdered alloys were examined with a diffractometer in the usual way. Powdered catalyst samples were prepared from 500 to 700 μm alloy pieces leached under the conditions described above. The powdered catalysts were pyrophoric and were therefore coated with collodion prior to examination.

The crystallite size in the reaction product was determined from the broadening of the Cu(200) diffraction line using the Scherrer equation. Corrections for instrumental broadening were obtained from the silicon (220) diffraction line. In both cases CuKα radiation was used and phase identification was accomplished by comparing diffraction patterns with those in the ASTM files. The ternary phase T was identified from the diffraction pattern reported by Köster and Moeller (10). The $CuZn_5$ phase was identified from the pattern reported by Owen and Preston (11).

The composition of the alloys and the completely extracted 500-700 μm catalyst pieces were determined by atomic absorption spectroscopy of acid digested samples. Copper and zinc analyses were determined by the standard addition technique, while aluminum was determined by comparing the unknown with matched standards.

Results

Micrographs in Fig. 2 show the interface, or reaction front, between the unaffected alloy and the reaction product zone which had developed after 4 hr of reaction. In all cases a clearly defined boundary was found to exist. At all reaction times investigated for all samples this boundary was found to be parallel to the original alloy surface. The cast alloy structures showed no preferential orientation except in the case of samples 2, 3, and 4 where some evidence of directional solidification was observed. In the cases where some directional solidification was evident in the alloy, the thickness of the reacted zone appeared not to vary with the angle between the directions of solidification and leach reactions (Fig. 3). Microprobe analyses for each of the phases seen in the micrographs are listed in Table II. No results are reported for alloys 5 and 6 in which the microstructure could not be resolved with the microprobe. Phases identified by x-ray diffraction for the alloys and their reaction products are shown in Table III.

Microprobe scans showed that no concentration gradient existed in any of the phases within the alloys. At the interface a discontinuous change in concentration for all three metals was observed. Analyses of

the phases in the reaction product zone were found to total substantially less than 100% indicating either that oxide is present or that the analysis of these porous materials is unreliable. Atomic absorption analysis of the catalyst particles (Table I) showed that there was no oxide present. Microprobe scans of the copper phase in the reaction product zone for alloys 1-4 showed that in each case an aluminum concentration gradient was present and in the case of alloys 2-4 a zinc concentration gradient was present. In each case the zinc and

aluminum were in greater concentration near the reaction interface.

The grain size of the primary precipitate in alloys 1-4 decreased as the copper content of the base alloy decreased. As expected from the phase diagram, the volume percent of $Cu(Zn)Al_2$ primary precipitate also decreased with increasing alloy zinc content. Results are reported in Table I. In alloys containing higher concentrations of zinc, the $Cu(Zn)Al_2$ phase could not be satisfactorily resolved with the microscope. The x-ray diffraction estimates of the copper crystallite size in the extracted catalyst pieces are shown in Table IV.

The reaction products of alloys 1, 2, and 3 showed the same morphologies at all stages of reaction. However, alloys 4, 5, and 6 exhibited a different reaction morphology in the initial stages of leaching. Micrographs in Fig. 4 show the development of this morphology for alloy 4. They show that for reaction times of up to 2 hr the reaction product zone consists of two layers, the outer layer containing dark colored grains and the inner layer light colored grains. Microprobe analysis showed that the grains in the outer layer were essentially copper while those in the inner layer were unreacted $Cu(Zn)Al_2$. The intergranular material had leached completely to leave void space in both layers.

Discussion

Alloy structures.—X-ray diffraction and microprobe results for the alloys confirmed one another except for the cases of the ternary phase, T, and the $CuZn_5$ phase. These two phases, which are minority phases when present in the alloy, could be detected by XRD but could not be distinguished with the microprobe. The ternary phase T has a field of existence of 56-58% Cu, 10-30% Zn (12).

The alloy microstructures are consistent with predictions for quenched alloys made from the liquidus projection diagram (Fig. 1). Alloys 1-4 have as their primary precipitate the phase $Cu(Zn)Al_2$ with the Zn content in this phase increasing with the alloy Zn level. This is consistent with the fact that the $CuAl_2$ phase can dissolve up to 2-3 w/o Zn with little change in lattice parameters (12). The primary precipitate for alloys 5, 6, and 7 is the aluminum-based solution.

The identity of the secondary precipitate is determined by the alloy Zn level. Alloy 1 produces as its secondary solidification product material of the composition of the binary Al-$CuAl_2$ eutectic. Alloys 2-4 precipitate the aluminum-based solution as their secondary product. Alloys 5 and 6 precipitate $Cu(Zn)Al_2$

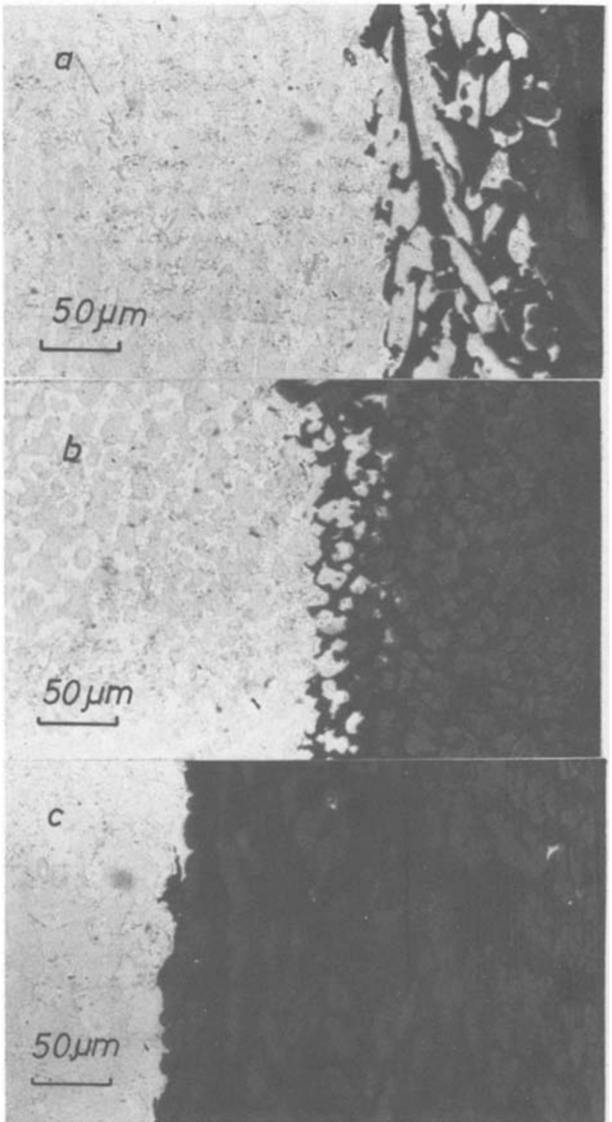

Fig. 4. Micrographs of sections through partially leached Al-33Cu-17Zn alloy showing morphological development: (a) 0.5 hr; (b) 1.0 hr; (c) 2.0 hr.

as their secondary product. On further cooling the ternary phase T is the final solidification product for alloys 2-5. Alloy 6 also contains the ternary phase T as well as having $CuZn_5$ as its final solidification product. The reactions forming the ternary phase T and the $CuZn_5$ phase are peritectic reactions. These peritectic reactions have been arrested by quenching to leave a very fine structure that could not be resolved by the microprobe. The intergranular material in sample 7 is zinc-rich frozen liquid.

Catalyst structure.—Examination of Fig. 2 together with Tables II and III reveals the morphology of the reaction product catalysts. Leaching of the $CuAl_2$ phase from alloy 1 leads to the formation of copper containing low levels of aluminum. Similarly the leaching of the $Cu(Zn)Al_2$ phase from alloys 2-4 leads to the formation of copper containing low levels of both aluminum and zinc.

In a subsequent paper (13), we show that the completely extracted catalyst pieces are highly porous, with a BET surface area of approximately 20 m^2/g, with pore radii ranging from 50-230Å.

The microstructure of the alloy, in samples 1-4, has been reproduced in the reaction product catalysts. Examination of the interface between alloy and catalyst

Table IV. Copper crystallite diameters and pore diameters (500-700 µm particles) for fully extracted Raney catalysts

Sample	Copper crystallite diameter (Å)	Pore diameter (Å)	Calculated interpore distance (Å)
1	112	460	194
2	112	354	182
3	104	332	171
4	104	284	138
5	70	230	119
6	62	101	69

shows that the size of the $Cu(Zn)Al_2$ grain has been preserved when leached to leave porous copper. Copper crystallite sizes given in Table IV show that for catalysts 1-4 there are no major differences in diameter. There is a marked decrease in the copper crystallite size for catalysts 5 and 6 which derive from alloys in which $Cu(Zn)Al_2$ is a secondary precipitate.

Pore volume and pore diameter measurements (13) were used to calculate average interpore distances on the assumption of parallel, straight, cylindrical pores the cross sections of which are hexagonally arrayed. The results of this calculation are compared with measured crystallite sizes in Table IV, and agreement is seen to be good. It is concluded that the microstructural rearrangement accompanying leaching takes place on an exceedingly small scale and that pore size and crystallite size are interdependent.

The leaching of the intergranular material from alloys 1-4 leads to void space in the reaction product zone. However, examination of the reacted rim near the reaction front for alloy 4 suggests that some of the intergranular material is still visible, but has disappeared at the outer surface where time of exposure has been greatest. The reason for the decrease in reactivity of the intergranular material with increased Zn levels could not be determined. Microprobe analysis of the intergranular material in the reaction product zone proved to be extremely unreliable, a fact which may be attributed to the porosity of the reaction product zone and to the fine scale of the microstructure in the intergranular material. X-ray diffraction did not constitute a satisfactory analysis technique for the intergranular material in the reacted catalyst pieces since the diffraction lines for the ternary phase T were either masked by elemental copper or were not visible. There was no diffraction attributable to the aluminum solid solution in the reaction product catalysts. Evidently the addition of zinc to the base alloy resulted in the intergranular material being more resistant to caustic attack than the Al-$CuAl_2$ eutectic. The present results do not show whether this is due to decreased reactivity of the Al-Zn solid solution or to increasing amounts of the ternary phase, T, which might be of low reactivity.

The leaching of the zinc-rich alloys 5 and 6 leads to void space from the aluminum solid solution and to pockets of porous copper from the intergranular material. The problems encountered with the microprobe and x-ray diffraction results for the copper-rich samples were again evident in the analysis of the reaction product zone. The leaching of alloy 7 leads to void space from the aluminum-rich primary precipitate while the zinc-rich frozen liquid appears to be unreacted at this stage.

Reaction morphology development.—In all samples studied there was a sharply defined alloy catalyst interface. As the reaction proceeds this interface appears to cut across the phases present. Thus apart from rare localized variations both the primary precipitate and the intergranular solidification product leach at the same rate. This observation is consistent with a diffusion-controlled reaction rate. The stability of the interface together with the speed of the reaction indicates that it is liquid phase diffusion which supports the reaction. This conclusion is supported by the observation that in the case of directionally solidified alloys (Fig. 3) the reaction rate is not a function of the orientation of the alloy grains with respect to the reaction front.

This description does not hold true for alloys containing 17 w/o Zn or more at short time periods. Examination of Fig. 4 shows that the intergranular solidification product leaches at a faster rate than the $Cu(Zn)Al_2$ phase at short time periods. However at longer leaching periods, 4 hr or greater, both the primary precipitate and the intergranular solidification product leach at the same rate. Thus it appears that the high zinc alloys leach according to a more complex mechanism in the early stages of the reaction but subsequently via a liquid phase diffusion-controlled process.

In the case of the low zinc alloys, the preservation of the alloy microstructure in the leached product suggests strongly that the reaction of the $Cu(Zn)Al_2$ grains proceeds via a selective dissolution process rather than a dissolution-reprecipitation process. The latter mechanism has been suggested to be operative under some circumstances in the dezincification of brass (5). Tht difference is readily explicable in view of the extremely low solubility of Cu in the caustic solutions used in the present work (14). The microstructure of the higher zinc alloys appears also to be preserved in their leach products, but the failure to obtain useful microanalysis results prevents a similar conclusion being reached.

It has been shown that the nature of Raney Cu-Zn catalysts is determined by the phase constitution of their precursor alloys. The principal leach reaction product is porous copper containing small amounts of zinc and aluminum. This product derives from the leaching of the alloy $Cu(Zn)Al_2$ phase. The other major alloy phase is an Al-Zn solid solution which usually leaches completely, leaving void space. At very high zinc levels, however, this phase becomes resistant to leaching. In all cases, the alloy microstructure is preserved in the reaction product and a sharp interface develops between the product and the as yet unaffected alloy. These observations are consistent with a selective dissolution reaction whose rate is controlled by diffusion through the product layer. The kinetics of this reaction are reported in the following paper (15).

Caustic Leaching of Al-Cu-Zn Alloys to Produce Raney Catalysts

II. Leaching Kinetics

ABSTRACT

The leaching kinetics of Al-Cu-Zn alloys containing 50 weight percent (w/o) Al in aqueous NaOH have been examined by measuring the depth of attack on the alloy pieces as a function of time and also by measuring the evolution of hydrogen as a function of time. Alloys containing approximately 0, 5, 10, 17, 26, and 33 w/o Zn were found to have parabolic leaching kinetics, the reaction mechanism being one of selective dissolution controlled by liquid phase diffusion through the product layer. The product layer was porous copper which resulted from leaching of the alloy $Cu(Zn)Al_2$ phase. This porous copper was found to contain a zinc and an aluminum concentration profile throughout the reacted zone. The shape of these profiles was consistent with liquid phase diffusion control except for a narrow region near the alloy surface where a degree of chemical reaction control was found. This observation is consistent with the experimental activation energy of 41 ± 5 kJ mol^{-1}.

It has been shown (1) that Al-Cu-Zn alloys containing 50 weight percent (w/o) Al leach in strong caustic solution at 50°C to produce a product layer of porous Cu containing small amounts of Al and Zn. This product layer is of uniform thickness and a sharply defined interface is established between it and the underlying, as yet unaffected alloy. The alloys contained as principal phases $Cu(Zn)Al_2$ and Al-Zn solid solution, the former of which leached to leave the porous copper whereas the latter reacted completely, leaving void space. The alloy microstructure was preserved in the product layers. These observations were interpreted as implying a reaction mechanism of selective dissolution whose rate was controlled by diffusion through the product layer.

Preferential removal of an alloy constituent by a chemical reaction which leaves unaffected a more noble alloy constituent is a common phenomenon and has been widely studied in connection with the dezincification of brass (2-4). Reaction rates are high when a porous product and a convoluted alloy-product layer interface are formed. This situation has been analyzed theoretically by Wagner (5) and the analysis applied to the kinetics of liquid metal and molten salt attack on binary alloys containing one component which was noble with respect to the environment (6). The observation of parabolic kinetics was attributed to rate control by diffusion in the liquid phase, rapid alloy diffusion being facilitated by the short diffusion distances associated with porous reaction product. More recently, the chlorination of Co-Pt and Fe-Pt alloys has been studied by Pickering (7) who showed that the formation of a volatile base metal chloride left a porous Pt layer which thickened at a rate independent of time. Since the chloride vaporization rate is independent of product layer thickness and since the reaction must be supported by microsegregation of Pt and base metal at the reaction front, it is apparent that the rate of this latter process is time independent.

It is apparent that a knowledge of the kinetics of the process whereby a solid leach residue accumulates is a valuable aid in the dissection of the reaction mechanism. This paper reports the results of an investigation of the leaching kinetics of a series of Cu-Al-Zn alloys and an account of the probable reaction mechanism.

Experimental

Several Cu-Al-Zn alloys were leached in 20 w/o aqueous NaOH solution. Alloy compositions, sample shape, and leaching procedures used for the kinetic investigation were fully described in the previous paper (1). The extent of reaction was determined by measuring the depth of attack on the alloy pieces as a function of time. The depth of chemical attack was measured at right angles to an original alloy face under an optical microscope with a graduated eyepiece. Measurements were taken after various periods of reaction up to a maximum of 24 hr.

The extent of reaction was also measured by monitoring the evolution of hydrogen as a function of time using a wet test gas meter. An amount of NaOH solution, equivalent to three times the stoichiometric amount of aluminum present in the alloy, was added to six alloy pieces at 50°C, after first purging the system with hydrogen. No means of stirring was provided. Readings were taken at the same time intervals used for the distance measurements.

Elemental concentration profiles were measured in the reaction product layer formed on alloys 1-4 by point counting on an electron probe microanalyzer. Temperature dependence experiments were carried out on an alloy of composition Al-36 w/o Cu-14 w/o Zn to determine an activation energy for the leaching reaction. The leaching experiments were carried out at temperatures of 6°, 27°, 54°, and 82°C and on roughly spherical alloy pieces of 2.4-4.0 mm diam. A 20g sample of alloy was placed in 111g of distilled water at the required temperature. 111g of 40 w/o aqueous sodium hydroxide solution was added after first purging the system with hydrogen. No means of stirring was provided. The extent of reaction was monitored by the evolution of hydrogen. Temperature control in these experiments was to within ±2.5°C.

Results

The thickness of the reaction-affected rim around the partially extracted alloy pieces as a function of leaching time is shown in Fig. 1. Data at 0.5 and 1 hr

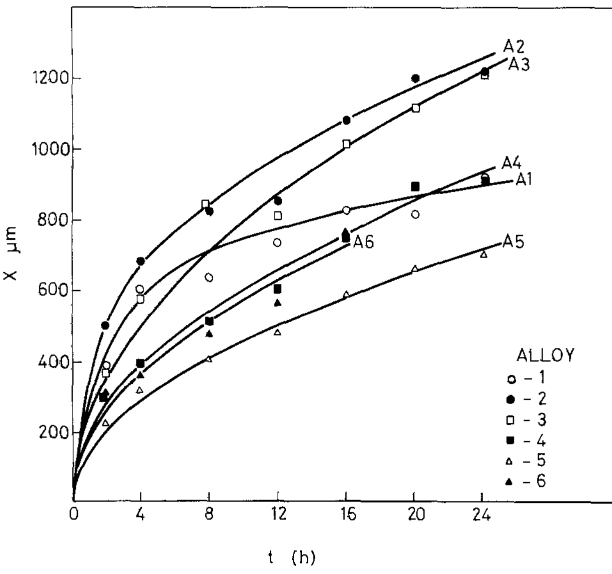

Fig. 1. Average thickness of reaction-affected rim as a function of leaching time.

have not been included in Fig. 1. The shape of the curves indicates parabolic leaching kinetics. Accordingly, the data have been replotted in Fig. 2 where the straight lines are the results of regression on the equation

$$X^2 = k_p t \quad [1]$$

where X is the thickness of the reaction-affected rim formed in time t and k_p is a parabolic rate constant. The 0.5 and 1 hr leaching data have been included in the regression calculation. Values of k_p are presented in Table I. Alloy 6, the high zinc alloy, showed irregular kinetics due to the product layer's inability to hold its structure around the alloy. Therefore data

Table I. Alloy composition and leaching rate constant for Al-Cu-Zn alloys

Alloy number	Alloy composition (w/o) Al	Cu	Zn	k_p (cm²/sec) × 10^7
1	50.2	50.6	0	1.09 ± 0.27
2	50.7	44.6	5.3	1.94 ± 0.32
3	50.3	39.3	9.8	1.76 ± 0.22
4	49.7	33.5	17.1	1.02 ± 0.10
5	49.8	24.6	26.0	0.60 ± 0.04
6	48.5	17.2	33.0	0.92 ± 0.18

after leaching times of 16 hr on alloy 6 were not considered.

The extent of reaction as measured by hydrogen evolution as a function of leaching time is shown in Fig. 3. The volume of hydrogen produced, V_H measured at 25°C, 1 atm, is related to the volume of alloy reacted, ΔV, by a stochiometric constant

$$V_H = k_H \Delta V \quad [2]$$

If corner effects are ignored, it may be shown that the volume reacted of a rectangular prism of original dimensions $L \times L \times W$ is related to the reaction zone depth by

$$\Delta V = 8X^3 - aX^2 + bX \quad [3]$$

where $a = 8L + 4W$, $b = 2L^2 + 4LW$. Combination of Eq. [1], [2], and [3] leads to the result

$$V_H = k_H[8(k_p t)^{3/2} - ak_p t + b(k_p t)^{1/2}] \quad [4]$$

Regression on this equation was carried out for the hydrogen evolution data for one alloy piece and the resulting estimates of k_H are shown in Table II along with values for the 95% confidence interval on the regression coefficient. The small values obtained for this latter quantity indicate that Eq. [4] fits the data well.

Temperature effects on leaching rates were determined from hydrogen evolution measurements. Since the relationship between hydrogen evolution and reaction product layer thickness is shape dependent, measurements were restricted to the early stages of reaction where such effects are small. The rate constant was determined from the expression

$$V_H^2 = k_a t \quad [5]$$

where an Arrhenius plot for k_a is shown in Fig. 4. The

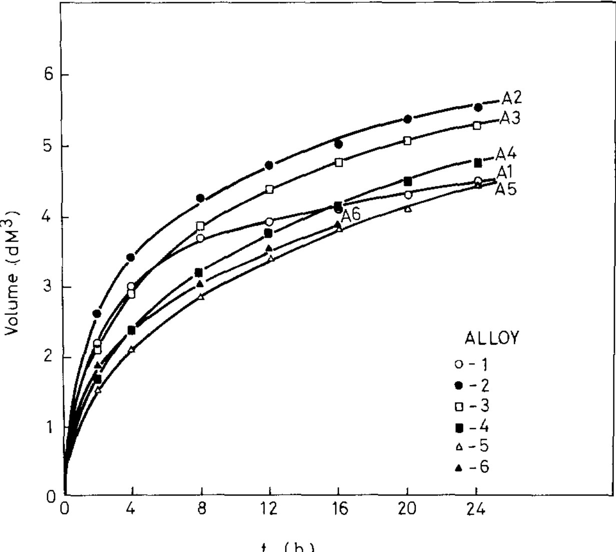

Fig. 3. Hydrogen evolution (corrected to 25°C, 1 atm) from the reaction-affected rim as a function of leaching time.

Table II. Stoichiometric constants for the leaching of the Al-Cu-Zn alloys

Alloy number	Regression coefficient k_H (Eq. [4]) × 10^{-3}	Stoichiometric coefficient k_H (Eq. [2]) × 10^{-3}
1	3.66 ± 0.57	3.37 ± 0.17
2	3.62 ± 0.38	3.40 ± 0.17
3	3.33 ± 0.19	3.36 ± 0.17
4	3.85 ± 0.15	3.37 ± 0.17
5	4.20 ± 0.10	3.52 ± 0.17
6	3.75 ± 0.35	3.54 ± 0.18

activation energy was determined to be 41 ± 5 kJ mol^{-1}.

Concentration profiles for aluminum and zinc in the copper phase of the reacted rim as determined by microprobe analysis for alloys 1-4 are shown in Fig. 5 and 6 where the position coordinate has been normalized with respect to layer thickness. The microprobe analyses of the copper phase in the reaction product zone were found to total substantially less than 100%, and these analyses have been normalized. Figure 7 shows the plot of zinc concentration as a function of position in the copper phase near the interface. The concentration of zinc in the copper phase is greater than would be expected from that zinc originally present in the $Cu(Zn)Al_2$ phase. Microprobe scans parallel to the interface through the copper grain near the interface showed no variation in zinc and aluminum concentration. Microprobe scans parallel and at right angles to the interface through a copper grain midway in the reaction product zone again showed no variation in zinc and aluminum concentration.

Discussion

The chemical reactions involved in the leaching of the Al-Cu-Zn alloy with caustic solution may be represented as (8)

$$Al + OH^- + 3H_2O = Al(OH)_4^- + \frac{3}{2}H_2 \quad [6]$$

$$Zn + 2\,OH^- + 2H_2O = Zn(OH)_4^{=} + H_2 \quad [7]$$

These reaction stoichiometries, combined with the values of alloy densities and Al and Zn concentrations, yield a value for the stoichiometric coefficient k_H appearing in Eq. [2] and [4]. Values of k_H calculated in this way are compared with the experimentally determined quantity in Table II. The experimental values are close to the values calculated from reaction stoichiometries, indicating that leaching is close to complete.

The parabolic kinetics of the leaching reaction suggest that the process is diffusion controlled. This diffusion control could arise from three mechanisms: (*i*) solid-state diffusion in the product layer, (*ii*) diffusion within the alloy where the noble metal remains as a continuous film at the alloy surface and selective dissolution proceeds by volume diffusion of the active metal through the noble metal layer, and (*iii*) liquid phase diffusion within the product layer. Mechanism (*i*) is extremely unlikely since solid-state diffusion in the product layer would be too slow to support the leaching rates experimentally determined.

To determine whether mechanism (*ii*) could support the observed leaching rate a calculation based on the mechanism proposed by Pickering and Wagner (2) is performed. According to these authors, the flux $J_{Al,Zn}$ of aluminum or zinc atoms toward the surface is given for high concentrations of Al or Zn by

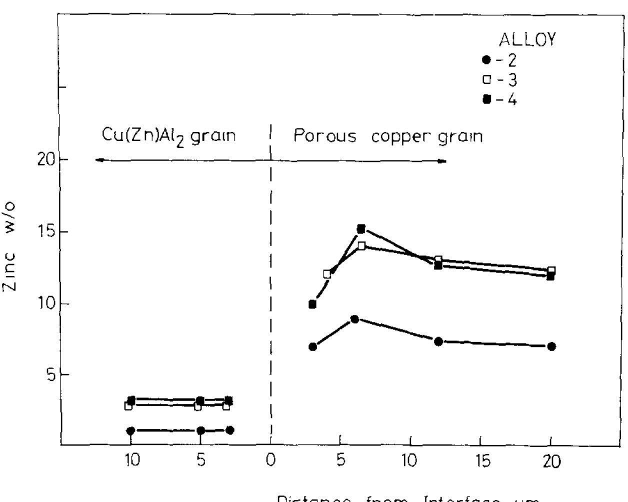

Fig. 7. Zinc concentration profile through a $Cu(Zn)Al_2$-Cu grain at the alloy-reaction product zone interface.

$$J_{Al,Zn} = \frac{N^o{}_{Al,Zn}}{V_m}\left[\frac{D_{Al,Zn}}{2(1 - N^o{}_{Al,Zn})t}\right]^{1/2} \quad [8]$$

where $N^o{}_{Al,Zn}$ is the bulk mol fraction of aluminum or zinc in the alloy, V_m is the molar volume which is approximated as a constant, and $D_{Al,Zn}$ is the alloy diffusion coefficient of aluminum or zinc. From the parabolic leaching kinetics, Eq. [1], it follows that

$$dX/dt = \tfrac{1}{2}(k_p/t)^{1/2} = k_p/2X \quad [9]$$

and the combined flux of aluminum and zinc arriving at the surface is

$$dX/dt = V_m(J_{Al} + J_{Zn}) \quad [10]$$

Combining Eq. [8], [9], and [10] and making use of the approximation $D_{Al} \simeq D_{Zn} = D_A$, one has

$$2D_A = k_p \Big/ \left[\frac{N^o{}_{Al}}{(1 - N^o{}_{Al})^{1/2}} + \frac{N^o{}_{Zn}}{(1 - N^o{}_{Zn})^{1/2}}\right]^2 \quad [11]$$

which can be used to estimate approximate values for alloy diffusion coefficients.

The average value of D_A from Eq. [11] for the range of alloys studied was found to be 3×10^{-8} cm²/sec. This value is far too high for the accepted values for alloy diffusion at the low temperatures studied and so mechanism (*ii*) is rejected as the rate-controlling step for the leaching reaction.

If liquid phase diffusion within the product layer is the rate-determining step then alloy diffusion, more specifically diffusion within the $Cu(Zn)Al_2$ phase, must be fast enough to support it. Alloy diffusion for a planar alloy-product layer interface would be impossible since diffusion distances would be quite large. However, the alloy-product interface is not planar but highly convoluted as is indicated by surface area and pore size measurements (9). A schematic representation is shown in Fig. 8. A similar situation can arise during the oxidation of alloys involving noble metals as has been discussed by Wagner (5) and explored experimentally (6). In the situation shown in Fig. 8

$$J_{Al,Zn} \simeq -D_{Al,Zn}\frac{\partial C_{Al,Zn}}{\partial y} \quad [12]$$

and

$$\frac{\partial C_{Al,Zn}}{\partial y} \simeq \frac{C^o{}_{Al,Zn}}{\delta} \quad [13]$$

where y is the position coordinate within the alloy, $C^o{}_{Al,Zn}$ is the bulk molar concentration of aluminum or zinc in the $Cu(Zn)Al_2$ phase, and δ is the effective thickness of the alloy interdiffusion zone. It follows immediately that

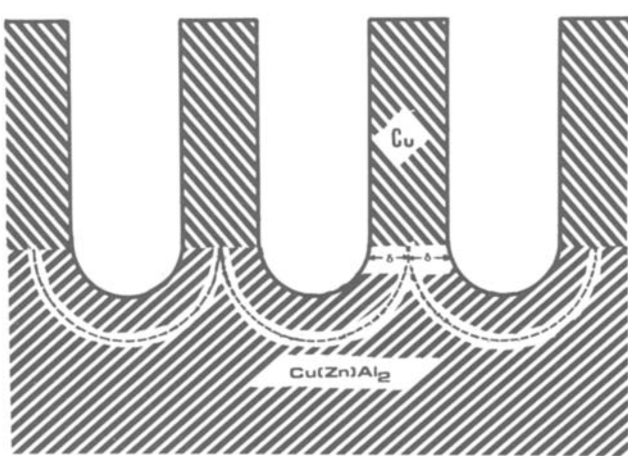

Fig. 8. Schematic representation of a $Cu(Zn)Al_2$-Cu grain at the alloy-reaction product zone interface.

$$J_{Al,Zn} = D_A\frac{C^o{}_{Al,Zn}}{\delta} \quad [14]$$

where use has again been made of the approximation $D_{Al} \simeq D_{Zn} = D_A$. Combining Eq. [9], [10], and [14] one obtains

$$D_A = \frac{\delta k_p}{2X(N^o{}_{Al} + N^o{}_{Zn})} \quad [15]$$

This result was used to estimate D_A on the assumption that δ approximately equals half the interpore separation distance. This distance has been estimated from pore volume and pore diameter measurements (9).

The average value of D_A calculated from Eq. [15] for the range of alloys studied was found to be 2×10^{-12} cm²/sec. Values of diffusion in solidified Cu-Al eutectic mixtures at high temperatures are reported by Smithells (10). A value of 3×10^{-25} cm²/sec was calculated at 50°C by extrapolation of this high temperature data. However, a value of 1.3×10^{-12} cm²/sec has been deduced by Pickering and Wagner (2) for the diffusion of copper atoms by divacancies at 25°C in a copper-gold alloy. This latter value compares favorably with the value calculated from Eq. [15]. It seems, therefore, that liquid phase diffusion within the product layer is the most likely mechanism, since alloy diffusion at the convoluted interface is probably fast enough to support it.

If the leaching reaction is controlled by diffusion in the liquid phase within the product layer then the reaction rate should reflect the mobilities of the solute species responsible for mass transport. The transport of hydroxyl ions from the bulk liquid to the alloy-product layer interface, where reaction occurs, is now considered. Since the product layer is composed largely of copper, no electrostatic potential gradient can be sustained and the appropriate transport equation is simply

$$J_{OH^-} = -D_{OH^-}\frac{\partial C_{OH^-}}{\partial x} \quad [16]$$

where x is the position coordinate. To a first approximation then

$$J_{OH^-} = D_{OH^-}C_{OH^-}{}^{(o)}/X \quad [17]$$

where $C_{OH^-}{}^{(o)}$ is the hydroxyl ion concentration at the outer surface of the product layer. In the steady state, the rate of arrival of hydroxyl ions at the alloy surface must be stoichiometrically equivalent to the rate of leaching

$$|J_{OH^-}| = J_{Al} + 2J_{Zn} \quad [18]$$

Since leaching is close to quantitative, the metal fluxes are related according to the bulk alloy composition

$$J_{Al}/J_{Zn} = N^o{}_{Al}/N^o{}_{Zn} \quad [19]$$

Thus the mass balance at the alloy-product layer interface is described by Eq. [18] and [19] which, together with Eq. [9] and [10] yield

$$k_p = 2V_m D_{OH^-}C_{OH^-}{}^{(o)}\left(\frac{1 + N^o{}_{Zn}/N^o{}_{Al}}{1 + 2N^o{}_{Zn}/N^o{}_{Al}}\right) \quad [20]$$

The application of this equation to present results, using the molar volume of Al, yields an estimate of $D_{OH^-} = 1 \times 10^{-6}$ cm² sec⁻¹, equivalent to a mobility of 3.6×10^{-5} cm² sec⁻¹ V⁻¹. This is significantly less than the reported value for hydroxyl ions of 2×10^{-3} cm² sec⁻¹ V⁻¹ at 25°C (11). In view of the fact that solution viscosity and pore tortuosity effects have not been taken into account, the agreement is reasonable. The appropriate data for $Al(OH)_4^-$ and $Zn(OH)_4^{2-}$ appears to be unavailable and no conclusion can be reached as to the nature of the rate-determining species in the solution.

The leaching of alloy 1, as seen in Fig. 1 and 3, displays a different trend to the alloys which contain zinc. This is possibly due to the higher copper content in the eutectic material. The effect of alloy composition on the leaching rate is shown in Fig. 9. Introduction of a small amount of zinc to the alloy substantially increases the leaching rate, but addition of more zinc results in a decrease in the leaching rate. If, as has been argued above, the leaching process is controlled by liquid phase diffusion, then these effects of alloy composition on the rate must indicate changes in the boundary values for the activities of the diffusing species. Since the hydroxyl ion activity is controlled at one boundary by the bulk solution and since its activity at the other boundary is probably very low, the hydroxyl ion diffusion rate is not expected to be sensitive to variation in alloy composition. However, the outward diffusion rates of $Al(OH)_4^-$ and $Zn(OH)_4^{2-}$ ions will depend on the boundary values of their activities at the product-layer alloy interface where they are created. These values are in turn expected to depend on alloy composition.

As zinc is added to the alloy its activity must rise and, if equilibrium at the alloy-product interface obtains, so too must the activity of $Zn(OH)_4^{2-}$ ion at this boundary. The effect on alloy aluminum activity may be seen by modeling the alloys as belonging to a simple two-phase system: $Cu(Zn)Al_2$ plus Al-Zn solid solution. It has been shown (1) that addition of zinc to the former phase is at the expense of the copper, the total effect being small. In the series of alloys under discussion, zinc has been incorporated at the expense of the copper, the aluminum concentration remaining constant. Most of this zinc is taken up in the Al-Zn solid solution, the volume fraction of which increases accordingly. The consequent decrease in $Cu(Zn)Al_2$ volume fraction is shown as a function of alloy zinc content in Fig. 9. As a result, the aluminum activity in the Al-Zn solid solution is expected to decrease with increasing alloy zinc content. If equilibrium exists within the alloy, the aluminum activity in $Cu(Zn)Al_2$ also decreases. If equilibrium obtains at the alloy-product layer interface, the decrease in alloy aluminum activity will lead to a decrease in the activity of $Al(OH)_4^-$ ion at this boundary. Consequently the rate of outward diffusion of this species will be lessened. Since the rates of leaching of aluminum and zinc are related by the mass balance, the overall leaching reaction is therefore decreased in rate. Such a model could explain the decrease in leaching rate observed as the alloy zinc content is increased from 5 to 26 w/o, but does not explain the increase in rate observed as the zinc level is increased from zero to 5 w/o. It is quite possible that at this low level of zinc, interactions within the ternary system are such as to increase the aluminum activity and hence accelerate the leaching process. Although qualitatively successful, this description is incomplete as it fails to take into account kinetic effects arising from a contribution to rate control due to the interfacial reaction. The importance of this chemical reaction control is now considered.

The activation energy deduced from Fig. 4 was 41 ± 5 kJ mol^{-1}. This value is higher than for a strictly liquid phase diffusion process where values of 8-25 kJ mol^{-1} have been reported (12). However, the activation energy is not quite in the chemical reaction region where values of 100-175 kJ mol^{-1} have been reported (12). Thus the value obtained for the activation energy suggests that there may be some element of chemical reaction control in the leaching process. Further support for this conclusion is provided by the shape of the concentration profiles in the product layers (Fig. 5 and 6).

The form of the transport equation appropriate to solute Al and Zn species in the liquid phase within the reaction product layer is given by Eq. [16]. For a divergence-free flux it follows, therefore, that the concentration gradient is constant. If local equilibrium exists between the copper and the adjacent liquid, it follows that the concentration gradients of Al and Zn within the solid must also be constants. The linear concentration profiles predicted from this model for alloy 3 are seen in Fig. 10 and 11 to be a reasonable approximation to experimental observation for both Al and Zn over most of the product layer thickness. It is apparent, however, that the model is inapplicable in the region adjacent to the alloy-product layer interface.

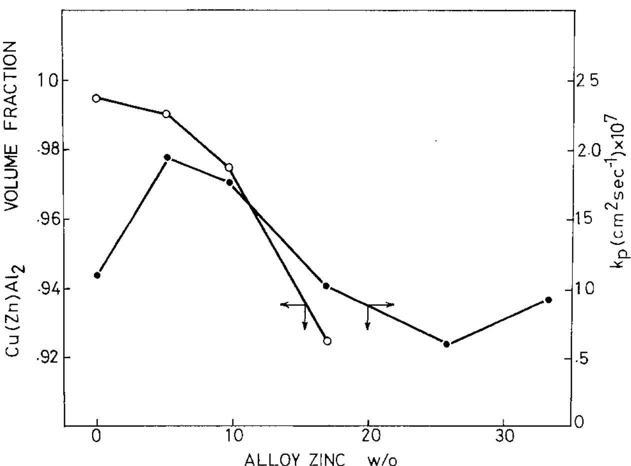

Fig. 9. Leaching rate constant and alloy volume fraction of $Cu(Zn)Al_2$ as a function of alloy zinc content.

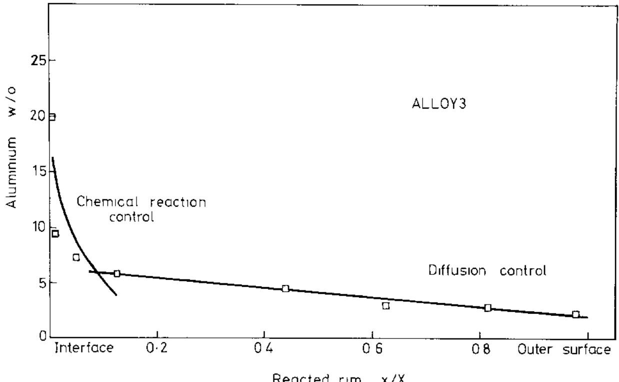

Fig. 10. Aluminum concentration profile in the porous copper grain of the reaction product zone for alloy 3 showing lines resulting from regression for diffusion control and for chemical reaction control, Eq. [23].

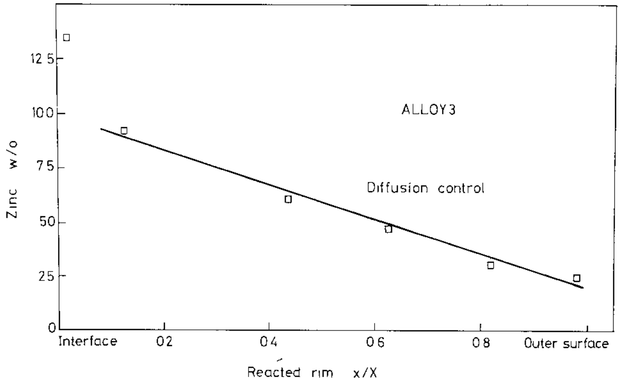

Fig. 11. Zinc concentration profile in the porous copper grain of the reaction product zone for alloy 3 showing the line resulting from regression for diffusion control.

If, instead of equilibrium, chemical reaction control prevails over the solid-liquid partition of Al and Zn within the product layer then the remnant concentrations of Al and Zn within the Cu phase are, to a first approximation, independent of liquid phase concentrations. Instead, the concentration of leachable elements will be determined by the rate law governing the reaction and by the time for which the portion of solid being considered has been exposed to the liquid phase. In this case, the reaction might well be pseudo-first order with respect to metal concentration

$$C_{Al,Zn} = C^{o}_{Al,Zn} \exp(-k_c t_e) \quad [21]$$

where t_e is the time of exposure and k_c is the reaction rate constant. If x is the position coordinate within the layer with $x = 0$ at the interface then, from Eq. [1]

$$t_e = \frac{2xX - x^2}{k_p} \quad [22]$$

Which, upon substitution in Eq. [21], yields

$$\ln (c/c^o)_{Al,Zn} = (x^2 - 2xX) k_c/k_p \quad [23]$$

Regression on this equation of the aluminum concentration data near the alloy-product layer interface revealed a better fit than the linear concentration profiles. An example is shown in Fig. 10. It is concluded that the leaching of aluminum proceeds under liquid phase diffusion control except when the concentration of Al is high, where chemical reaction control obtains. This latter regime is restricted to a narrow region of the product layer near the alloy surface. No such conclusion is possible in the case of Zn, where the concentration profile shows a maximum near the alloy-product layer interface (Fig. 7).

Values of the zinc concentration at the maximum points in the profiles are listed in Table III. Also shown in this table are the maximum concentrations of Zn predicted from the composition of the precursor $Cu(Zn)Al_2$ phase on the assumption that initially only Al is leached. Clearly the observed Zn levels cannot be accounted for on this basis and movement of Zn into the leached $Cu(Zn)Al_2$ grain from elsewhere must be occurring. The ultimate source of the excess Zn is, of course, the alloy Al-Zn solid solution phase. This phase leaches readily, leading to a high liquid phase activity of Zn. When such a liquid reacts with $Cu(Zn)Al_2$ to dissolve Al the hydroxyl ion activity is depleted. The solubilities of Al and Zn in caustic solutions are widely different (13): assuming that the precipitation product of Al is hydrargillite $Al_2O_3 \cdot 3H_2O$ and that of Zn is $Zn(OH)_2$ then the ratio of Al solubility to Zn solubility is 16/1. Clearly then, the dissolution of Al from $Cu(Zn)Al_2$ can deplete the OH^- activity to the point where Zn is precipitated. It is suggested that this is the reason for the observed accumulation of Zn in the solid phase near the reaction front. As that front recedes, the OH^- activity rises and Zn commences to redissolve. Simultaneously, further precipitation occurs near the receding reaction front where the OH^- activity is depleted. The location of the Zn concentration maximum in the solid phase is determined by the OH^- activity gradient in the liquid and is therefore found to follow the alloy-product layer interface.

Table III. Zinc concentration in the porous copper grains of the reaction product zone

Alloy number	Maximum zinc measured (w/o)	Maximum zinc expected from $Cu(Zn)Al_2$ grain (w/o)
2	9.6	2.1
3	14.1	5.3
4	16.0	5.8

Conclusions

It has been shown that the leaching kinetics of aluminum-copper-zinc alloys with aqueous sodium hydroxide are parabolic in nature. The reaction mechanism is one of selective dissolution where the rate is controlled by liquid phase diffusion through the product layer. The product layer consists of porous copper, derived from leaching the alloy $Cu(Zn)Al_2$ phase, containing a zinc and an aluminum concentration profile. The aluminum and zinc profiles in the porous copper were shown to be consistent with reaction control by liquid phase diffusion over most of the product layer. Chemical reaction control was shown to prevail near the alloy-product layer interface for aluminum leaching. No such conclusion is possible for zinc where the concentration profile shows a maximum near the alloy-product interface. A small component of chemical reaction control is consistent with minor deviations from parabolic leaching kinetics and an activation energy that does not quite fit into the diffusion control regime. An explanation for the unexpectedly high zinc content in the porous copper near the alloy-product layer interface has been proposed.

The Primary Passive Film on Li in $SOCl_2$ Electrolyte Solutions

R. V. Moshtev, Y. Geronov, and B. Puresheva

Central Laboratory of Electrochemical Power Sources, Bulgarian Academy of Sciences, Sofia 1040, Bulgaria

ABSTRACT

The primary passive film on Li in $SOCl_2$ electrolyte solutions is studied by galvanostatic pulse technique. The evolution of the resistance and capacitance of the Li electrode in $SOCl_2$ solutions of $LiAlCl_4$ under open-circuit conditions is interpreted in terms of a two-stage process involving the formation of a continuous dense LiCl film and its growth by ion migration and/or diffusion across the solid film. The film resistivity, its activation energy, the Tafel current-field relation, and the high field transients give evidence for an ion conducting solid film. The film growth is limited by its chemical dissolution. The rate of the latter controls the self-discharge rate of the Li anode as well as the growth of the secondary porous film, which is responsible for the voltage delay effects in Li/$SOCl_2$ primary cells.

In all nonaqueous electrolyte solutions used for practical Li cells, the Li anode is passivated by the formation of a protective film (1). In electrolyte solutions with organic solvents, *e.g.*, propylene carbonate, tetrahydrofurane, and acetonitrile with SO_2, the film is comparatively thin and of no great consequence to the cell performance. In $SOCl_2$ electrolyte solutions, however, the film grows almost throughout the whole useful life of the cell and causes the severe voltage delay problems. It is evident that the film which is capable of inhibiting completely one of the most vigorous chemical reactions between the most negative metal and one of the most powerful oxidants should possess exceptionally good insulating properties. One could hardly assume, however, that the coarse crystalline, porous film exhibited in the SEM pictures in the papers of Dey (1, 2) could have the barrier properties necessary for the complete passivation of Li. The full suppression of the corrosion of Li in $SOCl_2$ electrolyte solutions as revealed by the long storage life of practical Li/$SOCl_2$ cells used in pacemakers (3, 4) strongly suggests that beneath the porous film observed under the microscope there exists a thinner nonporous film, serving as an efficient barrier between the metal and the oxidant.

In two preliminary communications (5, 6) it was reported that the primary passive film on Li in $SOCl_2$ solutions has a high specific resistance and conducts according to the law of field-assisted ionic migration. Later Peled *et al.* (7) developed similar ideas on the properties of the passive film on lithium in $SOCl_2$ electrolyte solutions.

Chua *et al.* (8) have studied the composition of the secondary passive film on Li obtained in $SOCl_2$ solutions using energy dispersion spectrometry and x-ray diffractometry. They have shown that the film consists essentially of LiCl with minor amounts of S. The SEM pictures of Dey (1), showing the cubic crystallites of LiCl forming the film, confirm these findings. It is usually assumed that the reaction leading to the initial formation of the LiCl film is

$$Li + \tfrac{1}{2}\,SOCl_2 = LiCl + \tfrac{1}{2}\,SO \qquad \Delta G = -84\ \text{kcal/mole} \qquad [a]$$

However, as shown by the recent Auger electron spectroscopic (AES) measurements of David *et al.* (9), even at extremely low oxygen exposures (66 Langmuirs) the freshly cut Li surface is immediately covered by an Li_2O film. Under practical conditions in Ar flushed dry boxes the exposure time and oxygen concentration are much higher and one should always take into account the thin oxide film on the Li surface which could modify the mechanism and kinetics of growth of the primary passive film in $SOCl_2$ solutions.

Using AES technique Keil *et al.* (10) have demonstrated under stringently controlled environmental conditions that the reaction of the oxide-covered Li surface with $SOCl_2$ vapors produces a thin LiCl film ($\sim$100Å) as a primary reaction product. The free energy change of this reaction

$$\tfrac{1}{2}\,Li_2O + \tfrac{1}{2}\,SOCl_2 = LiCl + \tfrac{1}{2}\,SO_2 \qquad \Delta G = -12.8\ \text{kcal/mol} \qquad [b]$$

is much lower than that of reaction [a]. This explains the absence of a strong exothermal effect upon the immersion of Li in $SOCl_2$.

Experimental

Three-compartment cells were used housing the test, the counter, and the reference electrode, all made of Li metal (Merck). The free surface area of the test electrodes was 0.1-0.3 cm^2. The reference was an Li wire with 1 mm OD plugged in Teflon. The test electrode was polished by pressing a freshly cut disk to a polyester foil, whereby the Li surface acquired a mirror-like appearance. The electrodes and the cells were prepared and assembled in an Ar flushed dry box (H_2O less than 20 ppm). A second dry box was used for the electrolyte preparation and for the filling of the cell with the solution in order to eliminate the tarnishing of the Li surface by $SOCl_2$ vapors.

Thionyl chloride (Merck) was distilled after refluxing for several hours with Li wire. Reagent grade LiCl was recrystallized and dried under vacuum at 160°C for 24 hr. P.a. grade $AlCl_3$ was resublimated 3 times before use. The $LiAlCl_4$ solutions were prepared by the successive dissolution method. A 10% excess of LiCl over the stoichiometric ratio was added in some cases to neutralize completely the free $AlCl_3$. Water content in the solvent and in the solutions was determined by *IR* spectroscopy (11, 12) and did not exceed 50 ppm.

The changes occurring at the surface of the Li test electrode after its immersion in the $SOCl_2$ electrolyte solution were followed by measuring periodically the electrode resistance and capacitance by means of the galvanostatic pulse technique. The capacitance and the *IR* drop in the solution were determined by applying short galvanostatic pulses (5-20 μsec) with an ampli-

Key words: batteries, passivity, film formation.

tude not exceeding 2 mA/cm^2. The initial slope of the potential-time transients recorded by a Textronix 5541 storage oscilloscope (Fig. 1a) was used to estimate the electrode capacitance. The electrode resistance was assessed from longer cathodic galvanostatic pulses (0.5-5 msec) but with a lower amplitude (<0.5 mA/cm^2) whereby the steady-state overvoltage in the transient (Fig. 1b) did not exceed 10-20 mV (*i.e.*, in the linear polarization range). In both measurements the charge associated with the pulses was less than 2 $\mu C/cm^2$ corresponding to a film thickness less than 0.4Å. Thus any changes in the film thickness due to the measuring pulses were much smaller than the thickening of the film during the polarization-free interaction between the Li surface and the $SOCl_2$ solution. The temperature of the cell was maintained at 25°C with the aid of a small air thermostated dry box.

Results and Discussion

Evidence for a nonporous film.—One of the first questions arising when studying a thin passive film is whether it is porous or compact. In order to answer this question an Li electrode was kept for 24 hr in a 1M $LiAlCl_4$ solution whereby the resistance and the capacitance attained steady-state values: $R = 247\ \Omega \cdot cm^2$ and $C = 0.267\ \mu F/cm^2$, implying that the growth of the primary passive film has ceased. After that the electrolyte solution in the cell was substituted by a 0.1M $LiAlCl_4$ solution and the values of R and C were determined again and after 2, 6, and 16 hr. In all the measurements R remained exactly the same (247 $\Omega \cdot cm^2$), while C showed a slightly lower value of 0.216 $\mu F/cm^2$. After that the electrolyte solution was changed once more to the initial 1M concentration. The measurements immediately after the change revealed that the initial values of R and C were restored (247 $\Omega \cdot cm^2$ and 0.267 $\mu F/cm^2$).

The constancy of the film resistance R when the electrolyte solution resistance was lowered by one order of magnitude ($\varkappa$ of 1M $LiAlCl_4$ in $SOCl_2$ is 1.5×10^{-2} $\Omega^{-1} \cdot cm^{-1}$ and that of 0.1M $LiAlCl_4$, 1×10^{-3} $\Omega^{-1} \cdot cm^{-1}$) lends a strong evidence for a dense, pore-free passive film. The decrease of the electrode capacitance, on the other hand, with the lowering of the electrolyte concentration suggests that the electrode impedance comprises a series capacitance reflecting the diffuse double layer ((dl) in the electrolyte solution.

Ionic conduction of the primary passive film.—Figure 2 presents a typical set of experimental plots reflecting the increase of the electrode resistance R and the reciprocal capacitance $1/C$ with time of an Li electrode immersed in a 0.5M $LiAlCl_4$ solution in $SOCl_2$. Figure 3 gives the same experimental data in the form of a $1/C$ *vs.* R plot, each point (full symbols) pertaining to one and the same moment. It was found in more than 50 separate experiments, carried out in solutions with various electrolyte concentrations, that in all cases the $1/C$-R plots reveal two distinct rectilinear regions

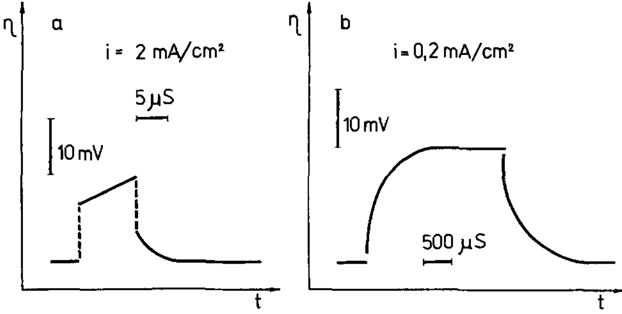

Fig. 1. Typical potential-time transients: a, short transient for the measurement of the electrode capacitance; b, long transients for the measurement of the electrode polarization resistance.

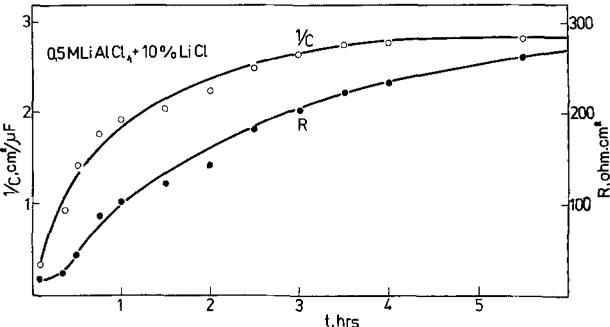

Fig. 2. Increase with time of the electrode reciprocal capacitance $1/C$ and the electrode resistance R.

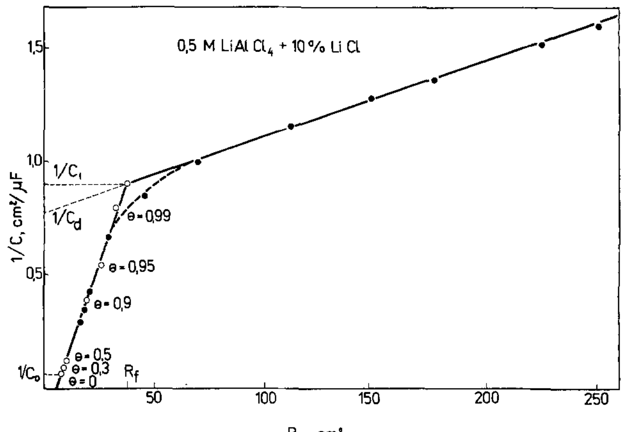

Fig. 3. Typical $1/C$ *vs.* R plot

with different slopes, as illustrated by Fig. 3. Depending on the electrolyte composition and the thickness of the initial oxide film, the ratio of the slopes in the two regions may vary from 3:1 to 10:1 and the transition from the first to the second straight line is in most cases abrupt.

The slope in the first region $k_1 = (d(1/C)/dR)$ varied in the separate experiments from 0.02 to 0.05 $\mu F^{-1} \cdot \Omega^{-1}$. No relation was found between k_1 and the electrolyte composition. The extrapolated value of $R = R'$ at $1/C = 0$ is from 0 to 6 $\Omega \cdot cm^2$.

Special experiments were carried out to assess the initial (in time) values of R and C as soon as possible after the contact of Li with the solution, *i.e.*, when the surface of the metal is essentially free of an LiCl film ($\Theta = 0$). The limiting values of R and C were $C_o = 14$-$18\ \mu F/cm^2$ and $R_o = 2$-$6\ \Omega \cdot cm^2$ for times not exceeding 3-4 min.

The present findings could be interpreted in terms of a two-stage growth of the primary passive film on Li. The first stage is assumed to involve the formation of LiCl crystal nuclei and the increase of their number with time. The increase of $1/C$ and R with time at this stage is assigned to the increase of the electrode coverage Θ by LiCl grains. In the second stage the increase of $1/C$ and R is determined only by the increase of the LiCl film thickness which eventually grows by ionic migration across the solid phase.

For a more comprehensive discussion of the present experimental results the following simplified equivalent circuit is assumed (Fig. 4). Here R' denotes the small intercept of the $1/C$-R plot at $1/C = 0$, presumably due to incorrectly compensated IR drop in the solution. C_o and R_o represent the capacitance and resistance of the initial thin oxide film. C_f and R_f pertain to the completed layer of the primary LiCl film with an initial thickness y_i at the moment when the coverage Θ has reached unity.

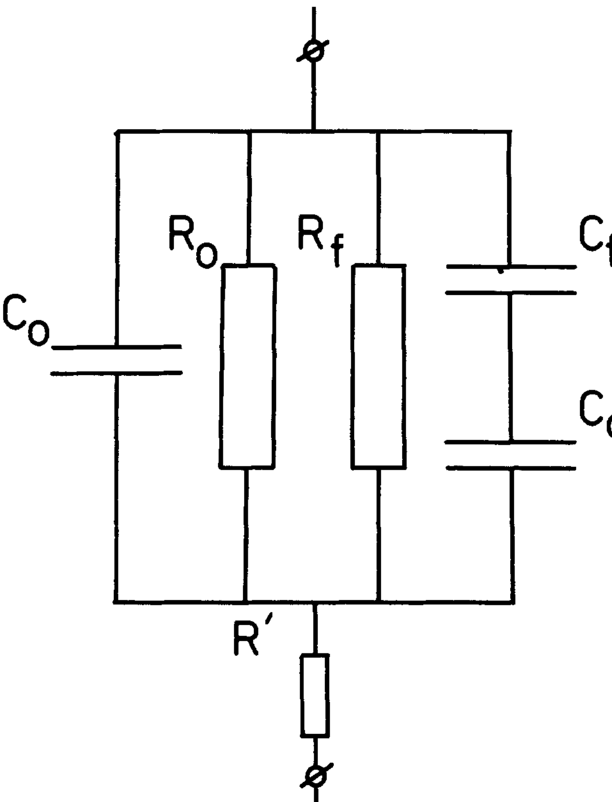

Fig. 4. Simplified equivalent circuit of the Li electrode during the formation and growth of the primary passive film (see text).

It is difficult to assess directly the physical meaning of the capacitance C_d in series with the film capacitance C_f. The results in the previous section, showing that the electrode capacitance decreases with the lowering of the electrolyte concentration, suggest that C_d might reflect the dl capacitance in the diffuse layer of the liquid electrolyte solution.

During the first stage of the film formation both C and R are functions of Θ according to

$$C = (1 - \Theta)C_o + \Theta C_f \cdot C_d/(C_f + C_d) \quad [1]$$

$$R = R_o \cdot R_f/[\Theta R_o + (1 - \Theta)R_f] + R' \quad [2]$$

where C_o, R_o, C_f, R_f, R', and C_d are assumed to be independent of Θ. This implies that the oxide film thickness and the average size of the LiCl nuclei remain practically constant during the formation of the film in the first stage.

It is reasonable to suppose that the intersection point of the two rectilinear portions of the $1/C$-R plot (Fig. 3) corresponds to the conditions $\Theta = 1$ and hence from the values of $C = C_1$ and $R = R_1$ at this point one can obtain $R_f = R_1 - R'$ and $1/C_f = 1/C_1 - 1/C_d$ pertaining to the first completed layer of the LiCl primary film.

By way of an example, Eq. [1] and [2] were exploited with the experimental data shown in Fig. 3: $1/C_o = 0.063$ cm²/µF, $1/C_d = 0.72$ cm²/µF, $1/C_1 = 0.84$ cm²/µF, $R_1 = 32\ \Omega \cdot cm^2$, $R_o = 2\ \Omega \cdot cm^2$, $R' = 1\ \Omega \cdot cm^2$ at several values of Θ. The calculated points (open symbols) fall closely on the experimental line (full symbols) and give an idea of the effect of Θ on R and $1/C$ during the first stage of the film formation. This result implies that the slope

$$k_1 = \frac{\partial(1/C)/\partial\Theta}{\partial R/\partial\Theta} \approx 1/R_oC_o \quad [3]$$

is independent of Θ and is a function only of the properties of the initial oxide film residing on the Li surface prior to its contact with the $SOCl_2$ solution. It should be noted that Eq. [3] is valid only in cases like the present where $R_f >> R_o$, $1/C_f >> 1/C_o$, and $1/C_d >> 1/C_f$.

The thickness of the primary LiCl film y can be calculated by the formula of the parallel plate capacitors connected in series

$$y = 8.85 \times 10^{-8}\epsilon\sigma(1/C - 1/C_d), \text{cm} \quad [4]$$

where the capacitances are in µF/cm² and σ is the roughness coefficient. The thickness of the film can be estimated also from the film resistance by

$$y = \varkappa R \cdot \sigma, \text{cm} \quad [5]$$

with R in $\Omega \cdot cm^2$ and $\varkappa$ in $\Omega^{-1} \cdot cm^{-1}$. By equating [4] and [5] and differentiating, one can obtain the slope of the $1/C$-R plot in the second region

$$k_2 = \frac{\partial(1/C)/\partial y}{\partial R/\partial y} = [\partial(1/C)/R] = \frac{\varkappa}{\epsilon \cdot 8.85 \times 10^{-8}}, \quad \mu F^{-1} \cdot \Omega^{-1} \quad [6]$$

It was established that the slope k_2 is strongly dependent on the concentration of the free Lewis acid $AlCl_3$ in the 1M $LiAlCl_4$ solution as shown in Fig. 5. On the other hand, it is known that $LiAlCl_4$ solutions in $SOCl_2$ prepared by the successive dissolution method (as in the present investigation) always contain some free $AlCl_3$ since the neutralizations of the last portions of $AlCl_3$ by LiCl proceed rather slowly. This fact explains the results in Fig. 6 where the slope k_2 is plotted *vs.* the time of neutralization of the free $AlCl_3$ in a 0.5M $LiAlCl_4$ solution containing 10% excess of LiCl above the stoichiometric amount. Each point in Fig. 6 reflects the value of k_2 obtained with a new Li electrode immersed in the solution after the latter has been kept for neutralization for the time shown on the abscissa. It can be seen that with the progress of the neutralization, k_2 diminishes to reach a steady-state value of 2.8×10^{-8} $\mu F^{-1} \cdot \Omega^{-1}$ after 20 days.

The application of Eq. [4] and [5] for the determination of the film thickness requires the knowledge of $\varkappa$ and ϵ. Data of $\varkappa$ and ϵ for thin LiCl films are not available so one is compelled to use values reported for bulk samples. Hence we shall use here $\epsilon = 10.62$ reported for pure LiCl bulk samples (13).

The specific conductivity of bulk samples of pure and Mn^{2+}-doped LiCl crystals has been studied in detail by Haven (14). In the impurity region (130° < t° < 400°C) the temperature dependence of $\varkappa$ is described by

$$\log \varkappa = \log N - W/2.3kT \quad [7]$$

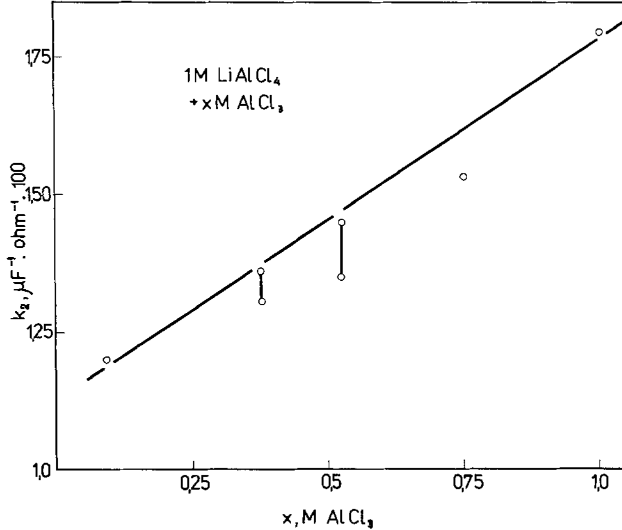

Fig. 5. Effect of the concentration of free $AlCl_3$ in a 1M $LiAlCl_4$ solution on the slope k_2 (Eq. [6]) of the $1/C$-R plots.

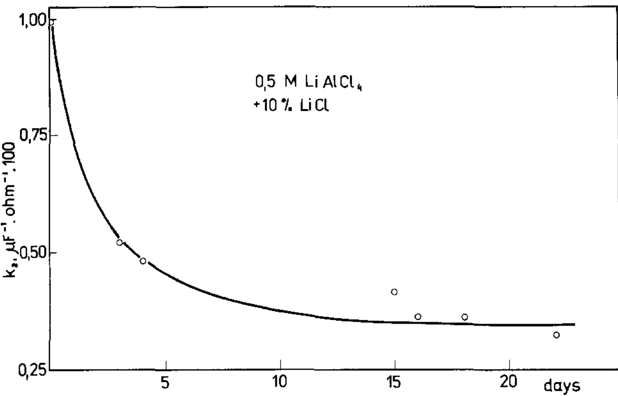

Fig. 6. Effect of neutralization of a 1M $LiAlCl_4$ solution with 10% excess of LiCl on the slope k_2 (Eq. [6]).

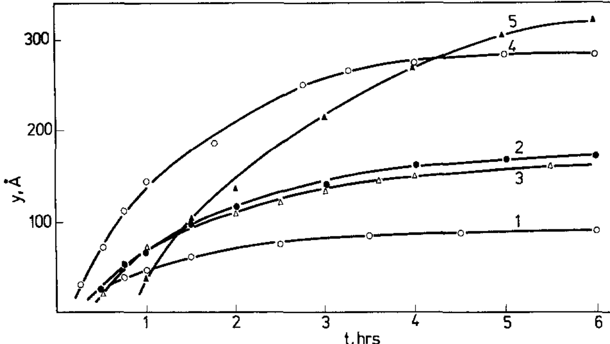

Fig. 7. Kinetic curves for the growth of primary passive films on Li with various specific conductivities (Ω^{-1} cm^{-1} $\times$ 10^{-8}): curve 1, 0.39; curve 2, 0.74; curve 3, 0.94; curve 4, 1.03; curve 5, 1.27.

where N is proportional to the impurity concentration and $W = 0.41$ eV. The value of $\varkappa$ at 298 K calculated by Eq. [7] with $N = 0.03$ pertaining to undoped LiCl samples with the lowest impurity level (14), was found to be 3.7×10^{-9} $\Omega^{-1} \cdot cm^{-1}$. Introducing the above values of $\varkappa$ and ϵ in Eq. [6] for the slope k_2 we obtain 3.9×10^{-3} $\mu F^{-1} \cdot \Omega^{-1}$. This is fairly close to the present experimental value $k_2 = 2.8 \times 10^{-3}$ $\mu F^{-1} \cdot \Omega^{-1}$, observed for an Li electrode immersed in a 0.5M $LiAlCl_4$ solution, which has been kept prior to the experiment for 20 days with a 10% excess of LiCl (Fig. 6). Since the dielectric constant of ionic crsytals is not very sensitive to aliovalent impurities it is reasonable to assign the effect of $AlCl_3$ on k_2 (Eq. [6]), demonstrated in Fig. 5 and 6, to the increase of $\varkappa$ only. This effect is supposedly associated with the inclusion of Al^{3+} in the crystal lattice of LiCl leading to a respective increase in the cation vacancy concentration. A substitution of Li^+ by Al^{3+} appears feasible in view of the ionic radii of these ions: 0.68Å for Li^+ and 0.57Å for Al^{3+}.

The agreement (within 30%) between the experimental and calculated values of k_2 offers a certain reliability in the estimation of the film thickness by Eq. [4] or [5] using the experimental values of R and C. It should be noted that the film thicknesses thus evaluated ought to be regarded as relative values, until experimental data acquired by direct optical or physical methods become available.

It was found that the thickness of the first complete layer of the primary LiCl film y_1 at $\Theta = 1$ varies from 11 to 60Å in the separate experiments. The mean value of $y_1 = 32 \pm 5$Å corresponds to 5 ± 1 monolayers of LiCl (lattice parameter 5.13Å).

The apparent activation energy $W = 0.37$ eV of the ionic conductivity was assessed by the temperature dependence of $\varkappa$ of a primary film with a constant thickness ($y = 400$Å) in the temperature range $-38°$ to $+7°$C. This is close to the value $W \pm 0.41$ eV reported by Haven (14) for LiCl bulk samples in the temperature range 130°-400°C.

Unfortunately, there is no literature data for W in the lower temperature range for a more complete comparison.

Kinetics of the film growth.—The kinetics of the primary film growth was studied by y-t plots using y values estimated by Eq. [4] or [5] with data of $\varkappa$ and $1/C_d$ calculated from the respective $1/C$-R plot assuming $\epsilon = 10.62$ and $\sigma = 1$. Figure 7 presents a series of y-t plots of films with various specific conductivities. It is seen that the rate of growth at one and the same thickness increases as the specific conductivity grows. The inspection of numerous kinetic curves showed that they all have an initial parabolic region, followed by an asymptotic one. These results as well as the high field behavior of the film suggest that the primary film grows through ionic migration and/or ionic diffusion in the solid phase and is at the same time subjected to a slow chemical corrosion.

As a first approximation the instantaneous net rate of the film growth v can be expressed by the general differential equation

$$\left[\frac{\partial v}{\partial t}\right] = v = v_g + v_d - v_c, \quad \text{cm/sec} \quad [8]$$

The first term v_g reflects the rate of the film growth by ionic migration due to a small constant potential difference $\Delta\phi$, set up by the redox couple in the solution $SOCl_2/Cl^-$.

The second v_d accounts for the film growth by ionic diffusion due to the eventual concentration difference ΔC at the two interfaces (metal/film and film/solution) of the diffusing species, *e.g.*, the cation vacancies.

The third term v_c expresses the rate of the film corrosion v_c due to its chemical dissolution, which is assumed to be constant under isothermal conditions.

Assuming the validity of Ohm's law at the prevailing low electric field, we may write

$$v_g = \left(\frac{1}{y}\right)\left[\frac{\Delta\phi \cdot V_m \cdot \varkappa}{\mathbf{F}}\right], \quad \text{cm/sec} \quad [9]$$

with $V_m = 20.6$ cm^2/mol the molar volume of LiCl.

Assuming further the validity of the Nernst-Einstein relation, the second term of [8] can be given by

$$v_d = \left(\frac{1}{y}\right)[\Delta C \cdot D \cdot V_m] = \left(\frac{1}{y}\right)\left[\frac{\Delta C}{C} \cdot \frac{\varkappa \cdot V_m RT}{\mathbf{F}^2}\right] \quad \text{cm/sec} \quad [10]$$

with D the diffusion coefficient of the diffusing species.

Introduction of [9] and [10] into [8] and rearrangement yields

$$v = \left(\frac{1}{y}\right)\left[\frac{\varkappa \cdot V_m}{\mathbf{F}}\right]\left[\Delta\phi - \frac{\Delta C}{C} \cdot \frac{RT}{\mathbf{F}}\right] - v_c, \quad \text{cm/sec} \quad [11]$$

or

$$v = A/y - v_c, \quad \text{cm/sec} \quad [12]$$

with

$$A = \left[\frac{\varkappa \cdot V_m}{\mathbf{F}}\right]\left[\Delta\phi - \frac{\Delta C}{C} \cdot \frac{RT}{\mathbf{F}}\right], \quad \text{cm}^2\text{/sec} \quad [13]$$

Figure 8 illustrates the experimental check of Eq. [12] where the net rate of the film growth v, obtained by graphical differentiation of the y-t curves in Fig. 7, is plotted *vs.* the reciprocal film thickness $1/y$. The slope of the v-$1/y$ relations gives the value of the kinetic constant A, Eq. [12], while its intercept on the abscissa yields the steady-state thickness y_∞, which is

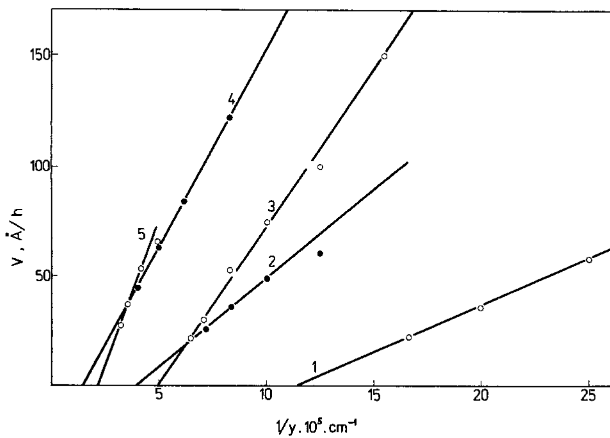

Fig. 8. Dependence of the net rate of the film growth v on the reciprocal film thickness 1/y for films with various conductivities as shown in Fig. 7.

attained at a zero rate v. Under this condition Eq. [12] can be used to determine the corrosion rate of the film

$$v_c = A/y_\infty, \quad \text{cm/sec} \quad [14]$$

Figure 9 illustrates the effect of the specific conductivity $\varkappa$ of the films, as presented by their kinetic curves in Fig. 7, on the kinetic constant A. The latter is estimated from the slope of the respective v-$1/y$ plot in Fig. 8. As expected from Eq. [14]. A is proportional to $\varkappa$. The slope of the plot in Fig. 9, according to Eq. [13], yields the value of $(\Delta\phi - C/C \cdot RT/\mathbf{F}) = 0.2$ mV.

Assuming the maximum range of $\Delta C/C$ from 0 to +1 the value of $\Delta\phi$ should vary from 0.2 to 26 mV.

Table I presents the kinetic data obtained from the plots in Fig. 7 and 8.

It is seen from Table I that while A grows with $\varkappa$, v_c is not dependent on $\varkappa$. The steady-state thickness y_0 increases with A according to Eq. [12].

The integration of Eq. [12] from y_1 to y and from 0 to t yields

$$t = [(y_1 - y)/v_c] - (y_\infty/v_c) \ln [(y_0 - y)/(y_\infty - y_1)], \quad \text{sec} \quad [15]$$

Since $y_1 << y_\infty$ Eq. [15] becomes

$$t = [(y_1 - y)/v_c] - (y_\infty/v_c) \ln (1 - y/y_\infty), \quad \text{sec} \quad [16]$$

It can be shown that at low film thicknesses when $y/y_\infty < 0.3$ the first parabolic term prevails, while at larger thicknesses the second asymptotic term is determining. A good correlation between the experimental y-t curves and those calculated by Eq. [16] was found when using the values of y_∞ and v_g determined from the respective differential plots.

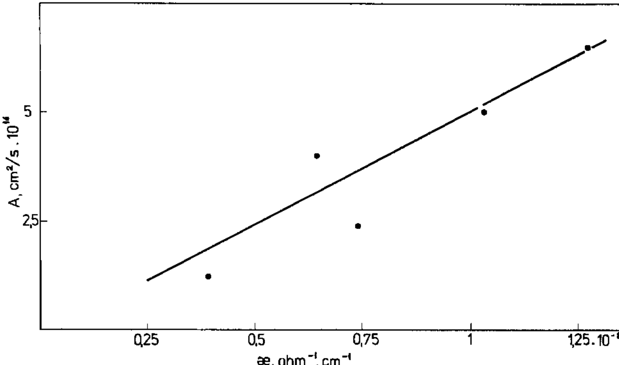

Fig. 9. Dependence of the kinetic constant A (Eq. [12]) on the specific conductivity of the film.

Table I.

Curve No.	$\varkappa$, $\Omega^{-1}\cdot$ cm^{-1} × 10^8	A, cm$^2\cdot$ sec^{-1} × 10^{16}	v_c, cm $\cdot$ sec^{-1} × 10^{10}	y_∞, Å
1	0.39	1.2	1.4	85
2	0.64	4.0	2.0	200
3	0.74	2.4	0.96	250
4	1.03	5.0	0.75	660
5	1.27	6.5	1.4	460

Despite the fact that the present kinetic data cannot claim a high accuracy, they nevertheless give qualitatively the effect of the factors governing the kinetics of the primary film growth.

The film corrosion and self-discharge.—The corrosion rate of the primary LiCl film, *i.e.*, the dissolution rate of the LiCl crystals in a heterogeneous chemical process, is governed by the diffusion conditions. Being essentially a solvation process it can be also limited by the solvation rate of Li^+ and Cl^- by $SOCl_2$ which appears to be rather low. As seen from Table I the value of v_c varies from 0.8 to 2.0 × 10^{-10} cm/sec or 30-72 Å/hr. The mean value 1.3 × 10^{-10} cm/sec expressed in current units amounts to 0.60 μA/cm^2, which approximates the rate of self-discharge of Li in Li/$SOCl_2$ cells for cardiac stimulators, 0.07 μA/cm^2, for a period of 4-5 years as reported by Babai and Gal (4).

On the other hand, the results of Dey (1, Fig. 45) reveal that the rate of growth of the secondary porous film, observed by SEM, remains constant over a period of 160 days. The rate of growth in a 0.5M $LiAlCl_4$ solution at 25°C determined from the slope of his y-t plot, 1.4 × 10^{-10} cm/sec is almost equal to the average corrosion rate of the primary passive film found here. The constancy in the rate of the secondary film growth clearly demonstrates that this film does not possess any protective properties. Likewise, Babai and Gal (4) have established that the self-discharge rate of Li in $SOCl_2$ is practically independent of the storage time, despite that the secondary film grows continuously during the entire test period (~4 years).

The agreement between the rate of the primary film corrosion and the rate of the secondary film growth clearly shows that the secondary film grows at the expense of the dissolution of the primary one. The dissolved Li^+ ions accumulate at the primary film surface and LiCl crystals are precipitated when the necessary supersaturation is attained.

High field transients.—It was established that the primary passive film on Li can withstand short galvanostatic cathodic pulses with very high amplitudes without any appreciable damage (breakdown, dissolution). Figure 10a illustrates an overvoltage transient recorded with an Li electrode covered by a primary film 250Å thick upon the application of a cathodic pulse of 133 mA/cm^2 for 1.5 msec. The peak overvoltage corrected for ohmic drop in the solution is 2.9V which corresponds to an electric field of 1.2 × 10^6 V/cm. Similar high field transients have been observed

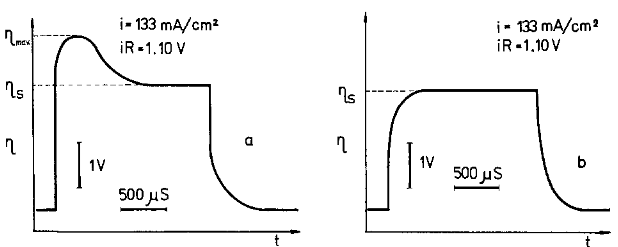

Fig. 10. Overvoltage transients at high electric field of a film-covered Li electrode: a, the first pulse transient; b, the transient at the 5th pulse in a series applied at a frequency 3 pulses per sec.

by Dewald (15), who studied the transient behavior of anodic oxide films on Ta. The overvoltage maxima are attributed by Dewald to high-field generation of carriers which are subsequently annihilated during their migration across the film through capturing by vacancies. It is assumed that in the case of oxide films the excess carriers are most probably interstitial cations, but the model developed by Dewald is claimed as valid regardless of the nature of the excess carriers.

The transient behavior of the primary film on Li was qualitatively studied by repetitive pulse application. It was found that when the high-field pulses are applied at an interval of 10 sec or more the transients are completely reproduced with the shape of the first one, as shown in Fig. 10a. This implies that a rest period of 10 sec is sufficient for the capturing of all the excess carriers generated during the preceding pulse and that the high cathodic pulse cannot change appreciably the resistance and hence the thickness of the film.

When, however, the interval between the pulses was 0.3 sec or less the peak on the overvoltage transients was leveled off after 4-5 pulses so that the initial overvoltage became equal to the steady-state overvoltage η_s as shown in Fig. 10b. Evidently a rest interval of 0.3 sec is not sufficient for the annihilation of the excess carriers. If the pulse interval is again increased to 10 sec the initial transient as that in Fig. 10a is reproduced. The recovery of the initial transient after such a short pause (10 sec) cannot be associated with the build-up of the film after its eventual damage during the preceding pulses, since the growth of the film is incomparably slower.

Tafel plots.—The current-voltage charactertistics of the primary passive film on Li at higher electric fields is illustrated by the Tafel plot in Fig. 11. A constant film thickness of 500Å was obtained by keeping an Li electrode for 16 hr in a 0.5 $LiAlCl_4$ solution at 25°C. The dependence is plotted with the peak overvoltage values recorded on oscilloscopic traces similar to that shown in Fig. 10a. According to the high field ionic migration theory (16) at fields higher than 10^6 V/cm the ionic current should obey the expression

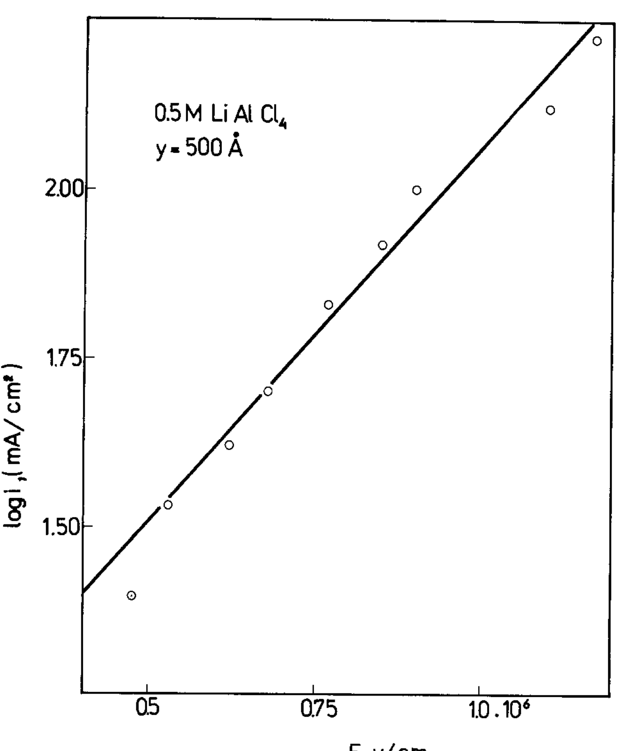

Fig. 11. Tafel plot obtained from the peaks in the overvoltage transients on a film 500Å thick in a 0.5M $LiAlCl_4$ solution.

$$i = 2Fan\nu \exp(-W/kT) \exp(qaE/kT) = i_o \exp(BE), \quad A/cm^2 \quad [17]$$

where a is the half-jump distance of the migrating species with a concentration n, q is its charge, ν the jump frequency, and W the apparent activation energy.

As seen in Fig. 11, the Tafel slope becomes linear at fields somewhat lower than 10^6 V/cm. Despite this discrepancy the slope of the Tafel dependence 1.1×10^{-6} cm/V yields according to Eq. [17] the half-jump distance $a = 2.8$Å in close agreement with the interionic distance Li-Cl in the crystal lattice of LiCl, 2.75Å. From the pre-exponent $\log i_o = 0.95$ (mA/cm^2) one can estimate the ionic conductivity of the film by the low-field approximation formula $\varkappa = i_o \cdot B$, which gives $1.0 \times 10^{-8}\ \Omega^{-1} \cdot cm^{-1}$. This is close to the value of $\varkappa = 1.3 \times 10^{-8}\ \Omega^{-1} \cdot cm^{-1}$ calculated by Eq. [4] from the slope of the respective $1/C$-R plot of the same Li electrode measured during the growth of the film.

Mechanism of the film growth.—In the lower temperature region ($T < 670$ K) the conductance of LiCl is determined by the migration of cation vacancies. The latter are usually due to the inclusion of aliovalent cations (*e.g.*, Mn^{2+}, Al^{3+}) in the crystal lattice of LiCl (14). Being a typical ionic crystal with a large forbidden gap LiCl is an electronic insulator, which makes it difficult to explain the film growth at electric fields as low as several thousand volts per cm. According to Mehl and Hale (17) however, when an insulator is put in contact with an oxidant, electrons are transported from the solid to the insulator/solution interface, where they are consumed by the cathodic reaction. Simultaneously the excess carriers (in the present case holes) are injected into the valence band and enhance the electronic conductivity of the film.

Another possibility for enhanced electron transport in ionic crystals is pointed out by Kleitz *et al.* (18). It is assumed that the Fermi level is located very close to the relevant surface state. As a result alkali metals generally induce large electronic conductivities in the alkali metal halides with which they are in equilibrium (18).

The above considerations are corroborated by the recent finding of Povarov *et al.* (19), that the Li electrode in 1M $LiAlCl_4$ solutions of $SOCl_2$ exhibits photoelectrochemical properties, which are usually associated with the formation of colored centers.

Conclusions

1. The passivity of Li in $SOCl_2$ electrolyte solutions is due to a thin (150-500Å) dense insulating film of LiCl and not to the thicker (1-2 μm) porous film.
2. The passive film grows by ionic migration and diffusion in the solid phase, while the secondary porous film grows by a dissolution-precipitation mechanism.
3. The values of the specific conductivity and the field coefficient, the Tafel dependence, and the high field transient behavior of the passive film describe the latter as a typical ionic crystal insulating film.
4. The passive film is dissolved at a constant rate which controls the limiting film thickness and determines the rate of self-discharge of the Li electrode in $SOCl_2$ electrolyte solutions.
5. The specific conductivity of the primary passive film is dependent on the concentration of aliovalent cations in the electrolyte solution.
6. The value of the specific ionic conductivity of the passive film and its activation energy are practically equal to those of bulk samples of LiCl.

Kinetics of GaAs Plasma Anodization

P. Friedel, S. Gourrier, and P. Dimitriou

Laboratoires d'Electronique et de Physique Appliquée, 94450 Limeil-Brévannes, France

ABSTRACT

The kinetics of GaAs plasma anodization at constant total current have been studied. The plasma source is a multipole (hot cathode associated with a magnetic confinement). The results show a decrease of the growth rate as the oxide thickness increases, in contrast with wet anodization at constant total current. The presence of unoxidized arsenic in the bulk and at the oxide semiconductor interface, which is characteristic of plasma grown GaAs oxides, does not seem to have a significant influence on the kinetics. An ion space charge which can modify the ratio of the electronic and ionic currents during the growth can account for the observed kinetics. Satisfactory agreement is obtained by using a very simplified space charge model. The calculations give order of magnitude of phenomenological ion "migration" (*i.e.*, field aided diffusion, etc.) coefficients which are much larger than usual diffusion coefficients.

Field-assisted transport processes which occur during wet (1) or plasma (2) anodization are still poorly understood. In fact, motions of charged species under high electric fields may be very specific phenomena. Complex reactions at both interfaces (oxidizing medium/oxide and oxide/substrate) also play a determinant role in the oxide growth process. In addition to these general features plasma anodization is characterized by a large electron flow through the oxide and by electron-induced reactions at the oxide surface which most probably (2) create the majority of the oxygen ions involved in the growth. These complex factors control the oxide growth kinetics. In particular, significant differences exist between the kinetics of wet and plasma anodization. As an example we study and discuss in this paper the kinetics of constant current GaAs plasma anodization.

Experimental

Description of the system.—The plasma source is a multipole and has been described in detail elsewhere (3). A hot cathode associated with a magnetic confinement creates an homogeneous plasma of density 10^{10}-10^{11} cm^{-3} at low oxygen pressures (10^{-2}-10^{-1} Pa). The sample (n-type GaAs with an impurity concentration of 2×10^{18} cm^{-3}) is placed on a copper sample holder which can be biased with respect to the plasma. The area exposed to the plasma is defined by an alumina cap with a circular opening of 10 mm in diameter. In order to control the actual current flowing through the exposed area of the sample, care has been taken in insulating any other biased surface (metallic parts of the sample holder, connections). The back side of the sample is thermoregulated with an accuracy of ± 5°C. A liquid nitrogen trap is mounted near the sample, and the base pressure of the system is in the high 10^{-5} Pa range. The thickness of the oxide can be continuously measured by *in situ* real time ellipsometry at 632.8 nm. Anodizations can be carried out either at constant anodization voltage V_a (potential of the copper sample holder) or at constant total current density J_{tot}.

The voltage drop between the surface of the oxide and the back side of the sample was calculated by estimating the potential of the surface V_S. In the first experiments V_S was deduced by measuring the total current flowing through the sample and using a predetermined I-V characteristic obtained under the same plasma conditions with a gilded plate mounted in

Key words: oxidation, diffusion kinetics, semiconductor.

place of the sample. This method proved to be critically dependent on the discharge conditions (especially the ion and electron temperatures). Therefore we replicated the sample holder with a flat, gilded probe, surrounded by an alumina cap, and placed it on the axis of the multipole chamber. Simultaneous I-V characteristics of this probe and of a gold plate mounted in place of the sample differed by less than 1V under typical discharge and anodization conditions (surface potential lower than the plasma potential V_p). The potential of this probe was taken to be the surface potential of the sample. This method, as well as the previous one, neglected the work functions difference between gold and the oxide (2). We assumed this difference to be small (1-2V).

Results.—Figure 1 shows typical oxide growth kinetics at constant current (density 7.7 mA/cm^2) at temperatures ranging from 50° to 200°C. The inset shows V_a *vs.* time. The initial growth rates vary from 24 to 90 nm/m and large thicknesses can be obtained in a reasonable time (450 nm in 10m at 200°C). Note the decrease of the oxidation rate as the thickness increases. This has been frequently reported (2, 3) in constant current plasma anodization experiments. In contrast, no saturation is observed in anodization of GaAs in an aqueous electrolyte (4); the rate of growth is constant during the experiment.

In the next section we analyze this different behavior and deduce information concerning the transport mechanisms during GaAs plasma anodization.

Discussion

Exposed conducting surfaces.—Since the plasma expands around the sample holder, a "leakage current" flows through any exposed surface. This surface is at the anodization potential and the "leakage" current should increase with time, thus reducing the current flowing through the sample. However, in our system, this "leakage" current is found to be very small. An anodization voltage of 100V applied to the sample holder under typical plasma conditions with a glass plate mounted in place of the sample corresponds to "leakage" currents of the order of 10 μA, three orders of magnitude lower than the total anodization current (in the mA range).

Charge effects on the alumina cap result in unoxidized edges around the anodized area. These edges are exposed to the plasma and may modify the current distribution around the sample and the kinetics. Their influence was ruled out by the following experiment: After anodization up to a certain depth, the protecting cap was replaced by a smaller one covering the edges of the previously anodized area. The sample was then

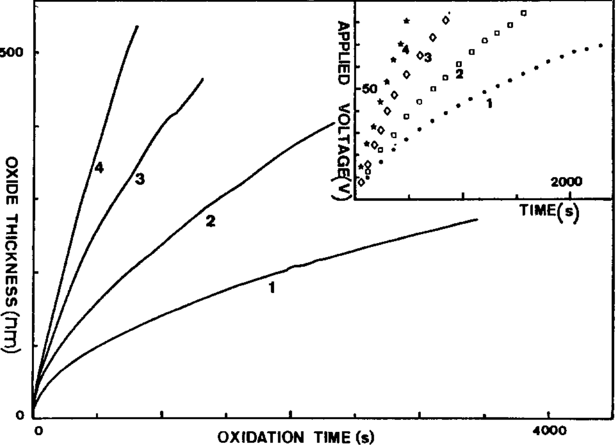

Fig. 1. Experimental kinetics at 4 different temperatures (curve 1, 50°C; curve 2, 100°C; curve 3, 150°C; curve 4, 200°C). The insert represents anodization voltage *vs.* time.

further anodized using the same current density. The initial growth rate was equal to the final rate at the end of the first anodization, indicating that the presence of unoxidized edges has no significant influence on the kinetics.

Role of the nature of the oxides.—Spectroscopic ellipsometry (5) on plasma-grown GaAs oxides indicates the presence of an optically absorbing material (above 3.5 eV) in the bulk and of a highly absorbing interface layer between the oxide and the semiconductor (6). According to thermodynamics (higher stability of gallium oxide), the absorbing material is probably unoxidized arsenic. Auger spectroscopy (7), TEM observations (8), and Raman scattering (9) also confirm the presence of an amorphous elemental As layer at the oxide/semiconductor interface. The thickness of this layer increases with the oxide thickness. In contrast, wet anodic oxides (and their interfaces with GaAs) are almost nonabsorbing below 4.5 eV (10). In order to estimate the influence of this striking difference in composition between wet and plasma-grown oxides, an oxide was grown in an H_3PO_4 solution up to ~150 nm and further oxidized in the plasma. The kinetics were then exactly the same as in the case of an oxide entirely grown in the plasma, indicating that the presence of unoxidized As has no influence on the kinetics. In another experiment, an oxide was formed in the plasma up to 200 nm and was ion sputtered down to 75 nm to produce a film with an artificially thick As interfacial layer. A further anodization of this oxide using the same current density yielded the same growth rate as during the first anodization (before erosion) at 75 nm; therefore, the As interfacial layer does not control the kinetics. It may, however, have an influence on the early stage of oxidation on clean surfaces of GaAs (below 1-5 nm). In summary, those two experiments show that the nature of the oxide (either wet anodic or plasma grown with an abnormally thick As interface layer) does not strongly influence the growth.

Diffusion-limited kinetics.—Another possibility would be a limitation due to the diffusion of the oxidizing species through the oxide. Such a process is known to lead to a parabolic ($t^{1/2}$) law of kinetics (11). This dependence was not found on our experimental curves above 20 mA whereas power laws in t^q exist for 6 mA. The exponent q is an increasing function of temperature and varies from 0.55 at 50°C to 0.8 at 200°C. Thus, pure diffusion transport cannot account for the observed kinetics. This is expected because ions are the mobile species during anodic oxidation, and therefore their transport is controlled by the high field in the oxide.

Space charge layer.—During plasma anodization, a very large electron flux is supplied to the sample (2). This is one of the most striking differences between wet and plasma anodization. Some of these electrons have relatively large energies; for instance, in the multipole plasma source, primary electrons of typical energy 50 eV are emitted by the filament and can reach the sample. Energetic electrons can be injected in the conduction band of the oxide, resulting in a large electronic current in the oxide. The current efficiency (ratio of the ion current to the total current) is very low (a few percent). In contrast, in most cases (Si is an exception) current efficiencies above 90% are reported in wet anodization experiments (1). During plasma anodization at constant total current, a small change in the field through the oxide can create a small relative change in the electronic current, resulting in a large relative change in ionic current and in the kinetics. Variations of the field can originate from a gradient of uncompensated ionic charges in the bulk of the oxide. This will be studied in more detail using a space charge model developed by Fromhold

(12) for wet anodization and applied by Labunov *et al.* for Al plasma anodization (13).

The model relies on several basic assumptions.

1. The boundary concentrations of mobile ions are time independent and fixed by interfacial reactions and not by the field in the oxide. Interfacial reactions are fast enough to compensate the loss of ions due to the migration in the oxide. This seems plausible, at least for oxygen ions, which are to a large extent only created by plasma electron assisted surface reactions. Other space charge models are based upon the oxide field created by trapped charges in the oxide (2). Our assumptions only take into account the ion concentration gradient imposed by the interfacial reactions.

2. There is only one ionic species movement during the growth. This allows a rather simple mathematical treatment of the problem. However, it is not generally true. In most cases, wet or plasma anodization proceeds by simultaneous transport of negative oxygen ions toward the substrate and positive substrate cations toward the surface [Zr is an exception (14)]. As an example, plasma anodization of Al/GaAs (15) or Si/GaAs (3) structures have demonstrated that both As and Ga positive ions and oxygen negative ions are mobile during GaAs anodization. Calculations taking into account two kinds of ionic mobile species have been carried out. However, they lead to a system of equations which is analytically tractable only in a few very limiting cases. Therefore, we restrict ourselves to one kind of mobile species model assuming either oxygen movement or cations movement. The migration coefficients and activation energies for both processes can then be calculated. We assume that they give the correct order of magnitude of the actual values. Such a procedure seems plausible, because anodization of Al/GaAs structures have shown that the contributions to the oxide thickness of oxygen transport and cations transport are comparable (3, 15).

3. The only mobile species are ions.

4. The migration of ions in the oxide can be described using a periodic potential barrier W, which is lowered in the presence of the field.

5. A quasi-steady state is met at every oxide thickness (interface reactions are fast compared to bulk migration).

The expression of the ion current density J_i can be written

$$J_i(x) = Z \times e \left(\frac{D\,C(x)}{a} \sinh \frac{Z \times e\,a\,E(x)}{kT} - D \frac{d\,C(x)}{dx} \cosh \frac{Z \times e\,a\,E(x)}{kT} \right)$$

where $E(x)$ is the electric field at depth x in the oxide (the origin is at the surface or at the oxide/GaAs interface for oxygen and cations movement, respectively); $Z \cdot e$ is the net charge of the migrating species; $2a$ is the distance between two minima of the potential energy (typically, distance between two oxygen atoms in the oxide); $C(x)$ is the concentration of migrating ionic species; and D is the "migration" coefficient corresponding to the motion of ionic species under a high field. We use the term "migration" since it can be different from the diffusion coefficient, as will be discussed later.

The field in the oxide is of the order of a few 10^6 V/cm. We are in the high field limit ($E(x) >> kT/Z \cdot e\,a$). Therefore, neglecting the effect of the concentration gradient (dC/dx should be of the order of C/a for this term to be appreciable), we obtain

$$\boldsymbol{J_i(x) = Z \times e \frac{D\,C(x)}{2a} \exp\left(\frac{E(x)\,Z \times e\,a}{kT} \right)} \quad [1]$$

The steady-state assumption $J_i(0) = J_i(x) = J_i(L)$ where L is the oxide thickness, and the integration of Poisson's equation[1] yields

$$J_i = Z \cdot e \frac{D\,C_o}{2a} g(L) \exp\left(-\frac{u}{LE'} + 1 \right) \quad [2]$$

$$g(L) = \left(1 + \frac{L}{L'}\right)^{-(1+L'/L)} \qquad L' = \frac{\epsilon\,\epsilon_0\,kT}{(Z_e)^2\,aC_o}$$

where C_o is the boundary concentration of ions; ϵ is the dielectric constant of the oxide; u is the voltage drop through the oxide; L' is the typical width of the space charge layer (to a first approximation, it corresponds to the depth at which the concentration of mobile ions is one-half of the boundary concentration); and $g(L)$ represents the reduction of the ionic current due to the space charge (as compared to the homogeneous field case). Typical values are several orders of magnitude lower than unity.

A complete theoretical treatment requires the knowledge of the electronic current density J_e as a function of the field in the oxide. In agreement with Labunov *et al.* (13) we assume that this current is a function of the mean field $\overline{E}$ in the oxide.

The determination of the electronic current density is made using constant voltage anodization and recording simultaneously the current and the oxide thickness. The ionic current estimated from the growth rate (see below) was subtracted from the total current to yield the electronic current. The voltage drop through the oxide is calculated by estimating the surface potential as a function of the current. Since GaAs anodization requires holes (4), an additional voltage drop appears in the semiconductor at the oxide interface to generate electron-hole pairs. Neglecting any radiation-induced generation process, we assume that the holes are created by avalanche breakdown, which corresponds in our case (GaAs n-type impurity concentrations 2×10^{18} cm^{-3}) to a voltage drop of 3V (16). Figure 2 shows the electronic current as a function of the field in the oxide for temperatures of 20°, 40°, and 100°C.

The lower part of the curves (steep slope) is sample temperature dependent, and therefore seems to be due to an oxide limited conduction. The mechanism of this conduction is not clear; most probably insulator conduction processes [such as Frenkel Poole conduction (13, 16)] are superimposed on the transport of energetic electrons injected directly from the plasma to the conduction band of the oxide.

[1] Poisson's equation was written $\frac{\partial E}{\partial x} = \frac{Z \cdot eC(x)}{\epsilon\epsilon_0}$ neglecting the electronic density $C_e(x)$. We shall see later on that most of the electronic current is very likely due to hot ballistic electrons, with high velocities of the order of 10^6 m/sec. With typical values of electronic current, C_e is of the order of 10^{10} cm^{-3}, which is much lower than the ion concentration, as will be seen later.

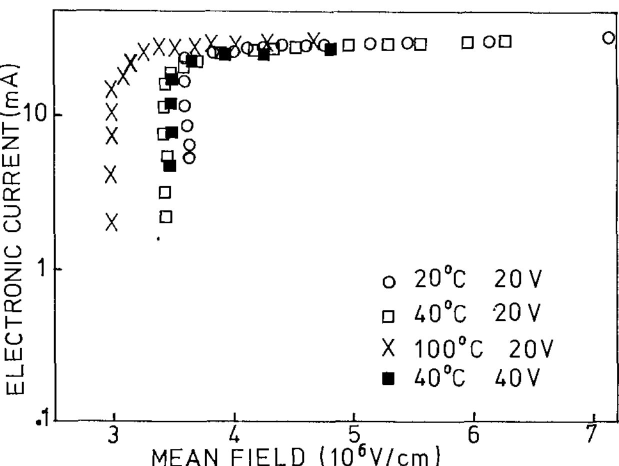

Fig. 2. Electronic current vs. mean field at 20°, 40°, and 100°C measured during constant voltage anodizations at 20 and 40V.

The upper part of the curves is sample temperature independent, and therefore is most likely due to a plasma-limited charge supply. The sample probably behaves like a flat probe for which a large increase of the surface potential above the plasma potential results in a small current increase (because of the small relative extension of the sheath around the sample).

At this point, three equations

$$J_i = \frac{D C_o}{2a} \exp\left(\frac{\overline{E}}{E'} + 1\right) g(L)$$

$$J_i + J_e = J_{tot}$$

$$J_e = f(\overline{E})$$

can be resolved for given D, and C_o to give $J_i = f(L)$. J_i is directly related to dL/dt by assuming that each ion reaching the boundary corresponds to an increase v in oxide volume. The volume v is estimated using the atomic density of Ga and As in the semiconductor (2.2×10^{22} cm^{-3}); the volume increase of GaAs after oxidation (~1.6) (3); and the assumption of composition $Ga_2O_3 + As_2O_3$. We then obtain

$$J_i = \frac{Z \cdot e}{v} \frac{dL}{dt} \quad \text{with} \quad \frac{1}{v} = 4.14 \times 10^{22} \text{ cm}^{-3}$$

The relation $J_i = Z \cdot e/v \; dL/dt = f(L)$ can be numerically integrated to give the kinetics $L = f(t) \cdot D$ and C_o are adjusted to fit the experimental curves. The results of this method (assuming only oxygen transport) are given in Table I and Fig. 3 for an anodization at $J_{tot} = 25.6$ mA/cm^2 at 50°C. The fit is satisfactory up to 250 nm.

This technique is rather tedious and depends on the reproducibility of the plasma conditions between the experiments used to calculate $J_e = f(\overline{E})$ and the anodizations. Small errors in the calculation of $\overline{E}$ due to surface potential variations can result in order of magnitude changes in D and C_o.

A simplified procedure which does not use the electronic current was then applied. It can be noted that the mean field $\overline{E}$ calculated from Eq. [2] as a function of thickness is almost constant except for small thicknesses ($L \leq L'$) where variations remain small (at 50°C in a typical anodization $\overline{E}$ varies from 3.1 to 3.4 $\times 10^6$ V/cm from $L = 0$ to $L = L'$). This is consistent with the experimental curves of voltage drop *vs.* thickness shown in Fig. 4. A constant value of $\overline{E}$ is therefore determined from the experimental data and injected in Eq. [2]. As in the previous technique, a numerical integration gives the kinetics curve which is fitted to the experimental ones by adjusting D and C_o.

Fits of the kinetics assuming only oxygen movements are presented in Fig. 5. Figure 6 shows D and C_o deduced from the fits as a function of $1/T$ for oxygen anions movement and cations movement. The activation energies of D are 0.6 and 0.8 eV for oxygen and cation movement, respectively. These activation energies are relatively low and correspond to very large values of D (10^{-10} cm^2/sec), several orders of magnitude higher than usual diffusion coefficients. In fact, assuming such large values for the diffusion coefficient after anodization would lead to a fast flattening of any concentration gradient in the oxide. This is contradicted by Yamasaki and Sugano's results (17),

Table I.

C_o	$= 3.49 \times 10^{18}$ cm^{-3}
D	$= 4.07 \times 10^{-14}$ cm^{2}sec^{-1}
L'	$= 3.15$ nm
T	$= 300$ K
$2a$	$= 0.5$ nm
Z	$= -2$
ϵ	$= 8$

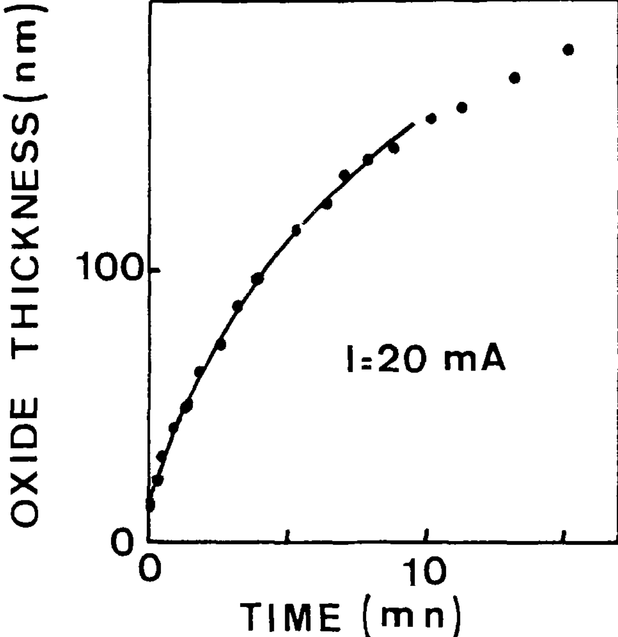

Fig. 3. Fit of constant current (20 mA) kinetics at 40°C by the first method. Dotted curve is experimental, full line theoretical.

who were able to measure ^{18}O and ^{16}O concentration gradients after sequential anodizations. We must then assume that the values of D deduced from the kinetics do not correspond to diffusion but rather to "migration," defined as the transport of charged species under a very high field.

C_o decreases with increasing temperature. This could indicate that ion desorption is much more thermally activated than surface ionization. The order of magnitude of C_o (assuming only oxygen transport) shows that the ratio of ionized oxygen to neutral oxygen on the oxide surface varies from 10^{-4} to 10^{-6} between 50° and 200°C.

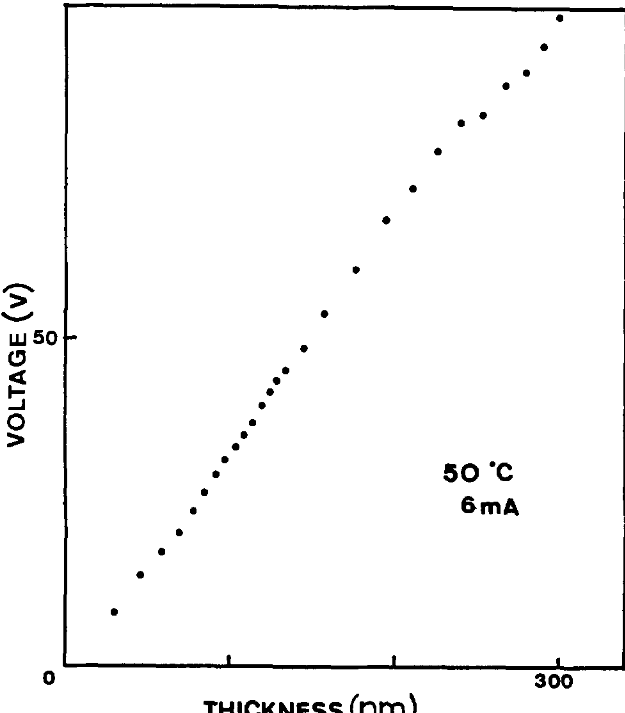

Fig. 4. Anodization voltage at 6 mA total current vs. oxide thickness at 50°C.

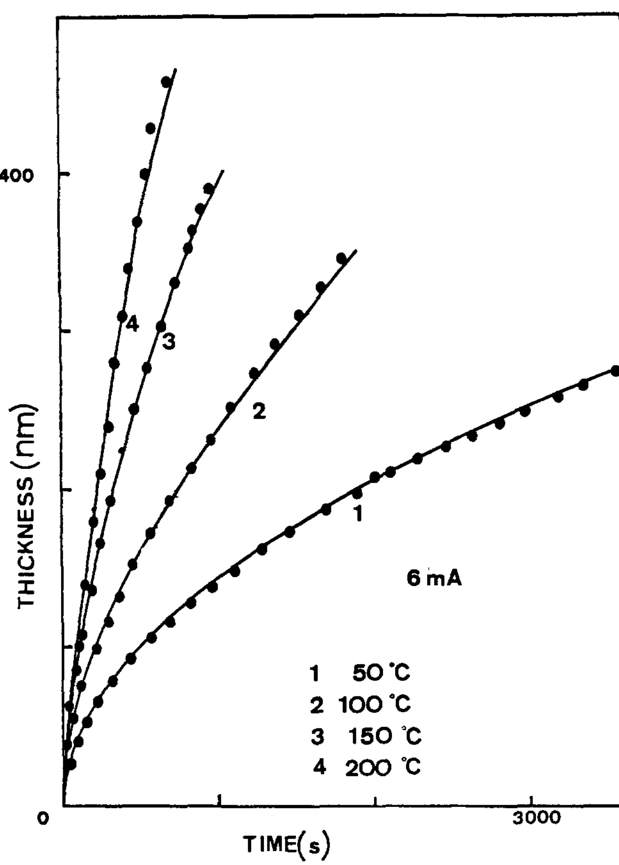

Fig. 5. Fit of constant current (6 mA) kinetics at 4 different temperatures (curve 1, 50°C; curve 2, 100°C; curve 3, 150°C; curve 4, 200°C) supposing only oxygen ions movement.

Conclusion

The kinetics of GaAs plasma anodization in a multipole at a constant total current show a decrease of the oxide growth rate as the thickness increases. The presence of unoxidized As in the bulk and at the oxide/semiconductor interface (which is a characteristic of GaAs plasma grown oxides) has no significant influence on the kinetics at least for thicknesses larger than a few nanometers. Satisfactory agreement was obtained by using a very schematic space charge model assuming one type of mobile ionic species. Using the model, values of "migration" coefficients are deduced which are much larger than usual diffusion coefficients in the absence of a field. They can be considered as characteristic of a field-enhanced transport mechanism.

The Effect of Fe(II) Ions on Kinetics and Mechanism of Anodic Dissolution and Cathodic Deposition of Copper

Z. D. Stanković*

The University of Belgrade, Faculty of Engineering Bor, 19210 Bor, J.N.A., 12 Yugoslavia

ABSTRACT

The influence of the presence of Fe(II) ions on kinetics and mechanism of anodic dissolution and cathodic deposition of copper in acidic sulfate system has been investigated. The galvanostatic single-pulse method has been used. Results indicate that the presence of Fe(II) ions decreases the exchange current density determined from the Tafel analysis of the cathodic reaction.

The influence of foreign cations on the kinetics and mechanism of anodic dissolution and cathodic deposition of copper has been scarcely investigated in spite of the great importance of this topic both for theoretical implications and for practical industrial consequences. Some evidence of effects of small amounts of foreign metal ions in solution on metal deposition kinetics and morphology as well as on corrosion behavior of metals can be found, particularly in the plating literature.

In the present work an attempt was made to obtain insight into the effect of Fe(II) ion on kinetics and mechanism of anodic dissolution and cathodic deposition of copper, since the solutions used in electrolytic plants for the production of copper usually contain some Fe(II) ions. The concentrations of Fe(II) ions in the acidic sulfate solutions investigated were chosen to be close to those in the commercial plants for the production of copper.

For the electrochemical dissolution and deposition of copper

$$Cu(II) + 2e \rightleftharpoons Cu \qquad [1]$$

it has been found by Mattson and Bockris (1) and verified by numerous authors (2-7) that in the acid sulfate system the reaction proceeds in two steps

$$Cu(II) + e \rightleftharpoons Cu(I) \quad \text{(slow)} \qquad [2]$$

$$Cu(I) + e \rightleftharpoons Cu \quad \text{(fast)} \qquad [3]$$

The assumption of Butler-Volmer kinetics with a symmetry factor $\beta = \alpha_c = 0.5$ for the slow reaction [2] and of equilibrium for the fast reaction [3] yields

$$j = j_o(\exp(\alpha_a \mathbf{F}\eta/RT) - \exp(-\alpha_c \mathbf{F}\eta/RT)) \qquad [4]$$

where j is the net current density, j_o is the exchange current density, α_a and α_c are the anodic and cathodic transfer coefficients, whose theoretical values are 1.5 and 0.5, respectively.

Experimental

Solutions were made from copper sulfate (p.a. Merck), ferrous sulfate (p.a. Merck), sulfuric acid (suprapure Merck), and bidistilled water. The concentrations of copper sulfate and sulfuric acid were 0.7M and 1.5M, respectively. The concentrations of ferrous sulfate were 0.005, 0.05, 0.15, and 0.3M. The solutions were deaerated by bubbling nitrogen of high purity for 1 hr. Stirring was effected by employing a magnetic stirrer. During measurements stirring was stopped while nitrogen was slowly bubbled through the solution.

* Electrochemical Society Active Member.

Key words: inhibition, Tafel slope, transients.

The cell was a commercial product (AMEL Model 494/GC + 494/TJ). The working electrode, a platinum sphere 0.55 mm diam (with an exposed surface area approximately 0.013 cm^2), was formed by melting an end of a platinum wire 0.3 mm diam in an oxy-coal gas flame. The counterelectrode was spiral-shaped Pt wire 0.5 mm diam and 20 cm length. A spectroscopically pure copper wire of the same quality, 4 cm in length, was used to equilibriate solutions (9), according to

$$Cu(II) + Cu \rightleftharpoons 2Cu(I)$$

Before measurements copper deposit was freshly grown on the counter and working electrodes for 30 min at 15 $mA \cdot cm^{-2}$ from the solutions employed in the subsequent experiments (1, 2). The potential difference between the electroplated and reference copper electrodes was always less than 5 mV in the absence of current.

The single pulse method was carried out using a potentiostat-galvanostat (AMEL Model 551) programmed with a function generator (AMEL Model 565). The pulse was made long enough for the activation overvoltage to reach a constant value. A series of transients was recorded covering the current density range 7.4×10^{-2} -7.4×10^{2} $mA \cdot cm^{-2}$. All anodic transients were taken first followed by cathodic ones, in the order from low to high current densities. The overvoltage-time transients were recorded on a storage oscilloscope (Tektronix Type 549 B). Temperature was maintained at 303 ± 0.1 K.

Results and Discussion

The rest potential of the working copper electrode in all solutions investigated was 0.316V *vs.* NHE. Quasi-steady-state overvoltage values at different current densities were found from the plateaus of the galvanostatic transients, and Tafel plots were established. This has been done for both the anodic and the cathodic directions of the process and for each of the solutions. The Tafel plots were made with the potential expressed against SCE, and a summary of the results is given in Fig. 1 and in Table I. All cathodic Tafel slopes were 115 mV, and anodic slopes between 40 and 50 mV. The corresponding transfer coefficients are $\alpha_c = 0.52$ and $\alpha_a = 1.35 \pm 0.15$. The sum of α_c and α_a is 1.87 ± 0.15, close to the theoretical value of 2.

The agreement between j_o's obtained by extrapolation of the cathodic and anodic Tafel lines at high potentials to $\eta = 0$ is fair, but it should be noted that there is a slight but definite tendency for the values from the anodic Tafel lines to be smaller, as can be seen in Fig. 1 and in Table I. The transfer coefficients and exchange current density obtained in this study agree closely with results obtained by Bockris and

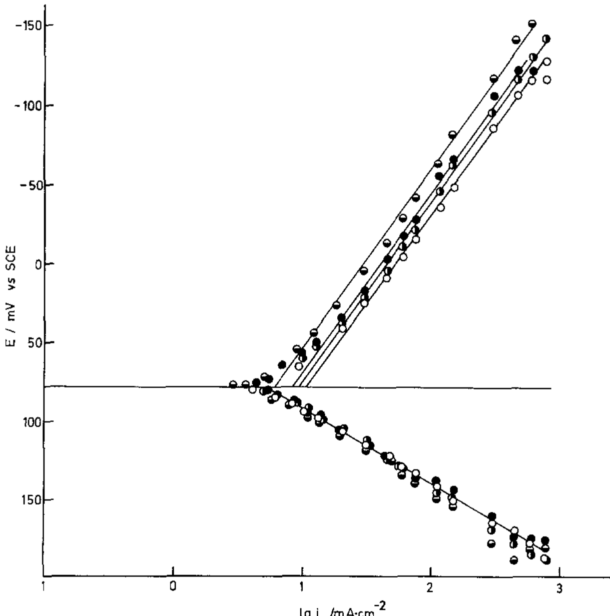

Fig. 1. Anodic and cathodic Tafel plots at different concentrations of Fe(II) ions: ○, 0.005M Fe(II); ◑, 0.05M Fe(II); ●, 0.15M Fe(II); ◒, 0.3M Fe(II).

Enyo (2), Bockris and Mattson (1), and Albaya and Lorenz (8) as can be seen in Table I.

The exchange current densities obtained from the cathodic Tafel lines for solutions with different concentrations of Fe(II) ions were found to decrease with increasing concentration of Fe(II) ions, as can be seen in Fig. 1-3.

Figure 2 shows that the decrease in the cathodic exchange current density with the increase in the concentration of Fe(II) ions can be expressed by the empirical relation

$$(j_o)_c = 9.45 \exp(-1.36\, C_{Fe(II)}$$

where 9.45 is the value for the exchange current density in the absence of Fe(II) ions, and $C_{Fe(II)}$ is the molar concentration of Fe(II) ions.

Figure 3 shows that the concentration dependence of the cathodic current density at any constant value of the potential in the cathodic region of 50-150 mV *vs.* SCE on the Fe(II) ion is

$$(\partial \log j_c/\partial \log C_{Fe(II)})_{E,C_{Cu(II)},T} = -0.14$$

A value of −0.14 indicates an inhibitive effect of Fe(II) ions on the Cu(II) discharge.

Drazić and co-workers (10) found a similar inhibitive effect of a foreign cation on the cathodic hydrogen evolution rate. Namely, they showed that the addition of Cd(II) ions at relatively small concentrations (10^{-2}-10^{-1}M) decreases the cathodic hydrogen evolution rate on iron and other non-noble metals. In a recently published paper by Jüttner (11) it was shown that Pb and Tl not only decrease the hydrogen evolution rate but also inhibit the dissolution of iron. The explanations given by the authors mentioned above for this phenomenon are in connection with the so-called "underpotential deposition" and the redistribution effect of cation adsorption. Nevertheless, it seems that an exact model for these effects is not known at present. The same could be said with respect to the inhibitive effect of Fe(II) ions on the electrodeposition of copper obtained in the present work. Any further interpretation of this phenomenon cannot be offered on the basis of the experimental results presented here. Nevertheless, the most likely explanation appears to be that given by Schmickler (12), which is based on electrostatic cation adsorption effects, in which the presence of an adsorbate alters the double layer structure and decreases the rate of an electrochemical reaction. On the other hand, Conway and co-workers (13) presented a so-called co-sphere/co-plane overlap model for interaction of hydrated ions in the double layer with each other and with the oriented water layer at the electrode. Based on these two theories, it may be assumed that the inhibitive effect of Fe(II) ions on the electrodeposition of copper is due to the electrostatic contact adsorption of Fe(II) ions, which decreases the free and active surface of the electrode, resulting in an increase of the overvoltage and the corresponding displacement of cathodic Tafel lines to the region of higher overvoltages.

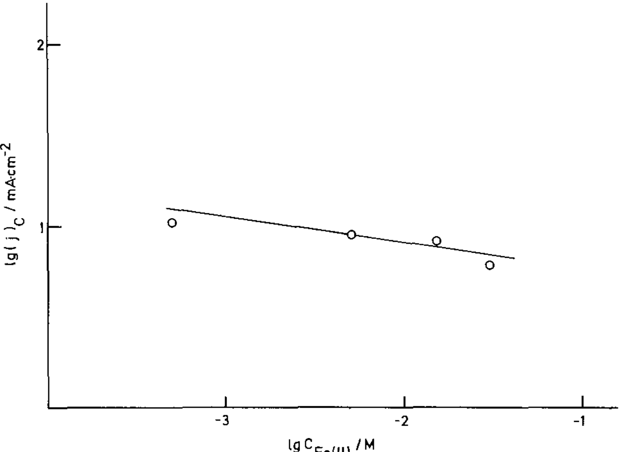

Fig. 3. Dependence of the cathodic current density at any constant value of the potential in the cathodic region of 50-150 mV vs. SCE on the concentration of Fe(II) ions.

Conclusion

The inhibitive effect of Fe(II) ions on the kinetics of the cathodic deposition of copper in the acid sulfate system has been demonstrated. The electrostatic cation adsorption and the co-sphere/co-plane overlap

model for interaction of hydrated ions in the double layer as well as the decrease of the active surface of the electrode, have been suggested for the explanation of this phenomenon. However, further systematic investigation is needed before a more definite interpretation can be offered.

ABSTRACT

Factors affecting the current efficiency of electrowinning processes are investigated theoretically, and the resulting expressions are testing experimentally for the electrodeposition of copper. The results derived predict the dependence of current efficiency on metal-ion concentration and on total current, for different thermodynamic and kinetic parameters of the electrowinning system. It is found that in rotating disk experiments, where transport parameters are independent of current density, the current efficiency can be approximated by the relationship $\epsilon = \epsilon_\infty[1 - \exp(-BC)/\Sigma i)]$. This result is further simplified in a model electrowinning circuit having gas-evolving electrodes where transport processes depend on current density and current efficiency can be represented with surprising accuracy by $\epsilon = \epsilon_\infty[1 - \exp(B'C)]$, where ϵ_∞ and B' are constants which depend on cell geometry and electrolyte composition.

In industrial electrowinning or electrorefining processes, concentration gradients of the metal ions are found within the electrolyte layer near the cathode. If current density is increased beyond a limiting value at which the metal ion concentration at the electrode reaches zero, competing processes take place and the quality of the deposit deteriorates. At the same time, the current efficiency of the desired process drops considerably below the limiting value which is observed at low current densities or high metal-ion concentrations.

In a typical electrorefining process, such as zinc electrodeposition from sulfuric acid electrolyte, a high current efficiency is maintained for the desired process, by using chemical replenishment to maintain metal ion concentration at a high level (typically 60 g/liter for Zn^{2+}) and by use of current densities below the limiting value (1.5 kA/m^2 for zinc) (1). In electrorefining processes such as the purification of blister copper, metal ion concentration is maintained fairly constant by electrochemical dissolution of the anode.

There are many industrial electrodeposition applications, however, in which metal-ion concentration varies sharply with time. Examples are the purification circuit of a copper electrorefinery (2) and circuits used for recovery and treatment of pickling and plating solutions (3-5). Also, although theoretical and experimental characterization of flow-through porous

* Electrochemical Society Active Member.

Key words: current efficiency, metal electrowinning, copper deposition.

electrodes is reaching an advanced state (6-8), it is likely that a large number of ill-defined reaction sequences will be encountered using these electrodes in plant-scale operations.

It is, therefore, pertinent to examine the current efficiency for metal-ion deposition as a function of concentration and current density. The ultimate objective is to use the resulting function for prediction of concentration profiles in dynamic electropurification and electrowinning circuits. This is the subject of part II of this series (9). The present paper deals with the current-efficiency function itself. Because of its practical importance, and because the more fundamental aspects have been thoroughly established (10-12), copper deposition has been chosen as the subject of experiments illustrating the theoretical development.

Theory

Most electrode processes are irreversible, and current is controlled not only by mass transport to the electrodes, but also by heterogeneous rate constants which account for the slow electron transfer or slow nucleation steps. The Tafel relationship is often used to describe such systems. However, when currents may approach their limiting values or when a reverse reaction such as dissolution of the electrodeposit may not be excluded, the behavior is better approximated by a more general expression

$$E = E_{1/2} + \frac{RT}{\alpha n\mathbf{F}} \ln \left(\frac{i - i_l^c}{i_l^a - i} \right) \quad [1]$$

The transfer coefficient α depends on the nature of the electrode reaction, while the half-wave potential $E_{1/2}$ is a function of the rate constant, the diffusion coefficient, and the standard reduction potential. Both α and $E_{1/2}$ may be readily determined from laboratory polarization experiments using expression [1]. This expression is valid for electrochemical reactions in which the transport process is the same for all reacting species.

While ohmic-resistance effects and deviations from uniform current distribution will affect measured potentials in practical systems, Eq. [1] is useful as a first approximation. It can serve to illustrate sensitivity to the three key parameters which determine electrodeposition current efficiency when two (or more) processes are possible, the desired process 1 and the undesired process 2. These are the difference in half-wave potentials $\Delta E_{1/2}$, the ratio of the limiting current densities i_l^c/i_{l2}^c, and the degree of reversibility of the two competing reactions as measured by $(\alpha n)_1$ and $(\alpha n)_2$.

Since current densities and not electrode potentials are normally controlled, it is instructive to plot current efficiency as a function of the ratio of the limiting current density for deposition of the desired metal to the total current density, $(i_l/\Sigma i)$. Figure 1 records typical results calculated from Eq. [1] for two closely-spaced ($\Delta E_{1/2} = 5 \times 0.059$V) cathodic processes. It is clear that when the two cathodic reactions are sufficiently separated in potential (curves f, h, and i), the result consists essentially of two straight-line sections. For current densities less than i_l the desired process 1 can furnish all of the current, while for current densities exceeding i_l the current efficiency decreases linearly as process 2 becomes increasingly important.

If the two waves are not sufficiently separated, the region around $i_l/\Sigma i = 1$ becomes rounded (curves e, c, and b in Fig. 1), while for a highly irreversible competitive process [curve a, $(\alpha n)_2 = 0.5$] the limiting current efficiency is significantly less than unity.

Figure 2 examines the sensitivity of current efficiency to limiting current density and $\Delta E_{1/2}$ for kinetic parameters characteristic of metal deposition in competition with hydrogen evolution, $(\alpha n)_1 = 2.0$ and $(\alpha n)_2 = 0.5$.

As the limiting current density for the competing process increases with respect to that for metal deposition (curves a, b, c, and e), the current efficiency decreases and the maximum becomes more pronounced. As $\Delta E_{1/2}$ decreases (curves f, e, and d) the desired process becomes increasingly inefficient.

In the example of zinc electrowinning from acid electrolyte, where $\Delta E_{1/2}$ is less than zero, the current efficiency approaches a maximum less than 1.0 as $i_l/\Sigma i$ increases, and decreases to zero at high values. In the case of copper deposition from acid electrolyte, of particular interest in this paper, $\Delta E_{1/2}$ is greater than zero, and three regions can be identified from examination of Fig. 1 and 2:

1. When current density greatly exceeds the limiting current density, efficiency will approach the asymptotic value $\epsilon_\infty = 1$ when the transfer coefficient for the metal deposition reaction is less than that for the competing reaction. In the more likely event that the competing reaction is the less reversible, the efficiency passes through a broad maximum and eventually approaches zero.

2. When current density greatly exceeds the limiting current density, then only the fraction $i_l/\Sigma i$ can be usefully employed even under ideal conditions. Since the limiting current density depends on the local concentration C and transport parameter k through the relationship $i_l = n\mathbf{F}kC$, the current efficiency will approach

$$\epsilon = \frac{i_l}{\Sigma i} = \frac{n\mathbf{F}kC}{\Sigma i} \quad [2]$$

Although the current efficiency always approaches this limiting behavior, for unresolved processes the limit may be reached at such high current densities, and at such low values of ϵ, that it is of little practical interest.

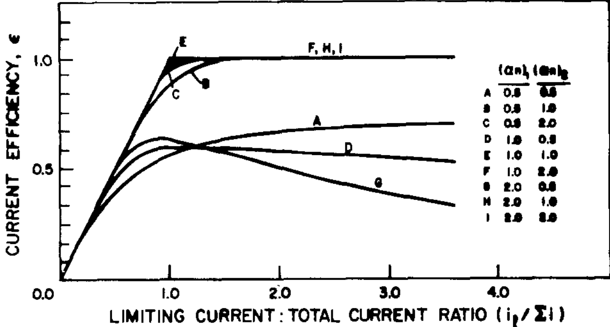

Fig. 1. Current efficiency as a function of current density for $i_{l2} = 100\ i_l$ and $\Delta E_{1/2} = 5 \times 0.059$V.

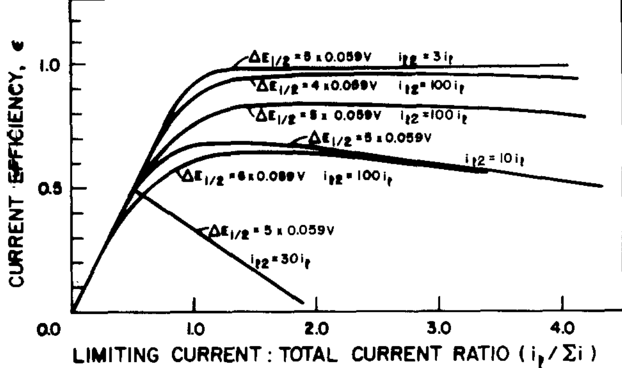

Fig. 2. Current efficiency variation for kinetic parameters characteristic of metal deposition in competition with hydrogen evolution, $(\alpha n)_1 = 2.0$ and $(\alpha n)_2 = 0.5$.

3. For the case of greatest practical interest, where the current density approaches the limiting current density, it is necessary to consider the respective equilibrium potentials and kinetic parameters of the two or more alternative current paths in order to arrive at a satisfactory description of the phenomena. A clear requirement for a descriptive function is that ϵ vary in a monotonic fashion from case 1 to case 2, and that $\lim_{C\to\infty} \epsilon = \epsilon_\infty$ and $\lim_{C\to 0} \epsilon = 0$

One convenient expression meeting these requirements for two closely spaced electrode processes is

$$\epsilon = \epsilon_\infty [1 - \exp(-B'' i_l/\Sigma i)] \quad [3]$$

Figure 3 illustrates how Eq. [3] can approximate the limiting behavior of the current efficiency quite closely, for representative values of the parameters ϵ_∞ and B''. The intermediate behavior for overlapping waves can be fitted quite satisfactorily, as exemplified by the agreement of curves d and e. Curve b overestimates the current efficiency somewhat at low $i_l/\Sigma i$ ratios, approaching 1.0 less quickly than calculated for the limiting case. Equation [3] cannot reproduce the maximum which appears under extreme conditions, for example for $i_{l_2} = 100\ i_l$ and $\Delta E_{1/2}$ less than 6×0.059V (*cf.* Fig. 2). Thus, numerical interpolation from experimental efficiency data may be necessary in some applications, for highest accuracy.

In summary, Eq. [3] can be considered a useful mathematical function which permits analytical treatment of a wide variety of electrode processes. A useful extension of this expression which is more directly applicable to experimental data is obtained by substituting for the limiting current density

$$\epsilon = \epsilon_\infty [1 - \exp(-BC/\Sigma i)] \quad [4]$$

Experimental

Preliminary deposition experiments were carried out using a Tacussel E5 rotating disk electrode. The surface was prepared by mechanically polishing the end of 2 mm copper wire which was embedded in a 1 cm Teflon disk followed by electrodeposition of copper at -0.35V *vs.* the standard calomel electrode (SCE) for 7 min from a 0.01M $CuSO_4$, 0.5M H_2SO_4 solution. Identical results were obtained for copper deposited in the same way on a platinum surface. The electrode pretreatment was repeated if the electrode was exposed to the atmosphere, or if its potential was moved outside the range -0.7 to $+0.1$V *vs.* SCE.

The electrolysis experiments were carried out in a Plexiglas purification cell fitted for 11 lead anodes and 10 copper cathodes, each having dimensions 9 $\times$ 9 cm. The electrodes could be mounted alternatively with a 1 cm spacing so that 20 individual compartments were formed, each of them holding about 160 cm^3 of electrolyte. This arrangement is illustrated schematically in Fig. 4. Solution could be passed as indicated at flow rates from 0 to 0.5 $cm^3\ sec^{-1}$, cascading from one compartment to the next. Direct current was applied either at fixed potential or at fixed current by a McKee Pederson MP 1026 or a Lambda Model LP 522 FM power supply. Acidified copper sulfate solutions for the electrowinning experiments (0.1M $CuSO_4$ and 2M H_2SO_4) were prepared in 20 liter batches from Analar reagent grade $CuSO_4$ and H_2SO_4. Copper concentrations were monitored, after dilution, by atomic absorption (Varian Spectrophotometer) and pulse polarography (Princeton Applied Research Model 174).

Current efficiencies were calculated by two methods. When a relatively small volume was circulated through a part of the test cell, or when the complete cell was used, calculations were based on the measured decrease in copper concentration. When a large volume of fixed concentration was quickly passed through the cell, efficiencies were determined by measuring the weight of copper deposited onto the cathodes. Electrolyte circulation within individual cells was assured by the gas evolution on the anodic and, in varying degrees, cathodic surfaces. The bulk flow rates in a direction perpendicular to the electrodes were not found to influence the limiting current significantly, and no other agitation was provided.

The mechanically polished cathode surfaces aged significantly during the course of a run. Both the appearance and adherence of electrodeposited copper varied greatly with the electrolysis conditions, but no effort was made to determine the exact physical nature of the deposits.

Results and Discussion

Rotating disk electrode experiments.—Voltammograms recorded with rotating copper disk electrodes in acidified copper sulfate solution were used to estimate the current efficiency as a function of electrode potential and copper concentration. The potential was scanned from 0.0V *vs.* SCE in the cathodic direction, and the scan was reversed when obvious hydrogen evolution occurred. Anodic and cathodic scans did not show a hysteresis unless an anodic current was inadvertently passed and the surface reoxidized. Current efficiencies were estimated by comparison of currents measured in the $CuSO_4/H_2SO_4$ electrolytes with currents measured in identical experiments using 0.5M H_2SO_4 electrolytes.

Results are recorded in Fig. 5. Current efficiency was found to decrease with increasing cathodic cur-

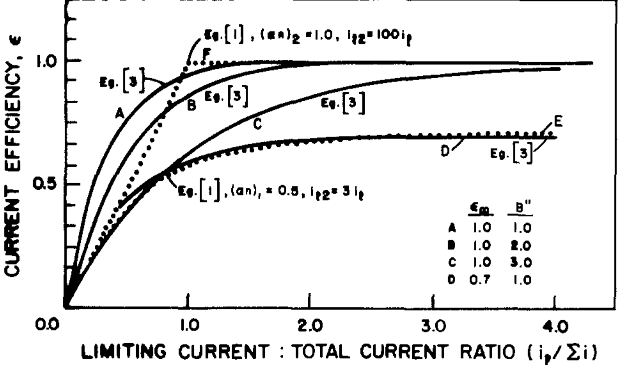

Fig. 3. Use of Eq. [3] for prediction of the current-density dependence of current efficiency, for cathodic processes having $\Delta E_{1/2} = 5 \times 0.059$V while $(\alpha n)_1 = 2.0$.

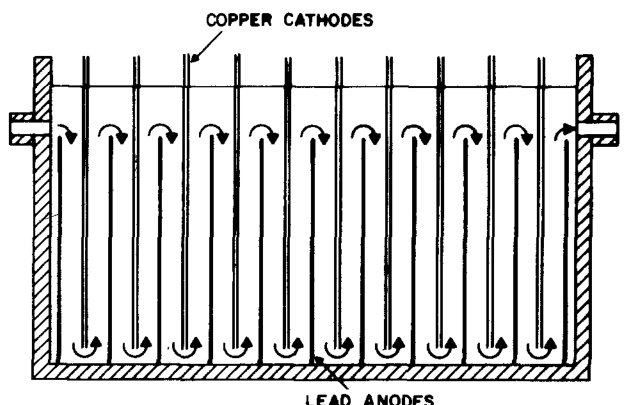

Fig. 4. Plexiglas electrolysis cell having provision for 11 lead anodes and 10 copper cathodes. Electrodes having dimensions 9 $\times$ 9 cm were spaced 1 cm apart, forming 20 cell compartments each having a volume of 80 cm^3.

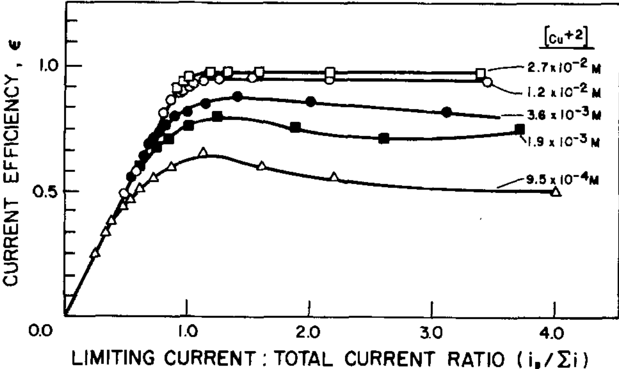

Fig. 5. Cathodic current efficiency for electrodeposition of copper on a rotating disk electrode, for different copper ion concentrations.

rent density and with decreasing copper concentration. When plotted as a function of $i_l/\Sigma i$, the current efficiency could be approximated by two straight-line portions at concentrations below 0.01M. In these cases, current efficiency exceeded 95% for current densities below the limiting value. At lower copper-ion concentrations, however, the current efficiency decreased to about 60% even under the most favorable current conditions. Detailed results showed the limiting current density, i_l, to be a linear function of copper concentration from 10^{-3} to 1.0M, and to vary with the square root of the rotational velocity of the disk down to 50 rpm, as expected from the Levich expression and reported earlier by Caban and Chapman (12). Plots of current efficiency *vs.* $i_l/\Sigma i$ at different rotational speeds (not shown) coincided at concentrations greater than 10^{-2}M Cu^{2+}.

Figure 6 records results obtained for current efficiency as a function of copper concentration. The data obtained at different current densities fell on a single curve, in good agreement with the prediction of Eq. [4]. The parameter B in this case reflects the transport characteristics of the system and can be expected to vary with the rotational velocity.

Isolated-cathode experiments.—A copper cathode was installed at one end of the electrowinning cell of Fig. 4 and was separated from a lead anode at the other end of the cell by a porous polypropylene diaphragm. The 1.6 liter volume of the cell assured relatively fixed copper concentration during electrolysis, and the cathode was effectively shielded from the gas evolution at the anode. The deposits obtained for copper ion concentrations greater than 3 g liter^{-1} were uniformly dense, bright, and pale colored, while those obtained at lower concentrations were generally fragile, porous, nonadherent, and subject to air oxidation which tended to form a dark copper-oxide film. Current efficiencies calculated from the weight gain of the copper sheet (100-300 mg) at fixed current densities (2-15 mA/cm²) are recorded in Fig. 7. Copper concentrations ranged from 0.02 to 0.1M. The current efficiencies tended to a limiting value of $\epsilon_\infty = 0.98 \pm 0.02$ at the higher concentrations and lower current densities. Unlike the results obtained using the rotating disk electrode (Fig. 6), the efficiencies measured at different concentrations did not coincide.

This apparent discrepancy can be rationalized based on the relatively low electrolyte circulation at the isolated cathode. The total current density can be expressed as

$$\Sigma i = i_{H_2} + 2Fk[Cu^{2+}] \quad [5]$$

The dotted line in Fig. 7 was calculated assuming a fixed k value estimated from the current at the onset of hydrogen evolution as 1.6×10^{-5} cm sec^{-1}. For a diffusion coefficient of 5×10^{-6} cm² sec^{-1} this would correspond to an effective diffusion-layer thickness $\delta \sim 0.033$ cm. The experimental current efficiencies of Fig. 7 are all higher than those predicted from the simple model.

The enhancement of the transport rate at gas-evolving electrodes has been studied extensively (13-16) and is described by the empirical relationship

$$\ln \delta = -m \ln i_{H^2} + C \quad [6]$$

Idl *et al.* (14) cite m values ranging from 0.25 to 0.59 for hydrogen evolution in acid media. More recently, Janssen (16) has reported values as high as $m = 0.9$ for horizontal electrodes. A close fit to the data of Fig. 7 is obtained using the parameters $m = 0.38$ and $C = -6.8$. Although this fit is relatively insensitive to the precise values of m and C, there is little doubt that the average transport parameter is enhanced by local stirring arising from bubble dislodgement.

Experiments in the electrowinning configuration.—Two types of experiments were performed in the electrowinning cell with copper cathodes suspended 0.9 cm from facing lead anodes. In the first series, the cell was fed with electrolyte having a known concentration between 0.01 and 0.1M. Typical values of the current efficiency calculated from cathode weight gain are recorded as solid circles in Fig. 8.

The limiting current efficiency at the higher concentrations was found to be 0.965 ± 0.02. Figure 9 illustrates the bubble distribution observed in the cell. Even at high copper concentrations (Fig. 9A) some oxygen bubbles came in contact with the copper cathode. This may partially account for the observed 3.5% efficiency loss. The hydrogen bubbles given off at the cathode at lower copper concentrations extended far less into the interelectrode space than they did in the isolated-cathode experiments described above. In agreement with results reported by Awakura *et al.*

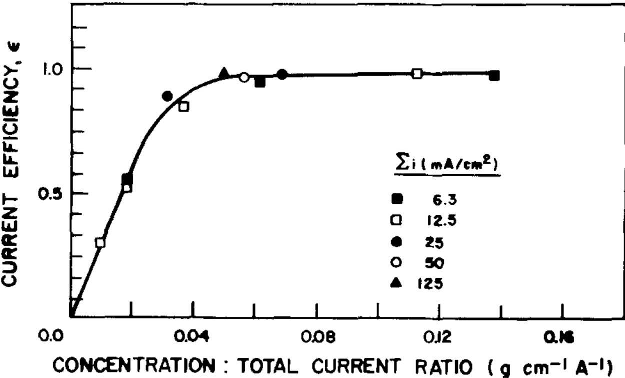

Fig. 6. Cathodic current efficiency for electrodeposition of copper on a rotating disk electrode. Rotation speed was 500 rpm, electrode area was 2 mm², and copper-ion concentration varied from 0.001 to 0.1M.

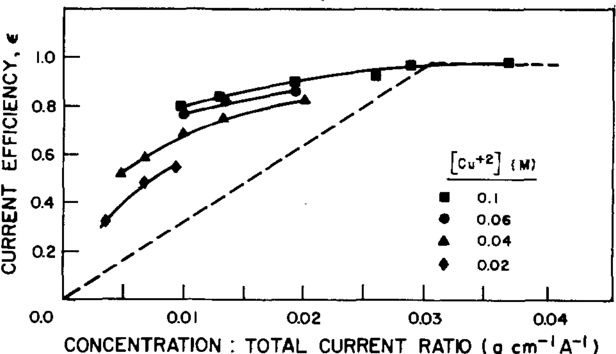

Fig. 7. Current efficiency for electrodeposition of copper at an isolated cathode. The solid lines are calculated using Eq. [6], while the dotted line represents predicted behavior for constant δ.

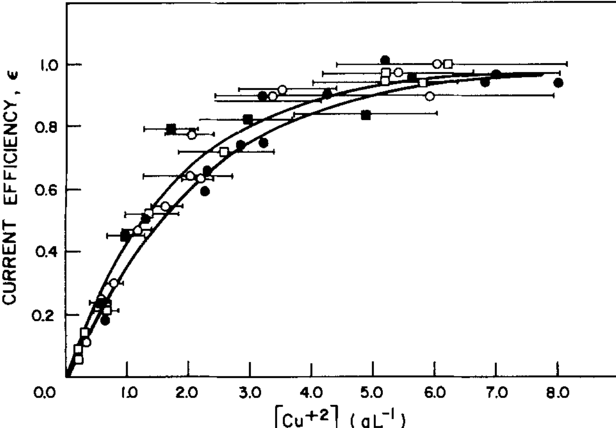

Fig. 8. Current efficiency for electrodeposition of copper. Solid curves are drawn from the expression $\epsilon = 0.965 [1 - \exp(-B'C)]$.

(17), thicker deposits and an upward movement of the electrolyte were observed near the lower part of the isolated cathode. In the electrowinning configuration, however, the deposit was more uniform, and downward electrolyte movement adjacent to the nongasing cathode was observed in agreement with the observations of Ettel, Tilak, and Gendron (13). Figure 9b shows that full turbulence is achieved near the electrodes at low copper concentration, and the downward movement of the electrolyte takes place near the center of the interelectrode region.

The second set of experiments approximated a batch purification process. A small volume (approx. 160 cm^3) of electrolyte was constantly recirculated through a single cell compartment, and 0.05 cm^3 samples were withdrawn periodically for analysis. Resulting current efficiencies are plotted in Fig. 8. The experimental uncertainty is quite high at the initial copper concentrations since current efficiency must be calculated from small differences in concentration.

The results of this experiment practically coincide with those obtained at constant concentration. Unlike data obtained with the rotating disk electrode which coincided as a function of $C/\Sigma i$ and those obtained at the isolated cathode which showed some enhancement of the transport parameter, the current efficiency in the electrowinning geometry appears relatively independent of current density. With reference to Fig. 8, the current efficiency is closely approximated by

$$\epsilon = 0.965[1 - \exp/(-B'C)] \quad [7]$$

here $B' = 0.55 \pm 0.05$ liter g^{-1} and C is expressed in g $liter^{-1}$.

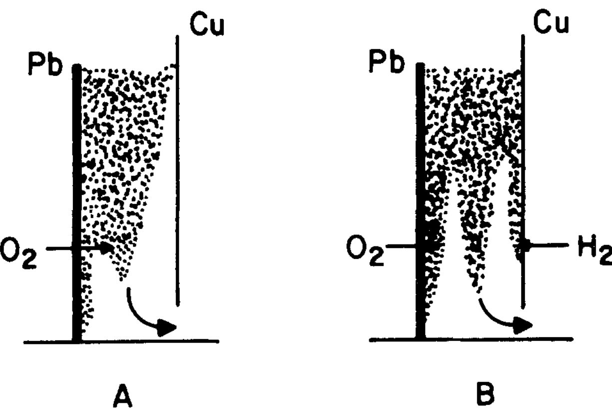

Fig. 9. Gas evolution during copper deposition at 3 mA/cm^2 at copper ion concentrations above 3.0 g $liter^{-1}$ (a) and below 1.0 g $liter^{-1}$ (b).

The apparent inconsistency between the rotating disk (Eq. [4]) and electrowinning cell (Eq. [7]) result is explained if the local transport parameter is directly proportional to the total current. This is reasonable, as the rate of anodic gas evolution is directly proportional to current and it is known that the transport parameter varies directly with air sparging rate (13, 14). Equation [7] may thus be considered a reasonable empirical relationship over the limited current range of practical interest. The parameter B' can be expected to vary with cell geometry, electrolyte viscosity, and temperature.

Conclusion

It has been shown that the current efficiency of metal electrodeposition at electrodes characterized by constant transport parameters is a function of the ratio of metal-ion concentration to the total current. This has been confirmed for the electrodeposition of copper at a rotating disk electrode, where the current efficiency can be adequately reproduced by the expression $\epsilon = \epsilon_\infty[1 - \exp(-BC/\Sigma i)]$.

In a typical electrowinning configuration, the experimental results suggest that the parameter B, which includes the local transport parameter, is directly proportional to the total current density, and thus that the current efficiency may be represented by the simple result $\epsilon = \epsilon_\infty[1 - \exp(-B'C)]$. This simple two-parameter relationship is found to describe the current efficiency of copper electrodeposition with surprising accuracy.

ABSTRACT

A simple expression has been derived in part I for current efficiency of an electrowinning process as a function of metal-ion concentration: $\epsilon = \epsilon_\infty[1 - \exp(-BC)]$. This semi-empirical relationship is used in this paper to predict the concentration variation with time during batch electrolysis, and the steady-state variation of concentration with distance in a flow-through electrowinning circuit. A method of calculation is reported which allows prediction of the transient or steady-state response of a flow-through electrowinning system, for any assumed dependence of the cathodic current efficiency on metal-ion concentration.

The mathematical description of electrowinning and electropurification systems is not unlike recent derivations for flow-through porous electrodes (1-4). A typical purification or electrowinning circuit consists of a series of cascading cell compartments with the electrolyte flowing from one cell to the next. A method for measuring the local mass-transport coefficient in such circuits has been developed by Ettel and his colleagues (5), based on analysis of traces of noble metals which are codeposited with copper ions. However, an analysis which allows calculation of the macroscopic properties of a practical electrometallurgical circuit, in particular the variation of metal-ion concentration with position and time, has not previously been available.

The local current densities during electrodeposition of copper are only uniform at very low current loadings (6). Under the conditions prevailing in an electrowinning or electropurification circuit where the total current density is an appreciable fraction of the limiting current density for metal-ion deposition, the current density is expected to vary as the -0.25 power of the vertical distance. In the latter stages of a purification circuit where applied current may exceed the limiting current density, extensive gas evolution will occur and fully turbulent flow may be expected. Thus *ab initio* calculations of limiting currents are not straight-forward for real systems. Fortunately, it is fairly easy to measure average parameters for narrow electrodes of a given height, and to apply these values to larger systems.

The treatment presented here is based on the fact that the current efficiency at electrowinning cathodes can be expressed as a function of concentration, and that it seems to be independent of current density over the fairly narrow concentration ranges which are important in industrial systems (7). Electrode dimensions and electrolyte flow may vary to such an extent that neither pure plug flow nor ideally mixed flow can adequately describe the system. It is supposed here that plug flow occurs within parts of the system and, when necessary, that complete mixing occurs before the electrolyte enters the next stage of the circuit. Adequacy of these assumptions is supported by the experimental results.

Theoretical Description of an Electrowinning Circuit

The general equation describing an electrowinning or electropurification circuit is derived by considering the portion of a cell between x and $x + dx$. Geometric parameters are defined in Fig. 1. Conservation of mass requires that the quantity of metal ions brought into the volume element dV by solution flow v in time dt be equal to the quantity carried out by the solution flow, plus the quantity electrowon on the electrode area dS, plus the increase within dV.

The net metal-ion outflow from dV in time dt, is given as $v\ \partial C/\partial x\ dt\ dx$, the gain within the volume element equals $\partial C/\partial t\ dt\ dV$, and the quantity electrowon is given as $\epsilon i/n\mathbf{F}\ dS\ dt$, where the surface element $dS = H\ dx$ and the electrode height h may vary as a function of distance. The volume element dV is equal to $A\ dx$, and the local current efficiency ϵ depends on the chemical nature of the process. Thus, the time and space-dependent differential equation can be written as

$$\frac{v\partial C}{\partial x} + \frac{A\partial C}{\partial t} + \frac{\epsilon ih}{n\mathbf{F}} = 0 \qquad [1]$$

* Electrochemical Society Active Member.

Key words: electrowinning, copper deposition, concentration profiles, dynamic flow system.

Fig. 1. Volume element of a flow-through electrowinning circuit, defining the geometric parameters.

When steady-state conditions have been attained, $\partial C/\partial t = 0$, and Eq. [1] becomes

$$\frac{v\partial C}{\partial x} + \frac{\epsilon i h}{n\mathbf{F}} = 0 \quad [2]$$

Equations [1] and [2] hold exactly for an infinitely small volume element. The current efficiency ϵ may be conveniently measured using a single cathode as the average current efficiency $\epsilon = \langle\epsilon\rangle$ at an average current density $i = \langle\Sigma i\rangle$. This experimental approach avoids the need to postulate the exact electrolyte and gas-flow characteristics in the interelectrode space. For the electrowinning of copper, we have shown that the current efficiency can be represented as a simple analytical function whose parameters seem to be independent of average current density over the narrow concentration range of interest (7). This facilitates considerably solution of Eq. [1]. However, the general approach remains valid for numerical solutions where current efficiency is only available as a function of copper concentration in tabulated form.

Steady-state profiles.—Solutions of Eq. [2] describe many practical electrowinning situations where the assumptions of ideal plug flow, constant incoming metal-ion concentration C^o, and uniform transport characteristics are reasonable approximations. To simplify the resulting expressions, it is further assumed that a uniform current distribution exists along an electrode (of constant height h and length l) in a direction perpendicular to the solution flow. Thus $I = i\ h\ l$ is the total current passed in the system.

If the current efficiency ϵ is a constant, equal to ϵ_∞, Eq. [2] is readily solved to yield

$$C = C^o\,[1 - x/x^o] \quad [3]$$

where

$$x^o = \frac{n\mathbf{F}vC^o}{\epsilon_\infty ih} = \frac{n\mathbf{F}vlC^o}{\epsilon_\infty I}$$

For this limiting case, the metal-ion concentration at the outlet of the cell is independent of the size and geometry of the system.

In the limit of high currents compared to the limiting current density or of low metal-ion concentrations, the current efficiency may be approximated as $\epsilon = \epsilon_\infty i_l/i$ and solution of Eq. [2] gives

$$C = C^o \exp\,(-x/x^*) \quad [4]$$

where

$$x^* = \frac{v}{\epsilon_\infty kh}$$

The metal-ion concentration decreases much more slowly according to this expression than the prediction of Eq. [3].

At intermediate (and industrially more important) current densities where the current efficiency can be described by the results of part I (7), the differential Eq. [2] becomes

$$\frac{v\partial C}{\partial x} + \epsilon_\infty\frac{ih}{n\mathbf{F}}\,[1 - \exp\,(-BC)] = 0 \quad [5]$$

Integration of this expression yields

$$C = \frac{1}{B}\ln\left\{1 + \left[\exp\left(\frac{-BxC^o}{x^o}\right)\right][\exp\,(BC^o) - 1]\right\} \quad [6]$$

Thus, the concentration initially decreases linearly with increasing distance from the cell inlet, and finally approaches zero in an asymptotic fashion.

Representative concentration profiles are plotted in Fig. 2 for $BC^o = 1, 2, 3$, and ∞, as a function of the dimensionless distance parameter x/x^o. From Eq. [3] it is clear that x^o corresponds to the distance necessary to deposit all of the metal ions if ϵ has a constant value ϵ_∞. The concentration at the exit ($x = l$) will depend on the ratio l/x^o. Increasing the concentration of the incoming liquor C^o, or decreasing the current density, will increase x^o. Current does not appear in Eq. [6], and according to this model (7) will not alter the current efficiency parameter B. Increasing C^o will move the concentration profile closer to the limiting curve d, but may increase x^o beyond the length of the purification cell. Optimization of the cell parameters to diminish the exit concentration becomes possible from considerations of results such as those presented in Fig. 2.

Time-dependent profiles.—Equation [1] can be solved by inspection for a closed system where the electrolyte flow rate is equal to zero and the current density is constant. The results are analogous to Eq. [3] and [6]. When the current efficiency has a constant value ϵ_∞, the metal-ion concentration decreases as

$$C = C^o\left(1 - \frac{t}{t^o}\right) \quad [7]$$

where

$$t^o = \frac{n\mathbf{F}VC^o}{\epsilon_\infty I}$$

In the general case

$$C = \frac{1}{B}\ln\left\{1 + \left[\exp\left(\frac{-BtC^o}{t^o}\right)\right][\exp\,(BC^o) - 1]\right\} \quad [8]$$

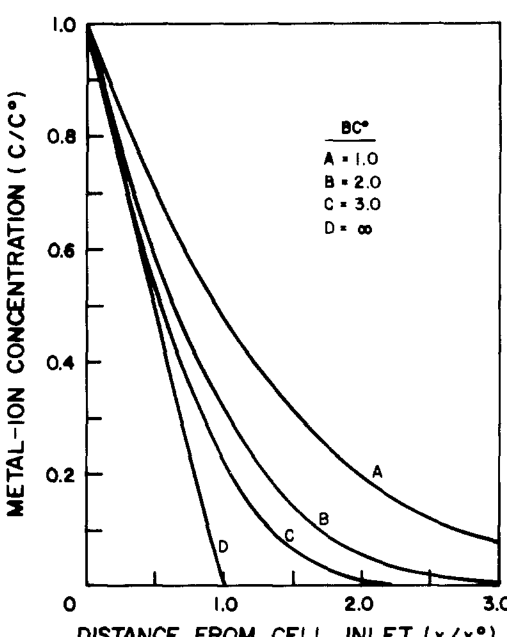

Fig. 2. Steady-state concentration profiles as a function of position in the electrowinning circuit, predicted by Eq. [6].

Thus in a closed system the concentration decreases linearly with time after the electrowinning current is first applied, and then approaches zero asymptotically.

Noting the parallel between Eq. [6] and [8], Fig. 2 can be interpreted as the time variation of metal-ion concentration in a closed system, if the abscissa is read as t/t^o. In this case t^o is interpreted as the time required to reduce metal-ion concentration to zero, when the current efficiency assumes a constant value ϵ_∞.

The full time-dependent Eq. [1] can be solved numerically, using the Newton Raphson iteration method. The expression is written in finite-difference form as

$$\frac{v([C]_{i,j} - [C]_{i-1,j})}{\Delta x'} + \frac{V([C]_{i,j} - [C]_{i,j-1})}{\Delta t} + \frac{I\epsilon}{n\mathbf{F}} = 0 \qquad [9]$$

If the number of segments $\Delta x'$ is small, then the iterative solution implicity assumes ideal plug flow from one segment i to the next segment $i + 1$, followed by ideal mixing within each segment after time interval Δt. If only one segment is considered, then ideal mixing is implicitly assumed within the entire cell. This approach allows treatment of several cells of different volumes and different electrolysis currents which are arranged in series, and it also allows use of an electrolyte-feed solution whose composition varies with time.

Experimental

Experiments were carried out in the 21-electrode model electrowinning cell described in part I (7). As in the earlier work, copper deposition was used as a model system.

For static tests with no solution flow, all of the copper cathodes were connected in parallel, as were all of the lead anodes. Copper concentrations were followed over 3-5 hr intervals, and average results are reported. For dynamic tests where fresh solution was continually pumped into the left compartment of the system and withdrawn from the right, electrical connections to each cathode were made through 0.03Ω nickel-chrome shunt resistors, so that current could be monitored. Connections to the anodes were through 1.0Ω 10W resistors. These resistors, together with the high oxygen overpotential, assured a minimum variation in the current flow despite the strong variations of copper concentration with position in the system.

Electrode potentials *vs.* a saturated calomel electrode were measured with an Orion *p*H meter using a 1 mm, sulfuric-acid-filled Luggin capillary whose L-shaped tip could approach the cathode without significantly disturbing the electrolyte or gas flow patterns. Overvoltage values were averaged for a number of vertical positions in each cell compartment, and showed a scatter of about 15 mV.

Results and Discussion

Static conditions ($v = 0$).—When the electrowinning cell was operated at no net electrolyte flow, the electrode potentials were observed to vary monotonically as electrowinning progressed. Typical results, recorded in Fig. 3, show that the anode potential remained constant after an initial 2 hr period. The cathode potential shifted to more negative values as the copper ions were depleted. The sharp potential drop corresponded to a rapid drop in cathodic current efficiency and the onset of vigorous hydrogen evolution. This potential shift could be used to control a purification circuit and avoid insipient hydrogen evolution (8).

As indicated in the theoretical development above, the copper-ion concentration profile of Fig. 3A can be predicted by solving Eq. [9] for any given relationship between the current efficiency and copper-ion concentration. Typical examples of such predictions are presented in Fig. 4 in comparison with the experimental data obtained. At 100% current efficiency the

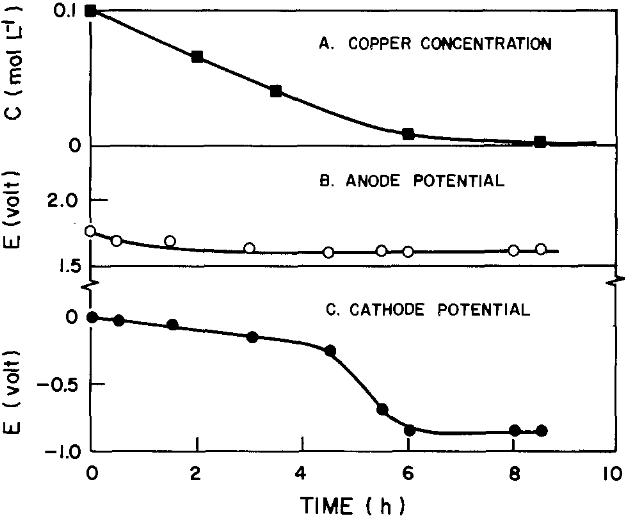

Fig. 3. Time dependence of copper-ion concentration and of the anode and cathode electrode potentials in a static system. Indicated potentials are with respect to the normal hydrogen electrode.

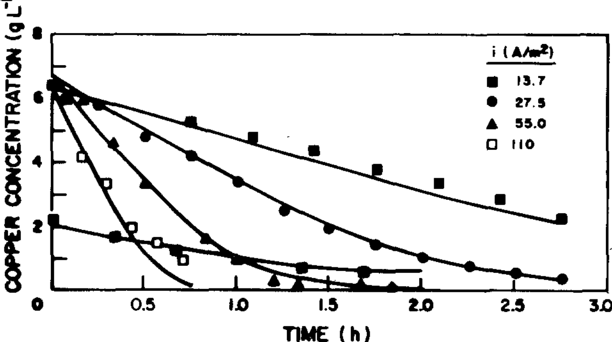

Fig. 4. Copper concentration profiles in a static system. Solid lines are calculated from Eq. [8] for a cell volume of 160 cm³, assuming $\epsilon = 0.965$ [I − exp(−0.575 C)].

copper concentration would decrease linearly with a slope directly proportional to the current (*cf.* Eq. [7]). However, if the current efficiency can be approximated by the result of part I (7), the quasi-exponential decay predicted by Eq. [8] is to be expected.

The theoretical curves of Fig. 4, based on the model $\epsilon = 0.965\ [1 - \exp(-0.575\ C)]$ are in very satisfactory agreement with the experimental data.

At the highest current density (110 A m^{-2}), the predicted decrease in copper-ion concentration was not quite attained below 2 g $liter^{-1}$. The deposit in this case was nonadhering and powdery, tending to break off and float about in the cell compartment. The relatively low efficiencies observed are attributed to redissolution of this powder in the presence of the anode gas. At 13.7 A m^{-2}, the experimental copper concentrations ($\simeq$ 4 g $liter^{-1}$) fell somewhat above the predicted line. There was little cathodic gas formation at this low current density. An appreciable (±10%) vertical concentration gradient was later found to exist in the absence of turbulent mixing at the cathode, and thus a non-negligible sampling error may be reflected in these low current-density results.

Dynamic-flow conditions.—All twenty cell compartments were used in a series of experiments with electrolyte cascading from cell to cell at a steady flow rate. Figure 5 illustrates the concentration profiles in the circuit as a function of the distance from the inlet (or the cell compartment number) and the electrolysis time. The applied current of 7.6Å was distributed evenly (0.76 ± 0.05A) over the ten cathodes, and a constant electrolyte flow rate of 0.41 $cm^3\ sec^{-1}$ was imposed throughout the run.

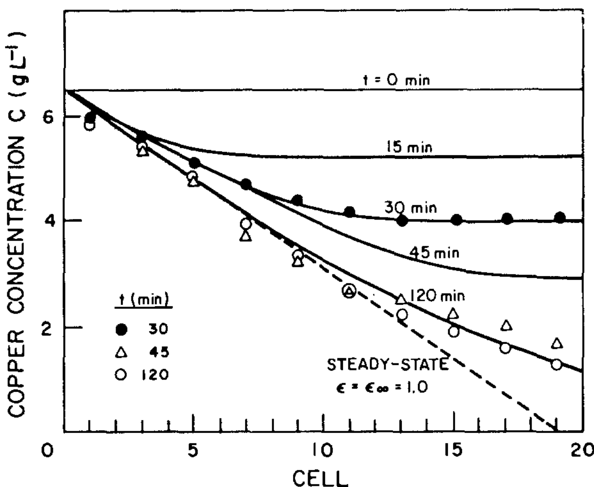

Fig. 5. Concentration profiles in the experimental purification circuit. Solid curves are calculated from Eq. [9] for an initial copper concentration of 6.56 g liters^{-1}, v = 0.42 cm^3 sec^{-1}, total current = 7.6A, V = 1.60 liters, and the same efficiency function as used for Fig. 4.

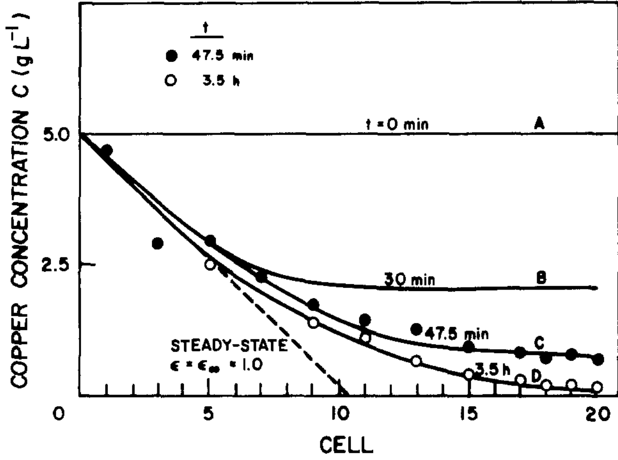

Fig. 6. Concentration profiles in the experimental purification circuit. Solid curves are calculated from Eq. [9] for an initial copper concentration of 5.01 g liter^{-1}, v = 0.34 cm^3 sec^{-1}, a total applied current of 10A, V = 1.50 liters, and the same efficiency function as used for Fig. 4.

The iterative solution of Eq. [9] is superimposed on Fig. 5, at different electrolysis times. This solution predicts a gradual depletion in copper concentration from the initial constant value of 6.56 g liter^{-1} to the profile b, c, and eventually reaching the steady-state profile f which is given by Eq. [3]. The electrowinning was clearly less efficient than would be predicted from the simplification $\epsilon = \epsilon_\infty$, although this approximation can be useful for copper-ion concentrations above 2 g liter^{-1}.

Assuming ideal plug flow, steady-state conditions should be attained at $t = V/v$, where V is the total volume of the system and v the electrolyte flow rate. The computer program, which assumes mixing within the twenty individual compartments, predicts steady-state profiles (to within 1%) after about 1.6 resistance times. Stable copper-ion concentrations are observed within 15 min in the first cell compartments and after about 2 hr in the last cells.

The agreement between theory and experiment was most satisfactory for the steady-state conditions where sampling could be carried out without interrupting the electrolysis system in any way. Nevertheless, some experimental points were consistently obtained which seemed to indicate greater than 100% current efficiency. The solution in each compartment was by no means homogeneous nor were the current densities uniform from the top to bottom of the cathodes. As was reported in part I (7), gas bubbles and convection currents took on a characteristic pattern which contributed to the scatter of the points in this small-scale electrolysis system.

The electrolyte can be decopperized further within the same cell geometry by several methods: decrease the inlet copper-ion concentration; increase the current density; or reduce the electrolyte flow rate. Any combination of these factors which reduces x^0 (Eq. [3]) to about one-half of the total electrolysis cell distance would decrease the final copper concentration to about 0.1 g liter^{-1}. All three parameters were altered for the experiment reported in Fig. 6. The dotted line in the figure indicates that ten cells would suffice if $\epsilon = \epsilon_\infty \simeq 100\%$, whereas nearly twenty are actually required when account is taken of the decreased current efficiency with decreasing copper concentration.

Again, despite some experimental scatter attributable to sampling errors, the agreement between the mathematical model and physical reality is striking. A simple expression for the current efficiency involving at most two adjustable parameters is able to predict transient and steady-state behavior in a model flow-through electropurification circuit. The parameter ϵ_∞ is primarily dependent on the chemical composition of the electrolyte and, in the absence of stray current paths, should not be greatly influenced by the cell geometry. The values obtained here fall within the range reported for commercial copper electrowinning systems. The parameter B varied little with current density (15-100 A/m^2) but preliminary work indicates that it varies with cell geometry, electrolyte temperature, surface tension, and viscosity, all of which were maintained constant throughout the experiments reported here.

Conclusion

The results obtained in both static and dynamic electrowinning circuits suggest that the two-parameter current-efficiency function $\epsilon = \epsilon_\infty [1 - \exp(-BC)]$ is a sufficiently close approximation to reality to be useful in projecting the performance of practical systems. It is likely that relatively simple laboratory experiments which are carried out using electrode spacings and compositions as found in a large-scale electrolysis circuit can be used to yield the values of the parameters ϵ_∞ and B which are needed to describe the current efficiency. With knowledge of these parameters, and of the cell volume, current, and electrolyte flow, a complete description of the time variation of concentration profiles in a particular electrowinning circuit can be derived.

Development of BN Felt Separator for Li-Al/MS_x Battery

Robert B. Swaroop* and James E. Battles*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

Boron nitride felts are being developed and evaluated for application as electrode separators in high temperature Li-Al/MS secondary batteries. Boron nitride fabric has been used as the separator material in most Li-Al/MS_x cells fabricated thus far. However, BN felt separators are presently under development because they are more porous and potentially less expensive than the BN fabric separators. As a preliminary evaluation, the physical properties of various BN felts were determined. Subseqently, felts were also tested in experimental cells operated for extended periods (>1000 hr). The tests indicated that the BN felt is compatible with cell components and is stable in the cell environment.

Electrode separators of boron nitride felt are being developed and evaluated for application in advanced secondary batteries. The cells for these batteries, which operate at temperatures of 400°-500°C, consist of lithium-aluminum alloy negative electrodes, FeS or FeS_2 positive electrodes, and molten LiCl-KCl electrolyte (eutectic melting point, ~352°C). The primary function of the separator is to provide electrical and mechanical separation of the electrodes without restricting ionic flow. The separator must fulfill several requirements: (*i*) low cost, (*ii*) chemical stability with the electrode materials and electrolyte, (*iii*) suitable specific gravity, thickness, and porosity chosen to minimize cell weight and resistance, (*iv*) adequate mechanical strength to accommodate stresses that occur during cell operation, and (*v*) wettability by the molten LiCl-KCl electrolyte.

The above requirement for a good electrical insulator at temperatures between 400° and 500°C precludes the use of metals or organic/polymeric materials. Thus, the selection of materials for the separator is limited to asbestos or ceramics. However, since asbestos will react with the free lithium in the cell, the choice appears to be limited to ceramic materials, namely, oxides and nitrides. A comparison (1) of the free energies of formation of Li_3N and Li_2O with those of ceramic materials indicated that the following ceramics should be stable at the cell operating temperature: BeO, MgO, Y_2O_3, CaO, BN, AlN, and Si_3N_4. The stability predicted by thermodynamic calculations, however, does not insure that a ceramic will be stable in the cell environment because lithium or sulfur may react with impurities in the ceramic. Therefore, an experimental program was launched to investigate the stability of ceramic candidate materials in the cell environment. The results (2) indicated that the ceramics most stable for extended periods of time (>1 year) are MgO, BN, and BeO. Of these materials, only BN is commercially available in fibrous form suitable for fabricating into a cloth or felt separator. Cloth or felt forms are desirable because of their flexible nature. Separators of BN cloth (3, 4) are currently being used in developmental cells. This material has the disadvantages of being expensive and technically undesirable because it has a high basic weight (*e.g.*, 110 mg/cm^2, 2 mm thick) and interstices in the cloth. Therefore, efforts have been directed toward the development of a felt separator (2, 5, 6). Felt separators are more porous, use less material (2/3 less material), are uniform in thickness, and are potentially much less expensive than fabric separators. For the development program, the Kennecott Corporation prepared BN felt which was then evaluated at Argonne National Laboratory.

Preparation of BN felt.—Boron nitride felts for application as separators in Li-Al/metal sulfide cells were developed by the Kennecott Corporation under a subcontract with Argonne National Laboratory. The process consists of forming a boron nitride fiber and boron oxide fiber slurry into a felt using Fourdrinier paper-forming technology. The final conversion of boron oxide bonds to boron nitride in a nitriding environment results in a boron nitride-bonded BN felt. Further details of the process may be noted elsewhere (7).

Evaluation techniques.—The BN felts were physically characterized in out-of-cell tests; then their stability was assessed in test cells.

* Electrochemical Society Active Member.

Key words: battery, separator, insulator.

Out-of-cell tests.—The felts were characterized by measurements of their thickness, porosity, burst strength, flexibility, and wettability. The thickness was measured with an Ames No. 16 Dial Comparator equipped to provide a contact pressure of 862 Pa. The porosity was calculated from measurements of thickness and weight per unit area (basic weight) of the felt and from the weight fractions and densities of the component materials. The burst strength was measured on a Mullen Burst Tester, Model C.

The wettability by the LiCl-KCl electrolyte was evaluated by the sessile drop technique (8). The felt was gradually heated to 450°C in a helium atmosphere glove box with solid electrolyte pieces on the felt. The wettability was considered to be "good" if the molten electrolyte drop was gradually absorbed into the felt. If evacuation and repressurization of the helium was required to wet the felt, the wettability was characterized as "fair."

In-cell tests.—The functional tests of BN felt as a separator material were performed in unsealed LiAl/LiCl-KCl/FeS prismatic cells; the schematic of this type of cell has been presented elsewhere (2). The cell dimensions were 7.6 × 12.7 × 2.5 cm and the theoretical capacity of each test cell was 48-50 A-hr. The negative and positive electrodes were made by hot pressing the appropriate mixture of LiAl and LiCl-KCl powders or FeS and LiCl-KCl powders, respectively. The electrodes were mechanically and electrically separated by BN-felt separators contained between screens. The cells were assembled in the 50% charged state in a helium-atmosphere glove box and were operated at 450°C in a furnace well attached to the glove box. The break-in of assembled cells before cycling required a special procedure, which was essential in order to assure the wetting of the felt separator by the electrolyte. In the normal procedure the assembled cell was heated gradually under a vacuum from room temperature to 450°C. Once at 450°C, the cell was pressurized with helium gas. One or two vacuum-repressurization cycles were sometimes required to completely wet the separator with electrolyte. This procedure was slightly modified if the separator felt had been treated with the $LiAlCl_4$ wetting agent (8). In the special procedure, the initial heating of the cell was conducted in helium gas, not under vacuum, and, once the operating temperature of 450°C was reached, one or two vacuum-repressurization cycles were not required.

During operation, the cells were cycled continuously between a discharge cutoff potential of 1.0V and a charge cutoff potential of 1.65V at a constant current density. In most of the cells, both charge and discharge current densities were increased in steps of 20 mA/cm^2. For lifetime testing, the cells were maintained at either 40 or 60 mA/cm^2 during the charge-discharge cycles until terminated either because end of test was reached (3000 hr of operation) or because cell performance declined. After termination of cell operation, a post-test examination of the cell was conducted to determine the extent of felt degradation, if any, and its effects on the cell. The examination was generally conducted using optical and scanning electron microscopes and x-ray diffraction equipment.

Results and Discussion

Physical and chemical properties.—The felts produced by the methods described in this paper require a stabilization process in nitrogen at 1750°C. Essentially the stabilization process evaporates the residual boron oxide left in the BN fibers and bonds. Neutron diffraction analyses indicated that unstabilized BN felts from Kennecott contained as much as 5-8% oxygen. After stabilization this oxygen content was generally found to be <1%.

Unstabilized felts were characterized for thickness, basic weight, porosity, burst strength, and deformation behavior. These measured properties are given in Table I. The felts were produced in thicknesses ranging from 1.25 to 3.40 mm with porosities between 92% and 94%. The thickness and porosity are useful in evaluating the resistance of the separator to ionic transport and the ability of the separator to prevent the escape of active materials from the electrodes. Thin felts with high porosity have low resistance to ionic transport, thus high utilization of active material. (This was observed during in-cell testing of felts.) The basic weight (per unit area) was measured to be 22, 34, and 43 mg/cm^2 for felts of 1.3, 1.9, and 3.1 mm thickness, respectively. The BN material used in the felt is only one-third the material needed to produce BN fabric. The burst strength of a felt indicates whether the material can maintain its integrity when dimensional changes occur in the electrodes during cell operation. The felts were between 3.5 and 5 kPA per millimeter of thickness. Table I also gives the physical properties of the felts after stabilization. As expected, the basic weight decreased because of B_2O_3 evaporation. The burst strength also decreased because of some degradation of the BN bonds. This slightly affected flexibility of the felts; nevertheless, no handling difficulties were experienced during the subsequent cell assembly.

The scanning micrograph of stabilized felt shown in Fig. 1 indicated that this BN felt consisted of large fibers (6-8 μm diam) that were bonded at a few random intersections with BN. The average size of the openings of the felt was approximately 25 μm diam.

The mechanical behavior of the felt was investigated to assess the deformation characteristics of felt at various stress levels. During cell assembly or cell operation, the internal stresses can reach as high as 200-250 kPa (5) which can adversely affect the porous structure of the felt. The stress-strain curves shown in Fig. 2 were measured for 2 mm thick felts. These curves indicate that the deformation behavior of unstabilized and stabilized felt is similar; the felt was reduced to almost half thickness at approximately 150 kPa. The latter finding indicates that at the internally developed stress levels (5) in an operating cell, the reduction in felt thickness could be as much as 50% of the original thickness. Further out-of-cell experiments were conducted to determine the ultimate strength level of the felts. It was found that felts (1.2-3.4 mm thick) were crushed to powder at 690-1035 kPa stress levels. It should be emphasized that such stress levels are not normally observed either during cell assembly or cell operation.

The wettability of untreated BN felt (as-produced and stabilized) by electrolyte was poor. This wettability was improved by the use of vacuum/pressurization cycles or the wetting agent $LiAlCl_4$ (8). Table II shows the quantity of $LiAlCl_4$ required to effectively wet BN felt by the electrolyte; the optimum quantity is approximately 10 mg/cm^2 per separator. The excessive use of this agent is not recommended because $LiAlCl_4$ dissociates into Al and LiCl at cell operating

Table I. Average properties of BN felt before and after stabilization*

Felt thickness (mm)	Basic weight (mg/cm^2)		Burst strength (kPa/mm)		Porosity (%)	
	Before	After	Before	After	Before	After
1.37 ± 0.13	21.86	20.26	5.05	4.45	92.20	92.40
1.91 ± 0.13	34.44	29.81	4.47	1.84	92.10	93.13
3.12 ± 0.15	42.86	40.97	3.78	1.67	93.37	93.65

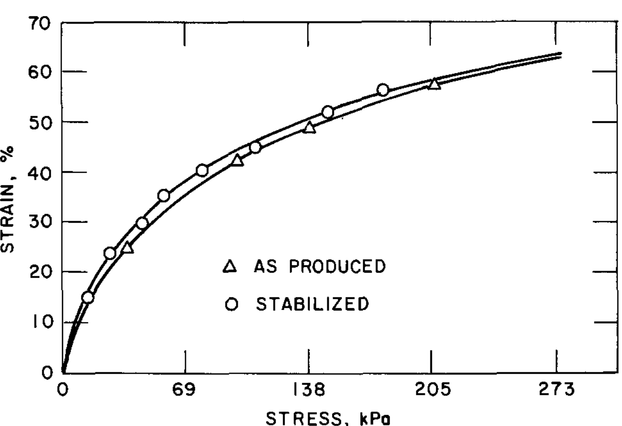

Fig. 2. Stress-strain behavior of BN felt

temperature when in contact with the Li-Al negative electrode. This reaction results in metallic aluminum depositions in the separator that could cause a short circuit. The experiments have shown that a specific procedure should be followed to start a cell which contains felt treated with $LiAlCl_4$ wetting agent; this procedure was explained in the Experimental section.

In-cell evaluation of felt.—In-cell testing of the separator felt was conducted to determine the material compatibility and adaptability to cell designs and the effects of the separator thickness on active material utilization. The active material utilization of the positive electrode is defined as the ratio of observed discharged capacity at a given current density to the theoretical capacity. The coulombic efficiency (or A-hr efficiency) is the ratio of observed discharged capacity to the charged capacity at a given current density.

Table II. Predusting of felt with $LiAlCl_4$

Cell No.	Concentration loading of $LiAlCl_4$ per separator (mg/cm^2)	Wetting condition
SC-27	30	Good
SC-34	20	Good
SC-30	14	Good
SC-33	12	Good
SC-32	8	Poor

Figure 3 shows both the coulombic efficiency and utilization of positive-electrode active material for a cell (SC-33) which had an unstabilized BN felt separator of 2 mm thickness. The capacity decreased from 77% to 40% as the discharge current density was increased in steps of 20 mA/cm^2 up to the maximum discharge current density of 120 mA/cm^2 at cycle 56. From the 56th cycle on, the charge and discharge current densities of the cell were maintained at 60 mA/cm^2, and the capacity remained steady at 55% for this period. As is shown in this figure, the utilization was sensitive to slight temperature excursion; as the temperature increased, the capacity also increased. The coulombic efficiency of this cell remained steady at 98-100% throughout the operation. At the 140th cycle (~2000 hr), cell operation as terminated because of a sudden declinc in coulombic efficiency and utilization.

Figure 4 shows the coulombic efficiency and capacity for a cell (SC-25) that used a 1.25 mm thick stabilized felt. The observed performance was similar to that for cell SC-33. The utilization was 68% at discharge current density of 40 mA/cm^2. This cell was operated for 98 cycles (1700 hr) before termination. Even though the felt used in cell SC-33 had almost 3-4 times the the oxygen content (as boron oxide) as that of the stabilized felt used in cell SC-25, the capacity and

Table III. Performance data of separator-test cells

Cell No.	Separator thickness (mm)	Theoretical capacity (A-hr)	Internal resistance (mΩ)	At 40* mA/cm² Percent utilization	At 40* mA/cm² Specific energy (W-hr/kg)	Operational cycles	(hr)
SC-19	2.8	50	18	62	55	205	3050
SC-25	1.25	51	16	72	66	98	1700
SC-27	1.6	48.5	15	69	59	72	1159
SC-30	3.2	48	18	60	54	90	1550
SC-33	2.0	50	15	67	62	145	2020

* Corresponds to approximately 10 hr discharge rate.

coulombic efficiency of these two cells were comparable once the effect of separator thickness on cell capacity and efficiency was taken into account (discussed below). Apparently the high oxide content (>2% oxygen) in the separator after long periods (>3000 hr) of cell operation may cause the cell performance to deteriorate.

Figure 5 shows the effect of the separator thickness on the utilization for cells SC-25, -33, -19, and -30 at various current densities. As indicated, utilization at a given current density was observed to be the best when the separator was the thinnest. Further, the utilization decreased as the current density was increased for any given thickness of felt. The dependence of utilization on felt thickness is further illustrated in Fig. 6. This figure indicates that utilization has a linear relationship with the felt thickness. This empirical relationship may be written as $U = mD + C$, where U is the utilization ratio, D is thickness of felt, m is material constant, and C is the discharge-current density constant. The numerical value of m lies between 0.04 and 0.06 $(\text{mm})^{-1}$. From these test results, it was postulated that thicker separators offer high resistance to ionic transport, thereby decreasing cell utilization.

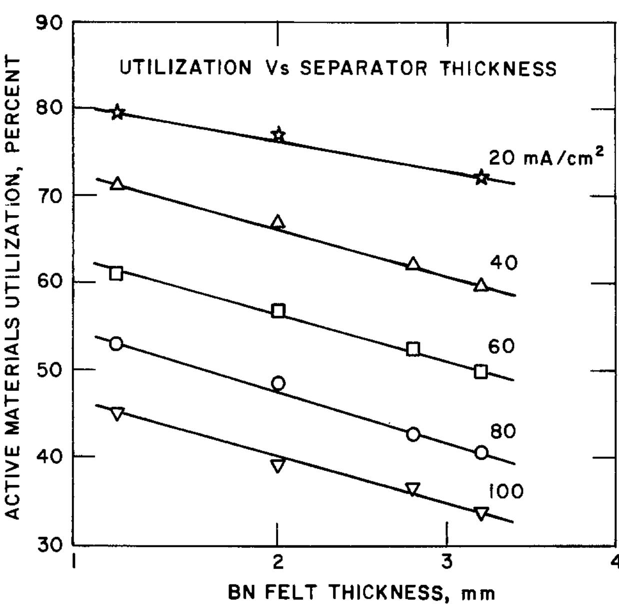

Fig. 5. Utilization performance of various BN felt cells

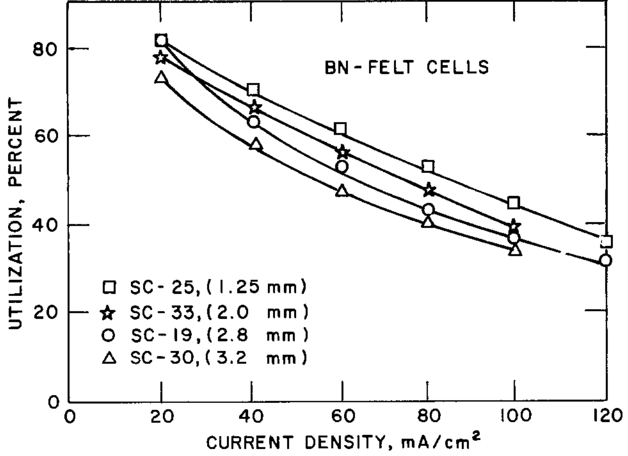

Fig. 6. Effect of felt thickness on utilization performance cells

Table III lists performance data (utilization, specific energy, resistance, and cycle life) for the five separator test cells. The thickness of the felt separator used in these cells ranged from 1.25 to 3.2 mm. These cells were cycled for 1159-3050 hr before termination of operation. The specific energy of a cell at a given current density is the watt-hour output per unit weight of the cell; the average weight of a test cell was 0.75 kg. The highest utilization and specific energy at a given current density were observed with the cell using the thinnest felt (cell SC-25). However, the use of thinner BN felt (<1.25 mm thickness) requires mechanically stronger and denser felts to withstand the internal stresses developed during cell operation. The internal resistance, which includes polarization effects, was measured at 50% state of charge for each cell. Even though a marked difference in internal resistance of these cells was not noticed, internal resistance appeared to increase as the separator thickness was increased.

Post-test examination.—Table IV summarizes the results of post-test examination for the separator test cells. The examinations revealed that BN felt is chemically stable in the cell environment. The felt was observed to be compressed between 30% and 50% of original thickness because of the internally developed stresses during cell operation. These stresses are generally caused by electrode swelling. However, the BN felt was never a cause of failure in these test cells. Most of the cell failures were caused by short circuits resulting from improper cell assembly or electrode swelling and subsequent extrusion of active material. The extrusion of material from one electrode has been eliminated by the use of finer (~200 mesh) retaining screens at the electrodes. Cell SC-33 developed a short

Table IV. Post-test examination of Bn felt cells

Cell No.	Cause of termination	Suspected reason of failure and felt condition
SC-19	Voluntarily	Felt was compressed by ~35% but no chemical attack; cell shorted after third thermal cycle
SC-25	Gradual decline in performance	Migration of fine particle through the felt toward negative electrode; felt was compressed by 45% but no chemical attack
SC-27	Internal short	Positive screen wire was touching against the negative electrode; felt was compressed about 40% but no chemical attack
SC-30	Gradual decline in performance	Probable cause was extrusion of positive electrode due to electrode swelling; felt compressed ~50% but no chemical attack
SC-33	External short	Salt bridging across the terminals

because evaporated salt had formed a bridge across the terminals. This cause of failure should not be a problem in sealed cells because of negligible salt evaporation.

Conclusions

Results have been reported on an evaluation program for BN felt separators which are being developed for application in Li/MS batteries. The physical characterization of the felts indicated that they have adequate strength, porosity, and handling flexibility for cell assembly and operation. In-cell tests of the felts indicated excellent physical compatibility with chemical stability in the cell environment. Although further development work to improve upon the physical properties of BN felt may be needed, the test results show that BN felt is a viable separator material for Li-Al/MS_x cells.

Investigation of Nickel Whisker Networks as Electrodes for Hydrogen and Oxygen Evolution

G. L. Cahen, Jr.,* P. J. Moran,*[1] L. L. Scribner, and G. E. Stoner*

Applied Electrochemistry Laboratory, Department of Materials Science, University of Virginia, Charlottesville, Virginia 22901

ABSTRACT

A new concept for the preparation of high surface area electrodes employing polycrystalline nickel whiskers has been demonstrated. Nickel whiskers were fabricated by chemical vapor deposition in the presence of an electromagnetic field. Electrode networks were constructed by a sintering process. The resultant electrodes have been analyzed as hydrogen and oxygen evolution electrodes in potassium hydroxide electrolytes. An improvement of 60-100 mV as compared to conventional nickel screens on an apparent current density basis has been observed for both reactions.

The energy efficiency of electrolytic processes is improved by reducing the overpotentials associated with the occurring reactions. One method of achieving this is by increasing the active electrode surface area. These electrode overpotentials can be represented as

$$\eta = a + b \log i$$

where a and b are constants for the particular electrochemical reaction under consideration. The constant b is commonly referred to as the Tafel slope with i representing the current density and defined as

$$i = I/A$$

where I is the total current and A is the active electrode surface area. Since most electrolytic processes are highly current efficient, the amount of product per unit time is proportional to the total current. In comparison, the electrode overpotentials, which directly influence efficiency, are a function of current density. As the electrode surface area is increased for a constant current, the current density is decreased with a corresponding decrease in electrode overpotentials and increase in efficiency.

A new type of high surface area electrode was examined for conditions of hydrogen and oxygen evolution in 30% by weight potassium hydroxide electrolytes. This is a typical electrolyte for commercial alkaline electrolyzers. Polycrystalline nickel whiskers[2] can be fabricated into an electrode network by sintering; the resulting high surface area obtained causes a de-

crease in electrode overpotentials. In the following sections, the fabrication, characterization, and utilization of these electrodes will be discussed.

Whisker Electrode Fabrication and Surface Area Analysis

Polycrystalline nickel whiskers are produced by chemical vapor deposition of nickel tetracarbonyl gas, $Ni(CO)_4$, in an electromagnetic field. The gas is fed into a chamber which is heated to 300°-350°C to accomplish gas phase decomposition. The chamber is surrounded by an electromagnet which creates magnetic field lines in the chamber parallel to the chamber's vertical axis. The liberated nickel particles align themselves along the field lines. Further deposition occurs along these aligned "substrates." The resulting whiskers, which have typical grain sizes of 200-400Å, are very strong, approaching 10^6 psi tensile strength, and possess very low dislocation densities. Diameters and lengths can be varied from 0.1 to 50 μm and from 1 mm to several cm, respectively. The whisker electrodes are then fabricated from these individual whiskers.

Whiskers electrodes (or networks) are constructed by the sintering of individual whiskers at 800°-1000°C under a pressure of a few psi in a reducing atmosphere for approximately one-half hour. The reducing atmosphere prevents surface oxidation or contamination thereby promoting bonding. The resultant network is porous and fibrous. A 200 mesh nickel screen is used as a substrate in this sintering process. The resultant whisker electrodes obtained from this method are cylindrical disks with a radius of 1.56 cm, a thickness of 0.2 cm, and a weight of about 2.3g. Porosities of these electrodes are as high as 90% by volume. For the higher porosity networks, the true surface area to volume ratio is 10^4 cm^2/cm^3 and the true specific surface area is 5×10^3 cm^2/g as determined by BET adsorption isotherm techniques. Figures 1 and 2 are scanning electron micrographs of a nickel whisker electrode. The surface roughness of the individual whiskers results from a characteristic nodular type growth (1). This is particularly noticeable on the larger whisker in Fig. 2.

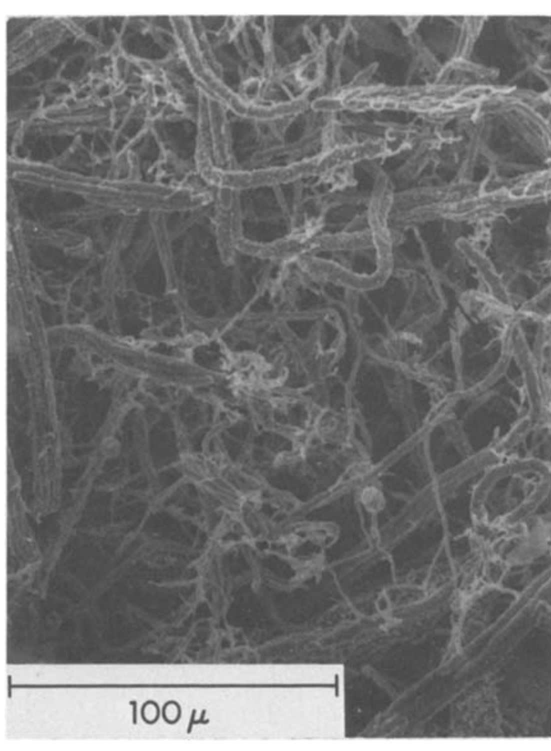

Fig. 1. Scanning electron micrograph of whisker electrode

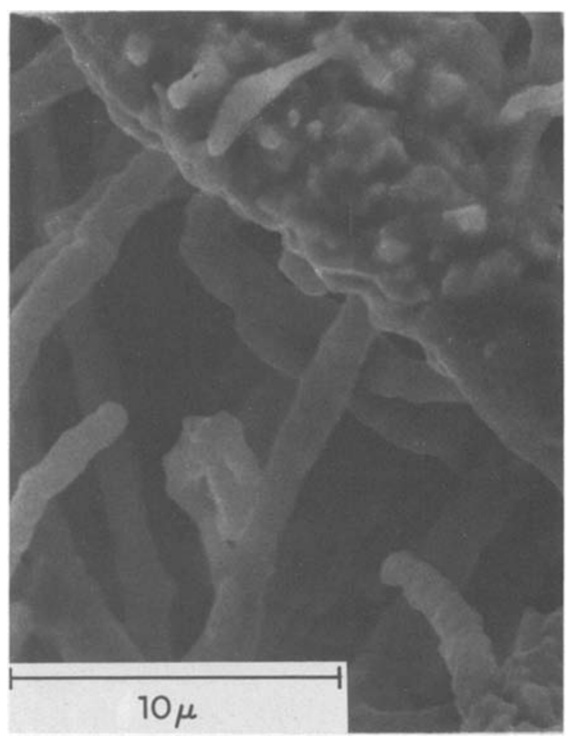

Fig. 2. Scanning electron micrograph of whisker electrode

The roughness factors can be calculated by either of two ways. The first method is by dividing the true surface area by the cross-sectional area of the electrode itself. This yields roughness factors on the order of 2×10^3 to 5×10^3. The second and more accurate method is to divide the true surface area by the geometric area of the individual whiskers considering them to be smooth cylinders. A distribution of whisker diameters was obtained by examining a collection of micrographs. The results are illustrated in Fig. 3. The following procedure was employed to calculate the roughness factor:

1. Estimate average whisker diameter from distribution graph, $\overline{d} \cong 8$ μm.

2. Calculate true surface area of the whisker electrode using BET isotherm data. Whisker electrode weight 2.3g, multiplied by 5×10^3 cm^2/g, corresponds to 11,500 cm^2 true surface area.

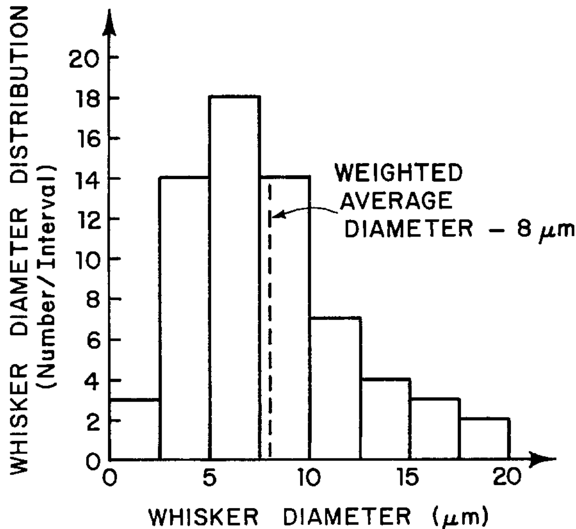

Fig. 3. Distribution of whisker diameters in whisker electrode

3. Calculate surface area of whiskers in electrode assuming one long smooth cylinder of diameter, $\bar{d}$ = 8 μm (from step 1).

4. Step 3 requires a knowledge of the nickel volume in the whisker electrode. 2.3g weight divided by the density of nickel (8.9 g/cm³) yields 0.258 cm³.

5. V = 0.258 cm³ = $\pi r^2 l$ for one long cylinder. Assuming r = 4 μm, the length of the cylinder can be calculated

$$l = \frac{V}{\pi r^2} = 5.13 \times 10^5 \text{ cm}$$

6. Whisker surface area can then be calculated SA = $2\pi r l$ = $2\pi(4 \times 10^{-4}$ cm) $(5.13 \times 10^5$ cm) = 1289 cm².

7. The roughness factor is then calculated by dividing the true surface area by the whisker surface area

$$11{,}500 \text{ cm}^2/1280 \text{ cm}^2 = 8.9$$

The model can be improved by various techniques such as better definition of whisker diameter. One such modification was employed by considering two radii intervals and the number fraction of each. The result was sufficiently close to the listed value as to accept the single radius calculation as a useful estimation.

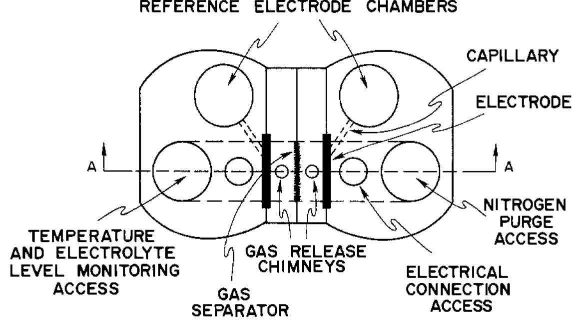
For the sake of comparison, the roughness factor for metal screens composed of drawn wire is about 2 to 3. The actual high surface area of the whisker electrodes is due to a high network porosity and a high roughness factor for the individual whiskers.

A similar technique was applied to the nickel screen electrode to determine its approximate geometric surface area. Wire lengths and diameters were measured with an optical profile projector. The calculated geometric surface area for the screen electrode was approximately 100 cm².

Electrochemical Properties of Whisker Electrodes

The mechanical integrity of sintered components is always a concern, especially where electrolytic gas evolution reactions occur. Whisker electrodes withstood hydrogen and oxygen evolution at current densities (based on electrode cross-sectional area) as high as 1000 mA/cm² for 48 hr with no apparent loss in integrity. These apparent current densities are considerably higher than those utilized in industrial electrolytic processes (200-500 mA/cm²) (2-4).

For electrochemical characterization, whisker electrodes were compared to Ni-200 screen electrodes of equal bulk geometry (diameter = 3.13 cm, thickness = 0.2 cm, and mass = 2.3g) for both hydrogen and oxygen evolution reactions in a 30% by weight KOH electrolyte. The Ni-200 screen electrode was fabricated by spot welding together 5 layers of 200 mesh screen. The surface area of the nickel screen electrode as determined by cyclic voltametric surface area analysis was 300 cm². A special Teflon cell was designed and constructed for the electrochemical characterization experiments. The cell schematic is shown in Fig. 4. Simultaneous monitoring of both electrode potentials *vs.* standard calomel or dynamic hydrogen reference electrodes can be achieved. A 1.0 mm capillary connects the reference electrode chamber to the bottom of the working electrode compartment. This configuration minimizes gas bubble clogging in the capillary and electrolyte contamination from the reference electrodes. The electrolyte used was 30 weight percent KOH prepared from A.C.S. certified Potassium Hydroxide Pellets and distilled water. The electrolyte was pre-electrolyzed for 24 hr prior to experimentation. The electrodes were cleaned by ultrasonic agitation for 10 min in Alconox solution followed by ultrasonic agitation for 10 min in alcohol and concluded by a 5-10 sec dip in 0.01M HCl and final rinsing with distilled water. The electrode leads were masked from the electrolyte with Teflon shrink tubing and Teflon tape. The experimentation was conducted galvanostatically. A problem of unstable voltages due to time variations in both anodic and cathodic overpotentials, as observed by other investigators was encountered (3, 5, 6, 7). To accommodate these effects, the experiments were conducted at successively higher currents beginning at 1 mA and allowing the electrode potentials to stabilize at each current level. A stable voltage was defined as one which varied less than 1 mV in a 2 min period. The higher currents required longer stabilization times. Results of the experimentation are shown in Fig. 5.



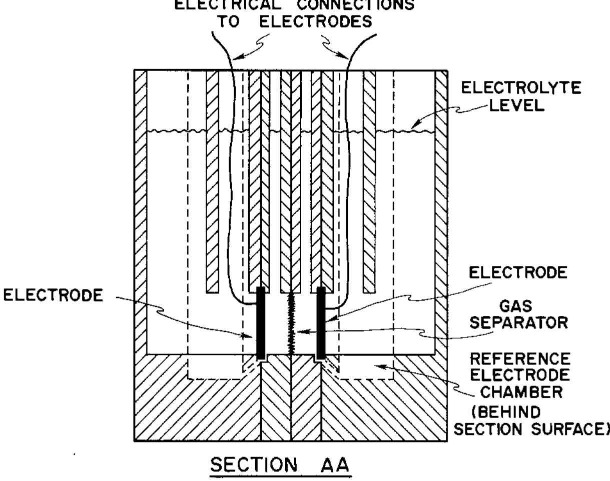


Fig. 4. Cell schematic for electrochemical experimentation with whisker electrodes.

The whisker electrodes exhibited a 60-100 mV lower overpotential (smaller negative number for hydrogen evolution) compared to the screen electrodes in both reactions at equal currents, or apparent current densities (both electrodes have the same cross-sectional area). The reduction in overpotentials represents about a 10% increase in the energy efficiency of water electrolysis. The improvement is presumably due to the higher surface area of the whisker electrodes.

Discussion and Conclusions

The electrochemical characterization of nickel whisker electrodes for hydrogen and oxygen evolution reactions in alkaline electrolytes demonstrates an attractive increase in efficiency by lowering activation overpotentials. The highly porous whisker disks utilized in this investigation are not the most ideal configuration for present day water electrolyzers; thus alternative techniques for affixing them to new or existing commercial electrodes are being considered. Commercial testing of such a whiskerized electrode is anticipated. The technique for growing whiskers directly onto an electrode substrate will prove useful by controlling whisker orientation and by eliminating the need to sinter individual whiskers to each other and/or onto a substrate.

Cation and Water Diffusion in Nafion Ion Exchange Membranes: Influence of Polymer Structure

H. L. Yeager* and A. Steck

Department of Chemistry, University of Calgary, Calgary, Alberta, Canada T2N 1N4

ABSTRACT

Membrane self-diffusion coefficients for sodium ion, cesium ion, and water have been measured for Nafion® 120 perfluorosulfonate ion exchange membranes. Values have been determined as a function of temperature, and as a function of membrane water content by studying samples in heteroionic forms. The diffusional properties of this polymer are found to differ from those of conventional polystyrenesulfonates in several respects, and the free volume theory which describes ionic diffusion in the latter is inappropriate to treat Nafion. Results indicate that cations may exist in two distinct regions in the polymer; the proportion of total cations in each region may depend on the ions size and charge density. A structural model of Nafion, which correlates the membrane's spectroscopic and diffusional properties, is proposed to explain the results.

Nafion[R] perfluorosulfonate ion exchange membranes (du Pont and Company), as well as similar carboxylate materials, are beginning to be used as separators in industrial electrolytic cell technologies. In particular, their chemical stability and excellent ionic transport capability are essential assets in the harsh environment of chlor-alkali cells, where hydrogen and chlorine gases and concentrated caustic and brine solutions contact the polymer at elevated temperatures. Several studies of transport, structural, and some thermodynamic properties have now been reported. This research is designed not only to provide a sound basis for the commercialization of these materials but also to learn more about the nature of the unusual ion-

clustered morphology of perfluorinated ionomers. The separation of ions and sorbed water into a separate micro-phase in Nafion was first indicated by small angle x-ray scattering (1, 2) and later confirmed by neutron scattering experiments (3, 4). A theoretical basis for the ion clustering phenomenon in Nafion has also been provided (5).

Models based on these experiments and calculations are characterized by an inverse micellar picture of Nafion, in which sulfonate groups at the ends of pendant side chains extend into approximately spherical clusters of water and hydrated cations (2, 5). These clusters are surrounded by fluorocarbon material, which appears to contain microcrystalline regions according to experimental evidence (1, 4, 5). [These microcrystalline regions can be removed for salt forms by heating to 330°C followed by rapid quenching (4).] The cluster-network model of Gierke describes the ionic regions as spherical with interconnecting channels (2), an approach which is reasonably successful in predicting current efficiency in chlor-alkali cells. The more recent approach by Rodmacq and co-workers describes three "phases:" fluorocarbon microcrystallites, ionic-water clusters, and a second ionic region of lower ion content (4). This latter region may be that of sulfonates which have not been formally incorporated into ion clusters.

The extent of sulfonate-counterion interaction is of course an important factor in determining the transport properties of these membranes. Olah and coworkers have shown that Nafion in the hydrogen ion form is an effective solid "superacid" catalyst for a variety of organic reactions (6, 7). Low sulfonate charge density is also indicated in the ion exchange selectivities of alkali metal ions in Nafion 120 (8, 9). Sodium 23 NMR studies do indicate that sodium ion-sulfonate contact ion pairs can form, but this occurs only when the water to sodium ion mole ratio in the polymer has been reduced to about five or less (10, 11). Thus, ion pairing does not appear to be a major factor for Nafion samples which have been equilibrated in dilute aqueous solution.

We have previously reported studies of ion exchange selectivities, membrane water contents (8, 9), and ionic diffusion for Nafion samples in both concentrated (12) and dilute solution environments (13, 14). Unusual alkali metal ion-hydrogen ion exchange selectivities and water sorption were found in comparison to conventional sulfonate ion exchange resins. Unlike the latter cross-linked materials, the water to exchange site mole ratio in the polymer varies widely depending on the counterion, from twelve for sodium ion to about seven for cesium ion forms (1200 equivalent weight polymer). Alkali metal ion diffusion coefficients in Nafion also show interesting differences from those in conventional sulfonate resins. The cesium ion self-diffusion coefficient in Nafion 120 is about twenty times smaller than the respective value for sodium ion; this is in marked contrast to sulfonate resins where the cesium ion-sodium ion diffusion coefficient ratio is about 1.5, as it is in pure water (15). Morphological changes caused by the large difference in water contents was suggested to be a contributing factor (14).

These diffusion measurements have been extended here to include measurements of ionic diffusion as a function of polymer water content and the diffusion of water in the polymer in various counterion forms. These results are discussed in terms of the free volume description of diffusion in water-swollen polymers, and in relation to structural models of Nafion.

Experimental

Two samples of 1200 equivalent weight Nafion (Plastics Department, E. I. du Pont de Nemours and Company, Wilmington, Delaware 19898), manufactured at separate times, were used in this work. The material has a nominal ion exchange capacity and thickness of 0.83 mequiv./g and 0.025 cm, respectively. Sodium and cesium chloride salts (Fisher Certified) were used as received. The radio-isotopes ^{22}Na and ^{137}Cs (obtained as carrier-free aqueous solutions) and tritium labeled water were obtained from commercial sources.

Details of membrane pretreatment, the measurement of membrane water contents, ion-exchange capacities, and membrane dimensions have been previously described, as well as the procedures involved in the determination of ionic self-diffusion coefficients using radiotracer methods (8, 9, 13, 14). The same general procedures were used to measure membrane self-diffusion coefficients of water, with the exception that tritium labeled water replaced radiotracer labeled 0.05M salt solutions. Standard liquid scintillation techniques were used to count the tritiated water samples. Some membranes were prepared in mixed ionic forms by equilibration in salt solutions of 0.05M total ionic strength and appropriate composition to yield the desired ionic fraction of each component. These solutions were prepared using previously published ionic selectivity coefficients (8, 9); sodium ion and cesium ion contents in the membranes were then accurately determined by flame emission spectroscopy.

Results and Discussion

Self-diffusion coefficients for sodium ion and cesium ion in 1200 equivalent weight Nafion are listed in Table I. Arrhenius plots of some of these data, the slopes of which yield activation energies of diffusion, are shown in Fig. 1. Two separate batches of Nafion were studied. For batch I, previously published diffusion coefficients were redetermined for this work; during the two year interval between measurements the membrane was stored in the dry as-received form. As seen in Fig. 1, results for sodium ion have changed little more than experimental error but cesium ion diffusion coefficients have increased greatly, with a corresponding decrease in the activation energy of diffusion. A second batch of Nafion of recent manufacture was kindly supplied by du Pont; diffusion results for this material are very similar to those of aged batch I for both cations. The water to exchange site mole ratio for sodium ion and cesium ion forms were reported to be 11.9 and 6.6, respectively (8). These water contents were remeasured for aged batch I and batch II samples; no change from these values within experimental error could be found for either material.

These results suggest that batch I has undergone some kind of slow morphological change, a change which affects cesium ion diffusion but not sodium ion diffusion. Results from batch II perhaps indicate an improved annealing process to produce a membrane with constant properties. The importance of these results lies in the difference in the behavior of the two cations to whatever polymer relaxation process did occur. It would appear that cesium ion diffuses in a different manner than sodium ion. Although the acti-

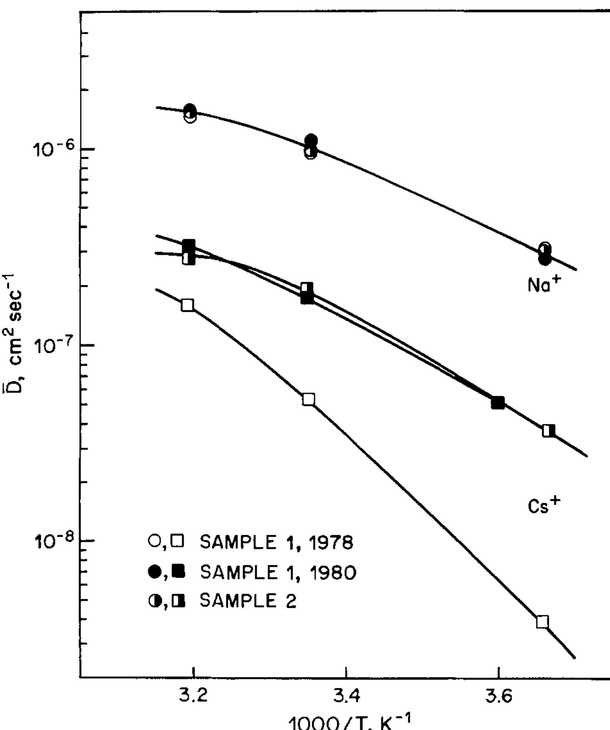

Fig. 1. Logarithm of self-diffusion coefficient vs. reciprocal of absolute temperature for Nafion 120.

vation energy for cesium ion diffusion is reduced to a value more typical of restricted diffusion compared to its original value of 66.1 kJ mol^{-1}, the anomaly in the cesium ion-sodium ion diffusion coefficient ratio remains. The value has increased to about 0.2 from the original value of 0.06 at 25°C, but it is still far from the expected result of about 1.5. Thus the more similar activation energies of diffusion for the two cations now suggests a common mechanism of diffusion but the low absolute magnitude of the cesium ion values still indicates a more tortuous diffusion path for this counterion.

We also wish to explore the dependence of these diffusion coefficients on membrane water content, in order to compare results to the free volume approach of describing diffusional processes. The diffusion coefficient of a molecule in a simple liquid has been represented by the equation

$$D = A \exp(-\gamma v^*/v_f) \quad [1]$$

where v^* is a characteristic volume for diffusion of the species, v_f is the "free volume" per solvent molecule, and γ and A are constants (16). Yasuda and coworkers (17) have adapted this approach to diffusion in water-swollen polymers, and developed an equation of the form

$$\bar{D} = D^\circ \exp[-bV_p/(1 - V_p)] \quad [2]$$

Here $\bar{D}$ and D° represent the membrane and aqueous diffusion coefficients respectively, V_p is the volume fraction of polymer in the water-swollen material, and b is a constant which is related to the exponent in Eq. [1], where now v_f would represent the free volume of water. Although several assumptions are needed to yield Eq. [2], the authors found that it works well to represent the binary diffusion coefficient of NaCl in a variety of hydrophilic polymer membranes for $\bar{D}$ values ranging over five orders of magnitude.

Fernandez-Prini and Philipp (18) have used Eq. [2] to correlate tracer self-diffusion coefficients of sodium ion and cesium ion in a variety of polystyrenesulfonate resins with excellent success. They find that the pre-exponential term is also a function of the electrostatic attraction of counterions for the charged matrix though, and that it is difficult to place a simple interpretation on the b coefficient. Lines which these authors found to represent the self-diffusion coefficients for sodium ion and cesium ion in polystyrene sulfonates are shown in Fig. 3, for data where V_p varied from 0.85 to 0.15.

In order to explore the relationship between diffusion coefficients and V_p in Nafion 120, the water content of the membrane must be varied in a controlled manner. Nafion has been found to have different stable water contents for two different treatments: Room temperature soaking, and extended boiling in water followed by room temperature soaking (9). These values are counterion dependent as well. To obtain additional water contents we take advantage of the observation that the membrane water-exchange site ratio in heteroionic forms is essentially a weighted average of the values for the respective homoionic forms, as seen in Fig. 2. Thus membrane samples with varied water contents were prepared for Na^+-Cs^+ mixed ionic forms, and in successive experiments the membrane diffusion coefficients of both counterions were determined. A possible objection to this approach is that the presence of a second counterion may alter the diffusion characteristics of the reference cation.

Results are shown in Fig. 3 for sodium ion and cesium ion. Values of V_p were calculated from water-exchange site mole ratios (9), the molar exchange site concentration in the swollen polymer, and the partial molar volume of water in condensed systems, which was taken to be 17 ml mol^{-1} (18). Solid symbols are those of normal and boiled homoionic forms. Relatively minor differences exist between results for pure and mixed ion forms, which lends support to this method of varying V_p.

Important differences are seen though for the dependence of these diffusion coefficients on the V_p function, compared to polystyrenesulfonates. Sodium ion has a much higher diffusion coefficient at all water levels. We might attribute this feature, at least partially, to greater organization of exchange sites and water in this ion clustered polymer, in contrast to the more uniform distribution in a cross-linked ion exchange resin. Thus it appears that tortuosity is reduced

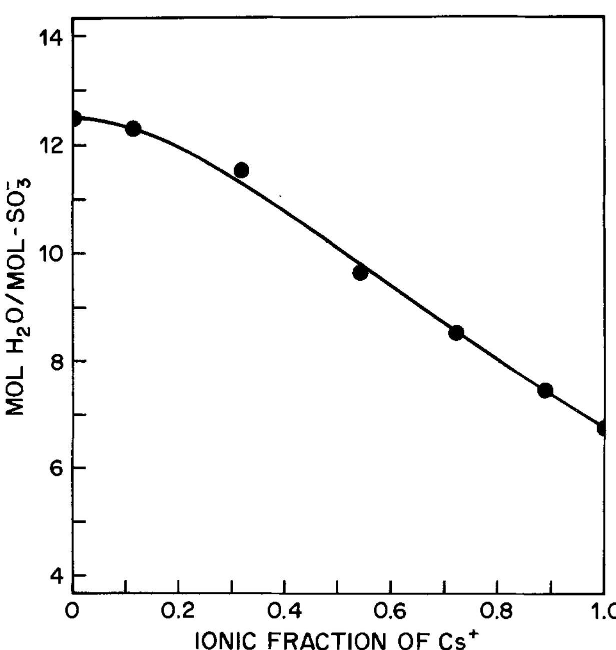

Fig. 2. Molar ratio of sorbed water to exchange site vs. ionic fraction of Cs^+ for Na^+-Cs^+ heteroionic forms of Nafion 120 at 25°C.

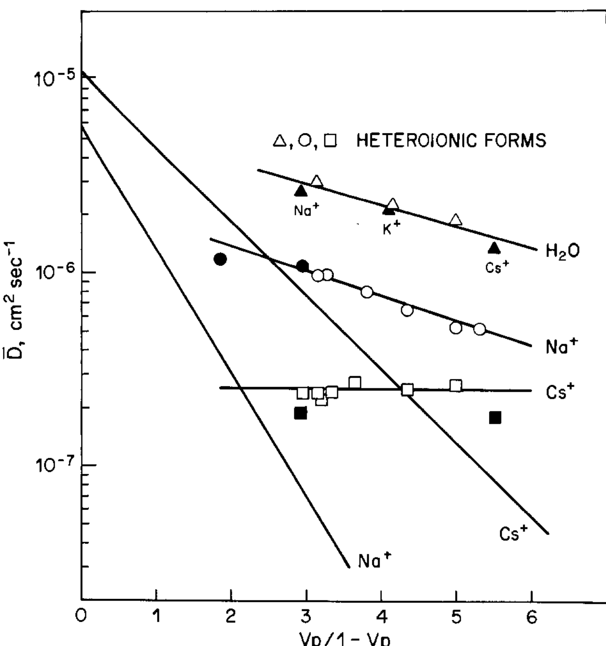

Fig. 3. Logarithm of self-diffusion coefficient *vs.* polymer fraction function for Nafion 120, 25°C. Na^+ and Cs^+ lines without data points: polystyrenesulfonate behavior, Ref. (18).

with the ion clustered morphology, which would be expected. For cesium ion a similar result is found for the unboiled cesium ion form. But as the water content increases, there is no dependence of the membrane diffusion coefficient on water content. For sodium ion, diffusion does increase with increasing volume fraction of water, but only modestly. (The percentage increases in the self-diffusion coefficients for cesium ion and sodium ion in boiled *vs.* unboiled membranes are 10 and 20%, respectively; for cesium ion this represents the entire V_p range studied.) In addition, the anomaly of the inverted order of cesium ion to sodium ion diffusion coefficients is not removed at high water contents; indeed the difference becomes greater. In Table I it is seen that the activation energy of diffusion for cesium ion is only slightly changed when the membrane is largely in the sodium form, again indicating that the mechanism of diffusion for this cation is essentially independent of membrane water content.

Self-diffusion coefficients of water in Nafion 120 are listed in Table II for three alkali metal ion forms. Previously reported approximate values of the water diffusion coefficient and activation energy of diffusion in the sodium ion form of 1150 equivalent weight Nafion are in good agreement with the present results (1). Values at 25°C are plotted in Fig. 3, along with self-diffusion coefficients for three sodium ion-cesium ion heteroionic forms. As seen in the figure, water diffusion shows a dependence on V_p which is similar to that of sodium ion. In general, these self-diffusion coefficients are quite large considering the relatively small fraction of water in the polymer. The activation energies of diffusion are low and similar to those found for water self-diffusion in the hydrogen ion form of an 8% cross-linked polystyrenesulfonate resin, 21.8 kJ mol^{-1} (19), and in pure water, 17.8 kJ mol^{-1}

(20) over the same temperature interval. The values for the cesium ion form confirm that there is excellent communication among the aqueous ion clustered regions even when the water-exchange site mol ratio is as low as seven.

In order to interpret the results presented here, two recent spectroscopic studies of Nafion are of particular interest. Lee and Meisel have studied the luminescence quenching of $Ru(bpy)_3^{2+}$ (bpy = 2,2′-bipyridine) in Nafion 120 (21). Results indicate that this cation interacts with the fluorocarbon portion of the polymer and not the sulfonate grouping, and that a probable location for the cation is in an interfacial zone between ion clusters and fluorocarbon backbone. This finding may be in part due to the large size and low charge density of this cation, but it suggests that a picture of ion clusters as simple aggregates of water, sulfonate exchange sites, and counterions could be an oversimplification. Falk has made a careful study of the infrared bands of sorbed water in Nafion in the sodium ion form, and was able to draw several conclusions (22). Water exists in two distinct environments. The first is one in which hydrogen bonding strength is about 60% of that in liquid water. About 75% of total sorbed water is in this environment, which is taken to be that of the ionic clusters. The remaining water molecules do not appear to be involved in hydrogen bonding, and thus would be exposed only to fluorocarbon phase. In consideration of the amount of nonhydrogen bonded water, Falk suggests that ion clusters may be nonspherical in shape and have extensive intrusions of fluorocarbon phase (22).

A structural view of Nafion which is consistent with these spectroscopic results and the diffusional properties reported here is diagrammed in Fig. 4. Three regions are indicated: Region A consists of fluorocarbon phase, ionic clusters form region C, and B is an interfacial region between A and C. Region A would contain fluorocarbon backbone material, some of which is in a microcrystalline form, as detected by Rodmacq and co-workers (4). Region C would incorporate sulfonate exchange sites, the majority of sorbed water, and some counterions as well. Region B is viewed as one of relatively large fractional void volume, con-

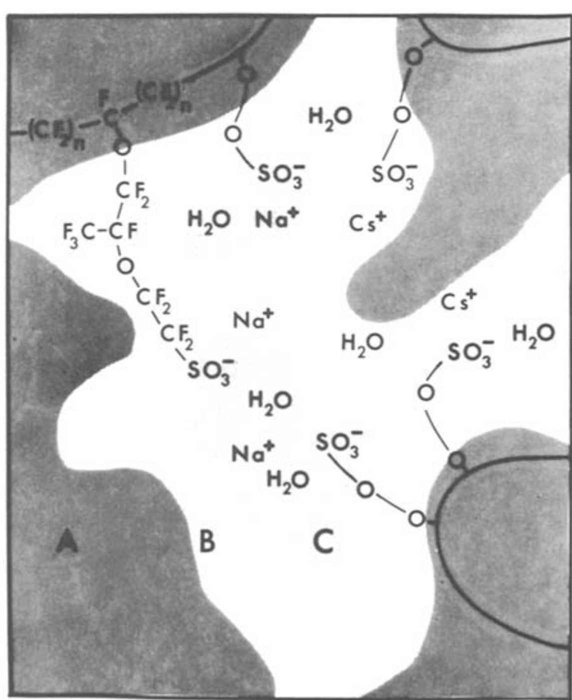

Fig. 4. Three region structural model for Nafion: A, fluorocarbon; B, interfacial zone; C, ionic clusters.

taining pendant side chain material, a smaller amount of sorbed water, some sulfonate exchange sites which have not been incorporated into clusters, and a fraction of the counterions. The relative proportions of counterions in regions B and C would depend upon the size, charge density, and hydration energy of the cation. Ions of low charge density or large size, such as $Ru(bpy)_3^{+2}$ and Cs^+, would prefer region B, while ions of larger charge density and hydration energy would localize in the more aqueous ionic clusters. Both types of cations and water would have relatively large microscopic diffusion coefficients in both the ionic clusters and the interfacial regions. As well, region B provides a continuous diffusion path among ion clusters. While region C is responsible for the peaks which are found in x-ray and neutron scattering studies, both regions C and B contribute to determine the overall diffusional properties of the polymer.

This model provides a reasonable explanation for the results obtained in this work. Cesium ion would have a lower overall diffusion coefficient because of its larger mean-free path in diffusing through the polymer, compared to sodium ion. Both would tend to have larger than expected diffusion coefficients compared to polystyrene sulfonates for a given V_p, because the volume fraction of polymer available for diffusion in region B is not properly taken into account in the calculation of V_p. The insensitivity of cesium ion's self-diffusion coefficient to increased water sorption would result because the majority of increased sorbed water is found in the ionic clusters. Thus the diffusion path of cesium ion would not significantly decrease as the volume fraction of region A increases.

It is interesting to speculate on the causes for the change in diffusional results for batch I of Nafion 120 due to aging of the material. The cesium ion activation energy of diffusion in new samples of batch I is extremely large, and more like values for ionic diffusion in ionic crystal lattices than in swollen polymers (14). This would occur if portions of region B were not originally as well formed as indicated in Fig. 4, but instead included irregular zones and diffusionally isolated regions. These regions would show very high diffusional activation energies. The measured activation energy of diffusion is the weighted average of all environments, and thus cesium ion would be more sensitive to such irregularities than would sodium ion. [All sulfonate sites are available for exchange processes on a long time scale though; the ion exchange capacity of batch I is found to be unchanged in the sodium ion, cesium ion, and other cationic forms (9).] Thus, while the aging process increased the sodium ion diffusion coefficient by 19% without a change in activation energy of diffusion, the cesium ion value increased by more than a factor of three with a new activation energy which is 60% of the original result.

This proposed structural view of Nafion is an extension of those developed by Gierke (2) and Rodmacq and co-workers (4) which provides a unified picture of a variety of observations, including these diffusional results. Additional spectroscopic studies are now needed to probe the microenvironments of ions in the polymer in order to test this model.

Acknowledgment

The authors thank E. I. du Pont de Nemours and Company for samples of Nafion, and Dr. Z. Twardowski and B. Kipling for useful discussions. Financial support was provided by the University of Calgary and the Natural Sciences and Engineering Research Council of Canada.

Manuscript submitted Nov. 20, 1980; revised manuscript received March 18, 1981. This was Paper 608 presented at the Hollywood, Florida, Meeting of the Society, Oct. 5-10, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.

Publication costs of this article were assisted by the University of Calgary.

The Effect of Mixing in Paired Dimerizations

D. K. Johnson[1] and R. E. W. Jansson

Chemistry Department, Southampton University, Hants, SO9 5NH England

ABSTRACT

Some paired electrosyntheses involve a sequence of chemical and electrochemical steps. Mixing processes may then be important if the kinetics are not extremely fast, and the physical nature of the cell and its operation may influence the selectivity of the overall reaction. Current efficiency may also be influenced through parasitic reactions which are transport dependent. In the prepilot scale synthesis of ethyl dimalonate and dimethyl adipate, these effects have been studied systematically in a variety of flow cells operated with batch recycling. It has been shown that under conditions of good mixing in all cells the selectivities of the major products are improved. For example, in parallel plate cells, the amount of Michael adduct is inversely proportional to Reynolds number. Similar observations have been made in other prepilot scale operations which strongly affect the choice of the most appropriate cell for a given synthesis.

In paired electrochemical syntheses there are two extreme cases: (*i*) When it is undesirable for anode and cathode products to be transported to the counterelectrode (*e.g.*, if the electrochemical reactions are reversible); and (*ii*) when it is necessary for the overall success of the reaction that mixing should occur or intermediates be transported to the region of the counterelectrode. The classical case of (*ii*) is the epoxidation of alkenes such as propylene using an electrogenerated oxidant such as hypobromous acid; with the correct contacting pattern 97% selectivity can be obtained at 95% current efficiency (1). The paired dimerization of methyl acrylate and diethyl malonate also comes into this category. Following the work of Thomas and Lux (2), Baizer and Hallcher (3) investigated the system across a wide range of variables obtaining good performance only when the acrylate and malonate were added dropwise during the electrolysis.

The principal reactions may be summarized as

Anode $$2I^- - 2e^- \rightarrow I_2 \qquad [1]$$

Cathode $$2CH_2{=}CHCO_2Me + 2e^- \rightarrow [MeO_2CCHCH_2CH_2CHCO_2Me]^{2-} \qquad [2]$$
$$2A + 2e^- \rightarrow A_2^{2-}$$

Bulk $$A_2^{2-} + 2CH_2(CO_2Et)_2 \rightarrow MeO_2C(CH_2)_4CO_2Me + 2[CH(CO_2Et)_2]^- \qquad [3]$$
$$A_2^{2-} + 2M \rightarrow A_2 + 2M^-$$

$$2[CH(CO_2Et)_2]^- + I_2 \rightarrow (CO_2Et)_2CHCH(CO_2Et)_2 + 2I^- \qquad [4]$$
$$2M^- + I_2 \rightarrow M_2 + 2I^-$$

Even though this is an abbreviated scheme (3) it can be seen that diethyl malonate acts as a proton source, and the dimerization of its anion requires a charge exchange reaction with electrogenerated iodine. A number of competing reactions are also possible, *e.g.*, a Michael reaction between malonate anions and methyl acrylate

$$[CH(CO_2Et)_2]^- + CH_2{=}CHCO_2Me \rightarrow [(CO_2Et)_2CHCH_2CHCO_2Me]^- \qquad [5]$$
$$M^- + A \rightarrow MA^-$$

which is important if the acrylate to iodine ratio is high. Malonate acts as a proton source for MA^- giving the normal Michael adduct

$$MA^- + CH_2(CO_2Et)_2 \rightarrow (CO_2Et)_2CHCH_2CH_2CO_2Me + M^- \qquad [6]$$
$$MA^- + M \rightarrow MA + M^-$$

Reactions [5] and [6] are therefore autocatalytic and preliminary work (4) has shown that much Michael adduct is made in cells with poor mixing.

If the I_2/M ratio is high, reaction [6] is replaced by a sequence of reactions which can be represented as

$$MA^- + I_2 \rightarrow (CO_2Et)_2CHCH_2CHICO_2Me + I^- \qquad [7]$$

$$(CO_2Et)_2CHCH_2CHICO_2Me + M^- \rightarrow \text{(cyclopropane: } MeO_2C, CO_2Et, CO_2Et, H, H, H\text{)} + M + I^- \qquad [8]$$

giving the cyclopropane form of the Michael adduct by 1,3 elimination. The combined amount of Michael adducts (*i.e.*, MA^-) produced therefore depends on the local ratio of A/I_2 near the cathode, while the ratio of normal to cyclopropane Michael adduct depends on the ratio of M/I_2.

It is now well established that there may be a high degree of segregation of electrogenerated species in various cells (5-7) so that different cells give different selectivities even though a reaction is carried out under the same nominal chemical conditions in each of them (4,8). Further work on the coupling of chemical and physical variables is the subject of this paper.

The Physical Environments in Various Cells

In parallel plate cells at low Reynolds numbers the flow can be modeled as a creeping layer adjacent to each electrode, with a faster though still laminar "core" flow in between (5, 9). Mass exchange does, of course, take place between these layers, but the effective degree of segregation is high (5, 10). At higher Reynolds numbers (>2000) the fluid in most of the channel is turbulent, hence well mixed, but some

[1] Present address: Department of Chemical Engineering, UCLA, Los Angeles, California 90024.

Key words: electrosynthesis, transport, kinetics.

degree of segregation is still evident. In parallel plate cells, then, cross-gap mixing of anode and cathode product is relatively poor, but increases with Reynolds number.

In a disk-stack (capillary gap) cell (11) similar evidence of segregation is seen (7) unless the channel Reynolds number, $Re_{ch} = Q/h\nu$, is very high ($>10^5$), but mixing in a geometrically identical pump cell at the same flow rate is much higher (7) due to the intense tangential shear introduced by rotating alternate electrodes. At all flow rates the fluid in a pump cell approximates to dispersive plug flow, while at low flow rates the segregation in a disk-stack cell approaches that of a parallel plate cell.

The bipolar trickle tower (or trickle bed) exhibits segregation at all flow rates, being modeled best as a reactor with fast and stagnant zones (12), however as the flow rate increases, the relative extent of the fast zone increases, indicating increased mixing (9). Note that the distribution of active zones in space means that the trickle bed approximates to a cross-flow reactor, which can lead to very high selectivities for sequential reactions (1).

The four reactors, parallel plate, pump cell, disk-stack, and trickle bed, represent most of the geometries of cell which have been used in organosynthesis (9).

Experimental

All cells used in this investigation were undivided and were operated in batch recycle mode, the anode and cathode material normally being graphite. The pump cell and disk-stack cell were operated with interelectrode gaps of approximately 1 mm, the anode and cathode areas each being 50 cm^2. In the parallel plate cell the interelectrode gap was 3 mm and the electrode area was again 50 cm^2 of each polarity. The trickle tower reactor consisted of 10 layers of graphite Raschig rings packed in semirandom array (1). Adjacent layers were insulated from each other by polyester nets, electrical continuity being provided by the reaction mixture which fell as a trickling film.

Each cell was inserted in turn into a reaction loop which consisted basically of the cell, a pump where necessary, a throttle valve, flow meter, heat exchanger, hydrocyclone gas disengager, and ports for monitoring temperature and for removing samples.

The composition of the electrolyte was normally 0.1 mol dm^{-3} of methyl acrylate, 0.1 mol dm^{-3} of diethyl malonate, and 0.05 mol dm^{-3} of tetra n-butyl ammonium iodide, all dissolved in acetonitrile.

Quantitative chemical analyses were carried out on a Perkin Elmer F17 gas chromatograph, using 2m columns of 3% OV-17 on Chromosorb W AW DMCS (80-100 mesh), with a programmed temperature rise of 100° → 290° at 20°C min^{-1}.

Results and Discussion

Laboratory organosyntheses are usually carried out with easily obtainable flow rates (normally in the range 0.5 to 2.5 liters min^{-1}) without regard to Reynolds number in the cell.

Examination of the performance of the malonate/acrylate system in the different cells at a representative high (2.3 liters min^{-1}) and low (0.3 liters min^{-1}) flow rate shows it to be highly sensitive to hydrodynamic conditions. Figures 1 and 2 show the selectivity achieved for production of dimethyl adipate and ethyl dimalonate plotted against theoretical conversion (charge passed ÷ charge required to convert all the starting material to the required product at 100% current efficiency). Although flow rate and composition were fixed, the performance of each cell was otherwise optimized so that best is compared with best.

Providing experiments are not continued much past 80% conversion of ethyl malonate, the major by-products were the two Michael adducts. The decrease in selectivity for dimalonate after this point is due to the further oxidation of the dimer to ethyl ethene tetracarboxylate. The rate of production of Michael adducts decreases with time, which is why the selectivities in both figures are lower at the beginning of experiments but improve with time. The lowest selectivity occurs when using the parallel plate cell at low flow rate, when the degree of mixing is poor (Re $\simeq$ 300) and large amounts of by-products are produced. On increasing the flow rate, and thus the degree of mixing (Re $\simeq$ 3400), the selectivity improves substantially. Similarly, in the capillary gap cell a low flow rate ($Re_{ch} \simeq 1 \times 10^4$) the flow is almost laminar (13) and so the segregation is high (7) and selectivity is poor. At the higher flow rate ($Re_{ch} \simeq 9 \times 10^4$) the fluid is just subturbulent (13), consequently the selectivity is much improved. Although the pump cell is geometrically identical to the capillary gap cell, it has an entirely different hydrodynamic environment (14), the degree of mixing depending almost entirely on the ro-

tational Reynolds number ($R_\phi = \omega r_o^2/\nu$) and being virtually independent of volumetric flow rate. In these experiments the rotational speed was 2800 rpm ($R_\phi \simeq 10^5$) and changes in flow rate were achieved by means of a throttle. Consequently, in the pump cell experiments good selectivities were obtained independently of changes in flow rate, hence residence time and conversion per pass. Unfortunately, the very high mixing also produced an adverse effect since the current efficiency was only about 35-40%, whereas in the disk-stack cell and parallel plate cell operated with high flow rates, current efficiencies of about 60% could be obtained. This loss of current efficiency is due to rapid transport of some of the anodically generated iodine to the cathode where it is reduced back to iodide. The high current density obtained was thus at least partially due to the parasitic I_2/I^- cycle.

In the trickle tower reactor, the net separators between layers provide good mixing near the most active parts of the rings (1) thus giving a high selectivity.

In this paired reaction malonate anions are produced near the cathode; they can then react either with iodine to produce the dimer, or take part in a Michael reaction with methyl acrylate. In cells with segregated flows the dispersion of malonate anions away from the cathode is slow. At the beginning of the experiment, when the bulk concentration of iodine is low, the Michael reaction proceeds rapidly but as the experiment continues the concentration of iodine builds up, limiting the Michael reaction, until the formation of Michael adduct effectively ceases. When the fluid is less segregated the malonate anions are more quickly dispersed away from the cathode, decreasing the amount of Michael adduct formed. From Fig. 3 it can be seen that in the parallel plate cell and capillary gap cell operated with a low flow rate, *i.e.*, conditions of poorest mixing and greatest segregation, the most Michael adduct is formed. As mixing improves less Michael adduct is produced, the pump cell producing the least. The effect was studied systematically in experiments using the parallel plate cell operated at different Reynolds numbers (Fig. 4). This shows that as the degree of mixing increases the total amount of Michael adduct anion (MA^-), the common intermediate to both propanes decreases, whereas the ratio of cyclopropane adduct to normal Michael adduct generally increases with Reynolds number due to the increased transport of anodically generated I_2 into the reaction zone

$$

The cyclopropane adduct may be a valuable product as an intermediate in pyrethroid synthesis, therefore it may be desirable actually to maximize its production. However, from above it can be seen that, while the ratio of cyclo to normal propane increases with Re, the total amount of Michael adduct falls. Figure 4 shows that the optimal Reynolds number is about 3000, in the transitional regime. Alternatively, the production of the cyclopropane may be maximized through choice of a suitable contacting pattern.

A good yield of the cyclopropane requires the production of the anion intermediate (MA^-), in the presence of iodine and the absence of a proton source. Experiments were therefore carried out using a parallel plate cell and a low flow rate to maximize production of the anion intermediate (MA^-), with the addition of aliquots of the ethyl malonate during the electrolysis to increase the iodine to malonate ratio. This proved unsuccessful as after the initial reduction the acrylate polymerized rather than hydrodimerized, due to the lack of a proton source.

From the reaction scheme it can be seen that if the conversion of ethyl malonate approaches 100% in a single pass through a cell, then in the presence of methyl acrylate and absence of iodine a high yield of the anion intermediate (MA^-) should be produced, since the concentration of proton donor is then low. If the MA^- is then introduced into a region of high iodine concentration the synthesis of the cyclopropane would be facilitated. An attempt to follow this strategy was carried out using the cell shown in Fig. 5, which had a carbon foam cathode. The electrolyte had the same composition as used in the earlier experiments; conversions of about 60% of the ethyl malonate were obtained. Unfortunately, very little of the cyclopropane was produced (material yields of 1% or less). The major product was the normal Michael adduct (material yields of about 30%) with large amounts of the diadduct (material yield of up to 20%) also. The long residence time of the malonate anions in the foam is probably the reason for this. To achieve a 100% conversion of ethyl malonate in a single pass required a flow rate of less than 1.1 ml min^{-1} at a current of 0.2A, or a residence time in the foam of more than 6 min.

At present, work is being carried out with cells of different contacting pattern to maximize the yield of the cyclopropane.

Conclusions

Ethyl dimalonate and dimethyl adipate may be electrosynthesized in good yield and high selectivity in cells capable of being scaled-up, provided that there is a good dispersion of malonate anions away from the cathode. Under conditions of very high cross-gap transport a loss in current efficiency is observed due to the parasitic iodine cycle. Good mixing conditions also favor production of the cyclopropane adduct, the potentially more valuable of the two by-products. By correct choice of reactor design it may also be possible to produce the cyclopropane adduct selectively.

Electrochemical Reduction of Aromatic Diazonium Salts

I. Electrochemical Behavior of *p*-Tolyl- and *p*-Anisyldiazonium Fluoborates at a Mercury Cathode: Evidence for the Corresponding Hydrazines Formation

ABSTRACT

Reduction of *p*-methyl and *p*-methoxyphenyldiazonium fluoborate in aqueous solutions at mercury micro and macroelectrodes results in formation of a primary hydrazine $ArNH\text{-}NH_2$. The radical $ArN = N\cdot$ formed in the first electrochemical step forms Ar-Hg-Ar; the product of the two electrons reduction forms Ar-NH-NH-Ar in competitive chemical reactions. Low temperature (4°C) and moderate stirring enable minimizing of these side reactions.

Aromatic hydrazines are at present time synthetized by chemical reduction of the corresponding diazonium salts. These chemical reductions involve the use of sodium sulfite (or hydrosulfite) or of stannous chloride as reducing agents which cause various environmental problems. An electrochemical reduction of diazonium salts might be an alternative process to obtain hydrazines.

The electrochemical preparation of aromatic hydrazines by reduction of diazonium salts or hydroxydiazo compounds has been studied by several authors (1-5) from 1929 to 1940. Using constant-current techniques and various cathode materials, these authors have obtained varying yields of hydrazines (not always properly identified). No attempts were made to elucidate the mechanisms of these processes.

Later investigations (6-20) were restricted to polarographic studies of diazonium salts in various solvents. Two reduction waves were observed in the majority of these studies. The first wave was attributed to a transfer of a single electron and was found to be *p*H independent, the second was considered to correspond to a transfer of 2, 3, 4, or 6 electrons. The formation of hydrazines was often indicated in the proposed mechanisms, but not proved.

In particular, Wawzonek (8) proposed that the first reduction wave corresponds to the formation of a free radical, with consecutive formation of diphenylmercury and phenylmercuric chloride. The limiting current of the second wave was found to be four times higher than that of the first one. Its half-wave potential depends on *p*H, and this wave was tentatively ascribed to the direct reduction of the diazonium cation to the corresponding primary hydrazine. However, coulometric measurements at potentials corresponding to the limiting currents of the first and second wave gave the same results.
